In Experiments 1 and 2, higher reaction temperature increased the yield of the coloring matter, but, on the contrary, the increase in the temperature decreased the yield in the Experiments 3 and 4. This may be due to the decomposition of II which on heating over approximately 200°C, gives up carbon dioxide and converts into resinous material of m. p. 50~55°C. Fig. 2 shows infrared spectrum of II and Fig. 3 that of its product obtained by heating. These spectra (in potassium bromide pellet) were obtained with Perkin Elmer 12B instrument.

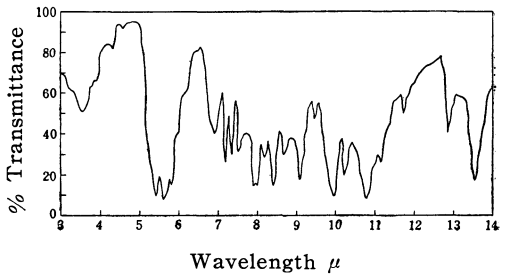

Fig. 2. Infrared spectrum of 3,4,5,6-tetrahydrophthalic anhydride (KBr).

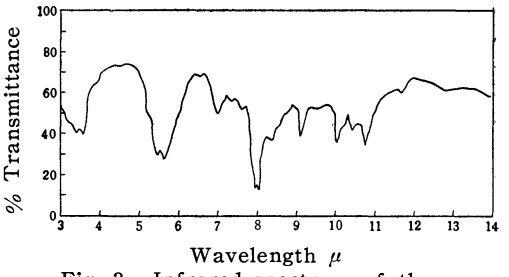

Fig. 3. Infrared spectrum of the product obtained by heating 3,4,5,6-tetrahydrophthalic anhydride (KBr).

In the reaction of II, higher reaction temperature seemed to decrease the yield of the coloring matter and accelerate the conversion into resinous material.

The author gratefully acknowledges the instruction of Dr. Ryozo Goto, Professor of Kyoto University; also Dr. Takahisa Nakamura and Dr. Wataru Ishikawa, Toyo Ink Mfg. Co. The author's thanks are also due to Mr. Ryuichi Kimura, Kyoto University, in measuring the infrared spectra.

Reduction of Copper Hexadecachlorophthalocyanine

By Masahiro SHIGEMITSU

(Received September 25, 1958)

It was manifest by the previous study[1] that the darkening of chlorinated copper phthalocyanine green by reducing agents was caused, not by variation in forms, but by variation in its crystal structure or in its chemical composition. The degree of discoloration corresponded, though very little, to that of decrease in chlorine content, from which it was inferred that hydrogen atoms had been introduced into phthalocyanine nucleus. If phthalocyanine nucleus is to be reduced, either C=C or C=N bond is considered to be the position of reduction. Whether the position attacked is C=C or C=N is made clear by using the exhaustively chlorinated compound (copper hexadecachlorophthalocyanine, I). Hence the author used I as a sample and studied the mechanism of reduction.

Experimental

Materials. — *Copper hexadecachlorophthalocyanine (I).*—The compound which was synthesized according to the method previously reported[2], was used as chlorinated copper phthalocyanine green. Reducing agent was made to act upon it, which was then oxidized, reprecipitated and heated as follows.

Pulverization.—I was dissolved in chlorosulfonic acid, poured into ice water, and deposited as fine particles. The chlorine content was 50.33% (Calcd. 50.34%) as previously indicated[2].

Reduction.—One gram of I and 30 cc. of 20% aqueous solution of rongalit (addition compound of formalin and sodium hydrosulfite) were placed in a stainless steel autoclave of 50 cc. capacity and heated at 150~155°C for 20 min. The product was filtered off, washed with water and dried. It was dark green particles.

Oxidation of the reduced product.—One gram of the reduced product was added to 80 cc. of 2% sulfuric acid containg 0.2 g. of ceric sulfate and heated at 70~80°C for 1 hr.

Reprecipitation of the reduced product.—One gram of the reduced product was dissolved in 30 g. of chlorosulfonic acid at room temperature and poured into ice water. The precipitate thus obtained was filtered and washed with water.

Heating of the reduced product.—The reduced product was heated at 250~255°C for 3 hr. in a stream of nitrogen.

Methods.—Variation in color observed in the case of reduction of I and of oxidation, reprecipitation and heating of the reduced product was studied by measuring the reflectance curves with a recording spectrophotometer (General Electric Co.). Samples for reflectance-curve measurement were made in the same procedure as previously reported[1]. X-ray diffraction patterns of I and its reduced product were obtained with a recording X-ray diffraction apparatus (Philips Co.) and variation in crystal structure was studied.

Then, elementary analysis of I and its reduced product was conducted. Also, infrared spectra (Nujol) were taken of I, its reduced product, the reoxidized reduced product and the reprecipitated reduced product, using a Perkin Elmer 12B instrument.

Results

Reflectance Curves. — Fig. 1 shows the reflectance curves of I, its reduced product

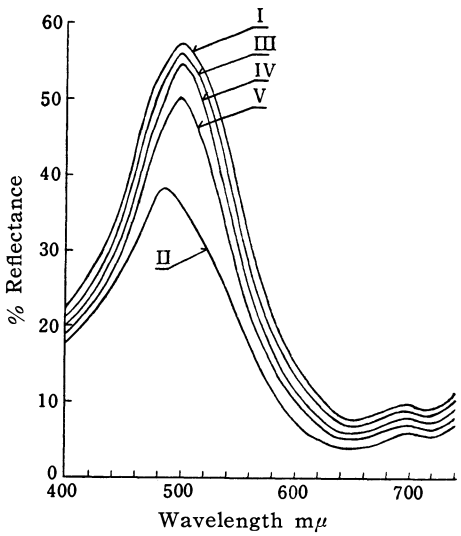

Fig. 1. Reflectance curves of copper hexadecachlorophthalocyanine (I), its reduced product(II), reoxidized reduced product(III), reprecipitated reduced product(IV) and heated reduced product(V).

1) M. Shigemitsu, This Bulletin, **32**, 502 (1959).
2) M. Shigemitsu, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **62**, 112 (1959) (presented at the Autumnal Meeting of Chemical Society of Japan, Tokyo, 1957).

(II), the reoxidized reduced product(III), the reprecipitated reduced product(IV) and the heated reduced product(V). Table I gives their C.I.E. Notations. In this table, Y denotes luminosity, P_e purity and λ_D dominant wavelength.

TABLE I. C.I.E. NOTATIONS

Sample	Y %	Pe %	λ_D mμ
I	30.34	36.8	492.6
II	22.18	39.1	488.9
III	29.96	37.2	490.8
IV	29.58	37.5	490.2
V	28.41	38.1	489.7

When a reducing agent acted upon I, its luminosity lowered from 30.34 to 22.18% and it darkened in color. When this darkened pigment was heated at 250~255°C for 3 hr. in nitrogen stream, its luminosity increased to 28.41% approaching that of untreated pigment; when being oxidized and reprecipitated, the pigment increased its luminosity to 29.96 and 29.58%, respectively, recovering color of luminosity approaching that of untreated material. Thus the variation in color is of a reversible trend.

X-ray Diffraction Patterns.—Figs. 2 and 3 show the X-ray diffraction patterns of I and its reduced product.

It was made clear by the previous study that the darkening by the action of reducing agent was not due to the change in the form of pigment particles. Now, with the aid of X-ray diffraction method, no change was observed in the crystal structure either. Thus the color change is supposed to be due to the difference in the chemical composition of the compounds in question.

Elementary Analysis.—Results of analysis of I and II are given in Table II.

TABLE II. RESULTS OF ELEMENTARY ANALYSIS

Sample	C %	H %	N %	Cl %	Cu %
I Found	34.10	0.09	9.90	50.33	5.64
I Calcd.	34.09	—	9.94	50.34	5.63
II Found	33.60	1.26	9.80	49.75	5.59
III*	33.67	1.23	9.82	49.71	5.57

*III, Calculated value when fourteen hydrogen atoms were added to I.

I contains no hydrogen, but, on reduction, its hydrogen content increased to 1.26% indicating the addition of fourteen hydrogen atoms.

Infrared Spectra.—Figs. 4, 5, 6 and 7 show infrared spectra of I, II, III and IV. Fig. 8 shows that of copper phthalocyanine containing no chlorine, which was measured by Tyler et al.[3] The lower curve in Fig. 8 denotes the use of Nujol and the upper curve, shown partly, denotes the use of hexachlorobutadiene.

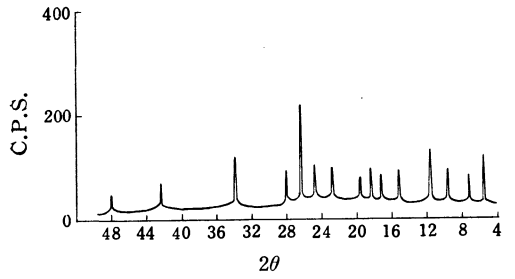

Fig. 2. X-ray diffraction pattern of copper hexadecachlorophthalocyanine (leaflet, fine particle).

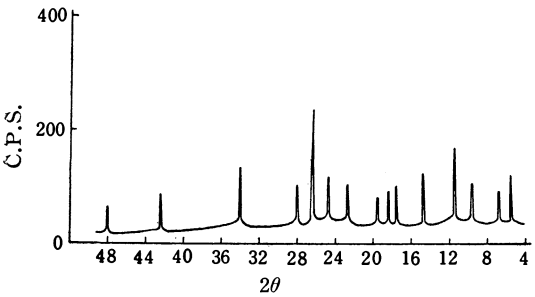

Fig. 3. X-ray diffraction pattern of reduced product of copper hexadecachlorophthalocyanine (leaflet, fine particle).

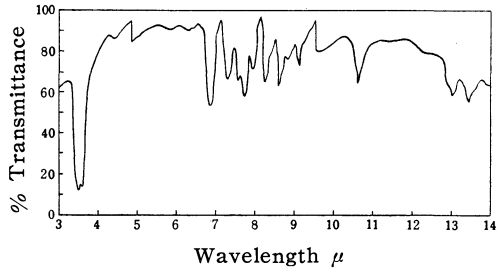

Fig. 4. Infrared spectrum of copper hexadecachlorophthalocyanine.

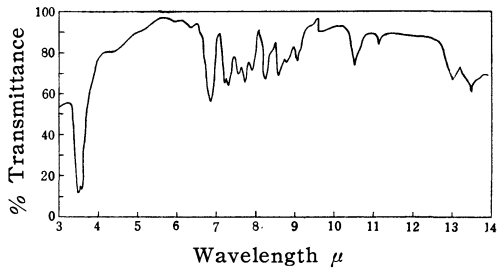

Fig. 5. Infrared spectrum of reduced product of copper hexadecachlorophthalocyanine.

3) J. E. Tyler et al., *Anal. Chem.*, **25**, 393 (1953).

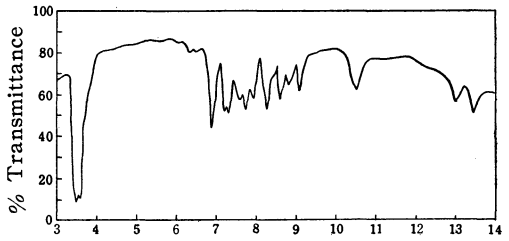

Fig. 6. Infrared spectrum of reoxidized reduced product of copper hexadecachlorophthalocyanine.

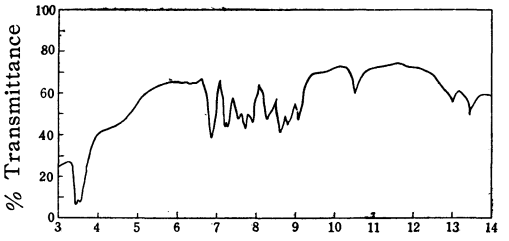

Fig. 7. Infrared spectrum of reprecipitated reduced product of copper hexadecachlorophthalocyanine.

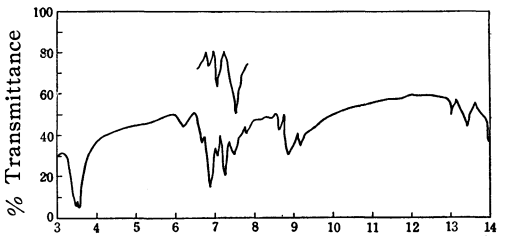

Fig. 8. Infrared spectrum of copper phthalocyanine.

When sixteen hydrogen atoms of copper phthalocyanine were chlorinated to give I, absorption bands at 720 cm^{-1}, 1090 cm^{-1}, 1125 cm^{-1}, 1290 cm^{-1} and 1415 cm^{-1} of copper phthalocyanine disappeared and those at 947 cm^{-1}, 1095 cm^{-1}, 1210 cm^{-1}, 1273 cm^{-1} and 1305 cm^{-1} were exhibited. The absorption band at 1415 cm^{-1} of copper phthalocyanine became even more conspicuous when hexachlorobutadiene was used instead of Nujol.

Discussion

Copper phthalocyanine, I and II are compared (Fig. 9). The absorption band at 1415 cm^{-1} of copper phthalocyanine disappears in I but, when being reduced, the compound shows again the absorption band at 1412 cm^{-1}. Therefore, this absorption band is due to the vibration of

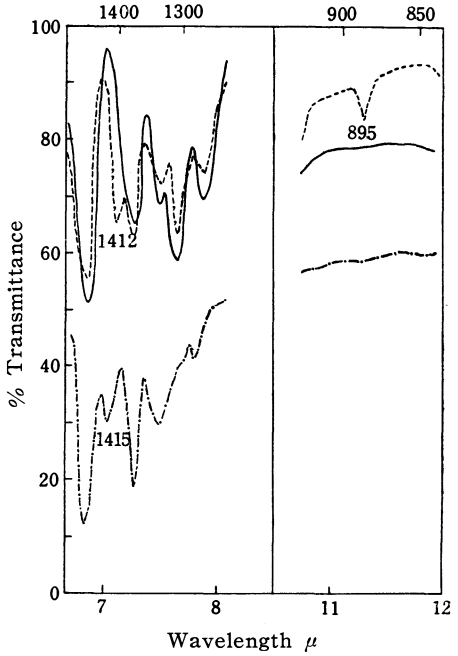

Fig. 9. Comparison of infrared spectra.
—— copper hexadecachlorophthalocyanine.
------ reduced product of copper hexadecachlorophalocyanine.
- - - copper phthalocyanine.

C–H bond of copper phthalocyanine. It is further inferred that, since C–H bending vibration appears in the range of 1475～1300 cm^{-1} [4], this absorption band may be due to the same vibration.

Further, a new absorption band appears at 895 cm^{-1} in II, but no such absorption band in I and copper phthalocyanine. Therefore, this absorption band may be attributed to the addition of hydrogen atoms. The position of the addition of hydrogen atoms is considered to be either C=C or C=N. Actually, the addition seems to proceed at C=N bond of the phthalocyanine nucleus, because the absorption band at 895 cm^{-1} corresponds to N–H bending vibration according to Colthup[4].

Gund[5] describes that cobalt phthalocyanine produces two N–H bonds when reduced. In the present experiment fourteen hydrogen atoms were added to phthalocyanine nucleus. Observing the absorption of C–H and N–H bonds which appeared in II, it is considered that twelve hydrogen atoms add to six C=C bonds and the remaining two hydrogen atoms, as inferred by Gund, produce two N–H bonds.

4) N. B. Colthup, *J. Opt. Soc. Am.*, **40**, 397 (1950).
5) F. Gund, *J. Soc. Dyers and Colourists*, **69**, 671 (1953).

Thus, the chlorination of copper phthalocyanine seems to facilitate hydrogenation at C=C and C=N bonds of phthalocyanine, and the darkening of color occurs as is observed in the reduced vat dyes.

The author gratefully acknowledges the instruction of Dr. Ryozo Goto, Professor of Kyoto University; also Dr. Takahisa Nakamura and Dr. Wataru Ishikawa, Toyo Ink Mfg. Co. The author's thanks are also due to Mr. Seiki Kato, Tokyo Institute of Technology, for his carrying out the X-ray analysis and Mr. Ryuichi Kimura, Kyoto University, for his measuring the infrared spectra.

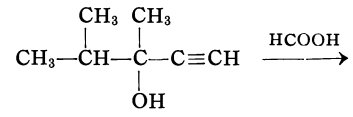
The Formic Acid Rearrangement of 3,4-Dimethyl-1-pentyn-3-ol and 3-Isopropyl-4-methyl-1-pentyn-3-ol

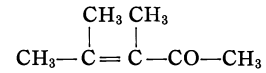
By Tatsuo TAKESHIMA, Ken NAGAOKA, Masataka YOKOYAMA and Shigeki MORITA

(Received November 4, 1958)

Continuing the study of Rupe reaction of ethynylcarbinols of type I[1], we now show that 3,4-dimethyl-1-pentyn-3-ol (II) and 3-isopropyl-4-methyl-1-pentyn-3-ol (III) on treatment with formic acid afford, in addition to ketone which forms the main product in each case, each corresponding aldehyde (II_b and III_b) in 5* and 6% yield respectively.

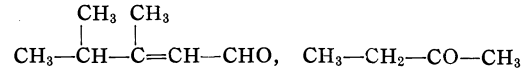


I



C^1: Tertiary carbon atom.

C^2: Other than secondary carbon atom.



The reaction product from II was separated into three fractions. The main bulk of the low-boiling fraction (fraction 1; 45% yield) consisted of 3,4-dimethyl-3-penten-2-one (II_a)[2]. The high-boiling fraction (faction 3; 5% yield) reacted with carbonyl reagents (consult Table I) and had an unsaturated aldehydic nature. On treatment with phenylhydrazine it gave a product which had a pyrazoline reaction of a coloration different from that in the case of II_a. The hydrogenation product of this fraction also was positive toward Schiff test, the coloration being different from that of the original substance. Thus, together with analyses, 3,4-dimethyl-2-pentenal (II_b) was assigned to the compound. The facts that it is impossible for the geometrical isomer to exist for II_a and also the trend of Rupe reaction are corroborative of the structure.

II

II_a (45%)

II_b (5%)*

The intermediate fraction (fraction 2) consisted of a mixture of II_a and II_b; the quantity of the aldehyde contained diminished on standing. The forerun in the case of the distillation contained a considerable amount of methyl ethyl ketone, which owes its origin possibly to the hydrolytic fission of II_a.

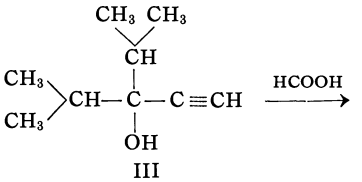
The reaction product of III was distilled and three fractions were collected. The greater part of the low-boiling fraction

1) T. Takeshima, K. Wakamatsu and A. Furuhashi, This Bulletin, 31, 640 (1958).

* The actual yield of the aldehyde seemed to be much more, considering its considerable amount contained in fraction 2.

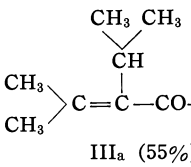
2) H. Favre and H. Schinz, *Helv. Chim. Acta*, 35, 2388 (1952); F. C. Whitmore et al., *J. Am. Chem. Soc.*, 63, 643 (1941).

TABLE I. REACTION PRODUCTS FROM II



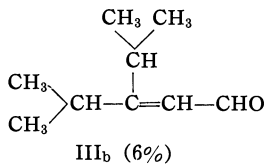
Fraction	B. p., °C	Yield, g. from 20 g. of II	Constituent
Forerun	~133	A small amount	Considerable amt. of methyl ethyl ketone
1	143~151	9	II_a
2	152~159	1.2	II_a, II_b
3	160~164	1.0	II_b

DERIVATIVES OF THE CARBONYL COMPOUNDS



Original Compd.	2,4-Dinitrophenylhydrazone		Semicarbazone	
	M. p., °C	Appearance	M. p., °C	Appearance
II_a	132~133[3]	Lustrous orange plates or long plates	185~187[4] (slow heating) 198~199[4] (rapid heating)	Colorless plates
II_b	205~206	Red plates	163~164 (slow heating) 173~174 (rapid heating)	Colorless plates

(fraction 1; 55% yield) was considered to be 3-isopropyl-4-methyl-3-penten-2-one(III_a) reported by Hickinbottom et al.[5]; it gave no crystalline derivative with common carbonyl reagents**.



The high-boiling fraction (fraction 3; 6% yield) had an unsaturated aldehydic nature, which gave characteristic derivatives with carbonyl reagents (consult Table II). On treatment with phenylhydrazine, it yielded an oily product which had a pyrazoline reaction of a coloration different from that in the case of III_a. Viewed from these facts together with analyses and also with the course of the reaction, the compound was assigned 3-isopropyl-4-methyl-2-pentenal (III_b). Here also, the absence of geometrical isomer substantiates the structure. Young and Roberts[6] reported the 2,4-dinitrophenylhydrazone of m.p. 151.5~153°C (from ethanol) as the one of III_b without rigid isolation of the original aldehyde which was formed by ozonolysis of crotyldiisopropylcarbinol. However the 2,4-dinitrophenylhydrazone obtained in the present experiment had m.p. 173.5~174°C; its appearance (light red plates) resembled that reported[7] (bright red). Further, III_b was hydrogenated to give a saturated aldehyde which afforded a characteristic 2,4-dinitrophenylhydrazone (consult Table II) and was considered to be 3-isopropyl-4-methylpentanal (IV_b).

III

III_a (55%)

III_b (6%)

The intermediate fraction (fraction 2) which was of a relatively small quantity also contained some III_b.

Experimental

3,4-Dimethyl-1-pentyn-3-ol (II).—The carbinol was prepared from methyl isopropyl ketone according to the usual manner[8]. B. p. 132~133°C.

The Formic Acid Rearrangement of II.—Twenty grams of II was gently refluxed for ca. 1 hr. with 160 g. of ca. 80% formic acid. The reaction mixture was allowed to cool and was worked up in the usual manner[1]. Fractions collected were: forerun up to 133°C, a small amount; (1) b. p. 143~151°C, 9 g., yield 45%; (2) b. p. 152~159°C, 1.2 g.; (3) b. p. 160~164°C, 1 g., yield 5%. All these fractions were colorless when freshly

3) Reported, 132~133°C. See Ref. 2.
4) Reported, 185.5~187.5°C and 194~196°C. See Ref. 2.
5) W. J. Hickinbottom, A. A. Hyatt and M. B. Sparke, *J. Chem. Soc.*, **1954**, 2529.
**Hydrogenation product of III_a which was considered to be 3-isopropyl-4-methyl-2-pentanone (IV_a), on treatment with 2,4-dinitrophenylhydrazine, gave only an oily yellow derivative, the color being apparently different from that in the case of the original ketone.

TABLE II. REACTION PRODUCTS FROM III

Fraction	b. p., °C	Yield, g. from 20 g. of III	Constituent
1	67～71 (19 mm.)	11	III_a
2	72～80 (19 mm.)	1	III_a, III_b
3	85～91 (19 mm.)	1.2	III_b

DERIVATIVES OF THE CARBONYL COMPOUNDS

Original Compd.	2,4-Dinitrophenylhydrazone		Semicarbazone	
	M. p., °C	Appearance	M. p., °C	Appearance
III_a	—	Red oil	Could not be obtained	
IV_a	—	Yellow oil	—	—
III_b	173.5～174[6]	Light red plates	208～210	Colorless micro-needles
IV_b	86～88	Yellow plates	—	—

distilled, hardly soluble in water, had camphor-like odor, instantly decolorized bromine water, and reacted with carbonyl reagents. Fraction 1 especially turned yellowish on standing. Fraction 3 had a less camphoraceous odor and, at the same time, a somewhat stimulative smell.

The lower-boiling fractions seemed, from ammoniacal silver nitrate test, still to contain a small amount of the unreacted original carbinol.

Fraction 1 (3,4-dimethyl-3-penten-2-one, II_a) was treated with phenylhydrazine hydrochloride in ethanolic acetic acid in the usual manner of preparation of pyrazoline. A trace of the reaction mixture thus formed gave a pyrazoline reaction of brownish purple color with sulfuric acid and sodium nitrite; the color was apparently different from that in the case of fraction 3; in the latter case a deep pink-purple color was produced.

Fraction 3 (3,4-dimethyl-2-pentenal, II_b) gave positive test with Schiff reagent (pink-purple color) and reduced ammoniacal silver nitrate. On heating it turned Fehling solution into turbid bluish green[1]. That the greater part of the fraction consisted of II_b was ascertained from the quantity obtained of its 2,4-dinitrophenylhydrazone mentioned below. A considerable amount of the same derivative was also obtained from fraction 2 when the fraction was treated immediately after the distillation; the aldehyde diminished on standing, owing possibly to autoxidation and polymerization.

Fraction 3 was hydrogenated with palladium. The crude oily product was positive toward Schiff test (pink color). The amount was insufficient for rigid purification.

The forerun up to 133°C, which was of a small amount, contained a respectable quantity of methyl ethyl ketone which was obtained in the form of its 2,4-dinitrophenylhydrazone; the derivative had m. p. 116～117°C which was undepressed on admixture with an authentic specimen.

2,4-Dinitrophenylhydrazone of II_a was recrystallized from pyridine-ethanol in lustrous orange plates or long plates, m. p. 132～133°C.

Anal. Found: N, 19.26. Calcd. for $C_{13}H_{16}O_4N_4$: N, 19.17%.

Semicarbazone of II_a was recrystallized from methanol, colorless plates, m. p. 185～187°C (slow heating), 198～199°C (rapid heating).

Anal. Found: N, 24.93. Calcd. for $C_8H_{15}ON_3$: N, 24.83%.

2,4-Dinitrophenylhydrazone of II_b was recrystallized from pyridine-methanol, red plates, m. p. 205～206°C, easily soluble in hot pyridine.

Anal. Found: C, 53.27; H, 5.61; N, 19.17. Calcd. for $C_{13}H_{16}O_4N_4$: C, 53.42; H, 5.52; N, 19.17%.

Semicarbazone of II_b was recrystallized from ethanol, colorless plates, m. p. 163～164°C (slow heating), 173～174°C (rapid heating).

Anal. Found: N, 25.33. Calcd. for $C_8H_{15}ON_3$: N, 24.83%.

3-Isopropyl-4-methyl-1-pentyn-3-ol (III).—Prepared from diisopropyl ketone according to the method used in the preparation of II. B. p. 161～164°C (reported 162～164°C; prepared by the liquid ammonia method)[9]. Yield, ca. 50%.

Diisopropyl Ketone.—A mixture of 80 g. of isobutyric acid and 110 g. of lead monoxide was refluxed for ca. 3 hr. The whole was heated under diminished pressure to remove water produced and the unreacted acid. The porous solid material obtained was then dry-distilled and finally under a diminished pressure. The crude ketone was washed with a concentrated solution of potassium carbonate, dried over calcium chloride, and distilled. B. p. 122～128°;C the greater part distilled out at ca. 125°C. Yield, 35%.

The Formic Acid Rearrangement of III.—Twenty grams of III was refluxed with 160 g. of ca. 80% formic acid for ca. 80 min. and worked up as usual. The product was separated into three fractions: (1) b. p. 67～71°C (19 mm.), 11 g., yield 55%; (2) b. p. 72～80°C (19 mm.), 1g.; (3) b. p. 85～91C° (19 mm.), 1.2 g., yield 6%; residue, a small amount of red oil. All these fractions were colorless, hardly soluble in water, had a camphoraceous odor (fraction 3 was accompanied by a somewhat stimulative smell), and instantly decolorized bromine water. The forerun, b. p. ca. 50～67°C (19 mm.) (ca. 2.7 g.) was somewhat yellowish and seemed still to contain a small quantity of the unreacted carbinol, a few white precipitates being produced with ammoniacal silver nitrate.

9) A. F. Thompson, Jr. et al., *J. Am. Chem. Soc.*, **63**, 186 (1941).

Fraction 1 was believed to be *3-isopropyl-4-methyl-3-penten-2-one* (*III_a*)[5]; its nature coincided with that reported by Hickinbottom et al. They obtained the compound also from III with the aid of Rupe reaction.

Anal. Found: C, 75.87; H, 11.32. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50%.

Somewhat greater deviation in the carbon content was due possibly to contamination with a compound enriched in oxygen, perhaps the acid formed on autoxidation of III_b.

This fraction, on treatment with 2,4-dinitrophenylhydrazine, only gave *an oily red derivative; the semicarbazone* could not be obtained. The fraction was refluxed with phenylhydrazine hydrochloride in ethanolic acetic acid, then water was added, and the brown oil separated out gave a pyrazoline reaction of deep bluish violet coloration with sodium nitrite and sulfuric acid.

The same fraction was hydrogenated with palladium to yield an oil of strongly camphoraceous odor, which afforded an oily yellow 2,4-dinitrophenylhydrazone.

Fraction 3 (*3-isopropyl-4-methyl-2-pentenal, III_b*) was positive toward Schiff test (violet color was gradually produced and turned deep pink-purple on standing), and reduced ammoniacal silver nitrate. That the greater part of this fraction consisted of the single compound was ascertained from the quantity obtained of its 2,4-dinitrophenylhydrazone.

The same fraction on being treated with phenylhydrazine in the manner indicated above, gave a brown oil which had a pyrazoline reaction of deep violet coloration.

2,4-Dinitrophenylhydrazone of III_b was recrystallized from pyridine containing a little ethanol, light red plates, m. p. 173.5~174°C (reported m.p. 151.5~153°C)[6]. The derivative became thick deep red prisms or needles when allowed to stand overnight in the acidic reagent (the 2,4-dinitrophenylhydrazine reagent was applied as a methanolic sulfuric acid solution). The melting point of the thick crystals was identical with that of the light red plates, the mixed melting point was undepressed. The light red plates also were converted into the thick crystals on several hours' standing in methanol containing a little sulfuric acid.

Anal. Found: N, 17.52. Calcd. for $C_{15}H_{20}O_4N_4$: N, 17.49%.

Semicarbazone of III_b was recrystallized from methanol, colorless micro-needles, m. p. 208~210°C.

Anal. Found: N, 21.56. Calcd. for $C_{10}H_{19}ON_3$: N, 21.30%.

Hydrogenation Product of III_b (IV).—Half a gram of fraction 3 was hydrogenated in ether with palladium. The reaction product, freed from the ether, was positive toward Schiff test, deep pink color (tinged with purple) being gradually produced. IV was considered to be *3-isopropyl-4-methylpentanal* (*IV*).

2,4-Dinitrophenylhydrazone of IV was recrystallized from pyridine-methanol, yellow plates, m. p. 86~88°C.

Anal. Found: C, 55.67; H, 6.62; N, 17.67. Calcd. for $C_{15}H_{22}O_4N_4$: C, 55.88; H, 6.88; N, 17.38%.

Fraction 2. — The intermediate fraction contained a considerable quantity of III_b as the 2,4-dinitrophenylhydrazone.

The initial distillate of the forerun in the case of fractionation of the rearrangement product, which was collected at ca. 51°C (19 mm.) and weighed 0.2 g., afforded a small amount of 2,4-dinitrophenylhydrazone of yellow plates, m. p. ca. 124°C (from pyridine-methanol). It seemed to be possibly the derivative of acetone produced by hydrolytic fission of III_a; the amount was insufficient for rigid identification.

Summary

The behavior of 3,4-dimethyl-1-pentyn-3-ol (II) and 3-isopropyl-4-methyl-1-pentyn-3-ol (III) toward formic acid was investigated. The carbinols, as in the previous report[1], were chosen as model ones in which the tertiary carbon atom is adjacent to the carbon atom carrying the hydroxyl group. Both carbinols gave a significant quantity of the respective aldehydes. These aldehydes were easily isolated on simple distillation.

II gave 3,4-dimethyl-3-penten-2-one (II_a) in 45% yield and 3,4-dimethyl-2-pentenal (II_b), a new aldehyde, in 5% yield. III gave 3-isopropyl-4-methyl-3-penten-2-one (III_a) in 55% yield and 3-isopropyl-4-methyl-2-pentenal (III_b) in 6% yield. These carbonyl compounds were characterized. III_b was hydrogenated to give 3-isopropyl-4-methylpentanal (IV) as the 2,4-dinitrophenylhydrazone.

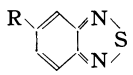
Studies on the Antitubercular Compounds. XVI. Preparation of Some Derivatives of 2, 1, 3-Benzothiadiazole***

By Isao SEKIKAWA



(Received November 19, 1958)

In a previous paper[1] the author has reported the syntheses of several kinds of 4- and 5-substituted 2, 1, 3-benzothiadiazole compound. These compounds have been shown to have no antitubercular activity in vitro. In the present paper, the new compounds listed in Table I and Table II were prepared in order to increase the antibacterial effect of the compounds of this series against *Mycobacterium tuberculosis*. 5-Bromomethyl-2, 1, 3-benzothiadiazole (I) was prepared by bromination of 5-methyl-2, 1, 3-benzothiadiazole with *N*-bromosuccinimide by the usual method, and readily converted into aminomethyl hydrochloride (II) by the Delepine reaction[2].

2, 1, 3-Benzothiadiazole-5-aldehyde (VI) was prepared from I in excellent yields through the hexaminium salt by Sommelet reaction[3]. Reaction of 2, 1, 3-benzothiadiazole with *N*-methylformanilide and phosphorous oxychloride in *o*-dichlorobenzene gave no formyl compound.

VI was readily oxidized into 5-benzothiadiazolecarboxylic acid (III) by the Delepine's method[4] in an alcoholic solution.

TABLE I. 5-SUBSTITUTED 2, 1, 3-BENZOTHIADIAZOLE DERIVATIVES

V	$-CONH_2$
VI	$-CHO$

By the oxidation of 5-methyl-2, 1, 3-benzothiadiazole with potassium permanganate, not only methyl group but also benzene nucleus was attacked, so that III could not be obtained. Chlorination of III with thionyl chloride afforded an acid chloride, which was smoothly converted into acid amide V. Acidhydrazide IV was prepared from III by the usual method. Semicarbazone (VII), thiosemicarbazone (VIII), picolinoylhydrazone (IX), nicotinoylhydrazone (X) and isonicotinoylhydrazone (XI) were derived from VI by condensation with semicarbazide, thiosemicarbazide, α-, β- and γ-pyridinecarbohydrazide, respectively.

A detailed report on the antitubercular activity of these compounds will appear elsewhere.

Experimental

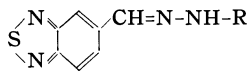
I.—A mixture of 4.5 g. of 5-methyl-2, 1, 3-benzothiadiazole, 5.4 g. of *N*-bromosuccinimide and 150 ml. of tetrachloromethane was refluxed for 18 hr. After cooling in ice bath, succinimide was removed by filtration and washed with 50 ml. of tetrachloromethane. After removing tetrachloromethane, the solidified residue was recrystallized from methanol to give 4.9 g. (70%) of lachrymatory white needles, m. p. 89~90°C.

Anal. Found: C, 36.41; H, 2.36. Calcd. for $C_7H_5N_2SBr$: C, 36.70; H, 2.20%.

II.—To a solution of 2.3 g. of I in 22 ml. of chloroform, 1.4 g. of hexamethylenetetramine was added. The mixture was allowed to stand overnight at room temperature, and the hexaminium salt was filtered and washed with 20 ml. of ether; yield 3.5 g., m.p. 182°C (decomp.)

A mixture of 1.2 g. of the hexaminium salt, 3 ml. of concentrated hydrochloric acid and 7 ml. of water was refluxed for 30 min., and the reaction mixture was concentrated to dryness under reduced pressure. The residue was recrystallized from water to give 0.4 g. of white needles, which softened at 235°C, became brown and decomposed at 245~246°C.

Anal. Found: C, 38.24; H, 4.87; H_2O, 8.10. Calcd. for $C_7H_5N_3S \cdot HCl \cdot H_2O$: C, 38.27; H, 4.59; H_2O, 8.20%.



VI.—A mixture of 3 g. of the hexamethylenetetramine salt, 0.1 g. of hexamethylenetetramine and 6 ml. of 50% acetic acid was refluxed

for 20 min. On cooling, a solid resulted. Recrystallization from methanol afforded 0.6 g. (47%) of white needles, m. p. 94°C.

Anal. Found: C, 51.25; H, 2.56. Calcd. for $C_7H_4ON_2S$: C, 51.21; H, 2.46%.

III.—To a solution of 0.9 g. of VI in 30 ml. of ethanol 2.3 g. of silver nitrate dissolved in 3 ml. of water was added. To the mixture was added 1.5 g. of sodium hydroxide in 10 ml. of water in small portions under stirring.

After being kept overnight, the deposited silver was removed and washed with 10 ml. of water. The solution was acidified with acetic acid to give an orange precipitate which was recrystallized from water to give 0.3 g. of white sandy crystals. It softened at 214°C and melted at 224~225°C.

Anal. Found: C, 46.63; H, 2.57. Calcd. for $C_7H_4O_2N_2S$: C, 46.66; H, 2.24%.

V.—A mixture of 0.4 g. of III and 5 ml. of thionyl chloride was refluxed for 1 hr. The excess of thionyl chloride was removed in a vacuum desiccator. The residue was dissolved in ether, saturated with ammonia and kept at room temperature for 1 hr. After removing ether, the solidified residue was recrystallized from water to give 0.3 g. of white needles, m.p. 202~203°C.

Anal. Found: C, 46.96; H, 3.01. Calcd. for $C_7H_5ON_3S$: C, 46.92; H, 2.81%.

IV.—A mixture of 0.15 g. of III, 3 ml. of absolute ethanol and 0.3 ml. of concentrated sulfuric acid was refluxed for 8 hr. After removing ethanol, the residue was treated with water and neutralized with sodium hydrogen carbonate. The resulting gray solid was heated with 0.1 ml. of hydrazine hydrate (80%) in 5 ml. of ethanol for 8 hr. The mixture was evaporated to dryness and the residue was recrystallized from water to give 0.1 g. of white needles, m.p. 180~181°C (decomp.).

Anal. Found: C, 42.99; H, 3.21. Calcd. for $C_7H_6ON_4S$: C, 43.29; H, 3.11%.

IX.—A mixture of 0.2 g. of VI, 0.16 g. of picolinic acidhydrazide and 5 ml. of ethanol was refluxed for 1 hr. The product was collected and recrystallized from ethanol to give 0.3 g. of yellow needles, m. p. 233~235°C.

Anal. Found: C, 55.13; H, 3.51. Calcd. for $C_{13}H_9ON_5S$: C, 55.11; H, 3.20%.

The Mechanical Behavior of Swollen Polystyrene, Poly-p-chlorostyrene and their Copolymers in Benzene. I. The Degree of Polymer-solvent Interaction and Thermoelastic Properties

By Kazuyoshi OGINO

(Received November 26, 1958)

In the previous papers[1], the influence of the polymer-solvent interaction upon the mechanical properties of the swollen polymethyl acrylate gels was discussed, and it was shown that the mechanical properties of these gels having various degrees of swelling can be interpreted as the function of the interaction force between polymer chains. The intermolecular force between chain polymers was controlled, however, by giving the different degrees of swelling through the use of several organic solvents of different solvent power.

It is interesting to examine, in the next step, how the mechanical properties of gels in a swelling equilibrium with solvents are influenced by the structural units in a polymer molecule.

In this paper, polystyrene, poly-*p*-chlorostyrene and their copolymers, slightly cross-linked with divinyl benzene, are carried into the swelling equilibrium in benzene, and the mechanical properties of these gels are studied.

At the swelling equilibrium with excess solvent, the following equation holds[2]

$$\ln(1-v_r)+v_r+\mu v_r^2=-\rho V_0 v_r^{1.3}/M_c$$

where v_r is the volume fraction of polymer, ρ the density of pure solvent, V_0 the molar volume of solvent, M_c the average molecular weight of polymer between junction points and μ a parameter which indicates the type and degree of interaction exhibited by the polymer-liquid system.

In the region in which the stress-strain curve is reversible, the force f required to extend a specimen to an extension ratio λ is given by[3]

$$f=2Av_r^{-1/3}(\lambda-\lambda^{-2})(C_1+\lambda^{-1}C_2) \qquad (1)$$

where A is an unstrained area of cross section in the dry state, and C_1 and C_2 are the parameters relating to the mechanical properties of the specimen.

At a high degree of swelling, we can obtain the following relation from statistical consideration,

$$C_1=1/2RTM_c^{-1}$$

From these relations, the next equation follows,

$$-\ln(1-v_r)-v_r-\mu v_r^2=2V_0C_1v_r^{1/3}/RT \qquad (2)$$

Thus, we can estimate the value of C_1 from Eq. 1 by plotting the value of $f\{2A_0(\lambda-\lambda^{-2})\}^{-1}v_r^{1/3}$ against λ^{-1} in the results of the stress-strain measurements, and then can obtain the parameter μ from Eq. 2 using this value of C_1.

On the other hand, the following thermodynamic relations can be deduced.

$$(\partial G/\partial\lambda)_T=fl_0 \qquad (3)$$

$$T(\partial S/\partial\lambda)_T=-Tl_0(\partial f/\partial T)_\lambda \qquad (4)$$

$$(\partial H/\partial\lambda)_T=T(\partial S/\partial\lambda)_T+(\partial G/\partial\lambda)_T \qquad (5)$$

where G is the freee energy, H the enthalpy and S the entropy. From the above relations, we can estimate the change of the thermodynamic functions by measuring initial stresses at various strains and temperatures.

Experimental

Samples.—Commercial monomeric styrene and divinyl benzene were purified by fractional distillation under the reduced pressure after the removal of inhibitor with aqueous alkaline solution.

Benzene was purified by the ordinary method.

p-Chlorostyrene was synthesized in the following way[4]. Purified commercial mono-chlorobenzene reacts with acetyl chloride in the presence of aluminum chloride (Friedel-Crafts' reaction), and the *p*-chloroacetophenone thus obtained was reduced to *p*-chloro-phenylmethylcarbinol by isopropyl alcohol saturated with aluminum isopropylate prepared freshly before

the reaction. Finally this carbinol was dehydrated by potassium bisulfate in the presence of picric acid[5] under reduced pressure.

Six cc. of styrene, or *p*-chlorostyrene or a mixture of these two monomers was polymerized with about 0.01 cc. of divinyl benzene in bulk in a sealed glass tube by the method described in the previous paper[1].

The polymer block was then cut into several parts about 1 cm. in length by a turning lathe. Care was taken so that the error in the diameter of the specimen was confined within 10^{-3} cm. These polymer rods were then dipped in the excessive amount of benzene, and brought into the swelling equilibrium.

Apparatus. — The apparatus used in this experiment is the same as that used in the previous experiment[1], and is shown in Fig. 1.

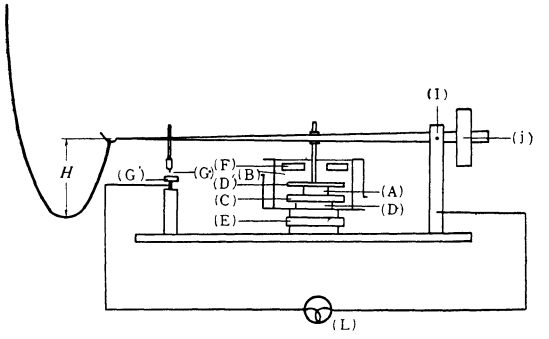

Fig. 1. The apparatus used in this experiment. (A), Specimen; (B), Solvent; (C), Iris; (D), Pressure plate; (E), Screw; (F), Desiccating agent; (G & G'), Contact; (J), Balancing weight.

The specimen in the swelling equilibrium with the solvent is placed between a flat brass block (D) and a pressure plate (D') in the solvent, and is strained vertically to a given extent, by rotating the screw (E) which is graduated to 1/100 mm. The initial stress is measured by the chain (H) using the value of its linear density.

The temperature of the specimen was controlled by circulation of water within the range of ± 0.5°C.

Results and Discussion

The plot of $f\{2A(\lambda-\lambda^{-2})\}^{-1}v_r^{1/3}$ against λ^{-1} at 25°C is shown in Fig. 2, and the values of μ for each polymer are given in Table I.

TABLE I. THE VALUE OF μ IN BENZENE AT 25°C

Polymer	μ
Polystyrene	0.47
Poly-*p*-chlorostyrene	0.49$_5$

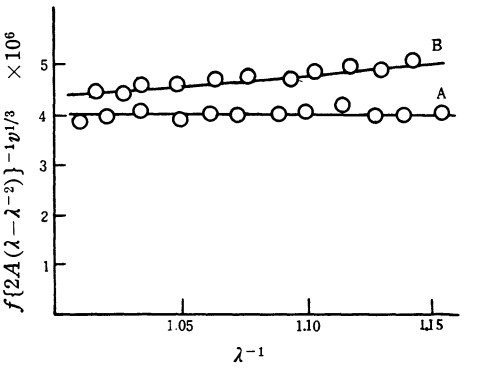

Fig. 2. Diagram of $f\{2A(\lambda-\lambda^{-2})\}^{-1}v_r^{1/3}$ against λ^{-1} for polystyrene-benzene (A) and poly-*p*-chlorostyrene-benzene (B) at 25°C.

The thermodynamic quantities in Eqs. 3, 4 and 5 at 25°C are shown in Figs. 3—6.

The value of μ of 0.47 for the system polystyrene-benzene differs from the value 0.453 by Boyer and Spencer[6] in their study of the stress-strain properties of this system.

Such a difference as this is also found among the other workers: Rivlin et al.[7] obtained the value of μ of 0.42 for natural rubber-benzene, and compared it with the value of 0.395 reported by Gee*. These two values were obtained from the stress-strain measurement of swollen rubbers. The measurements were conducted in ways similar to each other. Rivlin et al. considered that the source of the larger value of μ obtained in their investigation might be due to the degradation of the rubber during prolonged swelling in solvent in the determination of v_r.

An alternative source for the discrepancy in the values of μ originates from the effect of cross-linking as mentioned in the previous paper[1].

The fact that the value of μ of poly-*p*-chlorostyrene (0.49_5) is greater than that of polystyrene (0.47) shows that benzene is not so good a solvent for poly-*p*-chlorostyrene as for polystyrene. This may be due to the substituted chlorine atoms, for there appears a large polarity, and greater interaction may arise between long chain molecules. Thus, polymer-polymer contacts increase by the presence of chlorine atoms, and hence μ becomes larger.

The gradient of the curves of $f\{2A(\lambda-\lambda^{-2})\}^{-1}v_r^{1/3}$ against λ^{-1} is identical with C_2. It is well known that[3] the value of C_2 depends on the degree of swelling, v_r, and is found to be independent of the nature of the rubber polymer, the degree of vulcanization, and of the nature of the swelling liquid. It is associated primarily with the existence of secondary network. The experimental data in Fig. 2 shows a good linear relationship for these two polymers, and the gradients of these two lines, or C_2, are nearly equal to zero. But if we compare poly-*p*-chlorostyrene gel with polystyrene gel, the former has a slightly larger positive value of C_2. From this fact, it is reasonable to assume that the larger restriction to the possible configuration of the molecular chain exists in poly-*p*-chlorostyrene gel, and so the interaction force between long chain molecules can be considered to be stronger.

Deutsch, Hoff and Reddish[8] and also Scott and Magat[9] discussed the effect of some polar groups upon the mechanical and dielectric properties, or upon the cohesive energy density of polymer, and their results support the above consideration**.

The strength of intermolecular force between chain molecules is also estimated from the change of thermodynamic functions. The increase of chlorine content in copolymers corresponds to the large contribution of the term $(\partial H/\partial\lambda)$ to $(\partial G/\partial\lambda)$. The function H can be considered as the internal energy, and the large value of a change of this term may be due to the strong interaction between chlorine atoms, i. e., the change of internal energy when a strain increases is increased by the introduction of a stronger intermolecular force. As these systems are in the same solvent and have a nearly equal volume fraction v_r, we can assume that

the change of the value of μ or of thermodynamic functions comes from the presence of chlorine atoms.

In the present discussion, the author considered that the effect of chlorine atoms may prevail upon their volume effect in relation to the mechanical properties, and took into account only this effect. But, of course, there must exist some volume effect of this polar group, and this is neglected in the above discussion.

The effect of intermolecular forces upon the other mechanical properties by introducing chlorine atoms is now under study.

In concluding this paper, the author wishes to express his thanks to Professor H. Akamatsu and Assistant Professor T. Nakagawa for the advice and guidance given him during his study.

New Preparation of Diphenylsilanediol

By Toshio TAKIGUCHI

(Received November 29, 1958)

In separate papers[1,2] the author has described new methods of preparation of diphenylsilanediol (hereafter called diol), in which it has chiefly been aimed at for successful preparation to minimize the polymeric effect of hydrogen chloride produced thereby. In the present communication the author wishes to present some effective methods together with procedural details to prepare diol directly from diphenyldichlorosilane (DPDS). The first is the preparation from the reaction of DPDS with sodium or potassium hydrogen carbonate, the key feature of this method being the hydrolysis of DPDS with water produced by decomposition of the carbonates. The reaction can be represented summarily by the following equation for sodium hydrogen carbonate:

$$(C_6H_5)_2SiCl_2 + 2NaHCO_3 \rightarrow (C_6H_5)_2Si(OH)_2 + 2NaCl + 2CO_2$$

The fairly stable character of this diol has also prompted the second method which is possibly the simplest among the related works[3] and involves the direct hydrolysis of DPDS with a theoretical amount of water dissolved in inert organic solvents followed by complete removal of hydrogen chloride by using some appropriate reagents, e.g., calcium carbonate, sodium carbonate anhydride, calcium hydroxide, aniline or pyridine.

Experimental

Fine powdered inorganic salts in reagent-grades were used after prolonged drying in a vacuum-desiccator. Aniline and pyridine were distilled under reduced pressure after drying over potassium hydroxide. Reagent-grade acetone, benzene, ethyl acetate and ether were used without further purification. Highest-purity DPDS was received from the Shin-etsu Chemical Industrial Company.

(A) From the Reaction with Sodium or Potassium Hydrogen Carbonate. — Each carbonate undergoes reaction entirely similar to that of DPDS; a typical procedure is shown below. 25 g. (0.3 mol.) of sodium hydrogen carbonate and 200 ml. of acetone-benzene were placed in a one liter flask which had been kept in a water bath maintained at 50°C. A 25 g. portion (0.1 mol.) of DPDS dissolved in 50 ml. of acetone was added portion-wise to the flask which was shaken gently during the addition. On adding the silane solution, carbon dioxide was evolved readily and sodium chloride precipitated as fine white crystalline powder. After the addition was complete, the mixture was refluxed gently for 20 min. and then filtered under suction after cooling. On evaporating the filtrate to dryness on a water bath, a white crystalline mass was obtained from

3) W. Dilthey and F. Eduardoff, *Ber.*, **37**, 1139 (1904); G. Martin, ibid., **45**, 403 (1912); F. S. Kipping, *J. Chem. Soc.*, **101**, 2108 (1912); C. A. Burkhard, *J. Am. Chem. Soc.*, **67**, 2173 (1945); J. F. Hyde and R. C. DeLong, ibid., **63**, 1194 (1941); S. Fukukawa, *Science & Industry, Japan* (*Kagaku to Kogyo*), **30**, 71 (1956).

which 20 g. (93%) of pure diol was obtained by recrystallization from ethyl acetate.

(B) **Direct Hydrolysis Method.**— In a one liter flask, were placed 400 ml. of acetone-benzene and 7 g. (0.4 mol.) of distilled water. After the addition of 51 g. (0.2 mol.) of DPDS to the flask, the mixture was shaken gently for a few minutes. Then, fine powdered calcium carbonate was added portion-wise to the flask which had been preheated at about 50°C, whereby the carbonate decomposed exothermally, evolving carbon dioxide. The addition was continued until the crystal violet indicator (1 drop of 1% ethanol solution) which had been added gradually should acquire a distinct purple color. After the reaction was over, the mixture was treated similarly to A, yielding 39 g. (90%) of white needles.

The use of sodium carbonate in place of calcium carbonate yielded 84% (mean) of diol, while the use of calcium hydroxide gave a considerable amount of uncrystallizable oily product caused by the presumable polymeryzing effect of the hydroxide.

Lastly, the use of aniline[1] or pyridine as hydrogen chloride acceptor gave entirely similar results, whereby the hydrochloride of each base precipitated as fine crystalline powder, the yield of diol being 88~92%.

Some Properties of Diol.—The diol thus obtained has been identified by its infrared absorption data[4] and the interplaner spacing data[1] (by diffractometer). [Found: Si, 12.7; OH/molecule, 1.97 (Karl Fischer titration)[5]; mol. wt., 195~204 (glacial acetic acid)]. The density (measured in aqueous calcium chloride solution of the matched density) was 1.16. The melting point[6] showed a variety of 132~133, 142~144, 147~148, 155 and 158~160°C in spite of all careful measurements. Melting was always accompanied by decomposition and successive fusion always lowered the melting point.

The author gratefully acknowledges the helpful discussions with Dr. F. Hirata in whose laboratory this work was performed.

*Dye-sensitized Photopolymerization of Vinyl Compounds. Polymerization of Styrene by Cyanine Dyes. III**

By Ai WATANABE

(Received December 3, 1958)

As reported in the previous papers[1,2], the photopolymerization of styrene occurs when the mixture of styrene and butanol (15 : 1 in volume) involving various cyanine dyes is irradiated by the visible light. The dye, at the same time, is bleached and it was concluded that both these reactions are initiated by a direct interaction between the excited dye molecule and the styrene. Generally speaking, however, the initial processes for the two reactions are not identical, since, for example, the number of kinetic chains for one decomposed dye molecule is a function of temperature. The participation of halogen ion in the reaction is highly plausible because of a marked difference between the rates for pinacyanol-iodide and -chloride. In order to elucidate the photochemical processes in these reactions, it would be desirable to compare the kinetic features of bleaching and polymerization, but only studies on the latter will be reported in this paper. Activation energies for the chain initiation were determined for various dyes and the influence of halogen species was examined. In addition, the following two facts which had been tentatively described in the previous paper[2] were reconfirmed: 1) light promotes only the initiation process of polymerization; 2) the concentration of dye

* Presented before the Ninth Annual Meeting of the Chemical Society of Japan, held at Kyoto, April 1956 and the Tenth Meeting at Tokyo, April 1957.

does not affect the rate in the region of $6.3\times10^{-6}\sim19\times10^{-6}$ mol./l.

Experimental

Material.—Styrene and *n*-butanol were purified in the same way as in the previous paper[1]. Isocyanine iodide, pinacyanol iodide and kryptocyanine iodide were granted by the late Dr. T. Ogata of the Institute of Physical and Chemical Research, Tokyo. All the other dyes except the above three were kindly supplied by the Japanese Research Institute for Photosensitizing Dyes, Co., Ltd. in Okayama.

Apparatus and Experimental Procedure.—The apparatus employed and the experimental procedure are mostly identical with the previous ones[1], but the dilatometric technique was adopted to follow the course of polymerization. The type of dilatometer was almost the same as used by Nakatsuka[3] except that a drum-type reaction cell of about 5 cc. in capacity was made of quartz and connected to a tube of hard glass. The reaction cell was arranged so as to let the parallel light beam illuminate the whole plane surface of the drum. Matsuda color filters were used; V-O 2 for pinacyanol, kryptocyanine and isocyanine, and V-Y 1 for trimethinthiocyanine.

One volume of *n*-butanol solution of dye was mixed with 15 volumes of styrene and the mixture was extensively evacuated. The concentration of the dye is always 1.2×10^{-5} mol./l. unless otherwise cited.

The extent to which the polymerization proceeded was calculated from the volume contraction, as performed by Burnett[4] employing the data of density for monomer and polymer reported by Patnode and Scheiber[5]. The average degree of polymerization was determined as in the previous paper[1].

Experimental Results

The Characteristics of the Bleaching Reaction.—The absorption spectra of various dyes employed are shown in Figs. 1 and 2. To avoid the overlapping of curves, the plot of $\log I_0/I$ is suitably displaced for some dyes, the magnitude of displacement being given by X. It is evident from these figures that in the butanol solution the position of absorption maximum is not affected by the kind of halogen, but in the styrene-butanol solution the maximum is more or less displaced to the longer wavelengths, the magnitude of shift being slightly different according to the species of dye and halogen.

The butanol solution of each dye does not bleach practically at 60°C even after

(or does very slightly perhaps because of the dissolved oxygen or some impurities), but when illuminated, the bleaching occurs and at the same time the polymerization is promoted. The only curious exception is kryptocyanine bromide which is photobleached without inducing the polymerization, but retarding it very slightly at 60°C. Some of the absorption curves after the reaction for several hours are shown in Figs. 3, 4, 5 and 6. In case of pinacyanol, a new small absorption band appears in the visible region. So does it with isocyanine. In case of trimethinthiocyanine or kryptocyanine, the absorption curves merely decline over the whole visible region.

Effect of the Concentration of Dye.— Though it is a natural expectation that the rate of photochemical initiation is proportional to the intensity of light absorbed, there is some doubt about it under the present experimetal condition, since the dye of about 10^{-5} mol./l. in concentration absorbs nearly all the light and the distribution of the excited molecule in the system is not uniform. Hence it is desirable to check whether such a state of affairs does influence the rate or not. In the previous report it was perceived that the rate of polymerization is independent of the concentration of pinacyanol iodide in the range of $6\sim20\times10^{-6}$ mol./l. at 60°C, but this was not necessarily

conclusive since the styrene then used was not so carefully purified. Therefore the analogous experiment was repeated with more caution at 40°C. The results are tabulated in Table I. It is quite certain from Table I that the rate is completely independent of the dye concentration. In view of the absorbance of the dye the effective light is almost completely absorbed and the rate is not influenced by

TABLE I. EFFECT OF PINACYANOL IODIDE CONCENTRATION AT 40°C

Expt. no.	Dye concn. (10^{-6} mol./l.)	Relative rate (mm./hr.)
1	6.3	1.60
2	6.3	1.70
3	6.3	1.50
4	12	1.65
5	12	1.70
6	12	1.65
7	19	1.55
8	19	1.60

the dye concentration under the light intensity employed, but is determined by the quantity of excited dye produced in the whole system in a unit time.

The Relation between the Average Degree of Polymerization and the Overall Rate.—In the previous report[2], a test was made to see whether the irradiation only induces the chain initiation or also affects other steps such as propagation or termination. Using many data for several cyanine dyestuffs under various experimental conditions, the reciprocal of $\bar{P}_L$ (the average degree of polymerization for the polymer produced in the irradiated region of the reaction cell) was plotted against the overall rate V (the quantity of polymer produced in the irradiated region in a unit time). An approximately linear relationship was obtained supporting the view that the light only promotes the initiation process. But the points of data were not so satisfactory showing some scattering and it seemed desirable to repeat it again. In the present experiments, the solution of pinacyanol iodide of 1.2×10^{-5} mol./l. in concentration was used at 60°C and the intensity of light was varied by means of gauze wires. The results obtained by a similar treatment as in the previous paper are shown in Fig. 7. In this figure $\bar{P}_D$ is the average degree of polymerization in the dark part. The data are still distributed with some randomness, but in view of the fact that the value of $\bar{P}_D$ employed for the evaluation of

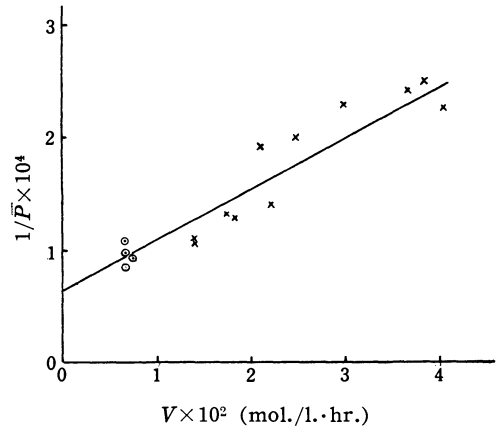

Fig. 7. Variation of the average degree of polymerization with the overall rate. ⊙, in dark; ×, in light.

$\bar{P}_L$ was a mean of many data in the dark, and further taking into account the poor reproducibility of the experiment the linearity can be regarded to hold.

Activation Energy. — The energy of activation was determined from rate measurements between 20° and 60°C under illumination and between 40° and 60°C in the dark using the dye solution of 1.2×10^{-5} mol./l. in concentration. The rate of photochemical reaction V_p was determined from the expression $V_p=\sqrt{V_l^2-V_d^2}$, where V_d is the rate of thermal reaction in the illuminated space and V_l is the total rate under illumination. The relation between $\log V_p$ and $1/T$ for various dyes is shown in Figs. 8, 9 and 10, where V_p are represented in per cent per hour. In case of pinacyanol iodide, V_p shows an abnormally high value at 50° and 60°C, but these are excluded from the calculation of

activation energy for the following reason. In the course of decomposition, this dye is transformed into a stable intermediate with a new visible absorption band, which is further decomposed by light absorption at 60°C accompanied with the induced polymerization. The above mentioned decomposition of the intermediate is far more rapid for iodide than for bromide or chloride as is evident from the Figs. 3, 4 and 5. Hence the polymerization induced by the decomposition of the intermediate is remarkable only for pinacyanol iodide at higher temperatures, while for bromide and chloride, in which similar intermediates are also produced, this secondarily induced polymerization is negligible at least in the initial stage of reaction due to their much lower rates of decomposition**. In case of isocyanine a new small peak also appears in the shorter wavelength region but the filter V-O 2 in this case does not transmit the light corresponding to the absorption of the intermediate, hence the polymerization due to its destruction will not take place. In case of kryptocyanine or trimethinthiocyanine the absorption declines monotonously in the whole visible region and the above considerations need not be taken into account. The values of the activation energy for the overall reaction thus evaluated are tabulated in Table II. By making use of Bamford's values[6] of activation energies for chain growth and chain termination (E_p=6.5 kcal./mol., E_t=2.8 kcal./mol.), the activation energy for initiation E_i can be calculated from the relation $E_i=2E-2E_p+E_t$. They are also included in Table II. Although the errors of these values are rather large owing to the poor reproducibility of experiments, some features can be seen and semi-quantitative discussions will be given below on the basis of these data.

TABLE II. ACTIVATION ENERGY (kcal./mol.)

Dye	Dark-reaction		Photo-reaction	
	E	E_i	E	E_i
No dye	22.9	35.6

Discussion

If the irradiation only promotes the

** Filter V-O 2 transmits the light including the absorption maximum of the intermediate as well as the two absorption peaks of the original dye.

6) C. H. Bamford and M. J. S. Dewar, *Proc. Roy. Soc.*, **A192**, 309 (1948).

chain initiation, then the following linearity between the reciprocal of $\bar{P}_L$ and V must hold as derived in a previous paper[2].

$$1/\bar{P}_L = k_t V/2\,k_p^2\,[M]^2 + (R_{tr\cdot M}[M] + k_{tr\cdot S}[S])/k_p[M] \quad (1)$$

where k_p, $k_{tr\cdot M}$, $k_{tr\cdot S}$ and k_t are the rate constants for propagation, monomer transfer, solvent transfer and termination, respectively, and $[M]$ and $[S]$ denote the concentrations of the monomer and the solvent, respectively. Under the present experimental conditions $k_{tr\cdot S}[S]$ can be neglected against $k_{tr\cdot M}[M]$, hence from the intercept and the inclination of the straight line in Fig. 7, $k_{tr\cdot M}/k_p$ and k_t/k_p^2 can be evaluated, to be 6×10^{-5} and 2.1×10^3 mol. l^{-1} sec., respectively. The value of $k_{tr\cdot M}/k_p$ obtained above shows an excellent coincidence with that reported by Mayo et al.[7] As for the value of k_t/k_p^2, Bamford's data[6], $k_t=4.6\times10^6$ l. mol^{-1} sec^{-1} and $k_p=60$ l. mol^{-1} sec^{-1} at 60°C, give $k_t/k_p^2=1.28\times10^3$ mol. l^{-1} sec., while Matheson's values[8], $k_t=7.2\times10^7$ l. mol^{-1} sec^{-1} and $k_p=176$ l. mol^{-1} sec^{-1}, give $k_t/k_p^2=2.32\times10^3$ mol. l^{-1} sec. and the present value is about the same as the Matheson's one. From the agreement of these constants it is certain that the irradiation only induces the chain initiation process and does not affect either the propagation nor the termination process. Thus there is no doubt that the mechanism of the photochemical initial process may be discussed on the basis of the values of E_i tabulated in Table II.

Table II indicates that mere interchange of the halogen often results in a marked change in E_i-value and it can be concluded that the halogen ion plays an essential rôle in the primary photoprocess. Next, broadly speaking, a tendency is noted that the larger the frequency of absorbed light, the smaller is the value of E_i. In the following, some considerations will be given about these results more closely.

From the fact that bleaching does not occur in the absence of monomer, there is no doubt that the photochemical process takes place between the excited dye and the monomer. Further the chain initiation of polymerization is considered to be induced by a radical, since the quantitative aspects of polymerization such as the values of k_t/k_p^2 and $k_{tr\cdot M}/k_p$ coincide with the data for the well-established radical polymerization. Of course, a detailed description of the photochemical primary process is beyond the scope of the present stage of investigation, but some consideration about it will be helpful for further investigation.

As regards the formation of the radical, it seems natural to suppose that in the course of attack of a styrene molecule on dye, an electron-transfer occurs, the electron of a halogen anion being transferred to a dye cation. Then, the styrene molecule may seize a halogen atom and the two radicals produced may sometimes both induce the chain-initiation, or otherwise the dye-radical produced may decompose of itself.

It will be described in the following how the above idea is materialized and how it can explain the present results. Firstly, according to the above idea, the photochemical primary process may be pictured as follows:

$$\underset{\text{Initial state}}{D^+{}^*\cdots X^-} + M \rightarrow \underset{\text{Activated state}}{D\cdots X\cdots M} \rightarrow \underset{\text{Final state}}{D\cdot + MX\cdot}$$

where D^+ and X^- are a dye cation and a halogen anion, respectively. The activated state would have a configuration in which an electron is transferred from X^- to D^+ and a bond is partially formed between X and M, these two processes chiefly determining the energy of the activated state.

In case of a common D, a) the ease of electron transfer would be in the order, $I > Br > Cl$, while b) the energy decrease due to $X-M$ partial bond formation would be in the reversed order $Cl > Br > I$. If a styrene molecule is separated from $D\cdots X$ in the activated state, then a) would be a chief factor in determining the activation energy. On the contrary, when a styrene molecule is in close proximity to X, the activation energy would depend largely on b). Such would be the reason why the influence of halogen on activation energy is different in each dye.

In case of different D, the maximum of absorption differs and at the same time the tendency of electron transfer would also do so. Roughly speaking, these two factors would commonly act in the same direction for the following reason. The longer the wavelength of the absorption maximum which in many cases is caused by the longer chain of conjugation, the higher the highest occupied level

7) F. R. Mayo, R. A. Gregg and M. S. Matheson, *J. Am. Chem. Soc.*, **73**, 1691 (1951).
8) M. S. Matheson, E. E. Auer, E. B. Bevilacqua and E. J. Hart, ibid., **73**, 1700 (1951).

(or the lowest vacant level) lies and an electron is expected to transfer from X^- to D^+ with more difficulty. Thus it is expected that activation energy becomes greater as the absorption band is situated in the longer wavelength. This expectation is in accord with a general trend of the results.

The above qualitative discussion can be stated in much clearer form for an ideal case in which only the electron transfer

$$(D^+X^-)^* \rightarrow D \cdot X \cdot$$

is essential. It would be convenient to discuss this problem in terms of potential energy curves drawn against the distance between D and X. In Fig. 11, 1 is a

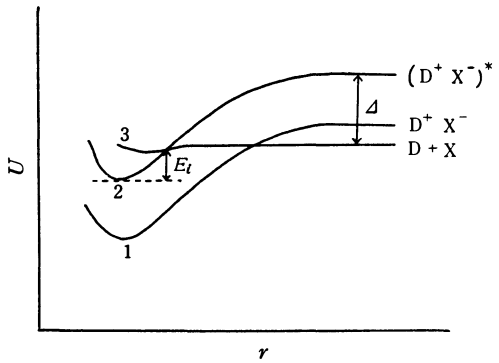

Fig. 11. Potential energy diagram.

potential energy curve of a dye in the ground state which is chiefly determined by the coulombic attraction between the solvated ions. 2 is the one of the excited dye, and 3 is a curve for the system after the electron is transferred from a halogen anion to a dye cation. The relative positions of the three curves are arbitrarily chosen but this does not essentially affect the discussion. Now at a larger distance, the energy difference between 2 and 3, Δ, is given by the equation

$$\Delta = I_D - A_X + h\nu - S \qquad (2)$$

where I_D is the ionization potential of a dye radical, A_X, the electron affinity of a halogen atom, $h\nu$, the energy of an absorbed quantum and S, a correction term related with the energy of solvation.

If the potential minimum in 1 and 2 is given by $e^2/\varepsilon r_X$ where r_X is the D–X distance in the minimum and ε is the effective dielectric constant, then the energy of activation is given by the following equation,

$$E_i = e^2/\varepsilon r_X - \Delta$$
$$= e^2/\varepsilon r_X - I_D + A_X - h\nu + S \qquad (3)$$

For a series of cyanine dyes with various halogens, E_i is determined by the value of

$$(e^2/\varepsilon r_X + A_X + S_X) = \delta_X$$

A_X for iodine, bromine and chlorine is respectively $72 < 81 < 87$ kcal./mol.[9] and S_X is most certainly in the same order. $e^2/\varepsilon r_X$ cannot always be determined by the size of a free ion, but may depend rather on the degree of solvation. In the former case it is in the order Cl > Br > I while in the latter case it might be reversed. If the magnitude of δ_X is mainly determined by $A_X + S_X$ then the activation energy will be in the order Cl > Br > I. Such would be the case for pinacyanol. The fact that there is no great difference in the values of E_i for isocyanine and kryptocyanine might be due to the participation of X–M bond energy in the activated state or to the contribution of $e^2/\varepsilon r_X$ in the inverse order depending on the structure of dye. In this connection, it seems suggestive that for trimethinthiocyanine and pinacyanol for which halogen anion can be placed naturally in between two N atoms, the value of E_i is much dependent on X, while for isocyanine and kryptocyanine for which halogen ion has to be situated in the neighborhood of one N atom apart from the other, the value of E_i is scarecely dependent at all on X. But it is a problem for the future why in the former pair, trimethinthiocyanine and pinacyanol, the effect of halogen is roughly in the inverse order.

Eq. 3 can also give a plausible interpretation of the results for various dyes with common X. With larger ν, I_D perhaps will also become larger, especially in cases when ν is largely dependent on the length of the chain and this causes E_i to become smaller. This is a general tendeny already mentioned.

Although a conclusive statement must await further investigation, the general feature of scheme would be as pictured above.

Summary

Extensive studies on the photopolymerization of styrene by virtue of cyanine dyes were performed and it was reconfirmed

9) A. Eucken and Landolt-Börnstein, "Zahlenwerte und Funktionen", I. Band, 1. Teil, Springer-Verlag, Berlin (1950), p. 213.

that only the chain initiation is promoted by the direct interaction between the excited dye and the styrene molecule. Activation energies for the photochemical initiation process were experimentally determined for several dyes of iodide, bromide and chloride. In general the activation energy depends on the kind of halogen ion and from this result it was concluded that halogen ion plays an essential rôle in the reaction. A general tendency was observed that the activation energy diminishes as the wavelength of absorption maximum of dyes becomes shorter. A plausible scheme for the chain initiation process was given, in which an electron transfer from X^- to D^+ is involved in the process of activation.

The author expresses her cordial thanks to Professor M. Koizumi of Tohoku University for his helpful discussions and to Professor R. Fujishiro and Professor S. Kawaguchi for their encouragement. She is also grateful to Dr. M. Banno of the Japanese Research Institute for Photosensitizing Dyes, Co., Ltd. in Okayama and to the late Dr. T. Ogata of the Institute of Physical and Chemical Research in Tokyo for their kind favors with dye samples. The cost of the present research has been partly defrayed from the Scientific Research Grant from the Ministry of Education.

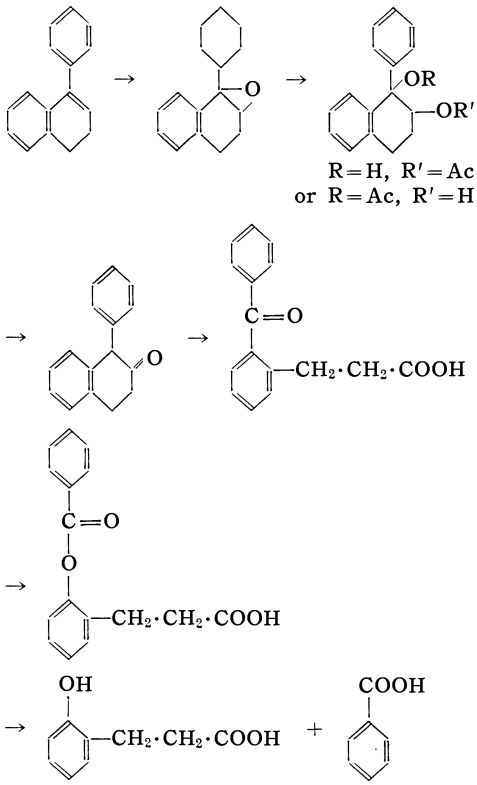
Oxidative Cleavage of 1-Phenyl-dialin with Peracetic Acid

By Yoshinobu ODAIRA and Shigeru TSUTSUMI

(Received December 4, 1958)



The present authors, recently, have carried out an extensive study on the oxidative cleavage of various compounds with peracetic acid, and it has been found that the hydroaromatic ring was readily dehydrogenated by peracetic acid. Our previous reports[1] indicated that the oxidative cleavage of dialin proceeded in two different reactions in an initial stage; the one was epoxidation and the other, dehydrogenation. On the contrary, the oxidative cleavage of 1-alkyl-dialin (4-alkyl-Δ^1-dialin) was shown to proceed by a predominant epoxidation with no dehydrogenation owing to the influences of alkyl groups.

In order to investigate the substituent-effects of phenyl group, the oxidative cleavage of 1-phenyl-dialin (4-phenyl-Δ^1-dialin) was carried out with peracetic acid. A mixture of 1-phenyl-dialin, ammonium molybdate and glacial acetic acid was heated at 40°C, and then 30% hydrogen peroxide solution was added. After the addition was completed, the reaction mixture was still maintained at the same temperature for further 12 hr.

From the neutral part, melilotine and 1-phenyl-tetralone-2 were isolated, and the presence of monoacetate of 1, 2-dihydroxy-1-phenyl-tetralin was confirmed, but unreacted 1-phenyl-dialine was not found. Moreover, the products obtained from the acidic part were benzoic acid, melilotic acid and the benzoate of melilotic acid. The benzoate of melilotic acid was confirmed by elementary analysis, infrared spectrum measurement and hydrolysis. In the ultraviolet spectrum of the compound in 95% ethanol, the maximum absorption is present in 263 mμ ($\log \varepsilon$ 3.45) and 272 mμ ($\log \varepsilon$ 3.35). It is very interesting to note that no product formed by dehydrogenation was isolated.

From these results and also by analogy with the case of 1-alkyl-dialin, it was concluded that the reaction of peracetic acid with 1-phenyl-dialin proceeded by a predominant epoxidation with no dehydrogenation, followed by the oxidative cleavage. Although *o*-carboxyethyl-benzophenone could not be isolated, it might be considered to be the precursor of the benzoate of melilotic acid. Thus the essential steps in the reaction were as follows;

1) Y. Odaira and S. Tsutsumi, *Technol. Repts. Osaka Univ.*, 8, 455 (1958).

In order to obtain further evidence for the above sequence, an authentic 1-phenyl-tetralone-2 was oxidized with peracetic acid and the benzoate of melilotic acid, benzoic acid and melilotic acid were isolated in good yields as the oxidation products.

Compared with the case of 1-alkyl-dialin, it is very interesting that the Baeyer-Villiger reaction occurred because of the effect of phenyl substituent in this case.

It is generally accepted that, in the cleavage of unsymmetrical diaryl ketones[2] by the Baeyer-Villiger oxidation, the migrating group is normally the more electron-releasing one. For example, treatment of *p*-methyl-benzophenone with peracetic acid gives benzoic acid and *p*-cresol; that is, *p*-tolyl group migrates more readily than phenyl group. On the other hand, the oxidation of *o*-methyl-benzophenone with peracetic acid[3] leads to the mixture of *o*-tolylbenzoate (12%) and phenyl-*o*-toluate (38%). Therefore, it is obvious that the ortho-effect can even overcome, to some extent, an electronic effect in the opposite direction (*o*-tolyl vs. phenyl).

In the series $Ph\cdot(CH_2)_n\cdot COOH$ it was found that, whereas the absorption band of benzoic acid is at 268 mμ (ε 1780), the ω-phenyl fatty acids from phenyl-butyric acid upwards have the absorption maximum at 260 mμ with greatly reduced intensity (ε ca. 200), and that this absorption is almost identical in every respect with that of a mixture of ethylbenzene and acetic acid[4]. Moreover, *o*-toluic acid and *o*-carboxyethyl-benzoic acid have the same maximum band at 278 mμ ($\log\varepsilon$ 3.15 and 3.08, respectively).

From the above ultraviolet spectra results, it may be assumed that no resonance between carboxyl group and benzoyl group in the molecule of *o*-carboxyethyl-benzophenone exhibits, and the compound will be considered as identical with *o*-methyl-benzophenone from the electronic point of view. If the above concept is true, phenyl group should migrate more easily than *o*-carboxyethyl-phenyl group owing to the ortho-effect, and one would expect the stronger retarding effect of *o*-carboxyethyl group, since this group is bulkier than methyl group. Actually, the reverse result was obtained in our experiments; namely, only the benzoate of melilotic acid was isolated and the migration of *o*-carboxyethyl-phenyl group occurred predominantly.

A more plausible explanation of such an abnormal phenomenon appears to be the steric assistance caused by steric interference of *o*-carboxyethyl group. Further discussion of the problem of the steric assistance in the Baeyer-Villiger reaction now requires more detailed experiments.

Experimental

Reagent.—1-Phenyl dialin, (b. p. 178~180°C/12 mmHg; $n_D^{20.5}$ 1.6323), was prepared from tetralone-1 according to the procedure of Weiss[5] in 55% yield. Ultraviolet absorption spectrum: λ_{max} 227.5 mμ, $\log\varepsilon$ 4.26; 265.0 mμ, $\log\varepsilon$ 3.92; λ_{min} 248.0 mμ, $\log\varepsilon$ 3.84 (*iso*-octane). Infrared absorption spectrum: ν_{max} 1500, 1600 cm^{-1} (aromatics), 827 cm^{-1} ($CR_1R_2=CHR_3$); no OH band.

Oxidative Cleavage of 1-Phenyl-dialin.—A mixture of 1-phenyl-dialin (15 g.), ammonium molybdate (0.13 g.) and glacial acetic acid (240 cc.) was heated at 40°C, and then 30% hydrogen peroxide solution (30 cc.) was slowly added with stirring in the course of 2 hr. After the addition, the solution was maintained at the same temperature with continued stirring for another 12 hr. To the above solution was added hot water (350 cc.) with stirring to decompose most of unreacted peracetic acid and allowed to stand

5) R. Weiss, *Org. Syntheses*, **24**, 84 (1944).

for 2 days. The reaction mixture was concentrated as completely as possible on a steam bath under reduced pressure (40°C/20 mmHg).

The orange residue obtained was dissolved in ethyl ether (350 cc.), the ethereal layer was extracted with three 200 cc. portions of 10% aqueous sodium bicarbonate and divided into the ethereal layer (I) and the sodium bicarbonate solution (II). The ethereal layer (I) was washed with water and dried over anhydrous sodium sulfate. After evaporation, 5.5 g. of the yellowish residual oil was distilled under reduced pressure. The product, on fractionation, gave: (i) b. p. 120~140°C/6 mmHg (0.5 g., n_D^{28} 1.5560); (ii) b. p. 180~195°C/6 mmHg (2.7 g., n_D^{28} 1.6080); and (iii) dark orange residue (2.0 g.).

The fraction i, having the perfume like coumarine, showed the presence of lactone group (ν_{max} 1786, 1754 cm^{-1}) and ortho-substitution (ν_{max} 757, 746 cm^{-1}) in the infrared spectrum, and gave 0.32 g. of melilotic acid, m. p. 82~83°C, by hydrolysis with 25% potassium carbonate.

Melilotic acid obtained showed no melting point depression by mixing with the authentic melilotic acid prepared from coumarine. From these facts, the above fraction i was determined as melilotine.

The fraction ii gave a positive Brady's test and showed the presence of carbonyl group in the infrared spectrum. Oxime of the fraction ii was obtained as colorless needles, m. p. 184~185°C.

Anal. Found: N, 5.97. Calcd. for $C_{16}H_{15}ON$: N, 5.90%.

Lit. b. p. 156~158°C/1 mmHg (n_D^{24} 1.6089) for 1-phenyltetralone-2; m. p. 184~185°C for oxime of 1-phenyltetralone-2.

From these facts, the carbonyl compound obtained in the fraction ii was confirmed to be 1-phenyl-tetralone-2. A mixture of the fraction iii and 30% sulfuric acid (15 cc.) was heated under reflux for 3.5 hr. After cooling, the reaction mixture was treated in the usual ways and gave 0.8 g. of brown oil. The oxime obtained from the above oil melted at 184~185°C and weighed 0.34 g. Since the oxime was identified as the oxime of 1-phenyl-tetralone-2, it might be considered that monoacetate of 1,2-dihydroxy-1-phenyl-tetralin was contained in the fraction iii, the yield calculated from the oxime obtained was 0.402 g.

The above sodium bicarbonate solution II was acidified with dilute hydrochloric acid and saturated with sodium chloride and extracted with ethyl ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After the solvent was evaporated, 10.7 g. of crude acid was isolated. The crude acid was distilled under reduced pressure. The product, on fractionation, gave: i b. p. 125~200°C/7 mmHg (3.2 g.); and ii brown viscous residue.

The fraction i was recrystallized from water to 1.1 g. of colorless needles, m. p. 121°C. *p*-Bromo-phenacyl-ester of this crystal was obtained as colorless needles, m.p. 119°C. Since this crystal showed no melting point depression by mixing with pure benzoic acid, and the infrared spectrum of this crystal was in good agreement with that of pure benzoic acid, the above crystal was confirmed to be benzoic acid.

The above recrystallization mother liquor was extracted with ethyl ether and dried over anhydrous sodium sulfate. After the solvent was evaporated, the yellowish residual oil was distilled, giving a colorless oil, b. p. 265~275°C. Hydrolysis of this oil with 25% potassium carbonate gave 0.45 g. of colorless needles, m. p. 82~83°C, identified as melilotic acid by mixed fusion.

The fraction ii, a brown viscous residue, was dissolved in benzene-light petroleum ether (1 : 1) and chromatographed by passing the solution through a silica-gel column. The column was then eluted with benzene and evaporation of benzene from the effluent left 3.3 g. of colorless crystals, m. p. 144~145°C. Recrystallization from benzene afforded colorless needles, m. p. 145.5°C.

Anal. Found: C, 70.96; H, 5.47. Calcd. for $C_{16}H_{14}O_3$: C, 71.10; H, 5.22%.

Infrared analysis showed the absence of diarylketone group and hydroxyl group, whereas the presence of the hydroxyl stretching vibration of carboxyl group (ν_{max} 2700 cm^{-1}) and carbonyl group (ν_{max} 1730, 1706 cm^{-1}). *p*-Bromo-phenacyl-ester of the above crystals was obtained as colorless needles, m. p. 166~167°C.

In the ultraviolet spectrum of the above crystals, m. p. 145.5°C, the maximum absorption lies at 263 mμ (log ε 3.447) and 272 mμ (log ε 3.555) in 95% ethanol.

Moreover, hydrolysis of 2 g. of the above substance by sodium-alcoholat gave 0.78 g. of benzoic acid and 0.86 g. of melilotic acid. From these facts, the above substance was identified to be the benzoate of melilotic acid.

Oxidative Cleavage of 1-Phenyl-tetralone-2.—A mixture of 1-phenyl-tetralone-2 (2.5 g.), ammonium molybdate (0.02 g.) and glacial acetic acid (40 cc.) was heated at 40°C, and then 30% hydrogen peroxide solution (50 cc.) was slowly added with stirring. After the addition, the reaction mixture was kept at the same temperature with continued stirring for 14 hr. The reaction mixture was treated in the usual ways. Remaining 1-phenyl-tetralone-2, the benzoate of melilotic acid, benzoic acid and melilotic acid were obtained, and the yields were 1.6 g., 12 mg., 0.25 g. and 0.22 g., respectively.

Intramolecular Interaction between Hydroxyl Group and π-Electrons. II[1]*. Limitation of the Interaction by Chain-length in ω-Hydroxy-1-alkenes**

By Michinori Ōki and Hiizu Iwamura

(Received December 16, 1958)

Recent studies on the intermolecular interaction between the hydroxyl group and aromatic nucleus have led some authors to examine the O–H stretching absorption band in the infrared region with compounds which are considered to possess possible intramolecular interaction between the hydroxyl group and aromatic nucleus. The first of these examples was found by Trifan and his co-workers in α-hydroxyethylferrocene and β-phenylethyl alcohol[2]. However, the phenomenon, splitting of the O–H stretching band, had been known for some years, although those authors who investigated the matter were not quite aware of the cause. That is to say, O–H stretching bands were found by Wulf[3] in 2-hydroxybiphenyl, by Fox and Martin[4] in benzyl alcohol and by Barnard and his collaborators[5] in cumene α-hydroperoxide.

Quite recently Goldman and Crisler[6] have also reported the existence of two O–H stretching bands in the first overtone vibrational region in some β-phenylethyl alcohol derivatives, but these examples mentioned here are all limited to the participation of an aromatic nucleus in the interaction as a hydrogen acceptor. Therefore, the authors felt that it was necessary to know whether a conjugated π-electron system, such as an aromatic ring, is really indispensable to this interaction and carefully investigated the O–H stretching absorption of ω-hydroxy-1-alkenes.

Although the only known example of the intermolecular interaction between the hydroxyl group and isolated double bond was the result of Lüttke and Mecke[7] who found it in cyclohexene and phenol, it turned out to be true that the intramolecular interaction between the hydroxyl group and π-electrons of an isolated double bond does exist, the result being in agreement with that obtained by Baker and Shulgin[8] who published a paper on the interaction in *o*-propenylphenol and *o*-allylphenol during the preparation of this paper.

Experimental

Measurement and Calculation. — The infrared absorption was measured with a Perkin Elmer Model 112-G Double Pass High Precision Grating Infrared Spectrometer[9], the spectral slit width being 1.0 cm^{-1} in the region required. Eastman-Kodak spectro grade or redistilled carbon tetrachloride was used as a solvent. A quartz absorption cell 2 cm. in length was used and the concentration of the solution was 0.0025～0.0032 mol./l. at which dilution the association of the solute is negligible. The temperature was 28.0～28.5°C.

The integrated intensities of the two bands were calculated according to the equations

$$A = \pi/2 \cdot \Delta\nu_{1/2} \cdot \log_e (I_0/I)_{max}$$

$$\log_e (I_0/I) = a/[(\nu-\nu_0)^2+b^2]$$

$$a/b^2 = \log_e (I_0/I)_{max}$$

$$2b = \Delta\nu_{1/2}$$

given by Ramsay[10], where A is the integrated intensity, $\Delta\nu_{1/2}$ the half-width, ν_0 the amount expressed by wave number at the band center and a and b are parameters. Because of the presence of two bands, four parameters had to be used.

Materials.—Allyl alcohol obtained from a commercial source was purified by redistillation using

carbon tetrachloride for removal of water[11], b.p. 96.0~96.3°C. 3-Buten-1-ol and 5-hexen-1-ol were prepared by action of formaldehyde on the corresponding alkenylmagnesium bromides and the physical constants were as follows: 3-buten-1-ol b. p. 113~113.5°C, $n_D^{26.5}$ 1.4185 (lit.[12] b. p. 112~114°, n_D^{25} 1.4189): 5-hexen-1-ol, b.p. 72.0~72.2°C/19.5mm., n_D^{30} 1.4353 (lit.[13] b.p. 155.6~156.0°C/718 mm., n_D^{20} 1.4364). 4-Penten-1-ol and 10-undecen-1-ol were prepared by lithium aluminum hydride reduction of the corresponding carboxylic acids and the following physical constants were obtained: 4-penten-1-ol, b. p. 63°C/3.0 mm., n_D^{21} 1.4292 (lit.[14] n_D^{20} 1.4299); 10-undecen-1-ol, b. p. 95.5~96°C /3.5 mm., n_D^{20} 1.4462 (lit.[15] n_D^{19} 1.4506).

Results and Discussion

The actual O–H stretching absorption curves of the alcohols are shown in Fig. 1 and the data of the two bands divided by the Ramsay's equations are given in Table I, in which, for the convenience of the discussion, the bands are named I and II rather than interacted and free.

As is seen from Fig. 1, the only example which showed two distinct bands is 3-buten-1-ol which can undoubtedly be said to possess intramolecular interaction between the hydroxyl group and π-electrons of the double bond.

The lower homolog of 3-buten-1-ol, allyl alcohol, was spectroscopically studied by Flett[16] in its O–H stretching region and reported to have a single band at 3620 cm^{-1}. However, the present authors' result with the instrument of high resolution shows that allyl alcohol possesses two bands at 3619.4 cm^{-1} and 3634.8 cm^{-1}, the latter corresponding to the normal vibration of aliphatic primary alcohols and is reminiscent of the result obtained by Fox and Martin[4] with benzyl alcohol. Since this kind of curve for O–H stretching vibration is obtained only with allyl alcohol or benzyl alcohol, the band at ca. 3620 cm^{-1} may be attributed to the interaction between π-electrons and the hydroxyl group.

Comparison of the curves for allyl alcohol and 3-buten-1-ol reveals that the number of internally interacted molecules is greater in allyl alcohol than in 3-buten-1-ol, provided that the absorption intensity of a molecule is equal in both free and interacted forms. This assumption is based on the fact that the sum of two integrated intensities is almost the same in the two compounds. This phenomenon seems to be rather striking, because it is a common concept that the difference in wave number corresponds to the energy[17], but can be explained in either of the following two ways. Firstly, the interactions occurring in allyl alcohol and in 3-buten-1-ol may be different in nature and, secondly, unfavorable entropy change in 3-buten-1-ol may limit the number of the internally interacted molecules, in spite of the greater stabilization in energy term. Although, as far as the present data are concerned, it is not clear which is the real cause, the accumulated data

in this laboratory suggest that the former is the preferable cause.

Higher homologs of 3-buten-1-ol, 4-penten-1-ol and 5-hexen-1-ol, possess an unsymmetric band, fatter at the smaller wave number side, and the band can be divided into two, assuming that the band is an overlapping of two symmetric bands which are expressed by the Lorentz function. The smaller peaks (band I) at ca. 3625cm^{-1} may be attributed to the presence of the hydroxyl group and π-electrons interaction but the minor peak (band I) also appears in 10-undecen-1-ol in which the intramolecular interaction is improbable in respect of the entropy increase. Moreover, these three curves are quite similar and suggest that the minor peaks do not represent the intermolecular interaction, since it is not plausible to consider that the same extent of intramolecular interaction between the hydroxyl group and π-electrons exists in these three compounds. In other words, this kind of interaction can not be found in higher homologs than 4-penten-1-ol. The origin of the minor peaks (bands I of 4-penten-1-ol, of 5-hexen-1-ol and of 10-undecen-1-ol) will be dealt with in the following paper.

It may seem to be rather strange that the interaction takes place up to 3-buten-1-ol in the homologs studied, in contrast with the finding of Baker and Shulgin who reported the existence of the interaction both in *o*-propenylphenol and *o*-allylphenol, the latter being an analog of 4-penten-1-ol. But the explanation can be given by considering the difference in proton donating ability of phenolic and alcoholic hydroxyl groups and the favorable structure of the phenols in which O–C–C–C bonds are fixed *cis*. The representative cases are under investigation.

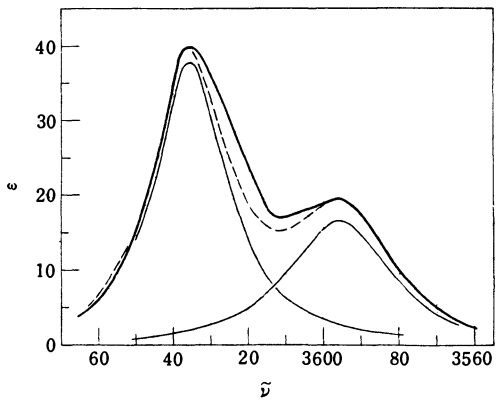

Fig. 2. ν_{O-H} absorption of 3-buten-1-ol.
—— observed curve
—— divided bands
---- calculated curve

It might also be mentioned here that, as shown in Fig. 2, the calculated band area of 3-buten-1-ol does not quite agree with the observed one. Namely, the computed value is always lower than the observed one at the valley of the band for 3-buten-1-ol, while that for the others

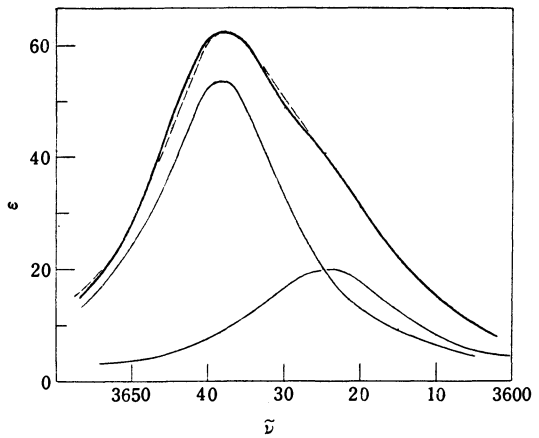

Fig. 3. ν_{O-H} absorption of 4-penten-1-ol.
—— observed curve
—— divided bands
---- calculated curve

agree, as shown in Fig. 3 (taking 4-penten-1-ol as an example). The cause of the disagreement is unknown but is quite understandable if one considers that another absorption band exists in this compound at about 3626 cm^{-1} corresponding to those in the higher homologs.

In closing, the authors would like to mention the terminology of this interaction. Although many authors[2,6,8] used "hydrogen bonding", "interaction" is the present authors' choice, since the definition of the hydrogen bonding was discussed at the international symposium[18] on the hydrogen bonding and an agreement that the interaction between a hydrogen donating group and an electron pair of an atom was hydrogen bonding, was reached. The interaction discussed here undoubtedly resembles the hydrogen bonding, but is still distinguishable from the hydrogen bonding because of the participation of the π-electrons of a double bond which are not on the same atom, although they overlap.

Summary

Infrared absorption was measured with

18) See: *Angew. Chem.*, **67**, 755 (1957).

five ω-hydroxy-1-alkenes in the 3 μ region, using an instrument of high resolution and the following results were obtained.

1) Intramolecular interaction between the hydroxyl group and π-electrons was found in allyl alcohol and in 3-buten-1-ol.

2) Interactions which occur in allyl alcohol and in 3-buten-1-ol may be of a different kind.

3) Higher homologs also possess two O–H stretching absorption bands but these bands can not be associated with the intramolecular interaction.

The authors are indebted to Professors Y. Urushibara and T. Shimanouchi for their valuable advice and encouragement and to Mr. I. Suzuki for his technical assistance throughout this work. A part of the cost was defrayed from the Grant in Aid for Fundamental Scientific Research of the Ministry of Education, for which the authors' thanks are due.

Analysis of the Multi-azeotropes in Terms of the Zeroth Approximation

By Ikuho YAMADA, Takatoshi YOSHIDA and Osamu KAWASE

(Received October 3, 1958)

Theoretical and experimental studies on the binary azeotropes, characterized by a maximum or a minimum in vapor pressure curves, have been made by many investigators. Among them, the theoretical studies of Prigogine[1], Mashiko[2] and Ikari[3], in terms of strictly regular solutions are viewed with interest.

However, most of these studies have dealt only with the case of binary systems. We shall report here the results obtained in the theoretical study of multi-azeotropes in the zeroth approximation by extending the method of Prigogine and Mashiko.

Theoretical Equation of the Vapor-liquid Equilibrium in Terms of the Zeroth Approximation.—The authors[4] have already published the theoretical equations of the vapor-liquid equilibrium in multi-component systems at the zeroth approximation.

Rewriting, now, the final result of activity coefficient γ_i of i-th component, the following equation is given

$$\boldsymbol{R}T \ln \gamma_i = \sum_{p=1}^{n}(1-x_i)x_p\omega_{ip}(i\neq p) - \sum_{p,q=1}^{n} x_p x_q \omega_{pq}\begin{pmatrix} p\neq q \\ p,q\neq i \end{pmatrix} \qquad (1)$$

where x is mole fraction of component of subscription $1, 2, \cdots\cdots, i, \cdots\cdots, n$ in liquid phase, ω the inter-molecular exchange energy in different molecules, $\boldsymbol{R}$ the gas constant and T the absolute temperature in the equilibrium state.

Taking as an example the case of a binary solution, Eq. 1 becomes as follows:

$$\begin{cases} \boldsymbol{R}T \ln \gamma_1 = (1-x_1)x_2\omega_{12} \\ \boldsymbol{R}T \ln \gamma_2 = (1-x_2)x_1\omega_{12} \end{cases} \qquad (2)$$

which is the same as given by Guggenheim[5].

Condition of the Azeotropic Formation in Multi-component System.—The activity coefficient of the i-th component in liquid phase is given by

$$\gamma_i = \pi y_i / p_i^\circ x_i \qquad (3)$$

where π is the total pressure, y the mole fraction in vapor phase and p° the vapor pressure of pure component at temperature T.

At an azeotropic point, $y_i = x_i$ and by the Clausius-Clapeyron's equation, $\ln \gamma_i$ is expressed as

$$\boldsymbol{R} \ln \gamma_i = \Delta H_i (1/T - 1/T_i^\circ) \qquad (4)$$

where ΔH is the heat of vaporization of

—Acetone (2)	61.7°C	$\Delta_{32}=$ 35.3	31.2	31.1	none-exist
—Water (3)		$\Delta_{13}=-43.5$	64.8	57.6	

B. P. shows the azeotropic point under 1 atm.

pure component and T° is the boiling point under the pressure π.

From Eqs. 1 and 4, the following expressions for the i- and j-th components can be deduced by substituting ΔS for $\Delta H/T$

$$\Delta S_i(T_i^\circ - T) = \sum_{p=1}^{n}(1-x_i)x_p\omega_{ip}(i\neq p) - \sum_{p.q=1}^{n}x_px_q\omega_{pq}\begin{pmatrix}p\neq q\\ p.q\neq i\end{pmatrix} \quad (5)$$

$$\Delta S_j(T_j^\circ - T) = \sum_{p=1}^{n}(1-x_j)x_p\omega_{jp}(j\neq p) - \sum_{p.q=1}^{n}x_px_q\omega_{pq}\begin{pmatrix}p\neq q\\ p.q\neq j\end{pmatrix} \quad (6)$$

and

$$T_i^\circ - T_j^\circ = \left\{\sum_{p=1}^{n}(1-x_i)x_p\omega_{ip}(i\neq p) - \sum_{p.q=1}^{n}x_px_q\omega_{pq}\begin{pmatrix}p\neq q\\ p.q\neq i\end{pmatrix}\right\}\Delta S_i^{-1} - \left\{\sum_{p=1}^{n}(1-x_j)x_p\omega_{jp}(j\neq p) - \sum_{p.q=1}^{n}x_px_q\omega_{pq}\begin{pmatrix}p\neq q\\ p.q\neq j\end{pmatrix}\right\}\Delta S_j^{-1} \quad (7)$$

When $x_j=1$, Eq. 7 shows a maximum and when $x_i=1$, a minimum, so that the following relation should hold.

$$-\omega_{ij}/\Delta S_j \leqq T_i^\circ - T_j^\circ \leqq \omega_{ij}/\Delta S_i \quad (8)$$

Hence, in the case of multi-azeotropes, the same relation as Eq. 7 should hold for all such combinations made of n components.

In the case of binary azeotropes, Eq. 8 takes the form given by Mashiko[6]. Table I shows the azeotropic relations from the given data[7], and the values of ω_{ij} are calculated from Eq. 1 for ternary systems.

Constancy of ω_{ij}.—The theoretical equations of the vapor-liquid equilibrium in multicomponent systems on the zeroth approximation have been derived by assuming that the molecular configurations have pairs in the liquid phase and intermolecular exchange energy between molecules i and j are independent of each other. If these assumptions are correct ω_{ij} should have a constant value for any pair of components.

ω_{ij} can be obtained by solving Eq. 1 for a given set of values of T, x_i and γ_i, i being $1, 2, \cdots\cdots, n$.

In the case of ternary azeotropes, the following solution can be obtained

$$\omega_{12}\Delta = \boldsymbol{M}$$

where

6) M. Mashiko, *Rep. Gov. Chem. Ind. Res. Inst. Tokyo*, **52**, 160 (1957).

7) L. H. Horsley, *Anal. Chem.*, **19**, 508 (1947); **21**, 831 (1949).

$$\Delta = \begin{bmatrix} (1-x_1)x_2 & -x_2x_3 & (1-x_1)x_3 \\ (1-x_2)x_1 & (1-x_2)x_3 & -x_1x_3 \\ -x_1x_2 & (1-x_3)x_2 & (1-x_3)x_1 \end{bmatrix}$$

and

$$\boldsymbol{M} = \begin{bmatrix} \Delta H_1(1-T/T_1^\circ) & -x_2x_3 & (1-x_1)x_3 \\ \Delta H_2(1-T/T_2^\circ) & (1-x_2)x_3 & -x_1x_3 \\ \Delta H_3(1-T/T_3^\circ) & (1-x_3)x_2 & (1-x_3)x_1 \end{bmatrix}$$

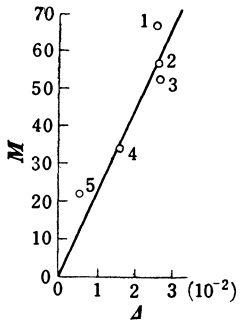
By plotting Δ vs. $\boldsymbol{M}$, a linear relation is obtained for several ternary systems as shown in Figs. 1—3.

Temperature Effect upon Azeotropic Compositions.—Taking the difference between $\ln\gamma_i$ and $\ln\gamma_{i+1}$ for all i's in Eq. 1, all second order terms $x_px_q\omega_{pq}$ cancel each other and the following equation can be obtained.

$$\Delta H_i(1-T/T_i^\circ) - \Delta H_{i+1}(1-T/T_{i+1}^\circ) = (x_{i+1}-x_i)\omega_{i\,i+1} + \sum_{p=1}^{n}(\omega_{ip}-\omega_{j+p})x_p \qquad (p \neq i, i+1) \quad (12)$$

where $i=1,2,\cdots\cdots,n-1$

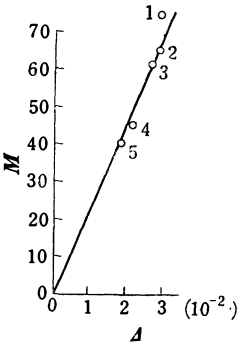
As $\sum x=1$, Eq. 12 becomes



$$\begin{bmatrix} 1 \\ \Delta\phi_{1\,2} \\ \vdots \\ \Delta\phi_{i\,j+1} \\ \vdots \\ \Delta\phi_{n-1,n} \end{bmatrix} = \begin{bmatrix} 1 & 1 & \cdots\cdots & 1 & 1 & \cdots\cdots & 1 \\ -\omega_{1\,2} & \omega_{1\,2} & \cdots\cdots & (\omega_{1\,i}-\omega_{2\,i}) & (\omega_{1\,i+1}-\omega_{2\,i+1}) & \cdots\cdots & \vdots \\ \vdots & \vdots & & \vdots & \vdots & & \vdots \\ (\omega_{1\,i}-\omega_{1\,i+1}) & (\omega_{2\,i}-\omega_{2\,i+1}) & \cdots\cdots & -\omega_{i\,i+1} & \omega_{i\,i+1} & \cdots\cdots & (\omega_{i\,n}-\omega_{i+1\,n}) \\ \vdots & \vdots & & \vdots & \vdots & & \vdots \\ (\omega_{1\,n-1}-\omega_{1\,n}) & (\omega_{2\,n-1}-\omega_{2\,n}) & \cdots\cdots & (\omega_{i\,n-1}-\omega_{i\,n}) & (\omega_{i+1\,n-1}-\omega_{i+1\,n}) & \cdots\cdots & \omega_{n-1\,n} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_i \\ \vdots \\ x_n \end{bmatrix} \qquad (13)$$

where

$$\Delta\phi_{i\,i+1} = \Delta H_i(1-T/T_i^\circ) - \Delta H_{i+1}(1-T/T_{i+1}^\circ)$$



Consequently, x's can be expressed by linear functions of T for given values ω_{ij}'s, ΔH_i's and T_i°'s.

For binary azeotropes, the following results can be given.

$$\begin{bmatrix} 1 \\ \Delta H_1(1-T/T_1^\circ) - \Delta H_2(1-T/T_2^\circ) \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ -\omega & \omega \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \qquad (14)$$

Consequently

$$2x_1 = 1 - \{\Delta H_1(1-T/T_1^\circ) - \Delta H_2(1-T/T_2^\circ)\}\omega^{-1} \qquad (15)$$

$$2x_2 = 1 + \{\Delta H_1(1-T/T_2^\circ) - \Delta H_2(1-T/T_2^\circ)\}\omega^{-1} \qquad (16)$$

Eqs. 15 and 16 agree with those given by Prigogine[8].

Breaking Point of Azeotropes. — When x_i obtained by solving Eq. 13 is equal to zero or unity, the multi-azeotropes are broken; these points are predicted by solving the equation for $i=1,2,\cdots\cdots,n$.

8) I. Prigogine and R. Defay, "Chemical Thermodynamics", Translated by D. H. Everett, Longmans, London, (1954), p. 462.

The closest value to initial T obtained for each may be considered as the break point.

Prediction of Azeotropic Temperature.— Substituting Eq. 4 and x_i given by Eq. 13 into Eq. 1, the azeotropic temperature can be predicted by solving the second-order equation in respect to T for given values of ω_{ii}, T_i°, ΔH and $\boldsymbol{R}$.

Summary

Assuming the zeroth approximation for the vapor-liquid equilibrium in multi-component systems the authors have analyzed multi-azeotropes, and the following results have been obtained.

1) For the condition of azeotropic formation in multi-component systems, Eq. 8 should hold for all combinations of n components.

2) The constancy of ω_{ij} is shown as Figs. 1 to 3.

3) Azeotropic composition effect upon temperature is given by solving Eq. 13, and the breaking temperatures are obtained by substituting $x_i=1$ or 0 into Eq. 13.

4) Azeotropic temperature can be deduced from Eqs. 2, 4 and 13.

Polarography of Tetracyano- and Dithiooxalato-Nickelate(II) Complexes[1]

By Nobufumi MAKI, Shigeo KIDA* and Ryutaro TSUCHIDA

(Received October 10, 1958)

There have been no reports on the polarographic reduction of dithiooxalatonickelate(II) complex, although some studies have been reported for tetracyanonickelate(II) complex by several authors[2-8]. For instance, Hume et al.[6] studied the polarographic behavior of the tetracyanonickelate(II) ion and found that the ion, $[Ni(CN)_4]^{2-}$, is irreversibly reduced in one step and the wave corresponds to a two-electron reduction of the ion to metal. They also found that the univalent nickel complex ion, $[Ni_2(CN)_6]^{4-}$, is oxidized, but not reduced polarographically.

Recently, Vlček[7,8] studied the mechanism of the electrochemical reduction of the ion, $[Ni(CN)_4]^{2-}$, in further detail and obtained the following results. The electrochemical reduction of the ion, $[Ni(CN)_4]^{2-}$, proceeds principally by the acceptance of two electrons. The reduction product of the two-electron reduction may be either metallic nickel or a complex of zero-valent nickel, $[Ni(CN)_4]^{4-}$, the latter of which is very unstable in solution and is immediately oxidized to univalent nickel with evolution of hydrogen and simultaneous formation of the deep red ion, $[Ni_2(CN)_6]^{4-}$.

$$2[Ni(CN)_4]^{4-} + 2H_2O = [Ni_2(CN)_6]^{4-} + 2CN^- + 2OH^- + H_2$$

The ion, $[Ni_2(CN)_6]^{4-}$, is also oxidized to $[Ni(CN)_4]^{2-}$, though the rate is very small. The increase of the current in solution with a high concentration of the cyanide ion was explained as being due to the regeneration of bivalent nickel from the product of the electrode reaction.

The present paper deals with the polarography of the tetracyano- and dithiooxalato-nickelate(II) ions. The main purpose of this study is to examine polarographically whether the mixed complex is formed or not in the solution when the two kinds of ion, $[Ni(CN)_4]^{2-}$ and $[Ni(C_2S_2O_2)_2]^{2-}$, were mixed together.

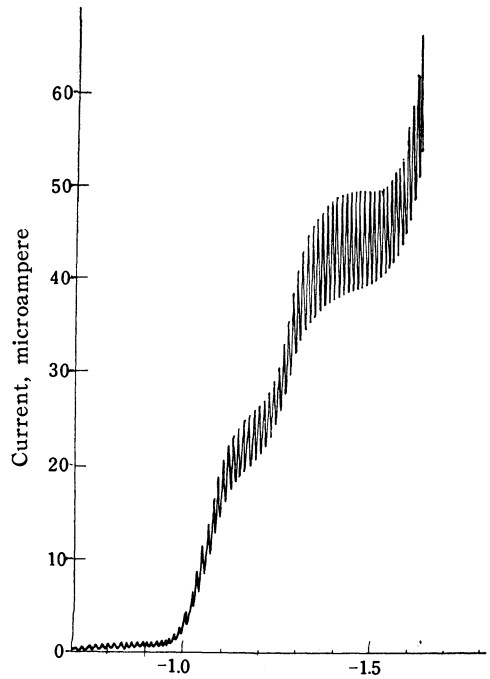
Experimental

Apparatus.—A Yanagimoto model 104 polarograph with a sensitivity of galvanometer (2×10^{-9} μA/mm./m.) was used. For the determination of the half-wave potentials, the method previously described was employed[9]. An H-type cell with a saturated calomel electrode was used. The capillary used had a rate of flow of mercury, 0.635 mg./sec., and a drop time of 4.16 sec. in the solution of 1 F potassium chloride at an open circuit with a mercury head of 66.5 cm. The capillary was connected with a mercury reservoir by a tube of polyvinyl chloride. All the measurements were made at 28±0.1°C, the temperature being maintained by a water thermostat. The reversibilities of the electrode reactions were tested by determining the slope of $\log i/(i_d-i)$ vs. potential. Slopes of the log plots indicated irreversible reduction throughout.

Material. — The complex compounds studied were prepared by the following methods.

1. *Tetracyanonickelate(II) complx*, $K_2[Ni(CN_4]\cdot H_2O$. — Pure potassium tetracyanonickelate(II) complex was prepared in the usual way by dissolving freshly precipitated nickel cyanide in potassium cyanide and evaporating the filtered solution. On recrystallization from hot water, an orange crystalline product was obtained.



2. *Dithiooxalatonickelate(II) complex*, $K_2[Ni\cdot(C_2S_2O_2)_2]$[10,11]. — Concentrated aqueous solutions of nickel sulfate (2 g. in 10 ml.) and potassium dithiooxalate (2 g. in 4 ml.) were mixed at room temperature; a deep purple solution was at once produced, from which small, almost black crystals separated. The product prepared in this way is contaminated by the remaining simple salt and may be purified by recrystallization from hot water. After dissolving the crystals in water at 40°C, one-half its volume of the saturated solution of potassium nitrate was added to the solution, from which the large iridescent bipyramidal crystals separated again on cooling. The crystals were filtered and washed several times with water and ethanol; then they were transferred to a vacuum desiccator to remove the remaining ethanol.

The complex compounds used were checked for purity by the comparison of the ultraviolet absorption spectra. Each solution for electrolysis was made freshly from the dry crystalline nickelate-(II) complexes before use. The solutions were mainly 0.005 F or 0.01 F with respect to the complex ion studied. In order to remove the dissolved oxygen, a vigorous stream of nitrogen which was purified from oxygen by means of an alkaline solution of pyrogallol was passed through the cell solution for an hour prior to each electrolysis, preventing the evaporation.

In order to examine the formation of the mixed complex, two kinds of solution of the same concentration for each ion were mixed together after the removal of the dissolved oxygen. After mixing, a stream of nitrogen was passed further for about ten minutes. Each polarographic run was completed within ten minutes. The maximum suppressor, Tween-80**, was added to the solution, which was enough to suppress the maxima of both the waves of the ions, $[Ni(CN)_4]^{2-}$ and $[Ni(C_2S_2O_2)_2]^{2-}$. (0.0032% Tween-80). The supporting electrolyte used was 1 F potassium chloride.

Results and Discussion

The dithiooxalatonickelate(II) complex ion, $[Ni(C_2S_2O_2)_2]^{2-}$, is reduced irreversibly in two steps at the dropping mercury electrode in the solution of 1 F potassium chloride, as is shown in Fig. 1. The waves have a maximum at around −1.1 V. (vs. S. C. E.), which could easily be suppressed in the presence of 0.0032% Tween-80. The ratio of the height of the first wave to that of the second is approximately 1 : 1. This ratio is independent

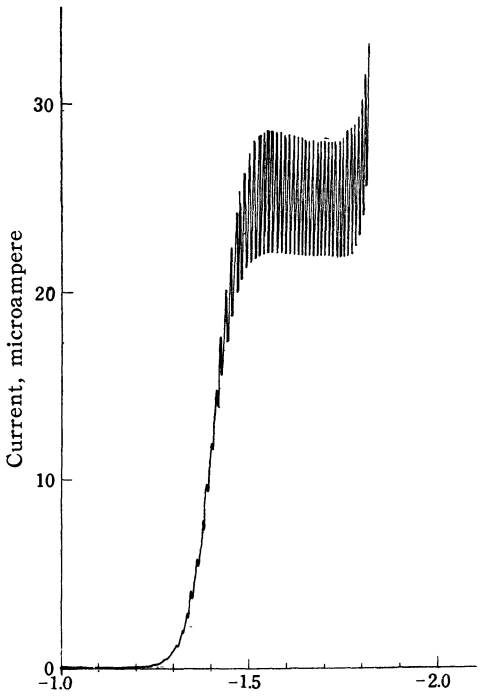
of the concentration of the complex ion. The limiting current for the unit concentration of the ion, i_l/c, becomes greater with the decreasing concentration of the ion. Table I shows the relation between the current value and the concentration. The fact that the heights of the waves of dithiooxalato complex are significantly greater than those of the usual nickel(II) complexes, such as $[Ni(CN)_4]^{2-}$, may well be explained as being due to the following reason. Namely, a part of the dithiooxalato complexes is considered to be present in solution as a form of the complex having protons to the sulfur atom.

For instance;

Hence, at the reduction potential of the complex, the hydrogen ion liberated from the complex is coreduced and contributes to the limiting current of the nickelate(II) complex. In conjunction with this consideration, the fact that the ratio of the height of the first wave to that of the second is always approximately 1:1 supports the idea that the dithiooxalatonickelate(II) complex might perhaps be reduced to the nickel(0) state in two steps. However, it appears desirable to delay further speculation on possible mechanisms of the reduction until more evidence, such as the data in buffer solution, is available. Concerning this point, further study is to be carried out in more detail and to be reported later.

On the other hand, the tetracyanonickelate(II) ion, $[Ni(CN)_4]^{2-}$, is reduced irreversibly in one step at the dropping mercury electrode in 1 F potassium chloride supporting electrolyte. (Fig. 2). The height of the wave is roughly proportional to the concentration of the complex ion. According to the results obtained by Vlček[7,8] and Hume et al.[6], the wave, corresponding to a gain of two electrons, represents the reduction for nickel(II) to nickel(0). In the solution of 1 F potassium chloride the wave of this ion indicated the maximum, which could be suppressed in the presence of 0.0016% Tween-80. In the solution of 0.5 F potassium sulfate it was very difficult to diminish the oxygen waves, which appeared at around −0.55 and −0.85 V. (vs. S. C. E.). Accordingly, the solution of 1 F potassium chloride was used as a supporting electrolyte to examine the formation of the mixed complex.



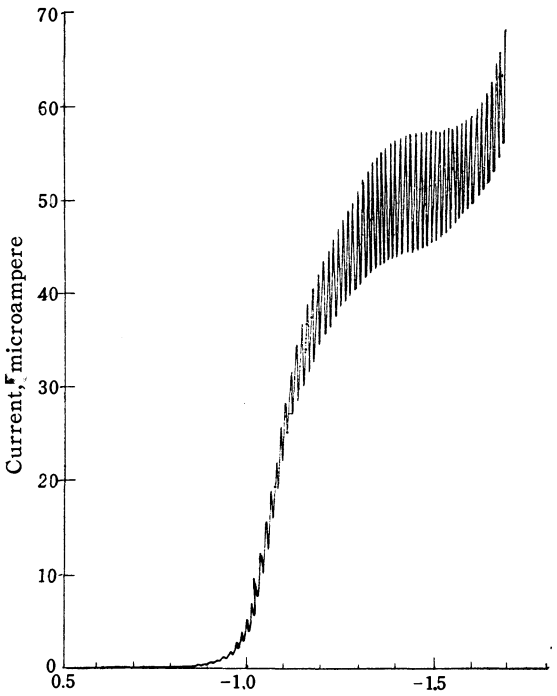


Fig. 2. The polarogram of $[Ni(CN)_4]^{2-}$ obtained in the solution of 1 F KCl at the concentration of 0.005 F in the presence of 0.0016% Tween-80. Sensitivity; 0.200 μA/mm., Damping; 200. $E_{1/2}=-1.38_5$ V. vs. S. C. E. $i_d=25.3$ μA.

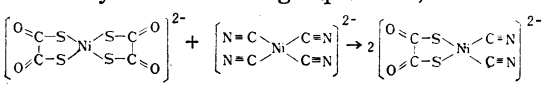
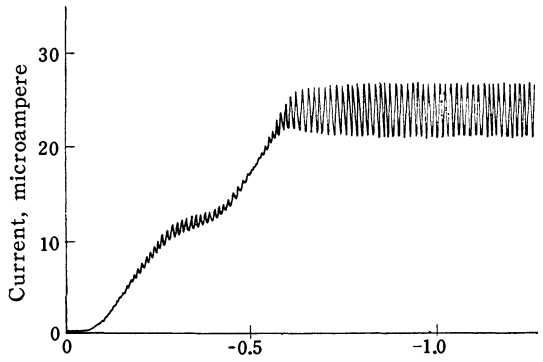
In order to confirm the formation of the mixed complex, the solution of tetracyanonickelate(II) ion, $[Ni(CN)_4]^{2-}$, and of dithiooxalatonickelate(II) ion, $[Ni\cdot(C_2S_2O_2)_2]^{2-}$, are mixed together at each concentration of 10^{-2} F in the presence of



0.0032% Tween-80 after the removal of the dissolved oxygen. The polarogram of the mixed solution was taken within about a quarter of an hour after mixing. If the reaction between the complex ions, $[Ni(CN)_4]^{2-}$ and $[Ni(C_2S_2O_2)_2]^{2-}$, takes place, it is expected that the new reduction wave of the mixed complex ion, $[Ni(C_2S_2O_2)(CN)_2]^{2-}$, is obtained. This is neither the wave of the ion, $[Ni(CN)_4]^{2-}$, nor that of the ion, $[Ni(C_2S_2O_2)_2]^{2-}$. In fact, both the waves of the original ions, $[Ni(CN)_4]^{2-}$ and $[Ni(C_2S_2O_2)_2]^{2-}$, almost disappeared and a new well-defined wave was obtained near the potential between the waves of the original ions. This fact may be regarded as a proof for the formation of the mixed complex ion, $[Ni(C_2S_2O_2)(CN)_2]^{2-}$, in the solution. (Fig. 3).

Applied potential, volt vs. S. C. E.

Fig. 3. The polarogram of the mixture of $[Ni(CN)_4]^{2-}$ and of $[Ni(C_2S_2O_2)_2]^{2-}$ at the equal concentration of 0.01 F for each complex ion obtained in the presence of 0.0032% Tween 80. The supporting electrolyte; 1 F KCl. $E_{1/2}$ of the wave $=-1.06$ V. vs. S. C. E. $i=47.6$ μA. Sensitivity; 0.400 μA/mm., Damping; 200.



It is considered that the reaction proceeds by the following equation;

The reaction was so fast that the progress of the reaction could not be detected nor traced by the classical polarographic method. The results obtained here are also supported by those of the spectrochemical study obtained by Kida[12].

The mixed complex ion, $[Ni(C_2S_2O_2)\cdot(CN)_2]^{2-}$, gives the irreversible wave of one step in the presence of 0.0032% Tween-80 in the solution of 1 F potassium chloride. The current is roughly proportional to the square root of the height of the mercury column. The straight line plot, however, does not pass through the origin but gives a negative intercept on the current axis. The height of the wave was not proportional to the concentration of the original ions. The half-wave potential of the wave shifts to the positive direction of potential with the decreasing concentration of the original ions.

For the same purpose as in the case of the dithiooxalatodicyanonickelate(II) complex, the polarogram of the mixed solution of the ions, $[Cu\ en_2^{***}]^{2+}$ and $[Cu\ ox_2^{***}]^{2-}$, was taken at equal concentration of both

Applied potential, volt vs. S. C. E.

Fig. 4. The polarogram of the mixed solution of $[Cu\ ox_2]^{2-}$ and $[Cu\ en_2]^{2+}$ obtained in the presence of 0.0032% Tween-80. The supporting electrolyte used is 0.5 F $NaClO_4$. The mixed solution was prepared by mixing the solution of the same amount of $[Cu\ ox_2]^{2-}$ and of $[Cu\ en_2]^{2+}$ at each concentration of 0.005 F at 25°C. The half-wave potentials of both the waves were quite the same as those of the original ions, $[Cu\ ox_2]^{2-}$ and $[Cu\ en_2]^{2+}$.
$E_{1/2}$ of $[Cu\ ox_2]^{2-}=-0.14_5$ V. vs. S.C.E.
$E_{1/2}$ of $[Cu\ en_2]^{2+}=-0.49$ V. vs. S.C.E.
While the height of the wave becomes one half, since one is diluted to double by another.

12) S. Kida, This Bulletin, **29**, 805 (1956).
*** The following abbreviation was used; en=ethylenediamine, ox=oxalate.

the ions in the presence of 0.0032% Tween-80. (Fig. 4). In this case, however, the reduction waves obtained were only those of the original ions, $[Cu\,en_2]^{2+}$ and $[Cu\,ox_2]^{2-}$, and the wave of the mixed complex, [Cu en ox], could not be found, though the presence of this was verified by Kida[12] and DeWitt et al.[13] Namely, the percentage of the mixed complex formed in the solution is calculated to be 64%**** when equal amounts of both the ions, $[Cu\,en_2]^{2+}$ and $[Cu\,ox_2]^{2-}$, were mixed together at room temperature. This fact is explained as being due to the presence of the fast equilibrium among these complexes, $[Cu\,en_2]^{2+}$, $[Cu\,ox_2]^{2-}$ and [Cu en ox]. In other words, at the reduction potential of the ions, $[Cu\,en_2]^{2+}$ and $[Cu\,ox_2]^{2-}$, the equilibrium shifts very fast to the direction for supplying these ions. Further, in the equilibrium of the system,

$$[Ni(C_2S_2O_2)_2]^{2-} + [Ni(CN)_4]^{2-} \rightleftarrows 2\,[Ni(C_2S_2O_2)(CN)_2]^{2-}$$

its rate is very small. Consequently, the reduction wave of the mixed complex can be found. This fact suggests that the coordinating bond of these complexes has a considerable covalent character, in spite of the fact that the exchange reaction of tetracyanonickelate(II) ion with radioactive cyanide in solution is very fast[14].

13) R. DeWitt and J. Watters, *J. Am. Chem. Soc.*, **76**, 3810 (1954).
14) F. A. Long, ibid., **73**, 537 (1951).
**** The influence of temperature on the percentage is considered to be small.

Summary

1. It was verified polarographically that the reaction between the ions, $[Ni(CN)_4]^{2-}$ and $[Ni(C_2S_2O_2)_2]^{2-}$, takes place and the mixed complex ion, $[Ni(C_2S_2O_2)(CN)_2]^{2-}$, is formed in solution. The rate of the reaction was so great that the progress of the reaction could not be traced by the usual polarographic method. Meanwhile the wave of the oxalato-ethylenediamine copper(II) complex, [Cu en ox], the presence of which in solution had been verified spectrophotometrically, was not detected polarographically. That is to say, the polarographic method can be applied to detect the formation of the mixed complex, the coordinating bonds of which have a considerable covalent character, such as $[Ni(C_2S_2O_2)(CN)_2]^{2-}$, but can not be applied to detect the mixed complex having ionic bonds.

2. The ion, $[Ni(C_2S_2O_2)_2]^{2-}$, is reduced irreversibly in two steps at the dropping mercury electrode in the presence of 0.0032% Tween-80, when 1 F potassium chloride solution was used as a supporting electrolyte. The heights of the two waves are not proportional to the concentration of the ion. The height of the wave for the unit concentration of the ion increases with the decreasing concentration of the ion.

The Kinetics of the Complex-forming Reaction between Nickel(II) and Ethylenediaminetetraacetate

By Nobuyuki TANAKA and Yasuhiko SAKUMA*

(Received December 8, 1958)

Although there are a number of papers concerning the inorganic reactions involving metal complexes, few of them deal with the kinetics of the complex-forming reactions between metal ions and organic ligands. Several investigations in which the dissociation reactions, the substitution reactions or the exchange reactions involving metal-ethylenediaminetetraacetate complexes were dealt with have given some information of the complex-forming reactions between the metal and ethylenediaminetetraacetate (EDTA)[1-5]. Those reactions, which are reactions of copper(II)[3], cadmium II)[2], lead(II)[5], nickel (II)[4], and iron(II)[1] with EDTA, proceed so rapidly that the direct measurement of the concentration-time relation by the conventional techniques seems to be difficult.

Recently, a rotated dropping mercury electrode (RDME) has been developed, which has a current sensitivity some ten times as great as that of the conventional dropping mercury electrode[6-12]. In this investigation, the rate of the complex-forming reaction between nickel(II) and EDTA was followed by measuring the limiting current of nickel(II) at the RDME. The mechanisms of the reaction and the rate constant for each reaction path are presented in this paper.

Theoretical

Let us consider a complex-forming reaction of nickel(II) with ethylenediaminetetraacetate (EDTA) in sodium acetate-acetic acid buffers which contain 0.1 M acetate. At pH of the acetate buffer, EDTA exists mainly in the form of H_2Y^{2-} and partly in the forms of H_3Y^- and HY^{3-}, where Y^{4-} denotes the completely dissociated EDTA anion. These species are in equilibrium given in Eqs. 1 and 2.

$$H_3Y^- \rightleftarrows H_2Y^{2-} + H^+ \quad (1)$$

$$H_2Y^{2-} \rightleftarrows HY^{3-} + H^+ \quad (2)$$

Nickel(II) forms acetato complexes in a solution containing acetate ions. It has been found that the monoacetatonickel(II) ion is a predominant species of acetato complexes unless the concentration of acetate exceeds 0.2 M[13]. The monoacetatonickel(II) and the hydrated nickel ions are in equilibrium according to the equation,

$$Ni^{2+} + OAc^- \rightleftarrows NiOAc^+ \quad (3)$$

The reaction between nickel(II) and EDTA may proceed through various reaction paths. Among three ionic species of EDTA mentioned above, H_3Y^- is considered to be the least favorable to react with nickel(II). The rate of the reaction between nickel(II) and H_3Y^- seems to be much smaller than those between nickel (II) and other ionic species of EDTA. From these considerations, the following reaction paths are assumed:

$$Ni^{2+} + HY^{3-} \xrightarrow{k_{1a}} NiHY^- \quad (4)$$
$$NiHY^- \rightleftarrows NiY^{2-} + H^+$$

$$Ni^{2+} + H_2Y^{2-} \xrightarrow{k_{2a}} NiH_2Y \quad (5)$$
$$NiH_2Y \rightleftarrows NiHY^- + H^+ \rightleftarrows NiY^{2-} + 2H^+$$

$$NiOAc^+ + HY^{3-} \xrightarrow{k_{1b}} NiHY^- + OAc^- \quad (6)$$
$$NiHY^- \rightleftarrows NiY^{2-} + H^+$$

13) N. Tanaka and K. Kato, This Bulletin, **32**, 516 (1959).

$$NiOAc^+ + H_2Y^{2-} \xrightarrow{k_{2b}} NiH_2Y + OAc^- \quad (7)$$
$$NiH_2Y \rightleftarrows NiHY^- + H^+ \rightleftarrows NiY^{2-} + 2H^+$$

From reactions 4 and 5, the rate of the decrease of $[Ni^{2+}]$ is expressed as,

$$-\frac{d[Ni^{2+}]}{dt} = k_{1a}[Ni^{2+}][HY^{3-}] + k_{2a}[Ni^{2+}][H_2Y^{2-}]$$
$$= \left\{k_{1a}\frac{K_{H_2Y}}{[H^+]} + k_{2a}\right\}[Ni^{2+}][H_2Y^{2-}] \quad (8)$$

where K_{H_2Y} represents the dissociation constant of H_2Y^{2-} ($= [HY^{3-}][H^+]/[H_2Y^{2-}]$). From reactions 6 and 7 the rate of the decrease of $[NiOAc^+]$ is expressed as,

$$-\frac{d[NiOAc^+]}{dt} = k_{1b}[NiOAc^+][HY^{3-}] + k_{2b}[NiOAc^+][H_2Y^{2-}]$$
$$= \left\{k_{1b}\frac{K_{H_2Y}}{[H^+]} + k_{2b}\right\}[NiOAc^+][H_2Y^{2-}] \quad (9)$$

The quantity of nickel(II) that is determined polarographically in acetate buffer is not the quantity of the hydrated nickel(II) ion, but the sum of those of the monoacetato- and the hydrated nickel ions[13]. If the sum is denoted by $[Ni^{2+}]_{app.}$,

$$[Ni^{2+}]_{app.} = [Ni^{2+}] + [NiOAc^+] \quad (10)$$

Therefore, the rate of the decrease of nickel(II) that is followed by the polarographic method is given as,

$$-\frac{d[Ni^{2+}]_{app.}}{dt} = -\frac{d\{[Ni^{2+}] + [NiOAc^+]\}}{dt}$$
$$= -\left\{\frac{d[Ni^{2+}]}{dt} + \frac{d[NiOAc^+]}{dt}\right\} \quad (11)$$

As for the EDTA present in the acetate buffer, the total concentratration of uncomplexed EDTA, $[EDTA]_f$, is represented by

$$[EDTA]_f = [HY^{3-}] + [H_2Y^{2-}] + [H_3Y^-] \quad (12)$$

From Eq. 12, $[H_2Y^{2-}]$ is given as

$$[H_2Y^{2-}] = \frac{[EDTA]_f}{\frac{[H^+]}{K_{H_3Y}} + 1 + \frac{K_{H_2Y}}{[H^+]}} \quad (13)$$

where K_{H_3Y} is the dissociation constant of H_3Y^- ($= [H_2Y^{2-}][H^+]/[H_3Y^-]$). The concentration of $NiOAc^+$ is written with the formation constant (K_{NiOAc}) and the concentrations of Ni^{2+} and OAc^-,

$$[NiOAc^+] = K_{NiOAc}[Ni^{2+}][OAc^-] \quad (14)$$

Introducing Eq. 14 into Eq. 10, $[Ni^{2+}]$ is given by

$$[Ni^{2+}] = \frac{[Ni^{2+}]_{app.}}{1 + K_{NiOAc}[OAc^-]} \quad (15)$$

Introducing Eqs. 8 and 9 into Eq. 11 and substituting Eq. 14 for $[NiOAc^+]$, we obtain

$$-\frac{d[Ni^{2+}]_{app.}}{dt} = \left[\left\{k_{1a}\frac{K_{H_2Y}}{[H^+]} + k_{2a}\right\} + \left\{k_{1b}\frac{K_{H_2Y}}{[H^+]} + k_{2b}\right\}K_{NiOAc}[OAc^-]\right][Ni^{2+}][H_2Y^{2-}] \quad (16)$$

Replacing $[H_2Y^{2-}]$ and $[Ni^{2+}]$ by the expressions given in Eqs. 13 and 15, respectively, and rearranging the resulted equation, Eq. 17 is obtained. Eq. 17 represents the overall rate expression for the complex-forming reaction between nickel(II) and EDTA whose reaction mechanisms are given by Eqs. 4 to 7. If $[H^+]$ and $[OAc^-]$ are not varied while the reaction proceeds, Eq. 17 can be written as

$$-\frac{d[Ni^{2+}]_{app.}}{dt} = k_{app.}[Ni^{2+}]_{app.}[EDTA]_f \quad (18)$$

where $k_{app.}$ means an apparent rate constant and corresponds to Eq. 19. The magnitude of $k_{app.}$ is dependent on both pH and the acetate concentration of the solution.

Experimental

Reagents.—A stock solution of disodium ethylenediaminetetraacetate was prepared by dissolving the commercial guaranteed reagent, and

$$-\frac{d[Ni^{2+}]_{app.}}{dt} = \frac{\{k_{1a} + k_{1b}K_{NiOAc}[OAc^-]\}\frac{K_{H_2Y}}{[H^+]} + \{k_{2a} + k_{2b}K_{NiOAc}[OAc^-]\}}{\{1 + K_{NiOAc}[OAc^-]\}\left\{\frac{[H^+]}{K_{H_3Y}} + 1 + \frac{K_{H_2Y}}{[H^+]}\right\}}[Ni^{2+}]_{app.}[EDTA]_f \quad (17)$$

$$k_{app.} = \frac{\{k_{1a} + k_{1b}K_{NiOAc}[OAc^-]\}\frac{K_{H_2Y}}{[H^+]} + \{k_{2a} + k_{2b}K_{NiOAc}[OAc^-]\}}{\{1 + K_{NiOAc}[OAc^-]\}\left\{\frac{[H^+]}{K_{H_3Y}} + 1 + \frac{K_{H_2Y}}{[H^+]}\right\}} \quad (19)$$

standardized against the standard copper(II) solution by amperometric titration using a dropping mercury electrode as an indicator electrode[14]. The copper(II) solution was prepared by dissolving recrystallized copper(II) sulfate, and its concentration was determined by electrogravimetry at constant potential by means of a Yanagimoto automatic potentiostat. The standard solution of nickel nitrate was obtained in the following way[15]. The alcoholic solution of dimethylglyoxime was added to the dilute solution of guaranteed nickel(II) nitrate. The precipitates were filtered and dissolved in guaranteed nitric acid. The nickel(II) solution obtained was made ammoniacal and subjected to the electrolysis. The nickel metal deposited was weighed accurately, dissolved in guaranteed nitric acid and diluted to the desired concentration with redistilled water. The concentration of nickel(II) of the solution was determined with the standard EDTA solution by amperometric trtration[16]. The concentration obtained was in good agreement with that determined by electrogravimetry.

Acetic acid-sodium acetate buffers were prepared with guaranteed sodium carbonate and acetic acid. Polyoxyethylene lauryl ether (LEO) with a mean molecular weight of 862 was used for a maximum suppressor. Other chemicals used were of guaranteed reagent grade.

Apparatus and Procedure.—The rate of the reaction between nickel(II) and EDTA was followed by measuring the change of the polarographic diffusion current of the nickel(II) with time. The current-time curves were recorded with a Yanagimoto Model PB-4 pen-recording polarograph using a rotated dropping mercury electrode (RDME)[6-12].

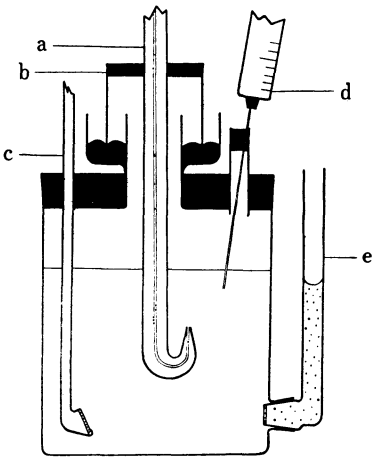

Fig. 2. Electrolysis cell: a, RDME; b, mercury seal; c, N_2 gas disperser; d, syringe; e, KNO_3-agar bridge.

In Fig. 1 is shown the RDME used in this study, which was similar to that reported by Okinaka and Kolthoft[9], being driven by means of a synchronous motor (Type A, provided with gears for speeds of 100, 150, 200 and 300 r.p.m., constructed by Yanagimoto Co., Ltd.). The electrode had an m value of 25.43 mg./sec. and a drop time of 2.95 sec. at 100 r.p.m., being measured at −0.60 volt vs. S.C.E. in air-free 0.2 M potassium nitrate solution containing 5×10^{-6} M LEO at 51.2 cm. of mercury head at 25°C.

The electrolysis cell in which the reaction took place was of a beaker-type of 100 ml. capacity as shown in Fig. 2. The cell was connected to a saturated calomel electrode through a potassium nitrate agar bridge. Special precautions were taken against the intrusion of atmospheric oxygen into the electrolysis cell during the measurement. A mercury seal was attached for this purpose. (See Fig. 2). The nitrogen gas was introduced into the solution through a gas disperser before and also during the measurement. The current measurement with the RDME was not disturbed by bubbling the gas through the solution. The rate of the flow of nitrogen gas was kept constant, being controlled by means of a flow-meter. The fluctuation of the residual current due to the change of the oxygen concentration was controlled within 0.05 microampere.

All kinetic measurements were made in acetate buffers of pH 3.8 to 5.2 at 0°C. The acetate concentrations were varied from 0.02 M to 0.1 M. The ionic strength was adjusted to be 0.2 with potassium nitrate. LEO was added as a maximum suppressor by 5×10^{-6} M in concentration. The pH of the solution was measured with a Hitachi Model EHP-1 pH meter, immediately after the measurements of current-time curves, within the accuracy of 0.02 pH unit.

The reaction was initiated by adding the air-free solution of the equivalent EDTA into the deaerated nickel(II) solution in the electrolysis

cell with the aid of a calibrated 1 ml. syringe. Since the RDME was driven and the nitrogen gas was bubbled throughout the measurement, reproducible current-time curves were able to be obtained immediately after the injection of the EDTA solution.

Results

A typical polarogram of nickel(II) which was obtained with 2×10^{-4} M Ni(II) in acetate buffer of pH 4.6 with the RDME is shown in Fig. 3. Although the limiting current plateau of the polarogram is not well-defined, the proportionality was found between the concentration of nickel(II) and the current that was measured at −1.35 V. vs. S.C.E. and corrected for the residual current, unless the concentration of nickel(II) exceeded 5×10^{-4} M. Therefore, current-time curves of the reaction mixtures were recorded at this potential. Typical examples of the current-time curves are reproduced in Fig. 4. Those curves were recorded at varied pH's with reaction mixtures in which the initial concentrations of nickel(II) and EDTA were each 1.00×10^{-4} M and the concentration of acetate was 0.1 M. It is expected from Eq. 18 that a plot of the reciprocal of $[Ni^{2+}]_{app.}$ against time gives a straight line with a slope of k_{app}. Some of the plots are given in Fig. 5, from which the values of $k_{app.}$ were determined.

The current-time curves were obtained

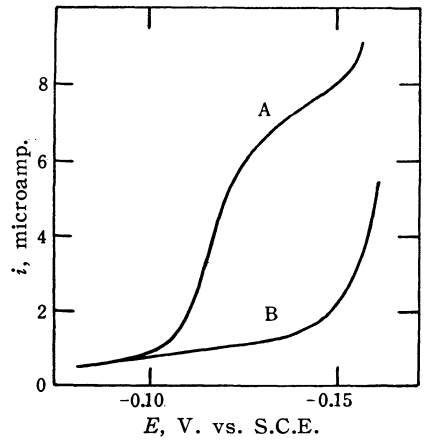

Fig. 3. Current-voltage curves of 2×10^{-4} M Ni(II) (curve A) and Ni(II)-EDTA (curve B) obtained at 0°C in acetate buffer-potassium nitrate solution of pH 4.6 and ionic strength 0.2 containing 0.1 M acetate and 5×10^{-6} M LEO.

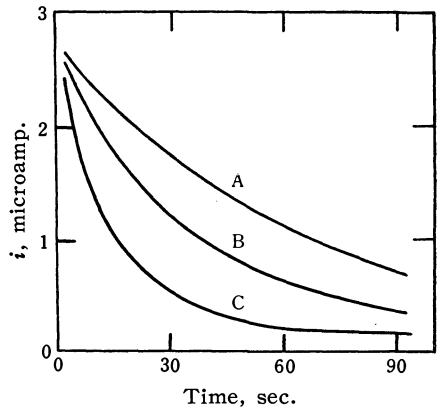

Fig. 4. Limiting current-time relation of the reaction between nickel(II) and EDTA, measured at −1.35 V. vs. S.C.E. at 0°C in acetate buffer-potassium nitrate solution of ionic strength 0.2 containing 0.1 M acetate and 5×10^{-6} M LEO, at pH 3.9 (curve A), pH 4.4 (curve B) and pH 5.0 (curve C). Initial concentrations of nickel(II) and EDTA are each 1.00×10^{-4} M.

5.01	0.125	0.01	0.04	7.60
5.16	0.089	0.00	0.06	10.0_0
5.21	0.079	0.00	0.07	10.3_3
5.26	0.071	0.00	0.08	11.2_5

* The solutions contain 0.05 M acetate. The initial concentrations of nickel(II) and EDTA are each 1.00×10^{-4} M.

at varied pH's in the range of pH 3.8 to 5.2 and at three different concentrations of acetate. It was found that the analysis of the current-time curves which were obtained with different initial concentrations of the reactants but at the same pH and acetate concentration gave the same $k_{app.}$ This fact confirmed that the reaction in question is of second order.

The magnitudes of $k_{app.}$ were determined at varied pH's and at three different concentrations of acetate. Examples of the experimental results which were obtained at 0.05 M acetate are given in Tabele I. From Eq. 19,

$$\alpha\beta k_{app.} = \{k_{1a} + k_{1b}K_{NiOAc}[OAc^-]\}\frac{K_{H_2Y}}{[H^+]} + \{k_{2a} + k_{2b}K_{NiOAc}[OAc^-]\}$$
$$= k_1\frac{K_{H_2Y}}{[H^+]} + k_2 \qquad (20)$$
$$\alpha = \frac{[H^+]}{K_{H_3Y}} + 1 + \frac{K_{H_2Y}}{[H^+]}$$
$$\beta = 1 + K_{NiOAc}[OAc^-]$$
$$k_1 = k_{1a} + k_{1b}K_{NiOAc}[OAc^-]$$
$$k_2 = k_{2a} + k_{2b}K_{NiOAc}[OAc^-]$$

are obtained. Eq. 20 indicates that a plot of the values of $\alpha\beta k_{app.}$ against the reciprocal of the hydrogen ion concentration should give a straight line, if $k_{app.}$'s were determined at the same concentration of acetate. The plots with the observed values of $k_{app.}$ gave the straight lines as shown in Fig. 6. The slope gave the value of $k_1K_{H_2Y}$ in Eq. 20 and the intercept at $1/[H^+]=0$, that of k_2. The relation between $\alpha\beta k_{app.}$ and the reciprocal of the hydrogen ion concentration was also treated by the method of least squares. The mean values and the probable errors of k_1 and k_2 were calculated as given in Table II.

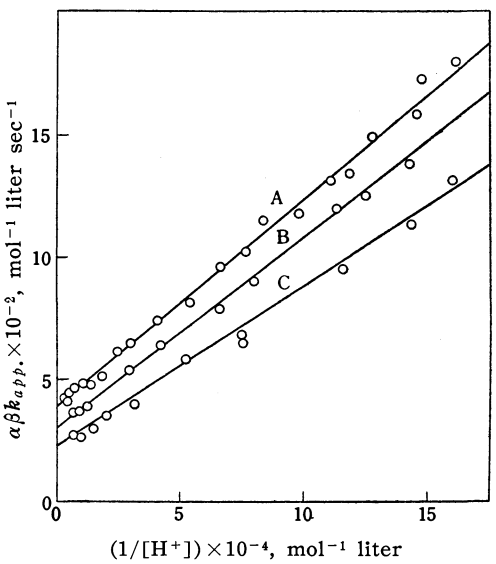

Fig. 6. Relations between $\alpha\beta k_{app.}$ and $1/[H^+]$ obtained at 0°C in acetate buffer-potassium nitrate solution of ionic strength 0.2 at acetate concentrations 0.10 M (curve A), 0.05 M (curve B) and 0.02 M (curve C).

TABLE II. OBSERVED VALUES OF k_1 AND k_2

Concn. of acetate, M	$k_1\times10^{-4}$, mol^{-1} liter sec^{-1}	$k_2\times10^{-2}$, mol^{-1} liter sec^{-1}
0.10	$1.73\pm0.01_6$	$3.89\pm0.06_7$
0.05	$1.41\pm0.01_8$	$2.95\pm0.15_3$
0.02	$1.18\pm0.00_9$	$2.42\pm0.07_6$

The hydrogen ion concentration used in this calculation was derived from the pH observed and the activity coefficient of the hydrogen ion. The pH of the solution was measured at 25°C and corrected for temperature to be reduced to the value at 0°C. The activity coefficient of the hydrogen ion was calculated to be 0.78 at 0°C and ionic strength 0.2 according to Kielland[17]. The third dissociation constant of EDTA, K_{H_2Y}, which was determined by Schwarzenbach and Ackermann[18] at 20°C and $\mu=0.1$, was used after correction for ionic strength and temperature. The ion size parameters of H_2Y^{2-} and HY^{3-} were assumed to be the same as that of suberic acid given by Kielland[17]. The temperature correction for K_{H_2Y} was made with the aid of the ΔH value reported by Carini and Martell[19]. The resulted value of K_{H_2Y} was $10^{-6.27}$. On the other hand, there has been no publication concerning the temperature coefficient of K_{H_3Y}. In this calculation, therefore, the value of $10^{-2.67}$, which was obtained by Schwarzenbach and Ackermann[18] at 20°C and $\mu=0.1$, was used without further correction. Since this constant is concerned only with the calculation of α, in which the contribution of the term $[H^+]/K_{H_3Y}$ does not exceed 10% under the present condition, the use of K_{H_3Y} without correction seems to introduce no significant error into the calculation of the rate constant.

The formation constant of the monoacetatonickel(II) complex, K_{NiOAc}, was determined to be 3.0 at 0°C, by extrapolating the values obtained at 15°, 25° and 35°C in the solution of ionic strength 0.2[13].

From k_1 and k_2 in Table II, the values of k_{1a}, k_{1b}, k_{2a} and k_{2b} were calculated as given in Table III.

TABLE III. RATE CONSTANTS OF VARIOUS NICKEL(II)-EDTA REACTIONS

Reaction	Rate constant, mol^{-1} liter sec^{-1}
$Ni^{2+}+HY^{3-} \xrightarrow{k_{1a}} NiHY^-$	$1.0_6\times10^4$
$NiOAc^+ + HY^{3-} \xrightarrow{k_{1b}} NiHY^- + OAc^-$	$2.2_5\times10^4$
$Ni^{2+}+H_2Y^{2-} \xrightarrow{k_{2a}} NiH_2Y$	$2.0_4\times10^2$
$NiOAc^+ + H_2Y^{2-} \xrightarrow{k_{2b}} NiH_2Y + OAc^-$	$6.0_4\times10^2$

Discussion

The complex-forming reaction of nickel with ethylenediaminetetraacetate was found to proceed through four different reaction paths given in Eqs. 4 to 7 in acetate buffers of pH 3.8 to 5.2. The rate constants of those four elementary reactions were determined. It seems reasonable that the reactions involving HY^{3-} species are much faster than those involving H_2Y^{2-}.

On the other hand, the effect of acetate ions on the reaction rate was rather unexpected. The previous studies on the displacement reactions involving metal-EDTA complexes indicated that the reaction rate decreased with increasing concentration of acetate[20,21]. The rate of the complex-forming reaction between nickel (II) and EDTA, however, was found to decrease with decreasing concentration of acetate. The rate constants of the reactions involving the monoacetatonickel(II) ions were nearly twice as great as those of the corresponding reactions involving the hydrated nickel ions. A similar phenomenon was reported by Wilkins[22], who studied the exchange reaction involving the nickel(II)-2,3-diamino-2,3-dimethylbutane complex and observed the faster reaction rate in the presence of ammonium acetate. Although the effect of acetate on the nickel-EDTA reaction is not completely solved at the present moment, it may not be unreasonable to consider the decrease of the activation energy of the reaction as being due to the acetate co-ordinated.

It seems interesting to compare the rate constants obtained in this study with those obtained by Cook and Long[4]. They studied the exchange reaction between nickel(II) and nickel(II)-EDTA complexes with the aid of the radioactive isotope at 25°C and ionic strength 0.1, and determined the rate constants of several reaction paths including the following:

$$NiY^{2-} + H^+ \rightleftarrows Ni^{2+} + HY^{3-} \quad (21)$$

$$NiHY^- + H^+ \rightleftarrows Ni^{2+} + H_2Y^{2-} \quad (22)$$

The reactions given by Eqs. 21 and 22 correspond to the reverse of those given by Eqs. 4 and 5, respectively. The equilibrium constants of reactions 21 and 22,

$$K(\text{Eq. 21}) = [Ni^{2+}][HY^{3-}]/[NiY^{2-}][H^+] = 1/K_{NiY}K_{HY}$$

$$K(\text{Eq. 22}) = [Ni^{2+}][H_2Y^{2-}]/[NiHY^-][H^+] = 1/K_{NiY}K^{H}_{NiHY}K_{HY}K_{H_2Y}$$

were calculated, where K_{NiY} represents the formation constant of NiY^{2-}, K_{HY} and K_{H_2Y} the dissociation constants of HY^{3-} and H_2Y^{2-}, respectively, and K^{H}_{NiHY} the equilibrium constant of the reaction,

$$NiY^{2-} + H^+ \rightleftarrows NiHY^-$$

The values of K_{HY}, K_{H_2Y}, K_{NiY} and K^{H}_{NiHY} which were determined by Schwarzenbach and his co-workers[18,23] at 20°C and $\mu=0.1$ were used without further correction. With the equilibrium constants obtained and the rate constants given by Cook and Long, the rate constants for the reverse reactions of Eqs. 21 and 22 were calculated and compared with k_{1a} and k_{2a} as shown in Table IV.

Unfortunately, Cook and Long did not take into account the effect of the acetate

TABLE IV. COMPARISON OF THE RATE CONSTANTS

Reaction	Rate constant, mol^{-1} liter sec^{-1}: Calculated from data at 25°C given by Cook and Long[4]	Observed at 0°C in this study
$Ni^{2+}+HY^{3-} \longrightarrow NiHY^-$	3.0×10^5	$1.0_6\times10^4$
$Ni^{2+}+H_2Y^{2-} \longrightarrow NiH_2Y$	8.1×10^2	$2.0_4\times10^2$

20) H. Ackermann and G. Schwarzenbach, *Helv. Chim. Acta*, **35**, 485 (1952).
21) N. Tanaka and K. Kato, unpublished.
22) R. G. Wilkins, *J. Chem. Soc.*, **1957**, 4521.
23) G. Schwarzenbach, R. Gut and G. Anderegg, *Helv. Chim. Acta*, **37**, 937 (1954).

on the reaction mechanisms and gave no information of the concentration of acetate present in their reaction mixtures. Therefore, the rate constants given by those authors do not exactly correspond to those given in this study. Nevertheless, it may be concluded that the results obtained in both investigations are in reasonable agreement.

Bjerrum and Poulsen[24] studied the kinetics of the formation of nickel(II) and copper(II) complexes of ethylenediamine in methanol at 0°C. They found that copper(II) complexes are more labile than the corresonding nickel(II) compounds. The rate constants of the formation of $Ni(en)^{2+}$ was 2.5×10^{4} mol^{-1} liter sec^{-1} and that of $Cu(en)^{2+}$, 5×10^{11} mol^{-1} liter sec^{-1}, where en denotes ethylenediamine.

Recent studies[3,5] in this laboratory revealed that the rate constants of the formation of copper(II) and lead(II) complexes of EDTA through the reaction

$$M^{2+}+HY^{3-} \rightleftarrows MY^{2-}+H^{+}$$
$$(M=Cu \text{ or } Pb)$$

range from 10^{9} to 10^{11} mol^{-1} liter sec^{-1} at room temperature. The slower rate of the formation of nickel(II)-EDTA complexes is apparent as in the case of the formation of nickel-ethylenediamine complexes.

Summary

The complex-forming reaction of nickel (II) with ethylenediaminetetraacetate (EDTA) was found to proceed in acetate buffers of pH 3.8 to 5.2 through four different reaction paths,

$$Ni^{2+}+HY^{3-} \xrightarrow{k_{1a}} NiHY^{-}$$
$$NiOAc^{+}+HY^{3-} \xrightarrow{k_{1b}} NiHY^{-}+OAc^{-}$$
$$NiHY^{-} \rightleftarrows NiY^{2-}+H^{+}$$
$$Ni^{2+}+H_2Y^{2-} \xrightarrow{k_{2a}} NiH_2Y$$
$$NiOAc^{+}+H_2Y^{2-} \xrightarrow{k_{2b}} NiH_2Y+OAc^{-}$$
$$NiH_2Y \rightleftarrows NiHY^{-}+H^{+} \rightleftarrows NiY^{2-}+2H^{+}$$

The change in the polarographic diffusion current of nickel(II) at the rotated dropping mercury electrode was utilized to follow the decrease of the nickel(II) concentration in the reaction mixture after the initiation of the reaction. The rate constants of the reaction paths were determined at 0°C and ionic strength 0.2, with the results:

$k_{1a}=1.0_6\times10^{4}$ mol^{-1} liter sec^{-1}
$k_{1b}=2.2_5\times10^{4}$ 〃
$k_{2a}=2.0_4\times10^{2}$ 〃
$k_{2b}=6.0_4\times10^{2}$ 〃

These constants are much smaller than those of the corresponding reactions between copper(II) and EDTA.

The authors thank the Ministry of Education for the financial support granted for this research.

*Cation Arrangement in Lithium Ferrospinel-Lithium Aluminospinel Solid Solution**

By Eizo KATO**

(Received September 25, 1958)

A cation arrangement in a spinel structure shows how some cations of different valencies are distributed at tetrahedral interstices of the 8-fold position or octahedral ones of the 16-fold position in a spinel lattice, and it has given very interesting subjects concerning a correlation between crystal structure and physico-chemical properties. From the crystallographic aspect a spinel structure is specified into a normal and an inverse type by some difference of the cation arrangement, and only the ferrospinel of inverse structure can reveal ferromagnetism. These fruitful works in solid state physics were presented by Verwey and his co-workers' experiments[1] and by Néel's theory[2].

Cation arrangement in 2—3 ferrospinel*** solid solution, e.g., nickel-zinc ferrospinel, has been studied not only from the scientific aspect but also in reference to the improvement of magnetic materials[3]. At present the arrangement of trivalent cations is aimed at which is studied in nickel ferro-aluminospinel[4] and other ferro-aluminospinel solid solutions[1]. In the previous paper[5] LFS-LAS solid solution was found to show an order-disorder transition, in addition to showing properties seen in other ferro-aluminospinel solid solutions. On purpose to know correlations between the cation arrangements and other physico-chemical properties, X-ray diffraction intensities were measured and simple magnetic measurements were also carried out.

Experimental

Specimens.—Specimens were synthesized and heat-treated by the method mentioned already[5]. Specimen codes were A (=LAS), B, C, P, R, Q, D, E and F (=LFS), according to each chemical composition as is shown in Table I. The subscript "L" or "H" was supplied behind the code name of a specimen to show whether it was of ordered or disordered phase.

Apparatus.—X-ray diffraction intensities were measured by Norelco X-ray diffractometer with Co K_α radiation.

Magnitude of magnetization was determined by means of the measurement of distances at which small rods of a sample with dimensions (ca. 0.2 mm. diameter, ca. 3 mm. length) can be attracted by a magnet so as to give a definite attractive force.

Results and Discussion

A general expression of the cation arrangement in LFS-LAS solid solution, $LiFe_pAl_{(5-p)}O_8$, is as follows:

$$[Li_xFe_yAl_{(2-x-y)}]_{tet}\,[Li_{(1-x)}Fe_{(p-y)}Al_{(3+x+y-p)}]_{oct}O_8$$

where subscript "tet" means the tetrahedral site and "oct" the octahedral site. x and y are the numbers of lithium ions and ferric ions, respectively, located in the tetrahedral site. Then, the average atomic scattering factor for the cation mixture existing in the tetrahedral or the octahedral site, i.e., $\langle f_{tet}\rangle$ or $\langle f_{oct}\rangle$, is written as

$$2\langle f_{tet}\rangle = xf_{Li} + yf_{Fe} + (2-x-y)f_{Al}$$

$$4\langle f_{oct}\rangle = (1-x)f_{Li} + (5-y)f_{Fe} + (3+x+y-p)f_{Al}$$

where f_{Li} is the atomic scattering factor of lithium ion, f_{Fe} of ferric ion and f_{Al} of aluminum ion.

A cation arrangement in LFS is shown as $[Li_xFe_{(2-x)}]_{tet}\,[Li_{(1-x)}Fe_{(3+x)}]_{oct}O_8$, and $\langle f_{tet}\rangle$ and $\langle f_{oct}\rangle$ are written as

---

* Lithium ferrospinel and lithium aluminospinel are abbreviated to LFS and LAS, respectively, in the following.

4) E. W. Gorter, *Nature*, **173**, 123 (1954); J. S. Smart, *Phys. Rev.*, **94**, 847 (1954).

5) E. Kato, This Bulletin, **32**, 51 (1959).

$$2\langle f_{tet}\rangle = xf_{Li} + (2-x)f_{Fe}$$
$$4\langle f_{oct}\rangle = (1-x)f_{Li} + (3+x)f_{Fe}$$

The same procedure is available in case of LAS. Values of the structure amplitude for reflections were calculated through the above expressions.

Integrated intensity P, which is estimated from structure amplitude F, is proportional to diffractometric peak area A, i. e.,

$$\frac{A_{hkl}}{A_{lmn}} = \frac{P_{hkl}}{P_{lmn}} = \frac{[mF^2(1+\cos^2 2\theta)\ \mathrm{cosec}^2\theta\ \sec\theta]_{hkl}}{[mF^2(1+\cos^2 2\theta)\ \mathrm{cosec}^2\theta\ \sec\theta]_{lmn}}$$

where $h\,k\,l$ and $l\,m\,n$ show Miller's indices for two arbitrary reflections, m=multiplicity and θ=Bragg angle. By measurements of X-ray diffraction intensities for the fundamental reflections, which appear regardless of the existence of a superstructure in the crystal lattice, the cation arrangements can be determined not only in the disordered phase but also in the ordered phase by the above procedures. In order to estimate the cation arrangements in LFS, LAS and LFS-LAS solid solution, reflections 220, 311 and 400 were chosen. The values of the peak area are listed in Table I.

The cation arrangements in LFS and LAS**** are listed in Table II. In this table $[Fe_{2.0}]_{tet}[Li_{1.0}Fe_{3.0}]_{oct}O_8$ was given at both the ordered phase (FL) and the disordered phase (FH) of LFS, which agree with Braun's report[6]. At the ordered phase of LAS, AL, the cation arrangement is expressed in $[Li_{0.3}Al_{1.7}]_{tet}[Li_{0.7}Al_{3.3}]_{oct}O_8$ which also agrees with $[Li_{1/3}Al_{5/3}]_{tet}[Li_{2/3}Al_{10/3}]_{oct}O_8$ given by Verwey[3]. The error in x measurement decreases with increase in peak area, and the accuracy of x was estimated to range within ± 0.05 for LFS and within ± 0.1 for LAS.

To determine the cation arrangement in LFS-LAS solid solutions[7], it is necessary to assume an adequate value for x, because x and y are variables dependent on each other for any kind of reflection. The following postulations are offered;

1) In LAS a partition of lithium ions to the tetrahedral and to the octahedral site is proportional to that of aluminum ions. In LFS, lithium ions are located only in the octahedral site. In any LFS-LAS solid solution, it is assumed that the partitions of lithium and aluminum ions have the same value regardless of distribution of ferric ions, i. e.,

$$x/(1-x) = (2-x-y)/(3+x+y-p)$$

2) A structural parameter u for oxygen ion has near values both for LFS and for LAS, and u value is almost free in the calculations of structural amplitude in this case. Therefore, u in the solid solutions is assumed to have additive property.

The values of x and y are shown in Table I, and the resultant cation arrangements are listed in Table II. Though numerous errors may be found in the determination of x and y, qualitative conclusions can be proved from experiments of a series of specimens. Lithium ions and ferric ions are located in the different site in the ordered lattice of LFS. In LAS and LFS-LAS solid solution, lithium ions are insufficient in number to be arranged in their proper lattice points (the lithium sites), wherein lithium ions enter for the ordered state of LFS. It is expected that the lithium sites in LAS and LFS-LAS solid solution are occupied by all of the lithium ions in question and the remnants by a few aluminum ions or ferric ions divided into the octahedral site, because the diffraction intensities of LAS and of LFS-LAS solid solution have the same result as that of LFS. Therefore, the crystal structures of low-temperature forms of LAS and of LFS-LAS solid solutions may be considered as those of a sort of disordered state. The lattice points, where aluminum ions are exchanged for ferric ions, are mainly

AL→BL and QL→DL→EL at the tetrahedral site,

BL→CH→PH→RH→QL and EL→FL at the octahedral site.

In the previous paper[5], I have reported the distinction in physical properties between LFS-LAS solid solutions of iron-rich composition (above 68 mol. % LFS) and those of an aluminum-rich one (below 20 mol. % LFS). No change takes place in the cation arrangement at the octahedral site in spite of the change from AL to BL. It is considered that this fact makes the aluminum-rich solid solution stable in ordered state. The manner is similar for the cation exchange in the tetrahedral site from EL to FL. It is

---

**** As for structural parameter, u, following values were used; LFS: $u=0.382$[6]; LAS: $u=0.385$[1].

●: disordered phase

difficult at present to resolve physical changes in view of the cation arrangement.

Magnetism in a ferrospinel is explained by the theory of ferrimagnetism. Only ferric ions contribute to spontaneous magnetization in LFS-LAS solid solution, and the magnitude of magnetization is related both with the difference between numbers of ferric ions at the tetrahedral and at the octahedral site and with an interaction between cations at the tetrahedral and octahedral site (the latter relating to numbers of ferric ions located in two kinds of lattice point). Fig. 1 shows the relative magnitude of magnetization of LFS-LAS solid solutions at room temperature, measured by the distances capable of attracting specimens by a magnet, as a function of the chemical composition. The observed magnitudes of magnetization qualitatively agree with magnitudes presumed from the cation arrangement.

Now, a quenching effect of LFS-LAS solid solution will be discussed. In specimens C, P and R, magnitudes of magnetization in disordered phase were smaller than those in ordered phase. C, P and R in ordered phase were mixtures of two phases which roughly corresponded to B and D, so that magnetization of specimens was suitable to the resultant magnetization of two phases. When the configurational free energy of crystal lattice is scarcely changed by any cation arrangement, cations, owing to thermal agitation at high temperature, incline to be statistically distributed[8] rather than to be located in the most stable state. In CH, PH, RH, high-temperature form of E and FH, their statistical structures are not recognized. On the other hand, in D, the cation

8) "Statistical distribution" means that cations are distributed over all cation sites at random, while "disordered" phase as for ferrospinel indicates a phase in statistical distribution over the octahedral site alone.

arrangement in disordered phase differs from that in ordered phase, and its statistical distribution at a high temperature is recognized from magnetic measurements as well as from X-ray studies. In Q also, the magnetization in ordered phase results in the near magnitude to that in a disordered one, and the statistical distribution is demonstrated. Briefly summarizing, LFS-LAS solid solution gave different cation arrangements within the ordered and the disordered phase in general, but the possibility of the statistical distribution, as is shown in magnesium and cupric ferrospinels, can not yet be determined.

The author is indebted to Mr. Kazuo Sasaki of Osaka City University for his assistance in X-ray measurements.

The Mechanism of Reductive Cleavage Reaction of 2, 3-Dimethyl-3-cyanomethylindolenine

By Masao NAKAZAKI

(Received December 1, 1958)

Hoshino and Tamura[1] observed the unexpected formation of 2, 3-dimethylindole(II) by the reduction of 2, 3-dimethyl-3-cyanomethylindolenine(Ia) with sodium and ethanol.

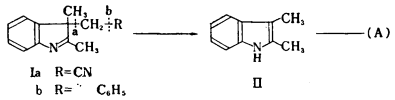

Fig. 1

Recently, we have reported[2] a conversion of 3-alkyl-2, 3-dimethylindolenines into 2, 3-dimethylindole by means of acid, and proposed a mechanism which could not be applied to the explanation of the mechanism of Hoshino's reaction mentioned above.

In some cases, the reductive cleavage of $-CH_2CN$ to CH_3 was reported[3]; however, a search of the literature failed to find analogous reaction[4] to Hoshino's reductive cleavage by the action of sodium and ethanol.

The study of elucidation of the mechanism of this novel reductive cleavage reaction was undertaken with the hope that this might lead to some bits of information which would be able to be applied to the structure determination of the indole alkaloids.

The simplest, but not so attractive, explanation would be the hydrogenolysis of bond a (Fig. 1). Since in many instances, a benzyl group is noticed to be split off very easily under various reductive conditions, 2,3-dimethyl-3-benzylindolenine(Ib) was treated with sodium and ethanol as a model experiment. But, as would be expected, 2, 3-dimethyl-3-benzylindoline, instead of II, was obtained from the reaction mixture, simply as the result of the reduction of indolenine double bond.

To examine another possible route, which would be initiated by an attack of ethoxide anion (Fig. 2. mechanism B), Ia was treated with sodium ethoxide in ethanolic solution.

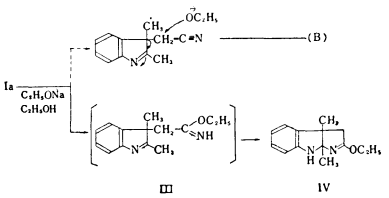

Fig. 2

It was unsuccessful to detect any trace of II, but a crystalline compound, m. p. 148~

3) J. J. Bloch, *Chem. Zentr.*, III, 609 (1919); see also R. B. Wagner and H. D. Zook, "Synthetic Organic Chemistry", John Wiley and Sons, Inc., New York (1953), p. 659.

4) In the case of indole compounds, the vulnerability of bond b (Fig. 1) is noticed, e. g., F. C. Uhle and L. S. Harris, *J. Am. Chem. Soc.*, **79**, 103 (1957); H. R. Snyder and D. S. Mattson, ibid., **79**, 2217 (1957); E. Lecte and L. Marion, *Can. J. Chem.*, **31**, 775 (1953).

149°C, was isolated, the molecular formula of which corresponded to Ia plus one molecule of ethanol. This compound could be prepared also by the action of ethanolic hydrochloric acid onto Ia, and was given the structure IV by the observation of I. R. (see, experimental part) and U. V. spectrum (Fig. 7).

The failure of the conversion of Ia into II only by means of sodium ethoxide indicated that course B must be ruled out, and the reductive condition seems to be imperative for the change Ia→II.

The fact that it was found possible for the compound IV, in turn, to afford II by the action of potasium and *tert*-butanol, led to the conclusion that Ia is not the only compound capable of undergoing Hoshino's reaction. This was confirmed further by the isolation of II, when sodium was added to the ethanolic solution of the indolenine ester V, prepared from Ia by the alcoholysis with ethanol and concentrated sulfuric acid.

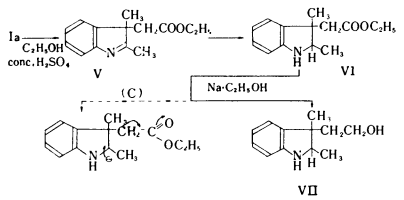

Fig. 3

The complexity encountered in the case of Ia suggested that the compound V appeared to be more suitable than Ia for the further study of Hoshino's reaction[5]. Having two reducible groups in the molecule, at the initial stage of the reaction, the compound V would be attacked by a reduction reagent either on the indolenine nucleus or on the side chain.

If the former is the case, the intermediate compound will be the compound VI which would give II, according to the mechanism C shown on Fig. 3. But VI, prepared by catalytic hydrogenation[6] of V with platinum oxide in acetic acid failed to afford II with sodium ethoxide or potassium *tert*-butoxide[7]. The reduction of VI with sodium and ethanol did not afford II either, but an alcohol VII was the sole product isolable from the reaction mixture. This alcohol was proved to be identical with the one prepared from VI by the lithium aluminum hydride reduction.

Thus, mechanism C had to be abandoned, and another conceivable route in which the reduction reagent would attack the side chain first was to be sought. To examine this possibility, an attempt was made to prepare the possible intermediate IX.

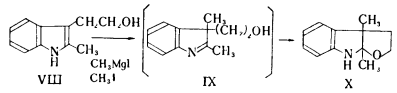

Fig. 4

The reaction of the Grignard complex of VIII with methyl iodide afforded a crystalline product, m. p. 51.5~52.5°C, to which the structure X[8] was assigned because of the lack of OH band but the presence of NH band in its I. R. spectrum, coupled with its indoline type absorption in the U. V. region (Fig. 7). This material again failed to give II, under the Hoshino's condition.

These observations lead one to conclude that: 1. the compounds of the general structure XI[9] (Fig. 5, where X is electronegative atom, such as oxygen or nitrogen.), furnish 2,3-dimethylindole with sodium and alcohol; 2. reduction reagent attacks simultaneously[10] the unsaturated bond of indolenine nucleus and the one on the side chain.

The most plausible mechanism, D, is shown on Fig. 5. A 1,4-biradical XII,

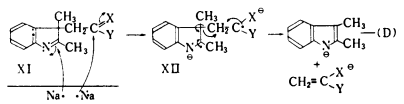

Fig. 5

5) Upon catalytic hydrogenation, V gave the compound VI as the result of the hydrogenation of the indolenine double bond, but in the case of Ia the side chain also would be reduced at the same time.

6) H. L. Holmes, H. T. Openshaw and R. Robinson, *J. Chem. Soc.*, **1946**, 910.

7) The formation of a small amount of *tert*-butyl ester by *tert*-butanolysis was presumed by effervescence of the crude picrate of recovered ester observed at its melting point.

8) T. Hoshino and K. Shimodaira (*Ann.*, **520**, 19 (1935)) succeeded in preparing the first compound which has the same skeleton as X, but they could decide whether their compound has the skeleton IX or X. Since our compound was established to have the structure X (3a, 8a-dihydro-3a,8a-dimethyl-2-furo [2.3-b] indole), their compound is 3a, 8a-dihydro-3a-methyl-2-furo [2.3-b] indole. See the nomenclature in "The Ring Index", by A. M. Patterson and L. T. Capell, Reinhold Pub. Corp., (1940), p. 198.

9) Under the reaction condition, the compound IV would be safely assumed to be converted back to III, which would be cleaved to give II. This causes a shift of equilibrum, and eventually all of IV would be transformed to II.

10) Though not necessarily at the very same instance, the reduction of one of two functional groups should not exceed the other, otherwise it would give either VI or X which can not give II.

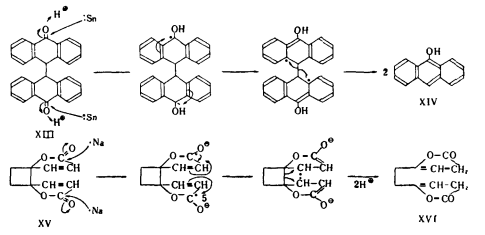

Fig. 6

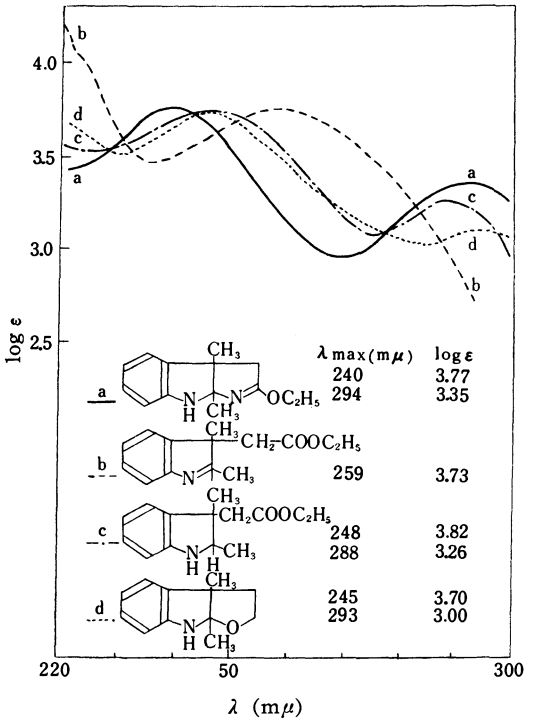

Fig. 7

which is caused by a nucleophilic attack[11] of the electron from sodium, is unstable[12] and suffered cleavage of bond a by the electron migration as indicated with arrows, resulting in end products.

According to this mechanism, in the case of Ia, the side chain split off is probably acetonitrile, which would be reduced further to give ethylamine. The actual isolation of ethylamine as the form of ethyloxamide from the reaction mixture of Hoshino's reaction of Ia, will support this mechanism.

The reductive cleavage of dihydrodianthrone(XIII) to anthrone(XIV)[13] with tin and acetic acid containing hydrochloric acid, and the conversion of anemonine (XV) into dihydroanemonine(XVI)[14] with sodium amalgam and acetic acid in methanolic solution appear to follow the analogous reaction pattern. (Fig. 6).

The driving force of the reaction could be sought in the steric strain of cyclobutane ring in the case of XV, and the tendency to aromatize into stable indole structure would play an important rôle in promoting Hoshino's reaction.

Experimental[15]

2, 3-Dimethyl-3-cyanomethylindolenine(Ia). —Ia was prepared following Hoshino and Tamura's procedure[1]. Attempts were made to improve the yield by using methyl bromide in place of the ethyl iodide used in their synthesis or employing "reversed Grignard synthesis". The best result was obtained when chloroacetonitrile was added rather rapidly. Grignard solution prepared from 1.2 g. of magnesium and 8.0 g. of methyl iodide in 30 cc. of absolute ether was cooled and 7.3 g. of 2, 3-dimethylindole in 35 cc. of ether was added dropwise onto it.

After the generation of methane subsided, the reaction mixture was stirred for 10 min. at room temperature and refluxed on a water bath for another 30 min. When 4.0 g. of chloroacetonitrile[16] was added during 5 min. into the cooled solution, a yellow viscous precipitate was observed on the wall of the reaction vessel.

After the solution was allowed to stand for 20 min. at room temperature, it was refluxed for 30 min. The Grignard complex was decomposed by the addition of 6 g. of acetic acid and 200 cc. of ice water, and the reaction mixture was thoroughly extracted with ether. Basic material was extracted by shaking with 2 N hydrochloric acid solution from the combined ether extract, and was precipitated from the solution as yellow oil by the addition of excess of 4 N sodium hydroxide solution. The oil was extracted with ether, and the ether extract was washed with water and dried over magnesium sulfate. Evaporation of

11) As for the action of sodium on organic compounds, see an excellent article by A. J. Birch, *Quart. Rev.*, **4**, 69 (1950).

12) R. C. Fuson, "Advanced Organic Chemistry", John Wiley and Sons, New York (1953), p. 72.

13) E. de Barry Barnett and M. A. Mathews, *J. Chem. Soc.*, **123**, 380 (1923).

14) Y. Asahina and R. Fujita, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), **448**, 471 (1919); ibid., **455**, 1 (1920). The position of the double bonds of dihydroanemonine (XVI) deduced by this mechanism agrees with the one established by their experimental results.

15) All melting points are uncorrected. All U. V. spectra were measured with an EPS-2 Hitachi Autorecording Spectrophotometer and I. R. spectra on a Perkin Elmer Model 12C. The analyses were performed in the microanalytical laboratory of the Institute of Polytechnics, Osaka City University.

16) Since trimethylbenzene recommended as solvent is not easily accessible, the procedure described in "Organic Syntheses" (Vol. **30**, 22 (1950)) was simplified as follows. An intimate mixture of finely powdered chloroacetamide (1 mol.) and phosphorus pentoxide (2.5 mol.) was placed in oil bath heated at 200~220°C beforehand, and the resulting chloroacetonitrile was distilled off at 80~100 mm. collected in a receiver chilled by a freezing mixture. Purification by further distillation gave a yield of 76%. ("Organic Syntheses": 61~70%).

the solvent furnished a yellow viscous residue which gave 2.6 g of Ia (28% yield), b. p. 140~145°C/1 mm. (literature[1]: b. p. 150°C/1 mm., 15% yield).

This compound has a characteristic odor of indolenine compound and solidified on standing to give m. p. 75~76°C after sublimation in vacuo.

Anal. Found: C, 78.41; H, 6.69; N, 15.17. Calcd. for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.21%.

The picrate was recrystallized to give yellow crystals, m. p. 175~178°C. (literature[1]: 177~178°C).

Anal. Found: N, 16.99. Calcd. for $C_{12}H_{12}N_2 \cdot C_6H_3O_7N_3$: N, 16.94%.

2,3-Dimethyl-3-benzylindoline.—To a stirred solution of 1.8 g. of Ib in 25 cc. of absolute ethanol, 2.1 g. of sodium was added in five portions. After the sodium disappeared, water was added and the reaction mixture was extracted with ether. The ether extract gave, after removal of the solvent, 1.8 g. of crystals which melted at 80~82°C after recrystallization from ethanol-water. I. R. spectrum[17]: 3.10 μ (NH). U. V. spectrum[17]: λ_{max} 273 mμ (log ε 3.35) in ethanol.

Anal. Found: C, 85.86; H, 8.10. Calcd. for $C_{17}H_{19}N$: C, 86.03; H, 8.07%.

The picrate was recrystallized to yield yellow needles, m. p. 177~179°C.

Anal. Found: C, 58.86; H, 4.87. Calcd. for $C_{17}H_{19}N \cdot C_6H_3O_7N_3$: C, 59.22; H, 4.75%.

1,2-Dehydro-2-ethoxy-9-methyldinordesoxyeseroline (IV).—*By the action of ethanolic hydrochloric acid on Ia.*—A solution of 4.35 g. of Ia in 45 cc. of absolute ethanol was cooled at −10°C, and saturated with dry hydrogen chloride. After the solution was kept at room temperature overnight, ethanol was removed by distillation in vacuo, and the residue was neutralized with 5% sodium carbonate solution to afford crystals, m. p. 151~152°C (4.2 g.) after recrystallization from water-ethanol. I. R. spectrum: 3.2 μ (NH), 6.33 μ (CN). U. V. spectrum: λ_{max} 240 mμ (log ε 3.77), 294 mμ (log ε 3.35) in methanol.

Anal. Found: C, 72.85; H, 7.70; N, 12.25. Calcd. for $C_{14}H_{18}ON_2$: C, 73.01; H, 7.80; N, 12.17%.

The picrate was recrystallized to give yellow needles, m. p. 174~175°C.

Anal. Found: C, 52.95; H, 4.96; N, 15.09. Calcd. for $C_{14}H_{18}ON_2 \cdot C_6H_3O_7N_3$: C, 52.28; H, 4.61; N, 15.25%.

By the action of sodium ethoxide on Ia.—To a solution of sodium ethoxide prepared from 0.2 g. of sodium and 20 cc. of absolute ethanol, 0.38 g. of Ia was added with 1 cc. of ethanol. After the solution was refluxed for 1 hr., the reaction mixture was subjected to steam distillation, but 2,3-dimethylindole could not be detected in the steam distillate.

The residue of the steam distillation afforded a pale yellow precipitate which was purified by recrystallization from ethanol-water to give crystals, m. p. 148~149°C, undepressed m. p. on admixture with that prepared by the method described above.

Reductive Cleavage of IV with Potassium and *tert*-Butanol.—To a solution of 0.8 g. of IV in 30 cc. of *tert*-butanol, 1.8 g. of potassium was added in small portions. After the solution was refluxed on a water bath for 2 hr., the reaction mixture was subjected to steam distillation. The crystals which separated on the condenser weighed 0.2 g., and melted at 101~104°C after recrystallized from petroleum ether (b. p. 50~70°C). This compound was proved identical with 2,3-dimethylindole by the mixed m. p. (101~103°C) with an authentic specimen (m. p. 104~105°C).

Anal. Found: C, 82.81; H, 7.42; N, 9.41. Calcd. for $C_{10}H_{11}N$: C, 82.72; H, 7.64; N, 9.65%.

Ethyl 2,3-Dimethylindolenine-3-acetate (V).—Ia (4.6 g.) was ethanolyzed by boiling with 20 cc. of 94% ethanol and 10 cc. of concentrated sulfuric acid for 8 hr. The cooled reaction mixture was poured onto a stirred solution of 40g. of sodium carbonate in 100 cc. of water and 100 cc. of ether which formed an upper layer. The ether extract, after being washed with water and dried over magnesium sulfate, was concentrated to give a yellow brown liquid which was distilled to afford 4.2 g. of pale yellow viscous oil with green-yellowish fluorescence, b. p. 120~130°C/6 mm. I. R. spectrum: 5.75 μ (ester carbonyl), 6.30 μ (indolenine C=N). U. V. spectrum: λ_{max} 259 mμ (log ε 3.75), λ_{min} 235 mμ (log ε 3.49) in ethanol.

Anal. Found: N, 6.01. Calcd. for $C_{14}H_{17}O_2N$: N, 6.06%.

The picrate was recrystallized to furnish yellow needles, m. p. 141~143°C.

Anal. Found: C, 52.47; H, 4.61; N, 12.22. Calcd. for $C_{14}H_{17}O_2N \cdot C_6H_3O_7N_3$: C, 52.17; H, 4.38; N, 12.17%.

Reductive Cleavage of V.—To a solution of 0.589 g. of V in 13 cc. of absolute ethanol, 1.0 g. of sodium was added in three portions as rapidly as the capacity of the condenser allowed, and after the disappearence of sodium the solution was heated on a water bath for 30 min. To the reaction mixture, 20 cc. of water was added and ethanol was removed to give a turbid solution from which a crystalline material (0.14 g.) precipitated. After recrysallization from petroleum ether (b. p. 50~70°C), this crystal showed m. p. 97~100°C, the identity of which with 2,3-dimethylindole was established by mixed m. p. determination with an authentic sample. Its picrate melted at 152~153°C alone and admixed with an authentic specimen.

Ethyl 2,3-Dimethylindoline-3-acetate (VI).—On catalytic hydrogenation of V (2.1 g.) with 69 mg. of platinum oxide in 10 cc. of acetic acid, the theoretical hydrogen up-take was completed after 2 hr. After the catalyst was filtered, the filtrate was poured onto a solution of 20 g. of sodium carbonate in 150 cc. of water, and extracted with ether. The ether extract,

17) Cf. M. Nakazaki and S. Isoe, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nipon Kagaku Zasshi*), **76**, 1161 (1955).

18) After the nomenclature of "The Ring Index", p. 196, this can be named as 3a, 8a-dihydro-1,2-dehydro-2-ethoxypyrrolo [2.3-b] indole.

after removal of the solvent, afforded a pale yellow oil, which gave 1.64 g. of (78% yield) VI, b. p. 153~154°C/6 mm. No fluorecence was observed. I. R. spectrum: 2.95 μ (NH), 5.76 μ (ester carbonyl). U. V. spectrum: λ_{max} 288 mμ (log ε 3.26), 248 mμ (log ε 3.82) in ethanol.

Anal. Found: C, 70.96; H, 8.24; N, 5.84. Calcd. for $C_{14}H_{19}O_2N$: C, 72.07; H, 8.21; N, 6.00%.

The picrate was recrystallized from ethanol to give yellow needles, m. p. 153°C.

Anal. Found: C, 51.95; H, 4.85; N, 12.12. Calcd. for $C_{14}O_{19}O_2N \cdot C_6H_3O_7N_3$: C, 51.95; H, 4.80; N, 12.12%.

The Action of Potassium *tert*-Butoxide on VI.—To a solution of potassium *tert*-butoxide prepared from 0.08 g. of potassium and 6 cc. of *tert*-butanol, a solution of 0.33 g. of VI in 2 cc. of *tert*-butanol was added. After the reaction mixture was heated for 1 hr. on a water bath, the solvent was removed under reduced pressure. After the residue was dissolved in water and saturated with sodium chloride, the solution was extracted with ether. The ether extract was shaken with 2 N hydrochloric acid solution to separate neutral and basic fractions. From the ether layer, after the usual work-up, there could not be detected anything but a faint smell of *tert*-butanol. The hydrochloric acid solution was made strongly basic, and the separated oily material was extracted with ether. The ether extract gave, after evaporation of the solvent, 0.25 g. of liquid which was converted into picrate directly. The crude picrate melted at 145~151°C with a little effervescence, but after two more recrystallizations from ethanol, its m. p. was 152~153°C and proved identical with the picrate of VI.

The Action of Sodium on the Ethanolic Solution of VI.—To a solution of 0.47 g. of VI in 9 cc. of absolute ethanol, 0.7 g. of sodium was added in three portions. After the sodium disappeared, the solvent was removed on a water bath, and water was added to the residue. The basic and neutral fractions were separated as mentioned above. From the neutral fraction, no 2,3-dimethylindole was found. The basic fraction gave 0.221 g. of a pale yellow liquid which afforded a yellow prismatic picrate melting at 152~154°C after recrystallization from ethanol. The mixed m. p. with the picrate of VII (m. p. 151~153°C) was 151~154°C.

Anal. Found: C, 51.84; H, 5.16; N, 13.23. Calcd. for $C_{12}H_{17}ON \cdot C_6H_3O_7N_3$: C, 51.42; H, 4.80; N, 13.33%.

β-(2, 3-Dimethylindolinyl)-ethanol (VII).—To a suspension of 0.15 g. of lithium aluminum hydride on 20 cc. of absolute ether, a solution of 0.909 g. of VI in 10 cc. of ether was added dropwise over a period of 30 min. After the reaction mixture was heated on a water bath for 1 hr., the excess of the reduction reagent was destroyed by the addition of ethyl acetate, and the resulting white voluminous precipitate was dissolved in 2N sodium hydroxide. Continuous extraction with ether (10 hr.) gave, after removal of the solvent, 0.635 g. of a viscous liquid, which was distilled at 136~145°C (air bath temperature) under 3 mm. to yield 0.53 g. of viscous oil. This solidified to give colorless needles, m. p. 100~101°C, after recrystallization from ethanol-petroleum ether.

Anal. Found: C, 75.63; H, 9.14; N, 7.38. Calcd. for $C_{12}H_{17}ON$: C, 75.35; H, 8.96; N, 7.32%.

The picrate was recrystallized to produce yellow crystals, m. p. 151~153°C.

2-Methyltryptophol (VIII).—To a slurry of 1.75 g. lithium aluminum hydride in 130 cc. of absolute ether, a mixture of 10 g. of ethyl 2-methylindole-3-acetate[19] in 50 cc. of ether was added dropwise at such a rate as to keep the ether boiling.

Stirring and refluxing was continued for 30 min., and 15 cc. of ethyl acetate was added to destroy the excess of the reduction reagent followed by the addition of dilute sulfuric aid. The aqueous layer was thoroughly extracted with ether, and ether extract was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, the ether extract gave a viscous liquid, which was purified by distillation in vacuo resulting in 6.0 g. of liquid (75% yield), b. p. 143~144°C/10^{-3} mm.[20]

3a, 8a-Dihydro-3a, 8a-dimethyl-2-furo(2.3-b)-indole (X).—A solution of 5 g. of VIII in 30 cc. of ether was added dropwise onto a stirred cold Grignard solution prepared from 2.08 g. of magnesium and 15.3 g. of ethyl iodide in 15 cc. of ether.

After being kept at room temperature for about 20 min., the reaction mixture was refluxed on a water bath for 1 hr. To this solution 9.3 g. of methyl iodide was added during 3 hr., and the mixture was kept at room temperature overnight. The Grignard complex was decomposed with acetic acid and water, and extracted with ether. From the ether extract the basic material was transferred into 1 N hydrochloric acid. The oily material, liberated by the addition of 2 N sodium hydroxide solution to the hydrochloric acid extract, was again extracted with ether. Distillation of the residue, after evaporation of ether, at a reduced pressure gave 0.94 g. of viscous oil, b. p. 125~126°C/5 mm.

This compound solidified gradually, and recrystallization from petroleum ether (b. p. 50~70°C) gave prismatic crystals, m. p. 51.5~52.5°C. I. R. spectrum: 3.00 μ (NH). U. V. spectrum: λ_{max} 245 mμ (log ε 3.7), 293 mμ (log ε 3.0).

Anal. Found: C, 76.29; H, 8.26. Calcd. for $C_{12}H_{15}ON$: C, 76.15; H, 7.99%.

The picrate gave yellow prisms from ethanol, m. p. 137~139°C.

Anal. Found: C, 52.01; H, 4.61; N, 13.39. Calcd. for $C_{12}H_{15}ON \cdot C_6H_3O_7N_3$: C, 51.67; H, 4.34; N, 13.39%.

The Action of Sodium on the Ethanolic Solution of X.—One gram of sodium was added in three portions to a solution of 0.26 g. of X in

19) M. V. Bulloch and S. W. Fox, *J. Am. Chem. Soc.*, **73**, 5156 (1951).

20) T. Hoshino and K. Shimodaira, *Ann.*, **520**, 19 (1935) prepared this alcohol by the Bouveault-Blanc reduction in a yield of 32%, b. p. 198°C/3.5 mm. and m. p. 55~56°C.

20 cc. of absolute ethanol. After the reaction was complete, water was added to the reaction mixture and saturated with sodium chloride. The solution was thoroughly extracted with ether, but the test of 2,3-dimethylindole was negative on the small amount of residue remaining after removal of the solvent.

Reductive Cleavage of Ia. Isolation of Ethylamine.—In a 100 cc. three-necked flask, provided with an inlet tube for dry nitrogen, a reflux condenser carrying a glass tubing which reached the bottom of a Erlenmeyer flask containing 10 cc. of 4 N hydrochloric acid solution, and an inlet tude for sodium, were placed 2.09 g. of Ia and 45 cc. of absolute ethanol. While nitrogen from a cylinder was passed through the flask, 3.5 g. of sodium was added in five portions as rapidly as the capacity of the condenser allowed. Volatile material was swept with nitrogen gas into the hydrochloric acid solution. After completion of the reaction, cooling water for the condenser was cut off, and about 5 cc. of ethanol was distilled through the condenser into the Erlenmeyer flask contaning the acid solution. Another 15 cc. of ethanol was distilled into the same receiver by the usual downward distillation.

Water was added to the residue which remained in the three-necked flask and the turbid solution was distilled with steam. From the distillate, 0.5 g. of 2, 3-dimethylindole was obtained, and identified by mixed m. p. determination with an authentic sample and as in the form of picrate.

The hydrochloric acid solution containing the basic material, was concentrated in vacuo to give a crystalline product which was soluble completely in absolute ethanol. The amine generated by the addition of 10 cc. of 4 N sodium hydroxide solution onto the above mentioned amine hydrochloride, was distilled with water into a flask containing 0.2 g., of diethyl oxalate and 1 cc. of water. The crystals separated from the cold solution, were washed with a small amount of cold water and dried in a desiccator to give 10 mg. of colorless needles, m. p. 178~179°C, which did not depress the mixed m. p. with an authentic sample of ethyloxamide (m. p. 178~180°C[21]). Their I. R. spectra could overlap in every respect.

Anal. Found: C, 50.28; H, 8.85: N, 19.40. Calcd. for $C_6H_{12}O_2N_2$: C, 49.98; H, 8.39; N, 19.43%.

On a control experiment using the same method, 65 mg. of ethyloxamide was isolated by the reduction of 600 mg. of acetonitrile with sodium-ethanol.

The author is very gratiful to Messrs. Kohei Tanno, Masaru Tamura and Munesuke Sato for their skillful technical assistance.

Indirect Complexometric Titration of Beryllium with Ethylenediaminetetraacetic Acid

By Seizo MISUMI and Tomitsugu TAKETATSU

(Recived December 19, 1958)

Ethylenediaminetetraacetic acid (EDTA) has been used for volumetric determination of various metal ions, but it can not be used for a direct titration of the beryllium ion nor for that of the sodium and the potassium ion because these metal ions do not form stable EDTA complexes. Flaschka[1] reported the indirect titration method for sodium, and Pilleri[2] and one of the present authors[3] that for potassium. Pirtea and Mihail[4] reported that beryllium was determined gravimetrically, producing the precipitate $[Co(NH_3)_6]\cdot[(H_2O)_2Be_2(CO_3)_2(OH)_3]\cdot 3H_2O$, by adding saturated hexammine cobaltic trichloride solution (Luteo salt) to beryllium carbonate solution. We studied the determination of beryllium ion concentration by volumetrically measuring the cobalt content in this precipitate. This method was proved to be quantitative and it was possible to separate and determine beryllium from iron (III), aluminum

and magnesium by using EDTA as a masking agent.

Experimental

Reagents.—Standard beryllium solution was prepared by dissolving the nitrate salt in distilled water and the concentration was determined gravimetrically as the oxide. The content (BeO) was 1.95 mg./ml.

Standard EDTA solution was obtained by dissolving the pure disodium salt of ethylenediaminetetraacetic acid dihydrate (Research Laboratory, Dojindo & Co., Ltd.) in distilled water. The concentration was determined by titrating standard zinc chloride solution with Eriochrome black T as indicator. The concentration was 0.01016 mol.

Hexammine cobaltic trichloride (Luteo salt) solution was prepared by Fernelius's method[5] and the supernatant liquid of the saturated solution was used in this experiment.

All other chemicals used were analytical reagent grades.

General Procedure.—An excess of ammonium carbonate was added to about 10 ml. of a slightly acidic solution containing 0.70 to 3.50 mg. of beryllium; a precipitate of basic beryllium carbonate was formed, which was then dissolved completely by stirring for a time. To this clear solution was added a few milliliters of saturated Luteo salt solution and an orange yellow precipitate[4] was obtained by stirring the solution. The solution containing the precipitate was stirred occasionally by a magnetic stirrer for several hours to make the precipitation complete. The precipitate was then filtered with a glass filter (1G. No. 4) and washed 2 to 3 times successively with 2 to 3 ml. of the following solutions: 0.2% Luteo salt solution, a mixture of ethanol and water (60 ml. +40 ml.) containing 2 to 3 drops of 0.2% Luteo salt solution, and absolute ethanol. The percipitate on the glass filter was dissolved in a small amount of 0.1 N hydrochloric acid. To decompose the Luteo salt in the solution obtained, one gram of sodium hydroxide was added to the solution and then the solution was boiled till the black-brown precipitate of cobalt (III) hydroxide was obtained. The solution containing the precipitate was acidified by adding hydrochloric acid and boiled to dissolve the cobalt hydroxide. By this procedure the valency of cobalt was reduced to II from III with hydrochloric acid and a solution containing cobalt (II) and beryllium ions was obtained. After the solution cooled, a small amount of malic acid was added to the solution and it was neutralized with aqueous ammonia (1:1, by volume). The cobalt in the solution was titrated with the standard EDTA solution by adding 0.2 g. of Murexide as indicator. The point at which the indicator attained its maximum violet color was as the end point.

1 ml. of 0.01 mol. EDTA solution
≡0.1803 mg. of berlliyum.

These procedures were carried out at 20~25°C except for boiling purposes.

Results and Discussion

In the general procedure described above, the following factors were specially considered; effects of the amount of ammonium carbonate, Luteo salt and malic acid, and of time allowed for the formation of the precipitate II*.

1) Relation between Ammonium Carbonate Added and the Time Required to Dissolve Basic Beryllium Carbonate.—When an excess of ammonium crabonate was added to about 10 ml. of solution containing 1.40 mg. of beryllium, basic beryllium carbonate was precipitated at first, but the precipitate was dissolved gradually by stirring, because beryllium carbonate complex was produced. The relation between the amount of ammonium carbonate added and the time required for dissolving the precipitate was studied and the results are shown in Table I. It is shown that the more the amount of ammonium carbonate, the shorter the time required for the dissolving of the precipitate.

TABLE I. RELATION BETWEEN THE AMOUNT OF AMMONIUM CARBONATE AND APPROXIMATE TIME REQUIRED TO DISSOLVE BASIC BERYLLIUM CARBONATE

Ammonium carbonate added, g.	Time for dissolving the precipitate, min.
0.5	>60
1.0	25~30
1.5	10~20
2.0	7~ 8
2.5	5~ 7
3.0	3~ 5
4.0	1~ 2

2) Effect of Luteo Salt Added.—To determine the optimum amount of Luteo salt added, various volumes of saturated Leuteo salt solution were added to the beryllium carbonate complex solution. In this case, all other conditions were kept constant. The results are shown in Table II.

It was found that the amount of the reagent added did not affect the determination of beryllium within the range 1 to 8 ml.

5) W. C. Fernelius," Inorganic Syntheses ", Vol. II, McGraw Hill Book Co., Inc., New York (1946), p. 217.

* The precipitate II means $[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3]\cdot 3H_2O$

TABLE II. EFFECT OF LUTEO SALT ADDED

Be taken, mg.	Saturated Luteo salt solution added, ml.	Vol. of 0.01016 mol. EDTA titrated, ml.	Be found, mg.	Error, mg.
1.40	1.0	7.72	1.41	+0.01
1.40	2.0	7.79	1.43	+0.03
1.40	4.0	7.61	1.39	−0.01
1.40	5.0	7.72	1.41	+0.01
1.40	8.0	7.65	1.40	±0.00

3) Relation between the Amount of the Precipitate and That of Ammonium Carbonate Added.—Since the amount of ammonium carbonate added had an effect on the formation of the precipitate II., the relation between the amount of the precipitate formed and that of ammonium carbonate added was studied at various time intervals after Luteo salt was added. The results are shown in Fig. 1.

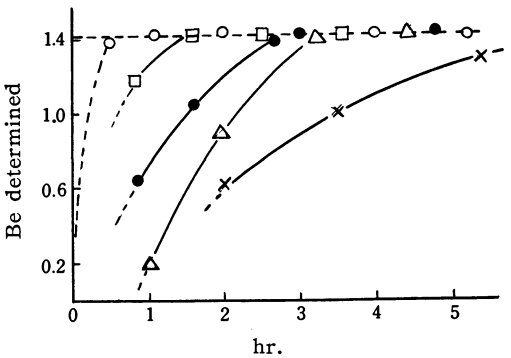

Fig. 1. Relation between beryllium determined v.s. time at various concentrations of ammonium carbonate added.

	Ammoium carbonate
—○—○—	1.0 g
—□—□—	1.5 g
—●—●—	2.0 g
—△—△—	3.0 g
—×—×—	4.0 g

When a small amount of ammonium carbonate had been added to the initial beryllium solution, the precipitate II was formed quantitatively as soon as Luteo salt was added. On the other hand, a longer time was necessary for the formation of the precipitate II with increase in the amount of ammonium carbonate. However, as it is convenient for the dissolution of the precipitate of basic beryllium carbonate to add a greater amount of ammonium carbonate as described above, 1.5 to 2.0 g. of ammonium carbonate was used in this experiment.

4) Effect of Malic Acid on the Titration of Cobalt. — When the titration of cobalt was carried out in an ammonium alkaline solution by using Murexide as indicator, beryllium precipitated as its hydroxide and the results, therefore, proved inaccurate. Since the hydroxide does not precipitate in general in the presence of malic acid, the effect of malic acid on the titration of cobalt was studied. The results are shown in Table III.

TABLE III. EFFECT OF MALIC ACID ADDED

Co taken, mg.	5% malic acid added, ml.	Vol. of 0.01016 mol. EDTA titrated, ml.	Co found, mg.	Error, mg.
3.64	0	6.08	3.64	±0.00
3.64	2	6.08	3.64	±0.00
3.64	4	6.08	3.64	±0.00
3.64	5	6.07	3.63	−0.01
3.64	10	6.05	3.62	−0.02

It is evident that the addition of 2 to 10 ml. of 5% malic acid solution did not give an error in the titration. But larger amounts of malic acid showed negative errors. Therefore, 2 ml. of 5% malic acid were used.

The results obtained from the titration of cobalt (3.64 mg.) with standard EDTA solution in the presence of 0.70 to 3.50 mg. of beryllium and 2 ml. of 5% malic acid are shown in Table IV. It was found that beryllium gives no effects in the titration of cobalt.

TABLE IV. TITRATION OF COBALT IN THE PRESENCE OF BERYLLIUM

Co taken, mg.	Be added, mg.	Vol. of 0.01016 mol. EDTA titrated, ml.	Co found, mg.	Error, mg.
3.64	0.70	6.08	3.64	±0.00
3.64	1.40	6.07	3.63	−0.01
3.64	1.40	6.09	3.65	+0.01
3.64	2.10	6.08	3.64	±0.00
3.64	3.50	6.07	3.63	−0.01

The optimum conditions for the general procedure were concluded as follows: the amount of ammonium carbonate added, 1.5 to 2.0 g.; the volume of saturated Luteo salt solution added, 2 ml.; the time allowed for the precipitate II to form, about 3 hr. after Luteo salt was added; the volume of 5% malic acid added, 2 ml.

5) Determination of Various Concentrations of Beryllium under the Optimum Conditions. — Various concentrations of

beryllium were determined by following the general procedure under the optimum conditions and the results are shown in Table V. Thus, it was concluded that the indirect titration of beryllium was satisfactorily carried out.

TABLE V. DETERMINTION OF VARIOUS CONCENTRATIONS OF BERYLLIUM AT THE OPTIMUM CNDITIONS

Be taken, mg.	Vol. of 0.01016 mol. EDTA titrated, ml.	Be found, mg.	Error, mg.
0.70	3.90	0.71	+0.01
0.70	3.84	0.70	±0.00
1.40	7.63	1.40	±0.00
1.40	7.68	1.41	+0.01
2.10	11.36	2.08	−0.02
3.50	19.02	3.48	−0.02

6) The Determination in the Presence of Iron (III), Aluminum and Magnesium. — After EDTA solution (0.1 mol., 5 ml.) and ammonium chloride (0.5 g.) were added to the sample solution containing iron(III), aluminum and magnesium, aqueous ammonia (1 : 1, 1 ml.) was added to the solution. At that time only beryllium hydroxide was precipitated. Then, 2 g. of ammonium carbonate was added to the solution and beryllium hydroxide was dissolved by stirring. The subsequent determination of beryllium was carried out by the procedure described above. In this case, iron, aluminum and magnesium were completely separated from beryllium when the precipitate II was formed and filtered. The results are shown in Table VI.

It is shown that the determination of berylium in the presence of these metals was carried out satisfactiorily. Therefore, this procedure is considered useful for a practical analysis of beryllium.

TABLE VI. DETERMINATION OF BERYLLIUM IN THE PRESENCE OF IRON(III), ALUMINUM AND MAGNESIUM

Be taken, mg.	Other metals added.	mg.	Vol. of 0.01016 mol. EDTA titrated, ml.	Be found, mg.	Error, mg.
1.40	Fe^{3+}	2.0	7.70	1.41	+0.01
1.40	Fe^{3+}	4.0	7.60	1.39	−0.01
1.40	Fe^{3+}	8.0	7.58	1.39	−0.01
1.40	Al^{3+}	1.7	7.64	1.40	±0.00
1.40	Al^{3+}	3.4	7.60	1.39	−0.01
1.40	Al^{3+}	6.8	7.55	1.38	−0.02
1.40	Mg^{2+}	2.1	7.65	1.40	±0.00
1.40	Mg^{2+}	8.3	7.69	1.41	+0.01

Summary

When Luteo salt was added to beryllium carbonate complex solution, the precipitate $[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3]\cdot 3H_2O$ was obtained. In this experiment, the indirect determination of beryllium was tried by the titration of the cobalt content in the precipitate with EDTA. The following procedures were examined mainly; the formation of the precipitate II, the decomposition of the precipitate and titration of cobalt in the presence of beryllium. In the optimum conditions, 0.70 to 3.50 mg. of beryllium were determined quantitatively. This method could be applied to separation and determination of beryllium from iron(III), aluminum and magnesium by using EDTA as a masking agent.

Molecular Rotations of Glucides in Relation to their Structures. VII.[1] *Internal Conformation of $O^{1\alpha}$—C^m Bond in $(OCH_3)^{1\alpha}$ of Methyl α-D-Xylopyranoside and of Methyl β-L-Arabinopyranoside in Aqueous Solutions*[2]

By Shukichi YAMANA

(Received October 21, 1958)

Although the internal conformation of $O^{1\alpha}$—C^m bond[3] in $(OCH_3)^{1\alpha}$ of methyl α-D-xylopyranoside[5,6] or of methyl β-L-arabinopyranoside[6,7] in crystalline state has been studied from the standpoint of X-ray analysis, those in the aqueous solutions have not yet been determined owing to the lack of a suitable method. (Fig. 1)

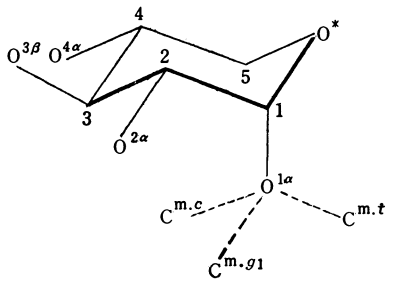

Fig. 1. Perspective drawing of the molecular model of methyl α-D-xylopyranoside: *t—trans* ($\phi_{1\alpha}=0°$), *g1—gauche* 1 ($\phi_{1\alpha}=120°$), *c—cis* ($\phi_{1\alpha}=180°$).

Hudson empirically observed the existence of a certain quantitative relationship between the structure of methyl glycosides and their molecular rotations, $[M]_D^{20}(W)$[8], but no one has attempted to utilize these $[M]_D^{20}(W)$ values for the determination of the internal conformation of their $O^{1\alpha}$—C^m bonds. Recently, the present author succeeded in presuming the internal conformation of C^6—O bond in D-mannopyranose in its aqueous solution by using $[M]_D^{20}(W)$ values of some glucides[9]. By a similar method, the internal conformation of $O^{1\alpha}$—C^m bond in $(OCH_3)^{1\alpha}$ of methyl α-D-xylopyranoside and of methyl β-L-arabinopyranoside in aqueous solutions has been presumed in this article.

Molecular Model and Data Used.—As the molecular model, the one proposed by McDonald and Beevers was used. The values of bond lengths and valency angles concerning the side chain are assumed as follows; $O^{1\alpha}$—C^m is 1.421 Å[a] and $\angle C^1O^{1\alpha}C^m$ is a tetrahedral angle (109° 28′). The unit groups in the glucide molecules under discussion and their corresponding molecular rotations are given in Table I.

As the optical data for OH, CH_3 and H, the values used in the previous papers[1,4]

TABLE I

Name	Unit groups	$[M]_D^{20}(W)$	Lit.
methyl α-D-xyloside	$[(OCH_3)^{1\alpha}$,[10] $(OH)^{2\alpha}$, $(OH)^{3\beta}$, $(OH)^{4\alpha}$, Ring]	252.6°	(b)

are again adopted in this article. In order to simplify the calculations, the optical centers of OH and CH_3 groups are assumed to be located at O and C atoms, respectively[13]. Accordingly, the value of ζ_{CH_3} becomes 0.2880 $(3/n^2+2)^{1/2}$ [14]. The refractive indices of the aqueous solutions of these methyl glycosides are presumed to be nearly equal to 1.34[15].

Method Proposed.—If the orientation of $(OH)^4$ in methyl β-L-arabinopyranoside is changed from β to α, methyl α-D-xylopyranoside is obtained[16]. But, throughout the course of this process, the distance between $(CH_3)^{\leftarrow 1\alpha}$ [17] and $(OH)^4$ is so much larger[18] than those between $(CH_3)^{\leftarrow 1\alpha}$ and the other atoms (than $(OH)^4$) in the same molecules, that the orientation-change of $(OH)^4$ should not cause any influence on the internal conformation of $O^{1\alpha}$—C^m bond. In other words, the internal conformation of $O^{1\alpha}$—C^m bond in $(OCH_3)^{1\alpha}$ of methyl α-D-xylopyranoside is said to be the same as that of methyl β-L-arabinopyranoside in their aqueous solutions. Then, the unit groups which can couple with $(OH)^4$ dynamically in the molecules of methyl α-D-xylopyranoside and of methyl β-L-arabinopyranoside are $(OCH_3)^{1\alpha}$, $(OH)^{2\alpha}$, $(OH)^{3\beta}$ and Ring[16]. Therefore, Yo. Diff.[20] between these two methyl glycosides is given by the following equation,

$$\{(4\alpha)-(4\beta)\}\lambda\{(OCH_3)^{1\alpha}+(2\alpha)+(3\beta)+R\}^{21)}=(4\alpha)\lambda(OCH_3)^{1\alpha}+(4\alpha)\lambda(2\alpha)+(4\alpha)\lambda(3\beta)+(4\alpha)\lambda R\}-\{(4\beta)\lambda(OCH_3)^{1\alpha}+(4\beta)\lambda(2\alpha)+(4\beta)\lambda(3\beta)+(4\beta)\lambda R\}\equiv I$$

Similarly, Yo. Diff. between α-D-xylopyranose and β-L-arabinopyranose is given by,

$$\{(4\alpha)-(4\beta)\}\lambda\{(1\alpha)+(2\alpha)+(3\beta)+R\}=\{(4\alpha)\lambda(1\alpha)+(4\alpha)\lambda(2\alpha)+(4\alpha)\lambda(3\beta)+(4\alpha)\lambda R\}-\{(4\beta)\lambda(1\alpha)+(4\beta)\lambda(2\alpha)+(4\beta)\lambda(3\beta)+(4\beta)\lambda R\}\equiv J$$

Accordingly, $I-J$ [22] $=\{(4\alpha)\lambda(OCH_3)^{1\alpha}-(4\beta)\lambda(OCH_3)^{1\alpha}\}-\{(4\alpha)\lambda(1\alpha)-(4\beta)\lambda(1\alpha)\}=(4\alpha)\lambda(OCH_3)^{1\alpha}-(4\beta)\lambda(OCH_3)^{1\alpha}\}-\{(4\alpha)\lambda(OH)^{1\alpha}-(4\beta)\lambda(OH)^{1\alpha}\}$ [23] (1)

$(OCH_3)^{1\alpha}$ may be considered to occur by replacing $H^{\leftarrow 1\alpha}$-atom[25] in $(OH)^{1\alpha}$ by $CH_3{}^{\leftarrow\alpha}$ group. And because of the small polarizability of $H^{\leftarrow 1\alpha}$, $(4\alpha)\lambda H^{\leftarrow 1\alpha}\simeq 0$ and $(4\beta)\lambda H^{\leftarrow 1\alpha}\simeq 0$. Therefore, Eq. 1 can be simplified as below;

$$I-J=[(4\alpha)\lambda\{O^{1\alpha}+(CH_3)^{\leftarrow 1\alpha}\}-(4\beta)\lambda\{O^{1\alpha}+(CH_3)^{\leftarrow 1\alpha}\}]-[(4\alpha)\lambda\{O^{1\alpha}+H^{\leftarrow 1\alpha}\}-(4\beta)\lambda\{O^{1\alpha}+H^{\leftarrow 1\alpha}\}]\simeq(4\alpha)\lambda(CH_3)^{\leftarrow 1\alpha}-(4\beta)\lambda(CH_3)^{\leftarrow 1\alpha}$$ [26]

The value of this $\{(4\alpha)\lambda(CH_3)^{\leftarrow 1\alpha}-(4\beta)\lambda(CH_3)^{\leftarrow 1\alpha}\}$ was calculated by PM-method[27] as a function of $\phi_{1\alpha}$[19]. These values, $[\mu]_{D\ obs}^{20}$ for $(I-J)$ are shown in Table II.

The corresponding observed value of $(I-J)$, given by $[\{([M]_D^{20}(W)$ of methyl α-D-xylopyranoside) minus $([M]_D^{20}(W)$ of

13) In Eq. 5 of the previous paper[1], ζ_{CH3} was calculated as 0.1962 $(3/n^2+2)^{1/2}$ on the supposition that the optical center of CH_3 group is located at the center of mass of ^rC—(CH_3) bond (cf. the foot-note *13 of the previous paper[12].) But here, since CH_3 group combines with O atom instead of ^rC-atom, the above value of ζ_{CH3} is hardly adoptable.

14) According to Hudson's data of L-arabinoses, $\zeta_{CH3}=0.6206(3/n^2+2)^{1/2}$. (Ref. the foot-note *31 in the previous paper[1]).

15) The refractive index (n) of an aqueous solution of methyl glycoside is 1.33~1.35[d]. When the value of n changes by 0.01, $(n^2+2/3)$ changes by $\partial/\partial n(n^2+2/3)\delta n\simeq 0.007$. The magnitude of this value of $(n^2+2/3)$-change is very small and may be neglected on comparison with that of $(n^2+2/3)\simeq 1.265$. On the other hand, $[\mu]_{D\ obs}^{20}$ contains the factor n in itself only in the form of $(n^2+2/3)$. (Ref. "**Theoretical Formulae**" in the previous paper[4].) Then, $[\mu]_{D_{obs}}^{20}$, resulting from the dynamical coupling between two definite unit groups may be considered to be constant in that range of $n=1.33\sim1.35$.

d) "International Critical Tables of Numerical Data", Vol. 7. p. 69.

16) Ref. Table I in this article.

17) $(CH_3)^{\leftarrow 1\alpha}$ indicates the CH_3 group which combines with $O^{1\alpha}$-atom, and so on. Therefore, $(CH_3)^{\leftarrow 1\alpha}$ is the CH_3 group in $(OCH_3)^{1\alpha}$. (Ref. Fig. 1).

18) Since C^1- and C^4-atoms are situated nearly on the opposite ends of a diameter of the aldopyranose-ring together, the distances between C^m-atom[3] in $(CH_3)^{\leftarrow 1\alpha}$ and the O atom in $(OH)^4$ are shown below:

	longest	shortest
$(OH)^{4\alpha}$	5.91 Å (at $\phi_{1\alpha}$[19]$=60°$)	3.63 Å (at $\phi_{1\alpha}=240°$)
$(OH)^{4\beta}$	5.60 Å (at $\phi_{1\alpha}=60°$)	4.23 Å (at $\phi_{1\alpha}=240°$)

19) The author defined an angle $\phi_{1\alpha}$ which determines the internal conformation of $O^{1\alpha}$—C^m bond as follows; (i) $\phi_{1\alpha}$ is zero at the situation where C^m— and C^2-atoms are in *trans* position each other. (ii) The value of rotation in the positive direction increases with the distance between C^*- and C^m-atoms. (Fig. 1).

20) Yo. Diff. is an abbreviated symbol of "yomeric difference". This is $[M]_D^{20}(W)$-change of a glucide, caused by the orientaionchange of $(OH)^4$ from β to α. (ref. the foot-note *10 in the previous paper[1].)

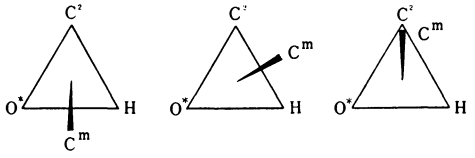
21) Ref. the foot-note *12 in the previous paper[1].

22) J is adopted only for the purpose of canceling the terms concerning the aldopyranose-ring, R, in I.

23) Ref. the foot-note *10 in the previous paper[24].

24) S. Yamana, This Bulletin, **30**, 916 (1957).

25) $H^{\leftarrow 1\alpha}$ means the H atom which combines with $O^{1\alpha}$-atom. (Cf. the foot-note 17 in this article).



26) In other expressions, $(OCH_3)^{1\alpha}\simeq(OH)^{1\alpha}+(CH_3)^{\leftarrow 1\alpha}$ $\therefore$ Eq. $1=[(4\alpha)\lambda(OCH_3)^{1\alpha}-(4\beta)\lambda(OCH_3)^{1\alpha}]-[(4\alpha)\lambda(OH)^{1\alpha}-(4\beta)\lambda(OH)^{1\alpha}]\simeq[(4\alpha)\lambda\{(OH)^{1\alpha}+(CH_3)^{\leftarrow 1\alpha}\}-(4\beta)\lambda\{(OH)^{1\alpha}+(CH_3)^{\leftarrow 1\alpha}\}]-[(4\alpha)\lambda(OH)^{1\alpha}-(4\beta)\lambda(OH)^{1\alpha}]=(4\alpha)\lambda(CH_3)^{\leftarrow 1\alpha}-(4\beta)\lambda(CH_3)^{\leftarrow 1\alpha}$

27) Ref. the foot-note *17 in the previous paper[12].

TABLE II. $\sum[\mu]^{20}_{Dobs}$ FOR THE DIFFERENCE BETWEEN TWO YOMERIC DIFFERENCE *I* AND *J*, AS A FUNCTION OF $\phi_{1\alpha}$

$\phi_{1\alpha}$	Isbell and Pigman's data of L-arabinoses	Hudson's data[14] of L-arabinoses

methyl β-L-arabinopyranoside)} minus {([M]$^{20}_{D}$(W) of α-D-xylopyranose) minus ([M]$^{20}_{D}$(W) of β-L-arabinopyranose)}], becomes −4.8 on the basis of the Isbell and Pigman's data of L-arabinoses or 12.4 on the basis of the Hudson's data of L-arabinoses[16]. The former value coincides with the calculated value when $\phi_{1\alpha}$ is 120° or 180° as seen in the second column of Table II and the latter value coincides with that when $\phi_{1\alpha}$ is 0° as seen in the third column of Table II. It follows from this result that there are three possible internal conformations of $O^{1\alpha}$—C^m bond as figured in Fig. 2.

trans $\phi_{1\alpha}=0°$ (Hudson) | *gauche* 1 $\phi_{1\alpha}=120°$ (Isbell and Pigman) | *cis* $\phi_{1\alpha}=180°$ (Isbell and Pigman)

Fig. 2. Internal conformation along $O^{1\alpha}$—C^1 axis.

Discussion of the Results

Among the above three possibilities, it seems difficult for a *cis* form to exist owing to the repulsion between C^2-atom and $(CH_3)^{\leftarrow 1\alpha}$. The internal conformation under consideration, therefore, should be either a *trans*- or a *gauche* 1 form.

C^5—O*—C^1—$O^{1\alpha}$—C^m moiety in methyl α-D-xylopyranoside (Ref. Fig. 1) and also in methyl β-L-arabinopyranoside, is considered to be a kind of polyoxymethylene-chain. The internal conformation of a polyoxymethylene-chain along its C—O axis has been investigated by the methods of measuring the dipole moment, infrared spectrum, etc.[28,29] And it has been concluded that the most stable form of —C—O—C—O—C— chain is a *gauche* type[30]. From these facts, O*—C^1—$O^{1\alpha}$—C^m moiety in the methyl glycoside under discussion is likely to exist in the conformation which corresponds to $\phi_{1\alpha}=0°$. This leads to the following anticipation.

The position of the minimal potential of $O^{1\alpha}$—C^m bond corresponds to $\phi_{1\alpha}=0°$. (Anticipation 1)

On the other hand, C^2—C^1—$O^{1\alpha}$—C^m moiety in metyl α-D-xylopyranoside and in methyl β-L-arabinopyranoside is a kind of polyethyleneglycol-chain. Because of the non-polar property of its C—C bond and of the steric repulsion between two C-atoms in —C—C—O—C— chain, —C—C—O—C— along its C—O axis is strongly expected to be more stable in a *trans* form than in a *gauche* form. This produces the conclusion that the conformation under discussion would be more advantageous at $\phi_{1\alpha}=0°$ than at $\phi_{1\alpha}=120°$. In other words,

$O^{1\alpha}$—C^m bond has a tendency to keep the position corresponding to $\phi_{1\alpha}=0°$ rather than that corresponding to $\phi_{1\alpha}=120°$. (Anticipation 2)

This anticipation is consistent with Anticipation 1. Therefore, concerning [M]$^{20}_{D}$ (W) of L-arabinoses, Hudson's data seem to be more reliable than Isbell and Pigman's data[31].

28) T. Uchida, Y. Kurita and M. Kubo, *J. Polymer Sci.*, **19**, 365 (1956).

29) A. R. Philpotts, D. O. Evans and N. Sheppard, *Trans. Faraday Soc.*, **51**, 1051 (1955).

30) Notice that the shape of a polyoxymethylene-chain shown by the word "*gauche* type" in this case is not the same as that of O*—C^1—$O^{1\alpha}$—C^m corresponding to the internal conformation of $O^{1\alpha}$—C^m bond of a *gauche* type in Figs. 1 and 2. O*—C^1—$O^{1\alpha}$—C^m moiety in Figs. 1 and 2 can become a *gauche* type of polyoxymethylene-chain when $\phi_{1\alpha}$ is 0° and become a *trans* type of polyoxymethylene-chain when $\phi_{1\alpha}$ is 120°. (Ref. Fig. 3).

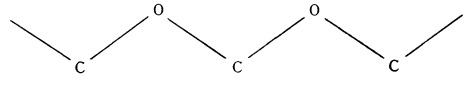

Fig. 3. Polyoxymethylene-chain of *trans* type.

31) If Isbell and Pigman's data are correct, it must be concluded that the internal conformation of $O^{1\alpha}$—C^m bond corresponds to $\phi_{1\alpha}=120°$. In this case, a kind of the attractive force should be considered between $O^{2\alpha}$-atom and C^m-atom (strictly speaking, the H atom which is combined with C^m-atom).

Summary

By the author's new method, the internal conformation of $O^{1\alpha}—C^{m}$ bond in $(OCH_3)^{1\alpha}$ of methyl α-D-xylopyranoside and of methyl β-L-arabinopyranoside in aqueous solutions was presumed. At the same time, Isbell and Pigman's data and Hudson's data of $[M]_D^{20}(W)$ of L-arabinoses were discussed.

The author wishes to express his sincere gratitude to Professor S. Tanaka (Kyoto University) and Professor T. Yamamoto (Kyoto University) who is studying in the University of Oregon for their special interests in this series of research.

On the Intramolecular Charge Transfer Spectra and Structure of Isomeric Aminopyridines

By Noboru MATAGA and Shizuyo MATAGA

(Received November 6, 1958)

In a series of papers, we have reported detailed theoretical studies on the electronic structure and the nature of electronic transitions of nitrogen heterocycles[1-5]. The detailed Hartree-Fock SCF study has been made only for nitrogen heterobenzenes such as pyridine[1], pyrazine[1], *sym*-triazine[1] and *sym*-tetrazine[2]. In addition, some extensions to larger molecules such as quinoline[3,5], isoquinoline[3,5], phthalazine[5], quinoxaline[5], acridine[4,5] and phenazine[4,5] have been made on the basis of the results obtained for nitrogen heterobenzenes, employing the perturbation method based on the Hartree-Fock SCF theory. Thus a theoretical ground for the classification and interpretation of the electronic spectra of nitrogen heterocycles has been given. As an extension of these investigations, we have studied the electronic structure and the spectra of some substituted nitrogen heterocycles. Among these, we have taken up the isomeric aminopyridines. There have been some disputes concerning the molecular forms of these molecules, especially 2- and 4- aminopyridines, i. e., imine-enamine tautomerism[6]. However, the possibility of the existence of imino-form was rejected by Anderson and Seeger[7] by spectral studies of these and related molecules and also Angyal and Angyal[8] reported that these compounds exist predominantly in the amino-form by critically surveying the foregoing data and arguments and also by the measurement of pK_a values of these molecules and related ones. Nevertheless, there seem to remain some ambiguities about this problem, even now. Morita[9] has calculated the electronic spectra of 4-aminopyridine by a method analogous to Dewar and Paoloni[10], assuming various models with respect to the molecular forms of this molecule. However, no definite conclusion about the form of this molecule has been derived from his calculation. We have tried to make clear the interrelation among the isomeric aminopyridines and their relation to aniline, pyridine and benzene, with respect to the electronic structure and spectra. We have assumed the amino-form of these isomers and attempted to interpret the observed spectra. It will be expected that some contributions to the problem of the tautomerism of these molecules will be made also by such a study even if it is by an indirect method.

Method

Previously, Tsubomura[11] has studied the electronic spectra of substituted pyridines by the electron migration theory of Sklar and Herzfeld[12]. The general features of the substituted pyridine spectra have been well comprehended by his study. As pointed out by Goodman and Shull[13] in the case of substituted benzene spectra, however, for certain very strongly conjugating substituents, e. g., $-NH_2$, such a simplified perturbation method may be essentially invalid, and a more rigorous method will be needed. In the present study we have used the method developed by Longuet-Higgins and Murrell[14] for the study of the composite system. An excellent treatment based on an analogous idea has been developed independently by Nagakura and Tanaka[15]. Hereafter the outline of the method will be mentioned briefly.

Generally speaking, the electron transfer states are of two kinds, according as the electron is transferred from pyridine to the substituent or from the substituent to pyridine. In the present case, however, the substituent is a fairly strong electron donor and accordingly the configuration in which the electron is transferred from pyridine to the substituent will have a very high energy compared with the opposite case and may be neglected.

With this approximation, the problem is reduced to an evaluation of the interaction between the locally excited states of pyridine and one set of electron transfer states in which the electron is transferred from the substituent to pyridine.

If the SCFMO's of pyridine are written $\phi_1 \cdots\cdots \phi_p$ and those of the substituent $\theta_1 \cdots\cdots \theta_s$, then the energy of the electron transfer configuration $\chi_{s\to k}$ where one electron is transferred from an occupied orbital θ_s to an unoccupied orbital ϕ_k, is given by

$$E(\chi_{s\to k}) = \varepsilon_k - \varepsilon_s - \int \theta_s^2(i) \frac{e^2}{r_{ij}} \phi_k^2(j) \mathrm{d}v(i) \mathrm{d}v(j) \quad (1)$$

where ε_k and ε_s are SCFMO energies of ϕ_k and θ_s, respectively, and ϕ_k's are linear combinations of $2p\pi$ AO's $\phi_1 \cdots\cdots \phi_p$ of carbon or nitrogen

$$\phi_k = \sum_\mu c_{k\mu} \phi_\mu \quad (2)$$

Now, in actual computation, ε_s will be given, to a good approximation, by the ionization potential of ammonia. The difference of the observed[16] and calculated[17] values of electron affinity of benzene, $\Delta A = A_{\text{benz}}^{\text{obs}} - A_{\text{benz}}^{\text{calc}}$ has been added to the calculated values of ε_k's.

With neglect of differential overlap, the integral in 1 is reduced to

$$\sum_\mu \gamma_{s\mu} = \sum_\mu \int \theta_s^2(i) \frac{e^2}{r_{ij}} \phi_\mu^2(j) \mathrm{d}v(i) \mathrm{d}v(j) \quad (3)$$

These integrals have been replaced by the interaction energy of point charges centered on the substituent and on the μ atom, taking the length of bond joining the substituent and pyridine to be 1.46 Å. The matrix elements of the interaction between the various configurations have been evaluated from the following formulae,

$$(\chi_{s\to k} | \boldsymbol{H} | \chi_{j\to l}) = -\delta_{kl} \int \theta_s(i) H(i) \phi_j(i) \mathrm{d}v(i) \quad (4)$$

$$(\chi_{s\to k} | \boldsymbol{H} | \chi_0) = \sqrt{2} \int \theta_s(i) H(i) \phi_k(i) \mathrm{d}v(i) \quad (5)$$

$$(\chi_{s\to k} | \boldsymbol{H} | \chi_{s\to l}) = -(sk|G|sl) = -\int \theta_s^2(i) \frac{e^2}{r_{ij}} \phi_k(j) \phi_l(j) \mathrm{d}v(i) \mathrm{d}v(j) \quad (6)$$

The integral $\int \theta_s(i) H(i) \phi_j(i) \mathrm{d}v(i)$ can be reduced to $c_{jr} \int \theta_s(i) H(i) \phi_r(i) \mathrm{d}v(i)$ the substitutent being attached to carbon atom 'r'.

We have used a reasonable value for $\beta_{RS} = \int \theta_s(i) H(i) \phi_r(i) \mathrm{d}v(i) = -1.6$ eV. which is the same value as that used by Murrell[14] for the study of aniline. The wave functions and energies above the ground state of locally excited states of pyridine to be used in the present calculation are as follows[15]:

Results and Discussion

The interactions which occur between the various electronic states are shown in Table I.

As shown in Table I, in the case of 4-amino-pyridine, the seventh order matrix splits off into fourth and third order matrices, owing to the c_{2v} symmetry of the molecule.

Now, the wave functions and energies of the electronic states of 4-amino-pyridine are easily obtained as shown in Table II by solving the secular equations. In Table II, the corresponding quantities for aniline* are also indicated for the purpose of comparison.

4.704	$\Psi_{\mathrm{I}}(B_1)$	0.942	−0.092	0.316	
6.348	$\Psi_{\mathrm{II}}(B_1)$	0.296	0.702	−0.646	
7.588	$\Psi_{\mathrm{III}}(B_1)$	0.169	−0.704	−0.689	

As shown in Table II, in both 4-amino-pyridine and aniline, $\Psi_{\mathrm{I}}(B_1)$ is mainly contributed by L_b of pyridine and benzene, respectively, and accordingly the band due to the transition to this state may be regarded as a slightly modified L_b band in both of these molecules.

Contrary to this, $\Psi_{\mathrm{I}}(A_1)$ is mainly contributed by $\chi_{s\to4}$. Although the contribution of L_a to this state is still fairly great in the case of aniline, it becomes less prominent in the case of 4-amino-pyridine, and the contribution of $\chi_{s\to4}$ becomes more predominant (~80%). Therefore, the band due to the transition to this state in the case of 4-amino-pyridine may be called an intramolecular charge transfer band according to the naming of Nagakura and Tanaka[15].

Such a clear-cut classification of band character, however, does not hold in the case of the other isomers, various configurations being mixed in each state.

Now, whereas the MO ϕ_5 has the nodal plane through the C_2 axis of pyridine, the coefficient of AO at nitrogen has fairly great value in the MO ϕ_4. Accordingly, the increase of π-electron density or ring nitrogen caused by the substitution of an amino group for hydrogen may be determined by the degree of contribution of $\chi_{s\to4}$ to the ground state. This contribution is the greatest in the case of 4-amino-pyridine and the smallest in the case of

* The wave functions and energies of elctronic states of aniline collected in Table II are slightly different from those calculated by Murrell[14] because, in the present work, our parameters[1-5] have been used to calculate the wave functions and energies of benzene.

18) H. C. Longuet-Higgins, *J. Chem. Phys.*, 18, 275 (1950).

TABLE III. THE WEIGHT (%) $\chi_{s\to4}$ IN THE GROUND STATE WAVE FUNCTIONS OF ISOMERIC AMINOPYRIDINES

	% weight of $\chi_{s\to4}$	pK_a at 20°C
4-Amino-pyridine	6.9	9.17
2-Amino-pyridine	2.3	6.86
3-Amino-pyridine	1.4	5.98

3-amino-pyridine as shown in Table III. This is in accordance with the conclusion obtained by the qualitative discussion of resonance theory. In addition, this is in good correspondence with the experimental pK_a values as indicated in Table III, if it is allowed to be assumed that pK_a is proportional to the π-electron density on ring nitrogen[18],**. In Table IV, the calculated and observed spectra are compared, where only the two bands which originate from the transitions to the lowest and second lowest excited states are shown, because of the lack of experimental values for the other states.

TABLE IV. CALCULATED AND OBSERVED SPECTRA OF ISOMERIC AMINO-PYRIDINES

Excitation energy (eV.)		Obsd. intensity[a] (ε_{max})
Calcd.	Obsd.[a]	
	2-Amino-pyridine	
4.865	4.20	4000
5.266	5.26	12000
	3-Amino-pyridine	
4.845	4.13	3000
5.137	5.18	10000
	4-Amino-pyridine	
5.114	~4.6	weak
4.973	5.1	14000

a) Ref. 6.

In Table IV, we have assigned the 5.114 eV. band of 4-amino-pyridine to the observed lowest energy band because, according to the calculated result, this band can be regarded as a slightly modified L_b band and consequently is likely to be weak. Contrary to this, the 4.973 eV. band is likely to be strong since it is the intramolecular charge transfer band. Accordingly we have assigned this band to the observed strong band at 5.1 eV.

It is evident from Table IV that the calculated two excitation energies in the case of 4-amino-pyridine are close to each other, while those in the case of the other isomers are more separated. This theoretical prediction is in qualitative or semiquantitative agreement with the experimental observation. Eventually, the general features of electronic spectra and structure of the isomeric amino-pyridines are well comprehended by the present calculation assuming the amino-form of these molecules.

Summary

The electronic spectra and structure of isomeric amino-pyridines have been studied theoretically employing the general method for the study of a composite system. The calculated results correspond satisfactorily with the experiment, in general, and the nature of electronic transitions in these molecules has been made clear. Thus it is evident that there is no difficulty in assuming the amino-form of these molecules in interpreting theoretically their electronic spectra and structure.

We are grateful to Dr. S. Nagakura of the University of Tokyo, Mr. T. Morita of Tokyo Metroporitan University and Mr. T. Kubota of Shionogi Co., Ltd. for their fruitful discussions.

The Aconite Alkaloids. XXVIII.[1] *The Isolation of a New Alkaloid, Sachaconitine, from Aconitum Miyabei, Nakai*

By Harusada SUGINOME, Nobukatsu KATSUI and Gen HASEGAWA

(Received September 4, 1958)

In a previous paper of this series[2], it was reported that two alkaloids, miyaconitine, $C_{23}H_{29}O_6N$, and miyaconitinone, $C_{23}H_{27}O_6N$, had been isolated from the roots of Aconitum Miyabei, Nakai. The present paper describes the isolation and the characterization of a new alkaloid, sachaconitine, which was obtained, in addition to the above-mentioned alkaloids, from the same material.

In the isolation of miyaconitine and miyaconitinone[2], they were crystallized from fraction III[3] and their mother liquors still contained appreciable amounts of basic substances.

The amorphous base obtained from the mother liquors was dissolved in 1 N-acetic acid and 10 % aqueous sodium carbonate was added to the solution. The precipitate was filtered off, and the filtrate was extracted with ether. The extracted base was then converted into the perchlorate. The crystalline perchlorate is easily soluble in alcohol and in hot water. From alcohol it crystallized in needles, m. p. 188~189°C, $[\alpha]_D$ −23.72° and from water its trihydrate crystallized in prisms, m. p. 180~185°C after softening at 100°C.

The composition, $C_{23}H_{37}O_4N \cdot HClO_4$, compares favorably with the analytical results; the formula was ascertained by analyses of acid oxalate, m. p. 182~183°C, aurichloride, m. p. 198~199°C, free base, m. p. 129~130°C, $[\alpha]_D$ −13.08°, and the diacetyl derivative, m. p. 114~116°C, $[\alpha]_D$ −10.87°.

It appears that this alkaloid has not yet been described, and the name "sachaconitine" was given to the new alkaloid. The analyses do not discriminate between H_{37} and H_{39} in the composition. Though the analytical result of diacetyl sachaconitine favors the latter, the formula with H_{37} seems more probable since it brings sachaconitine into line with other aconite alkaloids for reasons described below.

The base is stable against alkali and acid and thus contains no ester group. Acetylation of the base with acetyl chloride yielded a diacetyl compound which gave the original base on saponification. The presence of two methoxyl groups was confirmed by the Micro-Zeizel methoxyl determination. Hence the base contains two hydroxyl and two methoxyl groups.

The base gave ethyl iodide in the Herzig-Mayer *N*-alkyl determination and acetaldehyde on oxidation with permanganate, similarly to other aconite alkaloids containing an *N*-ethyl group, for example, lycoctonine[4-6], delpheline[7], and aconitine[8]. Coockson and Trevett[7] and Abubakirov and Yunusov[9] succeeded in confirming the presence of a simple *N*-alkyl group by converting de-ethyl derivatives (nor-compounds) into the corresponding alkaloids. It appears, therefore, that the new alkaloid also contains a simple *N*-ethyl group.

On the other hand, it has been reported[10] that atisine with an oxazolidine ring[11] gave also ethyl iodide in the *N*-alkyl determination by the same method. But sachaconitine contains two methoxyl and two hydroxyl groups, and no more oxygen atoms to make such a ring.

The base was not hydrogenated with platinum oxide in acidic solution. The ultraviolet spectrum of the base showed only end absorption (Fig. 1) quite similarly

to lycoctonine[12] possessing no unsaturation.

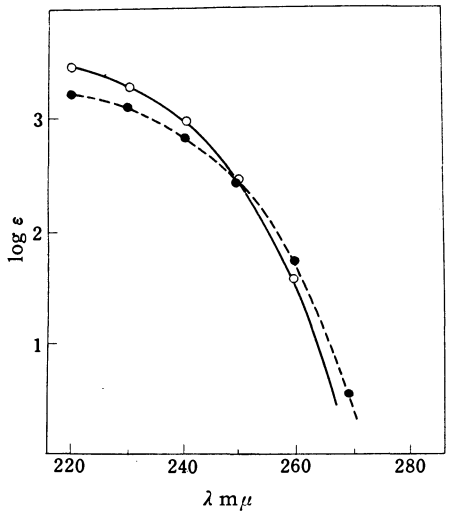

Fig. 1
Sachaconitine —○—○—
Lycoctonine ---●---●---

The above results relate the formula $C_{23}H_{37}O_4N$ of sachaconitine to other aconite alkaloids possessing the $C_{19}H_{29}N$ skeleton which is believed to be the fundamental base as pointed out by Suginome and Ohno[4], by Stern[13] and by Edwards and Marion[12]. Accordingly the formula can be extended as follows:

$$C_{19}H_{24}\begin{cases}(OCH_3)_2\\(OH)_2\\N-C_2H_5\end{cases}$$

The three alkaloids, miyaconitine, miyaconitinone and sachaconitine, were thus isolated from fraction III; they had no toxicity. In general, toxic bases containing an acyl and an aroyl group in aconite roots have been obtained from fraction I[3].

In attempts to isolate a crystalline substance from the amorphous base from the same roots, the fourth alkaloid, $C_{33}H_{45}O_9N$, m. p. 167~168°C, $[\alpha]_D$ +20.1° was isolated from fraction I. It agrees with delphinine in the composition but not in physical constants. Thus the name "base D" was assigned tentatively to this alkaloid. The investigation concerning the identification of "base D" with delphinine will be reported in a later paper.

Experimental

Isolation of Sachaconitine Perchlorate.— The residue of evaporation of the mother liquors from crystallization of miyaconitine and miyaconitinone perchlorate was converted into the free base by the usual method of treatment with chloroform and alkali. Amorphous basic material (14 g.) thus obtained was neutralized with 10% acetic acid and diluted with water. To the diluted solution 30% aqueous sodium carbonate was added until no more precipitate was produced. The precipitate was filtered off, but not examined.

The filtrate was subjected to continuous extraction with ether. Miyaconitinone remaining in the crude material separated out in prisms in 1 hr. Without removing it, extraction was continued further for 40 hr.

The extract, after being separated from miyaconitinone and dried over anhydrous sodium sulfate, was evaporated under reduced pressure to yield 7.5 g. of an amorphous material. This material was again neutralized with 0.1 N-hydrochloric acid and to the resulting solution 30% aqueous sodium perchlorate was added in small portions. On addition of the perchlorate the solution first became turbid but soon turned clear on stirring with further portions of the perchlorate solution. When turbidity was no longer noticed, the resulting solution was warmed on a steam bath until it became clear, treated with charcoal and filtered while hot. The perchlorate of the base separated as an oil on cooling the solution. The aqueous layer was decanted off and the oil was allowed to stand at room temperature overnight to give a gum containing some crystals which could not be separated. The gum was dissolved in a small amount of methanol and the solution was diluted with water until faint cloudiness remained. Concentration of the solution at room temperature gave 5 g. of crude sachaconitine perchlorate.

Sachaconitine perchlorate is easily soluble in alcohol and in hot water, and slightly soluble in cold water. From alcohol it crystallized in needles, m. p. 188~189°C, $[\alpha]_D^{20}$ −23.72° (C, 1.79 in alc.), and from water the trihydrate crystallized in plates, m. p. 188~189°C after softening at 100°C. The trihydrate gave the same m. p. and $[\alpha]_D$ after being dried over P_2O_5 under reduced pressure.

Anal. Found (anhydrous): C, 56.06; H, 7.70; N, 2.47; Cl, 7.34. Calcd. for $C_{23}H_{37}O_4N\cdot HClO_4$: C, 56.09; H, 7.72; N, 2.84; Cl, 7.21. Calcd. for $C_{23}H_{39}O_4N\cdot HClO_4$: C, 55.91; H, 8.16; N, 2.84; Cl, 7.18. Found (trihydrate): H_2O, 9.88. Calcd. for $C_{23}H_{37}O_4N\cdot HClO_4\cdot 3H_2O$: H_2O, 9.89%.

Sachatonitine. — The solution of the perchlorate in water was warmed to 50~60°C, and basified with aqueous sodium carbonate. The free base separated out as a resin, which soon solidified on cooling. Colorless plates from alcohol, m. p. 129~130°C, $[\alpha]_D^{20}$ −13.08° (C, 2.35 in 95% alc.).

Anal. Found: C, 70.35; H, 9.39; N, 3.59%. Calcd. for $C_{23}H_{37}O_4N$: C, 70.58; H, 9.46; N, 3.55%. Calcd. for $C_{23}H_{39}O_4N$: C, 70.19; H, 9.99; N, 3.56%.

The ultraviolet spectrum of the base showed only end absorption (Fig. 1).

The base was subjected to the Micro-Zeizel methoxyl, and the Herzig-Meyer *N*-alkyl determinations.

Anal. Found: CH_3O-, 15.91; C_2H_5-, 7.02. Calcd. for $C_{19}H_{26}O_2(OCH_3)_2 \cdot N \cdot C_2H_5$: CH_3O-, 15.85; C_2H_5-, 7.42%. Calcd. for $C_{19}H_{28}O_2(OCH_3)_2 \cdot N \cdot C_2H_5$: CH_3O-, 15.77; C_2H_5-, 7.38%.

The base (100 mg.) was submitted to the conventional Herzig-Meyer *N*-alkyl determination; the gases which evolved during pyrolysis of the hydroiodide were passed into a cold solution of trimethylamine in alcohol. The ethanol-soluble salt, ethyltrimethyl-ammonium iodide, was obtained from the trimethylamine solution.

Anal. Found: I, 59.27. Calcd. for $C_5H_{14}NI$: I, 59.04%.

The base absorbed no hydrogen in the presence of PtO_2 in acetic acid solution.

A solution of sachaconitine in 1N-potassium hydroxide in 50% aqueous methanol was refluxed on a steam bath for 30 min. From the resulting reaction mixture no acidic substance was detected, but unchanged sachaconitine was recovered.

Estimation of Acetaldehyde.—To a cold solution of 400 mg. of sachaconitine in 3 cc. of 1N-sulfuric acid, 15 cc. of 2% aqueous potassium permanganate was added dropwise in the course of 3 hr. After standing overnight, the manganese dioxide was filtered off and washed twice with water. The combined filterate and washings were distilled into a receiver containing 50 cc. of a slightly alkaline solution of 280 mg. of dimedone. Acidification with hydrochloric acid gave 73 mg. of acetaldehyde-dimedone, m. p. 139~140°C. It showed no depression of the melting point on admixture with an authentic specimen.

Sachaconitine Aurichloride. — The compound, prepared from the base and auric chloride, crystallized from a mixture of acetone and ether in prisms, m. p. 197~198°C (decomp.).

Anal. Found: Au, 26.88. Calcd. for $C_{23}H_{37}O_4N \cdot AuCl_3 \cdot HCl$: Au, 26.96%. Calcd. for $C_{23}H_{39}O_4N \cdot AuCl_3 \cdot HCl$: Au, 26.88%.

Sachaconitine Acid Oxalate.—The compound, prepared from the base and oxalic acid, crystallized from absolute alcohol in needles, m. p. 182~183°C, $[\alpha]_D^{20}$ −29.71° (C, 0.69 in 70% alc.)

Anal. Found: C, 61.70; H, 8.16. Calcd. for $C_{23}H_{37}O_4N \cdot C_2H_2O_4$: C, 62.35; H, 8.16. Calcd. for $C_{23}H_{39}O_4N \cdot C_2H_2O_4$: C, 62.09; H, 8.55%.

Sachaconitine Hydrochloride.—Dried hydrogen chloride was passed into a solution of the base in anhydrous acetone to produce a white precipitate. Reprecipitation by adding acetone to a very concentrated alcoholic solution of the precipitate gave sachaconitine hydrochloride in colorless needles, m. p. 203~204°C, $[\alpha]_D^{20}$ −30.43° (C, 0.78 in 95% alc.). No satisfactory analytical data have been found because of the extremely hygroscopic property of this compound.

Diacetylsachaconitine.—The base (1 g.) was treated with 4 g. of acetyl chloride in a sealed tube at room temperature for 5 days. The excess of the reagent was distilled off under reduced pressure and water was added. The aqueous solution was basified and extracted with chloroform. The residual product, obtained by evaporation of the chloroform, was crystallized from aqueous alcohol to give 400 mg. of plates, m. p. 114~116°C, $[\alpha]_D^{20}$ −10.87° (C, 1.70 in 95% alc.).

Anal. Found: C, 68.03, H, 8.92, N, 3.12. Calcd. for $C_{22}H_{35}O_2N \cdot (OCOCH_3)_2$: C, 68.18; H, 8.69; N, 2.95%. Calcd. for $C_{23}H_{37}O_2N \cdot (OCOCH_3)_2$: C, 67.89; H, 9.07; N, 2.93%.

On saponifying diacetylsachaconitine with alkali sachaconitine was regenerated.

Isolation of "Base D". — Fraction 1[3] (10 g.) was refluxed with 100 cc. of ether for 30 min. on a steam bath and the ether insoluble residue was again refluxed with 50 cc. of fresh ether. Complete removal of the solvent from the combined extracts gave 8 g. of amorphous yellow powder, which was neutralized with 1N-acetic acid and diluted to 100 cc. with water. To the resulting solution powdered sodium bicarbonate was added in small portions until no further precipitation was noticed. After being left to stand for 30 min., the resinous precipitate (Ia) was filtered off. From the filtrate a precipitate (Ib) was obtained on adding 50 cc. of 20% aqueous sodium carbonate, and another (Ic) on adding ammonia. No crystallizable alkaloids were obtaind from Ia and Ic. The fractional precipitation of Ib with sodium bicarbonate and carbonate was repeated twice; then 5 g. of powder precipitating with sodium carbonate was obtained. This material was dissolved in alcohol and the solvent was allowed to evaporate at room temperature, because heating of the solution caused crystallization with difficulty. Thus 2.5 g. of the crystalline "base D" was deposited from the alcoholic solution.

"Base D" is readily soluble in alcohol, chloroform and ether and insoluble in petroleum ether. It was recrystallized from a mixture of ether and petroleum ether in needles, m. p. 167~168°C, $[\alpha]_D^{20}$ +20.10° (C, 2.05 in 95% alc.).

Anal. Found: C, 66.13; H, 7.54; N, 2.23. Calcd. for $C_{33}H_{45}O_9N$: C, 66.09; H, 7.56; N, 2.34%.

Studies on Copper Phthalocyanine and its Chlorinated Derivatives Based upon the X-ray Diffraction Patterns

By Masahiro SHIGEMITSU

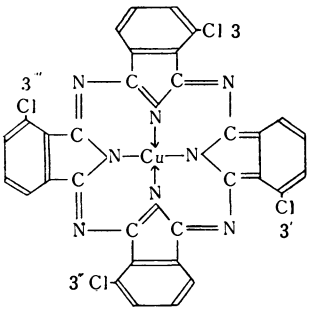
(Received August 13, 1958)

The molecular structure of copper phthalocyanine was first investigated by R. P. Linstead et al.[1] and later J. M. Robertson[2] studied its crystal structure by means of X-ray diffraction. He had only one form of copper phthalocyanine —namely, the α-form. This was prepared by sublimation as large needle crystal unsuited for pigment use. In order to reduce the particle size of copper phthalocyanine, the needle pigment is dissolved in concentrated sulfuric acid, and then is precipitated in fine particles by adding the acid solution to a large quantity of water with agitation. The first commercial pigment is the fine particles thus obtained. G. von Susich[3] showed that copper phthalocyanine conditioned in the above manner had a different X-ray diffraction pattern from that of the sublimed product studied by J. M. Robertson. Here the J. M. Robertson form is called α-form, because historically this crystal form was the first to be identified, and the first commercial pigment form is called β-form.

The copper phthalocyanine and lowly chlorinated copper phthalocyanines (containing chlorine atoms not more than six) are mostly used in blue pigments, while the highly chlorinated copper phthalocyanines (containing about 14 chlorine atoms) in green pigments. As to polymorphism of chlorinated copper phthalocyanines, D. N. Kendall[4], on the basis of infrared absorption measurement, reported that there were also two forms of crystal structures, α- and β-forms, in copper monochlorophthalocyanine (no mention is made of position of chlorine atom), whereas only one form of crystal structure was identified in highly chlorinated copper phthalocyanine green.

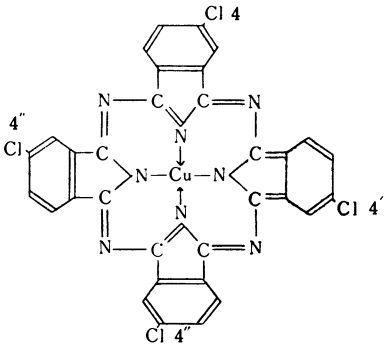
The author worked out X-ray diffraction patterns on twelve samples, six in needle forms and six in granular ones, of the following compounds; copper phthalocyanine, copper tetra-(3)-chlorophthalocyanine, copper tetra-(4)-chlorophthalocyanine, copper octa-(3, 6)-chlorophthalocyanine, copper octa-(4, 5)-chlorophthalocyanine and copper hexadecachlorophthalocyanine; the polymorphism was hereby investigated with copper phthalocyanine and its chlorinated derivatives.

Experimental



Materials.—Two forms of crystals, needle and granular forms, of copper phthalocyanine derivatives of different chlorine contents were synthesized as follows.

(1) *α-Form (I) and β-form (II) copper phthalocyanines.*—Synthesis of copper phthalocyanine was carried out following the method described in Ref. 5. From the product, then, α- and β-form crystals were obtained by the following procedure. First, copper phthalocyanine was put into a quartz glass tube, heated up to 550~580°C in an electric furnace, making the needle crystal of I sublime. α-Form crystal thus obtained was dissolved in 98% sulfuric acid of 20 times in weight at room temperature and allowed to stand 4 hr. Then, poured into ice water, granular II was formed, and separated through filtration. By chlorine analysis, it was found that there was just a trace of chlorine content, that is, 0.11%. Micro-Carius method was applied in all the following chlorine analyses.



Granular I of a size which seemed to be suitable for pigment was prepared by the method described in Ref. 6. Namely, 100 cc. of acetone, 1.2 kg. of steel shots of approximately 3 mm. in diameter and 5 g. of I in needle form which was obtained by sublimation were put into a porcelain pot of 500 cc. capacity and pulverized at 100 r. p. m. for 72 hr.; the product was granular I in brilliant greenish blue.

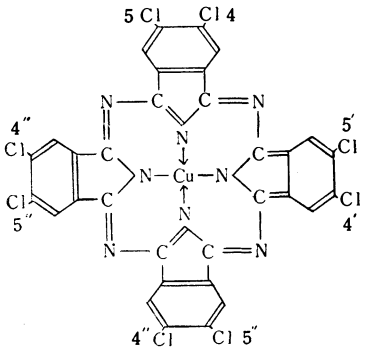
Copper tetra-(3)-chlorophthalocyanine



Copper tetra-(4)-chlorophthalocyanine

Fig. 1

Copper octa-(3, 6)-chlorophthalocyanine

Copper octa-(4, 5)-chlorophthalocyanine

Fig. 2

III and IV were prepared by condensing 3- and 4-monochlorophthalic anhydrides (see below) respectively with urea and copper in trichlorobenzene. From the mixture of monochlorophthalic anhydrides prepared following the method in Ref. 7, separated 3-monochlorophthalic anhydride, m. p. 121~122°C (reported m. p. 122°C)[8] (*Anal.* Found: Cl, 19.40%) and 4-monochlorophthalic anhydride, m. p. 97~98°C (reported m. p. 98°C°[8]) (*Anal.* Found: Cl, 19.44%) by repeating recrystallization with toluene-ethanol (1 : 1) solvent. The chlorine contents in III and IV derived from these 3- and 4-monochlorophthalic anhydrides were 19.72% and 19.80%, respectively.

Both of III and IV prepared in this way were of needle crystals. To convert them into granular forms, they were dissolved in 98% sulfuric acid of 20 times in weight at room temperature, allowed to stand for 4 hr. and poured into ice water.

Since chlorinated copper phthalocyanines do not sublime, it is impossible to obtain the needle crystals by sublimation, but they can be obtained by condensing various chlorophthalic anhydrides together with urea and copper in trichlorobenzene. Therefore, this method was adapted later in obtaining the needle crystals of various chlorinated copper phthalocyanines.

8) V. Villiger, *Ber.*, **42**, 3532 (1909).

(3) *Copper octa-(3, 6)-chlorophthalocyanine (V) and copper octa-(4, 5)-chlorophthalocyanine (VI).* —V which was synthesized following the method described in Ref. 7 was taken up; it showed a chlorine content of 33.21% and was of needle crystal.

VI was synthesized by condensing 4, 5-dichloro phthalic anhydride (see below) together with urea and copper in trichlorobenzene; it showed a chlorine content of 33.23% and was of needle crystal. 4, 5-Dichlorophthalic anhydride, m. p. 185~186.5°C (reported m. p. 185~187°C)[8] (*Anal.* Found: Cl, 32.60%) was separated from the mixture of dichlorophthalic anhydrides[7] with toluene-ethanol (1:1) solvent.

To convert them into granular forms, they were dissolved in chlorosulfonic acid of 20 times in weight at room temperature, allowed to stand 4 hr. and poured into ice water.

(4) *Copper hexadecachlorophthalocyanine (VII).* —Needle-formed VII synthesized following the method described in Ref. 7, with chlorine content of 50.33%, was used. Granular VII was prepared by dissolving needle-formed VII in chlorosulfonic acid of 30 times in weight at room temperature, allowing it to stand for 4 hr. and then pouring it into ice water.

Methods.—(1) *Observation of pigment forms.* —Two types of samples were prepared as follows. One was made first by washing with water the

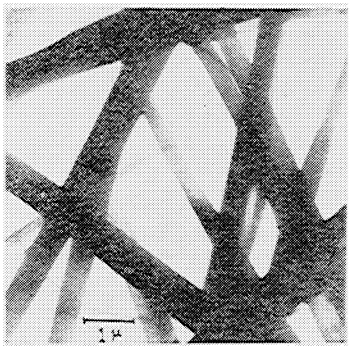


Fig. 3. α-Form copper phthalocyanine (I) (needle form)

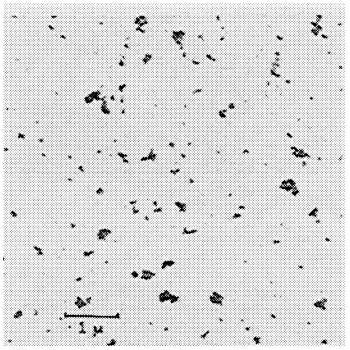

Fig. 4. β-Form copper phthalocyanine (II) (granular form)

granular pigments reprecipitated from the solution in 98% sulfuric acid of chlorosulfonic acid, and then placing and drying a drop of pigment suspension in water upon the collodion film of sample holder. The other was prepared first by drying the pigments obtained in any way other than by reprecipitation and then by sprinkling them over the collodion film of sample holder. The author photographed them with an electron microscope (Hitachi Works) at 2,000 direct magnification. The pictures were enlarged again by 10,000 times, and by means of these enlargements, their forms were closely examined.

(2) *Changes in pigment shade accompanied by being heated in trichlorobenzene.*—Granular pigments prepared by reprecipitation were heated in the boiling trichlorobenzene (b. p. 200~210°C) of 100 times in weight for 10 hr, and then filtered. After the sticking trichlorobenzene was eliminated by washing with ethanol, they were

dried at about 60°C. The pigments thus obtained and the original untreated ones were mixed respectively with polymerized linseed oil of 1.5 times in weight and were made into paste by grinding 400 rounds in a Hoover automatic muller. To 1 part of each paste was added 70 parts of zinc white paste (obtained by grinding 2 parts of zinc oxide with 1.5 parts of polymerized linseed oil), which was applied 0.5 mm. in thickness on a coated paper with a bladeoapplicator (Gardner Laboratory). These were dried at room temperature, their reflectance curves were obtained with a recording spectrophotometer (General Electric Co.), and calculation was thereby conducted.

acid and pouring them into ice water.

Fig. 7 shows the needle crystal prepared by boiling the granular III (Fig. 6) in trichlorobenzene for 10 hr. This change resembles the transformation of granular II into needle-formed I, which appears when the former is heated in organic solvents[9,10]. However, no change can be detected in case IV (Fig. 9) when it is heated in the boiling trichlorobenzene for 10 hr, as is manifested from Fig. 10.

It is known that, when a small amount of chlorine is introduced by the direct chlorination of copper phthalocyanine, a compound can be obtained which does not show any crystal growth in organic solvents[11]. In this case, chlorine is first substituted at the 4- or 5-position of phthalocyanine nucleus[7,12]. Meanwhile, according to Bansho et al.[13], no crystal growth takes place in the case of chlorinated copper phthalocyanine obtained from the direct chlorination or 4-monochlorophthalic anhydride. These facts are in good harmony with the results by the author.

As to copper octachlorophthalocyanines, on the other hand, no difference is formed any more in the crystal growth; independently of the positions which are occupied by chlorine atoms, 3,6- or 4,5-positions of phthalocyanine nucleus, no crystal growth takes place even in case copper octachlorophthalocyanines are boiled in trichlorobenzene for 10 hr. The case of granular VII is also quite the same.

(2) *Changes in pigment shade.* — Reflectance curves obtained with a recording spectrophotometer are shown (Fig. 17 to Fig. 23). Table I gives the data of these curves expressed in terms of C. I. E. Notation. In this table, *Y* denotes luminosity, *Pe* purity and λ_D dominant wavelength.

It is evident from Fig. 17, that granular I, even though boiled in trichlorobenzene for 10 hr.,

causes neither crystal growth nor color change, while in the case of granular II the crystal grows with remarkable change of shade, as shown in Fig. 18. As to the shade, its dominant wavelength shifts to the longer wavelength side by 4 mμ, that is, yellowishness increases.

Granular III grows into needle crystal and, as is clear from Fig. 19, changes in its shade. With a shift of its dominant wavelength by 2.7 mμ, it increases in yellowishness. On the contrary, its isomer, granular IV causes no crystal growth and scarcely changes at all in its shade, as shown in Fig. 20.

Though granular V causes no crystal growth, it changes in shade to some extent, its dominant wavelength making a shift to the longer wavelength side by 0.9 mμ just as illustrated in Fig. 21. On the contrary, its isomer, granular VI causes no crystal growth and scarcely changes in its shade at all, as shown in Fig. 22. It can be said that the effect of chlorine atoms at 3,6- or 4,5-positions on the color change is the same as far as tetrachloro- and octachloro-compounds are concerned.

Fig. 23 shows the color change of granular VII. As the degree of chlorination becomes higher, the color change caused by heating in trichlorobenzene tends to diminish, but even VII exhaustively chlorinated changes its shade to some extent and its dominant wavelength shifts to the longer wavelength side by 1.9 mμ with an increase in yellowishness. However, there is no such crystal growth here as is observed in the case of granular II and III.

Compared with the chlorine atoms of 4,5-positions, those of 3,6-positions have scarcely any power of checking the crystal growth in organic solvents, but they are very powerful in shifting their dominant wavelength to the longer wavelength side. The dominant wavelengths of granular III and its isomer, granular IV are 481.5 mμ and 478.3 mμ respectively, which show that chlorine atom of 3-position is more influential in making an increasing of yellowishness than that of 4-position. This is also the case with granular V and its isomer, granular VI. That is, the former has a dominant wavelength of 485.0 mμ while the latter one of 482.5 mμ.

(3) *X-ray diffraction patterns of pigments.*— X-ray diffraction patterns obtained with a recording X-ray apparatus are shown (Fig. 24 to Fig. 40).

Fig. 24 shows the needle-formed I prepared by sublimation and Fig. 25 shows the granular II prepared from the solution of I in 98% sulfuric acid through reprecipitation method. What is common to both of them is the line of 7°, but they have nothing in other respects. I has the second and third strongest lines at 9° and 23.6°, but II has them at 27.6° and 26.8°; this indicates that there is a great difference between the two forms.

Figs. 26 and 27 show respectively III in needle form as well as in granular form. Fig. 28 shows granular III boiled in trichlorobenzene for 10 hr. The line of 6.4° is the only point in

common to Figs. 26 and 27. When the granular product is boiled in trichlorobenzene, its diffraction pattern changes as shown in Fig. 28, approaching that of the needle product (Fig. 26). This phenomenon perfectly coincides with the shade change exhibited by reflectance curves and the form change exhibited by electron microscopic photos.

Figs. 29 and 30 show respectively IV in needle form as well as in granular form. Fig. 31 shows the granular IV boiled in trichlorobenzene for 10 hr. What is common to Figs. 29 and 30 is the neighborhood of 6°. In the needle product, the second, third and fourth strongest lines are found at 9°, 23.6°, and 26°, but in the granular product they are at 26.8°, 26.4° and 13.2°, no similarity being found between the two forms. The granular product, if boiled in trichlorobenzene, changes to some extent and, judging from the diffraction pattern (Fig. 29), approaches the needle product, as shown in Fig. 31.

The X-ray diffraction pattern of needle-formed IV (Fig. 29) closely resembles that of needle-formed I (Fig. 24), but needle-formed III (Fig. 26) differs from needle-formed I. Granular IV (Fig. 30) and granular III (Fig. 27) show different patterns as is the case with the needle forms. Between III and IV, no similarity is found either in needle forms or in granular forms.

Figs. 32 and 33 show respectively V in needle form as well as in granular form. Fig. 34 shows the granular V boiled in trichlorobenzene for 10 hr. In Fig. 32 the strongest line is at 6° and the second and third strongest lines at 27.2° and 8° respectively. In Fig. 33 such lines are at 26.4°, 6.4° and 5.8° respectively, but no similarity is found between the two forms. When the granular product is boiled in trichlorobenzene, a diffraction pattern very similar to the needle form (Fig. 32) is obtained as shown in Fig. 34.

Figs. 35 and 36 show respectively VI in needle form as well as in granular form. Fig. 37 shows the granular VI boiled in trichlorobenzene for 10 hr. In Fig. 35 the strongest line is at 6.4° and the second and third strongest lines at 30.4° and 15.2°. In Fig. 36 such lines are at 30.4°, 15° and 6.8° respectively. Though there is no similarity between the two forms, their X-ray diffraction patterns are considerably closer to each other than those of I, II, III, IV and V. The granular product has no line at 52.4° which is in the case of the needle product. But, when it is boiled in trichlorobenzene, 52.4° line appears and the tendency of approaching the X-ray diffraction pattern of the needles product (Fig. 35) is also recongnized. On the other hand, no similarity is found between V and VI; this fact reminds us of the relation of III to IV. Thus, the influence of the position of chlorine upon the crystal structure is quite evident.

Figs. 38 and 39 show respectively VII in needle form as well as in granular form. Fig. 40 shows the granular VII boiled in trichlorobenzene for 10 hours. In Fig. 38 the strongest line at 6.8° and the second and third strongest lines at 31.6° and 6.2°. In Fig. 39 such lines are at 26.4°, 11.6° and 5.6° respectively. Thus there is no similarity between the two forms. When the granular product is boiled in trichlorobenzene, the strongest line is at 26.8° and the second and third strongest lines at 26.4° and 25.9°, showing a tendency of approaching the X-ray diffraction pattern of the needle product, just as in the case already described.

Discussion

(1) Polymorphism of Copper Phthalocyanine and its Chlorinated Derivatives.—It has been obvious that copper phthalocyanine and copper monochlorophthalocyanine have two forms of crystal structures. The author could make it clear that, chlorinated copper phthalocyanine have two form of crystal structures, no matter how large or small the chlorine contents may be.

This fact must be verified for copper phthalocyanines that their chlorine numbers ranges from naught to sixteen. These chlorinated copper phthalocyanines are to be obtained from mono-, di- and trichlorophthalic anhydrides with chlorine atoms at definite positions and tetrachlorophthalic anhydride. But it becomes difficult for chlorinated derivatives of phthalic anhydride to react as the chlorine contents grow larger. To cite an example of the experiments by the author, in the formation of phthalocyanine from tetrachlorophthalic anhydride, dechlorination reaction occurred and copper hexadecachlorophthalocyanine the author aimed at was not obtained. Meanwhile, phthalocyanine formation was run on the mixture of a given amount of chlorinated phthalic anhydrides, but it was not confirmed whether they reacted uniformly or singly. Consequently, this experiment was discontinued and examination was done with the six kinds of samples listed above. The aimed object was satisfactorily achieved by the results with them.

(2) Crystal Growth of Chlorinated Copper Phthalocyanines.—It is known that the introduction of chlorine atoms into copper phthalocyanine can prevent the crystal growth in organic solvents. Particularly, no crystal growth is recognizable in copper phthalocyanine green with a large chlorine content, but the position of chlorine atom plays an important role in crystal growth of lowly chlorinated compounds. Namely, chlorine atom at 4-position gives forth a very great action

in suppressing the crystal growth but the one at 3-position gives hardly any effect.

When more than eight chlorine atoms are contained, crystal growth is not usually recognized. But, if boiled in such high boiling point organic solvent as trichlorobenzene, all the X-ray diffraction patterns of the products where no crystal growth is recognized tend to approach those of the needle products. This phenomenon is similar to the transformation of unstable β-form copper phthalocyanine into stable α-form by heating the former in organic solvents.

Study on Zinc Oxide-Chromium Oxide Catalyst. IV. Dependency of Catalytic Activity on Catalyst Structure

By Yoshisada OGINO, Masaaki OBA and Hiroshi UCHIDA

(Received November 13, 1958)

Our previous paper[1] reported that chromium oxide in a catalyst for methanol synthesis played two roles of promoting actions, intercrystalline on the one hand, and intracrystalline on the other hand. For the purpose of understanding the promoting actions from a structural viewpoint of the catalyst, this study has been made, and presents results on catalyst structures such as the crystal- and the macroscopic geometrical structure. On the basis of available data, the relationship between the catalytic activity and the catalyst structure is considered.

Taking the information thus obtained into consideration, we have attempted to prepare a catalyst of the higher activity for the methanol synthesis.

Experimental

Specimens of the same catalysts as described in our previous paper have been used in the present study. The catalysts were divided into three groups, catalysts A, B, and a catalyst S. A catalyst of the first group was a direct preparation from a paste of zinc oxide powder kneaded with a chromic acid solution, while one of the second group was produced from the solid matter remaining after washing of the paste with acetone. This last was prepared from a residue obtained by treating a reduced preparation of catalyst B with nitric acid. Table I shows Cr/Zn ratio determined for each catalyst, with its denotation. The previous paper[1] reported their catalytic activities for the methanol synthesis and decomposition, together with specific surface areas after reduction.

Part of the catalysts, both the raw and the reduced ones, were subjected to an X-ray study by means of a Geiger-counter spectrometer using filtered copper K_α ray.

Experimental data for the specific surface areas were supplemented with those determined on the raw catalysts by the BET method. From an extent of the surface area S, an average diameter d of particles in the catalyst granules was calculated by the aid of the relation of $d=6/(\rho S)$, where ρ was a catalyst density determined by the water-displacement method. Moreover, pore size distributions in three reduced preparations of the catalysts were determined by applying Barret's method[2] to nitrogen desorption isotherms at $-195°C$.

Experimental Results

Crystal Structure from X-ray Diagram. —Catalyst structures as revealed by X-ray diagrams are listed in Table II. Even the raw catalysts of a very low chromic

s, strong: w, weak: b, broad.

acid content (catalysts A-2, B-2) give diffraction patterns of zinc-hydroxychromates, such as III_β, II_α and II_β besides the strong pattern of zinc oxide[3]. As the chromic acid content increases, the pattern due to I_β begins to appear in place of the foregoing hydroxychromates, and that due to zinc oxide becomes weaker, disappearing finally (catalysts B-4, -5). The diagrams taken of catalysts B-7, -8, -9 and -11 of the highest chromic acid content (Cr/Zn ratio of 0.5) among the catalysts of to B series show only the sharp pattern due I_β, whereas the one taken of catalyst A-7 of the same Cr/Zn ratio gives, besides the above, a complicated pattern, which appears stronger in the diagram taken of catalyst A-8. The complicated one seems to refer to zinc bichromate, and presumably comes from the solid layer of a much higher chromic acid content which the liquid in the paste has left behind on the original solid particles (refer to 1).

The crystal structure of the catalyst is appreciably altered by reduction. Although the diagrams taken of the raw catalysts give patterns of various kinds of zinc-hydroxychromates and bichromate, those taken of the reduced catalysts give only two kinds of patterns referring to zinc oxide and zinc chromite spinel. Within a range of Cr/Zn ratio less than 0.5, the pattern of zinc oxide becomes the weaker and the broader for the increaing Cr/Zn ratios, whereas that of zinc chromite maintains a definite degree of broadening, notwithstanding the fact that the intensity is increasing. Catalyst A-10 of a high Cr/Zn ratio gives much sharper patterns of both kinds, and catalyst S, though it has a Cr/Zn ratio (1.6) a little less than the stoichiometric ratio (2) of zinc chromite spinel, gives the pattern due to zinc chromite spinel alone[5].

Rough calculations of linear dimensions D of zinc oxide and zinc chromite spinel crystallites have been made by the aid of Scherrer's formula, $D=k\lambda/\beta\cos\theta$, where k is a constant approximately 0.9, λ is wave length of an X-ray, β is diffraction breadth of a line, and θ is Bragg angle. In the calculation, respective (102) and (400) reflections of zinc oxide and zinc chromite spinel were employed.

In Fig. 1 linear dimensions of crystallites of zinc oxide and zinc chromite spinel are plotted as a function of Cr/Zn ratio, respectively. As Cr/Zn ratio increases, the crystallite size of zinc oxide which originally was as large as 500 Å in linear dimension diminishes rapidly. In this respect, the crystallites of zinc chromite spinel contrast sharply with the above, the linear dimension being kept within a narrow range of 60~100 Å. With an addition of the further increasing amounts

3) By Feitknecht et al.[4], the diffraction patterns as well as chemical formulae of zinc-hydroxychromates were given. The formulae are as follows:
III_β: $ZnCrOr_4\cdot 3Zn(OH)_2\cdot 4Zn(OH)_2$, II_α: $ZnCrO_4\cdot 2.5Zn(OH)_2\cdot 2H_2O$, II_β: $ZnCrO_4\cdot 2.5Zn(OH)_2$, I_β: $ZnCrO_4\cdot Zn(OH)_2$

4) W. Feitknecht and L. Hugi-Carmes, *Helv. Chim. Acta.*, **37**, 2107 (1954).

5) Our results have revealed more kinds of zinc-hydroxychromates than those found by Kawamura et al.[6] with their catalysts, which they prepared by a little different procedure from ours.

6) M. Kawamura, T. Irie, Y. Shiraishi et al., *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **60**, 162 (1957).

specific surface area: ●, raw catalyst (catalyst A), ○, (B), ▲, reduced catalyst (A), △, (B). □, activation energy for the synthesis, ■, frequency factor

of chromic acid beyond a Cr/Zn ratio of 0.5, the crystallites of both kinds grow to quite large ones.

Specific Surface Area and Average Size of Particles. — Specific surface areas of the raw catalysts as well as those of the reduced ones are shown as the function of Cr/Zn ratio in Fig. 2. Change in the areas of the former is small, the areas ranging from 7 to 20 $m^2/g.$, while the one in the area of the latter gives a remarkable peak at a Cr/Zn ratio of about 0.4～0.5, where the areas are five to ten times larger than those of the corresponding raw catalysts.

Granules of the raw catalysts are built up of particles as large as 1000～3000 Å in diameter. After reduction, the average size of the particles diminishes more or less remarkably according to chromic acid contents in the catalysts. Fig. 1 presents also the relationship between them. It shows that in a range of Cr/Zn ratio, less than 0.4, an average size of the particles is approximatly equal to the size of zinc oxide crystallites, and that in a range of higher Cr/Zn ratio, the particles are of much larger size than the crystallites of zinc oxide as well as zinc chromite spinel. The latter fact indicates that a particle is made up of a number of crystallites.

The growth of the particles as well as the crystallites, appearing in the catalysts of higher Cr/Zn ratios than 0.5, may be ascribed to thermal sintering[7] due to the glowing phenomenon that was once pointed out by Kawamura et al.[8] The glow has been found actually in the catalyst bed

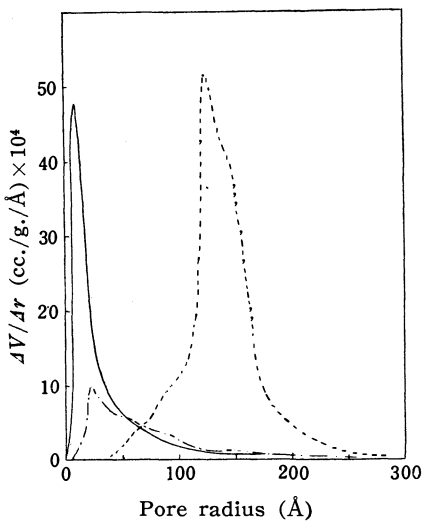

Fig. 3. Pore size distribution.
——, catalyst A-6: —·—·—, A-2: ····, A-10.

7) An assumption is also possible that crystallites of zinc chromite spinel are apt to aggregate with each other to become a large one, since there are not such a large number of zinc oxide crystallites as would be sufficient to prevent the aggregation. However, the assumption can not explain the simultaneous growth of zinc oxide crystallites.

8) M. Kawamura and T. Irie, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **60**, 166 (1957).

during reduction tending to appear more readily in the catalysts of the higher Cr/Zn ratios. It necessarily accompanies the growth to a greater extent.

Pore Size Distribution.--The results are shown in Fig. 3. Volumes of pores smaller than 300 Å in radius are 0.0588, 0.1178 and 0.2814 cc./g. for catalysts A-2, -6 and -10, respectively. A greater pore volume is not always associated with a larger extent of specific surface area, but the greater pore volume of extremely small pores with the larger extent of specific surface area.

Discussion

Intercrystalline Promoting Action of Chromium Oxide. — The intercrystalline promoter is a structural one responsible for production of a high-area structure. In this study, experimental evidences have been presented that a marked increase in the specific surface area takes place after reduction of the catalyst, and that well-grown particles of zinc-hydroxychromates in the raw catalysts disintegrate after reduction into extremely fine particles, which are often as small as the individual crystallites of zinc oxide and zinc chromite spinel[9], provided that scarcely any glow phenomenon has occurred during reduction. It has thus appeared that the formation of large particles of zinc-hydroxychromates in the raw catalysts is a requisite necessary for production of the extremely fine particles in the reduced catalysts, namely for the intercrystalline promotion of the activity by a chromic acid addition.

This picture[10] of structures of the raw and the reduced catalysts is consistent with the observations made by Matsui[12] on preparations of zinc-hydroxychromate II_β and its thermal decomposition products under an electron microscope. In his observations, the crystallites (100~500 Å, 500~600 Å in diameter for zinc chromite spinel and zinc oxide, respectively) were much larger in size than the ones defined in the present study. This may have been due mainly to a higher temperature (500°C), at which zinc-hydroxychromate II_β was decomposed, than to the reduction temperature in our study.

Compensation Effect in Catalytic Reactions[13].—We have found that catalyst S consists of zinc chromite spinel alone, and that a surface of the reduced zinc oxide-chromium oxide catalysts contains only two kinds of crystallites, crystallites of zinc oxide and zinc chromite spinel. As a consequence of the findings, we can expect according to the statement by Cremer[14] the compensation effect at the catalytic reactions on a series of the catalysts, under a reasonable assumption that crystallites of the different kinds simultaneously act as sites of a catalytic reaction[15]. On the other hand, the findings lead to the following expression of the intracrystalline promoting action of chromium oxide[1]; namely both the activation energy and the frequency factor based on unit surface area simultaneously fall with increasing proportions of zinc chromite spinel in the surface, the highest levels being thore of zinc oxide and the lowest levels being those of zinc chromite spinel (refer to Fig. 2). The expression coincides with the concept of the compensation effect by Cremer.

According to the aforegoing concept, an overall rate constant, k, is given by

$$k = F_1 A_1 \exp(-E_1/RT) + F_2 A_2 \exp(-E_2/RT) \quad (1)$$

where F is a fraction of the surface, subscripts 1 and 2 mean zinc oxide and zinc chromite spinel, respectively, and hence F_1 and F_2 stand for fractions of the surface occupied by zinc oxide and zinc chromite spinel, respectively. E is an activation energy, and A is a frequency factor based on unit surface area. Moreover, the finding in this study presents the following relationship,

$$F_1 + F_2 = 1 \quad (2)$$

As each value of A_1, A_2, E_1 and E_2 has already been known (refer to 1), F_1 and F_2 for any catalyst of the series can be evaluated from Eq. 1 and 2 by employing a value of k at a high temperature.

9) Comparatively large values of both the zinc oxide crystallite size and the average particle size determined for the catalysts of low Cr/Zn ratios are due to the presence of original large crystals of zinc oxide which have not been brought to a reaction with chromic acid.

10) The picture dose not exactly agree with the one for our previous catalysts[11], which were prepared by a somewhat different procedure from the present one.

11) H. Uchida and Y. Ogino, This Bulletin, **29**, 587 (1956).

12) T. Matsui, *J. Research Inst. Catalysis, Hokkaido University*, **4**, 109 (1956).

13) In this study the reactions include the methanol synthesis and decomposition.

14) E. Cremer, "Advances in Catalysis", Vol. VII, Rheinhold Publishing Corporation, New York (1956), p. 85.

15) According to the statement by Cremer, the compensation effect can be expected at the catalytic reactions on a series of the catalysts whose surface contains different activation energies, and in which the proportions of the sites are shifted with the chemical composition.

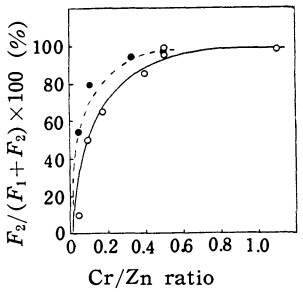

Fig. 4. Fraction of surface occupied by zinc chromite spinel as function of Cr/Zn ratio.
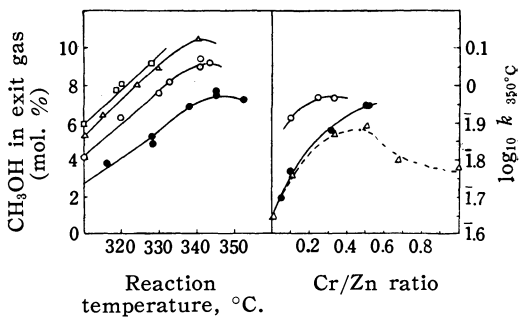
○, calculated from rate constant of synthesis, ●, calculated from rate constant of decomposition.

The results are shown in Fig. 4 as plots of $F_2/(F_1+F_2)$ vs. Cr/Zn ratio. This suggests migration of chromium ions from the particle interior into the surface taking place during reduction of the catalyst, but we can say nothing decisive in this respect as yet.

Attempt to Prepare Catalyst of Higher Catalytic Activity.—From the result that zinc chromite spinel yielded the lowest activation energy of the synthesis, it occurred to us first that a catalyst made of the spinel would be expected to give high activity, if it were provided with a large extent of surface area. However, an addition of chromic acid excessive to the amount corresponding to I_β always caused considerable decline in the surface area due to glowing in reduction. In this connection, we have made various efforts, e.g., reduction processes in hydrogen containing appropriate amounts of steam, to carry out the reduction without the glowing, but with no success. Another procedure, the simultaneous precipitation of hydroxides of zinc and chromium from a mixed solution of the nitrates with ammonia, yielded a catalyst of the desired chemical composition, but scarcely any evidence of zinc chromite spinel has been found unless the precipitate was heated at temperatures higher than 600°C[16]. The heating reduced the activity to a large extent, and we were unsuccessful in putting our first expectation into practice.



Our results[1] furthermore demonstrate that the specific catalytic activity, i. e., the activity based on unit surface area, for the methanol synthesis is increased appreciably by an addition of a small amount of chromic acid to such a level that is only a little lower than that of zinc chromite spinel. Natta[17], on the other hand, pointed out that zinc oxide produced by decomposition of zinc acetate was of a smaller crystallite size, and consequently showed higher activity than the usual ones. In view of the facts, it can next be expected that a catalyst of even a low chromic acid content may give higher activity, when it happens to have contained zinc acetate in the raw material. In producing a catalyst along with this expectation, the amount of chromic acid should be kept so low as not to provoke glowing during reduction, and hence a paste of the rather small Cr/Zn ratio of 0.25 has been chosen as a starting material, during the kneading of which appropriate amounts of acetic acid are added[18].

The results are given in Table IV, and Figs. 5A and 5B. A comparison of the

TABLE III. INCREASE IN SPECIFIC SURFACE AREA BY ACETIC ACID ADDITION

18) By an acetic acid addition, the more violent glowing comes to take place.

table with the figures indicates a nearly parallel increase in the activities to the increasing extent of surface area. The figures disclose that the activity for decomposition rises more remarkably than the synthetic activity does. This leads to a premise that the addition of acetic acid does not result in surface enlargement of zinc chromite spinel, but results in that of zinc oxide whose synthetic activity is apt to decline rapidly with time (refer to 1). The premise can be confirmed from a constant value, 28.8 kcal./mol., of the activation energy of the synthesis independent of amounts of acetic acid added.

Summary

So far as catalysts made from pastes of zinc oxide powders kneaded with chromic acid solutions are considered, granules in the reduced ones are built up of extremely fine particles which usually are as small as individual crystallites of zinc chromite spinel as well as zinc oxide. The fine particles appear by way of the large particles of zinc-hydroxychromates in the raw catalysts. However, once the raw catalyst comes to contain a greater amount of chromic acid than that corresponding to zinc-hydroxychromate I_β, the granules in the reduced one are composed of the larger particles, an individual one of which is an assembly of a number of the crystallites.

On the basis of the results available on the catalyst structures, the intracrystalline promoting action of chromium oxide can be explained from Cremer's viewpoint of the compensation effect. The catalytic activity can be increased by adding an appropriate amount of acetic acid into the paste, the increase being nearly parallel to an increasing extent of the specific surface area. The increase by the addition, however, is expected only with the catalyst produced from the paste of a low chromic acid content.

The authors wish to express their sincere thanks to Messrs. S. Kato and M. Taniguchi of Tokyo Institute of Technology for their taking X-ray diagrams.

The Normal Vibrations of Methanesulfonate Ion

By Kuniaki FUJIMORI

(Received October 28, 1958)

In the preceding paper[1] the infrared spectra of *n*-alkane-1-sulfonates were investigated and it was found that two S-O stretching vibrations and C-S stretching vibration were in the rock salt region.

In this paper the normal vibrations of the methanesulfonate ion were calculated, assuming the Urey-Bradley's field as the intra-molecular potential. This calculation was treated as a five-body problem, supposing the methyl radical to be one particle.

Calculation of Normal Vibration

Molecular Shape.—It was assumed that the methyl radical was one particle and the molecular shape of the methanesulfonate ion was similar to that of chloroform, i. e., this ion had the symmetry property of C_{3v}. This assumption is not reckless under the first order approximation[2].

Intra-molecular Potential. — As intra-molecular potential, the following Urey-Bradley's field[3] is assumed

$$V=\sum V_{r_i}+\sum_{i>j} V_{\alpha_{ij}}+\sum_{i>j} V_{q_{ij}}$$

where

$$V_{r_i}=K'_i r_i \Delta r_i+\frac{1}{2}K_i(\Delta r_i)^2$$

$$V_{\alpha_{ij}}=H'_{ij} r^2 \Delta\alpha_{ij}+\frac{1}{2}H_{ij}(r_{ij}\Delta\alpha_{ij})^2$$

2) A. Simon and H. Kriegsmann, *Chem. Ber.*, **89**, 1718 (1956).

3) H. C. Urey, C. A. Bradley, *Phys. Rev.*, **38**, 1969 (1931).

$$V_{q_{ij}}=F'_{ij}q_{ij}\Delta q_{ij}+\frac{1}{2}F_{ij}(\Delta q_{ij})^2$$

and

K_i and K'_i: stretching force constants
H_{ij} and H'_{ij}: bending force constants
F_{ij} and F'_{ij}: repulsive force constants
r_i: distance between the central atom and the i-th atom
q_{ij}: distance between non-bonded atoms
r^2_{ij}: equals r_ir_j
α_{ij}: valence angle.

G and F Matrixes.—The G and F marixes of this molecule were made by Wilson's method[4] and were factored by symmetry property of C_{3v}[5]. The following elements were obtained.

a) A_1 type vibration (totally symmetric vibration).—i) Elements of G matrix

$$g_{11}=\mu_S+\mu_R \qquad g_{22}=-\frac{1}{3}\mu_S+\mu_O$$
$$g_{12}=-\frac{1}{\sqrt{3}}\mu_S \qquad g_{23}=\frac{4}{3}\mu_S$$
$$g_{13}=-\frac{4}{\sqrt{3}}\mu_S \qquad g_{33}=\frac{16}{3}\mu_S+2\mu_O$$

ii) Elements of F matrix

$$f_{11}=K_{S-R}+3t^2_{R-O}F'_{R-O}+3s^2_{R-O}F_{R-O}$$
$$f_{12}=\sqrt{3}\,(-t_{O-R}t_{R-O}F'_{R-O}+s_{R-O}s_{O-R}F_{R-O})$$
$$f_{13}=\frac{\sqrt{3}}{2}(t_{R-O}s_{O-R}F'_{R-O}+t_{O-R}s_{R-O}F_{R-O})$$
$$f_{22}=K_{S-O}+t^2_{O-R}F'_{R-O}+s^2_{O-R}F_{R-O}+4s^2_{O-O}F_{O-O}$$
$$f_{23}=\frac{1}{\sqrt{2}}\{(t_{O-R}s_{R-O}F'_{R-O}+t_{R-O}s_{O-R}F_{R-O})\sigma-2t_{O-O}s_{O-O}(F'_{O-O}+F_{O-O})\}$$
$$f_{33}=\frac{1}{2}\{(H_{R-S-O}-s_{R-O}s_{O-R}F'_{R-O}+t_{R-O}t_{O-R}F_{R-O})\sigma+(H_{O-S-O}-s^2_{O-O}F'_{O-O}+t^2_{O-O}F_{O-O})\}+\frac{3}{\sqrt{8}}\kappa/r^2_{S-O}$$

b) E type vibration (doubly degenerated vibration).—i) Elements of G matrix

$$g_{11}=\frac{4}{3}\mu_S+\mu_O$$
$$g_{12}=-\frac{\sqrt{2}}{3}\left(\frac{3}{\sigma}+1\right)\mu_S$$
$$g_{13}=\frac{4\sqrt{2}}{3}\mu_S$$
$$g_{22}=\mu_O+\left(\frac{1}{\sigma}\right)^2\mu_R+\frac{1}{6}\left(\frac{3}{\sigma}+1\right)^2\mu_S$$
$$g_{23}=-\frac{2}{3}\left(\frac{3}{\sigma}+1\right)\mu_S+\frac{1}{2}\mu_O$$
$$g_{33}=\frac{8}{3}\mu_S+\frac{5}{2}\mu_O$$

ii) Elements of F matrix

$$f_{11}=K_{S-O}+t^2_{O-R}F'_{R-O}+s^2_{O-R}F_{R-O}+3^2t_{O-O}F'_{O-O}+s^2_{O-O}F_{O-O}$$
$$f_{12}=(t_{O-R}s_{R-O}F'_{R-O}+t_{R-O}s_{O-R}F_{R-O})\sigma$$
$$f_{13}=-t_{O-O}s_{O-O}(F'_{O-O}+F_{O-O})$$
$$f_{22}=(H_{O-S-R}-s_{R-O}s_{O-R}F'_{R-O}+t_{R-O}t_{O-R}F_{R-O})\sigma+\left(\frac{1}{\sqrt{8}}\right)\kappa/r^2_{S-O}$$
$$f_{23}=-\frac{\sqrt{2}}{2}\kappa/r^2_{S-O}$$
$$f_{33}=(H_{O-S-O}-s^2_{O-O}F'_{O-O}+t^2_{O-O}F_{O-O})+\frac{1}{\sqrt{8}}\kappa/r^2_{S-O}$$

where the following notations are used;

κ(intra-molecular tension)
$$=-(K'_ir^2_{ij}+F'_{q_{ij}}r_{ij}q_{ij}\sqrt{t_{ij}t_{ji}})$$
$\sigma=r_{R-S}/r_{S-O}$, $s_{ij}=(r_i-r_j\cos\alpha_{ij})/q_{ij}$
$s_{ji}=(r_j-r_i\cos\alpha_{ij})/q_{ij}$, $t_{ij}=r_j\sin\alpha_{ij}/q_{ij}$
and $t_{ji}=r_i\sin\alpha_{ij}/q_{ij}$

and μ_S, μ_O and μ_R are reciprocals of atomic weights for sulfur, oxygen and the methyl radical, respectively.

Constants Used in Calculation.—*a) Nuclear distances.*—

S–O : 1.50 A[6]
S–R : 1.80 A*

b) Valence angles.—Valence angles for O–S–O and R–S–O are assumed to equal the tetrahedral one, that is 109°28′.

c) Force constants.—K_{S-O}, H_{O-S-O} and F_{O-O} are taken from those for sulfate ion[8], and K_{R-S} is taken from H_{Me-S} of dimethyl sulfide[9]. H_{R-S-O} is taken from the mean of H_{O-S-O} for sulfate ion and $H_{CH_2-S-CH_2}$ for diethyl sulfide[9]. F_{R-O} is taken from the mean of F_{O-O} for sulfate ion and F_{Me-Me} for tetramethyl silane[8]. $\kappa_{MeSO^-_3}$ is taken

from the mean of $\kappa_{SO_4^{2-}}$ and $\kappa_{Si(CH_3)_4}$[8]. F' is assumed to be $-1/10\ F$[8]. In Table I values of these force constants are given.

TABLE I. FORCE CONSTANTS

F. C.	(dyn./cm.)$\times 10^5$	F. C.	(dyn./cm.)$\times 10^5$
K_{S-O}	6.01	F'_{O-O}	−0.076
K_{S-R}	3.01	F_{O-R}	0.397
H_{O-S-O}	0.43	F'_{O-R}	−0.0397
H_{O-S-R}	0.294	κ	0.328*
F_{O-O}	0.76		

* Unit is (dyn./cm.)$\times 10^{-11}$.

Results, Assignment and Comparison with Observed Data

As the results of calculation, the following values were obtained:

$\nu_1 = 788\ cm^{-1}$ $\nu_2 = 1002\ cm^{-1}$ $\nu_3 = 538\ cm^{-1}$

$\nu_4 = 1081\ cm^{-1}$ $\nu_5 = 537\ cm^{-1}$ $\nu_6 = 367\ cm^{-1}$

Of these vibrations ν_1, ν_2 and ν_3 are totally symmetric and ν_4, ν_5 and ν_6 are doubly degenerated.

These values are compared with the results of Raman spectra of potassium methanesulfonate in aqueous solution studied by Simon and Kriegsmann[6]. Relatively strong lines which could not be considered as C-H stretching and C-H deformation vibrations, are as follows: 348 cm^{-1}(5b), 533 cm^{-1}(2), 560 cm^{-1}(4), 789 cm^{-1}(8), 1054 cm^{-1} (10) and 1184 cm^{-1} (2b). (Number in brackets are intensities of Raman lines.)

They attributed the lines at 789, 1054 and 1184 cm^{-1} to ν_1 (C-S stretching vibration), ν_2 (S-O stretching totally symmetric vibration) and S-O stretching antisymmetric vibration, respectively.

By comparing the author's calculation with observed infrared spectra[1], the assignments can be made as indicated in Table II.

The agreement between the calculated and the observed frequencies is satisfactory except for S-O stretching vibration. The reason will be attributed to the fact that the S-O stretching force constant is taken from that of sulfate ion.

TABLE II. COMPARISON OF CALCULATED AND OBSERVED VALUES (in cm^{-1})

Assignment	Raman	I. R.	Calcd. I	Calcd. II
C-S Stretching	789	789	788	789
S-O Stretching	1054	1060	1002	1055
Deformation	533		538	536
S-O Stretching	1184	1192	1080	1182
R-S-O Deformation	560		537	557
O-S-O Deformation	348		367	349

The force constants were corrected as indicated in Table III, using the trial and error method combined with the method of least squares[10]. If the calculation of normal vibration is done again using these corrected force constants, the agreement between the calculated and observed values becomes much more satisfactory. The calculated values are indicated in Table II as "Calcd. II".

TABLE III. CORRECTED FORCE CONSTANTS

F. C.	(dyn./cm.)$\times 10^5$	F. C.	(dyn./cm.)$\times 10^5$
K_{S-O}	7.31	F'_{O-O}	−0.065
K_{S-R}	3.05	F_{O-R}	0.34
H_{O-S-O}	0.552	F'_{O-R}	−0.034
H_{O-S-R}	0.26	κ	0.328*
F_{O-O}	0.65		

* Unit is (dyn./cm.)$\times 10^{-11}$.

The Role of the Cationic Group in Anionic Detergents

By Maresuke KASHIWAGI and Heihachi EZAKI

(Received November 6, 1958)

It seems that sodium salt of alkyl sulfate has been extensively studied, while little data are known concerning organic salts of alkyl sulfate. It is therefore thought to be of interest to investigate the effect of the substitution of the cationic group attached to the hydrophilic portion of the detergent molecule. Such effcts should be studied both surface-chemically and from the viewpoint of bulk properties.

Materials used for those investigations were, as sulfate type, triethanolamine dodecyl sulfate (TDS), morpholine DS (MDS), pyridine DS (PDS), and sodium DS. As sulfonate type, triethanolamine alkyl benzene sulfonate (TABS) and sodium salt of the same sulfonate (SABS) were used.

Experimental

Materials.—All dodecyl sulfates were synthesized from dodecyl alcohol, chlorosulfonic acid and the corresponding base. The way of synthesis and the identification of product was given in detail previously[1].

Alkyl benzene, the raw material for the sulfonated detergent was the product of Oronite Chemical Co. and was redistilled at 130~136°C/3 mmHg. It was sulfonated with pure chlorosulfonic acid, at an equimolar ratio assuming the alkyl chain of the alkane to be mainly isododecyl, and neutralized either with aqueous sodium hydroxide or triethanolamine. The analysis of SABS showed that the amounts of unreacted alkane and inorganic material were less than 1.5%, respectively.

Measurements.—Monolayer experiments were carried out with the use of a Wilhelmy-type surface balance and surface tension was measured with DuNuoy's instrument. Foaming power was measured, at 40°C throughout, by Ross-Miles method[2,3], apparent viscosity was measured, at 30°C, with a modified Couette type rotational viscometer. Because of their extremely high solubility, the yield of TDS and PDS decreased considerably in the process of purification and we could not carry out whole-scale solubility measurements. Therfore, a Kraft point conventionally determined by dye color change[4] was adopted as a measure of solubility, since this method requires only a very small amount of the sample. It appeared that the Rhodamine 6G used for this purpose fortunately gave a clear color change at the K. P.

Results

1) **Substitution of the Cationic Group in Sulfate Portion.**—(*A*) *Surface Chemical Properties.* — (*1*) *Surface area.* — Surface areas of MDS, TDS and PDS on the substrate of 25% ammonium sulfate are calculated from $F-A$ curve and a surface equation of their state[5] developed by Pethica, $F(A-A_0)=nkt$, where A_0 refers to the surface co-area of the hydrophilic group in the molecule and n is a constant. A_0 is thus calculated to be 34 Å²/mol., identical for all three DS', between the surface areas of 70 Å²/mol. and 40 Å²/mol. and, at 40 Å²/mol., changes to 17 Å²/mol. which corresponds to the cross-sectional area of the hydrocarbon chain. Those values of A_0 are in excellent agreement with those of SDS[5]. The reason for this coincidence is now ascribed to the shielding effect of ammonium ions fully present in bulk phase since the colloidal electrolyte of the detergent may be considered to be equally accessible to both ammonium and organic cations.

(*2*) *Surface tension.* — Surface tension vs. concentration curves of both TDS and MDS are shown in Fig. 1, from which values of CMC are determined to be 0.004 M for both detergents. The CMC value of SDS is known to be about 0.007 M[6]. This value (0.004 M) is the same in the order of magnitude, but somewhat smaller than that of SDS. This small discrepancy may be ascribed both to the relatively large size of the counter ion[7,8] and the greater ions degree of hydration of these ions[9].

(*3*) *Foaming power.*—Foaming power vs. concentration curves of TDS and MDS are shown in Fig. 2, from which values of CMC for both detergents can be determined[2] to be 0.004 M and 0.003 M respectively. These values of CMC can be considered to be in good agreement with the values from surface tension measurements, as appeared in Fig. 1. Anyway, those two salts of DS exhibit approximately the same degree of foaming power, and moreover this in turn proves to be nearly equal to the foaming power of 186 mm. shown by aqueous SDS at its CMC.

(*B*) *Bulk Properties.* — (*1*) *Solubility.* — Solubility values of organic salts of DS, except for MDS, are found to be much higher than those of SDS. Solutions of both TDS and PDS at 30% remainded perfectly transparent even at 0°C, while MDS alone has very small solubility at 0°C, evidently much less than its CMC (i. e., less than 0.15%). The kraft points (K. P.) of both TDS and PDS are found to be less than 0°C, whereas the K. P. of MDS is found to be 30°C, compared with 10°C of SDS[10]. Thus a striking difference in solubility by the nature of the cationic group is observed as estimated from K. P. data.

(*2*) *Viscosity.*—Viscosity values of TDS and SDS at 30°C are listed in Table I. It is clear that SDS exhibits much higher viscosity than organic DS.

Table I. Viscosity of TDS and SDS at 30°C

	10%	20%	30%
TDS	1.5 c. poise	3	5
SDS	4.5	8.5	820

(II) Substitution of the Cationic Group in Sulfonate Portion.—Foaming power of TABS in a standard condition (0.25%, 40°C) is 193 mm., while that of SABS under the same conditions is found to 196 mm. in the Ross-Miles unit. Those values nearly equal each other. The relation is, however, quite different in solubility. TABS dissolves in the amount of 80%, at 0°C, while the solubility of SABS is found to be less than 10% at 20°C. Viscosity values at 30°C are 7 cp. at 30%, 2.5 cp. at 20%, and 1.4 cp. at 10% solutions for TABS, while the viscosity of SABS is found to be 5 cp. at 10% solution. Once again those data may be interpreted as an indication that the substitution of the cationic group in sulfonate portion does not virtually change surface chemical properties, but it does change the bulk properties.

Discussion

The results thus obtained are summarized in Table II. The value of CMC obtained for TDS and MDS, as they appeared in Table II, are in the same order but smaller than that of SDS. It has been shown that the value of CMC decreases when the counter ion becomes very large[7], or the degree of hydration of the counter ion decreases[8,9]. The

second factor would be less effective, because CMC values of potassium, sodium and lithium salts of DS are fairly close (7~10 mM)[9].

According to Klevens, these differences may be due to minor differences in the degree of ionization of the micelles, for it has been observed that the presence in small amounts of unionized additives (unreacted alcohol for example) will markedly decrease the CMC, whereas the use of an ionized additive of an equivalent chain length and the same charge will result in little change[11]. This is true of uni-univalent electrolytes. As for a polyvalent electrolyte, valence of cation may follow the Schulz-Hardy rule in decreasing CMC[12].

TABLE II. PROPERTIES OF VARIOUS SALTS OF DODECYL SULFATE

Surface properties

	TDS	PDS	MDS	SDS
Surface area of hydrophilic group on 25% $(NH_4)_2SO_4$	34Å²/mol.	34	34	34

Kraft P.	less than -5°C	less than 0°C	30°C	10°C
Estimated solubility grade	1	2	4	3
Viscosity	low	low	low	high

Summary

Various salts of dodecyl sulfate (DS) and alkylbenzene sulfonate have been investigated surface-chemically and from the viewpoint of their bulk properties. It was shown that these organic salts of DS occupy the same surface area as that of SDS, on the substrate of concentrated anmonium sulfate, independent of the nature of the cationic group attached to the sulfate anion. CMC values determined by two different methods (i. e., surface tension and foaming power) show practically the same value. These results are approximately in accord with the known principle that the number of carbon atoms in the molecule of the normal straight chain colloidal electrolyte of one particular class is the determining factor for the value of CMC, although a slight but definite shift in CMC value is observed with variation in substituting group. On the other hand, bulk properties such as viscosity and solubility are influenced remarkably by the substitution of cationic group in anionic detergents.

The author wishes to thank Professor R. Matsuura of Kyusyu University for his kind advice.

Polymerization of Aminoacetonitrile

By Hidesaburo HANAFUSA* and Shiro AKABORI

(Received October 28, 1958)

If the protein is absolutely essential for all living things, the non-enzymic formation of protein must have been prerequisite for the origination of life.

In 1936 Oparin[1] postulated that α-amino acids could have been formed non-biologically from hydrocarbons, ammonia and hydrogen cyanide at the age of the earth when atmosphere contained these substances in high concentrations. Bernal[2] emphasized the role played by ultraviolet light in the formation of organic compounds at a certain stage of the evolution of the earth. He also suggested that life

* Present Address: The Research Institute for Microbial Deseases, Osaka Univ., 3, Doshima Nishimachi, Osaka.

2) J. D. Bernal, "Physical Basis of Life", Routledge and Kegan Paul Ltd., London (1951).

might have originated on the surface of clay which accumulated large amounts of organic substances. Oparin's hypothesis has received strong experimental support from the recent work of Miller[3].

It has generally been accepted that the first proteins or fore-proteins were non-biologically formed by the polycondensation of preformed free amino acids. This belief is solely based on the fact that proteins in the present-day organisms are synthesized via free amino acids. Such non-biological formation of polypeptides and proteins, however, seems to be very difficult owing to the requirement of free energy, though Bresler[4] reported the reconversion of tryptic hydrolysates to the original proteins under an extremely high pressure.

In 1955 Akabori proposed[5] a hypothesis concerning the origin of the fore-protein and speculated that it must have been produced through reactions consisting of the following three steps.

I) $CH_2O + NH_3 + HCN \rightarrow NH_2—CH_2—CN + H_2O$

II) $n(NH_2—CH_2—CN) \rightarrow (—NH—CH_2—C(=NH)—)_n$

$\xrightarrow{+H_2O} (—NH—CH_2—CO—)_n + NH_3$

III) $(—NH—CH_2—CO—)_n \rightarrow (—NH—CH(R)—CO—)_n$

The first step is the formation of aminoacetonitrile from formaldehyde, ammonia and hydrogen cyanide. The second is the polymerization of aminoacetonitrile on a solid surface, probably in the state adsorbed on clay, followed by the hydrolysis of the polymer to polyglycine and ammonia. The third step is the introduction of side chains into polyglycine by the reaction with aldehyde or with unsaturated hydrocarbons. The reaction in the first step is well known as Strecker's reaction. Akabori and co-workers[6] reported some experimental results on the possibility of the third step.

The present paper deals with experiments concerning the second step in the formation of the fore-protein, that is the polymerization of aminoacetonitrile. Although acetamidine is formed from ammonia and acetonitrile in methanol solution, the condensation of primary amine with nitrile has been known very little. In the synthesis of purine derivatives, Traube[7] synthesized diamino thiopyrimidine by the condensation of thiourea and malonitrile. In this reaction sodium ethoxide was used as catalyst, and the anhydrous condition had been kept in the course of reaction.

Aminoacetonitrile prepared by the usual method was heated at 120~140°C for 3~5 hr. in the presence of clay, which was used as adsorbent of the nitrile and seemed to play a role as catalyst in this reaction. The product was extracted with water, dilute hydrochloric acid and sodium hydroxide solution. The presence of glycyl-glycine and glycyl-diglycine in extract and partial hydrolysate of extraction residue was confirmed by paper and column chromatography.

Experimental

Materials.—*Aminoacetonitrile sulfate;* According to Anslow and King's method[8] aminoacetonitrile sulfate was obtained, m. p. 164°C (decomp.). *Kaolin;* Commercial "Kaolin" was refluxed with hot water. After 2 hr., it was centrifuged, washed with distilled water and dried in an air bath. Kaolin treated with concentrated hydrochloric acid was used in some cases. *Other clays;* Japanese acid clay and bentonite were treated in the same way as kaolin. *Glycyl peptides;* Gly-Gly** and Gly-Gly-Gly** were synthesized in our laboratory and the purity was confirmed on paper chromatogram.

Procedures.—Several procedures were tried for polymerization of aminoacetonitrile. A typical method is the following.

One gram of amino acetonitrile sulfate was mixed with 20 times of kaolin and heated at 130~135°C for five hours. To heat uniformly, the mixture was taken in a wide bottomed flask and kept in an air bath at 130°C. As the liberation of ammonia was detected in the course of reaction, the top of flask was connected with a small tube of Dowex-50 (H-form). The reaction mixture, being of violet-grey color, was extracted with each 30 ml. of water, N/10 hydrochloric acid and N/10 sodium hydroxide successively in the cold (see Fig. 1). The pH of the water extract was about 5.5, and each of extracts showed a strong positive biuret reaction. A part of the residue was hydrolyzed with N/10 hydrochloric acid at 100°C for 1 hr. (KB) and another part was

hydrolyzed with 6 N hydrochloric acid at 100°C for 24 hr. (KC). For the purpose of the hydrolysis of imino group of polymerized product, combined extract (KA) was refluxed at pH 1 for 1 hr. After neutralization the component of each fraction was examined by paper chromatography and by paper and column chromatography after dinitrophenylation.

The Component of Product. — After concentration, an aliquot of each fraction was chromatographed on filter paper using 80% phenol as solvent. From this paper chromatogram, it was found that each fraction contained glycine, and KA and KC contained also glycyl peptide, probably Gly-Gly and Gly-Gly-Gly. These findings were confirmed by dinitrophenylation technique. This method is excellent for the reason that non-peptide basic substance which is ninhydrin positive can be separated from dinitrophenylated (DNP-) glycyl peptide. After each fraction was dinitrophenylated by the usual method, DNP-peptides were extracted with ethylacetate and *n*-butanol as shown in Fig. 2. Ethylacetate extract and ethylacetate-*n*-butanol extract were combined and dried in vacuo. After removing dinitrophenol by sublimation using cold-finger condenser[9], a part of this DNP-peptide fraction was subjected to one-dimensional chromatography on filter paper using *n*-butanol saturated with 1% ammonia as solvent. Several spots of R_f values 0.30, 0.17, 0.11 and lower ones were obtained; the first three spots were identified as DNP-derivatives of Gly, Gly-Gly and Gly-Gly-Gly in comparison with standard samples. Another part of the DNP-peptide fraction was chromatographed on a buffered celite column by a partly modified Perrone's method[10]. The solvent system used was ethylacetate-0.5 M phosphate buffer (1:1). After 10 parts of celite were mixed with 6.6 parts of the lower layer of the solvent mixture, celite was poured into the column of 20 cm. high and 2 cm. in diameter with the upper layer of solvent and packed with glass rod compactly. The upper half of the column was bufferized to pH 5.5 and the lower half to pH 6.4. Samples were charged on the column and developed with the upper layer of the solvent mixture of pH 5.5. DNP-Gly, DNP-Gly-Gly and DNP-Gly-Gly-Gly were separated each other forming sharp bands. The bands corresponding to DNP-Gly-Gly and DNP-Gly-Gly-Gly were cut off and eluted with ethanol acidified by small quantity of hydrochloric acid. The eluates were dried up and dissolved in 1% sodium bicarbonate. The optical densities were measured photometrically. After measurement, such DNP-peptides were hydrolyzed with 6 N hydrochloric acid for 5 hr. and DNP-derivative was removed by ethylacetate extraction. Aqueous layer was redinitrophenylated, extracted again with ethylacetate, separated by column chromatography and the quantity of DNP-Gly was measured. If the molecular extinction coefficients of dinitrophenyl

9) G. L. Mills, *Biochem. J.*, **50**, 707 (1952).

10) J. L. Perrone, *Nature*, **167**, 513 (1951).

amino acid and peptide are the same, the ratio of optical density of DNP-derivative before and after acid hydrolysis must indicate the length of the peptide. These ratios were 1:1.07 and 1:2.23 respectively for the two DNP-peptides, and were agreed with the expected value for DNP-Gly-Gly and DNP-Gly-Gly-Gly.

Residual aqueous layer (R) in Fig. 2, the yellow color of which shows the presence of unextracted DNP-derivatives, was hydrolyzed with 1 N hydrochloric acid at 100°C for 2 hr. By the same procedure for DNP-peptides, newly formed extractable DNP-derivatives were taken into ethylacetate-*n*-butanol layer. From this fraction, also, DNP-Gly-Gly and DNP-Gly-Gly-Gly were obtained. This fact shows that the extracts (KA and KB) might contain the longer glycyl peptide. From the procedures described above it was found that the reaction products contain many non-peptide compouds, for example, on the celite column chromatography there appeared DNP-derivatives which have an absorption maximum at 365~380 mμ and do not yield DNP-Gly by hydrolysis. Further, the first extracted solution of reaction product (KA) produces a black colloidal substance on standing at room temperature for 24 hr., and this substance precipitates on acidification.

In order to study the possibility that the polymerized substance remains in the residue as an adsorbed form, determination of nitrogen content of the residue and estimation of mean chain length of peptides were tried using micro-Kjeldahl method and dinitrophenylation technique. Nitrogen distribution in the process of reaction and extraction was shown in Table I. From these data obtained it seems reasonable to assume that not only the expected reaction, i. e., polymerization of aminoacetonitrile, but also the

Table I. Nitrogen distribution in the process of reaction and extraction

	mg. N	%
Starting material	540	100
After reaction period	376	70
Extract (KA)	149	28
Residue (KP)	29	5.3

reaction liberating nitrogen as ammonia or volatile form may take place. Nitrogen content of the residue was lower than expected, but this value varied from one reaction to another between 4~20 per cent. In order to determine the mean chain length of adsorbed polymer, the same procedure as used in the confirmation of two bands on the celite chromatogram was applied to the residue (KP) after refluxing at pH 1 for one hour.

The result of this experiment shows that the mean chain length of adsorbed substance is 1.8. However, it is hard to say that the reaction product involves long-chain, high molecular polyglycine although the residue might adsorb still low molecular peptide and contain the not-straight chain compound as diketopiperazine which produces DNP-Gly by hydrolysis and dinitrophenylation.

The presence of diketopiperazine in the reaction product was supposed by the qualitative test using picrate[11] and the different content of diglycine of the solution with and without alkaline treatment of the hot water extract of reaction product.

Change of Condition.—If the presence of the clay such as kaolin is advantageous for the proposed reaction, one of the effects must be the adsorption of starting material. The degree of adsorption of aminoacetonitrile on several kinds of clay was determined by the following way. The solution of 200 mg. of aminoacetonitrile sulfate in 4 ml. of water was mixed with 1 g. of clay; after shaking the suspension was allowed to stand overnight at 5°C and filtered. The concentration of free aminoacetonitrile in the filtrate and the control solution (without clay) was measured by ninhydrin reaction[12], which is used generally for the determination of amino acid. By a preliminary test it was confirmed that the aminoacetonitrile was not hydrolyzed in the process of determination and could be determined quantitatively, though the color yield is very low. As shown in Table II, the nitrile was adsorbed most

Table II. The degree of adsorption of aminoacetonitrile on the clay

5.5	51.4	8.7	36.5

on Japanese acid clay and at pH 7. This pH coincides with that of the solution of aminoacetonitrile sulfate neutralized with sodium hydroxide solution.

In an effort to study the effect of adsorption on the reactivity, aminoacetonitrile in an adsorbed state was used as starting material. After adsorption, as described above, Japanese acid clay was filtered, dried and heated at 130°C for 3 hr. in the same way as the typical method. In this case, yield of peptides was slightly high, but black colloidal material was produced abundantly at the same time. It may be concluded from the above fact that the adsorption on the clay

11) M. Frankel and E. Katchalski, *J. Am. Chem. Soc.*, **64**, 2264 (1942).

12) S. Moore and W. H. Stein, *J. Biol. Chem.*, **176**, 367 (1948).

activates the starting material to some extent but the effect is not specific for peptide synthesis.

When bentonite, silicic acid, silica gel and alumina were used as adsorbent, the yields of peptides were poor. Kaolin and Japanese acid clay treated with concentrated hydrochloric acid did not adsorb the aminoacetonitrile.

The effect of temperature was investigated between 100~150°C; below 120°C the reaction did not occur, and above 150°C the decomposition was predominant.

When methylene aminoacetonitrile was used instead of aminoacetonitrile as starting material, many spots appeared on the paper chromatograms of the extract of reaction product, but Gly-Gly-Gly could not be detected. In this case, the extracted solution (corresponding to KA) gave positive biuret reaction, but since several positive compounds besides poly-peptide have been known, biuret test is not suitable to such solutions which involve various unknown substances similarly as the test of diketopiperazine by picrate.

As cited in the introduction of this paper, diaminopyrimidine was synthesized from thiourea and malonitrile in ethanol in the presence of sodium ethoxide by Traube. If aminoacetonitrile reacts analogously, diimino-piperazine may be obtained from two molecules of aminoacetonitrile to yield diketopiperazine and diglycine by hydrolysis.

Four grams of aminoacetonitrile sulfate was suspended in 10 ml. of ethanol. To this suspension, 20 ml. of ethanol dissolving 1.4 g. of sodium was allowed to run from a dropping funnel under stirring. Two aliquots of the mixture were heated to 40°C and to boiling point, respectively, for 3 hr. In each case, the product was neutralized, dried in vacuo, and dissolved in 1 N sodium hydroxide. After 1 hr. the product was neutralized again, dried and subjected to paper chromatography. Only a trace of glycyl-glycine was observed, and here again the black colloidal substance appeared in the solution of the product.

Discussion

As aminoacetonitrile has a bifunctional group and an active methylene group, it may be reactive and be able to cause various reactions simultaneously. These characteristics are a strong point as well as a weak point in the case of polymerization which was tried. From the result of investigation, it was obvious that peptides were formed from aminoacetonitrile, but the presence of high polymer which might be firmly adsorbed on the clay was not confirmed. If the conditions may be found, in which polypeptide synthsis is promoted while the side reaction and decomposition are suppressed, poly-glycine should be yielded more easily. Because the heat reaction of aminoacetonitrile without clay was unsuccessful, the solid surface of clay seems to play a certain role in this reaction as in the case of activation of the methylene group of polyglycine[6].

In some cases, the formation of only glycyl-glycine was observed in the typical reaction procedure. Though it is hard to explain, this phenomenon suggests that the reaction proceeds in two directions, the one toward diketopiperazine formation and the other toward polyglycine formation similarly as the polymerization of glycine ethyl ester.

Summary

Aminoacetonitrile sulfate was heated with kaolin and/or Japanese acid clay at 120~140°C for 5 hr. The presence of glycyl-glycine and glycyl-diglycine in the extract and the partial hydrolysate of this reaction product was confirmed by paper and column chromatography.

Phase Transition of Li_2O-Fe_2O_3 System. III. Long-range Order in Lithium Ferrite and Lithium Ferrospinel

By Eizo KATO*

(Received July 22, 1958)

In the previous papers[1,2], the thermal and the electric properties of lithium ferrite and lithium ferrospinel were studied from the viewpoint of an order-disorder transition. Then the anomalous phenomena in these properties were observed at the transition.

The order-disorder transition in binary alloys has been widely studied by the statistical thermodynamics[3]. In order to specify the degree of order for the arrangement of atoms, two kinds of order parameters are defined. One is a long-range parameter introduced by Bragg and Williams, and the other is a short-range order parameter introduced by Bethe. When the former parameter is present, some super-stucture reflections appear in an X-ray diffraction. At the transition temperature, this parameter vanishes and the latter parameter remains in a diffuse scattering of X-rays.

The long-range order parameter in a substitutional transition, which was defined by Buerger[4], has not yet been measured except of binary alloys. As the first example of an extension of the transition theory for binary alloys to more complex crystals, temperature dependencies of the long-range order parameter for lithium ferrite and lithium ferrospinel were measured by an X-ray powder method.

Diffraction Theory of Long-range Order

The long-range order parameter S may be written as

$$S=(r_\alpha-p_A)/(1-p_A)=(r_\beta-p_B)/(1-p_B) \quad (1)$$

where r_α is the fraction of α site occupied by A ions and p_A is the fraction of A ions in the crystal, and so forth. S is, of course, defined so that it may be unity for the perfectly ordered state and zero for the perfectly disordered one. When the crystal is of AB type or of AB_3 type, S is given from Eq. 1.

$$S=2r_\alpha-1=2r_\beta-1 \quad \text{for AB type} \quad (2a)$$

and

$$S=(4r_\alpha-1)/3=4r_\beta-3 \quad \text{for } AB_3 \text{ type} \quad (2b)$$

Let us consider the order-disorder equilibrium, in which two kinds of ions in the crystal contribute to the transition, i.e.,

$$A_aB_bL_l\cdots\cdots N_n \rightleftarrows (A_aB_b)L_l\cdots\cdots N_n$$

where A_a means that a A ions are at the definite equivalent points, and so forth and (A_aB_b) means that a A ions and b B ions are randomly distributed to the points. According to the method used for binary alloys, the expression for the structure amplitude of any state is

$$F=[f_Ar_\alpha+f_B(1-r_\alpha)]G_\alpha + [f_Br_\beta+f_A(1-r_\beta)]G_\beta+\sum_L F_L \quad (3)$$

where f_A is the atomic scattering factor for A ion, f_B that for B ion, G_α and G_β are the geometrical structure factors referring only to the positions of α site and β site respectively, and $\sum_L F_L$ is the sum of structure amplitudes as to L,……, N ions which are independent of the transition. When A_aB_b is AB or AB_3, Eq. 3 is rewritten by introducing Eq. 2,

$$F=S(f_A-f_B)/2\cdot(G_\alpha-G_\beta) + (f_A+f_B)/2\cdot(G_\alpha+G_\beta)+\sum_L F_L \quad \text{for AB} \quad (4a)$$

and

$$F=S(f_A-f_B)/4\cdot(3G_\alpha-G_\beta) + (f_A+3f_B)/4\cdot(G_\alpha+G_\beta)+\sum_L F_L \quad \text{for } AB_3 \quad (4b)$$

For simplicity, both cases are expressed by a single form as

$$F=SF_{ss}+F_{fund} \quad (5)$$

where the subscript *ss* means the superstructure reflection and *fund* the funda-

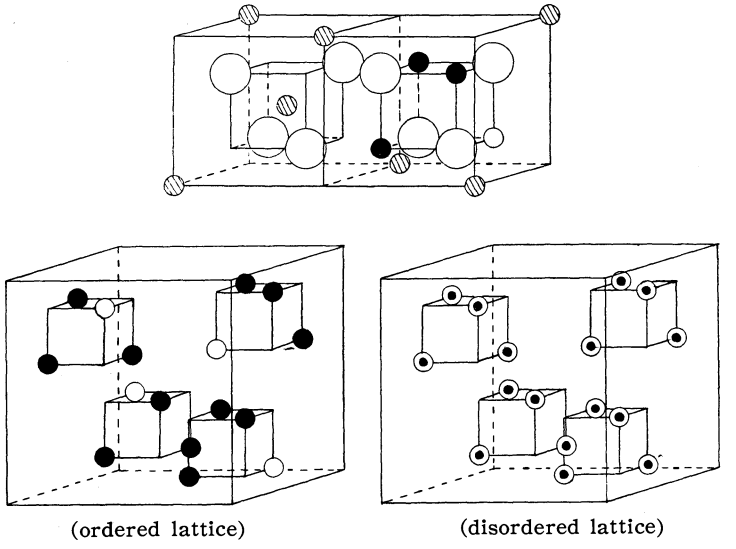
mental reflection. SF_{ss} and F_{fund} correspond respectively to the first term and the rest two terms in Eq. 4.

(ordered lattice) (disordered lattice)

Fig. 1. Crystal structures of lithium ferrite.
○ Li^+ ion ● Fe^{3+} ion ○ O^{2-} ion
⊙ $\frac{1}{2}$ ($Li^+ + Fe^{3+}$)

The above-mentioned procedures were applied to the transition between $D_{4h}^{19} - I4/amd$ and $O_h^5 - Fm3m$ in lithium ferrite, and to that between $O^6 - P4_33$ and $O_h^7 - Fd3m$ in lithium ferrospinel. The crystal structures of lithium ferrite are shown in Fig. 1, where oxygen ions are at the same equivalent point in either the perfectly ordered or the perfectly disordered state. The crystal structures of lithium ferrospinel are shown in Fig. 2, where the equivalent points of ferric ions (small shaded circles) at the tetrahedral sites of the eightfold position are the same in either state, and the structural parameter of oxygen ions (large circles) is 0.382[6] at the perfectly ordered state and 0.382 ± 0.005[7] at the perfectly disordered state. Under the following postulations,

(1) oxygen ions in lithium ferrite, and oxygen ions and tetrahedrally-coordinated ferric ions in lithium ferrospinel are independent of the transition mechanism,



(2) the migrating ions, i.e., all the cations in lithium ferrite or the octahedrally-coordinated cations in lithium ferrospinel, occupy the equivalent points invariable at any state of the transition,

the structure amplitudes of the superstructure reflection can be calculated from Eq. 4 as follows:

For lithium ferrite

$$|F_{ss}| = 2\sqrt{2}\,(f_{Fe} - f_{Li}),\quad h+k=2n+1,\quad l=m+1/2\ \ (L=2l=2m+1) \tag{6a}$$

and for lithium ferrospinel

(ordered lattice) (disordered lattice)

Fig. 2. Crystal structures of lithium ferrospinel. Above: One-fourth of a unit cell of the ordered lattice. Below: Total unit cell showing the tetrahedrons of $LiFe_3$.
◍: Fe^{3+} ion at the tetrahedral site ○: Li^+ ion at the octahedral site

$$\left.\begin{array}{l} |F_{ss}|=2(f_{Fe}-f_{Li}),\ h,k,l: \\ \quad \text{one even and two odd} \\ 2\sqrt{2}\,(f_{Fe}-f_{Li}),\ h,k,l: \\ \quad \text{one odd, one } 4n, \text{ one } 4m+2 \end{array}\right\} \quad (6b)$$

where f_{Li} is the atomic scattering factor for lithium ion and f_{Fe} that for ferric ion. Here, in lithium ferrite, l indicates the third index of a plane which refers to the cubic unit cell in the perfectly disordered state and L that referred to the tetragonal one in the perfectly ordered state, the latter cell being double of the former along c direction.

Experimental and Results

Specimens.—Lithium ferrite and lithium ferrospinel were prepared by the same method as in the previous papers[1,2]. The probes for X-ray measurements were made by quenching in water after heating for a necessary time at the definite temperatures which were listed in Tables I and II.

Apparatus.—The X-ray reflection intensity was measured by a Norelco diffractometer with filtered Co K_α radiation.

Procedures.—From the observed integrated intensities of a super-structure reflection and a fundamental reflection, S is computed by the following formula,

$$S^2=\left(\frac{P_{ss}}{P_{fund}}\right)\frac{F_{fund}^2[m(1+\cos^2 2\theta)\operatorname{cosec}^2\theta\sec\theta]_{fund}}{F_{ss}^2[m(1+\cos^2 2\theta)\operatorname{cosec}^2\theta\sec\theta]_{ss}}$$

where P: integrated intensity
m: multiplicity
θ: Bragg angle of the reflection

since $F_{ss}=0$ on the fundamental reflection and $F_{fund}=0$ on the super-structure reflection. The integrated intensity is proportional to the area A under the peak curve traced by diffractometer for the reflection, i.e.,

$$P_{ss}/P_{fund}=A_{ss}/A_{fund}$$

Lithium Ferrite.—The super-structure line $10\frac{1}{2}$ [8] and the fundamental line 200 were chosen. The final results are listed in Table I.

Lithium Ferrospinel.—The super-structure line 210 and the fundamental line 220 were chosen, and 0.382 was adopted for the value of structural parameter of oxygen ion. The final results are listed in Table II.

Discussion

The statistical theory[9] for the order-disorder transition has been studied on binary alloys. In the simplest case, the approximation is given by Bragg and Williams in which the effect of the nearest neighbors is neglected. Considering the nearest neighbor interaction only, the first approximation is derived from the Bethe's method. Although it may not always be valid to apply the theory for the order-disorder transition in binary alloys to such complex crystals as lithium ferrite and lithium ferrospinel it can be permitted, for the sake of simplicity, to make a trial as follows. Namely, if we neglect the ions which have no direct contribution to the transition, the remaining lattice constructed by the migrating ions alone belongs to the binary system to which the theory may be applied. This lattice is conveniently named a simplified lattice.

The simplified lattice of lithium ferrite belongs to AB type and its disordered lattice is a face-centered cubic. Comparison of the experimental results for lithium ferrite with the curves calculated by the zeroth approximation and the first one for AuCu[10], which is one of binary alloys

8) Here is represented the index of the plane referred to the disordered lattice.

9) See, for instance, E. A. Guggenheim, "Mixtures", Oxford Univ. Press, London (1952), p. 101.

10) The theory gives the following results: from the zeroth approximation $T/T_c=S/\tanh^{-1}S$, where T_c is the transition temperature; from the first approximation in which all combinations of the quadruplets of sites are considered, the value of S jumps from random value zero to the value $S=0.9828$ at T_c[9].

of face-centered cubic type, is shown in Fig. 3[11]. The experimental results are in qualitative agreement with the curve by the first approximation for AuCu. Comparing the crystal structures of the simplified lattice of lithium ferrite with those of AuCu lattice, both lattices have similar structure in disordered phase. The ordered AuCu lattice is pseudo-cubic (tetragonal but the axial ratio is 1.08 : 1.08 : $\sqrt{2}$), while the ordered lattice of lithium ferrite is a tetragonal one which is double the size of cubic lattice in the disordered state along c axis as is seen in Fig. 1. However, the number of the nearest neighbor is 12 in either lattice although the relative arrangement of A and B atoms on these 12 positions around the centered atom is different in both lattices. Hence under such a rough assumption as neglecting oxygen ions as mentioned above, lithium ferrite can be approximated to be LiFe as AuCu with respect to its transition.

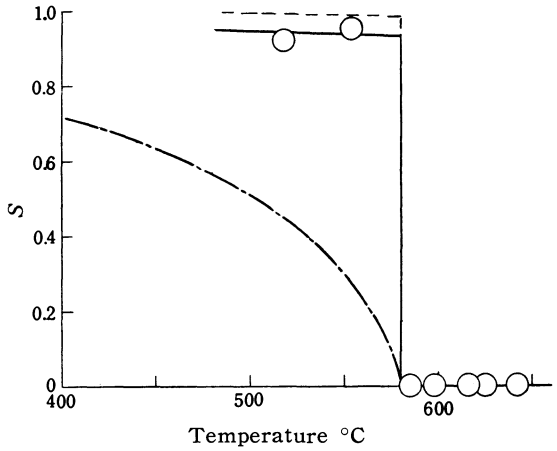

Fig. 3. Variation of long-range parameter for lithium ferrite, experimental and theoretical.
-○-: experimental
- · -: zeroth approximation
------: first approximation

On the other hand, the simplified lattice of lithium ferrospinel belongs to AB_3 type, the typical example of which is $AuCu_3$ (face-centered cubic type). Comparison of the experimental results for lithium ferrospinel with the curves calculated by the zeroth and the first approximation for $AuCu_3$[12] is shown in Fig. 4, where it is found that the experimental results are in good agrreement with the curve calculated by the first approximation. It is noted here that the groups of $AuCu_3$ are arranged side by side along the three directions while those of $LiFe_3$ are arranged tetrahedrally as is seen in Fig. 2, as a result of which the number of the first neighbors is 12 in $AuCu_3$ but 6 in $LiFe_3$[13]. In the present stage the effect of the number of the first neighbor is not ascertained.

In conclusion, it is very interesting that

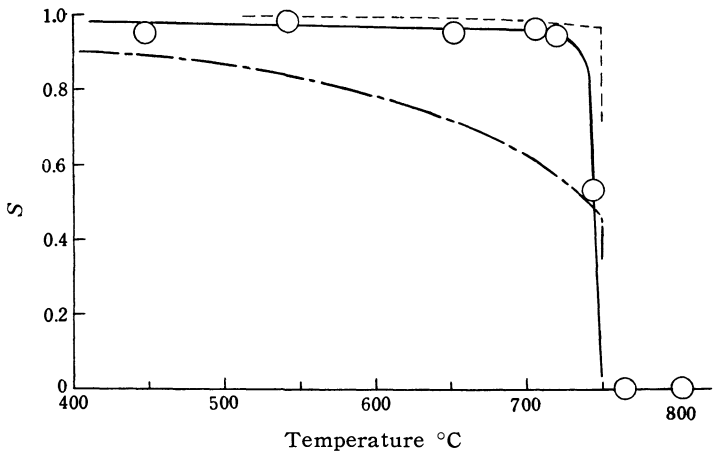

Fig. 4. Variation of long-range order parameter for lithium ferrospinel, experimental and theoretical.
-○-: experimental, - · -: zeroth approximation, ------: first approximation

11) Here T_c is conveniently assumed to be 580°C.

12) The theory gives the following results: from the zeroth aproximation $T/T_c=\frac{4.88\ S}{\ln\{1+16S/3(1-S)^2\}}$; from the first approximation in which all combinations of the quadruplets of sites are considered, the value of S jumps from the random value zero to the value $S=0.9557$ at T_c[9].

13) It may be shown that T_c can not exist in the case of six nearest neighbors (private communication from R. Fujishiro).

in spite of such a rough assumption as ignoring serveral ions having no direct contribution to the transition, statistical theory for order-disorder transition in binary alloys can be approximately applied to estimation of the long-range order parameter in such complex crystals as lithium ferrite and lithium ferrospinel. Moreover, it is emphasized that in the present stage where we have no theory including the effect of all ions in the complex crystal, the assumption of the simplified lattice which can reduce the complex system to a binary one is very useful in treating the order-disorder phenomena.

Transition Temperature of Lithium Ferrite.—As is shown in Fig. 3 the long-range order in lithium ferrite vanishes at 554~587°C[14]. In the previous paper[1] it was found that the anomalous thermal expansion took place at 660°C in the case of ascending temperature and no change was measured down to 550°C in the case of descending temperature. In both the differential thermal analysis and the electric measurement a change was recognized in the vicinity of 660°C. This discrepancy between the observed transition temperatures by X-ray method and those by others is due to the fact that the samples used in the X-ray method were annealed for a long time (20~30 days), while the dilatometry was measured under the non-equilibrium condition, because of its sluggish transition.

Transition Temperature of Lithium Ferrospinel.—The value of the transition temperature for lithium ferrospinel was decided to be 750±1°C from the dilatometry. This value was also given from the differential thermal analysis and the measurement of d.c. electric resistance. The diffractometric curves used for the determination of the transition temperature are shown in Fig. 5, where the superstructure lines 210 and 211 are as yet prominent at 744°C, but very faint at 747°C

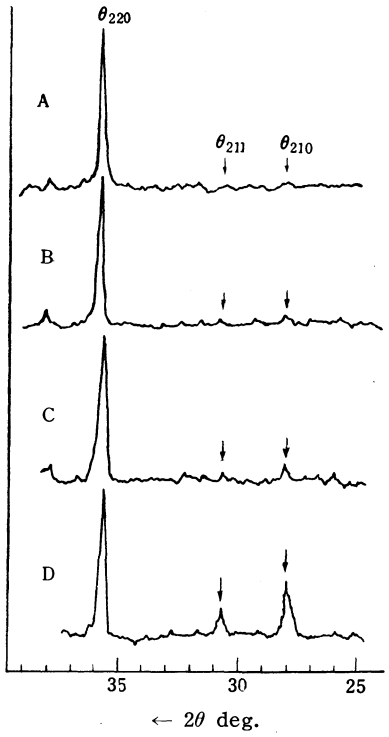

Fig. 5. Diffractometric curves for some samples of lithium ferrospinel in the neighborhood of the transition temperature.
A: 756°C, B: 747°C, C: 744°C, D: 721°C

and disappear completely at 756°C. Hence the probable value of the transition temperature can be estimated to be 750°C in good agreement with the value determined by other physical methods.

The author wishes to express his appreciation to Professor S. Nagaura for his encouragement during this work. He is also indebted to Professor R. Fujishiro for his kind instruction on the statistical treatment and to Professor Y. Saito for his suggestion on X-ray diffraction theory.

14) By R. Collongues (*Bull. soc. chim. France*, 1957, 261) the ordered phase was found at 600°C for a sample annealed for 25 days.

*Preparation of Chloropolysilane from the Copper-catalyzed Reaction of Silicon Metal and Hydrogen Chloride**

By Isao SHIIHARA and Jun IYODA

(Received November 13, 1958)

The copper-catalyzed reaction of silicon metal powder with hydrogen chloride by the flow method was studied in order to find a convenient preparative method for chloropolysilanes, and to elucidate the mechanism of this reaction which seems to have a close relationship with the so-called direct method of preparing alkylchlorosilanes. Hitherto, the conventional way to prepare chloropolysilanes has been to use a binary alloy such as magnesium-silicon[1,2] or ferrosilicon[1] so as to smooth the reaction of silicon and chlorine, and to work at a temperature as low as possible. However, the yields were not satisfactory.

The present investigation was carried out with several kinds of silicon-copper powder mixtures, varying the species of silicon metal, the reaction temperature, the flow velocity of reactant gas, and the ratio of copper powder to silicon. Under the optimum conditions, the yield of chloropolysilane was found to reach 30 wt. % based on the amount of hydrogen chloride. The preferable species of metallic silicon were those which contained aluminum as a main impurity.

Experimental

Materials. — *Metallic silicon of commercial grade.*—Three species of metallic silicon which contained aluminum (Samples A and C) and iron (Sample B), respectively, as main impurities were used in these experiments after being crushed and pulverized into minus 80 mesh. The analytical values of each sample were as follows:

Sample	Exptl. run No.	Fe%	Al%	Ca and Mg%	Particle size (mesh)
A	1, 4, 5, 7	2.70	1.60	0.2	80～150
B	2, 3	7.94	0.42	—	80～120
C[3]	6, 8	trace	0.52	—	120～170

Silicon-aluminum and silicon-calcium alloys. — An alloy having the composition Si:Al=8:2 was prepared by melting 98% silicon and aluminum block in a sealed graphite crucible. Another was a commercial silicon-calcium alloy. Both were crushed and pulverized into minus 80 mesh. The analytical values of the two alloys were as follows:

Sample	Si%	Al%	Fe%	Cu%	Ca%	Particle size (mesh)
Si-Al alloy	80.6	17.2	1.02	0.01	—	80～120
Si-Ca alloy	27.3	—	—	—	68.6	80～120

Copper powder.—Finely pulverized copper for catalyst, prepared by the Fukuda Metal Plate and Powder Mfg. Co., and known as "3L3" (Purity: >98%; size minus 200 mesh[4]), was used.

Hydrogen chloride. — It was prepared in the usual way by the reaction of ammonium chloride and sulfuric acid, washed and dried by concentrated sulfuric acid, and reserved in a 20 l. glass bottle tank which was sealed by concentrated sulfuric acid. The gas was made to flow by the pressure of the sealed liquid head and was measured by its volume (Fig. 1).

Apparatus and Experimental Procedure.— The whole apparatus is shown in Fig. 1. About 20～200 g. of contact mass was charged into a reaction tube of 3 cm. diameter and 1 m. length in an electric furnace. After replacing the air in the apparatus with nitrogen, it was heated to about 150°C in order to dry off the absorbed water and cooled. Then the temperature was raised again from room temperature at the rate of 4～5°C/min. while passing hydrogen chloride at the rate of 8 l./hr. The initiation of the reaction was observed by sudden rise of temperature, change in volume of evolved hydrogen gas, and fuming in the adapter part which was due to the generation of aluminum chloride or chlorosilanes. As explained in our former report[5], the temperature at which this initiation occurred was designated as initiation temperature, or I.T. as abbreviated. Once the reaction occurred, the contact mass was activated and thus the succeeding reaction could proceed at a somewhat lower temperature. Accordingly the reaction tube was cooled to room temperature and then re-heated gradually in order to determine the actual

starting point of reaction, or R.T. as abbreviated. After the confirmation of R.T., the reaction was carried out by making hydrogen chloride flow under the appropriate conditions. The condensates, both in the water-cooled receiver and in the Dry Ice trap, were combined and distilled through a Widmer column and separated into trichlorosilane, silicon tetrachloride and residue with a high boiling point. The residual contact masses were analyzed by the usual methods as to metallic silicon, volatile silicon component on treating with hydrofluoric acid, copper and chlorine. In each experiment, the unreacted hydrogen chloride and volatile chlorosilane in the effluent gas were absorbed in ethanol and the amount of acidic chlorine was measured by titration and silica by weight. Thus insoluble gas was accumulated as hydrogen in a Mariotte bottle and measured.

Results

Effect of the Other Metallic Ingredients in Silicon Metal.—In our previous experiments it was found that the species of silicon metal have a direct influence upon the so-called direct method of preparing methylchlorosilanes. Accordingly, in order to investigate the effect of ingredients in silicon metal, three representative species of silicon metal powder (Samples A, B and C) and silicon-calcium were chosen as contact masses in the present experiments. Because of the prominent catalytic action of copper in the reactions, experiments were conducted with special addition of 3 wt. % copper powder with three kinds of silicon metals. In the case of chips of silicon-calcium alloy no catalyst was used because of the great reactivity of the alloy at lower temperatures, i.e., about 150°C.

A summary of experimental results is shown in Table I. It was found that Sample A—fairly rich in aluminum ingredient—was the best contact mass among the four species tested, and showed its optimum temperature of 215°C for forming the best yield of chloropolysilanes. In silicon-calcium, the product was found to be almost exclusively chloromonosilane, although the R.T. was as low as 150°C.

Influence of Elapse of Reaction Time.—It was found that with long reaction runs the yield of chloropolysilane gradually increased as the reaction time increased. An example with the silicon Sample A is shown in Table III.

The flow rate of hydrogen chloride in the run was almost equal from beginning to end, i.e., 8 l./hr. It seems that the higher molecular weight polysilane derivatives which were produced on the contact mass as intermediates would increase as the elapse of reaction time, just as it will be shown in the case of the contact mass of high copper ratio. From these intermediates some lower series of chloropolysilanes, such as di- or trisilane, might be split out.

Effect of the Copper Catalyst.—As was known in many previous experiments, the reaction of silicon metal or silicon alloy with hydrogen chloride was promoted when a small per cent of copper was added as catalyst.

Copper enables this reaction to proceed even at 215°C; without the copper catalyst

a) 37 g. was sampling out at intervals.
b) When the content of chlorine and volatile silicon hydrides in contact masses was small, this value often became a negative value because of the increase of weight caused perhaps by oxydation of the contact mass in air.
c) This value was calculated so as to take the weight difference after and before the treatment of HF solution as silica, but presumable some Si—Cl and Si—H might be remained even if they were ignited in air.
d) % of recovery to the starting contact masses.

it was necessary to raise the temperature to 300°C[6] in order to get a sufficient yield of liquid product. This effect makes it possible to get chloropolysilane and silicon-hydrides in more satisfactory yield, which are both unstable at temperatures higher than 250°C, the temperature used in the hitherto-performed procedures.

As to the amount of the copper added to the silicon metal, it was remarkable that it showed optimum at 1~3 wt. % copper content, and the increased ratios of copper, for instance 10% or 20%, yielded less liquid chlorosilane (Table II). This was due to the formation of monochloromonosilane which could not be condensed in a Dry Ice-acetone trap but was absorbed in alcohol. The reason for the formation of a small amount of chloropolysilanes may be the smaller reactivity of some higher molecular weight cupropolysilanes which might be formed by the reaction of Eq. E proposed in the discussion part of this report. These compounds

6) F. C. Whitmore, *J. Am. Chem. Soc.*, **69**, 2108 (1947).

might be produced proportionally to the amount of copper, and would not be able to accept further cleavage reaction of hydrogen chloride and remained as solid materials on contact mass. Moreover, the life of contact mass was defined as the interval of the time in which the contact mass is active and forms the liquid product; then the life of the contact mass having a large amount of copper was very short. For instance, 10% and 20% copper masses, have lives of 6.9 and 7.8 hr. respectively as compared to the longer time of 3% copper (Table IV).

Composition of the Chloropolysilanes Condensates.—The contact masses have their own lives and lose their reactivity toward hydrogen chloride at the step where a considerably large amount of silicon component still remains in the residual contact masses (see Table VII). The total figures of a few runs are shown in Table IV. The mean yield of the liquid product was 800 g. from 200 g. silicon metals, and the yields of chloropolysilanes were found to be 8.1~28.8 wt. % as the high boiling residue in the crude product. Distillation analysis was carried out for several intervals of the run in order to investigate the change of the compositions of the crude chlorosilanes with elapse of reaction time (see Table III); however, the distillation of a high boiling point fraction was performed with the gathered sample of several runs. The physical constants of some chlorosilanes and chloropolysilanes of this experiment are shown in Table V. Upon distillation of these chloropolysilanes, the chlorodisilane fraction was found to be 80~85 wt. % and the higher fraction, chlorotrisilane, was found to be 14~17 wt. % based on the charged crude chloropolysilanes. The fraction of trisilane was found to be accompanied by some iron compound, and darkened after some elapse of time. This impurity finally deposited as a brown coagulate of ferric oxychloride, and the upper trisilane distillate became a colorless, transparent liquid. The residual gel substance which was obtained after distilling trisilane was brownish black, generated some hydrogen by hydrolysis in water, violently evolved hydrogen by cleavage in alkaline solution, burned in air with a red flame, and left white ashes. This must have been impure higher chloropolysilanes and did not contain any copper component although it had silicon, iron, aluminum and chlorine in it.

Naturally, it was expected that these chloropolysilanes would possibly have silicon hydride bonds in their molecules arising from the hydrogen atom of hydrogen chloride, contrary to the hitherto-used preparative methods in which chlorine and silicon alloys were used as starting materials. Among the series of $H_nSi_m \cdot Cl_{2m+2-n}$[7], both pentachlorodisilane HSi_2Cl_5 and heptachlorotrisilane HSi_3Cl_7, which were expected to be formed but unknown in literature, were found only in traces in the produced chloropolysilanes and moreover, judging from its boiling point and its hydrogen analysis (Table VI), it was found that the chlorodisilane fraction was rather pure hexachlorodisilane and the chlorotrisilane fraction was also octachlorotrisilane.

As to the hydrogen analysis of the chloropolysilane, there has been no adequate method hitherto[8], but the authors have found that silicon hydride bonds are reactive with metallic copper, especially in the presence of small amounts of anhydrous aluminum chloride when their reactions are carried out in liquid phase.

Therefore, this analysis was performed by the apparatus shown in Fig. 2 in which the polysilanes containing hydrogen were treated with copper powder and $AlCl_3$ in

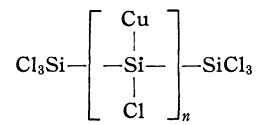
8) V. G. Fritz, Ibid., **280**, 135 (1955).

a bottle A. The method devised was almost analogous to that of Dumas' nitrogen analysis, i.e., the evolved hydrogen was carried by carbon dioxide and the hydrogen produced gathered in a gas burette on potassium hydroxide solution and measured. The results of this hydrogen analysis are shown in Table VI. This method was confirmed previously with the known silicon-hydride containing substance, for instance, with Ph_3SiH, and showed a fairly good agreement. The occurrence of silicon-copper bond which was made by the reaction of silicon hydride and copper may be recognized by the change of metallic copper to gray metallic silicon color. It was also known that the liberated gas was hydrogen. The contents of silicon hydride in these chloropolysilanes were proved to be very small according to this analysis.

One must be careful in treating chloropolysilanes, because they are apt to form certain dangerous materials. When hydrolyzed in air, they form compounds which exqlode with slight friction or shock. These chloropolysilanes have a flammable nature although they consist only of silicon and chlorine.

Composition of the Residual Reaction Mass.—The final residual masses which were left after reaction had an appearance of very voluminous light powder possessing no metallic lustre like starting silicon, and were caqable of burning in air when ignited, revealing a very brilliant blue flame by burner test.



The results of chemical analysis are shown in Table VII. The amounts of hydrogen evolved on treating the residues with alkali solution are given in Table VIII.

TABLE VIII. HYDROGEN GENERATION ON TREATING THE RESIDUAL MASSES WITH 10% SODIUM HYDROXIDE SOLUTION

Sample	(g.)	H_2 evolved (m mol./g.)	SiO_2 (g.)	Si%	H/Si atom ratio
H-2	0.1240	2.00	0.0114	4.30	2.61
H-2	0.1280	1.85	0.0160	5.65	1.78
H-3	0.1330	5.75	0.0412	14.50	2.23
H-3	0.0950	5.34	0.0351	17.20	1.74
H-4	0.1570	3.20	0.0461	13.70	1.31

These facts led to the conclusion that the remainder may be the higher molecular weight chloropolysilanes and that some chloropolysilanes, especially those which have much silicon-copper bond in them, could not be cleaved by hydrogen chloride even if the copper catalyst were present, and so the reaction ceased.

If it was supposed that all iron was converted into ferrous chloride and copper remained as metal[9], the residual number of chlorine atoms of the final contact masses in H-1 and H-2 would be almost equal to the number of the silicon atoms, and the hydrogen atoms generated by alkali solution would be also twice as much as the silicon atoms (Table VIII). As the final reaction temperature, rather high temperatures, say 475°C for H-1, 460°C for H-2, were applied, and so it may be reasonably considered that all the iron changed to ferrous chloride, and in the final stage of this reaction almost every silicon atom has one chlorine atom linked to it, and the silicon atoms are linked to each other with silicon-silicon bonds. Thus, the proposed structure of these chloropolysilanes is as follows:

However, the contact mass in the reaction course was thought to contain much more silicon hydride bond than the final structure proposed above, because samples H-3 and H-5 in the reaction were of a more flammable nature than that of H-1, H-2 and H-4 of the final stages. The amount of silicon hydride bond in the former contact masses was measured by the generation of hydrogen with copper and aluminum chloride and found to be high (Table VI).

I. T. and R. T. Measurements.—Many I. T. and R. T. measurements were performed at the beginning of each run and with the special contact mass species. The results of observations are listed in Table IX, and also some examples of the graph with I. T. and R. T. measurements are shown in Fig. 3. The sudden rise in the temperature curve in comparison with the blank curve[10] showed the occurrence

9) The forms of iron and copper componet were found by extracting H-1, H-2 residual contact masses with dimethylformamide. Their salts are both soluble in this solvent, but the extracted ones were almost ferrous chloride and not cuprous chloride.

10) The blank curves were figured separately by measuring temperature versus time at several voltages in an electric furnace. Nitrogen gas was passed at the rate of 8 l./hr. (the same as that of hydrogen chloride) into the reaction tube containing the same amount of contact mass as in the actual measurements. This was repeated several times and each time the same curve was obtained. Thus, this curve could be considered as a blank.

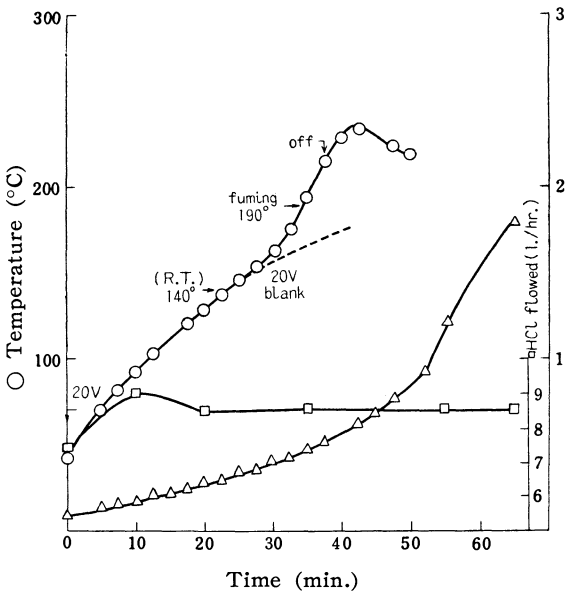

Fig. 3b. An example of the graph with R.T. measurement (H-3-2).

of the reaction about the contact mass. At this critical point, usually some gas evolution, or rate change of gas generation, or fuming caused by the product in the adaptor part were also present, and these could be also considered the evidence of the reaction occurrence, but these

TABLE IX. I.T. AND R.T. OF THE REACTION OF SOME SILICON CONTACT MASSES WITH HCl UNDER ATMOSPHERIC PRESSURE

Silicon materials	Catalyst (%)	I.T. (°C)	R.T. (°C)

phenomena often had time lags and the precise points could not be determined by them. Therefore, only the temperature curve was chosen for determining the precise value. It was found from many observations that the I. T. value is not always the same in a contact mass, sometimes as much as 10°C difference, although it is always higher than R. T. The I. T. values obtained in the present experiment seemed to originate mainly from the composition of the materials or alloys of the contact masses tested, even though these values fluctuated somewhat with the changes of the particle surfaces. As to the R. T. value, there are more than two values for some samples of silicon metal or alloy. Moreover, as was seen in many observations, the 50, 105, 145 and 170°C points are prominent and sometimes common to the same kind of contact mass species. They seemed to correspond to the R. T. as shown in the following reaction Eqs. A, B, C and D.

$$\text{Al (in solid phase Si—Al)} + \text{HCl} \xrightarrow{50^\circ\text{C}} \text{AlCl}_3 + \text{H}_2 \quad \text{(A)}$$

$$\text{Fe (in solid phase Si—Fe)} + \text{HCl} \xrightarrow{105^\circ\text{C}} \text{FeCl}_2 + \text{H}_2 \quad \text{(B)}$$

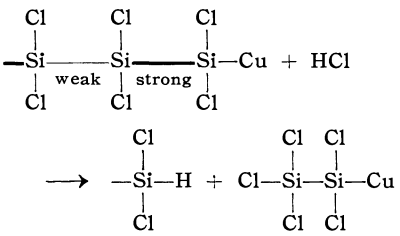
$$\equiv\text{Si—Al}= \text{(in solid phase Si—Al)} + \text{HCl} \xrightarrow{145^\circ\text{C}} \equiv\text{Si—H} + =\text{AlCl} \quad \text{(C)}$$

$$\equiv\text{Si—}\underset{\displaystyle|}{\overset{\displaystyle|}{\text{Si}}}\text{—H} + \text{HCl} \xrightarrow[\text{AlCl}_3 \text{ present as catalyst}]{170^\circ\text{C}} \equiv\text{Si—H} + \underset{\displaystyle|}{\overset{\displaystyle|}{\text{ClSi}}}\text{H} \quad \text{(D)}$$

The following is a brief explanation to substantiate this relation. As is seen in

Table IX, Si (C)[11] and Si—Al alloy have almost the same R. T. at 50°C, as in the case of the metallic aluminum and hydrogen chloride reaction[12]. Therefore, Eq. A, which mainly concerns the presence of metallic aluminum in the contact mass, was given for the 50°C value. By the same speculation, 105°C value corresponding to the iron component which exists as the other main impurity in most silicon metal or silicon alloys, is indicated by Eq. B[13], the 145°C value has been assigned to Eq. C[5] by the authors. In almost all the reactions the forming of chlorosilane actually began at 170°C. Thus it was plausible that Eq. D was adequate for this R. T. value.

It was very interesting and important that when a small amount of anhydrous aluminum chloride was added to the contact masses as mixture or as vapor, the I. T.'s of these reactions were depressed close to the R.T.'s of their own. The fact that the commercial silicon Si(A)—fairly rich in aluminum ingredient—had a good yield of liquid product (Table I), might be proved by the above effect of aluminum chloride. Because in this reaction system the aluminum chloride could be easily derived from the reactions shown as Eqs. A and C. However, the remarkable effect of copper to each contact mass could not be understood from the results of I. T. and R. T. Unexpectedly the copper was reasonably considered only to promote the rate of this reaction.



Discussion

The results of this experiment mentioned above and an assumption which will be proposed afterward afford the following reaction mechanism of the formation of chloropolysilane, i.e., the activation and main course stages for the reaction between commercial silicon and hydrogen chloride which gave monosilanes were explained as the formulae A, B, C and D mentioned above, but by those mechanisms alone no important part of the mechanism of forming chloropolysilane using copper catalyst could be explained. It might be reasonable to assume that copper combines with Si—H bond on the silicon mass which is formed as an intermediate of the C or D reactions (see Table VI):

$$\equiv SiH + Cu \xrightarrow[AlCl_3 \text{ catalyst}]{150^\circ C} \equiv Si—Cu + 1/2\ H_2 \qquad (E)$$

Hence, the co-catalytic action of aluminum chloride, produced by A and C reactions in the above reaction, is seen in the comparison of the experiments No. 1 and 2 in Table VI. Therefore, apart from the before mentioned I. T. depressing effect of aluminum chloride, it is preferable to use commercial silicon metal which has a small amount of aluminum as impurity or the vapor of aluminum chloride purposely conducted to the reaction zone of the pure silicon metal.

The authors have proposed the following assumption for the catalytic action of copper, i.e., the silicon-silicon bond which is adjacent to the silicon-copper bond formed by E reaction is difficult to be cleaved by hydrogen chloride as was shown in the above-mentioned results and the supposed cleavage is as follows:

This assumption may also facilitate the understanding of the mechanism of the chlorodisilane formation, and the catalytic action of copper for the present reaction. This unequalness of silicon-silicon bond strength may well be explained by the unequal electron density on the silicon atoms like the alternative strength-change theory of carbon bonds proposed by Ingold. If this assumption is correct at all, the reasons for the large yield of chlorodisilane in the main course of reaction by addition of a few per cent of copper and its sharply diminished formation at the final stage of the reaction may also be plausible. Hence, the copper content at the surface of the contact mass at the final stage may become so high that the copper atoms can be distributed enough through the adjacent silicon atoms.

11) As was mentioned Si (C) was originated from the Si-Al alloy. It was somewhat curious that Si (A), Si (B) which had more aluminum content than Si (C) did not show this 50°C R. T. value. However, this may be explained by the fact that iron masked the free aluminum character, perhaps by forming some kind of alloy.

12) J. Iyoda and I. Shiihara, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), in press.

13) Generally speaking, the iron component in a silicon alloy must form some intermetallic compounds with silicon, but here in these contact masses, part of it combined with aluminum, forming some kind of easily reactive alloy.

The reaction between a typical silicon-copper bond and hydrogen chloride is shown as follows:

$$\equiv Si—Cu + HCl \longrightarrow \equiv Si—H + CuCl \qquad (F)$$

This reaction can also explain the formation of much H_3SiCl when a large amount of copper is added as catalyst. However, the reason for the meager existence of Si—H bond in chloropolysilane product seems to be plausible when the hydrogen chloride exchange reaction with some species of compounds on contact mass is assumed. A typical reaction can be considered:

$$Cu—\overset{Cl}{\underset{Cl}{Si}}—\overset{Cl}{\underset{Cl}{Si}}—H + HCl \xrightarrow{AlCl_3} Cu—\overset{Cl}{\underset{Cl}{Si}}—\overset{Cl}{\underset{Cl}{Si}}—Cl + H_2 \qquad (G)$$

The reverse reaction of F about the Si—H in the above compound is excluded from the results of experiments No. 3 and 4 in Table VI, and the possibility of E reaction of the Si—H is also taken to be small, since the chance of Si—H in this compound fixed on contact mass coming in contact with copper metal is supposed to be slight.

Also, the reaction of silicon and cuprous chloride is excluded under the reaction temperature of this experiment as 215°C, which is far from the R.T. value[14] (295°C) of this reaction.

$$\equiv Si—Si\equiv + CuCl \xrightarrow{R.T.\ 295°C} \equiv Si—Cu + \equiv Si—Cl \qquad (H)$$

Therefore, cuprous chloride produced by F reaction may be reduced[15] mainly by hydrogen formed by E and G reactions.

$$2CuCl + H_2 \longrightarrow 2Cu + 2HCl \qquad (I)$$

And so regenerated metallic copper can be recycled to E reaction.

Summary

The copper catalyzed reaction of silicon metal powder with hydrogen chloride by flow method was studied in order to find a convenient preparative method of chloropolysilane, and also to elucidate the mechanism of this reaction.

This reaction was found to start at about 170~230°C, and once the reaction occurred, the contact mass is activated and the reaction takes place even at 170°C. When the most adequate conditions were adopted, chloropolysilanes were obtained in the condensate as efficiently as 30 wt.% yield based on hydrogen chloride.

As to the mechanism of the reaction, it seems to be plausible that the first step of the reaction is an attack of hydrogen chloride on aluminum which is usually present in the commercial silicon metal. The second step is the reaction between silicon hydride, which is derived from the first step reaction upon the silicon contact mass and metallic copper forming the silicon-copper bonding. The third step is the cleavage reaction of copper-activated silicon by hydrogen chloride to produce chlorosilanes under the presence of aluminum chloride. The aluminum chloride is also derived from the first step reaction, and copper is regenerated in metal form which can circulate among the latter two reaction steps as long as the effective silicon component is present.

The authors are indebted to Mr. S. Hara of their Institute for the analyses of residual masses, and to Mr. H. Takahashi of their laboratory for the analysis of siliconhydride.

The Study of the Adsorption of Detergents at a Solution-Air Interface by Radiotracer Method. III. The Effect of Inorganic Electrolytes on the Adsorption of Sodium Dodecyl Sulfate

By Ryohei MATUURA, Hideo KIMIZUKA and Katsumasa YATSUNAMI

(Received November 17, 1958)

Roe and Brass[1], Nilsson[2] and Salley et al.[3] have checked the Gibbs adsorption equation with potassium palmitate, sodium dodecyl sulfate and Aerosol OTN in the presence of potassium hydroxide, sodium chloride and Aerosol OT, respectively. They have obtained the result that the adsorption of detergent at the air-solution interface takes place in accordance with the Gibbs adsorption equation. It was suggested also through the observation of the change with time in surface tension of detergent solution that the addition of excess electrolytes increases the adsorption rate of surface active ion[4].

However, the adsorption isotherm and adsorption rate for the detergent solution in the presence of various electrolytes, especially in the presence of the salts containing no common ion with the detergent, has not yet been measured directly. In the present study, we have succeeded by the aid of the radiotracer method in measuring directly the adsorption of dodecyl sulfate ion (abbreviated as DS^-) at the solution-air interface from the solutions containing sodium dodecyl sulfate (abbreviated as SDS) and excess inorganic electrolytes. The surface tension of the solution has been measured and the Gibbs adsorption equation has been checked.

Experimental

Materials. — The radioactive SDS used was synthesized as described in the preceding paper[5]. Of the inorganic electrolytes, manganous and aluminum chlorides were those of extra pure reagents and purified by recrystallization, while sodium, potassium and magnesium chlorides were those of guaranteed reagents and used without further purification. For the preparation of the solution under investigation, SDS was dissolved in the aqueous solution of respective inorganic electrolyte with a given concentration.

Method.—The procedure used for the measurement of the surface excess of DS^- was the same as described in the preceding paper[5,6]. The surface count of radioactive sodium sulfate solution was taken as the same as that of the bulk of radioactive SDS solution, both containing excess of salts.

The surface tension measurement was carried out by means of the du Noüy tensiometer. The temperature of the experiment was maintained at 29±1°C.

Results and Discussion

It was found that the adsorption of DS^- in the presence of excess salts with or without common ions was so rapid that

the equilibrium was attained within one minute, while without added salts it took several minutes or more to reach the adsorption equilibrium at the solution-air interface as was reported in the preceding paper[6]. Fig. 1 is an example of counts vs. time relation of SDS solution (concentration is 5.543×10^{-4} mol./l.) containing 0.3 N sodium chloride. t_0 in Fig. 1 is the starting time of counting. It is seen that a linear relation is held between count and time, showing that the adsorption has already reached equilibrium at the starting time (t_0) of counting. It has already been known that the presence of inorganic salts makes faster the attainment of equilibrium of surface tension of the detergent solution[4]. In the present study, the effect of the presence of sodium chloride on the change with time of surface tension of SDS solution was also measured by means of the Wilhelmy plate method. Fig. 2 shows an example of the effect of the presence of sodium chloride on the rate of surface tension lowering. It may easily be seen that the presence of salt not only makes faster the attainment of equilibrium of surface tenstion, but also lowers the surface tension value. Furthermore, it may be pointed out that in the presence of salt the surface tension almost reaches equilibrium even at the starting time of experiment. The present experiment, therefore, clearly shows that the rapid rate of surface tension lowering actually corresponds, as might be expected, to the rapid rate of adsorption at least qualitatively. However the rate of adsorption was too rapid to measure precisely and so the quantitative relation between the surface tension lowering and the adsorption before reaching equilibrium could not be determined in the present study. The results and discussions below therefore are concerned only with the equilibrium state of adsorption and surface tension.

First the effect of sodium chloride of various concentrations on the adsorption of DS^- was measured and the result is shown in Fig. 3. It is obvious that the presence of excess sodium chloride increases the adsorption of DS^- considerably. Here it is to be noted that, although below 0.1 N of sodium chloride the adsorption of DS^- increases with the concentration of the salt, above 0.1 N of sodium chloride the values of surface excess of DS^- fall within a range almost independent of the concentration of the salt. On the contrary, the surface tension of SDS solution containing sodium chloride decreases regularly with the concentration of the salt up to 1 N, as shown in Fig. 4.

When the Gibbs adsorption equation for the solution of surface active electrolyte is written in the form

$$\Gamma = -\frac{1}{nRT}\frac{\partial\gamma}{\partial \ln C}$$

where Γ is the surface excess, γ, surface tension, C, concentration of the detergent and R and T are gas constant and temperature, respectively. n is expected, from theoretical considerations, to be unity in the presence of large excess of salts

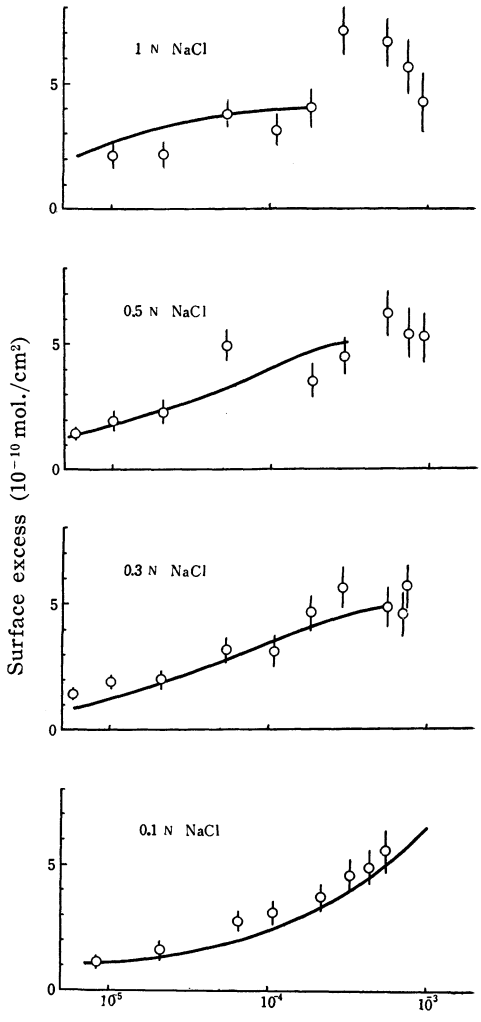

Fig. 5. Adsorption of DS^- from SDS solution containing sodium chloride. Full lines represent calculated relations from surface tension vs. logarithmic concentration curves by using the Gibbs adsorption equation of $n=1$.

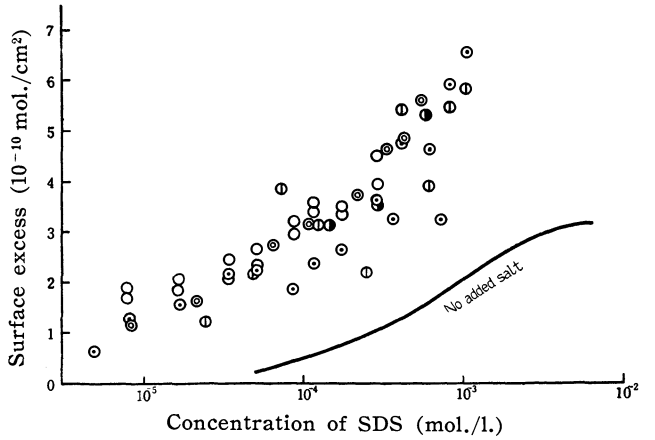

Fig. 6. Effect of added electrolytes on the adsorption of DS^-, 29±1°C. Concentration of electrolytes are all 0.1 N.

or alkalis[5]. From the data in Fig. 4 we can calculate Γ of DS^- in the presence of sodium chloride and check the Gibbs equation*. The results are shown in Fig. 5 for various concentrations of sodium chloride. From these figures it is reasonable to conclude that the Gibbs adsorption equation of $n=1$ is a fair expression for the adsorption of DS^- below cmc in the presence of sodium chloride.

Next the effect of various inorganic electrolytes having no common ion with the detergent was measured. Some salts made precipitates even in the dilute solution of the detergent and so the kinds of salts investigated were limited. The salts used in the present experiment were potassium chloride, magnesium chloride, manganous chloride and aluminum chloride and SDS was dissolved in the aqueous solution of each electrolyte of the concentration of 0.1 N. The relation between the surface excess of DS^- and SDS concentration in the presence of 0.1 N inorganic electrolytes is shown in Fig. 6. From this figure we can see that the presence of excess of inorganic salts makes considerable increase in the adsorption of the detergent, regardless of the type of the salts added.

* Strictly speaking, the concentration in the Gibbs equation should be replaced by the activity. However it may not cause serious errors to use concentration instead of activity *below cmc* of the detergent even in the presence of excess salt as in the present experiment[2,3].

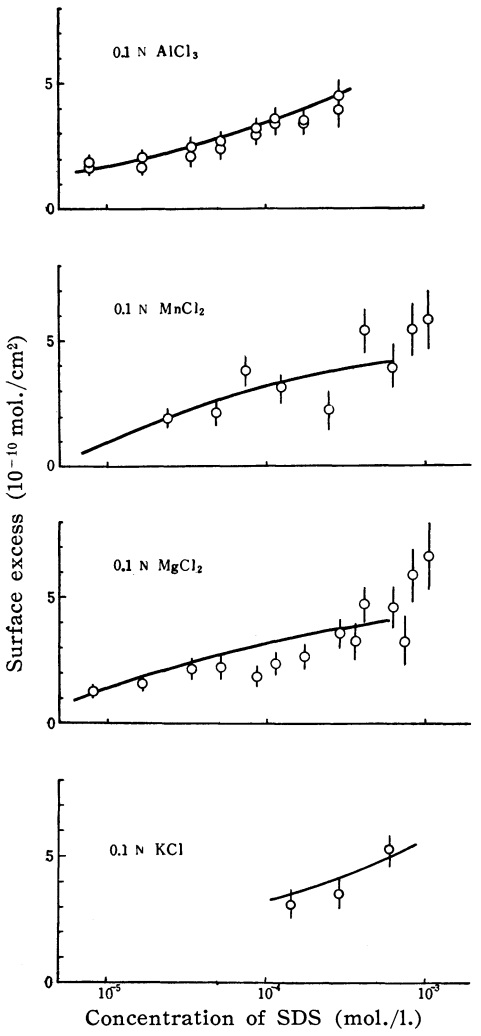

Fig. 8. Adsorption of DS^- from SDS solution containing 0.1 N excess of salt. Full lines represent calculated relations from surface tension vs. logarithmic concentration curves by using the Gibbs adsorption equation of $n=1$.

The surface tension vs. concentration relation of these systems is shown in Fig. 7. It is interesting to note that the surface tension decreases regularly with the valency of cation of added salts, while the surface excess shows no such regular relations.

Using the data in Fig. 7, the surface excess was calculated by the Gibbs equation putting $n=1$ and compared with the observed value. The results are plotted in Fig. 8. From these results it will be possible to say that the Gibbs equation of $n=1$ represents approximately the experimental values of surface adsorption of DS^- even in the presence of inorganic salts having no common ions with the detergent.

Summary

The direct measurement of the adsorption of ^{35}S labelled dodecyl sulfate ion at the solution surface and the measurement of the surface tension were carried out on the aqueous solutions of sodium dodecyl sulfate containing a given concentration of an excess salt. The salt concentrations studied were 0.01, 0.1, 0.3, 0.5 and 1 N for sodium chloride, and 0.1 N for potassium-magnesium, manganous and aluminum chlorides.

1. The adsorption of dodecyl sulfate ion reaches equilibrium within one minute for all the systems under investigation.
2. The presence of excess of salt gives rise to the remarkable increase in the adsorption of dodecyl sulfate ion, but at the concentrations of excessive salts of about 0.1 N or more, the effects of the concentration and nature of the salts on the adsorption of dodecyl sulfate ion are not so appreciable.
3. The adsorption of dodecyl sulfate ion was well expressed by the Gibbs adsorption equation of $n=1$ for the systems under investigation.

In conclusion the authors express their hearty thanks to Professor T. Sasaki of Tokyo Metropolitan University for his kind advice and encouragement in the course of this study. The cost of this study was defrayed from the Chemical Research Grant of the Ministry of Education, to which the authors' thanks are also due.

SHORT COMMUNICATIONS

Polymerization of Methyl Methacrylate Initiated by a Combined Action of Di-p-tolyl Disulfoxide, Dimethylaniline and Oxygen in Air

By Ryoichi UEHARA

(Received February 27, 1959)

The effects of *p*-toluenesulfinic acid (TSA) upon polymerization of vinyl monomers have been noted by Hagger[1] and Bredereck[2]. In a previous paper by the present author[3], results of studies on the kinetics of the polymerization of methyl methacrylate (MMA) initiated by the system of TSA, dimethylaniline (DMA) and oxygen in air have been reported. The polymerization was initiated at room temperature by means of this system. TSA is not so stable even at room temperature, and by being left in air changes into *p*-toluenesulfonic acid (TSOA), di-*p*-tolyl disulfoxide(DTDS) and water through the following reaction[4]:

$$3CH_3C_6H_4SO_2H = CH_3C_6H_4SO_3H + (CH_3C_6H_4SO)_2 + H_2O$$

Owing to this deterioration, the activity of TSA as a component of the initiating system of the room-temperature polymerization of MMA is reduced gradually[5]. The present author has examined the effects of TSOA and DTDS upon the polymerization of MMA at various temperatures, and found that the polymerization was initiated by a combined action of DTDS, DMA and oxygen in air at above 60°C. TSOA could not initiate the polymerization in combination with DMA and oxygen. It has been found by the present author that several compounds related to TSA, e.g., *p*-tolyl methyl sulfone[6] and di-*p*-tolylsulfonylhydroxylamine[6], initiated the polymerization of MMA in combination with DMA and oxygen. DTDS is a new material which belongs to this group of compounds. In the present communication, some results of experiments are given. The nature of the effects of the polymerization-initiating system will be discussed in future.

In Table I, per cent conversions after 1 hr. at various temperatures are given (DTDS 2.34×10^{-2} mol./l. and DMA 2.58×10^{-2} mol./l. in air). For the initiation of the polymerization, the coexistence of the three components of the initiating system was necessary. Namely, in the cases when MMA was heated at 70°C with DTDS 2.51×10^{-2} mol./l. and DMA 2.52×10^{-2} mol./l. in the atmosphere of nitrogen or with DTDS 2.48×10^{-2} mol./l. alone in air, no polymerization took place, and when DMA 2.52×10^{-2} mol./l. alone was employed in air, only trace of polymethyl methacrylate (PMMA) was obtained after 3 hr. at 70°C. In Fig. 1, per cent conversions of the bulk polymerization of MMA at 70°C in air (DTDS 2.16×10^{-2} mol./l. and DMA 2.20×10^{-2} mol./l.) are plotted against the time of polymerization. A time conversion curve of the polymerization by means of benzoyl peroxide (BPO, 2.0×10^{-2} mol./l.) in nitrogen is shown by the dotted line in the figure. From the beginning of

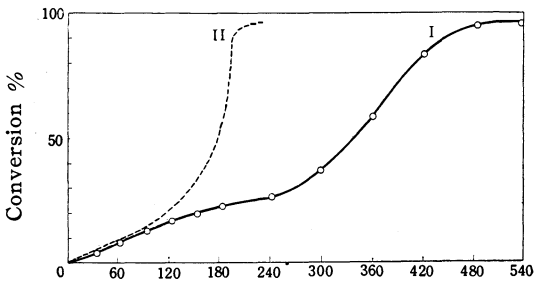

Fig. 1. Time versus conversion curve of bulk polymerization of MMA at 70°C in air. I, DTDS 2.16×10^{-2} mol./l. and DMA 2.20×10^{-2} mol./l. II, BPO 2.0×10^{-2} mol./l. (under nitrogen).

the polymerization until the conversion reached to 15%, the rate of polymerization initiated by the system of DTDS, DMA and oxygen was only slightly smaller than that of the polymerization by BPO. After this period, the polymerization initiated by the system of DTDS, DMA and oxygen proceeded at a moderate rate and somewhat acceleratively in the final period, while the polymerization by BPO run quite acceleratively and almost explosively at the final stage. In the polymerization initiated by the system of DTDS, DMA and oxygen, the conversion reached to 90% after 450 min. from the beginning of the reaction, but in case of the polymerization by BPO the conversion reached to the same extent after 190 min. In the bulk polymerization of MMA, gelation of the reacting system occurs when the conversion reaches to 20~30%. So, it is very probable that the polymerization initiated by the system of DTDS, DMA and oxygen does not proceed so acceleratively owing to the fact that the rate of diffusion of oxygen from air into the reacting system is reduced due to the gelation. On the other hand, DTDS alone did not affect upon the polymerization of MMA initiated by BPO under nitrogen, i. e., per cent conversion after 1 hr. and the degree of polymerization (DP) of PMMA were not changed by the addition of DTDS (Table I).

TABLE I. RESULTS OF THE BULK POLYMERIZATION OF METHYL METHACRYLATE

Atmosphere	Initiator (mol./l. × 10^2)	°C	% Conversion after 1 hr.	DP
Air	[DTDS (2.34) DMA (2.58)]	40	0	
Air	[DTDS (2.34) DMA (2.58)]	50	1.5	
Air	[DTDS (2.34) DMA (2.58)]	60	3.7	4900
Air	[DTDS (2.34) DMA (2.58)]	70	8.7	2850
Air	[DTDS (2.34) DMA (2.58)]	80	17.4	1390
Air	DTDS (2.48)	70	0*	
Air	DMA (2.52)	70	trace*	
Nitrogen	[DTDS (2.51) DMA (2.52)]	70	0*	
Nitrogen	BPO (2.0)	70	10.3	3900
Nitrogen	[BPO (2.0) DTDS (2.51)]	70	10.9	3780

* After 3 hr.

Experimental — DTDS was prepared by heating TSA (20 g.) with water (60 cc.) in a boiling water bath. TSA was dissolved and then an oily material separated gradually. After 5 hr., the oil was washed with 5% aqueous sodium hydroxide and pure water, and cooled. Crude DTDS was recrystallized three times from a mixture of methanol and ether (1 : 1 by volume), and pure DTDS (6.5g.) was obtained, m.p. 78.5°C. Purification of MMA and DMA have been mentioned in a previous paper[7]. The polymerization in air and under nitrogen were carried out respectively in open test tubes[3] and sealed tubes[7]. DTDS and DMA were dissolved in MMA cooled in an ice-salt bath. The solution (5 cc.) was placed in a test tube and heated with shaking. Per cent conversion of the polymerization was estimated from the weight of PMMA. Details of the procedures have been given previously[7]. DP of PMMA was calculated from the intrinsic viscosity in chloroform by using the equation of Sakurada[8].

On the Concentration Potential

By C. V. Suryanarayana and
V. K. Venkatesan*

(Received April 2, 1959)

Vaidhyanathan[1] is in great error in his 'Remarks on the composition potential' in regard to a quantity defined by us[2] recently. We defined a quantity C_p as the ratio of the mole fraction of the solute at any given molal concentration to that at saturation at the same temperature. Precisely we called this ratio C_p, the concentration potential and not the composition potential as he states in his remarks. What is most amusing is that Vaidhyanathan imagines that we have stated the above ratio as being a truly thermodynamic potential. We have not done so. A careful perusal of our paper (loc. cit.) shows that the wording is as follows:

"The concentration potential newly conceived herein is a truly thermodynamic *concept of concentration* dependent only on

* Present address: Central Electrochemical Research Institute, Karaikudi, India.

1) V. S. Vaidhyanathan, This Bulletin, **32**, 99 (1959).

2) C. V. Suryanarayana and V. K. Venkatesan, ibid. **31**, 442 (1958).

the initial and final states of stability of a solution and independent of any arbitrary scale of concentration or the nature of both the solvent and the solute". The *concept* is a thermodynamic one as explained by the rest of the above sentence but definitely it can never even imply that the ratio called by us 'concentration potential' is ever a thermodynamic potential at all.

We must point out incidentally that the definition of thermodynamic potentials given naively by Vaidhyanathan is in serious error. He states: "The potentials that can be defined as 'thermodynamic potentials' and which conform to this statement are the Gibbs and Helmholtz functions, energy, enthalpy, entropy and the chemical potential and they alone". Excepting the last mentioned chemical potential which is the derivative of the Gibbs free energy with respect to the number of moles of the species at constant temperature and pressure all the other functions are extensive properties and are not called thermodynamic potentials merely by themselves. They have of course the properties of exact differentials. Thermodynamic potentials are always intensive[3] (expressed per mol.) especially for the chemist when dealing with solutions. Further what he states in the first part of his last para has either no purpose or contradicts the last part of his first para and hangs loosely.

What may be really a pertinent question is the reason why we have called the newly defined ratio a concentration potential. An answer to this is due to appear elsewhere (under publication), and is briefly as follows. When we picture what happens when a soluble solid solute is added to a solvent, we can imagine its dissolution at any instant giving in the vicinity of the solute a successive series of layers of solutions, the most concentrated one being nearest the solid and the least concentrated one the pure solvent itself. The most concentrated one is the saturation concentration and the lowest concentration is zero. In between, there is to be imagined a concentration gradient. It is so clear that the saturation concentration has a directive influence on the concentration gradient. Our main purpose in defining this new ratio is to indicate the soundness of comparing a physical property of solutions of two different solutes in a given solvent at identical gradients and not at identical arbitrary concentrations as is being done so far. In this context any arbitrary concentration between the saturation and zero values has been visualized as better represented by the ratio of mole fraction to that at saturation and called the concentration potential due to its relation to the above mentioned gradient. Any arbitrary concentration for a salt must occur in the concentration gradient given in the above picture of the dissolution of the same salt. The situation is similar to the well-known classical law of corresponding states. But it is too early to predict the usefulness of the newly defined ratio, especially whether equally important generalizations will accrue out of the use of C_p. Of course, C_p has the properties of an exact differential between the limits of zero concentration and saturation.

Again Vaidhyanathan states that apart from the fact that C_p is an intensive variable and is dimensionless, no other thermodynamic significance can be attributed to it. We should say that the above reasons are not enough to say that no other thermodynamic significance can be attributed to it. An understanding of the thermodynamic significance of the saturation state of a solution will be the final deciding factor in assessing the thermodynamic significance of the concentration potential defined by us. A perusal through Walden[4], van Laar[5], and Ricci and Davis[6] indicates enough thermodynamic importance of the saturated state.

In this back ground, though we should have no objection to call the concentration potential by any other name for any good reasons, we fail to see why it should not be called so as at present.

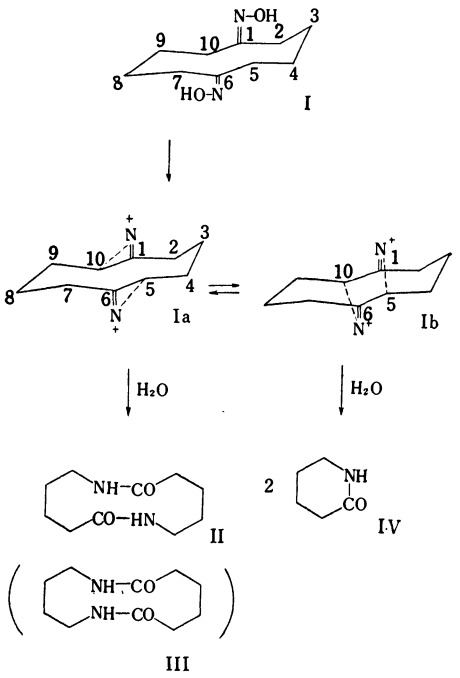
A Transannular Beckmann Rearrangement in Liquid Sulfur Dioxide



By Niichiro Tokura, Ritsuro Tada and Kunio Suzuki

(Received April 15, 1959)

In medium sized alicyclic compounds, transannular reactions have often been observed[1-3]. This communication is concerned with an abnormal Beckmann rearrangement, the nature of which should be attributed to a novel transannular type of reaction.

When cyclodecane-1,6-dione dioxime (I) reacted with sulfur trioxide in liquid sulfur dioxide at room temperature for twelve hours, followed by elimination of sulfur dioxide by evaporation and addition of ice water to the reaction residue, a hitherto unreported cyclic oligomer of δ-valerolactam, 1,7-diaza-6,12-dioxocyclododecane (II) (yield 75%), separated out as fine crystals, m.p.(purified by sublimation) 264~266°C (Found: N, 13.9%. Calcd. for $C_{10}H_{18}O_2N_2$: N, 14.1%; mol. wt. Found: 215. Calcd. 198; ninhydrin test, negative[4]; I. R. ν_{max}^{KBr}: 1650 (CO), 3280 (NH) cm^{-1}). The I. R. spectrum of II closely resembles the spectra of cyclic oligomers of ε-caprolactam[4]. As we could find no diamine or dicarboxylic acid in the acid hydrolyzed product of II, absence of III (another possible product of rearrangement) in the reaction mixture was proved.

However, when the reaction was carried out with thionyl chloride in place of sulfur trioxide in liquid sulfur dioxide similarly as described above, followed by extraction with chloroform and evaporation of the solvent, I afforded a brown viscous nitrogen-containing liquid (27%), the structure of which was difficult to be identified. The residual solution after the extraction was made slightly alkaline with sodium hydroxide and again extracted with chloroform. The chloroform solution was condensed and the residue was subjected to distillation in vacuo. A yellow oil(IV) b.p. 90~93°C(2mmHg) was obtained. IV was identified as δ-valerolactam (33%),

n_D^{17}=1.5339 (Found: N, 13.8%. Calcd. for C_5H_9ON: N, 14.1%, N-(4-carboxyl butyl) phthalimide, m. p. and mixed m. p. with an authentic specimen, 117.5~118.5°C[5]). Its I. R. spectrum also coincided with that of IV described in the literature[6]. That δ-valerolactam (IV) was not a secondary product derived from II was demonstrated when II reacted in liquid sulfur dioxide with thionyl chloride at room temperature. No appreciable formation of IV was observed.

As the distances between the nitrogen atoms and carbon atoms (C_5 and C_{10}) are sufficiently close to permit an equilibrium state between the structures Ia and Ib, the latter being favored by thionyl chloride, the completion of the rearrangement, involving cleavage of C_1-C_{10} and C_5-C_6 linkages, gives rise to formation of IV. In such a case, a transannular Beckmann rearrangement is the most plausible explanation for the formation of IV from I in liquid sulfur dioxide.

The authors wish to thank the Befu Chemical Industries Co. for the donation of liquid sulfur dioxide.

NMR Spectra of Formals, Acetals and the Related Compounds

By Kenkichi NUKADA and Utako MAEDA

(Received April 22, 1959)

It is interesting to study the NMR spectra of formals (R_1-O-CH_2-O-R_2), acetals (R_1-O-CH(CH_3)-R_2) and the related compounds (H-C(OR)$_3$ and R-(O-CH_2-CH_2)$_n$-OR), as these compounds contain functional groups such as CH_3-O, CH_3-CH_2-O, O-CH_2-CH_2-O, O-CH_2-O, H-C(O)(O)-CH_3, etc. It is quite difficult, or sometimes perfectly impossible, to identify some of these functional groups by the infrared spectroscopy[1]. We have tried to identify them by the high resolution NMR spectroscopy[2]. JNM-3 (Japan Electron Optics Laboratory Co.) and 4300-B (Varian Associates) spectrometers were used.

Fig. 1 shows the NMR spectra of benzene solutions of several compounds except dimethyl acetal (CH_3-O-CH(CH_3)-O-CH_3), acetal (C_2H_5-O-CH(CH_3)-O-C_2H_5) and diethylene-glycol diethyl ether (C_2H_5-(O-CH_2-CH_2)$_2$-O-C_2H_5). The spectra of these three compounds were obtained in pure liquid phase and reference bands are shown with arrows on the peaks of each spectrum. The unit of abscissa means the chemical shift from the signal of benzene protons. The tentative assignments are shown on the tops of each peak.

TABLE I. THE VALUES OF CHEMICAL SHIFTS OF FUNCTIONAL GROUPS

Type of group	Chemical shift from benzene protons ($\times 10^{-7}$)
H-C(O)(O)(O)	21.3
(H)-C(O)(O)-CH_3	27.5
O-CH_2-O	27.8±1.0
O-CH_2-C	37.8±2.0
CH_3-O	40.3±0.8
(CH_3)-C(O)(O)-H	62±2
(CH_3)-CH_2-O	61±3

A New Compound of Tin(IV) with 8-Quinolinol and its Use in Gravimetric Analysis

By Hiroshi Hamaguchi, Nagao Ikeda and Kazuya Osawa

(Received May 8, 1959)

Shiba[1] reported that tin(II) was precipitated with 8-quinolinol (oxine) from dilute ammoniacal solution. As to the oxinate of tin(IV), Gentry and Sherrington[2] found that tin(IV) was extractable by oxine chloroform solution. They estimated the formula of the extractable oxinate of tin to be $Sn(C_9H_6NO)_4$. No report has been published, however, on the formation of a stable precipitate of oxine compound of tin(IV).

According to the present authors' experiments, tin(IV) is precipitated quantitatively from 0.2 N hydrochloric acid solution by adding oxine solution, but at the other concentrations of hydrochloric acid, the precipitation is not complete, as is shown in Fig. 1.

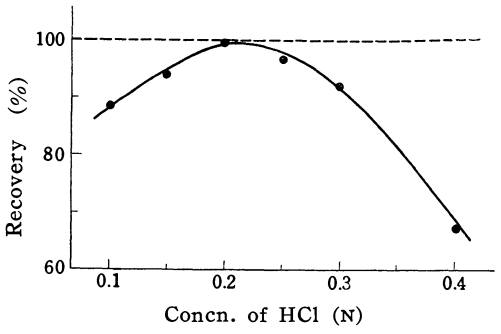

Fig. 1. Effect of hydrochloric acid concentration on the precipitation of tin(IV) oxinate.

The color of the precipitate is brilliant yellow. The compound is stable against heating at least up to 360°C. It is insoluble in mineral acid or alkaline solutions except for concentrated sulfuric acid. It is also insoluble in ordinary organic solvents. The chemical composition of the precipitate is as follows:

Anal. Found: Sn, 24.9; Cl, 15.2; C, 45.05; H, 2.63; N, 5.68*. Calcd. for $SnCl_2(C_9H_6NO)_2$; Sn, 24.8; Cl, 14.8; C, 45.2; H, 2.54; N, 5.87%.

The ionic species of tin(IV) in 0.2 N hydrochloric acid solution was examined by the aid of ion-exchange resin (Dowex 50), and it was found the charge of the species to be +2, which seems to justify the above mentioned chemical composition of the compound.

The application of this compound to the gravimetric determination of tin was then examined. The recommended procedure is the following.

Adjust the acidity to 0.2 N hydrochloric acid. Add the same volume of 2% oxine solution**. Keep the solution at 70~90°C for 1.5~2 hr. Filter with a glass filter, wash with 3 N hydrochloric acid, dry at 110~120°C and then weigh as $SnCl_2(C_9H_6NO)_2$.

Table I. Determination of tin as oxinate

Sn taken (mg.)	Sn oxinate (mg.)	Sn found (mg.)	Error (mg.)
1.00	3.5	0.87	0.13
1.99	8.0	1.99	0.00
2.99	11.9	2.96	0.03
4.98	19.2	4.77	0.21
9.96	39.5	9.81	0.15

Some results are shown in Table I. No metallic salt except molybdenum interferes. Bismuth and antimony should be absent because of their hydrolysis in the condition of the procedure. Presence of nitrate or phosphate leads to the hydrolysis of stannic ions. The precipitate of oxinate is not formed under the presence of tartrate.

*Chemical Shifts of the Proton Magnetic Resonance in Alkylhydroperoxides**

By Shizuo FUJIWARA, Mikio KATAYAMA and Shinichi KAMIO**

(Received May 12, 1959)

Chemical shifts of the proton magnetic resonance in alkylhydroperoxides were measured in order to obtain the NMR informations of these compounds which have not been reported. The samples are listed in Table I with their characteristic data. All of them except *tert*-butylhydroperoxide were synthesized by one of us (S. K.) according to the methods reported by Williams and Mosher[1]. The *tert*-butylhydroperoxide was obtained commercially from the International Chemical Company.

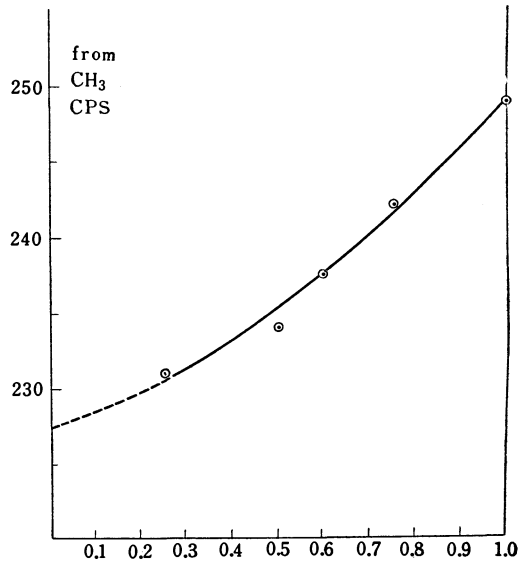

TABLE I. SAMPLES OF NMR MEASUREMENTS

n-Propyl hydroperoxide	35°C/20 mm.	$n_D^{25}=1.3890$
n-Butyl hydroperoxide	28~29°C/5 mm.	$n_D^{20}=1.4057$
sec-Butyl hydroperoxide	41~42°C/11 mm.	$n_D^{20}=1.4050$
n-Amyl hydroperoxide	41~42°C/4 mm.	$n_D^{20}=1.4146$
n-Octyl hydroperoxide	64~66°C/0.7 mm.	$n_D^{20}=1.4311$

tert-Butylhydroperoxide was obtained commercially.

The apparatus used for the measurements of the chemical shifts is the one constructed in this laboratory using the permanent magnet manufactured by the Indiana Steel Company and the resonant frequency is about 27.030 Mc. (H_0=6300 gauss). The chemical shift of the OOH proton resonance in each compound was measured as the separation from CH_3 signal appearing as the peak in the highest field on the recorded charts taking the cyclohexane and benzene mixture (0.28 g. +0.30 g.) as the reference to show the separation of 227 cps. at 40 Mc.

According to the results of the measurements, the resonant positions for the OOH protons are in the field lower than those for CH_3 by about 245 (±5) cps., being close to the value for COOH proton in aliphatic acid, 267 (±3) cps. for *n*-butylric acid, or about 280~230 cps.[2], and less shielded than the OH protons in alcohols which were measured as 120 (±5) cps. or 120~100 cps[2]. The propylhydroperoxide showed a very small value of 222 (±5) cps., and this was assumed to be due to the decomposition of the compound. The figures showing the variations of the observed data are due to the overlapping and the incomplete separation of the signals of CH_3 and CH_2's.

Mol. fraction of *n*-butyl HPO in CCl_4

Fig. 1

In order to investigate the effects of the decomposition of the samples, the concentration dependence of the shifts were measured for the carbon tetrachloride solutions of the *n*-butylhydroperoxide.

* Presented before the 12th Annual Meeting of the Chemical Society of Japan in April, 1959.

** Railway Technical Research Institute, Japanese National Railways, Minato-ku, Tokyo, Japan.

1) H. R. Williams and H. S. Mosher, *J. Am. Chem. Soc.*, 76, 2984 (1954).

2) These values were obtained from Fig. 6 in the article given by N. F. Chamberlain, *Anal. Chem.*, 31, 56 (1959).

The results are as shown in Fig. 1, it is seen that the OOH signal is shifted to the lower field with the increase of the concentration of the hydroperoxide, and this result will be interpreted in terms of the destruction of the structures of associated molecules as in the cases of other hydrogen-bonded liquids[3,4]. The susceptibility corrections are not made in the results of Fig. 1. Since the concentration dependence is so large that the results of the measurements with one another shifts are to be compared to each other at the same conditions of concentration. As the hydroperoxides are unstable and, moreover, it is rather difficult to determine their concentrations, we made the measurements immediately after the preparation of the samples. Hence, the results of Fig. 1 are assumed to refer to those for the actually pure hydroperoxides which are not so much different from one another in the concentration. It is also noted that α-CH_2 protons in all the samples fall in almost same position of about 79 ($\pm$1) cps. away from CH_3. Since the α-CH_2 protons in alcohols with the same carbon number as the samples showed the value of 65 ($\pm$2) cps., we notice that α-CH_2 protons in hydroperoxides are less shielded than those in alcohols as well as OOH protons. In comparison with aliphatic acids, the COOH protons which are expected to be away from CH_3 by about 275~230 cps.[2] are, as noted above, very close to the OOH protons in hydroperoxides, while α-CH_2 protons in acids are only 35 cps.[2] away from CH_3 and more shielded than those in hydroperoxides and in alcohols. Therefore, it is a quite interesting problem to investigate the chemical characters of alcohols, hydroperoxides and acids from the viewpoint of structures and of electronic distributions of OH, OOH and COOH groups.

The Roles of Prolyl Residue in Polypeptide Monolayers. II. On the Surface Viscosity and Types of Monolayers

By Shoichi IKEDA and Toshizo ISEMURA

(Received November 17, 1958)

In the preceding paper[1] we have described the effects of prolyl residue in polypeptide monolayers revealed in the surface pressure and potential behavior and deduced their roles in the chain configuration, chain flexibility and intrachain interaction in the polypeptide monolayers. It was found that, as for the polypeptides examined, the presence of prolyl residues makes the monolayers more expanded as their content becomes increased, in spite of the peptide carbonyl groups having the same orientation at the interface. (However, the carbonyl groups in poly-L-proline film are oriented in a different manner.) This expanded nature of monolayer was attributed to the flexible chain configuration of polypeptide arising mainly from the decrease in number of hydrogen bonds. Conversely, the ordinary non-electrolytic polypeptide forms a monolayer of condensed type due to its rigidly held configuration with the strong intrachain hydrogen bonds.

In the study of monolayer the measurement of surface viscosity also gives information concerning its structure and other characteristics. Cumper and Alexander[2], and also Isemura and Hamaguchi[3] established the β-configuration in monolayers of non-electrolytic polypeptides from the surface viscosity measurement. Later, it was noticed[4] that in the monolayer of an amphoteric polypeptide the surface viscosity rises even at the area of low surface pressure if the pH of the aqueous subphase is near the isoelectric point, while the surface viscosity rises at the area of high surface pressure on either side of this pH. Generally, the former behavior appears to be observed in the monolayer of condensed type and the latter in that of expanded type. Such aspects of surface viscosity may be expected in the monolayers of polypeptides with the various proportions and arrangements of prolyl residues and may be related to their chain configuration, chain flexibility and intrachain hydrogen bonding.

In this paper we will report the results of surface viscosity measurements for poly-DL-alanine, poly-L-prolyl-L-leucylglycine and copoly-1:1:1-(L-proline, L-leucine, DL-alanine) and give a further confirmation of inferences obtained from the surface pressure and potential measurements.

Experimental

Materials.—The polypeptide samples were poly-DL-alanine, poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) which were the same as those reported in the preceding paper[1]. Their degrees of polymerization and spreading solvents were as follows:

	D. P.	Spreading solvent dichloroacetic acid-benzene
Poly-DL-alanine	300	1 : 9
Poly-L-prolyl-L-leucylglycine	13	1 : 4
Copoly-1:1:1-(L-proline, L-leucine, DL-alanine)	129	1 : 4

Methods.—The lower portion of surface pressure was measured by a surface balance of float type and the higher portion (for the other two polypeptides) by a surface balance of hanging plate type. The surface pressures measured by these two balances were ascertained to be identical in the cases of the latter two polypeptides.

Surface viscosity was measured by the damped rotatory oscillation of a disk, utilizing the relation

$$\eta=\frac{2.303I\cdot\Delta\lambda}{2\pi P}\left(\frac{1}{a^2}-\frac{1}{b^2}\right)$$

where I is the moment of inertia of the disk, P the period of oscillation, $\Delta\lambda$ the difference between logarithmic decrements of oscillation in the presence of film and in its absence, a the radius of disk and b the distance between the center of disk and the edge of trough. Usually an outer edge concentric with the disk is put on the aqueous surface in order to calculate surface viscosity by means of the above formula, but its

use makes the reproducibility of measurement unsatisfactory for the monolayer of condensed type such as poly-DL-alanine, because it is difficult for it to flow into the annular region under high compression and it makes a heterogeneous film. It was found that substantially equal values of surface viscosity can be obtained for monolayers of expanded type such as copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) whether the concentric edge is put on or not. Hence, all the measurements were carried out on the surface without concentric edge. In the present apparatus, I was measured to be 43.45 g. cm^2, P 7.50 sec., a 1.28 cm. and b 7.00 cm. and the measurable range of surface viscosity was 10^{-3} to 2×10^{-1} surface poise, where the flow was Newtonian.

To regulate the temperature, a glass serpentine coil was put in the trough, through which water at constant temperature was passed from a thermostat.

Results

The surface pressure-area (Π-A) and surface viscosity-area (η-A) curves of poly-DL-alanine are shown in Fig. 1. The monolayer is of condensed type. Surface

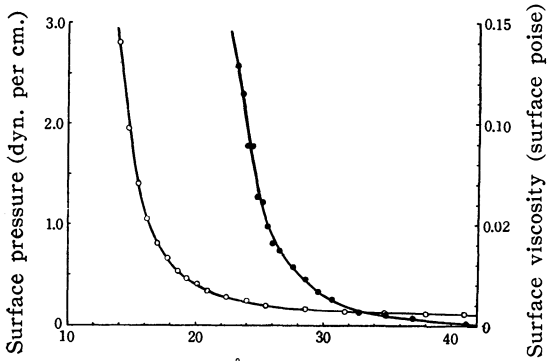

Fig. 1. The surface pressure-area (○) and surface viscosity-area (●) curves of poly-DL-alanine at 9°C.

viscosity begins to rise at the area of 42 Å^2 per residue and gelates at 22 Å^2 per residue and at the surface pressure lower than 0.3 dyn. per cm. Surface viscosity of poly-DL-alanine could be readily measured at room temperature. It appears to be slightly affected by temperature and to increase with the rise of temperature. However, its temperature dependence was not reproducible.

The Π-A and η-A curves of polyl-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) are shown in Figs. 2 and 3, respectively. Both films are of expanded type. While their close-packed areas are 57 and 46 Å^2 per three amino acid residues, respectively, both surface

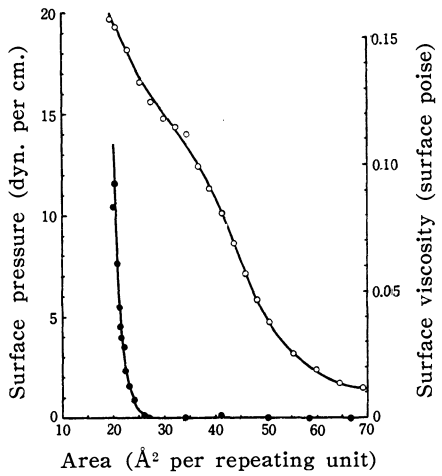

Fig. 2. The surface pressure-area (○) and surface viscosity-area (●) curves of poly-L-prolyl-L-leucylglycine at 16.7°C.

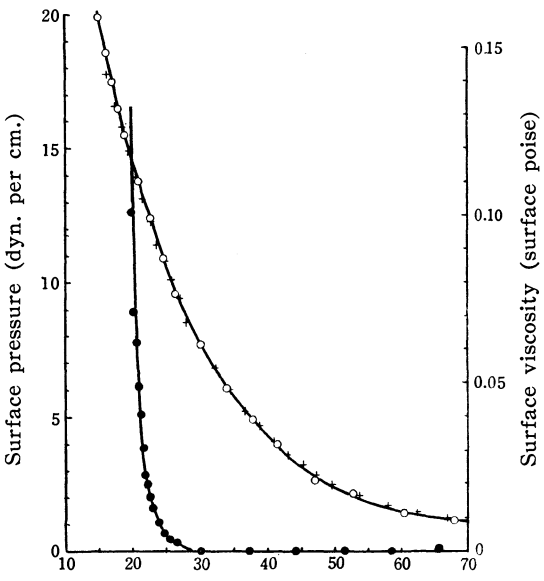

Fig. 3. The surface pressure-area curve (○, at 10.8°C; +, at 26.4°C) and the surface viscosity-area curve (●, at 16.7°C) of copoly-1:1:1-(L-proline, L-leucine, DL-alanine).

viscosities rise at the area less than about 29 Å^2 per three amino acid residues. The corresponding surface pressures range over 15 to 21 dyn. per cm. for the former polypeptide and over 10 to 16 dyn. per cm. for the latter, as the latter film is more expanded than the former. Thus these two polypeptides show almost the same behavior in surface viscosity, irrespective of their different behaviors in surface pressure.

It should be added here that surface

viscosities of these two polypeptides rise at such a small area that films can not occupy an area large enough to spread as complete monolayers. They were initially spread on the surface with an area therefore of about 80 Å^2 per three amino acid residues which is not a sufficiently large area compared with the close-packed areas, and the *Π-A* curves in Figs. 2 and 3, therefore, shift to a smaller area than those obtained when spread on larger areas. The film of copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) was readily compressed even in the high surface pressure region, but the film of poly-L-prolyl-L-leucylglycine required some minutes after compression to establish the final surface pressure.

Surface viscosities of poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) were found to be markedly dependent of temperature. They were quite reproducible and, to some extent, reversible for compression and expansion. The variation of *η-A* curves with temperature are shown in Figs. 4 and 5, for the respective polypeptide. The higher the temperature is, the lower is the surface viscosity. Both values of surface viscosity and their temperature dependence are almost identical for these two polypeptides. However, as illustrated in Fig. 3, surface pressure was not changed by temperature.

Discussion

Surface Viscosity as a Function of Surface Pressure. — It was noticed that surface viscosity of poly-DL-alanine film is already high at the area where surface pressure is sufficiently low and surface viscosities of the other two polypeptide films are detected at the area where surface pressures are considerably high. In other words, surface viscosity of condensed film is actually measured for the monomolecular layer, but that of expanded film is presumably for folded monolayer. Such a difference in surface viscosity was already pointed out by Isemura and Hamaguchi[4] for the film of an electrolytic copolypeptide. It may be attributed to

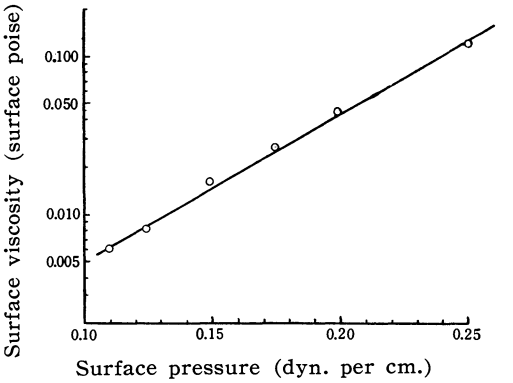

Fig. 6. The log *η-Π* curve of poly-DL-alanine.

the difference in chain configurations of spread polypeptides.

The monolayer of poly-DL-alanine is of condensed type. It was found that for the condensed films of fatty acids[5] and their mixtures[6] the logarithm of surface viscosity is in a linear relation to surface pressure. As shown in Fig. 6, the poly-DL-alanine monolayer follows the same relation as fatty acid films over the region of temperature, 8 to 12°C, and of area, 24 to 34 Å^2 per residue, although the surface pressure at which surface viscosity was measured is much lower. This relation is expressed by

$$\log \eta = \log K + c\Pi \qquad (1)$$

where $\log K$ and c are constants, the values of which are shown in Table I.

TABLE I

	$\log K$	c	B

Poly-L-Pro-L-Leu-Gly	−22.5	0.46	3560
Copoly-(L-Pro, L-Leu, DL-Ala)	−17.3	0.33	3370

On the other hand, poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) give monolayers of expanded type. It was observed[7] that for the expanded monolayer of polyvinyl acetate the logarithm of surface viscosity changes also linearly with surface pressure at constant temperature. Joly[8] has tabulated the values of surface viscosity as a function of surface pressure for various protein films. These films are probably of expanded type, as they are spread on 0.01 N hydrochloric acid and will be ionized completely. If these values are plotted on a semilogarithm scale, again linear relations are obtained, particularly for the film of gliadin. As shown in Figs. 7 and 8, the films of the two polypeptides also follow the linear relation over the region of temperature, 5 to 30°C, and of area, 21 to 24 Å^2 per three amino acid residues. The relation is written as

$$\log \eta = \log \mu + c\Pi \qquad (2)$$

where c is a constant but $\log \mu$ is a function of temperature, as seen in Table II. Further, the temperature dependence of $\log \mu$ is found to be given by

$$\log \mu = \log K + B/T \qquad (3)$$

where $\log K$ and B are constants, the

values of which are also shown in Table II.

Surface Viscosity as a Function of Temperature. — As mentioned before, surface viscosity of poly-DL-alanine monolayer scarcely varies with temperature but tends to increase slightly as temperature is raised. This appears to be a general aspect of the monolayer of condensed type.

For the films of poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) surface viscosities diminish as temperature rises and it was found that plots of logarithm of surface viscosity against the inverse of temperature are linear over the region of temperature, 5 to 30°C, and of areas, 21 to 24 Å^2 per three amino acid residues, as illustrated in Figs. 9 and 10. That is, the relation is fitted to the Andrade equation

$$\log \eta = \log \nu + B/T \qquad (4)$$

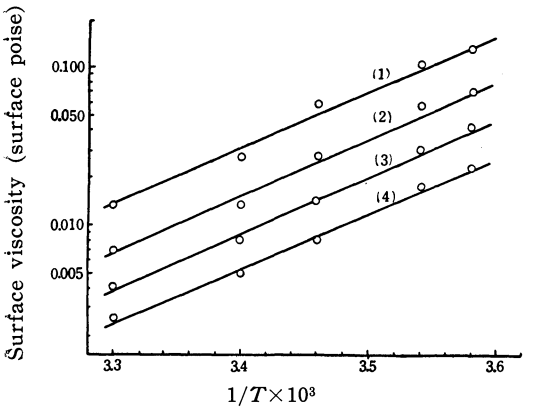

Fig. 9. The $\log \eta - 1/T$ curves of poly-L-prolyl-L-leucylglycine at various areas (at various surface pressures). Curves (1) 21.0 Å^2, (2) 22.0 Å^2, (3) 23.0 Å^2 and (4) 24.0 Å^2.

11.4	−13.66	3390	

where B is a constant but $\log \nu$ depends on surface pressure. This has already been established for films of polyvinyl acetate[9] and 6-nylon[10], although the dependence of $\log \nu$ on surface pressure is not explicitly indicated. The values of B and $\log \nu$ are given in Table III. It can be seen that $\log \nu$ is represented by

$$\log \nu = \log K + c\Pi \qquad (5)$$

as a function of surface pressure, where both $\log K$ and c are constants the values of which are also shown in Table III.

From the data given in Tables II and III, numerical coincidences may be noticed between $\log K$ in Eqs. 3 and 5, between c in Eqs. 2 and 5 and between B in Eqs. 3 and 4. Consequently, the surface viscosity equation is reduced to

$$\log \eta = \log K + c\Pi + B/T \qquad (6)$$

for the films of poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine). Values of constants are listed in Table I. The values of B for these two polypeptides are found to be almost equal to each other, which should be the necessary condition for the equal temperature coefficient of surface viscosity.

Configuration and Flexibility of Polypeptide Chains. — In comparing the close-packed area with the area where surface viscosity was measured, it will be evident that surface film in this region corresponds to liquid or melt in bulk rather than to dilute solution, and accordingly, surface viscosity to viscosity of liquid or melt. It is generally accepted that a transition takes place at the glass temperature or the second-order transition temperature for polymers, below which the segmental motion becomes frozen-in. The segmental motion is exhibited in the behavior of

9) T. Isemura and K. Fukuzuka, *Mem. Inst. Sci. Ind. Res., Osaka Univ.*, 14, 169 (1957).
10) K. Inokuchi, This Bulletin. 28, 453 (1955).

melt viscosity[11]. At the transition temperature melt viscosity decreases markedly with the rise of temperature. While above the transition temperature melt viscosity alters with temperature in such a way as expressed by the Andrade equation, below that temperature it is not influenced by temperature very much but rather depends on other complicated factors[12]. The temperature at which such freezing-in of the segmental motion will occur depends on the structural factors such as inter- or intrachain interaction, chain flexibility or steric effect. Then at a given temperature a polymer will behave as liquid or glass whether that temperature is higher or lower than the glass temperature. This idea can be adequately applied to explain the observed behavior of surface viscosity of monolayer. Thus the monolayers of expanded type and condensed type might be correlated reasonably with a melt and glassy state in bulk, respectively. In other words, a spread polymer which gives a film of expanded type will behave as an ordinary liquid at the temperature where film properties are measured, since the segmental interaction is weak and the molecular chain is flexible; also the segmental motion of a spread polymer in a film of condensed type is inhibited at that temperature, since the chain is rigidly held owing to the strong segmental interaction. The difference is revealed most distinctly in surface viscosity behavior.

Eyring et al.[13,14] derived the surface viscosity equation by a simple analogy with liquid viscosity, regarding monolayer as a two-dimensional liquid. According to them, surface viscosity is expressed by

$$\eta = \frac{\boldsymbol{h}}{A_f} \exp\left(\frac{\Delta F^{\ddagger}}{\boldsymbol{k}T}\right) \tag{7}$$

where $\boldsymbol{h}$ is the Planck constant, $\boldsymbol{k}$ the Boltzmann constant and A_f is the area occupied by a unit of flow. The free energy of activation for flow per unit, $\Delta F^{\ddagger}$, is given by

$$\Delta F^{\ddagger} = \Delta E^{\ddagger} + \Pi \Delta A^{\ddagger} - T\Delta S^{\ddagger} \tag{8}$$

where $\Delta E^{\ddagger}$ and $\Delta S^{\ddagger}$ are the energy and the entropy of activation per unit, respectively, and $\Delta A^{\ddagger}$ is the increment of area in the activated state over that of the initial state. Substituting Eq. 8 into Eq. 7, the final equation becomes

$$\ln \eta = \ln \frac{\boldsymbol{h}}{A_f} - \frac{\Delta S^{\ddagger}}{\boldsymbol{k}} + \frac{\Delta A^{\ddagger}}{\boldsymbol{k}T}\pi + \frac{\Delta E^{\ddagger}}{\boldsymbol{k}T} \tag{9}$$

This equation has the same form as Eqs. 1 and 6. From their comparison it can be seen that

$$\Delta E^{\ddagger} = 2.303\,\boldsymbol{k}B \tag{10}$$

$$\Delta A^{\ddagger} = 2.303\,\boldsymbol{k}Tc \tag{11}$$

$$\frac{\boldsymbol{h}}{A_f} \exp\left(-\frac{\Delta S^{\ddagger}}{\boldsymbol{k}}\right) = K \tag{12}$$

Thus $\Delta E^{\ddagger}$ and $\Delta A^{\ddagger}$ may be calculated from the data in Table I. Although the value of $\Delta S^{\ddagger}$ can not be determined uniquely from a single experimental value of log K, its approximate value may be assigned, as it is not very sensitive for the choice of values of A_f. Table IV shows these data for the polypeptide films studied in the present investigation.

TABLE IV

	$\Delta E^{\ddagger}$ (kcal./mol.)	$\Delta A^{\ddagger}$ (Å^2)	$\Delta S^{\ddagger *}$ (e. u.)
Poly-DL-Ala	0	8000	$-110 \sim -120$
Poly-L-Pro-L-Leu-Gly	16.3	420	$-21 \sim -29$
Copoly-(L-Pro, L-Leu, DL-Ala)	15.4	300	$-45 \sim -50$

* Values when A_f is assumed to be 10 Å^2 to $\Delta A^{\ddagger}$

For the monolayer of poly-DL-alanine, $\Delta E^{\ddagger}$ was found to be nearly zero. This suggests that the flow mechanism is different from that in liquid state and the polypeptide molecules flow under shear by breaking the entanglement or linkages such as van der Waals or hydrogen bonds between them. This may be expected from the discussion above that such a flow occurs for the film of polypeptide in which the segmental interaction is strong and the rigidity of the chain is high. This result is consistent with that deduced for the condensed nature of this film in the previous paper[1]. Further support is provided by estimating the value of $\Delta A^{\ddagger}$, which was found to be about 8000 Å^2 per flow unit. Since the close-packed area of poly-DL-alanine is 15 Å^2 per residue, the area obtained above is occupied by about 500 residues. Taking account of the ambiguity concerning the degree of polymerization of material, 300, it may be roughly assumed that a unit of flow is composed of a poly-DL-alanine molecule. In addition, a large

11) T. Alfrey, G. Goldfinger and H. Mark, *J. Appl. Phys.*, **14**, 700 (1943); E. Jenkel, *Kolloid-Z.*, **120**, 160 (1951).
12) K. Ueberreiter and H. J. Orthmann, ibid., **126**, 140 (1952).

negative value for $\Delta S^{\ddagger}$, -120 e. u., was assigned to the polypeptide. In view of the deduction concerning dependence of the entropy of activation for flow in bulk on chain length of polymers[15] and the result on surface viscosity of polyvinyl acetate[7], the entropy of activation for flow in film might be scarcely influenced by the degree of polymerization of polymers, that is, the term involving the degree of polymerization contributes to the entropy only a few e. u. Then the large negative value for $\Delta S^{\ddagger}$ should be characteristic of the monolayer of poly-DL-alanine. It might be attributed to the highly disordered configuration of flow unit or molecule of poly-DL-alanine at the interface. Probably the spread molecule is coiled and held together in monolayer.

On the other hand, for the films of poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) values of $\Delta E^{\ddagger}$ are not zero but 16.3 and 15.4 kcal. per mole, respectively, and nearly equal to each other. These are of comparable order of magnitude with those reported, namely, 12.7 kcal. per mole for the film of polyvinyl acetate[9] and 6.4 kcal. per mole for the film of 6-nylon[10], although the sizes of their unit of flow will be different from one another. But the larger values for these two polypeptides than the other might come from the additional energy necessary for breaking (more) hydrogen bonds when units of flow move. The values of $\Delta A^{\ddagger}$ were 420 and 300 $Å^2$ per three amino acid residues, respectively. The size of flow units can not be estimated in the same way as above, as the viscous flow takes place at such small areas that they do not always correspond to a monomolecular layer. The polypeptide chains are probably in a folded configuration partly submerged into the aqueous subphase in these areas. The small negative values of $\Delta S^{\ddagger}$, -25 and -50 e. u., respectively, would be an indication of the relatively regular configuration of chains. Both the mechanism of flow through the activation process and the regular folding of chains under compression favor the weak interaction and the flexibility of chains. This supports the results obtained in the previous paper[1].

All the differences in surface viscosity behavior between poly-DL-alanine and the other two polypeptides are based on the types of monolayers, namely, the nature of condensation and expansion of films. The types of monolayers depend on the structural factors defined by the proportion and arrangement of prolyl residues in polypeptide chains. But the surface viscosities and their temperature dependences were found to be equal to each other for poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine), which will originate from their identical chain configurations, irrespective of their different amino acid sequences in chains. The fact that the surface pressure of the former polypeptide is higher than that of the latter and shows some time effect. will mean that the former chain folds itself by compression with greater difficulty, as described in the preceding paper[1].

Summary

To investigate the roles of prolyl residue in polypeptide monolayers, surface viscosity was measured for the monolayers of poly-DL-alanine, poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine).

For the monolayer of poly-DL-alanine which is of condensed type, the surface viscosity was found to rise at the area larger than the close-packed area and scarcely to be dependent of temperature. This result was correlated with that observed in the glassy state of polymers in bulk and interpreted by assuming that the polypeptide chain is rigid owing to the strong interaction. For the films of the other two polypeptides which are of expanded type appreciable surface viscosities were manifested at the areas much smaller than their close-packed areas and temperature exerted marked influence on surface viscosities. Their chain configurations were considered to be flexible owing to the weak interaction, since the flows in films occur as in melt of polymers in bulk.

Further evidence for this inference was obtained from the results on dependences of surface viscosity on surface pressure and temperature. The dependences were found to follow Eyring's equation of surface viscosity. It was found that in the monolayer of poly-DL-alanine a unit of flow is roughly composed of a molecule and its chain is rather coiled at the interface, but the chains of the other two polypeptides are in a regularly folded configuration partly submerged into the

15) W. Kauzmann and H. Eyring, *J. Am. Chem. Soc.*, **62**, 3113 (1940). See also Ref. 14, p. 501.

aqueous phase when compressed, as they are flexible.

The difference in surface viscosity behavior between poly-DL-alanine and the other two polypeptides was related to the condensed and expanded nature of films, which is defined by the content and distribution of prolyl residues in polypeptide chains. It was, however, observed that poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) exhibit the same surface viscosity behavior, irrespective of their different distribution of prolyl residues in chains, while the former has a higher surface pressure than the latter.

All the results obtained were found to confirm the view deduced from the surface pressure and potential measurements.

Role of Dielectric Constant at the Miscibility Point in the Ternary System 2-Propanol-Water and Carbon Tetrachloride

By C. V. SURYANARAYANA and K. M. SOMASUNDARAM

(Received December 26, 1958)

Two liquids are known[1] to be miscible in all proportions when both are sufficiently alike to obey Raoult's law. Only when the internal forces are quite unlike, separation of two liquid phases is known to occur. The fundamental question underlying all problems relating to solubility is the nature and the strength of intermolecular forces. The thermodynamic condition for equilibrium in any system is that the total free energy should be a minimum. If separation into two layers minimises the free energy of the system, it will happen so. Deviations from ideal behavior occur either owing to lowering the temperature or by choosing components more unlike in attractive forces. Either of these changes, when pursued far enough, can bring about a separation into two liquid phases.

A new outlook is developed in the following investigations. The work of Coomber[2] and McC. Lewis[3] shows that dielectric constant of a liquid system is related to its internal pressure. To an inhomogeneous mixture of two liquids progressive addition of a third component which happens to mix with both the liquids entails in a distribution of the added component between the two layers. With successive additions of the third component there is to be expected, as a result of the distribution between the two phases a progressive variation of the physico-chemical properties in the two layers. Just at the miscibility point these properties in the respective layers should tend to a limit at which the phase boundary just disappears forming a homogeneous system. Since internal pressure is connected with the dielectric constant (loc. cit.), at the transition when the phase boundary disappears, we may expect a quantitative relationship among the values of dielectric constant of the solution and those of the three pure components. The ternary system 2-propanol–water–carbon tetrachloride has been studied from the above point of view. We have reported[4] earlier our results on the ternary system 1-propanol–water–toluene.

Experimental

Preparation of solutions, measurements of dielectric constant, density and viscosity were done as given in our previous paper (loc. cit., this bulletin).

Purification of the Components.—E. Merck's purest 2-propanol was refluxed[5,6] with an excess of freshly burnt calcium oxide and distilled. The distillate was dried over small pieces of magnesium ribbon and fractionally distilled. The fraction boiling at 82.4°C was collected and stored in a pyrex bottle. E. Merck's pro analysi carbon tetrachloride was distilled, the distillate boiling at 76.8°C was collected and stored in a Pyrex bottle. Conductivity water was distilled once more in a Pyrex outfit and this was preserved free from carbon dioxide. A dielectric constant check was made now and then. This was used throughout the investigation.

All the experiments were performed at 35°C. Results obtained are given in Tables I to VI.

Discussion

In our previous publication in this bulletin[4] on the ternary system 1-propanol-water-toluene we had derived the equation

$$\sum_k L_k x_k = L_{1,2\ldots k} \qquad (1)$$

where L_k is the volume polarization of the k-th component, $L_{1,2\ldots k}$, that of the mixture of k components and x_k, the mole fraction. This derivation was made on the usual assumption of isomegethic solutions as done in some theories of solutions which means that

$$\bar{v}_1 = \bar{v}_2 = \cdots\cdots = \bar{v}_k \qquad (2)$$

On this assumption,

$$V_k = \frac{v_k}{\sum v_k} = \frac{n_k \cdot \bar{v}_k}{\sum n_k \cdot \bar{v}_k} = \frac{n_k}{\sum n_k} = x_k$$

But the above assumption 2 is not correct with real solutions. We rarely meet with solutions wherein the molecules of the components have the same molar volume. We shall now consider the consequences of this assumption.

Turning to the experimental values, Table II shows that Eq. 1 holds excellently well at the point of disappearance of the phase boundary, whereas the well known equation.

$$\sum_k P_k \cdot x_k = P_{1,2\ldots k} \qquad (3)$$

fails thoroughly.

5) A. I. Vogel, "Practical Organic Chemistry", Longmans, 2nd Ed., London (1951), p. 168.
6) A. A. Maryott, *J. Am. Chem. Soc.*, **63**, 3079 (1941).

Comparison of Tables IV and VI shows that in the case of 2-propanol–water system both Eq. 1 and 3 hold excellently, whereas with 2-propanol–carbon tetrachloride system both the Eq. 1 and 3 are inapplicable. Akerlöf[7] determined the dielectric constants of mixtures of 2-propanol–water at 25°C. Our data in Table III were collected at 35°C.

In this laboratory[8] the general observation made was that in about thirteen ternary systems investigated so far, Eq. 3 fails thoroughly while Eq. 1 succeeds just at the point of disappearance of the phase boundary. Further in polar-polar binary mixtures both Eqs. 1 and 3 are applicable, whereas in polar-nonpolar binary combinations both Eqs. 1 and 3 fail. From these observations one conclusion can be drawn, that Eq. 1 is in now way better than Eq. 3 in general but the former seems to be holding excellently at the transition of disappearance of the phase boundary.

We have pointed out above that the derivation of Eq. 1 assumes that the molar volumes of the participating species of molecules must be the same, which is not really so, as far as the three components 2-propanol, water and carbon tetrachloride are concerned. Even then, if Eq. 1 should hold good specially at the transition of disappearance of the phase boundary, one has to conclude that at the transition when the two phases should disappear, conversely one should obtain the condition that the molar volumes of the different species of molecules must be the same. That means condition 2 is satisfied at the transition. This may perhaps mean that for two phases to become homogeneous condition 2 is to be satisfied.

Let us examine the implication of condition 2 being satisfied at the transition of the disappearance of the phase boundary. Usually we obtain the molar volume of a substance by dividing the molecular weight by the macroscopic bulk density. The molar volume thus obtained is actually due to the molecules as well as the voids. Obviously such a computation is no indication of the actual size of the molecules. Molar volume thus obtained may be written as $(V_{ma}+\phi_v)$, where V_{ma} is the actual volume due to the molecules and ϕ_v that due to the voids. In this context, if Eq. 1 holds good at the transition of the disappearance of the phase boundary, by converse the condition

$$(V_{ma}+\phi_v)_1=(V_{ma}+\phi_v)_2=(V_{ma}+\phi_v)_3 \quad (4)$$

is valid. Of course ϕ_v is a characteristic constant for a given liquid at a particular temperature. In other words satisfaction of condition 4 seems to be a precondition for liquid-liquid miscibility. Relation 4 seems to imply that just at the transition when a phase boundary disappears to form a homogeneous system, there seems to be occurring an equipartition of space by the different species of molecules, irrespective of their sizes, constituting the homogeneous system resulting from the disappearance of the phase boundary. For a successful theory of liquid–liquid miscibility the future seems to revolve on a thorough understanding of the ϕ_v factor in Eq. 4 in all its qualitative and quantitative aspects.

In the binary system 2-propanol-carbon tetrachloride the viscosity variation is anomalous. A plot of viscosity against mole per cent of 2-propanol shown in the graph exhibits a minimum at about 45 mole per cent of 2-propanol. Sugden[9] explained a similar phenomenon of negative viscosity in aqueous solutions as due to the strong dipole action of one of the constituents in the solution having the effect of depolymerizing the associated molecules of the other constituent entailing in a decrease of viscosity. But in this binary system carbon tetrachloride molecule is not a dipole. Sometimes a shortening of the length of the associated polymers is given as an explanation for lowering of viscosity. But then this presupposes a length of the associated polymer of the alcohol more than that due to two molecules. Of course, we can not assume a long chain formation of a compound between 2-propanol and carbon tetrachloride. The situation, therefore, leaves us in doubt as to what is the causative factor for such a decrease in viscosity.

Summary

To understand why a heterogeneous system of two immiscible liquids so exists without mixing we have made a new approach of studying the physical properties of the system just at the transition of the disappearance of the phase

boundary after the addition of an optimum amount of a third component which is freely miscible with the two heterogeneous components thus resulting in the formation of a ternary system. At the transition of the disappearance of the phase boundary we have found that $\sum_3 L_3 x_3 = L_{1,2,3}$, wherein L represents volume polarization and x the mole fraction, holds good. The implications of the validity of the above equation have been discussed.

*Stereoregular Polymers. II. Polymerization of Alkenyltrimethylsilanes with Ziegler Catalyst**

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Masao SUMI

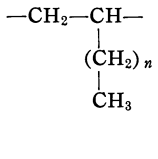
(Received November 17, 1958)

Isotactic polymers of normal α-olefins have been known to have a maximum melting point at polypropylene (165°C), a minimum value at polyhexene-1 (−55°C), and after that show a gradual increase of melting points with the higher members[1,2]. On the other hand, isotactic polymers of branched α-olefins, which are shown in Table I by the general formulae II and III, have considerably higher melting points than those of the corresponding polymers of normal olefins.

The present study was undertaken to see if (i) the polymerization of alkenyltrimethylsilanes with Ziegler catalyst could lead to crystalline polymers and (ii) the similar melting behaviors could be expected in the case of polyalkenyltrimethylsilane having the same structure of monomer as type III of branched olefins.

A survey of the literature of the subject reveals that the polymers of alkenyltrimethylsilanes hitherto obtained are all liquid polymers of low molecular weight. Kanazashi[3] studied the polymerization of vinyltrimethylsilane with peroxide catalysts at 120°C and with Friedel-Crafts catalysts at 150°C, and obtained oily polymer in the former case and no polymer in the latter case. Polymerization of allyltrimethylsilane was attempted by Sommer[4] with Friedel-Crafts catalysts and also by Petrov[5] and Polyakova[6] at 130°C under a high pressure in the presence of peroxide catalysts. However, in both the cases the product was viscous liquid polymers. Polymerization of 3-butenyltrimethylsilane was also carried out by the latter author[6] to yield only a viscous liquid.

The present authors have prepared three alkenyltrimethylsilanes of the general formula $CH_2=CH(CH_2)_nSi(CH_3)_3$ ($n=0, 1$ and 2), i. e., vinyl-, allyl-, and 3-butenyltrimethylsilane, and subjected them to polymerization by means of Ziegler catalyst. It was found from the experiments that the alkenyltrimethylsilanes could polymerize to high polymeric products having high melting points and, furthermore, the polymers were proved to be highly crystalline by X-ray investigation**.



Polymerization. — Polymerization was carried out in *n*-heptane in the presence of Ziegler catalyst, that is, triethylaluminum and titanium tetrachloride. Considering the question from the results of the preceding paper[7], a method which had given a good yield of isotactic polystyrene was adopted in the present study;

* Presented at the 11th Meeting of Chem. Soc. of Japan in Tokyo, April 4, 1958. A brief description of this work was published in *Annual Report of the Institute of Fiber Research (Japan)* (*Sen'ikagaku Kenkyusho Nenpo*), 11, 23 (1958).

that is, the catalysts were prepared without stirring and polymerizations were carried out also without stirring.

The conversions of both allyl- and 3-butenyltrimethylsilane were moderately high, but the conversion of vinyltrimethylsilane was very low (Table II).

Separation of Crystalline Polymers. — In the polymerizate of vinylmethylsilane, the existence of polyethylene was recognized from the analytical data and X-ray diffraction pattern. The separation of the polyethylene was effected by extraction with hot toluene. The occurrence of the polyethylene is considered to be due to the polymerization of ethylene which evolved during the preparition of the heterogeneous catalyst[7]. Polyvinyltrimethylsilane is insoluble in most organic solvents.

The amorphous polymer in the polymerizate of allyltrimethylsilane could be separated from the crystalline part by extraction with toluene. It was found that the crystalline part is soluble only in hot high-boiling solvents such as α-methylnaphthalene and dioctylphthalate.

In the case of 3-butenyltrimethylsilane, the separation of amorphous polymer was effected by hot extraction with ether, and also the extraction with cold *n*-heptane was found to be effective, wherein the

a) Measured at room temperature by flotation method.
b) Upon being heated on a free flame in a nitrogen atmosphere the polymer decomposed to a volatile liquid.

crystalline part was insoluble. It was found to be soluble in decalin and hot tetralin. The experimental results of extraction and the analytical data of both the amorphous and crystalline fractions were summarized in Table III.

Physical Properties.—The X-ray photograph of the extraction residue of polyvinyltrimethylsilane showed a sharp Debye reflection, indicating the highly crystalline nature of the polymer. The photographs of the fractions of polyvinyl-, polyallyl-, and poly-3-butenyltrimethylsilane were presented in Fig. 1. In all the cases the residual part of solvent extraction showed marked crystalline patterns, while the extracts showed only minor extents of crystallinity. From the crystalline part of poly-3-butenyltrimethylsilane an extruded filament was obtained, which could be drawn at 100°C to several times of its original length, and gave a fine X-ray fiber diagram. From the analysis of the fiber diagram, a helical structure containing three monomeric units per identity period was established as follows***.

Rhombic $\begin{cases} a=10.97\ \text{Å} \\ b=20.02\ \text{Å} \\ c=6.46\ \text{Å (fiber axis)} \end{cases}$

No. of monomeric unit in unit cell=6

ρ(X-ray)=0.902 g./cm^3

ρ(obsd.)=0.889 g./cm^3

The crystalline polymers of other monomers than 3-butenyltrimethylsilane considered to be isotactic by analogy to the case of poly-3-butenyltrimethylsilane, but their fiber diagrams could not be obtained because of the difficulty of drawing.

Melting points and glass transition temperatures were determined dilatometrically on the amorphous as well as the crystalline parts of the polymers. The results and other properties are shown together in Table IV. As was expected, the melting points of the crystalline parts are very high in all cases and the polymer with the larger branch has the lower melting points. Particularly, the first member of this series, polyvinyltrimethylsilane has an extremely high melting point and was completely insoluble in all organic solvents examined.

Experimental

Monomers. — Vinyltrimethylsilane was synthesized through two different ways. One is the methylation of vinyltrichlorosilane by methylmagnesium bromide[8]. Refluxing the ethereal reaction mixture for 6 hr. gave 58% of the product, b. p. 55.0~55.2°C. The other way is the Wurtz-Wittig's reaction between trimethylchlorosilane and vinylchloride[9]. The yield was 55.6% based on trimethylchlorosilane used, b. p. 55.0~55.2°C.

Allyltrimethylsilane was also synthesized through two alternating methods. One is the methylation of allyltrichlorosilane**** by methylmagnesium bromide[10] and the other is the reaction of allylmagnesium bromide on trimethylchlorosilane[5]. The former yielded 53% of allyltrimethylsilane calculated from allyltrichlorosilane used and the latter yielded only 19.3% of the product after refluxing the ethereal solution for 8.5 hr.

3-Butenyltrimethylsilane was synthesized according to Petrov's method: that is the reaction between allylbromide and trimethylsilylmethylmagnesium chloride[5]. After refluxing the ether solution for 5 hr., 35.2% of the product was obtained, b. p. 118.5~111.7°C.

Materials.—Triethylaluminum was the product of Mitsui Chem. Ind. Co. Thirty percent solution in *n*-heptane was prepared in a modified Schlenk's apparatus and separated in small portions into sealed ampoules.

*** Details of the structural annalysis of the polymer will be published elsewhere by Mr. Y. Chatani of Nitta's laboratory. We are very grateful to him for the X-ray data.

8) R. Nagel and H. W. Post, *J. Org. Chem.*, 17, 1379 (1952).
9) M. Kanazashi, This Bulletin, 26, 493 (1953).
**** Allyltrichlorosilane was kindly offered by Dr. R. Okawara at Faculty of Engineering, Osaka University.
10) C. A. Burkhard, *J. Am. Chem. Soc.*, 72, 1078 (1950).

Titanium tetrachloride was the product of Osaka Titanium Co. and 21% solution in *n*-heptane was used.

n-Heptane was purified by shaking with fuming sulfuric acid, washing with water and aqueous sodium hydroxide, and was dried over calcium chloride, distilled and stored over sodium chips.

Polymerization. — Polymerization was carried out in the same apparatus as in the preceding paper[7]. The solution of $AlEt_3$ was added first to *n*-heptane and mixed thoroughly, and the solution of $TiCl_4$ was dropped slowy along the wall of the vessel without stirring. The solid brown mass was observed to form at the bottom of the flask. Finally the monomer was added and the polymerization was carried out without stirring.

Polymerization was stopped by adding 2 ml. of methanol and 0.3 ml. of concentrated hydrochroric acid, and the reaction mixture was poured onto about 100 ml. of methanol. After being kept overnight, the polymer was collected and washed thoroughly with methanol. The results of polymerization were given in Table II.

Separation of Crystalline Polymers from Crude Products. — When the crude polyvinyltrimethylsilane was extracted with hot toluene, a precipitate was obtained from the cooled extract. The precipitate was ascertained to be polyethylene from the analytical data and X-ray powder pattern. The insoluble part was nearly pure polyvinyltrimethylsilane.

Crude polyallyltrimethylsilane was refluxed gently with a large volume of toluene for several hours. After being cooled, the insoluble part was separated from the solution by a centrifuge. The intrinsic viscosity of the amorphous part in toluene was 0.087 at 30°C.

In the case of poly-3-butenyltrimethylsilane, the separation was effected by hot extraction with ether using a modified Soxhlet apparatus. The separation could also be done by cooling the hot solution of the crude polymer in *n*-heptane; only the crystalline polymer was precipitated when being cooled, while the amorphous polymer still remained in solution. Intrinsic viscosities of the amorphous and the crystalline part in decalin were 0.169 and 1.21 at 30°C, respectively.

Analysis of Silicon. — Analysis of silicon in the polymers was carried out by wet digestion using fuming sulfuric acid in a platinum crucible. The ignited silica was ascertained by treating with 60% hydrofluoric acid.

Properties. — Melting points and glass transition temperatures were determined dilatometrically. The polymer was melted in vacuum to form a small rod prior to measurement.

Density was measured by the flotation method at room temperature using the mixtures of carbon tetrachloride and alcohol.

Summary

Vinyl-(I), allyl-(II), and 3-butenyl-trimethylsilane(III) were polymerized at 70°C in *n*-heptane with the heterogeneous catalyst of Ziegler's type. The monomer I gave only a small yield of polymer, while the monomers II and III gave moderate amounts of polymers.

The amorphous and crystalline polymers of these monomers were separated by extraction with appropriate solvents. As regards the crystalline polymers, solubility property, density, dilatometrical melting point, and X-ray spectra were described. Glass transition temperatures of the amorphous polymers are also determined.

The authors wish to thank Mitsui Chemical Industry Co. for the supply of triethyltitanium aluminum and Osaka Titanium Co. for tetrachloride.

Absorption Spectra of Dyes. III[1]. *On the Composition of Complexes Formed in Mixtures of Chlorazol Sky Blue FF and p-Nitroaniline→γ Acid in Aqueous Solution**

By Teruaki KOBAYASHI, Yoshié TANIZAKI and Noboru ANDO

(Received November 22, 1958)

The fact that complexes are formed between some kinds of dyes in aqueous solution has been revealed by means of spectroscopic measurements[2-4], and the mixtures of some direct dyes have been measured qualitatively in order to investigate the composition of the complexes formed[3,4].

The authors reported in the previous paper[1] that the mixtures of Chlorazol Sky Blue FF and some acid dyes, *p*-X-aniline→γ acid (X=H, CH_3, OCH_3, Cl or NO_2), did not show additive spectra in aqueous solution at room temperature, and that, of these mixtures, a pair of Chlorazol Sky Blue FF and *p*-nitroaniline →γ acid underwent the greatest change in spectrum. In the present paper the authors selected the combination of Chlorazol Sky Blue FF with *p*-nitroaniline→γ acid and investigated its spectrum at 620 mμ where the most remarkable change was seen in the whole region measured, in order to obtain some information about the composition of the complexes formed.

Experimental

Materials.—All the dyes used are the same as those used in the previous paper[1].

Preparation of Samples.—The dye solutions were prepared by using conductivity water whose specific conductivity was about 3.5×10^{-7} mho. All of the concentrations were determined by weight.

Absorption Spectra.—All the absorption spectra of the dyes in aqueous solution were measured by means of the Shimadzu QB-50 or QR-50 spectrophotometer at room temperature. Absorption cells were about 0.2 to 5 cm. thick.

Results

Hereafter Sky Blue will stand for Chlorazol Sky Blue FF, and NO_2-α for the acid dye made by coupling diazotized *p*-nitroaniline with γ acid in acid, and NO_2-β for the same in alkali.

It has already been shown[1] that the absorption spectrum of the mixture of Sky Blue and NO_2-α or NO_2-β in aqueous solution does not coincide with the sum of the spectra of individual dye, and this non-additivity is the most remarkable in the neighborhood of 620 mμ in wavelength. This spectral change is characterized by a marked decrease in optical density, with a slight shift of absorption maxima to longer wavelengths. For example, the absorption spectra of solutions containing

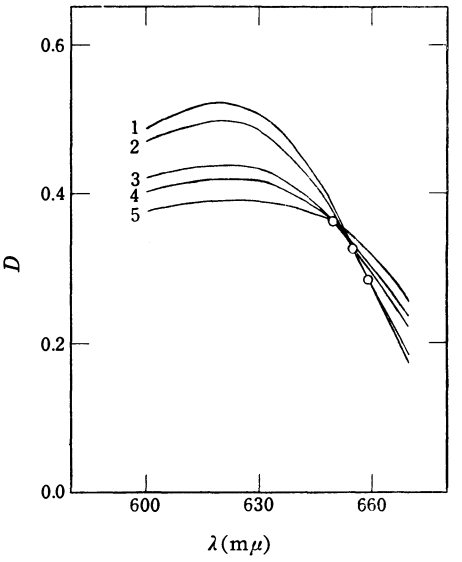

Fig. 1. Absorption spectra of mixtures of Sky Blue and NO_2-α in aqueous solution at room temperature. The concentration of Sky Blue is 1.41×10^{-5} mol./l., and that of NO_2-α is $1=2.72\times10^{-6}$, $2=6.98\times10^{-6}$, $3=2.11\times10^{-5}$, $4=3.51\times10^{-5}$ and $5=8.36\times10^{-5}$ mol./l. The absorption of NO_2-α alone is subtracted from each curve.

a given amount of Sky Blue and different amounts of NO_2-α are illustrated in Fig. 1, in which each absorption of NO_2-α alone is subtracted from that of the corresponding mixture. The figure shows that the spectra obviously indicate no isobestic point and the intersections of the adjacent curves are gradually shifted to shorter wavelengths. Therefore, it is clear that the formation of only a 1:1 complex does not adequately explain the data over the whole concentration range measured. Plotting the observed optical density, D, of this mixture at 620 mμ in relation to the concentration of NO_2-α, we obtain the curves as shown in Fig. 2, where the concentrations of Sky Blue indicated by the curves I and II are 6.02×10^{-6} and 1.41×10^{-5} mol./l., respectively. Inspection of these curves shows that in either case the optical density decreases with the concentration of NO_2-α to the amount about four times as great as that of Sky Blue, and then increases with the further increase of NO_2-α. The same

[Blue], mol./l.

Fig. 5. The relation between the difference in density, ΔD, of the combination of Sky Blue with NO_2-α and the concentration of Sky Blue at 20~22°C. 1 cm. thick, λ=620 mμ. The concentration of NO_2-α is $I=4.0\times10^{-6}$ and $II=5.97\times10^{-6}$ mol./l.

tendency was also observed in the mixture of Sky Blue and NO_2-β.

Now, let us consider the difference between the sum of densities of its components and that of the mixture, ΔD. The relation between ΔD and the concentration of NO_2-α or of NO_2-β for a given concentration of Sky Blue is shown in Fig. 3. Both the curves in the figure curve upwards in the whole region and are inclined to approach certain values.

On the other hand, corresponding series of measurements were also carried out with mixtures containing various amounts of Sky Blue and given amounts of NO_2-α, and the results are shown in Figs. 4 and 5. Here celles were selected so as to make values of density fall in 0.3 to 0.7, but all the observed values were converted into those for 1 cm. cell. Similarly, Fig. 4 indicates the relation between ΔD at 620 mμ and the concentration of Sky Blue, where the curves I, II and III correspond to the concentration of NO_2-α 2.00×10^{-6}, 2.02×10^{-5} and 6.41×10^{-4} mol./l., respectively. Fig. 5 shows the same relation as that in Fig. 4, but the curves I and II correspond to the concentrations of NO_2-α, 4.0×10^{-6} and 5.97×10^{-6} mol./l. The optical densities were measured at about 21°C unlike the former case (at about 15°C). It will be seen at once from these curves that the higher the concentration of acid dye, the more remarkable the difference (Figs. 4 and 5), and that each curve bends downwards and upwards relatively to the low and high concentrations of Sky Blue, respectively (Fig. 5). Moreover, its point of inflexion moves towards a smaller value of concentration of Sky Blue in accordance with an increase in that of NO_2-α. These are distinctly different from the case of the curves of ΔD-concentration of NO_2-α or ΔD-concentration of NO_2-β.

Discussion

Lemin and Vickerstaff[3] showed by the spectroscopic measurement that Chlorazol Sky Blue FF and Durazol Red 2B formes a 1:1 complex in aqueous solution at room temperature. On the other hand, Derbyshire and Peters[4] examined the mixture of Chlorazol Sky Blue FF and Chrysophenine G in aqueous solution by the spectroscopic and calorimetric measurements and concluded that the formation of a 1:1 complex occurs to an appreciable extent even at 90°C, while higher complexes are formed to a certain extent in the presence of an excess of Chrysophenine G. Now, as for the present case, it was stated in the last section that the formation of a 1:1 complex does not explain all the spectral change, judging from the fact that the absorption spectra of solutions containing Sky Blue and NO_2-α showed no isosbestic point anywhere over the region measured (Fig. 1).

The fact that most direct dyes aggregate more or less in aqueous solution and that this aggregation is increased by adding neutral salts has been confirmed by measuring conductivity, absorption spectra, etc.[5] And it has also been recognized that the absorption spectrum of Sky Blue in aqueous solution does not obey Beer's law[3]. In addition, it can safely be considered as a matter of course that another dye added to Sky Blue solution exerts such a salt effect on this dye. In spite of these facts, however, it will be assumed here that the effect of the self-aggregation of the individual dye, which is induced by its increased concentration or by the addition of another dye, can be disregarded as compared with the effect of the complex formation, because the change in optical density of either component caused by increasing its concentration was of comparatively small magnitude compared with that produced by mixing**. Further the change in density of Sky Blue produced by the salt effect of the acid dyes can also be disregarded on account of the fact that an addition of sodium

Soc.* (*London*), **A148**, 681 (1935); N. Ando, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **64**, 1192, 1431 (1943); Y. Tanizaki and N. Ando, ibid., **78**, 343 (1957).

** The variation of the molar extinction coefficient of Sky Blue with respect to its concentration is shown in Table I. The measurement was carried out at 620 mμ over a range of concentration up to 3.97×10^{-5} mol./l. This table shows that the deviation from Beer's law is negligible. On the other hand, the aggregation of the acid dye itself, even if it occurs, could be disregarded, because its absorption at 620 mμ is very small.

TABLE II. OPTICAL DENSITY OF CHLORAZOL SKY BLUE FF (6.66×10^{-6} mol./l.) IN SODIUM CHLORIDE SOLUTION AT ROOM TEMPERATURE
1 cm. thick, $\lambda=620$ mμ

chloride to Sky Blue solution, in a range of concentrations comparable to those of the acid dyes used here, showed no significant change in optical density of Sky Blue***. Based on these assumptions, the observed result will be discussed as follows.

Now, in order to investigate the composition of the complexes formed, let us suppose m mol. of Sky Blue, B, and n mol. of any acid dye, A, have produced one mole of complex, C, in solution, that is,

$$m\mathrm{B} + n\mathrm{A} \rightleftarrows \mathrm{C}$$

According to the law of mass action, we can rewrite this as follows:

$$K=[\mathrm{C}]/([\mathrm{B}]-m[\mathrm{C}])^m([\mathrm{A}]-n[\mathrm{C}])^n \quad (1)$$

where [C], [B] and [A] mean the concentration in mol./l. of the complex and the initial concentrations of Sky Blue and the acid dye, respectively; and K is the equilibrium constant. When the absorption layer is regarded as unity, the observed optical density, D_{obs}, at any wavelength of a mixture will be

$$D_{obs}=([\mathrm{B}]-m[\mathrm{C}])\varepsilon_B + ([\mathrm{A}]-n[\mathrm{C}])\varepsilon_A + [\mathrm{C}]\varepsilon_C$$

where ε_B, ε_A and ε_C signify the molar extinction coefficients of Sky Blue, the acid dye and the complex, respectively. On the other hand, the sum of optical densities of the components, D_{sum}, is

$$D_{sum}=[\mathrm{B}]\varepsilon_B+[\mathrm{A}]\varepsilon_A$$

so the difference, ΔD, becomes

$$\Delta D=(m\varepsilon_B+n\varepsilon_A-\varepsilon_C)[\mathrm{C}] \quad (2)$$

Since the molar extinction coefficients may be assumed to be unvarying, ($m\varepsilon_B+n\varepsilon_A-\varepsilon_C$) can be described as a constant, k, provided that m and n are not changed in the entire concentration range of the dyes. As [C] is a function of [B] and [A] (Eq. 1), ΔD can be expressed as a function of them. According to the usual method[3], K and k can be determined. A calculated value of K by making use of the observed values of optical density indicated by full lines in Fig. 3 was 8.0×10^4 for the mixture of Sky Blue and NO_2-α when $m=n=1$. K values calculated by various observed optical densities were not so different from one another. Now, in order to investigate the relation between ΔD and the concentration of NO_2-α, curves were drawn in accordance with Eq. 2. The results are shown in Fig. 6, in which the full lines indicate the calculated ones

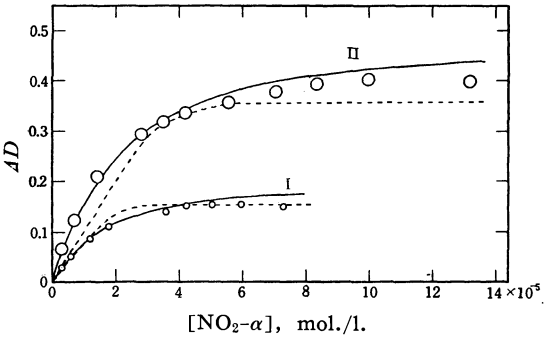

Fig. 6. The comparison between the differences observed and calculated by Eq. 2 for the mixtures of Sky Blue and NO_2-α at 15°C. 1 cm. thick, $\lambda=620$ mμ. The concentration of Sky Blue is I $=6.02\times10^{-6}$ and II $=1.41\times10^{-5}$ mol./l. The full lines signify calculated 1 : 1 curves ($K=8.0\times10^4$), the dotted lines 1 : 2 curves ($K=7.1\times10^{10}$) and the circles the corresponding observed values.

and the circles the corresponding observed values. From the figure it will be seen at once that the curves of $m=n=1$, namely of a 1 : 1 complex, suit the observed values comparatively well. A minute observation shows, however, that the calculated values are somewhat greater than the observed ones where the concentration of NO_2-α is higher than that of Sky Blue. As Derbyshire and Peters reported[4], while Chlorazol Sky Blue FF and Chrysophenine G form a 1 : 1 complex in aqueous solution, they form higher complexes richer in Chrysophenine G in presence of an excess of this dye. If this happens in the present case and higher complexes richer in the acid dye are formed, a curve of $m=1$ and $n=2$,

*** As is shown in Table II, the effect of sodium chloride on Sky Blue solution in a range of concentrations comparable to those of the acid dyes used here is not so great as can be observed, so we leave the salt effect by the acid dye out of consideration.

namely of a 1:2 complex, should fit the observed values better than the 1:1 curve in the higher concentration region of the acid dye. The 1:2 curves ($K=7.1\times10^{10}$ which was calculated by making use of the observed values of optical density shown by the dotted lines in Fig. 3) are indicated by the dotted lines in Fig. 6. These curves differ extremely from the observed ones in the region where the 1:1 curve was rather suitable, but they are more suitable in the higher concentration range of the acid dye where the 1:1 complex curve has not fitted well. These facts suggest that a 1:1 complex is formed first and then higher complexes richer in the acid dye are formed with an increase of its concentration. If this is the case, the region of low concentration of the acid dye in the mixtures containing a given amount of Sky Blue should correspond to that of high concentration of Sky Blue in the mixtures containing a given amount of the acid dye. Actually, the curves of ΔD-concentration of Sky Blue (Figs. 4 and 5) are obviously different in shape from the curves of ΔD-concentration of NO_2-α, and become similar to the 1:1 curve in a region of high concentration of Sky Blue. Probably all the experimental results would be explained by a combination of a 1:1, a 1:2 and other complexes, or by a combination of several complexes different in their compositions. Exactly the same result has been obtained in the mixture of Sky Blue and NO_2-β. It is concluded here that one kind of complex does not explain all the exprimental data, and the comparison between the calculated and observed curves shows that a 1:1 complex occurs to a greater extent over a range of relatively low concentration of acid dye and that higher complexes richer in the acid dye may be formed in the presence of an excess of it.

Summary

1. The change in spectrum at 620 mμ of the mixture of Chlorazol Sky Blue FF and *p*-nitroaniline→γ acid in aqueous solution was measured in detail at room temperature, by varying the concentration of the component dyes.

2. On the assumption that the spectral change is due to the complex formation, the composition of complexes was discussed by comparing the observed and the calculated difference in optical density.

3. It may be supposed that a 1:1 complex occurs to a great extent over a range of low concentration of *p*-nitroaniline→γ acid as compared with that of Chlorazol Sky Blue FF, and that higher complexes are formed in the presence of an excess of the acid dye.

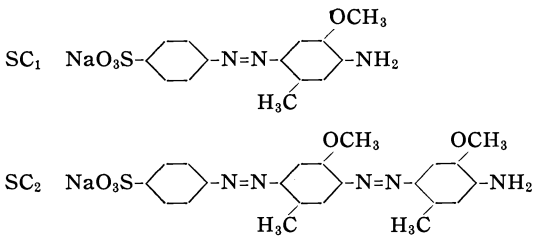
Absorption Spectra of Dyes. IV[1]. *Absorption Spectra of Mixtures of Chlorazol Sky Blue FF and Dyes Prepared from Sulfanilic Acid and Cresidine*



By Teruaki KOBAYASHI, Yoshié TANIZAKI and Noboru ANDO

(Received December 19, 1958)

In the previous papers the authors have reported that binary mixtures of Chlorazol Sky Blue FF and certain monoazo acid dyes in aqueous solution show non-additivity in absorption spectrum at room temperature, explained qualitatively the spectral change assuming the formation of loose complexes[2], and then discussed their compositions[1]. In the present paper, absorption spectra of the binary mixtures in aqueuos solution of Chlorazol Sky Blue FF, as the one component, and dyes prepared from sulfanilic and cresidine, as the other, were analyzed, and the result obtained was examined.

Experimental

Dyes.—Chlorazol Sky Blue FF (called Sky Blue) is the same as used before[1,2]. SC_1 and SC_2 will signify the dye obtained by coupling diazotized sulfanilic acid with cresidine and that obtained by coupling diazotized SC_1 with cresidine. Their structures are as follows:

Both of them are carefully prepared from purified intermediates. SC_1 was purified by the recrystallization from water and SC_2 by the Robinson and Mills' method until no change in spectrum was observed. It was noticed that the solubility of SC_2 in water is extremely dependent on pH, and that its flocculent precipitate was easily produced by carbon dioxide from the air. The dye solutions, therefore, were once heated in order to remove carbon dioxide.

Measurements of Absorption Spectra.—All the absorption spectra of the dyes in aqueous solution were measured by means of the Shimadzu QR-50 spectrophotometer at room temperature. Absorption cells used were 0.2, 0.5 and 1 cm. thick. All the experimental values were converted into those corresponding to 1 cm. cell.

Results

The absorption spectrum of a mixture of Sky Blue (7.44×10^{-6} mol./l.) and SC_1 (3.58×10^{-5} mol./l.) is shown by a full line in Fig. 1, together with each spectrum of Sky Blue (curve I) and of SC_1 (curve II). The sum (curve III) of curves I and II coincides completely with the observed one (curve IV) in the whole region measured. The additivity in spectrum, however, does not come into being in the mixtures containing a great excess of SC_1. The results are given in Fig. 2, where the dotted line shows the absorption spectrum of Sky Blue alone (7.42×10^{-6} mol./l.) and curves I and II those of mixtures containing Sky Blue and SC_1 49.4 and 137 times as much as Sky Blue, respectively. In this wavelength region, SC_1 does not absorb light. As this change in spectrum is similar to that of certain benzidine disazo dyes like Sky Blue caused by the salt effect[3], it is supposed that it may be due to the self-aggregation of Sky Blue. Then the variation in optical density at 620 mμ of Sky Blue (7.42×10^{-6} mol./l.) in sodium chloride solution was examined, in order to investigate whether or not the change

is due to the salt effect of SC_1. The results are shown in Table I. It shows clearly that no significant departure from Beer's law is observed, even though the amount of sodium chloride becomes 140 times as much as that of Sky Blue. Therefore, we must consider that the spectral change shown in Fig. 2 is not due to the self-aggregation of Sky Blue caused by the salt effect of SC_1 added, but due to the interaction between the two dyes. It will be seen that the spectra pass through an isosbestic point at about 640 mμ, where the absorption of SC_1 does not appear (Fig. 1). This suggests that one Sky Blue molecule interacts with SC_1 molecules, or that $1:n$ complexes are formed. But the number n of SC_1 component in one complex molecule has not been known. These results mean that even if the additive spectrum appears in an equimolar or nearly equimolar mixture, the spectrum of the same mixture will often become non-additive with an increase of one component, and the interaction between the two components will occur.

The absorption spectrum of a mixture of Sky Blue and SC_2 is given in Fig. 3, where curves I and II show each absorption spectrum of Sky Blue and of SC_2, curve III the sum of them, and curve IV the observed one of the mixture. Inspection of them shows that the observed curve is weaker in intensity than the resultant curve both in the neighborhood of 620 mμ (the first band of Sky Blue) and at absorptions in the ultraviolet region, but stronger in the neighborhood of the first band of SC_2 (505 mμ).

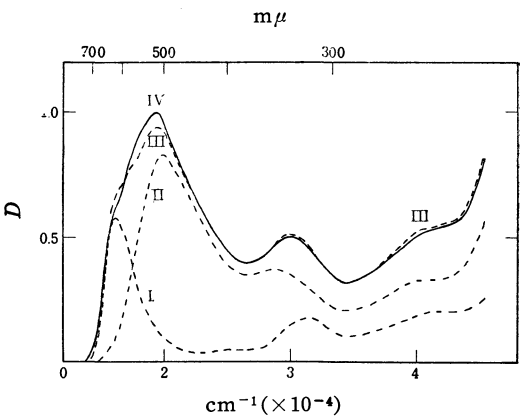

Fig. 3. Absorption spectra of Sky Blue, SC_2 and their mixture in aqueous solution at room temperature (30°C). 1 cm. cell.

II: SC_2 (3.01×10^{-5} mol./l.)
III: Sum of curves I and II
IV: Mixture

This spectral change was more systematically examined by varying the concentration of SC_2 and keeping that of Sky

Blue constant (5.90×10^{-6} mol./l.). The results are shown in Fig. 4, in which each absorption of SC_2 is subtracted from the corresponding observed curve. The curves in the figure pass through a well-defined isosbestic point at about 650 mμ; this means that one Sky Blue molecule interacts with a molecule or molecules of SC_2.

On the other hand, the relation between the concentration of SC_2 added and the

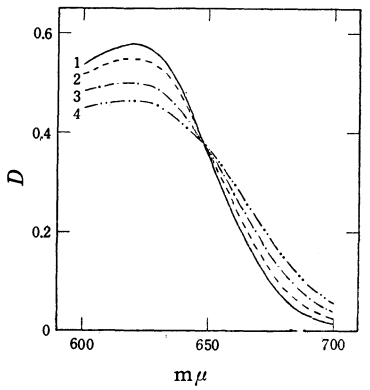

Fig. 4. Absorption spectra of mixtures of Sky Blue and SC_2 in aqueous solution at room temperature (30.5°C), where each absorption of SC_2 is subtracted from the corresponding mixture curve. 1 cm. cell. Concentration of SC_2 is 1: zero, 2: 6.08×10^{-6}, 3: 3.01×10^{-5} and 4: 1.20×10^{-4} mol./l. that of Sky Blue is 5.90×10^{-6} mol./l;

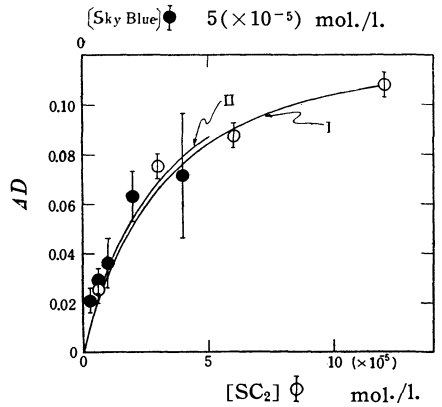

Fig. 5. The relation between the difference in density, ΔD, of the combination of Sky Blue with SC_2 and the concentration of SC_2 or of Sky Blue. 1 cm. cell, $\lambda=620$ mμ. $K=3.8\times10^4$ (at 30.5°C).
I: Calculated difference when the concentration of Sky Blue is constant (5.90×10^{-6} mol./l.); the white circles are corresponding observed values at 30.5°C.
II: Calculated difference when the concentration of SC_2 is constant (6.07×10^{-6} mol./l.); the black circles are representing observed values at 28.2°C.

difference between the sum of optical densities of the components and that of the mixture, ΔD, at 620 mμ is plotted by white circles in Fig. 5. Now, if a 1:1 complex is assumed to be formed in the solution, and if the mass action law is applied to it, an equilibrium constant, K, will be obtained by the method mentioned before[1]. Thus the obtained value of K was 3.8×10^4 at 30.5°C. Here were used the observed values of ΔD, when the concentrations of Sky Blue and of SC_2 are 5.90×10^{-6} mol./l. and up to 1.20×10^{-4} mol./l., respectively. Curve I in the figure was drawn by making use of this value of K. It will be seen at once from the figure that the observed values (white circles) well fit the calculated curve; this means the formation of a 1:1 complex. If a 1:1 complex is formed, the curve of ΔD should show the same feature when the concentration of Sky Blue is varied, while that of SC_2 is kept constant, because of the symmetry of the equation. The curve of ΔD-concentration of Sky Blue is also shown in Fig. 5, where the black circles denote the observed values and curve II the calculated. These two also well fit each other within an experimental error. Therefore, the formation of a 1:1 complex of Sky Blue and SC_2 would well explain all the results obtained.

The absorption spectrum of the 1:1 complex of Sky Blue and SC_2 will, therefore, be obtained experimentally by making use of the equilibrium constant*.

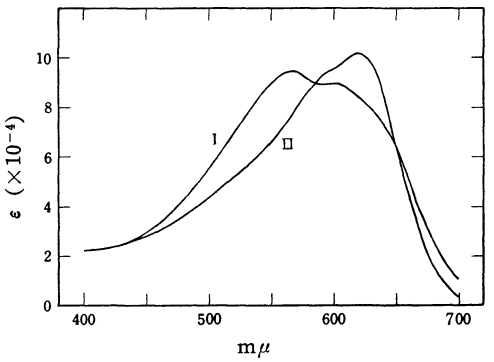

Fig. 6. Absorption spectrum of the 1:1 complex of Sky Blue and SC_2.
I: Complex
II: Sum of absorptions of the components (both 2.9×10^{-6} mol./l.)

* If the equilibrium constant is known, the concentration of the complex corresponding to given amounts of the components can be calculated and then that of the components free from the complex formation will be known. Therefore, the absorption of the complex will be obtained by subtracting absorptions of the free components from that of the mixture.

The absorption spectrum of the complex (curve I) obtained from the experimental results shown in Fig. 3 is indicated in Fig. 6, together with the sum of those of the components (curve II). The figure shows clearly that the absorption of the complex is weaker in intensity than that indicated by the resultant curve at the first absorption band of Sky Blue (620mμ), but stronger at that of SC_2.

Discussion

It has been reported before[1] that Sky Blue and certain monoazo acid dyes (*p*-nitroaniline $\rightarrow\gamma$ acid) form higher complexes richer in the acid dyes in presence of an excess of these dyes, when mixed in water[4]. Though SC_1 and *p*-nitroaniline $\rightarrow\gamma$ acid are both monoazo acid dyes, only the former shows an isosbestic point in spectra when mixed with Sky Blue (Fig. 2). It seems that such a difference has relation to the fact that the substantivity of dyes increases with the length of the conjugated double bonds chain connecting their auxochromes[5], and that at the same time they come to associate with themselves easily[6].

According to measurements of the conductivity of SC_1 and SC_2[6], the association of SC_1 with itself is not noticed over a range of concentrations $(3\sim60)\times10^{-4}$ mol./l., while the formation of ion-micelles of SC_2 is clearly observed. From these results, Ando considered, according to the substantivity theory, that the length of the conjugated double bonds was closely related to the aggregation of SC_1 and SC_2**. It has also been known that, of dyes with various substituents, similar to Congo Red in constitution, those which have the stronger substantivity show the greater spectral change caused by their association[3]. Therefore, though it is impossible to explain briefly the fact that a larger quantity is needed for SC_1 than for SC_2 to cause a change in spectrum when mixed with Sky Blue***, it may be said that this is partly due to the difference in the substantivity of SC_2 and of SC_1.

Derbyshire and Peters[7] obtained experimentally the absorption spectrum of a 1 : 1 complex of Sky Blue and Chrysophenine G. To be compared with the present result (Fig. 6, curve I), their spectra are shown in Fig. 7, in which curve I shows the absorption of the 1 : 1 complex and curve II the sum of those of the components. Inspection of these figures shows that the absorption of each mixture corresponding to the first band of the dye combined with Sky Blue shifts to longer wavelengths with an increase in intensity. On the other hand, the absorption corresponding to the peak of the first band of Sky Blue (620 mμ) shifts to longer wavelengths, with a peak getting more distinct, in the complex of Chrysophenine G, while it disappears in the complex of SC_2. Derbyshire and Peters[7] consider that Sky Blue and Chrysophenine G can approach in parallel with each other and form a complex, because while Sky Blue has its charged groups at the ends of the linear molecule, the corresponding groups of Chrysophenine G are near the centre, so the repulsion between them is small. On the other hand, if SC_2, which has its charged group at an end of the molecule, forms a complex in parallel with Sky Blue, it may be repelled by the charged groups of Sky Blue. The difference between the spectra of the two complexes and their stabilities may be related to the fact just mentioned. Further, the fact

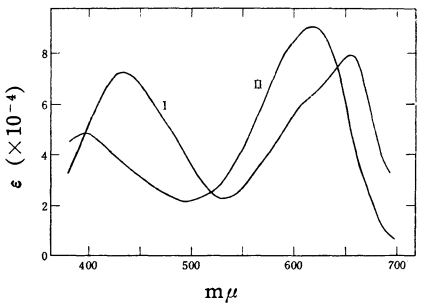

Fig. 7. Absorption spectrum of the 1 : 1 complex of Sky Blue and Chrysophenine G (quoted from the result of Derbyshire and Peters).
I: Complex
II: Sum of absorptions of the components

4) This fact has been recently confirmed by dyeing measurements from mixtures of the same pairs of dyes. [Y. Horiki, Y. Tanizaki and N. Ando, This Bulletin, to be published.]

5) E. Schirm, *J. prakt. Chem.*, **144**, 69 (1935).

6) N. Ando, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **64**, 1305 (1943).

** The number of sulfonic groups per molecular weight of SC_2 is smaller than that of SC_1, and the former is more insoluble in water. This may be one of the reason why SC_2 more easily associates with itself.

*** If a complex is formed from two dyes, the extent of the change in spectrum of the mixture also depends on wavelengths of corresponding absorptions of the component dyes and the relative direction of their transitions (Ref. 2).

7) A. N. Derbyshire and R. H. Petes, *J. Soc. Dyers Col.*, **72**, 268 (1956).

that the increasing order of length of the conjugated chain connecting the auxochromes is SC_2 <Sky Blue<Chrysophenine G may also be related to the difference between the spectra, according to the following reason. The first absorption band of a dye has close relation to the electron donating power of its auxochromes containing lone paired electrons[8], which are more easily affected by outer conditions than other π electrons under consideration. It will be seen that if both of the components approach in parallel with each other to form a complex, the auxochromes at both ends of Sky Blue get out of place from the π electron system of SC_2 or only one of them approaches it, though they draw near that of Chrysophenine G.

From the above discussion, it may be considered that the pair of Chrysophenine G and Sky Blue has a smaller intermolecular distance in a complex than that of SC_2 and Sky Blue. The amount of delocalization energy of π electrons between two components in a complex formed from molecules containing no lone pair electrons has been estimated[9]. If this idea can be applied to the present discussion, it will turn out that the pair of Chrysophenine G and Sky Blue is more stable than that of SC_2 and Sky Blue, and that the spectral change of the former is also larger; that is, in case of the former the electron transition corresponding to the first absorption band of Sky Blue will change more remarkably with larger intermolecular charge transfer (probably through auxochromes) than in case of the latter. Thus the character of the absorption spectra of the complexes can be explained qualitatively.

The above discussion will be applied to the difference between spectral characters of the pairs of SC_1 and Sky Blue and of SC_2 and Sky Blue.

Summary

1. The absorption spectra of the binary mixtures in aqueous solution of Chlorazol Sky Blue FF and sulfanilic acid → cresidine and sulfanilic acid → cresidine → cresidine were measured at room temperature.

2. The mixture of Chlorazol Sky Blue FF and sulfanilic acid → cresidine shows the additive spectrum when the ratio of the two dyes is about 1:5 but the non-additive one when it is about 1:40. From this fact the authors pointed out that even if an equimolar or nearly equimolar mixture shows the additive spectrum, it often exhibits the additive one with a relative increase of one component, due to the interaction between the components. That the spectra of the mixture pass through an isosbestic point means that a Sky Blue molecule interacts with n molecules of sulfanilic acid → cresidine (n is unknown).

3. It was indicated that the mixture of Chlorazol Sky Blue FF and sulfanilic acid → cresidine → cresidine showed the non-additive spectrum, and that this was well explained by assuming the formation of a 1:1 complex over the range of concentrations measured.

4. The authors discussed qualitatively the characters of the spectra and the stability of these complexes, comparing them with the complex of Sky Blue and Chrysophenine G, etc.

The intermediates used were presented by the Sumitomo Kagaku Kogyo Co. Ltd. through Dr. S. Arikawa and Dr. M. Okazaki. The authors wish to express their gratitude to them.

The Volume Change on Neutralization of a Strong Acid with a Strong Base[1]

By Akira TSUJIOKA

(Received November 23, 1958)

A method of calculation has been proposed by which we may evaluate the changes of volume on neutralization of various acids and bases at a constant temperature. The values of volume change fraction on neutralization of hydrochloric acid with sodium hydroxide solution at 20°C have been calculated. These calculated values have shown a good agreement with the observed ones. We have, on the other hand, shown that the volume change fraction of the reaction between a strong acid and a strong base of equal concentrations is represented by a simple function of the initial concentration.

It was noticed in an early period that there is an expansion on the neutralization of a strong acid with a strong base[2], but there are only a few data[3]. In particular, there are few data regarding the volume change on neutralization of an acid and a base of unequal concentrations. No investigation has as yet been made to correlate quantitatively the change of volume with concentration. Therefore we devised a method of calculation by which still more data can easily be provided, and then derived the relationship between the volume change on neutralization and the concentration of an acid or a base.

Now, if the density of a salt solution produced by neutralization is obtained, the volume change which occurs in this case can readily be evaluated. Then we have evaluated the density of the salt solution from the density table. That is, the weight per cent concentration of the resulting salt solution can be evaluated from the initial concentrations, so the density of this solution may be obtained by interpolation from the density table. The densities of electrolyte solutions have been fully known at intervals of one or two per cent concentration, so this interpolation does not cause any appreciable errors, as will be dealt with later.

The method mentioned above can be applied to the neutralization not only of a strong acid and a strong base, but also of both weak electrolytes or a strong electrolyte and a weak one.

Calculations

In considering the volume changes on neutralization of various acids and bases, we shall deal with both 1-1 strong electrolytes. In the other cases, we may deal with them in the manner described below.

If V_a ml. of a C_a mol./l. acid (the density, d_a) is neutralized with V_b ml. of a C_b mol./l. solution of a base (the density, d_b) at constant temperature, the volume change can be calculated as follows.

The weight per cent concentration of the resulting salt solution, denoted by a, is represented by the equation,

$$a = M_s/10(d_a/C_a + d_b/C_b) \tag{1}$$

where M_s is the molecular weight of the salt. If the density of this solution is denoted by d_s, the apparent molar volume of the acid by Φ_a, that of the base by Φ_b and that of the salt by Φ_s, these apparent molar volumes are defined by the following equations, respectively.

$$\Phi_a = \{1000 - (1000d_a - C_aM_a)/d_w\}/C_a \tag{2}$$

$$\Phi_b = \{1000 - (1000d_b - C_bM_b)/d_w\}/C_b \tag{3}$$

$$\Phi_s = 1000(d_a/C_a + d_b/C_b)(1/d_s - 1/d_w) + M_s/d_w \tag{4}$$

where d_w is the density of water, M_a, the molecular weight of the acid and M_b, that of the base.

Then it may be presumed that the volume change on neutralization is due to the change in the apparent molar volume of the solute, so that the volume change denoted by ΔV ml. is given by

1) A part of this paper was presented at the 11th Annual Meeting of the Chemical Society of Japan, held in Tokyo in April, 1958.

2) J. R. Partington, "An Advanced Treatise on Physical Chemistry", Vol. 2, 1st Ed., Longmans, Green and Co., London (1951), p. 33.

3) J. D'Ans and E. Lax, "Taschenbuch für Chemiker und Physiker", 2nd Ed., Springer Verlag, Berlin (1949), p. 821; Landolt-Börnstein, "Physikalisch-Chemische Tabellen", Erg. B. II, Springer Verlag, Berlin (1931), p. 274.

$$\Delta V=(\Phi_s+\Phi_w-\Phi_a-\Phi_b)C_aV_a/1000 \quad (5)$$

where Φ_w is the apparent molar volume of water, equal to M_w/d_w (M_w is the molecular weight of water). In Eq. 5, ΔV has been defined as a positive value when there is an expansion in total volume.

On the other hand, ΔV may be directly represented by means of the equation,

$$\Delta V=(d_aV_a+d_bV_b)/d_s-(V_a+V_b) \quad (6)$$

We may choose between Eqs. 5 and 6 to evaluate ΔV, because substitution of Eqs. 2, 3 and 4 into Eq. 5 gives Eq. 6.

Neutralization at Equal Concentrations. —The equations by which we may evaluate the volume change on neutralization of a C mol./l. acid, which occupies a volume V ml., with a base of an equal concentration can be derived by replacing V_a and V_b in Eqs. 5 and 6 by V, and C_a and C_b in Eqs. 1—5 by C.

The weight per cent concentration of the resulting salt solution is obtained by

$$a^*=M_sC/10(d_a+d_b) \quad (7)$$

Therefore, in the case of neutralization of an acid with a base of equal concentration, the increase in total volume is

$$\Delta V^*=(\Phi_s^*+\Phi_w-\Phi_a-\Phi_b)CV/1000 \quad (8)$$

where

$$\Phi_s^*=1000(d_a+d_b)(1/d_s^*-1/d_w)/C+M_s/d_w$$

or by an alternative formula (using Eq. 6).

$$\Delta V^*=\{(d_a+d_b)/d_s^*-2\}V \quad (9)$$

The subscripts refer to salt, water, acid and base, respectively, and the asterisk indicates that the salt concentration is a^* %.

Then replacing $(\Delta V^*/2V)\times10^3$ by Ψ in Eqs. 8 and 9, we have

$$\Psi=(\Phi_s^*+\Phi_w-\Phi_a-\Phi_b)C/2 \quad (10)$$

$$\Psi=\{(d_a+d_b)/2d_s^*-1\}\times10^3 \quad (11)$$

Now we will for convenience' sake call Ψ, which represents the rate of change of the volume upon neutralization, "Volume Change Fraction". The numerical value of Ψ represents the change in the total volume observed on mixing the acid, which amounts to 500 ml., with an equi-volume of the base, of which the concentration is equal to that of the acid. The value of Ψ has the same sign as ΔV^*, so it is positive when the total volume expands on mixing the two solutions.

Results and Discussion

The values of volume change fraction on neutralization of a hydrochloric acid with a sodium hydroxide solution of equal concentration at 20°C have been calculated by the method mentioned in the previous section.

The weight per cent concentration of the resulting sodium chloride solution has been evaluated by Eq. 7, so the density of this solution has been obtained by interpolation from the density data of the "International Critical Tables"[4].

Therefore, the value of Ψ has been calculated by Eq. 11. The results obtained here are shown in Table I. In this table the values of the fifth column are those observed by Saslawsky et al.[5] and those in the last column are those calculated by Eq. 24, which will be derived later.

In Table II are shown volume changes

on neutralization at unequal concentrations, which are calculated by Eqs. 1 and 6.

The Degree of Inaccuracy in Ψ.—Whether or not the values of Ψ in Table I and ΔV^* in Table II are nearly the same as those obtained by a strict experiment depends upon the extent to which an error is made in evaluating the density of the resulting solution by interpolation. Therefore, we will discuss the error in density caused by interpolation[6].

In the case of sodium chloride, the maximum error in density caused by interpolation at intervals of four per cent concentration is 0.007~0.015 per cent in each range of concentration. It is proved by a mathematical calculation that the error in density caused by interpolation at intervals of two per cent concentration is less than one fourth of that at intervals of four per cent concentration, so that it would be rightly considered that the maximum of the errors which would be expected by interpolation at intervals of two per cent concentration is less than 0.004 per cent. If the density data are given at intervals of one per cent concentration, it is needless for us to consider the error in density caused by interpolation.

On the other hand, an error of 0.001 per cent in density would cause an inaccuracy of about 0.01 in Ψ. It is derived from Eq. 11 or deduced from the inaccuracy in Φ (cf. Eq. 10)[7]. Therefore, each of the calculated values of Ψ in Table I may be slightly less than the corresponding true value of Ψ, but the difference between the two does not exceed 0.04.

It is of course true that the above-mentioned discussion can be applied not only to Ψ in Table I, but also to ΔV^* in Table II.

Further, densities of the solutions of acids and bases at 20°C shown in Table III have been evaluated by the following equations, which have been suggested by Root[8].

$$d_{HCl} = 0.99823 + 0.01870\,C - 0.00087\,C^{3/2} \quad (12)$$

$$d_{NaOH} = 0.99823 + 0.04744C - 0.00454C^{3/2} \quad (13)$$

where C is the concentration in mol./l. of the electrolyte solution. These equations have been derived by using the values of Φ^0 and S_v for each electrolyte shown in Table IV.

TABLE III. DENSITIES OF HYDROCHLORIC ACIDS AND SODIUM HYDROXIDE SOLUTIONS AT 20°C

NaCl	15.82	2.32

6) It has been fully discussed in "Changes of Volume of Mixing Electrolytic Solutions with Water", presented at the 10th Annual Meeting of the Chemical Society of Japan, held in Tokyo in April, 1957; A. Tsujioka, *Proc. of Faculty of Eng., Keio Univ.*, **10**, 47 (1957).

7) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions", 2nd Ed., Reinhold Publishing Co., New York (1950), p. 251.

8) W. C. Root, *J. Am. Chem. Soc.*, **55**, 850 (1933).

At this point, therefore, the errors other than those caused by interpolation would be introduced in the values of Ψ and ΔV^* shown in Tables I and II, because they were evaluated by using the data in Table III. In conclusion, the values of Ψ and ΔV^* shown in Tables I and II appear to leave more or less room for doubt at 2 places of decimals. Nevertheless, the agreement between our data and Saslawsky's data has been found very satisfactory in Table I.

Relationships between the Volume Change Fraction and the Concentration.— Since the discovery by Masson[9] that the apparent molar volume of a dissolved salt is a linear function of the square root of the volume concentration, several investigators[10,11] have made extensive tests of the applicability of this relationship. It was found valid for a number of electrolytes over a surprisingly large concentration range. In the range of high dilution, however, the apparent molar volumes Φ_v of strong electrolytes in solution confirm the limiting law derived from the Debye-Hückel theory[12,13]. That is, the function $\Phi_v - S_v C^{1/2}$ is linearly related to the volume concentration C, where S_v is the universal limiting slope. (The experimental limiting slopes determined from the results above 0.25 N are specific[14].)

Therefore, the following Masson's linear relationships hold over a wide range of concentration except at high dilution.

$$\Phi_a = \Phi_a^0 + S_a\sqrt{C} \tag{14}$$

$$\Phi_b = \Phi_b^0 + S_b\sqrt{C} \tag{15}$$

$$\Phi_s^* = \Phi_s^0 + S_s\sqrt{C_s^*} \tag{16}$$

where Φ_a^0, Φ_b^0, Φ_s^0, S_a, S_b and S_s are constants, and C_s^* is the concentration in mol./l. of the salt solution, of which the concentration has been denoted by a^* % in the above section, obtained on neutralization of an acid with a base of equal concentration, C mol./l. Accordingly Eq. 10 for Ψ can be reduced to

$$\Psi = \{(\Phi_s^0 + \Phi_w - \Phi_a^0 - \Phi_b^0) + S_s\sqrt{C_s^*} - S_a\sqrt{C} - S_b\sqrt{C}\}C/2 \tag{17}$$

The resulting salt solution has a volume $(2V + \Delta V^*)$ ml., as has been indicated in the previous section. Hence the following equation:

$$C_s^* = C/2(1 + 10^{-3}\cdot\Psi) \tag{18}$$

Where Ψ, equal to $(\Delta V^*/2V)\times 10^3$, is the volume change fraction. Substituting Eq. 18 in Eq. 17 and then putting it in order by the binomial formula, we find the following equation.

$$\Psi = [(\Phi_s^0 + \Phi_w - \Phi_a^0 - \Phi_b^0) + (S_s\sqrt{2C}/2) \times\{1 + \sum_{r=1}^{\infty}\binom{-1/2}{r}(10^{-3}\cdot\Psi)^r\} - S_a\sqrt{C} - S_b\sqrt{C}\,]C/2 \tag{19}$$

In this equation, the terms $\sum_{r=1}^{\infty}\binom{-1/2}{r}(10^{-3}\cdot\Psi)^r$ are small and can usually be ignored[15], so that we may write,

$$\Psi = \{(\Phi_s^0 + \Phi_w - \Phi_a^0 - \Phi_b^0) + (S_s\sqrt{2C}/2)(1 - \Psi/2000) - S_a\sqrt{C} - S_b\sqrt{C}\}C/2 \tag{20}$$

Solving this equation with respect to Ψ, we may readily derive the following equation.

$$\Psi = \{(\Phi_s^0 + \Phi_w - \Phi_a^0 - \Phi_b^0) + \sqrt{C}(\sqrt{2}S_s/2 - S_a - S_b)\}(1 - \sqrt{2}S_sC^{3/2}/8000)C/2 \tag{21}$$

Consequently we obtain the following equation for Ψ.

$$\Psi = K_1C + K_2C^{3/2} - K_3C^{5/2} - K_4C^3 \tag{22}$$

where
$$K_1 = (\Phi_s^0 + \Phi_w - \Phi_a^0 - \Phi_b^0)/2$$
$$K_2 = (\sqrt{2}S_s - 2S_a - 2S_b)/4$$
$$K_3 = (\sqrt{2}S_s/8000)K_1$$
$$K_4 = (\sqrt{2}S_s/8000)K_2$$

In most cases K_3 and K_4 are small and can be ignored, so that Eq. 22 is approximately represented by means of the following equaiion.

$$\Psi = K_1C + K_2C^{3/2} \tag{23}$$

As an example, we shall deal with the reaction between a hydrochloric acid and a sodium hydroxide solution. Values of the parameters of Eqs. 14, 15 and 16 at 20°C obtained by the present writer are shown in Table IV[16]. The limiting law of the apparent molar volume has been

9) D. O. Masson, *Phil. Mag.*, 8, 218 (1929).
10) W. Geffcken and D. Price, *Z. physik. Chem.*, **B26**, 81 (1934).
11) A. F. Scott, *J. Phys. Chem.*, **35**, 2315 (1931).
12) B. B. Owen and S. R. Brinkley, Jr., *Ann. N. Y. Acad. Sci.*, **51**, 753 (1949).
13) O. Redlich and J. Bigeleisen, *J. Am. Chem. Soc.*, **64**, 758 (1942).
14) See Ref. 7, p. 523.
15) The largest one of these terms, $\binom{-1/2}{2}(10^{-3}\cdot\Psi)^2$, is generally less than 0.001. So it would be rightly considered that the contribution of these terms to the value of Ψ does not exceed 0.1 per cent.
16) These values were not evaluated from data at high dilution.

confirmed for aqueous solutions of sodium chloride up to 0.75 N and of hydrochloric acid up to 0.2 N[12,13]. Therefore the empirical equations, which will be derived below, should not be extrapolated to lower concentrations. Again for aqueous solutions of a few acids (i. e., perchloric acid and sulfuric acid) the apparent molar volume show an unusual dependence on the concentration[17-19].

It appears to be the same for aqueous solutions of hydrogen halides[20]. For hydrochloric acid, however, this deviation from Masson's rule is negligibly small[21,22], so we have not taken it into consideration.

By using the data in Table IV, the coefficients K_1, K_2, K_3 and K_4 in Eq. 22 have been calculated as follows.

$$K_1=11.76,\ K_2=-1.89,\ K_3=4.8\times10^{-3},$$
$$K_4=-7.7\times10^{-4}$$

In this case, therefore, we obtain

$$\Psi=11.76\,C-1.89\,C^{3/2} \qquad (24)$$

The correctness of this equation has been found very satisfactory in Fig. 1 and Table I. In Fig. 1, values of $2\Psi/C$ have been plotted against the square root of the concentration. The numerical value of $2\Psi/C$ represents the volume change in ml. on neutralization of an acid and a base of equal concentrations, C mol./l., which occupy the equal volume, v ml.,

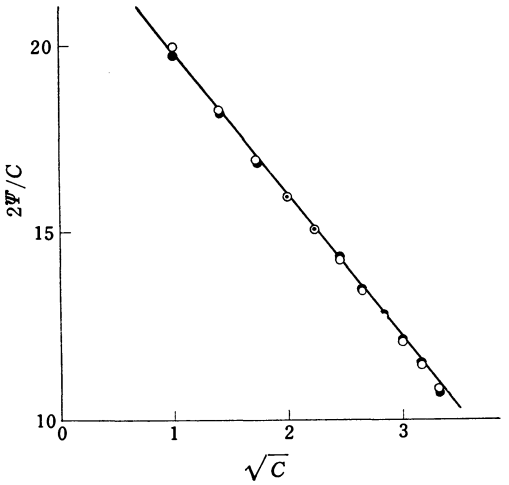

Fig. 1. Dependence of the volume change per mol., on neutralization of hydrochloric acid with sodium hydroxide of equal concn., upon concentration, at 20°C.
——, Calculated by Eq. 24, i.e., $2\Psi/C=23.52-3.78\sqrt{C}$;
○, Tsujioka's data; ●, Saslawsky's data

where v is the volume of the solution, expressed in ml., containing one mole of the solute[23].

On the other hand, in the case of volume changes on neutralization of acids and bases of unequal concentrations, it has been shown in Table II that the expansion in total volume on neutralization gets larger as the range of concentration gets lower, and that the volume change which occurs when hydrochloric acid is more concentrated than sodium hydroxide is larger than that in the reverse case, and so on. These facts, together with the discussion of Eq. 24, may be explained by considering the volume change on dilution. It will be reported in this bulletin shortly.

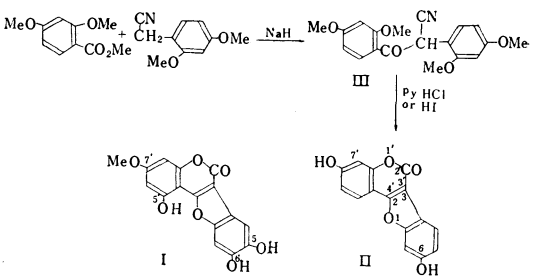
23) Then C is equal to $10^3/v$, and the volume change fraction Ψ is equal to $(\Delta v/2v)\times10^3$, as has been defined in the previous section, where Δv is the volume change in ml. on neutralization. Therefore it follows that $\Delta v=2\Psi/C$.

Reactions of Active Methylene Compounds. VI. A New Synthesis of Coumestrol, 6,7'-Dihydroxycoumarino (3',4':3,2) coumarone

By Yoshiyuki KAWASE

(Received December 13, 1958)



It has been reported that naturally occurring wedelolactone[1] (I) and coumestrol[2] (II) are 5,5',6-trihydroxy-7'-methoxy and 6,7'-dihydroxy derivatives of coumarino (3',4':3,2) coumarone, respectively.

The synthesis of coumarino (3',4':3,2) coumarones has been achieved by the action of hydrobromic acid[3] or pyridine hydrochloride[4] on 3-(2'-methoxyphenyl)-4-hydroxycoumarin derivatives; wedelolactone trimethylether[3,4], from which wedelolactone[5] was derived, was prepared by this method, and coumestrol has recently been synthesized by the action of aniline hydrochloride or hydriodic acid on 3-(2',4'-dimethoxyphenyl)-4,7-dihydroxycoumarin[6].

Another synthetic route to coumarino-(3',4':3,2) coumarone was reported by Chatterjea and Roy, which involves the action of hydrobromic acid on 2-methoxybenzoyl-2-methoxyphenylacetonitrile[7].

The author also has achieved independently the synthesis of 3-phenyl-4-hydroxycoumarins[8] and coumarino (3',4':3,2) coumarones[9] from methoxy derivatives of benzoyl-phenylacetonitrile or corresponding ester by the action of hydrobromic or hydriodic acid or pyridine hydrochloride or anhydrous aluminum chloride.

Now, the synthesis of coumestrol has been carried out by the action of pyridine hydrochloride or hydriodic acid on 2,4 dimethoxybenzoyl-2,4-dimethoxyphenylacetonitrile (III). The acetate of coumestrol thus obtained, m.p. 227~228°C (uncorrected), was identical with the sample, m.p. 227~228°C (uncorrected), which was kindly sent by Dr. Emerson.

Experimental[10]

Ester Condensation.—To a solution of methyl 2,4-dimethoxybenzoate (3.5 g.) and 2,4-dimethoxyphenylacetonitrile (3 g., prepared by azlactone-method[11]) in anhydrous benzene (100 cc.), sodium hydride (ca. 0.6 g.) was added, and the mixture was heated on an oil bath (ca. 95~100°C) for 4 hr. under anhydrous condition, most of the benzene having been distilled off in the meantime. After being well cooled, the mixture was treated with a small amount of ethanol to destroy the excessive sodium hydride, and then diluted with water. Insoluble starting materials being extracted with ether (from the residue of the ether solution, 1.5 g. of the nitrile was recovered through crystallization from methanol), the alkaline solution was acidified and the separated product was collected, washed with aqueous sodium bicarbonate solution and recrystallized from ethanol to give III in colorless needles, m.p. 97~98°C; yield 2.4 g. or 40% (yield was raised to 70% when recovery of the nitrile was taken into account).

Anal. Found: C, 67.01; H, 5.72; N, 4.25. Calcd. for $C_{19}H_{19}O_5N$: C, 66.85; H, 5.61; H, 4.10%.

Coumestrol.—(*a*) *By pyridine hydrochloride.*—A mixture of III (0.7 g.) and anhydrous pyridine hydrochloride (3.5 g.) was refluxed for 40 min.

Syntheses of Chlorinated Copper Phthalocyanines from Chlorophthalic Anhydrides

By Masahiro SHIGEMITSU

(Received December 16, 1958)

As a method of synthesis of copper phthalocyanine, the urea-method[1] resorting to the condensation of phthalic anhydride, urea and copper salts prevails. Chlorinated copper phthalocyanines can be obtained by the use of chlorophthalic anhydrides instead of phthalic anhydride. However, since chlorinated copper phthalocyanines are manufactured by chlorinating copper phthalocyanine, little work has been done upon the syntheses of them from chlorophthalic anhydrides.

The author carried out the syntheses of chlorinated copper phthalocyanines by the urea-method, using chlorophthalic anhydrides instead of phthalic anhydride and studied the effect given by the chlorine atoms of starting materials.

Experimental

Materials.—*Phthalic anhydride* (I).—Commercial phthalic anhydride was used with further purification (m. p. 130~131°C).

Monochlorophthalic anhydrides. — By the improved V. Villiger's method[2,3], phthalic anhydride was chlorinated with chlorine gas at 50~55°C in an iron closed vessel, using oleum as solvent and iodine as catalyst. From the mixture of monochlorophthalic anhydrides thus prepared, were separated 3-monochlorophthalic anhydride (II), m. p. 121~122°C (reported m. p. 122°C[4]) (*Anal.* Found: Cl, 19.47%) and 4-monochlorophthalic anhydride (III), m. p. 97~98°C (reported m. p. 98°C[4]) (*Anal.* Found: Cl, 19.44%) by repeating recrystallization with toluene-ethanol (1 : 1) solvent.

Dichlorophthalic anhydrides. — From the mixture of dichlorophthalic anhydrides prepared by the same procedure as above, were separated 3,4-dichlorophthalic anhydride (IV), m. p. 120~121°C (reported m. p. 120~121°C[4]) (*Anal.* Found: Cl, 32.68%), 3,6-dichlorophthalic anhydride (V), m. p. 190~191°C, (reported m. p. 190~191°C[4]) (*Anal.* Found: Cl, 32.71%) and 4,5-dichlorophthalic anhydride (VI), m. p. 185.5~186.5°C (reported m. p. 185~187°C[4]) (*Anal.* Found: Cl, 32.66%) with toluene-ethanol (1:1) solvent.

1) U. S. Pat. 2,197,458 (1940).

2) V. Villiger, *Ber.*, **42**, 3538 (1909).

3) M. Shigemitsu, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **62**, 110 (1959). (Presented at the Autumnal Joint Meeting of Chemical Society of Japan with other Societies, Tokyo, 1957).

4) V. Villiger, *Ber.*, **42**, 3532 (1909).

Trichlorophthalic anhydrides.—From the mixture of trichlorophthalic anhydrides prepared by the same procedure as above, were separated 3,4,6-trichlorophthalic anhydride (VII), m. p. 147.5~148.5°C (reported m. p. 148°C[5]) (*Anal.* Found: Cl, 42.19%) and 3,4,5-trichlorophthalic anhydride (VIII), m. p. 155.5~156.5°C (reported m. p. 157°C[6]) (*Anal.* Found: Cl, 42.20%) with toluene-ethanol (1:1) solvent.

Tetrachlorophthalic anhydride (IX).—By N. Juvalta's method[7], phthalic anhydride was chlorinated with chlorine gas at 50~60°C and thereafter 200°C in oleum, using iodine as catalyst, and the product was recrystallized with toluene-ethanol (1:1) solvent; m. p. 255~256.5°C (reported m. p. 255~256.5°C[8]) (*Anal.* Found: Cl, 49.22%).

Methods.—Into a three-necked flask of 300 cc. capacity equipped with a stirrer, a thermometer and a reflux condenser were placed 4 : 20 : 1 mol. ratio mixture of phthalic anhydride or its chlorinated derivatives, urea and cuprous chloride as indicated in Table I, and 150 g. of trichlorobenzene used as solvent.

The mixture was stirred at room temperature for 30 min., and then heated to 175°C for 1 hr. at a uniform rate and finally at 175~180°C for 3 hr. After the reaction was complete, trichlorobenzene was removed by steam distillation and the product was heated with 5% hydrochloric acid and then with 2% caustic soda, filtered, washed with water and ethanol and dried at 95~100°C.

In the case of tetrachlorophthalic anhydride, the reaction was conducted with the addition of ammonium molybdate[9], boric acid[1], zirconium tetrachloride[10] and titanium tetrachloride[10] as catalysts of condensation.

Results and Discussion

Results of condensation of phthalic anhydride or its chlorinated derivatives with urea and cuprous chloride are given in Table I.

Phthalic anhydride easily reacts with urea and cuprous chloride and forms copper phthalocyanine. However, when the chlorine content of phthalic anhydride increases, the yield of the product decreases.

The yields obtained in Experiments 3, 6 and 8 are all larger than those obtained in Experiments 2, 5 and 7. Experiment 4 shows the yield between those obtained in Experiments 5 and 6. It is recognized from the above experiments that chlorinated copper phthalocyanines are formed from chlorophthalic anhydrides more easily when chlorine atoms are in 4,5-positions of phthalic anhydride than when they are in its 3,6-positions.

Although copper hexadecachlorophthalocyanine should be obtained in Experiment 9, the chlorine content of the product coincides with that of copper dodecachlorophthalocyanine. The author further studied this matter as follows.

Ammonium molybdate, boric acid, zirconium tetrachloride and titanium tetrachloride are used as catalysts to increase the yield of phthalocyanine formed in

urea-method. Using these compounds as catalysts and under the reaction conditions in Table I, IX was condensed with urea and cuprous chloride. The results are given in Table II.

In Table II, the yield in Experiment 12 is the largest, but it is only 60%. The larger the yield, the larger the chlorine content is. However, all the chlorine contents in Table II are smaller than that of copper hexadecachlorophthalocyanine and close to that of copper dodecachlorophthalocyanine.

As it was considered that dechlorination reaction might possibly occur in the formation of phthalocyanine, the product obtained in Experiment 9 (Table I) was examined. Based on the method in Ref. 11, 3 g. of the product was decomposed by oxidation with ceric sulfate, which gave 2.0 g. of 3,4,5-trichlorophthalic anhydride, m. p. 156~157°C (reported m. p. 157°C[6]) (*Anal.* Found: Cl, 42.17%). It was evident from the above experiments that the chlorine atom at 6-position of IX separated and condensed with urea and cuprous chloride.

Summary

Syntheses of chlorinated copper phthalocyanines from various chlorophthalic anhydrides were conducted. Formation of phthalocyanine depends upon the contents and positions of chlorine atoms of chlorophthalic anhydrides.

The author extends his sincere thanks to Dr. Ryozo Goto, Professor of Kyoto University, for his kind guidance. Thanks are also due to Dr. Takahisa Nakamura and Dr. Wataru Ishikawa, Toyo Ink Manufacturing Company, for their help.

Color Characteristics of Copper Phthalocyanine and its Chlorinated Derivatives

By Masahiro SHIGEMITSU

(Received December 16, 1958)

Copper phthalocyanine pigments range in shade from blue to green, and are very strong and bright. Arranged in order of increasing greenness or of decreasing redness, they are listed as follows:

(1) Copper phthalocyanine (β-form)
(2) Copper phthalocyanine (α-form)
(3) Copper semichlorophthalocyanine
(4) Copper polychlorophthalocyanine

They are used as coloring matters dispersed in various vehicles such as polymerized linseed oil, nitrocellulose and miscellaneous synthetic resins.

In order to study the effects of the crystal structures, the numbers and positions of chlorine atoms and the pigment contents on the variation of color, the author formulated coloring matter with polymerized linseed oil used as the vehicle, and measured the reflectance curves.

Experimental

Materials.—*α-Form* (I) *and β-form* (II) *copper phthalocyanines.* — A mixture of phthalic anhydride, urea and cuprous chloride was heated in trichlorobenzene at about 190°C for 3 hr[1]. The reaction product was treated with 5% hydrochloric acid and 2% caustic soda, filtered off, washed with water and ethanol, and dried.

The crystal structure of copper phthalocyanine thus prepared was α-form (I)[2,3]. It was pulverized in a ball mill by the method described in Ref. 4.

To transform it into β-form (II), it was dissolved in 98% sulfuric acid, poured into water and deposited as fine crystals[5].

Copper octa-(4,5)-chlorophthalocyanine (III) *and copper octa-(3,6)-chlorophthalocyanine* (IV).— First, from the mixture of dichlorophthalic anhydrides prepared by chlorinating phthalic anhydride in oleum by the improved V. Villiger's method[6,7], 4,5-dichlorophthalic anhydride, m. p. 185.5～186.5°C (reported m. p. 185～187°C[8]) (*Anal.* Found: Cl, 32.66%) and 3,6-dichlorophthalic anhydride, m. p. 190～191°C (reported m. p. 190～191°C[8]) (*Anal.* Found: Cl, 32.71%) were separated with toluene-ethanol (1:1) solvent.

III (*Anal.* Found: Cl, 33.21%) and IV (*Anal.* Found: Cl, 33.23%) were synthesized respectively from 4,5- and 3,6-dichlorophthalic anhydrides by the urea-method[1]. They were respectively dissolved in chlorosulfonic acid and poured into ice water and reprecipitated as fine crystals.

Copper hexadecachlorophthalocyanine (V). — V was prepared by chlorinating copper octa-(3,6)-chlorophthalocyanine (*Anal.* Found: Cl, 50.33%)[7]. It was dissolved in chlorosulfonic acid, poured into ice water and reprecipitated as fine crystals. Particle size distributions of these materials were obtained with an electron microscope[9]. The diameters of these particles were 200～400 mμ and the mean value was about 250 mμ.

Methods.—A mixture of an equal quantity of each pigment and polymerized linseed oil was made into paste (A) by grinding 400 rounds in a Hoover automatic muller. A mixture of an equal quantity of aluminum hydroxide and polymerized linseed oil was made into paste (B) as above. A and B were mixed and pastes of each pigment, having pigment contents of 30, 25, 20, 15, 10, 7.5 and 5%, respectively, were prepared. These were applied 0.5 mm. in thickness on coated papers with a bladeoapplicator (Gardner Laboratory) and dried at room temperature. Reflectance curves of these samples were measured with a recording spectrophotometer (General Electric Co.) and C. I. E. Notations were obtained.

Results

Tables I, II, III, IV and V show the C. I. E. Notations of I, II, III, IV and V. In these tables, *Y* denotes luminosity, *Pe* purity and λ_D dominant wavelength.

7.5	25.56	30.5	489.3
5	34.24	28.5	492.0

In all cases, luminosities and dominant wavelengths decreased as the pigment contents increased, but variations of purities differed depending upon the kinds of pigments. I and II gave the maximum purities when their pigment contents were 20 and 25% respectively. On the other hand, purities of IV and V increased as their pigment contents increased. III showed a tendency similar to I and II. Fig. 1 shows the relation between purities and luminosities.

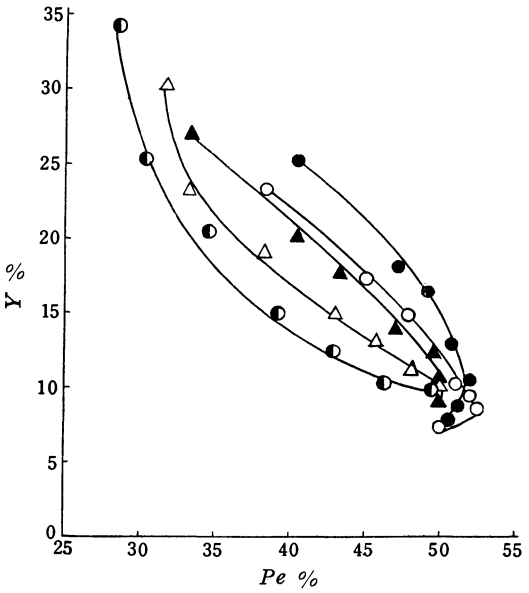

Fig. 1 Relation between purity and luminosity.
-●- Copper phthalocyanine (β-form).
-○- Copper phthalocyanine (α-form).
-▲- Copper octa-(4, 5)-chlorophthalocyanine.
-△- Copper octa-(3, 6)-chlorophthalocyanine.
-◐- Copper hexadecachlorophthalocyanine.

The purity of II was higher than that of I. The luminosities of I and II increased and decreased from the points of maximum purities with the variations in their purities, and the tendency in II was more conspicuous than in I. On the other hand, the luminosities of IV and V decreased with the increase in their purities.

Summary

The variation of color of copper phthalocyanine and its chlorinated derivatives in polymerized linseed oil was investigated.

The β-form of copper phthalocyanine is more conspicuous than the α-form in their variation of color.

Chlorine atoms at 3, 6- or 4, 5-positions of phthalocyanine nucleus give very different actions according to their variations of color, even if their chlorine contents are the same.

The author extends his sincere thanks to Dr. Ryozo Goto, Professor of Kyoto University, for his kind guidance. Thanks are also due to Dr. Takahisa Nakamura and Dr. Wataru Ishikawa, Toyo Ink Manufacturing Co., for their help.

Hydrothermal Reaction of Aluminumtrihydroxides

By Goro YAMAGUCHI and Kenichi SAKAMOTO

(Received December 17, 1958)

Recently, many studies of thermal transformation of the aluminumtrihydroxides have been reported[1] and we have got details of the mechanism of thermal change. Moreover, there are many experiments dealing with the digesting of gibbsite in an autoclave, but there is no consistent theory of the mechanism of the digesting reaction. The present authors studied and tried to explain the mechanism of hydrothermal reaction of aluminumtrihydroxides. Details are shown as follows.

Experimental

· Materials. — The aluminumtrihydroxides employed in this experiment were gibbsite and bayerite. The gibbsite was a commercial product. It was washed with pure water. Ignition loss was 34.40%. The bayerites were prepared by three methods. The details of the methods had already been reported by the authors[2]. Three bayerites are named bayerite-*a*, -*b* and -*c*. In this study, the *a* was prepared by aging alumina-gel in ammonia water, the *b* was precipitated from sodium aluminate solution by means of a current of carbon dioxide, and the *c* was prepared by auto-precipitation from sodium aluminate solution. The main impurity was sodium oxide of 0.10~0.50%. The crystallinities of bayerites were quite different according to their processes of preparation. They were identified by X-ray analysis.

(1) Teflon packing, (2) double thermocouples, (3) sample holders, (4) thermometer.

Apparatus and Procedure.—The authors devised an apparatus for differential thermal analysis in saturated vapor. The diagram is shown in Fig. 1. Air-tightness of the part 1 is kept by packing many thin Teflon sheets. This part is cooled in runs to protect the Teflon packings from thermal damage. Sample holders are silica vessels with 1 cm. diameter and 1.5 cm. depth.

The sample was about 1.5 g. in weight, and soaked with 1.5 cc. of water or alkali solutions of various concentrations. In some cases samples were mixed with boehmite. The reaction products were checked by X-ray diffraction.

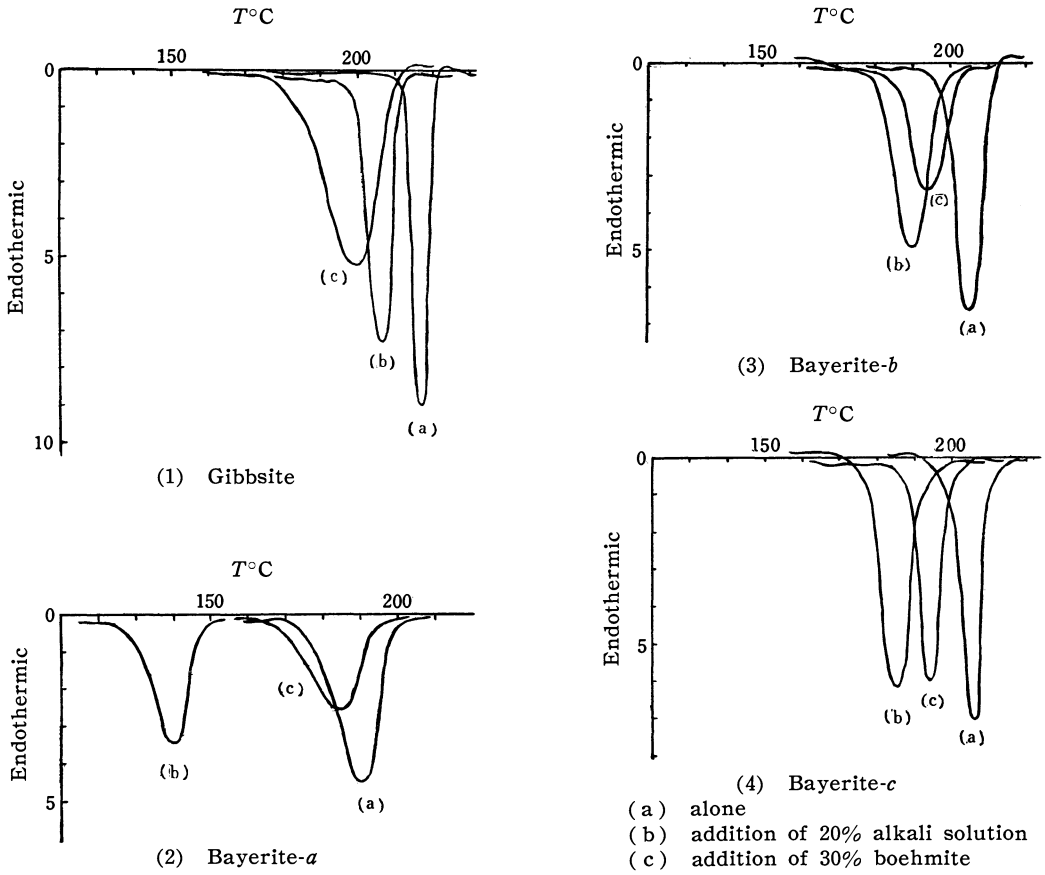

Fig. 2. DTA-curve of aluminumtrihydroxides.

Result

The results of the differential thermal analysis were shown in Fig. 2 and Table I. Gibbsite decomposes endothermally into boehmite. When gibbsite is immersed in alkali solution the peak temperature shifts to a lower point and the breadth at the half value of the endothermic peak becomes greater. The fall in peak temperature and the widening in breadth are very striking at the mixture of gibbsite and boehmite. In the case of 30%-boehmite, the peak temperature lowers to 200°C and the breadth becomes as wide as 17°C. These facts indicate that the alkalinity and the existence of boehmite lower the transformation temperature, that is, accelerate the transformation velocity.

About bayerites, it is clear that they have different stabilities according to the process of preparation. The bayerite-*a* exhibited the lowest peak temperature, and the temperature at the beginning of the transformation is also low. The peak temperature of DTA-curve is lowered remarkably by the addition of alkali. This indicates that this type of bayerite dissolves faster than it does in water. On the other hand, boehmite has only a little effect on the transformation of bayerite-*a*. Bayerite-*b* and -*c* showed similar characters. Added alkali lowers the peak temperature of these two bayerites, and makes the breadth wider. Boehmite lowers also the peak temperature of these bayerites, but has a different effect upon their width. The width of DTA-curve for bayerite-*c* is not effected by the addition of boehmite but the width for bayerite-*b*, becomes wider.

Consideration

Bauermeister and Fulda[3] and also Ginsberg and Koester[4] reported that the transformation of gibbsite to boehmite in an autoclave was accelerated by a small amount of alkali being added. Their

4) H. Ginsberg and M. Koester, *Z. anorg. u. allgem. Chem.*, **271**, 41 (1952).

results agree with the present results. Further Russell and his co-workers[5] reported that gibbsite transformed quickly to boehmite in a concentrated alkali solution. Bauermeister explained the transformation from gibbsite to boehmite as a dissolution change, but Ginsberg, and also Sato[6] supposed this reaction to be solid-decomposition. Now, the authors support the resolution reaction through which the transformation proceeds. This reaction consists of two steps ; the dissolution of trihydroxides and the crystallization of boehmite. We can represent this reaction as follows :

$$Al(OH)_3 + (OH)^- \rightarrow Al(OH)_4^-$$

$$Al(OH)_4^- \rightarrow AlO(OH) + (OH)^- + H_2O$$

Thus, we can understand the effect of boehmite as the seed of the crystallization of boehmite. In this region boehmite is very stable, so it is unnatural to suppose that this boehmite reacts directly with aluminumtrihydroxide. This is quite analogous to the effect of gibbsite-seed in the Bayer-process.

About bayerites, it was found that their stabilities were quite different according to the process of their preparation. Also in reference to X-ray diffraction data, it is sure that stabilities of bayerites correspond to their crystallinities. So, the properties which bayerite-*a* exhibited, i.e., the low temperature of the beginning of the transformation and the broad width of the DTA-curve, are attributed to its poor crystallinity. This bayerite was prepared by aging an alumina gel in ammonia solution. So it is supposed that this bayerite consisted of components with different crystallinities. The stability of the composition with poor crystallinity is very small, so this part begins to change into boehmite at temperature as low as 165°C. When alkali solution was added to this bayerite the peak temperature lowered remarkably. This is explained as follows: The part with poor crystallinity dissolves faster in alkali solution than in water, then boehmite crystallizes quickly from this aluminate solution, so this boehmite acts as the seed for the following crystallization. Therefore, the peak temperature fell remarkably, and the width of the DTA-curve remained as before.

Finally, it is emphasized that the transition of aluminumtrihydroxides in saturated vapor does not proceed as an equilibrium transition but as the change from an unstable system to a stable one. This means that the transition velocity at the equilibrium state is very slow and the first phase exists unchanged. A sufficiently high temperature is necessary for rapid change of aluminumtrihydroxides. When this condition is fulfilled, the transition proceeds quickly and shows a sharp endothermic peak of DTA-curve. This was realized in the thermal analysis of trihydroxides without alkali and boehmite (Fig. 2). In this case, the endothermic peak is very sharp and seems to be the peak of a monovariant reaction. But this is attributed to the large velocities of dissolution of aluminumtrihydroxides and of crystallization of boehmite.

In general the change of the Gibbs free energy of any reaction is represented by the next formula

$$\Delta G = \Delta H - T\Delta S$$

In this experiment, the chemical change proceeds as follows :

$$Al(OH)_3 + (OH)^- \rightarrow Al(OH)_4^-$$

$$Al(OH)_4^- \rightarrow AlO(OH) + (OH)^- + H_2O$$

in short

$$Al(OH)_3 \rightarrow AlO(OH) + H_2O$$

Under this condition, of course, ΔG must be negative. ΔH was found to be positive, and the entropy change is positive, because entropy increases at dehydration reaction. When this entropy term overcomes the enthalpy term, then the reaction proceeds. Russell and his co-workers studied the equilibrium constants to form aluminate ion from gibbsite and boehmite and found the transition temperature from gibbsite to boehmite in pure water to be 27°C. Also they found that the trihydrates transformed rapidly to α-monohydrate at solution temperatures above 100°C. This is consistent with the present results.

Summary

In saturated vapor, the aluminumtrihydroxides dissolve in the water and the velocity of dissolution of the trihydroxides becomes larger as the temperature rises. When this solution is supersaturated over the solubility of boehmite, transformation proceeds. The alkalinity and the boehmite added to the hydroxides accelerate

the transition. The former makes easy the dissolution of trihydroxides, and the latter acts as the seed and accelerates the velocity of the crystallization of boehmite.

A Convenient Method for the Calculation of the π-Electronic Structures of Aromatic Derivatives

By Kichisuke NISHIMOTO and Ryoichi FUJISHIRO

(Received January 12, 1959)

Theoretical investigations about the π-electronic structures of the aromatic derivatives based on the LCAO MO method have been carried out by many authors[1]. According to the results obtained by them, the molecular properties have been well correlated with their π-electronic structures, if the parameters appearing in the method have been properly chosen. But the actual calculation of the π-electronic structure of the molecule by means of the MO method is in general rather laborious. Therefore, it will be very convenient if one can find the method by which the calculation is simplified. In this paper we shall provide a convenient method using the set of vacant orbitals for the calculation and apply this method to the calculation of the molecular diagrams of the benzene hydroxy derivatives. In later discussions, we shall refer to this method as the "VO method" (vacant orbital method).

Method

The method is based on the framework of LCAO MO approximation, neglecting the differential overlap. When the molecule contains $2p\pi$ atomic orbitals (AO) in number of n, the molecular orbitals (MO), φ_i, are expressed by the linear combination of these AO's as follows:

$$\varphi_i = \sum_{\mu}^{n} \phi_\mu c_\mu \qquad (1)$$

where ϕ_μ is the μ-th $2p\pi$AO and c_μ is the coefficient to be determined by the variational method. When the following matrix notations which are the same as in Roothaan's paper[2] are used

$$\boldsymbol{\Phi} = (\varphi_1 \varphi_2 \cdots\cdots \varphi_n)$$

$$\boldsymbol{\phi} = (\phi_1 \phi_2 \cdots\cdots \phi_n)$$

$$\mathbf{C} = \begin{pmatrix} c_{11} & c_{12} & \cdots\cdots & c_{1n} \\ c_{21} & c_{22} & \cdots\cdots & c_{2n} \\ \vdots & \vdots & & \vdots \\ c_{\mu 1} & c_{\mu 2} & \cdots\cdots & c_{\mu n} \\ \vdots & \vdots & & \vdots \\ c_{n1} & c_{n2} & \cdots\cdots & c_{nn} \end{pmatrix}$$

we may write then for Eq. 1

$$\boldsymbol{\Phi} = \boldsymbol{\phi}\mathbf{C}$$

If we multiply the right-hand side by $\boldsymbol{\Phi}^*$ and the left-hand side by $\boldsymbol{\phi}^*\mathbf{C}^*$, then the following relation may be obtained,

$$\mathbf{C}^*\mathbf{C} = \mathbf{E}$$

or

$$\sum_{\mu}^{n} c_{\mu i}^* c_{\mu i} = 1 = \sum_{\mu}^{occ} c_{\mu i}^* c_{\mu i} + \sum_{\mu}^{vac} c_{\mu i}^* c_{\mu i}$$

$$\sum_{\mu}^{n} c_{\mu i}^* c_{\nu i} = 0 = \sum_{i}^{occ} c_{\mu i}^* c_{\nu i} + \sum_{i}^{vac} c_{\mu i}^* c_{\nu i} \qquad (2)$$

where $\sum_{i}^{occ}$ and $\sum_{i}^{vac}$ mean the summation over the set of occupied orbitals and that of vacant orbitals, respectively. According to the definitions, the charge density q_μ and the bond order $p_{\mu\nu}$ may be written as,

$$2\sum_{i}^{occ} c_{\mu i}^* c_{\mu i} = q_\mu$$

$$2\sum_{i}^{occ} c_{\mu i}^* c_{\nu i} = p_{\mu\nu}$$

1) See, e.g., B. Pullman and A. Pullman, "Les Theories Electroniques de la Chimie Organique", Masson et Cie, Paris (1952).

2) C. C. J. Roothaan, *Rev. Modern Phys.*, **23**, 69 (1951).

It is convenient to introduce q^v_μ and $p^v_{\mu\nu}$ as the corresponding quantities for the set of vacant orbitals, that is,

$$2\sum_i^{vac} c^*_{\mu i}c_{\mu i}=q^v_\mu$$

$$2\sum_i^{vac} c^*_{\mu i}c_{\nu i}=p^v_{\mu\nu}$$

Using these quantities, Eq. 2 can be rewritten as

$$(q_\mu-1)=-(q^v_\mu-1)$$

$$p_{\mu\nu}=-p^v_{\mu\nu} \qquad (3)$$

$(q_\mu-1)$ represents the net charge at the position of the μ-th carbon atom belonging to the parent hydrocarbon system. As seen in Eq. 3, the set of vacant orbitals may become a mirror image of that of occupied orbitals. For the case of substituents which have only the lone pair orbitals, such as OH, NH_2, Cl, etc., the net charge must be expressed by $(q_\mu-2)$ instead of $(q_\mu-1)$. Therefore, in this case $-q^v_\mu$ may directly measure the net charge at the substituent. Using the relation 3, the calculation of the molecular diagram of the aromatic derivative may be considerably simplified, because

(1) the number of vacant orbitals is always less than that of occupied orbitals, and

(2) the vacant orbital and their energies differ only slightly from those of the reference system, since the large differences in orbital energies between the occupied and the vacant orbitals in the reference system may restrict the deformation of the vacant orbitals by conjugation to small extent. Here, we call the system in which the interactions between the parent hydrocarbon system and the substituents do not take place, as the reference system.

Pople's method for the LCAO SCF MO calculation tells us that the matrix elements of the Hartree-Fock Hamiltonian can be expressed by q_μ's, $p_{\mu\nu}$'s and the fundamental atomic integrals. Therefore, the SCF calculation based on his method may substantially expedited by the use of VO method, because

(1) the calculations of q_μ's and $p_{\mu\nu}$'s are easily carried out, and

(2) the rapid convergence to the SCF MO's may be expected, since the vacant orbitals may differ only slightly from those of the reference system.

When the square of the coefficient of the carbon atom to be bonded with the substituent in the lowest vacant orbital (frontier orbital) of the parent hydrocarbon system has considerably large value, the deformation for the lowest vacant orbital by conjugation may be greater than for others. Thus, in this case the frontier orbital will make the greatest contribution to the mirror image relations. Actually, it is well known[3] in many cases that the frontier orbital theory provides satisfactory information for the discussion of chemical reactions.

Next, we shall show a mirror image relation of orbital energies. The energy, ε_i, of the φ_i is determined by the solution of the secular determinant of n-th degree, that is,

$$\det|H_{\mu\nu}-\delta_{\mu\nu}\varepsilon|=0$$

where $H_{\mu\nu}$ is the matrix element of the Hamiltonian, which is expressed by

$$H_{\mu\nu}=\int\phi^*_\mu H\phi_\nu\,dv$$

where H is the (effective or Hartree-Fock) Hamiltonian operator. According to the algebraic theory, the total sum of roots is equal to the negative value of the coefficient of ε^{n-1} term in the development of the secular determinant in terms of ε, that is,

$$\sum_i^n\varepsilon_i=\sum_\mu^n H_{\mu\mu}=\sum_i^{occ}\varepsilon_i+\sum_i^{vac}\varepsilon_i \qquad (4)$$

From this equation we obtain

$$2\sum_i^{occ}\varepsilon_i-\sum_\mu^n H_{\mu\mu}=-(2\sum_i^{vac}\varepsilon_i-\sum_\mu^n H_{\mu\mu}) \qquad (5)$$

For many purposes, only the extra delocalization energy, $\Delta\varepsilon$, arising from the delocalization of the $2p\pi$ electrons by substitution may be important. $\Delta\varepsilon$ is defined as follows:

$$\Delta\varepsilon=2(\sum_i^{occ}\varepsilon_i-\sum_i^{occ}\varepsilon^0_i) \qquad (6)$$

where ε^0_i is the orbital energy in the reference system. Similar relation to Eqs. 4 and 5 may also be obtained for the case of reference system, that is,

$$\sum_i^n\varepsilon^0_i=\sum_\mu^n H^0_{\mu\mu}=\sum_i^{occ}\varepsilon^0_i+\sum_i^{vac}\varepsilon^0_i$$

$$2\sum_i^{occ}\varepsilon^0_i-\sum_\mu^n H^0_{\mu\mu}=-(2\sum_i^{vac}\varepsilon^0_i-\sum_\mu^n H^0_{\mu\mu}) \qquad (7)$$

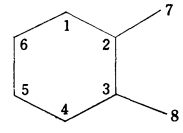
-1.0346	$\varphi_3^v=0.5663(\phi_1+\phi_4)-0.3076(\phi_2+\phi_3)-0.2783(\phi_6+\phi_5)+0.0849(\phi_7+\phi_8)$
	Resorcinol
-2.0480	$\varphi_1^v=0.4125\phi_1-0.4224(\phi_2+\phi_6)+0.3943(\phi_3+\phi_5)-0.3850\phi_4+0.0833(\phi_7+\phi_8)$
-1.0987	$\varphi_2^v=0.5129(\phi_2-\phi_6)-0.4668(\phi_3-\phi_5)-0.1381(\phi_7-\phi_8)$
-1.0313	$\varphi_3^v=0.5258\phi_1-0.2711(\phi_2+\phi_6)-0.3389(\phi_3+\phi_5)+0.5791\phi_4+0.0752(\phi_7+\phi_8)$
	Hydroquinone
-2.0475	$\varphi_1^v=0.4180(\phi_1-\phi_4)-0.3990(\phi_2-\phi_3-\phi_5+\phi_6)-0.0826(\phi_7-\phi_8)$
-1.1269	$\varphi_2^v=0.5748(\phi_1+\phi_4)-0.2702(\phi_2+\phi_3+\phi_5+\phi_6)-0.1532(\phi_7+\phi_8)$
-1.0000	$\varphi_3^v=0.5000(\phi_2-\phi_3+\phi_5-\phi_6)$
	Phloroglucinol
-2.0698	$\varphi_1^v=0.4111(\phi_1+\phi_3+\phi_5)-0.3973(\phi_4+\phi_2+\phi_6)-0.0806(\phi_7+\phi_8+\phi_9)$
-1.0987	$\varphi_2^v=0.2961(2\phi_1-\phi_3-\phi_5)+0.2695(2\phi_4-\phi_2-\phi_6)-0.0797(2\phi_7-\phi_8-\phi_9)$
-1.0987	$\varphi_3^v=0.5129(\phi_3-\phi_5)-0.4668(\phi_2-\phi_6)-0.1381(\phi_8-\phi_9)$
	2, 3, 5, 6-Tetrahydroxybenzene
-2.0923	$\varphi_1^v=0.3909(\phi_1-\phi_4)-0.4090(\phi_2-\phi_3-\phi_5+\phi_6)+0.0797(\phi_7-\phi_8-\phi_9+\phi_{10})$
-1.1827	$\varphi_2^v=0.4838(\phi_2-\phi_3+\phi_5-\phi_6)-0.1261(\phi_7-\phi_8+\phi_9-\phi_{10})$
-1.0664	$\varphi_3^v=0.5571(\phi_1+\phi_4)-0.2971(\phi_2+\phi_3+\phi_5+\phi_6)+0.0810(\phi_7+\phi_8+\phi_9+\phi_{10})$

We may now define $\Delta\varepsilon^v$ as follows:

$$\Delta\varepsilon^v=2\left(\sum_i^{vac}\varepsilon_i-\sum_i^{vac}\varepsilon_i^0\right) \tag{8}$$

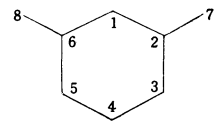
Then the following expression may be derived from above equations,

$$\Delta\varepsilon-\sum_i^n(H_{\mu\mu}-H_{\mu\mu}^0)=-\left[\Delta\varepsilon^v-\sum_\mu^n(H_{\mu\mu}-H_{\mu\mu}^0)\right] \tag{9}$$



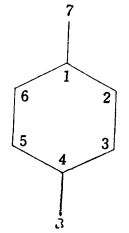
When $H_{\mu\mu}=H_{\mu\mu}^0$, which is the case in the simple LCAO MO treatment neglecting the inductive effect, Eq. 9 becomes

$$\Delta\varepsilon=-\Delta\varepsilon^v$$



Thus the mirror image relation of orbital energies is established.

Calculation of the Molecular Diagrams



We shall apply VO method to the calculation of the molecular diagrams of benzene hydroxy derivatives. The method is based on the framework of simple LCAO AO method neglecting the inductive effect. The parameters used are the same as those of phenol[4]. All the hydroxy derivatives have only three vacant orbitals, since the reference systems have

only three vacant orbitals, respectively. Therefore, the calculation based on the VO method is an easier task than that employing the set of occupied orbitals. The numbering of atoms is shown in Fig. 1. The calculated vacant MO's, ϕ_i^v, and their energies are collected in Table I, with those of a benzene molecule. Comparison of ϕ_1^v's of hydroxy derivatives with that of benzene indicates that the former are polarized regularly along the direction toward the substituent; but their magnitudes are rather small. On the other hand, the frontier orbitals, φ_2^v and φ_3^v, seem to reflect roughly the characters of the ground states of the molecules. The molecular diagrams calculated are given in Fig. 2. When we try to plot the magnitude of the charge migration, Δe, from the substituents into the benzene ring, against the extra delocalization energy, $\Delta\varepsilon$, a linear relationship is obtained as shown in Fig. 3.

Summary

It was shown that the set of vacant orbitals of the conjugated system would be a mirror image of that of occupied orbitals. Using this relation the calculations of the π-electronic structures of the aromatic derivatives are considerably simplified. As an example, the molecular diagrams of the benzene hydroxy derivatives were calculated.

Isomerism and Polymorphism of Cinnamic Acids and Deuterated Allocinnamic Acids

By Minoru HIROTA and Yoshiyuki URUSHIBARA

(Received January 17, 1959)

Since the three polymorphic forms of allocinnamic acid were found and studied by Liebermann[1], by Paal[2], and by Biilmann[3], they have been the subject of many researches[4] including those on the dipole moment[5], the infrared absorption[6], other physical properties, and the transition between them[7].

In the course of the studies of the polymorphic behaviors of the compounds with group $C_6H_5CH=CHCO$[8], deuterated allocinnamic acids have been investigated in comparison with the ordinary allocinnamic acid, the powder X-ray diffraction and ultraviolet absorption spectra of α,β-d_2-allocinnamic acid and *O*-*d*-allocinnamic acid being measured. The X-ray diffraction patterns of the *O*-*d*-allocinnamic acid showed an expansion of the crystal lattice. No remarkable difference was found among the ultraviolet absorptions of three polymorphic forms of allocinnamic acid. In an experiment of catalytic hydrogenation of phenylpropiolic acid to allocinnamic acid, a new polymorphic form, m. p. 120°C, of (*trans*-)cinnamic acid was obtained by chance, and its transition to the stable form, m. p. 133°C, was observed.

Experimental

Partial Hydrogenation of Phenylpropiolic Acid.—Phenylpropiolic acid was prepared from commercial cinnamic acid according to the method of "Organic Syntheses"[9,10], and catalytically hydrogenated to allocinnamic acid. Palladium catalysts, e. g., Pd-$BaSO_4$[11] Pd-poly(vinyl alcohol)[12] and Pd-Na protalbinate[13], and the Urushibara catalysts[14,15], e. g., U-Ni-B and U-Co-A, were used in the partial hydrogenation and the latter catalysts were found useful for the purpose. The U-Ni-B catalyst gave the purest allocinnamic acid, while the palladium catalysts yielded hardly crystallizable products which had to be purified through the aniline salt[16]. The results of the catalytic hydrogenation with various catalysts are summarized in Table I.

The 58°-form[17] of allocinnamic acid was prepared by recrystallization of the hydrogenation products, the 68°-form through the aniline salt and the 42°-form by cooling suddenly the melt of the 58°-form or 68°-form in dry ice.

Preparation of Deuterated Allocinnamic Acids.—α,β-d_2-Allocinnamic acid was prepared by the catalytic deuteration of sodium phenylpropiolate with deuterium in a solution in 99.7% heavy water produced by the Norsk Hydro-Elektrisk Kvaelstofaktieselskab, Norway. The deuterium was generated by the electrolysis of the heavy water by using anhydrous sodium sulfate as the electrolyte, platinum electrodes, and an electric current of density 0.02~0.03 amp./cm^2 and 6~8 V. Palladium on barium sulfate, which was chosen on account of its small content of exchangeable hydrogen, was first deuterated in the heavy water and then employed for the catalytic deuteration. It was presumed without any determination that the α,β-d_2-allocinnamic acid contained nearly 100% deuterium in the α and β positions.

In order to deuterate the carboxylic hydrogen, allocinnamic acid was recrystallized once from 47.4% D_2O and then from 99.7% D_2O. The deuterium content of allocinnamic acid deuterated in this way was determined to be 80±5% of the carboxylic hydrogen.

Measurements of Absorption Spectra.—Ultraviolet absorptions were measured in ethanolic solution in the range of wavelengths 2100~4000 Å with a Beckman Model DU spectrophotometer. Infrared absorptions were measured with a Baird Model B infrared recording spectrophotometer in

TABLE I. PARTIAL HYDROGENATION OF PHENYLPROPIOLIC ACID WITH VARIOUS CATALYSTS*

Catalyst	Conditions of hydrogenation	Forms of cinnamic acid obtained
U-Ni-B	Na salt in water	*cis*-58°**
U-Ni-A	Acid in ethanol	*cis*-58°
U-Co-A	Na salt in water	*cis*-58°, *cis*-68°
U-Co-A, then U-Ni-A	Acid in ethanol	*trans*-120°
U-Co-B	Na salt in water	*cis*-58°**
Pd-Na protalbinate (colloidal)	Na salt in water	Oil, *cis*-68° through aniline salt
Pd-charcoal	Na salt in water	Oil, *cis*-68° by recrystallization
Pd-$BaSO_4$	Na salt in water	*cis*-58°
Pd-poly(vinyl alcohol) (colloidal)	Na salt in water	Oil (*cis*-58°)**
U-Ni-B and active charcoal	Na salt in water	*cis*-68°, *cis*-58°

* Hydrogenation was stopped when one mole of hydrogen was absorbed.
** Phenylpropionic acid was obtained.

Nujol and in carbon tetrachloride solution when necessary.

Measurements of X-ray Diffraction Patterns. — The powder method was used with a Norelco X-ray diffractometer. The identity and the difference among polymorphic forms were determined by the diffraction patterns, the diffraction angles being mainly taken into consideration for the identification and the intensity of the diffracted beams being only auxiliarily respected.

Results and Discussion

Ultraviolet Absorption.—Guy[18] observed that polymorphic forms of allocinnamic acid give different infrared spectra especially in the finger print region, and Urushibara, Iimura and Ikeda[8,19] showed that polymorphic forms of chalcones differ not only in infrared but also in ultraviolet spectra. The ultraviolet absorptions of cinnamic acid and allocinnamic acid have been reported with no notice of any difference in polymorphic forms[20].

TABLE II. ULTRAVIOLET ABSORPTION SPECTRA OF CINNAMIC ACIDS IN ETHANOL

	Form	λ_{max}(Å)	ε_{max}
Cinnamic acid	133°	2730	20500
(*trans*)	120°	2725	19000
Allocinnamic acid	58°	2670	9500
(*cis*)	68°	2660	9800
	42°	2630~2650	ca.10000

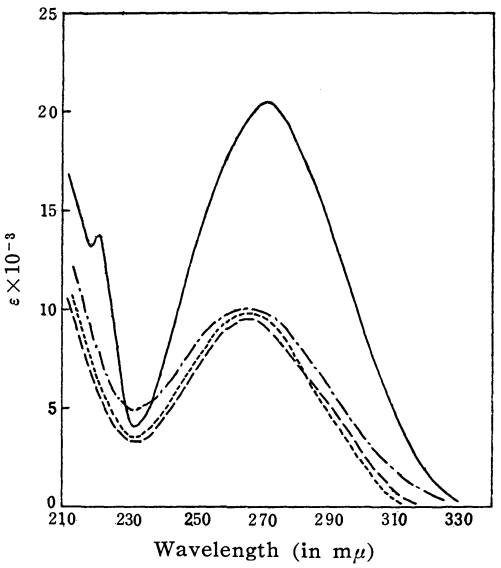

Fig. 1. The ultraviolet spectra of cinnamic acids.
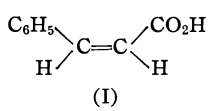
Cinnamic acid 133°-form ————
Allocinnamic acid 42°-form —·—·—
58°-form ·····
68°-form ————



Ultraviolet absorption spectra in ethanol were measured with all the polymorphic forms of cinnamic acid and of allocinnamic acid with the results shown in Table II and Fig. 1. The three forms of allocinnamic acid gave similar absorption curves with no remarkable differences in either the locations or the intensities of the absorption maxima. Moreover, cinnamic acid and allocinnamic acid absorbed almost the same wavelength but the intensity of the former was roughly twice as strong as the latter.

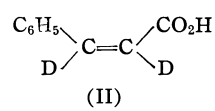
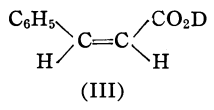
20) A. E. Gilam and E. S. Stern, "Introduction to Electronic Absorption Spectroscopy in Organic Chemistry", Edward Arnold Ltd., London (1954); H. M. Hershenson, "Ultraviolet and Visible Absorption Spectra, Academic Press Inc., New York (1956), p. 233.



Braude and his co-workers[21-23] have extensively studied the relations between the ultraviolet spectra and the steric hindrance in conjugated systems and concluded that, when the steric hindrance is not so large as to prevent the conjugation, the sterically hindered *cis*-isomer gives an absorption maximum almost at the same location as the unhindered *trans*-isomer but having a remarkably lower intensity. The appearance of polymorphism in a molecule with a partially hindered conjugated system is caused by the existence of metastable, rotationally hindered, forms conditioned by both the steric hindrance and the π-electron interaction between two parts of the molecule[24,25]. The interpretation that the polymorphism of cinnamic acids is based on such causes is supported by the different infrared spectra of the polymorphic forms.

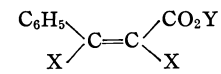
The ultraviolet spectra of the deuterated allocinnamic acids revealed no isotope effect in any polymorphic forms.



Polymorphism of Deuterated Allocinnamic Acids.—Measurements of the powder X-ray diffraction with α,β-d_2-allocinnamic acid (II) and *O*-*d*-allocinnamic acid (III) in comparison with the ordinary allocinnamic acid (I) showed that the diffraction patterns of the polymorphic forms of *O*-*d*-allocinnamic acid deviate from those of the corresponding forms of the other

(I)

(II)



(III)

two, respectively. The deviations are comparatively remarkable, though small, in the two polymorphic forms melting at 58°C and at 68°C, and noticeably in the direction of smaller diffraction angles, suggesting a lattice expansion caused by deuteration. Deviations observed in the 42°-form permit to conclude neither a lattice expansion nor a lattice contraction.

The lattice expansion observed in the two forms of *O*-*d*-allocinnamic acid is supposed to be due to the deuterium bond which is weaker than the hydrogen bond in the corresponding forms of the ordinary allocinnamic acid. Such an isotope effect is known in oxalic acid[26] and other compounds[27] and explained on the basis of the weaker deuterium bond.

TABLE III. THE MELTING POINTS OF ALLOCINNAMIC ACIDS

Form	I X=Y=H	II X=D, Y=H	III X=H, Y=D
68°	67.5~68.0°	67.0~68.0°	66.5~67.0°
58°	57.5~58.5°	55.0~57.5°	54.5~55.0°
42°	41.0~42.5°		41.5~42.0°

Some forms of the deuterated allocinnamic acids melted lower than the corresponding forms of the ordinary allocinnamic acid, as shown in Table III, and, since the melting point of either the 58°-form or the 68°-form of the ordinary allocinnamic acid was lowered by recrystallization from heavy water, it can be concluded that the lowering of the melting points of *O*-*d*-allocinnamic acid is connected with the lattice expansion.

Formation and Properties of the Metastable Form, m. p. 120°C, of Cinnamic Acid.—The new form of (*trans*-)cinnamic acid was obtained in an experiment to prepare allocinnamic acid from phenylpropiolic acid. The experimental sequence was as follows: When phenylpropiolic acid was hydrogenated with the U-Co-A catalyst, the reaction was too slow to be completed. Then U-Ni-A was added with an intension of finishing the partial hydrogenation to allocinnamic acid. After being left to stand for a day, the product was isolated from the reaction mixture, but it melted at 120°C and did not coincide with any form of allocinnamic acid. The product proved a new form of (*trans*-)cinnamic acid, since it gave an infrared absorption in solution quite similar to that of the known form (m. p. 133°C) of cinnamic acid except for a slight difference in the finger print region, and an ultraviolet absorption also similar to that of the 133°-form of cinnamic acid (120°-form: λ_{max} 2725 Å, ε_{max} 19000; 133°-form: λ_{max} 2730 Å, ε_{max} 20500). On the other hand,

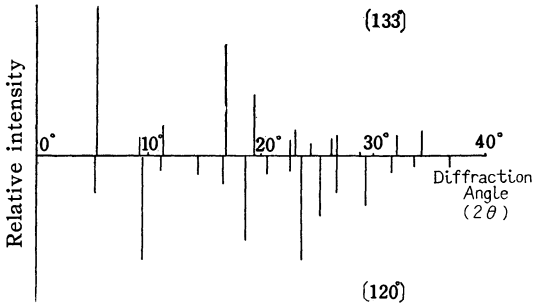

Fig. 2. The X-ray diffraction patterns of the 120°-form and the 133°-form of (*trans*-)cinnamic acid.

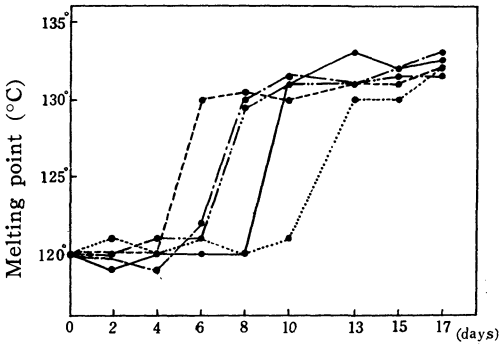

Fig. 3. Changes of the melting points of the 120°-form of cinnamic acid.

the X-ray diffraction pattern of the 120°-form is clearly different from that of the stable 133°-form of cinnamic acid, as shown in Fig. 2.

The formation of the new form of cinnamic acid in the hydrogenation of phenylpropiolic acid is explained by assuming that the allocinnamic acid formed by the catalytic hydrogenation was isomerized to a metastable form of the *trans*-isomer during its contact with the catalyst. The 120°-form was transformed into the 133°-form in one week or two, when it was kept in a dark place at room temperature. All attempts to repeat the preparation of the metastable form failed and the *cis*-isomer was always obtained instead. Further, it was observed that the transition of the metastable form to the stable form occurred abruptly when it once started by chance. Namely, when five portions of the metastable form were kept in a dark place at about 15°C, the melting points of these portions, determined every second or third day, changed suddenly but at different times, as shown in Fig. 3.

The authors wish to acknowledge their indebtedness to the late Dr. Iimura, and to express their thanks to Dr. Ōki and to Dr. Kobayashi, for their helpful discussions, to Dr. Nishimura and Dr. Sugimori for catalytic hydrogenation, and to Dr. Hayashi for measurements of the infrared spectra.

Non-benzenoid Aromatic Heterocycles. I. Reactions of 4-Pyrone, 4-Thiopyrone, and their Pyrylium Salts with Active Methylene Compounds

By Masaki OHTA and Hiroshi KATO

(Received January 9, 1959)

It has been widely accepted that the -O- group is equivalent to the -CH=CH- group, thus 4-pyrone and 4-thiopyrone can be regarded as heterocyclic tropone analogues. The physical and chemical properties of these compounds can be more adequately explained in terms of formula Ia than in terms of the conventional formula Ib. In the same sense the pyrylium salts Ic derived from them can be considered as heterocyclic tropylium salt analogues.

In this respect, it is of interest to study some of their reactions. The concept that the carbonyl group of 4-pyrone behaves anomalously and does not react with most carbonyl reagents had long been accepted until Woods' report[1], where he has shown that 2,6-dimethyl-4-pyrone(II) undergoes condensation with malonitrile by refluxing in acetic anhydride. The present authors have tried further the condensation of II and 2,6-dimethyl-4-thiopyrone(III) with active methylene compounds aiming to show, to what extent the carbonyl or thiocarbonyl group of these compounds is active, and to distinguish the difference between these two compounds. 2,6-Dimethyl-4-pyrone(II) reacted with malonitrile, ethyl cyanoacetate, or rhodanine to give the corresponding condensation product IV~VI under the condition reported by Woods, but it failed to react with diethyl malonate, acetylacetone, cyclopentadiene, or nitromethane. Just the same result was obtained when III was treated with the above-cited compounds; this fact indicates essentially the same carbonyl character of these two compounds. The fact that the same condensation products are obtained starting from II or III unequivocally proves the structures of the condensation products. It is noteworthy that the condensation is not effected by the usual catalysts, e.g., sodium ethoxide or *tert.*-butoxide, sodium acetate, or piperidine. This fact suggests anomalous character of pyrone carbonyl group.

Woods reported that IV was hydrolyzed to the corresponding dicarboxylic acid, but in the authors' experiment, the corresponding nitrile-amide VII was the sole product. In this connection, it is worthy of note that malonic acid reacted with II or III by gently warming in acetic anhydride, but the reaction was accompanied by decarboxylation, and the product obtained in each case was black unpurifiable powder.

Recently, Dimroth et al.[2] have reported that 2,4,6-trialkylpyrylium borofluorides or perchlorates, when treated with potassium *tert*-butoxide in nitromethane, give the corresponding nitrobenzene derivatives. As 4-methoxy- or 4-methylmercaptopyrylium perchlorate, derived from II or III respectively, is structurally similar to trialkylpyrylium salts, the present authors predicted the reaction of the same type. This occurred as expected, and when 4-methoxy-2,6-dimethylpyrylium perchlorate (VIII) was treated with nitromethane and sodium *tert*-butoxide, 4-methoxy-2,6-dimethylnitrobenzene(IX)* was obtained. This compound IX was converted into 3,5-dimethyl-4-nitrophenol(X)* by refluxing

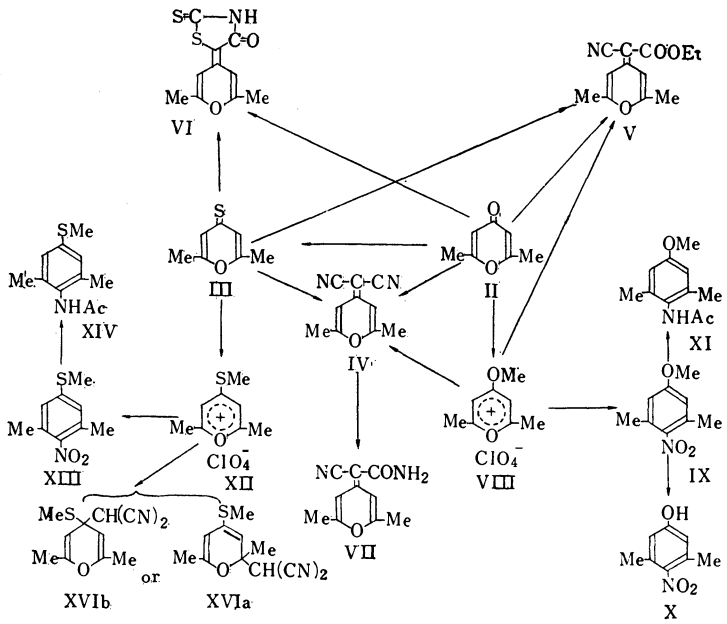

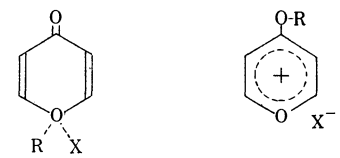

Fig. 1. Reactions of 2,6-dimethyl-4-pyrone and their derivatives with active methylene compounds.

with hydrobromic acid, and to 2,6-dimethyl-*p*-anisidine** by reduction with zinc and hydrochloric acid, which was identified as its acetyl derivative XI. Similarly, 4-methylmercapto-2,6-dimethylpyrylium perchlorate(XII) gave 4-methylmercapto-2,6-dimethylnitrobenzene(XIII) by the reaction with nitromethane and sodium *tert*-butoxide. This compound XIII was reduced, by zinc and hydrochloric acid to the corresponding amine, which was identified as an acetyl derivative(XIV)***. As Dimroth et al. have pointed out, these reactions are of value as a convenient preparatory method of the otherwise unobtainable or not easily accessible compounds. Moreover, the results of these reactions clearly reject the structure XVa which was once proposed for the salts****, and add an unambiguous proof of the widely accepted structure XVb.

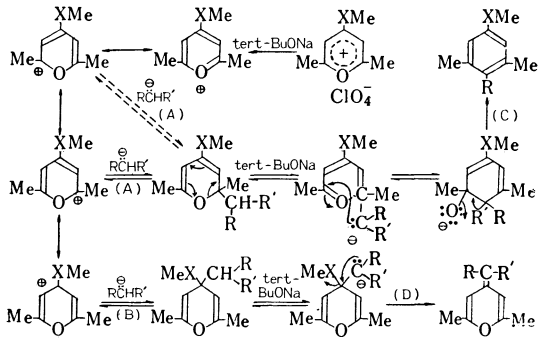
XVa XVb

Dimroth et al.[6] have briefly reported that the reaction of 2,4,6-trialkylpyrylium salts with ethyl cyanoacetate leads to benzonitrile derivatives. The present authors have expected the reaction of the same type with VIII, but in this case, the condensation at the position 4 of the salt VIII occurred, and gave exclusively 4-(ethoxycarbonylcyanomethylene)-2,6-dimethyl-4H-pyrane(V). Similarly, when VIII was treated with malonitrile, 4-(dicyanomethylene)-2,6-dimethyl-4H-pyrane (IV) was obtained. In the case of XII, the splitting up of methyl mercaptan did not occur, and the compound of the type XVIa or XVIb was obtained.

These reactions can be interpreted if the reaction mechanism shown in Fig. 2 is taken into account.

In Fig. 2, the key steps which determine the reaction routes are assumed to be steps A, B, C and D. The reactions with nitromethane take place smoothly by way of the steps A and C, but in the reaction with ethyl cyanoacetate, the step

** Bamberger et al.[4] prepared this compound by treating 2,6-dimethylphenylhydroxylamine with methanol in the presence of sulfuric acid.



4) E. Bamberger, *Ber.*, **36**, 2028 (1903).

*** This compound was prepared by Kloosterziel et al.[5], starting from 2,6-xylidine via thiocyano compound followed by reduction with lithium aluminum hydride and methylation.

X = O or S

Fig. 2. Mechanism of the condensation reaction.

D (demethoxylation) is more favorable than the step C (decarbethoxylation), and the reaction leads to the condensation at the position 4. The same reaction mechanism can be assumed to the reaction with malonitrile. In the case of trialkylpyrylium salts, the step D corresponds to dealkylation which is hindered, thus the reaction proceeds thoroughly via the step C to give benzonitrile derivatives, as is observed in Dimroth's report.

As 4-pyrone perchlorate is believed to possess the structure of the pyrylium salt type, the reaction between this compound and malonitrile was tried in hopes of effecting a condensation reaction, but when 2,6-dimethyl-4-pyrone perchlorate was treated with malonitrile and sodium *tert*-butoxide, free 2,6-dimethyl-4-pyrone was obtained.

Experimental

2,6-Dimethyl-4-pyrone (II)[7].—Dehydroacetic acid (100 g.) was refluxed in concentrated hydrochloric acid (400 ml.) for an hour, and the solution was boiled for two hours to concentrate, and finally concentrated nearly to dryness under reduced pressure. The residue was dissolved in water, and the solution was washed with benzene, saturated with potassium carbonate and extracted with chloroform. The extract, after being dried with potassium carbonate, was evaporated and the residue was collected. Yield, 71 g. (97%); m. p. 130°C. The product was pure enough for use in the subsequent experiments.

2,6-Dimethyl-4-thiopyrone (III).—This compound was prepared by King's method[8].

Condensation of II or III with Active Methylene Compounds.—2,6-Dimethyl-4-pyrone (II) (1 g.) or -thiopyrone (III) (0.5 g.) and 1 mol. each of active methyl or methylene compounds were refluxed in acetic anhydride for an hour. Solvent was removed under reduced pressure, and the residue was collected, washed with ether and recrystallized.

The following results were obtained (Yield A refers that from II and Yield B that from III):
Malonitrile: pale yellow needles (from ethanol), m. p. 191°C[9]. Yield A, 90%; B, 33%.
Ethyl cyanoacetate: pale yellow needles (from ethanol), m. p. 184°C. Yield A, 31%; B, 44%.

Anal. Found: C, 65.51; H, 6.10; N, 6.67. Calcd. for $C_{12}H_{13}O_3N$ (V): C, 65.74; H, 5.98; N, 6.39%.

Rhodanine: yellow needles (washed with benzene and recrystallized from acetone), m. p. 260°C. Yield A, 32%; B, 59%.

Anal. Found: C, 49.93; H, 4.12; N, 5.17. Calcd. for $C_{10}H_9O_2NS_2$ (VI): C, 50.21; H, 3.79; N, 5.86%.

The products obtained from III were identified by their melting points, and by the failure of m. p. depressions on admixture with the specimens prepared from II.

These condensations could not be effected by sodium ethoxide or *tert*-butoxide, sodium acetate, or piperidine as catalyst.

In the case of diethyl malonate, acetylacetone, cyclopentadiene, or nitromethane, the reaction occurred neither with II nor with III, and the starting material was recovered unchanged.

When malonic acid (3 g.) was gently warmed in acetic anhydride (15 ml.) with II or III (3 g. each) a marked evolution of gas was observed and black unpurifiable powder (3 g.) was obtained after removal of the solvent. This substance was soluble in aqueous solution of sodium bicarbonate, but insoluble in most solvents.

Hydrolysis of IV.—A suspension of IV (7 g.) in a mixture of concentrated hydrochloric acid (40 ml.) and ethanol (40 ml.) was refluxed for twenty-four hours and then poured into water. The precipitate was collected and recrystallized from ethanol giving pale yellow amorphous powder with green fluorescence. (5 g.) m. p. 252°C (decomp.).

Anal. Found: C, 62.61; H, 5.35; N, 14.42. Calcd. for $C_{10}H_{10}O_2N_2$ (VII): C, 63.15; H, 5.30; N, 14.73%.

No dicarboxylic acid was obtained when refluxing was prolonged for another thirty hours.

4-Methoxy-2,6-dimethylpyrylium Perchlorate (VIII).—This compound was prepared by Baeyer's method[10].

4-Methylmercapto-2,6-dimethylpyrylium Perchlorate (XII).—This compound was prepared by Arndt's method[11].

4-Methoxy-2,6-dimethylnitrobenzene (IX).—A hot solution of sodium *tert*-butoxide (0.47 g. of metallic sodium in 30 ml. of *tert*-butanol) was added into a solution of VIII (2.4 g.) in nitromethane (10 ml.) under stirring and reflux. After refluxing for an hour, the mixture was

7) This is a modification of the procedure reported by Cornubert et al. (*Bull. soc. chim. France*, **1950**, 40) and by King et al.[8]
8) L. C. King et al., *J. Am. Chem. Soc.*, **73**, 300 (1951).
9) Woods[1] reports the m. p. 190~192°C.

11) F. Arndt and P. Nachtwey, ibid., **59**, 446 (1926).

poured into dilute hydrochloric acid (200 ml. containing 2 ml. of concentrated hydrochloric acid) and the solution was extracted with chloroform. The extract was dried with potassium carbonate, the viscous oily residue which remained after removal of the solvent was distilled under reduced pressure, and the fraction distilling at 129°C/8 mmHg was collected; it soon solidified to pale yellow needles (1 g.), m. p. 50°C [12].

Anal. Found: C, 59.68; H, 6.43; N, 7.67. Calcd. for $C_9H_{11}O_3N$ (IX): C, 56.66; H, 6.12; N, 7.73%.

4-Methylmercapto-2, 6-dimethylnitrobenzene (XIII). — A hot solution of sodium *tert*-butoxide (0.32 g. of metallic sodium in 30 ml. of *tert*-butanol) was added to a solution of XII (1.7 g.) in nitromethane (8 ml.), and was treated by essentially the same method as described above. A fraction which was distilled at 148～149°C/8 mmHg was collected, and it solidified to yellow needles (0.6 g.), m. p. 62～63°C.

Anal. Found: N, 7.39. Calcd. for $C_9H_{11}O_2NS$ (XIII): N, 7.10%.

3, 5-Dimethyl-4-nitrophenol (X).—A solution of IX (0.5 g.) in a mixture of hydrobromic acid (48%, 10 ml.) and acetic acid (5 ml.) was refluxed for three hours and the reaction mixture was extracted with chloroform. Removal of the solvent left yellow residue, which was recrystallized from ethanol giving yellow plates (0.4 g.), m. p. 107～108°C [13].

Anal. Found: N, 8.34. Calcd. for $C_8H_9O_3N$ (X): N, 8.38%.

***N*-Acetyl-2, 6-dimethyl-*p*-anisidine (XI).** — To a solution of IX (1 g.) in a mixture of hydrochloric acid (10%, 20 ml.) and acetic acid (10 ml.) was added zinc dust (5 g.) portionwise under warming. After two hours, the mixture was extracted with chloroform, and the residue, left after removal of the solvent, was warmed with acetic anhydride. After removal of the solvent, the residue was recrystallized from ethanol giving colorless plates (0.8 g.), m. p. 178°C.

Anal. Found: N, 7.22. Calcd. for $C_{11}H_{15}O_2N$ (XI): N, 7.25%.

12) Rowe et al.[3] report the m. p. 53°C.
13) Rowe et al.[3] report the m. p. 107～108°C.

***N*-Acetyl-4-methylmercapto-2, 6-dimethylaniline (XIV).**—Treatment of XIII (0.4 g.) by the same procedure as described above gave white needles (0.4 g.), m. p. 155～156°C [14].

Anal. Found: N, 6.80. Calcd. for $C_{11}H_{15}ONS$ (XIV): N, 6.69%.

Reaction of VIII with Ethyl Cyanoacetate. —A solution of VIII (2.4 g.) in a mixture of ethyl cyanoacetate (10 ml.) and *tert*-butanol (10 ml.) was treated by the same method as described in the reaction with nitromethane. Distillation gave solid distillate, which on recrystallization from ethanol gave orange leaflets (0.7 g.), m. p. 185°C. (Found: N, 6.35%). No melting point depression occurred when admixed with the authentic specimen V prepared by the condensation of II with ethyl cyanoacetate.

Reaction of VIII with Malonitrile.—A solution of VIII (2.4 g.) in a mixture of malonitrile (3 g.) and *tert*-butanol (15 ml.) was treated as described above. After refluxing for an hour, the mixture was poured into dilute hydrochloric acid and the yellow precipitate which separated out was collected. Yield, 1.7 g., m. p. 189°C. (Found: N, 15.99%.). No melting point depression occurred when admixed with the authentic specimen IV[1].

Reaction of XII with Malonitrile. — Into a suspension of XII (2.6 g.) in a mixture of malonitrile (1 g.) and *tert*-butanol (30 ml.) was added a hot solution of sodium *tert*-butoxide (0.47 g. of metallic sodium in 30 ml. of *tert*-butanol) under stirring and reflux. After refluxing for an hour, the mixture was poured into dilute hydrochloric acid and the precipitate which separated out was collected and recrystallized from ethanol giving yellow plates; m. p. 132～133°C.

Anal. Found: C, 60.14, N, 5.54; H, 12.87. Calcd. for $C_{11}H_{12}ON_2S$ (XVI): C, 60.00; H, 5.49; N, 12.72%.

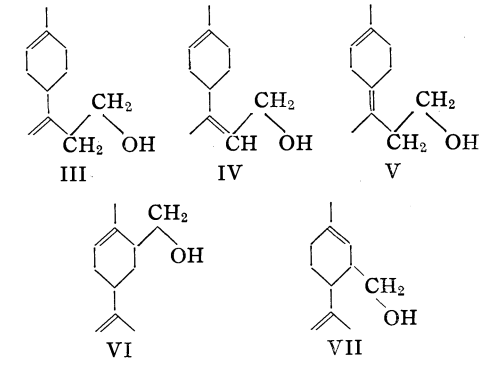
Synthesis of 1,8(9)-p-Menthadien-10-yl-carbinol



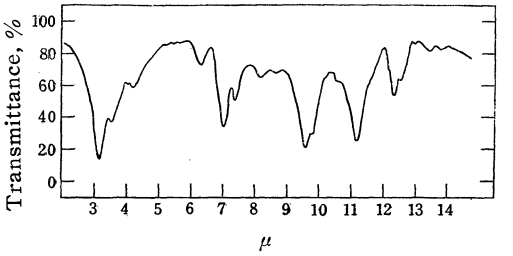
By Kyoichi SUGA, Juichi ISHII and Shoji WATANABE*

(Received January 17, 1959)

The addition of formaldehyde to olefines is known as Prins reaction[1]. For the first time Ladenberg[2] discovered that formaldehyde can be added to terpenes and Kriewitz[3] researched this reaction with β-pinene. Lombard[4] obtained alcohol (IV) from *d*-limonene, using zinc chloride as a catalyst. The present authors investigated the addition reaction of *d*-limonene and formaldehyde, and prepared a limonenylcarbinol in high yields (30%), the structure of which was proved to be 1,8(9)-*p*-menthadien-10-yl-carbinol (III).

d-Limonene(I) and paraformaldehyde(II) scarcely reacted at all when the mixture was agitated in the presence of zinc chloride for 3 hr. at about 80°C; neither aluminum chloride nor ferric chloride in place of zinc chloride gave good results. When a mixture of one mol. each of I and II was heated for 12 hr. at 200~220°C in a sealed tube, a yellow viscous oil was obtained (yield, 11%). It gave a phenylurethan, m. p. 54~55°C, which was analyzed as the phenylurethan derived from an alcohol, $C_{11}H_{18}O$. As this procedure did not give satisfactory yields, a mixture of I, II and acetic anhydride was heated in an autoclave, and a limonenylcarbinyl acetate was obtained in a yield of 30%. The use of 0.5 mol. or more of acetic anhydride per one mol. of I, the reaction temperature 180~190°C, and the reaction time 4~5 hr., gave the best result. A limonenylcarbinol was prepared by the saponification of the acetate. The acetate could not be saponified by the action of 20% aqueous or alcoholic potassium hydroxide at 100°C, but the carbinol was produced almost quantitatively by heating the acetate with 20% aqueous potassium hydroxide for 3~4 hr. at 180~190°C in an autoclave. The carbinol is a colorless liquid and it smells like cineol. The analysis of its phenylurethan, m. p. 56~57°C, indicated that the alcohol was a limonenylcarbinol. The velocity of esterification of phenylacetic acid with the carbinol showed that the carbinol was a primary alcohol.

In the addition of formaldehyde to terpenes or other compounds[5], formaldehyde adds usually at an end methylene group[6] or an active methylene group[9] adjacent to a double bond. Thus it is considered that the limonenylcarbinol possesses one of structures III, IV, V, VI and VII.



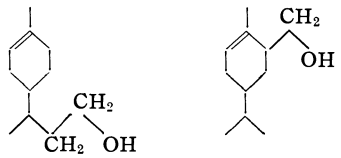


Fig. 1. The infrared absorption spectrum of the limonenylcarbinol(III).

The infrared absorption spectrum (Fig. 1) indicates the presence of a primary alcohol group (absorption peak at 9.6 μ) and an end methylene group (strong band at 11.25 μ), which excludes IV and V.

The optical activity ($[\alpha]_D^{10}$ +37.2) also makes V improbable. Formula III was concluded from the comparison of the infrared spectrum of the product(VIII), prepared by catalytic hydrogenation of the end methylene group of the carbinol, with that of 1(2)-*p*-menthen-6-yl-carbinol (IX) which was prepared from 1(2)-*p*-menthene and paraformaldehyde. The 1(2)-*p*-menthen-6-yl-carbinol (IX) showed remarkable doublet absorption peaks[11] at 7.2 μ (1390 cm^{-1}) and 7.3 μ (1370 cm^{-1}), and

VIII IX

medium absorption peaks at 8.55 μ (1170 cm^{-1}) and 9.05 μ (1150 cm^{-1})[12] owing to an isopropyl radical (Fig. 2). On the other hand, the hydrogenation product from the limonenylcarbinol gave the strong single band of a methyl group at 7.25 μ, but no absorptions of an isopropyl group at 8.55 μ and 9.05 μ (Fig. 3). These results suggest the structure of 1,8(9)-*p*-menthadien-10-yl-carbinol (III) for the limonenylcarbinol.

Experimental

***d*-Limonene(I).**—Commercial *d*-limonene was distilled with a rectifying column. B. p. 64～65°C/15 mmHg; d_4^{15} 0.8494; n_D^{15} 1.4756; $[\alpha]_D^{10}$ +113°.

Reaction in a Sealed Tube. — A mixture of 20 g. (0.15 mol.) of I, 4.5 g. (0.15 mol.) of II and 10 g. of ethanol was sealed in a hard glass tube, and heated at 200～220°C for 12 hr. in an electric furnace. The reaction mixture was poured into water and extracted with ether, and the ethereal solution was washed with water and dried over anhydrous sodium sulfate. By fractional distillation, 14 g. of I and 2.8 g. of the limonenylcarbinol were obtained. B. p. 102～105°C/4 mmHg; d_4^{8} 0.9612; n_D^{12} 1.5069. Yield, 11%.

Phenylurethan.—It was prepared as usual and recrystallized from methanol. Colorless needles, m. p. 54～55°C.

Anal. Found: N, 4.79; Calcd. for $C_{18}H_{23}O_2N$: N, 4.91%.

Limonenylcarbinyl Acetate (1,8(9)-*p*-Menthadien-10-yl-carbinyl Acetate).—A mixture of 45.3 g. (0.333 mol.) of I, 10 g. (0.333 mol.) of II and 20 g. (0.196 mol.) of acetic anhydride was heated at 180～190°C for 4～5 hr. in an autoclave. The reaction mixture was washed with water and dried over anhydrous sodium sulfate. Fractional distillation gave 20.5 g. of the crude acetate. B. p. 96～106°C/4 mmHg Yield, 29.6%. It was redistilled for characterization. B. p. 103～107°C/5 mmHg; d_4^{28} 0.9618; n_D^{28} 1.4790; molecular refraction 61.38 (Calcd. for $C_{11}H_{17}O\cdot COCH_3$, F_2, 60.75).

Limonenylcarbinol (1,8(9)-*p*-Menthadien-10-yl-carbinol).—A mixture of 13 g. of the crude acetate and 6 g. of potassium hydroxide (20% aq. solution) was heated at 180°C for 4 hr. in an autoclave. After cooling, the reaction mixture was extracted with ether, and the extracts were washed with water and dried over anhydrous sodium sulfate. Fractional distillation gave 10 g. of the limonenylcarbinol in a yield of 96%. B. p. 102～106°C/4 mmHg; d_4^{17} 0.9603; n_D^{17} 1.5020; molecular refraction 51.04 (Calcd. for $C_{10}H_{15}CH_2OH$, F_2, 51.39) $[\alpha]_D^{10}$ +37.2.

Phenylurethan.—It was prepared as usual and recrystallized from methanol. Colorless needles, m. p. 56～57°C.

Anal. Found: N, 4.86. Calcd. for $C_{18}H_{23}O_2N$: N, 4.91%.

Velocity of Esterification of Phenylacetic Acid with the Limonenylcarbinol.—The nature of the hydroxyl group of the limonenylcarbinol was determined by Murahashi's method[13]. A small amount of the carbinol was heated with phenylacetic acid at 150°C for an hour in a sealed glass tube. The initial rate of esterification in an hour was found 63% showing the carbinol is a primary alcohol.

1(2)-*p*-Menthen-10-yl-carbinol (VIII). — In methanol solution 3.93 g. of the limonenylcarbinol was hydrogenated with Pd-$BaSO_4$ containing 3%

13) E. Funakubo, "Identification of Organic Compounds, I" (Yuki Kagobutsu Kakuninho I), Yokendo, Tokyo (1951), p. 11.

Pd, and absorbed 583 cc. of hydrogen (760 mmHg, 20°C) to give 3.0 g. of VIII. B. p. 100~103°C/4.5 mmHg; n_D^{13} 1.4923.

***d*-Limonene Hydrochloride**[14,15].—In a 200 cc. three-necked flask equipped with a mechanical stirrer, a thermometer and a gas inlet tube, 100 g. of I was placed. The flask was cooled to −5°C in an ice-salt freezing mixture. Anhydrous hydrogen chloride was passed into the solution for 2 hr. The reaction mixture turned deep purple in color and sticky. It was washed with water, dried over anhydrous sodium sulfate and fractionally distilled to give a fraction of b.p. 65~68°C/4 mmHg. By redistillation 84 g. of *d*-limonene hydrochloride was obtained. B. p. 73~75°C/5 mmHg; n_D^{12} 1.4850.

1(2)-*p*-Menthene[14,16]. — Sodium (40 g.) was added gradually in an hour to a mixture of 40 g. of *d*-limonene hydrochloride and 200 g. of absolute ethanol with ice cooling. After sodium ethylate was decomposed with water, the product was extracted with ether and the ethereal solution was washed with water and dried over anhydrous sodium sulfate. By fractional distillation, 22 g. of 1(2)-*p*-menthene was obtained. B. p. 50~54°C/3.5 mmHg; n_D^{12} 1.4766.

1(2)-*p*-Menthen-6-yl-carbinol (IX). — To a mixture of 12 g. of 1(2)-*p*-menthene, 3 g. of II, 17 g. of 95% acetic acid and 4 g. of ether, cooled to −2°C, a mixture of 7 g. of 95% acetic acid and 2.5 g. of 98% sulfuric acid was added, and the mixture was agitated for 5 hr. After being allowed to stand overnight, it was extracted with ether and the ethereal solution was washed with aqueous sodium bicarbonate and with water, dried over anhydrous sodium sulfate, and fractionally distilled to give 3 g. af 1(2)-*p*-menthen-6-yl-carbinyl acetate. B. p. 90~100°C/4 mmHg; n_D^6 1.4860.

A mixture of 3 g. of the acetate, 4 g. of potassium hydroxide, 40 cc. of methanol and 1 cc. of water, was refluxed on a warm water bath for 3 hr. The product was extracted with ether, and the ethereal solution was washed with water and dried over anhydrous sodium sulfate. Evaporation of the ether and fractional distillation gave 2 g. of the carbinol (IX). B. p. 95~97°C/3 mmHg; n_D^9 1.4896.

Distribution of Neptunium between TBP and Some Mineral Acids

By Tomitaro ISHIMORI and Eiko NAKAMURA

(Received January 20, 1959)

Tri-*n*-butyl phosphate*, an excellent solvent which plays an important role in the Purex process, attracts the attention of chemists. For example, the distribution of plutonium was studied by McKay et al.[1] in the TBP-nitric acid system. Peppard et al.[2-5] are aggressively studying the behaviors of both actinides and lanthanides in TBP-mineral acid systems.

Although the extraction of neptunium with TBP has caused deep concern in connection with the isolation of the element[6,7], systematic studies on the behavior of the element are not known. Besides, the existence of three kinds of oxidation states of the element, (IV), (V) and (VI) makes the study complicated.

In the present paper, extraction of neptunium with TBP is studied systematically with the emphasis on its oxidation states.

* Tri-*n*-butyl phosphate is denoted by "TBP" in the present paper.

Experimental

Sources of Materials.—Neptunium-239 tracer is prepared from uranyl nitrate hexahydrate irradiated by JRR-1 reactor for 2 hr. After cooling several hours, the irradiated uranyl salt is converted into chloride and dissolved in 0.5 M hydrochloric acid solution. After reduction by a small amount of granulated zinc**, neptunium is extracted by about 5% TTA***-benzene. After rinsing with a small portion of 0.5 M hydrochloric acid solution, the benzene layer is contacted with >3 N hydrochloric, nitric, perchloric or sulfuric acid according to preference. Neptunium is thus obtained as acid solution. The TTA which might go into the tracer solution is removed by contact with benzene. The radiochemical purity of the tracer is checked by both gamma spectrometry and the decay measurement. Separation from fission products is excellent. But a small remaining amount of uranium was still found by a color reaction with hydrogen peroxide.

Protactinium-233 is isolated from irradiated thorium nitrate by solvent extraction. Irradiation is carried out in conditions similar to those mentioned above. Protactinium is separated from thorium by contacting concentrated nitric acid solution with 10% TBP-toluene. In this separation protactinium is extracted into the organic phase leaving thorium in the aqueous phase. After washing with concentrated nitric acid, protactinium is recovered by shaking with water. The resultant solution of protactinium-233 gives no precipitate by adding aqueous ammonia, showing that practically thorium does not remain. The radiochemical purity of protactinium-233 thus prepared is checked again by both γ-spectrometry and the measurement of the decay curve.

Hafnium-181 received from Oak Ridge National Laboratory is used without further purification.

Thorium-234 is prepared according to Dyrssen's[8] method. The radiochemical purity is checked by determining its half life of 24.1 days.

Determination of Distribution Ratios. — In the determination of the distribution ratio, *Kd*, of a specific nuclide, defined as the concentration of nuclide in the organic phase divided by that of nuclide in the aqueous phase of two equilibrated liquid phases, a portion of aqueous acid of the indicated concentration containing a radioactive nuclide is equilibrated against a portion of solvent which is previously pre-equilibrated with respect to the corresponding barren aqueous acid. Every contact is carried out on a milliliter scale. For example, a 2.5 ml. portion of 10.1 M nitric acid containing approximately 10^5 cpm neptunium-239 is equilibrated with a 2.5 ml. portion of undiluted TBP which was previously contacted with three successive equal-volume portions of barren 10.1 M nitric acid. All solvent pre-equilibrations are made immediately before the use to avoid any complications arising from solvent hydrolysis. Aliquots of each phase are pipetted into small glass tubes for gamma counting. Gamma counting is made by means of Philips' scintillation counter with bed type head. Scrubbings are carried out both for aqueous and organic phases, if necessary. The *Kd* values are calculated dividing cpm of the organic phase by that of the aqueous phase after making a correction for natural counting.

Results and Discussion

Nitric Acid-TBP System. — Nitric acid solution of neptunium tracer prepared as mentioned above contains both neptunium (IV) and (V). The relative abundance between neptunium(IV) and (V) varies according to the treatment of the tracer solution. The freshly prepared solution contains only a very small amount of neptunium(V), whereas standing for a few days or warming in boiling water makes neptunium(V) rich.

Nitric acid solution containing both neptunium(IV) and (V) is contacted with TBP. The resultant organic or aqueous

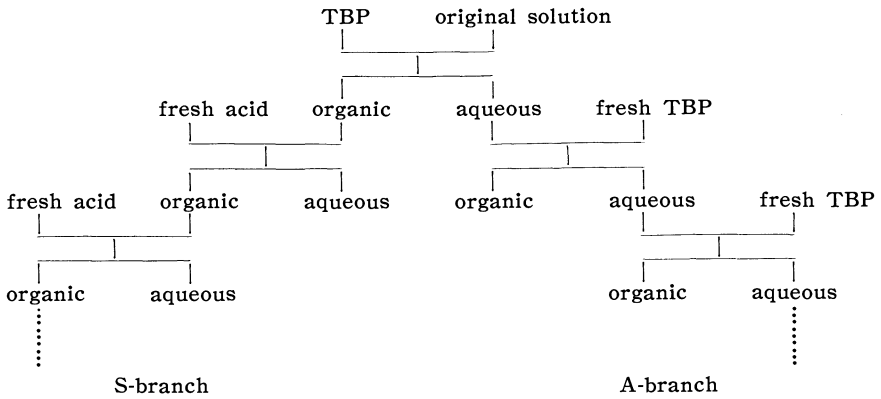

Fig. 1. The extraction scheme of neptunium.

** In order to avoid reduction of uranyl ion, reduction with zinc should be carried out at room temperature for only a few minutes.

*** Thenoyltrifluoroacetone

8) D. Dyrssen, *Svensk. Kem. Tid.*, **62**, 153 (1950).

phases are scrubbed with fresh acid solution or TBP, respectively. Scrubbings are carried out as shown in Fig. 1, until *Kd* values become practically constant, keeping the acidity of aqueous solution the same all through the procedures. Thus two values of *Kd*, Kd^{IV} and Kd^{V}, are obtained from S- and A-branches of the scrubbing scheme. Species which give Kd^{IV} and Kd^{V}, are assigned to neptunium (IV) and (V) respectively by the chemical behaviors against zinc, potassium bromate or TTA-benzene, to be mentioned below.

(*a*) *Oxidation with potassium bromate.* — The species which gives Kd^{IV} can not be oxidized with potassium bromate. At 0.5 N nitric acid Kd^{IV} value is 2.5. After adding the oxidant and scrubbing with a few portions of fresh acid, the *Kd* value remains almost constant, 2.7, showing that the species which gives Kd^{IV} is not practically oxidized.

On the other hand, Kd^{V} which is about 0.026 at 1 N nitric acid becomes about 16.3 after oxidation with potassium bromate and scrubbing with fresh acid solution. This change shows that the species which gives Kd^{V} is easily oxidized by potassium bromate. Besides that, the new third *Kd* value is also different from Kd^{IV} value of the same acidity. Accordingly this third value is supposed to be assigned to the hexavalent state. It is well known that neptunium(V) is easily oxidized by potassium bromate to neptunium(VI) state, whereas neptunium(IV) is not[9].

(*b*) *Reduction with zinc metal.* — Kd^{IV} value (6.92 at about 1 N) remains almost the same after adding zinc and heating on a water bath, whereas Kd^{V} value (0.026 at 1 N) becomes 7.8 after reduction with zinc metal****. This value almost coincides with that of Kd^{IV} at the same acidity, showing that the species which gives Kd^{V} is reduced to another species which gives Kd^{IV}.

(*c*) *Extraction with TTA.* — The comparison of extraction behaviors of the two species are given in Table I. The difference shown in the table again shows that the species which gives high Kd^{IV} in TBP-nitric acid system has high *Kd* in TTA extraction and is assigned to tetravalent[10], whereas another species which gives low Kd^{V} in TBP-nitric acid system has low *Kd* in TTA extraction and is assigned to quinquevalent[10].

TABLE I. THE BEHAVIOR OF NEPTUNIUM ON TTA EXTRACTION AT 1 N NITRIC ACID

Concn. of TTA in benzene (%, w/v)	*Kd* for the species which gives Kd^{IV} in TBP-HNO_3 system	*Kd* for the species which gives Kd^{V} in TBP-HNO_3 system
5.0	4.11	0.017
2.5	0.95	0.021
1.25	0.31	0.011

The variation of Kd^{IV} or Kd^{V} caused by changing the acidity of aqueous phase is shown in Fig. 2. In Fig. 3 acid dependences of neptunium(IV) and (V) are compared with those of hafnium(IV), thorium(IV), protactinium(V) and plutonium(IV). The thorium line is written according to Peppard et al.[2] and that of plutonium(IV) is rewritten based upon the values of McKay et al.[1] The behavior of neptunium(IV) shows strong similarity to that of plutonium(IV). However, *Kd* value of neptunium(IV) always lies below that of plutonium(IV) at the same acidity. *Kd* values of neptunium(IV) and thorium are almost the same at acidities less than 10 N. But the neptunium(IV) curve shows a maximum at about 9 N while that foi

—□— U(VI) at 0.27 N HNO_3

thorium does not. Hafnium shows a quite different behavior from that which neptunium(IV) does.

The behavior of neptunium(V) resembles that of hafnium(IV) more than that of protactinium(V).

As mentioned already neptunium(VI) is prepared easily by oxidation of neptunium (V) with potassium bromate and scrubbing of TBP phase with fresh acid solution in order to remove neptunium(V). Alternatively ceric ammonium nitrate works well as the oxidant in this case. The acid dependence of *Kd* value for neptunium(VI) is also given in Fig. 2. A comparison of *Kd* values for uranium(VI), neptunium(VI) and plutonium(VI) is also seen in Fig. 4. Naito[11] gave *Kd* values for macro amounts of uranium in 20% TBP in carbon tetrachloride-nitric acid system. He also found second power dependence of *Kd* in this system. Accordingly the present authors rewrite uranium (VI) curve of Fig. 4 multiplying Naito's *Kd* value with the factor of 25 in order to make it represent *Kd* values for 100% TBP-nitric acid solution system. Broken plutonium(VI) curve of Fig. 4 is rewritten

in a similar way correcting the values of McKay et al.[1] which were obtained with diluted TBP. The other plutonium(VI) curve represents values obtained by one of the present authors. As is known very well, correction with solvent dependence is not so satisfactory. Besides that, there might be some differences between behaviors of macro and micro amounts of actinide elements. Therefore, the comparison with each other of 3 curves in Fig. 4 will not be valid for a strict discussion. But it is remarkable that all of them show a maximum *Kd* value at about 6 or 7 N.

Solvent dependence of *Kd* value for neptunium is checked at 10 N nitric acid. As shown in Fig. 5, neptunium(VI) shows second power dependence. The figure shows also second power solvent dependences of uranium(VI) and plutonium(VI) according to the values obtained by Naito for uranium[11] and Mckay et al. for plutonium[1]. Here again strong similarity is shown among hexavalent uranium, neptunium and plutonium.

Hydrochloric Acid-TBP System. — Neptunium(VI) prepared by oxidizing neptunium(IV) and (V) with potassium chlorate and heating in boiling water shows *Kd* values as shown in Fig. 6. *Kd* values of uranium obtained by using uranium-233 as the tracer in the form of uranyl chloride are also show in the same figure in order to compare them with those for neptunium(VI). The acid dependences of these two elements are very similar in the shape indicating strong similarity in the chemical behaviors of these two species. However, neptunium(VI) is more extractable than uranium(VI) all through the acidity range investigated.

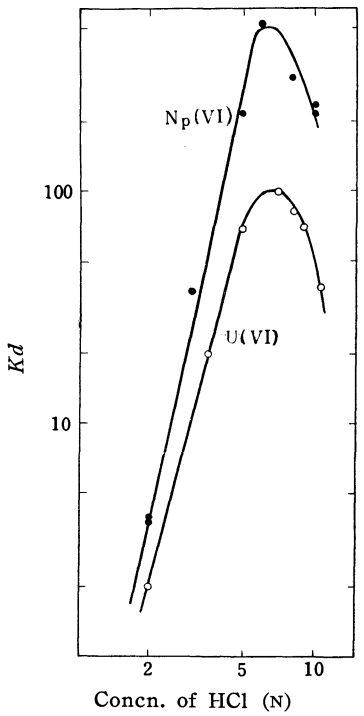

Fig. 6. The acid dependence of *Kd* values for neptunium and uranium.
—●— Np(VI) —○— U(VI)

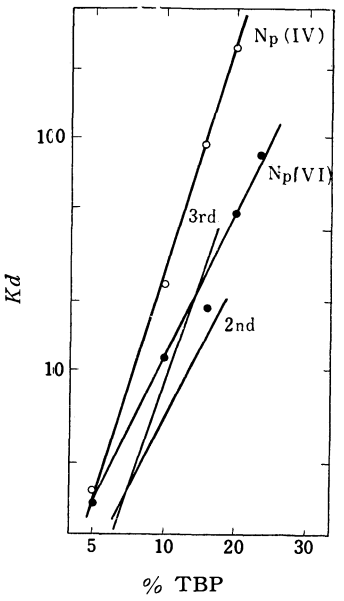

Fig. 7. The *Kd* values in diluted TBP-HCl system.
—●— Np(VI) at 6 N HCl
—○— Np(IV) at 8 N HCl

The solvent dependence of *Kd* for neptunium is studied at 6 N hydrochloric acid and found to be of second power as is seen in Fig. 7. Diluent used is toluene and TBP concentration is shown in volume per cent.

Neptunium(V) is prepared in hydrochloric acid solution by reducing neptunium(VI) with hydrazine sulfate. On the other hand, a solution of neptunium (IV) is prepared by recovering neptunium from TTA-benzene with hydrochloric acid (>3 N) and then treating it with hydroxylamine hydrochloride, granulated zinc or ascorbic acid in order to reduce neptunium(V) which comes into the solution in very small amount. Fig. 8 shows acid dependences of *Kd* values for both neptunium(V) and (IV) as well as those for hafnium, thorium and protactinium. The

11) K. Naito, In press.

neptunium(V) line is quite different from that of protactinium(V). In the range of 9~4 N, *Kd* of neptunium(IV) shows almost the same slope as those of thorium(IV) and hafnium(IV). It is notable that the acid dependence of neptunium(IV) shows a maximum at about 8 N.

The solvent dependence of *Kd* values for neptunium(IV) is studied at 8 N using toluene as the diluent. The result shows third power dependence as given in Fig. 7.

Sulfuric Acid-TBP System.—Neptunium (VI) in sulfuric acid solution is prepared by oxidation of the mixture of neptunium (IV) and (V) with ceric sulfate, while neptunium (V) is prepared by reducing neptunium (VI) with hydrazine sulfate. Variation curves of *Kd* values for both neptunium (V) and (VI) caused by the variation of the acidity in aqueous phases are given in Fig. 9. Extraction can not be carried out in the acidity range over about 20 N, because TBP becomes miscible with aqueous phase at such high acidity. Generally *Kd* values for both neptunium(V) and (VI) are small, their highest values being only about 2.5. The acid dependence of *Kd* values for protactinium is shown in Fig. 9 in order to compare it with that for neptunium(V).

Neptunium(IV) is prepared by contacting sulfuric acid solution with TTA-benzene which contains neptunium. In order to prevent contamination of neptunium (V), the resultant acid solution is treated

with hydroxylamine hydrochloride and ferrous sulfate or 0.1 M hydroquinone and potassium iodide at higher acidities, while it is treated with granulated zinc at lower acidities. Acid dependence of *Kd* values for neptunium(IV) can also be seen in Fig. 9 where those for hafnium and thorium are added for comparison. These three curves resemble each other considerably. It is noted that in the range of lower acidities neptunium (IV) gives lower *Kd* values than neptunium(V) does.

The solvent dependence of *Kd* values for neptunium(IV) is studied at 20 N sulfuric acid and found as a third power. (Fig. 10).

Perchloric Acid-TBP System.—Perchloric acid (>3 N) solution obtained by contacting with neptunium solution in TTA-benzene contains only neptunium(V). This assignment is based on the following experiments:

(a) 3.4 N perchloric acid containing neptunium(V) is contacted with almost equal volume of TBP pre-equilibrated with 9 N hydrochloric acid. The resultant organic phase is equilibrated with many portions of 9 N hydrochloric acid successively. In this way, the system is converted to hydrochloric acid-TBP system. Finally *Kd* value approaches that of neptunium(V) at 9 N hydrochloric acid. (b) By oxidation with silver peroxide this species becomes another species which could be assigned to neptunium(VI).

The acid dependences of *Kd* values for both neptunium(V) and (VI) are given in Fig. 11 as well as that of protactinium.

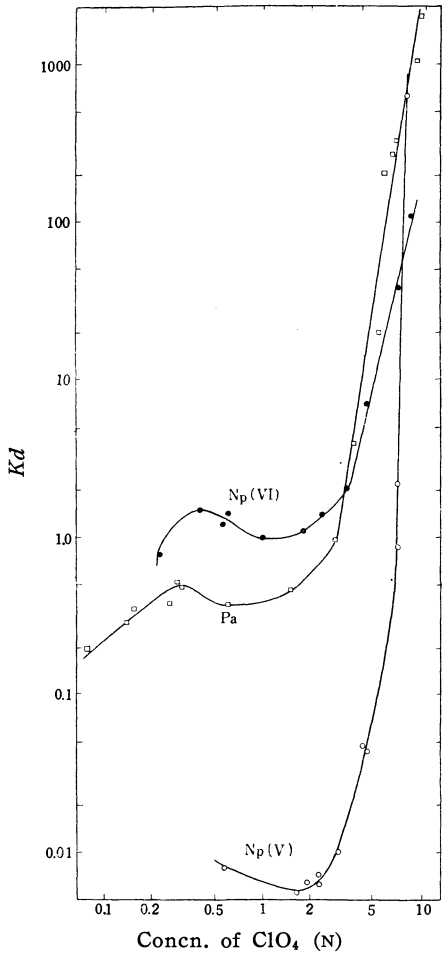

Fig. 11. The *Kd* values of neptunium and protactinium in $HClO_4$-100% TBP system.
—●— Np(VI) —□— Pa —○— Np(V)

It is characteristic that the neptunium(V) curve shows very rapid increase in *Kd* at the range of 3~8 N acidity. As will be shown later, this can be utilized for isolation of neptunium from irradiated uranyl nitrate.

As 8 N perchloric acid, the solvent dependence of *Kd* values for neptunium(V) is studied. The result is shown in Fig. 10.

The Reduction of neptunium(V) with hydroquinone and potassium iodide, hydrogen peroxide, granulated zinc or 3% zinc amalgam is not successful. Accordingly *Kd* values which could be assigned to the tetra-positive state can not be found.

Isolation of Neptunium from Irradiated Uranyl Nitrate. — As Fig. 11 shows, *Kd* for neptunium(V) in perchloric acid-TBP system varies from 800 at 8 N to 0.006 at 2 N. This is utilized in the isolation of

neptunium without introducing any other reagent.

Procedure. — Neutron irradiated uranyl nitrate hexahydrate is dissolved in a small volume of concentrated perchloric acid. The solution is heated under an infrared lamp in order to expel nitric acid. The residue is taken up by a few ml. of concentrated perchloric acid and the resultant solution is heated by dipping in boiling water for about 10 min. After cooling, it is shaken with 100% TBP. The organic phase contains neptunium(V) and uranium, while most of the fission products remain in the aqueous phase. The separated organic phase is shaken with 3 portions of 2 N perchloric acid. The resultant aqueous phase contains neptunium(V) and a small amount of uranium, while a large amount of uranium remains in organic phase. The resultant aqueous phase is washed with benzene in order to remove TBP, dried up under the infrared lamp, and dissolved into concentrated perchloric acid. The whole procedure is repeated as shown in Fig. 12.

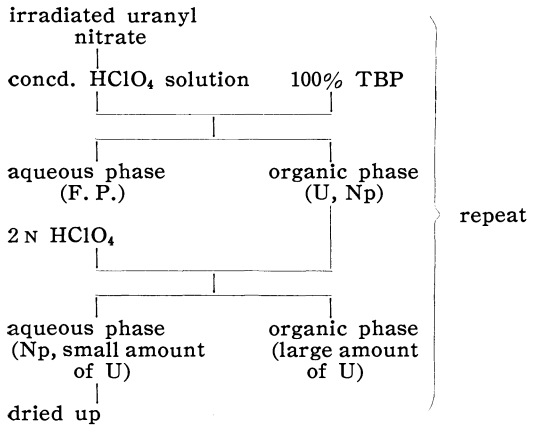

Fig. 12. Scheme for isolation of Np.

The yield of neptunium is 99%, and the decontamination of fission products is excellent. A very small amount of uranium remains.

Summary

Neptunium-239 is used as the tracer for studies on solvent extraction behaviors of neptunium in the following system:

1. Nitric acid solution and TBP.
2. Hydrochloric acid solution and TBP.
3. Sulfuric acid solution and TBP.
4. Perchloric acid solution and TBP.

Kd values are measured by combinations of scrubbing techniques and chemical treatments. In nitric, hydrochloric and sulfuric systems, neptunium gives three kinds of *Kd*, distribution ratio which could be assigned to oxidation states of (IV), (V) and (VI). On the other hand, in the perchloric system neptunium does not show *Kd* value which should be assigned to the oxidation state(IV).

Some of these results are compared with those of uranium, plutonium and other elements. In the nitric system, neptunium(VI) shows an acid dependence of *Kd* value similar to those of uranium (VI) and plutonium(VI). *Kd* values of neptunium(IV) and plutonium(IV) vary in almost the same way against the acid concentration of nitric acid. There is also a strong similarity between acid dependences of uranium(VI) and neptunium (VI) in the hydrochloric system.

Behavior of neptunium(V) are compared with those of protactinium.

Finally a simple method for isolation of neptunium from irradiated uranyl salt is stated.

The authors wish to express their sincere thanks to Dr. Kenjiro Kimura who afforded them convenience for this study in many ways.

Spectrochemical Study of Microscopic Crystals. XIX[1] *The Structure and Absorption Spectra of Fremy's Salt*

By Shoichiro YAMADA and Ryutaro TSUCHIDA

(Received February 4, 1959)

In the nineteenth century, Fremy[2] isolated an interesting compound having an empirical formula of $ON(SO_3)_2K_2$, which is violet-blue in solution and yellow in the crystalline state. This phenomenon, which has been studied by a number of investigators[3,4] was eventually understood on the assumption that the compound might consist of monomeric ions in solution and of dimeric ions in the crystalline state[5-7]. Aside from the electronic structure of the monomeric ion involving a queer type of bonding, the structure of the dimeric ion was often discussed by the earlier investigators, but still remains in dispute. Although the compound has been studied from various sides, no spectral data have so far been reported. In an attempt to elucidate the structure of Fremy's salt, we have carried out a spectroscopic study with this salt and related compounds.

Experimental

Materials. — Potassium peroxylamine disulfonate, $K_2(O_3S)_2NO$, was prepared by the method of Haga[8] with slight modification. To a solution of 17.5 g. of sodium nitrite in 50 ml. of water were added 100 g. of crushed ice, a solution of 25 g. of sodium hydrogen sulfite in 50 ml. of water under continuous stirring, and finally 10 ml. of glacial acetic acid. After a few minutes the reaction mixture was rendered alkaline by the addition of 7 ml. of concentrated aqueous ammonia (*d*, 0.880), and then a solution of 6.3 g. of potassium permanganate in 200 ml. of water was added under stirring. The precipitate of manganese dioxide which was at once formed was removed by filtration. To the violet-colored filtrate was added 250 ml. of a saturated solution of potassium chloride. Orange-yellow crystals which precipitated were filtered by suction, and washed successively with a 5% solution of potassium hydroxide, ethanol and acetone. Recrystallization from water yielded orange-yellow crystals of Fremy's salt, which showed the typical reactions of Fremy's salt. Thus the crystals were dissolved in water to give a blue-violet solution, from which the orange-yellow crystals separated again on concentration. Potassium peroxylamine disulfonate thus prepared was found to form blue-colored mixed crystals with potassium hydroxylamine disulfonate, which was prepared in colorless crystals according to the method of Rollefson and Oldershaw[8].

The mixed crystals were prepared in the following way. Into 45 ml. of a 5% solution of potassium hydroxide were added 1 g. of potassium hydroxylamine disulfonate and 0.5 g. of potassium peroxylamine disulfonate at 45°C. The solution was filtered and cooled with crushed ice. After twenty hours large mixed crystals which were blue in color began to separate together with the crystals of potassium peroxylamine disulfonate. The blue mixed crystals were picked up from the mixture mechanically. Accurate determination of the $K_2(O_3S)_2NO$ content in the mixed crystal was not made, but approximate estimation from the intensity of the "NO band" showed it to be only a few per cent. The value seems to agree well with those reported earlier[5].

Measurements.—Quantitative dichroism measurements in the visible and ultra-violet regions were carried out at room temperature by Tsuchida and Kobayashi's microscopic method[9].

Absorption spectra of the compounds in aqueous solution were determined at room temperature by a Beckman DU spectrophotometer.

Infrared absorption spectra of the compounds in Nujol mulls and in potassium bromide discs were determined in the rock salt region by a Hilger H 800 infrared spectrophotometer.

The notations in the present paper are the same as those used in the former papers of this series.

Results and Discussion

Visible and Ultra-violet Absorption Spectra.—The mixed crystal formed from $K_2(O_3S)_2NOH$ and $K_2(O_3S)_2NO$ shows an absorption band at 52×10^{13}/sec., as seen

in Fig. 1. It has been found by the present measurements that for the band at 52×10^{13}/sec. the A-absorption in Fig. 1 is at least ten times stronger than the B-absorption. The difference in intensity between the two absorptions was so great that exact determination of the dichroic ratio could not be made.

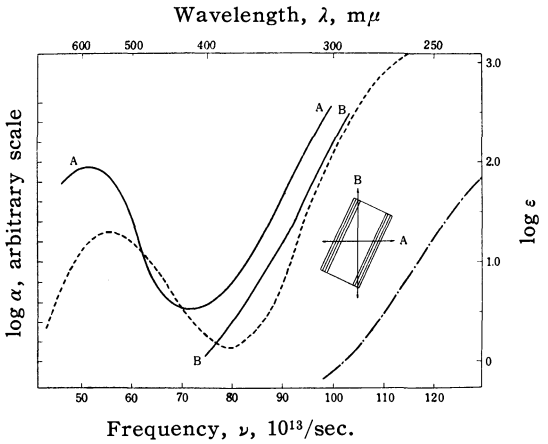

Fig. 1. Absorption spectra of a mixed crystal from $K_2(O_3S)_2$ NO and $K_2(O_3S)_2$·NOH, and its components: the mixed crystal in the solid state, ——: $K_2(O_3S)_2$·NO in 5% KOH solution, ----: $K_2(O_3S)_2$·NOH in water, ·—·—.

Comparison of the absorption spectrum of the mixed crystal with the spectra of $K_2(O_3S)_2NOH$ and $K_2(O_3S)_2NO$ in solution (Fig. 1) reveals that the band at 52×10^{13}/sec. of the mixed crystal in the solid state may evidently be ascribed to the component, $K_2(O_3S)_2NO$, since the other component has no absorption in the neighborhood of this absorption band. It is presumed, in a similar way, that the state of the peroxylamine disulfonate ion in the mixed crystal is similar to that of Fremy's salt in water. Previously Asmussen[7] concluded from magnetic measurements that $K_2(O_3S)_2NO$ in aqueous solution consists largely of monomeric ions; the three-electron bond is usually assumed to be involved in the bonding within the NO-group of the monomer. Therefore, it may be certain that Fremy's salt exists as a monomeric form when incorporated into the mixed crystal with $K_2(O_3S)_2NOH$. Thus the band at 52×10^{13}/sec. of the mixed crystal may be ascribed to the $(O_3S)_2NO^{2-}$ ions under the effect of the field by the surrounding ions. The band is, therefore, regarded as due primarily to the NO-group in the monomeric ion under small perturbation from the surrounding ions, although the bonding around the NO-group should not be considered, in a strict sense, to be isolated from the other part of the ion. The present measurements show that *the NO-band, in which the three-electron bond may be involved, is highly polarized.*

The effects of solvents upon the absorption band have also been examined. Formerly the "nitroso-band" at about 700 mμ of nitroso-derivatives and the band at about 350 mμ of a nitrite ion were reported to undergo a "blue solvent effect"[10]. This fact was then assumed to show that both the bands were due to $n-\pi^*$ transitions. On the contrary, the present measurements indicate that the absorption band at about 55×10^{13}/sec. (540 mμ) of the $ON(SO_3)_2^{2-}$ ion is displaced to longer wavelengths on changing a solvent from ethanol to water. The "red shift" of the band seems to show that the band may originate from a $\pi-\pi^*$ transition[10], although the intensity of the band is rather small for this type of transition. This appears to be consistent with the electronic structure of the NO group having a sort of three-electron bond, since the absorption band in question may originate from a transition of one of the three bonding electrons to an excited level.

It was reported earlier that the above mentioned bands, ascribed to the $n-\pi^*$ transition, were polarized perpendicularly to the plane of the NO-group in nitrosobenzene and its derivatives[11] or to the plane of an NO_2^- ion[12]. As for the band of the monomeric ion of $ON(SO_3)_2^{2-}$, which possibly originates from a $\pi-\pi^*$ transition and may be different in its origin from the above mentioned bands, we are inclined to regard it likely that the polarization of the band would be along the plane of the NO-group. Thus the A-absorption in Fig. 1 may correspond to the electric vector along the NO-group, and the B-absorption to the electric vector perpendicular to the NO-group. In order to confirm this suggestion, however, further study seems to be desirable.

Infrared Absorption Spectra. — Results of the present measurements are shown in Table I. Tentative assignment of the

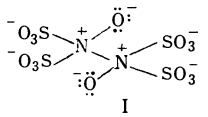
observed absorption bands to particular group-vibrations was made using the assignment by Drago[13] for $K_2(O_3S)(NO)_2$ and by Griffith and others[14] for Fremy's salt. Griffith and others have also reported the infrared absorption spectrum with Fremy's salt[15]. Unfortunately they did not state whether the measurements refer to the compound in the solid state, or in aqueous solution. Their measurements were probably made in the solid state in which the compound consists of the dimeric form, since their data agree with ours for the $[(O_3S)_2NO^{2-}]_2$ ion. They have not presented any detailed discussion about the infrared spectrum or the structure of the dimer, but mentioned the compound as having an N-N linkage. It seems, however, that no reports have appeared which may be regarded to establish the structure of the dimeric ion with certainty, as far as literatures accessible to us are concerned.

The infrared absorption bands of the monomeric $ON(SO_3)_2^{2-}$ ion were determined by comparing an absorption spectrum of the mixed crystal from Fremy's salt and potassium hydroxylamine disulfonate with the spectrum of the latter alone. Although some effects, such as hydrogen bonds, which possibly exist in the mixed crystal, are liable to complicate the spectrum and make the exact assignment of the absorption bands difficult, the interpretation of the absorption spectrum of $K_2(O_3S)_2NO$ has been possible. In a strict sense, the infrared absorption bands are not to be ascribed to particular groups within a molecule, but to a molecule or an ion as a whole. Nevertheless, the discussion, as is given here, may be correct for the nature and the purpose of the present work.



The vibrations which are ascribed to the $(O_3S)_2NO^{2-}$ ion in the mixed crystal are given in Table I, where the vibrations due to the sulfonate groups are added together, since the ion would certainly show the vibrations of the sulfonate groups. A rather strong band at 1620 cm^{-1} of the monomeric $(O_3S)_2NO^{2-}$ ion may be due possibly to an NO-stretching vibration. This assignment is regarded as reasonable, in view of the NO-frequencies which were formerly reported for other compounds: nitroalkyls[16] 1560~1500 and 1350~1300 cm^{-1}, dimeric nitrosomethane[17] 1282 cm^{-1}, nitrosamine 1455 cm^{-1} in a monomeric form and 1310 cm^{-} in a dimeric form[18]. Thus the rather high frequency of the NO-vibration for the monomeric $(O_3S)_2$ NO^{2-} ion is found to correspond to comparatively high bond-order of the NO-linkage, being in agreement with the assumption of the three-electron bond.

The Structure of the Dimeric Form of Fremy's Salt. — The structure of the dimeric form of Fremy's salt has formerly been examined by a number of investigators. Hantzsch and Semple[5] assumed that the violet-blue and the yellow form are, respectively, the monomeric and the dimeric form of Fremy's salt, comparing the relation between them to that between nitrogen dioxide and dinitrogen tetroxide. Investigating chemical property of Fremy's salt in aqueous solution, Haga and Divers[6] proposed a structure, $K_4(O_3S)_2NO\cdot ON(SO_3)_2$, for the monomeric form of Fremy's

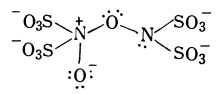
salt in solution and double the formula for the dimeric form. Much later, Asmussen[7] investigated the compound magnetochemically only to reaffirm Hantzsch and Semple's hypothesis, and regarded that Fremy's salt in aqueous solution exists as an equilibrium mixture consisting of a monomeric form in most part and a dimeric form in a very small amount. Neither Asmussen nor Hantzsch and Semple, however, presented a structural formula for the dimer after all. The structures, as proposed long ago for the dimer of Fremy's salt by Rasching[3] and by Claus[4], are not quite satisfactory, in view of insufficient materials available as well as because of poor knowledge at that time about the chemical bonds in general. Thus the problem of the structure of the dimer is not to be regarded as settled, but reexamination of the structure seems to be most desirable.



Examination of the possible electronic structures seems to indicate that the following three configurations (Fig. 2) may most probable for the dimer, the structures with resonance which involves the sulphonate-groups being omitted.

I

II

III

Fig. 2. Possible configurations for the dimeric form of Fremy's salt.

Examination of the steric requirements using molecular models shows that structure I seems to be very difficult, although it might not be quite impossible. Thus crowding of one oxygen atom and two sulfonate-groups around the nitrogen atom would hinder dimerization through an N–N linkage. Structure III is also difficult sterically, although this may not be impossible. On the other hand, structure II suffers no steric hindrance. Structure II, therefore, seems to be most probable from this standpoint.

The present measurements of UV spectra show that the electronic state of the dimer deviates greatly from the state of the monomer, since the UV absorption spectrum of Fremy's salt in the crystalline state is quite different from that of the monomer (Fig. 3). Thus the absorption band at about 55×10^{13}/sec., which is due primarily to the NO-group in the monomer, disappears with the dimer. Instead, the latter shows a few absorption

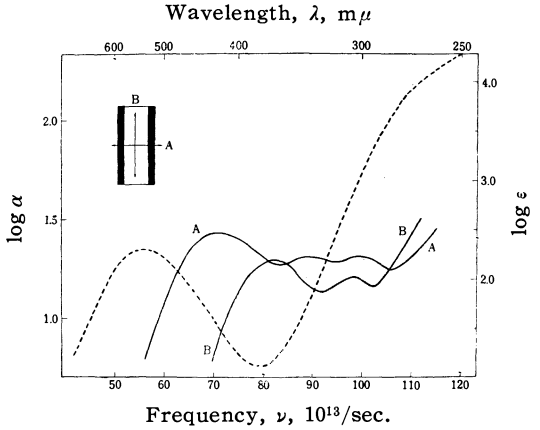


Fig. 3. Absorption spectra of Fremy's salt in the crystalline state (——) and in aqueous solution (----).

bands in the visible region and its neighborhood. If the dimer were represented by structure I, it would not exhibit an absorption band in the visible region, as is readily expected from absorption spectra of its related compounds. Previous data indicate that the dimer of nitrosomethane, which has a configuration similar to structure I, shows an absorption band at about 280 mμ (107×10^{13}/sec.) but no absorption band in the visible region, much less the "nitroso-band" at about 650 mμ (46×10^{13}/sec.). Since inspection of the structural formulae shows that structure I might involve N–O bonds with lower bond order than that of the N–O bond in the dimer of nitrosomethane, the ion represented by structure I would not show an absorption band in the neighborhood of the visible region. In fact, the present measurements indicate that the dimer of Fremy's salt has a few absorption bands in this wavelength range. Structure I, therefore, is rejected on the basis of the UV absorption spectra as well as of the steric requirements.

Absorption spectra of the compounds

which are somewhat similar to the compound represented by structure II have previously been studied. Thus Kortüm and Finckh[19] reported absorption spectra of sodium nitrite, pernitrite, hyponitrite and related compounds in solution, which were found to display absorption bands in the comparatively long wavelength region. Structure II, therefore, may not be inconsistent with the present observation that the compound in question displays absorption bands in the visible region and its neighborhood. Structure III, however, may not be excluded from the visible and ultra-violet spectrum alone.

The above discussion on the structure of the dimer of Fremy's salt is corroborated by the infrared absorption spectra. It is seen in Table I that the monomeric ion of $(O_3S)_2NO^{2-}$ shows a strong band at about 1620 cm^{-1} which is due to the N–O stretching vibration, whereas the dimeric ion shows the corresponding bands at 1260 cm^{-1}. Structure III would show the corresponding bands of high intensity due to the N–O stretching vibrations at wavenumbers smaller than the vibration of the monomer. Thus, at least a few absorption bands due to the N–O stretching vibrations might be observed in the infrared spectrum for structure III, since three kinds of the NO-groups are involved in this structure and those vibrations are all infrared active. The fact that there is observed only one absorption band of this sort for the dimer is not consistent with structure III, although a possibility might remain that some of the absorption bands would be hidden under strong bands due to the sulfonate groups.

On the contrary, structure II has only one kind of N–O bond, and the symmetric vibration due to the NO groups is infrared inactive. Only the symmetric vibration is infrared active, and may be regarded as corresponding to the band at 1260 cm^{-1}. Thus the infrared spectrum may be reconciled in a satisfactory way with structure II. Further evidence for this conclusion may be obtained by complete analysis of the infrared absorption spectra, which, however, requires data of the Raman spectrum with this compound. The determination of it would be enlightening in this respect. Based on the infrared spectrum alone, structure I might also be possible, but this structure has been shown in the preceding part of the present paper to be inconsistent with the UV spectra and steric requirements.

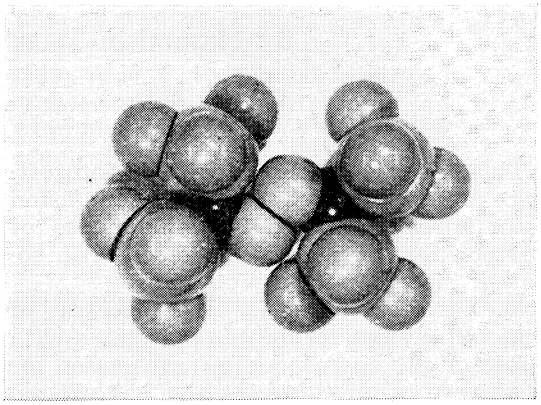

Fig. 4. Stuart model of $(O_3S)_2NO\cdot ON(SO_3)_2^{4-}$.

All the above materials combined seem to favour most strongly structure II having an O–O linkage. — A Stuart model representing structure II is shown in Fig. 4. This conclusion on the structure of the dimer seems to be noteworthy, since it is known that most nitroso-derivatives tend to form dimers involving a linkage of an N–N type.

Summary

Absorption spectra in the visible and ultra-violet region have been determined at room temperature by Tsuchida and Kobayashi's microscopic method with crystals of Fremy's salt and related compounds. Infrared absorption spectra have also been measured with these compounds.

The results of the measurements are discussed in relation to the structure of the compounds. A steric condition, visible and ultra-violet absorption spectra and infrared spectra are found to be in best agreement with a structure having a peroxide grouping.

The present authors wish to thank the Ministry of Education for a grant-in-aid, Mr. H. Nakamura for experimental assistance, and Mr. Ishikawa for infrared spectra.

On the Difference between L-Forms and the Corresponding DL-Forms of Amino Acids in their Solid-State Infrared Spectra

By Masamichi TSUBOI and Tadao TAKENISHI

(Received February 6, 1959)

This paper is concerned with an interesting fact which led us to a conclusion that there are three different modes of composition of D- and L-molecules in so-called racemates of amino acids.

We have compared infrared spectra[1] of optically active forms in solid states with those of the corresponding racemates for a variety of amino acids, and have found that these results of the comparisons are grouped in three classes, A, B and C, as given below. It is remarkable that the distinction between these classes is sharp and that there is none intermediate between them.

(A) In class A, *the spectra of the L- and DL-forms are identical.*—Examples[1]: threonine, histidine hydrochloride monohydrate. Here, every band of the DL-form is observed at the same position with the same relative intensity as the corresponding band of the L-form, within the limits of experimental error.

(B) In class B, *the spectra of the L- and DL-forms are a little different from each other.*—Examples[1]: tyrosine (see Fig. 1), alanine, leucine, phenylalanine, asparagine, tryptophan. Here, as illustrated in Fig. 1, some of the bands of the DL-form are observed at different positions and/or with different relative intensities from the corresponding bands of the L-form, but all the bands of the DL-form are observed within 20 cm^{-1} from the corresponding bands of the L-form. Sometimes a band of the L-form splits into two in the DL-form, or a band of the DL-form splits into two in the L-form. But the splitting is mostly observed within a distance of 20 cm^{-1}.

(C) In class C, *the spectra of the L- and DL-forms are greatly different from each other.*—Examples[1]: aspartic acid (see Fig. 2), valine, isoleucine, serine, methionine, proline, lysine hydrochloride. Here, as illustrated in Fig. 2, many of the bands of the DL-form have no corresponding bands within 20 cm^{-1} in the spectrum of the L-form; and/or many of the bands of

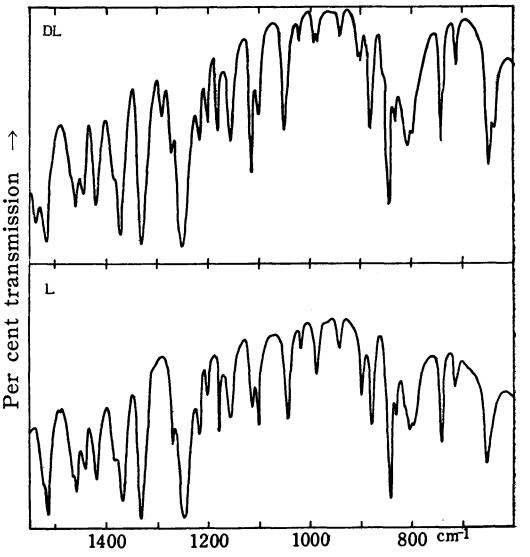

Fig. 1. Infrared spectra of DL- and L-forms of tyrosine in KBr disks.

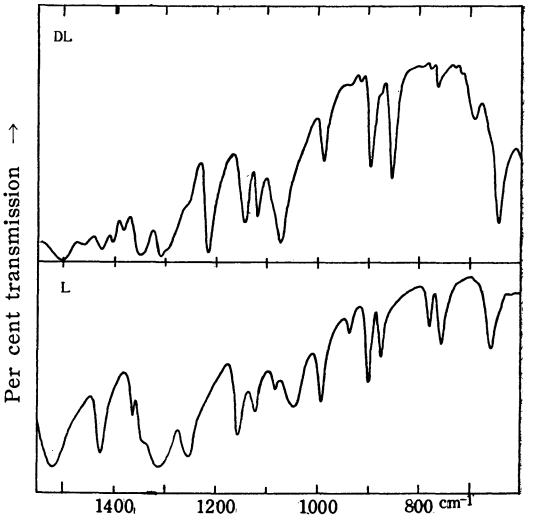

Fig. 2. Infrared spectra of DL- and L-forms of aspartic acid in KBr disks.

1) For the infrared spectra observed, see M. Tsuboi and T. Takenishi, *J. Japanese Chemistry* (*Kagaku-no-Ryoiki*), *Zokan*, No. 7, Nankodo Co. (1959).

the L-form have no corresponding bands within 20 cm^{-1} in the spectrum of the DL-form.

The comparisons of the infrared spectra in the solid states of optically active forms with those of the corresponding racemates have also been made by several authors[2-6] for several amino acids. All of these results, so far as is known to us, are grouped, without exception, in the same way as above.

From the above, we are led to consider that the three classes correspond to three different modes in which the D- and L-forms compose the DL-forms in solid states. Thus, in class A, the DL-form is merely a racemic mixture of the D- and L-forms; in class B, the crystal of the DL-form has a lattice composed of the D- and L-molecules, but the composing molecules are essentially identical in configuration with the molecules in the crystal lattice of the active forms; and in class C, the molecules composing the DL-form take different configurations from those in the D- and L-forms.

In the case where the crystal lattice of a racemate is composed of D- and L-molecules, the crystalline force field in it must of course be different from that in the lattice of the optically active crystal which is formed solely by the D- or L-molecules. This difference in the force field must be essentially of the same degree as that between different polymorphic forms of an ionic crystal[7], and must cause just as much difference in spectra as actually observed in class B.

On the other hand, no spectral difference is expected between a mechanical mixture of the D- and L-crystals and its component crystals, because all factors influencing the molecular and lattice vibrations must be exactly identical in the D- and L-crystals, as well as in their mixtures. Then, it may be concluded that the DL-form in class A is a mechanical mixture of the D- and L-crystals. For threonine, one of the examples for class A, Shoemaker et al.[8] reached, from X-ray examinations, a conclusion consistent with the above.

Considered on the basis of the accumulated knowledge on the internal rotations around the C–C and other single bonds[9,10] many of the amino acid molecules are expected to form rotational isomers with small energy differences. For such amino acids, the different crystalline force fields between the DL- and L-forms may result in occurrence of different rotational isomers[11]. Between these rotational isomers a great difference is expected in their infrared spectra. The great spectral difference actually observed in class C may be attributed to such rotational isomerism.

We wish to express our sincere thanks to Professor San-ichiro Mizushima, Dr. Takehiko Shimanouchi and Dr. Haruomi Oeda for their kind encouragements and valuable suggestions.

Studies on the Graphitization. III. The Sub-Structure of Heat-Treated Coke*

By Haruo KURODA

(Received January 29, 1959)

Carbons made by carbonizing organic substances at a temperature lower than 1000°C are made up of minute crystallites of non-graphitic structure and disordered phase consisting of carbon, hydrogen and oxygen. The heat-treatment at a higher temperature causes in carbons the decrease of disordered phase and the crystallite growth as well as the improvement of the stacking order of the layer lattice in crystallites.

The progress of the structural change in the heat-treatment differs greatly depending on the characters of carbons even if they are heat-treated under the similar conditions. The crystal structure of carbons can be well defined by the analysis of their X-ray diffraction pattern[1]. Graphitization has been discussed hitherto mainly based on the knowledge concerning the crystal structure. The difference in graphitizability, however, can not be explained by comparing the crystal structure alone.

In the previous papers[2], we pointed out that the particular features in graphitization of carbon blacks are due to the substructure of carbon black particles. It might be natural that the graphitizability of carbon is strongly influenced by the character of crystallite boundaries, alignment of crystallites or other similar aspects of its structure which we shall call micro-structure distinguished from crystal structure. From such a point of view, we investigated the micro-structure and its change after heat-treatments in petroleum coke, which is known to be one of the well-graphitizable carbons.

Experimental and Results

Heat-Treatment and Crystal Structure.— Petroleum coke of Great Lake Co. was heat-treated in vacuo at several temperatures from 1000°C to 3000°C. X-ray diffraction was studied using a commercial X-ray diffractometer, with Cu K_α radiation. Diffractometer records of 10 diffraction are reproduced in Fig. 1. As seen in this figure, the raw coke has non-graphitic structure, and the improvement of the stacking order of layer lattice starts at a temperature around

1900°C. When H.T.** is 2500°C, the observed value of layer spacing is 3.365 Å. This indicates that nearly 65% of layers are in graphitic orientation. It becomes 3.351 Å after the heat-treatment at 3000°C.

The crystallite sizes determined from the breadth of diffraction peak are given in Table I. At lower temperatures crystallite size increases only a little. The rapid growth starts at a temperature around 1900°C.

TABLE I. GROWTH OF CRYSTALLITE DIMENSION IN PETROLEUM COKE WITH HEAT-TREATMENT

H.T. (°C)	L_a (Å)	L_c (Å)
Original	38	37
1400	40	38
1550	42	49
1720	87	71
1850	110	93
2040	276	180
2500	392	202
3000	444	213

Grains of Coke Powder.—After the heat-treatment, coke was milled into a fine powder and observed under the electron microscope***. Minute flaky grains can be observed with the raw coke as shown in Fig. 2. They have a jagged outline and the appearance of the granular structure. Most of them are of several microns in transverse direction and less than 1000 Å in thickness. The granular appearance is removed by the heat-treatment. When H.T. is higher than 2000°C, it entirely disappears. After the heat-treatment with high H.T., the stepwise variation of electron transmission is seen at edges of grains. It can be found also at the inner part of grains when its thickness is very small. These facts indicate that each grain is a bundle of many thin lamellae. The thickness of one lamella seems to be in the order of 200~300 Å.

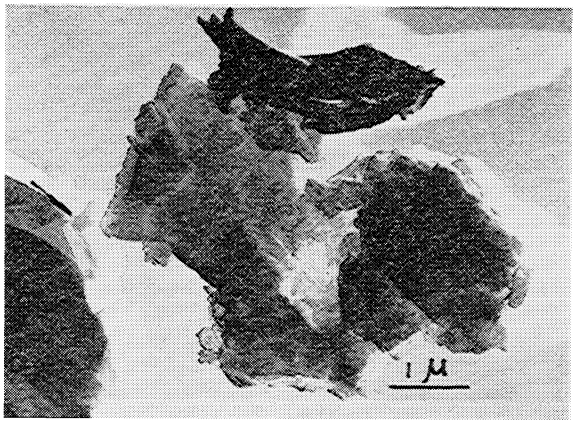
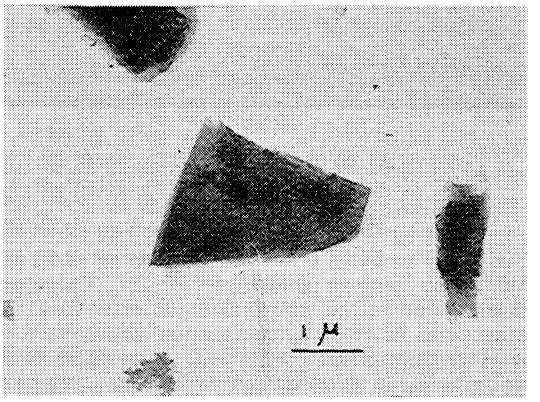
** The temperature of heat-treatment is abbreviated to H. T.

*** Electron microscopic studies were made using Hitachi Electron Microscope, Model 10-A.





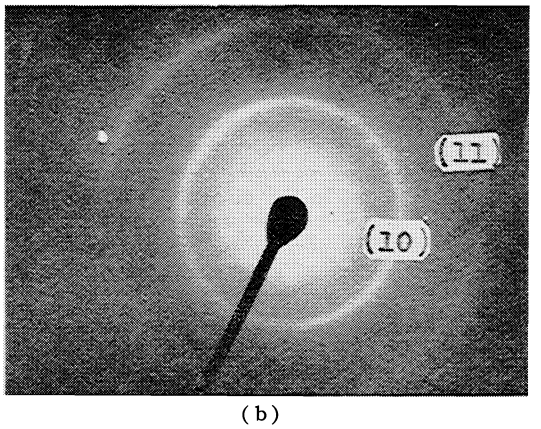


Fig. 3. Electron micrograph of coke grains, (H.T., 2500°C). (shadowed with Ge)

As can be seen in Figs. 3 and 6, in every coke grain are sub-boundaries, which are dividing it into smaller grains.

The electron diffraction pattern corresponding to each grain was studied by the method of selected-area electron diffraction. One of the typical results with the raw coke is given in

(b)

Fig. 6. A coke grain, (H.T., 3000°C): (a) electron micrograph, (b) selected-area electron diffraction.

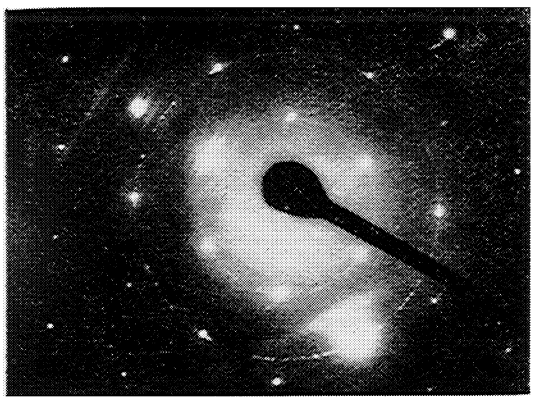

Fig. 4. The flaky grain in Fig. 4a gives a diffuse diffraction pattern shown in Fig. 4b. The spacings related to the two halos indicate that the inner one is (100) diffraction and the outer one is (110) diffraction. (002) and (004) diffractions are missing in this diffraction pattern. They are always either missing or very weak in every selected-area electron diffraction pattern of the grain of the raw coke. After heat-treatment, diffraction rings become clear and sharp as seen in Figs. 5 and 6. In both of them, diffraction rings correspond to (100), (110),(200), (210) and (300) diffractions, respectively. Most of the grains give such a polycrystalline diffraction pattern consisting of ($h\,k\,0$) diffractions alone. c-axis should be in the direction parallel to the incident electron beam, hence parallel to the direction that is normal to the surface of the grains, in order to give such diffraction patterns. Thus each coke grain is a group of many crystallites with a preferential orientation of c-axis. In Fig. 5a diffraction rings have homogeneous intensity distribution in all directions, hence a-axis direction is quite random in the plane of the grain. In Fig. 6b however, diffraction rings split into many spots. Many grains give such a pattern if H.T. is 2500~3000°C. There are some grains which give a diffraction pattern like that of a single crystal. They seem to be a quasi-single crystal. As shown in Table I, the crystallite size along a-axis determined from X-ray diffraction is only 400~500Å, even if H. T. is around 3000°C. From the selected-area diffraction, however, the average dimension of the area, in which a-axis direction is the same, seems to be very much larger than the crystallite size.

A grain shown in Fig. 7a has a round outline and looks quite different from those already shown. Its diffraction pattern is a single-crystal pattern with Kikuchi-lines as shown in Fig. 7b. This is a single crystal of graphite. Grains of this kind can be found in the powders of various heat-treated carbons if H.T. is very high. Their size and shape do not depend on the characters of the original carbons. It seems that they are due to the crystal growth from vapor[3]. Since the formation of such single-crystal grains has no essential role in the principal process of graphtiization, we shall not further discuss it in this paper.

3) The growth of graphite crystals by the dislocation mechanism was observed and discussed by T. Tsuzuku, *Tanso* (*Carbons*), **5**, 2 (1955); T. Tsuzuku and T. Komoda, *Acta Cryst.*, **9**, 90 (1956).

(a)

(b)

Fig. 7. A single-crystal grain: (a) electron micrograph, (b) selected-area electron diffraction.

Structure of Coke Grains.—If the direction of the incident electron beam is parallel to the texture axis, we can not find any difference between ($h\ k$) two-dimensional diffraction and ($h\ k\ 0$) diffraction. This is the case in the diffraction patterns shown above. We studied the oblique diffraction pattern of coke grains in order to know their structure.

If coke grains have the textured polycrystalline structure, they should give oblique texture patterns[4]. The reciprocal lattice of non-graphitic structure consists of a series of (0 0 1) points along c-axis and ($h\ k$) lines parallel to it. Hence a grain should give an oblique pattern consisting of continuous ellipses if crystallites in it have non-graphitic structure. As the stacking order of layer lattice is improved, the structure factor has a periodic variation on each ($h\ k$) line in the reciprocal lattice. Thus the stacking order in the crysallites can be known from the intensity variation on the elliptical pattern in the oblique texture pattern.

Fig. 8 is one of the diffraction patterns obtained with the raw coke. The long arc-patterns are (10) and (11) diffractions and the short ones are (002) and (004) diffractions. It can be seen from this diffraction pattern that the direction of the texture axis, c-axis, has fluctuation around that which is normal to the surface of the grain. Most of the grains in the raw coke give such diffraction patterns. This is the case also in the heat-treated coke if H.T. is low. The fluctuation of c-axis direction decreases as H.T. is raised, and it almost disappears when H.T. is higher than 1850°C. The indication of the improvement of the stacking order, however, is not observed with the grains which have appreciable fluctuation of c-axis direction. The improvement of the crystallite alignment seems to proceed in advance of the change in the stacking order.

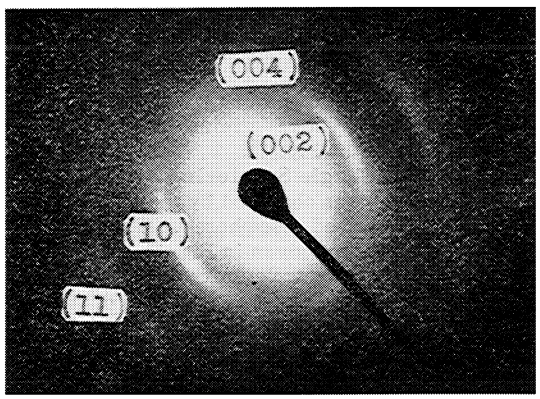

Fig. 8. An oblique pattern of a coke grain, (raw state). The oblique angle is larger than 80°.

In the X-ray diffraction pattern, the modulation of two-dimensional diffraction peak appears when H.T. is around 2000°C. The indication of the change in the stacking order can be observed also in electron microdiffraction from H.T. around 1900°C. One of the typical diffraction patterns corresponding to the earlier stage of graphitization is shown in Fig. 9. As H.T. is raised, the diffraction pattern becomes that of the textured polycrystalline structure of graphite. Some grains

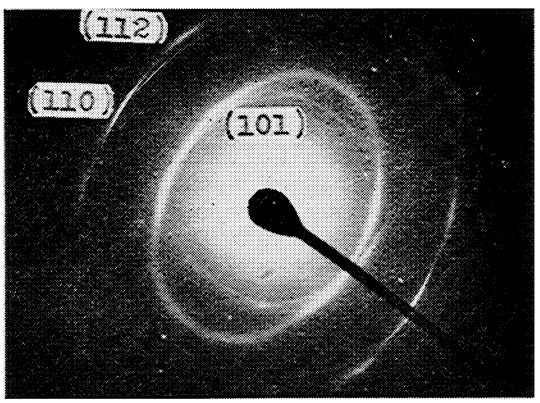

Fig. 9. An oblique pattern of a coke grain, (H.T., 1850°C). The oblique angle is 43°.

give a single crystal pattern. A typical diffraction pattern for coke grains heat-treated at 3000°C is shown in Fig. 10.

X-ray Small-Angle Scattering.—X-ray small-angle scattering was observed by the experimental procedures described elsewhere[5]. The observed intensity curves are given in Fig. 11. The small-angle scattering of petroleum coke is very weak, and, as H.T. is raised, the gradient of the intensity curve becomes very steep. It is difficult to make an accurate measurement when H.T. is high. As can be seen from Fig. 12, the intensity is nearly proportional to $h^{-2.3}\sim h^{-2.5}$ throughout the observed range of scattering angle. Such a relation can not be expected if the system is made up of spherical particles. The result seems to suggest that the structural units responsible for the observed scattering are thin plates.

Kratky and Porod[6] have derived an approximate formula for the scattering function of a thin disk of thickness $2H$ and diameter $2R$****.

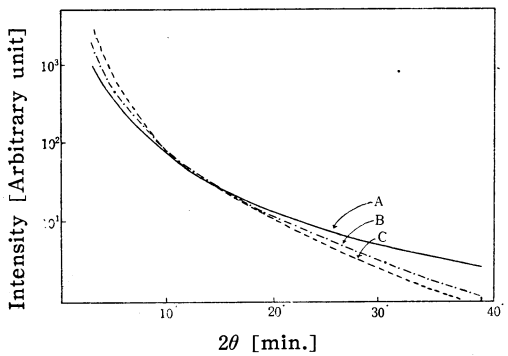

Fig. 11. Intensity curves of X-ray small-angle scattering: (A) raw state, (B) H.T., 1725°C, (C) H.T., 1850°C.

**** $h=4\pi\sin\theta/\lambda$ and n is the number of electrons in the particle.

$$\overline{F^2(h)} = (2n^2/h^2R^2)\exp(-h^2H^2/3)$$

This can be used in the range of angle, $1/R<h<1/H$. When the system consists of thin plates of different sizes and random orientation, the small-angle scattering intensity might be roughly expressed by the following formula at the angle where h is large with respect to $1/\bar{R}$ but small with respect to $1/\bar{H}$.

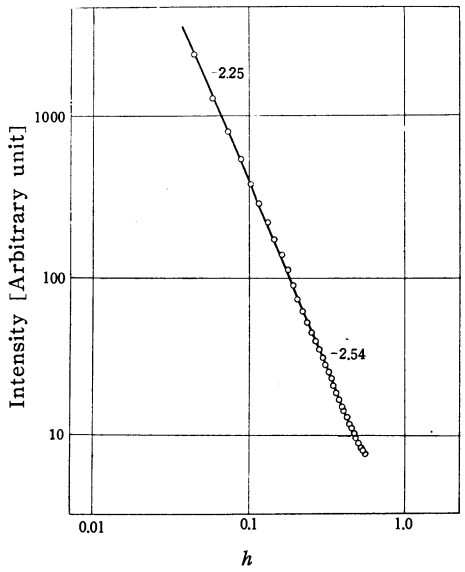

Fig. 12. Plot of $\log I(h)$ versus $\log h$, (raw state). The numbers on the curve indicate the inclination.

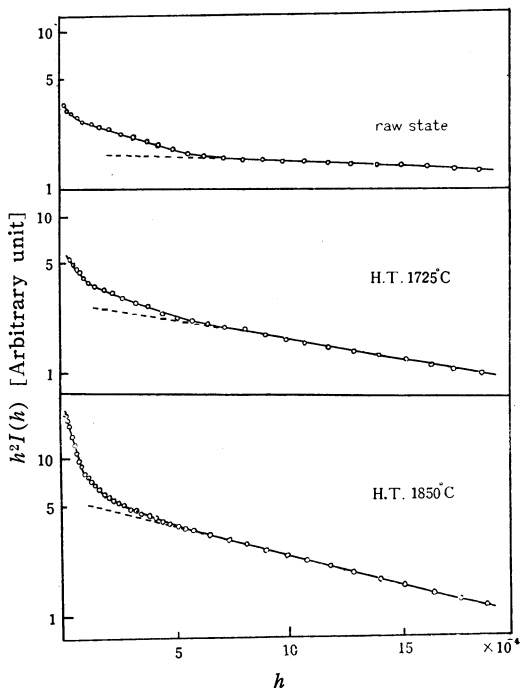

Fig. 13. Plot of $\log h^2I(h)$ versus h^2.

$$h^2I(h) = \text{const} \sum M(H_i) H_i \exp(-h^2H_i^2/3)$$

where $M(H_i)$ is the mass-fraction of plates with thickness of $2H$, and $\bar{R}$, $\bar{H}$ are the average value of R and H, respectively.

The curves of $\log h^2I(h)$ versus h^2 are shown in Fig. 13. There is a wide linear part in each curve. The value of $2H$ corresponding to the inclination of this part is given in Table II. They are of the same magnitude with crystallite size.

TABLE II. VALUES OF $2H$

H.T. (°C)	Range of the linear part (h)	Inclination of the linear part	$2H$ (Å)	L_c (Å)
Original	$>7.3\times10^{-4}$	3.48×10^2	49	37
1720	$>5.8\times10^{-4}$	10.72×10^2	86	71
1850	$>5.1\times10^{-4}$	14.51×10^2	100	93

$2H$ was calculated assuming that the inclination is equal to $-0.434H^2/3$.

Although we are not sure whether the structural units responsible for the observed small-angle scattering are the groups of crystallites or the voids between them, the results seem to suggest that petroleum coke has some kind of lamellar units in its structure even in the raw state and after heat-treatment at low temperatures.

Discussion

It has been found that petroleum coke can be disintegrated into minute flaky grains. When H.T. is high, it has been observed that each coke grain is made up of smaller grains or lamellae in which carbon crystallites are aligned so as to make their c-axes normal to the plane of the lamella. When H.T. is low, the lamellar structure can not be seen, but the alignment of crystallites is already not at random, c-axis direction being nearly perpendicular to the surface of grain. X-ray small-angle scattering suggests also the presence of lamellar units in the structure of petroleum coke.

It has been frequently presumed hitherto as the structural model for cokes that carbon crystallites are randomly linked to one another with chain-like molecules in disordered phase. Such a model, however, is not satisfactory for petroleum coke, since it is disintegrated into grains as mentioned above, and it must be made up of lamellar groups of crystallites with the preferential orientation concerning c-axis.

As mentioned already, the textured structure can be found even in the raw coke. It seems to have been formed during the carbonization process. If each crystallite is separated from the neighboring ones by a large amount of disordered phase, it might be difficult to form a large group of crystallites in which c-axis direction is nearly the same. The textured structure will be explained if we presume that there is a comparatively small amount of disordered phase between neighboring crystallites.

It has been known that the disordered phase is made up of mainly aliphatic C–C bonds, C–H bonds, C–O, bonds etc. Since these chemical bonds are thermally unstable compared with aromatic C–C bond, they can be broken at a lower temperature which can not provide a sufficient energy to break up residual bonds of aromatic character. Thus, when H.T. is low, the crystallite growth will proceed solely at the expense of disordered phase. This will cause only a slight increase of crystallite size. This is actually the case as seen in Table I. The crystallite alignment, however, is to be improved well in this stage. At the extreme of the crystallite growth of this mechanism, there should be only a very narrow disordered region or slight structural defects between the neighboring crystallites. The remaining residual bonds might be of aromatic character at this stage. If H.T. is high enough to provide sufficient energy to break them up, the rapid growth will proceed by the condensation of the neighboring crystallites. Actually it starts at a temperature around 2000°C which is known to be a temperature at which the plastic deformation can occur in various carbons. If we presume such a mechanism of crystal growth, the structural change in petroleum coke will be explained well.

In a carbon black particle, c-axis direction of crystallites is considered to be nearly normal to the surface of the particle. When crystallite grows well, a carbon black particle becomes polyhedrone. If the crystallite size increases too much, a stress will be created in the particle. As has been shown in the previous papers, this situation sometimes causes the disintegration of carbon black particle into smaller units. There is no situation like this in the crystallite growth in petroleum coke if it proceeds within each textured polycrystalline group.

The micro-structure pictured in this paper is not to be considered as the special one that can be found only in petroleum coke. The similar structure can be found widely in soft cokes. In hard cokes, the

textured polycrystalline group does not exist, or, if it exists, the crystals are of small dimension. The large difference in graphitizability seems to be due to such a situation.

The author wishes to express his thanks to Professor H. Akamatu for his kind direction, and to Dr. H. Takahashi for his valuable advice. He is also indebted to Mr. S. Sakata for his kind help in the experiment.

Theoretical Study on the Mechanism of the Aromatic Substitution[1)]

By Saburo NAGAKURA and Jiro TANAKA

(Received July 30, 1958)

As is well known, the mechanism of aromatic substitution may be regarded as one of the most typical problems to which the quantum mechanical theory has been applied with success. Since 1940, a number of notable theoretical papers on this subject have already been published by several authors[2-8)]. In these papers, some quantum mechanical concepts useful for interpreting chemical reactivity of the aromatic molecule have been introduced. They are such concepts as π-electron density, free valency, localization energy, frontier electron density, etc.[9)] By means of them, one has succeeded in explaining the orientation rule observed with some aromatic substitution reactions. It seems hasty, however, to consider that all the problems in this field have been settled completely. In fact, one can easily find some facts which can hardly be interpreted by any theory presented hitherto. For instance, the facts that the aliphatic hydrocarbon like methane is generally less susceptible to the electrophilic substitution than the aromatic hydrocarbon is, and that the silver cation is difficult to cause the substitution reaction with benzene while the nitronium cation is well known as a typical reagent for it, are not thought to be explained satisfactorily by the previous theories.

In the present paper, it is undertaken to study the mechanism of the aromatic substitution with reference to the relative heights of energy levels of the reagent to those of the aromatic molecule. From the consideration of these energy levels, it is concluded that a large electron transfer necessarily occurs from the aromatic molecule towards the reagent and in the reverse direction for the electrophilic and the nucleophilic substitution, respectively. On the basis of this electron transfer mechanism, conditions necessary for causing the aromatic substitution are reasonably introduced. It is shown, moreover, that the orientation in the aromatic substitution can properly be predicted by the free valency values evaluated with the aromatic cation, the neutral molecule and the anion for the electrophilic, the radical and the nucleophilic substitution, respectively.

9) Some of these concepts are in intimate relations to one another. This problem has been discussed by Baba and also by Fukui et al. (cf. H. Baba, This Bulletin, **30**, 147, 154 (1957); K. Fukui, T. Yonezawa and C. Nagata, *J. Chem. Phys.*, **26**, 831 (1957)).

Determination of Energy Level Diagrams of Some Reagents and Aromatic Molecules

According to the authors' method described in the previous papers[10], the highest occupied (H) and the lowest vacant (V) orbital of a certain molecule can be determined by the aid of the experimental data on the ionization potential and the near ultraviolet absorption spectrum. The same method was applied to the determination of orbital energies of the neutral molecules and radicals considered in the present paper. Concerning electrophilic reagents, such as the nitronium (NO_2^+), chlorine (Cl^+), bromine (Br^+), iodine (I^+), and hydrogen cations[11], the lowest vacant orbital was set equal to the ionization potential of the corresponding neutral molecule or atom. On the other hand, the highest occupied orbital of the nucleophilic reagent, such as hydroxyl (OH^-) or chlorine (Cl^-) anion, was estimated from the electron affinity of the corresponding neutral radical or atom. The results thus obtained are shown in Fig. 1, where energy levels of the silver cation (Ag^+) and the iodine molecule are also given for the purpose of comparison. It is worthy of notice that both of them can form the stable charge transfer complex with the aromatic molecule[12-14] but are difficult to cause the substitution reaction.

Consideration of the Reaction Mechanism from Energy Level Diagrams[15]

First of all, let us consider the electrophilic substitution. It is evident from Fig. 1 that the lowest vacant orbital (hereafter abbreviated to V) of the typical electrophilic reagent lies definitely below the highest occupied orbital (hereafter abbreviated to H) of the aromatic molecule which is susceptible to the substitution reaction. On the other hand, the V orbitals of the silver cation and the iodine molecule, which can not act as the electrophilic reagent for the substitution, are apparently higher than the H orbitals of the aromatic molecules. This remarkable fact suggests that it may be necessary for the occurrence of the electrophilic substitution that the V orbital of the reagent is considerably lower than the H orbital of the aromatic molecule. Under this assumption, moreover, the fact that the simple aliphatic hydrocarbon like methane is attacked with difficulty by the electrophilic reagent can readily be understood. As is shown in Fig. 1, the H orbital of methane which exists at -13.0 eV. is clearly lower than or almost equal to the V orbitals for most electrophilic reagents. In this case, therefore, it is difficult to fulfil the necessary condition for causing the electrophilic substitution.

The above-mentioned fact probably gives an interesting suggestion concerning the mechanism of the electrophilic substitution. According to Mulliken's theory relevant to the intermolecular charge transfer phenomenon, the electron transfer occurs to some extent from a donor towards an acceptor when these two components approach each other[14]. For example, in the case of the molecular complex between benzene (electron donor) and iodine (electron acceptor), the magnitude of this electron transfer was estimated by Mulliken to be about 3%. On the basis of the molecular energy level diagrams shown in Fig. 1, this intermolecular charge transfer phenomenon can approximately be represented by the interaction of the H orbital of the electron donor with the V orbital of the electron acceptor. The simple LCMO treatment on this interaction leads to a qualitative conclusion that the magnitude of the electron transfer increases as the V orbital becomes lower or the H orbital higher if the resonance integral between these two orbitals remains almost constant. In fact, in the

11) The reagent ion in solution is undoubtedly stabilized by the orientation of surrounding solvent molecules. In the present state of the study, however, it is difficult to make quantitative discussion on the solvation energy of the ion under actual conditions of reaction. Therefore, the effect of the solvent upon the orbital energies of the ion was not taken into account in the present treatment.

15) The description in this chapter is an extention of the basic idea mentioned in the preliminary papers published in 1954[1]. The present authors' view on the importance of the electron transfer in the aromatic substitution is based on the energy level diagrams of the reagent and the aromatic molecule, which are determined by the use of the experimental data on the ionization potential and the near ultraviolet absorption spectrum. On the other hand, Fukui et al. have discussed a similar problem from the purely theoretical point of view and derived the equations representing the dependence of the electron density on the reagent upon the Coulomb and resonance integrals (K. Fukui, T. Yonezawa and C. Nagata, *J. Chem. Phys.*, **27**, 1247 (1957).

case of the iodine complex with triethylamine whose H orbital is much higher than that of benzene[16], the extent of the electron transfer certainly exceeds 50% as is revealed from the big dipole moment (11.3D)[17].

Applying the above consideration on the electron transfer to the system consisting of the aromatic molecule and the electrophilic reagent, one may be led to the conclusion that there necessarily occurs an extremely large electron transfer from the former towards the latter, because in this system the V orbital of the reagent is extraordinarily low and even lower than the H orbital of the aromatic molecule as mentioned above. This means that the electrophilic substitution proceeds passing through a stage at which the reagent cation robs almost one electron from the aromatic molecule and consequently the former changes nearly to the neutral radical and the latter nearly to the cation. On the present study of situation, it is difficult to ascertain whether or not this stage corresponds to the so-called transition state, namely the highest point in the potential energy curve for the reaction. According to our opinion, however, it is probably just before the transition state assumed by Wheland[2]. In other words, the above-mentioned large electron transfer may be accompanied by changes of the hybridizations and geometrical configurations in both the reagent and the aromatic molecule, and then a new σ bond may be formed between the former and a carbon atom of the latter

16) The ionization potential of triethylamine was determined as 7.50 eV. by Watanabe (K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957), whereas the ionization potential of benzene is 9.24 eV.

17) S. Nagakura, *J. Am. Chem. Soc.*, **80**, 520 (1958); H. Tsubomura and S. Nagakura, *J. Chem, Phys.*, **27**, 819 (1957).

(Wheland's activated complex, type II)[18]. This view is schematically shown in Fig. 2. In this figure, stages B and C correspond to the electron transfer state and Wheland's transition state, type II, respectively.

Spectrophotometric studies by Reid[19] and also by Gold and Tye[20] show that the aromatic carbonium ion $(ArH)^+$ can be formed by the interaction of the aromatic molecule with proton under suitable conditions. This kind of ion, which is called $b\pi$, $h\sigma$ inner complex and σ-complex by Mulliken[7] and by Brown[21], respectively, may be thought to take a structure similar to that of Wheland's activated complex, type II. Hence, the present theory may be said to clarify the necessary conditions for forming the inner complex.

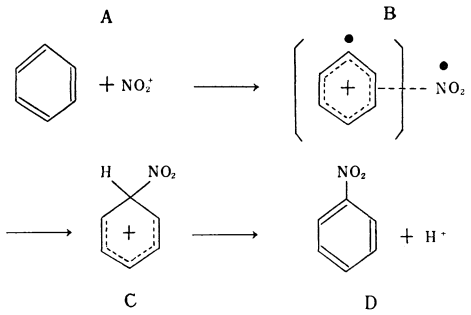

Fig. 2. Schematic diagram depicting the process of the substitution reaction between benzene and nitronium cation.

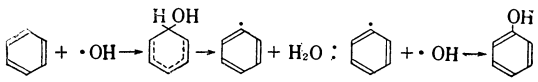
Let us now turn to the nucleophilic substitution. As is clearly seen from Fig. 1, the H orbital of the nucleophilic reagent is generally very high and may be regarded as comparable to the V orbital of the aromatic molecule. It is inferred from this that in this case a large electron transfer occurs from the reagent towards the aromatic molecule, and consequently the reaction takes place passing through the state in which the reagent becomes a nearly neutral radical and the aromatic molecule becomes an anion.

On the other hand, in the case of the radical substitution one may not expect such a large electron transfer as in the case of the heterolytic substitution, because unpaired electron levels of most radicals lie in an intermediate position between the H and the V orbitals of the aromatic molecule[22]. Thus in our opinion, the distinction between the heterolytic (electrophilic and nucleophilic) and homolytic (radical) substitutions is made in terms of the magnitude of the electron transfer between the reagent and the aromatic molecule. Furthermore, it is sure that in the electrophilic and the nucleophilic substitutions the directions of electron transfer are opposite to each other.

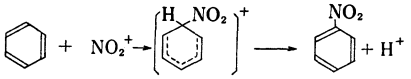
The present theory seems to have intimate relations with that presented by Weiss[23]. In 1946, Weiss emphasizes almost intuitively the importance of the electron transfer in many kinds of organic reactions. However, the grounds for his insistence concerning the aromatic substitution seem to be indefinite. The present theory has an advantage in that the necessity of a large electron transfer is reasonably concluded from the consideration of energy level diagrams of the reagent and the aromatic molecule.

Now, some consideration will be taken of the orientation in the aromatic substitution reaction, namely, the relative rate of substitution on various positions of the aromatic molecule. According to the present authors' view, in the heterolytic substitution the electron transfer takes place and consequently the reagent ion may be thought to attack the substrate as the radical. In other words, after the occurrence of the electron transfer, the mechanism of the heterolytic substitution may be regarded as similar to that of the homolytic substitution. Moreover, as is



18) The authors wish to express their sincere thanks to Professor Mulliken at Chicago and Professor Coulson at Oxford for their kindness in giving helpful suggestions on this respect. According to the present authors' opinion, Wheland's transition state, type II, corresponds to a basin in the potential energy curve for the substitution reaction.

19) C. Reid, *J. Am. Chem. Soc.*, **76**, 3264 (1954).



20) V. Gold and F. L. Tye, *J. Chem. Soc.*, **1952**, 2184.

21) H. C. Brown and J. D. Brady, *J. Am. Chem. Soc.*, **74**, 3570 (1952).

22) It is doubtful if the radical and the nucleophilic substitution proceed completely parallel to the electrophilic substitution. For example, the substitution of the hydroxyl radical for the hydrogen atom of benzene is considered to take place through the following procedures (G. Stein and J. Weiss, *J. Chem. Soc.*, **1949**, 3245):

This mechanism is apparently different from that of the electrophilic substitution such as

However, both reactions pass commonly through Wheland's type II transition state where the attacked point is clearly determined. Therefore, it seems reasonable to consider that concerning the orientation rule parallel treatment can be applied to the three types of aromatic substitution reactions.

23) J. Weiss, *Trans. Faraday Soc.*, **42**, 116 (1946).

well known, in the homolytic substitution the concept of free valency is very useful for explaining the orientation rule[8a,24,25]. Hence, it is quite natural to consider that the orientation in the electrophilic and nucleophilic substitutions can be predicted on the basis of the free valency value of the aromatic cation and of the anion, respectively.

Calculation of the Free Valency and Consideration of the Results

Free valency of the r-th atom(F_r) can be evaluated with the aid of the following equation:

$$F_r = F_{\max} - \sum_s p_{rs}$$

where $F_{\max}$ is the maximum value of the total π bond order of the carbon atom and estimated at $\sqrt{3}$[24], and p_{rs} is the π bond order of the r-s bond, where s denotes the adjacent atom to the r-th one. The value of p_{rs} can be calculated by the aid of the following equation:

$$p_{rs} = \sum_i n_i C_{ri} C_{si}$$

Here C_{ri} is the coefficient of the r-th atomic orbital in the i-th molecular orbital and n_i is the number of π-electron occupying it. The calculation of C_{ri} was made on the basis of the usual LCAO method under the assumption of orthogonality between adjacent $2p\pi$ atomic orbitals. Moreover, it was assumed that one electron is removed from the highest occupied orbital and is added to the lowest vacant one for the cation and the anion, respectively. In molecules containing hetero-atoms, evaluated values of free valency are rather sensitive to the assignment of the Coulomb and resonance integrals[26]. In the present calculation, the Coulomb integral for the hetero-atom was estimated with reference to its electronegativity and the resonance integral was set proportional to the corresponding overlap integral. By employing the self-consistent procedure which was certified to be useful for calculating the electron density for various molecules such as acetamide[27], tropolone[28], furan, pyrrole and thiophene[29], it was proved that the dependence of free valency upon the assignment of the Coulomb integral decreases considerably. The C_{ri} values for aniline, nitrobenzene, benzaldehyde and chlorobenzene were evaluated by the use of this iterative procedure. The C_{ri} values for phenol were calculated by Tsubomura[30]. The free valency values finally obtained in the present study are given in Tables I—III. In these tables, observed orientation rules are also given for the purpose of comparison.

It is seen from these tables that free valency values calculated for the aromatic cation, neutral molecule and anion can explain without contradiction the orientation observed with the electrophilic, radical and nucleophilic substitutions, respectively. Especially, it is worth notice that the free valency values calculated for the cations of the so-called o-, p-directing monosubstituted benzene molecules generally decrease in the order of $p > o > m$. This order is in complete accordance with the experimental results on the electrophilic substitution.

It is known that in some monosubstituted benzene molecules such as toluene[31] and styrene the radical substitution takes place in the side chain. In the case of styrene, this fact is coincident with the theoretical conclusion as is shown in Table II. The free valency of the carbon atom in the substituent group of benzaldehyde is also great compared with that of each atom in the benzene ring. This predicts the possibility that this molecule may be attacked on the carbon atom of the substituent group by the radical reagent.

The only exception in which the order of the free valency values does not agree with that of the observed reactivities in various positions is the case of radical substitution of biphenyl. In this case, free valencies decrease in the order of $2 > 4 > 3$, while the 4-position is most reactive from the experimental point of view. This descrepancy may be due to steric hindrance in the 2-position.

Such a satisfactory agreement between theoretical and experimental results as is seen from Tables I—III seems to support our view that at some stage of the heterolytic substitution reaction a large electron transfer takes place between the aromatic

molecule and the reagent, and consequently the orientation in the substitution can be determined by free valency values of the aromatic cation, neutral molecule and anion for the electrophilic, radical and nucleophilic substitutions, respectively.

Finally it may be necessary to add a note on the reaction between the OH radical and the aromatic molecule. According to the measurement by Robertson[32], the ionization potential of the OH radical is determined as 13.75 eV. This means that the energy of its unpaired electron orbital is fairly low and a large electron transfer from the aromatic molecule may be expected for this radical as well as for the electrophilic reagent. From this it is inferred that the orientation rule for this radical becomes somewhat similar to that for the electrophilic reagent. In this respect, it seems interesting that in the radical substitution of nitrobenzene and of benzoic acid, the ratio of *m*-derivative to *o*- or *p*-derivative is conspicuously greater for the hydroxyl radical than for the phenyl radical (cf. Table IV). One of possible explanations for this is presumably that the hydroxyl radical partly possesses the characteristic of the electrophilic reagent.

32) A. G. B. Robertson, *Trans. Faraday Soc.*, **48**, 228 (1952).

Summary

The mechanism of the aromatic substitution was studied on the basis of the energy level diagrams determined for both the aromatic molecule and the reagent. From the consideration of the relative heights of the highest occupied and lowest vacant orbitals of the former to those of the latter, it was deduced that a large electron transfer occurs at some stage of the reaction from the aromatic molecule towards the reagent for the electrophilic substitution and in the reverse direction for the nucleophilic substitution.

In connection with this electron transfer mechanism, it was expected that the orientation rule observed with the aromatic substitution can be explained by free valency values of the aromatic cation,

neutral molecule and anion for the electrophilic, radical and nucleophilic substitutions respectively. It was shown that this expectation is fully satisfied for various aromatic substitutions.

The authors wish to express their sincere thanks to Professor K. Higasi and Professor O. Simamura for their kind advice. Their thanks are also due to Assistant Professor H. Baba and Mr. Y. Mizuno for their helpful discussion.

*The Crystal Structure of Bis(succinonitrilo)copper(I) Nitrate**

By Yukio KINOSHITA, Ikuo MATSUBARA and Yoshihiko SAITO**

(Received January 25, 1959)

It is well known that cuprous ion plays an important role in the dyeing of polyacrylonitrile fibers with anionic dyes; cuprous ion is readily absorbed by the fibers which then acquire an almost unlimited affinity for anionic dyes, which ordinarily can not be applied to this class of fibers.

Blaker et al.[1] suggested that the high affinity of cuprous ion for polyacrylonitrile is due to the inherent capability of nitrile groups in the fibers to absorb cuprous ion through formation of complexes analogous to those described by Morgan[2] for simple nitriles. These complexes, which may act as positive sites for fixation of dye anions, are considered to be of the type,

To verify this hypothesis, Rath et al.[3] have prepared similar complexes from nitriles of aliphatic dibasic acids. It would be of interest to determine the crystal structures of these compounds, since they would shed light on the mechanism of the dyeing.

The crystal structure of bis(succinonitrilo) copper (I) nitrate, $[Cu(NC-CH_2-CH_2-CN)_2]NO_3$, has been determined as a part of a program to establish the configurations of these complexes. Furthermore, the infrared spectrum of this complex has been investigated in relation to the crystal structure.

Experimental

Bis(succinonitrilo)copper(I) nitrate was prepared according to the directions of Morgan[2] by dissolving silver nitrate into succinonitrile at 60°C and adding an excess of copper powder. After black spongy silver was deposited, the mixture was filtered while warm and the filtrate was extracted with a mixture of ether and alcohol. On cooling, the clear extract deposited colorless crystals. This compound shows no definite melting point.

Anal. Found: C, 33.24; H, 2.99; N, 24.85; Cu, 22.12. Calcd. for $C_8H_8N_5O_3Cu$: C, 33.63; H, 2.82; N, 24.51; Cu, 22.24%.

Rotation and Weissenberg photograph showed the crystal to be monoclinic with

$a=11.62\pm0.03$Å, $b=5.31\pm0.01$Å, $c=9.53\pm0.03$Å, $\beta=98.8°\pm0.2°$.

Systematically absent reflections were $(h\,0\,l)$ for h odd, which indicated space groups $P2/a$ or Pa. The statistical method of Howells, Phillips and Rogers[4], when applied to the $h\,0\,l$ data, indicated the presence of a center of symmetry, which enabled us to adopt the space group $P2/a$ for the crystal. The density, determined by floatation, was found to be 1.634 g./cc., while

* Presented in part at the Symposium on the Chemistry of Complex Compounds, Tokyo, November 16, 1958.

that calculated assuming two formula units per cell was 1.633 g./cc.

Intensity data were obtained by visual estimation of *a*-, *b*- and *c*-axis zero-layer Weissenberg photographs taken with Cu $K\alpha$ radiation. A multiple-film technique was used and the intensity was corrected for geometrical and polarization factors. The final set of data consisted of 122 ($h\,0\,l$), 66 ($h\,k\,0$) and 54 ($0\,k\,l$) terms of measurable amplitudes. Absorption corrections were not made, but errors were minimized by selecting small and as well-formed crystals as were available.

The infrared absorption spectra of bis(succinonitrilo)copper(I) nitrate and succinonitrile in the wavelength region from 2 to 15 microns were obtained with a Perkin-Elmer model 21 spectrophotometer (with NaCl optics).

Structure Determination

Space group $P2/a$ contains fourfold general point positions. Since the unit cell contains only two formula units, the copper atom and the nitrate ion must lie either on a twofold symmetry axis or on a center of symmetry. The latter can be excluded since a tetrahedral coordination of a cuprous ion and trigonal configuration of a nitrate ion are to be expected. The copper atom and the central nitrogen atom(N_1) of the nitrate ion, therefore, must lie on twofold axes. The Patterson function was computed for the *b*-axis projection, which could be solved without difficulty, because of the occurrence of the copper atoms on special positions. Approximate *x*- and *z*-coordinates of all the lighter atoms were obtained at once.

A Fourier synthesis of the electron density projected along the *b*-axis was computed and this enabled all the *x*- and *z*-coordinates to be fixed. The Patterson function for the *a*- and *c*-axis projection could be solved successfully by trial

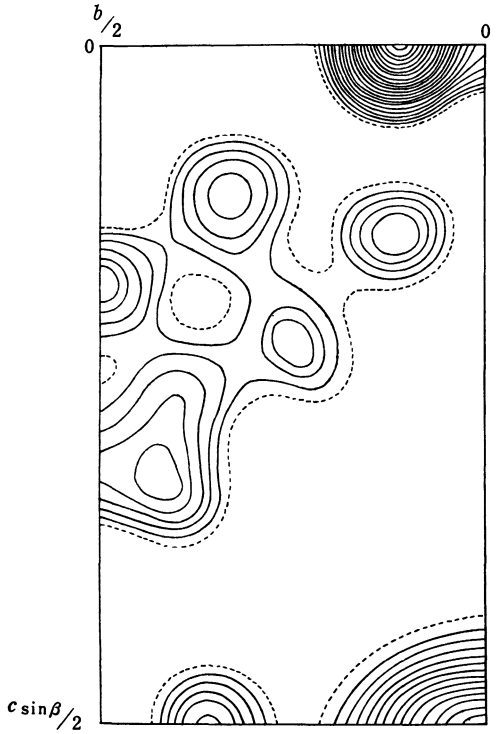

Fig. 2. Final Fourier projection of electron density along [1 0 0]. Contours are drawn at intervals of 2 eÅ^{-2} for copper and nitrate group except O_1. Those for other atoms are at intervals of 1 eÅ^{-2}, the lowest being 2 eÅ^{-2} (broken).

studies with models having suitable interatomic distances and bond angles. Approximate y-coordinates of all the atoms were thus obtained. Fourier projections of the electron density along [1 0 0] and [0 0 1] were then computed. Fourier refinements were repeated as usual. The final projections along [0 1 0] and [1 0 0] are shown in Figs. 1 and 2, respectively.

The final set of parameters is listed in Table I. This gave the reliability index $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ of 0.124, 0.106 and 0.134 for $(h\,0\,l)$, $(h\,k\,0)$ and $(0\,k\,l)$, respectively. A mean isotropic temperature factor with B=4.0 Å^2 was found to be satisfactory for the three equatorial zones. Observed and calculated structure factors are shown in Table II.

Calculation of the structure factors as well as that of the electron density was carried out with Remington Rand UNIVAC 120 electronic computer quite effectively.

Description of the Structure

The interatomic distances and the bond angles calculated on the basis of the above parameter values are given in Table III. Calculation of the standard deviation of atomic coordinates by Cruickshank's

method[5] for each projection gives 0.025Å for the resolved carbon and nitrogen atoms. This suggests a standard deviation of about ±0.04 Å in the Cu-N bond length determination.

The projections of the structure of bis-(succinonitrilo)copper (I) nitrate along [0 1 0] and [1 0 0] are shown in Figs. 3 and 4, respectively.

It is evident from the figures that the structure consists of nitrate ions and a polymeric chain of the composition,

which runs parallel to the *a*-axis. A copper atom is surrounded tetrahedrally by four nitrogen atoms with Cu-N distances of 1.96 and 2.02 Å. A succinonitrile molecule in the complex takes a *gauche* configuration with respect to the central C_2-C_3 bond, the azimuthal angle of internal rotation being 127° with the *trans* position taken as the origin. The observed C-N distance of 1.14 Å is, within the limits of error, close to the value expected for triple C-N bond length. The N-C-C bond as well as the Cu-N-C bond is found to be approximately linear. It is possible accordingly that the bond character in the C-N group may be expressed as C≡N.

The nitrate ion exists on a twofold symmetry axis. The shape and size of the ion is as listed in Table III. These data are in good agreement with those obtained for other crystals.

Infrared Spectrum as Related to the Configuration of the Ligand Molecule

The vibrational spectrum of the free succinonitrile molecule was investigated by Fitzgerald and Janz[6], who concluded that this molecule exists as an equilibrium mixture of two rotational isomers, *trans* and *gauche*, the latter being the more stable configuration. Nakagawa and Tokumaru[7] also studied the vibrational spectrum of this substance and reached a similar conclusion. In considering the infrared spectrum of the complex compound it was first assumed that the interaction forces between ligand molecules are so small that the main features of the spectrum may be explained from consideration of an isolated succinonitrile molecule. The infrared spectra of bis-(succinonitrilo)copper(I) nitrate and free succinonitrile are shown in Fig. 5. In Table IV are listed the vibrational frequencies and the assignments for the infrared absorption bands of these substances in the region 1300~700 cm^{-1}. In fact, all the main bands of the complex in this region may be assigned to the vibrations of the

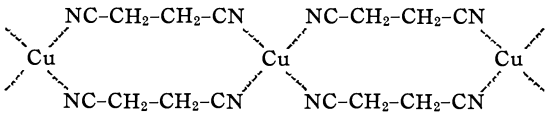
c) Based on Nakagawa and Tokumaru's results



gauche configuration of succinonitrile, which is in complete agreement with the X-ray results.

The spectral features in the nitrile absorption region show strong evidence of tetrahedral coordination of the nitrile groups to the copper sp^3 orbitals; the complex compound shows two intense bands with peaks at 2278 cm^{-1} and 2381 cm^{-1}, instead of the one at 2257 cm^{-1} corresponding to the C≡N stretching vibration of the free succinonitrile. These two bands are certainly to be assigned to the C≡N stretching modes characteristic to the tetrahedral configuration of the complex compound, although the vibrational shifts towards higher frequencies with respect to the free nitrile may require further considerations.

The intense bands at 830 cm^{-1} and near 1380 cm^{-1} and a weak band at 749 cm^{-1} are assigned to the vibrations of the nitrate ion. A weak band at 1042 cm^{-1} may correspond to an infrared inactive frequency for the nitrate ion which is considered to become active because of the breakdown of the selection rule in the crystalline field.

Summary

The crystal structure of bis(succinonitrilo)copper(I) nitrate has been determined by two dimensional Fourier method. It is monoclinic $P2/a$ with two formula units in a cell of dimensions: $a=11.62\pm0.03$ Å, $b=5.31\pm0.01$ Å, $c=9.53\pm0.03$ Å and $\beta=98.8°\pm0.2°$. The crystal consists of nitrate ions and polymeric chains of the following composition:

These chains run parallel to the a-axis. A succinonitrile molecule takes a *gauche* form with respect to the central C_2–C_3 bond. A copper atom is surrounded tetrahedrally by four nitrogen atoms with Cu–N distances of 1.96 and 2.02 Å. These facts are in close agreement with infrared spectral observations.

All the atoms in the group Cu–N–C–C lie almost on a straight line. This fact and the observed C–N distance of 1.14 Å suggest that the bond character in the C–N group may essentially be expressed as C≡N.

The authors wish to express their hearty thanks to Dr. K. Hoshino and Dr. K. Kato of the Central Research Laboratories of Toyo Rayon Co., Ltd. for their kind encouragement in the course of this study. They also wish to thank Mr. K. Yoshida of Toyo Rayon Co., Ltd. for carrying out the mechanical computations.

Electron Diffraction Investigation on the Molecular Structure of n-Butane

By Kôzo KUCHITSU

(Received December, 27, 1958)

The structural parameters of normal hydrocarbons have not yet been thoroghly studied[1], except the simplest ones, methane[2] and ethane[3-5], though there are many investigations on their halogen derivatives[6]. The results which have so far been obtained, except the above two, are on propane by Pauling and Brockway[7], C-C=1.54±0.02A, and ∠C-C-C=111.5°±3°, and on *n*-butane by Wierl[8], C-C=1.51± 0.05A. As the technique has since been developed, more accurate results are expected to be given in the determination of the C-C distances and the C-C-C valence angles. Furthermore, the position of hydrogen atoms may be located with considerable accuracy, because these molecules do not include heavier atoms than carbon. Accordingly, it seems worth while to investigate the structure of *n*-butane.

Various spectroscopic and thermodynamic studies have shown that rotational isomers exist in the normal paraffins higher than propane[6]. As for *n*-butane, it was first noticed by Kohlrausch and Köppl[9] in their study of the Raman spectra. It was soon confirmed by Mizushima, Morino and Nakamura[10] in their study of the Raman spectra in the liquid and solid. They found that two forms exist in the liquid whereas only the *trans* form remains in the solid. The energy difference between the isomers was measured by Szasz and his co-workers in the liquid phase[11,12]. They obtained from the measurement of the temperature dependence of the Raman intensity the value of 770±90 cal./mol.[11], or 760±100 cal./mol.[12] (the *trans* form being the more stable). This result is in good agreement with the value of 800 cal./mol. which was estimated by Pitzer[13] from the entropy of *n*-butane[14] and used in the studies of the thermodynamic functions of hydrocarbons. Thus the rotational isomerism seems to be well established in the liquid phase, but no experimental evidence concerning the energy difference in the vapor is so far available[12]. While it seems probable that the magnitude is nearly the same as in the liquid because of the nonpolar nature of the molecule, the infrared spectrum of the vapor of *n*-butane was interpreted by Gates[15] in terms of a single form. However, as pointed out by Axford and Rank[16], his interpretation seems to rest on a rather insecure foundation and a further study on this point will make the situation clear. In the present study it is confirmed that two isomers exist, the *trans* and the *gauche* forms, in the vapor of *n*-butane, the energy difference being nearly equal to that in the liquid.

Experimental

The electron diffraction instrument used in this study was designed by Morino, Kimura and Iwasaki[17]. The details of the apparatus and procedure were reported previously[18-20]. Diffraction photographs were taken through an r^3-sector

(in the case of the shorter camera length, 11.8 cm.) or an r^2-sector (in the case of the longer camera length, 27.9 cm.). The sectors were carefully cut to fit the proper shape within a hundredth of a millimeter[21]. They were mounted on a ball-bearing race and rotated rapidly during the exposure. In taking the diffraction photographs particular care was taken in regard to the constancy of the electron wavelength, the reducing of the extraneous scattering, and a good localization of the sample vapor.

The electron beam was focused to a spot of about 0.1 mm. in diameter. The fluctuation or the drift of the accelerating voltage was regulated within 0.1%. The wavelength of the beam was determined to be about 0.0556Å by a transmission pattern of gold foil. In order to reduce the extraneous scattering, a beam stopper of a shape similar to that described by Brockway[22] or Bastiansen[23] was mounted at the center of the sector[21]. The effect of the stopper on reducing the extraneous background was clearly seen on the photometer trace; the blank line of the photometer curve was nearly on the same level as the center line screened by the stopper, illustrating the fact that the extraneous background was not significant. Further evidence was given by a "blank test"[24] (taking photographs under the same condition as the experiment but without a sample jet), or by the "shadow test"[24] (taking photographs with the sample jet through a non-rotating sector) showing that there was no appreciable extraneous scattering caused by the main beam, nor by the scattering on the edge of the sector, of the slit, and of the nozzle aperture.

A "Research Grade" sample of *n*-butane of Phillips Petroleum Company was kindly furnished by Mr. T. Takatani of the Hitachi Central Research Laboratory. The sample (gas at room temperature) was introduced into a glass container of about 1 liter and the pressure was kept at about 20 mmHg. A liquid air trap was placed just over the nozzle to prevent the sample from diffusing through the camera. The flowing rate of the sample gas was carefully controlled, and diffraction photographs were taken with a long exposure time (a few minutes)[23,25]. A set of three photographs of different exposures were taken successively and developed at one time in the same bath. Two of the better photographs among them were used for the density-intensity calibration.

The photographs were scanned by a Riken B-type recording microphotometer of Nagoya University to measure the optical density as a function of the radius[18]. The photographic plate was rotated rapidly about the center of the pattern while being scanned by the photometer.

The measurement of the photometer curves was carried out with a Riken two-dimensional comparator in the interval of $\Delta q=0.5$. Optical densities thus measured were converted into relative intensities either by Karles' method[26] or by Bartell's method[27] by using the set of two density curves. The resulting intensity curves were averaged respectively for each set. The agreement between the calibration curves obtained by either method was satisfactory. The curves obtained in both procedures were used in the analysis described below.

The averaged intensity curve was multiplied by $q^{1/2}$ to accentuate the molecular oscillations, and a smooth background line I_B was drawn through the curve. After a few steps of redrawing of the line, a reasonable background which satisfies Karles' criterion[24,26], that is, no fluctuation (0.0 through 0.7Å) and non-negativeness of the baseline of the radial distribution curve was obtained. The corresponding molecular intensity curve $qM(q)$ was readily calculated by using the following equation[26]:

$$qM(q)=q(I/I_B-1) \tag{1}$$

The above procedures were repeated one by one for the three sets of plates taken with the shorter camera length, and finally five molecular intensity curves shown in Fig. 1 were obtained: two from the curves calibrated by Karles' procedure, two by Bartell's procedure, and one for which the density is nearly linear so that the same molecular intensity curve was obtained by both calibrations. The average deviations of the peak positions and intensities, listed in Table I,

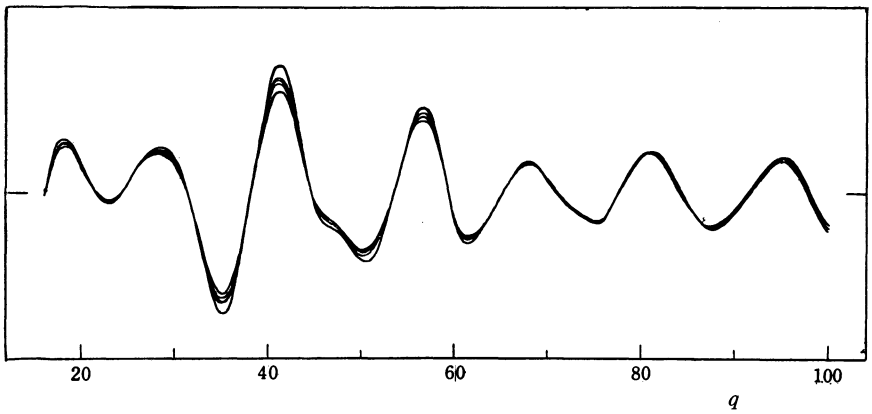

Fig. 1. Experimental molecular intensity curves for *n*-butane. Five experimental intensity curves are given in the same coordinate. The maximum average deviations among these intensities (near $q=40$) amounts to about 6%.

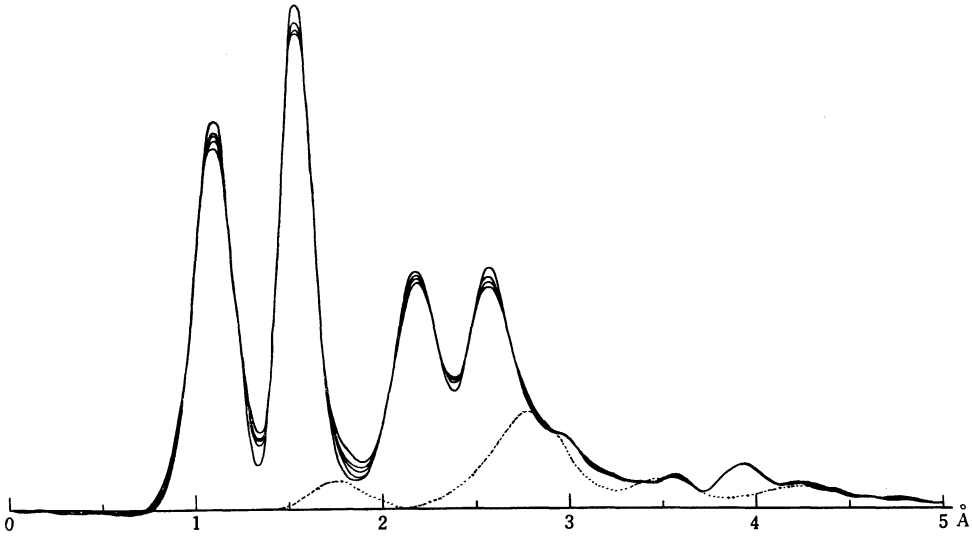

Fig. 2. Experimental RD curves. The RD curves computed from the five experimental intensity curves (Fig. 1) are illustrated in the same scale. The average deviations at the larger peaks are 1~2%. The dotted line denotes a minor contribution from the atomic pairs including hydrogen computed by use of a self-consistent model (see text). It is seen that the curves are non-negative everywhere within the experimental uncertainty.

are important measures for estimating the experimental errors of the structure analysis.

Analysis of the Radial Distribution Curve

Procedure.—Modified radial distribution curves[28] (they will be abbreviated as RD curves) were calculated from the molecular intensity curves, changing the Fourier integral into summation[29,30],

$$f(r)=\sum_{q=1}^{100} qM_c(q)\sin(\pi qr/10)\exp(-b\pi^2q^2/100) \quad (2)$$

where $qM_c(q)$ is the observed molecular intensity corrected for the non-nuclear scattering. Since the experimental intensity extends to $q=100$, a constant b was chosen to be 0.002333 to make the summation converge rapidly.

The summation was performed by the use of a punched-card machine[29]. The detail of the computation was given elsewhere[31]. Near the end of the study, a

TABLE II. SELF-CONSISTENT ANALYSIS FOR THE STRUCTURE (in Å unit)

Atomic pair	A		B		C	
	Distance	Mean amplitude	Distance	Mean amplitude	Distance	Mean amplitude
C-H	1.090	0.078	1.092	0.0830	1.092	0.0823
C-C	1.540	0.050	1.540	0.0534	1.539	0.0530
C-H (nonbonded)	2.163	0.110	2.178	0.1075	2.179	0.1005
C-C (nonbonded)	2.515	0.070	2.552	0.0739	2.553	0.0726
C-C (*gauche*)	2.949	0.160	(3.047)[a]	(0.160)[a]	3.12	0.125
C-C (*trans*)	3.876	0.070	3.906	0.0749	3.914	0.065

A: The model assumed at the first stage.
B: Result of the first analysis.
C: Result of the second analysis.
a) The *gauche* distance and its mean amplitude could not be measured accurately in the first analysis. Therefore, the values in brackets were used as the basis of the second analysis. The distance was calculated by using the result of the first analysis and the assumption that the azimuthal angle was 60°.

parametron digital computor became available at Department of Physics of the University of Tokyo. Some of the calculations were carried out by the use of this machine[32].

The RD curves thus obtained for the five molecular intensity curves are illustrated in Fig. 2; the agreement is satisfactory. A detailed analysis was made for the averaged RD curve.

Care was taken in the analysis in regard to the following points: a) the structure assumed in the analysis, b) a correction for the non-nuclear scattering, and c) minor contributions of hydrogen terms.

a) In the calculation of the RD curve, the inner region ($q=0\sim15$) of the molecular intensity curve was spliced by a theoretical intensity curve $qM_c(q)$ computed with an assumed model*. The model listed in the first column A of Table II was assumed at the first stage; in this model all angles were assumed to be tetrahedral and the mean amplitudes calculated theoretically (see section V) were used**. The result of the first analysis was used to calculate the second RD curve, and as shown in the second B and the last column C of the table the second-stage parameters were made self-consistent with the final result of the analysis.

TABLE III. SELF-CONSISTENT ANALYSIS FOR THE FRACTIONS OF THE ISOMERS

Series		A	B	C	D
I	*trans*	100%	65%	67%	65%
II	〃	0%	48%	57%	61%

Besides the assumptions on the structural parameters, assumptions had to be made for the rotational isomers, i.e., the configurations and the fractions of the isomers[19]. It was found that the shape of the RD curve beyond 2.3Å is sensitive to these assumptions, though they had no appreciable effect on the inner part of the RD curve. A method of analysis similar to that used by Iwasaki[33] was applied as follows. The process is shown in Table III. Theoretical curves were calculated first for 100% *trans* form (azimuthal angle 180°) (Series I), and for 100% *gauche* form (azimuthal angle assumed to be 60°) (Series II). The frame structure was based on the model C of Table II. The area under the *trans* C–C peak in the resulting RD curve was compared with the theoretical value and the fraction of the *trans* form was estimated from the ratio (IB and IIB). A theoretical curve of the mixture of two isomers in this fraction was then spliced to the experimental curve and the same analysis was carried out. This procedure was repeated until a self-consistent result for

32) Y. Morino, K. Kuchitsu and M. Shibuya, Symposium on Structural Chemistry, Kyoto, Japan, Oct. 1958.

* The contribution of the theoretical molecular intensity curve spliced in the inner region ($q=0\sim15$) to the RD curve is such a slowly fluctuating function that slight changes in the parameters have no essential influences on either the peak positions or the peak widths, though there may be considerable changes in the peak areas. Account was taken of this point for estimating the errors.

** The hydrogen atoms in the methyl groups were assumed to be at the staggered configuration in euqilibrium with respect to the hydrogen and carbon atoms in the methylene groups. See L. G. Smith, *J. Chem. Phys.*, **17**, 179 (1949), Refs. 4 and 5 for ethane, Ref. 50 for ethyl chloride, and K. S. Pitzer, ibid., **12**, 310 (1944), for propane.

33) M. Iwasaki, S. Nagase and R. Kojima, This Bulletin, **30**, 230 (1957).

the fraction of the isomers was obtained (C and D). Since both series gave nearly the same values, the fraction of the *trans* form was thus found to be 60~65% in this analysis. The area under the *gauche* peak in the final RD curve was found to be about 35~40% of the theoretical maximum value (that is, the area which could be expected if the *gauche* form only were present), also in agreement with this result.

In conclusion, the model used for calculating the final RD curve was made sufficiently self-consistent, so that the result of the following RD analysis is essentially free from any arbitrary assumptions.

b) A correction for the non-nuclear scattering was made by using the method of Bartell[34]. A minor correction term $\Delta M(q)$ was subtracted from the observed molecular intensity $qM(q)$ to obtain $qM_c(q)$. The function $\Delta M(q)$, which is defined as

$$\Delta M(q) = qM(q) - qM_c(q)$$
$$= \sum_{i,j}{}' (c_{ij}/r_{ij})(\mu_{ij}-1)\exp(-l^2_{ij}s^2/2)\sin sr_{ij} \quad (3)$$

where

$$\mu_{ij} = c_{ij}/c_{ij}$$
$$c_{ij} = (Z_i - f_i)(Z_j - f_j)/\sum[(Z_i - f_i)^2 + S_i]$$

and

$$c_{ij} = Z_iZ_j/(\sum Z_i^2 + Z_i)$$

was calculated theoretically on the base of an assumed model. As in the former case a), the structure first assumed was that listed in the first column of Table II; and then ΔM was calculated again by using the second column of the same table. The elastic scattering factors for carbon and hydrogen atoms, $f(s)$, were taken from the tables of Viervoll and Ögrim[35], McWeeny[36], and Berghuis[37]. For the inelastic scattering factor of carbon, $S_C(s)$, Bewilogua's function[38] was used; as pointed out in his paper, this function which is based on the Thomas-Fermi model is still a good approximation for carbon. The *S*-function for hydrogen, $S_H(s)$, is approximated by $S_H(s) = 1 - [f_H(s)]^2$ after the argument of Mott and Massey[39]. In order to make the magnitude of the ΔM-function smaller, the value Z_H in Eq. 3 was put equal to 1.25. It seems probable that uncertainties in these factors have a negligible effect on the final result as compared with the experimental errors.

c) As there are many non-equivalent C–C, C–H and H–H distances in *n*-butane, (twenty-seven in the *trans* form, and thirty-five in the *gauche* form), thorough analysis of all distances is obviously too

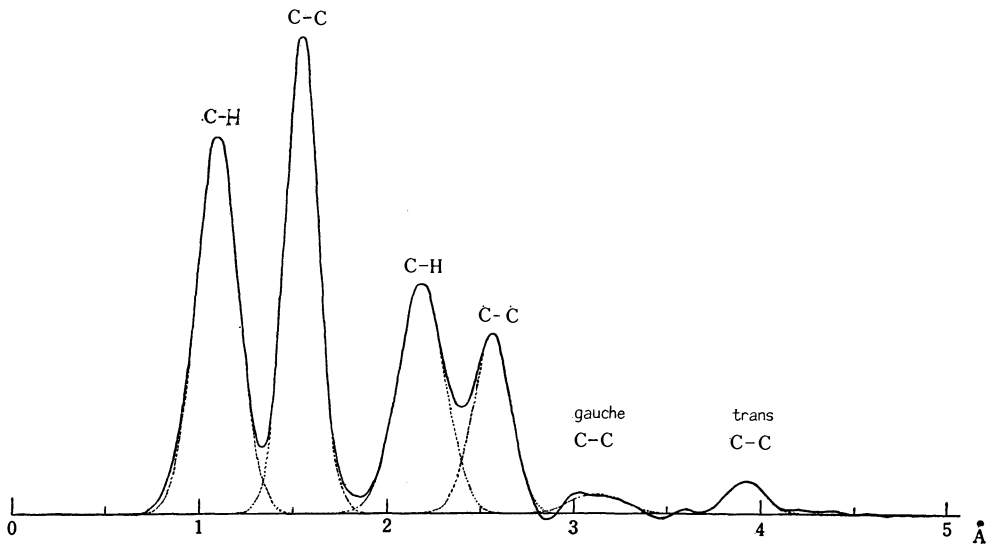

Fig. 3 Analysis of the average RD curve. The minor contribution illustrated in Fig. 2 is subtracted from the total curve. The dotted curves denote the best-fit Gaussian curves. The peaks represent (from left to right) the C–H, C–C, nonbonded C–H, nonbonded C–C, *gauche* C–C, and *trans* C–C distances, respectively.

complicated to be feasible. However, the structure of this molecule is principally determined by four main structure parameters, i.e., the C–H (average), C–C (average), C—H (average), and C—C distances. Since the contribution from these distances are exceedingly greater than that from the other distances, it is advantageous to subtract the minor contributions from the total RD, leaving the contributions from the principal parameters, which can then be analyzed uniquely. The minor contributions calculated by use of a self-consistent model are illustrated in Fig. 2 as a dotted line. The same procedure of obtaining such a self-consistent model as that discussed in a and b was undertaken. Tables II and III show that for the procedures a, b and c the model was simultaneously made self-consistent in two steps. The result is shown in Fig. 3.

Least-square Analysis of the Main Peak*.—The peak at 1.1Å in the RD curve (Fig. 3) corresponds to the C–H distance. The center of gravity which is equal to the mean distance was readily determined. The peak was found to be symmetrical with respect to the center, and accordingly, the curve could be fitted to a Gaussian function**.

The Gaussian function to be fitted is

$$y=y_0\exp(-Hx^2),\quad x=r-r_g \tag{4}$$

where r_g is the center of gravity. By taking the logarithm of both sides, the following linear equation is obtained.

$$Y=q-pX \tag{5}$$

where

$$X=x^2,\quad Y=\log_{10} y,\quad p=H\log_{10} e$$
$$\text{and}\quad q=\log_{10} y_0 \tag{6}$$

About ten sets of the observed values X_i's and Y_i's were used to determine the parameter p, under the condition that

$$\sum_i (\mathrm{d}y_i)^2=(\log_{10} e)^{-2}\sum_i y_i^2(\mathrm{d}Y_i)^2=\text{minimum} \tag{7}$$

Solving the equation for p,

$$p=\frac{[\sum y_i^2X_i]\,[\sum y_i^2Y_i]-[\sum y_i^2]\,[\sum y_i^2X_iY_i]}{[\sum y_i^2]\,[\sum y_i^2X_i^2]-[\sum y_i^2X_i]^2} \tag{8}$$

The parameter is related to the mean amplitude as

$$p=\log_{10} e/(4b+2l^2) \tag{9}$$

and

$$l=(\log_{10} e/2p-2b)^{1/2} \tag{10}$$

Since the standard error of the parameter p is given by

$$\sigma_p^2=\frac{[\sum y_i^2]}{[\sum y_i^2]\,[\sum y_i^2X_i^2]-[\sum y_i^2X_i]^2}\cdot\frac{\sum(\mathrm{d}y_i)^2}{n-2} \tag{11}$$

the standard error of the parameter l is readily obtained as*

$$\sigma_l=-\frac{\log_{10} e}{4lp^2}\sigma_p \tag{12}$$

The second peak at 1.54Å corresponds to the C–C distance. Because of the separation of 0.45Å between the C–H and C–C distances, a similar least-square analysis could be made with no ambiguity. The peaks for the non-bonded C–H and C–C distances are in a slightly closer separation. However, they were resolved by using the left side of the C–H peak, and the same procedure was applied. The results are listed in Table IV.

In the region beyond 3Å, two peaks

TABLE IV. RESULT OF THE LEAST-SQUARE ANALYSIS OF THE MRD CURVE

	$r_g(1)$[a]	Apparent mean amplitude	Area[b]
C–H (average)	1.092	0.084_6	0.987
C–C (average)	1.539	0.054_0	0.994
C–H (average)	2.179	0.103_2	0.970
C–C	2.553	0.074_8	1.060
C–C *trans*	3.914	0.069_6	0.590[c]

∠C-C-H (average) = 110°40′[d]

∠C-C-C = 112°6′

a) in Å unit

b) the ratio with respect to the theoretical absolute value

c) to be regarded as the fraction of the *trans* isomer

d) the value derived from $r_g(1)$ by Eq. 24

* The least-square analysis of RD curve has been reported recently by Bastiansen and Cyvin (O. Bastiansen and S. J. Cyvin, *Acta Chem. Scand.*, 11, 1789 (1957).). For a similar treatment of a $\sigma(r)$ curve, see the paper by Cruickshank et al. (D. W. J. Cruickshank and H. Viervoll, *Acta Chem. Scand.*, 3, 560 (1949).).

** The middle points of the curve at various peak heights were constant to a third decimal place of an angstrom. Strictly speaking, an $f(r)$ peak is expressed as

$$f(r)=\frac{c(\pi H)^{1/2}}{2r_e}\exp(-Hx^2)(1+ax+bx^2+cx^3+\cdots\cdots),\quad x=r-r_e$$

showing a slight distortion in trems of the parameters of anharmonicity and of the perpendicular amplitudes. However, the distortion is often so small that the curve can be interpreted as Gaussian. As will be shown later, the mean amplitude for $f(r)$ curve is almost the same as that for the probability distribution.

* The standard error is about 1%, being considerably smaller than the random errors estimated in section IV B.

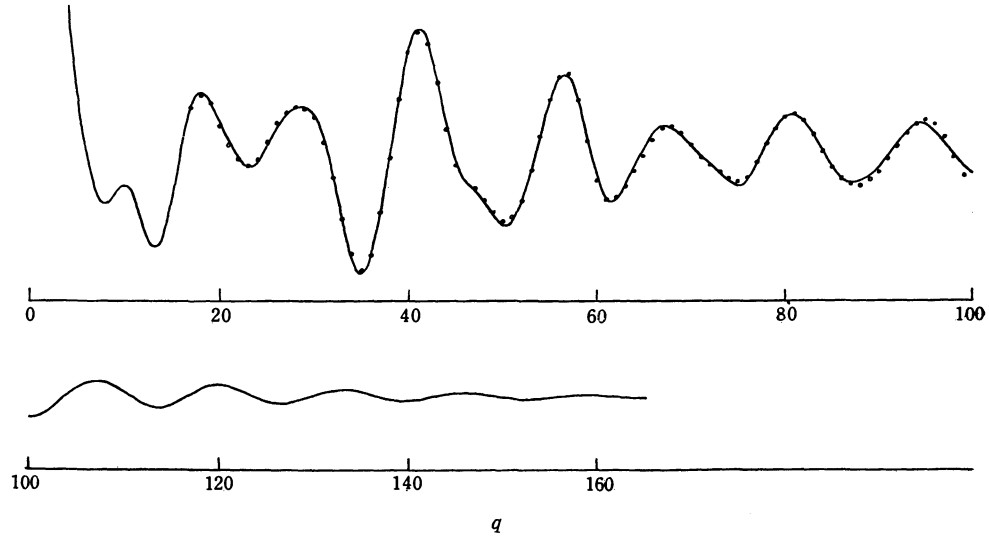

Fig. 4. Comparison of the observed and calculated molecular intensity curves. The solid line denotes the theoretical intensity calculated from the result of the MRD analysis (Table IV). The dots are the averaged experimental molecular intensity. These intensities fit within the experimental uncertainty illustrated in Fig. 1. The theoretical curve is extended beyond $q=100$, and is used in the UMRD analysis.

appeared at 3.1Å and 3.9Å, corresponding to the *gauche* and the *trans* C–C distances, respectively. It affords a definite evidence for the rotational isomerism in this molecule. As the shape of the latter peak is practically Gaussian, the same procedure was applied, whereas only approximate values for the distance and its mean amplitude were estimated from the former peak. A theoretical intensity curve and an RD curve were calculated by the use of the result listed in Table IV. The agreement with the experimental curve is satisfactory, as shown in Figs. 4, 5 and Table V. The average index of resolution is about 99%.

Unmodified Radial Distribution Curve.—By the same procedure as that described by Morino and Hirota[28], an unmodified radial distribution curve (UMRD), Eq. 13, was calculated for a further refinement of the analysis:

$$f(r)=\sum_{q=0}^{\infty}[w(q)qM_c(q)_{obs}+(1-w)qM_c(q)_{calc}]\times\sin\frac{\pi}{10}qr \qquad (13)$$

where $qM_c(q)_{obs}$ is the observed molecular intensity corrected for the non-nuclear scattering[34] and $qM_c(q)_{calc}$ is the calculated intensity based on the result of the analysis of the modified RD curve (Table IV and Fig. 4). The weight function $w(q)$ was so chosen that $w(q)\propto\exp[-c\Delta(q)^2]$, where $\Delta(q)$ is the amount of fluctuation among the observed intensity curves at a point q (Fig. 1), and c is a constant. The value $w(q)$ fluctuates somewhat irregularly with q between 100 and 80% for most of the experimental region ($q=17\sim95$), and is zero for the inner and outer parts. The UMRD curve is shown in Fig. 6. The analysis was carried out in the same way as that of the MRD curve (item 2). The results are given in Table VI and Fig. 6.

Estimation of the Errors in the Measurement of Interatomic Distances.—For the estimation of errors in the interatomic distances, sources of systematic errors in the scale factor and other errors in the observed RD curve must be considered. The main sources of systematic errors may be as follows.

a) The uncertainty in the scale-magnification ratio on the microphotometer trace, which is estimated to be about 0.1%.

b) The uncertainty in the camera length: it comes mainly from the difference between the position of the scattering center of the sample and that of the reference, and from the uncertainty in the position of the photographic plate. This error is about 0.1%.

c) The errors involved in the measurement of $L\lambda$: the product of the camera length L and the wavelength λ is determined by the measurement of the transmission pattern of gold foil. The standard error of the measurement is about 0.1%.

d) The drift of the wavelength: since a few minutes were required for exposure, the drift of the wavelength may be a cause of systematic error. In this experiment, however, the drift was controlled to within 0.05% by use of voltage stabilizers.

e) Errors in the determination of the

center in the photometric trace: they will cause error of less than 0.05%*. Assuming that these errors occur independently, a standard error in the scale factor is estimated to be about 0.2%.

f) A finite size of the light beam in the photometry: if the light beam has the rectangular shape of $a \times b$ on the photographic plate which is being measured (a being measured in the radial, and b in the perpendicular direction), the location of a halo of radius R on the plate suffers an inward shift of about $b^2/24R$. Since $a \times b = 0.1\,\text{mm.} \times 1\,\text{mm.}$ in this experiment, this shift has a uniform dependence on q, which is about 0.1% at $q=20$, and 0.01% at $q=60$. The correction was made for this effect though the magnitude is not important compared with other random errors.

For the standardization of the absolute scale factor, an analysis of carbon tetrachloride was made to check the apparatus and the method of analysis[19]. The C–Cl distance (the center of gravity of the $f(r)$ curve) was found to be 1.766Å, in good agreement with the results reported in the literature[34,40] within the experimental error.

Other errors were estimated from the variance of the results of the analyses for each of the five experimental RD curves, by using the standard statistical method on the assumption that this variance was caused by random errors. For the non-bonded peaks, possible sources of errors caused by the processes a, b and c stated in item 1 and the process of the decomposition of the composite peaks were also taken into account, the results of the above estimation are given in Table VI.

The Meaning of the Values Measured.— It is important to define clearly the meaning of the distances determined in this analysis, as pointed out by Bartell[41]. While the distance obtained above is the "center of gravity" or the "mean distance" of the $f(r)$ curve, it seems useful to correlate it to the $r_g(0)$ value, or the center of gravity of the probability distribution curve $P(r)$.

Including the anharmonicity in molecular vibrations[41] and the correction for the perpendicular amplitude, $P(r)$ may be expanded as (See f on page 756)

$$P(x) = (h/\pi)^{1/2} \exp(-hx^2) \times (1 + \alpha x + \beta x^2 + \gamma x^3 + \cdots\cdots) \tag{14}$$

where

$$x = r - r_e, \quad h = 1/2 < \Delta z^2 > \tag{15}$$

Then the mean value of the distance, $r_g(0)$, is expressed as

$$r_g(0) = \frac{\int_0^\infty r P(r)\,dr}{\int_0^\infty P(r)\,dr} = \frac{\int_{-\infty}^\infty (r_e + x) P(x)\,dx}{\int_{-\infty}^\infty P(x)\,dx}$$

$$= r_e + \alpha l^2 + \left(3\gamma - \frac{3}{2}\alpha\beta\right) l^4 + \cdots\cdots \tag{16}$$

where l^2 is the mean square amplitude, $< \Delta z^2 >$. On the other hand, the center of gravity of $f(r)$ is written by using the relation between $P(r)$ and $f(r)$,

$$f(r) = (\pi/16b)^{1/2} \int_{-\infty}^\infty [P(\rho)/\rho] \times \exp[-(r-\rho)^2/4b]\,d\rho \tag{17}$$

as

$$r_g(f) = \frac{\int_0^\infty r f(r)\,dr}{\int_0^\infty f(r)\,dr} = \frac{\int_0^\infty P(r)\,dr}{\int_0^\infty (P(r)/r)\,dr} \tag{18}$$

Therefore, it is equal to the center of gravity of the $P(r)/r$ curve, $r_g(1)$. By using Eq. 14, the difference between the above two is approximated by

$$r_g(0) - r_g(1) \cong \frac{l^2}{r_e} + \cdots\cdots \tag{19}$$

It amounts to a few thousandth of an angstrom; the second term is of the order of 10^{-5}Å. If a Morse-type potential function for the ground state of a diatomic molecule is assumed, as done by Bartell[41], the constants in Eq. 14 are in the following approximate relations,

$$\alpha = a, \quad \beta = 0, \quad \gamma = ah/3 \tag{20}$$

where a is a parameter of the Morse potential function, and Eqs. 16 and 19 agree with his expression (Eq. 4 of his paper). On the other hand, the center of gravity of the $rf(r)$ curve is given by

$$r_g(rf) = r_g(0) + 2b/r_g(1) \tag{21}$$

the difference being dependent on the damping factor b. The distance $r_g(0)$ can be obtained either from Eq. 19 or from 21. It is also obtained from the UMRD curve. The values of $r_g(0)$ obtained in this way are given in Table VI.

* The error due to an imperfect centering of the photographic plate during the scanning by the photometer is negligible, being of the order of a few ten thousandth of an angstrom, since the center was adjusted to within 5/100 mm. The error due to the deviation of the electron beam from the correct center of the sector during the exposure (which was within 5/100 mm.) is also negligible.

40) I. L. Karle and J. Karle, *J. Chem. Phys.* **17**, 1052 (1949).

41) L. S. Bartell, ibid., **23**, 1219 (1955).

TABLE VI. THE MEAN DISTANCES[a] AND ANGLES[b]

	MRD	UMRD	Standard error
C-H (average)	1.098	1.100	0.003
C-C (average)	1.540	1.539	0.003
C-H (nonbonded average)	2.182	2.181	0.005
C-C (nonbonded)	2.554	2.554	0.005
C-C (*gauche*)	3.12	3.13	0.02
C-C (*trans*)	3.913	3.911	0.009
∠C-C-H (average)	110°32′	110°22′	15′
∠C-C-C	112° 1′	112° 9′	9′

a) $r_g(0)$ in Å unit
b) the "mean angle" derived from $r_g(0)$ by Eq. 24

The mean square amplitude af a distance is defined by*

$$l^2(0)=\left[\int_0^\infty r^2P(r)\mathrm{d}r\right]\Big/\left[\int_0^\infty P(r)\mathrm{d}r\right]-[r_g(0)]^2 \tag{22}$$

whereas the mean square amplitude obtained from the radial distribution curve is

$$l^2(f)=\left[\int_0^\infty r^2f(r)\mathrm{d}r\right]\Big/\left[\int_0^\infty f(r)\mathrm{d}r\right]-[r_g(1)]^2 \tag{23}$$

A simple calculation using Eqs. 14 and 17 shows that the latter is equal to the mean square amplitude for the $P(r)/r$ curve, $l^2(1)$, plus $2b$, and the difference between $l^2(0)$ and $l^2(1)$ is only a minor correction as compared with the experimental error. (See f on page 756).

Determination of Valence Angles.—Following the above argument, the "mean angle" may be defined as the angle α derived by the following equation

$$\cos\alpha=(r_A^2+r_B^2-r_C^2)/(2r_Ar_B) \tag{24}$$

where r_A, r_B, and r_C are the mean values of the respective distances. The standard error of the angle is readily calculated to be

$$\sigma_\alpha=\left\{\left(\frac{1}{r_B}-\frac{\cos\alpha}{r_A}\right)^2\sigma_{r_A}^2+\left(\frac{1}{r_A}-\frac{\cos\alpha}{r_B}\right)^2\sigma_{r_B}^2+\left(\frac{r_C}{r_Ar_B}\right)^2\sigma_{r_C}^2\right\}^{1/2}\Big/\sin\alpha \tag{25}$$

The systematic error of the scale factor, 0.2%, is not included in σ_r's, because it has no effect on the angle. The result is given in Table VI.

Discussion Concerning the Longer Distances.—The *trans* C-C distance is calculated from the C-C distance $r_g(0)$ and the C-C-C angle assuming that the four carbon atoms are coplanar; it was found to be 3.926±0.003Å. On the other hand, the observed distance was 3.911±0.004Å*. The shortening, 0.015±0.005Å, can be interpreted as "significant", according to Cruickshank's definition[42]. It is likely that the shift is caused by a hindered rotation of the ethyl groups around the C-C axis taking the equilibrium position on the plane. The shift due to this effect was calculated theoretically by Karle and Hauptman[43]. It is calculated in a similar manner that the shift is 0.0120Å when the barrier V_0 is equal to 3.6 kcal./mol., and 0.0155Å when it is equal to 3.0 kcal./mol., in satisfactory agreement with the experimental shift. It is therefore inferred that the barrier height lies close to these values, in agreement with the value estimated by Pitzer, 3.6 kcal./mol.[14]

The azimuthal angle of the *gauche* form was calculated from the *gauche* C-C distance R_g(3.13±0.01Å) to be 67.5°±1.1°. The angle is thus nearly 60° as was usually assumed but possibly a little larger than that.

Estimation of Errors in the Mean Amplitude

The mean amplitudes listed in Table IV include both systematic and random errors. They were either corrected or estimated as shown in the following table.

A. Systematic errors
  Experimental
    a) effect of finite sample size: corrected,
    b) multiple or extraneous scattering: negligible,
    c) density-intensity calibration: estimated,
  Theoretical
    d) failure of Born approximation: corrected,
    e) effect of the possible difference in length between non-equivalent bonds: estimated,
    f) effect of perpendicular amplitude and of anharmonicity: negligible,
    g) effect of series termination: negligible, (in the case of MRD)
B. Random errors*

* The definition corresponds to u_a used by A. Reitan (Ref. 53).

* The error of the scale factor is not included in this comparison.

42) D. W. J. Cruickshank, *Acta Cryst.*, 2, 65 (1949).

43) J. Karle and H. Hauptman, *J. Chem. Phys.*, 18, 875 (1950).

* Errors which could not be treated as systematic errors were simply regarded as random errors though they might not be purely random in a strict sense.

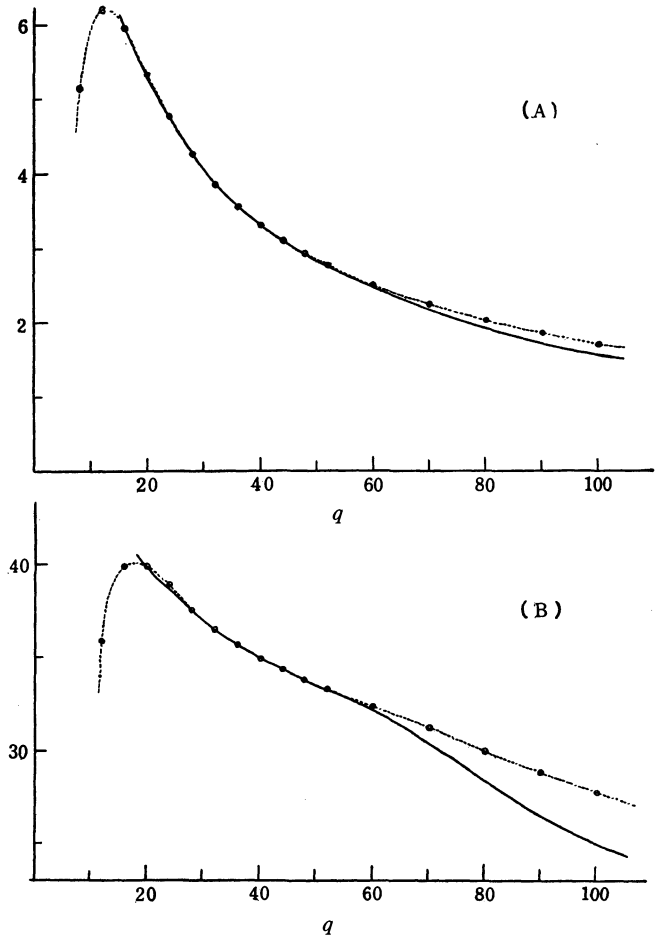

Fig. 7. Comparison of the background lines. Soild line: experimental; and dotted line: theoretical. The ordinate scales are adjusted in such a way that two curves coincide at $q=40$. (A) The background line obtained by use of an r^3-sector. (B) The curves shown in A are multiplied by $q^{1/2}$ to accentuate the difference; it amounts to about 10% at $q=100$.

Experimental: treated with a simple statistical method,
Computational: estimated.

These errors will be discussed as follows.

A. Systematic Errors.—*a) Effect of finite sample size.*—This effect was extensively studied by Karle[24], and also Harvey et al.[44] It is easily estimated if the distribution of the sample gas around the nozzle is known. The shape of the background line was found to be useful in this case for estimating the distribution. In Fig. 7 is shown a comparison of the observed background line with the calculated curve based upon the assumption that the diffracting molecules are located at an infinitesimal volume. The agreement is good in the inner region, whereas the deviation of the observed curve is clearly recognized beyond $q=60$. The nozzle used in this experiment is illustrated in Fig. 8. If this effect is attributed to the "screening" of the electrons at the nozzle edge, the distribution is estimated with the following simple assumptions:

1) The decrease in the observed background compared with the theoretical background is essentially caused by process in which a small fraction of the electrons scattered by the sample hit the wall of nozzle and do not reach the photographic plate (Fig. 8).

2) Since the beam diameter is much less than the nozzle aperture, a one-dimensional distribution of the sample gas, the area being normalized, is considered. Then the decrease is determined by the area of the shadowed region in Fig. 8.

44) R. B. Harvey, F. A. Keidel and S. H. Bauer, *J. Appl. Phys.*, **21**, 860 (1950).

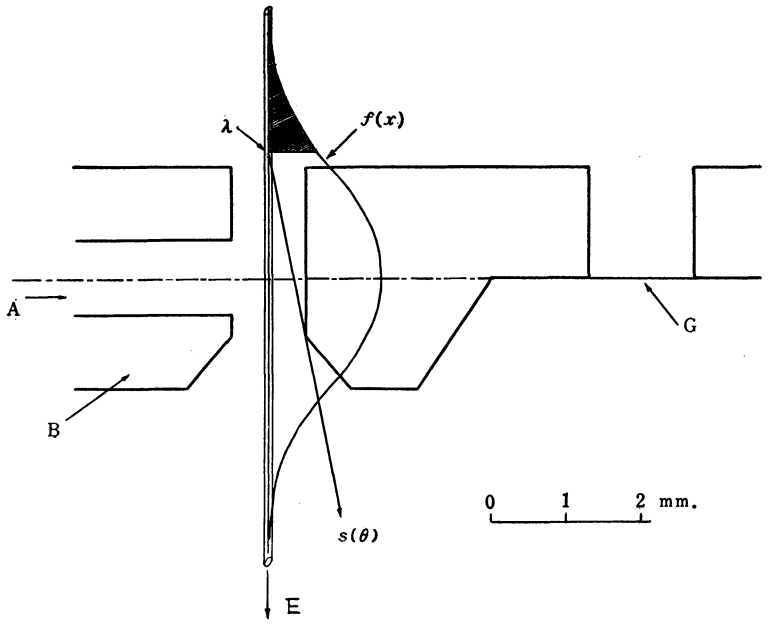

Fig. 8. "Screening effect" of the nozzle. An enlarged cross section of the drum-type nozzle is illustrated. A: gas inlet; B: nozzle body; E: electron beam (the cylinder represents a rough measure of the diameter); $f(x)$: normalized one-dimensional distribution of the gas; G: gold foil used as the reference. It is assumed that the electrons scattered at the point farther than the critical point $\lambda(\theta)$ (shaded region) in the direction of $s(\theta)$ are completely screened by the wall of the nozzle and do not reach the photographic plate, and that the scattered intensity undergoes a fractional decrease proportional to the shaded area.

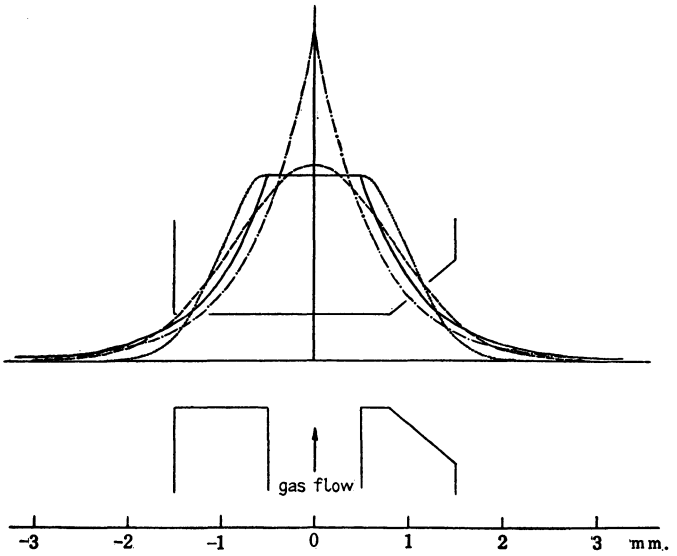

Fig. 9. Distribution functions of the gas spreading. It is assumed that they are symmetrical across the center of the nozzle inlet, and the areas are normalized. Solid line : flat and exponential; dotted line: flat and Gaussian; chain line: exponential; and broken line: Gaussian. It is seen that the distributions are all practically zero outside the nozzle.

3) The distribution is symmetrical across the center of the nozzle inlet.

In additon to these assumptions, the following simple analytical functions were assumed for the distribution, and parameters were determined to reproduce the experimental fractional decrease. The shapes of the distribution functions assumed are:

Exponential:

$$f(x)=\frac{1}{2}\rho\exp(-\rho|x|),\quad \rho=1.593 \tag{26}$$

Gaussian:

$$f(x)=(\sigma/\pi)^{1/2}\exp(-\sigma x^2),\quad \sigma=0.700 \tag{27}$$

Flat and exponential:

$$f(x)=c,\quad |x|\leq x_0,\quad c=0.45$$
$$f(x)=c\ \exp(-\alpha|x|),\ |x|>x_0,\ \alpha=1.636 \tag{28}$$

and Flat and Gaussian:

$$f(x)=c,\quad |x|\leq x_0,\quad c=0.45$$
$$f(x)=c\exp(-\beta x^2),\ |x|>x_0,\ \beta=2.103 \tag{29}$$

where x is the distance in millimeters measured from the center of the nozzle inlet, and $x_0=0.5$ mm. is the radius of the inlet. The distribution is illustrated in Fig. 9. It is seen that the density is practically zero outside the nozzle, though the localization is somewhat poorer than that of Karles' nozzle estimated in their paper[24].

The distribution function being assumed, the damping of the molecular intensity (a contribution of a particular atomic pair whose equilibrium distance is r) caused by the spreading of the sample is calculated by the following integration:

$$M=\int_{-\infty}^{\infty}M(s)f(x)\mathrm{d}x=\int_{-\infty}^{\infty}(\text{const.})\times\exp\left(-\frac{l^2}{2}s^2\right)\frac{\sin sr}{sr}f(x)\mathrm{d}x \tag{30}$$

where s is a function of the camera length L, which is the sum of L_0+x, L_0 being the camera length referred to the nozzle center. This may be expressed as:

$$s(x)=\frac{2\pi R}{\lambda}\frac{1}{(L_0+x)}\left[1-\frac{3}{8}\frac{R^2}{(L_0+x)^2}\right]$$
$$=\frac{2\pi R}{\lambda L_0}\left(1-\frac{3R^2}{8L_0^2}\right)\left(1-\gamma\frac{x}{L_0}\right) \tag{31}$$
$$=s_0\left(1-\gamma\frac{x}{L_0}\right)$$

$$\gamma=1-\frac{3R^2}{4L_0^2}\sim 1-7\times10^{-5}s_0^2 \tag{32}$$

where R is the radius on the photographic plate. Substituting Eq. 31 into 30 and remembering that $f(x)$ is assumed to be a symmetrical function of x, Eq. 30 is transformed into Eq. 33 giving the damping of the molecular intensity:

$$M/M_0=\int_{-\infty}^{\infty}f(x)\cos\alpha x\mathrm{d}x,\ \alpha=\gamma s_0 r/L_0 \tag{33}$$

where $M_0(s_0)$ refers to L_0 (the molecular intensity scattered by a point source).

TABLE VII. CORRECTION AND ESTIMATION OF ERRORS IN THE MEAN AMPLITUDES

		C-H_{av}	C-C_{av}	C-H_{av}	C-C	C-C_{trans}

Standard error (A)		0.004	0.003	0.005	0.007	0.007

cor: corrected; est: estimated; neg: negligible

a) The meaning of the symbol $<\pm$ is that the sign may be positive or negative, but that the absolute value should not exceed the given figure.

b) The uncertainties involved in the corrections a and d are estimated to be $\pm70\%$ of the correction values.

On calculating the damping function (Eq. 33) analytically using Eq. 26 through 29 for $f(x)$*, it was found that all assumed distributions give nearly the same result, and it can be expressed in a good approximation in the form

$$M/M_0=\exp(-\varepsilon s^2) \tag{34}$$

An apparent increase in the mean amplitude is accordingly given by

$$(l+\Delta l)^2=l^2+2\varepsilon, \quad \Delta l\sim\varepsilon/l \tag{35}$$

The percentage correction for each interatomic distance is given in Table VII. It should be noted that the parameter ε is a function of r, and that the correction is greater for the longer distance, and for the harder distance (i.e., the distance which has a smaller mean amplitude), as already pointed out[24,44].

b) Effect of multiple or extraneous scattering.—This effect was considered to be negligible in view of the following argument.

1) No appreciable extraneous scattering was found to be present, as stated in the experiment part.

2) Care was taken in the experiment to reduce the sample pressure during the exposure[25]; the flow rate was sufficiently "slow" in the sense discussed by Harvey et at.[44] to avoid the multiple scattering.

3) The observed background line agrees well with the theoretical form, showing no appreciable multiple scattering present (Fig. 7).

4) The index of resolution is nearly unity, which affords another point of support.

5) It was shown by Karle[24] theoretically that even if a considerable amount of multiple scattering were present, it would raise the background uniformly and decrease the molecular intensity also in a uniform manner. Consequently it does not change the damping factor of the molecular term significantly.

c) Uncertainty in the density-intensity calibration curve. — This effect may be estimated in the following way. Suppose the calibration function $E(D)$, in which E and D denote the intensity and density, respectively, is obtained experimentally instead of the true function $E^0(D)$ which is unknown. Since the functions E^0 and E are both uniform functions of D, their ratio may be expanded as

$$E(D)/E^0(D)=c(1+\alpha D+\beta D^2+\cdots\cdots) \tag{36}$$

If the maximum or the minimum point of the intensity curve and the background intensity of the same point are denoted by E_1 and E_2 respectively, and the densities which correspond to E_1 and E_2 on the $D-E$ curve by D_1 and D_2, the fractional error R in the molecular intensity obtained from Eq. 1 is given by

$$\begin{aligned} R&=\left\{\frac{E_1^0(1+\alpha D_1+\beta D_1^2)}{E_2^0(1+\alpha D_2+\beta D_2^2)}-1\right\}\Big/\left\{\frac{E_1^0}{E_2^0}-1\right\} \\ &=1+\frac{E_1^0}{E_1^0-E_2^0}\{\alpha(D_1-D_2) \\ &\quad+(2\beta-\alpha^2)D_2(D_1-D_2)\} \end{aligned} \tag{37}$$

Since D is nearly proportional to E,

$$R\sim1+\alpha D_1+(2\beta-\alpha^2)D_1D_2 \tag{38}$$

On the other hand, the experimental measure of the uncertainty in the $D-E$ curve may be estimated 1) by the variance of the slope of the observed background lines, and 2) by the difference between the $D-E$ curve obtained by Karles' method and that obtained by Bartell's method using the same density curves.

It was found that the magnitude of the parameters α or β is about ±0.05. Since the maximum density in this experiment was about 0.8, the upper limit of the error in the molecular intensity was estimated to be 10%. Possible error in the mean amplitude caused by this effect is accordingly estimated for each distance by fitting roughly to an exponential function, and listed in Table VII.

d) Failure of Born approximation. — It is well known that the theoretical expression 4 for the scattering of electrons by molecules is derived by Born approximation, which is not always justified[39]. The failure of Born approximation was first pointed out by Schomaker and Glauber[45,46], and discussed by Hoerni and Ibers[47]. The effect on the mean amplitude, an apparent increase, was discussed by Bartell and

* For example, the use of Eq. 26 gives

$$M/M_0=\rho^2/(\alpha^2+\rho^2)$$

and the use of Eq. 27 gives

$$M/M_0=\exp[-\alpha^2/(4\sigma)]$$

The latter formula corresponds to Eq. 13 of Karles' paper[24]. More strictly, the upper limit of the integral 30 should be the cut-off point, λ, shown in Fig. 8, which is a function of s. A detailed calculation shows, however, that the molecular term assumes an additional factor and a phase shift which are both of a negligible order of magnitude.

45) V. Schomaker and R. Glauber, *Nature*, **170**, 291 (1952).
46) R. Glauber and V. Schomaker, *Phys. Rev.*, **89**, 667 (1953).
47) J. A. Hoerni and J. A. Ibers, ibid., **91**, 1182 (1953).

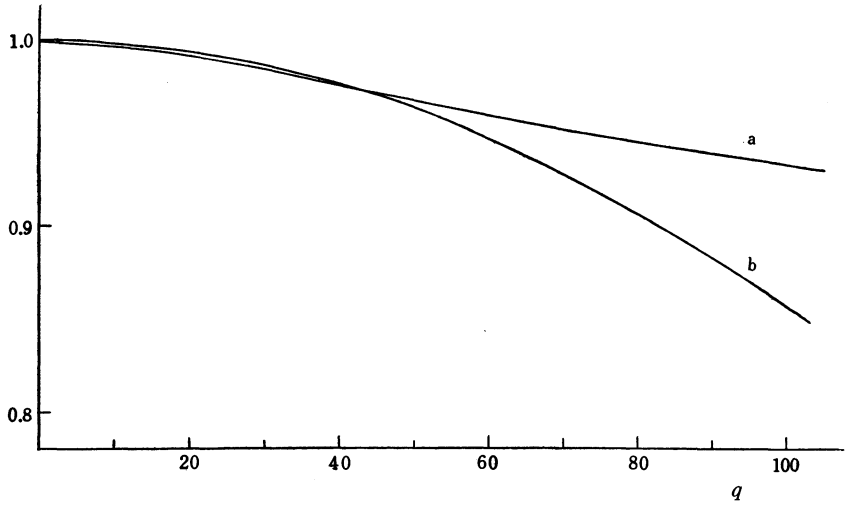

Fig. 10. Approximation of the phase shift $\cos \Delta\eta$ by an exponential function. a) $\cos \Delta\eta$ for the C-H pair; and b) $\exp(-\delta s^2/2)$ where $\delta=3.096\times10^{-4}$. The deviation is about 7% at $q=100$.

Brockway[48,34]. In the following a similar correction for this effect is carried out.

The expression is given by

$$sM(s)=\sum_{i,j}{}'(c_{ij}/r_{ij})\exp\left(-\frac{l_{ij}^2}{2}s^2\right)\times\cos\Delta\eta_{ij}\sin sr_{ij} \quad (39)$$

$$\Delta\eta_{ij}=\eta_i(s)-\eta_j(s) \quad (40)$$

The C-H pairs are the only objects to be considered for this molecule, since the phase shift $\Delta\eta$ appears only for a pair of different atoms. The phase function $\eta(s)$ was calculated and tabulated by Ibers and Hoerni[49]. Since the values are based on the Thomas-Fermi model, they may naturally be a poor approximation for carbon and hydrogen. According to their argument[49], however, the phase shift $\Delta\eta$ is probably reliable, and in addition, the magnitude of η for hydrogen is very small. The Eq. 13 of their paper is available to convert the values to η for the accellerating voltage used in this experiment.

The damping function $\cos\Delta\eta_{C-H}$ was approximated by an exponential form, as discussed by Bartell,

$$\cos\Delta\eta_{C-H}(s)\sim\exp(-\delta s^2/2) \quad (41)$$

the value δ being derived numerically in the following average, taking the damping function (including the artificial temperature factor) as a weight $w(s)$

$$\int w(s)\,[\cos\Delta\eta-\exp(-\delta s^2/2)]\,ds=0 \quad (42)$$

$$w(s)=\exp\left(-\frac{l^2_{C-H}}{2}s^2\right)\exp(-bs^2) \quad (43)$$

The value thus obtained is

$$\delta=3.096\times10^{-4}\ \text{Å}^2 \text{ for bonded C-H,}$$

and $\delta'=3.431\times10^{-4}$ Å^2 for non-bonded C-H.

The maximum deviations of the exponential functions from the cosine functions were about 7% (Fig. 10). These deviations were further corrected by introducing a δM-function in a way similar to that discussed in the case of non-nuclear scattering[34],

$$\delta M(s)=M_{C-H}(s)\{1-\cos\Delta\eta/\exp(-\delta s^2/2)\}+M'_{C-H}(s)\{1-\cos\Delta\eta/\exp(-\delta' s^2/2)\} \quad (44)$$

The order of magnitude of this function is less than 1% of the molecular intensity, and therefore it barely contributes to the RD curve.

The percentage correction for this effect to the mean amplitude is given in Table VII.

e) Effect of the possible difference in the distances between non-equivalent bonds. — It should be noted that the C-H, C-H (non-bonded), and C-C distances observed are the average values of the two respective non-eqivalent distances, i.e., C-H (methyl) and C-H (methylene), and C-C (end) C-C (central). Should these distances differ slightly, as may be the case, observed mean amplitudes will show apparent increase.

This effect is readily treated as follows. Suppose there are two Gaussian peaks 1 and 2 (peak positions r_1 and r_2, and peak

48) L. S. Bartell and L. O. Brockway, *Nature*, 171, 978 (1953).
49) J. A. Ibers and J. A. Hoerni, *Acta Cryst.*, 7, 405 (1954).

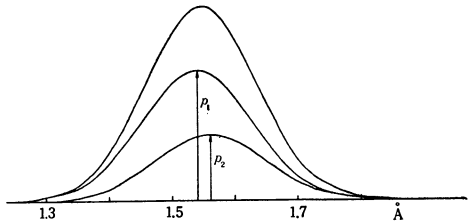

Fig. 11. A composite peak of non-equivalent C-C distances. The peak is slightly broader than each of the component peaks.

heights p_1 and p_2, respectively) close together (Fig. 11). Their mean amplitudes are assumed to be the same, l. The composite peak will then be given by

$$P=p_1\exp\{-H(r-r_1)^2\}+p_2\exp\{-H(r-r_2)^2\} \quad (45)$$
$$H=(2l^2+4b)^{-1}$$

If the origin of the distance r is chosen at the center of gravity, the composite peak is expresed as

$$P=\exp(-Hr^2)\,[\sum P_i\exp(2Hr_ir)] \quad (46)$$
$$P_i=p_i\exp(-Hr_i^2), \qquad i=1,2 \quad (47)$$

The term in the bracket being expanded,

$$\sum_{1,2} P_i\exp(2Hr_ir) = (P_1+P_2)+2H^2rp_1r_1(r_1^2-r_2^2) + 2H^2r^2(P_1r_1^2+P_2r_2^2) \quad (48)$$

The second term is about a small percentage of the third term and does not affect the width. Therefore, the peak is expressed as a Gaussian function to a good approximation:

$$P=(P_1+P_2)\exp(-H'r^2) \quad (49)$$

where

$$H'=H-2H^2(P_1r_1^2+P_2r_2^2)/(P_1+P_2) \quad (50)$$

The coefficient H is related to l in Eq. 45, so that the apparent increase in l is calculated by Eq. 50.

The splittings of the distances are definitely too small to be detected in this experiment; the only available references seem to be the splitting of the C-H distances in ethyl chloride estimated in the microwave spectroscopy[50],

C-H(methyl) = 1.110Å

C-H(methylene) = 1.101Å

and the plausible values predicted by Glockler from the consideration of bond-energy data[51],

C-H(methyl) = 1.097Å

C-H(methylene) = 1.0985Å

C-C(end) = 1.559Å

C-C(central) = 1.564Å (in *n*-butane)

The maximum possible percentage apparent increases listed in Table VII are calculated by inserting in Eq. 50 the value:

r_1-r_2(C-H bonded) = 0.01Å

r_1-r_2(C-H non-bonded) = 0.02Å

and r_1-r_2(C-C bonded) = 0.02Å

It is seen that this effcet is possibly negligible.

f) The effect of perpendicular amplitude and of anharmonicity. — The probability distribution function of an interatomic distance including both parallel and perpendicular amplitudes was derived by Morino and Hirota[52]

$$P(r)=(h/\pi)^{1/2}\exp(-hx^2)\times(1+c_1x+c_3x^3+\cdots\cdots) \quad (51)$$

where

$$h=1/2<\Delta z^2>, \qquad x=r-r_e$$

and

$$c_1=(h/r_e)\,[<\Delta x^2>+<\Delta y^2>-6h(<\Delta z\Delta x>^2+<\Delta z\Delta y>^2)] \quad (52)$$
$$c_3=(4h^3/r_e)\,[<\Delta z\Delta x>^2+<\Delta z\Delta y>^2] \quad (53)$$

On the other hand, the following $P(r)$-function including anharmonic vibration was given by Bartell[41] and by Reitan[53].

$$P_{anh}(r)=(h/\pi)^{1/2}\exp(-hx^2)\times(1+a_1x+a_2x^2+a_3x^3+\cdots\cdots) \quad (54)$$

Since these effects introduce only slight modifications on the Gaussian distribution, the combined effect may be written in the first approximation,

$$P(x)=(h/\pi)^{1/2}\exp(-hx^2)(1+c_1x+c_3x^3)\times(1+a_1x+a_2x^2+a_3x^3) \quad (55)$$
$$=(h/\pi)^{1/2}\exp(-hx^2)\times(1+\alpha x+\beta x^2+\gamma x^3+\cdots\cdots) \quad (14)$$

The mean square amplitude for this distribution is readily calculated as

$$l^2(0)=<\Delta z^2>+\left(2\beta-\frac{3}{2}\alpha^2\right)(<\Delta z^2>)^2 \quad (56)$$

$l^2(0)$ can be obtained from $l^2(f)$ by the equation,

50) R. S. Wagner and B. P. Dailey, *J. Chem. Phys.*, **23**, 1355 (1955).
51) G. Glockler, ibid., **17**, 747 (1949).
52) Y. Morino and E. Hirota, ibid., **23**, 737 (1955).
53) A. Reitan, *Acta Chem. Scand.*, **12**, 131, 785 (1958).

$$l^2(0)=l^2(f)-2b+\left[\frac{1}{2}\alpha^2+\frac{3\alpha}{2r_e}-3\alpha\beta r_e+4\beta+4\beta^2 r_e^2-\frac{1}{r_e^2}\right]l^4+\cdots\cdots \quad (57)$$

It is to be noted that a minor fractional correction is of the order of $l^2/2r_e^2$, which is less than 0.5%. Thus the effect of anharmonicity or the perpendicular amplitude are regarded as negligible, at least in obtaining the mean amplitude defined in Eq. 56.

Care should be taken, however, in the comparison of the amplitudes observed in this way with that calculated from the vibrational data. For the influence of anharmonicity on the mean amplitudes, interesting discussions were made by Reitan[53]. According to his calculation, apparent mean amplitudes of O-H and H-H bonds in water molecule based on the harmonic approximation are about 5% smaller than those which include the anharmonic effect. For heavier molecules such as Br_2, the correction was shown to be negligible.

g) Effect of series termination. — The MRD function was computed by use of Eq. 2 taking the upper limit of the integral as q_{max} instead of infinity. According to Waser and Schomaker[54], an exponential damping function $\exp(-bs^2)$ was adopted in the present analysis for the modification of the RD, the factor b being chosen following the usual convention that $\exp(-bs_{max}^2)=0.1$.

Since the intensity curve multiplied by the damping factor is given by a sum of the contribution of the component terms,

$$sM(s)=\sum_n sM_n(s)=\sum_n (c_n/r_n)\times\exp(-s^2/4H_n)\sin sr_n \quad (58)$$

the Fourier inversion is also expressed as a sum,

$$f(r)=\sum_n\int_0^\infty sM_n(s)\sin sr\,ds-\sum_n\int_{s_{max}}^\infty sM_n(s)\sin sr\,ds=f_0(r)-f'(r) \quad (59)$$

The RD function actually obtained is the sum of $f_0(r)$, the true RD function, and $-f'(r)$, additional ripples. Taking out the n-th contribution to $f'(r)$, and using Eq. 58, $f'_n(r)$ is given by

$$f'_n(r)=(c_n/2r_n)\left\{\int_{s_{max}}^\infty \cos s(r_n-r)\times\exp(-s^2/4H_n)ds-\int_{s_{max}}^\infty \cos s(r_n+r)\exp(-s^2/4H_n)ds\right\} \quad (60)$$

where the second term is usually negligible. At the center of the RD peak, i.e., $r=r_n$, the function $f'_n(r)$ has its maximum value, which is expressed in terms of the error integral, $\Phi(s_{max}/\sqrt{2H_n})$. Elsewhere, $f'_n(r)$ reveals itself as a ripple of the period of slightly less than $2\pi/s_{max}$. It is obviously symmetrical across the center of the peak and damps slowly as $|r-r_n|$ increases.

In the present example, $s_{max}=10\pi$, $H_n\sim 66$ for the C-C bond which has the smallest damping factor, and $H_n\sim 50-30$ for the other bonds. By the evaluation of the error integral, it was found that the maximum magnitude of f'_n is about 0.6% of the peak height for the C-C peak, and less than 0.1% for the others. The effect is thus unquestionable except for the C-C peak, and even in that case, it causes a slight symmetrical distortion of the C-C peak itself and an apparent increase of about 0.7% in its mean amplitude. A shift of the distance r_g of the adjacent peaks due to this effect amounts to only a few ten thousandth of an angstrom.

A similar, but more extensive discussion was carried out by Morimoto in his recent RD analysis of evaporated crystallites[55]. The result is in agreement with the estimation described above.

B. Random Errors.—The main origins of experimental random errors are 1) errors introduced in the photographic process (exposure, development, etc.), 2) errors of the microphotometry, 3) errors of the measurement of the photometer curve, and 4) errors introduced in the failure of drawing a proper background line, etc.

These errors are included in the molecular intensity and, being Fourier inverted, reveal themselves as random fluctuations or "ghosts" in the RD curve, which cause errors in the measurement of mean amplitudes.

The following features may be used as the measures of these fluctuations.

1) Fluctuations of the baseline in the regions where no interatomic distance should exist: as shown previously, there are no appreciable fluctuations in the baseline from 0 through 0.7Å (Fig. 3). Beyond 2.8Å of the RD curve, however, there

54) J. Waser and V. Schomaker, *Revs. Modern Phys.*, **25**, 671 (1953).

55) H. Morimoto, *J. Phys. Soc. Japan*, **13**, 1015 (1958).

appear small fluctuations, which probably come from the experimental errors together with the computational errors.

2) Difference among RD curves illustrated in Fig. 2, obtained by the independent procedure: the maximum deviation amounts to a small percentage of the peak height.

3) The standard errors given in the least-square analysis of the mean RD curve (Eq. 12): they were found to be about 1% of the mean amplitudes.

4) Deviations of the areas of the RD peaks from the theoretical values: the ratios listed in Table IV show that the deviations amount to a small percentage.

In order to estimate the random errors in the mean amplitudes, it seems possible to make use of one of the following methods:

1) Use of the variance in the results of the least-square analysis of the individual RD curves, which may correspond to the "mean square deviation between classes",

2) Use of the square sum of the residuals in the process 1, which may correspond to the "mean square deviation within classes",

3) Use of the difference among the RD curves to estimate the standard error at each point of the peak.

Each method was used in the present estimation together with Eqs. 11 and 12. Errors introduced in the computational process were also taken into account. Important ones among them would be 1) errors in the computation (rounding-up errors, etc.), 2) improper assumptions used in the analysis (structure, scattering factors, etc.), 3) ambiguity in the decomposition of the composite peak, and 4) improper correction for various systematic errors. A plausible estimation was made utilizing the experience in the self-consistent analysis described above. As for the effect 4, the corrections for systematic errors were considered to include ±70% uncertainties.

The results of the estimation of random errors are listed in Table VII. In the last row of the table are listed the mean amplitudes for which suitable corrections have been made, with their total standard errors which include all errors estimated in the above consideration.

Calculation of the Mean Amplitudes

In order to correlate the observed mean amplitudes to be spectroscopic data, a calculation of the mean amplitudes was carried out. Because of the lack of knowledge of the force constants, a simple and approximate treatment was made.

First the skeleton vibrations were considered by assuming a methyl or a methylene group as a particle for the *trans* and the *gauche* forms. The Wilson's G and F matrices for the *trans* form given as follows[56,58].

$$\begin{array}{lll} & \text{G} & \text{F} \\ \text{A}: & \begin{bmatrix} 2\mu_0 & & \\ 2\mu_0\cos\varphi & \mu_0+\mu & \\ -\sqrt{2}\rho_0\mu_0\sin\varphi & -2\rho_1\mu_0\sin\varphi & \rho_0^2(\mu_0+\mu)+4\mu_0(\rho_1^2-\cos\varphi) \end{bmatrix} & \begin{bmatrix} K_0+2a_0F & & \\ \sqrt{2}cF & K_1+a_1F & \\ \sqrt{2}\rho_1d_0F & \rho_0d_1F & H+bF \end{bmatrix} \\ \text{B}: & \begin{bmatrix} \mu_0+\mu & \\ 0 & \rho_0^2(\mu_0+\mu) \end{bmatrix} & \begin{bmatrix} K_1+a_1F & \\ \rho_0d_1F & H+bF \end{bmatrix} \end{array} \quad (61)$$

TABLE VIII. COMPARISON OF THE NORMAL FREQUENCIES FOR THE TRANS FORM

		Skeleton vibration	Observed (cm^{-1})			Calculated (cm^{-1})	
			a	b	c	A set	B set

TABLE IX. CALCULATED VALUES FOR THE MEAN AMPLITUDES (skeleton) (in Å unit)

Atomic pair	Observed (UMRD)	Calculated			
		trans Form		*gauche* Form	
		A set	B set	A set	B set
C-C (CH_2-CH_2)	$0.052_6\pm0.003$	0.048_7	0.049_8	0.049_1	0.049_9
C-C (CH_2-CH_3)		0.051_6	0.048_9	0.051_3	0.049_0
C-C (nonbonded)	$0.077_6\pm0.007$	0.069_2	0.079_4	0.068_2	0.078_2
C-C (*gauche*)	0.136	—	—	0.161_1	0.169_1
C-C (*trans*)	$0.067_7\pm0.007$	0.070_4	0.079_2	—	—

where the symbols have their usual meaning[57,59]. Two different sets of Urey-Bradly force constants were taken. One set A is that given by Shimanouchi[60], which was selected to the fit to Raman spectra of *n*-butane,

$K_0=4.0$, $K_1=3.2$, $H=0.11$, $F=0.96$ and $F'=0$

The other set B is that reported as the force constants of methyl and methylene groups[59], and taken by Hayashi in his calculation of the normal vibration of *n*-pentane molecule as a five-body problem[61].

$$K_0=3.7,\quad K_1=4.0,\quad H=0.20,\quad F=0.33$$
$$\text{and } F'=-0.1F$$

These force constants being inserted in Eq. 61, it is an easy and straightforward computation to obtain the normal frequencies[56,57] and the mean amplitudes[62,63]. A comparison of the frequencies for the *trans* form is given in Table VIII. The assignment of the skeleton frequencies was made by several authors[11,15,60,64], and there seems to be no difficulty except in the lowest B_u (bending) mode*. Although the band 215.0 cm^{-1} observed in the far infrared spectra was assigned to this mode by Gates, and no other band was found between 400 and 170 cm^{-1}, it seems likely that this mode has a little higher frequency. The agreemment of the calculated frequencies with the observed is much better for the A-set. Accordingly, the mean amplitudes calculated with the A-set may be the more reliable.

For the mean amplitudes of the *gauche* form the barrier against the torsional motion was assumed to be 3.6 kcal./mol.[14] An approximate method[63] was applied. These results are shown in Table IX. The larger amplitude obtained for the *gauche* C–C distance as compared with the *trans* C–C is just as expected.

For the mean amplitudes of the distances including hydrogen atoms, methyl groups were approximated by chlorine atoms, that is, the mean amplitudes of the H–H and C–H atom pairs in 1,2-dichloroethane were calculated, be cause the L matrices for this molecule calculated by Nakagawa[65] were available. Although this approximation apparently seems drastic, past experience on the calculation of mean amplitudes assures that it will give sufficiently correct values for this purpose[63]. The results obtained are listed in Table X. The mean amplitude of the C–C distance agrees with the previous values given in Table IX.

TABLE X. COMPARISON OF THE OBSERVED AND CALCULATED MEAN AMPLITUDES (FOR PAIRS INCLUDING HYDROGEN) (in Å unit)

Pairs	Observed	Calculated
(C-C)	$0.052_6\pm0.003$	0.050_3
C-H	$0.083_1\pm0.004$	0.078_3
C-H (nonbonded)	$0.097_5\pm0.005$	0.109_7
H-H (nonbonded)	—	0.126_8
H-H (*trans*)	—	0.128_2
H-H (*gauche*)	—	0.156_8

The comparison of the calculated amplitudes with the observed values is given in Table IX and X. The agreement is satisfactory, taking account of the experimental error, and of the uncertainty in the theoretical values (possibly a small

percentage), caused by the approximate nature of the calculation, the uncertainty in the force constants, and the neglect of anharmonicity in the vibration.

Analysis of the Intensity in the Small-angle Region

The intensity curve in a small-q region was analyzed for the purpose of obtaining further information on the rotational isomerism. The detail of the method was described in a previous paper[19,66].

Diffraction photographs were taken at the longer camera length through an r^2-sector with a multiple-layer stopper of the same type as that used by Bastiansen[23]. The density measured was converted into the intensity by Karles' procedure[26]. Independent observations gave good agreement with one another.

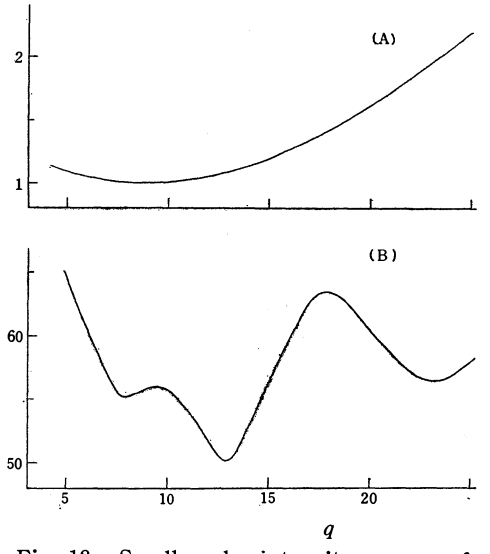

Fig. 12. Small-angle intensity curve of *n*-butane. (A) $f(q)$ curve; and (B) $f(q)I(q)$ curve.

The intensity $I(q)$ was multiplied by a smooth function $f(q)$ (Fig. 12) to make the background line nearly flat, where

$$f(q)=1+0.0054(q-9)^2+3\times10^{-6}(q-9)^4 \quad (62)$$

A background function $I_b(q)$ was calculated by the following equation,

$$I_b(q)=f(q)I(q)/(1+cM(q)_{\mathrm{calc}}) \quad (63)$$

where $M(q)_{\mathrm{calc}}$ is the theoretical molecular intensity divided by q, and c is the index of resolution[34,44]. A criterion that I_b should be a smooth function of q can be used to select a reasonable model[19].

The frame structure and the mean amplitudes determined by the analysis described on pages 750~757 was used to compute the theoretical molecular intensity, together with the same assumption discussed in *procedure* of that section. Two parameters of the rotational isomerism, the *gauche* azimuthal angle ϕ and the fraction of the *trans* form n_t, were varied systematically. The index of resolution was estimated to be 0.90±0.10.

It was found that when n_t was assumed to be less than 30% or more than 70%, the I_b functions (Fig. 13) showed such large fluctuations irrespective of the choice of angle ϕ, that the existence of both rotational isomers was definitely confirmed. It gives an independent support to the conclusion of the RD analysis.

For the estimation of the parameters and their limits, the maximum possible ripples caused by experimental errors or by theoretical uncertainties were regarded as about 1% of the I_b function*. The result of the analysis is

$$\phi=65°\pm10°, \text{ and } n_t=65\sim35\%$$

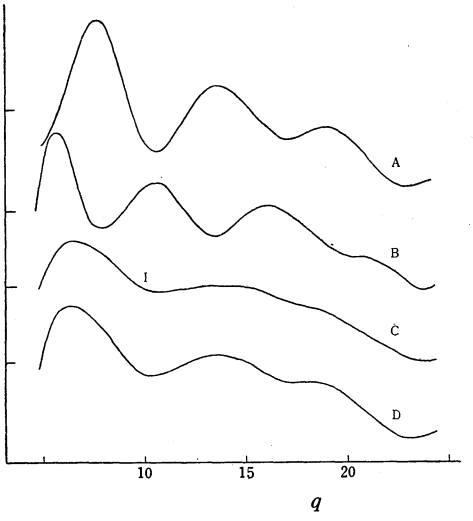

Fig. 13. I_b functions of *n*-butane for models (A) *trans* 100%; (B) *gauche* ($\phi=65°$) 100%; (C) a mixture of *trans* and *gauche* ($\phi=65°$) in 1:1; and (D) a mixture of *trans* and *gauche* ($\phi=50°$) in 1:1. The index of resolution is 0.90. The curve C is in the acceptable region. The vertical line denotes the amplitude of a one per cent fluctuation of the I_b curve.

66) K. Kuchitsu, This Bulletin, **30** 391, 399 (1957).

* This estimation was based on a similar argument given in the previous paper on *n*-propyl chloride (Ref. 19), but a larger value should be taken for the uncertainty in this case, since the contribution of the internal rotation is less (being about 20% of the total intensity), and the uncertainty of the assumptions is more serious (particularly for the position of the hydrogen atoms).

TABLE XI. COMPARISON OF THE STRUCTURES OF RELATED MOLECULES

Molecule	Ethane			Propane	Butane

which is consistent with the result on pages 750~757 within the limit of uncertainty.

Discussion

The C–H and C–C distances were obtained with accuracies of better than 0.01Å (Table VI). These distances are the average values of two non-equivalent distances, but they may not differ more than 0.01Å. It is seen that the values are close to the "normal" bond lengths[67] accepted generally: C–H=1.09Å, and C–C=1.54Å. This result therefore gives some support for these standard values.

The average C–C–H angle was found to be slightly larger than the tetrahedral angle. The structures of methyl groups have been obtained by means of microwave spectroscopy for a number of simple molecules[68]; the angles C–C–H differ slightly from one molecule to another around the tetrahedral angle.

The structural data for normal paraffins comparable with the present result are those for ethane and propane (Table XI). The spectroscopic value r_0 is slightly different from $r_g(0)$ (probably about 0.01Å or less), and the values given by electron diffration may be $r_g(1)$, although not stated explicitly. The general agreement shows that there may be no conspicuous difference between the structures of these hydrocarbons.

It was confirmed that the angle C–C–C is definitely larger than tetrahedral (112°9′). A similar but not so accurate result was obtained in propane (111.5°±3.5°)[7]. It is interesting to note that a similar fact was known for higher normal paraffin crystals studied by the X-ray diffraction; it was first noticed by Bunn[69], and confirmed in a recent study of Shearer and Vand[70], who found that ∠C–C–C=112°1′± 21′ for $C_{36}H_{74}$. This fact is consistent with the earlier theoretical prediction of Ingold[71] based on organic reactions.

As for the rotational isomerism, it was definitely confirmed that there are two isomers, the *trans* and the *gauche* forms, in the gaseous phase. The fractions of these forms were found to be about 60% for the *trans* form and about 40% for the *gauche* form. Since the complete assignment of the vibrational frequencies is not available at present, the partition functions can not be calculated. If the ratio of the functions is assumed to be unity, (the statistical weight for the *gauche* form being 2), then the energy difference between the two forms is about 650 cal./mol., the *trans* form being the more stable. This value is close to that of liquid *n*-butane[11,12], as expected. The azimuthal angle of the *gauche* form was found to be slightly larger than 60°. The effect of hindered internal rotation around the *trans* position was observed in the shift of the *trans* C–C distance. An evaluation of the barrier height gave a rough but reasonable order of magnitude for this value.

A precise measurement of the structure of *n*-butane has been made by Bartell[72]. His result is in satisfactory agreement with the present result, except slight discrepancies in atomic distances (less than 0.7%) which may be partly due to uncertainties in the scale factor.

Summary

The molecular structure of *n*-butane has been investigated by means of the sector-microphotometer method of electron diffraction. The least-square analysis of the radial distribution curve has been carried out both for modified and unmodified curves giving the internuclear

distances as well as their mean amplitudes and the bond angles. The estimation of experimental standard errors has been made by examining various sources of errors. Important results are the following:

a) The average distance of the C–C bonds is 1.539±0.003Å.

b) The angle C–C–C is 112°9′±9′, is considerably greater than the tetrahedral angle.

c) The position of hydrogen atoms is located with considerable accuracy; C–H =1.100±0.003Å and ∠C–C–H=110°22′±15′.

d) The mean amplitudes measured are in agreement with the calculated values within the limit of error.

e) The existence of rotational isomers, the *trans* and the *gauche* forms, are confirmed. The structure and the fraction of the isomers are determined. The result is consistent with the spectroscopic results.

The author wishes to express his sincere gratitude to Professor Yonezo Morino for his kind guidance and encouragement throughout this work. He is also indebted to Mr. H. SHORT COMMUNICATIONS

Far Infrared Spectrum of Gaseous Formic Acid

By Kozo HIROTA and Yasuo NAKAI

(Received April 20, 1959)

Since the first report of Bonner and Kirby-Smith[1] on a Raman line of formic acid, low frequency vibrations of the acid have not been studied till recently. However, it is interesting to investigate the vibrational bands in relation to the anomalous band features of OH groups due to hydrogen bonding found in both near infrared and infrared regions[2]. Sato and Nagakura explained their results by the motion of the proton in the double minimum potential. Oshida, Ooshika and Miyasaka[3] also explained these phenomena theoretically by the same model, and predicted appearance of new bands in the far infrared region. However, though Pitzer et al.[4] observed two bands of gaseous formic acid at 237 cm^{-1} and 160 cm^{-1}, they ascribed[5] them to the intermolecular vibrations between the two monomers making up formic acid dimer by hydrogen bonding.

In the course of studies[6] on chemisorption of gaseous formic acid HCOOH to the silver surface, the present authors also found two bands independently[7]. In connection to this measurement they extended their research over the region 85~300 cm^{-1} not only on formic acid HCOOH but also on formic acid-d HCOOD, and found some new knowledge, the essential point of

which will be reported.

Formic acid of chemically pure grade (Edogawa Kagaku Kogyo Co.) was repeatedly vacuum-distillated, crystallized, and dehydrated with unhydrous copper sulfate. Formic acid-d was prepared by the reaction of sodium formate, whose degree of purity was the same as formic acid, with sulfuric acid-d D_2SO_4 (36%). Method of purification was the same as described on formic acid. It was confirmed that formic acid-d thus obtained does not include H_2O and HCOOH so much as can be detected by use of the NMR method (Apparatus: Varian V 4300 B).

The spectrometer made by Yoshinaga et al.[8], Engineering Faculty of Osaka University, was used. During the measurement, the apparatus was kept constant at 21°C, while the pressure of the acid in the measuring cell was about 30 mmHg. Gratings, light sources, reststrahlen filter and width of slits were changed according to the spectrum range as shown in Table I.

TABLE I

Wave number (cm^{-1})	Light source	Reststrahlen filter	Slit width (mm.)
300～190	Pt-source	NaCl	0.36
190～155	Hg lamp	NaCl	0.50
160～130	〃	KCl	0.47
140～105	〃	KBr	0.68
110～ 85	〃	KBr	1.30

The experimental results are shown in Figs. 1 and 2 and in Table II, where the data of Pitzer[4] and Simova[9] are compared for the sake of discussion. However, Simova's values seem to be of less confidence, because they were estimated from the combination bands of a Raman line.

b) L. M. Sverklow, *Izv. AN. USSR*, 17, 567 (1953).

The important point obtained from the present data is as follows. Strong bands are observed at 240 cm^{-1} and 155 cm^{-1} in both acids, but it is noteworthy that their feature differs markedly; i.e., (a) in case of HCOOH the 240 cm^{-1} band is broad and begins at 278 cm^{-1}, making a sharp contrast with the beginning at ca. 258 cm^{-1} in case of HCOOD, and (b) small bands can be detected at ca. 270 cm^{-1} and 175 cm^{-1} as shoulders of the 240 cm^{-1} and 155 cm^{-1} bands, respectively, in case of HCOOH. These shoulders become conspicuous if the pressure of formic acid is increased to ca. 40 mmHg as shown in Fig. 1. The second point to be mentioned is appearance of sharp bands at 202 cm^{-1} and 126 cm^{-1} in case of HCOOD. Besides, a new band is observed at ca. 110 cm^{-1} in both acids. Their nature, however, will not be discussed in the present note*),

9) P. Simova, *Izv. Bulgar. Akad. Nauk. Otdel. Fiz. Mat. i Tekh., ser. Fiz.*, 2, 107 (1951).

*) Their frequency is too high if they are the lowest infrared active band predicted by Miyazawa and Pitzer.

except to mention that a Raman line has been observed in the neighborhood of this band (110 cm^{-1}).

The strong and broad bands at 240 cm^{-1} and 155 cm^{-1} seem to correspond to those at 238 cm^{-1} and 160 cm^{-1} observed by Pitzer et al. and can be assigned to the bands produced by the intermolecular vibration between the two monomers making up formic acid dimer as already done by Miyazawa and Pitzer. They may be two higher frequency bands of the three infrared active ones which are expected from the symmetry of the dimer (C_{2h}). It is necessary, therefore, to introduce another cause in order to explain the appearance of two bands of the similar form at 270 cm^{-1} and 175 cm^{-1} in case of HCOOH. Taking the fact into consideration that the ratio of their wave number to that of the sharp bands at 202 cm^{-1} and 126 cm^{-1} in case of HCOOD nearly equals $\sqrt{2}$, respectively, it may presumably be reasonable to assign them to the bands due to the motion of the proton in the double minimum potential, as proposed several years ago[2,3,10].

In conclusion, the present authors express their sincere thanks to Professor H. Yoshinaga and the members of his laboratory (Dr. S. Fujita, Dr. Y. Yamada and Dr. A. Mitsuishi) without whose assistance the present research could not be carried out, and they are much indebted to Professor S. Nagakura of the University of Tokyo and also to Associate Professor S. Seki of Osaka University for helpful discussion of the problem here considered.

Poly-p-halostyrenes. I. Preparation of Crystalline Poly-p-chlorostyrene

Kazuo NAGAI, Masamichi KOBAYASHI and Eiichi NAGAI

(Received May 12, 1959)

Recently Natta et al. reported[1] that while some substituted polystyrenes prepared by Ziegler catalyst were crystalline, others were amorphous. To the contrary of Natta et al.'s results that poly-*p*-chlorostyrene is not crystalline, we find that a small part of poly-*p*-chlorostyrene prepared by Ziegler catalyst is crystalline.

p-Chlorostyrene (4.4 g.) prepared by an usual method[2], enclosed in a glass tube with $Al(C_2H_5)_3$ (0.53 g.), $TiCl_4$ (0.18 g.) and *n*-heptane (20 cc.) is polymerized at 70°C

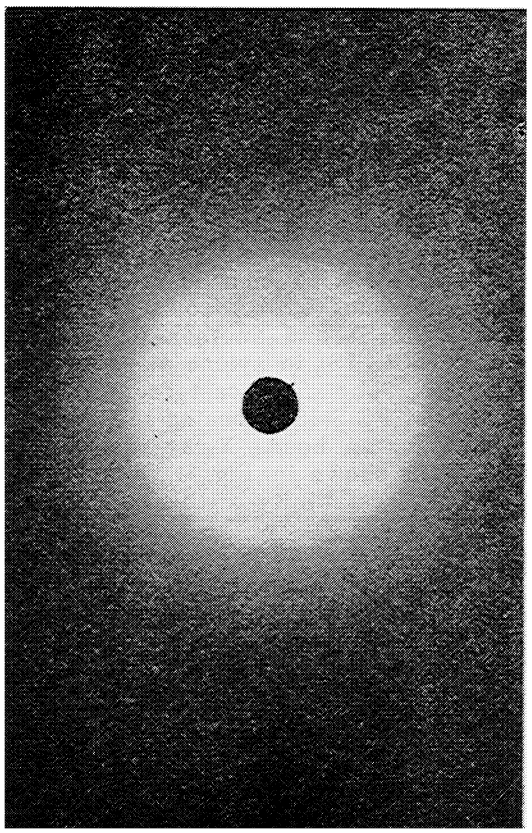

Fig. 1. X-ray diagram of poly-*p*-chlorostyrene (PClS-IS)

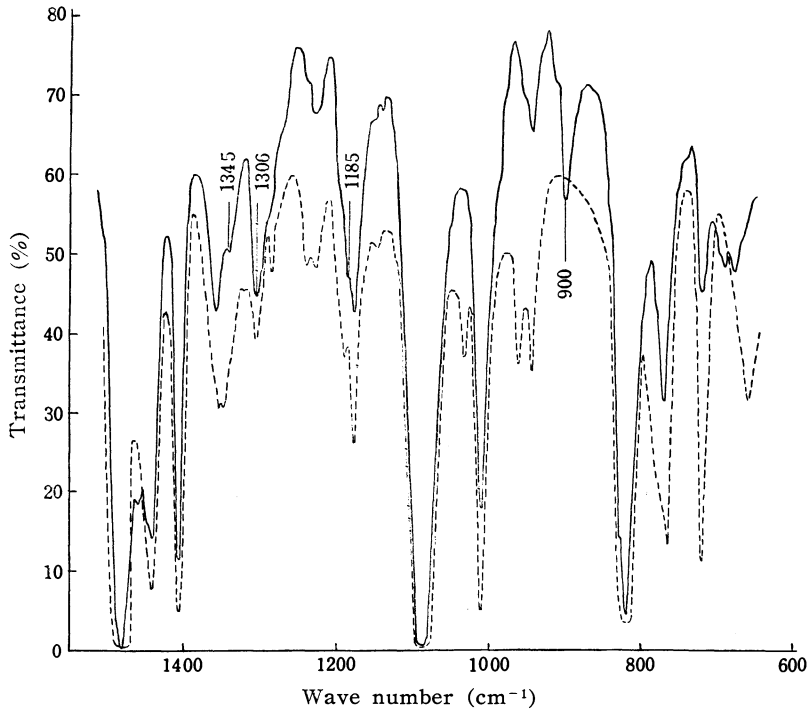

Fig. 2.

for about 10 hr. The product washed by hot ethanol and then boiled in water is dissolved in boiling xylene and the solution is filtered to separate from titanium oxide. By centrifuging this solution kept at room temperature the polymer is devided into two parts; one (2.20 g.) soluble (refered as to PClS-S) and another (0.13 g.) insoluble (PClS-IS) in xylene at room temperature. The film cast from toluene solution of PClS-IS is heated in silicon oil at 160°C for an hour. X-ray diagram of this film is shown in Fig. 1, manifesting moderate crystallinity of this sample.

In Fig. 2 are shown the infrared spectroscopic data of PClS-IS (full line) and radically polymerized poly-*p*-chlorostyrene (PClS-At) (dashed line), both previously heated at 160°C for an hour. It is expected that in the crystalline region and in the amorphous region, so far as the short portion of the polymer chain is concerned, the skeletal chain of PClS-IS has a helical structure, although whether 3-fold helix as in the case of polystyrene is still kept or not is not obvious, owing to the steric effects of chlorine atoms. Recently Tadokoro et al.[3,4] showed that the absorption bands ascribed to deformation vibrations of CH_2 and CH groups of the skeletal carbon chain, and to C–C stretching vibration were affected by the configurations of the skeletal chain, and bands at 1364, 1314, 1297 and 1185 cm^{-1} of isotactic polystyrene and *p*-deuterostyrene were assumed to be characteristic to 3-fold helical structure. Moreover, in our investigations on the infrared spectroscopy of the crystalline poly-*p*-fluorostyrene, we found[5] the bands at 1330 and 1302 cm^{-1} as to be charasteristic to the helical structure of the skeletal chain. From these results, the bands 1345, 1306 and 1185 cm^{-1} of PClS-IS are assumed to be characteristic to the helical structure. A band at 900 cm^{-1} probably corresponds to crystallization sensitive band. The spectroscopic data of PClS-S are almost similar to those of PClS-At. Investigations are in progress on the bands appearing at near 700 cm^{-1} and longer wavelength region.

We thank Mr. S. Kuribayashi for his preparation of X-ray diagram.

On the Magnetic Susceptibility of Hexabenzocoronene and Triphenylene

By Hideo Akamatu
and Minoru Kinoshita

(Received May 15, 1959)

Hexabenzocoronene is an extremely stable, pale yellow hydrocarbon. Clar and Ironside suggested that it contains exclusively benzenoid rings interlinked by quasi-single bonds[1]. Afterwards, however, they found an asymmetric effect of the electronic interaction between benzenoid rings, and proposed a formula of hexabenzocoronene consisting of a triphenylene complex and 4 benzenoid rings[2]. Magnetic susceptibility of hexabenzocoronene would be interesting for these points of view, as the effect of the aromatic conjugation should reflect on its value. We measured the magnetic susceptibility of hexabenzocoronene and triphenylene; the samples were provided by C. T. Ironside and M. Zander, respectively.

The purification of the specimens was made by sublimation in vacuo at about 490°C for hexabenzocoronene, and at about 120°C for triphenylene. The magnetic measurement was made by the Gouy method at room temperature. The observed values are as follows. Hexabenzocoronene (M.W. 522.6, density 1.57[3]) :

$-\chi_g \times 10^6 = 0.662 \pm 0.002$ per gram,

$-\chi_M \times 10^6 = 346.0$ per mole.

Triphenylene (M.W. 228.3, density 1.30).

$-\chi_g \times 10^6 = 0.686 \pm 0.001$ per gram,

$-\chi_M \times 10^6 = 156.6$ per mole.

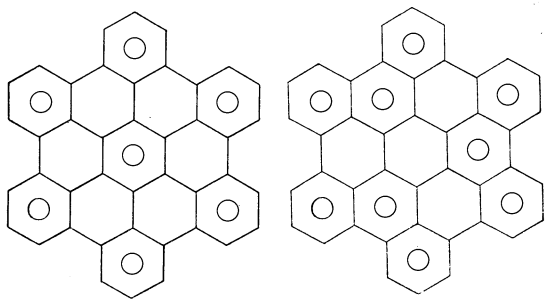
The magnetic susceptibilities of related compounds are as follows.

Phenanthrene :

$-\chi_g \times 10^6 = 0.718$; $-\chi_M \times 10^6 = 127.9$

Benzene :

$-\chi_g \times 10^6 = 0.712$; $-\chi_M \times 10^6 = 55.6$



Atomic susceptibility of hydrogen ;

$-\chi_M(\mathrm{H}) \times 10^6 = 2.93$

Hexabenzocoronene can be presumed as being made of seven benzenoid rings interlinked by quasi-single bonds (Formula 1), or consisting of triphenylene and four benzenoid rings. The expected value of each formula will be respectively,

$$-\chi_M \times 10^6 = 7\chi_M(\text{Benzene}) - 24\chi_M(\text{H}) = 318.9$$

$$-\chi_M \times 10^6 = \chi_M(\text{Triphenylene}) + 4\chi_M(\text{Benzene}) - 18\chi_M(\text{H}) = 326.3$$

Formula (1) Formula (2)

Fig. 1. Hexabenzocoronene

The observed value is higher than those of anticipated formulae. The other formula which is conceivable consists of three phenanthrene rings connected by contact bonds (Formula 2). This leads to the expected value as,

$$-\chi_M \times 10^6 = 3\chi_M(\text{Phenanthrene}) - 12\chi_M(\text{H}) = 348.5 \; ; \quad -\chi_g \times 10^6 = 0.667$$

This value is very near to the observed one. It is likely that a small effect of the electronic interaction takes place between benzenoid rings, its amount is in the same order as the aromatic conjugation in phenanthrene molecule.

The mean susceptibility of triphenylene was measured by Honda and Ōuchi[4]. Their observed value is $\chi_g = -0.685 \times 10^{-6}$, which is in good agreement with the present result. From the observed susceptibility and using the empirical formula[5], the principal diamagnetic susceptibilities of triphenylene molecule can be estimated as $K_1 = -95.6 \times 10^{-6}$ and $K_3 = -278.6 \times 10^{-6}$, where K_1 is in the plane of molecule and K_3 is perpendicular to it. This leads to the diamagnetic anisotropy of $\Delta K = -183.0 \times 10^{-6}$. This value is 3.4 times of the diamagnetic anisotropy of benzene, ΔK (Benzene) $= -54 \times 10^{-6}$. The molecular

orbital calculation[6], however, gave 4.08 for this ratio, which is too large compared with the above value.

Our estimated values of the principal diamagnetic susceptibility are likely to be reasonable from the following reason. Triphenylene crystal is orthorhombic, and its principal susceptibilities along the crystal axes were measured by Banerjee and Guha[7]. Their observed values are $\chi_a = -150.1 \times 10^{-6}$, $\chi_b = -149.5 \times 10^{-6}$ and $\chi_c = -174.2 \times 10^{-6}$. Using these values combined with the above values for K_1 and K_3, we can estimate the orientation of the molecule to the crystal axes. The procedure has been given by Lonsdale and Krishnan[8]. This gives the result that the plane of molecule makes the angle of 50°20′ to the *ab*-plane. This value is in good agreement with the observed angle, 50°30′, by Klug[9] who made the X-ray crystal analysis of triphenylene.

The authors wish to express their thanks to Dr. E. Clar and his school who provided them with the samples of hexabenzocoronene and triphenylene.

Added in Proof:

E. Clar proposed* the other possible formula for hexabenzocoronene, after we had made our communication. He suggested that the induced sextet in the center ring of triphenylene may rotate or oscillate through the ring system of hexabenzocoronene, as if the Formulae 1 and 2 are overlapping with each other. In this case, the induced sextet in triphenylene (the center ring) has magnetic susceptibility of

$$\chi_M(\text{Triphenylene}) - 3[\chi_M(\text{Benzene}) - 2\chi_M(\text{H})] = -7.4 \times 10^{-6}$$

Three times this value (-22.2×10^{-6}) added to the value for Formula 1, it leads to -341.1×10^{-6} which is near to the observed value.

Isodelphinine, a New Alkaloid from Aconitum miyabei, Nakai

By Nobukatsu KATSUI

(Received May 26, 1959)

Recently a third new alkaloid, sachaconitine, and a fourth probably new alkaloid (I)[1], base D, having the same empirical formula, $C_{33}H_{45}O_9N$, as that of delphinine (II)[2] but different m.p. and $[\alpha]_D$, were isolated from Aconitum *miyabei*, Nakai. As described below, I has the same empirical formula and the same functional groups as II, but differs distinctly from II as shown by the mixed m. p. and infrared spectra. Thus the name isodelphinine was assigned to I. This substance, m. p. 167~168°C, $[\alpha]_D^{20}$ + 20.1°, gave a perchlorate, m. p. 171~172°C, $[\alpha]_D^{20}$ −2.38°. (*Anal.* Found: C, 56.35; H, 4.97; Cl, 4.87. Calcd. for $C_{33}H_{45}O_9N \cdot HClO_4$: C, 56.55; H, 5.19; Cl, 5.06%). The aurichloride crystallized from chloroform-ethanol in prisms, m. p. 228~229°C. (*Anal.* Found: Au, 20.96. Calcd. for $C_{33}H_{45}O_9N \cdot HAuCl_4$: Au, 20.94%). Other salts of I, for example, acid oxalate or hydrochloride, did not crystallize although the corresponding salts of II had been obtained[3] as crystals.

On acetylation with acetyl chloride I gave a monoacetate, m.p. 188~190°C. (*Anal.* Found: C, 65.43; H, 6.81. Calcd. for $C_{35}H_{47}O_{10}N$: C, 65.55; H, 6.76%). Saponification of I gave benzoic acid which was identified with an authentic sample, and acetic acid which was confirmed as silver salt. (*Anal.* Found: Ag, 64.49. Calcd. for $C_2H_3O_2Ag$: Ag, 64.67%). The presence of four methoxyl groups was determined by the micro-Zeizel determination. (*Anal.* Found: OCH_3, 20.11. Calcd. for $C_{29}H_{33}O_5N \cdot 4(OCH_3)$: OCH_3, 20.63%). In the Herzig-Meyer *N*-alkyl determination, I gave methyl iodide which was confirmed as tetramethylammonium iodide. (*Anal.* Found: I, 67.46. Calcd. for $(CH_3)_4 \cdot NI$: I, 67.86%).

Above evidences show that the formula of I may be extended as follows in the same way as that of II:

1) H. Suginome, N. Katsui and G. Hasegawa, This Bulletin, **32**, 604 (1959).
2) R. H. F. Manske and H. L. Holmes, "The Alkaloids", Vol. IV, Academic Press Inc., New York (1954), p. 275.
3) T. Walz, *Arch. Pharm.*, **260**, 9 (1922); W. A. Jacobs and L. C. Craig, *J. Biol. Chem.*, **127**, 301 (1939).

$$C_{19}H_{21}\begin{cases}(OCH_3)_4\\OH\\OCOCH_3\\OCOC_6H_5\\N\text{-}CH_3\end{cases}$$

The infrared spectra of I and II were quite similar except for the region due to ester carbonyl groups : compound I showed two bands at 1720 cm^{-1} and 1702 cm^{-1}, whilst II one band[4] at 1720 cm^{-1}.

On the basis of the same extended formula and the resemblant spectra, it may be reasonable to consider that I possesses a skeletal formula closely related to that of II. Furthermore, the same ring structure has been suggested for several alkaloids[5] of two genera, Aconitum and Delphinium, in which oxygen atoms are similarly located although the substituents are different. And then it may be considered that the substituents of I and II are also similarly located. On the other hand, it is well known[6] that the benzoyl group in II covers a secondary hydroxyl group which is vicinal to a free *tert* hydroxyl group.

If above consideration is correct, a simple explanation of the difference in infrared spectra of I and II may be that the free hydroxyl and the benzoyl group have *trans* orientation in II against *cis* in I.

In the *cis* orientation, an ester carbonyl band displacement[7] to lower frequencies due to hydrogen bonding is considerable. An experiment to clarify the relation of I and II is in progress and will be reported in a later paper.

The author is grateful to Professor Harusada Suginome, President of Hokkaido University, for his unfailing kindness in encouraging this work, and to Dr. S.W. Pelletier for his courtesy in sending the sample of delphinine.

Visible Absorption Spectra of Colored Solutions Produced by Adding Alkali to Nitro-, Dinitro-, and Trinitro-substituted Benzenes in Acetone

By Takehiro Abe

(Received May 28, 1959)

In the course of my visible absorption studies on the color reactions of polynitrobenzenes with alkali, it has been found that nitrobenzene, *o*-, *m*-, and *p*-dinitrobenzene, and 1,3,5-trinitrobenzene, all in acetone give intense absorption bands at the visible region when they are treated with a few drops of dilute aqueous solution of sodium hydroxide at room temperature, as shown in Fig. 1. Dinitrobenzenes slowly yield reddish-violet colors. Trinitrobenzene at once gives a red color, while a red color can be observed by standing the nitrobenzene solution containing sodium hydroxide (in a brown desiccator to avoid light) for a long time. These red colors show the maximum

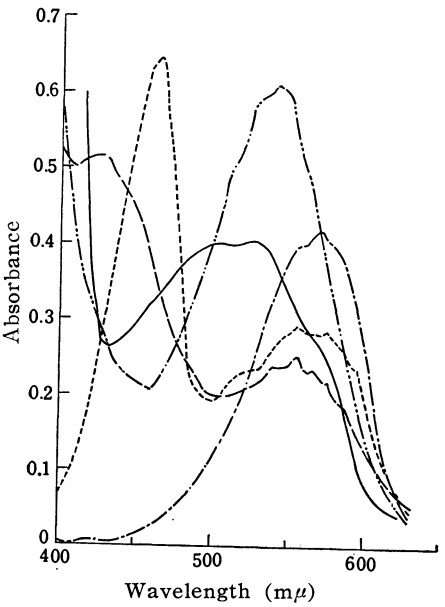

Fig. 1. Absorption spectra of the colored solutions produced by adding a few drops of dilute sodium hydroxide solution to nitrobenzene (——), *o*-dinitrobenzene(—·—), *m*-dinitrobenzene (—··—), *p*-dinitrobenzene (—···—), and 1,3,5-trinitrobenzene (----), in acetone at room temperature.

absorption bands at longer wavelengths as compared with the maximum absorption bands observed for the solutions that are obtained by adding sodium hydroxide into aqueous solutions of polynitrobenzenes[1]. There is no simple relation between numbers of nitro group and the positions of the absorption maxima, although the aromatic nitro compounds show the absorption bands at longer wavelengths in the aqueous solutions of sodium hydroxide as the number of nitro group increases[1].

The absorption curve of the red-colored solution produced by treating trinitrobenzene in acetone with sodium hydroxide solution, giving the intense maximum absorption band at about 460 mμ and several bands at 510~590 mμ, is greatly different from that of the red complex of trinitrobenzene with ammonium hydroxide[2]. Fig. 2 shows the absorption curves of the red solutions produced by adding a few drops of dilute sodium hydroxide solution, of dilute calcium hydroxide solution, or of concentrated ammonia water into the acetone solutions of 1,3,5-trinitrobenzene. It may be known from Fig. 2 that the absorption curves of the colored solutions produced by treating with strong alkalies (sodium hydroxide and calcium hydroxide) is different from that of the red solution obtained by addition of a weak alkali (ammonia). The maximum absorption band of the red complex of trinitrobenzene with ammonium hydroxide lies at the longer wavelength in acetone than in ethanol and in water[2].

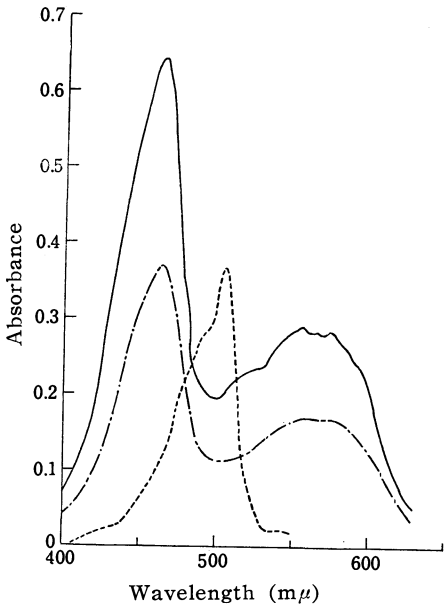

Fig. 2. Absorption spectra of the colored solutions produced by adding a few drops of dilute sodium hydroxide solution (——), of dilute calcium hydroxide solution (—·—), and of concentrated ammonia water (----) to 1,3,5-trinitrobenzene in acetone at room temperature.

Although weak alkali and strong alkali give different absorption curves, all the above red colors seems possibly to be owing to formation of the same transition complexes of Meisenheimer's type as the intermediates presented for the color reactions of trinitrobenzenes and dinitrobenzens with alkalies[1-8].

The author is particularly indebted to Professor Y. Nomura for his suggestion and encouragement through this work.

*On the Mechanism of Oxidation by Cuprous Chloride, Pyridine and Air. I. The Properties of the Reaction**

By Keizō KINOSHITA

(Received September 30, 1958)

It was previously reported that by aerial oxidation catalyzed by cuprous chloride in a pyridine solution, benzoin was primarily converted into benzil, which was further oxidized to benzoic acid almost quantitatively[1]. In this reaction, "oxidant A", a product of aerial oxidation of cuprous chloride pyridine complex, is considered to be the actual oxidant[2]. On the other hand, with cupric chloride as a catalyst, no benzoic acid is obtained, although benzoin is converted into benzil almost quantitatively[1].

$$\underset{\text{Benzoin}}{C_6H_5CHOHCOC_6H_5} \xrightarrow[\text{Air}]{Cu_2Cl_2+\text{Pyridine}} 2C_6H_5COOH \quad (1)$$

$$C_6H_5CHOHCOC_6H_5 \xrightarrow[\text{Air}]{CuCl_2+\text{Pyridine}} \underset{\text{Benzil}}{C_6H_5COCOC_6H_5} \quad (2)$$

Terent'ev et al.[3] reported that by aerial oxidation catalyzed by cuprous chloride in a pyridine solution, aromatic amines were converted into the corresponding azo compounds, but that with cupric chloride as a catalyst, these azo compounds were never obtained.

$$2C_6H_5NH_2 \xrightarrow[\text{Air}]{Cu_2Cl_2+\text{Pyridine}} C_6H_5N=NC_6H_5 \quad (3)$$

This paper describes the properties of these reactions.

Experimental

Materials.—Benzil was prepared by oxidation of benzoin with nitric acid, and recrystallized from alcohol, m.p. 94~95°C[4]. Aniline (b.p. 184~185°C) was redistilled immediately before use. Cuprous chloride was prepared by reduction of cupric chloride with sodium sulfite[5], washed with acetone and dried.

(1) Aerial Oxidation of Aniline Catalyzed by Cuprous Chloride in a Pyridine Solution.—A mixture of aniline (2.0 g., 2.2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.) and pyridine (50 cc.) was stirred in a stream of air for 5 hr. at room temperature. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). After removal of the ether, the residue was extracted with light petroleum (b.p. 40~60°C), and chromatographed on activated alumina (Wako Pure Chemical Industries, Ltd.). Azobenzene (1.2 g., 60%) was obtained; m.p. 67~68°C. (Lit. 68°C). It was identified with azobenzene by a mixed melting point determination and an analysis.

Anal. Found: C, 79.27; H, 5.57; N, 15.36. Calcd. for $C_{12}H_{10}N_2$: C, 79.12; H, 5.49; N, 15.38%.

(2) Oxidation of Aniline in the Absence of Air.—Cuprous chloride (8.0 g., 4/100 mol.) in pyridine (100 cc.) was oxidized with air for 3 hr. at room temperature. A mixture of aniline (2.0 g., 2.2/100 mol.) and "oxidant A" thus prepared, was stirred for 5 hr. at room temperature in a stream of nitrogen. The resulting mixture was acidified with 6N-H_2SO_4 and extracted with ether. White precipitate remained. From the ether solution, azobenzene (0.5 g.) was obtained as in Experiment 1; m.p. 67~68°C, its melting point was not depressed on admixing with an authentic sample. A trace of red substance remained on top of the activated alumina.

The color of the aqueous layer was at first pale blue, but after the solution was kept in air its color turned to darker blue. The white precipitate was dissoluble in an aqueous ammonia solution. The color of the ammonia solution kept in air turned to blue. These results suggest that cuprous chloride was produced during the oxidation of aniline.

(3) Attempted Aerial Oxidation of Aniline in the Presence of Acetic Acid.—A mixture of aniline (2.0 g., 2.2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.), acetic acid (1.8 g., 3/100 mol.) and pyridine (100 cc.) was treated as in Experiment 1. A trace of red substance remained on top of the activated alumina, and no other neutral substance was obtained. The color of the aqueous solution was blue.

(4) Reaction of Cupric Chloride Pyridine Complex with Potassium Hydroxide.—(a) Cupric chloride (3.4 g., 2/100 mol.) was refluxed in pyridine (50 cc.) until all the precipitate was turned into blue needles. Potassium hydroxide (1.1 g., 2/100 mol.) in methyl alcohol (50 cc.) was added dropwise under stirring to the cooled pyridine solution of cupric chloride pyridine

* The present work was presented partly at the Symposium on the Mechanism of Organic Chemical Reaction of the Chemical Society of Japan, held at Osaka in October, 1955, and partly at the similar symposium of the same society, held at Nagoya in October, 1957.

complex. The color of the resulting mixture was green.

(b) When potassium hydroxide (1.1 g., 2/100 mol.) in methyl alcohol (50 cc.) was added to the copper complex prepared in Experiment 4a, pale blue precipitate was formed from the green solution.

(5) Oxidation of Benzil with the Copper Complex Prepared in Experiment 4.—(a) A mixture of benzil (2.0 g., 1/100 mol.) and the copper complex prepared in Experiment 4a was stirred at 30°C for 2 hr. in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). The ethereal layer was extracted with aqueous sodium carbonate solution. After removal of the ether, the residue was benzil (0.7 g., 35%); this melted at 94~95°C alone or with an authentic sample of benzil. The aqueous layer was acidified by 6N-H_2SO_4 and extracted with ether. After removal of the ether, the residue was sublimed to give benzoic acid (1.4 g., 57%), m.p. 121~122°C; its melting point was not depressed on admixing with an authentic sample.

(b) A mixture of benzil (1.0 g., 1/200 mol.) and the copper complex prepared in Experiment 4b was treated as in Experiment 5a. Benzil (0.9 g., 90%) was recovered; m. p. 94~95°C, its melting point was not depressed with an authentic sample. No benzoic acid was obtained.

(c) When diethylamine (10 g., excess) was added to the copper complex prepared in Experiment 4a, the color of the solution did not change. A mixture of benzil (1.0 g., 1/200 mol.) and the resulting copper complex was treated as in Experiment 5a. Benzoic acid (1.1 g., 90%) was obtained; m. p. 121~122°C, its melting point was not depressed on admixing with an authentic sample. No benzil was recovered.

(d) When trimethylamine hydrochloride (3.9g., 3/100 mol.) was added to the copper complex prepared in Experiment 4a, blue needles appeared, and trimethylamine was separated. The mixture of benzil (1.0 g., 1/200 mol.) and the resulting copper complex was treated as in Experiment 5a. Benzil (0.9 g., 90%) was recovered; it melted at 94~95°C alone or with an authentic sample of benzil. No benzoic acid was obtained.

(6) Oxidation of Aniline in the Presence of Methyl Alcohol.—(a) A mixture of aniline (2.0 g., 2.2/100 mol.) and the copper complex described in Experiment 4a [prepared from $CuCl_2 \cdot 2H_2O$ (3.4 g.), KOH (1.1 g.), methyl alcohol (10 cc.) and pyridine (50 cc.)] was treated as in Experiment 1. Azobenzene (0.9 g., 45%) was obtained; it melted at 67~68°C alone or with an authentic sample of azobenzene.

(b) A mixture of aniline (2.0 g., 2.2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.), methyl alcohol (100 cc.) and pyridine (50 cc.) was treated as in Experiment 1. Azobenzene (0.1 g., 5%) was obtained; it melted at 67~68°C alone or with an authentic sample of azobenzene.

(7) Effect of Bases on "Oxidant A".—(a) Cuprous chloride (2.0 g., 1/100 mol.) in pyridine (50 cc.) was oxidized with air at room temperature for 2 hr.

(b) When potassium hydroxide (1.1 g., 2/100 mol.) in methyl alcohol (50 cc.) was added to the copper complex prepared in Experiment 7a, brown precipitate appeared. Its mixture with benzil (1.0 g., 1/200 mol.) was treated as in Experiment 5a. The same results as in Experiment 5b were obtained.

(c) When diethylamine (10 g., excess) was added to the copper complex prepared in Experiment 7a, no color change occurred. A mixture of benzil (1.0 g., 1/200 mol.) and the resulting copper complex, was treated as in Experiment 5a. The same results as in Experiment 5c were obtained.

(d) When trimethylamine hydrochloride (3.9 g., 3/100 mol.) was added to the copper complex prepared in Experiment 7a, blue needles were formed, and trimethylamine was separated. A mixture of benzil (1.0 g., 1/200 mol.) and the resulting copper complex, was treated as in Experiment 5a. The same results as in Experiment 5d were obtained.

Results and Discussion

By aerial oxidation catalyzed by "oxidant A", aniline is converted into azobenzene in a yield of about 60%. Through the treatment of aniline with "oxidant A" in the absence of air, azobenzene and cuprous chloride are obtained (Table I). These results suggest that "oxidant A" is the actual oxidant in the aerial oxidation of aniline catalyzed by cuprous chloride in a pyridine solution. Similar facts were found in the oxidative cleavage of benzil under the similar condition[2].

TABLE I. OXIDATION OF ANILINE BY CUPROUS CHLORIDE, PYRIDINE AND AIR

Catalyst	Cu_2Cl_2 in the catalyst g. (mol.)	Pyridine cc.	Azobenzene g. (%)
Oxidant A*	8.0 (4/100)	100	0.5**
Cu_2Cl_2	2.0 (2/200)	50	1.2 (60)
Oxidant A	1.0 (1/200)	50	1.2 (60)
Oxidant A	2.0 (2/200)	50	1.2 (60)
Oxidant A	3.0 (3/200)	80	1.2 (60)
Oxidant A	4.0 (4/200)	100	1.2 (60)

Aniline (2.0 g., 2.2/100 mol.) was treated.
* Nitrogen atomosphere.
** Cuprous chloride was obtained.

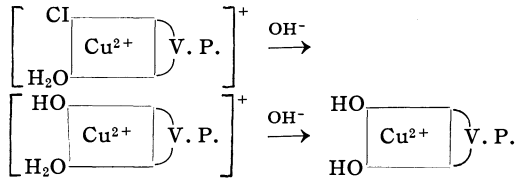
In the presence of an excess of acidic substance "oxidant A" has no longer its catalytic activity (Table II). The oxidation of benzil is stopped after a definite amount of benzil is oxidized[2], because the produced benzoic acid retards the reaction. On the other hand, "oxidant A" keeps its catalytic activity during the

aerial oxidation of aniline, because acidic substance is hardly produced in the reaction.

TABLE II. EFFECT OF ACIDIC SUBSTANCE

Cu_2Cl_2 g. (mol.)	Acidic substance g. (mol.)	Azobenzene g.
2.0 (1/100)	Acetic acid 1.8 (3/100)	0
2.0 (1/100)	Ammonium chloride 1.6 (3/100)	0
2.0 (1/100)	Trimethylamine hydrochloride* 3.9 (3/100)	0

Aniline (2.0 g., 2.2/100 mol.) was treated in pyridine (100 cc.).
* Trimethylamine was separated.



Another catalyst for benzil is obtained from reaction of cupric chloride pyridine complex with a methyl alcohol solution of potassium hydroxide — not with its aqueous solution. With a methyl alcohol solution of potassium hydroxide, cupric chloride pyridine complex—blue needles —turns to a greenish solution, as far as the molar ratio of cupric chloride to potassium hydroxide reaches 1 : 1.5. Benzil is oxidized to benzoic acid by aerial oxidation catalyzed by this greenish cupric complex—"oxidant B". The amount of oxidized benzil apparently increases in accordance with the amount of added potassium hydroxide (Table III).

TABLE III. OXIDATION OF BENZIL BY "OXIDANT B" AND AIR

$CuCl_2 \cdot 2H_2O$* g. (mol.)	KOH g. (mol.)	Benzoic acid g. (%	Sample (recovered) g. (%)
3.4 (2/100)	0	0	1.8 (90)
3.4 (2/100)	0.6 (1/100)	0.6 (25)	1.4 (70)
3.4 (2/100)	1.1 (2/100)	1.4 (58)	0.7 (35)
3.4 (2/100)	1.7 (3/100)	2.0 (82)	0.3 (15)

Benzil (2.0 g., 1/100 mol.) was treated.
* Cf. Experiment 4a.

The following change was postulated in the reaction of dichloro-(2-vinyl pyridine)-copper(II) with potassium hydroxide[6] (Reaction 4). It was reported that by reaction of an aqueous cupric salt pyridine complex solution with equimolar potassium hydroxide, a solution of hydroxy cupric salt pyridine complex ion [I] was produced[7] (Reaction 5). All this seems to lead to the conclusion that "oxidant B" is hydroxy cupric chloride pyridine complex.

(4)

$$2\,Cu^{2+} + 4\,Py + 2\,OH^- \rightleftarrows Py_2Cu(OH)_2CuPy_2^{2+} \quad [\mathbf{I}] \qquad (5)$$

(V. P.: Vinyl pyridine, Py: Pyridine).

By aerial oxidation catalyzed by "oxidant B", aniline is converted into azobenzene, although the yield of azobenzene is decreased in the presence of an excess of methyl alcohol. The aerial oxidation of aniline catalyzed by "oxidant A" is also retarded by an excess of methyl alcohol (Table IV).

TABLE IV. EFFECT OF METHYL ALCOHOL ON THE AERIAL OXIDATION OF ANILINE

Copper salt in the catalyst* g. (mol.)		KOH in the catalyst g. (mol.)	Methyl alcohol cc.	Azobenzene g. (%)
Cu_2Cl_2	2.0 (1/100)	0	100	0.1 (5)
$CuCl_2 \cdot 2H_2O$	3.4 (2/100)	0	20	0
	3.4 (2/100)	1.1 (2/100)	100	0
	3.4 (2/100)	1.1 (2/100)	20	0.3 (15)
	3.4 (2/100)	1.1 (2/100)	10	0.9 (45)

Aniline (2.0 g., 2.2/100 mol.) was treated.
* Pyridine (50 cc.) was used as a solvent.

When equimolar potassium hydroxide in methyl alcohol is added "oxidant A" or "oxidant B", these complexes are destroyed and their catalytic activity is lost. However, when "oxidant A" or "oxidant B" is treated with excessive diethylamine or benzylamine, they keep their color and their catalytic activity. Through the reaction between trimethylamine hydrochloride and "oxidant A" or "oxidant B", trimethylamine separates. The resulting complexes no longer have their catalytic activity. This fact suggests that "oxidant A" and "oxidant B" have stronger basicity than trimethylamine (Ref. 7).

All the phenomena described above suggest that there is a remarkable resemblance between "oxidant A" and "oxidant B".

Summary

(1) By aerial oxidation of aniline catalyzed by cuprous chloride in a pyridine solution, azobenzene of about 60% is

6) J. F. Pudivin et al., *J. Am. Chem. Soc.*, **78**, 2104 (1956).

*On the Mechanism of Oxidation by Cuprous Chloride, Pyridine and Air. II. The Mechanism of Formation of Azobenzene from Aniline**

By Keizō KINOSHITA

(Received September 30, 1958)

Terent'ev et al.[1] reported that when aerial oxidation of aniline was carried out in a pyridine solution catalyzed by cuprous chloride, azobenzene was obtained in a good yield. In Part I of this series, the details of this reaction were studied and it was considered that the actual oxidant of this oxidation was "oxidant A" obtained by aerial oxidation of cuprous chloride pyridine complex[2]. In this paper, the mechanism of this reaction is discussed.

Experimental

Materials.—Aniline (b. p. 184~185°C), *o*-toluidine (b. p. 199~200°C) and *o*-anisidine (b. p. 225°C) were redistilled immediately before use. Extra chemical pure grade *p*-toluidine (m. p. 44~45°C) and *p*-anisidine (m. p. 56~57°C) were used. Cuprous acetate pyridine complex was prepared as follows. When cupric acetate (3.8 g., 2/100 mol.) in pyridine (50 cc.) was refluxed for 2 hr., deep blue crystals were formed (cupric acetate pyridine complex). A mixture of metallic copper (0.5 g. excess) and the above pyridine solution of cupric acetate pyridine complex was stirred at 60°C in a stream of nitrogen until the color of the solution was turned to dark yellow.

(1) Attempted Aerial Oxidation of Aniline Catalyzed by the Copper Acetate Complexes.—(a) A mixture of aniline (2.0 g., 2.2/100 mol.) and the above-mentioned cuprous acetate pyridine complex in pyridine was stirred for 5 hr. at 30°C in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). After removal of the ether, a trace of residue was obtained. The residue was dissolved with light petroleum (b. p. 40~60°C) and chromatographed on activated alumina (Wako Pure Chemical Industries, Ltd.). All the substance remained on top of the activated alumina. No azobenzene was obtained. The color of the aqueous layer was blue.

(b) Potassium hydroxide (1.1 g., 2/100 mol.) in methyl alcohol (10 cc.) was added to a cupric acetate pyridine complex in pyridine (described in the preparation of cuprous acetate pyridine complex). A mixture of aniline (2.0g., 2.2/100 mol.) and the resulting copper complex was stirred at 80°C for 5 hr. in a stream of air. The resulting mixture was treated as in Experiment 1a. The same results as in Experiment 1a were obtained.

(2) Oxidation of Substituted Anilines.—(a) A mixture of *p*-toluidine (2.2 g., 2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.) and pyridine (50 cc.) was stirred for 5 hr. at room temperature in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). After removal of the ether, the residue was dissolved with benzene, and chromatographed on activated alumina. 4,4'azotoluene (2.0 g., 90%) was obtained; m. p. 142~143°C (Lit. 143°C). It was identified with 4,4'azotoluene by a mixed melting point determination and an analysis.

Anal. Found: C, 80.10; H, 6.92; N, 13.16.

* The present work was presented at the Symposium on the Mechanism of Organic Chemical Reaction of the Chemical Society of Japan, held at Nagoya in October, 1957.

Calcd. for $C_{14}H_{14}N_2$: C, 80.00; H, 6.66; N, 13.33%.

A trace of black substance remained on top of the activated alumina.

(b) A mixture of *p*-anisidine (2.5 g., 2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.) and pyridine (50 cc.) was treated as in Experiment 2a. 4,4'Azoanisol (2.2 g., 88%) was obtained; m. p. 162~163°C (Lit. 163°C). It was identified with 4,4'azoanisol by a mixed melting point determination and an analysis.

Anal. Found: C, 69.54; H, 5.96; N, 11.47. Calcd. for $C_{14}H_{14}O_2N_2$: C, 69.42; H, 5.78; N, 11.57%.

A trace of black substance remained on top of the activated alumina.

(c) A mixture of *o*-toluidine (2.2 g., 2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.) and pyridine (50 cc.) was treated as in Experiment 2a. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). After removal of the ether, the residue was distilled with steam; then a large amount of substance remained in the vessel. From the distillate 2,2'-azotoluene (0.3 g., 14%) was obtained; m. p. 54~55°C (Lit. 55°C). It was identified with 2,2'-azotoluene by a mixed melting point determination and an analysis.

Anal. Found: C, 79.93; H, 6.89; N, 13.19. Calcd. for $C_{14}H_{14}N_2$: C, 80.00; H, 6.66; N, 13.33%.

The aqueous layer was dark violet.

(d) A mixture of *o*-anisidine (2.5 g., 2/100 mol.), cuprous chloride (2.0 g., 1/100 mol.) and pyridine (50 cc.) was treated as in Experiment 2a. 2,2'-Azoanisol (0.4 g., 16%) was obtained; m. p. 153~154°C (Lit. 153°C). It was identified with 2,2'-azoanisol by a mixed melting point determination and an analysis.

Anal. Found: C, 69.41; H, 5.98; N, 11.44. Calcd. for $C_{14}H_{14}O_2N_2$: C, 69.42; H, 5.78; N, 11.57%.

A large amount of substance remained on the activated alumina. There were some substances which did not dissolve in ether. The color of the aqueous layer was dark violet.

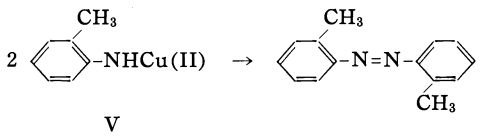
(3) Oxidation of Hydrazobenzene. — Cuprous chloride (2.0 g., 1/100 mol.) in pyridine (50 cc.) was oxidized with air for 2 hr. at room temperature. When hydrazobenzene (2.0 g., 1.1/100 mol.) was added to the resulting copper complex, the color of the solution was turned to yellow. The yellow solution was stirred for 1 hr. at room temperature in a stream of air. From the resulting mixture azobenzene (1.9 g., 95%) was obtained; melted at 67~68°C alone or with an authentic sample of azobenzene.

(4) Competitive Oxidation of Aniline and *p*-Anisidine.—A mixture of aniline (3.6 g., 4/100 mol.), *p*-anisidine (5.0 g., 4/100 ml.), cuprous chloride (1.0 g., 1/200 mol.) and pyridine (50 cc.) was stirred at room temperature in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4 and filtered. The residue was continuously extracted for 24 hr. with light petroleum (b. p. 40~60°C, 100 cc.). A trace of black substance remained. From the extract 4,4'azoanisol was separated; this melted at 163~164°C alone or with an authentic sample of 4,4'azoanisol. When the reaction was carried out for 30 min. and 60 min., the obtained 4,4'azoanisol amounted to 1.2 g. and 2.3 g. respectively, and the residues, after removal of the mother liquor, were 0.1 g. and 0.2 g., respectively.

Results and Discussion

Since it was reported that the chlorine ion in cupric chloride complexes was easily substituted[3], chlorine ion in "oxidant A" I may also be substituted by aniline or methyl alcohol (Reactions 1 and 2). On the other hand, acetate ion in cupric acetate complexes may not be substituted easily by the above compounds (Ref. 3).

$$\underset{}{C_6H_5NH_2} + \underset{}{Cu(II)\text{-}Cl} \rightleftarrows \underset{II}{[C_6H_5NH_2Cu(II)]^+Cl^-} \quad (1)$$
$$\quad\quad\quad



$$\underset{\text{II}}{[\text{Cu(II)-NH}_2\text{C}_6\text{H}_5]^+\text{Cl}^-} \rightarrow \underset{\text{I}}{\text{Cu(II)-Cl}} + \underset{\text{III}}{\text{NHC}_6\text{H}_5} \quad (3)$$

By aerial oxidation of an equimolar mixture of aniline and *p*-anisidine catalyzed by a small amount of cuprous chloride, 4,4'azoanisol is selectively obtained in the early stage of this reaction (Experiment 4). This result suggests that IV reacts with another IV to produce 4,4'azoanisol (Reaction 4), because the reaction between IV and free amines, may accompany 4-methoxy azobenzene with 4,4'azoanisol, even in the early stage of this reaction.

$$2\ \underset{\text{IV}}{(p\text{-})\text{CH}_3\text{OC}_6\text{H}_4\text{NH-Cu(II)}} \rightarrow (p\text{-})\text{CH}_3\text{OC}_6\text{H}_4\text{N=NC}_6\text{H}_4\text{OCH}_3(p\text{-}) \quad (4)$$

By aerial oxidation catalyzed by cuprous chloride in a pyridine solution, *p*-toluidine and *p*-anisidine are converted into the corresponding azo compounds almost quantitatively, while *o*-toluidine and *o*-anisidine are converted into the corresponding azo compounds only in a poor yield, although many other products are formed besides the azo compounds (Table II).

It was reported that the yield of azo compounds from substituted anilines were hardly affected at all by the position of the substituents in these amines, if these azo compounds were produced from the dimerisation of intermediate free radicals[5,6]. On the other hand, the steric hindrance of ortho substituent in V may interfere with the approach of two nitrogen atoms to decrease the yield of 2,2'-azotoluene,

V (5)

if 2,2'azotoluene is produced from a reaction of V with another V, (Reaction 5). The experimental results prove this to be valid.

Hydrazobenzene is converted into azobenzene almost quantitatively, by aerial oxidation catalyzed by "oxidant A" in a pyridine solution (Experiment 3). Accordingly, it is reasonable to assume that III is converted primarily into hydrazobenzene, which is further oxidized to azobenzene[5,6].

$$2\ \underset{\text{III}}{\text{C}_6\text{H}_5\text{NH-Cu(II)}} \rightarrow \text{C}_6\text{H}_5\text{NH-NHC}_6\text{H}_5 \rightarrow \text{C}_6\text{H}_5\text{N=NC}_6\text{H}_5 \quad (6)$$

In a pyridine solution, it was reported that cuprous salts and complexes increased in their stability[7]. Consequently, the activated complex may be as VI[8]. By the reaction of VI with another VI, hydrazobenzene and cuprous complex are produced. Hydrazobenzene is further oxidized to azobenzen (Reaction 7).

$$\underset{\text{III}}{\text{C}_6\text{H}_5\text{NH-Cu(II)}} \rightleftarrows \underset{\text{VI}}{[\text{Cu(I)-}\dot{\text{N}}\text{HC}_6\text{H}_5]}$$

$$2\ [\text{Cu(I)-}\dot{\text{N}}\text{HC}_6\text{H}_5] \rightarrow \text{C}_6\text{H}_5\text{NH-NHC}_6\text{H}_5 + 2\ \text{Cu(I)}$$

$$\text{C}_6\text{H}_5\text{NH-NHC}_6\text{H}_5 \rightarrow \text{C}_6\text{H}_5\text{N=NC}_6\text{H}_5 \quad (7)$$

TABLE II. OXIDATION OF SUBSTITUTED ANILINES

Amine g.(mol.)	Cu_2Cl_2 g.(mol.)	Time (hr.)	Azocompound g. (%)

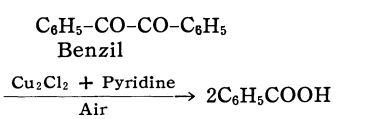
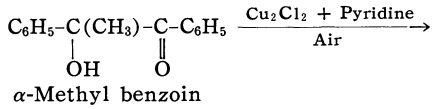
*On the Mechanism of Oxidation by Cuprous Chloride, Pyridine and Air. III. On the Mechanism of Oxidative Cleavage of Benzil, α-Methyl Benzoin and Hydrobenzoin**



By Keizō KINOSHITA

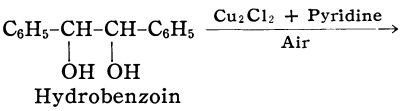
(Received September 30, 1958)

An earlier work reported that by aerial oxidation catalyzed by cuprous chloride in a pyridine solution, benzoin, benzil, α-methyl benzoin and hydrobenzoin were oxidized to break down as follows[1].



Benzoin

Benzil



(1)

α-Methyl benzoin

(2)

Hydrobenzoin

(3)

It was also discovered that in these reactions, the actual oxidant was " oxidant A " which was produced by aerial oxidation of cuprous chloride pyridine complex[2]. In this paper, the mechanism of oxidative cleavage of the above compounds is discussed.

Experimental

Materials.—Benzil was prepared by oxidation of benzoin with nitric acid, and recrystallized from alcohol, m.p. 94～95°C[4]. α-Methyl benzoin was prepared by reaction of benzil with methyl magnesium iodide, and recrystallized from ligroin (b.p. 80～100°C), m.p. 90～91°C[5]. Hydrobenzoin was prepared by reduction of benzoin with aluminum *iso*-propylate, and recrystallized from aqueous alcohol, m.p. 135～136°C[6].

(1) Preparation of Catalysts.—(a) " Oxidant A ": Cuprous chloride (4.0 g., 2/100 mol.) in pyridine (50 cc.) was oxidized with air for 2 hr. at room temperature.

(b) " Oxidant B ": Potassium hydroxide (2.2 g., 4/100 mol.) in methyl alcohol (50 cc.) was added with stirring to cupric chloride pyridine complex (prepared from $CuCl_2 \cdot 2H_2O$ (6.8 g., 4/100 mol.) and pyridine (50 cc.)).

(c) " Oxidant C ": Cuprous acetate pyridine complex[3] (prepared from $Cu(OAc)_2 \cdot H_2O$ (3.8 g., 2/100 mol.) and pyridine (50 cc.)), was oxidized with air for 2 hr. at room temperature.

(d) " Oxidant D ": Potassium hydroxide

* The present work was presented at the Symposium on the Mechanism of Organic Chemical Reaction of the Chemical Society of Japan, held at Sendai in October, 1956.

2) K. Kinoshita. ibid., **75**, 175 (1954).

3) K. Kinoshita, Part II of this series in This Bulletin, **32**, 780 (1952).

4) R. Adams, "Organic Synthesis", Vol. I, John Wiley & Sons, Inc., New York (1921), p. 25.

5) R. Nodzu et al., *J. Chem. Soc. Japan* (*Nippon Kagaku Kaishi*), **59**, 1237 (1938).

6) H. Lunde, *Ber.*, **70**, 1520 (1937).

(2.2 g., 4/100 mol.) in methyl alcohol (50 cc.) was added with stirring to cupric acetate pyridine complex (prepared from $Cu(OAc)_2 \cdot H_2O$, (7.6 g., 4/100 mol.) and pyridine (50 cc.)).

(2) Oxidation of Benzil.—(a) When methyl alcohol (50 cc.) was added to "oxidant A", the color of the solution turned to green. A mixture of benzil (2.0 g., 1/100 mol.) and the greenish solution was stirred at 30°C for 2 hr. in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). The ethereal layer was washed with water and extracted with aqueous sodium carbonate solution. After removal of the ether, a trace of the substance remained. The sodium carbonate solution was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). After removal of the ether, the residue was sublimed to give benzoic acid (2.1 g., 86%); it melted at 121~122°C alone or with an authentic sample of benzoic acid.

The same results were obtained with "oxidant C" or "oxidant D" in place of "oxidant A".

(b) When trimethylamine hydrochloride (7.8 g., 6/100 mol.) was added to "oxidant C or D", trimethylamine was separated, and dark blue needles appeared. The mixture of benzil (2.0 g., 1/100 mol.) and the resulting complex was treated as above. No benzoic acid was obtained. Benzil 1.8 g., 90%) was recovered; it melted at 94~95°C alone or with an authentic sample of benzil.

(3) Oxidation of Hydrobenzoin.—(a) A mixture of hydrobenzoin (2.0 g., 1/100 mol.), methyl alcohol (10 cc.) and "oxidant A" (prepared from Cu_2Cl_2 (2.0 g., 1/100 mol.)) was stirred at 30°C for 4 hr. in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). The ethereal layer was washed with water, and extracted with aqueous sodium carbonate solution. After removal of the ether, the residue was treated with aqueous sodium hydrogen sulfite solution. The mixture was filtered. The precipitate was washed with water and dried. Hydrobenzoin (1.3 g., 65%) was recovered; m.p. 135~136°C, its melting point was not depressed on admixing with an authentic sample. From the sodium hydrogen sulfite solution, benzaldehyde phenyl hydrazone (0.8 g., 20%) was obtained; m.p. 155~156°C (Lit. 156°C). It was identified with benzaldehyde phenyl hydrazone by a mixed melting point determination and an analysis.

Anal. Found: C, 79.36; H, 6.38; N, 14.32. Calcd. for $C_{13}H_{12}N_2$: C, 79.59; H, 6.12; N, 14.28%.

From the sodium carbonate solution, a trace of benzoic acid was obtained. It was identified by converting it into salicylic acid[7].

(b) A mixture of hydrobenzoin (2.0 g., 1/100 mol.) and "oxidant C or D" was stirred for 4 hr. in a stream of air. Although the oxidation was attempted at 30, 60 and 80°C, no oxidation products were obtained, and hydrobenzoin (1.8 g., 90%) was recovered; it melted at 135~136°C alone or with an authentic sample of hydrobenzoin.

(4) Reaction of Cupric Chloride with Hydrobenzoin in the Presence of Potassium Hydroxide. — When cupric chloride (1.7 g., 1/100 mol.) in methyl alcohol (20 cc.) was added to a mixture of hydrobenzoin (4.0 g., 2/100 mol.), potassium hydroxide (2.8 g., 5/100 mol.), pyridine (20 cc.) and methyl alcohol (20 cc.), a deep blue solution was formed. When ethylene glycol was used in place of hydrobenzoin, a similar result was obtained. But in the absence of such glycols, brown precipitate appeared. Even after this deep blue solution was kept for 24 hr. room temperature, cuprous oxide did not appear.

(5) Oxidation of α-Methyl Benzoin.—(a) A mixture of α-methyl benzoin (2.0 g., 0.8/100 mol.), "oxidant A" and methyl alcohol (50 cc.) was stirred at 30°C for 4 hr. in a stream of air. The resulting mixture was acidified with 6N-H_2SO_4, and extracted with ether (500 cc.). The ethereal layer was washed with water, and extracted with aqueous sodium carbonate solution. After removal of the ether, the residue was treated with aqueous semicarbazide hydrochloride and sodium acetate solution. The resulting mixture was filtered and washed with benzene. The residue was pure acetophenone semicarbazone (0.6 g., 40%); m. p. 197~198°C (Lit. 198°C). It was indentified with acetophenone semicarbazone by a mixed melting point determination and an analysis.

Anal. Found: C, 61.15; H, 6.52; N, 23.72. Calcd. for $C_9H_{11}ON_3$: C, 61.00; H, 6.25; N, 23.72%.

After removal of the benzene, the residue was recrystallized from ligroin (b. p. 80~100°C). α-Methyl benzoin (0.7 g., 35%) was recovered; m.p. 90~91°C, its melting point was not depressed on admixing with an authentic sample. From the sodium carbonate solution, benzoic acid (0.5 g., 50%) was obtained; it melted at 121~122°C alone or with an authentic sample of benzoic acid.

(b) A mixture of α-methyl benzoin (2.0 g., 0.8/100 mol.) and "oxidant C or D", was stirred for 4 hr. in a stream of air. Although the oxidation was attempted at 30, 60 and 80°C, no oxidation products were obtained, and α-methyl benzoin (1.7 g., 85%) was recovered, m.p. 90~91°C; its melting point was not depressed on admixing with an anthentic sample.

Results and Discussion

Cuprous acetate pyridine complex has a similar catalytic activity as cuprous chloride pyridine complex for aerial oxidation of benzil. Hydroxy cupric acetate pyridine complex (Experiment 1d) has a similar activity as cuprous acetate pyridine complex for these reactions (Experiment 2a). Furthermore, the oxidation of benzil is hardly retarded at all by an excess of methyl alcohol (Table I).

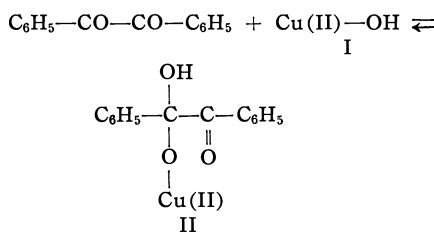
TABLE I. EFFECT OF METHYL ALCOHOL ON THE OXIDATION OF BENZIL

Catalyst	Copper salt in the catalyst	Methyl alcohol	Benzoic acid
	g.	cc.	g. (%)
Oxidant A*	Cu_2Cl_2, 4.0	50	2.1 (86)
Oxidant A*	Cu_2Cl_2, 4.0	100	2.1 (86)
Oxidant B*	$CuCl_2 \cdot 2H_2O$, 6.8	50	2.0 (82)
Oxidant B*	$CuCl_2 \cdot 2H_2O$, 6.8	100	2.0 (82)

Benzil (2.0 g.) was treated.
* Cf. Experiment 1.



It was reported that strong bases were capable of combining to the keto group of benzil in alcohol[5,8]. (Reactions 4 and 5).

(4)

(5)

"Oxidant A, B, C** and D**" are belived to be strong bases[9]. Since "oxidant B" I is considered to have hydroxy group[9], it can also combine with benzil at its keto group to form II —— this addition reaction seems not to be easily retarded with an excess of methyl alcohol. Since "oxidant A" and "oxidant B" bear a remarkable resemblance, a similar intermediate may be produced by reaction of benzil with "oxidant A".

(6)

An attempt to oxidize hydrobenzoin by aerial oxidation catalyzed by "oxidant C" or "oxidant D" is unsuccessful even at 80°C. (Experiment 3b), although it is oxidized to benzaldehyde by aerial oxidation catalyzed by "oxidant A" or "oxidant B". Furthermore, an excess of methyl alcohol retards the oxidation (Table II).

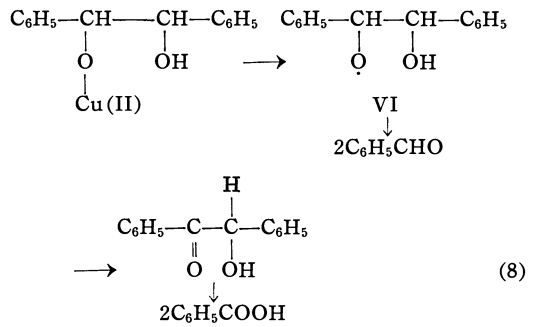
** Cf. Experiment 1.
9) K. Kinoshita, Part I of this series in This Bulletin, **32**, 777 (1959).

TABLE II. EFFECT OF METHYL ALCOHOL ON THE OXIDATION OF HYDROBENZOIN

Catalyst	Methyl alcohol	Benzaldehyde	Benzoic acid	Sample (Recovered)
	cc.	g. (%)	g. (%)	g. (%)
Oxidant A*	0	1.0 (50)	0.1 (4)	0.6 (30)
Oxidant A*	10	0.4 (20)	trace	1.3 (65)
Oxidant A*	50	0.2 (10)	trace	1.5 (75)
Oxidant B**	10	0.5 (25)	trace	1.1 (55)
Oxidant B**	50	trace	trace	1.7 (85)

Hydrobenzoin (2.0 g.) was treated.
* Cu_2Cl_2, 2.0 g. ** $CuCl_2 \cdot 2H_2O$, 1.7 g.



These results are similar to those obtained in the aerial oxidation of aniline[3]. Thus a similar intermediate to that postulated in the oxidation of aniline, may be produced (Reaction 7) (Ref. 3).

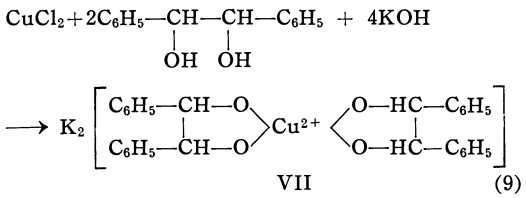
(7)

* Cu(II)-Cl stands for "oxidant A".

If V is converted directly into benzaldehyde, a free racidal such as VI would appear in this reaction.

(8)

On the one hand, VI seems to be converted into benzaldehyde. On the other hand, VI seems to be converted into benzoin, which is further oxidized to benzoic acid. Thus, if VI appears in this reaction, a good amount of benzoic acid may be

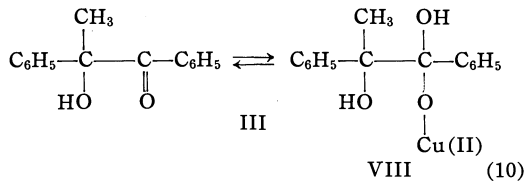


obtained. Since this assumption is not supported by the experimental results[1], it is postulated that such a free radical as VI hardly ever appears in this reaction. Moreover, if VI were intermediate, the stability of benzyl alcohol to "oxidant A" (Ref. 2) would be inexplicable.

Deep blue color is developed upon the addition of cupric chloride—methyl alcohol solution—to a mixture of hydrobenzoin and potassium hydroxide—pyridine-methyl alcohol solution (Experiment 4). For the following reason (1—3), this complex seems to be a chelate compound such as VII.

(1) In the absence of hydrobenzoin, this complex is never formed.

(2) In the presence of ethylene glycol in place of hydrobenzoin, a similar complex is formed.



(3) It was reported that *bis*-glycolatocopper(II) complex was produced upon the addition of cupric nitrate to aqueous erythritol anhydride solution in the presence of sodium hydroxide[10].

VII (9)

Cuprous oxide does not appear even after 24 hr. from this deep blue solution and the formation of chelate compounds such as VII seems to have no effect upon the oxidation of hydrobenzoin.

Because strong bases can combine with the keto group of α-methyl benzoin in alcohol[5,11], an intermediate VIII may be produced by the reaction of α-methyl benzoin with "oxidant A" (Reaction 10).

III VIII (10)

However, α-methyl benzoin is not oxidized in aerial oxidation catalyzed by "oxidant C" or "oxidant D" (Experiment 5b). Furthermore, the oxidation of α-methyl benzoin is retarded by an excess of methyl alcohol (Table III).

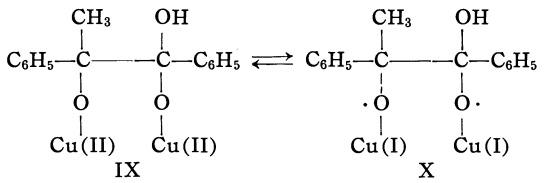


TABLE III. EFFECT OF METHYL ALCOHOL ON OXIDATION OF α-METHYL BENZOIN

Catalyst	Methyl alcohol	Benzoic acid	Aceto-phenone	Sample (Recovered)
	cc.	g. (%)	g. (%)	g. (%)
Oxidant A*	0	0.8 (80)	0.8 (80)	0.1 (5)
Oxidant A*	50	0.5 (50)	0.4 (40)	0.7 (35)
Oxidant A*	100	0.2 (20)	0.2 (20)	1.3 (65)
Oxidant B**	50	0.5 (50)	0.5 (50)	0.6 (30)
Oxidant B**	100	trace	trace	1.7 (85)

α-Methyl benzoin (2.0 g.) was treated.
* Cu_2Cl_2, 4.0 g. ** $CuCl_2 \cdot 2H_2O$, 6.8 g.

These results suggest that the hydroxy group of α-methyl benzoin in VIII must be combined with "oxidant A" to form IX.

The oxidative cleavage of IX probably takes place through activated complex X (Ref. 3). As two unpaired electrons are located on both oxygen atoms of α-methyl benzoin respectively in X, it causes a cleavage of α-methyl benzoin (Reaction 11)***.

IX X

$\longrightarrow C_6H_5COCH_3 + C_6H_5COOH + 2Cu(I)$ (11)

Benzil or hydrobenzoin may be oxidized under the same mechanism as described above.

In Part II, the mechanism of the formation of azobenzene in aerial oxidation of aniline catalyzed by cuprous chloride, was discussed[3]. It is believed that the copper-nitrogen linkage in oxidative dimerisation of aniline, is similarly situated to the copper-oxygen linkage in oxidative cleavage of α-methyl benzoin. Thus, the oxidative dimerisation of aniline and oxidative cleavage of α-methyl benzoin, are carried out through similar mechanism.

Summary

(1) Benzil is oxidized by aerial oxidation catalyzed by "oxidants A, B, C and D".

(2) α-Methyl benzoin or hydrobenzoin is oxidized by aerial oxidation catalyzed by "oxidants A and B" only. This reac-

Mild Oxidation of Alicyclic Secondary Amines. I. On Formation of Isonitrone from Perhydroquinoline Series

By Nobukatsu KATSUI and Yoshiyuki ICHINOHE

(Received October 28, 1958)

In recent years, a few papers concerning the nitrones of alicyclic secondary amines, especially piperidine[1,2] and pyrrolidine[3], have been reported. But the obtaining of isonitrone from alicyclic scondary amine has not yet been described. This paper reports on some of the isonitrones obtained from polycyclic compounds in the alicyclic secondary amine series.

Oxidation of *trans*-decahydroquinoline (I) with silver oxide in 30%-methanol solution at a temperature of 30~40°C gave a product, $C_9H_{15}ON$*, m.p. 280~282°C (IV). This product is different from a compound obtained by Witkop[5] from an air oxidation of I. Also from *cis*-decahydroquinoline (II), the same compound IV was obtained under the same condition. This compound was moreover formed by the treatment of I and II with 30%-hydrogen peroxide, perbenzoic acid, or with *N*-bromosuccinimide (NBS) although accompanied by the known hydroperoxide (XIV)[6].

This new substance (IV) was easily soluble in a polar solvent, but not in a non-polar one. In the infrared spectrum (in Nujol) of IV, the NH-stretching band at 2.96 μ which had been observed in that of *trans*-decahydroquinoline (I), disappeared. This compound IV had no unsaturated nature** and did not react with phenylisocyanate. It was reduced with sodium borohydride, sulfurous acid or with acidic potassium iodide, giving I in all cases.

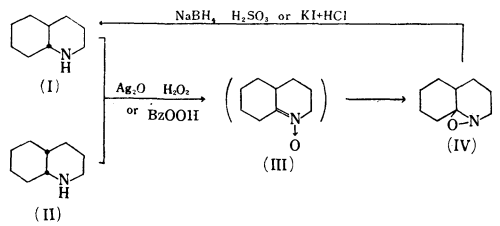

Fig. 1

When α-perhydroacridine (*trans-syn-trans*) (V)[7] was treated with 30%-hydroperoxide at room temperature for a week, it gave a crystalline product, $C_{13}H_{21}ON$*, (sublimed with decomposition at near 320°C) (VI). On the other hand, α-perhydrophenanthridine (*trans-anti-trans*) (VII)[8] reacted with silver oxide at a temperature of 90~100°C, producing a new

* It is well known that aromatic amine oxides do not appear to form definite hydrates[4a]. Henry and Leete[4b] have recently reported that gramine oxide has hydrogen peroxide of crystallization which is determined by iodometry. These new compounds, IV, VI and VIII, had hydrogen peroxide determined by the same method (described in experimental part).

substance, $C_{13}H_{21}ON$*, (sublimed with decomposition at near 325°C) (VIII), although it did not react with hydrogen peroxide. Both compounds, VI and VIII, showed extreme susceptibility to reduction as well as IV, and the infrared absorption spectrum similar to that of IV. On the basis of these data, it seems reasonable to assume that these two products were derived by the reaction of the same type as that which occurred in decahydroquinoline.

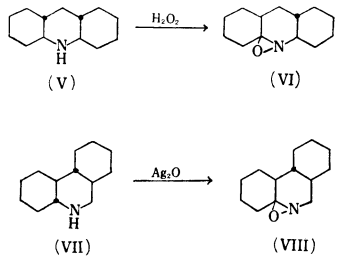

Fig. 2

In order to confirm the constitution of IV, VI and VIII, the compound IV was mainly examined since many oxidation products of decahydroquinoline have already been prepared and characterized in detail. *cis*-*N*-Benzoyldecahydroquinoline could be recovered unchanged after attempting silver oxide oxidation of it under various conditions, hence it would be expected that basic nitrogen is concerned in this reaction. On the other hand, the same product (IV) was obtained not only from *trans*(I), but also from *cis*(II) as described above. Therefore, it is considered that this reaction involves change in the nitrogen $C_{(9)}$ atoms.

As to the conversion of the bond between nitrogen and $C_{(9)}$ atom in decahydroquinoline, four possibilities are considered. The first is the formation of an *N*-hydroxyl derivative corresponding to that obtained from piperidine (IX)[9]. The second is the formation of a dimer corresponding to that produced from *N*-hydroxyl piperidine (X)[1]. The third is the formation of a nitrone and the fourth is the formation of an isonitrone***.

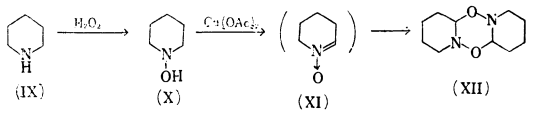

Fig. 3

(i) The new compounds, IV, VI and VIII, had no characteristic absorption of the hydroxyl group in the infrared spectra and IV did not react with phenylisocyanate as has been above mentioned. Therefore, no *N*-hydroxyl group is present in these compounds.

(ii) 1,4,2,5-Dioxa-diazine ring formed in the dimer (XII) has been reduced only by catalytic hydrogenation giving X, but not so with lithium aluminum hydride or with sulfurous acid. On the contrary, these compounds, IV, VI and VIII, were readily reduced with sodium borohydride or even with acidic potassium iodide. Hence the dimer as mentioned under the second possibility is not considered.

(iii) The new compounds, IV, VI and VIII, are similar to a nitrone in physical properties (i.e., in higher melting point or insolubility to non-polar solvents, etc.). These compounds however showed no ultraviolet absorption maxima at near 220~230 mμ[3,11,12] and no infrared absorption band at 6.25μ[12] probably due to the CN-double bond of nitrone. Therefore, it is not needful to consider the structure of nitrone for these compounds.

(iv) On the basis of these considerations three of the four possibilities described above are excluded; then the fourth is the most reasonable. It has been reported that isonitrone is readily reduced by acidic potassium iodide[11-13] and these compounds, IV, VI and VIII, also were reduced by the reagent as above mentioned. These compounds formed stable chloroplatinates although they did not form stable salts with some of the usual acids. The compound IV showed instability to any acidic reagent**** and to alkaline potassium ferricyanate[14]. As shown by these chemical behaviors, these new compounds were considered to be analogous with isonitrone. Krimm[12] reported recently that a characteristic band of isonitrone appears at near 7μ in the infrared

9) R. Wolffenstein, *Ber.*, **25**, 2777 (1892).

*** The isonitrone has a three membered ring consisting of nitrogen, oxygen and carbon atoms, and was recently named by Krimm[10]. Although the presence of this ring has been discussed for a long time, it has recently been synthesized from the Schiff base by means of hydrogen peroxide or peracetic acid. Emmons[11] suggested the name "oxazirane" for this compound.

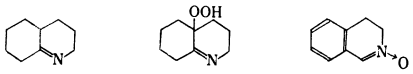
11) W. D. Emmons, *J. Am. Chem. Soc.*, **78**, 6208 (1956).

12) H. Krimm, *Ber.*, **91**, 1057 (1958).

13) L. Horner and E. Jürgens, ibid., **90**, 2184 (1957).

**** When IV was treated with acetic anhydride it gave oily products which could not yet be characterized.

14) Oxidation of IV with alkaline potassium ferricyanate gave a neutral product, m. p. 56~57°C, which has not been characterized.



spectrum. Similar absorption was observed in these compounds, IV, VI and VIII. However, the settlement of the absorption[15] (due to near 7μ) will be deferred until more evidences are available on the various isonitrones.

In the course of the oxidation of decahydroquinoline, two pathways are considered reasonable.

i) Carbinol amine (as initial intermediate) is converted to the Schiff base by dehydration and then is further changed to isonitrone by the addition of oxygen.

ii) *N*-Hydroxyl amine (as initial intermediate) is converted to nitrone by dehydrogenation and then changed to isonitrone.

In the first case, the formation of carbinol amine has usually been observed in a reaction of tertiary amine with silver oxide[16a,b] or NBS reagent[16b]. It has been reported that the formed C(OH)–NH group is readily dehydrated to C=N-group[17]. Cohen and Witkop[6] have reported that 10-hydroperoxy-$\Delta^{1(9)}$-octahydroquinoline (XIV) is formed by the oxidation of $\Delta^{1(9)}$-octahydroquinoline (Schiff base) (XIII). Moreover, isonitrones have been obtained directly by oxidation of the Schiff base[10,11]. Accordingly, it is considered that the reaction of decahydroquinoline with silver oxide or NBS may proceed through the Schiff base stage (XIII) since the isonitrone (IV) was produced together with the hydroperoxide (XIV) in NBS oxidation as above mentioned.

(XIII) (XIV) (XV)

Fig. 4

In the second case, the formation of *N*-hydroxyl amine has commonly been observed in an oxidation of secondary amine with hydrogen peroxide[9] or perbenzoic acid[18]. It has been reported that further oxidation of *N*-hydroxylamine led to the corresponding nitrone by dehydrogenatian. If the nitrone (III) arose from the reaction of decahydroquinoline with hydrogen peroxide or perbenzoic acid, it has no stability because there is no conjugated double bond with nitrone group as shown in 3,4-dihydroisoquinoline-*N*-oxide (XV)[2]. Consequently, the nitrone (III) is converted to the corresponding isonitrone (IV). In this case, no formation of a dimer will result from a steric effect, although that point is not sure.

Further study of the other compounds related to isonitrone derived from alicyclic secondary amine series is in progress.

Experimental

Formation of Isonitrone (IV) from *trans*-Decahydroquinoline (I).—(i) *Oxidation with silver oxide.*—To a solution of 1 g. of *trans*-decahydroquinoline in 20 cc. of 30% aqueous methanol, silver oxide which was freshly prepared from 5 g. of silver nitrate was added. When the resulting suspension was warmed at 30~40°C, a silver mirror gradually formed. After 6 hr. the mixture was cooled and filtered. The methanol of the filtrate was removed under reduced pressure and the resulting aqueous solution was extracted with chloroform after being made alkaline with sodium hydroxide solution. Drying and concentration of the extract left a residue, from which 170 mg. of the product crystallized readily after the addition of ether. Unreacted *trans*-decahydroquinoline could be removed readily by means of addition of ether followed by filtration because of its great solubility in the solvent. The product insoluble in ether was recrystallized from a mixture of ethanol and ether as white needles, m.p. 280~282°C. This substance was readily soluble in polar solvents, i.e., alcohol, water or chloroform, but insoluble in non-polar solvents, i.e., ether, benzene or tetrahydrofurane. It could also be purified by sublimation at 200°C at 5 mm. and had hygroscopic property under high moisture, but did not show any change in the melting point even in that case. It could be heated over its melting points, and recovered unchanged. It formed an aurichloride, m.p. 126~127°C, and a chloroplatinate, m.p. 176~177°C.

In the infrared absorption spectrum (in Nujol) the substance showed peaks at 7.32, 7.46, 7.61, 7.80, 7.94, 8.27, 9.36, 9.53, 10.27, 10.35, 10.48, 10.81, 11.06, 11.30, 11.57, 11.86 and 12.04 μ.

Anal. Found: C, 60.72; H, 9.58; N, 7.43; H_2O_2, 13.70. Calcd. for $C_9H_{15}ON \cdot {}^3/_4\ H_2O_2$: C, 60.48; H, 9.31; N, 7.84; H_2O_2, 14.27%.

ii) *Oxidation with hydrogen peroxide.*—When a suspension of 1 g. of *trans*-decahydroquinoline in 20 cc. of 30%-hydrogen peroxide solution was left at room temperature, *trans*-decahydroquinoline dissolved during the course of the reaction and a deep orange-yellow color gradually developed. After 3 days the reaction mixture was made alkaline with concentrated ammonium hydroxide solution under cooling with water. The alkaline

15) It has been reported that the N-O-stretching vibration in amine oxide shows at near 10.6~10.8μ [R. Mathis Noel et al. *Compt rend.*, **242**, 1873 (1956)], and the characteristic absorption of grouping -O-C-N in oxazolidine ring displays at 8.63, 8.92 and 9.06μ, respectively [E. D. Bergmann, *Chem. Rev.*, **53**, 326 (1953)].

16a) H. Suginome and K. Ohno, *J. Fac. Sci. Hokkaido Univ. Ser. III Chem.*, **4**, 36 (1950).

16b) O. E. Edwards, F. H. Clarke and B. Douglas, *Can. J. Chem.* **32**, 235 (1954).

17) D. H. R. Barton, *J. Chem. Soc.*, **1953**, 1027.

18) M. A. T. Rogers, ibid., **1955**, 769.

solution obtained was extracted with chloroform in as short a time as possible; the extract was washed with water and then dried with sodium sulfate. The residue that remained after evaporation of the solvent crystallized on the addition of ether. The product (185 mg.) was recrystallized from a mixture of ethanol and ether and melted at 280~282°C. It was proved to be identical (mixed melting point and comparison of infrared absorption spectra) with the product from the silver oxide oxidation.

iii) *Oxidation with perbenzoic acid.*—A solution of 100 mg. of *trans*-decahydroquinoline in 100 cc. of chloroform was treated with 150 mg. of perbenzoic acid for a day at room temperature. After this treatment, the chloroform solution afforded 13 mg. of a product which melted at 280~282°C after recrystallization and was proved to be identical also with the product obtained by the oxidation with silver oxide.

iv) *Oxidation with N-bromosuccimide (NBS).*—A solution of 1 g. of *trans*-decahydroquinoline in 40 cc. of acetone containing 10 cc. of water was treated with 1.28 g. of NBS overnight in an atmosphere of nitrogen at room temperature. The solution was then refluxed in a stream of nitrogen for 20 min. After removal of the acetone under reduced pressure the aqueous solution was extracted with ether. The ethereal extract was subjected successively to drying, removal of the solvent and distillation in vacuo. The distillate obtained at 52~53°C at 5 mmHg consisted mainly of unreacted *trans*-decahydroquinoline. The distillate obtained above the temperature of 52~53°C deposited as needle crystals on being allowed to stand in an ice box cooled at −5°C. Separation by filtration and recrystallization from ethyl acetate led to a product which melted at 96~98°C, and was positive to the starch-potassium iodide test. Its crystal form changed from needle to plate on standing. From these properties the product appeared to be identical with 10-hydroperoxy-$\Delta^{1(9)}$-octahydroquinoline, but it was necessary to carry out a further investigation for the identification because of the shortage of the material. On standing for several weeks the mother liquor of the above crystals deposited a further amount of crystals. This compound had m.p. 280~282°C after recrystallization from a mixture of ethanol and ether. It showed no depression on admixture with isonitrone (IV) obtained by the oxidation with silver oxide.

Formation of Isonitrone (IV) from *cis*-Decahyhdroquinoline (II).—When *cis*-decahydroquinoline was treated with silver oxide or hydrogen peroxide under the same conditions as *trans*-decahydroquinoline was, it produced the same isonitrone (IV) which was confirmed by the mixed melting point method and the comparison of infrared spectra.

Action of Silver Oxide on *cis*-*N*-Benzoyl-decahydroquinoline.—*cis*-*N*-Benzoyl-decahydroquinoline was nearly inert to the reagent at 30~40°C under the conditions as described under oxidation of *trans*-decahydroquinoline. Furthermore, the compound proved to be inert to silver oxide even at 80~90°C in aqueous methanol.

Reduction of Isonitrone (IV).—i) *Reduction with sodium borohydride.*—A solution of 10 mg. of sodium borohydride in 2 cc. of methanol was added to a solution of 40 mg. of isonitrone (IV) in 2 cc. of methanol under cooling with water. After having been heated for 30 min. on a steam bath, the solution was concentrated to near dryness under reduced pressure. The residue was then taken up in ether, washed with water, dried and evaporated to dryness. There were thus obtained 34 mg. of crystals which were recrystallized from petroleum ether, m.p. 46~48°C, and proved identical with *trans*-decahydroquinoline[19] by mixed melting point not only as free base but also as hydrochloride.

ii) *Reduction with sulfurous acid.*—Sulfur dioxide was saturated into a solution of 50 mg. of isonitrone (IV) in 5 cc. of water under cooling with water. After being kept for two days the resulting solution was alkalized with sodium carbonate solution and extracted with chloroform. After drying, evaporation of the extract left a residue which crystallized on standing for a few hours, giving 23 mg. of the product. On recrystallization from petroleum ether the product melted at 46~48°C and was proved identical with *trans*-decahydroquinoline.

iii) *Reduction with acidic potassium iodide.*—To a solution of 82 mg. of isonitrone (IV) in 1 cc. of 2 N-hydrochloric acid was added 1 cc. of an aqueous solution saturated with potassium iodide. On standing at room temperature iodine was gradually separated. After being kept overnight the mixture was concentrated to a syrup in a desiccator under reduced pressure and methanol was then added. Evaporation of the methanolic solution from which inorganic salt was removed by filtration left 12 mg. of a product. On washing with ether and recrystallization from a mixture of ethylacetate and chloroform, the product melted at 274~278°C and showed no depression of the melting point by admixture with *trans*-decahydroquinoline hydrochloride.

Action of Phenylisocyanate on Isonitrone (IV).—Isonitrone (IV) did not react with phenylisocyanate in dioxane on treatment for 16 hr. at room temperature.

Oxidation of α-Perhydroacridine with Hydrogen Peroxide.—A half g. of α-perhydroacridine was treated with an excess of 30% hydrogen peroxide solution at room temperature for a week. The reaction mixture gradually colored orange-yellow. The solution was made alkaline with sodium hydroxide solution under cooling with cold water and extracted with chloroform as quickly as possible. The resulting chloroform extract was washed once with water, then dried (sodium sulfate) and concentrated to dryness. On treatment with ether, the crystals could be separated into soluble and insoluble parts for the solvent. The soluble

19) Cohen and Witkop[5] and Leonard et al. (*J. Am. Chem. Soc.*, 78, 3463 (1956)) reported that derivatives of $\Delta^{1(9)}$-octahydroquinoline were reduced to the *trans*-form of decahydroquinoline in good yields by lithium aluminum hydride reduction.

part was unchanged amine. The insoluble part was recrystallized from a mixture of chloroform-ethanol as thin plates, giving 230 mg. of the product, isonitrone (VI), which sublimed with decomposition at near 320°C. This isonitrone was completely insoluble in a non-polar solvent, less soluble in water and alcohol, and more soluble in chloroform. The VI formed a chloroplatinate, m. p. 248~250°C (decomp.) In the infrared absorption spectrum (in Nujol) the substance showed peaks at 7.32, 7.46, 7.61, 7.80, 7.96, 8.17, 8.27, 8.46, 9.12, 9.56, 9.72, 10.09, 10.35, 10.50, 10.81, 11.04 and 11.91 μ.

Anal. Found: C, 67.36; H, 10.10. Calcd. for $C_{13}H_{21}ON \cdot 3/4H_2O_2$: C, 67.06; H, 9.74%.

Oxidation of α-Perhydrophenanthridine (VII) with Silver Oxide.—A mixture of 0.5 g. of α-perhydrophenanthridine and silver oxide (freshly prepared from 2 g. of silver nitrate) in 3 cc. of methanol and 30 cc. of water was refluxed at 90~100°C on a steam bath for 3 hr. A silver mirror was gradually formed. The solids were removed by filtration and washed thoroughly with hot methanol. After removal of methanol from the combined filtrate and washings, the aqueous solution was made alkaline with sodium hydroxide solution, filtered and extracted with chloroform. On evaporation of the solvent after drying, the chloroform extract afforded crystals. Since the unchanged base (VII) was readily soluble in ether, it could be separated from the reaction product by the addition of ether. The insoluble ether part was recrystallized from a mixture of ethanol and ether as needles giving 318 mg. of the product, which sublimed with decomposition at near 325°C. The property of solubility in a polar solvent was closely like that of isonitrone (IV). This product (VIII) formed a chlorofolatinate; m.p. 228~229°C (resolidified at 121°C). In the infrared absorption spectrum (in Nujol) the substance showed peaks at 7.32, 7.46, 7.61, 7.78, 7.80, 8.17, 8.27, 8.44, 9.12, 9.58, 9.72, 10.02, 10.09, 10.35, 10.52, 10.81, 11.04 and 11.91 μ.

Anal. Found: C, 66.80; H, 9.79; H_2O_2, 11.26. Calcd. for $C_{13}H_{21}ON \cdot 3/4H_2O_2$: C, 67.06; H, 9.74; H_2O_2, 10.96%.

Reductions of Isonitrone, VI and VIII, with Sodium Borohydride.—The isonitrones, VI and VIII, were respectively reduced to the original bases, V and VII with sodium borohydride in a good yield by the same treatment as described under the reduction of isonitrone (IV).

The present research was conducted under the supervision of Professor Harusada Suginome, President of Hokkaido University. The authors are also deeply indebted to Mr. Tadashi Masamune for his interest and advice and for supplying the material.

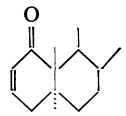
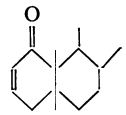
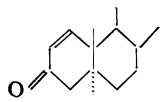
Studies on the Sapogenins of Dioscorea tokoro Makino. II[1]. *The Structure of Tokorogenin*

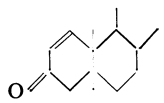
By Katsura MORITA

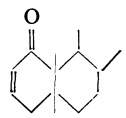
(Received November 4, 1958)

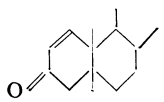












Although it was postulated that the three hydroxyl groups in tokorogenin are situated at positions 1, 2 and 3 of the steroid nucleus[2], their configuration and the nature of the A/B ring junction still remained unclarified. To make these points clear it was most desirable to establish a correlation of tokorogenin with a known sapogenin, which has been done as described in the present paper.

In the presence of a small amount of chlorosulfonic acid tokorogenin reacted with acetone and with cyclohexanone to give an isopropylidenetokorogenin (tokorogenin acetonide) and a cyclohexylidenetokorogenin, respectively. On treatment with pyridine and *p*-toluenesulfonyl chloride, the isopropylidenetokorogenin gave a tosylate, which on heating in 80% acetic acid solution furnished tokorogenin monotosylate. When the monotosylate was further treated with alkali in methanol, a crystalline, substance, soluble with difficulty, was obtained and analyzed as $C_{27}H_{42}O_4$. It was presumed to be an oxido-spirostanol,

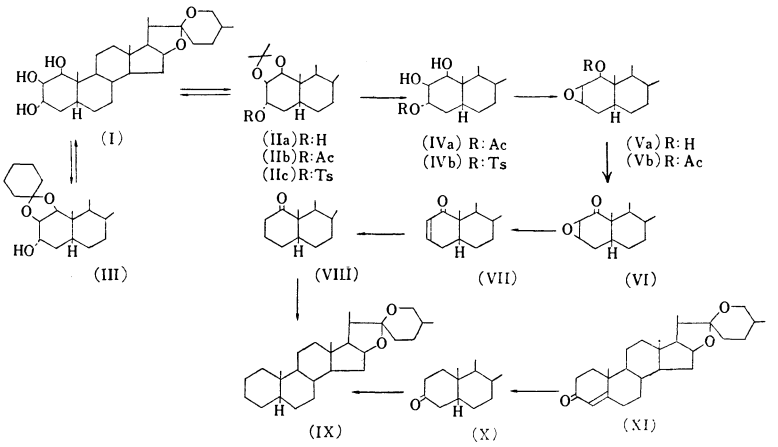
anhydrotokorogenin, from the reaction sequence. The anhydrotokorogenin gave a monoacetate and infrared absorption spectra exhibiting no characteristic band of the carbonyl group. It is, therefore, evident that the substance possesses a hydroxyl an oxido group. Oxidation of the anhydrotokorogenin with chromic anhydride-pyridine furnished a ketone, anhydrotokorogenone.

In the light of the structure of tokorogenin suggested in the previous paper[2] and the reaction sequence described above, the anhydrotokorogenone is either 2,3-oxido-spirostan-1-ol or 1,2-oxido-spirostan-3-ol. Since such an α,β-oxido-ketone has been known to undergo reduction with chromous chloride[3] giving the corresponding α,β-unsaturated ketone, the reaction was applied to the anhydrotokorogenone. As expected, anhydrotokorogenone gave an α,β-unsaturated ketone, which showed a specific U. V. absorption band at 225 mμ.



Catalytic hydrogenation of the α,β-unsaturated ketone furnished a saturated ketone, which showed marked depression of the melting point on admixture with smilagenone (X)[4]. Finally, the product from the Huang-Minlon reduction[5] of the saturated ketone proved to be identical with 25D-5β-spirostan (IX), prepared from smilagenone (X) by the known method[6]. The identity was established by the mixed melting point and the infrared absorption spectra.

The above reactions correlate tokorogenin with the known 25D-5β-spirostan (IX), and show that tokorogenin is an isosapogenin. Since the saturated ketone was not identical with smilagenone (X) as mentioned above, the structure 25D-5β-spirostan-1-one (VIII) has to be assigned to the saturated ketone from tokorogenin, and accordingly 25D-5β-spirost-2-en-1-one

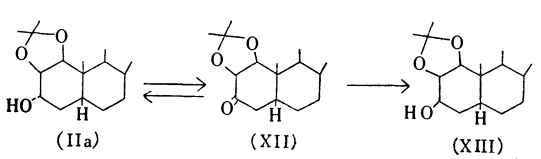
Chart 1



(VII) to the α,β-unsaturated ketone. These conclusions are further supported by the ultraviolet absorption spectrum of the α,β-unsaturated ketone (VII) which is in complete accord with those of known Δ^2-1-ketosteroids as shown in Table. I.

Thus, it is reasonable to assign the structure of $2\xi,3\xi$-oxido-25D-5β-spirostan-1-one to anhydrotokorogenone and that of $2\xi,3\xi$-oxido-25D-5β-spirostan-1ξ-ol to anhydrotokorogenin. Since the two hydroxyl groups in positions 1 and 2 in tokorogenin take part in the formation of the acetonide and therefore are *cis*-oriented, and the third in position 3 is *trans* to the other two, tokorogenin is either $1\alpha,2\alpha,3\beta$-triol or $1\beta,2\beta,3\alpha$-triol.

From the above arguments and on the basis of the assumption that the configuration of the hydroxyl group in position 3 of tokorogenin is α, all the reactions can be represented by the scheme shown in Chart 1.

Evidence for the α-configuration of the 3-hydroxyl group is given by the following experiment: Treatment of isopropylidenetokorogenin (IIa) with chromic anhydride-pyridine furnished isopropylidenetokorogenone (XII). Reduction of the ketone (XII) with lithium aluminum hydride gave a mixture of isopropylidenetokorogenin (IIa) and its C_3-epimer (XIII), which were separated by careful chromatography on Florisil, the latter being eluted first and then the former.

Chart 2

It has been generally accepted[8] that when a mixture of two epimeric steroidal alcohols is chromatographed, the one having an axial hydroxyl group moves more rapidly than the other. The above experiment, therefore, suggests that the 3-hydroxyl group in isopropylidenetokorogenin (IIa) is α-oriented (equatorial). In this way the structure of tokorogenin has been determined to be 25D-5β-spirostan-1β, $2\beta,3\alpha$-triol (I).

Experimental

Isopropylidenetokorogenin (Tokorogenin Acetonide) (IIa).—a) A suspension of 1 g. of tokorogenin (I) in 100 ml. of acetone containing 0.1 ml. of chlorosulfonic acid was vigorously stirred at room temperature for sixty minutes. When tokorogenin was dissolved and the acetonide was completely precipitated, the precipitates were collected, washed with ethanol and dried, m. p. 290~295°C. Yield, 1.0 g.

For analysis the substance was recrystallized from a large volume of hot methanol or dimethylformamide, m. p. 309~312°C.

Anal. Found: C, 73.50; H, 9.90. Calcd. for $C_{30}H_{48}O_5$: C, 73.73; H, 9.90%.

b) A solution of 100 mg. of tokorogenin in 100 ml. of acetone containing 50 mg. of *p*-toluenesulfonic acid was boiled under reflux for three hours and the solution was allowed to stand at room temperature overnight to separate fine needles of tokorogenin acetonide, m.p. 300~305°C, mixed m. p. with the above specimen, 305~309°C. When the acetonide was boiled in 80% acetic acid for several minutes and the solution was cooled, tokorogenin was precipitated in colorless needles melting at 273~275°C.

Cyclohexylidenetokorogenin (III).—Tokorogenin in cyclohexanone was treated with a few drops of chlorosulfonic acid under the conditions

described in the case of the acetonide. Recrystallization of the crude product from methanol furnished III melting at 288~290°C.

Anal. Found: C, 74.91; H, 10.04. Calcd. for $C_{33}H_{52}O_5$: C, 74.96; H, 9.91%.

When the cyclohexylidene compound (III) was boiled in ethanol containing a few drops of hydrochloric acid for one hour, tokorogenin was recovered.

Isopropylidenetokorogenin Acetate (IIb). — Isopropylidenetokorogenin (IIa) was acetylated by the usual means with pyridine and acetic anhydride to give the acetate (IIb), m. p. 207~208°C.

Anal. Found: C, 72.42; H, 9.70. Calcd. for $C_{32}H_{50}O_6$: C, 72.41; H, 9.50%.

Tokorogenin Monoacetate (IVa).—Isopropylidenetokorogenin acetate (IIb) was boiled in 80% acetic acid and the solution was cooled to separate colorless needles of tokorogenin monoacetate (IVa). The analytical sample recrystallized from methanol melted at 237~239°C.

Anal. Found: C, 70.75; H, 9.61. Calcd. for $C_{29}H_{46}O_6$: C, 70.98; H, 9.45%.

Isopropylidenetokorogenin Tosylate (IIc). —To a solution of 2.3 g. of isopropylidenetokorogenin (IIa) in 80 ml. of pyridine 5 g. of *p*-toluenesulfonyl chloride was added and the mixture was kept at 50°C for one hour and then at room temperature for two days. Then a large volume of water was added and the precipitate of the crude tosylate (IIc) was filtered, washed with water, and dried. Recrystallization from ether afforded colorless platelets melting at 198°C followed by immediate decomposition to a tar. Yield, 2.0 g.

Anal. Found: C, 68.94; H, 8.63. Calcd. for $C_{37}H_{54}O_7S$: C, 69.13; H, 8.47%.

Tokorogenin Monotosylate (IVb).—A suspension of 500 mg. of isopropylidenetokorogenin tosylate (IIc) in a small volume of 80% acetic acid was heated on a steam bath for twenty minutes till the solution became clear. The solution was then cooled to furnish colorless needles, m. p. 192°C (decomp.). Yield, 370 mg.

Anal. Found: C, 67.28; H, 7.96. Calcd. for $C_{34}H_{50}O_7S$: C, 67.75; H, 8.36%.

2β, 3β-Oxido-25D-5β-spirostan-1β-ol (Anhydrotokorogenin) (Va).—A methanol solution of 2.0 g. of potassium hydroxide was added to a solution of 1.0 g. of tokorogenin monotosylate (IVb) in 80 ml. of methanol and the solution was boiled under reflux for one hour and cooled. The hardly soluble crystalline solid was collected, washed with methanol, and dried, m. p. 237~239°C. Yield, 500 mg.

Anal. Found: C, 75.44; H, 9.88. Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83%.

2β, 3β-Oxido-25D-5β-spirostan-1β-ol Acetate (Vb). — A portion of 2β,3β-oxido-25D-5β-spirostan-1β-ol (Va) was acetylated by the usual means with pyridine and acetic anhydride to furnish the acetate (Vb) as colorless prisms melting at 246~249°C.

Anal. Found: C, 73.51; H, 9.49. Calcd. for $C_{29}H_{44}O_5$: C, 73.69; H, 9.38%.

2β, 3β-Oxido-25D-5β-spirostan-1-one (Anhydrotokorogenone) (VI). — To a solution of 800 mg. of 2β,3β-oxido-25D-5β-spirostan-1β-ol (Va) in 50 ml. of pyridine was added with vigorous stirring 1.0 g. of chromic anhydride in small portions. The reaction mixture was gradually heated to 40°C and was kept at this temperature for three hours and then at room temperature for twenty-four hours. Water was added and the mixture was extracted with ether. The ethereal solution was thoroughly washed and dried, and evaporation afforded 700 mg. of needles, m. p. 238~239°C, I. R. in Nujol λ_{max} 5.86 μ (1-c=o).

Anal. Found: C, 75.35; H, 9.40. Calcd. for $C_{27}H_{40}O_4$: C, 75.66; H, 9.41%.

25D-5β-Spirost-2-en-1-one (VII).—To a suspension of 650 mg. of 2β,3β-oxido-25D-5β-spirostan-1-one (VI) in 5 ml. of acetic acid was added 20 ml. of a chromous chloride solution[10] at one time with vigorous stirring in nitrogen stream. The oxide (VI) dissolved immediately and soon 25D-5β-spirost-2-en-1-one (VII) was precipitated. Water was added and the mixture was extracted with ether. The ethereal solution was thoroughly washed and dried and evaporation furnished colorless needles, m. p. 222~223°C. Yield, 320 mg.; U. V. in EtOH λ_{max} 225 mμ (ε: 7690).

Anal. Found: C, 78.54; H, 9.51. Calcd. for $C_{27}H_{40}O_3$: C, 78.59; H, 9.77%.

25D-5β-Spirostan-1-one (VIII).—A solution of 300 mg. of 25D-5β-spirost-2-en-1-one (VII) in 50 ml. of methanol was subjected to catalytic hydrogenation over 1 g. of 5% palladium-charcoal catalyst. When 16 ml. of hydrogen was absorbed in five minutes the catalyst was removed and the filtrate was evaporated to give colorless prisms, m. p. 183~184°C. Yield, 220 mg.

Anal. Found: C, 78.17; H, 10.00. Calcd. for $C_{27}H_{42}O_3$: C, 78.21; H, 10.21%.

25D-5β-Spirostan (IX). — a) A mixture of 150 mg. of 25D-5β-spirostan-1-one (VIII), 5 ml. of diethylene glycol and 0.2 ml. of 80% hydrazine hydrate was heated to 160~170°C till the solution became clear. Potassium hydroxide (300 mg.) was added to the solution and the temperature was gradually raised to 200°C and kept there for two hours. After cooling, water was added and the mixture was extracted with petroleum ether. Evaporation of the thoroughly washed and dried extract furnished a crystalline solid. Recrystallization from methanol containing ether afforded colorless platelets, m. p. 136~137°C. Yield, 98 mg.

Anal. Found: C, 80.62; H, 11.05. Calcd. for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07%.

b) Smilagenone (X) was subjected to the same treatment as the above to give 25D-5β-spirostan (IX).

Comparison of the I. R.-spectra and mixed melting point determination with the two specimens showed that they were in complete accord in all respects.

25D-5β-Spirostan-1β, 2β-diol-3-one Acetonide (Tokorogenone Acetonide) (XII).— To a solution of 1 g. of tokorogenin acetonide (IIa) in

10) A solution of chromous chloride was prepared by the method of Cole and Julian[3].

150 ml. of pyridine was added 700 mg. of chromic anhydride in small portions with vigorous agitation. Temperature was kept at 45~50°C for forty hours, and stirring was continued throughout this time. After cooling, the mixture was diluted with a large volume of water and extracted with ether. The ether solution was thoroughly washed, dried and evaporated. Recrystallization of the residue from methanol yielded colorless needles melting at 225~228°C. Yield, 800 mg. The analytical sample recrystallized from the same solvent melted at 229~231°C. I. R. in Nujol, λ_{max} 5.80 μ (3-c=o).

Anal. Found: C, 73.98; H, 9.29. Calcd. for $C_{30}H_{46}O_5$: C, 74.03; H, 9.53%.

Lithium Aluminum Hydride Reduction of 25D-5β-Spirostan-1β, 2β-diol-3-one Acetonide (Tokorogenone Acetonide) (XII).—A solution of 300 mg. of $LiAlH_4$ in 50 ml. of anhydrous ether was added in small portions to a solution of 200 mg. of 25D-5β-spirostan-1β,2β-diol-3-one acetonide (XII) in 150 ml. of the same solvent. After being left to stand overnight at room temperature, the reaction mixture was poured into ice-water and extracted with methylene chloride. The organic layer was washed with water, dried, and evaporated to give a crystalline solid, which was re-dissolved in methylene chloride and subjected to careful chromatography on Florisil.

Fraction 1 (30 ml., CH_2Cl_2),
needles, 20 mg., m. p., 204~206°C
Fraction 2 (30 ml., CH_2Cl_2),
needles, 50 mg., m. p., 208~210°C
Fraction 3 (30 ml., CH_2Cl_2),
needles, 35 mg., m. p., 210~240°C
Fraction 4 (30 ml., CH_2Cl_2),
needles, 35 mg., m. p., 295~300°C
Fraction 5 (50 ml., CH_2Cl_2)

Fraction 6 (50 ml., ether)

The substances from Fractions 1 and 2 were the same and did not show depression of m. p. on admixture. They were combined and recrystallized to give an analytical sample, m. p. 208~210°C.

Anal. Found: C, 73.77; H, 9.67. Calcd. for $C_{30}H_{48}O_5$: C, 73.73; H, 9.90%.

As already discussed it is 25D-5β-spirostan-1β, 2β,3β-triol 1,2-acetonide (XIII).

The substance from Fraction 4 proved to be identical with tokorogenin acetonide (IIa), and the substance from Fraction 3 is, therefore, very likely a mixture of IIa and XIII.

Summary

(1) The correlation of tokorogenin (I) with the known steroid, 25D-5β-spirostan (IX), was established: Tokorogenin formed an acetonide (IIa), which could be tosylated and then hydrolyzed to give tokorogenin monotosylate (IVb). On treatment with alkali, IVb was led to anhydrotokorogenin (Va), which on oxidation with Py.-CrO_3 and subsequent reduction with $CrCl_2$ gave rise to an α,β-unsaturated ketone (VII). Catalytic hydrogenation of VII followed by the Huang-Minlon reaction furnished 25D-5β-spirostan (IX).

(2) In order to determine the configuration of the hydroxyl group at C_3, IIa was oxidized with Py.-CrO_3 and the product was reduced with $LiAlH_4$ to give a mixture of IIa and XIII. Careful chromatography of the mixture revealed that the substance eluted first was XIII, while the second which eluted from the column was IIa, thus leaving only the structural possibility of 25D-5β-spirostan-1β,2β,3α-triol (I) to tokorogenin.

The author wishes to express his grateful thanks to Dr. Y. Asahina of the University of Tokyo, Dr. S. Kuwada and Dr. T. Matsukawa of Takeda Research Laboratories, for their encouragement throughout the work. Thanks are also due to Mr. H. Kamio for infrared- and ultraviolet-spectral measurements and to Mr. M. Kan for elementary analyses.

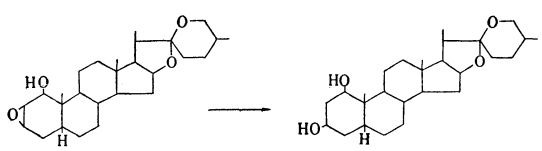
Studies on the Sapogenins of Dioscorea tokoro Makino. III[1]. *Synthesis of Isorhodeasapogenin and Some Reactions of Tokorogenin*



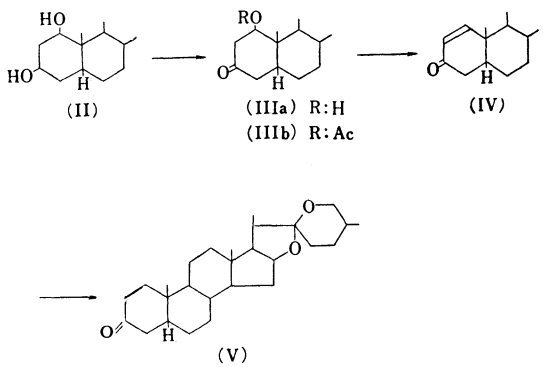
By Katsura MORITA

(Received November 4, 1958)

In order to obtain further information concerning the configuration of the hydroxyl groups in tokorogenin, the following reactions were investigated.

Reduction of anhydrotokorogenin (I) with lithium aluminum hydride in anhydrous ether caused ring-opening of the oxide giving a new dihydroxysapogenin, desoxytokorogenin. Since this dihydroxysapogenin neither formed an acetonide nor suffered oxidation by means of periodic acid and lead tetraacetate, the two hydroxyl groups in this substance have to be located at carbon atoms C_1 and C_3. As lithium aluminum hydride reduction of an oxide in the cyclohexane series is known to result in formation of an axial hydroxyl bond[2], the configuration of the hydroxyl group in position 3 of desoxytokorogenin must be β; that is, the structure of 25D-5β-spirostan-1β, 3β-diol (II) has to be assigned to this substance.

Chart 1



(I) (II)

Further evidence for the structure of desoxytokorogenin (II) is given by the following reaction sequence:

Desoxytokorogenin (II) was oxidized with *N*-bromoacetamide to 25D-5β-spirostan-1β-ol-3-one (IIIa), which was acetylated and then treated with activated alumina giving 25D-5β-spirost-1-en-3-one (IV)[3]. The U.V.-absorption spectrum of this substance (IV) showed a good identity with those of known Δ^1-3-ketosteroids[4]. Upon catalytic hydrogenation over $Pd/CaCO_3$ IV yielded smilagenone (V)[5].

Chart 2

(II) (IIIa) R:H (IIIb) R:Ac (IV) (V)

Some years ago, Nawa[6] isolated a new dihydroxysapogenin, rhodeasapogenin, from *Rhodea japonica* Roth. and suggested that it was 25L-5β-spirostan-2β, 3α-diol on the basis of various reactions, none of which led to a known steroid. Djerassi[7] attempted the oxidation of isorhodeasapogenin, an acid isomerization product of rhodeasapogenin, with chromic anhydride with the aim of obtaining a dibasic acid, isorhodeasapogenic acid, which he supposed to be identical with one of his four 2, 3- and 3, 4-seco-sapogenic acids. Unfortunately, the acid obtained by Djerassi was identical with none of his four sapogenic acids.

Quite recently, Takeda et al.[8] isolated a new dihydroxysapogenin, yonogenin, from *Dioscorea tokoro* Makino and defined its structure as 25D-5β-spirostan-2β, 3α-diol, which was the very one suggested

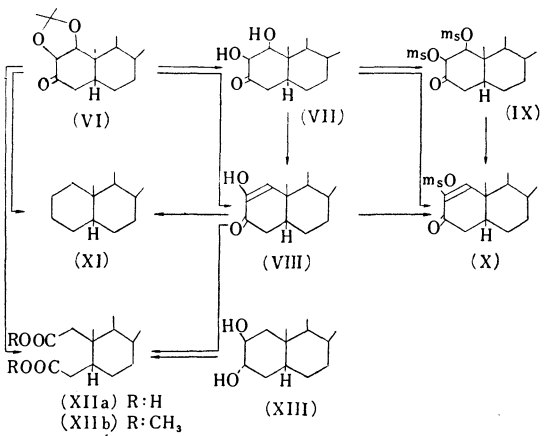
for isorhodeasapogenin. The present author also isolated the sapogenin from the same plant and confirmed that yonogenin was not identical with isorhodeasapogenin[9].

In the course of the present investigations it was noticed that the melting points of desoxytokorogenin (II) and its diacetate were similar to those of isorhodeasapogenin and its diacetate, respectively. Similarly, the melting points of tokorogenic acid[10] and its dimethyl ester[10] were found to be in close proximity to those of isorhodeasapogenic acid and its dimethyl ester, respectively.



Most of the evidence for a glycol structure of rhodeasapogenin had been sought by Nawa in the fact that the sapogenin underwent ready oxidation to a dibasic acid, rhodeasapogenic acid, but it seemed probable that desoxytokorogenin (II) would be able to undergo oxidation with the same reagent to an intermediate 1,3-diketone, which would enolize and suffer further oxidation to a dibasic acid, namely, tokorogenic acid. Comparison of the I.R.-spectra and determination of the mixed melting points proved that desoxytokorogenin (II) is identical with isorhodeasapogenin, and tokorogenic acid with isorhodeasapogenic acid. Basing on these findings, Nawa has recently corrected all the structural assignments of rhodeasapogenin and its derivatives[11].

When tokorogenone acetonide (VI) was heated with acetic acid and water, tokorogenone (VII) was obtained. Tokorogenone (VII), on heating with alkali in methanol solution, lost 1 mol. of water to give a diosphenol (VIII), $C_{27}H_{40}O_4$, U. V. λ_{max} in EtOH: 269.5 mμ (ε: 6900). Direct conversion of tokorogenone acetonide (VI) into the diosphenol (VIII) could also be effected by the action of alkali at 100°C.

Stiller et al.[12] reported that selenium dioxide oxidation of cholestanone gave a mixture of cholest-1-en-2-ol-3-one (diosphenol A) and cholest-3-en-3-ol-2-one (diosphenol B). They also demonstrated that in equilibrium diosphenol A predominated in alkaline medium, while diosphenol B in acidic solution. The diosphenol (VIII) from tokorogenone (VII), however, was transformed in a mineral acid solution into an unidentified isomeric substance ($C_{27}H_{40}O_4$), from which the diosphenol (VIII) could no longer be recovered by any means. This discrepancy seems to be due to the fact that cholestanone and its diosphenols are 5α-steroids (allo-series) while tokorogenone (VII) and its diosphenol (VIII) are 5β-steroids (normal-series).

Tokorogenone (VII), on treatment with mesyl chloride and pyridine, gave a mixture of a dimesylate (IX) and an enol mesylate (X). The latter (X) was yielded also by heating the former (IX) with pyridine or with sodium iodide in acetone, and by treating the diosphenol (VIII) with mesyl chloride and pyridine. These reactions unambiguously show that the diosphenol (VIII) has to be defined as 25D-5β-spirost-1-en-2-ol-3-one.

Chart 3

It is interesting to note that the Huang-Minlon reduction of the diosphenol (VIII) as well as of tokorogenone acetonide (VI) gave 25D-5β-spirostan (XI), while the reduction of the acid isomerization product of the diosphenol (VIII) did not lead to XI.

The diosphenol (VIII) suffered oxidation with hydrogen peroxide and alkali at room temperature to give samogenic acid (XIIa)[7]. The same acid was prepared also from yonogenin by the known method, and the identity of both specimens was established by the mixed melting point determination and by the comparison of their I.R.-spectra.

Experimental

25D-5β-Spirostan-1β,3β-diol (Desoxytokorogenin) (II).—A solution of 400 mg. of 2β,3β-oxido-25D-5β-spirostan-1β-ol (anhydrotokorogenin) (I) in 50 ml. of anhydrous ether was added to a solution of 1.5 g. of lithium aluminum hydride in 60 ml. of the same solvent through a dropping

9) A sample of yonogenin was kindly given by Dr. Takeda[8] and that of isorhodeasapogenin by Dr. Nawa[6] in Takeda Research Laboratories. The mixture of these specimens melted at a temperature lower than that of either.

10) See previous paper (Part I) in this series.

11) H. Nawa, *Chem. & Pharm. Bull.*, **6**, 255 (1958).

12) E. T. Stiller and O. Rosenheim, *J. Chem. Soc.*, **1938**, 353.

funnel with stirring. The reaction mixture was stirred for two hours at room temperature and poured into a large volume of ice-water, 10% sulfuric acid was added, and the mixture was extracted with ether. The ether solution was thoroughly washed, dried, and evaporated to give colorless needles, m. p. 236~238°C. Yield, 310 mg. Recrystallization from methanol raised the m. p. to 240~242°C.

Anal. Found: C, 74.82; H, 10.46. Calcd. for $C_{27}H_{44}O_4$: C, 74.96; H, 10.25%.

On admixture with a sample of isorhodeasapogenin the melting point of the diol (II) was not depressed. The infrared spectra also established the identity of the two specimens.

Treatment of the diol (II) with acetic anhydride and pyridine at room temperature for twenty-four hours furnished the diacetate, m. p. 207~209°C.

Anal. Found: C, 72.12; H, 9.64. Calcd. for $C_{31}H_{48}O_6$: C, 72.06; H, 9.36%.

The substance thus obtained showed a good identity with isorhodeasapogenin diacetate in all respects.

25D-5β-Spirostan-1β-ol-3-one (IIIa).—25D-5β-Spirostan-1β, 3β-diol (II) (200 mg.) was added to a solution of 139 mg. of *N*-bromoacetamide in 20 ml. of 90% acetone and the mixture was warmed on a steam bath for a short time to clear the solution. After one hour, a portion of the solution was titrated with 1/10-N sodium thiosulfate solution and potassium iodide and it was indicated that the reaction proceeded stoichiometrically. A large volume of water was added and the mixture was extracted with ether. The ethereal solution was washed, dried and evaporated to dryness. Recrystallization of the residue from methanol afforded colorless needles melting at 232~233°C (decomp.).

Anal. Found: C, 74.96; H, 9.63. Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83%.

25D-5β-Spirostan-1β-ol-3-one Acetate (IIIb).—25D-5β-Spirostan-1β-ol-3-one (IIIa) (70 mg.) was acetylated with acetic anhydride and pyridine to give colorless needles of the acetate (IIIb), m. p. 200~201°C.

Anal. Found: C, 73.66; H, 9.31. Calcd. for $C_{29}H_{44}O_5$: C, 73.69; H, 9.38%.

25D-5β-Spirost-1-en-3-one (IV).—A solution of 70 mg. of IIIb was passed through unwashed alumina to furnish 50 mg. of platelets melting at 191~192°C. U. V. λ_{max} in EtOH: 232.5 mμ (ε: 9700).

Anal. Found: C, 78.55; H, 9.63. Calcd. for $C_{27}H_{40}O_3$: C, 78.59; H, 9.77%.

25D-5β-Spirostan-3-one (Smilagenone) (V).—A solution of 35 mg. of 25D-5β-spirost-1-en-3-one (IV) in 30 ml. of methanol was subjected to catalytic hydrogenation over 5% palladium-charcoal catalyst in an atmospheric pressure. The solution rapidly took up 1.6 ml. of hydrogen and the reaction almost stopped. The catalyst was removed and the filtrate was concentrated under diminished pressure to give colorless platelets. Recrystallization from methanol afforded the pure material melting at 183~184°C.

The sample here obtained showed no depression of the melting point on admixture with an authentic specimen prepared from diosgenone by the known method[5].

25D-5β-Spirostan-1β, 2β-diol-3-one (Tokorogenone) (VII). — 25D-5β-Spirostan-1β, 2β-diol-3-one acetonide (VI) (100 mg.) in 3 ml. of 80% acetic acid was heated on a steam bath for forty minutes. The resulting solution was evaporated under diminished pressure to give a crystalline solid (VII), which upon recrystallization from methanol afforded thin plates melting at 224~227°C. Yield, 60 mg.

Anal. Found: C, 72.54; H, 9.57. Calcd. for $C_{27}H_{42}O_5$: C, 72.65; H, 9.42%.

A small portion of the diol (VII) was acetylated with acetic anhydride and pyridine by the usual means. Recrystallization of the crude acetate from methanol furnished colorless needles, m. p. 223~226°C.

Anal. Found: C, 70.10; H, 8.59. Calcd. for $C_{31}H_{46}O_7$: C, 70.16; H, 8.74%.

25D-5β-Spirostan-1β,2β-diol-3-one Dimesylate (IX) and 25D-5β-Spirost-1-en-2-ol-3-one Mesylate (X).—a) Mesyl chloride (1 ml.) was added to a solution of 500 mg. of 25D-5β-spirostan-1β, 2β-diol-3-one (VII) in 10 ml. of pyridine at 0°C and the solution was allowed to stand at room temperature in a dark place for three days. A large volume of water was added and the mixture was extracted with ether. The ether solution was thoroughly washed with water, dried and evaporated to furnish almost colorless needles of the dimesylate (IX), m. p. 223°C (decomp.). Yield, 340 mg.

Anal. Found: C, 57.71; H, 7.66. Calcd. for $C_{29}H_{46}O_9S_2$: C, 57.78; H, 7.69%.

The mother liquor from the above dimesylate (IX) was further concentrated and left overnight to give different crystals, m. p. 222~223°C. Yield, 120 mg. The substance here obtained showed a marked depression of the melting point on admixture with the dimesylate (IX). On the basis of the ultraviolet absorption spectrum and elementary analyses structure X was assigned to this substance. U. V. λ_{max} in EtOH: 238.5 mμ (ε: 7100).

Anal. Found: C, 66.10; H, 8.20. Calcd. for $C_{28}H_{42}O_6S$: C, 66.38; H, 8.36%.

b) A solution of 200 mg. of 25D-5β-spirostan-1β, 2β-diol-3-one dimesylate (IX) in 8 ml. of acetone containing 500 mg. of sodium iodide was heated in a sealed tube at 120°C for twenty-four hours. After cooling, the reaction mixture was diluted with water and extracted with ether. The ethereal solution was washed with water and then with sodium thiosulfate solution, dried, and evaporated to furnish colorless crystals, m. p. 222~223°C.

c) A portion of 25D-5β-spirost-1-en-2-ol-3-one (VIII) dissolved in pyridine was treated with mesyl chloride by the usual means. Dilution of the reaction mixture with water followed by washing, drying and evaporation afforded the same mesylate, m. p. 222~223°C.

25D-5β-Spirost-1-en-2-ol-3-one (Diosphenol) (VIII).—a) A solution of 25D-5β-spirostan-1β,2β-

diol-3-one (VII) (70 mg.) in 5 ml. of methanol containing 500 mg. of potassium hydroxide was boiled on a steam bath for thirty minutes. After cooling and diluting with a large volume of water, the mixture was extracted with methylene chloride. The organic layer was then washed, dried, and evaporated to give colorless needles. Recrystallization from methanol afforded the analytical sample, m. p. 227~228°C. Yield, 40 mg. U. V. λ_{max} in EtOH: 269.5 mμ (ε: 6900).

Anal. Found: C, 75.49; H, 9.37. Calcd. for $C_{27}H_{40}O_4$: C, 75.66; H, 9.41%.

b) A portion of 25D-5β-spirostan-1β, 2β-diol-3-one acetonide (VI) was treated with potassium hydroxide as described and the resulting solution was worked up as above to give the same diosphenol (VIII); mixed melting point with the specimen from a, 227~228°C.

Acid Isomerization of 25D-5β-Spirostan-1β, 2β-diol-3-one (VII), 25D-5β-Spirostan-1β, 2β-diol-3-one Acetonide (VI) and 25D-5β-Spirost-1-en-2-ol-3-one (VIII).—a) A solution of 70 mg. of 25D-5β-spirostan-1β, 2β-diol-3-one (VII) in 5 ml. of methanol containing 0.2 ml. of concentrated hydrochloric acid was boiled under reflux for thirty minutes. After concentration under reduced pressure, water was added and the mixture was extracted with methylene chloride. Thorough washing with water followed by drying and evaporation furnished a crystalline solid, m. p. 245~248°C. Recrystallization from methanol raised the m. p. to 254~255°C. The ultraviolet absorption spectrum of this substance showed a slight shift to a lower wavelength than that of the alkali isomerization product VIII, i. e., U. V. λ_{max} in EtOH: 267 mμ (ε: 5700), no hydroxyl absorption bands being noticed.

Anal. Found: C, 75.49; H, 9.37. Calcd. for $C_{27}H_{40}O_4$: C, 75.66; H, 9.41%.

b) 25D-5β-Spirostan-1β, 2β-diol-3-one acetonide (VI) was subjected to acid isomerization under the conditions described above. The crude product after recrystallization from methanol showed the same melting point as that of the specimen from a.

c) A solution of 70 mg. of 25D-5β-spirost-1-en-2-ol-3-one (VIII) in 5 ml. of methanol containing 0.2 ml. of concentrated hydrochloric acid was boiled under reflux for thirty minutes. Working up of the reaction mixture by the same procedure as described in a and b yielded fine needles melting at 254~255°C.

All the specimens from a, b and c were confirmed to be identical with one another by mixed melting point determination.

25D-5β-Spirostan (XI).—25D-5β-Spirostan-1β, 2β-diol-3-one acetonide (VI) (500 mg.) was dissolved in 20 ml. of diethylene glycol containing 1 ml. of 80% hydrazine hydrate and 2.0 g. of potassium hydroxide. The mixture was heated at 200°C in an oil bath for three hours. After cooling, the reaction mixture was diluted with a large volume of water and extracted with ether. The ethereal solution was washed with water, dried, concentrated, and chromatographed on Florisil. 25D-5β-Spirostan (XI) was eluted from the column by petroleum ether and recrystallization from methanol-petroleum ether gave the analytical sample melting at 136~137°C. Identity of the substance here obtained was confirmed by comparison of the I. R.-spectra and the mixed melting point determination with an authentic specimen. When 25D-5β-spirostan-1β, 2β-diol-3-one (VII) and 25D-5β-spirost-1-en-2-ol-3-one (VIII) were subjected to the same reaction, 25D-5β-spirostan (XI) was obtained.

Samogenic Acid (XIIa).—Thirty per cent hydrogen peroxide (1 ml.) was added to a solution of 300 mg. of 25D-5β-spirost-1-en-2-ol-3-one (diosphenol) (VIII) in 5 ml. of methanol containing 200 mg. of potassium hydroxide and the solution was left standing at room temperature for one hour. A large volume of water was added, the resulting clear solution was extracted once with ether, and the ether solution was discarded. The aqueous solution was acidified and extracted with ether and the ethereal solution was washed with water, dried and evaporated to give a crystalline solid. Recrystallization of the solid from methanol furnished colorless thin plates melting at 271~273°C. Yield, 200 mg.

By the action of diazomethane, the acid (XIIa) afforded the dimethyl ester (XIIb), m. p. 147~148°C, $[\alpha]_D^{31}$: −28° (*c*; 0.5% in $CHCl_3$).

Summary

(1) Reduction of anhydrotokorogenin with lithium aluminum hydride led to a new dihydroxysapogenin, desoxytokorogenin; the structure 25D-5β-spirostan-1β, 3β-diol was assigned on the basis of various reactions and theoretical considerations.

(2) Desoxytokorogenin, 25D-5β-spirostan-1β, 3β-diol, was incidentally found to be identical with isorhodeasapogenin, the structure of which had so far been left unclarified.

(3) Identity of tokorogenic acid with isorhodeasapogenic acid was also confirmed.

(4) Tokorogenin was correlated with samogenic acid and yonogenin via a diosphenol, 25D-5β-spirost-1-en-2-ol-3-one, whose structure was unambiguously established.

The author wishes to express his grateful thanks to Dr. Y. Asahina of the University of Tokyo, Dr. S. Kuwada and Dr. T. Matsukawa of Takeda Research Laboratories for their encouragement throughout the work. Thanks are also due to Dr. K. Takeda of Shionogi Research Laboratories for the gift of a sample of yonogenin, to Mr. H. Kamio for infrared- and ultraviolet-spectral measurements and to Mr. M. Kan for elementary analyses.

Studies on the Sapogenins of Dioscorea tokoro Makino. IV[1]. *The Contents of Tokorogenin, Yonogenin and Diosgenin*

By Katsura MORITA

(Received November 4, 1958)

Until recently, three steroids of natural origin possessing a hydroxyl group in position 1 had been announced. They are ouabagenin[2], acovenosigenin A[3], both being cardiac aglycones, and ruscogenin[4], a steroidal sapogenin isolated quite recently by C. Sannié et al. from *Ruscus aculeatus* L. and defined by Benn et al.[5] as 25D-spirost-5-en-1ξ, 3β-diol. Tokorogenin and rhodeasapogenin[6] are further additions to the examples of 1-hydroxylated steroids of natural origin. Tokorogenin is the only known steroid possessing a glycerol moiety in ring A, its structure having been defined by the author as 25D-5β-spirostan-1β, 2β, 3α-triol.

As described in a previous paper[7], tokorogenin was isolated from the rhizomes of *D. tokoro* Makino in a poor yield compared with diosgenin, which had been regarded as the sole steroidal sapogenin in the same plant. In the course of the present investigation, however, it was noticed that the rhizomes of *D. tokoro* Makino collected at Gotenba in Shizuoka Prefecture yielded extraordinarily large amounts of tokorogenin and a new sapogenin[8] and a minute quantity of diosgenin, compared with those collected in other places. No difference in appearance could be found between the rhizomes and the plants collected at Gotenba and those from other places.

In the light of these findings it was presumed that the rhizomes of *D. tokoro* Makino from certain districts other than Gotenba might be an excellent source of tokorogenin or other sapogenins, and the author started investigations on the sapogenin contents in the same plant species from various districts in Japan.

For this purpose, dried and sliced rhizomes collected at various sites were subjected to digestion with 1.2-N hydrochloric acid for six hours followed by drying and extraction with ether in a Soxhlet apparatus. The ether extract separated a voluminous jelly comprising tokorogenin, yonogenin and other unknown impurities. The jelly yielded rather impure tokorogenin and yonogenin by chromatographic purification on Florisil, while the mother liquor yielded almost pure diosgenin.

Since the above procedure was rather troublesome and unsuitable for rapid estimation with many samples, the following process was used: The ether extract was evaporated to dryness, and the residue was dissolved in methylene chloride and chromatographed on Florisil to give a diosgenin fraction and a yonogenin-tokorogenin fraction; both fractions were then evaporated and weighed to find roughly the amount of diosgenin and the total amount of other sapogenins. The results are summarized in Table I, which shows that the amount of diosgenin and that of other sapogenins vary markedly according to the site of collection of the rhizomes. It is especially noteworthy that the rhizomes collected even in neighboring villages (No. 21—No. 25) in Gotenba showed considerable differences in their sapogenin contents.

In order to obtain further information on these points, similar experiments were carried out with the rhizomes cultivated in the Experimental Farm of our company[9], each sample being prepared from one plant and by the same process.

A methanol extract of a rhizome was

hydrolyzed with ethanolic hydrochloric acid[10], extracted with methylene chloride, chromatographed on Florisil and finally subjected to the colorimetric estimation of the three sapogenins by means of Yamagishi's method[11]. The results of the analyses tabulated in Table II reveal that the plants containing diosgenin as the major ingredient contain very small amounts of tokorogenin and yonogenin or lack them, while those containing large amounts of tokorogenin and yonogenin give only minute yields of disogenin or lack it. These findings are very interesting in view of the fact that the structures of tokorogenin and yonogenin are closely related (5β,2β-OH, 3α-OH), while diosgenin is considerably different from these two sapogenins (Δ^5, 3β-OH). In this connection it is also interesting to point out that the Shionogi's workers have isolated the fourth sapogenin, kogagenin, from the vines and leaves of the same plant[8] and suggested a structure of 25D-spirostan-1β, 2β,3α,5β-tetrol for the new sapogenin[12].

Experimental

Improved Isolation of Diosgenin, Yonogenine and Tokorogenin from the Rhizomes of *D. tokoro* Makino (Collected at Gotenba). —Dried rhizomes (1 kg.) collected at Gotenba was gently heated with 4.6 l. of 1,2-N hydrochloric acid for six hours and the hydrolyate was centrifuged, and the solid was washed with water and dried to give 186 g. of a dark brown cake. The cake was then extracted with petroleum benzine in a large Soxhlet apparatus for five hours, whereby diosgenin separated out as a white crystalline solid during the extraction. Ether was then substituted for petroleum benzine and extraction was continued for twenty more hours to give voluminous precipitation of dark brown jelly, which was filtered, washed with ether and dried. It weighed 18.7 g.

TABLE III

Sample	Content		
	Diosgenin (%)	Yonogenin (%)	Tokorogenin (%)
Dried rhizomes 1 kg.	0.82	0.63	0.50
Acid hydrolysate 186 g.	4.32	3.1	2.6
Jelly 18.7 g.	—	30	24

10) Hydrolysis was carried out by Marker's standard method.

11) M. Yamagishi and I. Nakamura, *Chem. & Pharm. Bull.*, **6**, 421 (1958).

12) At the Meeting of Organic Chemistry of Naturally Occurring Substances, October 18, 1958.

The analytical data shown in Table III[13] indicate that the procedure described above is satisfactory for the separation of diosgenin and a mixture of tokorogenin and yonogenin from the rhizomes.

For the separation of tokorogenin from yonogenin, the jelly (18.7 g.) was acetylated with pyridine-acetic anhydride and the acetylated mixture dissolved in ether was repeatedly washed with dilute aqueous alkali until washings became colorless. After the ether solution was dried and evaporated, the residue was redissolved in hot ethanol and treated with charcoal. Upon the solution was cooled tokorogenin triacetate was precipitated as almost colorless leaflets melting at 250~255°C. For analysis the crude material (m. p. 250~255°C) was dissolved in methylene chloride and the solution was passed through a column of Florisil, and concentration of the solution and recrystallization of the residue from ethanol raised the m. p. to 260~263°C. Yield, 4.7 g. The mother liquor, after hydrolysis with methanol and alkali, was poured into water and extracted with ether. The ether solution was washed with water, dried and evaporated to dryness. Chromatography of a portion of the residue on Florisil furnished yonogenin from methylene chloride-ethyl acetate (4 : 1) eluates and a small amount of tokorogenin from ethyl acetate eluates. After recrystallization from hot ethanol[14] the sample of yonogenin melted at 238~240°C and was identified with an authentic sample.

Yonogenin Acetate. — A small portion of yonogenin was acetylated with pyridine and acetic anhydried to give colorless needles of the diacetate, m. p. 213°C, $[\alpha]_D^{17}$ −17° (c=1.0%, $CHCl_3$). The sample showed no depression of m. p. on admixture with an authentic specimen.

Hydrolysis of the diacetate with alkali and methanol led to needles of the free sapogenin melting at 238~240°C.

Summary

(1) Improved isolation of tokorogenin, yonogenin and diosgenin from the rhizomes of *D. tokoro* Makino collected at Gotenba is described.

(2) The sapogenin contents in rhizomes of *D. tokoro* Makino collected in various districts in Japan were examined by means of chromatography.

(3) The sapogenin contents in rhizomes of cultivated plants of *D. tokoro* Makino were examined and it was found that the plants containing diosgenin as the major ingredient contain very small amounts of tokorogenin and yonogenin or lack them, while those containing large amounts of tokorogenin and yonogenin give only minute yields of diosgenin or lack it.

13) Analyses were carried out by Yamagishi's colorimetric method[7].

14) A solution of yonogenin in organic solvents showed strong tendency to form a gel.

The author wishes to express his grateful thanks to Dr. Y. Asahina of the University of Tokyo, Dr. S. Kuwada and Dr. T. Matsukawa of Takeda Research Laboratories for their encouragement throughout the work. Thanks are also due to Dr. K. Takeda of Shionogi Research Laboratories for the gift of a sample of yonogenin, to Dr. S. Yamagishi and Mr. I. Nakamura for the analyses of the sapogenins, to Dr. T. Watanabe for the collection of the plants, and to Mr. R. Hatta of their Experimental Form in Kyoto for the growing of the plants.

On the Crystal Growth of Zinc Sulfide Phosphor

By Yoshiro ŌTOMO

(Received November 12, 1958)

When zinc sulfide is fired, usually the flux is to be used, which 1) protects the phosphor from oxidation[1], 2) acts as the co-activator[2-4] and 3) promotes its crystallization. Concerning those functions, there have been few detailed reports on 3), the crystallization of the phosphor.

The author has made observations with an electron microscope on the process of crystallization of the phosphor, with and without flux — here, 2 wt. % of sodium chloride has been added — and, at the same time, he has determined the sizes and the forms of crystals, using a NORELCO X-ray diffractometer. It is found that, before firing, the raw material of zinc sulfide is a large aggregate of crystallites of β-form with 8% of α-form of the same material, and through firing, the process of crystal growth is much affected by the addition of flux. Also, he has discussed the effect of flux on the size of the grown crystals, the forms of crystals and their transition velocities.

Experimental Results and Discussion

The Crystal Growth and the Electron Microscope Observation.—A special replica method was used for the electron microscope observation. The phosphor powder was scattered on rock salt and Pt-Pd metal was evaporated on it obliquely from one direction. Carbon was then evaporated to cover the Pt-Pd metal and the phosphor crystal. After those procedures, rock salt was dissolved in water and zinc sulfide was dissolved in 6 N-hydrochloric acid. Thus, the Pt-Pd metal covered with carbon film was left, and was put on the mesh as a sample.

The base material of zinc sulfide phosphor was precipitated through the reaction of hydrogen sulfide gas with the solution of zinc sulfate. The precipitate was washed with de-ionized water and dried at room temperature. The precipitate was observed by the electron microscope and was found to be a large aggregate of needle-like crystallites, as is demonstrated in Fig. 1. In order to see the crystal structure of the aggregate, a NORELCO X-ray diffractometer was used and $10\bar{1}0$, 0002 and $10\bar{1}1$ patterns, the strongest patterns of α-form crystal, and 111 pattern, the strongest pattern of β-form, were checked. It was found that the raw material of zinc sulfide was not amorphous but consisted of nearly perfect crystals of β-form containing approximately 8% of α-form.

Assuming that they are perfect β-form crystals, the mean diameter of the crystals, d, is obtained from the half-peak breadth, B, of the 111 diffraction pattern, using

$$B = K\lambda/d\cos\theta \qquad (1)$$

where λ is the wavelength of X-ray and θ is the angle of diffraction. For $K \approx 1$, the diameter of the unfired zinc sulfide crystal, d, is evaluated to be about 150 Å from our X-ray diffraction measurements.

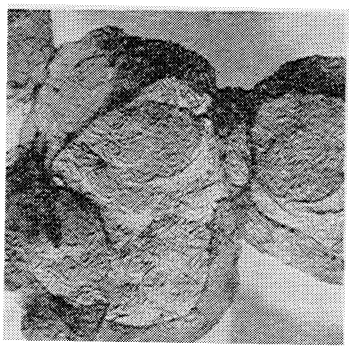

Fig. 1. Unfired ZnS: Ag.
Electron micrograph×5,000

In Figs. 2a and 2b, the processes of crystal growth during the firing of the precipitated zinc sulfide are shown. The processes of crystalization of the samples added with or without the flux of 2 wt. % of sodium chloride were investigated with an electron microscope. In both cases, no difference is observed up to 400°C and a slight change in the crystalline state is observed at 500°C in case of a sample with 2 wt. % of sodium chloride. At 600°C, the crystallites of zinc sulfide have grown together considerably in both cases, and, at 700°C, perfectly grown crystallites were observed with 2 wt. % of sodium chloride. But without flux, the rapid crystal growth is seen at temperatures between 800 and 900°C. However, the difference between the two cases is not only in the speed of crystal growth, but also in some other aspects of growing processes. Considerations on the later aspects are given below.

For the modes of crystal growth of such sulfides, two processes are mainly considered; the one, through the screw dislocation and the other, the surface nucleation[5].

The zinc sulfide molecule, which is adsorbed on the step of the crystal, diffuses towards the kink and forms a part of the crystal lattice, pushing the step out and making the crystal larger. The diffusion length, l_d, of zinc sulfide is given by

$$l_d=\sqrt{D\tau}$$

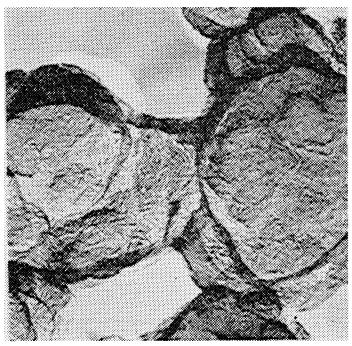
where D is the diffusion constant and τ is the lifetime of the molecule adsorbed on the surface.

By the addition of 2 wt. % of sodium chloride the diffusion is made more active, and D becomes larger. And, through the interaction with the flux, there will be more possibilities of forming kinks at the surface of crystals, and the mean distance, l_k, between kinks will become smaller. Hence, the relationship

$$l_d \gg l_k$$

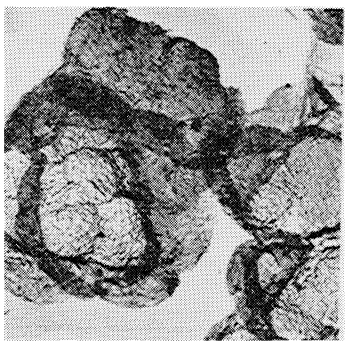
will be satisfied easily and the growth of the steps at crystal surfaces will become independent of the crystal symmetry, resulting in the circular step-wise crystals. Such cases are given in Fig. 2a; one for the sample fired at 700°C and another for that fired at 1000°C. Without flux, the diffusion of zinc sulfide molecules along the crystal surfaces is not active, and D becomes smaller. Also, the kinks at the surfaces are not formed so easily, and l_k becomes larger.

Hence, the relationship, $l_d \gg l_k$, is no longer satisfied, resulting in the considerable influence of crystal symmetries on the growth of steps at the surfaces and the anisotropic crystal growth. Some examples are given in Fig. 2b. For the firing at temperatures above 900°C, the straight step, perpendicular to the direction of crystal growth, is seen clearly. At 1100°C, the α-form crystal of zinc sulfide is observed, especially along (0001) crystal surface, which is developed as pyramids.



Relationship between the Firing Condition and the Diameter of Crystals.—The half-peak breadth of the X-ray diffraction pattern was corrected for the characteristic width of the instrument, and the crystal sizes of various zinc sulfide phosphors were obtained by using Eq. 1.

The results are given in Fig. 3. In this diagram, the solid line shows the diameter of crystals without flux and the dotted line shows that with 2 wt. % of sodium chloride as flux. For both cases, up to 400°C, little crystal growth is observed and no difference can be seen compared with the material before firing. At about 500°C, the crystal growth begins and, at 600°C, it becomes extremely rapid. When the flux is added, the growth, at temperatures around 600°C, is especially remarkable. Those results show a rather good correspondence with the behaviors of crystal growth shown in Fig. 2.



Comparison between the measured crystal diameters obtained through the X-ray diffraction method and the electron microscope is made below.

In Fig. 2b, the picture of the sample fired, without flux, at 800°C shows that the diameter of the crystal agrees with that obtained by X-ray diffraction which

is about 0.2 μ. This is also true for the sample fired by 600°C. However, for the sample fired at 600°C with flux, as shown in Fig. 2a, the diameter is 0.1 μ from X-ray diffraction and is 0.3~0.4 μ from the electron microscope experiment. The disagreement is probably due to the growth of thin plate-like crystals under this particular condition.

Relationship between the Firing Temperature and the Crystal Forms.—The transition of the crystal forms of zinc sulfide takes place at about 1020°C[6]. It is known that, below 1050°C, the β-form is stable and, above 1100°C, the hexagonal α-form is stable[7]. However, from our experiments the situation seems to be a little more complicated.

In Fig. 4, the ratio of the amount of α-form to that of β-form in crystal was given, which was obtained by comparing the strengths of the strongest diffraction patterns, $10\bar{1}0$, 0002 and $10\bar{1}1$ of α-form, with that of β-form, 111. The measurements were made for zinc sulfide phosphors fired for three hours at various temperatures ranging from 500°C to 1100°C, with the raw material containing 8% of α-form.

As is seen in Fig. 4, the amount of α-from in the material without flux decreases as the firing temperature increases, and the transition from α-from to β-form is observed. However, at about 900°C, the content of α-form begins to increase again and becomes 18% at 1000°C and 73% at 1100°C. For the sample with the flux of 2 wt. % of sodium chloride, the α-form begins to decrease at about 700°C. Almost all of the α-form changes into β-form at 800°C, and the amount of α-form becomes nearly equal to zero. As the temperature increases, the α-form appears again at about 1000°C and more than 90% of α-form is found at 1100°C.

The above results show the fact that the transition velocity of crystal forms is much influenced by the existence of the flux and that the transition, α-form $\leftrightarrow$ β-form, becomes easier with 2 wt. % of sodium chloride, but is difficult without it.

The increase of α-form is observed at 600°C for the sample with 2 wt. % of sodium chloride, but the same phenomenon appears in the cases with fluxes other than sodium chloride. The explanation of this is not given yet, and the author is planning to check whether it originates from the existence of some meta-stable state which promotes the formation of α-state, because of some critical temperature to stimulate the sudden crystallization, or whether it is due to the existence of a

6) E. T. Allen and J. L. Crenshaw, *Am. J. Science*, **34**, 341 (1912).
7) R. H. Bube, *J. Chem. Phys.*, **20**, 708 (1952).

state where the α-form is essentially stable.

Influence of Time of Firing.—Fig. 5 gives the relationships among the time of firing, the crystal forms and the intensity of luminescence. At firing temperature of 1000°C, there is not much difference in crystal forms between the sample fired for ten minutes and that fired for three hours, and the former shows a considerably better luminescence intensity. This fact implies that the crystallization has taken place during the firing for a short period. At firing temperature of 800°C, the amount of α-form decreases with the time of firing and the greater part of the crystals are of β-form after firing for thirty minutes. The intensity of luminescence shows a similar tendency and attains the limiting value in thirty minutes.

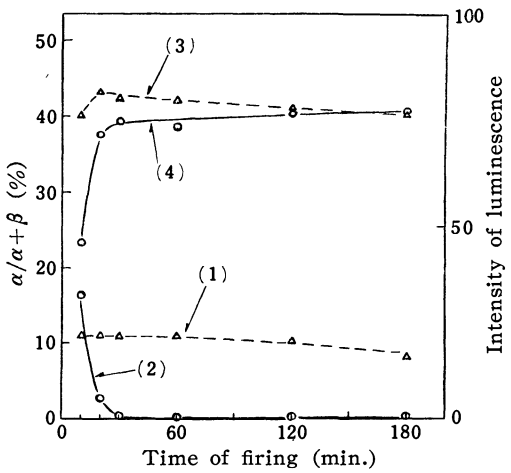

Fig. 5. Relationships among the time of firing, the crystal forms and the intensity of luminescence.
(ZnS: Ag added 2 wt. % NaCl as flux.)
(1) Content of α-form (fired at 1000°C).
(2) Content of α-form (fired at 800°C).
(3) Intensity of luminescence (fired at 1000°C; 12 kV. C.R. excitation).
(4) Intensity of luminescence (fired at 800°C; 12 kV. C.R. excitation).

Those facts imply that the complete change from α-form into β-form is finished within ten minutes when fired at 1000°C and after thirty minutes when fired at 800°C, both with 2 wt.% of sodium chloride as flux.

Summary

(1) The zinc sulfide, before firing, is a large aggregate of crystallites with the crystal diameter of about 150 Å and contains about 8% of α-form.

(2) The crystal growth of zinc sulfide phosphor takes place at about 500°C regardless of whether there is flux or not, but the rate of the growth is much affected by the flux. Without flux, the crystal grows as step-wise piled layers, but, with flux, it grows isotropically showing no influence from the crystal symmetry. Concerning the above difference, there has been discussion, taking into account the density of kinks at the step-wise surfaces of crystals and the change of diffusion constant of zinc sulfide molecules adsorbed at the surfaces.

(3) The transition, α-form $\leftrightarrow$ β-form, of zinc sulfide phosphor is rather easy, but becomes difficult without flux. Also, the transition is completed in thirty minutes of firing at 800°C with the flux of 2 wt.% of sodium chloride, but it is completed within ten minutes of firing at 1000°C.

(4) It is probable that there is a metastable state of α-form at about 600°C, but it requires further consideration.

The author wishes to express his thanks to Mr. T. Mitsuishi and Mr. H. Nagasaki for their cooperation in the X-ray diffraction measurements and the electron microscope experiments.

Recombination of Hydrogen Atoms on Various Transition Metal Surfaces

By Kazuo NAKADA

(Received January 20, 1959)

Apart from the well-known research of Bonhoeffer[1], in which the order of recombination activity of metals was found to be in good accordance with the series of hydrogen over-voltage, comparison of the relative activities of various kinds of metals for the recombination of hydrogen atoms was made by Katz et al.[2] However, our present knowledge about the recombination activity of transition metals is not sufficient for the detailed discussion.

From the works just cited, it is immediately noticed that the transition metals have the highest activity among all sorts of metals, noble metals follow them, and polyvalent metals have much lower activity as compared with the former two. However, it is not yet well understood why such a distinct change in activity appears when metal species are altered, even though it might be inferred that different electronic band structures are responsible for the difference in activity.

In order to examine the dependence of recombination activity principally on the *d*-band hole, the comparison of activities was made for several transition metals available for us.

We further attempted to obtain the information about the correlation between the work function and the recombination coefficient, which had attracted our attention ever since Suhrmann[3] had made clear many years ago the linearity between them, for it seems to be open to question whether the exact linearity would hold over all kinds of metals at all.

Trapnell et al.[4] intended to interpret the origin of different activities in terms of the so-called Pauling's *d*-character. It is another aim of the present work to make clear in what manner the *d*-character can be related to the catalytic activity.

Experimental

In order that the place where the recombination proceeds was confined to the metal surface concerned, a method adequate to be called "an effusion method" was adopted here instead of the usual flow method.

The relative activities of Ta, W, Mo, Ti, Co and Cr were determined with respect to Ni. In the series of Fe, Cr, Mn and Cu, Cu was chosen as a standard of comparison. In another series of Ti, Zr and Th, Ti was adopted as a standard metal. U was compared only with Mo.

Samples.—Most metal samples used were in the form of a circular disk (15 or 20 mm. in diameter and 0.1~0.3 mm. thick), but Ti and Zr were ribbon-like foil. Fe and Mn were electrically plated on one side of copper plate, while Cr was evaporated on copper plate in a vacuum.

Two kinds of metals, one of which was chosen as the standard metal, were stuck together back to back by soldering or spot welding or, in unavoidable cases, by means of synthetic resin adhesives. Their surfaces were polished with 06 emery papers, but no other treatment like chemical etching or electropolishing was done at all.

T: The top tube inside of which the city water was allowed to flow.

Apparatus and Procedure.—Only the main part of apparatus, made of hard glass, was shown in Fig. 1. Hydrogen atoms were produced in a Wood's discharge tube. The electric discharge was carried out by an alternating current from 5 kW. transformer giving up to 4000 V. The voltage across the electrodes was of the order of 1000~1500 V.

The hydrogen gas including hydrogen atoms was allowed to effuse into the reaction chamber (B) through a small circular hole (h) provided at the end of the side tube (S). In this chamber the sample metal disk was hung by molybdenum wire (0.3 mm. in diameter) at the front of the hole. This chamber was strongly pumped off by an oil diffusion pump backed by a rotary oil pump, but could not be evacuated to less than 5×10^{-4} mmHg on account of leakage gas from the hole.

Even such a non-high vacuum seems to be sufficiently good to ensure that the reaction gas reaches the catalyzing metal surface not by diffusion but rather by effusion, considering the much shorter distance between the sample surface and the hole than the mean free path at the vacuum of 10^{-3} mmHg.

The temperature rise of the sample caused by recombination heat liberating on it was followed by measuring the electromotive force of Pt/Pt-Rh thermocouple attached to the sample by use of a K-type potentiometer. The sample metal disk could be allowed to turn over by virtue of the ground glass joint. Inside the tube (T), in the bottom of which molybdenum lead was sealed, the city water was allowed to flow in order to diminish the effect of the drift of room temperature on the measurements. This procedure was useful to eliminate the error resulting from temperature variation, because the drift of city water temperature was smaller than that of room temperature by a factor of about 5.

Hydrogen. — Commercial cylinder hydrogen was used. The gas was allowed to bubble through a saturated solution of sodium hydroxide. After being dried with sulfuric acid, it was passed over the platinized asbestos (ca. 400°C), and dried again over the phosphoric pentoxide. Hydrogen thus dried was sent to 3 l. flask equipped with a manostat capable of keeping the pressure constant within 0.1 mmHg.

Hydrogen was allowed to diffuse into the discharge tube through a capillary. At this stage the pressure was lowered enough to permit the electric discharge.

In order to keep the catalytic action of discharge tube wall as constant as possible, hydrogen at a pressure of about 150 mmHg was saturated with water vapour on the saturated solution of sodium hydroxide.

Result. — The electromotive forces of two thermocouples, one of which was attached to the sample and the other was immersed in a city-water stream, was read simultaneously for the intervals of 5 min. over the range of 1 to 2 hr. before and during the course of electric discharge. The values averaged over all the reads are taken as expressing the temperatures of the sample and the city-water. The difference of these temperatures varied before and after the discharge was switched on. This variation of temperature difference was adopted as the rise of temperature due to the recombination heat.

At first the temperature rise for the metal aimed at was determined, then the same procedure was applied to the standard metal of another side. The ratio of the former to the latter was adopted as a measure of the recombination coefficient. The values thus determined were summarized as follows:

a) for the case when nickel was adopted as a standard metal, Co(118), Ni(100), Ta(88), Mo(86), W(84), Ti(83) and Cr(71):

b) for the case when copper was a standard metal, Fe(167), Cr(120), Mn(111) and Cu(100).

The latter case could be converted into the former case as given below:

Fe(99), Cr(71), Mn(66), and Cu(59).

In the series of Ti, Zr and Th, the order of activity was determined as follows:

$$Zr>Ti>Th$$

From the comparison of U with Mo, the relation

$$Mo>U$$

was obtained.

Discussion

In this section, present results have been discussed from several points of view through comparison of activity with physical properties. At first we confine ourselves to metals belonging to the first long period of the periodic table.

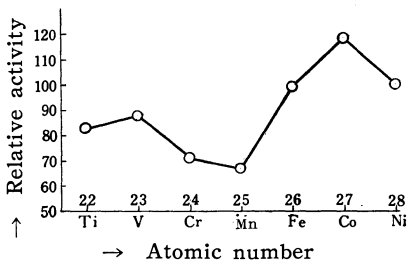

Fig. 2. The dependence of relative activity on atomic number, where Ta is taken in place of V.

In Fig. 2 is given the dependence of the recombination activity on atomic number, where tantalum is used in place of vanadium. It is perceived that this plot has two peaks at group V and group VIII. On the other hand, if the cohesive energy[5] is plotted against the atomic number, Fig. 3 curve a is obtained. It is noticed that this plot has also two peaks at the same positions. When other physical properties, e. g., the effective electron number per atom[6], density of states per eV. per atom[7], etc., are plotted against the atomic number, plots similar to the above are obtained as shown in Fig. 3 curve b. From the resemblance of these plots to the plot in

5) C. Kittel, "Introduction to Solid State Physics", John Wiley & Sons, New York (1956), p. 99.
6) Ibid., p. 132.
7) Ibid., p. 259.

Fig. 2, it is suggested that these physical properties are more or less related to the catalytic activity.

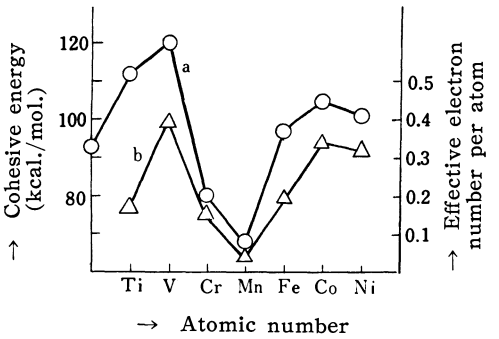

Fig. 3. Curve a, plot of cohesive energies versus the atomic number and curve b, plot of the effective electron number versus the same.

Let us consider a little further the correlation of activity with the cohesive energy. From the resemblance between the plot of cohesive energy versus the atomic number and that of activity versus the same, it is suggested that the bond strength of chemisorption which can be evaluated by an approximate method stated just below, may have an important connection with the catalytic activity. Recently, a method for evaluating the bond strength of chemisorption approximately by use of the experimental heat of sublimation and the electronegativity had been presented by Eley[8]. More recently, a somewhat different method was offered by Stevenson[9], in which the work function was used instead of the value of dipole moment in evaluating the ionic contribution.

If the semi-empirical values of bond strength of chemisorption evaluated by the above two kinds of methods are taken, plots quite similar to the relation between cohesive energy and atomic number must be obtained. From this fact, the conclusion may be drawn that metals having strong bond strength of chemisorption should have high activity. However, the statement given below has made such a view less convincing.

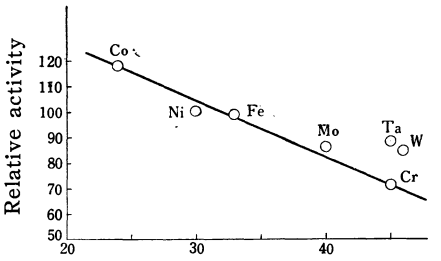

Fig. 4. The dependence of the relative activity on the experimental heat of chemisorption, where the data are taken from Stevenson's report.

Alternatively, if the recombination activities are plotted against the data on the experimental heat of chemisorption quoted by Stevenson, it is found that almost all points fall on a straight line aside from the slight upward deviation of tantalum and tungsten as shown in Fig. 4. From this fact, it is suggested that metals with strong bond strength of chemisorption are less active in contrast to the above statement deduced from the comparison of the dependence of cohesive energy on atomic number with that of activity on the same.

In order for the surface recombination to proceed, if the Rideal mechanism is assumed, hydrogen atoms need be chemisorbed first on bare metal surface and yet their bonds must have moderate strength to be ready to break on the attack of a chemisorbed layer by hydrogen atoms from the gas phase so as to reproduce hydrogen molecules, for it is supposed that the activation energy for the latter process can be approximated to be proportional to the chemisorption bond strength[10].

Obviously, the reason why polyvalent metals have low activity comes from the fact that the Brillouin zone is almost fully filled and, accordingly, only a few sites can be used for hydrogen atom chemisorption. On the contrary, in the case of transition metals with unfilled *d*-orbitals capable of supplying ample sites for the appreciable adsorption to occur, it seems likely that the bond strength of chemisorption may play a more important role in

9) D. R. Stevenson, *J. Chem. Phys.*, **23**, 203 (1955).
The surface M-H bond can be calculated from Pauling's equation
$E(\mathrm{M-H})=1/2\{E(\mathrm{M-M})+E(\mathrm{H-H})\}+23.06(x_{\mathrm{M}}-x_{\mathrm{H}})^2$
where $E(\mathrm{M-M})$ is one sixth of the experimental sublimation energy and $E(\mathrm{H-H})$ is the dissociation energy of hydrogen molecule. The difference of electronegativity, $x_{\mathrm{M}}-x_{\mathrm{H}}$, can be approximated as equal to the dipole moment of the bond in debyes, the values of which are known from the data on contact potential.

In the three-atom reaction AB+C→A+BC, the activation energy can be approximated to be 0.055D′, where D′ is the dissociation energy plus zero point energy of AB molecule.

determining the catalytic activity than the number of sites. The correlation between the experimental heat of chemisorption and recombination activity may be understood, in a sense, in terms of different bond strength of chemisorption.

Even though it is not known at what degree of coverage recombination would proceed in the present experimental condition, the above slight deviation in the case of tantalum and tungsten might be attributed in part to such a character of adsorption as that when the heat of chemisorption of hydrogen on them decreases more markedly with increasing coverage than the case of nickel and iron[11].

However, there seems to be another explanation of the origin of low activities of some transition metals (e.g., Ti, Zr and Th). The transition metals can be grouped into two main classes[12], because of wide diversity of their behavior for hydrogen absorption. Namely, metals of group A absorb hydrogen endothermically and those of group B exothermically. As a whole, it is permissible to say that the former just corresponds to the more active group, and the latter to the less active group. Though it is not clear to what extent the parallelism between hydrogen absorption and adsorption would be preserved, some kinds of resemblance between them may be excepted to exist concerning the state of hydrogen atoms in and on metals. With this in mind, the different activities of group A and B metals can be explained in the following way: In the case of group B metals a hydride layer on which hydrogen atoms are adsorbed with difficulty, would be formed. Contrary to this, in the case of group A the usual monoatomic chemisorbed layer of hydrogen is formed serving as the intermediate compound of this recombination reaction.

Next, let us examine how the physical properties, e.g., work function, *d*-character and surface potential of chemisorbed hydrogen atom layer, may correlate to recombination activity.

In view of Suhrmann's old work it is permissible to say that the larger the work function, the higher the activity. As shown in Fig. 5 curve a, the values of work function[13] of the first long period metals show a tendency to increase with

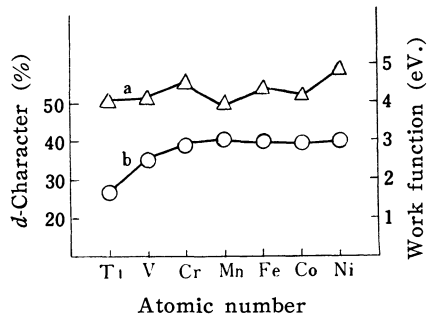

Fig. 5. Curve a, plot of the work function versus the atomic number and curve b, plot of the *d*-character versus the same.

the atomic number, despite the existence of rather complex ups and downs. Such a tendency as that where both catalytic activity and work function increase with the atomic number seems to support Suhrmann's view in the limited sense. However, this view may be, if anhything, an approximation, considering the fact that with respect to recombination activity, for example, the relation Ni<Co, Ti<Zr, and W<Mo was obtained by the present author, while the opposite relation holds for the work function.

Trapnell et al.[14] predicted that the *d*-character, which was defined by Pauling, might play an important role in the present reaction. From the present author's result it can be said that metals with large *d*-character have, on the whole, high activity. However, the monotonous increase of *d*-character with atomic number, as shown in Fig. 5 curve b is not adequate to explain the existence of two peaks in the activity-atomic number plot.

So long as the data[15] available up to date are concerned, metals can be roughly classified into two groups according to the magnitude of the absolute values of surface potential of chemisorbed hydrogen layer. The first group metals corresponding to the higher value, to which W (−0.48 or −0.65 V.) and Ta (−0.9, −1.2 or −0.43 V.) belong, have lower activity than the second corresponding to the lower value, to which Fe (−0.19 or −0.47 V.), Ni (−0.1 or −0.12 V.) and Co (0.06 V.) belong. This is naturally accepted from the statement given before, considering the fact that metals corresponding to large surface potential values have generally large experimental chemisorption heats. Accordingly, there seems to be no direct connection between

the degree of polarization of chemisorbed hydrogen atom and recombination activity.

Our attempt to explain the different recombination activities in terms of any one of physical properties proves less successful. This is probably because there is no strict theory capable of connecting the activity to the physical properties. At any rate, it is apparent that many more quantitative experiments remain to be done before a systematic account can be given concerning the origin of different activities of transition metals for this recombination reaction.

Summary

A study has been made of surface recombination of hydrogen atoms on various transition metals.

Hydrogen atoms were produced in the electric discharge tube by use of an alternating current. In order to prevent the reacting gas from reaching the undesired part of the sample, a method which may be called "an effusion method" was adopted here. The relative activity of two kinds of metal plates, stuck together by the solder or some such material, was determined, comparing the temperature rises of the sample by means of alternative exposure of each side surface to the reacting gas.

The following results were obtained:

a) Co> Fe> Ni> Ta> Mo> W> Ti> Cr > Mn> Cu

b) Zr> Ti> Th

c) Mo> U

These orders of activity were examined from several points of view through the comparison of recombination activity with the work function, the *d*-character, the experimental heat of chemisorption, etc.

The present results are still fragmentary but may suffice to show a qualitative trend.

The author wishes to express his gratitude to Professor S. Shida for his kind encouragement and to Mr. I. Yasumori for his helpful advice.

On the Reactivity of Amide Group of ε-Caprolactam Derivatives

By Naoya OGATA

(Received January 28, 1959)

The bond between carbon and nitrogen of an amide has appreciably double bond character due to resonance[1], and the configuration of amide linkage tends to be a planer structure and two configurations of *cis* and *trans* forms are possible as follows:

cis form *trans* form

ε-Caprolactam is the *cis* form[2], while monosubstituted acid amide RNHCOR′ is the *trans* form[3]. It was ascertained[4] that ε-caprolactam caused an amide interchange reaction with a *trans* amide and the reaction rate of ε-caprolactam with its ring oligomers became faster with the enlargement of the ring. When it is compared with the polymerization of ε-caprolactam, the equilibrium between ring and chain structures shifts to the ring form in the case of the polymerization of substituted ε-caprolactam such as γ-methyl-ε-caprolactam, and *N*-methyl-ε-caprolactam is too stable to polymerize[5]. Therefore, this study was undertaken in order to elucidate the difference in reactivity of amide group of ε-caprolactam derivatives.

Experimental

1. Determination of the Dipole Moment of Amides.—The dipole moment of ε-caprolactam, γ-methyl-ε-caprolactam and *N*-methyl-ε-caprolactam was determined in benzene solution at 25°C, as shown in Table I. The molecular polarization of ε-caprolactam or γ-methyl-ε-caprolactam decreased with the increase of the concentration but that of *N*-methyl-ε-caprolactam was almost constant, as shown in Fig. 1.

TABLE I. THE DIPOLE MOMENT OF ε-CAPROLACTAM DERIVATIVES

Sample	Dipole moment (D)
ε-Caprolactam	3.88
γ-Methyl-ε-caprolactam	5.48
N-Methyl-ε-caprolactam	4.23

2. Determination of the Reaction Rate of Hydrolysis.—ε-Caprolactam, *N*-methyl-ε-caprolactam or ring oligomers of ε-caprolactam which were obtained by repeated recrystallizations of the water extract of poly-ε-capramide, at the amount of 10^{-2} mol., was heated in 20 ml. of sulfuric acid in sealed glass tubes and then the solution was neutralized quickly. The quantities of ε-aminocaproic acid formed in the case of ε-caprolactam or its ring oligomers could be determined by the formol titration method but the quantitative determination of *N*-methyl-ε-aminocaproic acid was possible by neither the formol titration nor the method using an ion exchange resin. *N*-methyl-ε-aminocaproic acid could be quantitatively determined in the mixed solvent of ethanol and 30% formalin (1:1). The neutralized solution of *N*-methyl-ε-aminocaproic acid was filled up to 50 ml. and 10 ml. of the solution were dried and then the residue was dissolved in 10 ml. of ethanol and 30% formalin. The solution was titrated by 0.1 N sodium hydroxide solution with phenolphthalein as an indicator. These results are shown in Tables II, III and IV.

The hydrolysis of lactam in the presence of large quantities of water is the first order reaction and the rate constant is calculated by the following equation, where a designates the mole of amide and x the mole of amino acid formed at t hr.

$$k=2.303/t\cdot\log a/(a-x) \qquad (1)$$

The rate constants, which are shown in Table V, are proportional to the concentration of sulfuric acid, as shown in Figs. 2 and 3.

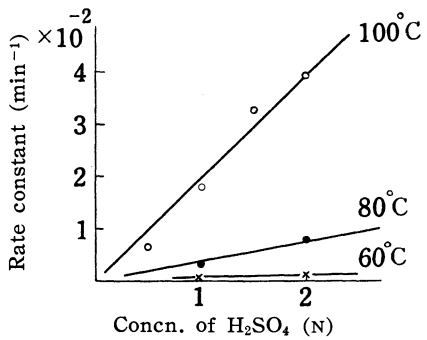

Fig. 2. The rate constant of hydrolysis of ε-caprolactam.

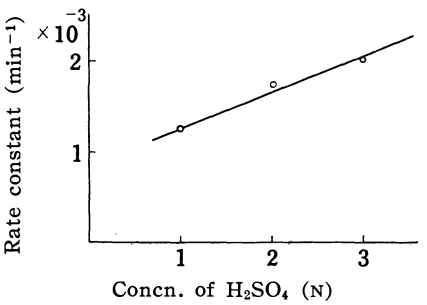

Fig. 3. The rate constant of hydrolysis of *N*-methyl-ε-caprolactam at 100°C.

TABLE V. THE RATE CONSTANT OF HYDROLYSIS OF ε-CAPROLACTAM DERIVATIVES

Sample	Temp. (°C)	Concentration of H_2SO_4 (N)	Rate constant (min^{-1})

3. Determination of Infrared Spectrum.—The infrared spectrum of ε-caprolactam, ring-dimer, -trimer and -tetramer, which is shown in Figs. 4, 5, 6 and 7, was measured in a potassium bromide disc with a Hitachi model EPI-2 spectrophotometer, with a rock-salt prism. The absorption band of N-H of ε-caprolactam appears at 3215 and 3077 cm^{-1}, while that of ring-dimer at 3279 and 3077 cm^{-1}. The absorption band of CO of ε-caprolactam appears at 1650 cm^{-1}, while that of ring-dimer at 1639 cm^{-1}. The spectrum of ring-dimer shows absorption maximum at 1555 cm^{-1}, which is not found in ε-caprolactam. The absorption bands of N-H of ring-trimer and -tetramer appear at 3289 and 3077 cm^{-1} and the spectra come to resemble that of poly-ε-capramide (Fig. 8).

When dry hydrogen chloride was introduced into carbon tetrachloride solution of ε-caprolactam, a white crystal was precipitated. This crystal was decomposed easily in the air, evolving hydrogen chloride. It was filtered off in dry hydrogen chloride atomosphere and dried, and then its infrared spectrum was measured, in a potassium bromide disc, which is shown in Fig. 9. The absorption bands of N-H at 3215 and 3077 cm^{-1} disappear and new ones appear at 2730, 2500 and 2398 cm^{-1}. The absorption band of N-H of dibutylamine $(C_4H_9)_2N$-H appears only at 3311 cm^{-1}, while that of its hydrochloride at 2564, 2463 and 2398 cm^{-1}. Therefore, these new bands are estimated to be the absorption of N-H of the reaction product which was produced by adding hydrogen chloride to the nitrogen atom of ε-caprolactam. The absorption band of CO of the

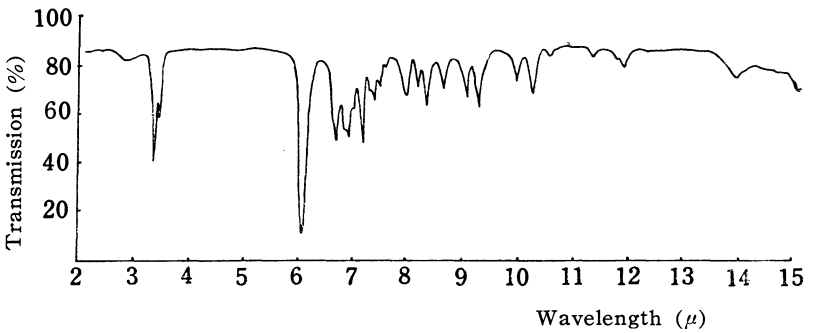

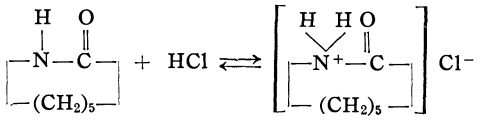

Fig. 11. The infrared spectrum of *N*-methyl-ε-caprolactam (liquid).

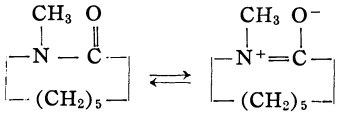
reaction product shifts from 1650 to 1681 cm^{-1}.

When dry hydrogen chloride was introduced into carbon tetrachloride solution of *N*-methyl-ε-caprolactam, a white crystal was precipitated but it dissolved again by the further introduction and *N*-methyl-ε-caprolactam was floated on carbon tetrachloride. The infrared spectrum of the crystal formed at first was measured in a potassium bromide disc, which is shown in Fig. 10. A new broad absorption appears at 2398 cm^{-1} which is tentatively assigned to the N-H band of the addition product of *N*-methyl-ε-caprolactam. The absorption band of CO of *N*-methyl-ε-caprolactam appears at 1645 cm^{-1}, which is shifted to the lower frequency than that of normal carbonyl compound, as shown in Fig. 11.

Discussion

ε-Caprolactam forms an addition compound with hydrogen chloride in carbon tetrachloride solution as follows



The ring opening reaction of ε-caprolactam in the presence of the ammonium cation[6] is presumed to be caused by the addition of the ammonium cation to the amide group.

The rate constant of hydrolysis of *N*-methyl-ε-caprolactam is about one twentieth of that of ε-caprolactam. The activation energy of hydrolysis of ε-caprolactam is calculated from the temperature dependence of the rate constants to be 20 kcal./mol., while that of *N*-methyl-ε-caprolactam 22 kcal./mol.

Since the molecular polarization of *N*-methyl-ε-caprolactam is almost constant with the increase of concentrations, it is expected that molecules do not associate at all. However, the absorption of CO in its infrared spectrum appears in much lower frequency than that of carbonyl compounds (about 1700 cm^{-1}). The dipole moment of *N*-methyl-ε-caprolactam is larger than that of ε-caprolactam.

From these results as stated above, it is expected that the amide linkage of *N*-methyl-ε-caprolactam has considerably ionic character due to resonance by the effect of methyl group as shown below and the stability of ring structure increases.

The rate constant of hydrolysis of ring-dimer is remarkably smaller than that of ε-caprolactam and that of ring-oligomers becomes faster as the ring becomes larger. It is ascertained[2,7] that the absorption of N-H of the *trans* or the *cis* amide appears in the 3370 to 3290 cm^{-1} or the 3240 to 3170 cm^{-1} regions in the infrared spectrum. The infrared spectrum of ring dimer, in the crystalline state, shows absorption maxima at 3279 and 3077 cm^{-1} and the configuration is expected to be not *cis*-[8] but *trans*- form. As the absorption band of CO of ring dimer appears in lower frequency than that of ε-caprolactam, ring-trimer or -tetramer, the low reactivity of ring dimer can be explained from the expectation that two amide groups are particularly favorable for the formation of two intramolecular hydrogen bonds and its structure is presumed to be as shown in Fig. 12. As amide groups lie too far apart to form the intramolecular hydrogen bond with the enlargement of the ring, the reactivity of ring oligomers becomes larger.

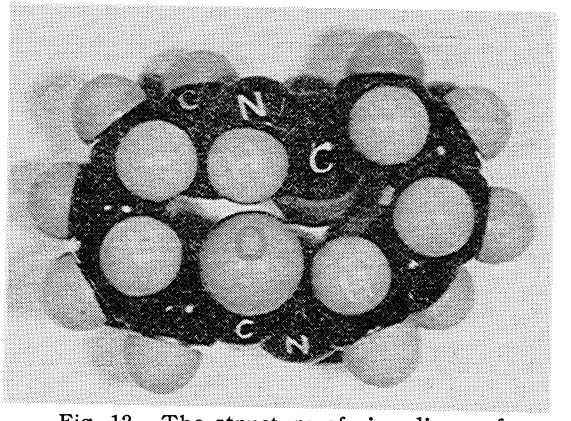


Fig. 12. The structure of ring dimer of ε-caprolactam.

Summary

The dipole moments, infrared spectra and rate constants of hydrolysis of ε-caprolactam derivatives have been determined in order to elucidate the difference in reactivity. The great stability of *N*-methyl-ε-caprolactam is expected, due to the increase of reasonance of amide linkage. Ring dimer of ε-caprolactam is stable for hydrolysis due to the strong intramolecular hydrogen bonds and the reactivity

(Received September 4, 1958)

The total structure of de-(hydroxymethylene)-lycoctonine (I) was determined by Przybylska and Marion[1] by X-ray crystallographic method, and that of lycoctonine (II) was proposed by Edwards, Marion and Stewart[2] on the basis of chemical evidences for the location of the hydroxymethylene group.

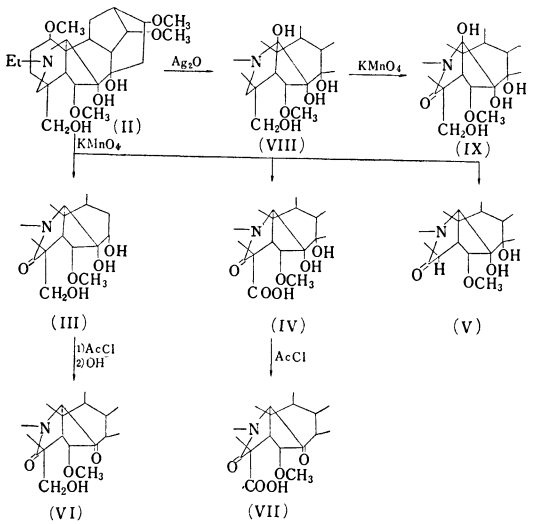
(I)

Fig. 1.

Most of the reactions and products have been interpreted[2,3] on the basis of these formulae; some of them are indicated in Fig. 2.

Since two new oxidation products from lycoctonine have been obtained, the present authors wish to report several arguments concerning their chemical properties and their relationship to other lycoctonine derivatives.

Oxidation of lycoctonam (III)[4] with chromic anhydride in N sulfuric acid solution gave three compounds, lycoctonamic acid (IV)[4], formic acid and a new neutral



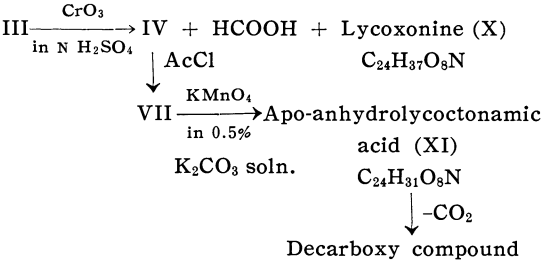


Fig. 2.

product, lycoxonine (X), $C_{24}H_{37}O_8N \cdot 4H_2O$, m. p. 80~83°C, $[\alpha]_D$ +40.8°.

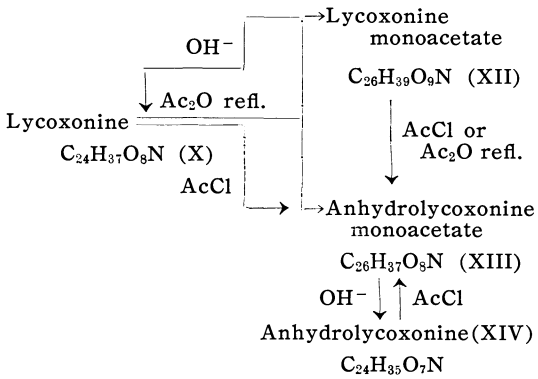
2) O. E. Edwards, Léo Marion and D. K. R. Stewart, ibid., **34**, 1351 (1956).

3) O. E. Edwards, Léo Marion and K. H. Palmer, *J. Org. Chem.*, **24**, 1372 (1957).



4) O. E. Edwards and Léo Marion, *Can. J. Chem.*, **30**, 627 (1952). These compounds had been isolated independently in these laboratories. (A report on them was read before the Annual Meeting of the Chemical Society of Japan, held in Tokyo, April, 1949, and the Meeting of the Hokkaido Branch of the Chemical Society of Japan, held in Sapporo, July, 1949). The names oxolycoctonine, L-acid and anhydro-L-acid were assigned for III, IV and VI, respectively.

On oxidation of anhydrolycoctonamic acid (VII)[4] with potassium permanganate in 0.5 per cent potassium carbonate solution, a new acid, apo-anhydrolycoctonamic acid (XI), $C_{24}H_{31}O_8N$, m. p. 183~184°C, $[\alpha]_D$+37°, was yielded.

Lycoxonine (X) contains an *N*-ethyl and four methoxyl groups as does lycoctonam (III). In the infrared spectra of both compounds no decisive difference could be detected in the hydroxyl region because of the broad absorption. On the other hand, the bands due to lactam carbonyl were distinctly different (lycoxonine showed at 1631 cm^{-1} and lycoctonam at 1618 cm^{-1}). The same shift has been observed[4] between lycoctonam and the compounds in which the primary hydroxyl group has been acetylated or replaced by hydrogen. Since, from the above observations, the properties of the primary hydroxyl group were considered to be different, the acetylation of lycoxonine was examined.

Lycoxonine was acetylated with acetyl chloride at room temperature yielding anhydrolycoxonine monoacetate (XIII), m. p. 232~234°C, $[\alpha]_D$+37.8°, or with acetic anhydride under reflux yielding the same anhydro monoacetate (XIII) and lycoxonine monoacetate (XII), m. p. 222~225°C. The compound XIII gave anhydrolycoxonine (XIV), m. p. 160~162°C, by hydrolysis.

However, lycoxonine is not acetylated on treatment with acetic anhydride and pyridine at room temperature, but lycoctonam (III) or other lycoctonine derivatives containing original the primary hydroxyl group have been readily acetylated[4] under the same conditions. Thus the formation of anhydro monoacetate (XIII) indicates the existence of the original glycol system and at least another hydroxyl group in lycoxonine (X). However, the hydroxyl group to be acetylated in lycoxonine is no longer the original primary one in view of the difficulty of acetylation.

This interpretation is in concordance not only with the properties of lycoxonine (whilst lycoctonam has been oxidized readily, lycoxonine is stable), but also with the observation of the infrared spectra of anhydrolycoxonine (XIV) and anhydrolycoctonam (VI) (the latter compound is derived from lycoctonam (III) by pinacolic dehydration). The absorption band at 3413 cm^{-1}, characteristic of the hydroxyl in compound VI, disappeared and a new band at 3534 cm^{-1} appeared in compound XIV. From the above results of acetylation, oxidation, and examination of spectra and compositions, it may be concluded that the properties of lycoxonine (X) are probably consistent with a structure in which the hydroxymethylene of lycoctonam (III) has been removed and a hydroxyl group has been produced.

It has been reported[2-4] that the substituent group, which is located at the bridgehead of the azabicyclo [3,3,1]-nonane system in the skeleton of lycoctonine, is readily removed. For example, de-(hydroxymethylene)-lycoctonam (V) has been formed during the permanganate oxidation of lycoctonine, and it has been obtained also by decarboxylation of lycoctonamic acid (IV). Thus, on the basis of the ready removal of the hydroxymethylene group, it may be considered that compound V is an intermediate in the formation of lycoxonine from lycoctonam. If this consideration is correct, the formation of formic acid during the oxidation will be explained by the analogous mechanism which has been suggested by Edwards, Marion and Stewart[2].

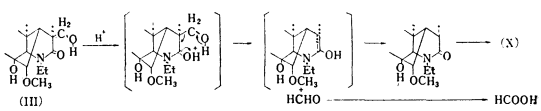


Fig. 3.

However, on the same treatment with chromic anhydride in N-sulfuric acid solution, de-(hydroxymethylene)-lycoctonam (V) is very stable against the reagents. On more vigorous treatment of lycoctonam (III) with the acid only, the hydroxymethylene group is left intact while lycoctonam undergoes extensive change[5]. It is, therefore, unlikely that de-(hydroxymethylene)-lycoctonam (V) is an intermediate. An attempt was made to determine the location of the new hydroxyl

5) O. E. Edwards, Léo Marion and R. A. McIvor, *Can. J. Chem.*, **32**, 708 (1954).

group, but decisive conclusions have not yet been obtained.

Recently an interesting compound, which may be related to the change from lycoctonam to lycoxonine, has been reported by Edwards, Marion and Stewart[2]. This compound was obtained by the action of lead tetraacetate on hydroxylycoctonam (VIII). It was suggested that it had a structure in which the hydroxymethylene group of compound VIII had been replaced by a new hydroxyl group and the glycol system had been cleaved.

Therefore, except for the cleavage of glycol, the properties of this compound appear to be closely analogous to those of lycoxonine. The same investigators[2] suggested in addition that it is difficult to demonstrate whether the skeleton of hydroxylycoctonine[6] (VIII) is or is not the same as that of lycoctonine. Hence, it is of interest to compare the action of chromic anhydride upon lycoctonam (lycoctonine skeleton) with that upon hydroxylycoctonam (hydroxylycoctonine skeleton), and to investigate whether the new hydroxyl group in lycoxonine is or is not located at the same position as that of the compound obtained by the above workers.

On treatment of hydroxylycoctonam (IX) with chromic anhydride in N sulfuric acid solution, two acids, Y-acid, m. p. 193~195°C, and C_I-acid, m. p. 220~222°C, and two neutral compounds, Y, m. p. 177~180°C, and Z, m. p. 226~227°C, were obtained. The properties of these compounds will be reported later.

The new acid, apo-anhydrolycoctonamic acid (XI), obtained by alkaline permanganate oxidation of anhydrolycoctonamic acid (VII), still contains an *N*-ethyl group. It shows the lactam band at 1597 cm^{-1} in the infrared spectrum, and gives a decarboxy-compound, m. p. 105~110°C. These evidences have been observed[4] analogously as in the case of the starting acid (VII), but the apo-acid (XI) contains only three methoxyl groups while the starting acid contains four.

In the ultraviolet spectrum the apo-acid (XI) shows the maximum at 305 mμ (log ε 2.07) which is usual in position but unusual in intensity; the maximum of dehydro-compounds from lycoctonine has been shown at 305 mμ (log ε 1.89). In addition, an oxime of the decarboxy-compound derived from the apo-acid shows the ultraviolet maximum still at 305 mμ, but the intensity is usual (log ε 1.85).

From the above observations, the conversion of anhydro-lycoctonamic acid (VII) to apo-anhydrolycoctonamic acid (XI) seems to involve the loss of one methoxyl and the formation of one carbonyl group. The detection of the produced carbonyl group was unsuccessful in the infrared spectrum, but the above consideration is supported by the chemical evidence that, whilst the starting acid VII is resistant to carbonyl reagents, the apo-acid consumes bromine quickly although the starting acid does not. The decarboxy compound from the apo-acid gave a 2,4-dinitrophenylhydrazone, m. p. 221~222°C, and an oxime, m. p. 140~142°C.

In the apo-acid (XI), the location of the removed methoxyl and the newly produced carbonyl group have not yet been determined. However, it is sure that the carbonyl group in anhydrolycoctonamic acid (VII) exerted some effects upon this conversion, because the analogous conversion was not observed in lycoctonamic acid (IV).

Experimental

Lycoctonam (III).—To a solution of 1 g. of lycoctonine in 70 cc. of acetone containing 7 cc. of water, was added 0.6 g. of powdered potassium permanganate in small quantities at room temperature; the resulting solution was left at room temperature overnight. After filtration of manganese dioxide, the filtrate was evaporated to syrup under reduced pressure. When the syrup was further concentrated in a desiccator, crystalline lycoctonam was separated. A further amount was deposited by the addition of ether. Thus 0.7 g. of crystal was obtained. This substance was recrystallized from ethyl acetate in needles, m. p. 95~98°C, $[\alpha]_D^{14}$ +67.5° (C, 1.10 in water).

Anal. Found: C, 58.05; H, 8.24; N, 2.74; H_2O, 6.94. Calcd. for $C_{25}H_{39}O_8N \cdot 2H_2O$: C, 58.01; H, 8.37; N, 2.71; H_2O, 6.96%.

In the infrared spectrum in Nujol, this compound showed broad bands at 3367, 3401 and 3460 cm^{-1} in the region of hydroxyl group. This compound was identical with lycoctonam, obtained in the same way as reported by Edwards and Marion[4].

Oxidation of Lycoctonam with Chromic Acid.—To a solution of 4 g. of lycoctonam in

6) It was reported in a previous paper[7] that hydroxylycoctonine was obtained from lycoctonine on oxidation with Ag_2O; Cookson and Trevett[8] reported that they had obtained also the same compound by means of lead tetraacetate. The present authors found that this compound was produced by treatment not only with the above reagents but also with potassium ferricyanide.

7) H. Suginome and K. Ohno, *J. Fac. Sci., Hokkaido Univ., Ser. III. Chem.*, **4**, 36 (1950).

8) R. C. Cookson and M. E. Trevett., *Chem. & Ind.*, **1956**, 276.

100 cc. of N sulfuric acid was added a solution of chromic anhydride in a small volume of water with ice-cooling. When the resulting solution was left at room temperature overnight, an acidic product a was separated in needles. After filtration of the acid a, the filtrate was extracted with chloroform. The chloroform extract containing the acidic and neutral materials was shaken with diluted aqueous ammonia. On evaporation the chloroform solution gave 1.15 g. of the neutral product, lycoxonine (see below).

When the aqueous ammonia layer was acidified with dilute sulfuric acid, an acidic product b was obtained. Thus the combined acidic product, a and b, weighed 1.45 g. After recrystallization from aqueous ethanol, this acid was confirmed to be identical with lycoctonamic acid (IV)[4], m. p. 200~203°C, after softening at 95~100°C, $[\alpha]_D^{14}$+94.2° (C, 1.66 in ethanol).

Estimation of Formic Acid Formed during Oxidation. — Lycoctonam was oxidized with chromic anhydride in the same way as described above. After being kept overnight, the major amount of the solution was distilled. When the distillate was just neutralized with 0.05 N sodium hydroxide and evaporated to dryness, crystals were obtained which decomposed at 250~253°C (authentic sodium formate decomposed at 255°C). The acidic material was confirmed to be formic acid by the chromotropic acid test after it was reduced to formaldehyde.

Lycoxonine (X).— This compound was obtained as described under oxidation of lycoctonam. It crystallized from water as a tetrahydrate in rhombic forms. After recrystallization it melted at 80~83°C and had $[\alpha]_D^{13}$+40.8° (C, 1.66 in ethanol). In the infrared spectrum in Nujol, lycoxonine showed the broad band at 3448 cm^{-1} in the region of hydroxyl group.

Anal. Found: C, 53.75; H, 8.48; H_2O, 13.52. Calcd. for $C_{24}H_{37}O_8N \cdot 4H_2O$: C, 53.42; H, 8.41; H_2O, 13.35%.

This compound was subjected to the Micro-Zeisel methoxyl, Herzig-Meyer *N*-alkyl and Ginger *C*-methyl[9] determinations.

Anal. Found: C_2H_5, 4.83; OCH_3, 23.20, CH_3, 2.45. Calcd. for $C_{18}H_{28}O_8N(CH_2 \cdot CH_3)(OCH_3)_4$: C_2H_5, 5.36; 4-OCH_3, 23.00; CH_3, 2.78%.

De-(hydroxymethylene)-lycoctonam (V).— Since this compound could not be isolated directly from the oxidation products of lycoctonine, the present authors obtained it by pyrolysis of lycoctonamic acid in the same manner as described in Edwards and Marion's report[4]. The compound obtained was recrystallized from water as a trihydrate, m. p. 110~113°C.

The melting point and the form of the trihydrate were not in agreement with the above report[4]. However, the derivatives of this compound, de-(hydroxymethylene)-lycoctonine perchlorate and anhydro-de-(hydromethylene)-lycoctonam, were well in agreement with those of the same report.

Upon subjection to the same treatment with chromic anhydride as described under oxidation of lycoctonam, this compound V did not react for more than three days.

Acetylation of Lycoxonine.—(i) Lycoxonine tetrahydrate (0.5 g) was treated with 2 cc. of acetyl chloride in a sealed tube at room temperature overnight. Excessive reagent was removed under reduced pressure, and water was added. On standing, the resulting aqueous mixture gave 0.2 g. of a crystalline product, anhydrolycoxonine monoacetate (XIII). It was recrystallized readily from ethanol in rosette forms, m. p. 225~230°C, $[\alpha]_D^{15}$+37.8° (C, 3.30 in ethanol). The ultraviolet absorption spectrum showed the maximum at 305 mμ (log ε 1.85).

Anal. Found: C, 63.38; H, 7.72; N, 2.67. Calcd. for $C_{24}H_{34}O_6N(OCOCH_3)$: C, 63.52; H, 7.59; N, 2.85%.

(ii) Anhydrous lycoxonine (0.1 g.), obtained by drying the hydrate under reduced pressure over phosphorous pentoxide, was treated with 1 cc. of acetic anhydride and 0.5 cc. of pyridine in a sealed tube at room temperature, but lycoxonine was recovered unchanged after more than 80 hr.

(iii) A solution of 0.5 g. of anhydrous lycoxonine in 0.7 g. of acetic anhydride was refluxed for 3 hr. and the solution was then concentrated to a syrup in a desiccator under reduced pressure. When a small amount of water was added to the resulting syrup, a crystalline product was obtained. This product could be separated into two parts by treating it with hot water. The first part was insoluble in hot water whilst the second was readily soluble. The insoluble material was identical with anhydrolycoxonine monoacetate which was obtained by acetyl chloride treatment (i). The readily soluble material was lycoxonine monoacetate (XII); it was recrystallized from water in prisms, m. p. 222~225°C.

Anal. Found: C, 61.35; H, 7.78; $OCOCH_3$, 10.43. Calcd. for $C_{24}H_{36}O_7 \cdot (OCOCH_3)$: C, 61.28; H, 7.71; $OCOCH_3$, 10.02%.

Lycoxonine monoacetate gave anhydrolycoxonine monoacetate upon further treatment with acetyl chloride or acetic anhydride as described above.

Anhydrolycoxonine (XIV).—Anhydrolycoxonine monoacetate was saponified by 50% potassium hydroxide in aqueous methanol on a steam bath for 30 min. The solution was neutralized with dilute hydrochloric acid and evaporated under reduced pressure to dryness. The resulting residue was extracted with ethanol. When the alcoholic solution was evaporated at room temperature, anhydrolycoxonine was separated in plates. After recrystallization from aqueous ethanol, it melted at 160~162°C and showed the maximum at 305 mμ (log ε 1.85) in ultraviolet spectrum.

Anal. Found: C, 64.38; H, 7.90; N, 3.21. Calcd. for $C_{24}H_{35}O_7N$: C, 64.12; H, 7.85; N, 3.12%.

Anhydrolycoctonamic Acid (VII).—Lycoctonamic acid (1 g.) was treated with 4 cc. of acetyl chloride in a sealed tube overnight. After evaporation of excess of the reagent, water was

9) L. G. Ginger, *J. Biol. Chem.*, **156**, 453 (1944).

added to the resulting residue. Then, 0.5 g. of an amorphous material was obtained, which crystallized readily from ethanol in prisms, m. p. 177~178°C, $[\alpha]_D^{13}$+52.8° (C, 1.00 in ethanol), λ_{max} 305 mμ (log ε 1.87). This product was identical with anhydrolycoctonamic acid reported by Edwards and Marion[4].

Anal. Found: C, 62.47; H, 7.38. Calcd. for $C_{25}H_{35}O_8N$: C, 62.87; H, 7.39%.

Apo-anhydrolycoctonamic Acid (XI).—To a solution of 0.5 g. of anhydrolycoctonamic acid in 100 cc. of water containing 0.5 g. of potassium carbonate, 0.3 g. of powdered potassium permanganate was added in portions at room temperature. The potassium permanganate was consumed very slowly in three days.

The manganese dioxide was filtered off and washed with 0.1% potassium carbonate solution. When the combined filtrate and washings were acidified with diluted sulfuric acid, apo-anhydrolycoctonamic acid was obtained. Yield, 0.19 g. It was recrystallized from ethanol in thin plates, m. p. 183~184°C, $[\alpha]_D^{13}$+37° (C, 1.00 in ethanol). This acid was considerably less soluble in ethanol than anhydrolycoctonamic acid. The ultraviolet spectrum of this acid showed the maximum at 305 mμ (log ε 2.07).

Anal. Found: C, 62.14; H, 6.69; OCH_3, 20.20. Calcd. for $C_{24}H_{31}O_8N$: C, 62.45; H, 6.77; 3-OCH_3, 20.17%.

On oxidation in the same way as described above, lycoctonamic acid was not affected.

The apo-acid decolorized one mole of bromine within 30 min. in acetic acid, while anhydrolycoctonamic acid did not do so within 24 hr.

Decarboxy Compound of Apo-anhydrolycoctonamic Acid.—(i) On treatment of apo-anhydrolycoctonamic acid in the same way as reported by Edwards and Marion[4], no crystalline product was isolated.

(ii) A solution of 40 mg. of the apo-acid in 0.3 cc. of acetic anhydride was refluxed for 3 hr. The solution was poured into 10 cc. of water, and the resulting aqueous solution was extracted with chloroform. After being washed with diluted potassium hydroxide and then with water, the chloroform extract was evaporated to dryness. When ether was added to the residue, crystals were deposited from the ether solution in prisms. The substance was recrystallized from water as a polyhydrate, which melted at 110~113°C after softening at 100°C.

Formation of Oxime and 2,4-Dinitrophenylhydrazone from the Decarboxy Compound.—(i) To a solution of 40 mg. of the decarboxy compound in 1 cc. of ethanol was added a solution of 40 mg. of hydroxyl amine hydrochloride in 0.4 cc. of water containing 40 mg. of potassium carbonate; the resulting solution was warmed on a steam bath for 4 hr. When the alcoholic solution was concentrated under reduced pressure, the oxime of the decarboxy compound was separated in needles, m. p. 140~142°C. In the ultraviolet spectrum, this oxime showed the maximum at 305 mμ (log ε 1.85).

Anal. Found: N, 6.54. Calcd. for $C_{23}H_{32}O_6ON$: N, 6.48%.

(ii) To a solution of 20 mg. of the decarboxy compound in 2 cc. of ethanol was added four drops of the solution of 0.5 g. of 2,4-dinitrophenylhydrazine and 1 cc. of 90% sulfuric acid in 7 cc. of ethanol. When the resulting solution was allowed to stand at room temperature for several hours, it deposited 2,4-dinitrophenylhydrazone of the decarboxy compound in yellow needles, m. p. 221~222°C.

Anal. Found: N, 11.54. Calcd. for $C_{29}H_{35}O_9N_5$: N, 11.72%.

On treatment of anhydro-de-(hydroxymethylene)-lycoctonam with either of the above reagents, the starting compound was recovered without change.

Hydroxylycoctonine (VIII).—A solution of lycoctonine in 20 cc. of methanol was mixed with a solution of 1.2 g. of potassium hydroxide in 20 cc. of methanol. Then, a solution of 5.4 g. of potassium ferricyanide in 25 cc. of water was added to the above alcoholic solution and cooled in water. Then the resulting solution was left at room temperature overnight. After evaporation of the methanol under reduced pressure, the solution was extracted with chloroform. The chloroform extract was evaporated to dryness after being washed with water and then dried with anhydrous sodium sulfate. When ether was added to the resulting residue, 2 g. of the product was obtained. It crystallized readily from ethyl acetate in little buttons. After recrystallization from the same solvent, the compound melted at 152~154°C and did not depress the melting point of an authentic hydroxylycoctonine, prepared by silver oxide oxidation[7].

Hydroxylycoctonam (IX).—This compound was obtained by treatment analogous to that reported by Edwards and Marion[10]. To a solution of 5.32 g. of hydroxylycoctonine in 400 cc. of water was added 3.45 g. of powdered potassium permanganate in small portions at room temperature. After the addition of the entire amount of the oxidant, the reaction mixture was left at room temperature overnight, and the resulting manganese dioxide was filtered off. The filtrate was extracted with chloroform, and the resulting extract was washed with diluted hydrochloric acid and then with water. When the washed chloroform solution was evaporated, a resinous material remained. This material was crystallized by the addition of acetone-ether. It was recrystallized from acetone as a monohydrate, m. p. 200~203°C.

Anal. Found: C, 58.31; H, 7.98. Calcd. for $C_{25}H_{39}O_9N \cdot H_2O$: C, 58.24; H, 8.01%.

Oxidation of Hydroxylycoctonam (IX) with Chromic Anhydride.—In 10 cc. of 5% sulfuric acid solution, 0.51 g. of hydroxylycoctonam was treated with 0.4 g. of chromic anhydride in just the same way as described under oxidation of lycoctonam. The oxidation of this compound was slower than that of lycoctonam, and required more than a week. After reducing the oxidant

10) O. E. Edwards and Léo Marion: *Can. J. Chem.* **32**, 1146 (1954).

the solution was extracted with chloroform, and the extract was shaken with dilute aqueous ammonia. When the chloroform layer was evaporated, there remained resinous products a. Yield, 0.20 g. (see below).

The aqueous layer was acidified with dilute hydrochloric acid and then extracted with chloroform. On evaporation of the solvent, the chloroform extract gave acidic products which were crystallized by the addition of ether. These products were separated into two acids, one readily soluble in acetone and the other less soluble. The readily soluble acid was recrystallized from acetone-ethanol in prisms melting at 220~222°C (decomp.) after softening at 200°C. This acid was named C_1-acid. The less soluble acid was crystallized from hot water in plates, melting at 193~195°C. This acid was named Y-acid.

The neutral product a was separated into two parts, one insoluble in benzene and the other soluble. The insoluble part crystallized from acetone in small buttons, which weighed 80 mg. each and melted at 177~180°C after recrystallization from acetone. This neutral product was named Y. The benzene-soluble part, weighing 100 mg., was subjected to chromatography on alumina. Elution with 5% methanol in benzene gave a product which crystallized from acetone in rhombic forms, m. p. 226~227°C. This product was named Z.

The Aconite Alkaloids. XXX. On Lucidusculine*

By Harusada SUGINOME, Takashi AMIYA and Takeo SHIMA

(Received November 15, 1958)

Lucidusculine, $C_{24}H_{35}O_4N$, was previously isolated from the roots of *Aconitum luciduscului* Nakai by R. Majima and S. Morio[1,2], and studied by H. Suginome and his collaborators[3-5]. Lucidusculine is a monoacetate of a trihydric amino alcohol, luciculine, $C_{22}H_{33}O_3N \cdot H_2O$[2,5], which was obtained by hydrolysis of the former. The presence of an *N*-ethyl group was confirmed by the formation of mesoluciculine, $C_{21}H_{31}O_3N \cdot H_2O$[5], on Hofmann degradation of luciculine. Further, as lucidusculine absorbed one mole of hydrogen on catalytic hydrogenation, it was assumed that the base has one double bond[4].

On the basis of the above results, the partial structure of lucidusculine was previously represented as:

$$C_{20}H_{25} \begin{cases} (OH)_2 \\ OCOCH_3 \\ >N-C_2H_5 \\ 1\,F \end{cases}$$

Luciculine shows absorption peaks in the infrared spectrum at 6.09 and 11.27 μ and lucidusculine diacetate[4] shows peaks at 6.08 and 11.32 μ. Nevertheless, dihydrolucidusculine diacetate shows no peak near the above-mentioned region[6]. These data suggest the presence of a terminal methylene group in each of luciculine and lucidusculine diacetate, which is also supported by the isolation of formaldehyde as the dimedone complex in ozonolysis experiment with lucidusculine and lucidusculine diacetate. Further, mesoluciculine gave 0.45 mol. of acetic acid on Kuhn-Roth oxidation, while dihydromesoluciculine[7] yielded 0.92 mol. of acetic acid on the same oxidation. The difference (0.47 mol.) can be explained by the following scheme:

$$\underset{\text{Mesoluciculine}}{>C=CH_2} \xrightarrow{H_2} \underset{\text{Dihydromesoluciculine}}{>CH-CH_3}$$

From these results and the biogenesis of the aconite alkaloids[8], the formula of

lucidusculine may be extended further as follows:

$$C_{18}H_{23}\begin{cases}(OH)_2\\OCOCH_3\\>N-C_2H_5\\>C=CH_2\end{cases}$$

Lucidusculine is assumed to have a hexacyclic structure based on the skeletal formula $C_{19}H_{29}N$[3].

Amiya and Nagaoka previously isolated lucidusculine and jesaconitine from the roots of *Aconitum* species from Shoya, Hidaka in Hokkaido[9]. Extraction with ethanol and the following treatment were done in the same way as in the case of other aconite roots[10], and these two alkaloids were isolated from the water-insoluble portion. Now, quantitative separation of these alkaloids from mother-roots and from daughter-roots of the above-mentioned *Aconitum* plants by Ochiai's chromatographic method[11] was tried. As a model experiment, aconitine, jesaconitine and lucidusculine were dissolved in chloroform which was saturated with concentrated ammonia water[12], the solution was passed through a column of alumina, and the column was eluted with chloroform-ammonia water, followed by acetone and then methanol. The residue from the chloroform-ammonia water elute was found to be composed of aconitine and jesaconitine and that from the acetone elute was composed of lucidusculine only. Thus, the same procedure was applied to the above-mentioned water-insoluble portions with results as follows:

Weights of dried roots	Water-insoluble portions	Crystalline alkaloids	
Mother-roots 4.5 kg.	4.4 g.	Jesaconitine	0.4 g.
		Lucidusculine	0.2 g.
Daughter-roots 4.5 kg.	20.5 g.	Jesaconitine	1.4 g.
		Lucidusculine	0.8 g.

Experimental

Ozonolysis of Lucidusculine.—Lucidusculine (95 mg.) was ozonized in 20 ml. of chloroform-acetic acid (1 : 1 by volume) at −25～−35°C with three moles of ozone. The solution was hydrogenated with 5% palladium-carbon for 15 min. After removal of the palladium-carbon, dimedone (75 mg.) was added to the solution. After standing overnight, the solvents were completely evaporated in vacuo. To the residue, 10% sodium hydroxide solution (5 ml.) was added. When the solution was washed with chloroform and acidified with hydrochloric acid, the crystalline dimedone-formaldehyde complex was separated. It was extracted with chloroform and the chloroform solution was evaporated in vacuo to give a crystalline residue. Recrystallization from ethanol yielded 10 mg. of the dimedone-formaldehyde complex, which melted at 190°C and showed no depression of the melting point on admixture with an authentic specimen.

Ozonolysis of Lucidusculine Diacetate.—Lucidusculine diacetate (350 mg.) was ozonized and treated in the same way. Thus, 65 mg. of the dimedone-formaldehyde complex was obtained.

Kuhn-Roth Oxidation.—Mesoluciculine and dihydromesoluciculine were oxidized by L. G. Ginger's method[13]. The results were as follows:

Mesoluciculine: *Anal.* Found: (C)-CH_3, 1.84 (0.45 mol.). Calcd. for $C_{21}H_{31}O_3N\cdot H_2O$: 1 (C)-$CH_3$, 4.13%.

Dihydromesoluciculine: *Anal.* Found: (C)-CH_3, 3.71 (0.92 mol.). Calcd. for $C_{21}H_{33}O_3N\cdot 1.5H_2O$: 1 (C)-$CH_3$, 4.01%.

Model Experiment of Separation.—Lucidusculine, aconitine and jesaconitine (100 mg. each) were dissolved in 10 ml. of chloroform-ammonia water, the solution was passed through a column (1.4 cm. in diameter) of 90 g. of alumina, and the column was eluted with 280 ml. of chloroform-ammonia water, 100 ml. of acetone and 100 ml. of methanol in succession. The chloroform-ammonia water elute gave 200 mg. of a residue. The solution of the residue (0.661 mg.) in methanol (10 ml.) gave an ultraviolet absorption spectrum, λ 220 mμ (E 0.69)[14], λ_{max} 232 mμ (E 0.91), λ_{min} 245 mμ (E 0.78) and λ_{max} 259 mμ (E 1.10). The solution of 0.323 mg. of aconitine and 0.323 mg. of jesaconitine in 10 ml. of methanol showed an identical ultraviolet spectrum[15]. The acetone elute gave 100 mg. of lucidusculine melting at 170°C alone and on admixture with an authentic specimen.

Isolation of Alkaloids.—The dried roots were divided into mother-roots and daughter-roots.

Isolation of alkaloids from mother-roots.—The mother-roots (4.5 kg.) were ground and percolated with ethanol. The percolate was treated as in the case of other aconite roots[10]. The water-insoluble portion (4.4 g.) was dissolved in 10 ml. of chloroform-ammonia water and the solution was passed through a column (1.4 cm. in diameter) of 90 g. of alumina, and the column was

eluted with 280 ml. of chloroform-ammonia water, next with 100 ml. of acetone and then with 70ml. of methanol. The basic substance was obtained from the entire amount of the chloroform-ammonia water elute. It was purified as perchlorate by recrystallization from ethanol and 0.5 g. of pure perchlorate was obtained, m. p. 220~230°C (decomp.). The base (0.670 mg.) liberated from the perchlorate by means of ammonia water was dissolved in 10 ml. of methanol. The solution showed ultraviolet absorption, λ 220 mμ (E 0.55), λ_{min} 225 mμ (E 0.44) and λ_{max} 259 mμ (E 1.44). The solution of 0.130 mg. of aconitine and 0.540 mg. of jesaconitine in 10 ml. of methanol showed an identical ultraviolet spectrum. The spectral observations and the experiments mentioned below indicate that jesaconitine is contained in the material in an amount of about 80%[15,16].

The remaining portion of the free base was extracted with ether in a Soxhlet extractor for 3 hr.; and the extracted base was transformed into the perchlorate. The salt yielded 0.1 g. of the salt of "jesaconitine-rich base" upon recrystallization from ethanol. The purified salt had m. p. 230°C (decomp.), $[\alpha]_D^{25}$ −12.6° (methanol). The jesaconitine-rich base (0.673 mg.) prepared from the above salt was dissolved in 10 ml. of methanol. The solution showed ultraviolet absorption, λ 220 mμ (E 0.50), λ_{min} 225 mμ (E 0.32) and λ_{max} 259 mμ (E 1.79). The solution of 0.060 mg. of aconitine and 0.615 mg. of jesaconitine in 10 ml. of methanol showed an identical ultraviolet spectrum. The salt of the jesaconitine-rich base was analyzed.

Anal. Found: C, 53.72; H, 6.44; N, 2.06. Calcd. for $C_{35}H_{49}O_{12}N \cdot HClO_4$[17]: C, 54.15; H, 6.49; N, 1.80%.

After evaporation of the acetone elute in vacuo, the residue yielded 0.2 g. of lucidusculine by recrystallization from ethanol, m. p. 170°C with no depression on admixture with an authentic specimen.

Isolation of alkaloids from daughter-roots. — The water-insoluble portion (20.5 g.) from 4.5 kg. of the daughter-roots was treated in the same way as in the case of the mother-roots. The basic substance was obtained from the entire portion of the chloroform-ammonia water elute. The perchlorate of the base was recrystallized from ethanol. The free base liberated from the perchlorate was neutralized with 0.77 N hydrobromic acid. The solution of the resulting hydrobromide gave 0.08 g. of a crystalline material on standing[18]. The free base (0.665 mg.) prepared from the hydrobromide was dissolved in 10 ml. of methanol. The solution showed ultraviolet absorption, λ_{max} 232 mμ (E 0.90), λ_{min} 245 mμ (E 0.71) and λ_{max} 259 mμ (E 1.03). The solution of 0.356 mg. of aconitine and 0.309 mg. of jesaconitine in 10 ml. of methanol gave an identical ultraviolet spectrum.

The mother liquor from the hydrobromide was treated with ammonia water, yielding 1.7 g. of the free base. The solution of the free base (0.667 mg.) in 10 ml. of methanol showed ultraviolet absorption, λ 220 mμ (E 0.55), λ_{min} 225 mμ (E 0.44) and λ_{max} 259 mμ (E 1.53). The solution of 0.120 mg. of aconitine and 0.545 mg. of jesaconitine in 10 ml. of methanol showed an identical ultraviolet spectrum.

The spectral observations and the experiments described below indicate that jesaconitine was contained in an amount of about 80%.

The remaining portion of the above free base was extracted with ether in a Soxhlet extractor for 3 hr.; and the extracted base was transformed into the perchlorate. The crude perchlorate yielded 0.2 g. of the perchlorate of a jesaconitine-rich base upon recrystallization from ethanol. The purified perchlorate had m. p. 230°C (decomp.), $[\alpha]_D^{25}$ −14.8°C (methanol). The solution of jesaconitine-rich base (0.673 mg.), prepared from a part of the perchlorate, in 10 ml. of methanol showed ultraviolet absorption, λ 220 mμ (E 0.50), λ_{min} 225 mμ (E 0.32) and λ_{max} 259 mμ (E 1.79). The solution of 0.060 mg. of aconitine and 0.615 mg. of jesaconitine showed an identical ultaviolet spectrum. The purified perchlorate was analyzed.

Anal. Found: C, 53.92; H, 6.50; N, 1.91. Calcd. for $C_{35}H_{49}O_{12}N \cdot HClO_4$: C, 54.15; H, 6.49; N, 1.80%.

Hydrolysis of the ether-insoluble portion (1.1 g.) of the above base gave 50 mg. of anisic acid and 300 mg. of aconine hydrochloride, which melted at 176°C and was analyzed.

Anal. Found. C, 52.65; H, 8.16; N, 2.43. Calcd. for $C_{25}H_{41}O_9N \cdot HCl \cdot 2H_2O$: C, 52.48; H, 8.04; N, 2.45%.

The acetone elute gave 0.8 g. of lucidusculine as in the case of the mother-roots, m. p. 170°C with no depression on admixture with an authentic specimen.

Summary

1. In lucidusculine the presence of a double bond had previously been assumed. Further, on the basis of observations of the infrared spectra of luciculine, lucidusculine diacetate and dihydrolucidusculine diacetate, the presence of a terminal methylene group in lucidusculine was suggested.

Kuhn-Roth oxidation of mesoluciculine and of dihydromesoluciculine and ozonolysis of lucidusculine and of lucidusculine diacetate supported the suggested presence of a terminal methylene group. These results and the biogenesis of the aconite

16) On account of the the existence of the benzoyl ester of an alkaloidal amino alcohol, aconitine was assumed to be present.

17) If the salt is composed of 1 mol. of jesaconitine and 1/10 mol. of aconitine, the calculated values are: C, 54.19; H, 6.44%.

18) The benzoyl ester of an alkaloidal amino alcohol may be aconitine; this seems to be supported by the fact that the crystalline hydrobromide of the ester alkaloid is slighthly soluble in water.

alkaloids show that the double bond in lucidusculine belongs to a terminal methylene group.

2. The roots of *Aconitum* species from Shoya, Hidaka in Hokkaido, were divided into mother-roots and daughter-roots; the water-insoluble basic portions were obtained from both; lucidusculine and jesaconitine were isolated by the chromatographic method.

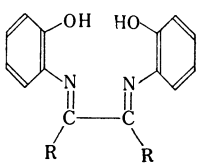
On the Structure of Condensation Products of o-Aminophenols with α-Dicarbonyl Compounds. I

By Ichiro MURASE

(Received December 11, 1958)

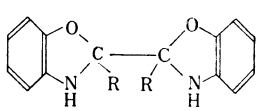
The condensation reaction between *o*-aminophenol and diacetyl was first carried out by Kehrmann in 1895, who tentatively suggested for the condensation product the eight-membered ring structure containing a diphenyl ether bond as shown in the formula A[1].

(A)



Recently, Bayer assigned Schiff base structures to the compounds obtained by the condensation of *o*-aminophenol with glyoxal and diacetyl and reported that glyoxal bis-(2-hydroxy anil) gave chelates with copper, nickel, cobalt, etc., but diacetyl bis-(2-hydroxy anil) did not form a metal chelate[2].

The present investigation was undertaken in order to confirm the structure of these condensation products.



o-Aminophenol smoothly condensed with glyoxal and with diacetyl by heating the mixture in an aqueous or alcoholic solution. The product I from glyoxal was colorless needles, m. p. 210°C*, and the product II from diacetyl was colorless plates, m. p. 241°C**.

The Schiff base structure is represented as the formula B.

It was confirmed in some cases that condensation products of β-aminoalcohols and carbonyl compounds are oxazolidine or equilibrium mixtures of the Schiff base with the former[3]. Along with these facts, the alternative structure of I and II is bibenzoxazoline (C).

(B)

R : H (I)
R : CH_3 (II)

(C)

Only a few instances of benzoxazoline structure were reported concerning the condensation products of *o*-aminophenols and carbonyl compounds[4], but their structures were not always confirmed exactly. It has been accepted that the benzoxazole owes its formation to pyrolysis of the benzoxazoline primarily formed in the condensation of *o*-aminophenol with ketone[5].

TABLE I. INFRARED ABSORPTION SPECTRA OF I, II AND RELATED SCHIFF BASES NEAR 3000 cm^{-1} AND 1600 cm^{-1} REGION

I	II	Diacetyl dianil	Glyoxal bis-(4-hydroxy anil)	Glyoxal bis-(4-dimethyl-amino anil)	Salicyl-idene *o*-amino-phenol	Bissalicyl-aldehyde ethylene-diimine	Assignment
3378	3358						NH stretching
		1631	1610	1605	1631	1631	Conjugated C=N
1613	1613						
1600	1587	1587	1595		1619	1613	Phenyl ring
1585	1580	1577	1580	1567	1597	1582	
1499	1497	1490	1513	1517	1531	1506	

Eventually, a Schiff base structure or an oxazoline structure will be the only choice offered for the determination of the structure of the condensation products of *o*-aminophenol with glyoxal and diacetyl. The following investigations led to the conclusion that the structures of these are not so much a Schiff base type as an oxazoline type.

Behaviors to Mineral Acid and Aqueous Alkali.—I and II are insoluble in dilute mineral acids and stable to such an extent that they are not hydrolyzed after standing overnight at room temperature with 3 N hydrochloric acid, but hydrolyzed by heating with 6 N hydrochloric acid; thus they were gradually hydrolyzed and *o*-aminophenol hydrochloride was obtained quantitatively. I and II were not only insoluble in dilute aqueous alkali, but also stable at room temperature. On heating them with a ten per cent aqueous sodium hydroxide solution, *o*-aminophenol was obtained and identified as the *N*-acetyl derivative.

Spectroscopic Investigation. — Infrared and ultraviolet absorption spectra of I and II are shown In Figs. 1 and 2 respectively***. The assignment of the infrared absorption bands and the ultraviolet absorption maxima are summarized and compared with those of the related Schiff bases in Tables I and II, respectively.

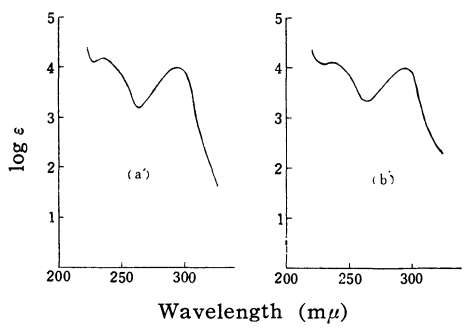

Fig. 2. Absorption curve of the compounds I (a') and II (b'), (ethanol solution).

*** The infrared spectra were obtained with a Perkin-Elmer Model 21 and an Oyōkōken D-201 spectrometer using NaCl prism. Ultraviolet spectra were obtained with a Beckman Model DK-2 spectrometer.

TABLE II. THE ULTRAVIOLET ABSORPTION SPECTRA OF I, II AND RELATED SCHIFF BASES IN ETHANOL

Compound	λ (mμ)	ε	λ (mμ)	ε	λ (mμ)	ε
I	236	14340	294	9880		
II	236	13200	293	9880		
Diacetyl dianil	227	40700			332	4360
Glyoxal bis-(4-hydroxy anil)	244	13200	296	8300	383	23980
Glyoxal bis-(4-dimethyl-amino anil)	253	15760	318	5700	450	37200

If the Schiff base structure (B) is adopted, the bands in the 3000 cm^{-1} region of infrared are assigned to OH vibration, 1613 cm^{-1} being a C=N vibration shifted by the strong conjugation in the same manner as in the case of the Schiff bases quoted.

Intermolecular hydrogen bondings, however, should be present in this case; a hydrogen bonding causes a shift of the OH stretching band to the lower frequency and broadening of the band[6]. From these circumstances, the shape and the position of these bands (Fig. 1) are more plausibly explained to correspond to the NH vibration. Furthermore, the ultraviolet absorption spectra of I and II (Fig. 2) are closely related to that of *o*-aminophenol itself (λ_{max} 232 mμ, ε_{max} 7240; λ_{max} 286 mμ, ε_{max} 4270)[7], thus the presence of the chromophore, such as conjugated azomethine linkages which cause a bathochromic effect, should be discounted.

It is well known that a compound having an anilino structure has an infrared absorption band near 1600 cm^{-1} region[8]. From the investigations of indolenine derivatives, Witkop and Patrick[9] have quoted a band at 1613 cm^{-1} as being typical of the structure C_6H_5–NH–$\overset{|}{\underset{|}{C}}$–. Since the structure of bibenzoxazoline (C) resembles that of indolenine and an absorption similar to that of the latter is present at 1613 cm^{-1}, the author concluded the absorption to be caused by the same structural element, and at least shouldered bands are regarded as phenyl ring vibrations; it is not completely clear whether this absorption arises from an NH deformation or from a phenyl ring.

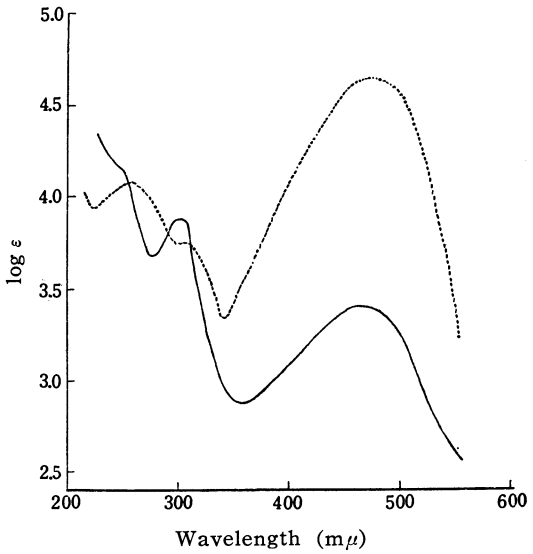

Fig. 3. Absorption curve of the compound I+KOH: —— and glyoxal bis-(4-hydroxy anil)+KOH: ·····.

Although compound I was insoluble in aqueous alkali, a reddish yellow color was produced when an excess of potassium hydroxide was added to its ethanol solution, and another absorption maximum was observed at 467 mμ (ε, 2445) as shown in Fig. 3.

In the case of glyoxal bis-(4-hydroxy anil), the absorption maximum shifted from 367 mμ to 470 mμ when potassium hydroxide was added. The explanation of this phenomenon is that when a proton acceptor such as a hydroxyl ion is present in the ethanol solution, bibenzoxazoline (C′) tautomerizes to Schiff base B′ under ring opening. The above consideration is tenable in view of the fact that oxazolidine tautomerizes to Schiff base resulting in an equilibrium mixture of the two structures[3].

The curve in Fig. 4 means that the Schiff base is produced as a result of tautomerism and the solution reaches an equilibrium. The curve comes up again after standing for a long time, because hydrolysis sets in.

The formation of a metal chelate I is also explained by the tautomeric change.

9) B. Witrop and J. B. Patrick, *J. Am. Chem. Soc.*, **73**, 713 (1951).

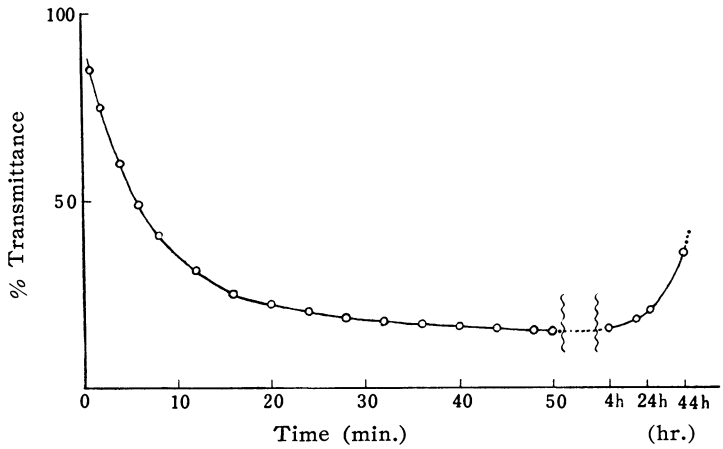

Fig. 4. Variation of the transmittance of the absorption maximum of I in ethanol (about 1/2000 mol.) at 470 mμ after the addition of potassium hydroxide.

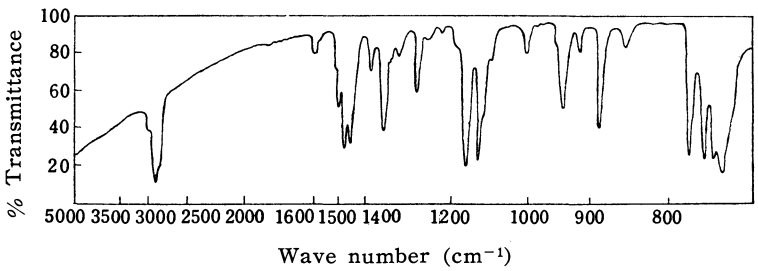

Fig. 5. Infrared spectrum of 2,2'-bibenzoxazole (Nujol mull).

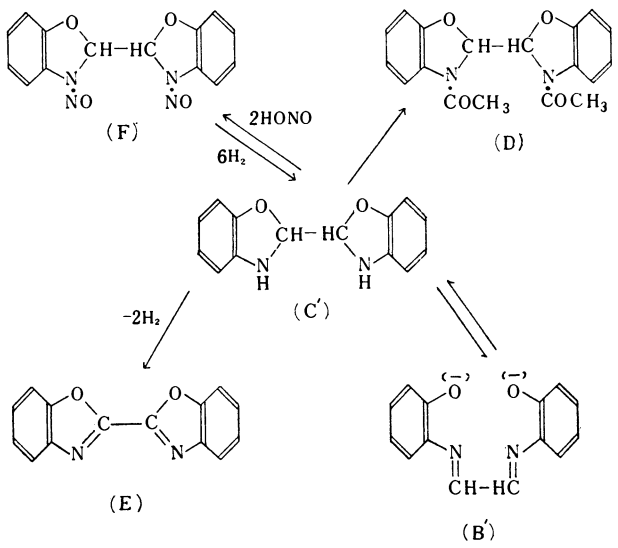
When metal acetate has been added to the solution, an acetate ion acts as a proton acceptor and an anion of Schiff base is produced in the same manner as in the case of potassium hydroxide. The structure of a metal chelate thus formed, has been represented by Bayer as an ionic one of glyoxal bis-(2-hydroxy anil).

Compound II failed to give a new absorption band at a visible region on addition of potassium hydroxide to its ethanol solution. Accordingly, II lacks the feature of tautomerism in contrast with I, and the inability to form a metal chelate is well understood.

Chemical Properties.—Methylation of I and II was attempted using sodium amide and methyl iodide in dioxane or diazomethane in ether, but only an unchanged material was recovered.



By the acetylation of I with acetic anhydride, a crystalline diacetyl derivative was obtained, m. p. 263~265°C. It was not hydrolyzed by acid or alkali and the infrared spectrum showed absorptions at 1670 cm^{-1} (C=O stretching) and 1587 cm^{-1} (phenyl ring) and no absorption was observed in the 3000 cm^{-1} region. Thus, the diacetyl derivative proved to be *N,N'*-diacetyl-2,2'-bibenzoxazoline(D).

When the dilute solution of I in acetone was carefully treated with potassium permanganate, a dehydrogenation product was obtained in pale yellow prisms, m. p. 257°C. It was confirmed to be 2,2'-bibenzoxazole (E) from mixed melting point test with the authentic sample[10] prepared by the oxidative condensation of benzoxazole with copper acetate. 2,2'-Bibenzoxazole was also obtained by the oxidation of I with lead dioxide in benzene. The infrared absorption pattern (Fig. 5) of the dehydrogenation product was quite identical with that of the authentic sample.

Similar oxidation did not proceed in the case of II under the same conditions.

By the nitrosation of I, yellow dinitroso derivative (F) was obtained. It has no absorption band near 3000 cm^{-1} of infrared; the substitution of nitroso group occurred at imino hydrogen in the bibenzoxazoline (C'). By the catalytic hydrogenation of

10) D. R. Pat., 650,050 (1936); *Chem. Zentr.*, **1937**, II, 4395.

F, six moles of hydrogen were absorbed and I was reproduced.

The above reactions are summarized in the following schema.

Thus, the most reasonable conclusion to be drawn from the available data is that the condensation product of *o*-aminophenol with glyoxal is 2,2'-bibenzoxazoline and with diacetyl is 2,2'-dimethyl-2,2'-bibenzoxazoline as shown in the formula C. Bayer's investigation concerning the structure of metal chelates would be supported along with the consideration that 2,2'-bibenzoxazoline tautomerizes to glyoxal bis-(2-hydroxy anil).

Condensation products of many other *α*-dicarbonyl compounds with *o*-aminophenol derivatives and their structures will be reported in the subsequent paper.

Experimeatal

2, 2'-Dimethyl-2, 2'-bibenzoxazoline. — Prepared from *o*-aminophenol and diacetyl according to Kehrmann's method. Colorless plates, m. p. 241°C. The substance afforded a deep reddish violet color when dissolved in concentrated sulfuric acid. The aqueous alcoholic solution did not show the color reaction with ferric chloride.

Anal. Found: C, 71.97; H, 6.22; N, 10.52. Calcd. for $C_{16}H_{16}N_2O_2$: C, 71.67; H, 6.01; N, 10.44%.

2, 2'-Bibenzoxazoline.—To a solution of 10 g. of *o*-aminophenol in 90 ml. of hot ethanol, 15 g. of 30% aqueous glyoxal was added and gently refluxed for thirty minutes. The mixture became dark brown and the crystals separated out. The crystals collected after being cooled were washed with ethanol to give almost colorless ones. Recrystallization from ethanol using a Norit gave colorless needles, m. p. 210°C. Yield, 6 g.

2,2'-Bibenzoxazoline is soluble in methanol, benzene and dioxane and insoluble in water and chloroform. The substance afforded a deep green color when dissolved in concentrated sulfuric acid.

Anal. Found: C, 70.34; H, 4.86; N, 11.30. Calcd. for $C_{14}H_{12}N_2O_2$: C, 69.99; H, 5.03; N, 11.66%.

Acetylation of 2, 2'-Bibenzoxazoline : *N, N'*-Diacetyl-2-2'-bibenzoxazoline. — A solution of 0.5 g. of 2,2'-bibenzoxazoline in 20 ml. of acetic anhydride was gently refluxed for ca. 2 hr. The reaction mixture became dark brown. The solvent was removed under reduced pressure, and the resulting dark brown tarrish residue was treated with a small amount of benzene, filtered, and the remaining crystals were washed with benzene and methanol, and recrystallized from dilute acetic acid. Colorless crystals, m. p. 263~265°C, were obtained in a poor yield.

This diacetyl derivative is slightly soluble in benzene and soluble in dioxane and afforded a red color in warm concentrated sulfuric acid.

Anal. Found: C, 66.17; H, 4.97; N, 8.67. Calcd. for $C_{18}H_{16}N_2O_4$: C, 66.65; H, 4.97; N, 8.67%.

Potassium Permanganate Oxidation of 2, 2'-Bibenzoxazoline : 2, 2'-Bibenzoxazole.—To a solution of 0.5 g. of 2,2'-bibenzoxazoline in a mixture of 250 ml. of pure acetone and 50 ml. of water, 0.5 g. of potassium permanganate in 100 ml. of acetone was added dropwise with stirring and gentle boiling. The addition required ca. 3 hr. and the reaction mixture was boiled for an additional 1 hr. After being kept overnight, the reaction mixture was filtered and the filtrate was concentrated under reduced pressure. The yellowish brown residue was recrystallized twice from dioxane and then from chlorobenzene to give pale yellow prisms, m. p. 257°C.

Anal. Found: C, 71.27; H, 3.52; N, 11.60. Calcd. for $C_{14}H_8N_2O_2$: C, 71.18; H, 3.41; N, 11.86%.

Lead Dioxide Oxidation of 2, 2'-Bibenzoxazoline : 2, 2'-Bibenzoxazole. — To a solution of 2, 2'-bibenzoxazoline in 80 ml. of hot benzene, was added 20 g. of lead dioxide. The mixture was refluxed for ca. 6 hr. and turned dark brown. The hot mixture was filtered and the solvent was distilled off. The reddish brown residue was treated with alcohol, dried and dissolved in 20 ml. of benzene. The benzene solution was chromatographed over commercial activated alumina and developed with the same solvent. The first fraction which was obtained almost unabsorbed amounted to ca. 100 ml.; the solvent was removed by evaporation, the pale yellow residue was treated with hot alcohol and recrystallized twice from dioxane to give pale yellow crystals, m. p. 256°C. Mixed melting point with the authentic sample showed no depression.

Nitrosation of 2, 2'-Bibenzoxazoline. — A mixture of 1 g. of 2, 2'-bibenzoxazoline in 130 ml. of benzene and 1.1 g. of sodium nitrite in 20 ml. of water was warmed at 50°C and stirred vigorously. To the mixture, 10 ml. of 1 N hydrochloric acid was gradually added; then the benzene layer became yellow. The benzene layer which separated was washed with water and dried over anhydrous sodium sulfate. The solvent was distilled off under reduced pressure and the residue was recrystallized from ca. 150 ml. of alcohol to yield yellow needles, m. p. 157°C (decomp.).

This dinitroso derivative was not hydrolyzed even by boiling with dilute mineral acid or aqueous alkali, but dissolved in concentrated sulfuric acid with a green color and evolution of nitrogen monoxide (potassium iodide starch paper test).

Anal. Found: C, 56.36; H, 3.47; N, 18.13; mol. wt. (cryoscopic method, benzene), 301. Calcd. for $C_{14}H_{10}N_4O_4$: C, 56.39; H, 3.36; N, 18.77%; mol. wt., 298.27.

Hydrogenation of *N*, *N'*-Dinitroso-2, 2'-bibenzoxazoline. — A solution of 0.1 g. of the dinitroso compound in ca. 50 ml. of alcohol was hydrogenated using Adams catalyst at atmospheric pressure and room temperature. The yellow solution became colorless on absorption of a slight excess of hydrogen. The catalyst was filtered and the filtrate was evaporated under reduced pressure. The remaining crystals were recrystallized from alcohol, colorless plates, m. p. 209°C (decomp.). The substance was identical with 2, 2'-bibenzoxazoline. From the gas in the hydrogenation vessel, ammonia was detected (Nessler's reagent).

Glyoxal Bis-(4-hydroxy anil).—To a solution of 1 g. of freshly recrystallized *p*-aminophenol in a small amount of 80% alcohol, was added 1.2 g. of 30% aqueous glyoxal, and the mixture was heated on a water bath for several minutes. Then, crystals were separated out and the mixture was cooled and filtered. Recrystallization from a large amount of alcohol gave yellow needles, m. p. 212~213°C (decomp.).

Anal. Found: C, 70.04; H, 5.10; N, 11.47. Calcd. for $C_{14}H_{12}N_2O_2$: C, 69.99; H, 5.03; N, 11.66%.

The author wishes to express his thanks to Professor Tokuichi Tsumaki and Professor Takeichi Nishikawa for their exceedingly kind direction of this work. The author also thanks Dr. Yo Ueda and Mr. Hiroshige Yano of the Department of Pharmacy for their measurement of infrared and ultraviolet spectra and Mr. Michio Shido and Miss Sachiko Indo for microanalysis.

Polarographic Studies of Metallic Complexes. V[1]. *Tetrammine Series of Cobalt(III) Complexes*[2]

By Nobufumi MAKI, Yoichi SHIMURA and Ryutaro TSUCHIDA

(Received December 24, 1958)

In the earlier papers of this series[1,3] the orders of the polarographic stability were determined for cobalt(III) complexes of pentammine and bisethylenediamine series, $[Co(NH_3)_5X]$, $[Co\ en_2X_2]$ or $[Co\ en_2Y]$. For the same purpose, the comparison of the half-wave potentials of the first waves has been carried out for the cobalt(III) complexes of tetrammine series, $[Co(NH_3)_4X_2]$ or $[Co(NH_3)_4Y]$, which has been briefly reported in the present paper. Some studies[4-10] were found in literature for the hexammine and the tetrammine cobalt(III) complexes of $[Co(NH_3)_4X_2]$ type, but few reports were found on the $[Co(NH_3)_4Y]$ type[10].

Experimental

A Yanagimoto model 104 polarograph similar to that previously described[1] was used to obtain the polarograms. The rate of flow of mercury, m, and the drop time, t, of the dropping mercury electrode were 0.635 mg./sec. and 6.92~7.32 sec., respectively, being measured in the solution of 0.1 F potassium chloride or 0.5 F potassium sulfate at an open circuit with a mercury head of 66.5 cm. A saturated calomel electrode (S.C.E.) was used for a reference electrode and connected to the cell solution through an agar bridge. The cell temperature was maintained at 25±0.1°C by means of a water thermostat. For accurate evaluation of curves and half-wave potentials the method previously described[10] was used. The oxygen dissolved in solution was expelled by passing a stream of nitrogen through the cell solution for an hour prior to each electrolysis. The reversibilities of the electrode reactions were examined by determining the slopes of $\log i/(i_d-i)$ vs. potential. The slopes of the log plots indicated irreversible reduction throughout.

The complex compounds studied were prepared by the methods described in literature. (The references are given in Tables I and II.) Each solution for electrolysis was made freshly from the dry crystalline cobalt(III) complexes before use and the polarographic measurements were made as soon as possible after the removal of oxygen. The concentration of the solution was 0.001 gram complex ion per litre. No maximum suppressor was used for the purpose of comparing the half-wave potentials of the complexes with one another. The presence of the maximum suppressor causes the lowering of the diffusion current and the shift of the half-wave potential to the negative direction. For instance, the half-wave potential of the first wave of the complex,

* Maximum wave

$[Co(NH_3)_4alan^*]SO_4$, shifts towards the negative direction by -0.12_5V. (vs. S.C.E.) in the presence of 0.0032% Tween-80**, as is shown in Fig. 1.

The supporting electrolytes used are 0.1 F potassium chloride and 0.5 F potassium sulfate.

Results and Discussion

In Tables I and II are shown the half-wave potentials of the cobalt(III) complexes of tetrammine series.

All the compounds are reduced irreversibly in two steps at the dropping mercury electrode in 0.1 F potassium chloride or 0.5 F potassium sulfate except the complexes which aquate easily in solution. The ratio of the height of the first wave to that of the second is approximately 1:2. The heights of the first and the second waves are roughly proportional to the concentration of the complex ion at the concentration of $5\times10^{-3}\sim10^{-4}$ gram complex ion per litre. Consequently, it is considered that the first wave, corresponding to a gain of one electron, represents the reduction to cobalt(II) state and the second, corresponding to two electrons, represents the reduction to the metal. The half-wave potentials of the latter are always close to that of the hexaquocobalt(II) ion, $[Co(OH_2)_6]^{2+}$. ($E_{1/2}=-1.428$ V. vs. S.C.E. in 0.5 F K_2SO_4 solution[4].)

The reduction processes of tetrammine cobalt(III) complexes are considered as follows:

$$[Co(NH_3)_4X_2]^{(3-2n)+}+e^- \rightarrow [Co(NH_3)_4X_2]^{(2-2n)+}$$

$$[Co(NH_3)_4X_2]^{(2-2n)+}+mH_2O \xrightarrow[\text{rapidly}]{} \begin{cases} [Co(OH_2)_6]^{2+}+2X^{n-}+4NH_3 \\ [Co(OH_2)_5X]^{(2-n)+}+X^{n-}+4NH_3 \\ [Co(OH_2)_4X_2]^{(2-2n)+}+4NH_3 \\ \text{etc.} \end{cases}$$

$$\begin{cases} [Co(OH_2)_6]^{2+}+2e^- \rightarrow Co+6H_2O \\ [Co(OH_2)_5X]^{(2-n)+}+2e^- \rightarrow Co+5H_2O+X^{n-} \\ [Co(OH_2)_4X_2]^{(2-2n)+}+2e^- \rightarrow Co+4H_2O+2X^{n-} \\ \text{etc.} \end{cases}$$

From the above scheme of the reduction it may be seen that the first step in the polarographic reduction of these cobalt(III) complexes corresponds to the disruption of the complexes, so its half-wave potential may be regarded as a measure of the stability against the polarographic reduction.

The polarographic stability of the cobalt(III) complexes of tetrammine series increases in the following order of the ligands; for the complexes of $[Co(NH_3)_4X_2]$ type,

$$IO_3^-,\ Cl^- < NO_2^- < NH_3 < OH_2 < SO_3^{2-}$$

(supporting electrolyte; 0.5 F K_2SO_4)

and for the complexes of $[Co(NH_3)_4Y]$ type,

$$leuc^- < ox^{2-} < alan^- < CO_3^{2-} < gly^- < en$$

(supporting electrolyte; 0.5 F K_2SO_4)

The order of the stability for the latter type was found to be altered between carbonate and ethylenediamine in the supporting electrolyte of 0.1 F potassium chloride.

$$leuc^- < ox^{2-} < alan^- < gly^- < en < CO_3^{2-}$$

(supporting electrolyte; 0.1 F KCl).

No special relation between the orders of the polarographic stability and that of the spectrochemical series could be found.

The half-wave potentials of the first waves for the complexes of the tetrammine series, $[Co(NH_3)_4X_2]$ or $[Co(NH_3)_4Y]$, exhibit always less negative values than those of the corresponding complexes of bisethylenediamine series, $[Co\ en_2X_2]$ or $[Co\ en_2Y]$, as is shown in Table III. This means that the two ethylenediamine chelate rings have the ability of forming the more stable cobalt(III) complexes against the polarographic reduction than the coordination of the corresponding four ammonia ligands. The result is quite in agreement with that obtained in the previous paper[10].

Fig. 2 shows the polarograms of *cis*-diaquotetramminecobalt(III) ion, $[Co(NH_3)_4(OH_2)_2]^{3+}$, in neutral supporting electrolyte. The slope of the tangent at the half-wave potential of the first wave is very small and the current rising gradually near the zero potential just like a residual current was observed as well as in the case of

The data for the cobalt(III) complexes of bisethylenediamine series were quoted from N. Maki, Y. Shimura and R. Tsuchida, This Bulletin, 32, 150 (1959). The concentration of complex: 0.001 gram complex ion per litre. Potential unit: V. vs. S.C.E.

* Maximum wave

** The data quoted from J. B. Willis, J. A. Friend and D. P. Mellor, *J. Am. Chem. Soc.*, 67, 1680 (1945).

*** The data adopted from H. F. Holtzclaw, Jr. and D. P. Sheetz, ibid., 75, 3053 (1953).

**** The data obtained in the presence of 0.0016% Tween-80.

diaquobisethylenediaminecobalt(III) complex[1] and could not be diminished only by the removal of the oxygen dissolved in solution. In perchloric acid, on the other hand, the first wave becomes steeper as is shown in Fig. 3. The reason for this is considered to be quite similar to the case of *cis*-diaquobisethylenediaminecobalt(III) complex. Namely, in neutral aqueous solution, the hydroxytetramminecobalt(III) ions are formed by the following ligandolysis.

$$[Co(NH_3)_4(OH_2)_2]^{3+} \rightleftarrows [Co(NH_3)_4(OH_2)(OH)]^{2+} + H^+$$

$$[Co(NH_3)_4(OH_2)(OH)]^{2+} \rightleftarrows [Co(NH_3)_4(OH)_2]^{+} + H^+$$

The monohydroxymonoaquo complex ions formed here polymerize to the various kinds of the polynuclear cobalt(III) complex with the lapse of time, as was verified by the spectrochemical studies of Rasmussen et al.[23]

For instance,

$$2\ cis\text{-}[Co(NH_3)_4(OH_2)(OH)]^{2+} \rightarrow \left[(NH_3)_4Co\begin{matrix}OH\\OH\end{matrix}Co(NH_3)_4\right]^{4+} + 2H_2O$$

Accordingly, in neutral solution the several kinds of these cobalt(III) complexes having similar structures are considered to be reduced almost at the same time.

The above mechanism well explains the fact that the overlapped waves of small slope are obtained for the diaquotetramminecobalt(III) complex. In perchloric acid, on the other hand, the above equilibrium is markedly shifted to the left hand due to the presence of an overwhelming hydrogen ion. Hence, the polymerization is quite inhibited and only the original ion is present in solution. Consequently, the wave of steep slope was obtained.

23) S. E. Rasmussen and J. Bjerrum, *Acta Chem. Scand.*, 9, 735 (1955).

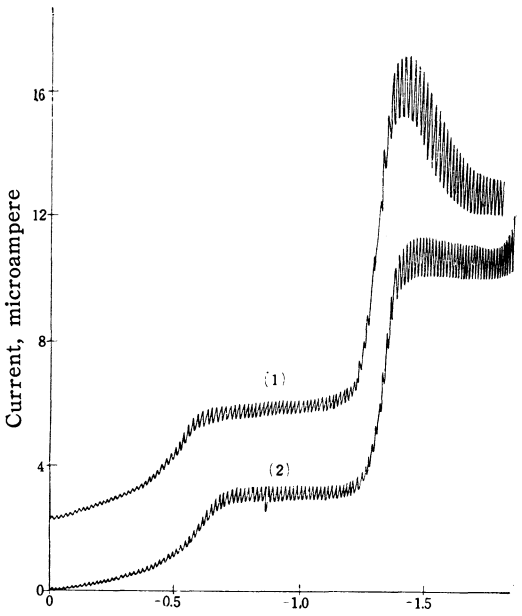

Fig. 2. The polarograms of *cis*-diaquotetramminecobalt(III) complex, $[Co(NH_3)_4(OH_2)_2](SO_4)_3 \cdot 3H_2O$, obtained at the concentration of 0.001 gram complex ion per litre in 0.5 F K_2SO_4 solution.
1. In the absence of the maximum suppressor.
2. In the presence of 0.0032% Tween-80.
Sensitivity: 0.08 μA/mm. Damping: 200.

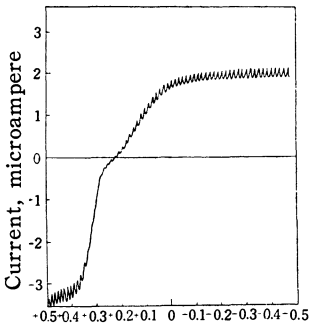

Fig. 3. The polarogram of *cis*-diaquotetramminecobalt(III) ion, $[Co(NH_3)_4(OH_2)_2]^{3+}$, obtained in 1 F perchloric acid at the concentration of 0.001 gram complex ion per litre.

The wave of *cis*- or *trans*-dichlorotetramminecobalt(III) ion which appeared at around −0.42 V. (vs. S.C.E.) is considered to correspond to the reduction of the aquated species such as $[Co(NH_3)_4(OH_2)Cl]^{2+}$ and $[Co(NH_3)_4(OH_2)_2]^{3+}$, since the half-wave potential is in proximity to that of diaquotetramminecobalt(III) ion. ($E_{1/2}$= −0.40$_2$ V. vs. S.C.E. in 0.1 F KCl). Judging from the wavelet, the reduction wave of the original ion is believed to be in the positive region of potential.

As to the wave of diiodatotetramminecobalt(III) complex, $[Co(NH_3)_4(IO_3)_2]IO_3 \cdot HIO_3$, the half-wave potential of the first wave is in the positive region of potential and the second wave is covered by the reduction wave of the hydrogen ion liberated from iodic acid.

Summary

1. All the cobalt(III) complexes of tetrammine series, $[Co(NH_3)_4X_2]$ or $[Co(NH_3)_4Y]$, were reduced irreversibly in two steps at the dropping mercury electrode. The first wave, corresponding to a gain of one electron, represents the reduction of Co(III)→Co(II) and the second, corresponding to two electrons, represents the reduction of Co(II)→Co(0).

2. The polarographic stability of the cobalt(III) complexes of tetrammine series are ranked in the following order of the ligand; for the complexes of $[Co(NH_3)_4X_2]$ type,

IO_3^-, $Cl^- < NO_2^- < NH_3 < OH_2 < SO_3^{2-}$

(supporting electrolyte; 0.5 F K_2SO_4),

and for the complexs of $[Co(NH_3)_4Y]$ type,

$leuc^- < ox^{2-} < alan^- < CO_3^{2-} < gly^- < en$

(supporting electrolyte; 0.5 F K_2SO_4).

3. The half-wave potentials of the reduction step of Co(III)→Co(II) for all the tetrammine cobalt(III) complexes exhibit always more positive values than those of the corresponding bisethylenediamine cobalt(III) complexes.

Alkylation of 2,3-Dimethylindole in Liquid Ammonia

By Masao NAKAZAKI

(Received February 9, 1959)

In the previous paper[1], formation of both 9-alkyltetrahydrocarbazoles (IIa, b, c) and 11-alkyltetrahydrocarbazolenines (IIIa, b, c) by the alkylation of tetrahydrocarbazole(I) in liquid ammonia with sodium amide and alkyl halides was reported. But, when isopropyl iodide was employed as alkylation reagent, 11-isopropyltetrahydrocarbazolenine (IIId) was a sole product isolated. These 11-alkyltetrahydrocarbazolenines could be also prepared by the Grignard synthesis, contrary to the negative result of Witkop[2].

b, R=CH_2-CH=CH_2 b, R=CH_2-CH=CH_2
c, R=$CH_2C_6H_5$ c, R=$CH_2C_6H_5$
d, R=$CH(CH_3)_2$

When these experiments had been completed, Patts and Saxton[3] published a paper in which they reported formation of *N*-methyl derivatives in excellent yield from various indole derivatives by the alkylation with sodium amide and methyl iodide in liquid ammonia.

Beside indole itself, all compounds they tried were 2- or 3-monosubstituted indole, and no 2,3-disubstituted indole was subjected to their alkylation method.

Since tetrahydrocarbazole is a 2,3-disubstituted indole, and affords both 9- and 11-alkyl derivatives by the alkylation in liquid ammonia, 2,3-dimethylindole can be expected to give indolenine derivatives by this method.

When the same procedure used in the alkylation of tetrahydrocarbazole was employed, 2,3-dimethylindole gave *N*-methyl derivative (Va) accompanied by a small amount of 2,3,3-trimethylindolenine (VIa), but using allyl bromide and benzyl chloride there were found *N*-alkyl (Vb, c) and indolenine derivatives (VIb, c) in about the same amount.

Isopropyl bromide failed to afford *N*-isopropyl derivative and a small amount of 2,3-dimethyl-3-isopropylindolenine (VId) was the only prduct isolated. These results are exactly parallel to the one observed in the case of the alkylation of tetrahydrocarbazole in liquid ammonia.

The structures of all indolenine compounds provided by the alkylation in liquid

2) B. Witkop, *J. Am. Chem. Soc.*, **72**, 614 (1950).
3) K. T. Patts and J. E. Saxton, *J. Chem. Soc.*, **1954**, 2641. In our independent work, indole was found to give *N*-benzyl and *N*-allylindole in liquid ammonia with sodium amide and benzyl chloride and allyl bromide, respectively.

ammonia, were confirmed by the comparison with the specimens prepared by the Grignard synthesis, and their properties were shown in Table I, together with the one of *N*-alkyl-2,3-dimethylindoles.

Since 2,3-disubstituted indoles, as this experiment clearly shows, must be expected to give a considerable amount of indolenine derivatives even when methyl iodide is employed in the alkylation in liquid ammonia, adequate caution should be paid at the application of this alkylation method to the structure determination or the synthesis of indole alkaloids and the related compounds[4].

Experimental

N-Methyl-2,3-dimethylindole (Va) and 2,3,3-Trimethylindolenine (VIa). — *Alkylation in liquid ammonia.*—To 150 cc. of liquid ammonia collected in a three-necked flask chilled in a dry ice-acetone bath, 0.05 g. of ferric nitrate was added followed by the addition of 0.8 g. of sodium. After the blue color disappeared, a solution of 5 g. of 2,3-dimethylindole in 20 cc. of ether was added dropwise with stirring. After a mixture of 5 g. of methyl iodide and 5 cc. of ether was added over 20 min., the cooling bath was removed and the flask was allowed to stand overnight at room temperature to evaporate the ammonia off. Water was added to the residue left in the flask, and the oil separated was extracted with ether.

The ether extract was washed with water to neutral, and dried over anhydrous magnesium sulfate. After removal of the solvent, yellow residue was distilled under reduced pressure.

A forerun (1 g.) which boiled below 117°C at 6 mmHg and had a smell reminiscent of jasmine was dissolved in ether.

The basic fraction extracted with 4 N hydrochloric acid was liberated by the addition of 2 N sodium hydroxide solution and taken up in ether. An pale yellow oil (0.5 g.) obtained after removal of the ether, was converted into picrate which melted at 158°C after recrystallization from ethanol. The mixed melting point with the picrate of 2,3,3,-trimethylindolenine (m. p. 158~160°C) prepared by the Grignard synthesis was 158~161°C.

The main fraction boiling at 117~120°C/6 mmHg, weighed 3.2 g. (58% yield).

Anal. Found: C, 82.80; H, 8.29; N, 8.80. Calcd. for $C_{11}H_{13}N$: C, 82.97; H, 8.24; N, 8.80%.

The picrate was recrystallized from benzene to yield brown-black needles, m. p. 148~149°C. (literature[5]): m. p. 150°C). The mixed m. p. with the picrate of 2,3-dimethylindole (m. p. 152~153°C) was 140~143°C.

Grignard synthesis.—2,3,3-Trimethylindolenine was prepared following Hoshino's procedure[6], b. p. 113°C/21 mmHg. The picrate was recrystallized to give yellow needles melting at 158~160°C (literature[6]: m. p. 160~161°C).

N-Benzyl-2,3-dimethylindole (Vb) and 2,3-Dimethyl-3-benzylindolenine (VIb).—*Alkylation in liquid ammonia.*—Into a solution of sodium amide prepared from 200 cc. of liquid ammonia, 0.05 g. of ferric nitrate and 0.78 g. of sodium, a mixture of 5 g. of dimethylindole in 10 cc. of ether was added followed by the addition of 4 g. of benzyl chloride in 10 cc. of ether with stirring. After being kept overnight at room temperature in order to evaporate the ammonia, the residue was extracted with ether, and a basic fraction was extracted with 2 N hydrochloric acid. The basic fraction was liberated by the addition of 4 N sodium hydroxide solution to the hydrochloric acid solution, and extracted with ether. The ether layer, after being washed with water and dried, was evaporated to afford a viscous liquid which solidified gradually (1.80 g.). A small amount was sublimed to give crystals, m. p. 48~49°C. This was found identical with 2,3-dimethyl-3-benzylindolenine prepared by the Grignard synthesis[7] by mixed m. p. determination.

The picrate was recrystallized from ethanol to yield yellow needles, m. p. 138~140°C. The mixed melting point with the picrate prepared from the indolenine synthesized by the Grignard synthesis[7] was 138~141°C.

The natural fraction. — The ether layer freed of the indolenine was washed with water and dried. The solvent was removed to give 5.74 g. of a brown viscous liquid which solidified when allowed to stand at room temperature overnight. After 1.4 g. of dimethylindole (m. p. 94~97°C. picrate: m. p. 153~154°C, identified by mixed m. p. determinations) was recovered by sublimation at 3 mmHg, the residue was distilled in vacuo. A pale yellow fraction boiling at 110~115°C/1.5 mmHg was collected (1.7 g.) and recrystallized from methanol to give large needles, m. p. 59~60°C.

Anal. Found: C, 86.74; H, 7.32. Calcd. for $C_{17}H_{17}N$: C, 86.77; H, 7.28%.

The picrate was recrystallized to give brown black needles, m. p. 98~99°C.

Anal. Found: C, 59.79; H. 4.60; N, 12.20. Calcd. for $C_{23}H_{20}O_7N_4$: C, 59.88; H, 4.34; N, 12.06%.

N-Allyl-2,3-dimethylindole (Vc) and 2,3-Dimethyl-3-allylindolenine (VIc).—*Alkylation in liquid ammonia.* — To a solution of sodium amide prepared from 200 cc. of liquid ammonia, 0.05 g. of ferric nitrate and 1.2 g. of sodium, 7.0 g. of dimethylindole was added with 20 cc. of ether followed by the addition of a mixture of 7.7 g. of allyl bromide and 10 cc. of ether. The basic and neutral fractions were separated by the procedure described above.

4) M. F. Bartlett, D. F. Dickel and W. I. Taylor., *J. Am. Chem. Soc.*, **80**, 126 (1958), in which is obtained the only *N*-methylibogaine from iboganine (a 2,3-disubstituted indole) following the procedure of Patts and Saxton.

5) J. Degen, *Ann.*, **236**, 162 (1886).

6) T. Hoshino, ibid., **500**, 35 (1932).

7) M. Nakazaki, S. Isoe and K. Tanno, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **76**, 1262 (1955).

The basic fraction boiled at 128~132°C/12 mmHg and weighed 3.82 g. This 2,3-dimethyl-3-allylindolenine (VIc) was very sensitive to air oxidation and rapidly turned brown at the surface, but was able to be kept a little while in a refrigerator in a sealed bottle.

Anal[8]. Found: C, 82.75; H, 8.32; N, 7.06. Calcd. for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56%.

The picrate was recrystallized from ethanol to give yellow needles, m. p. 156~157°C, and it was found identical with the picrate of 2,3-dimethyl-3-allylindolenine prepared by the Grignard synthesis (vide infra).

The neutral fraction boiled at 159~160°C/16 mmHg and weighed 3.22 g.

Anal. Found: C, 84.11; H, 8.38; N, 7.35. Calcd. for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56%.

The picrate was recrystallized from ethanol to give brown black needles, m. p. 86°C.

Anal. Found: C, 54.85; H, 4.34; N, 13.37. Calcd. for $C_{19}H_{18}O_7N_4$: C, 55.07; H, 4.38; N, 13.52%.

Grignard synthesis.—To a Grignard compound prepared from 11.1 g. of methyl iodide and 1.9 g. of magnesium in 20 cc. of ether, a solution of 7.0 g. of dimethylindole in 20 cc. of ether was added dropwise over a period of 25 min. After generation of methane subsided, 7.7 g. of allyl bromide was added slowly over 20 min., and stirred for one additional hour. The ether layer was separated, after the Grignard complex was decomposed by the addition of 4 cc. of acetic acid with 15 cc. of water, and the aqueous layer was extracted thoroughly with ether. The combined ether extracts were shaken with 2 N hydrochloric acid to extract the basic fraction.

The oil which separated from the hydrochloric acid solution by being made alkaline was extracted with ether. After removal of the solvent, the residual liquid was distilled in vacuo to give a liquid which had a camphor-like smell, b. p. 80~90°C/2 mmHg, weighed 4.05 g.

2,3-Dimethyl-3-allylindolenine was found quickly to turn brown in color by air oxidation.

Anal[8]. Found: C, 82.86; H, 8.41; N, 6.95. Calcd. for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56%.

The picrate was recrystallized from ethanol to give yellow crystals, m. p. 157~158°C.

Anal. Found: C, 55.22; H, 4.60; N, 13.54. Calcd. for $C_{19}H_{18}O_7N_4$: C, 55.07, H, 4.38; N, 13.52%.

2,3-Dimethyl-3-isopropylindolenine (VId). —*Alkylation in liquid ammonia.*— To a solution of sodium amide prepared from 250 cc. of liquid ammonia, 0.1 g. of ferric nitrate and 1.5 g. of sodium in a 3-necked flask chilled in a dry ice-acetone bath, 7.0 g. of dimethylindole was added with 20 cc. of ether, followed by the addition of 7.5 g. of isopropyl bromide over 20 min. with stirring. The cooling bath was removed and the reaction mixture was allowed to stand at room temperature overnight to evaporate the ammonia. Following the same procedure described above, the basic and neutral fractions were separated. The basic fraction boiled at 100~110°C/11 mmHg, weighed 0.2 g. This compound was noticed to have a characteristic indolenine smell.

Anal. Found: C, 82.62; H, 9.59; N, 7.92. Calcd. for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

The picrate was recrystallized to give yellow crystals, m. p. 173~174.5°C.

Anal. Found: C, 55.00; H, 5.08; N, 13.92. Calcd. for $C_{19}H_{20}O_7N_4$: C, 54.80; H, 4.84; N, 13.46%.

The neutral fraction weighed 7.9 g., and from it 4.6 g. of dimethylindole was recovered by sublimation. But attempts to isolate *N*-isopropyl derivative from the viscous residue in the form of picrate failed, and the picrate of dimethylindole was the only material traceable.

Grignard synthesis.— To a Grignard solution prepared from 1.9 g. of magnesium and 11.1 g of methyl iodide in 20 cc. of ether, a mixture of 7.0 g. of dimethylindole in 10 cc. of ether was added dropwise.

After the evolution of methane subsided, 7.9 g. of isopropyl bromide was added over a period of 30 min. with stirring and cooling in an ice bath. After being kept at room temperature for 2 hr., the Grignard complex was decomposed by the addition of 4 cc. of acetic acid and 15 g. of ice. The basic and neutral fractions were separated by the same procedure described above.

The basic fraction was distilled in vacuo to give a liquid which boiled at 75~90°C/10 mmHg. Yield, 0.7 g.

The picrate was recrystallized to afford yellow crystals, m. p. 173~175°C which melted at 172~173°C when admixed with the picrate of 2,3-dimethyl-3-isopropylindolenine prepared by the alkylation of dimethylindole in liquid ammonia. From the neutral fraction, only dimethylindole was recovered.

The authors is very grateful to Mr. Muneo Sato for his enthusiastical technical assistance.

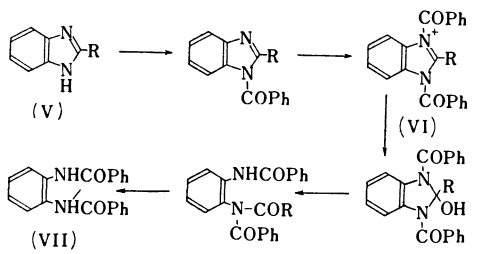
8) This rather poor result may be due to the sensitivity of the indolenine to air oxidation.

Benzoylation of 1,3-Diazaazulene[1]

By Ichiro MURATA

(Received February 6, 1959)



In 1949, Nozoe[2] predicted the possibility that the so-called 2-aminotropoimine and azaazulenes, which may be considered as the nitrogen homolog of tropolone and azulene respectively, are stable enough to exist. Later studies have confirmed their presence by the syntheses of azaazulenes such as 1-azaazulene (I)[3] and 1,3-diazaazulene (II)[4].

(I) (II) (III) (IV)

However, the only derivative of 2-aminotropoimine (III) known to date is 2,5-diaminotropoimine (IV)[5] obtained by the reduction of 5-nitrosotropolone dioxime (*p*-tropoquinone trioxime)[6].

In a sense, 1,3-diazaazulene (II) may be considered as a seven-membered ring homolog of benzimidazole (V). From such a view point, the cleavage reaction of an imidazole ring by the Schotten-Baumann method, known as the Bamberger reaction[7,8] in imidazole compounds, was applied to II.

Scheme 1.

The Bamberger reaction is considered to poceed as indicated in Scheme 1, starting with benzoylation, followed by the formation of a quaternary base (VI) by the presence of excess benzoyl chloride and the cleavage of the base by the action of alkali hydroxide, forming *o*-phenylenediamine dibenzoate (VII)[8].

II differs from the imidazole ring in not possessing an N-H group that could be benzoylated. However, since II easily forms a methiodide[4], the possibility of its ring fission may be considered and examination of this reaction was made.

A solution of II dissolved in 4 molar equivalents of sodium hydroxide solution, and chilled in ice, was added with 4 molar equivalents of benzoyl chloride, the mixture was shaken thoroughly, and allowed to stand overnight. This was extracted with chloroform and the brown oil obtained from the extract was separated and purified by alumina chromatography, from which yellow scales (VIII), m. p. 157 ~158°C, and pale yellow needles (IX), m. p. 94~95°C, were obtained besides recovery of the starting II.

By exactly the same procedure, the reaction of 6 molar equivalents of sodium hydroxide and 4 molar equivalents of benzoyl chloride gave a small amount of pale yellow prisms (X), m. p. 158°C, besides VIII and recovery of II.

When this reaction was carried out at 70~72°C, the kind and amount of the products obtained were different, as indicated in Table I.

The reaction of II and benzoyl chloride

TABLE I. REACTION OF 1,3-DIAZAAZULENE AND BENZOYL CHLORIDE

Molar ratio			Temp.	Product (%)			
II	NaOH	C_6H_5COCl	(°C)	VIII	IX	X	II

afforded, according to conditions of the reaction, VIII and IX or X. Examinations were made on the structure of these three products.

VIII and X show the same melting point but a distinct depression of the melting point occurs on their admixture and they show different degrees of solubility, color, and crystal form. The ultraviolet absorption spectra[9] of the two compounds, shown in Fig. 1, are also entirely different. Elementary analytical values of X correspond to the molecular formula of $C_{14}H_{10}N_2$, not containing any oxygen. It easily forms a picrate of m. p. 210°C, a styphnate of m. p. 231°C (decomp.), and a hydrochloride of m. p. 210°C (decomp.), whose analytical values also agree with those calculated for a salt of the foregoing composition.

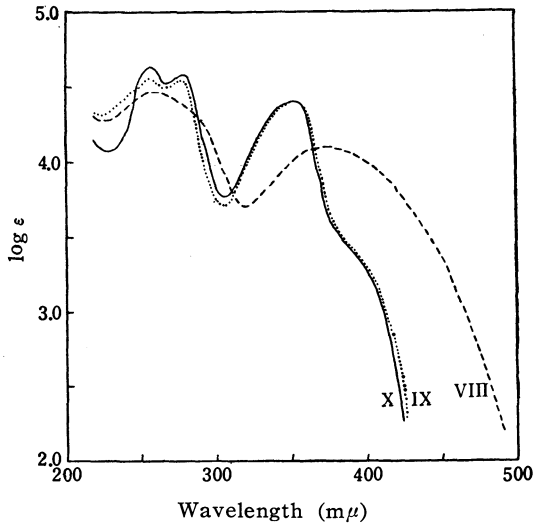

Fig. 1. U. V. absorption spectra of VIII, IX and X in methanol.

The infrared absorption spectrum[10] of X (Fig. 2) exhibits an absorption band at 1604 cm^{-1}, corresponding to the C=N stretching vibration or ring vibration (1602 cm^{-1}) in 1,3-diazaazulene, and absorption bands at 717 and 686 cm^{-1} due to the C-H out-of-plane vibration of mono-substituted benzene. These facts suggest that X is a phenyl derivative of II.

Oxidation of X with potassium dichromate in diluted sulfuric acid affords 2-phenylimidazole-4,5-dicarboxylic acid(XI)[11] of m. p. 264°C (decomp.), and its decarboxylation gives 2-phenylimidazole (XII)[11] of m. p. 143°C, which showed no depression on admixture with XII synthesized from tartaric acid. The ultraviolet absorption spectra of these two compounds were also identical. It follows, therefore, that the structure of X is 2-phenyl-1,3-diazaazulene.

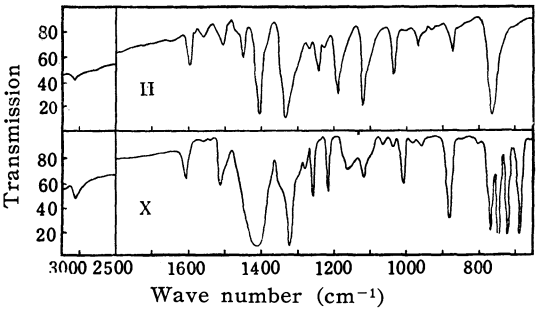

Fig. 2. I. R. absorption spectra of II and X in KBr.

IX is converted into X merely by mild treatment with dilute alkali and liberates one molar equivalent of benzoic acid during this course. The ultraviolet spectrum (Fig. 1) of IX is almost identical with that of X except for the absorption at around 230 mμ[12]. Since the heating of X with an equivalent amount of benzoic acid in ethanol results in quantitative formation of IX and from the analytical

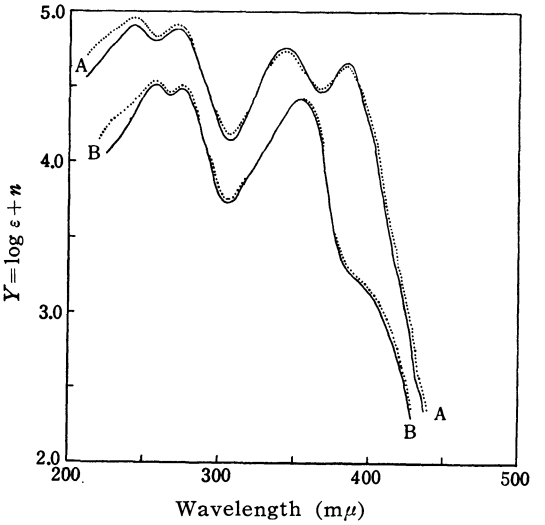

Fig. 3. U. V. Absorption spectra
—— X ····· VIII
A, in 0.1N HCl ($Y=\log\varepsilon+0.5$)
B, in 0.1N NaOH ($Y=\log\varepsilon+0$)

9) Measured by the Beckman Model DU Spectrophotometer.

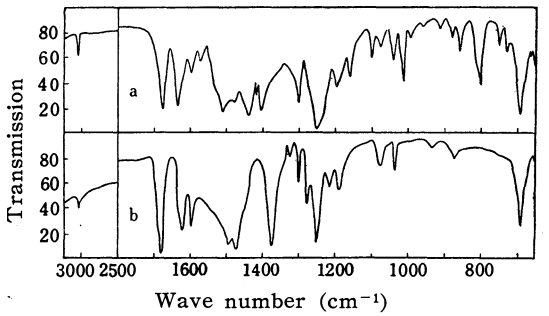
10) I. R. spectra are measured using Perkin-Elmer Model 21 double beam spectrophotometer by Mr. Y. Ikegami of this Institute, to whom the author is deeply indebted.

11) R. G. Fargher and F. L. Pyman, *J. Chem. Soc.*, **115**, 217 (1919).

12) This is considered to have appeared by the overlapping of the K-band of benzoic acid. Cf. A. E. Gillam and E. S. Stern, "An Introduction to Electronic Absorption Spectroscopy in Orgaic Chemistry", Edward Arnold Publishers, London (1954), p. 126.

values of IX, it is assumed that IX is a benzoic acid salt of X.

Analytical values of VIII agree with $C_{21}H_{16}O_2N_2$. Its mild treatment with dilute acid or alkali affords X from the basic portion and one molar equivalent of benzoic acid from the acid portion. The ultraviolet spectrum of VIII (Fig. 1) shows an entirely different curve from those of IX and X, but its spectrum in acid and alkaline solvents (Fig. 3) shows a curve extremely similar to the absorption of X in acid and alkaline media with the exception of the absorption at around 230 mμ[12].



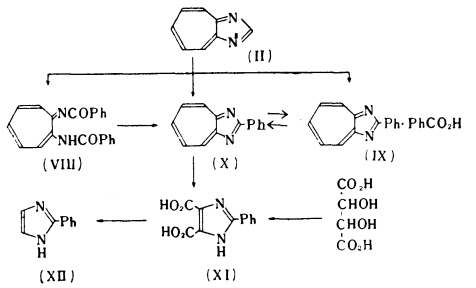


Fig. 4. I. R. absorption spectra of VIII.
a, in KBr-pellet; b, in CCl_4 soln.

In the infrared absorption spectrum of VIII (Fig. 4), there are absorptions considered to be the C=O stretching vibration of secondary amide[13] at the wave number[15] of 1683 (1676), the N-H deformation vibration at 1492 (1515), the N-H strectching vibration at (3290), and the C=O stretching vibration of tertiary amide at 1622 (1630).

Scheme 2.

The foregoing results suggest that VIII is 2-aminotropoimine dibenzoate formed by the ring-cleavage of II. These changes are presented in Scheme 2.

Attempts were made to remove the benzoyl group from VIII by hydrolysis and to obtain the parent structure, 2-aminotropoimine (III), but the attempts failed because of the extreme facility with which VIII underwent cyclization[16] and its facile conversion to X under the conditions for hydrolysis.

Experimental[17]

Reaction of 1,3-Diazaazulene (III) and Benzoyl Chloride.—a) To a solution of 300 mg. (2.3 mmol.) of II dissolved in a solution of 370 mg. (9.2 mmol.) of sodium hydroxide in 8 cc. of water, 1.29 g. (9.2 mmol.) of benzoyl chloride was added in one lot, under ice cooling, and the mixture was stirred thoroughly. This treatment is accompanied by a considerable generation of heat and the mixture must be chilled efficiently. When yellowish brown clay-like substance began to separate out on the wall of the vessel, the mixture was allowed to stand overnight and extracted with chloroform, from which 1.02 g. of brown oily substance was obtained. This oil was dissolved in 2 cc. of mixture of benzene and petroleum ether (1 : 1), and the solution was passed through a column (10×150 mm.) of alumina. The column was eluted with petroleum ether and 80 mg. of yellow crystals, m. p. 146~151°C, was obtained. Four recrystallizations from ethanol afforded 2-aminotropoimine dibenzoate (VIII) as yellow scaly crystals, m. p. 157~158°C.

Further elution of the alumina column with mixture of benzene and petroleum ether (1 : 1) afforded 90 mg. of pale yellow oil which was crystallized from cyclohexane to crystals of m. p. 91~92°C. Recrystallization from benzene-cyclohexane mixture afforded 2-phenyl-1,3-diazaazulene benzoic acid salt (IX) as pale yellow needles, m. p. 94~95°C.

Further elution of the column with benzene, followed by elution with ethanol, gave dark brown oil from both. These products were derived to respective picrates and decomposed by dilute hydrochloric acid, from which 110 mg. of unchanged II was recovered.

b) To a solution of 500 mg. (3.8 mmol.) of II dissolved in a solution of 915 mg. (22.8 mmol.) of sodium hydroxide in 16 cc. of water, 2.13 g. (15.2 mmol.) of benzoyl chloride was added and reacted as in a). Purification through a column (10×180 mm.) of alumina was carried out similarly and 140 mg. of VIII from the fraction eluted with petroleum ether and 25 mg. of yellow crystals,

13) Absorption of 2-benzoylaminotropone[14] as the secondary amide with unsaturated seven-membered ring was as follows: 1685 (1678), 1502 (1513), 3270 (3275); these values were read by the author.

14) T. Nozoe, S. Seto, H. Takeda, S. Morosawa and K. Matsumoto, *Science Repts. Tohoku Univ.*, **I**, **36**, 126 (1952).

15) Measurements were made by the KBr-pellet method. Values in parentheses are of those measured as CCl_4 solution.

16) It has been also known that *o*-phenylenediamine dibenzoate also undergoes facile dehydration and cyclization to 2-phenylbenzimidazole. Cf. O. Gerngross, *Ber.*, **46**, 1913 (1913).

17) All melting points are uncorrected. Petroleum ether used in this work was of b. p. 40~60°C. The microanalyses were carried out by Mr. S. Ohyama and Miss A. Iwanaga, to whom the author's deep gratitude is hereby expressed.

m. p. 142~153°C, from a fraction eluted with benzene-petroleum ether were obtained. Recrystallization of the latter from benzene-petroleum ether mixture afforded 2-phenyl-1, 3-diazaazulene (X) as yellow prisms, m. p. 158~159°C.

c) A solution of 830 mg. (6.34 mmol.) of II dissolved in a solution of 1.02 g. (25.5 mmol.) of sodium hydroxide in 26 cc. of water was heated to 70~72°C on a water bath and 3.57 g. (25.5 mmol.) of benzoyl chloride was added in one lot with stirring. The mixture was maintained at this temperature for 1 hr., cooled, and extracted with chloroform. The oily substance obtained from this extract was purified by chromatography and 510 mg. of IX was obtained besides recovery of 155 mg. of II.

d) A solution of 850 mg. (6.5 mmol.) of II dissolved in a solution of 1.56 g. (39 mmol.) of sodium hydroxide in 27 cc. of water was reacted with 3.64 g. (26 mmol.) of benzoyl chloride as in c) and 520 mg. of X and 120 mg. of II were obtained.

Found (in a sample dried over P_2O_5 at 50°C/10 mmHg): C, 81.28; H, 4.95; N, 13.82. Calcd. for $C_{14}H_{10}N_2$: C, 81.53; H, 4.89; N, 13.58%.

a) Hydrochloride of X: Pale yellow prisms, m. p. 210°C (blacken) as recrystallized from ethanol.

Anal. Found: N, 11.47. Calcd. for $C_{14}H_{10}N_2 \cdot HCl$: N, 11.53%.

b) Picrate of X: Pale yellow, silky needles, m. p. 209~210°C, as recrystallized from water.

Anal. Found: C, 55.12; H, 3.43; N, 16.17. Calcd. for $C_{14}H_{10}N_2 \cdot C_6H_3O_7N_3$: C, 55.18; H, 3.01; N, 16.09%.

c) Styphnate of X: yellow silky needles, m. p. 231°C (decomp.), as recrystallized from 50% ethanol.

Anal. Found: C, 52.87; H, 3.24; N, 15.31. Calcd. for $C_{14}H_{10}N_2 \cdot C_6H_3O_8N_3$: C, 53.22; H, 2.90; N, 15.52%.

d) Benzoic acid salt (IX) of X: A solution of 50 mg. of X and 20 mg. of benzoic acid dissolved in 1 cc. of ethanol was heated for a few minutes, ethanol was evaporated, and the residue was recrystallized from benzene-petroleum ether mixture to pale yellow needles, m. p. 93~94°C, which showed no depression on admixture with IX.

Oxidation of X with Potassium Dichromate.—A solution of 150 mg. of X and 490 mg. of potassium dichromate dissolved in 12 cc. of 6 N sulfuric acid was heated on a water bath for 45 min. and the mixture was allowed to stand for 3 days at room temperature. The crystals that separated out were collected by filtration and 55 mg. of XI, m. p. 263~264°C (decomp.), was obtained. This XI was sublimed under diminished pressure to effect decarboxylation and 30 mg. of colorless crystals, m. p. 138~140°C, was obtained which showed no depression in the melting point on admixture with 2-phenylimidazole (XII), synthesized from tartaric acid[18].

Hydrolysis of VIII.—a) A mixture of 200mg. of VIII in 1.5 cc. of 2 N sulfuric acid was heated on a water bath for a few minutes, by which time the crystals dissolved to form an orange solution. This solution was extracted with chloroform and 50 mg. of crystals; m. p. 111~120°C, was obtained. Recrystallization from petroleum ether raised the melting point to 119~120°C, undepressed by admixture with benzoic acid. The aqueous layer separated after chloroform extraction was made weakly alkaline with sodium hydrogen carbonate and extracted with chloroform, from which 125 mg. of crystals melting at 156~157°C, identified with X, was obtained.

b) A mixture of 50 mg. of VIII dissolved in 1 cc. of ethanol and 0.5 cc. of 2 N sodium hydroxide solution was refluxed on a water bath for 5 min., ethanol was evaporated, and the residual solution was diluted with water. This was extracted with chloroform and 20 mg. of X was obtained from the extract. Extraction of the aqueous layer after acidification afforded 10 mg. of benzoic acid.

The author takes this opportunity to express his deep gratitude to Professor Tetsuo Nozoe for his unfailing guidance and to Assistant Professor Toshio Mukai for much helpful advice.

18) Ultraviolet absorption spectra of the sample and synthesized product were in good agreement, both showing λ_{max}^{MeOH} 269 mμ (log ε 4.20) and λ_{min}^{MeOH} 230 mμ (log ε 3.37).

The Kinetic Study of Surface-chemical Reactions at Extremely Low Pressures. II. The Thermal Reaction between Water Vapor and a Tungsten Filament. Part II

By Takuya HAMAMURA

(Received August 15, 1958)

It has been shown previously[1] by a hot filament method that the major part of water molecules impinging on the hot surface of tungsten filament rebound without reaction even at high temperatures. These results, however, were not free from the end effect of the filament, since it was kept cooler at the both ends, where it was joined with leads which were much thicker than the filament and hence practically not heated at all by an electric current; the reaction probability* determined directly from the observed rate of reaction is, in consequence, an average one being smaller than that at the middle portion. The present paper is concerned with the elimination of the effect of the above-mentioned end losses.

Several devices[2] have been reported for the elimination of end losses, e. g., to heat the leads with auxiliary heaters attached to them or to heat the filament from outside of the vessel by an electric furnace, but the former is complicated in structure and the latter is not suitable for the present purpose. The use of a long filament often employed for this purpose is not appropriate to the flow method, since the pressure difference along the filament becomes too large at a high rate of reaction.

Two-filament Method. — In the present work, two filaments differing in length are used and the end effect of the longer filament is compensated with that of the shorter one. Two filaments, one longer (main) and the other shorter (compensating), of the same diameter and material are mounted in the vessel and heated one by one with the same current to obtain the reaction probabilities separately. Then, the reaction probability free from the end effect is obtained as follows. Let L_m and L_c denote the lengths of the two filaments ($L_m > L_c$) and k_m and k_c the respective reaction probabilities. Dividing the main filament into two end portions $L_c/2$ in length each and the middle portion $L_m - L_c$ in length, the reaction probability k_m can be expressed as a weighted mean of the probability k'_c at the end portions and k' at the middle portion. Then, k' is given by

$$k' = (k_m L_m - k'_c L_c)/(L_m - L_c) \qquad (8)^{**}$$

When the two filaments are heated with the same current, the end portions of the longer one will attain the same distribution of temperature as that along the compensating filament, and the middle portion at a uniform temperature provided that the filaments are long enough. Therefore, k'_c is equal to k_c if the reaction probability is independent of the pressure of water vapor, and is equal to k_c at the same partial pressure of water vapor as that under which k_m is obtained if the probability depends upon the pressure. Therefore, if k_c is obtained at various pressures P of water vapor and plotted against P, k'_c is obtained graphically, and hence k', the reaction probability free from the end losses, can be evaluated by Eq. 8. Although the two filaments are heated under the same initial pressure, the partial pressure while the respective filament is being heated is not the same, owing to the difference in the reacting areas of the filaments.

Experimental

Apparatus. — The apparatus was essentially the same as that of the previous paper. Only the changed points will be described below.

A reaction vessel was 7.0 cm. in diameter and 30 cm. in length. In it two tungsten filaments each 0.114 mm. in diameter and 128 mm. and 81 mm. long, respectively, were mounted perpendicular to the axis of the vessel at a distance of 5 cm. from each other. The distributions of

** Eqs., Figs. and Tables are numbered following consecutively those of the previous paper (Ref. 1).

temperature along the filaments were previously determined by the method of Langmuir and others[3]. The tungsten filaments used were taken from the same spool as that used in the previous experiments and pretreated in a similar manner. A Pirani gauge having a sensitivity of 1.42×10^{-5} mmHg for hydrogen was attached to the glass balloons in place of McLeod manometer M_3. The wall in front of the filaments was protected from the blue deposit of reaction product by a glass tube containing an iron rod which was hung in the vessel with a thin wire and shifted by a solenoid only when the temperature was measured by an optical pyrometer.

Procedure.—Procedures of evacuating the apparatus, degassing the filaments and introducing water vapor into the vessel have been described previously[1]. When the flow of water vapor became stationary, the main filament was heated and the temperature was measured with an optical pyrometer. As the reaction proceeded the pressure in the glass balloons increased gradually and this increase was measured with the Pirani gauge, every two minutes for sixteen minutes. The filament was then cooled and the balloons were evacuated. After this treatment, the compensating filament was heated with the same current and the pressure increase was measured similarly for the same time. The pressure increase gave the rate of reaction, and hence k_m[4] and k_c were evaluated by Eq. 7 and P by Eq. 6. Variations of k_m and k_c with P at a definite temperature were determined by a series of the experiments carried out by heating the filaments with a fixed current under various initial pressures of water vapor.

The temperature of the vessel remained at room temperature throughout the experiments, the effect of the heated filament being negligible at its highest temperature.

Results and Discussion

The experiments were carried out at temperatures from 1430 to 1940°K and initial pressures of water vapor from 12×10^{-5} to 125×10^{-5} mmHg. Values of k_m and k_c obtained were plotted against P in a log–log plot, respectively. Some of them are shown in Fig. 5.

From these plots, values of k_m and k'_c at a definite pressure were obtained, and the probability k' free from the end losses was evaluated by Eq. 8. Values of k_m, k'_c and k' at 60×10^{-5} mmHg pressure of water vapor thus obtained are given in Table II. Plots of $\log k'$ vs. $1/T\times10^3$ at 30×10^{-5} and 60×10^{-5} mmHg of water vapor are given in Fig. 6. Humps observed in the curves in the vicinity of 1700°K were not observed in the previous experiments, perhaps because of insufficient points of observation. No hysteresis was observed in the whole range of temperatures. The apparent heat of activation at 60×10^{-5} mmHg of water vapor is plotted against the filament temperature in Fig. 7.

Plots of $\log k'$ vs. $\log P$ at various temperatures are also shown in Fig. 5. It is evident that the elimination of end losses is significant especially at lower temperatures. It was found from this figure that the reaction probability decreased with increase of the pressure of water vapor. Although this decrease seemed to be

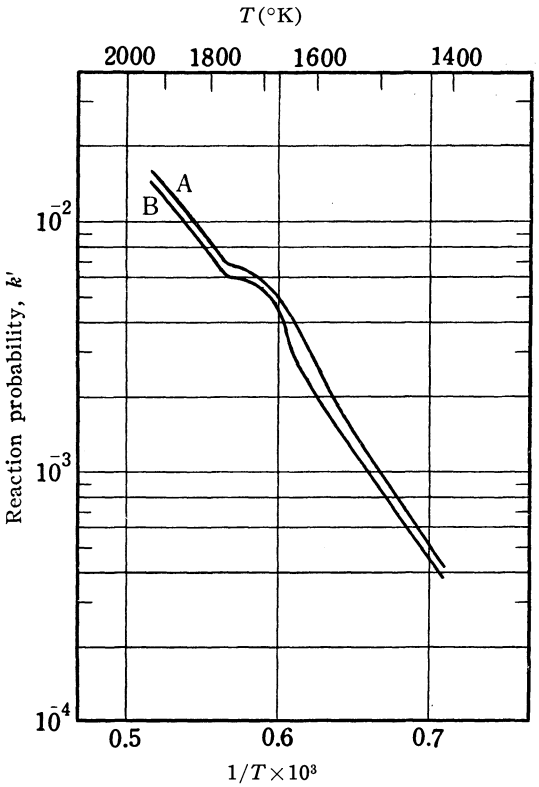

Fig. 6. Effect of filament temperature on the reaction probability k' at 30×10^{-5} and 60×10^{-5} mmHg of water vapor. A—30×10^{-5} mmHg, B—60×10^{-5} mmHg.

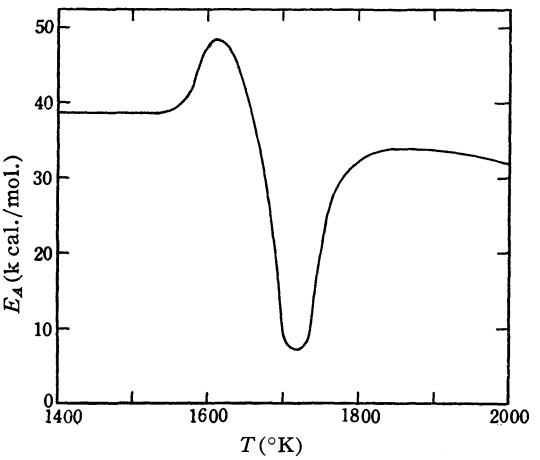

Fig. 7. Apparent heat of activation at 60×10^{-5} mmHg of water vapor.

caused by cooling of the filament by water vapor or by decrease of the reaction probability itself, the lowering of the temperature was not observed by either the optical pyrometer or the resistance of filament.

At filament-temperatures and pressures of water vapor plotted in Fig. 5, the reaction rates were independent of hydrogen pressures. Effect of hydrogen pressure on the reaction rate will be described in the following paper.

From the plot of $\log k'$ vs. $\log P$ the order n of reaction with respect to water vapor can be determined. As described in the previous paper, the rate of reaction D is given by

$$D=k'SBP \tag{5}$$

The reaction rate depends only upon the pressure of water vapor, when the filament temperature is fixed, as

$$D=KP^n \tag{9}$$

where K and n are constants. Eliminating D from Eqs. 5 and 9, k' is given by

$$k'=K/SB\times P^{n-1} \tag{10}$$

or

$$\log k'=\log(K/SB)+(n-1)\log P \tag{11}$$

The value of $n-1$ is thus given as the slope of the curve of $\log k'$ plotted against $\log P$ as in Fig. 5. The order of reaction thus obtained are tabulated in Table III. The reaction is nearly the first order.

TABLE III. ORDER OF REACTION

Temp. of filament (°K)	1505	1610	1710	1850	1940
Order of reaction, n	0.8_0	0.6_0	0.8_6	0.8_0	0.8_0

Summary

1) The end effect of filament upon the reaction probability was eliminated by means of the two-filament method. Its principle and procedure were described.

2) Reaction probabilities were determined at temperatures from 1430 to 1940°K and pressures of water vapor from 12×10^{-5} to 125×10^{-5} mmHg.

3) The reaction probability increased remarkably with the increase of temperature, but the rate of increase became smaller in the vicinity of 1700°K.

4) The order of reaction with respect to water vapor was found to lie between 0.6_0 and 0.8_6.

The Kinetic Study of Surface-chemical Reactions at Extremely Low Pressures. III. The Thermal Reaction between Water Vapor and a Tungsten Filament. Part III

By Takuya HAMAMURA

(Received March 17, 1959)

In continuation of the previous papers[1,2] in which the kinetics of the reaction of water vapor with tungsten was studied, this paper is concerned with the study of the effect of hydrogen pressure on the reaction rate, which seems to give some information about the adsorbed layer on the filaments surface.

Experimental

Apparatus. — The apparatus was essentially the same as that used in the previous experiments, except for an equipment for the control of hydrogen pressure. The pressure of hydrogen in the reaction vessel was changed by an adjustable needle valve placed in the path between trap 6 and diffusion pump 7 in Fig. 1*. If the flow of hydrogen in the path obeys Knudsen's law of molecular flow and the back diffusion through the pump is negligibly small, the quantity D in moles of hydrogen which flow into the balloons per second is given by the following equation similar to Eq. 1'

$$D=A'\bar{B}'P' \tag{12}$$

where A' is the over-all conductance of the path from the reaction vessel to the pump, $\bar{B}'$ is a constant determined experimentally, and P' is the partial pressure of hydrogen in the vessel. Therefore, when A' was changed by varying the conductance of the needle valve, P' was changed correspondingly. The above procedure, however, did not change the pressure of water vapor in the vessel, since the conductance A of the path from the vessel to trap 6 was not changed even if A' was changed. The value of $A'\bar{B}'$ could be determined experimentally by measuring D and P' while hydrogen was flowing through the path. Thus after knowing $A'\bar{B}'$, P' could be calculated from the measured value of D.

The needle valve is shown schematically in Fig. 8. When the mercury was lowered, hydrogen flowed mainly through the wide tube, and when the mercury was raised to cut the wide tube off, it flowed through the capillary with a smaller conductance, then by moving a glass needle containing an iron rod by a solenoid into the capillary, the conductance could be decreased further. The over-all conductance of the path from the reaction vessel to the diffusion pump was 4.90×10^{-3} cm^2 when the mercury was lowered, 1.21×10^{-3} cm^2 when the mercury was raised and the needle was drawn out of the capillary, and 3.15×10^{-4} cm^2 when the whole length of the needle was in the capillary.

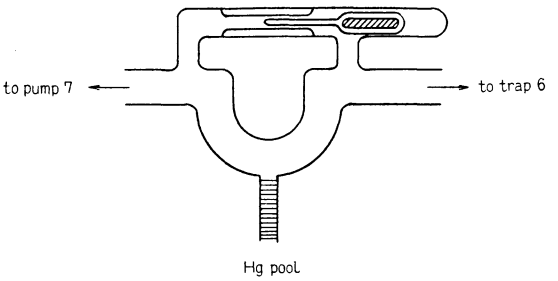

Fig. 8. The needle valve.

A tungsten filament 0.114 mm. in diameter and 81 mm. long was used. This was taken from the same spool as that used in the previous experiments and pretreated in a similar manner. A Pirani gauge of the same type as that attached to the glass balloons was attached to the reaction vessel.

Procedure.—The procedures of evacuating the apparatus, degassing the filament and introducing water vapor into the vessel were described previously. When the flow of water vapor became stationary, the pressure was measured with a quartz fiber manometer, and the filament was then heated to a desired temperature, the conductance of the needle valve being kept at a desired value. The pressure increase of the glass balloons was measured in a similar manner as mentioned previously. The pressure increase gave the reaction rate, and the hydrogen pressure in the vessel was calculated by Eq. 12. Thus, the effect of hydrogen pressure on the reaction rate was determined by the experiments carried out by heating the filament under various conductances of the valve at a fixed temperature and a constant initial pressure of water vapor. The temperature of the reaction vessel remained at room temperature throughout the experiments.

Results

The experiments were carried out at filament temperatures of 1850 and 1940°K

1) N. Sasaki and T. Hamamura, This Bulletin, **29**, 365 (1956).
2) T. Hamamura, ibid., **32**, 845 (1959).

under 12×10^{-5} and 32×10^{-5} mmHg initial pressures of water vapor and at 1510, 1615, 1850 and 1940°K under 62.5×10^{-5} mmHg.

The reaction rate was independent of the hydrogen pressure below 1850°K at all the initial pressures of water vapor studied. At 1940°K, however, the reaction rate was independent of the hydrogen pressure at 62.5×10^{-5} mmHg of water vapor, but decreased with the increase of hydrogen pressure gradually at 32×10^{-5}

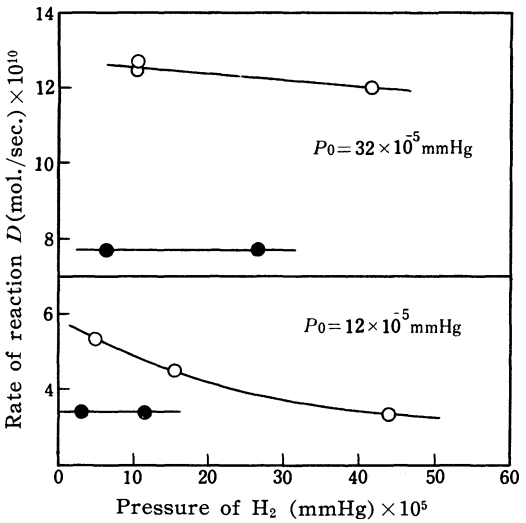

Fig. 9. Effect of hydrogen pressure on the reaction rate. ●-1850°K, ○-1940°K.

mmHg and steeply at 12×10^{-5} mmHg. These are shown in Fig. 9. It was apparent from these results that the reaction rate was independent of the hydrogen pressure at lower filament temperatures or higher pressures of water vapor but decreased with the increase of hydrogen pressure at higher filament temperatures and lower pressures of water vapor. Moreover, the reaction rate decreased more steeply as the temperature increased or the pressure of water vapor decreased.

Discussion

The reaction rate might decrease owing to the retardation of the reaction by hydrogen or might decrease owing to the uptake of hydrogen by the wall, because the rate was calculated from the pressure increase of the glass balloons. The independency of reaction rates upon the hydrogen pressures at lower filament temperatures or higher pressures of water vapor might suggest that neither retardation nor uptake occurred under these conditions. As for the uptake, the following facts are known by the studies[3,4] of Langmuir: when a tungsten filament is heated above 1300°K in hydrogen at low pressure, the hydrogen gradually disappears. This action is caused by the hydrogen dissociated into atoms in contact with the filament, the atom then being driven on to the bulb and there held by adsorption. But the disappearance of hydrogen is suppressed almost completely by a trace of oxygen or water vapor at lower filament temperatures, presumably because of the formation of an adsorbed layer of oxygen acting as a catalytic poison against the dissociation of hydrogen. In the present work, too, the filament surface might be covered with oxygen at lower temperatures or higher pressures of water vapor, and in consequence neither retardation nor uptake occurred. However, the disappearance is known to take place again when the filament temperature rises or the pressure of oxygen or water vapor decreases, probably because of desorption of the adsorbed layer. In the present work, the reaction rate was found to decrease at higher temperatures and lower pressures of water vapor. This seemed to suggest that the decrease was caused by the uptake of hydrogen by the wall, the effect being known as "clean up".

Summary

Hydrogen hardly affected the reaction at lower filament temperatures or higher pressures of water vapor, but it decreased the rate of reaction at higher temperatures and lower pressures, as ascribed to the "clean up" of hydrogen by the filament.

The Infrared Spectra of Alkane-1-sulfonates

By Kuniaki FUJIMORI

(Received September 13, 1958)

Several investigations have been made on the characteristic infrared absorptions of sulfur-oxygen compounds such as sulfones or sulfone amides, and 1350~1300 cm^{-1} and 1160~1120 cm^{-1} bands were attributed to $-SO_2-$ group[1,2]. On sulfonic acids or their salt, however, there can not be found any systematic studies on their characteristic infrared absorptions. Bellamy[3] proposed 1200~1160 cm^{-1} and 1060~1030 cm^{-1} bands as the characteristic infrared absorptions of $-SO_3-$ group based on his results for aromatic sulfonates. Simon and Kriegsmann[4] investigated Raman and infrared spectra of alkali metal salts of methanesulfonic acid, and discussed these spectra under the assumption that methanesulfonate ion has the symmetry property of C_{3v}. Houlton and Tartar[5] investigated Raman spectra of several *n*-alkane-1-sulfonates in aqueous solution, compared these spectra with those of other sulfur compounds, and proposed some assignments.

Since the assignments so far given seem not to be decisive, the author studied infrared spectra of alkane-1-sulfonates where carbon numbers are 1—8 and 12 in the solid state. Taking into account the theoretical result given in the succeeding paper[6] and the spectra of CXY_3 type molecules, the spectra of methanesulfonate ion were assigned. Furthermore, the characteristic infrared absorptions of sulfonic group and C-S bond in the sulfonic acids were assigned for higher sulfonates.

Results and Discussion

The infrared spectra of sulfonates are shown in Figs. 1—9.

As to the assignments of S–O stretching and C–S stretching vibrations methanesulfonate ion was dealt with at first. In this case relatively stronger absorptions at 1192, 1060 and 789 cm^{-1} were found. As shown in the preceding paper[6], only three stretching vibrations, ν_1, ν_2 and ν_4, are expected to appear in the rock salt region, where ν_1 is S–CH_3 stretching, ν_2 S–O symmetric stretching, and ν_4 S–O degenerate stretching vibration. From the result of normal coordinate treatment and the comparison of similar molecules given in Table III, the assignments for the spectra of methanesulfonate ion are determined as shown in the table.

TABLE III. COMPARISON OF THE SPECTRA OF $(CH_3)SO_3^-$ AND SIMILAR MOLECULES (in cm^{-1})

Molecules	ν_1	ν_2	ν_4

CCl_3Br	418	710	765
$SO_3(CH_3)^-$	789	1060	1192

The weak absorption at 970 cm^{-1} may be attributed to the rocking vibration of the methyl radical. Simon and Kriegsmann[4] and Siebert[7] reached the same conclusion.

Comparing the absorptions of the higher sulfonates with those of methanesulfonate, the assignments can be made as listed in Tables IV—VI.

About C–S stretching vibration, Simon and Kriegsmann[4] and Siebert[7] reached almost the same conclusion for the cases of

TABLE VII. ROCKING VIBRATION OF $-(CH_2)_n-$ GROUP (in cm^{-1})

n	Wave No.	n	Wave No.
2	726 (w)	5	720 (w)
3	759 (m)	6	720 (w)
	723 (m)	7	720 (w)
4	720 (w)	11	721 (w)

methane- and ethane-sulfonates. However, the rocking vibration of $-(CH_2)_n-$ group in the *n*-alkyl radical is expected to be at about 750 cm^{-1} when n is 2 and at 730~720 cm^{-1} when n is greater than 3. Some irregularity found in Table VI may be due to the coupling of C-S stretching vibration with this CH_2 rocking vibration of $-(CH_2)_n-$ group is summarized in Table VII.

The absorptions at 1250 cm^{-1} of methane- and ethane-sulfonates, at 836 cm^{-1} of ethane-sulfonate may be attributed to overtones or combination tones.

Experimental

Samples. — *Methanesulfonate.* — Methanesulfonic acid (pure reagent grade) was distilled in vacuo (b. p. 160°C at 5 mmHg) and the aqueous solution was neutralized with sodium carbonate and evaporated to dryness. Sodium methanesulfonate was recrystallized from 90% ethanol.

Ethanesulfonate.—Ethyl mercaptane (b. p. 37°C) was oxidized with concentrated nitric acid[8] and the reaction mixture was neutralized with sodium carbonate (10% aqueous solution), the sulfonate solution was evaporated to dryness and extracted with hot ethanol to separate inorganic salts. The sulfonate was recrystallized from ethanol.

Other sulfonates.—Sulfonates other than above described were prepared by Strecker reaction[9]. Corresponding chloride was heated from 180 upto 200°C in a stainless steel autoclave for 10~16 hr. with sodium sulfite (anhydride) and water. The reaction mixture was filtered and evaporated to dryness. The residue was washed with petroleum ether (b. p. 30~40°C) and the sulfonate was extracted with hot ethanol and recrystallized from ethanol.

Absorption Measurement. — The infrared spectra were obtained with a Perkin-Elmer Model 21 double beam infrared spectrophotometer using NaCl prism. The KBr disk method was employed to obtain the spectra in solid state.

The author expresses his indebtedness to Dr. A Kotera, Professor of Tokyo University of Education, and Dr. T. Shimanouchi, Assistant Professor of the University of Tokyo, under whose kind direction this work was performed. He also thanks Mr. Y. Ikegami, Fellow of Tohoku University, for his cooperation to obtain infrared spectra and Mr. Y. Akai, Chief of Research Section of Funakawa Refinery, for his encouragement of this research.

LCAO SCF Calculation on Anthracene and Reactivity Indexes in SCF Method

By Kenichi FUKUI, Keiji MOROKUMA and Teijiro YONEZAWA

(Received January 30, 1959)

In order to interpret chemical reactivity of conjugated molecules, there have been proposed several quantum-mechanical methods in LCAO MO treatment, such as the frontier electron method (frontier electron density and superdelocalizability as reactivity indexes[1]), the static method (total π-electron density and self-polarizability for an ionic reaction and free valence for a radical reaction)[2], the localization method (localization energy)[3], and so on.

Within the scope of the simple LCAO MO treatment, where electronic interaction is not explicitly considered, total π-electron density of an alternant hydrocarbon is unity for all the positions[4], and accordingly in terms of the static method the ionic reactivity is to be determined by self-polarizability of each position. But once electronic interaction is taken into account, the uniformity of total π-electron distribution is immediately extinguished, so that its magnitude comes to correspond to the ionic reactivity in a molecule in the static method. For *trans*-butadiene the coefficients of AO's in MO's, calculated in semi-empirical SCF method[5], in non-empirical SCF method[6] and in non-empirical SCF CI method[7], show the larger π-electron density, i. e., the larger electrophilic reactivity, at the position 2, contradictory to the experiments. Further, semi-empirical SCF calculation on naphthalene leads to an erroneous prediction of electrophilic reactivity[8].

For the purpose of obtaining more information on reactivity indexes, in the first two paragraphs of the present paper, we determine the coefficients of AO's in MO's of anthracene by semi-empirical LCAO SCF method and discuss on some physico-chemical properties. In the last paragraph it is examined whether or not each of total π-electron density, free valence and frontier electron density remains a good index of chemical reactivity in SCF treatment.

Method

Roothaan has developed in detail the general formalism of LCAO SCF method for the closed configuration of a molecule[9]. This will not be repeated here for the sake of brevity. Using his theory with only π-electrons considered explicitly, we numerically calculate the coefficients of AO's in SCF MO's of the ground state of anthracene.

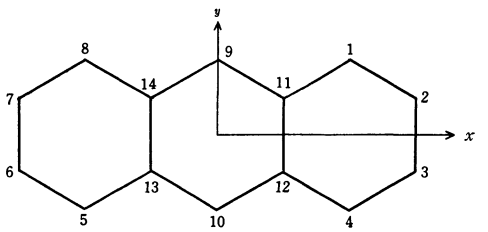

Fig. 1. The numbering of atoms and the coordinate of symmetry operation of anthracene.

The numbering of atoms and the coordinate of symmetry operation are shown in Fig. 1. The bond distances are taken to be 1.370 Å for the bond 1—2, 1.396 Å for 9—11, 1.408 Å for 2—3, 1.423 Å for 1—11 and 1.436 Å for 11—12, and all the bond angles are assumed in a good approximation to be 120° [10].

Necessary numerical evaluation of the reasonance integral, $\beta_{\mu\nu}$, and the coulomb repulsion integral, $\gamma_{\mu\nu}$, are carried out on the semi-empirical formulae proposed by

TABLE I. SCF MO'S AND THEIR ORBITAL ENERGIES OF ANTHRACENE

Symmetry	Orbital energy[a]	MO	
b_{1u}	$\varepsilon_1 = -5.762$	$\psi_1 = 0.4887\sigma_4 + 0.4448\sigma_5 + 0.3323\sigma_6 + 0.6730\sigma_7$	occupied
b_{2g}	$\varepsilon_2 = -5.190$	$\psi_2 = 0.5818\sigma_8 + 0.6276\sigma_9 + 0.5174\sigma_{10}$	
b_{1u}	$\varepsilon_3 = -3.350$	$\psi_3 = 0.3108\sigma_4 + 0.7098\sigma_5 - 0.3717\sigma_6 - 0.5113\sigma_7$	
b_{3g}	$\varepsilon_4 = -3.196$	$\psi_4 = 0.6278\sigma_{11} + 0.3465\sigma_{12} + 0.4423\sigma_{13} + 0.5386\sigma_{14}$	
a_{1u}	$\varepsilon_5 = -2.433$	$\psi_5 = 0.7932\sigma_1 + 0.4861\sigma_2 + 0.3668\sigma_3$	
b_{2g}	$\varepsilon_6 = -1.9935$	$\psi_6 = 0.0792\sigma_8 + 0.5894\sigma_9 - 0.8039\sigma_{10}$	
b_{3g}	$\varepsilon_7 = -0.2930$	$\psi_7 = 0.5130\sigma_{11} + 0.4221\sigma_{12} - 0.6793\sigma_{13} - 0.3117\sigma_{14}$	
b_{1u}	$\varepsilon_8 = +7.1389$	$\psi_8 = 0.4431\sigma_4 - 0.3746\sigma_5 - 0.7573\sigma_6 + 0.2997\sigma_7$	unoccupied
a_{1u}	$\varepsilon_9 = +7.6451$	$\psi_9 = 0.0811\sigma_1 + 0.5125\sigma_2 - 0.8548\sigma_3$	
b_{2g}	$\varepsilon_{10} = +9.124$	$\psi_{10} = 0.8095\sigma_8 - 0.5087\sigma_9 - 0.2932\sigma_{10}$	
b_{1u}	$\varepsilon_{11} = +9.668$	$\psi_{11} = 0.6843\sigma_4 - 0.3974\sigma_5 + 0.4219\sigma_6 - 0.4425\sigma_7$	
b_{3g}	$\varepsilon_{12} = +9.726$	$\psi_{12} = 0.1781\sigma_{11} - 0.5967\sigma_{12} - 0.5090\sigma_{13} + 0.5943\sigma_{14}$	
a_{1u}	$\varepsilon_{13} = +11.747$	$\psi_{13} = 0.6035\sigma_1 - 0.7079\sigma_2 - 0.3671\sigma_3$	
b_{3g}	$\varepsilon_{14} = +12.069$	$\psi_{14} = 0.5576\sigma_{11} - 0.5880\sigma_{12} + 0.2895\sigma_{13} - 0.5095\sigma_{14}$,	

where[b]

$\sigma_1 = (1/2)(\phi_1 - \phi_4 + \phi_5 - \phi_8)$, $\sigma_2 = (1/2)(\phi_2 - \phi_3 + \phi_6 - \phi_7)$, $\sigma_3 = (1/2)(\phi_{11} - \phi_{12} + \phi_{13} - \phi_{14})$,
$\sigma_4 = (1/2)(\phi_1 + \phi_4 + \phi_5 + \phi_8)$, $\sigma_5 = (1/2)(\phi_2 + \phi_3 + \phi_6 + \phi_7)$, $\sigma_6 = (1/\sqrt{2})(\phi_9 + \phi_{10})$,
$\sigma_7 = (1/2)(\phi_{11} + \phi_{12} + \phi_{13} + \phi_{14})$, $\sigma_8 = (1/2)(\phi_1 + \phi_4 - \phi_5 - \phi_8)$, $\sigma_9 = (1/2)(\phi_2 + \phi_3 - \phi_6 - \phi_7)$,
$\sigma_{10} = (1/2)(\phi_{11} + \phi_{12} - \phi_{13} - \phi_{14})$, $\sigma_{11} = (1/2)(\phi_1 - \phi_4 - \phi_5 + \phi_8)$, $\sigma_{12} = (1/2)(\phi_2 - \phi_3 - \phi_6 + \phi_7)$,
$\sigma_{13} = (1/\sqrt{2})(\phi_9 - \phi_{10})$, $\sigma_{14} = (1/2)(\phi_{11} - \phi_{12} - \phi_{13} + \phi_{14})$

a) W_{2p} as standard. In units of eV. b) ϕ_i is the AO on the i-th atom.

Pariser and Parr[11]. In the expression of the coulomb integral, α_μ,

$$\alpha_\mu = W_{2p} - \sum_{\nu(\neq\mu)} \{\gamma_{\mu\nu} + (\nu : \mu\mu)\} \qquad (1)$$

no particular values of the coulomb penetration integral, $(\nu : \mu\mu)$, have been given by Pariser and Parr, and on the theoretical consideration[12] we have determined its average value as 0.85 eV. when the atoms μ and ν are adjacent, as 0.08 eV. when μ and ν are separated by a single atom, and as zero otherwise. W_{2p} in Eq. 1 is as usual the electronic energy of a carbon atom in its valence state and is regarded as a constant.

Results and Discussion on Anthracene

The obtained SCF MO's, ϕ_i, of the ground state of anthracene and their orbital energies, ε_i, are collected in Table I, together with non-occupied MO's.

Ionization Potential. — Putting $W_{2p} = -11.28$ eV.[11], we obtain 11.57 eV. as the first ionization potential of anthracene, which is, though no experimental results are available, much larger than the estimated value, 7.23 eV., by Matsen[13]. Giving too large calculated value is not particular to the case of anthracene, but the general tendency of SCF calculation[5,6,8]; on this point a discussion shall be made in near future.

Electronic Spectra. — The energies of configurations, the values of interconfigurational matrix elements and wave functions of the excited states are listed in

TABLE II. THE ENERGIES OF CONFIGURATIONS, THE VALUES OF INTERCONFIGURATIONAL MATRIX ELEMENTS AND THE EXCITED STATES WAVE FUNCTIONS[a]

B_{2u}: $[66 \mid 99] = 5.535$, $[69 \mid 96] = 0.551$,

Table II, where only four lower excitations are considered. The calculated excitation energies and oscillator strengths are given in Table III, together with the observed values. The agreement with experiments is good, but for the inversion of excitation energies of $^1B_{2u}^-$ band and $^1B_{3u}^+$ band, which will be improved by the inclusion of more possible configurations.

Bond Order and Bond Distance. — Our SCF bond orders and observed bond distances are collected in Table IV, in comparison with the SCF bond orders by Pritchard and Sumner in a rough approximation[14] and with the bond orders in simple LCAO treatment. It is seen in Table IV that SCF bond orders in the present calculation are parallel with the observed bond distances except for the bond 11—12, in accordance with Pritchard and Sumner's result. The discrepancy in the bond 11—12 seems to indicate that the bond order of a bonding is not determined only by its length but by its nature; namely, whether the ending carbons of this bonding are primary, secondary or tertiary.

TABLE IV. THE BOND ORDERS AND OBSERVED BOND DISTANCES OF ANTHRACENE

Bond	Bond order			Obsd. bond distances (Å)[b]
	Present treatment	Pritchard and Sumner[a]	Simple LCAO	
1—2	0.8347	0.8422	0.7374	1.370
9—11	0.6107	0.6318	0.6061	1.396
2—3	0.4542	0.4493	0.5859	1.408
1—11	0.4383	0.4178	0.5354	1.423
11—12	0.5533	0.5484	0.4849	1.436

b) Ref. 10.

SCF Reactivity Indexes

First of all we define SCF frontier electron density in the same way as in simple LCAO treatment[1], where the frontier orbital denotes the highest occupied one for an electrophilic reaction, the lowest unoccupied one for a nucleophilic reaction, and both for a radical reaction.

The calculated results of total π-electron density, free valence and frontier electron densities of anthracene are given in Table V. Values of these reactivity indexes in SCF method of naphthalene and *trans*-butadiene are collected in Tables VI and VII, respectively.

Total π-electron density of anthracene is the largest at the position 11 and decreases in the order of 2, 1 and 9. The position 11 being out of the question because of its lack of hydrogen to be substituted, an electrophilic substitution should take place at the position 2 and a nucleophilic substitution at the position 9 on the basis of the static method. This prediction contradicts experimental results that the position 9 is the most reactive in an electrophilic substitution. Concerning naphthalene the position 2, where SCF total π-electron density has the largest value as shown in Table VI, does not actually suffer from an electrophilic substitution. Furthermore, as for butadiene Table VII shows that total π-electron densities by semi-empirical SCF method, by non-empirical SCF method and by non-empirical SCF CI method lead to the same erroneous prediction that the position 2 is the most susceptible to an electrophilic reaction. Thus SCF total π-electron density is no longer a good index for chemical reactivity.

On the contrary, it will be valuable to emphasize that SCF frontier electron density correctly predicts the most reactive positions, that is, the position 9 in anthracene, 1 in naphthalene and 1 in

14) H. O. Pritchard and F. H. Sumner, *Proc. Roy. Soc.*, **A226**, 128 (1954); H. O. Pritchard, private communication. Their assumptions are the same as those that are presented by Pople[15], the main points of which are (1) neglect of the coulomb penetration integral, and (2) assumption of equi-bond-length and of regular hexagone of carbon ring, and (3) that the coulomb repulsion integral, $\gamma_{\mu\nu}$, is expressed in the following form.
$\gamma_{\mu\nu}=e^2/R_{\mu\nu}$ ($R_{\mu\nu}$: distance between the atoms μ and ν)
15) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953).

TABLE V. VALUES OF SCF REACTIVITY INDEXES OF ANTHRACENE

Position	Total π-electron density	Free valence	Frontier electron density		
			Electrophilic	Nucleophilic	Radical

	6	0.436
Pyrene	1	0.432
	2	0.395
	4	0.485

a) Ref. 14.

butadiene for all the three kinds of reactions. It may be, therefore, concluded that frontier electron density remains a good reactivity index even when the electronic interaction is explicitly included.

So far as our approximation is concerned, free valence seems to give correct results in the three hydrocarbons, as shown in Tables V, VI and VII. In comparison with this, we have collected in Table VIII values of free valence of some hydrocarbons, which have been derived from the SCF bond orders obtained by Pritchard and Sumner[14]. It can be seen in Table VIII that this free valence leads to a seriously erroneous conclusion for anthracene and for pyrene: anthracene is, as is well known, the most susceptible to a radical attack at the position 9, and pyrene is so at 1. On inspection of these and other results of SCF calculation[16], it

16) G. Berthier, *J. chim. phys.*, **50**, 344 (1953); I. Tanaka, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **75**, 218 (1954); H. O. Pritchard and F. H. Sumner, *Trans. Faraday Soc.*, **51**, 457 (1955); etc.

may be said that the value of bond order, or that of free valence, varies very easily depending on the degree or approximation employed and on the semi-empirical method of evaluating atomic integrals. Such an unstable quantity would probably not deserve a reliable reactivity index.

*Interaction entre les colorants et les surfactifs. II**

Par Tamotsu KONDO, Kenjiro MEGURO et Hidero NITO

(Reçu le 11 février 1959)

Dans le rapport précédent[1], les phénomènes de floculation et de défloculation de la rhodamine et de l'éosine en présence de surfactifs ont été systématiquement étudiés, et les mécanismes de ces phénomènes ont été proposés.

Nous allons essayer, dans le présent travail, d'élucider l'influence de la structure chimique de divers colorants sur les phénomènes de floculation et de défloculation.

Expériences

Matériels. — Les colorants que nous avons utilisés sont classifiés dans le Tableau I.

TABLEAU I. COLORANTS UTILISÉS

Classification	Valence	Nom
Colorants acides	−1	Orange de méthyle
	−1	Orange II
	−1	Na de sulfonate de *p*-hydroxyazobenzène
	−2	Orange G
	−2	Ponceau R
	−2	Tartrazine
Colorants basiques	+1	Jaune d'acridine
	+1	Bleu de méthylène
	+1	Violet de méthyle
	+1	Vert de méthyle
Colorants directs	−2	Benzopurpurine 4B
	−2	Rouge de congo
	−2	Chrysophénine G

Les surfactifs employés sont le bromure de dodécyl-pyridonium et le sodium de dodécyl-sulfate (que nous appellerons B.D.P. et S.D.S.). Leurs préparation et purification ont été déjà décrites dans un autre article[2].

Méthodes expérimentales.—Les méthodes adptées pour observer les phénomènes de floculation et de défloculation des colorants sont les mêmes que nous avons écrites précédemment[1].

Résultats

Floculation et défloculation des colorants par le B.D.P.—L'addition d'un peu de B.D.P. aux solutions de colorants acides a généralement causé la floculation des colorants. Dans le cas de la tartrazine, cependant, on n'a pas observé la floculation, mais on a trouvé seulement l'apparition de la turbidité.

Les floculés colorés ainsi formés étaient solubles dans le chloroforme qui ne dissout pas les colorants acides employés dans ce travail. On a pu extraire un corps coloré dans le chloroforme du mélange de tartrazine et de B.D.P. en solution. On doit alors penser que les floculés et le corps coloré sont des complexes formés entre les colorants et le B.D.P.

On a vu que les floculés ont été remis en solution en présence d'une quantité supérieure de B.D.P. Les concentrations de B.D.P. auxquelles les floculés commencent à défloculer étaient indépendantes de la C.C.M. (concentration critique micellaire) de cet agent cationique.

La valeur de floculation et celle de défloculation du B.D.P. étaient définies comme le minimum des concentrations nécessaires de cet agent pour floculer le colorant, et pour défloculer complètement le floculé[1], respectivement. Celle-là

* Une partie de ce rapport a été présentée à la réunion de chimie colloïdale de la société chimique du Japon qui s'est tenue à Kanazawa, au mois d'octobre 1957.

1) T. Kondo et K. Meguro, Ce Bulletin, **32**, 267 (1959).

2) O. Yoda, K. Meguro, T. Kondo et T. Ino, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **75**, 1272 (1954).

était presque indépendante de la structure chimique du colorant et celle-ci ne l'était pas. La différence de ces deux valeurs, que nous appellerons désormais la largeur de la zone de floculation, s'est accrue lorsqu'on a augmenté la concentration de colorant en solution. La Fig. 1 représente la relation entre la largeur de la zone de floculation et la concentration de colorant.

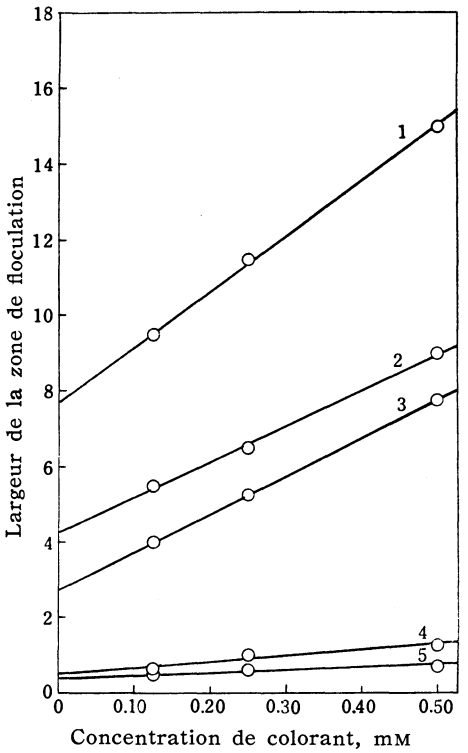

Fig. 1. Relation entre la largeur de la zone de floculation et la concentration de colorant. (1).

TABLEAU II. VALEURS DU N_d DU B.D.P.

Colorant	N_d
Orange de méthyle	14.8
Orange II	9.6
Na de sulfonate de *p*-hydroxyazobenzène	1.6
Orange G	10.2
Ponceau R	0.5

Le talus des lignes droites est caractéristique de chaque colorant et donne le nombre minimum des ions de surfactif qui est nécessaire pour disperser une molécule de complexe. Ce nombre a été nommé le nombre de défloculation, N_d, du surfactif[1]. Les valeurs obtenues sont données dans le Tableau II.

Floculation et défloculation des colorants basiques par le S.D.S.—La floculation du jaune d'acridine et du bleu de méthylène s'est effectuée par le S.D.S., tandis que celle du violet de méthyle et du vert de méthyle n'a jamais lieu par cet agent.

La formation d'un complexe coloré a été vérifiée par l'essai d'extraction dans le chloroforme ou l'acetate d'éthyle pour chaque cas de ces colorants. On a observé la défloculation du floculé en présence d'une quantité supérieure de S.D.S. La Fig. 2 fournit le diagramme qui indique la relation de la largeur de la zone de floculation avec la concentration de colorant.

On obtient la valeur du N_d du S.D.S. qui est de 9.8 et 8.1 pour le jaune d'acridine et le bleu de méthylène, respectivement, en utilisant le talus des lignes droites dans la Fig. 2.

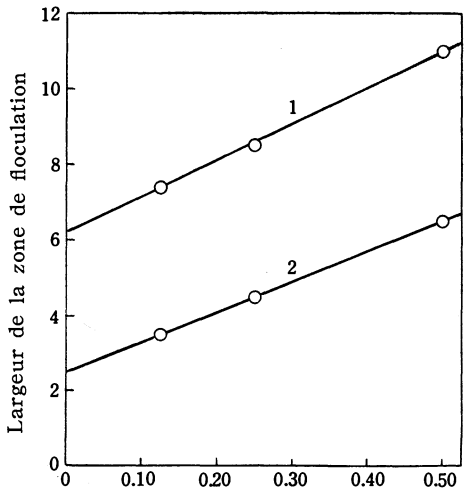

Fig. 2. Relation entre la largeur de la zone de floculation et la concentration de colorant. (2).

Floculation et défloculation des colorants directs.—Tous les colorants directs utilisés ont été floculés par un peu de B.D.P. Les concentrations de B.D.P. qui sont nécessaires pour la floculation des colorants étaient presque égales. Malgré l'addition d'une grande quantité de B.D.P., la défloculation de la benzopurpurine 4B n'a jamais été observée. Dans le cas du rouge de congo, le floculé a dispersé d'abord et ensuite refloculé, lorsque la concentration en agent cationique croît graduellement. On a trouvé pour la chrysophénine G que la zone de floculation et celle de défloculation ont paru deux fois alternativement quand on a graduellement

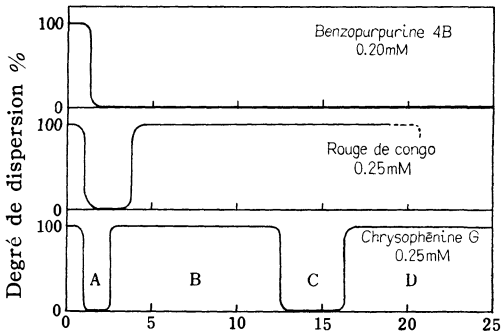

Fig. 3. Schéma de floculation des colorants directs.
A, Première zone de floculation;
B, Première zone de défloculation;
C, Deuxième zone de floculation;
D, Deuxième zone de défloculation.

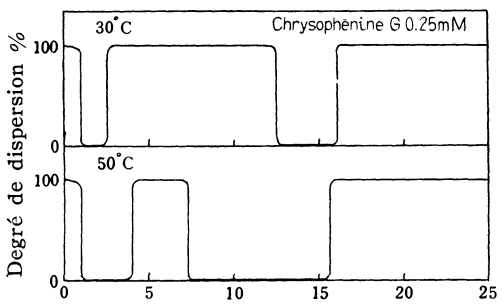

Fig. 4. Influence de la température sur la floculation de la chrysophénine G.

augmenté la de quantité B.D.P. en solution. Lorsqu'on a centrifugé les solutions de la première zone de défloculation, on a constaté qu'il y a eu la précipitation d'un corps coloré. La Fig. 3 donne le schéma de floculation de ces colorants directs.

L'élevation de la température a été accompagnée par la contraction de la première zone de défloculation de la chrysophénine G. Cela est indiqué dans la Fig. 4.

Considérations

Nous avons conclu précédemment[1] que la défloculation d'un complexe est due à la combinaison d'un certain nombre des ions de surfactif avec ce complexe et que le N_d n'y est pas nécessirement égal. A ce point de vue, nous allons examiner les résultats expérimentaux de la défloculation, car la floculation ne dépend pas rigoureusement de la structure chimique des colorants.

L'influence de la structure chimique du colorant sur le N_d.—Comparons d'abord les valeurs du N_d des colorants acides monovalents l'une à l'autre. Ces valeurs sont de 14.8, 9.6 et 1.6 pour l'orange de méthyle, l'orange II et le sodium de sulfonate de *p*-hydroxyazobenzène respectivement. Ces trois colorants ne diffèrent dans leur structure chimique que par le groupe nonionique lié au radical azoïque, comme le montre la Fig. 5.

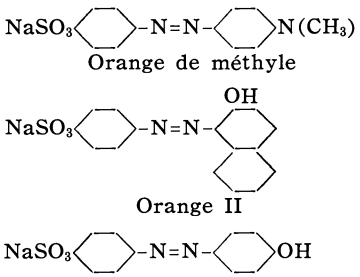

Fig. 5. Structures chimiques des colorants acides.

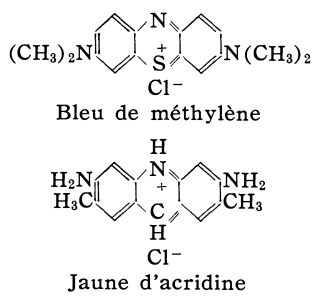
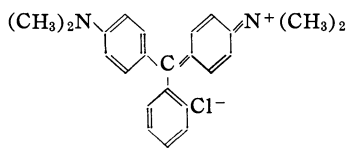
On doit, par suite, attribuer la différence de la valeur du N_d à celle de la structure du groupe nonionique du colorant.

Les affinités du phénol, du naphthol β et de la diméthylaniline pour l'eau diminuent dans l'ordre suivant:

Phénol > naphthol β > diméthylaniline.

On pourra conclure, en conséquence, que la valeur du N_d dépend profondément de l'affinité du groupe nonionique du colorant pour l'eau. C'est-à-dire, plus grande est l'affinité du groupe nonionique pour l'eau, plus petite est la valeur du N_d. L'ordre des valeurs du N_d pour ces colorants acides est en accord avec celui de leurs solubilités dans l'eau. En ce qui concerne des colorants acides bivalents, on peut aussi constater qu'un petit N_d de colorant amène une grande solubilité dans l'eau. La valeur du N_d du ponceau R, par exemple, est moins grande que celle de l'orange G qui est moins soluble que celui-là.





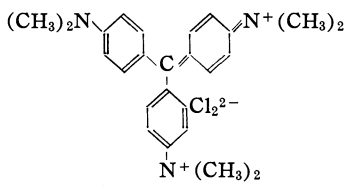


Fig. 6. Structures chimiques des colorants basiques (1).

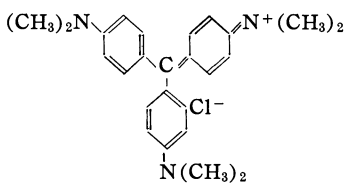
Le jaune d'acridine et le bleu de méthylène ont les structures chimiques semblables l'une à l'autre comme les montre la Fig. 6. Le fait que les valeurs du N_d pour ces deux colorants sont presque égales sera du à la similarité des structures chimiques de ces colorants.



Floculation et défloculation des colorants de triphénylméthane.—On a déjà décrit que le violet de méthyle et le vert de méthyle, colorants de triphénylméthane, ne sont pas floculés par le S.D.S. La comparaison des résultats expérimentaux concernant le vert de malachite, qui est floculé et défloculé par le S.D.S.[3], à ceux du violet de méthyle et du vert de méthyle nous amène à examiner de l'influence de la structure chimique de ces colorants sur leur comportement dans les solutions du S.D.S. La Fig. 7 fournit les structures chimiques de ces trois colorants.

Vert de malachite

Vert de méthyle

Violet de méthyle

Fig. 7. Structures chimiques des colorants basiques (2).

Notons, par exemple, la différence de la structure entre le vert de malachite et le violet de méthyle. Comme le montre cette figure, le vert de malachite et le violet de méthyle ont, respectivement, deux et trois groupes diméthylaminés entre lesquels une charge électrique positive est mise en résonance. Ce fait empêche la localisation d'une charge électrique et amènera, par conséquence, la diminution du pouvoir de la combinaison du colorant avec un ion de sulfate de dodécyl. En outre, plus les structures mises en résonance sont nombreuses, plus le degré de localisation d'une charge sera faible. Alors, le complexe se forme suffisamment en solution pour que l'on puisse observer sa floculation dans le cas du vert de malachite et ne l'est pas dans le cas du violet de méthyle.

Lorsque la quantité de S.D.S. augmente davantage en solution, la combinaison de l'ion de sulfate de dodécyl au complexe a lieu et ce complexe commence à se disperser.

Floculation et défloculation des colorants directs.—Il est bien connu que les molécules de colorant direct se forment l'agrégat dans l'eau, donc l'interaction entre le colorant et le surfactif doit être, dans ce cas, celle entre l'agrégat des molécules de colorant, que nous appellerons le micelle de colorant, et les ions de surfactif.

Cette considération nous amène à conclure que le mécanisme de la floculation du colorant direct sera le même que celui qui a été proposé par les présents auteurs pour la floculation des particules colloïdales par le surfactif[4]. C'est-à-dire, la surface du micelle de colorant perd l'affinité pour l'eau, et il en résulte la floculation.

La tendence vers l'agrégation dépend de la structure chimique du colorant. Pour des colorants directs employés dans ce travail, cette tendence augmente dans l'ordre suivant[5]:

Chrysophénine G < rouge de congo < benzopurpurine 4B.

On pourra expliquer plausiblement les résultats expérimentaux obtenus pour la défloculation, si l'on présume qu'un micelle de colorant est partagé en certains submicelles ou en molécules individuelles par l'addition d'une grande quantité de surfactif et que le micelle de la benzopurpurine est partageable le moins facilement. En d'autres termes, on présume que la défloculation du colorant direct succède au partage du micelle de colorant par le surfactif.

La dispersion du submicelle, correspondant à celle dans la première zone de défloculation, sera due à l'adsorption des ions de surfactif, orientant leur groupe ionique vers l'eau, sur la surface hydrophobique du submicelle floculé.

Lorsque la concentration de surfactif

croît de plus en plus, le submicelle commence à se diviser. Les charges électriques qui ont été cachées apparaîtront alors et les ions de surfactif se déposeront sur ces charges. La deuxième zone de floculation parait ici.

L'élévation de la température accélère le partage du micelle du colorant[5]. Ce fait causera la contraction de la première zone de défloculation, qui a été observée dans le cas de la chrysophénine G.

Le mécanisme de la défloculation dans la deuxième zone sera le même que celui suggéré pour les colorants acides ou basiques.

Catalytic Hydrogenation of Aromatic Nitriles

By Kazuo HATA and Ken-ichi WATANABE

(Received February 17, 1959)

Catalytic hydrogenation of various aromatic nitriles has been investigated using nickel-copper-kieselguhr catalyst in vapor phase. An earlier study has been made by P. Sabatier[1], but it was only reported that benzonitrile was reduced to toluene and ammonia, while a different result was presented by A. Frébault[2]. Systematic study in this field has never been made and the mechanism of hydrogenation of nitriles has not yet been thoroughly established, although some views have been presented during the past half century[3]. In this paper, results of a systematic study on the catalytic hydrogenation of various aromatic nitriles are presented. The effect of various substituents in aromatic ring is discussed, along with the factor of promotion and retardation in hydrogenation. Further, the mechanism of the hydrogenation of nitriles has been investigated and some views are presented.

1) **Hydrogenation of Aromatic Nitriles in Vapor Phase.**—It was previously reported that nitrile is hyrogenated to methyl compound and ammonia in vapor phase[1] (1), whereas to amines in liquid phase[3] (2).

$$RCN \xrightarrow{H_2} RCH_3 + NH_3 \quad (1)$$

$$RCN \xrightarrow{H_2} RCH_2NH_2,\ (RCH_2)_2NH \quad (2)$$

The original purpose of the present study was to investigate whether or not aromatic nitriles of any kind undergo hydrogenolysis to methyl compounds in vapor phase. Various aromatic nitriles listed in Table I have been hydrogenated. The vapor of nitrile, mixed with an excess of hydrogen, was passed over a catalyst in a reaction tube, which was heated to an appropriate temperature between 200 ~350°C in an electric furnace. The catalyst, which consists of 60% of reduced nickel and 40% of reduced copper, was prepared according to Sabatier's method[1], and supported on purified kieselguhr. Representative experimental results of the hydrogenations are summarized in Table I. As seen in the table, it has been proved that aromatic nitriles are generally hydrogenated to the corresponding methyl compounds according to Formula 1 except for some special cases. However, it is important to note that this cleavage reaction of the nitrile group could not be complete unless sufficient condition for hydrogenation was given[4].

It is now apparent that the reaction temperature at which the hydrogenolysis is effectively carried out is governed by the nature of the compound to be hydrogenated. A well defined range of temperature for the efficient cleavage reaction was found for each compound. It has been found that, in general, a scission of C–C bond between nitrile group and

aromatic ring occurs as shown in Formula 3, when the hydrogenation is carried out at higher temperature (e. g., Experiment No. 2).

$$RCN \xrightarrow{H_2} RH + CH_3NH_2^* \quad (3)$$

The data given in Table I, are the results of the hydrogenation which give the best yield of the methyl compound among several experiments carried out under various conditions, especially under various reaction temperatures (except for Experiment No. 2). On the other hand, ammonia, which was liberated from the nitrile group during hydrogenation, was introduced to normal sulfuric acid solution and was determined by a titration with baryta water. The yield of ammonia suggests the degree of the cleavage reaction of the nitrile group. When the condition of hydrogenation is changed, somewhat different results can be observed for each compound. It is significant that the cleavage of the nitrile group is largely dependent upon the kinds and the positions of substituents in the aromatic ring.

Besides the normal cleavage reaction of nitriles, various side reactions were observed. For example, reductive cyclization was remarkable in the reaction of ethyl *o*-cyanobenzoate[5]. Sometimes, the side reaction was so complicated that the products could not be identified.

1) Effect of Substituents in Aromatic Ring on the Hydrogenation of Nitriles.— It is very difficult to estimate the effect of substituents on the hydrogenation of the nitrile group, because catalytic reaction is complicated with many factors. Nevertheless, it is conceivable that the relative reactivity of the cleavage reaction may be estimated by comparing the yields of the products, although a vapor phase hydrogenation is carried out ordinarily under such a drastic condition that it may cause undesirable side reactions. In general, it has been proved that a substituent in the aromatic ring exhibits both electronic and steric effects on the hydrogenation of the nitrile group. Any substituent seems to depress the hydrogenation of the nitrile group.

As for the electronic effect, electron-releasing substituents give less effect, while electron-attracting substituents such as nitro, cyano, ethoxycarbonyl and aldehyde groups restrain the hydrogenation of the nitrile group remarkably. However, the effect due to the electronic characteristics of the substituent is not always observed clearly since the catalytic hydrogenation is also governed by many other complicated factors.

In the catalytic reaction, it is the first requisite for the initiation of the reaction that the compound should be adsorbed on the surface of the catalyst. This consideration has led to the inference that the nitrile group will be unfavorably hydrogenated, if another substituent in the same ring undergoes competitive hydrogenation or interferes with the adsorption of the nitrile group on the catalyst by steric effect. As for the steric effect, it is expected that the nearer the substituent to the nitrile group is, the larger is its effect. This effect is observed distinctly about nitro, amino, cyano, hydroxyl and ethoxycarbonyl groups, and may be expressed in terms of "ortho effect" in hydrogenation. When two substituents are introduced in both ortho positions beside the nitrile group, a greater steric effect is observed (Table I, Experiments No. 21 and 26). This "ortho effect" could not be obviously observed in the previous studies of hydrogenation in liquid phase. Further investigation of this effect should be made in connection with a mechanism of the reaction on the surface of catalyst.

A special interfering effect of the nitro and amino groups on the hydrogenation of the nitrile group, has been studied in particular[6]. It was first pointed out in the liquid phase hydrogenation by H. Rupe[7], that the nitro group has an interfering effect on the hydrogenation of the nitrile group, and it was shown extensively that the nearer the nitro group is to the nitrile group, the greater is the effect. Hydrogenation of nitro and aminobenzonitriles in vapor phase also gave less yield of the hydrogenolysis products (Table I, Experiments No. 7—11). In order to solve this problem, some experiments on mixed hydrogenation were made. The vapor of benzonitrile was mixed with that of nitrobenzene, aniline or water, and the mixture was hydrogenated as usual. On the other hand, benzonitrile was hydrogenated on the catalyst which had been previously used for the hydrogenation of nitrobenzene or aniline. The results of the experiments

* Methylamine may be further hydrogenated to methane and ammonia in high reaction temperature.

b) Cf. Table V, Experiment No. 6.

are shown in Table II. From these results, it is inferable that the nitro group is first reduced to the amino group and suppresses the hydrogenation of the nitrile group by a competitive reaction. It is further proved that the amino group produced from the nitro group acts poisonously for the catalytic activity (cf. Section 4). However, the hydrogenolysis of *p*-aminobenzonitrile could not be affected by the *p*-substituted amino group. This can be interpreted by the steric ineffectiveness of the *p*-substituted amino group as a poison for the catalyst.

3) **Investigation of Hydrogenation Mechanism of Nitriles.**—The investigation of the behavior of various nitriles in the hydrogenation has led to the study of hydrogenation mechanism of nitriles, which is complicated owing to the presence of secondary products. Generally, it has been known[3] that the main process of the hydrogenation of nitriles may be shown as follows:

$$RCN \rightarrow RCH=NH \rightarrow RCH_2NH_2 \rightarrow RCH_3+NH_3 \quad (4)$$

$$RCH=NH+RCH_2NH_2 \rightarrow RCH=NCH_2R \rightarrow (RCH_2)_2NH \quad (5)$$

$$3\,RCH=NH \rightarrow RCH(N=CHR)_2 \rightarrow RCH=NCH_2R \rightarrow (RCH_2)_2NH \quad (6)$$

It is conceivable that the course of the

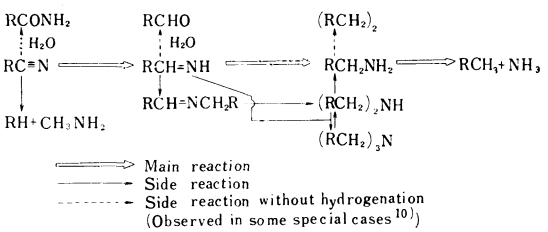
a) The nickel catalyst was previously treated with the vapor of these compounds, and then the nitrile was hydrogenated.
b) 25 g. of catalyst was used except for Experiments No. 2, 3 and 6.
c) The mixture of benzonitrile and ammonia was hydrogenated.

reaction is nearly the same whether in liquid phase or in vapor phase although some differences are found. Some factors in the hydrogenation may forcibly control the process of these reactions. The normal process of the hydrogenation of nitrile in vapor phase follows the course shown in Formula 4, and other side reactions or interruption of the process 4 may be caused by inadequate conditions of the hydrogenation. Such a hydrogenation under insufficient conditions may give ample facilities for the study of hydrogenation mechanism. Therefore, some hydrogenation experiments were tried intentionally under insufficient conditions (quantity of catalyst, feeding velocity of sample and hydrogen, etc.)[4]. It has been shown that the course of the reaction can be controlled in the expected way according to the condition of the hydrogenation. The examples of these experimental results are summarized in Table III.



In the hydrogenation of *o*-tolunitrile (Experiments No. 1—5), the yield of the methyl compound through course 4 decreased according to the decreasing quantity of catalyst used, alternatively yielding the increasing quantity of primary and secondary amines. When a small amount of hydrogen was fed during the hydrogenation, a similar result was obtained (Experiment No. 6). In Experiment No. 7, benzonitrile was hydrogenated in three portions successively on the same catalyst, and the products were collected separately for every portion. The components of the reaction products were varied according to the proceeding of the reaction, whereby the changing feature of the reaction was observed.

To ascertain the hydrogenation mechanism, the investigation of the behavior of the intermediate compounds in the process is useful. Thus, the further hydrogenation of amines, which have been found to be intermediate of the process, was carried out[8]. The results of the experiments are summarized in Table IV. When benzylamine was hydrogenated, toluene was obtained and no dibenzylamine was found. But the yield of toluene from benzylamine by the hydrogenation was less than that from benzonitrile, and a small quantity of unidentifiable by-product was obtained from benzylamine. It has been found that benzylamine was smoothly hydrogenated and toluene was obtained in good yield, when a small quantity of thiophene was added to the catalyst (Experiment No. 3). On the other hand, when dibenzylamine was hydrogenated, toluene was obtained in considerable yield, along with a small amount of benzylamine and other unidentified by-product.

It was reported previously by v. Braun[3] that the secondary amine is formed by interaction between a primary amine and an aldimine when aromatic nitrile is hydrogenated in liquid phase (process 5). According to the present investigation in vapor phase, it is evident that dibenzylamine can scarcely be obtained by the hydrogenation of benzylamine, or of the mixture of benzonitrile and benzylamine. It is assumed subsequently that the formation of dibenzylamine in the hydrogenation under insufficient conditions, proceeds through hydrobenzamide and Schiff base as an intermediate according to Formula 6.

It has been found that, when aromatic nitriles are hydrogentated in vapor phase at a higher temperature, the ordinary hydrogenation to methyl compound (reaction 1) is generally accompanied with the hydrogenolysis of C–C bond between the nitrile group and aromatic ring (reaction 3). It has been proved that this cleavage of C–C bond occurs mainly before the hydrogenation of C–N bond does[9]. This cleavage reaction also occurs even at a temperature not so high, when the hydrogenation of the nitrile group happens to be interfered with by the effect of other substituents (Table I, Experiments No. 9 and 11). The cleavage of this type is observed especially in some ortho-substituted benzonitriles (Table I, Experiments No. 21 and 26).

Considering the results of these experiments, the hydrognation mechanism of aromatic nitriles in vapor phase is assumed to be as follows:

Expt. No.	Weight of thiophene (g.)	Hydrogen absorbed (%)	Time (hr.)	Products and yields (%)		
				Prim. amine	Sec. amine	Aldehyde
1.	0	90	1⅔	47	23	11
2.	0.007	93	2⅙	61	13	11
3.	3.5	89	11	56	11	15

4) Factors for Promotion and Retardation in Hydrogenation of Nitriles.—It has been widely known that the result of the hydrogenation reaction varies according to the character of the catalyst, which can be controlled by the addition of appropriate promoter or poisonous matter. The promotion or retardation of the hydrogenation was also observed in aromatic nitriles. The effect of various substances on the character of the nickel catalyst has been investigated[8], and the results of these experiments are summarized in Table V. When benzonitrile was hydrogenated with nickel catalyst which was previously treated with a small amount of thiophene, toluene was obtained in high yield, little by-product being found (Experiment No. 2). On the contrary, when the catalyst was previously treated with ammonia, amine or pyridine, the formation of toluene was suppressed and considerable amounts of by-products were obtained (Experiments No. 7—13). In some experiments, the mixture of benzonitrile and some other basic substances was hydrogenated with the ordinary nickel catalyst, and the results were similar to those in Table V (except the experiment with ammonia, cf. Experiments No. 7 and 8). A similar effect of thiophene has been observed in the liquid phase hydrogenation of benzonitrile (shown in Table VI)[11].

As the result of these experiments, the addition of basic substances (such as amine) has been found to cause retardation of the hydrogenation of nitrile. On the other hand, it has been found that the addition of a small quantity of thiophene causes promotion and increases the yield of the methyl compound, whereas the formation of secondary products is considerably suppressed. Thus, it is evident that the suitable amount of thiophene on the catalyst retards the side reaction of nitriles (e. g., the formation of secondary amine). This effect was especially remarkable in the case of hydrogenation under insufficient conditions. For example, toluene was obtained in high yield from benzonitrile, even when a small quantity of the catalyst was used (Experiment No. 2, compared with Experiment No. 7 in Table III). On the contrary, a large amount of thiophene acts as poison for all the various sorts of the reaction: a large quantity of the nitrile was recovered unchanged (Experiments No. 3 and 4).

On the Dissolution of Na_2O-CaO-SiO_2 Glass in Acid and in Water

By Shoji TSUCHIHASHI and Eiichi SEKIDO

(Received February 26, 1959)

The "chemical durability of glass" is one of the research items of great academic interest, and of leading technical importance as well. Accordingly, there have been many papers published on this subject.

The usual way of representing the results of durability tests is to express them in the equivalent concentration of sodium oxide leached out from the glass surface; sometimes from glass powder to accelerate the attack on glass, or from the glass container itself to make the data more practical. For many purposes this way of presenting data is very useful, because the varying alkalinity of the solution stored in a glass container is often a matter of serious concern.

In multi-component glasses, sodium oxide is not the only substance which passes into solution, even in the initial stage when the silica network remains unchanged. Investigating the change of interference colors produced by the changing thickness of the silica-layer remaining on the surface of some flint glasses immersed in nitric acid solution, the author could confirm the fact that the chemical attack proceeds through the exchange reaction between cations such as Na^+, K^+ and Pb^{2+} in glass on the one hand and H^+, or H_3O^+ in solution on the other[1]. Moreover, the exchange between Na^+, K^+ in glass and H^+ in solution takes place at a rate far greater than that between Pb^{2+} in glass and H^+ in solution, so that the rate of diffusion of Pb^{2+} through glass network determines the rate of reaction.

In studying the mechanism of chemical attack on glass by using soda-lime-silica glass which is simpler in composition and of more practical importance, the optical method fails in its object, because both the rate of reaction and the difference in refractive index between the surface layer and the body are smaller than when we use flint glass.

Hence, in order to draw a clear picture of the complete set of chemical reactions, the components leached out from glass by the conventional powder method were completely analyzed.

Experimental Methods

Preparation of the Solution for Analysis. —1) *Sample.*—The glass plates of composition given in Table I were crushed in a percussion mortar, and the powder was sieved to classify it into three meshes, namely, 16~20 (0.833~0.991 mm.), 20~24 (0.701~0.833 mm.), 24~32 (0.495~0.701 mm.), washed thoroughly with methanol to remove all fine particles adhering to the grains, and finally dried at 120°C.

TABLE I. COMPOSITION OF GLASS (weight %)

SiO_2	Na_2O	CaO	MgO	$Fe_2O_3+Al_2O_3$
73.64	13.12	8.44	2.37	2.37

2) *Acid solution.*—As it is necessary to deal exhaustively with an extremely small amount of ions, the water used for the experiments was completely demineralized by treating it successively with ion-exchange resins. This treatment was used also for preparing hydrochloric acid and sulfuric acid solutions, the concentrations of which were 1 N throughout the experiments.

3) *Apparatus.*—The apparatus used for the leaching out experiments is shown in Fig. 1. It is a three-necked flask with a stirrer, both of which are made of Pyrex glass.

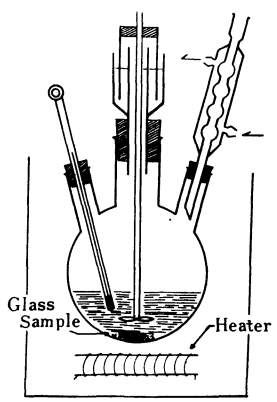

Fig. 1. Apparatus used for the durability test.

4) *Procedure.*—1.00 g. of the glass powder was accurately weighed out and transferred into the flask containing 100 ml. of reagent. Under continuous stirring the temperature was raised as quickly as possible to 100°C, at which it was kept

constant for one or three hours, and then the flask was cooled to room temperature. The solution was separated carefully from the glass powder and subjected to chemical analysis.

A series of blank tests were made in order to determine the amount leached out from the container wall and from the stirrer. The figures obtained, although negligibly small, were subtracted from the results in order to obtain the actual net values.

Chemical Analysis of the Solution.—I. *Silica.*—In order to determine an extremely small amount of silica which had passed from the glass into the liquid, the spectrophotometric method based on the measurement of yellow or blue molybdo-silicic acid was used. There are, however, some points which should be made extremely clear in order to get reliable results. It is known that the color developed changes with the state of existence of silica in solution, namely, whether it is in ionic state, in molecular state or in colloidal state[2-5]. The following conditions should be taken into account.

1) *pH value.*—Quite recently Narita[6] investigated the relation between the quantity of silica in ionic state and the pH of sodium silicate solutions with the result shown in Fig. 2. Since his experiments covered higher percentages of silica than in the present instance, the authors made experiments on the solutions containing smaller amounts of silica, whose compositions are given in Table II.

The silica content was exactly 5 p. p. m. after 6 hr. and 5 p. p. m. after 6 days in pH 12 solution, but was reduced to 0.5 p. p. m. in a 1 N sulfuric acid solution. By adding Ca^{2+} to the solution the

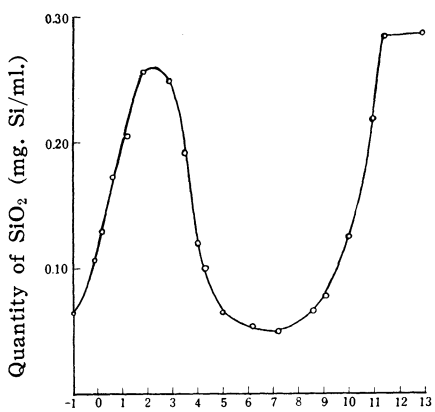

Fig. 2. The relation between the quantity of SiO_2 in ionic state and the pH of solution (after Narita).

TABLE II. DETERMINATION OF SiO_2 INFLUENCED BY OTHER ELEMENTS

Sample solutions	Value of measurements	
	After 6 hr.	After 6 days
5 p.p.m. SiO_2 in 1N H_2SO_4	5 p.p.m.	0.5 p.p.m.
5 p.p.m. SiO_2+5 p.p.m. Ca^{2+}, in 1 N H_2SO_4	5	0
5 p.p.m. SiO_2 in pH 12 solution	5	5
5 p.p.m. SiO_2+5 p.p.m. Ca^{2+}, in pH 12 solution	5	2.9

quantity of ionic silica was reduced; for instance, to 0 in a 1 N sulfuric acid solution, and to 2.9 in an alkaline solution of pH 12. From these observations it may be concluded that the quantity of ionic silica does not depend on the pH of that solution alone. As it has already been shown that the optimum pH value to determine the amount of silica is 1~1.6, we also followed these conditions in performing our experiments.

2) *Quantity of ammonium molybdate.*—The absorption spectra of the solutions, one containing 2 p. p. m. of silica and various amounts of molybdate and the other 20 p. p. m. of silica and various amounts of molybdate, were measured with the result that the addition of 5 ml. of 10% solution of molybdate to 50 ml. solution containing silica gave the greatest sensitivity to the spectra, and that the addition of a larger amount than 5 ml. brought about an undesirable influence[5,7].

3) *Wavelength.*—The published photometric procedures have proved to be of no practical use for measuring the absorption of the yellow molybdo-silicic acid at the optimum wavelength. The recommended wavelengths in millimicrons were: 370[8], 380[7], 390[9], 390 to 400[10], 400[11], 405[12], 416[6,7,13], 420[14], 425[15] and 436[16]. Taking into account these facts, the authors used 410 mμ ("yellow" method) and 810 mμ ("blue" method).

4) *Calibration curve.*—Beer's law was applicable whithin the range from 0 to 60 p. p. m. of silica, and the authors used this calibration curve for the quantitative determination of silica.

We measured the absorbance of the solution as soon as possible after adding the ammonium molybdate to that solution to prevent the influence of Ca^{2+} and other ions. Moreover, in order to examine whether or not any trace of silica might escape as colloid without forming silico-molybdate, alkali was added to the solution to digest the last trace of colloid before it was subjected to analysis.

16) H. Pinsl, *Z. Metallkunde*, **27**, 107 (1935).

The results obtained with such treatment and those without it were quite the same, which proves that the present method is satisfactory.

II. *Sodium Oxide.*—Sodium oxide was determined by flame photometry using the spectral line at 589 mμ. As long as the concentration of alkali ions was in the order usually found in the durability tests, all substances except acids[17] were found to be harmless. The disturbance of acids was taken into full account, and the calibration curves were used to prevent the data from being influenced by coexisting anions.

III. *Calcium Oxide.*—Calcium oxide was determined by flame photometry using a calcium oxide band spectrum at 554 mμ. As it was found necessary to make clear the influence of coexisting ions on the result, a series of preliminary experiments were carried out.

1) *Influence of sodium ion.*—A 5 p. p. m. calcium standard solution containing 0 to 100 p. p. m. Na^+ and a 1 p. p. m. solution containing 0 to 20 p. p. m. Na^+ were aspirated to observe the change of the flame intensity, and it was possible to confirm the fact that there was no detectable influence of coexisting Na^+ so far as its concentration did not exceed 15 times the amount of Ca^{2+}.

2) *Influence of iron(III) ion.*—Carrying out the same experiments as the above using a 20 p.p.m. calcium standard solution containing 0 to 50 p.p.m. Fe^{3+}, it was recognized that the limiting concentration of Fe^{3+} was 0.5 times the amount of Ca^{2+}. As the amount of Fe^{3+} in the durability tests never exceeded this limiting value, the influence of coexisting Fe^{3+} may be ignored.

3) *Influence of silica.*—The change of the flame intensity of a 2 p. p. m. calcium standard solution containing silica (up to 5, 10 and 20 p.p. m., respectively) is shown in Figs. 3, 4 and 5. The curves show a general trend indicating that the flame intensity was reduced at first by the addition of silica and brought, by further addition, to a constant value approximately at the point

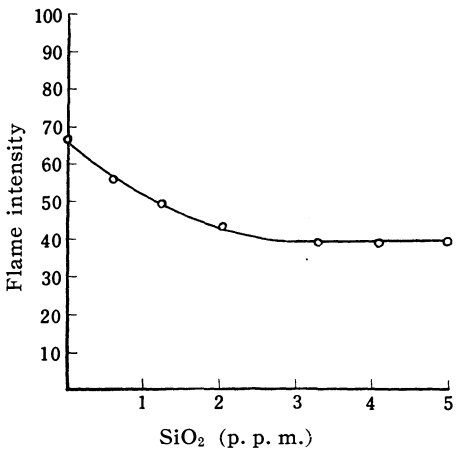

Fig. 3. Flame intensity of Ca^{2+} containing SiO_2
(Ca, 2 p. p. m.; SiO_2, 0～5 p. p. m.)

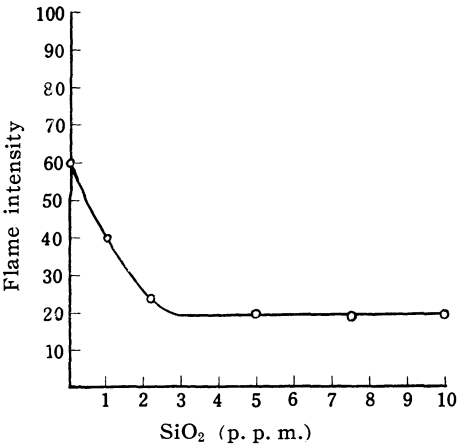

Fig. 4. Flame intensity of Ca^{2+} containing SiO_2
(Ca, 2 p. p. m.; SiO_2, 0～10 p. p. m.)

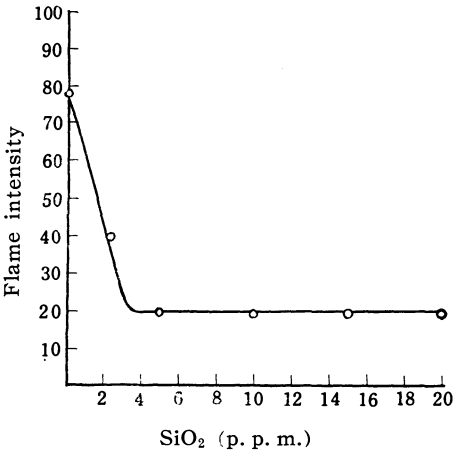

Fig. 5. Flame intensity of Ca^{2+} containing SiO_2
(Ca, 2 p. p. m.; SiO_2, 0～20 p. p. m.)

corresponding to the composition Ca : SiO_2=2 : 3. Thus, for the solution containing silica more than 3/2 of calcium, the calibration curve was drawn by analyzing the solution containing a known quantity of Ca^{2+}.

4) *Influence of acids.*—The disturbance of acids[18] was taken into full account and the calibration curves were made to make the results free from the influence of acids.

Results and Discussion

The data obtained by the durability tests are listed in Table III. The figures indicate that much larger amounts of silica were clearly leached out by water than by acids, and that silica probably placed a check on the rate of dissolution. In

The ratio in base glass (weight per cent)						0.18

every case, however, larger quantities of silica than those of sodium oxide, and much smaller quantities of calcium oxide than of the other two were found in the solution. As usual, the total amount of dissolved matters inceased in proportion to the length of time, and in inverse proportion to the grain size of the glass powder.

As for the ratio Na_2O/SiO_2, the figures in the sixth and last rows show that the solution had practically the same proportion of sodium oxide to silica as the base glass, and also that the attack of water on glass presumably caused the collapse of the whole structure. The acids did not seem to be so destructive to the network structure, since the ratios were always higher. This indicates that the exchange reaction between H^+ in solution and Na^+, Ca^{2+} in glass is governed by the rate of migration of the ions through the glass network to the surface.

The idea of the collapse of the whole glass structure is strongly supported by the experimental results obtained by Tieze[18] and others[20,21] who confirmed the successive exfoliation of the silica layer during the durability test. This was also proved by the gradual increase of the quantity of dissolved substances.

Action of Water on Glass. — Let us first focus our attention on the network former, silica, which has non-bridging oxygen bonded with Na^+, and try to explain why the ratio of components in the solution was practically the same as that in the base glass when it was attacked by pure water. For this purpose it will be convenient to consider the whole process in two separate stages, i. e., (1) the initial stage and (2) the depth action, although there is no sharp boundary-line between them.

The reactions in the initial stage are illustrated schematically in Fig. 6. At first there will be the migration of Na^+ from the glass into the liquid, which gives rise to the place exchange between H^+ and Na^+. In the meantime Na^+ in the glass

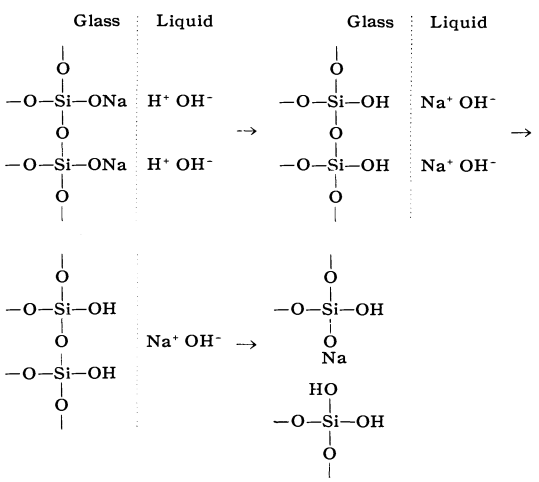

Fig. 6. Schematic representation of the chemical attack of water on glass surface.

19) P. Tieze, *Sprechsaal*, **61**, 809 (1928).
20) Tielsh and Zimmer, ibid., **66**, 285, 303, 319 (1933).
21) I. Sawai, M. Tashiro et al., *J. Ceram. Assoc. Japan (Yogyo Kyokai Shi)*, **52**, 258 (1944).

will diffuse to the surface through the network without producing any appreciable influence upon its structure. The continuous supply of Na^+ from inside, however, will accumulate sodium hydroxide at the surface, which then will begin to attack the bonding oxygen to open the network, so that silica also passes into the solution with gradual increase in its concentration. Hence in the initial stage, more sodium oxide goes into the solution than silica; that is, Na_2O/SiO_2 is higher than that of the base glass. The high value of the ratio Na_2O/SiO_2 in the initial stage is shown in Table III.

In the second stage, the depth action extending inward from the surface should be taken into account. As the reaction proceeds through the mutual diffusion of Na^+ and H^+ (this H^+ can easily migrate through the network and can penetrate deep into the electron cloud of non-bridging oxygen), the structure of sodium silicate changes into that of silicic acid in the layer near the glass surface. Using sodium silicate or dense flint glass, existence of a sharp boundary-line at the surface may easily be observed under a microscope.

Protons penetrate into the electron cloud of oxygen. As a result, the change from ONa to OH brings about the change of electronic configuration around the non-bridging oxygen, which in turn induces the stress in the network. The strain thus developed in the surface layer induces the exfoliation of the skeleton en masse so that all glass components go completely into the solution, with the ratio of components remaining unchanged, whether they are in glass or are dissolved in the solution.

Attack of Acids on Glass.—It requires only a glance at Table III to observe the fact that there is a marked difference between the action of water and of acids. Two remarkable features may be pointed out:

(1) Acids accelerated the leaching of the metallic ions, while they reduced notably the rate of dissolution of silica.

(2) Each component showed different behavior when attacked by different acids.

The question why acids check the dissolution of silica may be answered quite easily, when we take into account the fact that silica network can not be opened until a sodium hydroxide attacks the bridging oxygen, since H^+ in acid solution has no power to open the silica network. In fact, vitreous silica is resistant to the attack of acids, though it is not resistant to that of alkalis.

In the glass containing modifier cations in its network there will be only the place exchange between H^+ and the metallic cation.

It should be noticed that, with a few exceptions, sulfuric acid was stronger than hydrochloric acid in the power of leaching out the cations, while the hydrogen ion concentrations of the solutions are in reverse order, namely,

$$HCl : 0.8 > H_2SO_4 : 0.55$$

This discrepancy may be explained by taking into account the nature of the negative charge distribution in the liquid at the boundary layer surrounding the glass particles. The negative charge of anions reduces the repulsion between the cations which are just going to leave the lattice points and those already existing in the solution. In short, the anion plays an important role in drawing out the cations from the glass network.

Summary

(1) The first step in the attack of water on glass is the exchange reaction between the proton and Na^+ on the glass surface. Sodium hydroxide thus produced in the boundary layer opens the Si-O-Si bond, and consequently silica passes into solution.

(2) When the exchange reaction between Na^+ in glass and H^+ in acid solution takes place, more metallic ions will be drawn out of the network owing to the influence of anions existing in the solution. Consequently more cations pass into the solution, while the silica network will be stabilized by acid so that the silica in the solution will be reduced remarkably.

Complexometric Titration of Rare Earth Elements. Dissolution of the Rare Earth Oxalate with Ethylenediaminetetraacetic Acid and Back Titration with Magnesium Sulfate

By Seizo MISUMI and Tomitsugu TAKETATSU

(Received March 23, 1959)

Complexometric titration of the rare earth ions in solution has been studied widely by many investigators[1-3]. The rare earth oxalate is usually precipitated from a weak acid solution and used for the gravimetric determination of the rare earth elements. Oxalic acid is the most excellent precipitating reagent for the rare earth ion. However, according to the fact that the rare earth oxalate was dissolved in alkaline solution by adding the excess of ethylenediaminetetraacetic acid(EDTA), Marsh[4] studied the fractional precipitation of the rare earth elements, using a different solubility of each rare earth-EDTA-oxalate complex anion in successive decreases of pH of solution. The present authors found that the rare earth ion, in the presence of a large amount of the oxalate ions, could be determined by back titration of the excess of EDTA with standard magnesium sulfate solution using Eriochrome black T as indicator under certain conditions. Thus, the rare earth ion was precipitated as the oxalate, the precipitate was separated and an excess of standard EDTA solution was added to dissolve the precipitate. After the oxalate was completely dissolved, the excess of EDTA in the solution was back titrated with standard magnesium sulfate solution, using Eriochrome black T as indicator. The conditions of dissolution of the rare earth oxalate and of the back titration were studied in detail and the optimum conditions were obtained for the determination of the rare earth elements. This procedure affords good and accurate results for the determination of 1 to 5 mg. of rare earth elements contained in solution under certain conditions. Especially, it is more rapid and rather simpler than the usual gravimetric procedure.

Experimental

Preparation of Standard Solution and Reagents.—*Standard EDTA solution.*—A certain quantity of disodium ethylenediaminetetraacetate dihydrate (analytical grade pure) was dissolved in distilled water and standardized by titration with standard zinc chloride solution, using Eriochrome black T as indicator. Concentration of the standard EDTA solution: 0.01030 mol./l.

Standard magnesium sulfate solution. — The weighed pure magnesium sulfate heptahydrate was dissolved in distilled water and standardized by titration with standard EDTA solution, using Eriochrome black T as indicator. Concentration of the standard magnesium sulfate solution: 0.01131 mol./l.

0.5% *Eriochrome black T (E. B. T.) solution.*— A half gram of E. B. T. and 4.5 g. of hydroxylamine hydrochloride were dissolved in absolute ethanol and the total volume was filled up to 100 ml. with ethanol.

Buffer solution. — Ammonium chloride-ammonium hydroxide buffer was used. Each equivalent quantity of 1 mol. ammonium chloride solution and 1 mol. ammonium hydroxide solution were mixed.

Rare earth chlorides were prepared from the pure rare earth oxides which were all of extra pure grade, specially purified with ion-exchange resins. La_2O_3: more than 99.99%, CeO_2: more than 99.99%, Pr_6O_{11}: more than 99.99%, Nd_2O_3: more than 99.99%, Sm_2O_3: 99.98%.

All other reagents were of analytical reagent grade.

Apparatus.—Two or five ml. microburette (corrected) was used. One drop was equal to 0.005 or 0.006 ml. Micro glass filters (No. 4) and beakers were all boiled in 2% alkaline EDTA solution for about three hours and allowed to stand overnight and washed with distilled water thoroughly before use. The measurements of pH were carried out with the glass electrode pH meter EHM-1 Type of Hitachi & Co.

A sample solution, containing 1 to 5 mg. of the rare earth ion, was taken, the crystalline rare earth oxalate was precipitated, filtered and separated. An excess of the standard EDTA

2) H. Flaschka, *Mikrochim. Acta*, **1955**, 55.
3) G. Brunisholz and R. Cohen, *Helv. Chim. Acta*, **39**, 324 (1956); ibid., **39**, 2136 (1956).
4) J. K. Marsh, *J. Chem. Soc.*, **1950**, 1819.

solution was added and then the solution was made alkaline with dilute aqueous ammonia. The oxalate was completely dissolved as the rare earth-EDTA-oxalate complex anion[4]. By back titration of the excess of EDTA in the solution with standard magnesium sulfate solution, the rare earth was determined indirectly. The basis of calculation is derived from the fact that the rare earth-EDTA-oxalate complex is known as the 1 : 1 complex[4], which contains one gram atom of rare earth and one molecule of EDTA.

Results and Discussion

Back Titration in the Presence of Oxalate Ion.—Rare earth oxalate was dissolved as the complex anion with an excess of EDTA (HY^{3-}) in the solution and this reaction is supposed to proceed as follows: that is,

$$R_2(C_2O_4)_3+2HY^{3-} \rightarrow 2[RHYC_2O_4]^{2-}+C_2O_4^{2-}$$

in alkaline solution, where R^{3+} indicates the tripositive rare earth ion. When the excess of EDTA in the presence of the rare earth complex ion was back titrated with standard magnesium sulfate solution, using Eriochrome black T as indicator, the interference of the oxalate ion in solution was studied. To the aqueous solution of lanthanum or cerium chloride (content of rare earth ion: 2~4 mg.), about 10 to 70 mg. of oxalic acid was added and the crystalline rare earth oxalate was precipitated. Then an excess of standard EDTA solution was added and the solution was made alkaline with dilute ammonia water solution to dissolve the oxalate completely. After the pH was accurately adjusted to 10.0~10.5 with dilute ammonia water, 5 drops of 0.5% Eriochrome black T solution were added and the excess of EDTA remaining in solution was back titrated with standard magnesium sulfate solution till the blue color of the solution changed into red at the end point. The results are shown in Table I.

It had been supposed that the great excess of the oxalate ions would cause the end point of back titration to be ambiguous. But for 1 to 5 mg. of the rare earth ion, it was found that the addition of 30 mg. of oxalic acid did not interfere with the titration at all. Therefore, provided that the rare earth oxalate can be precipitated, separated and dissolved completely with a known amount of standard EDTA solution, the back titration of the excess of EDTA with standard magnesium sulfate solution is readily carried out in the presence of the oxalate ions and the rare earth-EDTA-oxalate complex ions in solution.

Studies on Various Conditions for the Determination of the Rare Earth Element.—Further, the conditions for this procedure for the determination of the rare earth elements were studied concerning the following matters, i. e.,

a) The process for the precipitation of crystalline rare earth oxalate. The crystalline oxalate was precipitated from a solution of rare earth chloride.

b) The amount of EDTA added for the complete dissolution of the oxalate. The use of 5 ml. of 0.01 M standard EDTA solution was optimum.

c) The amount of the buffer solution added to the solution obtained. The use of 2 ml. of the buffer solution was optimum.

d) The temperature for dissolution of the oxalate with the EDTA solution. 50 to 60°C (5 min.) was the best temperature

TABLE I. EFFECT OF VARIATION IN AMOUNT OF OXALIC ACID ADDED ON THE BACK TITRATION

Lanthanum taken=2.333 mg. pH=10.2~10.5

Oxalic acid added, mg.	La found, mg.	Error, mg.	%	Remarks
10	2.325	−0.008	−0.34	end point sharp
15	2.333	±0.000	±0.00	〃
20	2.333	±0.000	±0.00	〃
30	2.325	−0.008	−0.34	〃
40	2.317	−0.016	−0.69	lacks sharpness
50	2.317	−0.016	−0.69	〃
70	2.270	−0.063	−2.70	obscure

Cerium taken=3.595 mg. pH=10.2

Oxalic acid added, mg.	Ce found, mg.	Error, mg.	%	Remarks
20	3.586	−0.009	−0.25	end point sharp
30	3.576	−0.019	−0.53	〃
40	3.567	−0.028	−0.78	lacks sharpness

for the complete dissolution.

e) Adjustment of the pH for micro titration. The pH 10.2~10.5 was the optimum value which must be accurately kept.

f) On the indication of accurate end point of the back titration with standard magnesium sulfate solution in the presence of oxalate ion, using Eriochrome black T as indicator. The end point was defined to be accurately at the point where the blue color changed completely into the red color.

As the result of these experiments, the optimum conditions are found as follows.

Recommended Procedure.—1) *Precipitation and filtration of the crystalline rare earth oxalate.* — 10 ml. of a weak acid aqueous solution of the tripositive rare earth elements (content of R^{3+} ion: 1~5 mg.) is warmed at 60°C for a few minutes and 20 ml. of the saturated oxalic acid solution is added. The solution is warmed at the same temperature for several hours and then left to stand overnight. Large crystals of the rare earth oxalate are completely precipitated. The precipitate is filtered slowly with the micro glass filter (No. 4) by suction and washed with a saturated oxalic acid solution.

2) *Dissolution of crystalline rare earth oxalate.*—The precipitate is put into a small beaker together with the glass filter, about 25 ml. of distilled water is added and the mixture is warmed at 50~60°C for a few minutes. Then an excess of 0.01 M standard EDTA solution and 2 ml. of 2 N ammonia water are added and the mixed solution is warmed again carefully at 50~60°C for about 5 minutes. The precipitate is thus completely dissolved by this process. After complete dissolution of the precipitate, the solution is cooled rapidly and the glass filter is removed by washing with the distilled water which is added to the original solution.

3) *Back titration with standard magnesium sulfate solution.*—The pH of the solution obtained, must be correctly adjusted to 10.5 with 2 ml. of the buffer solution and dilute ammonia water. Then the total volume of the solution is filled up to about 60 ml. with distilled water. As this indicator, 5 drops of 0.5% E. B. T solution are added and the excess of EDTA in the solution is back titrated with 0.01 M standard magnesium sulfate solution. At the end point, the blue color changes completely into red.

The results obtained by this procedure are given in Table II.

TABLE II. MICROTITRATION OF SOME RARE EARTH ELEMENT

Element	Taken mg.	Found mg.	Error mg.
La	0.935	0.914	−0.021
	2.332	2.332	±0.000
	4.688	4.704	+0.016
Ce	1.798	1.815	+0.017
	3.595	3.605	+0.010
	5.393	5.322	−0.011
Pr	2.582	2.557	−0.025
Nd	1.617	1.627	+0.010
Sm	1.140	1.167	+0.027

It is especially necessary to notice the following matters in this procedure.

a) Determination of the tetrapositive cerium. In the complexometric titration of cerium in alkaline solution, to prevent the oxidation by the tetrapositive ion, it is necessary, in general, to add a reducing agent (e. g., one such as ascorbic acid), but in the presence of the oxalate ion, owing to its reducing property, addition of the reducing agent was not required and the procedure could be applied also to the determination of the tetrapositive cerium ion.

b) Addition of ethanol to the solution for back titration. Wünsch[5] added ethanol for the determination of scandium by complexometric back titration. Generally, in the case of the usual back titration for the determination of rare earth ions, addition of ethanol makes the end point evidently clearer with E. B. T as indicator, but in the presence of the oxalate ion, on the contrary, low value was obtained by adding ethanol.

c) Treatment of the glass vessels with alkaline EDTA solution. As Flaschka and Amin[6] reported, it was seen that the glass vessels were attacked slightly by concentrated EDTA solution and if so, there must be a tendency that a slightly high value for the determination would be obtained. Therefore, the glass vessels which were used in this experiment, were boiled with 2 percent alkaline EDTA solution and left to stand overnight and washed thoroughly with distilled water before use. In this way, such errors, owing to EDTA, were not recognized at

5) L. Wünsch, *Collection Czechoslov. Chem. Communs.*, **20**, 1107 (1955).
6) H. Flashka and A. M. Amin, *Mikrochim. Acta*, **1953**, 410.

all and the value found was accurate and reproducible.

This procedure of complexometric titration to determine the small amount of the rare earth from the oxalate is rapid and precise and more excellent than the usual gravimetric method in its accuracy.

Summary

The processes for dissolution of the oxalate and complexometry to determine the small amounts of rare earth rapidly and accurately, were studied. Crystalline rare earth oxalate was precipitated and filtered. The precipitate was dissolved completely with EDTA in alkaline solution and the excess of EDTA in solution was back titrated with standard magnesium sulfate solution. By this procedure, rare earth in the range of a content about 1 to 5 mg., was determined rapidly with a good accuracy.

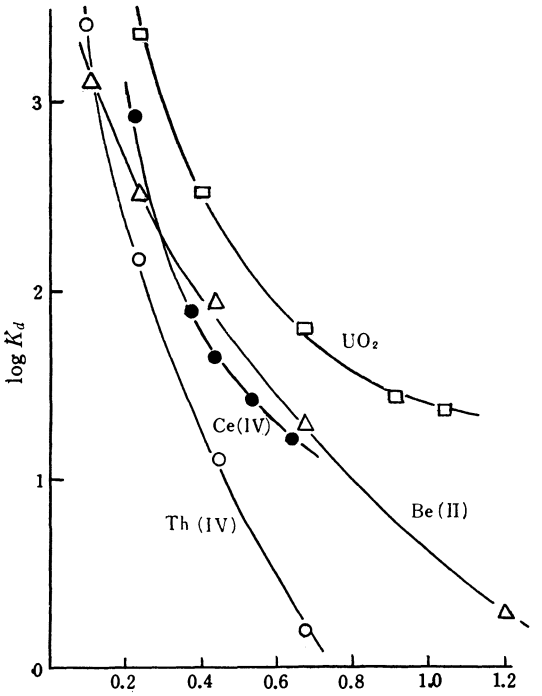
Anion Exchange Studies of Beryllium(II), Cerium(IV), Thorium(IV) and Uranium(VI) Carbonate Complex Ions

By Seizo MISUMI
and Tomitsugu TAKETATSU

(Received December 10, 1958)

Ishimori and Okuno[1] studied anion exchange behavior of uranyl carbonate complex ion in a sodium carbonate solution and Saito and Sekine[2] reported that of thorium carbonate complex ion. No investigation has been reported on the behavior of beryllium and cerium(IV) carbonate complex ions toward anion exchange resins. In this paper, anion exchange behavior of macro amounts of beryllium, cerium, thorium and uranyl carbonate ions formed in ammonium carbonate solution and of tracer amounts of cerium and thorium carbonate complex ions formed in potassium carbonate were studied, using the "Dowex 1, X-8" anion exchanger (50~100 mesh) of carbonate form.



The measurements of distribution coefficients were carried out as follows: one gram of the resin was added to 200 ml. of a series of ammonium carbonate solution of various concentrations containing an equal amount of beryllium carbonate complex ions. The solution was stirred frequently by a magnetic stirrer, allowed to stand for 12 to 20 hr. at about 20°C and the resin was rapidly separated from the solution with a glass filter. The metal ion in the resin was eluted by dilute hydrochloric acid and determined gravimetrically. The distribution coefficient K_d is given by:

$$K_d = [M_r] / [M_s] \quad (\text{ml./g.}) \qquad (1)$$

where M_r is the amount of metal ion in 1 g. of the resin and M_s is that in 1 ml. of the solution. The similar procedure was also applied to the cases of cerium, thorium and uranyl carbonate complex ions. The results are shown in Fig. 1.

It can be seen that beryllium and cerium ions formed the negatively-charged complex ions with ammonium carbonate in the similar manner to thorium and uranyl ions, and that the adsorbabilities of these metal carbonate complex ions decreased as the concentration of ammonium carbonate increased. It is expected from the difference of the values for K_d that

Concentration of ammonium carbonate (M)

Fig. 1. Distribution coefficients of beryllium, cerium, thorium and uranyl ions on anion exchanger in ammonium carbonate solution.
Amounts taken,
Be^{2+}: 11.7 mg (BeO)
Ce^{4+}: 7.3 mg (CeO_2)
Th^{4+}: 26.9 mg (ThO_2)
UO_2^{2+}: 61.0 mg (U_3O_8)

thorium ions can be effectively separated from uranyl ions with the ammonium carbonate solution.

The anion exchanger was saturated with beryllium carbonate complex ions in 0.1 M ammonium carbonate solution, and then washed with dilute ammonium carbonate solution. The results obtained for the exchange capacity by this measurement showed that one mole of beryllium ion corresponds to 1.97 ($\simeq$2.0) equivalents of the resin. This may indicate that the complex anion has a formula such as $[Be(CO_3)_2]^{2-}$ in 0.1 M ammonium carbonate solution.

Distribution coefficients of thorium-234 and cerium-144 in potassium carbonate solutions were determined by a similar procedure. Thorium or cerium in the resin was eluted with hydrochloric acid and the effluent was evaporated on a water bath. The measurements of radioactivities were carried out with a G-M tube. $\log K_d - \log(CO_3^{2-})$ curves plotted in

Concentration of potassium carbonate (M)

Fig. 2. Distribution coefficient of cerium-144 and thorium-234 on anion exchanger in potassium carbonate solution.

Fig. 2 show linearity for both elements from 0.25 to 0.60 M potassium carbonate solution. When only one species of negatively charged complex ion is assumed to be formed between a quadrivalent metal ion (M^{4+}) and carbonate ions, the main reaction would be

$$M^{4+} + xCO_3^{2-} = M(CO_3)_x^{4-2x} \quad (2)$$

$$K_1 = \frac{(M(CO_3)_x^{4-2x})}{(M^{4+})(CO_3^{2-})^x} \quad (2a)$$

Then the following equation is given as to the adsorption of the complex ion on the resin (R_2CO_3).

$$M(CO_3)_x^{4-2x} + (y/2)R_2CO_3 = R_yM(CO_3)_x + (y/2)CO_3^{2-} \quad (3)$$

$$K_2 = \frac{(R_yM(CO_3)_x)(CO_3^{2-})^{y/2}}{(R_2CO_3)^{y/2}(M(CO_3)_x^{4-2x})} \quad (3a)$$

Since the amount of M^{4+} is negligible compared with the amounts of "R_2CO_3", the latter can be regarded as a constant in the above equations. If the concentrations are replaced by thermodynamic activities, Eq. 1 is expressed as follows:

$$K_d = \frac{[M_r]}{[M_s]} = \frac{[R_yM(CO_3)_x]}{[M^{4+}] + [M(CO_3)_x^{4-2x}]} \quad (4)$$

In Eq. 3, y should be equal to $2x-4$ in order to preserve electrical neutrality in the resin. From Eqs. 2a, 3a and 4, the following equation is obtained:

$$\frac{d \log K_d}{d \log(CO_3^{2-})} = 2 - x \quad (5)$$

Since the slopes in Fig. 2 are numerically correspond to $-3.9 \sim -3.8$, the charges of

thorium and cerium(IV) carbonate complex ions could be -8 (their some portions seem to have other values, e.g., -6) in the range between 0.25 and 0.60 M potassium carbonate solutions on the basis of the assumption described above. However, it is probable that these carbonate complex ions include OH^- radicals. Further, it is also supposed that more than one species of negatively charged complex ions may exist and be adsorbed on the resin in other ranges of concentrations of potassium carbonate solutions.

Details of these results will be published elsewhere.

The Separation of Thorium(IV) and Cerium(III) Ions by Using Alginate as Cation Exchanger

By Takeo Takahashi and Shingo Miyake

(Received April 3, 1959)

Recently the separation of thorium(IV) and cerium(III) ions by the use of strongly acidic cation exchange resins, such as Dowex 50 or Amberlite IR-120 has been reported by a few workers[1-4].

The present authors will report here a new method for the separation of thorium (IV) and cerium(III) by using alginate as ion exchanger and dilute nitric acid as eluant.

Alginic acid, a natural polyacid, has a property of cation exchanger for several metallic ions in a moderately acid solution of pH 1~3. Metallic ions adsorbed on alginic acid can be eluted easily and separately with dilute acid solutions of varying concentration.

Preparation of Alginate Exchanger and Column.—The alginate exchanger was prepared by swelling the thread* of calcium alginate in a dilute sodium hydroxide solution (less than 0.1 N) for about 30 min. and then by immersing in 0.5 N nitric acid. The product was packed appropriately into a glass tube (1.5 cm. in diameter, 30 cm. in length). The column packed with the adsorption bed of alginate (length, about 20 cm.) was washed successively with 250 ml. each of 0.5 N nitric acid and distilled water. Thus, the alginate was converted completely into acid form.

Procedure.—The mixed solution of thorium(IV) and cerium(III) ions was poured onto the column, the pH being adjusted to 2~2.5 with aqueous ammonia. The bed was then washed with 100 ml. of distilled water, and 200 ml. of 0.075 N nitric acid was passed through the column at a flow rate of about 1 ml./min. By this treatment, all the cerium(III) ions were completely eluted, and then all the thorium-(IV) ions remaining on the column were eluted in the same manner with 100 ml. of 1 N nitric acid.

The amount of throium(IV) and cerium-(III) ions in the effluents was colorimetrically determined with Neo-thoron for thorium(IV) (580 mμ)[5] and with hydrogen peroxide for cerium(III) (320 mμ)[6].

Result.—An example of elution diagrams of the solution containing 35.5 mg. of thorium(IV) and 30 mg. of cerium(III) ions is shown in Fig. 1, and the amounts initially taken are given in Table I in comparison with the amount finally found.

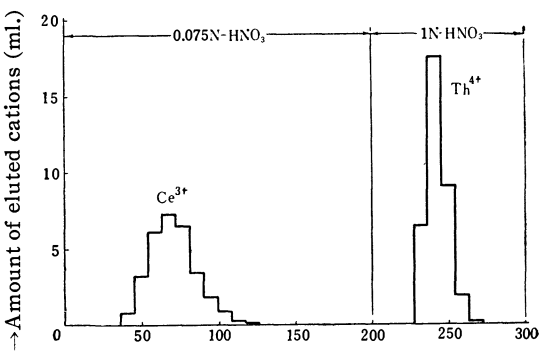

Fig. 1. The elution diagram in the separation of thorium(IV) and cerium(III). The eluants were 0.075 N nitric acid for cerium and 1 N for thorium.

TABLE I. ANALYTICAL RESULT
(CALCULATED FROM FIG. 1)

	Taken (mg.)	Found (mg.)	Error (mg.)
Th(IV)	35.5	35.4	0.1
Ce(III)	30·0	30.3	0.3

It would be concluded that the new method with alginate as ion exchanger has an advantage as an industrial and an analytical method for the separation of thorium(IV) and cerium(III).

Decomposition of Solid Ammonium Nitrate by γ-Ray

By Toshiaki SHIRAI
and Masaru NISHIKAWA

(Received May 8, 1959)

When irradiated with ultraviolet light or ionizing radiation, solid metal nitrates are reported to decompose, producing nitrite and oxygen[1]. However, no investigation has been reported on the decomposition of ammonium nitrate. Recently, the authors carried out the irradiation of ammonium nitrate by γ-ray from 1000 Curie ^{60}Co source at the Institute of Physical and Chemical Research. Decomposition products in gaseous phase were analyzed by a mass spectrometer of CEC 21-103A type and the effect of salt addition on the rate of decomposition was studied.

The irradiation of the salt was carried out in vacuo at a dose rate of 4.4×10^5 r/h, at 23°C. The irradiated sample was washed into a clean beaker with CO_2 free water and the resulting solution was titrated for ammonium ion by the method of Marcali and Rieman[2].

On dissolving the irradiated salt in water, copious effervescence occurred, similar phenomenon was reported for some metal nitrates[1b,c,d].

TABLE I. DECOMPOSITION OF AMMONIUM NITRATE BY γ-RAY

Total dose (10^7r)		4.2	7.1	10.5	15.6
W/W_0*		0.99	0.98	0.97	0.97
Total dose (10^7r)		4.1	6.9	11.1	
	Salt** added				
W/W_0*	$LiNO_3$	0.98	0.97	0.98	
	$NaNO_3$	0.98	0.98	0.97	
	KNO_3	0.98	0.97	0.96	

* W: Mass of ammonium nitrate present
W_0: Initial mass of ammonium nitrate
** Concentration, 5 mol. %

In some case, the solution was divided into two parts, one was titrated for the ammonium ion and the other for the nitrate ion with sodium hydroxide after conversion of ammonium nitrate into nitric acid by passing H-form cation exchanger. The amount of NO_3^- was exactly equivalent to that of NH_4^+ plus added metal ion. NO_2^- was not detected, with the method of Griess[3], in contrast to the case of metal nitrates. Table I shows that the decomposition is accelerated by the addition of metal ion. At this stage, however, no definite conclusion may be drawn in this connection, as decomposition was not carried far enough to show the effect clearly.

Following peaks were found in the mass spectrogram of decomposition products in gaseous phase; 14, 16, 17, 18, 28, 29, 30, 32, 44 and by *m/e*. Main peaks were 18, 28, 30 and 44 by *m/e* and they are assigned to be H_2O, N_2, NO, and N_2O, respectively. This feature is qualitatively the same as that obtained for the thermal decomposition of the salt[4]. The effervescence is ascribed to the gas captured in the solid. The quantitative analysis is now being done. This, together with a detailed discussion of the above results, will be reported elsewhere.

The authors wish to thank Dr. N. Matsuura for the valuable discussion and Mr. M. Takizawa in charge of operating the radiation source at the Institute of Physical and Chemical Research.

Cyclooctatetraene Iron Tricarbonyl

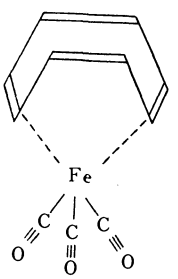
By Akira NAKAMURA and Nobue HAGIHARA

(Received May 8, 1959)

Recently Hallam and Pauson[1] investigated butadiene iron tricarbonyl and its derivatives and concluded that the conjugation of the double bonds was essential for the formation of such compounds. However, Pettit[2] reported the preparation of analogous compounds with non-conjugated bicyclo [2.2.1] heptadiene. He considered that a suitable spatial arrangement of the double bonds, not their conjugation was necessary for their effective overlap with the atomic orbitals of the metal which was an essential factor leading to the bond formation.

Since cyclooctatetraene(COT), in its tub form, seems to have such a suitable spatial arrangement of the double bonds, we have tried to prepare cyclooctatetraene iron tricarbonyl, $(C_8H_8)Fe(CO)_3$ (I), and its successful preparation is reported here*.

After irradiation of an equimolar mixture of COT and iron pentacarbonyl with sunlight for 8 hr. and subsequent removal of the unreacted starting materials under reduced pressure, dark red crystals were obtained in 10% yield. These crystals were purified by sublimation under reduced pressure (5 mmHg) at 80°C or by recrystallization from light petroleum.



Anal. Found: C, 54.31; H, 3.35; mol. wt. (Rast), 243. Calcd. for $C_{11}H_8FeO_3$: C, 54.14; H, 3.31%; mol. wt., 244.

The combustion analysis apparently conformed to the composition, $(CO)_3Fe.(C_8H_8)$ (I). The purified compound I was beautiful dark red needles, melting at 94°C without decomposition and was stable in air and readily soluble in most organic solvents including pyridine and glacial acetic acid. I dissolved in cold concentrated sulfuric acid and could be recovered unchanged on neutralization, but it decomposed when its solution in concentrated sulfuric acid was heated to 110°C. The solution of I in carbon tetrachloride reacted readily with bromine at room temperature to give ferric bromide and brominated products of COT. I could also be prepared by heating the both components under nitrogen at 120°C for 18 hr.

The infrared spectrum of I (in KBr disk) showed bands at 1961 and 2050 cm^{-1} and at 699, 716 and 720 cm^{-1}. The former group of bands is similar to those of butadiene iron tricarbonyl and the latter group of bands indicates the presence of *cis*-type double bonds.

In the visible region of the spectrum no distinct absorption maxima were observed. In the ultraviolet region it showed a weak absorption maximum at 300 mμ ($\log \varepsilon$: 3.99 in 95% alcohol) similar to that of COT. On treatment with aqueous potassium iodide-iodine solution at 50°C, the solution of I in benzene evolved 3 mol. of carbon monoxide indicating the presence of three $-C\equiv O$ groups in one molecule of I. For further proof of the structure of I, I was decomposed by iodine in toluene. COT was detected in the decomposition products by its reaction with mercuric sulfate to give phenyl acetaldehyde. COT formed was further identified and determined by gas chromatography (the yield of COT was 76%).

From the above results it may be concluded that COT is π-bonded to iron without change in its skeletal structure. It is a well established fact that the molecule of COT is not planar. Therefore, it may be reasonable to assume that COT molecule in I would not be planar, too; and the following structure of I is proposed:

(I)

Fig. 1

When iron pentacarbonyl was used in excess in the photosynthesis of I, yellow crystals were obtained in addtion to I in 3% yield from COT. These crystals were purified by fractional sublimation at 120°C (5 mmHg) followed by recrystallization

2) R. Pettit, *J. Am. Chem. Soc.*, **81**, 1266 (1959).

* After completion of our work, it has become known to us that T. A. Manuel and F. G. A Stone, (*Proc. Chem. Soc.*, **1959**, 90), also reported the preparation of cyclooctatetraene iron tricarbonyl and the related compounds. They suggested a planar structure to COT which was attached to the iron atom of cyclooctatetraene iron tricarbonyl. In their report, however, no practical description of the preparation of these compounds are given.

from benzene to give orange-yellow needles which decomposed at 185°C.

Anal. Found: C, 43.72; H, 2.35. Calcd. for $C_{14}H_8FeO_6$: C, 43.80; H, 2.11%.

The combustion analysis conformed to the composition, $(CO)_3Fe(C_8H_8)Fe(CO)_3$ (II). This compound II was slightly soluble in light petroleum and methanol, soluble in pyridine, glacial acetic acid and benzene, insoluble in hydrochloric acid and aqueous sodium hydroxide solution. It decomposed in concentrated sulfuric acid at room temperature.

(II)

Fig. 2

The infrared spectrum of II (in KBr disk) showed bands at 1972 and 2035 cm^{-1} for CO stretching region. The characterictic bands indicating the presence of *cis*-type double bonds which were shown in the infrared spectrum of I did not appeared and the whole spectrum was relatively simple compared with that of I, suggesting the higher symmetry of the molecule of II. The ultraviolet absorption spectrum of II had a shoulder at 258 mμ ($\log \varepsilon$: 3.15, in 95% ethanol) and no distinct absorption bands appeared in the visible region. Compared with the absorption band of I the shift of the band toward shorter wavelength and the decrease in intensity are apparent. These spectral changes in the ultraviolet region may be considered to indicate the immobility of the π-electrons of COT in II. From the above results the structure shown in Fig. 2 is proposed.

On the Preparation of Isotopically Pure Light Hydrogen

By Koshiro Miyahara and Takao Kwan

(Received June 8, 1959)

Natural abundance of heavy hydrogen isotope in the water is known to vary depending on the geochemical circumstances in which the water is found[1]. The standardization of the value of D-content in the water or the preparation of isotopically pure light hydrogen was thus needed and became the object of careful investigation particularly by Titani and his co-workers[2,3]. Electrolysis of water is known to produce hydrogen of less D-content. Combustion of the hydrogen followed by re-electrolysis leads to much less concentration in the heavy component. Repeating such procedure, these authors were able to obtain 125 g. light water, the atomic D% of which being $0.0002\pm20\%$, i.e., about one-hundredth of natural abundance.

Current investigation on the chromatography, on the other hand, showed that this technique is powerful for the separation of hydrogen isotopes. Glueckauf and Kitt[4] were able to isolate pure deuterium (99.5%) by a displacement technique using palladium as column packing. The work[5] of this laboratory proved that hydrogen isotopes are separated in the elution chromatogram when synthetic zeolite (Linde molecular sieve) is used as column packing and kept at $-195°C$.

Deuterium was found to adsorb strongly compared with ordinary hydrogen on this packing. As a result, self-displacement of a mixture of hydrogen isotopes through such a cooled column yielded pure hydrogen in the frontal band and then HD and D_2 in the succeeding band[5]. The detection of hydrogen isotopes were made in this case by the thermal conductivity gauge equipped in Shimadzu Gas Chromatograph GC 1A.

2) T. Titani, S. Horibe and M. Kobayakawa, *Mass Spectroscopy*, **9**, 32 (1957).
3) T. Titani, S. Horibe, T. Komori and M. Kobayakawa, ibid., **9**, 40 (1957).
4) E. Glueckauf and G. P. Kitt, "Vapour Phase Chromatography", Butterworths Scientific Publications, London, (1957), p. 422.
5) S. Ohkoshi, Y. Fujita and T. Kwan, This Bulletin, **31**, 771 (1958).

It is obvious that the latter technique is promising to obtain isotopically pure light hydrogen. An attempt was made therefore to investigate the isolation of light component from ordinary hydrogen by means of such chromatographic technique. A spiral Pyrex column 400 cm. long and 0.5 diameter was filled with molecular sieve 5A and degassed overnight at 300°C by mercury diffusion pump. Two liters hydrogen sample from commercial electrolytic hydrogen* was introduced into the one side of the column immersed in liquid nitrogen. About ten minutes later hydrogen was found to appear on the other side of the column. The initial portion of the hydrogen (100~200 cc. N. T. P.) was then collected in a flask (sample I). The remaining hydrogen, together with those adsorbed on the packing, were collected back to the original flask (sample II). The deuterium content of the two samples were analyzed by Hitachi Mass Spectrometer RMD-3. The result is shown in Table I.

TABLE I

Run	Hydrogen sample	Volume cc. N.T.P.	Atomic D%	Error
1	I	100	0.0000	±0.0005
	II	1900	0.0068	
2	I	200	0.0004	±0.0005
	II	1800	0.0068	

As shown in this table, the sample I was found almost perfectly free from heavy component within the accuracy of the mass spectrometer. Thus, it is quite evident that the chromatographic process is simple and efficient to prepare isotopically pure light hydrogen. At the same time, the process is of practical importance to enrich deuterium or tritium at least in laboratory scale[5].

Photosensitized Oxidation of Isopropylalcohol in the Presence of Zinc Oxide

By Isao Komuro, Yuzaburo Fujita and Takao Kwan

(Received June 8, 1959)

As reported previously[1], two of us (Y.F. and T.K.) found that photodesorption of oxygen takes place on reduced zinc oxide whereas it turns to irreversible sorption on oxidized sample. This opposite fashion of the photoresponse in the adsorption of oxygen stimulated us to investigate how these phenomena should be associated with the photosensitized oxidation reaction[2] known to occur on zinc oxide. Experiments were made, therefore, along with this interest.

The oxidation of isopropylalcohol by oxygen in liquid phase was chosen for the purpose. Commercial zinc oxide powder (guaranteed reagent) supplied by Kanto Kagaku was outgassed at 480°C for one hour in vacuo. On cooling it was poured into isopropylalcohol. This zinc oxide sample is called here as reduced zinc oxide. On the other hand, the commercial zinc oxide was used without any special pretreatment. The sample is supposed to be in oxidized state, since the d.c. electrical resistance measurement has shown that it possesses a resistance value as large as that of oxidized zinc oxide or is much larger than that of reduced zinc oxide.

A 50 ml. dried isopropylalcohol containing 2 g. reduced or oxidized zinc oxide was put into a round Pyrex flask having three openings, two of which being for thermometer and mercury manometer respectively and the remaining being connected to a reflux condenser and then to a gas burette.

Oxygen was introduced from the gas burette into the flask immersed in 65°C thermostat. The oxidation reaction was allowed to proceed with stirring reactant phase operated by magnetic rod placed in the flask. The apparatus was isolated when working. The rate of oxidation was followed by recording the decrease in the gas volume of the burette at a constant

pressure. The partial pressure of oxygen inside the flask was estimated to be 440 mmHg during the reaction.

Irradiation of light was made by Matuda Mercury Lamp SHL 100 UV without filter of any kind but through the window of the thermostat. The reaction product was pipetted and subjected to gas chromatographic and chemical analyses after the measurement of the oxidation rate. The temperature of the oxidation reaction was determined by the thermometer immersed directly in the liquid phase of the reacting system. Illumination caused the temperature of the system to rise less than 2°C.

It was confirmed that without illumination little consumption of oxygen occurs on reduced zinc oxide kept at 65°C. Illumination, however, brought forth distinct consumption of oxygen. On intercepting the light, the consumption occurring steadily was found to cease apparently. Reillumination caused consumption of oxygen again to proceed, so that the photocatalytic oxidation of isopropylalcohol was almost reversible with respect to on or off of the light switch.

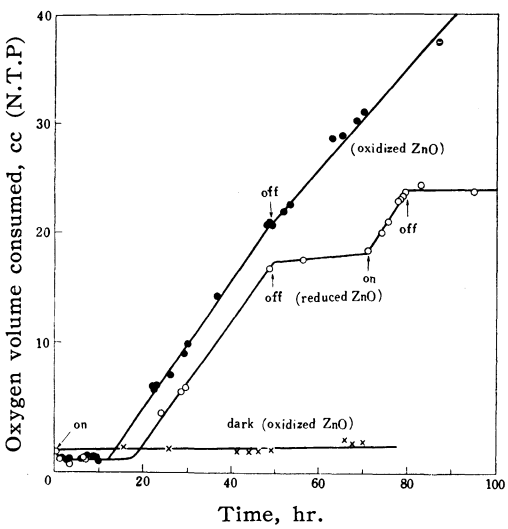

Fig. 1. Oxidation of isopropylalcohol by oxygen on zinc oxide with or without illumination.
T: 65~67°C. P_{O_2}: 440 mmHg.

Now, in the case of oxidized zinc oxide, the photosensitized oxidation reaction took place quite similarly as the case on reduced zinc oxide, while the reaction did not proceed without illumination beyond the period of 70 hr. However, strikingly different behavior was that interception of light still perimits the oxidation reaction to proceed with a speed almost equal to that of illumination. All the rate data for the oxidation of isopropylalcohol are shown in Fig. 1. Gas chromatographic and chemical analyses indicated that the product contains nothing other than acetone and hydrogen peroxide. The oxidation reaction may hence be expressed by

$$CH_3\text{-}\underset{\displaystyle OH}{\underset{|}{CH}}\text{-}CH_3 + O_2 = CH_3\text{-}CO\text{-}CH_3 + H_2O_2$$

As shown previously[1], adsorbed oxygen due to illumination was unable to desorb from the surface of oxidized zinc oxide on intercepting light whereas photodesorption was almost reversible on the surface of reduced zinc oxide. If it is accepted that the photoresponse of this kind should hold even during the oxdation reaction of isopropylalcohol, the different photocatalytic behavior shown above respectively on reduced and oxidized zinc oxide is to be anticipated. Because the catalyzing surface of reduced zinc oxide varies, when oxygen is present, depending on whether the light is switched on or off whereas the surface of oxidized zinc oxide, once experienced illumination, may maintain its state even during the light is intercepted.

On the other hand, almost identical photocatalytic activity shown by the two zinc oxide samples during the initial stage, including the induction period, and later is unexpected and rather embarrassing. Further work is in progress.

benzene ring. In these seventeen analogues, fourteen are new compounds and three have already been reported[1].

The results are shown in Figs. 1, 2, 3, 4, 5 and 6. It is of interest that the ortho substituted isomers are the most active on leaf growth and the activity decreases in the order of the meta and the para isomers. Furthermore, it is noteworthy that the activity of some ortho isomers in higher concentration is stronger than that of 6-(benzylamino)-purine in its optimum concentration, e.g., *o*-methylbenzylaminopurine (Fig. 1), *o*-hydroxybenzylaminopurine (Fig. 2) and *o*-chlorobenzylaminopurine (Fig. 6) and that the kinetin activity is decreased by both meta and para substitution. It is clear from the above facts that the kinetin activity is favored by the ortho-substitution but disfavored by the meta- or para-substitution.

Experimental.—The syntheses of substituted 6-(benzylamino)-purines were achieved by condensing 6-(methylmercapto)purine with various amines. In general, 6-(methylmercapto)-purine was heated with 2 to 3 molecular equivalents of an amine with or without a solvent in a sealed or open tube at the given temperature and for the period given in Table I.

6-(*o*-Chlorobenzylamino) purine.—A mixture of 0.3 g. of 6-(methylmercapto)-purine (3.5 mol.) and 0.87 g. of *o*-chlorobenzylamine (1 mol.) was heated for eleven hours under reflux at 125~130°C. After cooling, the reaction product was precipitated by the addition of acetone, collected, washed with acetone, and then recrystallized from ethanol to give the product, m.p. 227~228°C, in a yield of 60.8%.

*Syntheses of Kinetin-analogues. III**

By F. Shigeo Okumura, Noboru Enishi, Hiroyuki Itoh, Mitsuo Masumura and Susumu Kuraishi**

(Received June 8, 1959)

In the first paper of this series[1], the authors showed that 6-(*n*-hexylamino)-purine has almost the same activity on the growth of *Raphanus* leaf as kinetin, and the furan ring of kinetin can be replaced by an alkyl group without causing a remarkable decrease in the kinetin activity. It is very interesting to investigate the relation between the carbon

number in the side chain of 6-(alkylamino)-purines and the leaf growth activity.

Sixteen 6-(alkylamino)-purines have been synthesized for this purpose, eleven of which are new compounds, and tested for their physiological activity on the growth of the leaf of *Raphanus sativus L. var. acanthiformis* Makino. The results are shown in Fig. 1.

The activity of the first three members with 0, 1 and 2 carbon atoms in the side chain is very weak, but a sudden increase of activity is observed in 6-(*n*-propylamino)-purine and then the activity gradually increases with the carbon number until the peak of activity is attained in 6-(*n*-hexylamino)-purine, and then the activity decreases rapidly in 6-(*n*-heptylamino)- and 6-(*n*-octylamino)-purines. No activity was observed with higher homologues with 9, 10, 12 and 18 carbon atoms in the side chain.

The activities of 6-(dialkylamino)-purines such as 6-(dimethylamino)-, 6-(diethylamino)- and 6-(dibutylamino)-purines were very weak.

Experimental.—6-(Alkylamino)-purines were prepared by the reaction of 6-(methylmercapto)-purine with aliphatic amines. In general, the 6-(methylmercapto)-purine was heated with an amine in a sealed or open tube without any solvent, but an aqueous solution was used in the case of the volatile amines. After cooling, the reaction product was either precipitated by the addition of acetone, or it was obtained as a residue after evaporation of the excess of the amine under reduced pressure. The product was then recrystallized from an appropriate solvent.

6-(*n*-Hexylamino)-purine. — A mixture of 1.00 g. (1 mol.) of 6-(methylmercapto)-purine and 1.8 g. of *n*-hexylamine (3 mol.) was heated in a sealed tube at 130~135°C for 9 hr. After cooling, the reaction mixture was evaporated to dryness and the residue was recrystallized from 60% ethanol (yield, 0.4 g. or 31.5%).

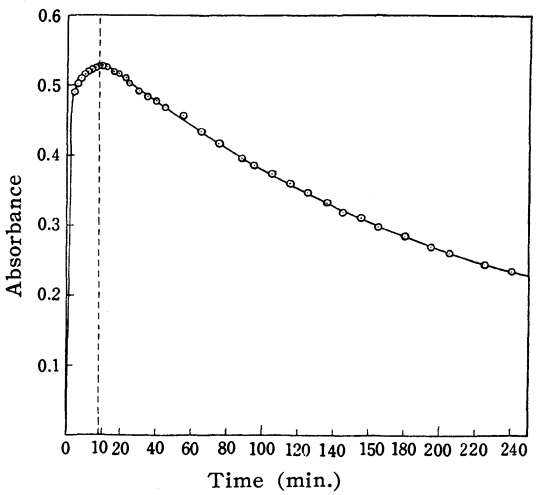
The Rate of the Color Reaction of m-Dinitrobenzene with Sodium Hydroxide in Acetone

By Takehiro Abe

(Received July 6, 1959)

Investigations of kinetics of the color reactions producing Meisenheimer's intermediates[1] have been studied by Caldin, Long and Ainscough[2,3] on the coloration reactions between trinitrobenzenes and ethoxide ion, and also by Nagakura, Oosawa and Tsubomura[4] on the decoloration reaction of the color product between 2, 4-dinitroanisole and hydroxyl.



The author has succeeded in pursuing changes in absorbance of a visible absorption of a colored species through both coloration and decoloration reactions in a whole substitution reaction of *m*-dinitrobenzene with sodium hydroxide in acetone.

In the previous paper[5], the author has reported the visible absorption curve (530~600 mμ) of the colored solution produced by adding sodium hydroxide to *m*-dinitrobenzene in acetone. This color becomes more intense for several minutes and then fades slowly. The result in Fig. 1 was obtained by following the absorbance *d* of the 560 mμ absorption of the colored species at 25°C. The coloration and decoloration reactions are formulated provisionally as

$$m\text{-Dinitrobenzene} + \mathrm{NaOH} \xrightarrow{\text{Coloration}} [m\text{-Dinitrobenzene}\cdot\mathrm{OH}]^- \text{ Colored species (transition complex)} \xrightarrow{\text{Decoloration}} \text{A final product}$$

Although both the coloration and the decoloration are actually concurrent, we assume that only coloration reaction proceeds till nine minutes, at which time the maximum absorbance is obtained, and that only the decoloration occurs from that time,

1) J. Meisenheimer, *Ann.*, **323**, 214, 241 (1902).

4) S. Nagakura, S. Oosawa and H. Tsubomura, Presented at the Symposium on Electron States of Molecules at Kyoto in October, 1958.
5) T. Abe, This Bulletin, **32**, 775 (1959).
6) T. Abe, to be published in ibid., **32**, No. 9 (1959).

Flg. 1. Change in the absorbance of the 560 mμ absorption for the colored solution of *m*-dinitrobenzene (2.33×10^{-5} M) and sodium hydroxide (3.49×10^{-3} N) in acetone, at 25°C (path length of absorption cells, 1 cm.).

since the rate of the coloration reaction is much greater than that of the decoloration, as can be known from Fig. 1. Moreover, on an assumption that *m*-dinitrobenzene completely changes into the colored species just after nine minutes, a value of 2.27×10^{4} can be obtained as a molar extinction coefficient ε of the 560 mμ absorption of the colored species. This value is of the same order, as compared with the molar extinction coefficients of the red complexes of trinitrobenzene and its derivatives with ammonium hydroxide[6]. From this it is, therefore, known that the above assumptions are very good. Under a condition that the concentration of sodium hydroxide is sufficiently larger than that of the colored species produced, the rate constant k_C of the coloration reaction of the second can be derived as follows:

$$k_C=\frac{1}{0.4343(C_{DNB}-C_{OH})(t-t_{0C})}\log\frac{C_{DNB}-d/\varepsilon}{C_{DNB}-d_{0C}/\varepsilon} \quad (1)$$

where C_{DNB} is the initial concentration of *m*-dinitrobenzene, C_{OH}, the initial concentration of sodium hydroxide, d, the absorbance of the colored species after t minutes, and d_{0C}, the value of d after arbitrary t_{0C} minutes. On the other hand, the following empirical formula of the first order satisfactorily represents the observed rate constants, as in the case of the decoloration of 2,4-dinitroanisole[4].

$$k_d=\frac{1}{0.4343(t-t_{0d})}\log\frac{d}{d_{0d}} \quad (2)$$

Here d_{0d} is the value of d after t_{0d}. By taking $t_{0C}=2$ and $t_{0d}=12$ in Eqs. 1 and 2, the values of k_C and k_d at 25°C are calculated respectively, as indicated in Table I.

TABLE I

t(min.)	k_C(mol^{-1}·sec^{-1})	t(min.)	k_d(sec^{-1})$\times10^3$

The means of k_C and k_d are 103 mol^{-1}·sec^{-1} and 3.57×10^{-3} sec^{-1}, respectively. In the decoloration reaction sodium hydroxide may probably interact with the colored species, because the higher the concentration of alkalies contained, the faster disappear the colors of the complexes of polynitrobenzenes with alkalies[4,6].

It is in progress to investigate the effect of the concentration of sodium hydroxide of the rate of the decoloration reaction, and to obtain energies of activation for the coloration and docoloration.

The author is particularly indebted to Professor Y. Nomura for his suggestion and helpful discussions.

Organic Spot Tests. II. Detection of 1,2-Dihydroxy Compounds (Differentiation of Polyhydroxy Compounds)

By Yujiro NOMURA

(Received July 7, 1959)

The micro detection of acid substances by the color reaction with the mixed solution of sodium sulfanilate, sodium nitrite and α-naphthylamine in aqueous alcohol or dioxan[1] has been developed to a new method of detection of 1,2-dihydroxy compounds.

Boric acid is so weak that the orange to orange red color begins to appear only in 10~15 min. after adding it to the reagent. It has long been known that addition of polyhydroxy compounds, e.g., glycerol, sorbitol and mannitol, to boric acid raises the acidity[2] and thus this weak acid can be titrimetrically determined[3]. This is due to the co-ordinate complex ester (I)[4] of boric acid with 1,2-dihydroxy compounds as follows:

(I)

It has been found that boric acid behaves as a strong acid in the presence of a 1,2-dihydroxy compound also in the above-mentioned reaction to give immediately an intense coloration and that boric acid reciprocally makes it possible to detect 1,2-dihydroxy compounds by the same color reaction. Thus, ethylene glycol, propylene glycol, glycerol and other various polyhydroxy compounds with adjacent hydroxyl groups gave positive reactions with the reagent in the presence of boric acid but trimethylene glycol was indifferent. Catechol also gave a positive reaction, while resorcinol and hydroquinone gave no reaction.

peri-Dihydroxy derivatives of naphthalene behave similarly in this new color reaction. Namely, disodium chromotropate (1,8-dihydroxynaphthalene-3,6-disulfonate) gave the same coloration when the above method was applied.

In the case of a polyhydroxybenzoic acid, its small quantity is evaporated to dryness with one drop of ammonia water in a microcrucible on a water bath and then it may be tested. In this way, 2,3-dihydroxybenzoic acid and gallic acid gave an intense red color, but 2,4-, 2,6- and 3,5-dihydroxybenzoic acids did not.

Accordingly the reaction described above gives a new method of detecting the presence of two hydroxyl groups in 1,2-positions.

General Procedure of the Test.—Several drops of the reagent solution are placed in a depression of a spot plate. A small amount of boric acid is added to it and stirred with a glass rod. One drop of the test solution or a pinch of the solid sample is added to it. An immediate orange red color indicates the presence of a compound with two or more adjacent hydroxyl groups. A blank test without addition of the sample, is recommended if only a small amount of a 1,2-dihydroxy compound is suspected. An acid substance which gives a positive reaction with the reagent solution alone (without the addition of boric acid) must be treated with ammonia water as in the case of the polyhydroxybenzoic acids before the present method is applied.

Measurement of Infrared Dichroism for the Crystal of Lauric Acid in the CsBr Region

By Takehiko SHIMANOUCHI and Michio KAWANO

(Received July 9, 1959)

For the measurement of infrared dichroism the silver chloride transmission polarizer is ordinarily used. However, in the region below 20 μ its performance is not satisfactory owing to its poor transmittance. For the purpose of measuring dichroism for saturated long chain monocarboxylic acids in the range from 600 to 350 cm^{-1} we tested a transmitting polarizer in which six polyethylene films are used instead of silver chloride plates.

The result is very satisfactory and the spectra for lauric acid are shown in Fig. 1. This polarizer is also used in the NaCl region except those about the 2900, 1475, 1375 and 720 cm^{-1} absorptions of polyethylene. In Fig. 2 the dichroism for the oriented crystals of lauric acid in the region from 1300 to 900 cm^{-1} measured by the polyethylene polarizer is given. For the purpose of comparison the same dichroism measured by a Perkin-Elmer AgCl polarizer is shown in Fig. 3. The result indicates that the performance of the present polarizer is as satisfactory as that of the AgCl polarizer.

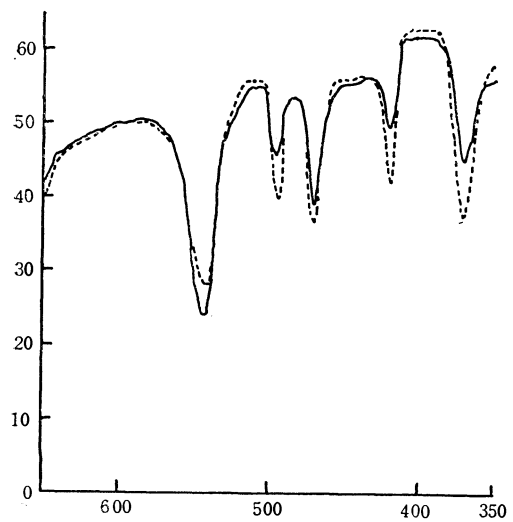

Fig. 1. The infrared dichroism of the oriented crystals of lauric acid (C form) in the CsBr region measured by a polyethylene polarizer.

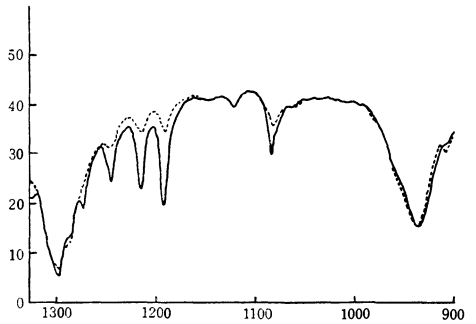

Fig. 2. The infrared dichroism of the oriented crystals of lauric acid (C form) in the NaCl region measured by a polyethylene polarizer.

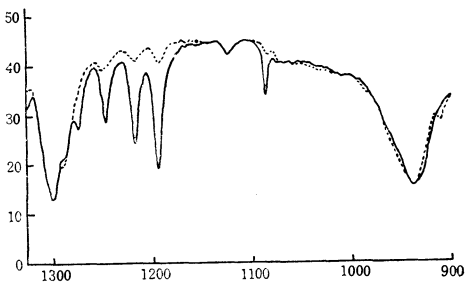

Fig. 3. The infrared dichroism of the oriented crystals of lauric acid (C form) in the NaCl region measured by an AgCl polarizer.

The thickness of the polyethylene film used was 0.02 mm. and an incline of approximately 60 degrees of the films gave the best perfomance. The measurement was made by a Perkin-Elmer Model 21 spectrometer equipped with NaCl or CsBr prism.

In Figs. 1, 2 and 3 the dotted and the full lines give the spectra for the incident light polarized along the *a*- and *b*-axes of the crystal, respectively. It is interesting to note that the four lines in the range from 350 to 500 cm^{-1} given in Fig. 1 have the opposite dichroism to that of the equally spaced progression of bands found in the region from 1180 to 1350 cm^{-1}. The interpretation of the result will be reported afterwards.

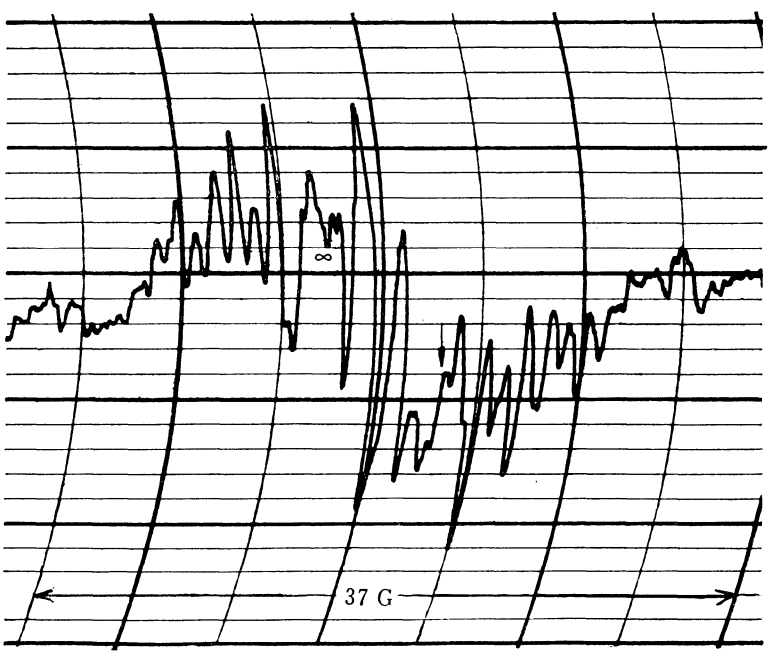
Added in Proof:
Recently H. Yoshinaga, S. Fujita, Y. Yamada and A. Mitsuishi have made a polyethylene film polarizer and used this for the region measured by the far-infrared grating spectrometer (Symposium on Molecular Structure and Spectroscopy at Columbus, June, 1959).

Paramagnetic Resonance Absorption in Solutions of the Sodium Adducts of Isoprene

By Keiji Kuwata, Kazuo Morigaki and Kozo Hirota

(Received July 9, 1959)



It has been found already by Weissman[1a] and others[2] that paramagnetic resonance absorption spectra are observed in the solutions of the sodium adducts of polynuclear aromatic hydrocarbons, e. g., naphthalene, phenanthrene, naphthacene, etc., and also of benzene derivatives[1b]. Recently, the list of such substances has been enlarged to another kinds of adducts by the present authors, i. e., the adducts of polymerizable vinyl monomers, such as styrene[3], α-methylstyrene[4], 1, 4-diphenylbutadiene[5].

However, since all the above hydrocarbons have one benzene ring at least, it will be interesting to investigate if the adducts of polymerizable vinyl monomers without aromatic rings have the same character. Using the method of preparation as described elsewhere[3], Na-adduct of isoprene was obtained as the solution of tetrahydrofuran. The sample colored brownish yellow, maximum absorption being near 375 mμ. Detailed discussion on the structure of the adduct will be published in a separate paper[6].

Measurement of paramagnetic resonance absorption on the sample gave an affirmative result for the object of the present research. A spectrum of the adduct of isoprene is shown in Fig. 1. Hyperfine structure of the spectra can be explained if a radical anion is assumed to exist, but detailed discussions will appear in future.

The writers express sincere thanks to Professor Junkichi Itoh of Osaka University who gave them much suggestion and convenience in the present research. A part of the expense for the research has been defrayed from a grant given by the Ministry of Education, to which the authors' thanks are due.

The Synthesis of dl-4(-3-Furyl)-1-methyl Quinolizidine; Demethyl Analogue of Deoxynupharidine

By Munio KOTAKE, Ichiro KAWASAKI, Tadashi OKAMOTO, Shiro KUSUMOTO and Takeo KANEKO

(Received June 30, 1959)

In 1956, structure (I) was assigned by Kotake, Kusumoto and Ohara[1] to deoxynupharidine; an alkaloid isolated from the roots of *Nuphar japonica* DC. A synthesis of *dl*-4(-3-furyl)-1-methyl quinolizidine is now reported which establishes the synthetic routes to the *dl*-deoxynupharidine*. The stages involved in the synthesis are as follows:

Compound II[2], b. p. 133°C/10^{-2} mmHg; III, (62%) b. p. 130°C/10^{-2} mmHg, I. R. bands at 1645 (amide), 1735 cm^{-1} (ester). *Anal.* Found: C, 64.78; H, 8.89; N, 5.80. Calcd. for $C_{13}H_{21}O_3N$: C, 65.24; H, 8.85; N, 5.85%; IV, (95%) m. p. 102~106°C. *Anal.* Found: C, 53.69; H, 9.13; N, 6.20. Calcd. for $C_{10}H_{19}O_2N$-HCl: C, 54.17; H, 9.09; N, 6.33%; V, (48%) b.p. 154°C/10^{-3} mmHg, I.R. bands at 875, 1505, 3110 (furan), 1573 (conjugated furan), 1625 (amide), 1735 cm^{-1} (ester). *Anal.* Found: C, 65.94; H, 8.24; N, 4.51. Calcd. for $C_{17}H_{25}O_4N$: C, 66.42; H, 8.20; N, 4.56%; VI[3], (56%) b. p. 81~84°C/10^{-3} mmHg, I. R. bands at 875, 1505, 3110 (furan), 1588 (conjugated furan), 1640 cm^{-1} (double bond); VII, (50%) b. p. 87~89°C/10^{-2} mmHg. Perchlorate, m. p. 193~194°C. *Anal.* Found: C, 52.56; H, 6.82; N, 4.34. Calcd. for $C_{14}H_{21}ON \cdot HClO_4$: C, 52.57; H, 6.93; N, 4.38%. Picrate, m. p. 172~174°C. *Anal.* Found: C, 53.30; H, 5.40; N, 12.79. Calcd. for $C_{20}H_{24}O_8N_4$: C, 53.57; H, 5.39; N, 12.50%.

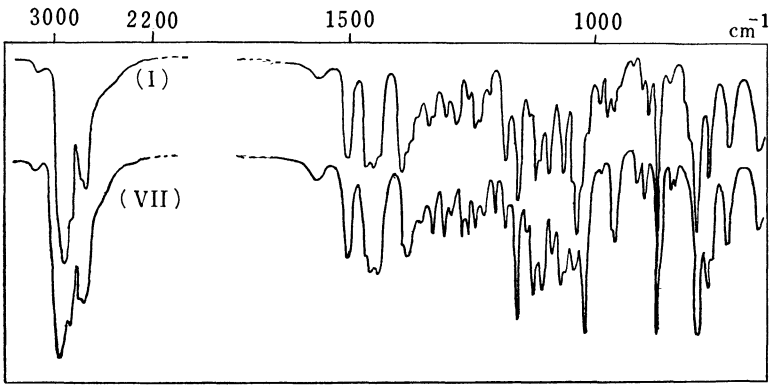

Fig. 1.

The I. R. spectra of compound VII are similar to that of the deoxynupharidine as indicated in Fig. 1.

The authors wish to express their thanks to Professor Takeo Sakan, Professor Takashi Kubota and Professor Yasuhide Yukawa for their encouragement throughout this work.

Bond Localization and the Hyperconjugative Effect in the Aromatic Carbonium Ions. II[1]. *Electronic Structures of the Carbonium Ions of Isomeric Xylenes*

By Toshifumi MORITA

(Received October 2, 1958)

Concerning the basic character of unsaturated hydrocarbons, there are several theoretical investigations[2-7] which have their theoretical standpoints on the localization of the C-H_2 bond of their carbonium ions. There are no reasons, however, for fixing the electronic structure of carbonium ions to only the bond localization one; in general, hyperconjugation of H_2 quasi-atom should also be taken into account. In this paper, the need for introduction of hyperconjugation will be revealed for protonated compounds of isomeric xylenes on the basis of the experimental basicity constants[8].

Dependence of Basicity of Isomeric Hydrocarbons on the π-Electron Energies of their Carbonium Ions

Gold and Tye[2], and also Heilbronner and Simonetta[3] have shown that the equilibrium constant K for carbonium ion formation is expressed as

$$-\boldsymbol{R}T \ln K = E_{BH^+} - E_B + \text{constant} \qquad (1)$$

where E_{BH^+} and E_B are π-electron energies of the aromatic carbonium ion, BH^+, and of the parent base, B, respectively. From Eq. 1, the following equation for the ratio of two K's is obtained:

$$K^I/K^{II} = \exp(-A/\boldsymbol{R}T) \qquad (2)$$

where

$$A = (E^I_{BH^+} - E^{II}_{BH^+}) - (E^I_B - E^{II}_B) \qquad (3)$$

Here superscripts I and II refer to either of the two isomeric types of a particular hydrocarbon.

In the case of xylene isomers, $E^I_B - E^{II}_B$ will be estimated from the empirical hyperconjugation energies obtained by Coulson and Crawford[9]. They have indicated that the empirical hyperconjugation energies per methyl group are 1.48, 1.39 and 1.27 kcal./mol. for *m*-, *p*- and *o*-xylenes, respectively. This shows that *m*-xylene is more stable than *p*-xylene by 0.18 kcal./mol., and *o*-xylene is less stable than *p*-xylene by 0.24 kcal./mol.

Now, from the evaluation of π-electron energies of protonated compounds, the basic strengths of *m*- and *o*-xylenes relative to that of *p*-xylene will be estimated by the use of Eqs. 2 and 3.

Consideration of Basicity of Isomeric Xylenes from the Standpoint of Bond Localization Model of their Carbonium Ions

There are several available points of proton attack in each isomer, and the position of highest proton affininity will be determined as that which makes the π-electron energy of the carbonium ion minimum. Now it will be indicated in the following discussion that only by the bond localization hypothesis the basic behaviors of isomeric xylenes can not be understandable. π-Electron energies of carbonium ions necessary for these considerations are calculated for all possible models with respect to the positions of proton attack on the basis of the bond localization hypothesis, using the semi-empirical LCAO MO method and solving numerically the secular equations constructed by the usual variational method. Several assumptions adopted in these calculations are as follows:

(1) the overlaps between the nearest neighboring atomic orbitals are included; (2) the resonance integral including overlap is proportional to the corresponding

overlap integral: $\beta_{C\text{-}H_2}=\beta_{C\text{-}H_3}=2.19\beta$ and $\beta_{C(ring)\text{-}C(methyl)}=0.8\beta$, where $\beta_{C\text{-}H_2}$ is the resonance integral between H_2 quasi-atom and the ring carbon atom connecting with it, $\beta_{C\text{-}H_3}$ is that between H_3 quasi-atom and carbon atom in the methyl group, $\beta_{C(ring)\text{-}C(methyl)}$ is that between the ring- and the methyl- carbon atoms, and β is that between the neighboring atoms in the benzene molecule; the other resonance integrals are taken to be β; (3) the Coulomb integral of H_2 or H_3 quasi-atom is taken as $\alpha_{H_2}=\alpha_{H_3}=\alpha-0.3\beta$, and that of the carbon atom next to H_2- or H_3-group is taken as $\alpha_{C(-H_2)}=\alpha_{C(-H_3)}=\alpha-0.1\beta$, where α is the Coulomb integral of a carbon atom of benzene molecule; the other Coulomb integrals are taken to be α.

Computational results are shown in Table I and in Fig. 1. Charge distributions of parent bases calculated by Crawford[10] are 1.0093, 1.0081 and 0.9995 at the positions 2, 4 and 5 in *m*-xylene (1,3-dimethylbenzene) and 1.0044 and 1.0035 at the positions 3 and 4 in *o*-xylene (1,2-dimethylbenzene), respectively. Inspection of these charge distributions predict the order of proton acceptance. Between this order of proton affinity and stabilities of protonated compounds (Table I), a parallel relation exists. This correlation agrees with experimental reactivity of electrophilic substitution except for the position 2 of *m*-xylene, which may be supposed to have low proton affinity because of the steric effect of two neighboring methyl groups, although it is theoretically the most active toward a proton. From their hydrogen isotope exchange reaction studies, Lauer et al.[11] have indicated that relative reactivity of the position 2 to 4 of *m*-xylene is 0.58 : 1.0. We must take such a fact into account. In *m*-xylene, numbers of position of proton attack will be 2.58 and the energy of its probable carbonium ion will be weighted mean of energies of Models I and I′. For *o*-xylene carbonium ion, the stabilities of Models III and III′ are identical, being in agreement with experimental reactivity, halogenation or nitration of *o*-xylene. We assume the energy of protonated *o*-xylene to be the mean of Models III and III′.

TABLE I. π-ELECTRON ENERGIES OF THE CARBONIUM IONS OF XYLENE ISOMERS (BOND LOCALIZATION MODELS)

Carbonium ions	Models	π-Electron energies (units of $-\beta$)
m-Xylene-	I	−11.4819
	I′	−11.5342
	I″	−11.4444
p-Xylene-	II	−11.4905
o-Xylene-	III	−11.4914
	III′	−11.4806

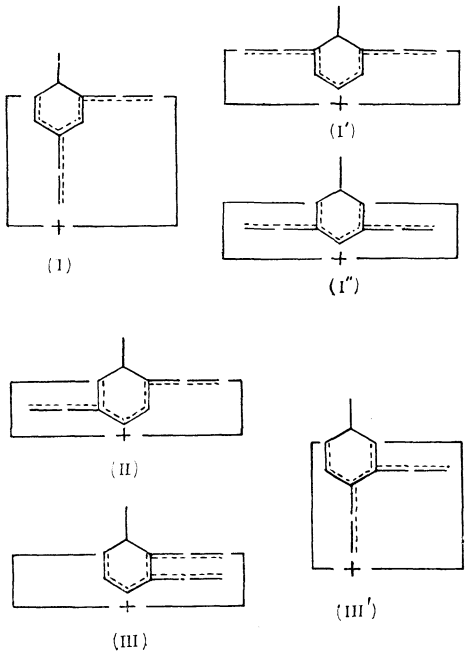

Fig. 1. Models of xylene carbonium ions.
I, I′ and I″: *m*-xylene carbonium ion
II : *p*-xylene carbonium ion
III, III′ : *o*-xylene carbonium ion

The ratio of basicity constants of *m*- and *o*-xylenes to that of *p*-xylene is estimated to be respectively 26 and 1.1 at 20°C from the measurement on the mixtures of these substances with anhydrous hydrogen fluoride[8]. In comparing these values experimentally observed with those theoretically calculated, it must be noticed that the number (Z) of positions of the highest proton affinity of *m*-, *o*- and *p*-xylenes are different from one another. For *m*-xylene, from our treatment mentioned above, $Z=2.58$. For *o*- and *p*-xylenes $Z=4$. Taking these Z values into consideration, the experimentally observed ratio of the reduced basicity constant[6] of *m*-xylene to that of *p*-xylene becomes 40.3 instead of 26, which is in disagreement with the theoretically calculated value, 1.0, using Eqs. 2 and 3. In the case of *o*-xylene, the experimental and theoretical values of K^{III}/K^{II} are 1.1 and 1.0, respectively, so the agreement between these two values

10) V. A. Crawford, ibid., **1953**, 2058.
11) W. M. Lauer, G. W. Matson and G. Stedman, *J. Am. Chem. Soc.*, **80**, 6437 (1958); see also, E. L. Mackor, P. J. Smit and J. H. van der Waals, *Trans. Faraday Soc.*, **53**, 1309 (1957).

is satisfactory[12]. Thus, basic behavior of isomeric xylenes is not understood by the bond localization hypothesis alone. It is natural to take hyperconjugation further into consideration, as is seen in the following section.

π-Electron Structures of Isomeric Xylene Carbonium Ions

In the following, as an example, the relative basicity of *m*-xylene compared to *p*-xylene will be discussed. From Eq. 3, A can be written as follows:

$$A=\{E^{I}_{BH^+}-(E^{I,0}_{BH^+}+0.18)\}-\{E^{II}_{BH^+}-E^{II,0}_{BH^+}\}-\{E^{I}_{B}-E^{II}_{B}\} \quad (4)$$

where, $E^{I}_{BH^+}$ is the π-electron energy for the actual state of the *m*-xylene carbonium ion, $E^{II}_{BH^+}$ is the similar quantity for the *p*-xylene carbonium ion; $E^{I,0}_{BH^+}$ and $E^{II,0}_{BH^+}$ are the π-electron energies for the bond localization models of protonated *m*- and *p*-xylenes, respectively; E^{I}_{B} and E^{II}_{B} are the π-electron energies of *m*- and *p*-xylenes, respectively; the numerical value 0.18 in the right hand side of Eq. 4 is necessary for making $(E^{I,0}_{BH^+}+0.18)=E^{II,0}_{BH^+}$. This value, which is expressed in the unit of kcal./mol. by the use of $\beta=-60$kcal./mol.[12], estimated by comparing the weighted mean of π-electron energies of types I and I′ for protonated *m*-xylene with the energy of type II for protonated *p*-xylene. Taking $E^{I}_{B}-E^{II}_{B}=0.18$ kcal./mol., Eq. 4 becomes as follows:

$$A=-x+c \quad (5)$$

where

$$-x=E^{I}_{BH^+}-E^{I,0}_{BH^+} \quad (6)$$

and

$$-c=E^{II}_{BH^+}-E^{II,0}_{BH^+} \quad (7)$$

The quantities x and c indicate respectively the stabilization energies through hyperconjugation of H_2 quasi-atom in the actual states of *m*- and *p*-xylene carbonium ions compared with their bond localization models. Experiments show $K^{I}/K^{II}=40.3$ [13] at 20°C, consequently from Eqs. 2, 3 and 5, we obtain

$$x=c+8.2 \quad (8)$$

Eq. 8 shows that, if the difference of hyperconjugation energies between protonated *m*- and *p*-xylenes is about eight kcal./mol., the experimentally observed basic behavior of *m*- and *p*-xylenes is understandable. A similar consideration suggests that no change in the hyperconjugation energies exists between *o*- and *p*-xylene carbonium ions. Indeed,

$$x=c+0.09$$

Here it will be noticed that the hyperconjugation energy of protonated *m*-xylene is the weighted mean of hyperconjugation energies by the methylene group for models I and I′, and that of protonated *o*-xylene is the weighted mean for the models III and III′. The value, 8.2 kcal./mol., of change in hyperconjugation energies between protonated *m*- and *p*-xylenes seems too great at first sight. This large difference may not be unreasonable, however, since the substances in question are the so-called "strongly hyperconjugated" systems[14,15].

Discussion

Brown and Brady[16] have shown that change in solvolysis rates between meta- and para-methyl substituted phenyldimethylcarbinyl chloride is explained reasonably, though qualitatively, in terms of valence bond structures. On the stabilities of the protonated isomeric xylenes also, treatment by means of valence bond structures may not be overlooked, and will be tried in the following way.

Model I of protonated *m*-xylene can resonate among three A (AI, AI_1 and AI_2), one B and one C structures (Fig. 2), according to Brown and Brady[16]. However, additional hyperconjugated structures by the two methyl substituents should be taken into account, such as four D, six E, one F, one G and five H structures. The number of resonance structures is altogether twenty-two (Fig. 2). For the models I′, I″, II, III and III′ similar types of resonance structures are considered. Numbers of resonance structures belonging to these types are indicated in Table II. Inspection of Table II suggests that model I is as stable as model I′, model I″ being less stable, and model III will possibly be more stable than model III′. Model I will probably be stable to almost

12) In these calculations, the unit of energy is expressed in kcal./mol. by the use of $\beta=-60$ kcal./mol. See, C. C. J. Roothan and R. S. Mulliken, *J. Chem. Phys.*, **16**, 118 (1948).

TABLE II. NUMBERS OF THE VALENCE BOND STRUCTURES

Models	A	B	C	D	E	F	G	H	Total
I	3	1	1	4	6	1	1	5	22
I′	3	1	1	5	6	2	2	3	23
I″	3	0	0	0	0	0	0	5	8
II	3	0	1	4	4	1	1	5	19
III	3	0	1	4	7	2	2	3	22
III′	3	1	0	4	4	1	1	2	12

the same extent as model III, which will be more stable than model II. These results are partly in disagreement with experiments. It may be said, however, that the difference of the stability of protonated compounds of xylene isomers will be attributable to that of numbers of hyperconjugation structures by the methyl group, irrespective of hyperconjugation or localization of the methylene.

From their electron spin resonance measurements of isomeric xylene negative ions, Tuttle, Jr. and Weissman[17] have indicated that methyl groups show hyperconjugation in a different manner among these substances and are more hyperconjugated in the *m*-xylene than in the *o*- and *p*-xylene negative ions. As has been hitherto accepted, the hyperconjugation phenomenon seems not so simple but complicated. At all events, it may be likely that the manner in which hyperconjugation occurs depends greatly on the environment of a methyl group.

17) T. R. Tuttle, Jr. and S. I. Weissman, ibid., **80**, 5342 (1958).

Summary

By means of the LCAO MO method, the π-electron energies of xylene carbonium ions are calculated, for all possible models, with respect to the positions of proton attack, on the basis of the bond localization hypothesis. It is indicated that the explanation of the basic behaviors of isomeric xylenes is impossible merely by the bond localization theory of their carbonium ions, and hyperconjugation should be taken into account.

It is indicated that, when the difference of hyperconjugation energies between protonated *m*- and *p*-xylene is about eight kcal./mol., the experimentally observed basic behavior of *m*- and *p*-xylenes is understandable.

The author wishes to thank Professor T. Titani (Tokyo Metropolitan University) for his interest, and Professor A. Kotera (Tokyo University of Education) for his guidance and instructive discussion.

Studies on Crystal Hydrates. IV. Dehydration and Rehydration, Stable and Metastable Equilibria and Transition between Hydrate Modifications of Potassium Mercury(II) Chloride Monohydrate, $K_2HgCl_4 \cdot H_2O$*

By Hideaki CHIHARA and Syûzô SEKI

(Received February 13, 1959)

Numerous reports may be found in the literature of the subject as to the dehydration and rehydration of crystal hydrates, but there are few investigations based on the exact thermodynamical precautions. Atomistic interpretation of the phenomena related to the behavior of water molecules in the dehydration reaction seems to have insufficient ground to advance. One of the principal reasons for this seems to be that there are complexities which enable us to obtain a material at the well-defined thermodynamical as well as molecular state only with extreme difficulty. Dehydration can frequently produce amorphous or colloidal material which gradually changes to stable crystalline solids[1]. Different methods of preparation sometimes produce materials of different free energy[2].

Many hydrates undergo phase transitions prior to dehydration in the heating experiments[3]. A study of the mechanism of such transitions will assist in understanding the law governing the dehydration reaction.

In the present paper, another example of the difficulty of obtaining the true equilibrium will be presented. It was inferred that $K_2HgCl_4 \cdot H_2O$ might undergo "zeolitic" dehydration, from its crystal structure[4], in which water molecules are packed in channel-like interstices. Although the direct evidence of such type of dehydration was not obtained, a consideration of the entropy of dehydration let us conclude that this is the case. An X-ray diffraction study of the phase transition and the rehydration will be briefly reported.

Experimental

Material. — KCl: Takeda Co., first grade. Purified by recrystallization from water.

$HgCl_2$: Takeda Co., analytical grade. Recrystallized from water. $K_2HgCl_4 \cdot H_2O$: Crystals were prepared according to the phase diagram[5] of the system KCl-$HgCl_2$-H_2O which is reproduced in Fig. 1. Because amorphous samples were often obtained depending on the method of preparation as will be described later, the following procedure was found most satisfactory by analogy of the system $MnCl_2$-NH_4Cl[6]. A saturated solution corresponding to the point a in Fig. 1 (25°C) was

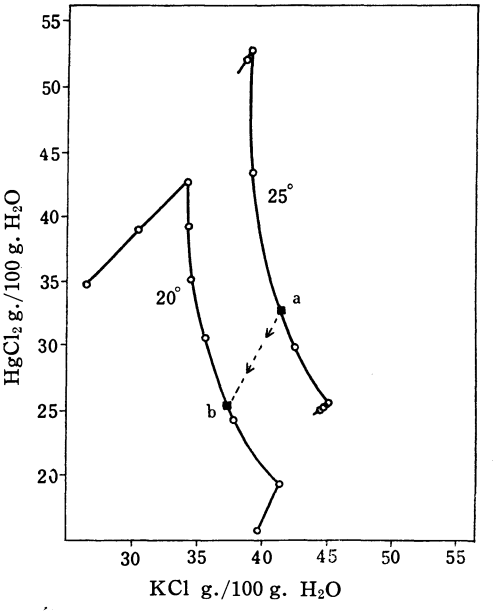

Fig. 1. Solution equilibrium diagram of the system KCl-$HgCl_2$-H_2O. Only a portion corresponding to the solid composition $K_2HgCl_4 \cdot H_2O$ is shown.

slowly cooled down to 20°C. A calculation shows that the solution changes its composition along the line a→b. The precipitate was filtered with a glass filter, pulverized, and then returned to

the mother solution for ten days in a closed vessel, being occasionally shaken. The X-ray photograph of the precipitate finally filtered was entirely consistent with the reported crystal structure[4].

Measurements of the Dehydration Pressures.—The dehydration pressures were measured by a simple mercury-in-glass manometer with the help of a traveling microscope to within ±0.01 mmHg. The water thermostat was kept at constant temperatures to within 0.005°C. In the experiment of the isothermal dehydration, the water vapor was trapped into a small capillary and weighed. The amount dehydrated was corrected for the mercury vapor condensing from the manometer into the trap.

Dehydration Equilibrium

The dehydration pressures of the crystalline $K_2HgCl_4 \cdot H_2O$ were measured between 26 and 40°C and the results are plotted in Fig. 2 by squares. The pressure equation is

$$\log P(\text{mmHg}) = 8.538 - (2161/T) \qquad (1)$$

The heating and cooling data were perfectly coincident within the experimental error and it was ascertained that equilibrium was attained with no hysteresis effect. The heat, the entropy, and the free energy of dehydration are given in Table I.

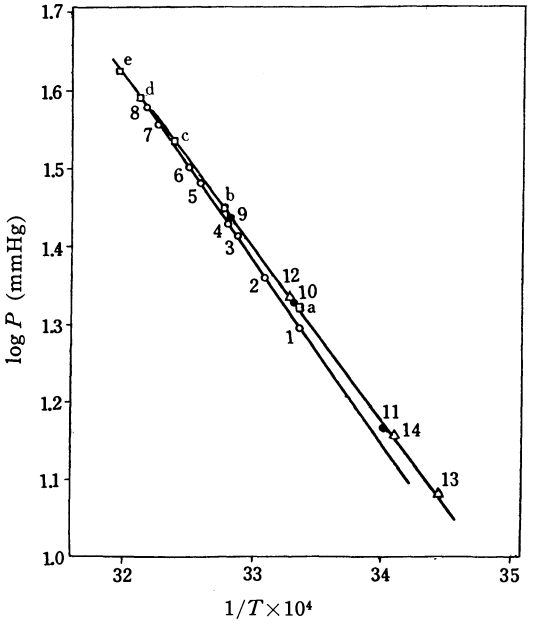

Fig. 2. Dehydration pressures of $K_2HgCl_4 \cdot H_2O$; □, crystalline hydrate (equilibrium data) (a-e); ○, heating direction of partly amorphous hydrate (1-8); ●, cooling direction of partly amorphous hydrate (9-11); △, subsequent heating and cooling measurements with partly amorphous hydrate (12-14).

TABLE I. CHANGES OF THE HEAT CONTENT, THE ENTROPY AND THE FREE ENERGY BY DEHYDRATION OF $K_2HgCl_4 \cdot H_2O$

ΔH kcal./mol.	ΔS cal./mol. deg.	ΔG at 25°C kcal./mol.
9.50	25.9	2.18

Results for Partly Amorphous Samples.—KCl 12.227 g. and $HgCl_2$ 15.459 g. were mixed with water 20 cc. and the solid was dissolved completely at high temperature by preventing evaporation. The solution was then cooled down to and kept at 20°C. It was deeply supercooled and no precipitation occurred before the entire solution reached 20°C. The solid precipitate after a few hours had the composition corresponding to $K_2HgCl_4 \cdot H_2O$ and the solution contained KCl 7.11 g. and $HgCl_2$ 6.13 g. The X-ray powder photograph of the solid thus prepared, however, showed that it was partly amorphous. The Debye rings, though faint, were consistent with the reported crystal structure of the hydrate[4]. The dehydration pressure of the partly amorphous hydrate showed a hysteresis phenomenon according to the pressure equations:

$$\log P(\text{mmHg}) = 9.139 - (2359/T)$$
in heating direction (2)

$$\log P(\text{mmHg}) = 8.595 - (2180/T)$$
in cooling direction (3)

The results are shown by open circles (heating direction) and by solid circles (cooling direction) in Fig. 2. The results of the subsequent heating and cooling experiments are indicated by triangles. It took about 20 days to reach an apparent dehydration equilibrium as compared with a few minutes in the case of the crystalline sample at 24.03°C.

The experiments of isothermal dehydration were made at 34.13°C. The initial formula of the hydrate was $K_2HgCl_4 \cdot 0.997 H_2O$. The constant value of the dehydration pressure was reached only after about 280 days (see Fig. 3). The calculated pressure from Eq. 2 was 31.09 mmHg and the apparent coincidence was good. The second equilibration with the composition $K_2HgCl_4 \cdot 0.965H_2O$ (water 0.032 mol. was taken from the original hydrate) was much slower than the first and then it was felt that further dehydration might accelerate the approach to the equilibrium. The third run, however, was even slower,

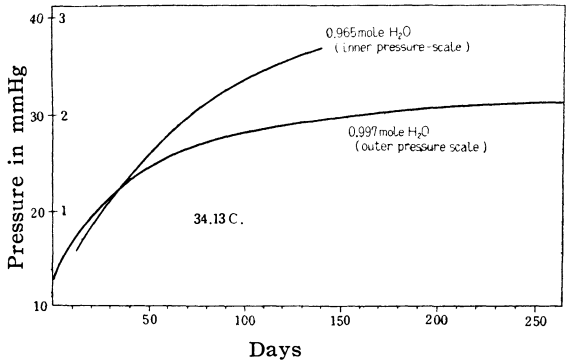

Fig. 3. Approach to the apparent equilibrium of isothermal dehydration of partly amorphous sample.

with 0.809 mol. of water per formula weight. The sample used in this experiment was taken out of the apparatus and examined by the X-rays. It was still partly amorphous but the crystallization seemed to have proceeded during the pressure measurements (longer than two and half years).

The differential thermal analysis of the partly amorphous sample gave only ill-defined peaks in comparison with the result for the crystalline sample which will be discussed below.

These results show that the crystallization of an amorphous solid is a very slow reaction at room temperature and that care must be exercised in the preparation of the solid substances, because an inadequate method of preparation sometimes produces materials of higher free energy than the one for the equilibrium product**.

Entropy of Dehydration

The value of entropy may be assigned to water molecules in the hydrate crystal by subtracting the experimental entropy of dehydration from the standard entropy of water vapor 45.1 cal./deg. mol. This method gives for the present case 19.2 cal./deg. mol. which amounts to roughly twice as large a value as in average hydrate crystals and shows that the dehydration is "zeolitic".

Transition and Dehydration in Air

The results of the differential thermal analysis are given in Fig. 4 which shows two heat-absorption peaks at 114 and 123°C, with a fine structure in the former peak. The shoulder at 107°C always appeared in several runs but one at 117.6°C was not always reproducible.

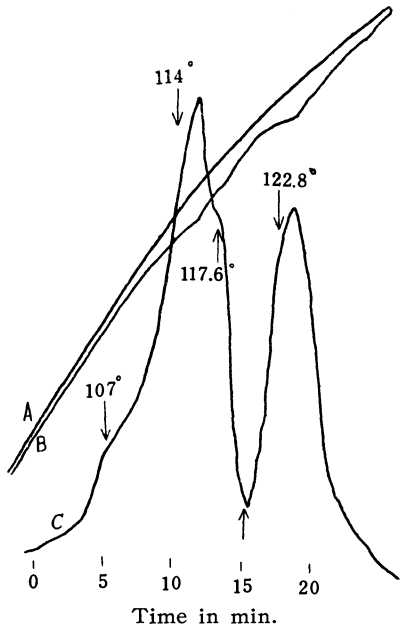

Fig. 4. Differential thermal analysis of crystalline $K_2HgCl_4 \cdot H_2O$; curve A, temperature of the reference NaCl powder; curve B temperature of the sample; curve C the temperature difference.

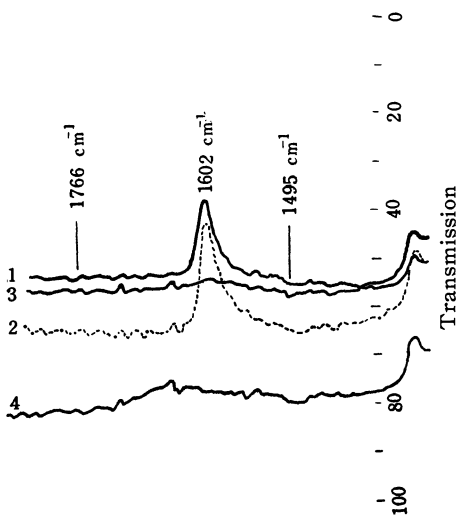

Fig. 5. Infrared spectra. (1) Room-temperature phase, (2) heated to 118°C, (3) heated to 130°C, (4) daifloil background.

There are evidences for the fact that the first peak at 114°C is due to a transition between two hydrate modifications

** A similar case is the dehydration and transition of $NiSO_4$ hexahydrate as reported by Simon and Knauer (*Z. anorg. u. allgem. Chem.*, **242**, 375 (1939)).

7) Full discussion of the entropy of dehydration is given in Part VI (This Bulletin, **32**, 908 (1959)).

and the second peak at 123°C is due to dehydration. There occurred no detectable evaporation and condensation of water in the apparatus of the thermal analysis[3] at the temperature between the two peaks, and also the infrared absorption spectrum*** of the hydrate crystals quenched from 118°C, at which the first heat effect completed its peak, retained the 6-micron absorption band of water (Fig. 5). The hydrate heated beyond the second heat-absorption temperature was not absorbed in this wavelength region; the heat absorption at 123°C is apparently due to dehydration.

An X-ray study was made of the transition of $K_2HgCl_4 \cdot H_2O$ at 114°C. The crystals were heated to 117°C in the apparatus of the differential thermal analysis (the transition was observed) and was rapidly cooled to room temperature and examined by the Norelco X-ray diffractometer. The scanning of the goniometer started about ten minutes after the sample was taken out of the heating vessel, with the scanning rate $2\theta = 0.5°$/min. The scanning was repeated according to the following succession:

12—61°, 35—46, 10—42, 10—35, 34—27 (reversely), 26—34, 10—14, 23—26, 28—31, 45—47, in 2θ values.

It took about 5.5 hr. for this series of scanning. The scanning was then repeated every day for the following six days. The change in the diffraction patterns with time was bewildering during the first few hours. Some of the typical results are reproduced in Fig. 6. The diffraction

patterns of the anhydrous crystal (Fig. 7a) and of the hydrate (Fig. 6a) which is stable at room temperature (α modification) are also given for the sake of reference. The series of patterns shows the change in the crystal structure from the high-temperature modification (β modification) to the low-temperature modification (α modification) slowly occurring at room temperature. Fig. 6b is itself an intermediate or a mixture of the two modifications. Attempts were made to assign the diffraction lines to either α or β modification by comparing the members of the series of the diffraction patterns. The results are summarized in Table II.

Although some of the lines ascribed to the β modification coincide with the lines of the α modification or with the lines of the anhydrous crystal, there exist lines essentially attributable to the β modification. The time change of the intensities also supports this view. The patterns of Fig. 6b and its succeeding changes can not be obtained by a mere superposition of the diffractions from the α-hydrate and those from the β-hydrate. In fact, the intensities of lines belonging to various crystalline forms show intricate changes, for example, (1) 24.1* line first becomes stronger with time, (2) 13.4 and 15.4 are both characteristic to the α-hydrate but their recovery in the intensity is not proportional with each other; the recovery is first more rapid in 15.4 line than 13.4 line, and then the recovery of 13.4 line predominates again, and (3) five lines between 28 and 31 do not change their intensities in a regular, simple way.

It was first supposed that the sample chilled from above the transition temperature might be a mixture of the α and the β modifications, and that the transition might be observed as the decrease in intensity of the characteristic lines of the β form accompanied with the increase in the intensities of lines of the α form by equal fractions. If so, it should be possible to determine the rate of transformation at a supercooled condition which is itself a rare experimental information. Instead, it has become very plausible that the transition is essentially of gradual nature: a structure does not abruptly transform itself into another but there is a continuous series of structures between the β and the α modifications.

This is an analogous situation to the order-disorder transitions in such respect that there are an infinite number of phases between two extreme phases**. But a difference from the order-disorder transition is that nothing like the order parameter may be introduced and that every step of the transition probably corresponds to an ordered state because no regular, proportional change in the diffraction intensities with time was observed in contrast to the case of order-disorder transitions, in which it is possible to calculate the order parameters from the monotonous change of a superstructure-line intensity with temperature[8]. In the case of order-disorder transitions, a unit cell within a crystal has only statistical significance in the sense that a particular unit cell has not necessarily the structure identical with the neighboring unit cell. In the present case of the transition in $K_2HgCl_4 \cdot H_2O$, every unit cell is considered to have the identical structure which gradually changes with time. This type of transition may be termed a slow "Martensite transition" which does not accompany nucleation-and-growth[9].

The determination of the precise structure of the β modification*** seems to be very difficult because the unit cell is relatively large, being

$$a=16.51\text{Å},\ b=23.26\text{Å},\ \text{and}\ c=8.89\text{Å}$$

and containing 16 formula units of $K_2HgCl_4 \cdot H_2O$. This cell is four times as large as the unit cell in the α modification[4] owing to the appearance of the line ($2\theta=11.75°$) which may be indexed as inhibited ($1\,1/2\,0$) on the basis of the structure of the α form.

Rehydration of Anhydrous Crystals

$K_2HgCl_4 \cdot H_2O$ was dehydrated in the apparatus of the differential thermal

* 2θ value (twice the diffraction angle).

** It may not be immediately evident that the transition at 114°C from the α to the β form is of the same nature as that from the β to the α form occuring at room temperature. But there is no reason, at present, to believe otherwise.

9) M. Cohen, "Phase Transformations in Solids", John Wiley & Sons, Inc., New York (1958), p. 588.

*** Kiriyama and Ibamoto[10] reported the structure of the high-temperature form of $K_2HgCl_4 \cdot H_2O$ by use of a high-temperature camera after prolonged heat-treatment at high temperature. Their experimental condition was very different from the present one. There are some discrepancies between their results and the results of the current investigation; for instance, the 11.75 line is missing from their X-ray photographs and therefore the unit cell dimentions are also different from those described here.

10) R. Kiriyama and H. Ibamoto, This Bulletin, 27, 317 (1954).

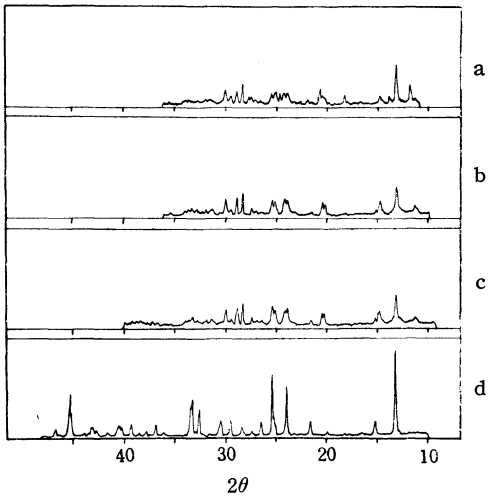

Fig. 7. Change of X-ray diffraction patterns due to rehydration of anhydrous crystal at room temperature; (a) Anhydrous phase, (b) after standing for 60 min. in the open air, (c) after 140 min. (d) after 30 hr. (α-modification of the hydrate).

analysis and it was immediately transferred to the goniometer of the Norelco X-ray diffractometer. It was observed that rehydration occurred in the open air at room temperature, at a measurable rate. This series of diffraction patterns, which is a cinematogram of the rehydration reaction, is reproduced in Fig. 7. It took about 30 hr. at about 30°C for the complete rehydration. This is a comparatively rapid rate of rehydration and therefore it is confirmed that the measurements of the dehydration pressures of the crystalline hydrate correspond to the equilibrium property of the system.

Summary

The dehydration pressures of the crystalline $K_2HgCl_4 \cdot H_2O$ are measured and given by $\log P = 8.538 - (2161/T)$ with P expressed in mmHg. No thermal hysteresis effect was observed. Production and some experiments for partly amorphous hydrate are briefly discussed. A consideration of the entropy of dehydration led to the conclusion that the dehydration is zeolitic. The differential thermal analysis revealed that there is a non-dehydrating transition at 114°C and that the dehydration occurs at 123°C. Infrared spectra of the solids showed that the 6-micron band of water persisted between 114 and 123°C. The X-ray study of the transition at the supercooled condition showed that this is a transition quite different in nature from those of ordinary nucleation-and-growth mechanism. The rehydration of dehydrated crystals was followed by the X-ray diffraction method and found to be relatively rapid at room temperature.

The authors wish to express their sincere thanks to Professor I. Nitta for his interest in the present investigation and to Assistant Professor K. Sakurai and Dr. K. Osaki for their discussions on the X-ray data. The cost of the research was partly defrayed by the financial support of the Ministry of Education to which the authors' appreciation is due.

Studies on Crystal Hydrates. V. Zeolitic Dehydration of DL-Tris-ethylenediamine-cobalt(III) Chloride Hydrate, DL-[Co en$_3$]Cl$_3$·nH$_2$O. Sorption and Desorption of Water Vapor. A Preliminary Study of the Dielectric Properties*

By Hideaki CHIHARA and Kazumi NAKATSU

(Received February 13, 1959)

Crystal hydrates may be classified into two extremes from the standpoint of the dehydration isotherm[1]:

i) crystals which are dehydrated in a stepwise manner (Fig. 1a); $CuSO_4 \cdot 5H_2O$ belongs to this class of hydrates,

ii) crystals which are dehydrated continuously (Fig. 1b); zeolite minerals belong to this class.

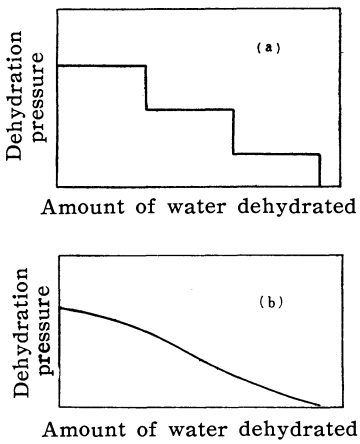

Fig. 1. Two extreme types of dehydration isotherm. (a) the stepwise dehydration, (b) the continuous dehydration.

Zeolites, chabazite, for instance, generally possess two or more kinds of channels of different diameter and each channel crosses with others at cage-like rooms[2]. Analcite has spiral channels which are relatively independent of each other but their diameter is not uniform throughout a channel[3]. We have long been looking for a type of crystal which belongs to the class ii and has only one kind of channel in which positions of water molecules can be located exactly by the method of X-ray analysis. If we can obtain such a crystal, it will provide us with an ideal model substance for examining the role of water in the stabilization of crystal lattice, the capillary condensation theory generally adopted in the adsorption research ane the state of aggregation of water molecules in the channels.

The crystal structure of DL-[Co en$_3$]Cl$_3$·nH$_2$O (n=3) has recently been determined[4] and this was found to be a substance that nearly meets our requirements.

The present paper deals with the experiments aiming at establishing the zeolitic nature of the dehydration of this crystal and with some results obtained in regard to the thermodynamic quantities of dehydration. A preliminary measurement of the dielectric absorption will also be briefly reported.

Experimental

Material.—The preparation of DL-tris-ethylenediamine-cobalt(III) chloride has already been described[4]. Crystals were purified by repeating recrystallization from aqueous solution (Found: C, 20.77; H, 7.01; N, 24.73; Cl, 29.83% on the basis of the anhydrous crystal. From the residue the Co purity was found to be 99.601% by the α-nitroso-β-naphthol method**). The measurements of the dehydration pressure were conducted with powdered crystals unless otherwise stated. Dielectric measurements were made with single crystals grown from the aqueous solutions.

Differential Thermal Analysis.—The differential thermal analysis (Fig. 2) shows that the dehydration takes place over the temperature region between 70 and 170°C. Such gradual

dehydration stands in contrast with the case of nickel sulfate hydrate, for example, and suggests the zeolitic nature of dehydration.

Dehydration Pressures. — The dehydration pressures of the hydrate were measured between 19 and 45°C at various water contents by using the apparatus already described in the preceding paper. The results are summarized in Table I and Fig. 3. The approach to the equilibrium was very rapid, not later than ten minutes after the water bath was thermostated. The pressure values were read by use of a traveling microscope to 0.01 mm. Corrections in the value of the water content for the amount of water present in the vapor phase were not made, since a rough estimate based on the dimensions of the manometer and the sample container showed that it was well within the experimental error. No hysteresis effect was observed: the pressures in the heating and in the cooling directions coincided with each other.

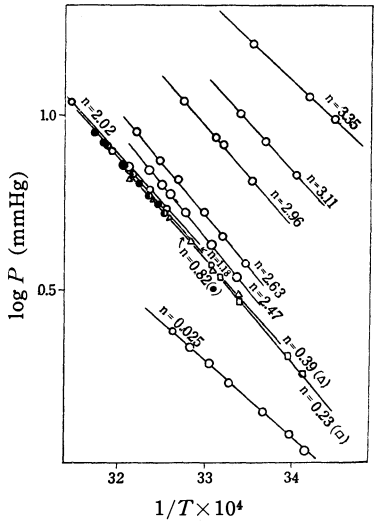

Fig. 3. Dehydration pressure of DL-$[Co\,en_3]Cl_3 \cdot nH_2O$ at different water contents n.

The experiments of dehydration and rehydration (desorption and sorption) of a single crystal was undertaken in order to compare it with the powder data. A single crystal (about 325.6 mg.) placed in a glass vessel (144.9 mg.) was hung under a quartz helical balance, the sensitivity of which was 0.2711 mm./mg. The water vapor pressure in the apparatus was kept constant by use of 72% sulfuric acid solution covering the water vapor pressures up to 13 mmHg. The results are plotted in Fig. 7. No hysteresis was observed between the dehydration and rehydrotion branches.

The differential molar heats and entropies of dehydration were computed from the pressure equations given in Table I. Table II lists these results and Fig. 6 indicates that there is a maximum both in the heat and in the entropy at a certain water content (approximately at $n=2.7$ mol. of water per formula weight of the hydrate).

Description of Crystal Structure

The crystal structure may be briefly outlined here with particular attention to the arrangement of the water molecules. The structure projected on the (0001) plane is represented in Fig. 4. A channel of hexagon cross-section filled with water molecules runs through the origin in the direction of the c-axis. The way in which the water molecules are arranged is schematically shown in Fig. 5 and the crystal data together with the atomic coordinates are reproduced in Table III.

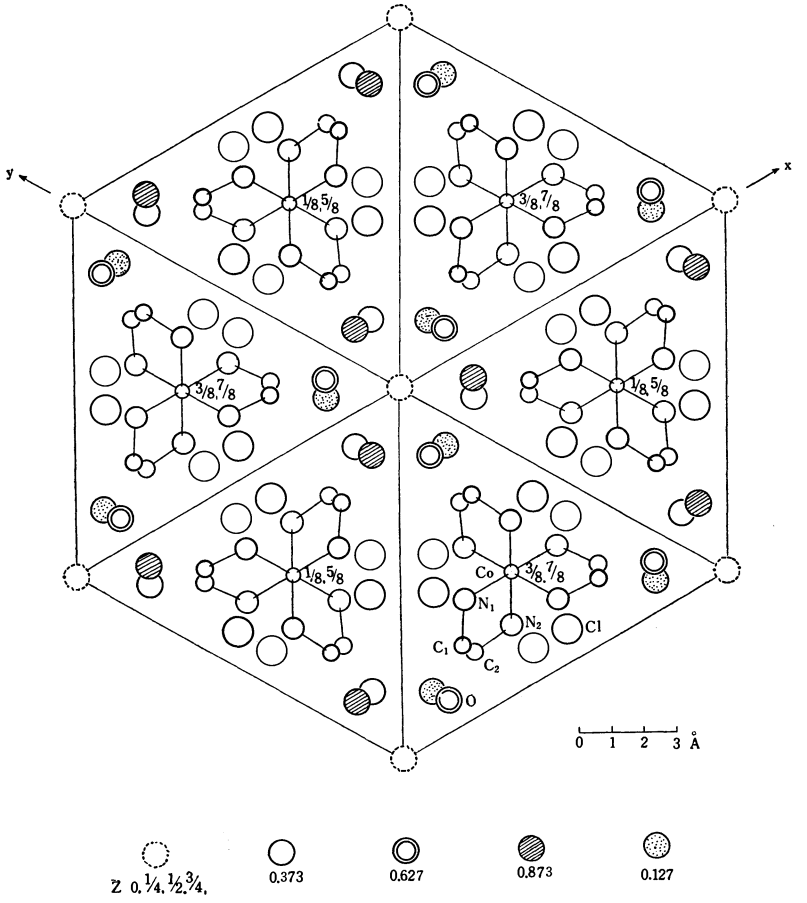

Fig. 4.

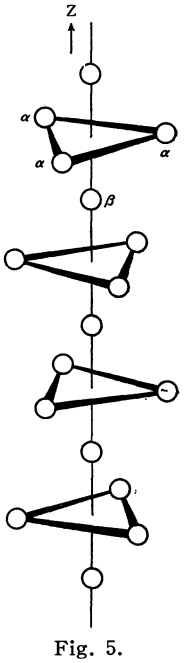

Fig. 5.

TABLE III. CRYSTALLOGRAPHIC DATA

$a=11.50\pm0.02$ Å, $c=15.52\pm0.04$ Å,
Density 1.504 (17°C), $Z=4$,
Space Group $P\bar{3}c1$-D_{3d}^4

Fractional atomic coordinate

Atom	No. of positions & Wyckoff notation	x	y	z
C_0	4d	1/3	2/3	0.125
Cl	12g	0.097	0.493	0.372
O_1	12g	0.087	0.225	0.873
O_2	2a	0	0	1/4
O_3	2b	0	0	0
C_1	12g	0.180	0.397	0.077
C_2	12g	0.215	0.397	0.173
N_1	12g	0.192	0.525	0.050
N_2	12g	0.333	0.535	0.200

TABLE IV. SOME INTERATOMIC DISTANCES

$O_\alpha\cdots Cl$	3.34 Å
$O_\alpha\cdots C_1$	3.36, 3.61 Å
$O_\alpha\cdots C_2$	3.12, 3.55 Å
$O_\alpha\cdots O_\alpha$	3.90, 4.19, 4.54 Å

Water molecules which occupy the 12g positions amount to three moles per formula weight of the hydrate ($n=3$). These positions will be referred to as the α-sites. In view of the long O···O distances listed in Table IV, if water molecules are to occupy only α-sites, and of the improvement of the reliability index by about 2%, it was concluded that water molecules are distributed also on the 2a and 2b special positions (referred to as the β-sites). The fact that the peak at the origin in the electron-density projection on the (0001) plane was not eliminated even at the final stage of the refinement of the structure analysis also led to this conclusion. This addition of water is also consistent with the chemical analysis that the water content of a freshly prepared crystal is $n=3.6$. The $O_\alpha \cdots O_\beta$ distances will then be 2.96 and 3.00 Å corresponding to weak hydrogen bonding.

A single-crystal oscillation photograph was obtained after the crystal was almost dehydrated and its unit cell dimensions were the same as those of the hydrate crystal.

Results and Discussion

The dehydration isotherm derived from the data of Table I by inter- or extrapolating them to 25°C is shown in Fig. 7

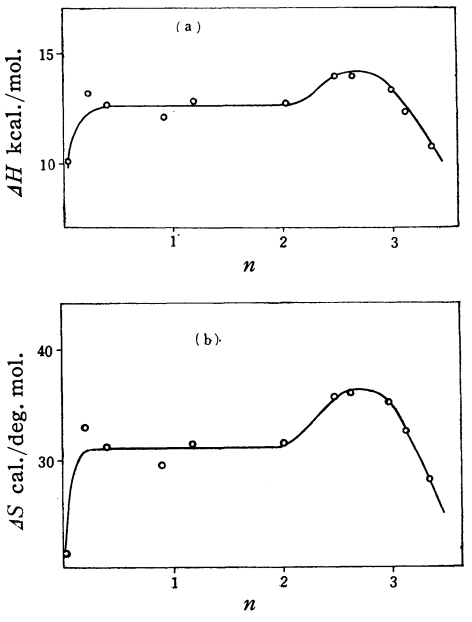

Fig. 6. Differential molar heat (a) and entropy (b) of dehydration as functions of water content n.

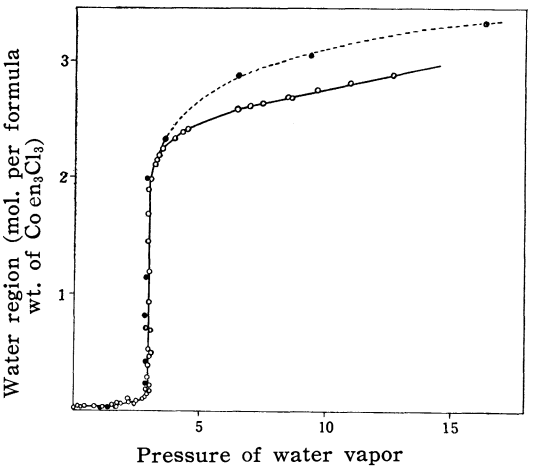

Fig. 7. Dehydration isotherm at 25°C derived from the powder data (solid circle) and determined directly for a single crystal (open circle).

by solid circles. The pressure at 25°C remains almost constant (2.85 mmHg) between the water contents $n=0.2$ and 2.5. Another independent direct measurement of the isotherm at 25°C for a single crystal (denoted by open circles in Fig. 7) gave nearly the same result as that derived from the powder data***. Important conclusions may be drawn from these experimental data.

(a) The fact that the powder and the single-crystal data give the same results clearly shows that the isotherm obtained for the single crystal is not due to adsorption of water vapor on the outer surface of the solid but to the sorption and desorption into and from the interior of the crystal lattice.

(b) That the pressure is constant over a wide range of n reminds us of the character of the destructive dehydration (class i). A close examination, however, shows that the boundary values of n (0.2 and 2.5) do not correspond to any single crystalline phases. In fact there is no set of equivalent positions in the space group $P\bar{3}cl$ that can accommodate the states $n=0.2$ or $n=2.5$. Therefore, it must be emphasized that an appearance of the stepwise dehydration does not always correspond to the destructive dehydration. This conclusion argues against the widely accepted criterion for zeolitic dehydration[1,5-7]. X-ray examination would be necessary for the decision as to whether

*** The small discrepancy at higher pressures is probably due to the larger adsorption of water on the outer surface of powdered crystals.

or not the dehydration is zeolitic.

(c) From the standpoint of the sorption-desorption system, the isotherm of Fig. 7 corresponds to the type V isotherm of the Brunauer-Emmett-Teller classification[8]. It is evident that the horizontal portion of the isotherm corresponds to the capillary condensation into pores of uniform size. Analogous transitions in adsorbed monolayer have been reported and interpreted by many investigators since Harkins and his collaborators observed the first-order phase transition of *n*-heptane on the surface of silver[9], although its reality was open to some discussion[10]. Recent investigations[11] show that such transitions are due to a kind of cooperative phenomena occurring in the assembly of adsorbed vapors. The transitions are sharp on a homogenous surface but they are diffuse on a heterogeneous surface. Capillary condensation phenomena that have been observed at any time are diffuse, because the experiments were carried out on gels which are inevitably inhomogeneous. The transition phenomenon observed in the present study is unique because it occurs in the true equilibrium system (the water regain of the solid did not change during 24 hr. after dosage of vapor; cf. E. V. Ballou, Ref. 10) and also because it is the capillary condensation entirely equivalent, in principle, to the transition on a uniform outer surface of a single crystal.

(d) The maxima in the differential molar heat and entropy in Fig. 6 will be accounted for by the theory of cooperative phenomena. Analogous results were reported by Rhodin[12] for nitrogen adsorbed on single crystals of copper, by Young[13] for argon absorbed on octahedral potassium chloride and by Hayakawa[14]. In all the adsorption systems ever examined, the maximum of the differential heat of adsorption appears when the amount of the gas adsorbed nearly suffices to cover the surface with a monolayer. This is also to be expected theoretically[15]. In the present case the maximum is also near the monolayer coverage of the inner surface of pores ($n=2.7$). The number of pairs of water molecules in a channel interacting with each other increases more rapidly than linearly as the coverage increases, even after the monolayer has been completed. The differential heat thus increases with the coverage on the assumption that the pair interaction energy is constant. On the other hand, the water molecules in the second layer (β-sites) interact with the lattice much more weakly than do the molecules in the first layer (α-sites). Those two counteracting effects give rise to the maximum of the heat of sorption branch.

(e) The differential heat and entropy are very small at very low n values. This is an extraordinary fact as many sorption systems exhibit a great increase in ΔH towards the lower surface coverage. On the surface of a single crystal, the differential heat is constant down to very low pressures[12]. The experimental error involved in the present determination of ΔH does not exceed 0.7 kcal./mol. and, therefore, the small value of ΔH and ΔS may possibly be due to a slight rearrangement of atoms in the completely dehydrated crystal lattice.

The Preliminary Results of Dielectric Measurements.—The dielectric power loss was measured of single crystals ($n=3.6$) between -180°C and room temperature in the frequency range of 300 c/sec. to 10 Mc/sec. The dielectric absorption was found with the electric field in the *c*-axis direction and perpendicular to the *a*-plane of the hexagonal crystal. The activation energies for the relaxation process were 7.7 and 6.3 kcal./mol., respectively. By extrapolation to room temperature, the relaxation times ($\log \tau = (1379/T) - 14.72$ for the *c*-plane) nearly agree with the relaxation time in liquid water and it was inferred that the absorption is due to the hindered rotation of water molecules. In the experiment with the electric field parallel to the *c*-axis, an additional absorption increasing progressively towards lower frequencies was observed. Further precise study of the dielectric properties and the d. c. conduction is going on and will be reported later.

Summary

The dehydration pressures of DL-$[Co\,en_3]Cl_3 \cdot nH_2O$ ($n \leqq 4$), were measured between 19 and 45°C at various water contents. The dehydration isotherm derived from the data is of type V of the BET classification with a constant pressure (2.85 mmHg at 25°C) region between $n=2.5$ and $n=0.2$, corresponding to the case of capillary condensation into pores of uniform size. The crystal lattice is stable after dehydration, showing the zeolitic nature of dehydration. The usual criterion of stepwise dehydration for the lattice-destructive dehydration does not apply to this type of crystal. The differential molar heat and entropy of dehydration have maximum values around $n=2.7$; this can be accounted for by the theory of co-operative phenomena. At very low water content, there is a possibility of rearrangement of atoms in the crystal as inferred by the entropy consideration. A preliminary study of the dielectric properties showed that the relaxation absorption occurs between −180°C and room temperature in the megacycle region with the activation energy for the relaxation about 7 kcal./mol. The dielectric loss due probably to the d. c. conduction was observed in the *c*-axis direction.

The authors with to thank Professor I. Nitta and Assistant Professor S. Seki of Osaka University and Professor Y. Saito of Osaka City University for their valuable discussions. The present study was partly supported by the financial aid of the Ministry of Education, to which the authors' thanks are also due.

Studies on Crystal Hydrates. VI[1]*. Thermodynamics of Dehydration of Crystal Hydrates. A New Criterion for the Continuous Zeolitic Dehydration. Capillary Condensation of Water Vapor into Exactly Uniform Pores and an Experimental Test of the Kelvin Equation. Case of* DL*-Tris-ethylenediamine-cobalt(III) Chloride Hydrate*

By Hideaki CHIHARA

(Received February 13, 1959)

A criterion has generally been adopted as to the manner of dehydration of a crystal hydrate, which makes use of the dehydration isotherm[1]. The experimental determination of a complete dehydration isotherm, however, is sometimes quite an elaborate matter owing to difficulty in obtaining the true equilibrium of dehydration[2]. It was found that a new criterion, which is equivalent to the "isotherm criterion", can be obtained by the measurement of dehydration pressures at different temperatures for a fixed content of water in the solid phase; the water content needs not be accurately known. This may be termed "entropy criterion" as it is based on the value of the entropy of dehydration.

Although the entropy criterion is exactly as useful as the isotherm criterion, both were found to fail to apply to a particular case of DL-tris-ethylenediamine-cobalt(III) chloride hydrate, in which only one kind of channel filled with water molecules runs parallel to the direction of the *c*-axis[1]. This cobalt complex presents a remarkable model substance as a crystal

hydrate of zeolite type, as a porous adsorbent having exactly uniform capillaries, as a host-lattice of an *Einchluss-verbindung* like a urea adduct, and as an isothermal order-disorder assembly of water molecules.

Thermodynamics of Dehydration

For a dehydration equilibrium

$$A\cdot nH_2O \rightleftarrows A\cdot(n-1)H_2O + H_2O(g)$$

the change in the standard entropy ΔS is given by

$$S_H - S_A = S_W - \Delta S$$

where S_H, S_A and S_W are the standard entropies of the hydrate, the lower hydrate (or the anhydrous crystal) and the water vapor (45.1 cal./deg. mol.), respectively. $S_H - S_A$ can be obtained from the measurements of the heat capacities and ΔS from the tensiometric measurements. Table I lists these values for a few hydrate systems. It is seen in Table I that $S_H - S_A$ is nearly constant being around 10 e. u., which is also nearly equal to the entropy of ice at the standard state. This shows that an additivity rule holds for these crystalline solids. The values of $S_W - \Delta S$, on the other hand, scatter far and wide, being as large as 21.6 e. u. and as small as -2.5 e. u. One of possible reasons for the discrepancies between $S_H - S_A$ and $S_W - \Delta S$ would be that the stable equilibrium may not have been attained in the tensiometric measurements. This may undoubtedly cause a serious discrepancy. However, it is readily shown that a discrepancy can naturally occur even if the equilibrium was obtained in both thermal and tensiometric measurements.

TABLE I. ENTROPY PER MOLE OF WATER IN CRYSTALLINE HYDRATES

Hydrate	$S_H - S_A$[3]	$S_W - \Delta S$
$MgCl_2\cdot 2H_2O$	10.2	10.8[4]
$MgCl_2\cdot 4H_2O$	10.1	10.4[4]
$MgCl_2\cdot 6H_2O$	12.2	13.9[5]
$CaSO_4\cdot \frac{1}{2}H_2O$	11.4	-2.5[6]
$ZnBr_2\cdot 2H_2O$	11.7	21.6[7]
$ZnSO_4\cdot 2H_2O$	10.4	8.5[8]
$ZnSO_4\cdot 7H_2O$	5.6	2.9[8]
$CdBr_2\cdot 4H_2O$	10.7	9.9[9]
$CdSO_4\cdot \frac{8}{3}H_2O$	10.1	12.6[10]
$CuSO_4\cdot H_2O$	8.7	7.9[11]
$CuSO_4\cdot 3H_2O$	9.0	11.6[10]
$CuSO_4\cdot 5H_2O$	9.6	8.0[10]
$NiCl_2\cdot 6H_2O$	8.3	13.2[4]
$BaCl_2\cdot 2H_2O$	8.5	6.8[12]

Let us consider a system consisting of a hydrate phase (denoted by the subscript 1), the anhydrous phase (subscript 2) and the water vapor phase (subscript 3) in equilibrium. The molar Gibbs free energy of the whole system is given by

$$G_m = (1-\theta)\mu_1 + \theta\mu_2 + c\theta\mu_3 \qquad (1)$$

in terms of the chemical potentials μ_i where θ corresponds to the degree of dehydration or the mole fraction of the anhydrous phase in the solid components. One mole of the hydrate is assumed to produce c moles of water vapor. The conditions for the stable equilibrium are

$$\frac{dG_m}{d\theta} = 0 \qquad \frac{d^2G_m}{d\theta^2} > 0 \qquad (2)$$

Case A.—The simplest case in which

$$\left(\frac{\partial\mu_1}{\partial\theta}\right)_{P,T} = \left(\frac{\partial\mu_2}{\partial\theta}\right)_{P,T} = 0 \qquad (3)$$

leads to the ordinary condition of equilibrium

$$\mu_1 = \mu_2 + c\mu_3 \qquad (4)$$

By defining the absolute activity λ_i by

$$\mu_i = kT\log\lambda_i \qquad (5)$$

the equilibrium constant K is then obtained as

$$K \equiv \frac{\lambda_1}{\lambda_2\cdot(\lambda_3^+)^c} = \left(\frac{p}{P^+}\right)^c \qquad (6)$$

where λ^+ and P^+ are the standard-state quantities. The pressure equation will then be

$$\log p - \log P^+ = \frac{1}{c}(\log\lambda_1 - \log\lambda_2 - c\log\lambda_3)$$
$$= -\frac{\Delta h}{kT} + \frac{\Delta s}{k} \qquad (7)$$

where

$$\left.\begin{aligned} \Delta h &= (h_2 + ch_3 - h_1)/c \\ \text{and} \quad \Delta s &= (s_2 + cs_3 - s_1)/c \end{aligned}\right\} \qquad (8)$$

Eq. 7 is the integrated form of the Clapeyron-Clausius equation. The second condition (Eq. 2) gives

$$\frac{\mathrm{d}\log p}{\mathrm{d}\theta} = \frac{\mathrm{d}}{\mathrm{d}\theta}\left\{-\frac{1}{kT}(\mu_1 - \mu_2 - c\mu_3{}^+)\right\} = 0 \qquad (9)$$

showing that the dehydration pressure should be constant over the range of the θ values or, in other words, the dehydration should be stepwise as is the case for $CuSO_4 \cdot 5H_2O$ and its lower hydrates. Eqs. 7 and 8 then indicate that the Clapeyron-type equation gives the integral heat and entropy of dehydration when the condition (3) is satisfied. The heat and entropy thus obtained should be comparable with the third-law values $S_H - S_A$. It is inferred that the condition (3) holds in hydrates for which one sees approximate agreement between $S_H - S_A$ and $S_W - \Delta S$ in Table I.

Case B.—In a general case where the condition (3) is not satisfied,

$$\left(\frac{\partial \mu_1}{\partial \theta}\right)_{P,T} \neq 0 \qquad \left(\frac{\partial \mu_2}{\partial \theta}\right)_{P,T} \neq 0 \qquad (10)$$

the condition for the equilibrium gives

$$-\log \lambda_1 + \log \lambda_2 + c \log \lambda_3 + (1-\theta)\left(\frac{\partial \log \lambda_1}{\partial \theta}\right)_{P,T} + \theta\left(\frac{\partial \log \lambda_2}{\partial \theta}\right)_{P,T} = 0 \qquad (11)$$

which then leads to the pressure equation

$$c \log(p/P^+) = \frac{1}{kT}\{\bar{h}_1 - \bar{h}_2 - ch_3{}^+ - T(\bar{s}_1 - \bar{s}_2 - cs_3{}^+)\} \qquad (12)$$

where $\bar{h}$ and $\bar{s}$ are the differential molar heat and entropy. The shape of the dehydration isotherm must satisfy the second condition for the equilibrium:

$$\frac{\mathrm{d}^2 G_m}{\mathrm{d}\theta^2} = \frac{\mathrm{d}}{\mathrm{d}\theta}\left\{-\mu_1 + \mu_2 + c\mu_3 + (1-\theta)\left(\frac{\partial \mu_1}{\partial \theta}\right)_{P,T} + \theta\left(\frac{\partial \mu_2}{\partial \theta}\right)_{P,T}\right\} > 0 \qquad (13)$$

which then leads to

$$\frac{\mathrm{d}}{\mathrm{d}\theta}(\bar{\mu}_2 + c\mu_3{}^+ - \bar{\mu}_1) = \frac{\mathrm{d}}{\mathrm{d}\theta}(\bar{\mu}_2 - \bar{\mu}_1) > 0 \qquad (14)$$

Differentiating Eq. 12 with respect to θ gives

$$ckT\frac{\mathrm{d}\log(p/P^+)}{\mathrm{d}\theta} = \frac{\mathrm{d}}{\mathrm{d}\theta}(\bar{\mu}_1 - \bar{\mu}_2 - c\mu_3{}^+) = \frac{\mathrm{d}}{\mathrm{d}\theta}(\bar{\mu}_1 - \bar{\mu}_2) \qquad (15)$$

Therefore we have

$$\frac{\mathrm{d}\log p}{\mathrm{d}\theta} < 0 \qquad (16)$$

This shows that the dehydration pressure decreases constantly with increasing θ, or it corresponds to the zeolitic dehydration. The Clapeyron-Clausius equation gives differential molar heat and entropy in this case.

$S_H - S_A$ as obtained from the calorimetric results corresponds to the difference in the integral entropies $s_1 - s_2$ which is related to ΔS by Eq. 8.

Now, it will be evident that the discrepancies between $S_H - S_A$ and $S_W - \Delta S$ may naturally occur if the dehydration proceeds zeolitically as the differential and the integral entropies of dehydration do not usually coincide with each other*, except for accidental coincidence.

In view of the fast that the integral entropy assigned to water molecules within a hyrate lattice is nearly constant being approximately 10 e. u., ΔS values obtained by the tensiometric measurements can be used to determine whether or not the dehydration is zeolitic even if the corresponding calorimetric data are unavailable. In Table I, the discrepancy is appreciable in $CaSO_4 \cdot \frac{1}{2}H_2O$, $ZnBr_2 \cdot 2H_2O$ and $ZnSO_4 \cdot 7H_2O$. The hemihydrate of $CaSO_4$ undergoes zeolitic dehydration as shown by the isotherm reported by Gregg and Willing[13]. The cases of $ZnBr_2$ and $ZnSO_4$ hydrates have not been examined in detail and it is not clear if these are really zeolitic cases.

TABLE II. COMPARISON OF THE ISOTHERM AND ENTROPY CRITERIONS FOR THE TWO TYPES OF DEHYDRATION

	For dehydration by which crystal lattice collapses	For dehydration by which lattice does not collapse
$S_H - S_A$	about 10 e. u.	about 10 e. u.
$S_W - \Delta S$	equal to $S_H - S_A$	not equal to $S_H - S_A$
Clapeyron eq. gives	integral heat and entropy	differential heat and entropy
Pressure vs. deg. of dehydration	constant pressure	monotonous decline

* It is possible to calculate the intergral entropy for zeolitic hrdrates, if complete data of isotherms are available particularly at a very low presure region. See T. L. Hill, P. H. Emmett and L. G. Joyner, *J. Am. Chem. Soc.*, **73**, 5102, 5933 (1951).

13) S. J. Gregg and E. G. G. Willing, *J. Chem. Soc.*, **1951**, 2373, 2916.

Table II summarizes and compares the "isotherm" and "entropy" criterions. The "entropy criterion" is thus entirely equivalent to the "isotherm criterion" which has widely been accepted. The applicability or the inapplicability should be the same for both criterions. The advantage of the "entropy criterion" rests on the fact that the measurements of the dehydration pressure at different water contents are not necessary.

A Notable Case in which the Criterions Fail to Apply

When one correlates a thermodynamic relation to an atomistic interpretation, there is a risk of his over-relying upon empirical rules. Thus the "isotherm criterion" depends on a lot of experimental facts on the isotherm determinations and the structural studies before and after dehydration. This is in a way based on the analogy between zeolitic dehydration and adsorption. The phase rule of course can make judgement if the number of phases is known unambiguously.

The case of DL-$[Co\ en_3]Cl_3 \cdot nH_2O$ ($n \leq 4$), the dehydration of which was reported in the preceding paper[1], provides us with a notable exception to both criterions, which are however mutually consistent. Fig. 1

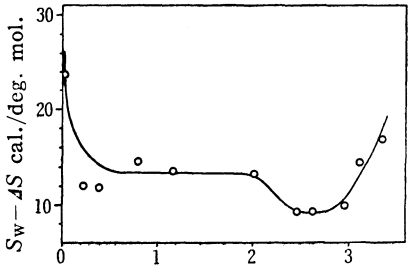

Fig. 1. Change with the water content in the differential molar entropy of water in $[Co\ en_3]Cl_3$ hydrate.

shows the change in $S_W - \Delta S$ as the hydration proceeds. $S_W - \Delta S$ is nearly constant between $n=0.2$ and 3 except for a minimum occurring around $n=2.6$[1]. Below and above this range of values of n, $S_W - \Delta S$ tends to increase, deviating from the additivity value of 10 e. u. The entropy criterion tells that the crystal undergoes zeolitic dehydration when $n \leq 0.2$ and when $n \leq 3$ and the lattice-destructive dehydration when n is between 0.2 and 3. This apparent conclusion is consistent with the isotherm criterion as judged from the isotherm given in Fig. 7 of the preceding paper[1], in which the pressure remains constant between $n=0.2$ and 3. However, as already reported[1], this conclusion is not justified by the crystal structure studies by which we see that the structure is unchanged by dehydration except for the loss of water molecules in the channels. This must evidently correspond to zeolitic dehydration and thus the failure of both criterions is apparent.

The extreme uniformity of the pore structure of this crystal seems to be responsible for the failure. There exists only one kind of pore running parallel in the direction of the *c*-aixs of the crystal. Such uniformity has never been realized in actual hydrate systems or adsorption systems and has been out of reach of empirical rules mentioned in the first paragraph of the present section. This type of isotherm should lead to a sharp distribution function of pore sizes if we treat it by a standard method utilizing the desorption branch of sorption isotherm[14].

The most reliable criterion would be the structure investigation by the X-rays but in most of zeolite minerals and gels there is a broad distribution of pore size, which necessarily gives rise to the isotherm corresponding to the *Case B*; $[Co\ en_3]Cl_3$ hydrate is one of the rarest exceptions. The "entropy criterion" as well as the "isotherm criterion" is, therefore, considered to be still valid in judging which type of dehydration a particular hydrate would undergo.

Comparison of Capillary Radius as Determined by Dehydration Isotherm and by X-ray Study

It will be interesting to see to what extent the well-known Kelvin equation

$$\log(p_r/p) = -2\sigma M/(\rho r \boldsymbol{R} T) \qquad (17)$$

gives reasonable pore radius when it is applied to the system of pores of molecular dimensions. p is the saturation pressure over a plane surface of the adsorbate liquid (water in the present case) whose surface tension is σ, density is ρ, and molecular weight is M. p_r is the saturation pressure over the surface, its radius of curvature being r. This equation has been known to hold for a macroscopic pore or a macroscopic droplet of liquid but we

14) C. Pierce, *J. Phys. Chem.*, **57**, 149 (1953).

seem to have available no direct experimental test of the equation down to pores of a few Ångstroms in radius.

The horizontal portion of the isotherm given in Fig. 7 of the preceding paper[1] gives $r=5.8$Å if $\rho=0.9971$, $\sigma=71.97$ dyn./cm., $p=23.756$ mmHg and $p_r=2.85$ mmHg are inserted in Eq. 17. It would not be necessary to add to r the thickness of a monolayer or of statistical layers as the capillary condensation begins at $n=0.2$, far below the monolayer capacity $n=3$**. On the other hand, the result of the crystal structure analysis[15] gives the distances from the origin (the center of a pore, see Fig. 3 of the preceding paper), in the plane parallel to the base of the hexagonal cell, 2.9 Å to the periphery of the van der Waals radius of the nearest CH_2 group and 3.4Å to the periphery of the nearest chloride ion (the inner wall of the pore is a little pleated).

We are now led to the conclusion that for water vapor as the adsorbate the Kelvin equation gives only the order of magnitude of the pores radius of micropores. We shall undertake experiments with nitrogen as the adsorbate later. For macropores the discrepancy would be much smaller. In view of the fact that the concept of the surface tension would undoubtedly lose its significance in such systems of water molecules, the Kelvin equation has been applied beyond its reasonable limit of application, although the method has been in extensive use for evaluating the pore size distribution in many adsorbents. The use of the Kelvin equation was partly justified for macropores by the experimental results that it gives the pore sizes in good agreement with those obtained by the mercury porosimeter method[16]. The present result gives some clue to the error caused by the use of the Kelvin equation for micropores.

Summary

A simple theory of the thermodynamics of hydrates is developed, which is able to show that the differential molar entropy of dehydration changes with the water content continuously if the hydrate undergoes zeolitic (continuous) dehydration. In this case the integral molar entropy of dehydration does not agree with the differential entropy. The same is true for the heat contents. For stepwise dehydration, on the other hand, both differential and integral entropies coincide in values. A new criterion, termed "entropy criterion", is presented that if the differential entropy of the water of crystallization, obtained by subtracting the entropy of dehydration (determined by the pressure measurements) from the standard entropy of water vapor 45.1 e. u., differs greatly from 10 e. u., the hydrate should undergo zeolitic dehydration and should have water molecules weakly bonded to the crystal lattice, from which water can be removed without causing collapse of the lattice. This new criterion is equivalent to using the current "isotherm criterion".

DL-$[Co\ en_3]Cl_3 \cdot nH_2O$ ($n \leq 4$) presents a notable exception to both criterions in that the crystal undergoes zeolitic dehydration in spite of its entropy of dehydration and its isotherm indicating the stepwise dehydration. The failure of the criterions in this crystal is due to the extreme uniformity of pore structure of the hydrate. The Kelvin equation for calculating the pore radius (giving 5.8Å) from the dehydration isotherm is tested against the pore radius obtained by the X-ray crystal structure analysis (giving 2.9 to 3.4Å). It may be concluded that the Kelvin equation is considered to give only the order of magnitude for micropore size. This cobalt complex hydrate is one of the rarest examples having exactly uniform pores and the criterion for the type of dehydration here presented is still effective in most cases.

The author wishes to express his sincere thanks to Professor I. Nitta and Assistant Professor S. Seki of the Department of Chemistry, Osaka University for illuminating discussions.

Quantum-Mechanical Considerations of Chemical Reaction Rates. II. The Transmission through Curved Reaction Path

By Iwao YASUMORI

(Received February 17, 1959)

Previous quantum-mechanical treatments[1-5] of chemical reaction rates deal principally with the behavior of the wave which represents the reacting system, passing from the region of the reactant to that of the resultant on the potential energy surface of reaction. These treatments also may be classed in two ways according to whether their objects are the transmission of the wave through the potential energy barrier[1-4] or through the curve or bend of the reaction path[5], for both the barrier and the bend are the important characteristics of the reaction path on the potential energy surface. Much knowledge of the microscopic feature of reaction rates, was obtained from these studies, but all these results were derived by the use of highly idealized models of potential, for example, one-dimensional square barrier or a path with a perpendicular turn, etc., to avoid mathematical difficulties.

Therefore, it is necessary to examine which of the conclusions correspond to the real behavior of reaction or are due merely to the used model itself.

For the purpose of considering the problem by the use of the more plausible potential models than those used before, Fueki and the present author have recently treated the transmission through the two-dimensional smooth barrier with a parabolic section and have made clear the properties of the quantum-mechanical correction which is necessary for the ordinary estimation of rate by the absolute reaction rate theory[6].

In this paper, another important problem, the transmission through the smoothly curved path with reasonable vibrational potential section is discussed in general and the extent of reflection and transmission is computed for some reaction examples. Then the inspection stated above is made comparing the present results with that of Hulburt and Hirschfelder's work[5] which was previously the first and only detailed one for the effect of the curved path. Also a consideration is made for their predictions of null transmission for the system with particular values of energy and of the availability of this effect for the isotopic separation.

Theoretical

Now we take, as a typical example of reaction, an elementary displacement reaction between atom A and molecule BC, A+BC→AB+C. The general feature of the potential energy surface for linear configuration is as shown in Fig. 1.

In order to discuss the transmission through the bend, we do not take the potential barrier into consideration and use a simplified surface and coordinate system shown in Fig. 2 hereafter.

We assume, as shown in Fig. 2, that the equi-potential lines are parallel with y and y' axes in regions I and II respectvely and that their radii at the bending part are constant. The dotted line shows the reaction path of radius r_e in region II, which traces minima in the direction of x, r or x' in the respective region.

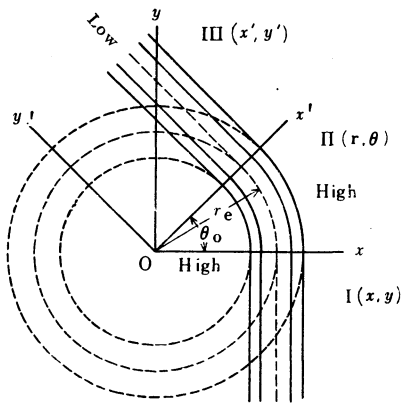

Fig. 2. Coordinate system of curved reaction path.

The wave equation to be satisfied by the system is

$$\nabla^2\Psi+\frac{8\pi^2\mu}{h^2}(E-V)\Psi=0 \tag{1}$$

where μ is the reduced mass of the system. According to the assumed form of potential V, the wave equation is separable with respect to the variables (x,y), (r,θ) and (x',y') in the regions I, II and III, respectively.

Now let us consider an incident wave of unit amplitude in region I, which expresses the state of reactant and comes from $y<0$ to the boundary $y=0$, being partly reflected at the boundary and partly transmitted through the bend.

Now, the wave functions which express the states of the system in each region are given as follows: In region I,

$$\Psi^{\mathrm{I}}=\phi_\kappa{}^{\mathrm{I}}(x)\cdot\exp\left(\frac{2\pi i}{h}p_\kappa\cdot y\right)+\sum_\lambda B_{\kappa\lambda}\phi_\lambda{}^{\mathrm{I}}(x)\cdot\exp\left(-\frac{2\pi i}{h}p_\lambda\cdot y\right) \tag{2}$$

where the first term represents the incident wave and the second the reflected waves. $\phi_\kappa{}^{\mathrm{I}}(x)$ is the eigenfunction of vibrational motion of the system in κ-th state and $\exp[(2\pi i/h)\cdot p_\kappa\cdot y]$ represents the eigenfunction of translational motion with the momentum p_κ. The total energy of the system, E, is equal to the sum of those of each motion, E_{vib} and E_{trans}. $B_{\kappa\lambda}$ is the coefficient of reflected wave referring to the transition between states, κ and λ.

In a similar way, the wave functions in regions II and III are expressed as

$$\Psi^{\mathrm{II}}=\sum_k[C_{\kappa k}\cdot\phi_k{}^{\mathrm{II}}(r)\cdot\exp(im_k\theta)+D_{\kappa k}\cdot\phi_k{}^{\mathrm{II}}(r)\cdot\exp(-im_k\theta)] \tag{3}$$

and

$$\Psi^{\mathrm{III}}=\sum_{\kappa'}F_{\kappa\kappa'}\phi_{\kappa'}{}^{\mathrm{III}}(x')\cdot\exp\left(\frac{2\pi i}{h}p_{\kappa'}\cdot y'\right) \tag{4}$$

where m_k is a constant and we may define a new constant q_k by the equation

$$m_k=\frac{2\pi}{h}\cdot q_k\cdot r_e \tag{5}$$

The coefficients of the transmitted waves, $C_{\kappa k}$ or $D_{\kappa k}$, are defined corresponding to the forward or backward translational motion in k-th state of region II and that of the transmitted wave, $F_{\kappa\kappa'}$ referring to κ'-th state in region III. We assume that all the wave functions for the vibrational motion, $\phi_\kappa{}^{\mathrm{I}}(x)$, $\phi_{\kappa'}{}^{\mathrm{III}}(x')$ and $\phi_k{}^{\mathrm{II}}(r)$ are normalized to unity.

Thus the following equations are readily obtained by the usual procedure of substituting the wave functions into the boundary conditions,

$$\Psi^{\mathrm{I}}=\Psi^{\mathrm{II}}\ \text{and}\ \frac{\partial\Psi^{\mathrm{I}}}{\partial y}=\frac{\partial\Psi^{\mathrm{II}}}{\partial y}=\frac{1}{r}\left(\frac{\partial\Psi^{\mathrm{II}}}{\partial\theta}\right)_{\theta=0} \tag{a), (b)}$$

at $y=0$ and

$$\Psi^{\mathrm{II}}=\Psi^{\mathrm{III}}\ \text{and}\ \frac{\partial\Psi^{\mathrm{III}}}{\partial y'}=\frac{\partial\Psi^{\mathrm{II}}}{\partial y'}=\frac{1}{r}\left(\frac{\partial\Psi^{\mathrm{II}}}{\partial\theta}\right)_{\theta=\theta_0} \tag{c), (d)}$$

at $y'=0$; we have

$$\delta_{\kappa\lambda}+B_{\kappa\lambda}=\sum_k(C_{\kappa k}+D_{\kappa k})u_{k\lambda} \tag{6}$$

$$\delta_{\kappa\lambda}p_\kappa-B_{\kappa\lambda}p_\lambda=\sum_k(C_{\kappa k}-D_{\kappa k})\cdot q_k\cdot v_{k\lambda} \tag{7}$$

$$\sum_k[C_{\kappa k}\cdot\exp(im_k\theta_0)+D_{\kappa k}\times\exp(-im_k\theta_0)]u'_{k\kappa'}=F_{\kappa\kappa'} \tag{8}$$

and

$$\sum[C_{\kappa k}\cdot\exp(im_k\theta_0)-D_{\kappa k}\times\exp(-im_k\theta_0)]\cdot q_k\cdot v'_{k\kappa'}=F_{\kappa\kappa'}\cdot p'_{\kappa'} \tag{9}$$

The expansion coefficients $u_{k\lambda}$'s and $v_{k\lambda}$'s are defined by the equations

$$[\phi_k{}^{\mathrm{II}}(r)]_{\theta=0}=\phi_k{}^{\mathrm{II}}(x)=\sum_\lambda u_{k\lambda}\cdot\phi_\lambda{}^{\mathrm{I}}(x) \tag{10}$$

and

$$\left[\frac{r_e}{r}\cdot\phi_k{}^{\mathrm{II}}(r)\right]_{\theta=0}=\frac{r_e}{x}\cdot\phi_k{}^{\mathrm{II}}(x)=\sum_\lambda v_{\kappa\lambda}\cdot\phi_\lambda{}^{\mathrm{I}}(x) \tag{11}$$

Similarly the coefficients $u'_{k\lambda'}$'s and $v'_{k\lambda'}$'s are also defined by the equations

$$[\phi_k{}^{\mathrm{II}}(r)]_{\theta=\theta_0}=\phi_k{}^{\mathrm{II}}(x')=\sum_{\lambda'}u'_{k\kappa'}\cdot\phi_{\lambda'}{}^{\mathrm{III}}(x') \tag{12}$$

and

$$\left[\frac{r_e}{r}\cdot\phi_k{}^{\mathrm{II}}(r)\right]_{\theta=\theta_0}=\frac{r_e}{x'}\cdot\phi_k{}^{\mathrm{II}}(x')$$

$$=\sum_{\lambda'} v'_{k\lambda'} \cdot \phi_{\lambda'}^{III}(x') \quad (13)$$

Eqs. 6—9 are expressed by the use of the matrix form as

$$1+B=(C+D)u \quad (6')$$

$$p-Bp=(C-D)qv \quad (7')$$

$$(CW+DW^*)u'=F \quad (8')$$

and $$(CW-DW^*)qv'=Fp' \quad (9')$$

where W and its complex conjugate W^* are diagonal matrices whose elements are $\exp(im_k\theta_0)$'s and $\exp(-im_k\theta_0)$'s, respectively. Accordingly the coefficient matrix of the reflected waves, B, and that of the transmitted waves, F, are formally derived as follows: We have

$$B=-(NWM'+MW^*N') \times (MWM'+NW^*N')^{-1} \quad (14)$$

and $$F=1/2\cdot[B(MW+NW^*)+(NW+MW^*)]\cdot u' \quad (15)$$

where

$$M=u^{-1}-pv^{-1}q^{-1} \quad (16)$$

$$N=u^{-1}+pv^{-1}q^{-1} \quad (17)$$

$$M'=u'-qv'p'^{-1} \quad (18)$$

and $$N'=u'+qv'p'^{-1} \quad (19)$$

By the use of the expressions of B and F, the reflection and transmission coefficients $\rho_{\kappa\lambda}$ and $\kappa_{\kappa\kappa'}$ are given by

$$\rho_{\kappa\lambda}=|B_{\kappa\lambda}|^2\cdot p_\lambda/p_\kappa \quad (20)$$

and $$\kappa_{\kappa\kappa'}=|F_{\kappa\kappa'}|^2\cdot p_{\kappa'}/p_\kappa \quad (21)$$

Furthermore, the total reflection and transmission coefficients from a definite initial κ-th state, ρ_κ, and κ_κ, are defined as

$$\rho_\kappa=\sum_\lambda \rho_{\kappa\lambda} \text{ and } \kappa_\kappa=\sum_{\kappa'}\kappa_{\kappa\kappa'} \quad (22), (23)$$

κ_κ may be estimated from the value of ρ_κ by the use of the following equation,

$$\kappa_\kappa=1-\rho_\kappa \quad (24)$$

For the simple case with a single boundary $y=0$, taking

$$D_{\kappa k}=0 \text{ and } F_{\kappa\kappa'}=0$$

the equations to be solved become

$$1+B=Cu \text{ and } p-Bp=Cqv. \quad (25), (26)$$

Then the formal solutions of B and C are

$$B=(S-1)\cdot(S+1)^{-1} \quad (27)$$

and $$C=2S(S+1)^{-1}\cdot u^{-1} \quad (28)$$

where the matrix S has the form of

$$S=pv^{-1}q^{-1}u \quad (29)$$

Therefore, the transmission coefficient, $\kappa_{\kappa k}$ is given by

$$\kappa_{\kappa k}=|C_{\kappa k}|^2\cdot q_k/p_\kappa \quad (30)$$

in this case.

It is very difficult to obtain explicitly the rigorous form of the coefficients $B_{\kappa\lambda}$, $F_{\kappa\kappa'}$ and $C_{\kappa k}$ for general cases. We, therefore, confine ourselves to the simple case where the radius of the path, r_e, is much larger than the classical amplitude of vibration, ρ_{max},

$$r_e \ll \rho_{max}$$

The approximate expressions of the coefficients in this case are given in Appendix I.

Vibrational Wave Function and Computation of the Coefficients

Now we treat the case in which the section of the channel is parabolic and the vibrational motion is simple harmonic. When we put, as the explicit form of vibrational potential,

$$V=2\pi^2\mu\nu_0^2x^2 \quad (31)$$

the normalized vibrational eigenfunction with the quantum number κ in region I is

$$\psi_\kappa^{I}(x)=N_\kappa\cdot\exp\left(-\frac{\alpha}{2}\rho^2\right)H_\kappa(\sqrt{\alpha}\cdot\rho) \quad (32)$$

where

$$\rho=x-r_e \quad \text{and} \quad \alpha=4\pi^2\mu\nu_0/h \quad (33)$$

$N_\kappa=[(\alpha/\pi)^{1/2}/2^\kappa\cdot\kappa!]^{1/2}$ is a normalization factor, $H_\kappa(\sqrt{\alpha}\cdot\rho)$ the κ-th Hermite polynomial and ν_0 the fundamental frequency of vibration. The total energy of the system in region I is

$$E=E_{vib}+E_{trans}=h\nu_0(\kappa+1/2)+(1/2\mu)p_\kappa^2 \quad (34)$$

The eigenfunction of κ'-th state in region III is readily obtained by replacing κ and x in the above expressions with κ' and x' respectively.

The radial function $\psi_k^{II}(r)$ in region II is obtained in the same way as the well-known treatment of the vibrational and rotational motions of diatomic molecule[7], since it is related to the circular potential shown in Fig. 2.

Therefore, under the condition $r_e \gg \rho_{max}$, an approximate form of $\psi_k^{II}(r)$ is given by

$$\psi_k^{II}(r)=\frac{n}{r^{1/2}}\cdot N_k\cdot\exp\left(-\frac{\alpha'}{2}\zeta^2\right)\cdot H_k(\sqrt{\alpha'}\cdot\zeta) \quad (35)$$

where

$$n\simeq[r_e(1+\beta)]^{1/2}\Big/\left[1+\frac{(2k+1)}{2\alpha r_e^2(1+\beta)^2}\right]^{1/2} \quad (36)$$

7) L. Pauling and E. B. Wilson, "Introduction to Quantum Mechanics", McGraw-Hill Book Co., Inc., New York (1935), p. 298.

$$\zeta = \rho - \beta r_e \tag{37}$$

$$\beta = \xi^2/(1+3\xi^2) \tag{38}$$

$$\nu' = \nu_0(1+3\xi^2)^{1/2} \tag{39}$$

$$\xi = q_k/2\pi\mu r_e\nu_0 \tag{40}$$

α' is obtained by replacing ν_0 in α, Eq. 33, with ν' and N_k by replacing κ and α in $N\kappa$ with k and α', respectively.

The total energy in this region is described as

$$E \simeq \boldsymbol{h}\nu'(k+1/2) + (1/2\mu)(1-\beta)q_k^2 \tag{41}$$

The matrix elements of u and v are calculated by Eqs. 32 and 35 as shown in Appendix II.

The above consideration is also applicable, in principle, to the potential with Morse function-type section, but the formulation will be quite tedious.

Few potential energy surfaces with considerable accuracy have been constructed except for the ortho-para hydrogen conversion reaction, $H+H_2 \rightarrow H_2+H$[8,9]. Therefore, we performed the computation of the reflection and transmission coefficients for the potential surfaces which have a similar fearture to that of this reaction except that the barrier is neglected.

The constants used in the computation are

$$\boldsymbol{h}\nu_0 = 12.56 \text{ kcal./mol.}$$

$$\mu = (2/3)\cdot m_H = 1.1156\times10^{-24} \text{ g.}$$

$$\theta_0 = 2\pi/3$$

and $r_e = 1.0$ and 0.5 Å

These values of r_e scarcely satisfy the condition $r_e \gg \rho_{max}$, since the classical amplitudes of vibrational motion for the ground and the first excited levels are 0.09 and 0.15Å, respectively. Calculations were performed for the range of the total energy $E < \boldsymbol{h}\nu_0(2+1/2) = 31.4$ kcal./mol. The obtained values of coefficients are shown in Figs. 3 and 4.

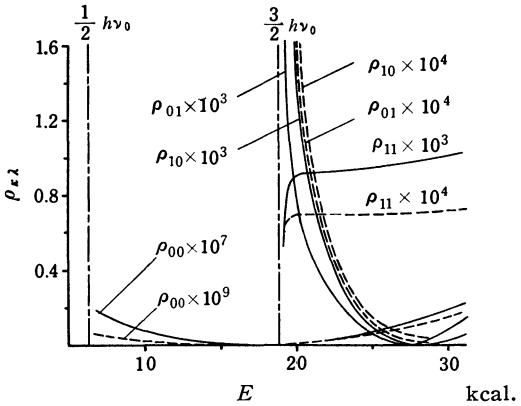

Fig. 3. Reflection coefficients for single boundary.
—— r_e=0.5Å, ---- r_e=1.0Å

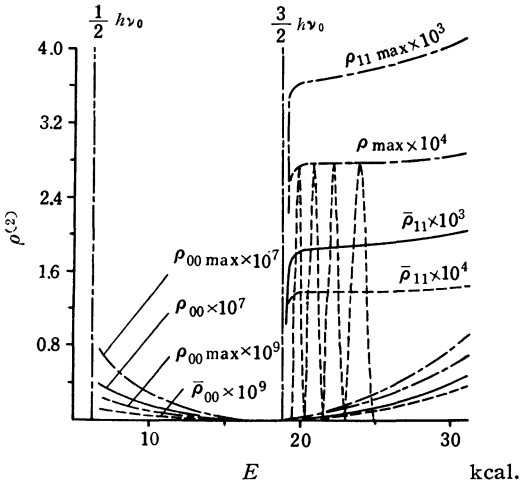

Fig. 4. Reflection coefficients for two boundaries.

Discussion

The present results agree, in many points, with those of Hulburt and Hirschfelder's in which the potential surface of square-well channel with 90° turn is used, but there are some noticeable differences between them.

That the reflection and transmission coefficients $\rho_{\kappa\lambda}$ and $\kappa_{\kappa\lambda}$ are not zero for $\kappa \neq \lambda$, shows the occurrence of the cross transition between the different vibrational states and also verifies their prediction about this occurrence obtained from the consideration of the classical motion of a particle in smoothly curved channel[10].

Apart from their absolute magnitude, the general properties of the coefficients resemble the results of Hulburt et al. for the case with vibrational transition.

In our case of single boundary with which their results include nothing to be compared, $\rho_{\kappa\kappa}$'s vary slightly with the increase of the translational energy, while $\rho_{\kappa\lambda}$'s, which rise where the translational energy is just equal to $\kappa\boldsymbol{h}\nu_0$ $(\kappa > \lambda)$ or $\lambda\boldsymbol{h}\nu_0$ $(\lambda > \kappa)$, fall rapidly and then increase

8) J. O. Hirschfelder, N. Rosen and H. Eyring, *J. Chem. Phys.*, **4**, 121 (1936).
9) J. O. Hirschfelder, H. Eyring and B. Topley, ibid., **4**, 173 (1936).
10) Ref. 5, p. 280.

gradually as the energy increases. In general, $\rho_{\varepsilon\lambda}$'s are much larger than $\rho_{\varepsilon\varepsilon}$'s in the available range of energy. For the case of two boundaries, the reflection coefficients are oscillating function of energy as shown in Fig. 4. This property is readily seen from the expressions of $B_{\varepsilon\lambda}$'s in Appendix I and those of ρ's, Eq. 20: By the introduction of such approximations as $(v_0^{-1}\cdot u_0)p \simeq q$, etc., the resultant forms are

$$\rho_{\varepsilon\varepsilon} \simeq 4\rho^{(1)}{}_{\varepsilon\varepsilon} \sin^2 m_\varepsilon\theta_0 \quad (42)$$

and $$\rho_{\varepsilon\lambda} \simeq 4\rho^{(1)}{}_{\varepsilon\lambda} \sin^2\{(m_\varepsilon + m_\lambda)/2\cdot\theta_0\} \quad (43)$$

where $\rho^{(1)}$'s represent those of single boundary under the same condition. The angle of bending, θ_0, which is related to the masses of component species, m_A, m_B and m_C, by the equation[11]

$$\sin(\theta_0 - \pi/2) = [m_A m_C/(m_A + m_B)(m_B + m_C)]^{1/2}$$

takes value which is between $\pi/2$ and π. A larger value of θ_0 makes the period of oscillation shorter (Fig. 5).

They also found such an oscillating property of coefficient as stated above and regarded it as an essential one for the transmission of waves through a bend. The present author presumes, however, that the property is partly of artificial nature being due to the form of potential models which have two discontinuous boundaries and is partly of real nature relating to the efficiency of energy transfer between the translational and vibrational motions, by the considerations given below.

The reasons why the form of potential model is responsible are as follows:

(a) Whatever the transmission to be estimated is for a bend or a barrier, all the reflection and transmission coefficients obtained change monotonously with energy in the case of smooth potential without any boundary[3,6], or even in those of single boundary[1], while they always oscillate in the cases of two boundaries[1,5].

(b) From the present result with two boundaries as shown in Fig. 4, it is found that the coefficients which are averaged over each period of oscillation[12] are about twice as large as those of a single boundary under the same condition. This property is based, perhaps, on the fact that the coefficients are the functions of amplitude of the standing waves which exist between boundaries and the amplitude of a wave with a definite phase varies periodically with respect to the momentum q and θ_0 at one of the boundaries. Therefore, when we take the average for each period of oscillation, which corresponds to superposition of all waves with any phase, the results seem to give good approximation for the actual behavior[13]. It goes without saying that such a property as stated above can not be expected in a real case, since the potential energy surface of reaction would be continuous everywhere considering the nature of valence force.

In the next place, their result that the oscillating transmission coefficients get zero values when the energy of translation is just equal to several energy units of quantized motion which is perpendicular to the direction of the above motion, is explained as the complete transfer of translational energy to the vibrational one. This property is also seen from the present result that the value of ρ_{01} rises steeply as the translational energy approaches to $h\nu_0$.

It seems that the speciality of the square-well channel with 90° turn used by them comprises incidentally these effects of real and of virtual: The wave functions which express the translational and vibrational motions are of similar form and their eigenvalues in the bending part are identical to each other.

From these considerations, it will be concluded that the total transmission coefficients κ_ε's decrease stepwise with the increase of energy on account of the entry of reflections in which the higher vibrational states are concerned. This tendency also agrees with that which Hulburt et al. pointed out previously.

Subsequently, the effect of the curvature is examined. A larger curvature (smaller radius) brings about the increase of reflection in both the cases with and without the vibrational transition (Figs. 3 and 4). Because of the smallness of net reflection, however, almost all systems pass through the bend, preserving initial vibration quanta. This persistency of vibrational state was also found for the transmission through the barrier which was treated in

11) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes", McGraw-Hill Book Co., Inc., New York (1941), p. 102.

12) Since $\frac{1}{\pi}\int_0^\pi \sin^2 x\,dx = 1/2$, the averaged value of $\rho_{\varepsilon\varepsilon}$ in Eq. 43, $\bar{\rho}_{\varepsilon\varepsilon}$, is expressed by $\bar{\rho}_{\varepsilon\varepsilon} \simeq 2\rho_{\varepsilon\varepsilon}{}^{(1)}$, where $\rho_{\varepsilon\varepsilon}{}^{(1)}$ is assumed to be nearly constant in each period. Other coefficients are also treated analogously.

13) A similar situation is held in the case of Ref. 1, p. 621, in which the transmission through an energy barrier was treated.

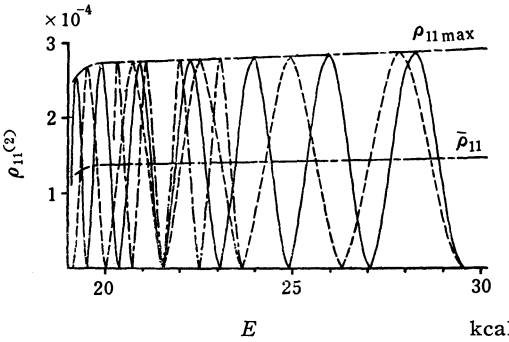

Fig. 5. Variation of $\rho_{11}^{(2)}$ with increase of bending angle θ_0.
r_e=1.0Å,
---- $\theta_0=\pi/2$, —— $\theta_0=2\pi/3$, —·—· $\theta_0=\pi$

Paper I of this series[14]. The case of Hulburt and Hirschfelder's, in which rather large decrease of transmission was estimated, corresponds to that of extremely small radius $r_e=\rho_{\max}$ in our case.

It is expected that the transmission coefficient becomes different for the system including isotopes, since the resultant μ changes its magnitude for the same value of energy. This effect was also pointed out by them and their result of oscillating coefficient with perfect reflection made them expect its availability for the isotopic separation. Since, however, the difference between reflections for isotopic reactions is also very small, the transmission through the bend seems not to be effective for the process.

As a quantum-mechanical correction necessary for the rate-estimation by the usual method, the overall transmission coefficient κ_{bend} is defined by[6]

$$\kappa_{\text{bend}}=\sum_{\varepsilon} e^{-\frac{E_{\text{vib}}}{kT}}\cdot\int_0^{\infty}\kappa_{\varepsilon}\cdot e^{-\frac{p_{\varepsilon}^2}{2\mu kT}}\cdot p_{\varepsilon}\,dp_{\varepsilon}$$
$$\times\left[\sum_{\varepsilon} e^{-\frac{E_{\text{vib}}}{kT}}\cdot\int_0^{\infty} e^{-\frac{p_{\varepsilon}^2}{2\mu kT}}\cdot p_{\varepsilon}\,dp\right]^{-1}$$
$$=1-(\mu kT)^{-1}\cdot(1-e^{-\frac{h\nu_0}{kT}})$$
$$\times\left[\sum_{\varepsilon=0} e^{-\frac{\varepsilon h\nu_0}{kT}}\cdot\int_0^{\infty}\rho_{\varepsilon}e^{-\frac{p_{\varepsilon}^2}{2\mu kT}}\cdot p_{\varepsilon}\,dp_{\varepsilon}\right] \quad (44)$$

Since the individual κ_{ε}'s are nearly equal to unity, the resultant κ_{bend} is also close to unity and gradually decreases as the temperature becomes higher. The values,

14) This effect means that the perturbation at the bend should be very small compared with the total energy of the system. The present condition, $r_e\gg\rho_{\max}$, which is equivalent to that in Ref. 6, p. 2, $a_0\gg aV_r(r)$, satisfies this restriction.

TABLE I. VALUES OF $(1-\kappa_{\text{bend}})$[15]

Temp. °K	300	500	1000	2000
r_e=0.5Å	3.0×10^{-8}	1.3×10^{-6}	3.8×10^{-4}	3.4×10^{-3}
r_e=1.0Å	2.0×10^{-11}	7.3×10^{-7}	2.3×10^{-4}	2.8×10^{-3}

$1-\kappa_{\text{bend}}$, for the hydrogen atom-molecule reaction, for example, are shown in Table I.

Finally, as concerns the reacting system which includes heavier species than hydrogen, it is very difficult to presume the exact behavior of the transmitting waves, because the factors μ, r, ν_0 and θ_0 change markedly for respective cases. In general, increased μ and lowered ν_0 provide an increase of the reflection which is canceled to some extent by an increased r_e. However, the deviation of the total transmission from unity will be very small after all, since the fact that the de Broglie wavelength corresponding to the translational motion becomes shorter than that of hydrogen atom-molecule reaction (1.8Å at 300°K) makes the classical consideration of motion more valid.

The author wishes to thank Professor S. Shida for his kind advice and encouragement. The author is also much indebted to Professor J. Horiuti and Dr. T. Toya of Hokkaido University and Dr. K. Fueki of Osaka University for their valuable discussion and suggestions.

Appendix I. Approximate Formulae of the Coefficients $B_{\varepsilon\lambda}$, $C_{\varepsilon k}$ and $F_{\varepsilon\varepsilon'}$

Under the condition $r_e\gg\rho_{\max}$, it is expected that the vibrational eigenfunction in region II, $\phi_k^{\text{II}}(r)$ becomes close to the function $\phi_{\varepsilon}^{\text{I}}(x)$ with $\varepsilon=k$ in its form at the boundary between regions I and II and that the matrix v is nearly equal to u. Accordingly, when we divide u into the two parts, u_0, the diagonal part of u, and u_1, the offdiagonal part,

$$u=u_0+u_1 \quad (A1)$$

and also
$$v=v_0+v_1 \quad (A2)$$

in a similar manner, it may be assumed that the elements of u_1 (or v_1) are small compared with those of u_0 (or v_0).

(a) The Case of Single Boundary.—We have the matrix S, Eq. 29, of the following approximate form,

$$S=pv_0^{-1}(1-v_1\cdot v_0^{-1})q^{-1}(u_0+u_1) \quad (A3)$$

or neglecting the term including $u_1\cdot v_1$,

15) In the estimation, the values of ρ_{10} and ρ_{01} at $E=3/2\cdot l.\nu_0$ were assumed for convenience to be unity.

$$S=S_0+S_1 \tag{A4}$$

where $S_0=pv_0^{-1}q^{-1}u_0$ (A5)

and $S_1\simeq pv_0^{-1}q^{-1}u_1-pv_0^{-1}v_1v_0^{-1}u_0q^{-1}$ (A6)

Since the matrix B of Eq. 27 is expressed by the use of the above equations, as

$$B=(S_0-1)(S_0+1)^{-1}+2(S_0+1)^{-1}S_1(S_0+1)^{-1} \tag{A7}$$

we can finally get the expressions of the coefficients of reflected waves $B_{\kappa\lambda}$'s and those of transmitted waves $C_{\kappa k}$'s,

$$B_{\kappa\lambda}=\frac{p_\kappa(v_0^{-1}\cdot u_0)_\kappa-q_\kappa}{p_\kappa(v_0^{-1}\cdot u_0)_\kappa+q_\kappa}\delta_{\kappa\lambda}+\frac{2p_\kappa(v_0^{-1})_\kappa[u_{1,\kappa\lambda}q_\lambda-q_\kappa v_{1,\kappa\lambda}(v_0^{-1}\cdot v_0)_\lambda]}{[p_\kappa(v_0^{-1}\cdot u_0)_\kappa+q_\kappa]\cdot[p_\lambda(v_0^{-1}\cdot u_0)_\lambda+q_\lambda]} \tag{A8}$$

and

$$C_{\kappa k}=\frac{2p_\kappa(v_0^{-1}\cdot u_0)_\kappa u^{-1}{}_{\kappa k}}{p_\kappa(v_0^{-1}\cdot u_0)_\kappa+q_\kappa}+\sum_\lambda\frac{2p_\kappa(v_0^{-1})_\kappa[u_{1,\kappa\lambda}q_\lambda-q_\kappa\cdot v_{1,\kappa\lambda}(v_0^{-1}\cdot u_0)_\lambda]u^{-1}{}_{\lambda\kappa}}{[p_\kappa(v_0^{-1}\cdot u_0)_\kappa+q_\kappa]\cdot[p_\lambda(v_0^{-1}\cdot u_0)_\lambda+q_\lambda]} \tag{A9}$$

(b) The Case of Two Boundaries.—By the introduction of the same approximations for u' and v' as those for u and v, the coefficients $B_{\kappa\lambda}$'s are expressed as follows:

$$B_{\kappa\kappa}=L_\kappa[(v_0^{-1}\cdot u_0)_\kappa p_\kappa{}^2-(u_0^{-1}\cdot v_0)_\kappa q_\kappa{}^2]\cdot(Q_\kappa)^{-1} \tag{A10}$$

and

$$\begin{aligned}B_{\kappa\lambda}=&2p_\kappa(Q_\kappa\cdot Q_\lambda)^{-1}\\&\times[(4-G_\kappa\cdot G_\lambda)q_\lambda q_\kappa\{(v_0^{-1})_\kappa v_{1,\kappa\lambda}p_\kappa\\&-(u_0^{-1})_\kappa u_{1,\kappa\lambda}p_\lambda\}\\&-L_\kappa L_\lambda\{(u_0^{-1})_\kappa v_{1,\kappa\lambda}(v_0^{-1}\cdot u_0)_\lambda p_\lambda q_\kappa{}^2\\&-(v_0^{-1})_\kappa\cdot u_{1,\kappa\lambda}(u_0^{-1}\cdot v_0)_\lambda\cdot p_\kappa\cdot q_\lambda{}^2\}\\&+G_\kappa L_\lambda q_\kappa\{(v_0^{-1})_\kappa\cdot v_{1,\kappa\lambda}(v_0^{-1}\cdot u_0)_\lambda p_\kappa p_\lambda\\&-(u_0^{-1})_\kappa\cdot u_{1,\kappa\lambda}(u_0^{-1}\cdot v_0)_\lambda q_\lambda{}^2\}\\&+G_\lambda L_\kappa\{(u_0^{-1})_\kappa\cdot v_{1,\kappa\lambda}q_\kappa{}^2\\&-(v_0^{-1})_\kappa\cdot u_{1,\kappa\lambda}p_\kappa p_\lambda\}]\end{aligned} \tag{A11}$$

where

$$\begin{aligned}Q_\kappa=&L_\kappa\{(v_0^{-1}\cdot u_0)_\kappa\cdot p_\kappa{}^2+(u_0^{-1}\cdot v_0)_\kappa\cdot q_\kappa{}^2\}\\&-2G_\kappa p_\kappa\cdot q_\kappa\end{aligned} \tag{A12}$$

$$G_\kappa=(W+W^*)_\kappa=2\cos m_\kappa\theta_0 \tag{A13}$$

and $$L_\kappa=(W-W^*)_\kappa=2i\sin m_\kappa\theta_0 \tag{A14}$$

The $F_{\kappa\kappa'}$'s is obtained by substituting the above expressions of $B_{\kappa\lambda}$'s into Eq. 15.

Appendix II. Calculations of $u_{k\lambda}$ and $v_{k\lambda}$

The matrix element $u_{k\lambda}$ is defined by

$$\psi_k{}^{\mathrm{II}}(x)\sum_\lambda u_{k\lambda}\cdot\psi_\lambda{}^{\mathrm{I}}(x) \tag{A15}$$

Making use of the property of ψ^{I}, we obtain

$$u_{k\lambda}=\int_{-\infty}^{+\infty}\psi_\lambda{}^{\mathrm{I}*}\cdot\psi_k{}^{\mathrm{II}}\mathrm{d}\rho \tag{A16}$$

where the lower limit of integration with respect to ρ can be practically extended to minus infinity instead of $\rho=-r_e$ because of the rapid diminution of $\psi_\lambda{}^{\mathrm{I}}$ and $\psi_k{}^{\mathrm{II}}$ where ρ is smaller than $-\rho_{\max}$.

From the condition $r_e\gg\rho_{\max}$, $\psi_k{}^{\mathrm{II}}(x)$, Eq. 35, is described approximately by

$$\psi_\kappa{}^{\mathrm{II}}(x)\simeq\frac{n}{r_e{}^{1/2}}\cdot\left(1-\frac{\rho}{2r_e}+\frac{3\rho^2}{8r_e{}^2}\right)\cdot N_k\times\exp\left(-\frac{\alpha'}{2}\zeta^2\right)\cdot H_k(\sqrt{\alpha'}\zeta) \tag{A17}$$

Accordingly, $u_{k\lambda}$ which is given by Eq. A16 consists of the sum of the general term,

$$\text{const.}\times\int_{-\infty}^{+\infty}\rho^n\cdot N_kN_\lambda\cdot\exp\left(-\frac{\alpha'}{2}\zeta^2-\frac{\alpha}{2}\rho^2\right)\times H_k(\sqrt{\alpha'}\cdot\zeta)\cdot H_\lambda(\sqrt{\alpha}\cdot\rho)\,\mathrm{d}\rho$$

which is resolved, furthermore, into the sum of the following integrals with some coefficients[16],

$$I_{\kappa\lambda}=N_kN_\lambda\cdot\int_{-\infty}^{+\infty}\exp\left(-\frac{\alpha'}{2}\zeta^2-\frac{\alpha}{2}\rho^2\right)\times H_k(\sqrt{\alpha'}\cdot\zeta)\cdot H_\lambda(\sqrt{\alpha}\cdot\rho)\cdot\mathrm{d}\rho \tag{A18}$$

Since

$$\alpha'\zeta^2+\alpha\rho^2=(\alpha+\alpha')\left[\rho-\left(\frac{\alpha'}{\alpha+\alpha'}\right)\beta r_e\right]^2=at^2 \tag{A19}$$

where a and t are defined by

$$a=\alpha+\alpha' \quad\text{and}\quad t=\rho-\left(\frac{\alpha'}{\alpha+\alpha'}\right)\beta r_e \tag{A20), (A21}$$

Eq. A18 is also written as

$$I_{k\lambda}=N_kN_\lambda\cdot\exp\left[-\frac{1}{2}\left(\frac{\alpha\alpha'}{\alpha+\alpha'}\right)(\beta r_e)^2\right]\times\int_{-\infty}^{+\infty}\exp\left(-\frac{a}{2}t^2\right)H_kH_\lambda\mathrm{d}\rho \tag{A22}$$

Transforming the variables, $\sqrt{\alpha}\cdot\rho$ in H_λ and $\sqrt{\alpha'}\cdot\zeta$ in H_k, into a new variable,

$$s=\sqrt{a}\cdot t \tag{A23}$$

we can write

$$H_\lambda(\sqrt{\alpha}\cdot\rho)=\sum_l g_{\lambda l}H_l(\sqrt{a}\cdot t) \tag{A24}$$

and $$H_k(\sqrt{\alpha'}\cdot\zeta)=\sum_l h_{kl}H_l(\sqrt{a}\cdot t) \tag{A25}$$

where $g_{\lambda l}$ and h_{kl} are coefficients of expansion.

Substituting Eqs. A24 and A25 into Eq. A22, we can get the final expression of $I_{k\lambda}$,

$$I_{k\lambda}=N_kN_\lambda\cdot\exp\left[-\frac{1}{2}\left(\frac{\alpha\alpha'}{\alpha+\alpha'}\right)(\beta r_e)^2\right]\times\sum_l g_{\lambda l}\cdot h_{kl}(N_l)^{-2} \tag{A26}$$

where N_l is obtained by replacing α and λ in N_λ with a and l respectively. In a similar way, the matrix element $v_{k\lambda}$

$$v_{k\lambda}=\int_{-\infty}^{+\infty}\left(\frac{r_e}{r_e+\rho}\right)\cdot\psi_\lambda{}^{\mathrm{I}*}\cdot\psi_k{}^{\mathrm{II}}\mathrm{d}\rho \tag{A27}$$

is computed, since the function $r_e/(r_e+\rho)\cdot\psi_k{}^{\mathrm{II}}(x)$ has the following approximate form,

16) See, for example, H. Eyring, J. Walter and G. E. Kimball, "Quantum Chemistry", John Wiley & Sons, Inc., New York (1949), p. 60.

$$\left(\frac{r_e}{r_e+\rho}\right)\cdot\psi_k^{\mathrm{II}}(x)\simeq\frac{n}{r_e^{1/2}}\cdot\left(1-\frac{3\rho}{2r_e}+\frac{15\rho^2}{8r_e^2}\right)\cdot N_k \times\exp\left(-\frac{\alpha'}{2}\zeta^2\right)\cdot H_k(\sqrt{\alpha'}\cdot\zeta) \tag{A28}$$

and can also be resolved into the sum of $I_{k\lambda}$ with reasonable coefficient as well as in the case of $u_{k\lambda}$.

The obtained expressions of $u_{k\lambda}$ and $v_{k\lambda}$ for $k,\lambda=0,1$ are shown as follows:

$$u_{00}=A_{00}\cdot\left[\left(1-\frac{1}{2}\varepsilon+\frac{3}{8}\varepsilon^2\right)+\frac{3}{8}\eta\right] \tag{A29}$$

$$u_{10}=2A_{10}\sqrt{\alpha'}r_e\cdot\left[\left(1-\frac{1}{2}\varepsilon+\frac{3}{8}\varepsilon^2\right)(\varepsilon-\beta)+\frac{1}{8}\{9\varepsilon-(4+3\beta)\eta\}\right]$$

$$u_{01}=2A_{01}\sqrt{\bar{\alpha}}\cdot r_e\cdot\left[\left(1-\frac{1}{2}\varepsilon+\frac{3}{8}\varepsilon^2\right)\varepsilon+\frac{1}{8}(9\varepsilon-4)\eta\right]$$

$$u_{11}=4A_{11}\sqrt{\alpha\alpha'}\cdot r_e^2\cdot\left[\left(1-\frac{1}{2}\varepsilon+\frac{3}{8}\varepsilon^2\right)(\varepsilon-\beta)\varepsilon+\frac{3}{8}\eta^2+\left\{\left(1-\frac{1}{2}\varepsilon+\frac{3}{8}\varepsilon^2\right)+\left(\frac{3}{4}\varepsilon-\frac{1}{2}\right)(2\varepsilon-\beta)+\frac{3}{8}(\varepsilon-\beta)\varepsilon\right\}\eta\right]$$

and

$$v_{00}=A_{00}\cdot\left[\left(1-\frac{3}{2}\varepsilon+\frac{15}{8}\varepsilon^2\right)+\frac{15}{8}\eta\right] \tag{A30}$$

$$v_{10}=2A_{10}\sqrt{\alpha'}r_e\cdot\left[\left(1-\frac{3}{2}\varepsilon+\frac{15}{8}\varepsilon^2\right)(\varepsilon-\beta)+\frac{1}{8}\{45\varepsilon-(12+15\beta)\}\eta\right]$$

$$v_{01}=2A_{01}\sqrt{\alpha}\cdot r_e\cdot\left[\left(1-\frac{3}{2}\varepsilon+\frac{15}{8}\varepsilon^2\right)\varepsilon+\frac{1}{8}(45\varepsilon-12)\eta\right]$$

$$v_{11}=4A_{11}\sqrt{\alpha\alpha'}\cdot r_e^2\cdot\left[\left(1-\frac{3}{2}\varepsilon+\frac{15}{8}\varepsilon^2\right)(\varepsilon-\beta)\varepsilon+\frac{15}{8}\eta^2+\left\{\left(1-\frac{3}{2}\varepsilon+\frac{15}{8}\varepsilon^2\right)+\left(\frac{15}{4}\varepsilon-\frac{3}{2}\right)(2\varepsilon-\beta)+\frac{15}{8}(\varepsilon-\beta)\varepsilon\right\}\eta\right]$$

where,

$$A_{k\lambda}=(n_k/r_e^{1/2})\,(N_kN_\lambda/\bar{N}_0^2)\times\exp\left[-\frac{1}{2}\left(\frac{\alpha\alpha'}{\alpha+\alpha'}\right)\cdot(\beta r_e)^2\right] \tag{A31}$$

$$\bar{\alpha}=(\alpha+\alpha')/2 \tag{A32}$$

$$\varepsilon=\{\alpha/(\alpha+\alpha')\}\beta \tag{A33}$$

$$\eta=(2\bar{\alpha}r_e^2)^{-1} \tag{A34}$$

and $\bar{N}_0$ is obtained from the normalization factor N_κ of vibrational eigenfunction by replacing α and κ with $\bar{\alpha}$ and zero.

The expressions of $u'_{k\lambda'}$ and $v'_{k\lambda'}$ are identical with the above, because the form of the potential channel is symmetrical at the two boundaries.

Hydrazinolysis of Nucleic Acids. I. The Formation of Deoxyribopyrimidinic Acid from Herring Sperm Deoxyribonucleic Acid

By Shosuke TAKEMURA

(Received March 23, 1959)

In spite of our recognition of the biological importance of nucleic acid, there are many points on the structure of nucleic acid still left ambiguous, i. e., the nucleotide sequence, the localization in the molecule of certain nucleotides, the structural differences between nucleic acids of different origin, and so on. Some fruitful information on the general structural features of deoxyribonucleic acid has been obtained by Chargaff et al. from chemical degradative studies of a derivative, named apurinic acid, in which deoxyribonucleic acid has been deprived of the purine constituents[1-4]. Many other chemical degradations of deoxyribonucleic acid by which the nucleotide sequence can be studied have been attempted[5-13]. These

studies have more or less utilized the particular instability of the purine deoxyribosidic linkages to even a mild acid hydrolysis. Therefore, the information about the nucleotide sequences has been exclusively limited to the pyrimidines in deoxyribonucleic acid. No information was available about the distribution of purines in deoxyribonucleic acid, or of either purines or pyrimidines in ribonucleic acid.

Attention was paid to the reaction of aqueous hydrazine with uracil[14], pyrimidine ribonucleosides[15,16] and ribomononucleotides[16]. Of the latter, uracil and cytosine residues were decomposed to pyrazolone and 3-aminopyrazole, respectively, and simultaneously, ribose 2- and 3-phosphate were obtained from the nucleotide isomers, a and b, respectively. This reaction of hydrazine was successfully applied to both ribo- and deoxyribonucleic acid from which for the first time nondialyzable derivatives almost free from the pyrimidines were obtained and the name ribo- and deoxyribo-apyrimidinic acid were proposed for the products[17,18]. These compounds, especially deoxyribo-apyrimidinic acid, may be useful for structural studies as well as apurinic acid[2,4] and aldehydoapurinic acid di(carboxymethyl)-dithioacetal[7,9].

Anhydrous hydrazine was used for this work, in order to avoid alkaline hydrolysis of the internucleotide linkage which might be caused by the basicity of hydrazine itself even if only a trace of water remained. Since powdered deoxyribonucleic acid of herring sperm took more than 30 min. for its complete dissolution in five parts of anhydrous hydrazine at 60°C, lyophilized preparations were used to prevent a heterogeneous reaction. Experiments using various reaction conditions were carried out and are summarized in Table I. In the course of dissolution in distilled water of the alcohol precipitates after the hydrazinolysis, the viscosity of the solution rapidly decreased. Hydrazine was expected to remain in the precipitates and to cause alkaline hydrolysis. Therefore, in the preparation of DAPYA V, V′ and V″, the alcohol precipitates were dissolved in 0.2 M phosphate buffer of pH 6 and dialyzed. The products thus obtained proved to have longer mean chain lengths and fewer periodate consumptions than others (Table V).

The hydrazinolysis of the deoxyribonucleic acid afforded products the nitrogen content and the N/P ratio of which were lower than those of the parent materials (Table II). Increased removal of the pyrimidines resulted in higher phosphorus contents (Table II). The color intensities by the reaction with diphenylamine were, on the basis of phosphorus content, much more than those given by the parent nucleic acids, although the color intensities were not always parallel to the degree of detachment of the pyrimidines. The estimation of reducing sugar proved that the products had a considerable amount of reducing power, whereas the nucleic acids had only a little. These results, together with the positive qualitative tests for reducing sugar, show that the bulk of the sugar moieties, which in the intact nucleic acid were pyrimidine nucleotides, are in nonglycosidic forms. During the hydrazinolysis and the subsequent treatment, there may be possibilities of side reactions, e. g., formation of hydrazonium salt, hydrazone and sugar alcohol. However, it can be seen from the ratio of N/P that these side reactions occur only slightly if at all.

As shown in Table III the greater part of the pyrimidines was removed from herring sperm deoxyribonucleic acids without impairment of the original interpurine ratios, but small amounts of thymine remained, even in the product obtained through the reaction by which the removal of the pyrimidines was most effective. As for pyrimidine ribomononucleotides, uracil was far more rapidly decomposed by aqueous hydrazine than was cytosine, which was studied by Baron and Brown[16]. Hence it is concluded that thymine is the most resistant to the hydrazinolysis among the main pyrimidine constituents in nucleic acids. The reaction of hydrazine, in the presence of water, gave directly ribose 3-phosphoric acid from pyrimidine ribonucleotides. In the absence of water, however, ureido-deoxyriboside phosphate residues may be formed from the pyrimidine nucleotide residues in the

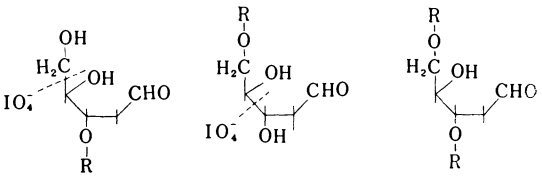
deoxyribonucleic acid. The subsequent treatment of the intermediate product may hydrolyze the glycosidic linkage between deoxyribose and urea which seems to be unstable in the presence of water. The deoxyribose phosphate residues thus formed may be present in an equilibrium between the furanose (III) and the free aldehydo-form (II) in the aqueous solution of the deoxyribo-apyrimidinic acid, but are certainly present to a considerable extent in the free aldehydo-form[19-21].

(I) (II) (III)



To remove both the purines and the pyrimidines, the apurinic acid from herring sperm deoxyribonucleic acid was treated with anhydrous hydrazine and the deoxyribo-apyrimidinic acid was treated with dilute acid. These products contained bases to the extent of about 10 to 15 mol. % of total phosphorus. The combination of the mild acid hydrolysis with the hydrazinolysis, however, caused greater degradation of the internucleotide linkages than did the hydrazinolysis alone. Moreover, the color intensities with diphenylamine and the estimations of reducing sugar of the products seem to show that a part of the deoxyribose moieties undergo some unknown decompositions.

The mean chain length of apurinic acid (Table V) corresponds to a mean molecular weight of about 5,000. This value is much lower than that obtained by Tamm et al. (15,000; light scattering method)[4] and that by Miura et al. (17,000; surface membrane method)[22]. This discrepancy may be partly due to the quality of the parent deoxyribonucleic acid and also to the presence of many terminal phosphate groups caused by the inclusion in the apurinic acid of a small amount of oligonucleotides. Consequently, it can be assumed that the deoxyriboapyrimidinic acids contain many fragments of much longer chain length than the mean, although fission of the phsophodiester linkages during the hydrazinolysis and the subsequent treatment may have been considerable. Periodate should be consumed only by the nonglycosidic deoxyribose residues which occupy the chain end of nucleotide and do not bear terminal phosphate groups IV and V. If both ends are occupied by nucleotides or bear the terminal phosphate group VI, periodate can not be consumed. Therefore, it is impossible to predict the amount of the periodate consumption of the hydrazinolysis products from their mean chain lengths. The ultraviolet absorption coefficient of the purines are, on the molar basis, greater than that of the pyrimidines. Hence, in addition to the hyperchromic effects of degradation, the removal of the

pyrimidines results necessarily in the higher absorption coefficient with respect to nucleotide phosphorus (E_{np}) than that of the apurinic acid and the deoxyribonucleic acid (Table IV).

Some fission of the internucleotide linkages occurred during the hydrazinolysis and the subsequent treatment, and small amounts of intact thymine were left in the preparations. However, there will be possibilities to improve the preparative method. Since about 80% of the material was nondialyzable and the interpurine ratios were not distorted during the reaction, the deoxyribo-apyrimidinic acid must be useful for the structural studies of deoxyribonucleic acid. The apyrimidinic acids were used for the study of the specificity of pancreatic deoxyribonuclease which are reported in the subsequent paper.

Experimental

Nitrogen was determined by micro-Kjeldahl method and phosphorus by Allen's method[23]. The color reaction of the hydrazinolysis products with diphenylamine[24] was carried out and compared with each parent deoxyribonucleic acid as the standard. The nonglycosidic deoxysugars which were initially bound to the pyrimidines also participate in the color reaction. Reducing deoxysugar was determined by means of Fujita-Iwatake's method[25]. These results are summarized in Table II. The base composition was determined chromatographically after hydrolyzing samples in a scaled tube with 70% perchloric acid at 100°C for 1 hr.[26] (propan-2-ol—hydrochloric acid[27], Toyo Roshi Co. 51a paper, descending). Each value listed in Table III represents the average of at least three individual determinations. The absorption spectra were determined in 0.1 M phosphate buffer of pH 7.0 (Fig. 1 and Table IV). The mean chain length was determined by the ratio of the total phosphorus to the terminal phosphate which was liberated as inorganic phosphorus by prostatic phosphomonoesterase[28] (Table V). The periodate consumption was carried out at pH 4 with sodium metaperiodate, in the dark at 10°C or below, for 60 min.; excess periodate was reduced with sodium arsenite at pH 8 and the excess arsenite was back titrated with standard iodine solution[29] (Table V).

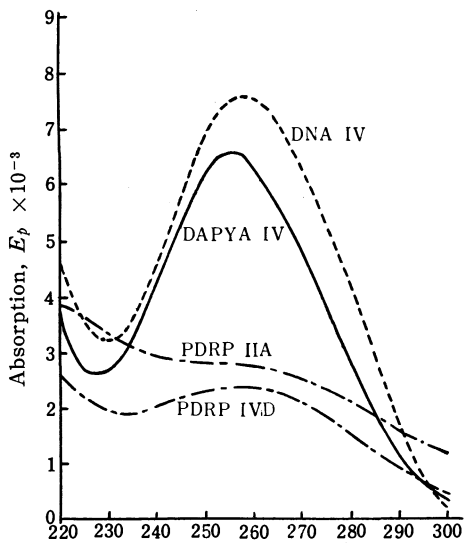

Fig. 1. Ultraviolet absorption curves of the hydrazinolysis products of herring sperm deoxyribonucleic acid in phosphate buffer, pH 7.
E_p=extinction per g.-atom of phosphorus.

Dehydration of Hydrazine.—Eighty per cent hydrazine hydrate was dehydrated with sodium hydroxide pellets at 113°C for 2 hr. and distilled[30]. For more strict dehydration, the distillate was again refluxed with sodium hydroxide pellets at 180°C for 3 hr. and distilled[31].

Deoxyribonucleic Acids.—Five preparations of the sodium deoxyribonucleate of herring sperm, DNA I to V, were used. DNA III was a highly polymerized specimen (MW. ca. 6×10^6)[32]. Before treatment with anhydrous hydrazine, the nucleic acids were dried over concentrated sulfuric acid in vacuo at 60°C for 5 hr. or at 100°C for 3 hr. The compositions of the specimens are summarized in Tables II and III.

Designation of the Reaction Products.—The hydrazinolysis gave products in which the nucleic acid was more or less deprived of the pyrimidines. In order to avoid confusion and to simplify descriprions, the name deoxyribo-apyrimidinic acid (DAPYA) is given to all the hydrazinolysis products and the name polydeoxyribose phosphate (PDRP) to the products obtained either by the hydrazinolysis of the apurinic acid (APA) or by the mild acid hydrolysis, as used for the preparation of apurinic acid, of the hydrazinolysis product. The preparation numbers of the reaction products are the same as those given to the parent deoxyribonucleic acids, i. e., DAPYA II and APA II were obtained from DNA II, PDRP IIA from APA II, and PDRP IID from DAPYA II.

Preparation of the Deoxyribo-apyrimidinic Acids.—The mixture of lyophilized herring sperm deoxyribonucleic acid and anhydrous hydrazine was kept free from moisture under the conditions described in Table I. Within a few minutes, the nucleic acid dissolved in the hydrazine, excepting deoxyribonucleic acid III which took about 10 min. for its complete dissolution. After cooling, absolute alcohol (5 vol.) was added to the highly viscous solution, the fibrous precipitate was made into a powder by scratching, centrifuged, washed with absolute alcohol, with ether, and dried. The dry solid was dissolved with cooling in cold distilled water and the solution dialyzed against running tap water for 20 hr., against frequent changes of distilled water at 4°C for 40 hr. and the inside fluid was freeze-dried. Light yelllow colored products were obtained. The composition of the products thus obtained is listed in Tables II and III.

When the alcohol precipitate was dissolved in 0.2 M phosphate buffer of pH 6 instead of distilled water, the solution was dialyzed against the same buffer at 4°C for 16 hr. against running tap water and finally against distilled water. Faint yellow products were obtained and are described as DAPYA V, V′ and V″ in the tables.

Preparation of Poly-deoxyribose Phosphate.—Apurinic acid was prepared from herring sperm deoxyribonucleic acid in the same way as it was prepared by Tamm et al.[1] Apurinic acid II was dried at 60°C for 5 hr. and then treated with anhydrous hydrazine as above. Deoxyribo-apyrimidinic acids I, II and IV were also treated by the same mild acid hydrolysis as used for the preparation of apurinic acid. The nondialyzable products of yellowish brown color were obtained from each treatment and were incompletely soluble in water, although these gave clear solutions before freeze-drying. The composition of these products is given in Tables II and III.

Qualitative Tests for Nonglycosidic Deoxysugar.—In contrast to the deoxyribonucleic acid, the hydrazinolysis products and the apurinic acid reacted with ammoniacal silver solution yielding brown precipitates, reduced Fehling's solution on warming, reacted with benzidine giving a brown color, reduced mercuric chloride solution yielding a white precipitate, and gave pink color with reduced fuchsin solution, but the reaction of the hydrazinolysis products was much slower than that of the apurinic acid. The hydrazinolysis products spotted on filter paper gave a reddish purple color with the aniline hydrogen phthalate reagent used for the development of chromatogram of reducing sugars[33].

The author thanks Professor F. Egami for his close interest and Professor I. Watanabe, the University of Tokyo, for a supply of herring sperm deoxyribonucleic acids. The expense of this study was defrayed in part by a grant from the Ministry of Education.

Hydrazinolysis of Nucleic Acids. II. The Formation of Ribo-apyrimidinic Acid from Yeast Ribonucleic Acid

By Shosuke TAKEMURA and Masazumi MIYAZAKI

(Received March 23, 1959)

In the preceding paper[1], one of the authors has dealt with the formation of a new derivative devoid of pyrimidines, named deoxyribo-apyrimidinic acid, by the hydrazinolysis of herring sperm deoxyribonucleic acid, by the hydrozinolysis of herring sperm deoxyribonucleic acid. In connection with studies on the specificity of pancreatic ribonuclease in which this laboratory is engaged[2-6], it was desired to prepare ribonucleic acid derivatives devoid of the pyrimidines. The hydrazinolysis was first investigated using yeast ribonucleic acid and gave, for the first time, a nondialyzable derivative free from the pyrimidines, for which the name ribo-apyrimidinic acid was proposed[7]. the problem of the specificity of ribonucleases which are reported in subsequent papers, some information about the general structure of ribonucleic acid may be derived from degradative studies of the derivative.

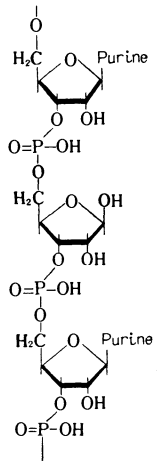
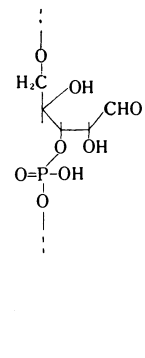
When yeast ribonucleic acid was treated with 80% aqueous hydrazine, a complete hydrolysis of the phosphodiester linkages resulted and only 2′- and 3′-isomers of purine mononucleotides were detected on the paper chromatogram, as the ultraviolet absorbing materials. In the case where anhydrous hydrazine was used, drastic condtions such as reaction at 90°C did not, however, offer any advantages, but indeed resulted in a serious destruction of the phosphodiester linkages and formation of considerable amounts of purine mononucleotide isomers. Experiments using various conditions of time and temperature were carried out and are summarized in Table I. The use of nucleic acid which was not purified and especially not lyophilized resulted in the incomplete removal of the pyrimidines. After treatment with hydrazine and precipitation with alcohol, there were difficulties in obtaining the derivatives without an accompanying serious destruction of the internucleotide linkages. In most cases, the alcohol precipitates were dissolved at 0°C in distilled water and the products precipitated with dilute hydrochloric acid. This procedure was effective for removign hydrazine, which was expected to be included as hydrazonium salt in the alcohol precipitates. However, it was thought that there might be possibilities of the formation of hydrazones or osazones using such acidic conditions. An experiment showed that the use of concentrated phosphate buffer of neutral range converted hydrazonium salts to sodium salts and minimized fissions of the phosphodiester linkages (see Table IV).

The reaction of the lyophilized ribonucleic acid of yeast with anhydrous hydrazine at 50°C for 60 min. was found to be most suitable for the preparation of ribo-apyrimidinic acid. Using these conditions, the product was practically free from pyrimidines and fissions of the phosphodiester linkages were not serious. As attempts to remove the pyrimidines with milder reagents than anhydrous hydrazine, anhydrous methylhydrazine and phenylhydrazine were used. The latter did not react but the former removed considerable amounts of uracil and a little cytosine when the reaction was carried out at 60°C for 90 min. The white product was obtained through acid precipitation and the yield was quantitative. The use of



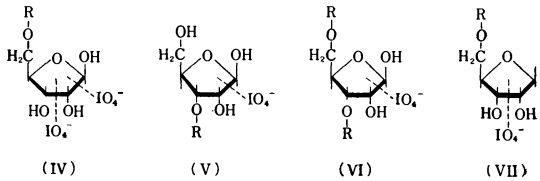
anhydrous methylhydrazine in a more drastic condition is, therefore, of great promise.

The hydrazinolysis products gave slightly higher values for the atomic N/P ratios than those expected from the base composition of the products. The products, excepting that obtained through the dissolution in the buffer, were slightly yellow. A small part of ribose residues may be present as hydrazone or osazone and also as ureido-ribose formed from the pyrimidine riboside moieties by the hydrazinolysis. From the color intensities in the reaction with orcinol and the estimation of reducing sugar, however, it can be seen that these possibilities occure only slightly, if at all. Direct evidence for the presence of free ribose residues in the hydrazinolysis products was obtained by treating one of the products with Takadiastase, which hydrolyses nucleic acids to nucleosides. Much ribose was liberated, as shown by paper chromatography. Qualitative tests for reducing sugar were also strongly positive.



During the hydrazinolysis and the subsequent treatment, the initial interpurine ratios were not distorted. This was most clearly confirmed by analyzing the dialyzable fragments. The base compositions of the dialyzable fragments were the same as those of the corresponding nondialyzable products. The removal of the pyrimidines from yeast ribonucleic acid was easier than that from herring sperm deoxyribonucleic acid. In the initial stage of the reaction, uracil was decomposed faster than was cytosine, but this was reversed later. Yeast ribonucleic acid is presumed to be hydrazinolyzed in a similar way to that shown in the preceding paper on the hydrazinolysis of herring sperm deoxyribonucleic acid[1]. Thus the ribose phosphate residues in the aqueous solution of the ribo-apyrimidinic acid may be present in the furanose form (II) rather than in the free aldehydoform (III)[8].

(I)



(II)

(III)

In alkaline solutions, the hydrazinolysis products were as unstable as ribonucleic acid. The product which is free from the pyrimidines was unstable, even in solutions of neutral pH or below at 37°C for one day, about 10% of its total phosphorus was rendered soluble in acid—uranyl reagent, but this was greatly reduced at 0°C. In spite of this instability, the product obtained using the most suitable conditions showed a fairly high mean chain length. Periodate should be consumed not only by the nonglycosidic ribose residues within VI or at the end of the chains (IV, V), but also by the purine nucleosides which occupy the chain ends and do not bear a terminal 3′-phosphate group (VII). The periodate consumption

(IV) (V) (VI) (VII)

R=nucleotides or phosphate

of a product obtained through the dissolution in the phosphate buffer was less than that obtained through the acid precipitation. The electrometric titration curve of the product obtained by the reaction at 65°C for 90 min. showed the disappearance of one -NH-CO- dissociation titrating in the range pH 8~12. This can be explained by the removal of uracil. The absence of the amino group of cytosine was, however, not clearly indicated, being obscured by the increased secondary phosphoric acid dissociations which are due to fissions of the phosphodiester linkages.

In the most suitable condition of the hydrazinolysis, about 90% of the material was nondialyzable. Moreover, the interpurine ratio was not distorted during the reaction. Hence, the ribo-apyrimidinic acid must be useful for the structural studies of ribonucleic acid.

Experimental

Nitrogen, phosphorus, reducing sugar (Table II), the ultraviolet absorption spectra (Table III and Fig. 1), the mean chain length and the periodate consumption (Table IV) were determined by methods described in the preceding paper[1]. The nucleotide composition (Table I) was determined chromatographically after hydrolyzing samples in a sealed tube with 1 N hydrochloric acid[9] at 100°C for 1 hr. (propan-2-ol—

hydrochloric acid[10], Toyo Roshi Co. No. 51a paper, descending). The color reaction of the hydrazinolysis products with orcinol[11] was compared with the parent ribonucleic acid (Table II). The ribose residues, which in the intact ribonucleic acid were in the pyrimidine nucleotides, also participate in the color reaction. For the electrometric titration of a product (RAPYA IX) a Beckman Type G pH-meter was employed. The measurement was carried out in the absence of carbon dioxide (Fig. 2).

Dehydration of Hydrazines. — Anhydrous hydrazine was prepared as described in the corresponding section of the preceding paper[1]. Fifty per cent aqueous methylhydrazine was dehydrated with sodium hydroxide pellets at 90°C for 12 hr., stood overnight at room temperature and distilled (b. p. 86.6~87.3°C)[12]. Phenylhydrazine was distilled under diminished pressure before use.

Ribonucleic Acid.—A commercial yeast ribonucleic acid, Schwarz Laboratories, Inc., was purified by Sevag's method[13] and freeze-dried. Before treatment with hydrazine, the nucleic acid was dried over concentrated sulfuric acid in vacuo at 60°C for 5 hr. The composition of the nucleic acid is listed in Tables I and II.

Preparation of Ribo-apyrimidinic Acid.— The hydrazinolyses at different conditions gave products in which the ribonucleic acid was more or less deprived of the pyrimidines (Table I). In order to simplify descriptions, the name ribo-apyrimidinic acid (RAPYA) is given to all nondialyzable products obtained by the reaction of the ribonucleic acid with anhydrous hydrazine. A typical preparation was as follows. The mixture of lyophilized and dried yeast ribonucleic acid (1.5 g.) and anhydrous hydrazine (3 ml.) was kept free from moisture at 50°C for 1 hr. Within a few minutes, the nucleic acid dissolved in the hydrazine, making a clear solution, with a slight evolution of heat and foam. After cooling, absolute alcohol (5 vol.) was added to the solution, the white precipitate thus formed washed with absolute alcohol and ether, and dried. The dry solid was then dissolved in cold distilled water at 0°C and the pH adjusted to 1.5 with dilute hydrochloric acid. The slightly yellow precipitate thus formed was washed with absolute alcohol and ether, dried, and then suspended in water and dilute alkali was added carefully until the solid just dissolved. The solution was dialyzed against frequent changes of distilled water at 4°C for 3 days. The nondialyzable fraction was freeze-dried. The light yellow product (RAPYA IV) was obtained in 88% yield with respect to phosphorus recovery. Other reaction products using different conditions were obtained by the same procedure, excepting RAPYA IV' and IV''. For the latter the procedure was modified as mentioned below since yellow materials were obtained at the step where the products were precipitated with acid. This was possibly due to reaction between hydrazine and free ribose residues. After treatment with hydrazine and precipitation with alcohol, the precipitate was dissolved in distilled water at 0°C and the pH was adjusted to 7. This solution was then dialyzed against frequent changes of distilled water and freeze-dried. The white product so obtained still contained hydrazine (RAPYA IV'). This was removed by dissolving the material in ice-cold 0.2 M sodium phosphate buffer (pH 6.2) and dialyzing it against the same buffer at 4°C for 8 hr., then against tap water (24 hr.) and finally against frequent changes of distilled water (48 hr.) and lyophilized (RAPYA IV'').

Reaction of Yeast Ribonucleic Acid with Anhydrous Methylhydrazine. — Lyophilized yeast ribonucleic acid (50 mg.) and anhydrous methylhydrazine (1.5 ml.) were kept free from moisture at 60°C for 90 min., then precipitated with absolute alcohol, dissolved in water, and precipitated with acid. This was again suspended in water and dissolved by the careful addition of dilute alkali and dialyzed. The white product thus obtained, in quantitative yield, contained 10.0 mol. of cytidylic acid and 4.6 mol. of uridylic acid per 10 mol. of adenine. The ratio of guanine to adenine was the same as in the parent nucleic acid.

Reaction of Yeast Ribonucleic Acid with Phenylhydrazine. — Freshly distilled phenylhydrazine (12 g.) and lyophilized yeast ribonucleic acid (0.5 g.) were kept at 150°C for 2 hr. and then treated as mentioned above. The material thus obtained was identical with the parent nucleic acid in the nucleotide composition.

Composition of the Dialyzable Materials. —In the preparation of ribo-apyrimidinc acid I, and also IV and V, the outside fluids of each dialysis were combined, adjusted to pH 7 and freeze-dried. The dialyzable fragments were hydrolyzed with 1 N hydrochloric acid and the products were separated by paper chromatography. The nucleotide compositions are shown

10) G. R. Wyatt, ibid., **48**, 584 (1951).
11) W. Mejbaum, *Z. physiol. Chem.*, **258**, 117 (1939).

13) M. G. Sevag, *Biochem. Z.*, **273**, 419 (1934).

in parentheses in Table I. Practically no differences were shown between the composition of the nondialyzable and the dialyzable materials.

Detection of Ribose and Nucleosides after Enzymic Hydrolysis. — Ribo-apyrimidinic acid IV was dissolved in 0.5 M acetate buffer of pH 5.0 and incubated with dialyzed Takadiastase solution at 37°C for 48 hr. The hydrolyzate was applied on paper and separated with *n*-butanol—ammonia[14]. Ribose was detected by spraying aniline hydrogen phthalate reagent[15]. The ultraviolet photo-print showed only the spots of adenosine and guanosine, whereas yeast ribonucleic acid was completely hydrolyzed to purine and pyrimidine nucleosides by this enzyme.

Qualitative Tests for Nonglycosidic Ribose. —0.2% aqueous solutions of ribo-apyrimidinic acid IV and of yeast ribonucleic acid, and 0.1% ribose solution were used for all tests. Excepting the ribonucleic acid, they reacted with ammoniacal silver solution when heated at 100°C for 15 min., reduced Fehling's solution when heated at 100°C for 5 min., gave a reddish brown color with benzidine in glacial acetic acid at 100°C in a few minutes, and reduced mercuric chloride solution at room temperature. Ribo-apyrimidinic acid IV reacted with phenylhydrazine hydrochloride when heated at 50°C for 15 min. and gave a brownish yellow product. All the hydrazinolysis products spotted on filter paper gave a reddish purple color with aniline hydrogen phthalate reagent used for the development of paper chromatograms of reducing sugars[15].

The authors thank Professor F. Egami for his close interest. The expense of this study was defrayed in part by a grant from the Ministry of Education.

Amino Acid Synthesis from Nitromalonic Ester. III[1]. *Note on the Synthesis of Glutamic Acid*

By Tôru OKUDA

(Received March 25, 1959)

Several amino acids have been prepared by means of the addition reaction of diethyl nitromalonate with α,β-unsaturated compounds such as acrylonitrile[2] and acrolein[1]. If the similar type of reaction could occur between nitromalonic and acrylic esters, an approach to the synthesis of glutamic acid would be possible. Both the esters have been found to react in the presence of a catalytic amount of triethylamine in alcoholic solution to give 2-carbomethoxyethyl-nitromalonic ester in a good yield. Elimination of one α-ester group of the substituted nitromalonic ester and subsequent hydrogenation[3] gave pyrrolidonecarboxylic ester, which was easily converted into DL-glutamic acid monohydrate. The overall yield was about 50%. Direct reduction of 2-carbomethoxyethyl-nitromalonic ester with Raney nickel in alcoholic solution gave 2-carbomethoxyethyl-malonic ester, indicating the hydrogenolysis occurred during the reaction[4].

Experimental

Diethyl 2-Carbomethoxyethyl-nitromalonate.—Forty-four grams of diethyl nitromalonate and 22 g. of methyl acrylate in 70 ml. of absolute alcohol were heated under reflux in the presence of 3 ml. of triethylamine for 7 hr. and after the concentration of the reaction mixture the residue was dissolved in 400 ml. of ether. The ether solution was extracted with cold aqueous sodium bicarbonate, washed with water and dried. Evaporation of ether gave 55 g. of crude product. When the crude product was distilled in vacuo, there was obtained 49 g. of the pure material boiling at 120~150°C/2 mmHg.

Anal. Found: C, 45.74; H, 6.07; H, 4.83. Calcd. for $C_{11}H_{17}O_8N$: C, 45.36; H, 5.84; N, 4.81%.

4) D. I. Weisblat and D. A. Lyttle, *J. Am. Chem. Soc.*, **71**, 3079 (1948).

Ethyl 2-Carbomethoxyethyl-nitroacetate[3,5].—A solution of 51 g. of crude diethyl 2-carbomethoxyethyl-nitromalonate in 450 ml. of dry ether was treated with 4.10 g. of sodium dissolved in 100 ml. of absolute alcohol at 0°C as already reported in the preceding papers[1,2]. The resulting slurry was transferred to a separatory funnel, 150 ml. of ether and 70 ml. of cold 10% hydrochloric acid were added and vigorous shaking was applied. The ether layer was separated and the aqueous layer was extracted with ether. The ether solutions were combined, washed with water and dried. Concentration and vacuum-distillation gave 34 g. of the product of b.p. 115~128°C/2 mmHg.

Anal. Found: C, 43.10; H, 5.95; N, 6.18. Calcd. for $C_8H_{13}O_6N$: C, 43.83; H, 5.98; N, 6.39%.

Ethyl Pyrrolidonecarboxylate.—The pressure-hydrogenation of 34 g. of 2-carbomethoxyethyl-nitroacetate was carried out using 150 ml. of ethanol and 4 g. of Raney nickel. The catalyst was filtered off, and the ethanol was evaporated. Crude ethyl pyrrolidonecarboxylate thus obtained weighed 22 g. This can be purified either by recrystallization from ether-petroleum ether or by distilling at 2 mm., m.p. 48~50°C, b.p. 153°C/2 mmHg.

Anal. Found: C, 53.80; H, 7.14; N, 8.99. Calcd. for $C_7H_{11}O_3N$: C, 53.49; H, 7.05; N, 8.91%.

The ester was converted into DL-glutamic acid monohydrate by acid hydrolysis. The overall yield with respect to diethyl nitromalonate was about 50%.

Anal. Found: C, 36.59; H, 6.62; N, 8.92. Calcd. for $C_5H_{11}O_5N$: C, 36.36; H, 6.71; N, 8.48%.

Diethyl 2-Carbomethoxyethylmalonate.—Twelve grams of diethyl 2-carbomethoxyethyl-nitromalonate was reduced in alcohol with 2 g. of Raney nickel. After the removal of the catalyst and the alcohol the residue was distilled. There was obtained 8 g. of diethyl 2-carbomethoxyethylmalonate boiling at 125~130°C/2 mmHg.

Anal. Found: C, 53.23; H, 7.73. Calcd. for $C_{11}H_{18}O_6$: C, 53.66; H, 7.32%.

Studies on the Silk-Palladium Catalyst. I. Preparation and Stability

By Yoshiharu IZUMI

(Received March 27, 1959)

A number of methods have so far been attempted in order to increase the active surface of hydrogenation catalysts of metal or metal oxide nature. Thus, for example, a method has been devised to deposit certain metals or metal oxides onto porous carriers such as carbon or Kieselguhr, to disperse them into colloidal states with the aid of various protective colloids, or to remove a constituent metal from an alloy by chemical treatments as in the case of preparation of Raney nickel. The other methods so far attempted are also based on physical or mechanical dispersion of catalyst metals into colloidal solutions or on the surface of porous substances.

A few years ago, Akabori et al.[1-3] for the first time reported an entirely new type of hydrogenation catalyst and showed that it was capable of catalyzing asymmetric reduction of certain unsaturated compounds. This catalyst was prepared by coordinating palladous chloride with silk fibroin fibers and then hydrogenating the resulting silk-$PdCl_2$ complex. Since palladous can form a chelate compound with silk fibroin, it is not unreasonable to assume that the palladium in the catalyst is firmly fixed to the asymmetric structure of the protein fibers in an almost atomic state. The capacity of asymmetric catalysis may be explained on the basis of the asymmetric structure of the carrier fibroin.

Although this catalyst was originally developed for the purpose of asymmetric synthesis, it also has a number of characteristics suitable for use as a general hydrogenation catalyst. Thus, it is quite easy to mix the catalyst with reacting substances because of its unusual low

2) S. Akabori, Y. Izumi, Y. Fujii and S. Sakurai, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77**, 1374 (1956).
3) S. Akabori, Y. Izumi, Y. Fujii and S. Sakurai, ibid., 78, 168 (1957).

density. The catalyst is also unique in that its carrier is a fibrous protein and therefore it can be spun or woven into sheets, cloth or fluffs. In hydrogenation catalysts hitherto devised, the metal is either bound to the carrier by simple mechanical attraction or finely dispersed as colloidal particles. Therefore, it is sometimes not very easy to separate the catalyst from the reaction mixture due to the detachment of the metal from the carrier or to the colloidal nature of the catalyst. With the silk-palladium catalyst, however, the catalyst can be readily separated from the reactants by simple filtration owing to the fact that the metal, though highly dispersed, is tightly held by the micelle structure of silk-fibroin.

The investigations to be reported in this and the following papers were undertaken with an object of obtaining some basic data concerning the applicability of this hydrogenation catalyst for general practical purposes. Also included in this series of papers are observations on the properties of a Nylon-palladium catalyst in which silk fibroin is replaced by the synthetic fiber, 6-Nylon, as the carrier.

Results and Discussion

Activity and Conditions of Preparation of Catalyst.—For the purpose of obtaining the catalyst of a high activity, optimum conditions were sought for the preparation of the catalyst. Table I records the palladium contents of various preparations prepared under different sets of conditions. As can be seen, the highest content was attained when 350 mg. of silk fibroin was boiled for 8 min. with 100 ml. of 0.1 N acetic acid containing 100 mg. of palladous chloride and the resulting chelate was reduced with hydrogen in an autoclave. These conditions were, therefore, used in preparing the catalysts studied in the following sections.

TABLE I. PALLADIUM CONTENTS OF CATALYSTS

Condition for preparation				Pd content in 50 mg. catalyst* (μg.)
Medium (ml.)		$PdCl_2$ (mg.)	Carrier (mg.)	
Water	100	100	Fibroin 350	2590
N/5 HOAc	50	〃	〃	3950
N/10 〃	100	〃	〃	4600
N/10 〃	100	〃	6-Nylon 350	1165
N/15 〃	50	〃	Fibroin 350	3700
N/30 〃	100	〃	〃	4300

* Pd contents were determinated with *p*-nitrosodimethylaniline.

Prolonged boiling for more than 8 min. resulted in an increased palladium content in the catalyst, but this increase was found to be mainly due to an easily detachable form of palladium and did not contribute to the activity. Although the solubility of palladous chloride could be considerably increased by the addition of sodium chloride or sodium acetate to the aqueous solution, these salts were found to inhibit the chelate formation between palladous chloride and fibroin and consequently lead to less active preparations. When silk fibroin was boild with palladous chloride in distilled water, a preparation containing less palladium was obtained as compared with the preparation which was boiled in dilute acetic acid.

The silk-palladium chelate was usually converted into the active catalyst by reducing it with hydrogen in an autoclave. When this activation was carried out by means of formic acid, the resulting catalyst showed appreciably less activity as shown in Table III.

Capacity of Asymmetric Catalysis.—The asymmetric catalyst reported in previous papers was prepared by boiling silk fibroin with palladous chloride in water. This catalyst, as reported previously, was able to catalyze, for example, the asymmetric hydrogenation of 4-benzylidene-2-methyl-oxazol-5-one(4-benzylidenazlacton) to give optically active products. The catalyst prepared in 0.1 N acetic acid instead of in water, and mainly used in this investigation failed to achieve asymmetric catalysis despite its higher palladium content. The reason for such a peculiar behavior of the silk-palladium catalyst is not yet clear. In any event, it seems that the mechanism responsible for the asymmetric catalysis is of a quite delicate nature and can be profoundly affected by slight alterations of the system.

Stability of Catalyst.—Table II is a summary of an investigation in which the activity of the catalyst and its precursor, silk-palladium chelate, was examined both immediately after preparation and after storage for several days in methanol or under dried condition. The activity of the chelate was of course measured after activation. The activity in the table is expressed in terms of "70% reaction time (t)" and reaction velocity (v) observed in the hydrogenation of nitrobenzene to aniline. The results recorded in Table II clearly show that both the catalyst itself and its precursor chelate are quite stable and can be stored for a long period

TABLE II. STABILITY OF CATALYST AND PRECURSOR CHELATE UNDER VARIOUS CONDITIONS

Sample	Storage condition	Storage time	70% Reaction time (min.)	Reaction velocity	Reaction temp. (°C)
Silk-Pd·Cl_2* 350 mg.	In dry state	0	15.5	6.5	16~17
		12 d.	15.0	6.7	〃

without loss of activity. Furthermore, no spontaneous combustion took place even when the catalyst was stored in air dried conditions.

TABLE III. ACTIVITY OF CATALYST ACTIVATED WITH FORMIC ACID

Catalyst (mg.)	70% Reaction time (min.)	Reaction velocity	Reaction temp. (°C)
Silk-Pd (350) Activated with HCOOH	15.0	6.7	20

Activation Energy of Hydrogenation Reaction.—The catalytic hydrogenation of nitrobenzene to aniline in the presence of the silk-palladium catalyst was measured at various temperatures. In Fig. 1 is plotted logarithm of reaction velocity (log v) against reciprocal absolute temperature ($^1/_T$). From this graph the activation energy of the catalyzed reaction was computed to be approximately 14.5 kcal./mol.

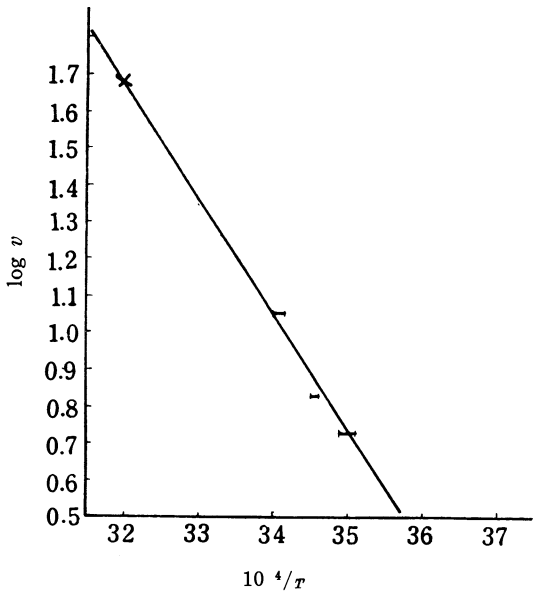

Fig. 1. Dependence of reaction velocity upon temperatures.

Nylon-Palladium Catalyst. — When 6-Nylon (caprolactam polymer) fibers were used as the carrier and treated in the same way as described for silk fibroin fibers, a 6-Nylon-palladium catalyst could be obtained. It was revealed, as shown in Table IV, that the Nylon-palladium catalyst also exhibits a high activity in catalyzing the hydrogenation of nitrobenzene. Nitrobenzene was readily reduced to aniline with hydrogen even at atmospheric pressure in the presence of this catalyst. It was found that the activity was proportional to the palladium content as shown in Table I.

TABLE IV. ACTIVITY OF NYLON-PALLADIUM CATALYST

Catalyst (mg.)	70% Reaction time (min.)	Reaction velocity	Reaction temp. (°C)
Nylon-Pd 350	65	1.5	10
Control (Silk-Pd)		4.9*	10

* Calculated value.

Experimental

I. Preparation of Catalyst. — *1) Palladous Chloridd Solutions.* — *a) Solution in water.*—One hundred milligrams of palladous chloride was added to 100 ml. of cold water and the mixture was stirred for 30 min. in the cold with the aid of a magnetic stirrer.

b) Solution in 0.1 N acetic acid.—One hundred milligrams of palladous chloride were dissolved at 60°C in 10 ml. of 1 N acetic acid and the solution was diluted 10-fold before use.

2) Silk-Palladium Chelate.—Three hundred and fifty milligrams of silk fibroin fibers previously cut into ca. 3 mm. pieces was mixed with 100 ml. of palladous chloride solution (palladous chloride,

100 mg.) and the mixture was boiled for 8 min. The fibers gradually became dense and brownish and finally precipitated as a dark brown mass. After cooling, the precipitated chelate was filtered, washed with water and then methanol, and finally air-dried.

3) Silk-Palladium Catalyst.—The chelate was converted to the active catalyst by the following two methods.

a) The chelate corresponding to 3.5 g. of silk fibroin was suspended in 50 ml. of methanol and reduced with hydrogen (80 kg./cm^2) at 100°C for 1 hr. in a 100 ml. autoclave. (80°C, 2 hr. for the Nylon catalyst).

b) The chelate corresponding to 350 mg. of fibroin was suspended in 30 ml. of 2% formic acid and boiled for 4 min. The chelate became black with vigorous evolution of hydrogen. In both cases, the catalyst, after cooling, was washed with water and methanol and then air-dried.

II. Determination of Palladium.—This was performed by the *p*-nitrosodiethylaniline method of Overholser[4].

III. Reaction Vessel.—A 100 ml. of autoclave was used as the vessel for hydrogenation reactions. The autoclave is illustrated in Fig. 2. The cap A was filled with absorbent cotton in order to prevent the catalyst from invading into the accessory parts of the autoclave. The apparatus was also so designed that the part B could be opened after the reaction. This device rendered it very easy to wash the inside of the tube. Although an aluminum packing was used

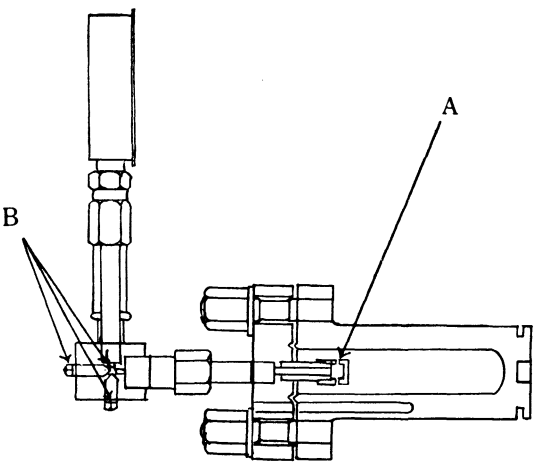

Fig. 2.

at the interface between the lid and the vessel, silver packings were employed in other parts to minimize the unfavorable effects due to metal ions. The autoclave was shaken 100 times per min. with an inclination angle of 15°.

IV. Reaction Velocity Measurement.—*1) Reaction Conditions.*—Four grams of nitrobenzene dissolved in 50 ml. of methanol and the catalyst to be tested were placed in the autoclave and it was filled with hydrogen to 90 kg./cm^2. The initial pressure was read after 15 sec. shaking for equilibriation and the shaking was continued until the theoretical amount of hydrogen was taken up.

2) Calculation of Reaction Velocity.—The reaction velocity (v) was calculated according to the equation,

$$v=\frac{100}{t}$$

where t is the time in minutes required until 70% of the theoretical hydrogen uptake occurred ("70% reaction time").

V. Isolation of Product.—The reaction mixture was filtered and 10 g. of acetic anhydride was added to the filtrate. The mixture was then evaporated to dryness. On cooling the residue after treating with 10 ml. of water, 4.0 g. of crude acetanilide (m. p. 111°C) was obtained. Its melting point was increased to 113°C on recrystallization from water.

VI. Tests of Stability.—*1) Stability Test of Chelate.*—Silk-palladium chelate was dried at 40°C and stored in a stoppered bottle. After 12 days it was activated by hydrogen as described above and its activity for the reduction of nitrobenzene was measured.

2) Stability Tests of Catalyst.—The catalyst preparations prepared by reduction with hydrogen were stored either in methanol or in the dry state (in a stoppered bottle). After suitable periods of storage, their activities were measured as above.

Summary

1. The highest hydrogenation activity was obtained when the silk-palladium catalyst was prepared by boiling the silk fibroin fibers with 0.1% palladous chloride solution in 0.1 N acetic acid for 8 min. and then hydrogenating the resulting chelate.

2. The catalyst prepared as above was, however, devoid of the capacity of asymmetric catalysis, although the same catalyst prepared in distilled water (instead of dilute acetic acid) was able to achieve asymmetric reduction.

3. The catalyst and its precursor chelate could be stored in dry state without any loss of activity.

4. The synthetic fiber, 6-Nylon, could be successfully used as the carrier in place of silk fibroin.

The author wishes to express his sincere thanks to Professor Shiro Akabori for valuable suggestions and encouragement throughout this work. He is also greatly indebted to the Toyo Rayon Co., Ltd. for the supply of 6-Nylon fibers used in this investigation. His thanks are also due to

Studies on the Silk-Palladium Catalyst. II. General Properties

By Yoshiharu IZUMI

(Received March 27, 1959)

In the previous paper[1] of this series it was reported that the silk-palladium catalyst possesses a number of excellent characteristics suitable for the purpose of catalytic hydrogenation. In order to obtain further information concerning the fundamental properties of the catalyst and to provide a basis for its practical application, it is intended in the present investigation to study its selectivity, durability and behaviors towards catalytic poisons. The present paper describes the results obtained in these experiments.

Results and Discussion

I. Selectivity of the Catalyst.—The catalytic efficiency of the silk-palladium catalyst was mainly examined in the previous paper[1] on the hydrogenation of nitrobenzene to aniline. In the present study the activity of the catalyst was examined with a variety of unsaturated compounds listed in Table I. The results obtained are also recorded in the same table.

Hydrogenation of C=C Double Bonds.—The C=C double bonds were found to be very easily reduced at low temperatures in the presence of the silk-palladium catalyst. For instance, it was found that mesityl oxide absorbed 70% of the theoretical amount of hydrogen at 30°C for 20 min. if the catalyst (containing ca. 0.08% of palladium metal per substrate) was supplied. This could be compared with the data obtained with 1% (by weight) Raney nickel in the presence of which it took 60 min. at 60°C for mesityl oxide to absorb the same amount of hydrogen. It was further noticed that the catalyst was able to selectively hydrogenate the C=C double bonds in mesityl oxide, crotonaldehyde and acrolein, leaving their carbonyl groups quite unattacked even at higher temperatures.

These results indicate that the silk-palladium catalyst is particularly suitable for the preparation of saturated aliphatic aldehydes and ketones from the corresponding unsaturated compounds. That azlactone and acetaminocinnamic acid are readily hydrogenated by the silk-palladium catalyst was previously reported[2-4]. The catalyst was, however, unable to reduce phenol at all, indicating that the double bonds in benzene rings are inert to the catalytic action.

Hydrogenation of Carbonyl Groups.—As described above, the silk-palladium catalyst was rather inactive in hydrogenating aliphatic carbonyl compounds. This conclusion was further confirmed in an attempt to reduce acetone and methyl ethyl ketone which were not reduced at all. It was, however, found that the hydrogenation of benzaldehyde in the presence of the catalyst readily gave rise to the formation of toluene. It is, therefore, probable that carbonyl groups attached to aromatic rings may be susceptible to the action of the catalyst. The catalyst which was recovered after having been used for the reduction of acetone was found to show no appreciable depression in the activity of hydrogenating nitrobenzene. It therefore seems that the failure in the hydrogenation of acetone (and other aliphatic

carbonyl groups) is an intrinsic property of the catalyst and not due to the poisoning by these compounds.

Reduction of Nitrile Groups.—It has already been mentioned that the catalyst was inactive in reducing the nitrile group of acrylonitrile, at least at low temperatures. Using acetic anhydride as a solvent, however, benzyl nitrile was converted to *N*-acetyl-phenethylamine in the presence of hydrogen and the silk-palladium catalyst.

Reductive Amination of α-Ketoglutaric Acid and Benzaldehyde.—The silk-palladium catalyst was able to convert α-ketoglutaric acid to glutamic acid in the presence of ammonia and hydrogen. When benzaldehyde was subjected to reductive amination under similar conditions, the main product obtained was identified as dibenzylamine.

Reduction of Nitro Groups.—In the previous paper[1] the reduction of nitrobenzene to aniline was employed as the test system for comparing the catalytic activity. In the present study, it was further found that 5-methyl-3-dimethyl-aminohexan-2-ol-*p*-nitrobenzoate hydrochloride (MDAN) was also readily hydrogenated by this catalyst to form the corresponding amine hydrochloride (MDAA) in as excellent a yield as in the case of the reduction of nitrobenzene. On the contrary, both ω-nitrostyrene and diethyl nitromalonate were reduced very slowly, yielding phenylacetaldoxime and diethyl acetamidomalonate, respectively; their yields also being low. It may be inferred that the catalyst is able effectively to catalyze the hydrogenation of aromatic nitro groups, but relatively weakly that of aliphatic nitro groups.

Reduction of Azobenzene.—Hydrogenation of azobenzene by means of the silk-palladium catalyst at low temperatures resulted in the formation of hydrazobenzene. At higher temperatures, on the other hand, the hydrogenation proceeded in two steps, as shown in Fig. 1, taking up more than one mole of hydrogen and the main product was aniline.

Reduction of Oximino Groups.—It was already reported[2-4] that the silk-palladium catalyst could catalyze the reduction of

benzyldioxime, α-acetoximino-phenylpropionic ethyl ester and glutaric diethyl ester to the corresponding amines. It was, however, found in the present study that both dimethylglyoxime and acetophenone oxime could not be reduced at all.

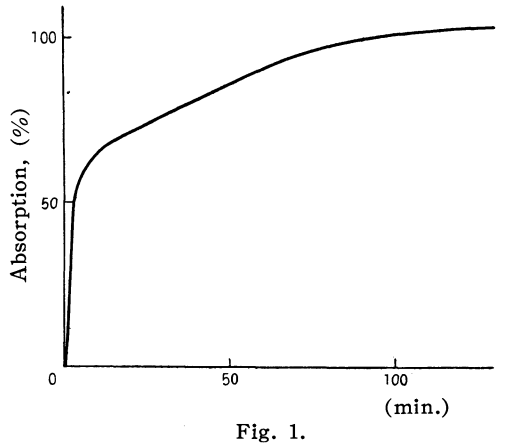

Fig. 1.

II. Durability of Catalyst.—The hydrogenation of diethyl maleate to diethyl succinate was selected as the test system to study the durability of the silk-palladium catalyst. The durability test was conducted in comparison to the carbon-palladium catalyst[5] commonly used as a hydrogenation catalyst.

The results of the test are summarized in Table II. As can be seen from Table II, a very interesting phenomenon was observed concerning the durability of silk-palladium catalyst. When freshly prepared silk-palladium catalyst was used, the temperature at which hydrogen absorption starts was relatively high (105°C) and the reaction proceeded rather slowly. In the hydrogenation using the catalyst recovered from the first run, however, the temperature of initial hydrogen uptake was not only considerably lowered (90°C), but also the reaction itself was accelerated. This elevated activity of pre-used catalyst persisted at least after the fifth run. Such a phenomenon was not observed with the carbon-palladium catalyst which showed the highest activity in the first run and lost it thereafter. It does not seem unreasonable to suppose that such an excellent durability of the silk-palladium catalyst is due to the possibility that the palladium attached to the carrier protein may be sterically rearranged after the first run in favor of the catalytic activity.

In connection with the durability, it might be pointed out that the relatively high ignition point (as compared to the carbon-palladium catalyst) and bulkiness of the fibrous silk-palladium catalyst were very convenient for its handling and recovery.

III. Poisoning of Catalyst.—The silk-palladium catalyst was found to be sensitive to poisonous substances or to various chemical treatments. In Table III are summarized the results of such inhibition studies. In examining the toxic effects, the hydrogenation of either nitrobenzene or diethyl maleate was adopted as the test system and the velocity of hydrogen uptake was calculated and compared as previously described. The carbon-palladium catalyst was also tested as a reference.

Inhibition by Mercaptan.—As can be seen from Table III, the addition of or treatment with ethyl mercaptan markedly decreased the catalytic activity of silk-palladium to hydrogenate both nitrobenzene and diethyl maleate. This poison, which is a well-known inhibitor of palladium catalysts, was also deleterious to the carbon-palladium catalyst. The silk catalyst was, however, much more

** The catalyst was brought in contact with 15 ml. of 0.02% EtSH methanol.

seriously poisoned by the mercaptan than the carbon catalyst. It was, however, noted that no palladium was extracted from the silk catalyst in the presence of ethyl mercaptan, in contrast to the considerable extraction observed in the case of the carbon catalyst. It appears probable that the mercaptan inhibits the catalysts by directly blocking the active palladium.

Inhibition by Metal Ions.—Unlike the carbon palladium and other palladium catalysts, the activity of the silk-palladium catalyst was greatly lowered in the presence of ferric and cupric ions as supplied in the form of nitrates. Cupric ion was somewhat more toxic than ferric ion. It is more likely that these metal ions form chelate linkages with the carrier protein, sometimes three-dimentionally, and thus prevent the reactant from approaching the active palladium atoms which are distributed inside the fibroin micelles.

Reactivation by Ethylenediamine Tetraacetic Acid.—The catalyst poisoned by ferric or cupric ion could be reactivated by treating it with ethylenediamine tetraacetic acid (EDTA). As a matter of especial interest it was revealed that the catalyst thus reactivated exerts very powerful catalytic activity. In fact, EDTA treatments of ferric ion- and cupric ion-poisoned catalysts produced preparations 2.5 and 3 times, respectively, as active as the control catalyst (pre-used once under normal conditions, see above). This peculiar phenomenon suggests that the internal structure of the carrier protein was altered on removal of the metal ions by EDTA to favor the catalytic activity.

Effect of Acetylation.—As previously reported[4], an acetylated silk-palladium catalyst prepared from pre-acetylated silk fibroin and palladous chloride in the usual manner is more active than the unacetylated silk-palladium catalyst in hydrogenating azlactone. Quite unexpectedly, however, it was found in the present investigation that acetylation with acetic anhydride of the pre-formed silk-palladium catalyst greatly depressed the activity. It may be inferred that acetylation of the carrier protein of silk-palladium catalyst blocks the

openings of the fibroin micelles in which the active palladium atoms reside and thus makes it difficult for the substrate to reach the active centers.

In short, there are two types of inhibition; the first, including ethyl mercaptan, inhibits the catalyst by directly combining with palladium atoms and the second, such as ferric ion, cupric ion, and acetylation, by modifying the structure of carrier fibroin. The latter type of inhibition is unique to the silk-palladium catalyst and has special bearings to the structural interpretation of the catalytic activity.

Experimental

I. Preparation of the Catalyst. — The catalyst was prepared by the method of previous papers.

II. Selectivity of the Catalyst.—*1) Reduction of C=C Double Bonds.—a) Reduction of fumaric acid.*—Seventy milliliters of aqueous solution containing 12 g. of fumaric acid adjusted to pH 7.0 with 20% sodium hydroxide and 100 mg. of the catalyst were shaken in 90 kg./cm^2 of hydrogen at 53°C. The reduction was complete after 28 min. The reaction mixture was filtered and the filtrate evaporated to 60 ml. which was then acidified with 20 ml. of concentrated hydrochloric acid. After standing overnight, 9.5 g. succinic acid (m.p. 184°C) was obtained. It was confirmed that the product is devoid of unsaturated bond by infrared spectroscopy.

b) Reduction of mesityl oxide.—Forty-one grams of mesityl oxide was reduced, using 350 mg. of the catalyst with 90 kg./cm^2 hydrogen at 30°C. The reduction was complete after an hour and 1 mol. of hydrogen was absorbed per 1 mol. of mesityl oxide. 36 g. of methyl isobutyl ketone (b. p. 113~115°/760 mm Hg) was obtained from the reaction mixture. Infrared spectroscopy showed a disappearance of unsaturated bond.

c) Preparation of Raney-nickel catalyst.—0.5 g. of Raney-nickel-alloy was added to 6 ml. of 25% sodium hydroxide solution in small portions during 5 min. and then heated for an hour on a water bath. The catalyst sludge was washed three times with each 30 ml. of water and washed with methanol decantation.

d) Reduction of crotonaldehyde. — Twenty-one grams of crotonaldehyde dissolved in 30 ml. of ether was reduced at 20°C with 85 kg./cm^2 hydrogen using 100 mg. of the catalyst. The reduction was continued for 102 min. The reaction mixture was distilled in a 30 cm. dephlegmator. Fifteen grams of butyraldehyde (b. p. 75°C) was obtained and this sample contained no C=C double bonds as examined by infrared spectroscopy.

Analysis of the dinitrophenylhydrazone of this compound showed the following results.

Anal. Found: N, 22.6. Calcd. for $C_{10}H_{12}O_4N_4$: N, 22.2%.

The aldehyde group of crotonaldehyde was never reduced even at higher temperature (130°C).

e) Reduction of acrolein.—When 13 g. acrolein in 20 ml. ether was reduced at 20°C with 85 kg./cm^2 hydrogen using 350 mg. of the catalyst, hydrogen was readily absorbed and the absorption ceased in 36 min.

On adding 2, 4-dinitrophenylhydrazone to 1/100 portion of the reaction mixture, there was obtained 550 mg. propionaldehyde-2, 4-dinitrophenylhydrazone with m.p. 126°C, indicating a yield of 100% in the reduction.

Anal. Found: N, 23.7. Calcd. for $C_9H_{10}O_4N_4$: N, 23.5%.

By distillation of the residue through 15 cm. Widmer column 2 g. of the distillate of b.p. 49°C was obtained. It was proved infrared spectroscopically that this material has no C=C double bond.

This catalyst did not catalyze the reduction of the aldehyde group of this product even when the reduction was carried out at 120°C.

f) Reduction of acrylonitrile. — Fifty grams of acrylonitrile was reduced at 6°C, 100 atm. with 100 mg. of this catalyst and spontaneously the reaction temperature rose to 24°C. The reaction was concluded for 71 min. By fractional distillation, 41 g. of ethyl cyanide (b. p. 96~98°C) was obtained. The product was identified by infrared spectroscopically and gas-chromatographically.

g) Reduction of phenol.—Phenol was not hydrogenated in methanol at 170°C with 80 atm./cm^2 hydrogen by 350 mg. of this catalyst.

2) Reduction of Carbonyl Compounds.—a) Reduction of acetone and methyl ethyl ketone.—Thirty grams of acetone (or methyl ethyl ketone) was not reduced with 90 kg./cm^2 hydrogen at 120°C in the presence of 350 mg. of the catalyst. (Activity of recovered catalyst was tested by the method of previous report[1]. It was clear that the activity of this catalyst was maintained through this condition).

b) Reduction of benzaldehyde.—Eleven grams of benzaldehyde dissolved in 40 ml. of methanol was reduced with 90 kg./cm^2 hydrogen at 27°C using 350 mg. of catalyst. The reduction was continued for 426 min. absorbing of hydrogen per mol. of the aldehyde. 4.3 g. of toluene was obtained from the reaction product, and identified by infrared spectrum.

3) Reduction of Cyanides.—Reduction of benzyl cyanide.—Using 350 mg. of the catalyst 6.0 g. of benzylcyanide was reduced with 100 kg./cm^2 hydrogen at 75°C in a mixture of 15 g. acetic anhydride and 30 g. of acetic acid. The reduction was completed in 276 min. Six grams of acetylphenethylamine (b. p. 145°C/5 mm Hg) was obtained by fractional distillation reaction mixture under reduced pressure.

Anal. Found: N, 8.35. Calcd. for $C_{10}H_{13}ON$: N, 8.58%.

4) Reductive Aminations of Carbonyl Compounds.—a) Reductive amination of benzaldehyde.—Using 350 mg. of the catalyst 10.6 g. of benzaldehyde was reduced in the presence of 6.7 ml. of aqueous ammonia and 25 ml. of methanol with 94 kg./cm^2 hydrogen at 80°C. The reduction was completed in 220 min. By fractional distillation, 6.4 g. of

dibenzylamine (b.p. 156°C/11mmHg) was obtained. The results of analysis were as follows:

Dibenzylamine. *Anal.* Found: N, 6.74. Calcd. for $C_{14}H_{15}N$: N, 7.07%.

Dibenzylamine hydrochloride. *Anal.* Found: N, 5.76. Calcd. for $C_{14}H_{16}NCl$: N, 6.00%.

b) Reductive amination of α-ketoglutaric acid.—Five grams of α-ketoglutaric acid, 14 ml. of 28% ammonia and 36 ml. of methanol were placed in the autoclave. Hydrogenation was carried out at 60°C, 90 kg./cm² for 1 hr. After the reaction mixture was filtered, the filtrate was evaporated in vacuo, dissolved in 5 ml. of water and adjusted to pH 3.2 with hydrochloric acid, then 2.5 g. of glutamic acid was obtained. This product was identified paper-chromatographically and was optically inactive.

5) Reductions of Nitro Compounds.—a) Reduction of nitrobenzene.—This was hydrogenated in the same way as previously reported[1].

b) Reduction of 5-methyl-3-dimethylaminohexyl-(2) p-nitrobenzoate hydrochloride (MDAN).—12.4 g. of MDAN in 40 ml. methanol was reduced at 60°C, 80 atm. for 90 min. with the 350 mg. catalyst. The reaction mixture was concentrated to a volume of 20 ml. and kept at 0°C overnight. There was obtained 8 g. of 5-methyl-3-dimethylaminohexyl-(2) *p*-aminobenzoate hydrochloride (MDAA) with m.p. of 217°C. The mixed melting point with an authentic sample showed no depression.

c) Reduction of ω-nitrostyrene.—When 15 g. of ω-nitrostyrene was hydrogenated at 20°C, 97 atm. in the presence of 350 mg. of the catalyst, the absorption of hydrogen came to an end in 23 min. Filtration, concentration and vacuum-distillation gave 6 g. of the product boiling at 96~108°C/2 mmHg, which crystallized on standing. 4.8 g. of the crystal (m.p. 102°C) obtained. The material was identified as phenylaldoxime.

Anal. Found: N, 10.0. Calcd. for C_8H_9ON: N, 10.4%.

d) Reduction of diethylnitromalonate.—Using 350 mg. of the catalyst 6.9 g. of diethylnitromalonate was reduced in a mixture of 16 ml. of acetic anhydride and 27 ml. of acetic acid with 100 kg./cm² hydrogen at 100°C for 90 min. Two grams of diethyl acetoaminomalonate (m.p. 89°C) was obtained from the reaction mixture after evaporation, addition of 5 ml. of ethyl acetate and overnight standing.

Anal. Found: C, 50.11; H, 7.13; N, 6.52. Calcd. for $C_9H_{15}O_5N$: C, 49.76; H, 6.96; N, 6.45%.

6) Reduction of Azobenzene.—a) Reduction to hydrazobenzene.—5.2 g. of azobenzene was reduced in 50 ml. of ethanol with 94 kg./cm² hydrogen at 20°C. The reduction was concluded for 185 min. absorbing 1 mol. of H_2 per mol. of azobenzene. The reaction mixture was evaporated and the residue was dissolved in 10 ml. of hot methanol. After cooling, 3.0 g. of hydrazobenzene (m.p. 288°C) was obtained as orange crystals. The crystals identified with infrared spectroscopy.

b) Reduction to aniline.—Ten grams of azobenzene was reduced with the 350 mg. catalyst under the same conditions as above except that the reaction temperature was elevated to 70°C. The reduction was concluded for 125 min. Thirteen grams of acetanilide (m.p. 112°C) was obtained from the reaction mixture by the following method. The filtered reaction mixture was evaporated in the presence of 10 g. of acetic anhydride and the residue dissolved in 10 ml. of water and cooled.

III. Durability of Catalyst.—*1) Preparation of the Carbon-Palladium Catalyst.*—The catalyst was prepared by the method of R. Mozingo[5] and stored in wetness.

2) General Procedures.—Hydrogenation experiments were carried out using an autoclave as already reported[1] and the reaction velocity of the hydrogenation of diethyl maleate was calculated according to the equation:

Reaction velocity = 100/reaction time (in min.)

where the reaction time is the time required from 30 to 70% of the hydrogen uptake proceeds.

IV. Poisoning of Catalyst.—*1) General Procedures.*—Hydrogenation velocity of diethyl maleate was measured by the III—*2* method and the reaction velocity of the hydrogenation of nitrobenzene was calculated by the method of the previous paper[1].

2) Inhibition of Mercaptan.—a) Preparation of inhibited catalyst.—Two hundred and fifty milligrams of the silk-palladium or carbon-palladium containing 20 mg. of palladium (In the following experiments, this amount of catalyst was used as a unit.) was mixed with 50 ml. of 0.02% ethyl mercaptan methanol solution, stirred for 15 min. at 20°C, filtered and washed with water and methanol.

b) Poisoning test by substrate containing mercaptan.—b-1) Reduction of nitrobenzene.—The reaction velocity was measured in relation to the reduction system containing 1 mg. of ethylmercaptan, 4 g. of nitrobenzene, 50 ml. of methanol and 1 unit of each catalyst.

b-2) Reduction of dietyl maleate (DEM).—The reaction velocity was measured in relation to 50 g. of DEM containing 4 mg. of ethyl mercaptan.

3) Inhibition by Metal Ions (Metal Ion Effect to the Reduction System of DEM).—Forty milligrams of $Fe(NO_3)_3 \cdot 12H_2O$ or 25 mg. of $Cu(NO_3)_2 \cdot 3H_2O$ was added to the reaction system containing 50 g. of DEM and 1 unit of each catalyst, and the reaction velocity was measured.

4) Reactivation by Ethylenediamine Tetraacetic Acid (EDTA).—Recovered catalysts of experiment (IV-*3*) were boiled with 0.5% EDTA for 5 min., filtered and washed with water and methanol. (Filtered solution was apparently colored with Cu^{2+} or Fe^{3+} EDTA complex.) Using this catalyst, 50 g. of DEM was reduced with hydrogen at 150°C.

5) Effect of Acetylation.—Acetylation of silk-palladium.—Three hundred and fifty milligrams of silk-palladium catalyst was boiled with 50 ml. of an acetic acid anhydride for 2 hr. filtered and washed with water and methanol.

Summary

1. The silk-palladium catalyst was found to catalyze the hydrogenation of

aliphatic C=C double bonds, aldehyde, nitriles and nitro groups directly attached to aromatic rings, azobenzene, and some oximino groups, but relatively weakly that of aliphatic nitro groups. The catalyst was completely inactive to aromatic C=C double bonds, aliphatic carbonyl (with the exception of α-ketoglutarate which was reduced to glutamate in the presence of ammonia), nitriles, and several oximes.

2. The catalyst, when used once, considerably increased its catalytic activity and this elevated activity persisted after several repeated uses.

3. Ethyl mercaptan was poisonous to the catalyst probably due to its combination with the active palladium atoms. Ferric and cupric ions inhibited the catalyst by forming chelate linkages with the carrier protein. The inhibition by these metal ions could be restored by ethylenediamine tetraacetic acid. Acetylation of the catalyst with acetic anhydride markedly reduced the activity, although the treatment of silk fibroin with acetic anhydride prior to the preparation of the catalyst gave a strongly active catalyst.

The author wishes to express his hearty gratitude to Professor Shiro Akabori for encouragement and valuable discussion. He is also indebted to Mr. Yasuo Fujii for cooperation in some phases of this work, to Dr. S. Sakurai and to the Ajinomoto Co., Inc. for the gift of diethyl maleate, and to Dr. R. Sato for his advice on preparing this manuscript.

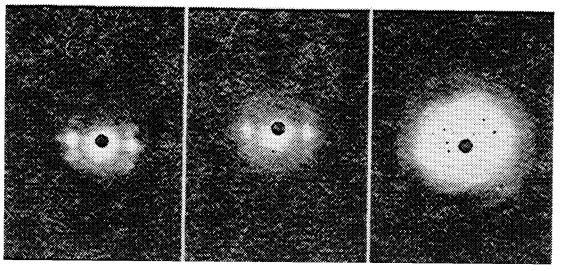
Studies on the Silk-Palladium Catalyst. III. Physicochemical Characterization

By Yoshiharu IZUMI

(Received March 27, 1959)

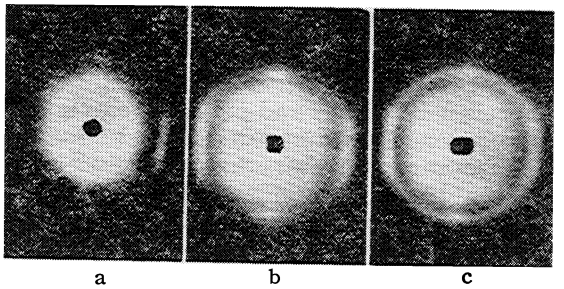
In the preceding papers of this series[1,2], it was reported that silk and 6-Nylon-palladium catalysts are in a number of respects superior as hydrogenation catalysts to carbon-palladium and other palladium catalysts hitherto described. It was also suggested that these catalysts resemble enzymes in that their activity is considerably affected by metal ions and other agents and some of them are endowed with an ability to catalyze asymmetric hydrogenation reactions[3-5].



It, therefore, seemed of special interest to study their structure and the process of their activation from physicochemical points of view. It was also hoped that such studies would shed some light on the mechanism by which some of these catalysts achieve the asymmetric reactions.

The present paper describes X-ray diffraction, infrared spectrophotometric experiments on silk fibroin,its palladous chloride chelate compound, and silk-palladium catalyst (samples of silk series) and on the corresponding samples of 6-Nylon* (samples of Nylon series). The behaviors of these samples towards *p*-nitrosodiethylaniline (PNDA), a specific reagent for palladium[6], were also included in this paper.

Results and Discussion



X-Ray Diffraction Studies. — X-ray diffraction pictures of fibrous preparations of the silk series and the Nylon series are shown in Figs. 1 and 2, respectively. X-ray diffraction measurements were also made on powdered samples of the silk series using a Norelco X-ray instrument and the charts obtained are reproduced in Fig. 3.

Fig. 2. X-ray diffraction pictures of Nylon series.

Diffraction angle (2θ)

Fig. 3. X-ray diffraction patterns of powdered silk series.

As has been known for some time, Figs. 1a and 2a clearly indicate that both silk fibroin and 6-Nylon fibers contain crystalline parts in their structures. The X-ray fiber diagrams of palladous chloride chelates of silk fibroin and 6-Nylon are essentially the same with those of silk fibroin and 6-Nylon, respectively, suggesting that the chelate formation with palladous chloride does not significantly alter the arrangement of these fibers. Conversion of these chelate compounds to catalytic active forms by hydrogenation, however, seems to cause some changes as can be judged from the distinct patterns due to palladium atoms seen in the diagrams of the catalysts.

The Norelco patterns of powdered samples of the silk series are in good agreement with the fiber diagrams of the corresponding preparations. It is noted that the pattern for the powdered silk-palladium catalyst shows in the low-angle region (ca. 3.5°), a peak of which may be due to a ca. 25 Å regular arrangement of the structure.

In summary, it may be concluded that a part of the palladium atoms in the silk-palladium catalysts are assembled in fine crystalline particles and the other part of the palladium probably becomes regularly arranged in the micelle structures of the fibers. However, the possibility that certain regular structures have emerged in the silk protein itself can not be excluded.

Infrared Absorption Measurements. — For the infrared absorption studies powdered samples of the silk series and thin sheet forms of the Nylon series were employed. The spectra of these samples are shown in Fig. 4. As a reference substance carbobenzoxy triglycylleucine and its palladous chloride complex were chosen, the spectra of which are shown in Fig. 4.

Generally speaking, the infrared absorption spectra of the samples of the silk series did not show any remarkable differences, probably due to the high polymeric nature of silk fibroin. Especially, the spectra of the Nylon samples were quite similar to each other, because of the fact that the measurements were made on thin sheet samples, and they contained only a small amount of palladium. However, it can be pointed out, on close examination of the spectra, that the powdered silk-palladium catalyst is similar to the silk fibroin powder rather than to the chelate preparation. A comparison of the infrared absorption spectra of carbobenzoxy triglycylleucine (Cbz. Trigly-Leu) and its palladous chloride complex on one hand and silk fibroin and its palladous chelate on the other hand reveals that an absorption at 3000 cm^{-1} region, which is due

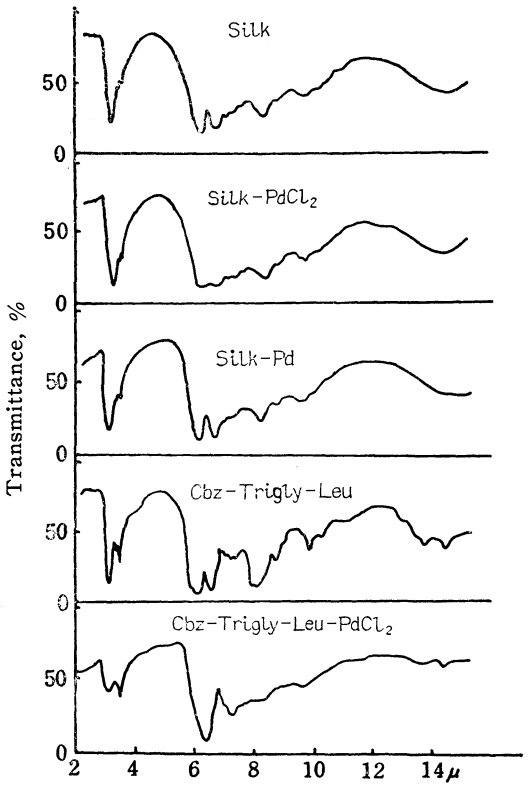

Fig. 4. IR-spectra of silk, silk-$PdCl_2$, silk-Pd, Cbz-Trigly-Leu and Cbz-Grigly-Leu-$PdCl_2$.

to NH groups (probably also OH groups) decreases on the formation of chelates. This suggests that the NH groups (probably also OH groups) of both silk fibroin and the carbobenzoxy tetrapeptide are involved in the chelation with palladous chloride. It may also be noticed that in the spectra of chelate compounds, absorptions at 1640 and 1530 cm^{-1} are diminished and that at 1590 cm^{-1} is increased as compared with the spectra of unchelated forms. The absorptions at 1640 and 1530 cm^{-1} are usually interpreted as caused by CO in COOH and CONH groups, and the absorption at 1590 cm^{-1} as caused by COO^- groups, and Gierer[7] has reported that the complex formation of an amide results in a shift of the absorptions due to CONH to longer wave-lengths. It is therefore probable that the observed changes in the region of 1530 to 1640 cm^{-1} are due to a complicated effect of chelate bond formation between palladous chloride and COOH and/or CONH groups.

It may be concluded that palladous chloride forms chelate linkages with NH_2 (-OH), CONH and COOH groups of fibroin and the dipeptide. These linkages appear to be broken on hydrogenation of the chelate. In the activated chelate, therefore, the palladium seems to be in an almost atomic state.

Behaviors towards *p*-Nitrosodiethylaniline (pNDA). — When silk fibroin and Nylon-$PdCl_2$ chelate compounds were treated with pNDA, a specific reagent for palladium, parts of palladous chloride were released. However, the rest of palladous chloride remained in fibers, although the fibers were strongly colored like pNDA-$PdCl_2$ complex. Furthermore, Fujii[8] observed that silk fibroin-$PdCl_2$ chelate treated with pNDA is more active than silk fibroin-$PdCl_2$ itself and pNDA in catalyzing the decarboxylation of oxalacetic acid. These facts suggest that a considerable part of the palladium is firmly kept in the fiber structure and that on treatment with pNDA the reagent becomes combined with silk fibroin through the mediation of palladium atom or pNDA-$PdCl_2$ complex becomes wrapped into the fiber micelles.

In summary, it can be inferred that palladous chloride is first dispersed in the fiber structures because of the chelate formation. On reduction, palladous chloride in the chelate is converted into an atomic state leaving the carrier protein.

Experimental

I. Preparation of Powdered Silk Fibroin Preparations. — One gram of silk fibroin was dissolved in a modified Schweizer reagent made from 1.6 g. of ethylenediamine and 1.2 g. of $Cu(OH)_2$, and the solution was neutralized with acetic acid and dialyzed. Five milliliters of 1% ethylene diamine tetraacetate solution and 0.1 g. of celite were added to the dialyzed solution and the mixture was filtered under suction. To the filtrate were gradually added 3 volumes of acetone and the precipitate formed was collected by centrifugation. The precipitate was dried at 50°C after washing 4 times with acetone and then once with ethyl ether. The dried silk fibroin was ground in a mortar and passed through a 200 mesh sieve. 0.5 g. of finely powdered silk fibroin was obtained.

This powdered fibroin was converted to palladous chloride chelate and catalyst forms according to the standard methods described in Part I. The chelate was brown in color, and the catalyst resembled active carbon in its appearance.

II. Preparation of 6-Nylon Catalyst Samples for X-ray Measurements. — In order to prevent the tangling of the chelate fibers during the reduction, they were fixed to a holder of the X-ray apparatus. After measurement of the

7) A. Gierer, *Z. Naturforsch*, 8b, 654 (1953).

8) Y. Fujii, *J. Biochem.*, in preparation.

X-ray diffraction, the holder with the chelate fibers in it was wrapped in gauze and then reduced in the autoclave.

III. 6-Nylon-$PdCl_2$ Complex.—The complex was prepared analogously to the silk fibroin-$PdCl_2$ complex.

IV. Triglycyl-carbobenzoxyleucine-$PdCl_2$ Complex. — Forty-four milligrams of triglycyl-carbobenzoxyleucine was boiled for 4 min. with 140 ml. 0.1 N acetic acid containing 140 mg. palladous chloride and the resulting peptide-$PdCl_2$ complex was isolated centrifugally and washed completely with water and then with methanol and dried.

V. X-ray Diffraction Measurements. — X-ray fiber photographs were taken with K_α line of copper filtered through a nickel filter. For powdered samples a Norelco X-ray instrument was used.

VI. Infrared Absorption Measurements. —A Perkin-Elmer apparatus was used. The measurements were made by the KBr tablet method.

Summary

1. From the infrared absorption measurements of silk fibroin, silk fibroin-$PdCl_2$ complex, and silk-palladium catalyst, it was concluded that the NH, OH, COOH and CONH groups of the fibroin participate in the chelate formation with palladous chloride. On reduction of the chelate with hydrogen, the chelate bonds are broken and the fibroin restores its original form.

2. X-ray diffraction pictures of the above-mentioned samples and of the corresponding preparations of the 6-Nylon series suggest that a part of the palladium atoms in the silk-palladium catalyst is assembled in fine crystaline particles and the other part of the palladium probably becomes regularly arranged in the micelle structures of the fibers. However, the possibility that certain regular structures have emerged in the carrier protein itself can not be excluded.

3. Part of the palladium in silk fibroin-$PdCl_2$ complex can be readily released with *p*-nitrosodimethylaniline, while the rest appears to be strongly kept in the fiber structure.

The author wishes to express his sincere thanks to Professor Shiro Akabori for encouragement and valuable advice. He is also indebted to Mr. Yasuo Fujii for skilful collaboration, to Dr. K. Ogawa for measurement of X-ray pictures, to Dr. H. Tadokoro and Mr. T. Inui for infrared measurements, to Mr. F. Sakiyama for the gift of tetrapeptide, to the Toyo Rayon Co. for the gift of 6-Nylon fibers, and to Dr. R. Sato for his advice on preparing this manuscript.

*The Reaction of the Aquopentamminechromium(III) Complex Ion in Aqueous Solution. I. Substitution Reaction of a Coordinated Water with a Chloride Ion**

By Shinpei HASHIMOTO

(Received January 6, 1959)

Garrick[1] and Adell[2] have investigated a substitution reaction of aquopentamminecobalt(III) ion in which a coordinated water molecule of the complex ion is replaced by a chloride ion[3]. They have reported that the reaction is of first order with respect to the complex ion and the chloride ion respectively, and that the reaction rate decreases markedly as ionic strength increases.

A similar substitution reaction occurs in the case of aquopentamminechromium (III) ion as well. On addition of hydrochloric acid to the aqueous solution of an aquopentamminechromium (III) complex salt, red crystals precipitate slowly. The

* Presented at the Symposium on Coordination Compounds, held at Nagoya, November, 1957.

1) F. J. Garrick, *Trans. Faraday Soc.*, **33**, 486 (1937).

2) B. Adell, *Z. anorg. u. allgem. Chem.*, **246**, 303 (1941).

3) In Ref. 6b, the reaction of this type was called "anation reaction". This word will be used in this paper for convenience.

absorption spectrum of a solution of the crystallines is identical with that of chloropentamminechromium(III) complex ion. The fact shows that the following substitution reaction occurs in the solution containing aquopentamminechromium(III) complex ion and chloride ion.

$$[Cr(NH_3)_5OH_2]^{3+} + Cl^- \rightarrow [Cr(NH_3)_5Cl]^{2+} + H_2O \quad (1)$$

Since aquopentamminechromium (III) complex ion is very similar to that of cobalt(III) in steric configuration, ionic size and charge, but different only in electronic configuration of the central metal ion, it is interesting to investigate whether this difference in electronic configuration may appear in the reactions of these two metal-ammine-complexes.

This paper presents a study of the substitution reaction in which a coordinated water molecule of aquopentamminechromium(III) complex ion is replaced by a chloride ion in aqueous solution. Furthermore, the influence of ionic strength on the aquation of chloropentamminechromium(III) complex ion is also reported.

Experimental

Materials. — Aquopentamminechromium (III) perchlorate was prepared by the method of Linhard et al.[4] and was purified by recrystallization from perchloric acid solution twice and then from warm water once.

Chloropentamminechromium(III) chloride was prepared according to the direction of Biltz[5]. The chloride was converted by treatment with perchloric acid into perchlorate, and the latter was purified twice by reprecipitation from cold perchloric acid solution.

Sodium chloride of reagent grade was used without further purification. Sodium perchlorate was prepared by neutralizing sodium hydroxide with perchloric acid both of which were of reagent grade. Absorbancies for solutions of sodium chloride and sodium perchlorate were both so small that they could be neglected practically. Their magnitudes for the solutions of unit molarity at 44000 cm^{-1}, where all rate measurements were carried out, were 0.015 and 0.020, respectively against water.

Measurements.—Experimental solutions were prepared as follows. The solution of aquo-complex salt (10^{-3}~10^{-2} M) which was acidified with perchloric acid was placed in a stoppered and brown-colored flask. The solution of sodium chloride (10^{-2}~1 M) whose ionic strength was adjusted with sodium perchlorate was prepared. These two solutions were kept at a constant temperature in a thermostat, and were mixed together quickly; then at intervals of a few minutes, the amount of chloropentamminechromium(III) ion formed was determined spectrophotometrically.

The measurement of absorbancy was made with a Beckman Model DU photoelectric spectrophotometer using stoppered 10 mm. quartz cells. The temperature of the cell compartment was kept constant within ±0.1°C by circulating thermostated water.

The aqueous solution of aquopentamminechromium(III) perchlorate which was acidified with perchloric acid did not change so fast as its neutral solution. When the pH of the solution was lower than approximately 4, no changes in absorbancy nor pH were observed during the course of measurements.

The aquation rate of chloropentamminechromium(III) ion was followed also spectrophotometrically. After dissolving chloropentamminechromium(III) perchlorate in a solution containing appropriate amounts of perchloric acid and sodium perchlorate at an experimental temperature, the change in absorbancy at 44000 cm^{-1} was followed with a thermostated spectrophotometer.

Results

Apparent Molar Extinction Coefficients of Complex Cations. — In order to determine the rate of the formation of chloropentamminechromium(III) complex ion by the measurements of a change in ultraviolet absorption, the correct molar extinction coefficients of complex ions under the reacting condition must be known. Table I shows the temperature dependence of molar extinction coefficients of chloro and aquopentamminechromium (III) ions at 44000 cm^{-1} in aqueous solution containing no chloride ion. These molar extinction coefficients were more or less greater when chloride ion was added.

Fig. 1 shows the variations of molar extinction coefficients of chloro and aquopentamminechromium(III) ions with respect to chloride ion concentration. This increase in extinction coefficients caused with chloride ion may be attributed

to the formation of outer sphere association complexes[6] between complex cations and chloride ion. Furthermore, since the formation of the association complex generally depends on the ionic strength of solution[7], the apparent extinction coefficient of a complex ion varies on addition of sodium perchlorate[8] to the solution containing chloride and complex ions. Extinction coefficients of complex ions under various conditions were obtained by extrapolating the absorbancies with regard to the time zero. On the estimation of the molar extinction coefficient of chloropentamminechromium(III) ion under reacting conditions, the small effect of ionic strength mentioned above was neglected. The magnitudes were determined from the data of Table I and Fig. 1, assuming that the temperature dependence of extinction coefficient of outer sphere association complex was similar to that of free complex ion.

The solution of chloropentamminechromium(III) ion obeys the Beer's law strictly where no chloride ion exists, and also satisfies it fairly well even in chloride solution.

The Rate of Formation of Chloropentamminechromium(III) Ion. — It is shown in Fig. 2 that the initial rates of the formation of chloropentamminechromium(III) ion in the solution of the constant ionic strength are proportional to the concentrations of aquo-complex cation and chloride ion, respectively. Accordingly the rate constants of the anation reaction 1 were calculated by the usual method based on Eq. 2, being regarded as a second order reaction. To obtain more correct values of the anation rate, a reverse reaction, that is, an aquation of chloropentammine-complex ion, was taken into account according to the method of Garrick[1].

$$\frac{d[[Cr(NH_3)_5Cl]^{2+}]}{dt} = \vec{k}_2[[Cr(NH_3)_5OH_2]^{3+}][Cl^-] \quad (2)$$

rates are independent of hydrogen ion concentrations so far as the solutions are acidic.

The reaction rate decreases remarkably with increasing ionic strength of solution. The influence is particularly significant in the lower ionic strength region. In Fig. 3, logarithms of rate constants measured at 45°C are plotted against the square root of the ionic strengths in molarity scale, which are calculated from the initial composition of solutions. Observed rates fluctuate markedly in a higher ionic strength region, whereas below a $\sqrt{\omega}$ of about 0.4, experimental results show a good regularity that can be reproduced by Eq. 3. The rate constant at infinite

$$\log \vec{k}_2 = -1.77 - \frac{3.09\sqrt{\omega}}{1+1.36\sqrt{\omega}} \qquad (3)$$

dilution at 45°C was evaluated to be 1.7×10^{-2} l. mol^{-1} min^{-1}.

The results obtained at 30, 35, 40, 45 and 52°C ($\omega=0.52\pm0.01$) give a good Arrhenius plot (see Fig. 4), leading to the value of 24.6 kcal. mol^{-1} for the experimental activation energy, and 1.2×10^{14} l. mol^{-1} min^{-1} for the frequency factor.

Aquation of Chloropentamminechromium (III) Ion.—In order to obtain more correct rate constants of anation reaction 1 it is necessary to take the rate of the aquation[9] into account. Accordingly we were obliged to determine the rate of aquation of chloropentamminechromium(III) ion under various conditions. The results obtained are summarized in Table III.

The influence of ionic strength on the aquation is quite different from that on the anation reaction. In lower ionic strength region, the reaction rate rather increases with increasing ionic strength; then the rate decreases gradually and the gradient of the relation is steepest about $\omega=0.4$, and after that the decrease in rate becomes gradual again. It was observed that the aquation rate was independent of perchloric acid concentration from

10^{-4} M to 10^{-1} M. The experimental activation energy and the frequency factor calculated from the temperature dependence of aquation rate were 22.8 kcal. mol^{-1} and 2.6×10^{13} min^{-1}, respectively. When the transmission coefficient is assumed to be unity, the activation entropy is calculated as -7 e. u.

Discussion

It is shown in Fig. 1 that the absorbancy of aquopentamminechromium(III) ion changes markedly with the concentration of chloride ion. The formation of outer sphere association complex, $[Cr(NH_3)_5\cdot OH_2]^{3+}\cdot Cl^-$, ought to be thought for the reason of this absorbancy change, as was indicated by Linhard[6] in the case of hexamminechromium(III) ion and chloride ion.

The anation reaction 1 is experimentally shown to be of second order and the rate constant varies with the ionic strength of solution as is reproduced by the Brönsted-Bjerrum-Christiansen type Eq. 3[6b], which is the kinetic equivalent of the Debye-Hückel equation. The slope of the line in Fig. 3 is -3.09 at infinite dilution. This value is in good agreement with what is expected from a term $2Az_+z_-$[10] in the Debye-Hückel equation. But it can not be concluded that the anation is a bimolecular reaction. Because these results may also be explained by the following unimolecular path through the outer sphere association complex.

$$[Cr(NH_3)_5OH_2]^{3+}+Cl^- \rightarrow [Cr(NH_3)_5OH_2]^{3+}\cdot Cl^- \quad \text{(fast)}$$

$$[Cr(NH_3)_5OH_2]^{3+}\cdot Cl^- \rightarrow [Cr(NH_3)_5Cl]^{2+}+H_2O \quad \text{(slow)}$$

The formation constant of the outer sphere association complex is about 10^2 under these experimental conditions[11], therefore, a considerable amount of association complex exists in solution. If the reaction proceeds through such an outer sphere association complex, the rate-determining step is not the process of bimolecular association, but the following unimolecular process in which central chromium(III) ion releases a coordinated water molecule.

It is noteworthy that the reaction rate varies regularly according to the Debye-Hückel equation in spite of the considerable formation of the association complex. Moreover, its formation is also found to vary roughly according to the Debye-Hückel equation[11]. These facts indicate that the path through a simple five coordinated intermediate is less probable. In other words, the outer sphere association complex releases its coordinated water molecule more easily than the free complex ion. In the water exchange of hexaquochromium(III) complex ion, Plane et al.[12] have found that various anions speed up the reaction. The fact is also explicable by assuming a higher lability of outer sphere association complex. On the other hand, the results of anation reaction for cobalt(III) complex ion obtained by Garrick[1] seem rather extraordinary from the viewpoint of a gradual slope as is shown in Fig. 3, which is about -1. This gradualness may be explained by assuming an inert association complex and the contribution of another path which has a simple five coordinated intermediate[13] in this case.

The effect of ionic environment on the aquation of chloropentamminechromium (III) ion is quite different from that on the anation reaction. The Brönsted-Bjerrum equation predicts a linear dependence of $\log \overleftarrow{k}_A$ ($\overleftarrow{k}_A$ is the rate constant of aquation) upon ionic strength ω[14] when the Hückel's empirical term is taken into account in the expression of activity coefficients. Though only sodium perchlorate and perchloric acid were used to adjust ionic strength, the dependence was not linear even in the lower ionic strength region. It seems that perchlorate ion may also have some specific effects on the aquation.

Summary

The substitution reaction of aquopentamminechromium(III) ion in which a coordinated water molecule is replaced by a chloride ion was investigated spec-

10) A denotes $0.4343\ e^3(2\pi N)^{1/2}/(10\varepsilon kT)^{3/2}$, and approximately equals 0.53 for aqueous solution at 45°C, z_+ and z_- are the ionic charges of reactants.

trophotometrically. The reaction proceeds according to the second order rate law, $d[[Cr(NH_3)_5Cl]^{2+}]/dt = \vec{k}_2[[Cr(NH_3)_5OH_2]^{3+}].[Cl^-]$, and the rate constant varies regularly with the ionic strength of solution according to the Debye-Hückel type equation. The formation of outer sphere association complex in the solution was detected from the change in ultraviolet absorption. From these results the rate-determining process of this reaction was inferred to be a unimolecular process through the outer sphere association complex. The experimental activation energy and the frequency factor of this reaction were determined to be 24.6 kcal. mol^{-1} and 1.2×10^{14} l. mol^{-1} min^{-1} ($\omega\sim0.52$), respectively.

The aquation of chloropentamminechromium(III) ion was also studied in the solutions of various ionic strengths and the reaction rate was found to vary to some extent with ionic environment.

The author wishes to thank Professor Y. Inamura for his guidance and encouragement throughout this work. Thanks are also due to Professor I. Tanaka for his kind and helpful advice and to Mr. H. Kobayashi and Mr. Y. Mori for many valuable discussions.

Intramolecular Interaction between Hydroxyl Group and π-Electrons. IV[1]. *Rotational Isomers of Alcohols and Shift of ν_{O-H} Absorptions in Phenyl Substituted Alcohols*

By Michinori ŌKI and Hiizu IWAMURA

(Received February 16, 1959)

The authors have found[2] an unsymmetric ν_{O-H} absorption band for 10-undecen-1-ol in the course of the investigation of the intramolecular interaction between the hydroxyl group and π-electrons of an isolated double bond. But the origin of the second minor band, obtained by dividing the band on the assumption that the unsymmetric band is an overlap of two symmetric bands which can be expressed by the Lorentz function, has been unknown. The present author expected that saturated aliphatic alcohols, such as ethanol, may also possess two ν_{O-H} absorptions as 10-undecen-1-ol does in spite of the improbable internal interaction. This has been found to be true.

Experimental

Measurement and Calculation.—They were carried out similarly as described previously[2].

Materials. — The materials, all being known compounds, were purified as stated in the literature. Their physical constants agreed with those reported.

Results aud Discussion

The apparent curves for methanol, ethanol, isopropyl alcohol and *tert*-butyl alcohol are given in Fig. 1. The ν_{O-H} absorption is one of the best explored and

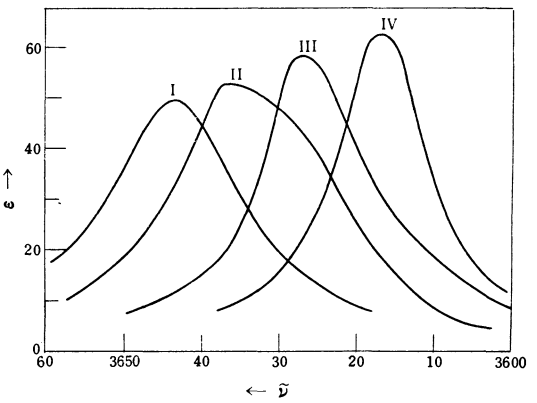

Fig. 1. ν_{O-H} Absorptions of methanol(I), ethanol(II), isopropyl alcohol(III) and *tert*-butyl alcohol(IV).

it is accepted that the wave number where the absorption maximum appears shifts to the lower side as the alcohol varies from primary to secondary and then to tertiary. The results obtained agree with the above rule, except that ethanol and isopropyl alcohol possess unsymmetric bands which were found with high resolvability of the grating spectrophotometer. The unsymmetric band is divided into two symmetric bands, on the assumption that the unsymmetric curve is an overlap of the two symmetric ones which obey the Lorentz function. The results are given in Table I with those of other aliphatic alcohols.

The origin of the second minor peak can not be the formation of the dimer, because Liddel and Becker[3] reported that they observed no dimer band at the concentration of 0.001~0.003 mol./l. at which the present measurement was carried out. Neither can be the origin the hydrogen bonding between the solute and the chlorine atom of carbon tetrachloride, since methanol, tertiary alcohols and phenols always show symmetric bands. Therefore it should be sought elsewhere.

Richards[4], Barrow[5] and Flett[6] tried to explain the shift of the ν_{O-H} absorption maxima, as the alcohol varies from primary to secondary and then to tertiary, on the basis of the mesomeric or inductive effect of the substituent. That is to say, the contribution of the resonance structure $H^-CH_2=O^+-H$ or $H^+CH_2=O^--H$ will increase as the result of stabilization due to the presence of the alkyl groups on the carbon atom to which the hydroxyl group is attached, and the resulting weaker force constants cause the ν_{O-H} absorption to appear at a lower wave number. However, this explanation is not convincing, since it does not explain the presence of the two bands for O-H stretching.

Badger and Bauer[7] found two ν_{O-H} absorptions for the primary alcohols and tried without success to assign them to the rotational isomers, because they failed to observe a doublet for the secondary alcohols. However, the idea of the rotational isomerism is attractive to the present authors, since this is a promising explanation for the existence of the two ν_{O-H} absorptions. Though the energy barrier for the rotational isomers around the O-C axis of the alcohols is estimated to be even lower than that of the rotation around the C-C axis of ethane derivatives, a 0.8 or 0.9 kcal./mol. energy barrier would suffice for the presence of the isomers at room temperature. Barrow[8] estimated the energy barrier 0.8 kcal./mol. for ethanol and Weltner and Pitzer[9] estimated 0.9 kcal./mol. for methanol around the O-C axis by comparison of the values obtained by computation and by observation of heat capacities and entropies. The energy barrier is also estimated by the microwave method as 1 kcal./mol.[10]

Now, let us consider the rotational isomers of aliphatic alcohols in respect of the O-C axis. In Fig. 2, the isomers are projected through the O-C axis and the oxygen atom is on the upper side. The circle indicates a carbon atom to which the hydroxyl group is attached.

In type I, the hydrogen atom of the hydroxyl group is situated between the two hydrogen atoms which are attached

Fig. 2.

to the next carbon atom; in type II, between carbon and hydrogen atoms; and in type III, between two carbon atoms. Then, it is quite understandable that methanol and *tert*-butyl alcohol have single symmetric bands because they have only one rotational isomer and that also ethanol, higher primary alcohols and secondary alcohols have two bands which form an apparently unsymmetric band because they have two rotational isomers.

It is also expected from the above models that the force field will be almost the same in type I, irrespective of the other part of the molecules, and the same situation is also expected for type II or III. Therefore, the type of the rotational isomers of the alcohols determines the wave number where the ν_{O-H} band appears. This turned out to be really the case. The ν_{O-H} absorption of type I appears at about 3640 cm^{-1}, that of type II at about 3626 cm^{-1} and that of type III at about 3617 cm^{-1} irrespective of the nature of the alcohols. The main peak for the primary alcohols comes from type I and that for the secondary alcohols comes from type II.

The reason for such assignment is as follows. When Table I is examined, it is obvious that primary alcohols possess the property of methanol to some extent, because they show one of the ν_{O-H} bands at about 3640 cm^{-1}. Thus the absorption at ca. 3640 cm^{-1} is assigned to type I. Comparison of the absorptions of secondary alcohols with those of tertiary alcohols in a similar way indicates that the band at about 3617 cm^{-1} must be assigned to type III. The remaining band at about 3626 cm^{-1} is assigned to type II.

The probability of type I for primary alcohols is considered one third and that of type II two thirds. Although such expectation does not agree with the results obtained with the primary alcohols, it does agree with those for the secondary alcohols. One of the possibilities which may explain this phenomenon is repulsion between the hydrogen atom of the hydroxyl group and the alkyl group attached to the alpha carbon. In order to clarify this point, a bulky substituent, such as isopropyl or *tert*-butyl group, is introduced to the primary or secondary alcohols. As to the integrated intensities, the steric effect of the substituent is clearly observed in the primary alcohols but not in the secondary alcohols; since the integrated intensity the ν_{O-H} band, affected by the steric environment, is the minor one in the former, while, in the latter both types are affected as far as the present compounds are concerned. The error included in dividing the unsymmetric band may not allow the drawing of a clear-cut conclusion, but it is still clear that the most stable point for the hydrogen atom of the hydroxyl group is pushed toward the hydrogen rather than the bulky group because of the steric effect and consequently the wave number at which ν_{O-H} absorption appears is heightened. Thus the main peak for *tert*-butylmethylcarbinol

appears very close to the main peak of the primary alcohols (type I). The same phenomenon is also observed in the primary alcohols, but in this case the more outstanding feature is the increase of the ratio of the integrated intensity of type I to that of type II. In other words, in neopentyl alcohol, A_I/A_{II} increased to 6.0 from about 2.0 for the other primary alcohols and the increase in the integrated intensity of type I must be attributed to the greater number of the molecules due to the steric requirement.

Thus, it is now evident that the second minor peaks of ν_{O-H} absorption found in 4-penten-1-ol, 5-hexen-1-ol and 10-undecen-1-ol[2] do not represent the intramolecular interaction between the hydroxyl group and the π-electrons of the double bond, but are attributable to the existence of the two rotational isomers which can be represented by types I and II.

It is expected from the above results that the idea of rotational isomerism will be applicable to the phenyl substituted alcohols and therefore the authors have extended their work to benzyl alcohol and its derivatives. The results are shown in Table II.

Ethylmethylphenylcarbinol and ethyldiphenylcarbinol are not included in Table II, because they show a nearly symmetric band which may be an overlap of two similar symmetric bands and can not be divided by the present technique.

It has long been in question why benzyl alcohol and allyl alcohol show an absorption band at about 3620 cm^{-1} in spite of the fact that they are primary alcohols, the only observation of the two bands for benzyl alcohol having been made by Fox and Martin[11]. Quite recently Schleyer, Trifan and Bacskai[12] also reported the existence of the two bands for the O–H stretching absorption of allyl and benzyl alcohols, their results being in good agreement with the present ones. Although the present authors as well as Schleyer et al. attributed the band at 3619 cm^{-1} to the intramolecular interaction between the hydroxyl group and π-electrons, it now seems probably correct to introduce the concept of rotational isomers involving the interaction mentioned above for the explanation of the phenomenon, because type IV shows the absorption band at 3636 cm^{-1} where the normal primary alcohols do, type V at 3618 cm^{-1} and type VI at 3610 cm^{-1}.

The fairly large shifts (7~8 cm^{-1}) between types II and V and between types III and IV are most conveniently explained by introducing the concept of neutralization or the intramolecular interaction between the hydroxyl group and the π-electrons. That is, when a π-electron exists at the β-carbon atom of the alcohol, the interaction takes place and the extension of the O–H bond length occures. Thus the force constant is weakened and the weaker force constant gives rise to the shift of the absorption maximum toward the lower wave number.

Then the rotational isomers represented in Fig. 3 must be somewhat different from those in Fig. 2. In benzyl alcohol it is understood that the hydrogen atom of the hydroxyl group is not in the midst of the two atoms attached to the α-carbon, different from the cases of aliphatic alcohols, but is located closely to the carbon atom which possesses a π-electron. But the O–H bond can not be *cis* in respect of the C_{Ph}–C_α bond; since, if it were, there should not be any difference between types V and VI or between benzhydrol and triphenylcarbinol. The intramolecular interaction in allyl alcohol may be of this type, because its interacted form shows an absorption band at 3619.4 cm^{-1}.

It is also noticed that the band intensity of type V is greater than that of type IV in benzyl alcohol in contrast with the reverse in the primary aliphatic alcohols. This fact can be attributed to greater stabilization of type V in benzyl alcohol

IV		—	—
V			—
VI	—		

Fig. 3.

than of type IV in aliphatic alcohols because of the intermolecular interaction.

The only unknown ν_{O-H} absorption for the rotational isomers in the alcohols now is the one which should be assigned to the type in which the hydrogen atom of the hydroxyl group is situated between the aromatic carbon and the aliphatic carbon (type VII). The example is provided by alkyldiphenylcarbinols. The absorption at 3617 cm^{-1} is assigned to this, since the other absorption at 3609 cm^{-1} has been assigned to type VI.

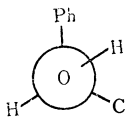

Fig. 4.

Theoretically, it is expected that alkylphenylcarbinols exhibit three ν_{O-H} absorptions, because they have the possibility of taking three types represented by II, V and VII. However, the ν_{O-H} absorptions of the types V and VII are so closely located that it is impossible to resolve them and consequently only two bands are observed for type II and for a mixture of types V and VII with methylphenylcarbinol.

There are some exceptions which are represented by dialkylphenylcarbinols. In these cases, the absorptions occur at 3620 cm^{-1} and at 3607 cm^{-1}, the latter being in the same position as type VI. However, the steric interference between the two alkyl groups and the ortho hydrogen atoms of the benzene nucleus causes the different situation from the others and the case is more complicated. The authors tentatively attribute this abnormality to the internal rotation around the C_{Ph}–C_{α} axis which is forced by the environment. Although the shift in wave number may be too great to assign the bands in an analogous way, it may still be valid that type VII of dialkylphenylcarbinol shows an absorption band at a lower wave number than type III because of the lowered force constant. Thus, the band at 3608 cm^{-1} is tentatively assigned to type VII and that at 3620 cm^{-1} to type III.

Summary

The authors observed symmetric ν_{O-H} absorptions for methanol and tertiary alcohols and unsymmetric bands for primary and secondary alcohols. The unsymmetric band was divided into two bands, assuming that the band is an overlap of the two symmetric bands. The idea of the rotational isomerism was successfully introduced for assigning the band and the following points were concluded.

1) Types I and IV show absorption bands at 3644~3636 cm^{-1}, type II at 3626~3629 cm^{-1}, type III at 3615~3618 cm^{-1}, type V at 3616~3619 cm^{-1}, type VI at 3608~3611 cm^{-1}, and type VII at 3613~3617 cm^{-1}.

2) The exception is dialkylphenylcarbinols which show the ν_{O-H} absorptions at about 3620 cm^{-1} and 3608 cm^{-1}, the former being assigned to type III and the latter to type VII. This ruling-out may be

attributed to the steric effect and the rotation around the C_{Ph}–C_{α} axis.

The steric effect on the integrated intensities and on the wave number where ν_{O-H} absorption falls is also discussed. The differences between types II and IV and between types III and VI were attributed to the existence of the intramolecular interaction between the hydroxyl group and π-electrons of the benzene nucleus. The same reason may cause allyl alcohol to show its main ν_{O-H} absorption at about 3620 cm^{-1}.

The authors are indebted to Professor Y. Urushibara and Professor T. Shimanouchi for their valuable suggestions and discussions. The authors also wish to express their hearty thanks to the Ministry of Education for the Grant in Aid for Fundamental Scientific Research.

Intramolecular Interaction between Hydroxyl Group and π-Eelctrons. V[1]. *Electronic Effect in Arylcarbinols and a Preliminary Note on the Interaction in Benzylaniline Derivatives*

By Michinori Ōki and Hiizu Iwamura

(Received March 17, 1959)

It has long been in question why absorption due to the O–H stretching vibration of benzyl alcohol or allyl alcohol appears at about 3620 cm^{-1}. However, from the standpoint of the rotational isomerism, the interaction between the hydroxyl group and the π-electrons will be a valuable explanation for the phenomenon, as suggested in the previous paper[1]. If the interaction is the real cause of the shift of the ν_{O-H} absorption, it is expected that the electron density of the carbon atom (C_1) to which the hydroxymethyl group is attached or the next (C_2) to it should have profound effect on the ν_{O-H} absorptions of arylcarbinols. Hence, fourteen meta- and para-substituted benzyl alcohols were prepared and their ν_{O-H} absorptions were determined with a grating spectrophotometer. Ortho-substituted benzyl alcohols are excluded because formation of the internal hydrogen bonding can not be avoided when an atom with a lone pair of electrons is involved.

Experimental

Measurement and Calculation.—They were carried out similarly as reported previously[2].

Materials.—The materials used for the measurement are known compounds, unless otherwise stated. Their physical constants agreed with those in the literature.

m-Cyanobenzyl alcohol.—It was prepared according to the procedure reported by Langguth[3]. Although he reported the compound as an oil, it boiled at 127~127.5°C/3 mm. and solidified to form colorless needles on standing. The melting point is 28~29°C.

m-Phenylbenzyl alcohol. — It was prepared by the lithium aluminum hydride reduction of *m*-phenylbenzoic acid. Although this compound has been reported[4] as syrup, it formed colorless needles, m. p. 55~55.5°C, on recrystallization from carbon tetrachloride—petroleum ether.

Anal. Found: C, 84.70; H, 6.59. Calcd. for $C_{13}H_{12}O$: C, 84.75; H, 6.57%.

m-Benzyloxybenzaldehyde.—To a sodium ethoxide solution prepared from 5.5 g. (0.24 atom) of sodium and 150 ml. of alcohol was added 24.4 g. (0.2 mol.) of *m*-hydroxybenzaldehyde followed by 27.8 g. (0.22 mol.) of benzyl chloride. The mixture was heated under reflux for five hours, cooled and filtered to remove insoluble materials. Evaporation of the solvent gave crystals which were recrystallized to colorless small plates, m. p. 52~53°C, from petroleum ether. Yield, 32.5 g. (82%).

Anal. Found: C, 79.29; H, 5.81. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

m-Benzyloxybenzyl alcohol. — To a slurry prepared from 1.5 g. (0.04 mol.) of lithium aluminum

1) Part IV: M. Ōki and H. Iwamura, This Bulletin, **32**, 950 (1959).
2) M. Ōki and H. Iwamura, ibid., **32**, 567 (1959).
3) St. Langguth, *Ber.*, **38**, 2062 (1905).
4) M. P. Adam, *Ann. Chim. Phys.*, **15**, 245 (1888).

hydride and 50 ml. of ether was gradually added 19.6 g. (0.1 mol.) of *m*-benzyloxybenzaldehyde in 50 ml. of ether and the mixture was stirred at room temperature for two hours. The excessive lithium aluminum hydride was decomposed by adding ethyl acetate in ether and finally the mixture was treated with dilute sulfuric acid. The aqueous layer was extracted with ether and the ethereal extract was washed with aqueous sodium hydroxide and dried over potassium carbonate. Fractional distillation furnished a colorless oil boiling at 160°C/3 mm. which solidified. Recrystallization from benzene-petroleum ether (3 : 7) gave the substance in colorless needles, m. p. 44.5~45°C. Yield, 16.0 g. (81%).

Anal. Found: C, 78.54; H, 6.70. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%.

N-(p-Methoxybenzyl)-p-anisidine. — A mixture of 3.0 g. of *N*-(*p*-methoxybenzylidene)-*p*-anisidine, 1 g. of Raney nickel T-4 catalyst[5] and 100 ml. of alcohol was stirred in an autoclave at 80~100°C with 100 kg./cm² initial pressure. The heating was discontinued after two hours and, after cooling, the catalyst was removed by filtration. Evaporation of the solvent afforded a crystalline residue which was recrystallized from petroleum ether. Colorless plates, m. p. 94.5~95.5°C, were obtained in 1.5 g. (50%) yield. The rather low yield must be attributed to the hydrogenolysis of the *p*-methoxybenzyl group, since the oder of *p*-cresol methyl ether was distinct in the hydrogenation product.

Anal. Found: C, 74.22; H, 7.23. Calcd. for $C_{15}H_{17}NO_2$: C, 74.05; H, 7.04%.

N-p-Methoxybenzylaniline.—It was prepared in an analogous way. Though the melting point of this material was reported as 64.5°C[6], it melted at 46~47°C (colorless plates from petroleum ether). Since the micro-analyses agreed with the calculated values, it seems that this is one of the polymorphs.

Anal. Found: C, 78.99; H, 7.18. Calcd. for $C_{14}H_{15}NO$: C, 78.84; H, 7.09%.

Results and Discussion

The apparent ν_{O-H} absorption curves of *p*-nitrobenzyl alcohol, *m*-cyanobenzyl alcohol, benzyl alcohol and *p*-benzyloxybenzyl alcohol are shown in Fig. 1. The selection was made because the para-nitro group is the most electron-attracting and the para-benzyloxyl group is the most electron-releasing group in respect of Hammett's σ values[7] among the compounds used in the present work and benzyl alcohol is an intermediate. *m*-Cyanobenzyl alcohol is also included because it gives two apparent maxima.

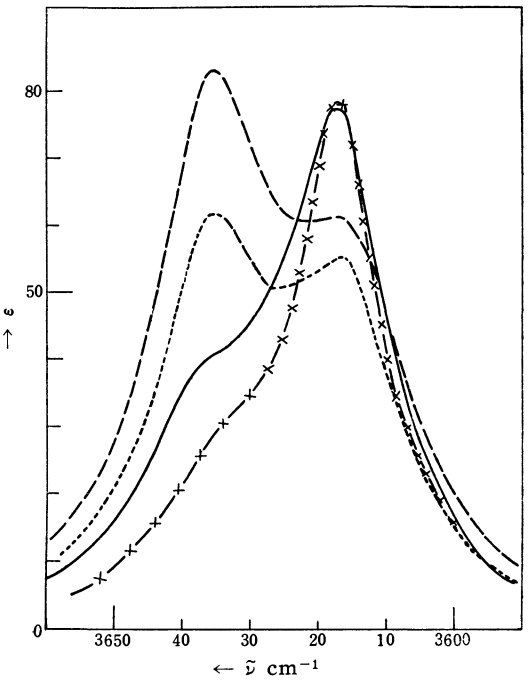

Fig. 1. ν_{O-H} absorption of *p*-nitrobenzyl alcohol (— — —), *m*-cyanobenzyl alcohol (--------), benzyl alcohol (- -) and *p*-benzyloxybenzyl alcohol (—×—).

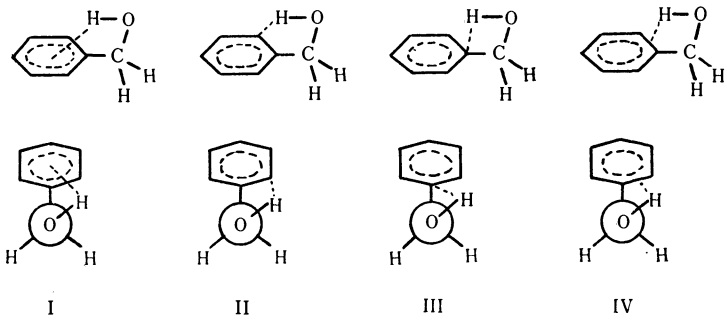
Introduction of an electron-releasing group such as a benzyloxyl group in the para position in respect of the hydroxymethyl group enhances the intensity of the band at 3617 cm^{-1} and an electron-attracting group such as nitro group in the para position enhances the band at 3636 cm^{-1}. Thus the main peak for the ν_{O-H} absorption of *p*-nitrobenzyl alcohol lies at ca. 3636 cm^{-1}. Splitting of the two bands into the two apparent maxima in *m*-cyanobenzyl alcohol will be a firm proof for the presence of the two ν_{O-H} absorption bands in benzyl alcohol derivatives. The results suggest that the number of molecules which possess internal interaction is greater in the benzyl alcohol with an electron-releasing group and this kind of electronic effect must be caused by the presence of the interaction between the hydroxyl group and the π-electrons, since such enhancement in the band intensities is naturally expected from the assignment suggested in the previous paper[1].



Now, when the internal interaction is taken into account, there are four possibilities in structure as shown in Fig. 2. The figures are presented both as sketches

I II III IV

Fig. 2.

and as projections through the O–C axis. The first (I) is the interaction between the hydroxyl group and the aromatic nucleus as a whole and this type of interaction was empirically quoted by Trifan and his co-workers[8] for α-hydroxyethylferrocene. In the second case (II), the direction of the hydrogen atom of the hydroxyl group points to the carbon atom (C_2) or the π-electron on C_2. This type of interaction has not been suggested, but the suggestion by Lüttke and Mecke[9] for 2-hydroxybiphenyl may fall into this category. In the third (III), the hydrogen atom of the hydroxyl group points to C_1 of the benzene nucleus or the π-electron on C_1. This type of interaction was implied by Goldman and Crisler[10] for phenethyl alcohol derivatives. The fourth case (IV) is the interaction in which the hydrogen atom turns toward the midst of C_1 and C_2, and the overlapping π-electrons on C_1 and C_2, take part in the interaction. The last case was suggested by Baker and Shulgin[11] for *o*-allylphenol and *o*-propenylphenol. Structures I and IV are considered as sorts of π-complexes and structures II and III σ-complexes.

Since the above assignments of the structures are all empirical, it is necessary to assign the structure on the basis of the experimental results. Now it can be hoped that the nature of the interaction may be clarified by changing the substituent on the benzene nucleus, because it is known, as mentioned above, that the interaction is markedly affected by the introduction of certain kinds of substituents. The same substituent was introduced into meta and para positions in respect of the hydroxymethyl group, because electron density on C_2 caused by a substituent in the para position should be roughly reproduced[12] on C_2 by introducing the same substituent into the meta position to the hydroxymethyl group.

If the π-complex (I or IV) is the real case, there should not be much difference between the two arylcarbinols which possess the same substituent, since the electron density of the aromatic ring as a whole must be the same and that in the middle of the two carbon atoms (C_1 and C_2) is considered to be nearly the same, although the effect of the substituent may be seen because of the different electron densities. If II is the case and an electron-releasing group is introduced, the meta-substituted benzyl alcohol would have a stronger absorption band at 3617 cm^{-1} than the para-substituted isomer, because the electron density on C_2 is higher in the meta-substituted compound than in the para-substituted one. And if III is the case, the situation must be opposite to that stated in case II and a compound with an electron-releasing group in the para-position to the hydroxymethyl group must have stronger absorption at 3617 cm^{-1} than the meta-substituted one.

The actual absorption curves are divided into two, assuming that the curves are the overlap of two symmetric bands which are expressed by the Lorentz function and the half widths and the integrated intensities are shown together with absorption maxima in Table I.

As is seen from Table I, an electron-releasing group in the para-position to the

12) In addition to the effect given by σ_p, we must consider σ_o because the ortho positions to the hydroxymethyl group correspond to ortho and para positions to a new substituent for meta-substituted benzyl alcohol. Therefore, the electron density on C_1 or C_2 is different, even if the effect of the hydroxymethyl group is neglected.

* i: denotes interacted form of the hydroxyl group.
** f: denotes free form of the hydroxyl group.
*** Taken from reference 1.

hydroxymethyl group enhances the intensity of the band at 3617 cm^{-1} more than one in the meta position and the tendency is opposite when an electron-attracting group is introduced. This fact excludes the possibility of structure I, II or IV. Hence it is concluded that the interaction between the hydroxyl group and the π-electrons of the aromatic nucleus in benzyl alcohol is of the type expressed by structure III.

The consistency of the wave number (3615.9~3617.4 cm^{-1} and 3635.2~3636.8 cm^{-1}) at which two absorption maxima exist is another proof that the origin of the bands is the rotational isomers, because in phenethyl alcohol derivatives the shift of the wave number, where an absorption of the interacted form appears, is observed[13].

The sum of the integrated intensities of the two bands is not always constant and there is a tendency that a more electron-attracting group gives rise to greater integrated intensity, as has been observed in substituted phenols[14]. However, when $\log \frac{A_i/A_f}{(A_i/A_f)_0}$, where A_i is the integrated intensity of the absorption band due to the interacted form, A_f that of free form and $(A_i/A_f)_0$ is the ratio given by benzyl alcohol, is taken into consideration, this value would represent the equilibrium constant and is in linear relation with

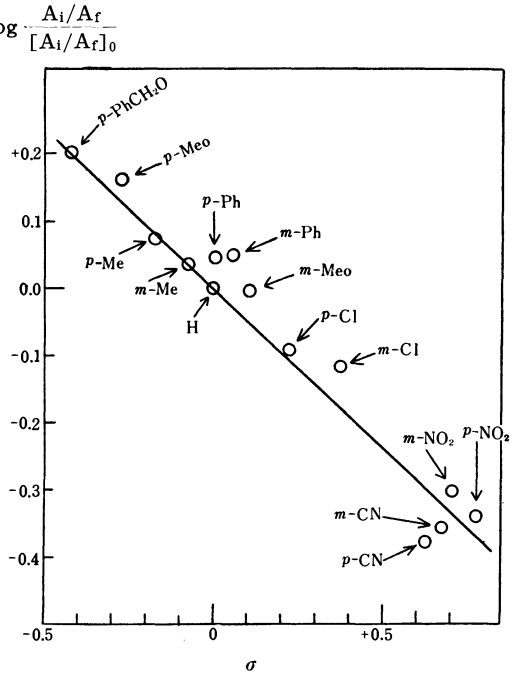

Fig. 3.

Hammett's σ values (Fig. 3). This linear relationship result is again a strong support to the idea of the existence of structure III. Although σ value for the *m*-benzyloxyl group has been unknown, it is now estimated from Fig. 2, by pointing 2.11 on the straight line and projecting to the σ axis, as -0.204.

A similar situation is expected for benzylaniline derivatives, which showed two distinct maxima for N-H stretching 30~40 cm^{-1} apart. The data are given in Table II.

It is understood from Table II, 1) that higher electron density on the benzene nucleus enhances the N-H stretching band at lower wave number, 2) that ν_{N-H} absorption shifts to lower wave number as Colichman & Liu[15] and also Krueger & Thompson[16] have pointed out for the arylamines, and 3) that $\Delta\nu_{max}$ is greater when the basicity of the arylamine increases. The full discussion will be presented in the near future.

Summary

Absorption due to the O-H stretching vibration in the fundamental region was measured with fourteen benzyl alcohol derivatives to see the electronic effect of the substituent on the interaction between the hydroxyl group and the π-electrons and the following conclusions are deduced.

1) The nature of the interaction or the structure of the molecule which gives rise to the ν_{O-H} absorption at 3617 cm^{-1} is discussed and the interaction between the hydroxyl group and the π-electron on the carbon atom to which hydroxymethyl group is attached (structure III) is favored.

2) The consistency of the wave numbers at which two ν_{O-H} absorptions appear, gives further support to the idea that these absorptions originate in the existence of the two rotational isomers.

3) $\mathrm{Log}\dfrac{A_i/A_f}{(A_i/A_f)_0}$ is in linear relation with Hammett's σ values and the σ value of the *m*-benzyloxyl group is estimated as -0.204.

A similar phenomenon is also observed in the substituted benzylanilines.

The authors are indebted to Professor Y. Urushibara and Professor T. Shimanouchi for their valuable advice and encouragement throughout this work, and their thanks are also due to the Ministry of Education for a Grant in Aid for the Fundamental Scientific Research.

Resonance Effect in Hammett Relationship. I. The Substituent Effect in the Acid Catalyzed Decompositions of ω-Diazoacetophenones in Acetic Acid

By Yuho TSUNO, Toshikazu IBATA and Yasuhide YUKAWA

(Received January 28, 1959)

As reported in a previous paper, the Curtius rearrangement of substituted benzazides in toluene did not give a linear Hammett relationship[1], whereas, the decomposition catalyzed by sulfuric acid[2] showed an approximately linear one, which had the negative ρ value. In such an electrophilic reaction, as has been pointed out frequently[3-7], electron releasing para substituents would favor the rate to a greater extent than would be expected from the normal Hammett constants. The same may be anticipated in this reaction. *p*-Hydroxyl and *p*-methoxyl groups indicated the tendency of some higher acceleration, but the scatters of the other groups, especially *p*-nitro group, made it impossible to ascertain this trend. The detailed re-examination as never improved the result. The acid catalyzed solvolytic decomposition of ω-diazoacetophenones is an electrophilic reaction of similar type. Hence, one might anticipate that para substituted derivatives probably show a similar behavior to what is seen in other electrophilic reactions. Furthermore, the rate changes of this reaction might suggest the contribution of substituents at least in such a reaction of which the substituent effects are transmitted through a carbonyl group to an electron deficient reaction center. Lane and coworkers[8], in their study of the substituent effect of this reaction, reported that the rate fitted the Hammett equation, whereas the effect of strongly electron releasing groups has not been reported. Therefore, kinetic study of decomposition of various substituted ω-diazoacetophenones was carried out in acetic acid, and the results are discussed on the basis of the Hammett relationship.

Experimental

Materials. — Substituted and unsubstituted diazoacetophenones used in this investigation were prepared by the usual procedure[8,9]; all benzoyl chlorides reacted satisfactorily with an excess of diazomethane in ethereal solution with cooling. After this solution was allowed to stand overnight at room temperature, the solvent was removed in vacuo and the residue was collected. Several recrystallizations from ligroin or benzene solution gave pale yellow crystals. The melting points of the diazoketones thus obtained are listed in Table I, together with the boiling points of the starting benzoyl chlorides.

Solvent. — Acetic acid was purified by the same method as that described in a previous paper[2]; b. p. 117.5~118.0°C.

Kinetic Experiments.—The rates of decompositions were determined in 75 ml. of anhydrous acetic acid at 40.00±0.01°C, by collecting the evolved nitrogen by an azotometer. The procedure and the apparatus were the same as those described in several recent papers[1,2,8]. The solution was not stirred but powdered glass was added to the solution in order to prevent the supersaturation of nitrogen gas evolved. In each run, the initial concentration of diazoketone was about 1/200 mol. Volume readings were taken covering the extent of 75% completion of reaction. The infinity reading was determined at the time after a period of 9—10 times as much as the half life of the reaction. The measurements were repeated at least three times for respective diazoketones in order to minimize the experimental error. The total volume of nitrogen collected was close to the theoretical amount. The change in the initial concentration did not show any effect on the rate.

Reaction Product. — The reaction solution was allowed to remain at 40.00°C in a bath until no further evolution of nitrogen occurred, and then the solvent was removed in vacuo. The

residues were recrystallized several times from ligroin or ethanol solutions. The corresponding phenacyl acetates having sharp melting points were obtained in quantitative yield (Table I). In the case of *m*-CH_3 and *m*-Br derivatives, the residues were not solidified.

Results and Discussion

The evolution of nitrogen followed strictly the first order equation

$$0.4343 \times kt = \log V_\infty - \log(V_\infty - V)$$

where V_∞ is the volume reading at the infinite time and V the readings at time t. Typical runs of the evolution of nitrogen are given graphically in Fig. 1. The rate constants obtained at 40.00°C are listed in Table II. The average deviations less than 0.7% are obtained in respective runs and the reproducibility of the results is estimated to be about 1%. Some of the rate constants obtained in the present study are slightly lower than those obtained by Lane et al.[8] This appears to be attributable to the difference of acetic acid used as solvent or that of the methods evaluating rate constants.

The mechanism of this reaction proposed is possibly represented as follows:

$$C_6H_5COCHN_2 \xrightarrow{H^+} C_6H_5COCH_2N_2^+$$

$$C_6H_5COCH_2N_2^+ + CH_3CO_2^- \rightarrow C_6H_5COCH_2{-}OCOCH_3 + N_2$$

the first step is the protonation (presumably reversible process) of diazoketone and the second is the rate determining decomposition of the protonated ketodiazonium ion to the acetate. With regard to the second step, two types of mechanism are possible; one is the unimolecular loss of nitrogen followed by the reaction with solvent of the carbonium ion so produced, another is the bimolecular reaction with solvent or acetate ion. Lane et al. suggested the latter one[8].

It will be of interest to discuss the substituent effects on the basis of the Hammett equation[10]. As is shown clearly in Fig. 2, the plot of log *k* against the corresponding Hammett σ-constants fails to give a linear relationship but concaves upward, in contrast to the result by Lane et al.[8] Only with respect to meta substituents and the *p*-nitro group, the linear correlation is obtained. The slope of this correlation line, the ρ_m value, is evaluated using the method of least squares[11] to be −0.830, the probable error of the fit 0.010 in log *k* and the correlation coefficient 0.999. On the other hand, the plots of log *k* vs. σ for para groups lie substantially above the meta line. The deviations appear to be entirely significant in view of the experimental uncertainty.

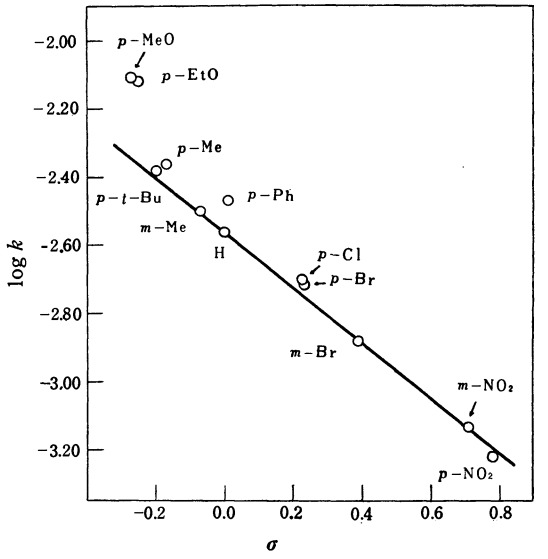

Fig. 2. The Hammett equation applied to the decomposition of ω-diazoacetophenones in acetic acid at 40.00°C.

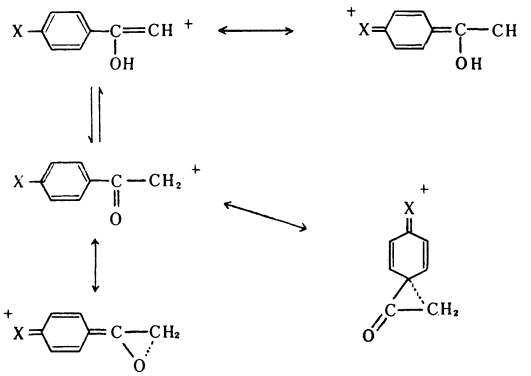
The above results are not unusual but may be reasonable at least in qualitative consideration. Although the Hammett equation correlates the rates or equilibria of an enormous number of reactions[10,11], some limitations have been noted. One of the limitations is the electrophilic reactions providing the deviations of the plots for electron releasing para substituents such as methoxy, methyl, phenyl and halo groups. In general, these groups show greater electron-release than described by the normal σ-constants in an electrophilic reaction[3-7]. The upward curvature of the plots for these groups is reasonably attributed to differing capacities of the substituents for resonance stabilization of a positively charged transition state. The same considerations as noted above might be employed in the case of the present reaction. If the upward deviations are referred to the resonance capacities, the transition state of this reaction must have a positively charged reaction center, and the charge must be, if possible, delocalized through resonance interaction. This appears to suggest that the driving force of the present reaction may be the elimination of the nitrogen molecule, followed by the attack of acetate ion upon the carbonium ion so produced.



$$C_6H_5{-}CO{-}CH_2N_2^+ \rightarrow C_6H_5CO{-}CH_2^+ + N_2$$

$$\xrightarrow{OAc^-} C_6H_5COCH_2OAc$$

Although this is somewhat inconsistent with Lane's conclusion, this consideration might be reasonable because the decomposition of the diazonium ion into nitrogen and carbonium ion undoubtedly does not

have high energy requirements[12]. At least the pull factor of the leaving nitrogen may predominate over the push of the attacking species, because of the high stability of the nitrogen molecule. The positive charge so produced at the reaction center would be delocalized through the resonance with powerfully electron releasing aryl groups;

These are consistent with the present data qualitatively. Then, it will be of further interest to treat the deviations in quantitative manner.

The Quantitative Treatment. — The recent advance in this field has prompted us to some attempts to correlate electrophilic reactions with an alternative set of substituent constants. These new substituent constants are denoted by σ^+[13]. Although a number of tentative sets of σ^+ have been proposed by various authors, it is Brown and Okamoto's set[6] that is apparently the most decisive one of general applicability. In Fig. 3 is demonstrated the correlation of present data with Brown and Okamoto's set of σ^+. Least squares treatment[11] indicates that the ρ^+ value, the slope of the regression line, is equal to -0.736 ± 0.0246, the correlation coefficient being 0.994. Brown and Okamoto's set of σ^+ correlates the present data more appropriately than does the normal Hammett constant, whereas it is worthy of remark that all the points for para substituents fall below the ρ_m line to a considerable extent. The ρ^+ value is clearly lower than ρ_m value. This would indicate that the σ^+ values employed for para substituents somewhat overcorrect the present situation. Furthermore, it might possibly be attributed to less availability of the *transition state resonance* of the present reaction than that described on the basis of σ^+. However, this is not surprising, because the contribution of resonance would not always be constant but would vary from reaction to reaction. Such failure of the linear relationship using the set of σ^+ is frequently observed. Some of the examples are provided by the solvolysis of neophyl brosylates[14] in which the resonance effect is less effective than described by Brown and Okamoto's σ^+ values, and the brominolysis of benzeneboronic acids[15] in which the contribution of *transition state resonance* appears greater

than the estimated. Hence, it is the exsistence of a unique set of σ^+ that would be rather surprising in itself.

On the other hand, through Deno's set of σ^+ [5] the present data can be correlated more successfully than through Brown and Okamoto's, as shown in Fig. 4. The ρ^+ value of this correlation is equal to -0.789 ± 0.024, the correlation coefficient being 0.996. It is evident that the points for para substituents come closer to fitting on the ρ_m line, while the ρ^+ value is not strictly equal to the ρ_m value. The set defined by Pearson from the Beckmann rearrangement[16] also gives a rather more satisfactory result for the present reaction than does Brown and Okamoto's set, although this has not been reported to show any applicability. These facts appear to indicate that the respective sets of σ^+ may be applicable only to respective limited regions of electrophilic reaction series. Then, it would be by no means meaningless to set up tentative σ^+ values from the present reaction. This is encouraged by the success of linear free energy relationship between present data

and the solvolysis rates of neophyl brosylates[14], as shown in Fig. 5. The new set of σ^+ is given in Table III, along with the values of other sets of substituent constants. The present set does not appear to be applicable to a great many reactions. In some cases, however, it does describe a better correlation than does Brown and Okamoto's. Fig. 6 exhibits the correlations of the Beckmann rearrangement of acetophenone oxime picryl ethers[17] with the present set and with Brown and Okamoto's σ^+. Some other reactions which are satisfactorily correlated by the present set are as follows: the acetolysis of neophyl brosylates[14], the Beckmann rearrangement of acetophenonoximes[16], Diels-Alder reaction of 1-phenyl-1, 3-butadienes with maleic anhydride[18] and acid catalyzed rearrangement of phenylpropenylcarbinols[19].

A particular interest is seen in Table III. For each substituent, σ^+ values become more negative in the following order; the present set $<$Deno's $<$Brown and Okamoto's. The correction relative to the normal substituent constant is great in magnitude in Brown and Okamoto's, small in Deno's and smaller in the present set of σ^+. This parallels presumably the degree of resonance stabilization of electron deficient transition states in respective reference reactions, if the other factors remain constant throughout respective substituted derivatives. Thus, the resonance contribution of substituents would be more important in Brown and Okamoto's reference reaction than in Deno's and of even greater importance than in the present reaction. This is consistent with the facts that in Deno's reference reaction, the dissociation of triphenylcarbinols, the charge delocalization is shared separately by three aryl groups and in the present reaction the resonance contribution of a substituent group is reduced through the carbonyl group.

All one can say is that the σ^+ is not essentially constant but variable with respect to the change in reaction. *Rho—Sigma*$^+$ equation should be applied to the limited reaction series in which the availability of *transition state resonance* is equivalent to that in respective reference reactions. Now, it is highly desirable to correlate these sets of σ^+ with a simple relationship, which will be described in Part II.

The authors are indebted to Mr. T. Shishido for performing microanalysis.

Resonance Effect in Hammett Relationship. II. Sigma Constants in Electrophilic Reactions and their Intercorrelation

By Yasuhide YUKAWA and Yuho TSUNO

(Received January 28, 1959)

Recently, Brown and Okamoto have demonstrated a practical success in correlating various electrophilic reactions by a single set of σ^+ [1,2], obtained from the substituent effects in solvolysis of phenyldimethylcarbinyl chlorides. Their treatment should involve the assumption that the substituent effects in electrophilic reactions remain constant relative to marked variation in the ρ value. This is inconsistent with our view[3] that the reasonance interactions by a para substituent would depend greatly on the nature of the reactions, so that the effects

1) H. C. Brown and Y. Okamoto, *J. Am. Chem. Soc.*, **79**, 1913 (1957); Y. Okamoto and H. C. Brown, *J. Org. Chem.*, **22**, 485 (1957).

in electrophilic reactions could not possibly be correlated with a unique set of σ^+. The present view may be reasonable and perhaps the general one[4,5]. Brown and Okamoto's view could be confirmed by the identity of σ^+ values independently derived from other reactions. However, the various sets of σ^+ are varied significantly with respect to changes in the reference reaction[3,6-11]. The reported fact that the σ^+ constant derived from the decomposition of ω-diazoacetophenones differed from the corresponding Brown and Okamoto's[3] constant may afford evidence in favor of the present view.

The variations of σ^+ value for a given para substituent are generally referred to different availabilities of the resonance in various reference reactions, if other factors are maintained constant. On the other hand, failure of the linear $\rho\sigma^+$ relationship could be attributable also to the change in mechanism in a reaction series[12]. Brown has quoted[1], as an example, the solvolysis of benzyl tosylates[5,7], in which the change from S_N1 to S_N2 mechanisms occurred through changes of substituent. In the decomposition of diazoacetophenones, it may be possible to consider that the dissociation of nitrogen molecule competes with the attack of acetate ion in the driving force of the reaction[3]. If this was true, both mechanisms should indicate different responses to the ionizing power of the medium possibly because the stabilization of the carbonium ion produced will be important only in the former mechanism. Therefore, the substituent effects may be sensitive to the changes of solvent. Accordingly, kinetic study of the decomposition of diazoacetophenones was carried out in 75% aqueous acetic acid solution at 25.20°C, in order to confirm the reliability of our σ^+ values.

To the completion of this study, the foregoing view has been concreted and our attention has been directed to correlate empirically these independent sets of σ^+ according to a simple but reasonable relationship. In this paper, the results of the kinetics and of an approach to the correlation of σ^+ are presented.

Experimental

All diazoacetophenones were prepared by the procedure described in the preceding paper[3]. The stock solvent was made up by mixing 75 parts by volume of acetic acid with 25 parts by volume of distilled water. Acetic acid was purified by the usual method[13] and carefully fractionated, b. p. 117.5~118.0°C.

Rate Measurements. — The rates of the decomposition were determined by following the rate of evolution of nitrogen. The apparatus and the procedures were similar to those described in previous papers[3,14]. The temperature of the reaction bath was controlled to 25.20°C within an accuracy of ±0.01°C. Measurements were carried out in 75 ml. of aqueous acetic acid. The quantitative amount of nitrogen was obtained by the decomposition of respective derivatives of diazoacetophenone in aqueous acetic acid at 25.20°C. The rate of evolution of nitrogen followed strictly the first order kinetic law. Individual runs showed average deviations of far less than 1%, and duplicate runs gave rate constants agreeing within 2% or better. *p*-Phenyl-, *p*-bromo- and *m*- and *p*-nitro derivatives are soluble with greater difficulty in this solvent at this reaction temperature than in anhydrous acetic acid. Nitro derivatives were warmed with vigorous shaking at about 40°C to complete dissolution, prior to measurement. But this could not be applied to other derivatives, because of their high reactivities. *p*-Phenyl derivative is far less soluble in this solvent and deviation from the first order kinetic law was observed. The calculated rate constant increased gradually as the reaction proceeded and reached a constant value at 60% completion of the reaction. The rate constants obtained are summarized in Table I.

Results

As listed in Table I, rates of the decomposition of diazoacetophenones are significantly increased in aqueous acetic acid relative to those in anhydrous acetic acid. Parallel to this, the sensitivity of the reaction to substituent effects appears to be considerably increased. Whereas the failure of the linear Hammett relationship is also observed in the aqueous medium just as in the case of an anhydrous medium[3]. Electron releasing para substituents supply higher acceleration than would be anticipated by the normal Hammett relationship (Fig. 1). Such a result has been discussed by us[3] and a number of other authors[1,2,4-12] and needs no further elucidation.

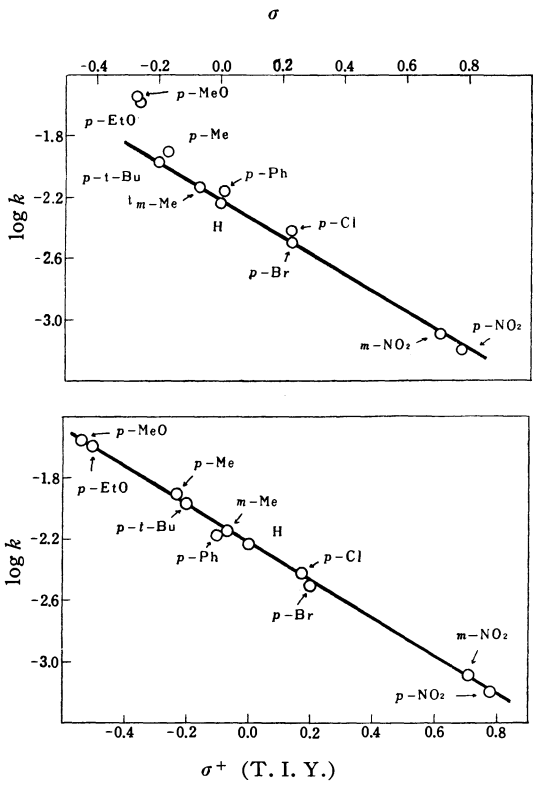

Fig. 1. Plot of the present data against the ordinary σ and our σ^+ constants.

In both reactions, the substituent effects would presumably be invariant, if the transition state remains approximately constant through changes of solvent. An evidence for the identity of substituent effects would generally be provided by a linear relationship between the corresponding $\log k/k_0$ of the two reactions. In fact, all the experimental points of $\log k/k_0$ in aqueous acetic acid fall just on the line expected from the $\log k/k_0$ in anhydrous medium. The correlation is given by an equation

$$\log (k/k_0)_{aq} = 1.510 \log (k/k_0)_{anhyd}$$

This indicates that the changes of medium reflect only ρ value and the substituent effect is not varied in either medium. The above correlation can of course be rewritten in terms of our σ^+ values[3] (Fig. 1). Statistical treatment[15] gives a correlation 1,

$$\log (k/k_0) = (-1.253 \pm 0.020)\sigma^+ \qquad (1)$$

The standard deviation of experimental $\log k$ from the best line is 0.027 and the correlation coefficient is 0.999. The ρ^+ value is closely equal to the ρ_{meta} value, 1.237 ± 0.018, which was obtained from points for m-CH_3, m-nitro, p-nitro and unsubstituted derivatives. On the basis of this ρ^+ value (1), a new set of σ^+ values can be derived from the rates in aqueous acetic acid. They are given in Table II. The present values agree with the previous one. p-Phenyl and p-bromo groups differ considerably in magnitude from the foregoing ones[3]. These are of no doubt attributable to the lower solubilities in aqueous acetic acid (see, *Experimental*). The discrepancies of others are substantially contained within experimental uncertainty. As a result, it may be conclusively suggested that the σ^+ derived from the previous result describes the best situation of the substituent effect in this reaction. Then, it appears to be evidently confirmed that the changes in mechanism as suggested by Brown and Okamoto might not occur through substituent changes in this reaction, and also that the rise in reactivities

TABLE II. σ^+ CONSTANTS

of electron releasing para substituents could be attributable entirely to the increase of the resonance contribution.

These facts appear evidently to support the present view in preference to Brown and Okamoto's[1,2].

The linear free energy relationship would essentially hold in more or less limited reaction series in which the substituent effects are close to each other[3]. With the above considerations in mind, a given electrophilic reaction should be correlated with one of these sets of σ^+ most suitable to the resonance effects of substituents in it. However, it appears to be inconvenient practically. Therefore, it is necessary and desirable to correlate these independent sets of σ^+ with a relationship of practical use.

Discussion

The substituent effect can generally be treated as the sum of independent contributions of inductive and resonance components[16]. The former contribution refers to the electron distribution through the *sigma* bonds of a benzene nucleus and the latter to the electron delocalization through the resonance interaction of a substituent with the benzene *pi* electron system. An ordinary Hammett σ constant could be represented according to Eq. 2,

$$\sigma = \sigma_I + \sigma_R \qquad (2)$$

where σ_I is an inductive effect and σ_R is a so-called *resonance polar effect*[16]; σ_R represents the substituent contribution through resonance with the benzene *pi* bonds to the electron density on the nuclear carbon atom at which the functional group is attached.

The substituent effect should be essentially independent of the reaction, whereas it is not always invariant, causing failure of the Hammett linear free energy relationship. The variation of substituent effect would be attributed only to the changes in contribution of the resonance component. The inductive component, the electron distribution through *sigma* bond, should essentially remain constant. The *resonance polar effect* may also be independent of the nature of reactions. However, the resonance component will no longer remain constant in the case of electrophilic reactions. The large electron demand produced at the reaction center of transition state must be delocalized[1-9]. This could be dissipated by the aid of the resonance interactions with electron releasing para substiuents through benzene *pi* orbitals. Then, the resonance effect becomes far greater than the ordinary *resonance polar effect*, σ_R, and σ^+ values result from this reason.

Brown and Okamoto's set of σ^+ may be represented[1]

$$\sigma^+ = \sigma_I + \sigma_R^+ \qquad (3)$$

where σ_R^+ is a resonance effect in the Brown and Okamoto's reference reaction[1,2]. Other authors' sets of σ^+ are also treated in the same manner, although the σ_R^+ are by no means invariant of reactions. In general, the quantity σ_R^+ should be a variable and a function of the resonating capacity of substituent with the electron deficient reaction center through the benzene *pi* electron system. Since σ_I may undoubtedly remain constant through the changes of reaction type[16], the attention could be centered on the changes of σ_R^+. Inductive effect can be eliminated, combining Eqs. 2 and 3

$$\sigma^+ - \sigma = \sigma_R^+ - \sigma_R \equiv G(R) \qquad (4)$$

Here, the quantity $\sigma^+ - \sigma$ should be a function of the resonance effect only, and this quantity just describes the magnitude of respective deviations of para substituents from the meta correlation line. Consequently, it may be anticipated that the analysis of the function $G(R)$ could provide a key to correlate the various sets of σ^+. The formulation of $G(R)$ will be realized practically by tracing changes of the quantity $\sigma^+ - \sigma$.

In actual practice, Brown and Okamoto's and Miller's quantities are plotted linearly against the corresponding quantities of the decomposition of diazoacetophenones, as illustrated in Figs. 2 and 3. These correlations are given by the following equations:

$$(\sigma^+ - \sigma)_{\text{Brown, Okamoto}} = 1.847(\sigma^+ - \sigma)$$

and

$$(\sigma^+ - \sigma)_{\text{Miller}} = 3.185(\sigma^+ - \sigma)$$

The standard deviations of the fits are ± 0.015 and ± 0.007, respectively. Then, the substituent effects in the decomposition of diazoacetophenones can be reproduced

16) R. W. Taft, Jr., in Newman's "Steric Effect in Organic Chemistry", Chapt. 13, John Wiley & Sons, Inc., New York (1956). R. W. Taft, Jr., *J. Am. Chem. Soc.*, **74**, 2729 (1952); ibid., **74**, 3120 (1952); ibid., **75**, 4231 (1953); ibid., **79**, 1045 (1957); R. W. Taft, Jr. and I. C. Lewis, ibid., **80**, 2436 (1958). Y. Yukawa and Y. Tsuno, "Yuki Hannokiko no Shimpo (Recent Advances in the Mechanism of Organic Reactions)", Vol. I, Maki Publishers, Inc., Tokyo (1958), p. 1.

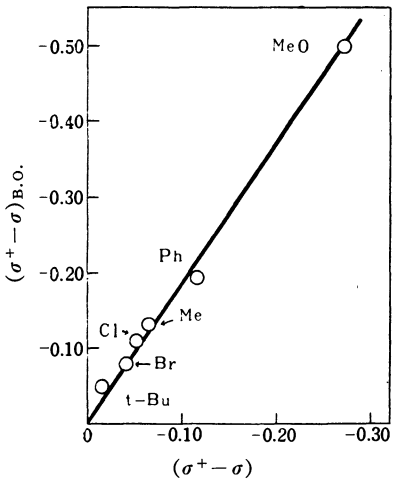

Fig. 2. Plot of Brown and Okamoto's quantity, $\sigma^+-\sigma$, against our quantity.

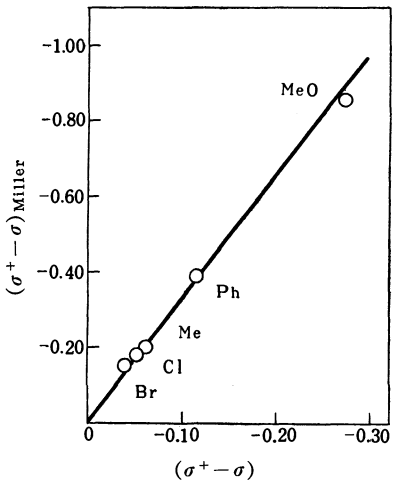

Fig. 3. The correlation between Miller's and our quantities, $\sigma^+-\sigma$.

precisely from various sets of σ^+. This may afford an indirect bit of evidence of our previous discussion of this reaction[3].

Furthermore, strictly linear correlations are observed in respective pairs of other sets of σ^+, as shown clearly in Figs. 4 and 5. These are represented as follows:

$$(\sigma^+-\sigma)_{Brown,\ Okamoto}=0.576(\sigma^+-\sigma)_{Miller}$$

$$(\sigma^+-\sigma)_{Brown,\ Okamoto}=1.347(\sigma^+-\sigma)_{Deno}$$

and

$$(\sigma^+-\sigma)_{Deno}=0.456(\sigma^+-\sigma)_{Miller}$$

The standard deviations are 0.015, 0.002 and 0.025, respectively. Then, these correlations can be held covering a wide range of substituent changes, especially, the last one covers the range from *p*-alkyl to *p*-dimethylamino groups. The same is

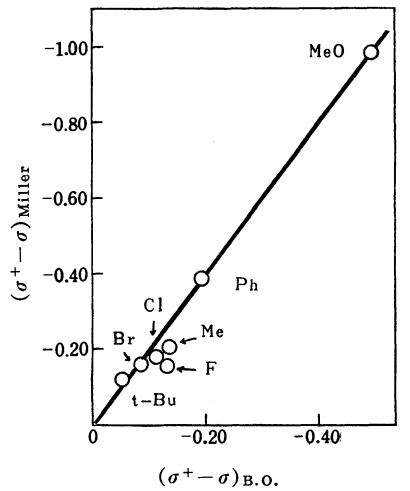

Fig. 4. Correlation of Miller's quantity, $\sigma^+-\sigma$, with Brown and Okamoto's one.

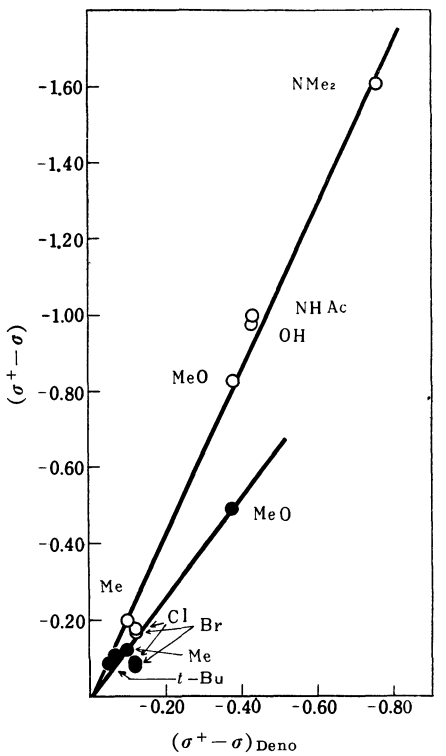

Fig. 5. Correlations of Miller's and Brown and Okamoto's quantities, $\sigma^+-\sigma$, with Deno's one: Open circles, Miller's and closed, Brown and Okamoto's.

true in the case of other sets, such as Packer's[11] and Pearson's[6].

As a conclusion, the function $G(R)$ can be regarded, to a first approximation, as a linear function of the quantity, $\sigma^+-\sigma$. Consequently, the general relationship 5 may be established empirically

a) The value calculated on the basis of our σ^+ value (Ref. 3).
b) Calculated from Miller's set of σ^+ (Ref. 10).
c) The value obtained from Deno's set of σ^+ (Refs. 7 and 8).
d) The value on the basis of σ^+ given by Packer et al. (Ref. 11) from the ethanolysis rates of benzhydryl chlorides (E. D. Hughes, C. K. Ingold and N. A. Taher, *J. Chem. Soc.*, **1940**, 949).
e) Calculated from Norris and coworkers' data on the solvolysis of benzhydryl chlorides in absolute ethanol (J. F. Norris and C. Benta, *J. Am. Chem. Soc.*, **50**, 1804 (1928); J. F. Norris and J. T. Blake, ibid., **50**, 1808 (1928): see, the forthcoming paper, (Y. Yukawa and Y. Tsuno, This Bulletin, **32**, 971 (1959).).
f) Brown and Okamoto's σ^+ value (Ref. 1).
g) The r value in the relationship 5; the proportionality constant of the quantity, $\sigma^+-\sigma$, to the corresponding one of Brown and Okamoto.
h) This value should essentially be equal to the difference of Brown and Okamoto's σ^+ from the ordinary Hammett σ constant. This could be regarded as a measure of the resonating power of respective substituents. This has been utilized successfully in regard to the resonance substituent constant, $\Delta\sigma_R^+$, and will be reported in a subsequent paper.
i) The value based on σ^+ obtained in the present study.
j) This group showed deviation from the correlation 5 setting r=1.847, and was omitted from the calculation. Such a deviation was observed in the Pearson's correlation of σ^+ (Ref. 6).
k) This group deviates seriously and was not included in the calculation.
l) Standard deviation.

$$(\sigma^+_A-\sigma)=r(\sigma^+_B-\sigma) \qquad (5)$$

where r is a parameter which remains constant in a reaction series but is a variable of reactions. This parameter may arise without doubt from differing contributions of the resonance effect in reference reactions.

The reliability of the approximation can be substantiated by the close agreement of calculated values on the basis of this relationship with an experimental one. This is clearly exhibited in the comparison of calculated with the experimental values of Brown and Okamoto's σ^+, as shown in Table III. Computed values for respective substituents are in accord with the experimental one, without serious exceptions. The averaged standard deviations of calculated values are estimated to be ±0.009. This is excellent as compared with the agreement of the comparision given by Deno[9], and by Brown and Okamoto[2]. Then, the results in Table III will possibly extend the utility of Brown and Okamoto's set to the substituents having no experimental σ^+ value in their scale.

Through these results, the particular

features of interest have arisen. As mentioned in the above discussion, the quantities $\sigma^+-\sigma$ may be regarded as a function of the resonance capacity of substituents. Therefore, the relationship 5 is in itself a linear resonance energy relationship. The σ^+ values, in turn, could be represented by the following relationship, using a proper set of the quantities $\sigma^+-\sigma$ in a single scale

$$\sigma^+=\sigma+r(\bar{\sigma}^+-\sigma)=\sigma+r\Delta\sigma_R^+$$

where $\bar{\sigma}^+$ is a correct set of σ^+ and $\Delta\sigma_R^+$ represents the standard set of the quantities $\sigma^+-\sigma$. Consequently, electrophilic reactions in general will possibly be correlated by a modified Hammett equation,

$$\log(k/k_0)=\rho(\sigma+r\Delta\sigma_R^+)$$

This has been realized by using the numerical values of $\Delta\sigma_R^+$ in Brown and Okamoto's scale. The utility of this relationship will be described in Part III.

The authors gratefully acknowledge the help of Mr. T. Ibata in the preparation of samples.

Resonance Effect in Hammett Relationship. III. The Modified Hammett Relationship for Electrophilic Reactions

By Yasuhide YUKAWA and Yuho TSUNO

(Received January 28, 1959)

As shown in Part II[1] of this series, the substituent constants in Brown and Okamoto's scale were derived for a number of electron releasing para substituents by correlating various sets of σ^+ [2-8]. These values will possibly extend the utility of the Brown and Okamoto's equation[2,10] over a wider range of substituent changes[1,5,10,11]. However, it is clear that the unique set of σ^+ does not always describe the best situation of substituent contributions in various reactions, even though Brown and Okamoto's σ^+ may have an apparent generality. It would be attributed to the changes in availability of the *transition state resonance* in various reactions. The resonance contribution of respective para substituents as well as the magnitude of σ^+ would not be maintained constant but varied from reaction to reaction[1]. Then, the Brown and Okamoto's and also other authors' sets of σ^+ [3-9] should be utilized respectively in the limited extent of reaction series[1,3].

Our success in correlating various sets of σ^+ by Eq. 1[1] appears to imply some suggestions in regard to the Hammett type treatment[12] of electrophilic reactions.

$$(\sigma^+{}_A - \sigma) = r(\sigma^+{}_B - \sigma) \qquad (1)$$

Here r is a proportionality constant, and $\sigma^+{}_A$ represents one of various sets of σ^+ and $\sigma^+{}_B$ another set of σ^+. In a given para substituent, the increments of various σ^+ values relative to the usual σ constant[12]

11) Brown has derived recently the averaged σ^+ values for *p*-NHe_2, *p*-NH_2 and *p*-OH, etc., from σ^+ values of other electrophilic reactions, while the agreement is by no means within satisfactory precision (Ref. 10). Deno's expansion of σ^+ in Brown and Okamoto's scale appears also to be unsuccessful (Ref. 5).
12) L. P. Hammett, *J. Am. Chem. Soc.*, **59**, 96 (1937); "Physical Organic Chemistry", McGraw-Hill Book Co., New York (1940), p. 194; H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

are possibly considered to be a function of its resonance ability. Then, the equation may be a linear resonance energy relationship. Therefore, it appears logical to extend this relationship to general electrophilic reactions combining with Hammett equation[12]. If the above relationship would hold in a variety of electrophilic reactions, the Hammett relationship for electrophilic reactions may be represented empirically according to Eq. 2,

$$\log k/k_0 = \rho(\sigma + r\Delta\sigma_R^+) \qquad (2)$$

where r is a reaction constant describing the degree of the transition state resonance or measuring the magnitude of positive charge to be necessarily stabilized at the transition state, and $\Delta\sigma_R^+$ which corresponds to a proper set of $\sigma^+ - \sigma$ is a substituent constant suggesting the resonating capacity of substituent. From the foregoing point of view, we are free to take one of various sets of the quantities $\sigma^+ - \sigma$ as a proper set of the $\Delta\sigma_R^+$.

The *resonance substituent constant*, $\Delta\sigma_R^+$, is now defined conveniently using the set of quantities $\sigma^+ - \sigma$ in Brown and Okamoto's scale[13]; i.e., the r is taken as unity in Brown and Okamoto's reference reaction, the solvolysis of aryldimethylcarbinyl chlorides in 90% aqueous acetone at 25°C,

$$\Delta\sigma_R^+ \equiv \sigma^+_{\text{Brown and Okamoto}} - \sigma \qquad (3)$$

Eq. 2 is undoubtedly to be satisfied by the reactions to which the Brown and Okamoto's equation was applicable, because the latter equation corresponds to the present Eq. 2 when r is equal to unity. The same is also certain in the electrophilic reactions which are correlated linearly with other sets of σ^+. The second term of Eq. 2 would vanish in the correlation of meta substituents, evidently because the Hammett relationship would hold in general electrophilic reactions as far as the mata substituents are concerned. Accordingly, ρ in Eq. 2 can be replaced by the ρ_{meta} value and the equation may be usually solved on the basis of ρ_{meta} value[14].

An empirical relationship should be required to examine critically the general applicability. Fortunately, in an enormous number of electrophilic reactions, satisfactory results have been realized in terms of this relationship. In the present paper, then, the results of application and generality of this relationship are described.

Correlation of Reactivities

In view of the origin of this relationship, it is a matter of course that the relationship should describe satisfactorily the substituent effect in the respective reference reactions, from which various sets of σ^+ were derived. These are clear in Figs. 1 and 2. The rates of decomposition of ω-diazoacetophenones both in acetic acid at 40.00°C[3] and in 75% aqueous acetic acid at 25.20°C[1] are reproduced strictly in terms of Eq. 2, setting r to be 0.556 and nearly the same value 0.60, respectively.

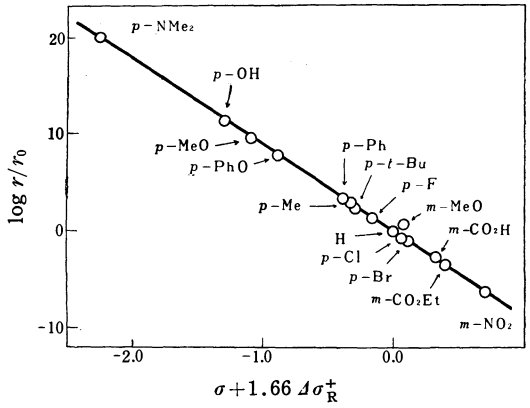

Fig. 1. Relative reactivities in halogenation of monosubstituted benzenes at 25°C (*3*).

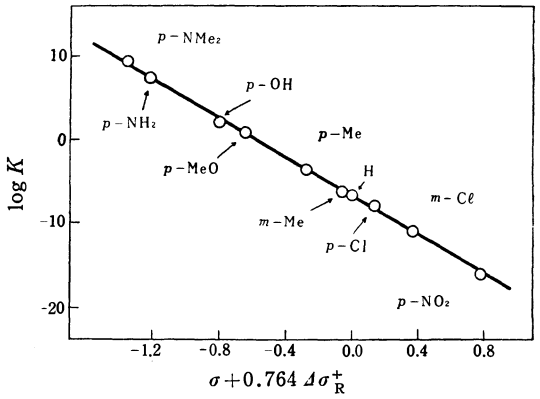

Fig. 2. Dissociation of triphenylcarbinols in sulfuric acid at 25°C (*22*).

13) A tentative set of $\Delta\sigma_R^+$ has been derived on the basis of Deno's reference reaction and applied preliminarily for several electrophilic reactions. [Y. Yukawa and Y. Tsuno, "Yūki Hannōkikō no Shimpo—Recent Advances in the Mechanism of Organic Reactions", (in Japanese) Vol. I, (1958), p. 1.]. However, the present definition of $\Delta\sigma_R^+$ in Brown and Okamoto's scale appears to be more available, in view of its frequent employment encountered in recent literatures.

14) Although various values of σ_{meta}^+ have been given by Brown and others (Refs. 2 and 10), the differences between σ^+_{meta} and σ_{meta} are of magnitude comparable to experimental error. Even if they were significant, the situation of the relationship is unaltered but ρ value must be calculated by solving the regression Eq. 4.

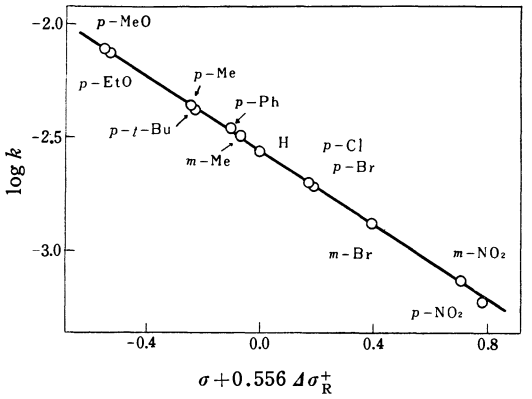

Fig. 3. Decomposition of ω-diazoacetophenones in acetic acid at 40.00°C (*25*).

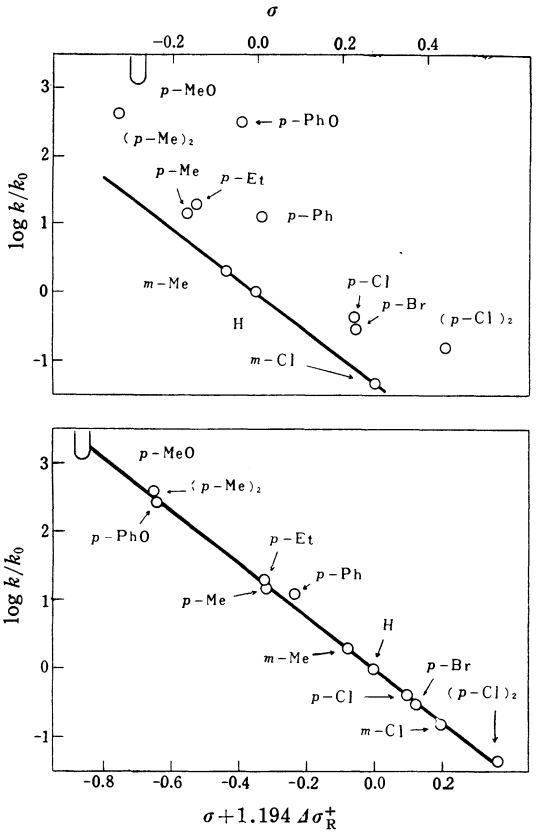

Fig. 4. Ethanolysis of benzhydryl chlorides at 25°C (*10*).

The Pearson's rate data of the Beckmann rearrangement[6] are also correlated in terms of $r=0.434$. The numerical values of $\Delta\sigma_R^+$ used are the one given in Table III of the foregoing paper.

A typical example of electrophilic reactions is the solvolysis of arylalkyl halides. Norris and coworkers[15] reported the ethanolysis rates of benzhydryl chlorides. The Hammett plots of para electron releasing substituents deviate markedly in the upper side of the meta correlation line. With regard to meta substituents, a linear Hammett relationship is obtained, and the slope, ρ_{meta}, is -3.72.

$$\log(k/k_0)_m = -3.72\,\sigma_{meta}$$

Using this ρ value, r is calculated to be 1.194. Then, the rates of the ethanolysis can be expressed by an equation

$$\log k/k_0 = -3.72(\sigma + 1.194\,\Delta\sigma_R^+)$$

In Fig. 4 is demonstrated the fine correlation of $\log k/k_0$ vs. $\sigma+1.194\,\Delta\sigma_R^+$. In the same manner, the rates of ionization of triarylcarbinyl chlorides to form the ion pairs

$$(C_6H_5)_3C\text{-}Cl \rightarrow (C_6H_5)_3C^+//Cl^-$$

in liquid sulfur dioxide[16] are correlated linearly. As is clear in Fig. 5, the correla-

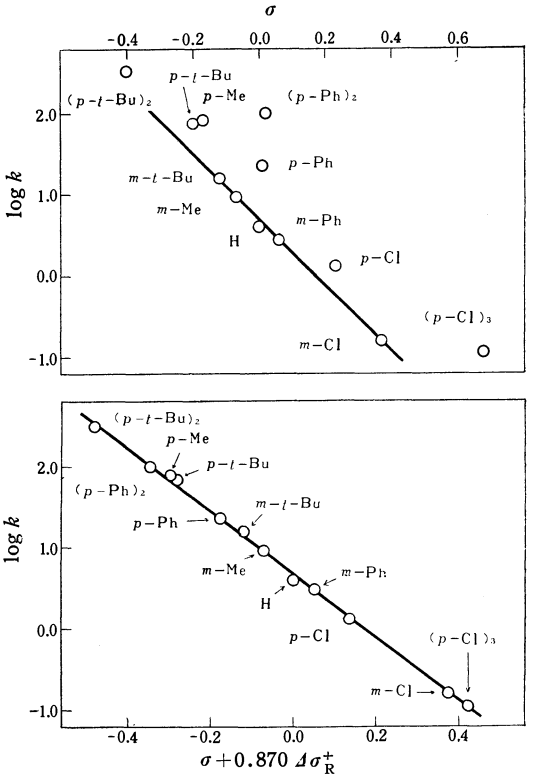

Fig. 5. Dissociations of triphenylcarbinyl chlorides in liquid sulfur dioxide at 0°C (*20*).

15) J. F. Norris and C. Benta, *J. Am. Chem. Soc.*, **50**, 1804 (1928); J. F. Norris and J. T. Blake, ibid., **50**, 1808 (1928).

16) N. N. Lichtin and M. J. Vignale, ibid., **79**, 579 (1957); N. N. Lichtin and P. D. Bartlett, ibid., **73**, 5530 (1951); N. N. Lichtin and H. Glazer, ibid., **73**, 5537 (1951); N. N. Lichtin and H. P. Leftin, *J. Phys. Chem.*, **60**, 164 (1956).

tion is fully satisfactory; $\rho=-4.046$ and $r=0.870$.

At the theoretical ground, the standard of correlation should be based on the meta correlation line, while there are relatively few adequate data which involve the rates of many meta derivatives. For the data involving a few rates of meta derivatives, the correlation is realized by solving the Eq. 4 for a and b on the basis of the method of least squares[17],

$$\log k = a\sigma + b\Delta\sigma_R^+ + \log k_0 \qquad (4)$$

where a and b correspond to ρ and $r\rho$, respectively. In this manner, the solvolysis rates of benzhydryl chlorides in methanol and in isopropanol[18] provide excellent correlations giving $r=1.234$ and 1.350, respectively. Similarly, the dissociation of identically substituted benzhydrols in sulfuric acid at 25°C[5] is correlated linearly in terms of $\rho=-9.112$ and $r=1.175$.

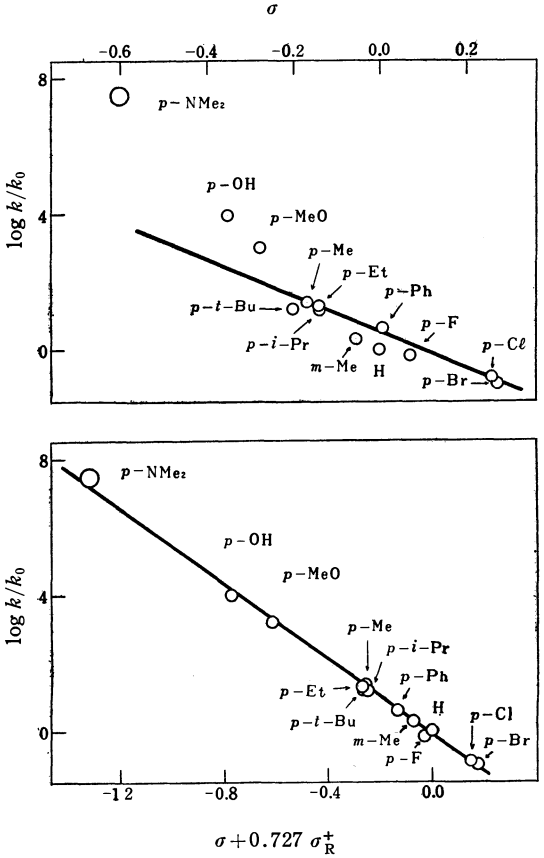

Fig. 6. Protodesilylation of phenyltrimethylsilanes (*23*).

The present treatment is successful not only in the solvolysis but in other types of electrophilic reactions, such as aromatic electrophilic substitutions. Recent data of the nitration[19] and the halogenation[6,20] of substituted benzenes, and protonolysis

of phenyltrimethylsilanes[21] (Fig. 6) are described satisfactorily. In the reactions quoted above, the Brown and Okamoto's relationship also results apparently but not strictly linear figures. This may be in accord with the fact that the r factors of these are considerably close to unity (see, Table I).

Recently, Winstein and coworkers[22] reported that the rates of acetolysis of neophyl brosylates failed to give a good result by the Hammett treatment, and also that the correlation was slightly improved by the Brown and Okamoto's. According to the latter treatment, para electron releasing groups fall below the meta line, contrary to the results of the

Hammett one. However, the present treatment produces a successful figure (Fig. 7) of this reaction, in terms of $r=0.542$. The Beckmann rearrangement of acetophenonoxime picrylethers[23] is correlated with Eq. 2, giving r to be 0.469, although the plot against Brown and Okamoto's σ^+ concaves downward. The rates of the rearrangement of phenylpropenylcarbinols[24] are of the same kind ($r=0.396$), as seen in Fig. 8. The resonance contribution of substituents in these reactions is estimated to be only a half of that in Brown and Okamoto's reference reaction. Therefore, it is natural that Brown and Okamoto's treatment overestimates the

a) The standard deviation of experimental points from the regression line.
b) The number of points involved in the calculation.
c) The correlation obtained on the basis of ρ_{meta} value which were derived from the rates for meta substituted and nonconjugating para substituted derivatives.
d) The correlation obtained in aid of Eq. 4.
e) The correlation obtained by setting a priori $r=1.000$.
f) The correlation of $r=2.05$ and $\rho=-4.31$ was resulted on the basis of Eq. 4.
g) *m*-Methoxy group was omitted from the correlation.
h) The point of *p*-carbethoxy group deviates considerably from meta line and was not included in the calculation of ρ_{meta} value.
i) The point for *p*-*t*-butyl group deviates seriously and was omitted from the calculation of *r* value.
j) *p*-Phenyl group supplies a greater driving force than that expected from this correlation.
k) *p*-Dimethylamino and *p*-phenyl groups were not included in the calculation.
l) *m*-*t*-Butyl group was not included in the calculation and experimental value of −0.078 was resulted for σ_{meta} of this group.
m) Points for meta derivatives deviate from the ρ_{meta} line.
n) *p*-Fluoro group deviates significantly.
o) σ value of +0.06 was employed for *m*-phenyl group. Trisubstituted derivatives were omitted from the calculation, since the cross conjugation effect appeared to be possibly involved.
p) Excepting *p*-dimethylamino and *p*-hydroxy groups, was obtained the partial correlation; $r=0.622$, $\rho=-5.535$ and $s=\pm0.026$. $\Delta\sigma_R^+$ values for these groups were calculated on the basis of this correlation; −1.20 for *p*-dimethylamino and −0.60 for *p*-hydroxy groups.
q) On the basis of ρ_{meta} value of −0.830, *r* value of 0.539 was obtained.
r) *p*-Phenyl group was not included in the calculation.

situation in these reactions. The same is true in the case of the decomposition of diazoacetophenones, as mentioned in the foregoing papers[1,3].

Conversely, the plots against Brown and Okamoto's σ^+ remain to be concaved upward in the brominolysis rates of benzeneboronic acids[25] and the migratory aptitudes of tetraphenyl pinacols[26], to the contrary, the present treatment exhibits fine correlations, whose *r* values are 2.29 and 1.60, respectively. These are the reverse of that mentioned above.

The curved correlation with Brown and Okamoto's σ^+ is fairly often observed in other reaction series, in accordance with the view that the availability of resonance contribution of para substituents is varied to a considerable extent by the changes of reaction series. Recently, Greene pointed out[27] that the rates of epoxidation of *trans*-stilbenes with phthaloyl peroxide satisfied the Brown and Okamoto's relationship. According to the present treatment, this reaction provides a fine figure of $r=1.388$. Similarly, the oxidation with perbenzoic acid is successful in terms of $r=0.713$[28]. Furthermore, the perbenzoic acid oxidation of *cis*- and *trans*-dimethylstilbenes[29] exhibits excellent correlations giving *r* of only 0.2∼0.3, in contrast with the failure of the Brown and Okamoto's. Fig. 11 demonstrates the correlation of

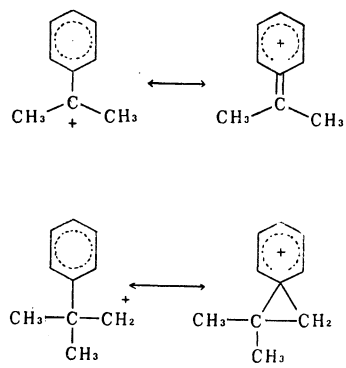
oxidation of the *cis*-dimethylstilbenes in benzene at 30°C, with Brown's and the present equations.



Discussion

As measured by the standard deviations, the fit is as excellent as that seen in the representative Hammett correlation[12]. It is also clear that the present relationship describes rather precisely or is applicable to a greater extent of electrophilic reactions than the Brown and Okamoto's.

According to the results, r varies over a wide range from 0.2 to 2.3 with respect to the change in reaction, and ρ also from -12 to -0.6. Furthermore, it is significant that the magnitudes of $\Delta\sigma_R^+$ are maintained precisely constant with large variation of ρ and r values. The r and ρ values obtained through Eq. 4 are usually equal within experimental uncertainty to those obtained on the basis of meta correlation line.

In comparison with Brown and Okamoto's results[2,10], the following facts may be pointed out. Brown and Okamoto's ρ^+ values appear to be somewhat more negative than ρ of the present paper, in the reactions giving r values greater than unity. Conversely, they are less negative than the present one when $r<1$. Considering that the present ρ values are identified with the corresponding ρ_{meta} values, it is clear that Brown and Okamoto's equation over- or under-corrects the validity of resonance contribution in these reactions. Only in the reactions having r within 0.7~1.3, the Brown and Okamoto's equation would be apparently successful. This indicates the limitation of the application of Brown and Okamoto's relationship[40]. The application for the reactions far out of the limitation would involve the possibility to lead to some erroneous conclusion. However, a relatively large number of reaction series in the literature appears to be involved in the region of r within 0.7~1.3. Then, the Brown and Okamoto's relationship would be applicable to a considerable extent of reaction series at the practical ground[2,10].

The modified Hammett relationship proposed in this paper involves an additional parameter and variable. The former is defined as a resonance parameter for a given substituent, but the latter is merely a proportionality constant in view of the origin of this equation. Accordingly, it is of interest and necessary to know the character of the latter quantity. Although both ρ and r are varied significantly with respect to the change in reaction series, the variation of r value does not appear to be dependent upon the change in ρ value. In the Beckmann rearrangement of acetophenonoximes in sulfuric acid (*30*)[6] and that of oxime picrylethers in dichlorobutane (*29*)[23], ρ differs greatly but r exhibits an identical value. The identical r value may give a good account of the close similarity of both transition states regardless of the different leaving groups and reaction conditions, while, little is described on the transition state model by the different ρ values. In the solvolysis of aryldimethylcarbinyl chlorides[2] and neophyl brosylates[22], the change in r is significant relative to the change in ρ. This may interpret plausibly the different modes of the resonance stabilizations of both transition states.

Therefore, it might be acceptable to say that the r would be a parameter characteristic of the structure of the possible transition state model as well as a parameter measuring the availability of the transition state resonance. As seen in Table I, approximately constant r of 1.2 is given for the reaction series to produce benzhydryl carbonium ions, and r of about 0.8 for those to produce trityl carbonium ions. The relatively small fluctuation would be presumably within experimental uncertainty. Unfortunately, few data are available in the literature to examine this concept more precisely.

40) The reactions quoted by Brown and Okamoto contains the reactions giving r less than 0.6 or more than 1.5. The standard deviations of these are slightly large, but the significant trend of curvature would not always parallel the standard deviation. It is evidently suggested by the difference between ρ^+ resulted and ρ_{meta} values.

The remaining subject of interest will be the theoretical consideration of the present relationship 2, and then the resonance substituent constant, $\Delta\sigma_R^+$.

The substituent effect would be considered to consist of inductive and resonance components[41,42], and the σ constant defined by Hammett is usually expressed by Eq. 5 [2,41,42],

$$\sigma = \sigma_I + \sigma_R \quad (5)$$

where σ_I is the inductive effect and σ_R is the resonance polar effect[42] of the substituent. Recently, Taft has evaluated the σ_I values by modifying his σ^* values for aliphatic series[42,43] on the basis of the Roberts' σ' scale[44], and the σ_R values by subtracting the σ_I values from the corresponding Hammett σ constants. It is well known that the substituent constant would not always be independent of the reaction nature. This would be referred to differing contributions of the resonance component of substituent effect[41], independently of the inductive component.

Furthermore, Taft has suggested that the linear free energy relationship would hold as far as the inductive component of reactivity is concerned[45].

Consequently, the Hammett equation may be expressed by Eq. 6,

$$\log k/k_0 = \rho_I\sigma_I + \boldsymbol{R} \quad (6)$$

In theory, the linear free energy relationship should suffice for the respective one of several components of substituent contribution[46]. If the residual $\boldsymbol{R}$, $\log k/k_0 - \rho_I\sigma_I$, consists of only the resonance contribution, the linear resonance energy relationship may be predictable in regard to the quantity, $\log k/k_0 - \rho_I\sigma_I$.

$$\log k/k_0 - \rho_I\sigma_I = \boldsymbol{R} = \rho_R\bar{\sigma}_R \quad (7)$$

where ρ_R is a reaction constant and $\bar{\sigma}_R$ is a proper parameter representing the resonating capacity of the substituent. Eq. 7 can be rewritten as Eq. 8,

$$\log k/k_0 = \rho(\sigma_I + q\bar{\sigma}_R) \quad (8)$$

where $\rho = \rho_I$ and $q = \rho_R/\rho_I$.

Here, $\bar{\sigma}_R$ should be essentially identical with σ_R in Eq. 5 since the $\bar{\sigma}_R$ corresponds to σ_R in the representative Hammett correlations. This relationship may be reasonably adopted also to electrophilic reactions.

On the other hand, the present equation can be formulated as Eq. 9,

$$\log k/k_0 = \rho(\sigma_I + \sigma_R + r\Delta\sigma_R^+) \quad (9)$$

Combining Eqs. 8 and 9, Eq. 10 is derived.

$$q\bar{\sigma}_R = \sigma_R + r\Delta\sigma_R^+ \quad (10)$$

Then, the linear relationship 11 must be derived, considering $\bar{\sigma}_R$ is identical with σ_R in Eq. 5,

$$\Delta\sigma_R^+ = q'\sigma_R \quad (11)$$

where q' is equal to $(q-1)/r$

The exact value of σ_R is difficult to evaluate, but it is logical to replace conveniently the theoretical values by the corresponding Taft's one. In practice, using the Taft's values instead of the σ_R, an apparently linear plot of $\Delta\sigma_R^+$ is provided, as shown in Fig. 12; given q' is equal to 0.962, the standard deviation of the fit being 0.121. If the Taft's σ_R value could describe suitably the σ_R component, it might be possible to realize generally the linear resonance energy relationship

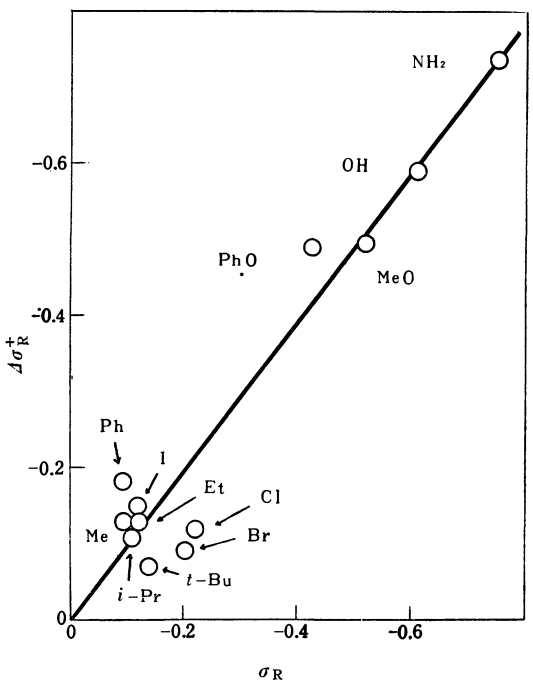


Fig. 12. Correlation of $\Delta\sigma_R^+$ with Taft's σ_R values.

41) The contributions of other specific effects such as solvation and bond energy effects are also involved but they are usually small relative to the above components.

46) Y. Yukawa and Y. Tsuno, see the *refrence* under Ref. 13; G. E. K. Branch and M. Calvin, "Theory of Organic Chemistry", Prentice-Hall, Inc., New York (1941), p. 192.

7, therefore, the general Hammett relationship 8. Then, it might be also possible to derive the unique set of σ_R and σ_I on the basis of the present results. However, Taft's σ_R value is by no means excluded from discussion, even though it may be acceptable from a theoretical standpoint. It is a question, at first, whether the Roberts' σ' scale may correspond strictly to that of the inductive effect in benzene system or not. The uncertainty of σ^* increasingly remains in his σ_I value, and must be accumulated in his σ_R value. Furthermore, the actual correlation of electrophilic reactions with his parameters is of considerably poorer precision[47]. On the other hand, $\Delta\sigma_R^+$ stands on a reasonable assumption that the increment of σ^+ relative to σ constant is attributed only to the resonance contribution. The uncertainty derived into this parameter may be entirely referred to only the experimental error of Brown and Okamoto's σ^+.

From these viewpoints, the general Hammett relationship with the parameters derived from $\Delta\sigma_R^+$, if possible, appears to be far more reliable than that with Taft's σ_I and σ_R values. However, it is the generality of Eq. 2, then the $\Delta\sigma_R^+$, that must be settled first. Unfortunately, further examination of the generality is limited by the lack of adequate data in literatures. The adequate literature data which contain rates of many meta derivatives constitute only one third of the data quoted in Table I. Without these reactions, the correlation obtained on the basis of Eq. 4 can not be referred to any standard of correlation such as meta line, although these are believed to be the best descriptions of their respective situations. Moreover, the utilities of $\Delta\sigma_R^+$ values for substituents more negative than *p*-methoxyl group have been scarcely examined at all. Then, the adequate data are highly desirable.

However, the excellent fit of the present relationship for 35 reaction series may be taken to be sufficient support for regarding this as a general relationship. Further investigations now in progress will be reported in forthcoming papers.

Institute of Scientific and Industrial Research
Osaka University
Sakai, Osaka

47) This conclusion is independent of Taft's results (Ref. 45). According to his result in the latest paper on the correlation of Brown and Okamoto's reference reaction, remarkable deviations are observed for *p*-CH_3O and *p*-F derivatives. Full discussion will be made in a proceeding paper, although his treatment disagrees with our concept.

Investigation on Mixed Complexes. II[1]. *Cyano Complexes of Copper and Nickel*

By Sigeo KIDA

(Received October 13, 1958)

A number of studies[2] have been made on the successive formation constants ($k_1, k_2, k_3,\ldots\ldots$) in a solution of metallic complexes, and it was found[3] that in any complex the ratio of the formation constants ($k_1 : k_2 : k_3\ldots\ldots$) is not far different from the statistically expected one, except in some special cases. Furthermore, recent studies of Watters et al.[4], Marcus[5], Yamatera[6] and the present author[1] have shown that the mixed complexes are formed generally in the statistical way.

These facts seem to imply that in a metallic complex the strength of a co-ordination bond is not seriously influenced

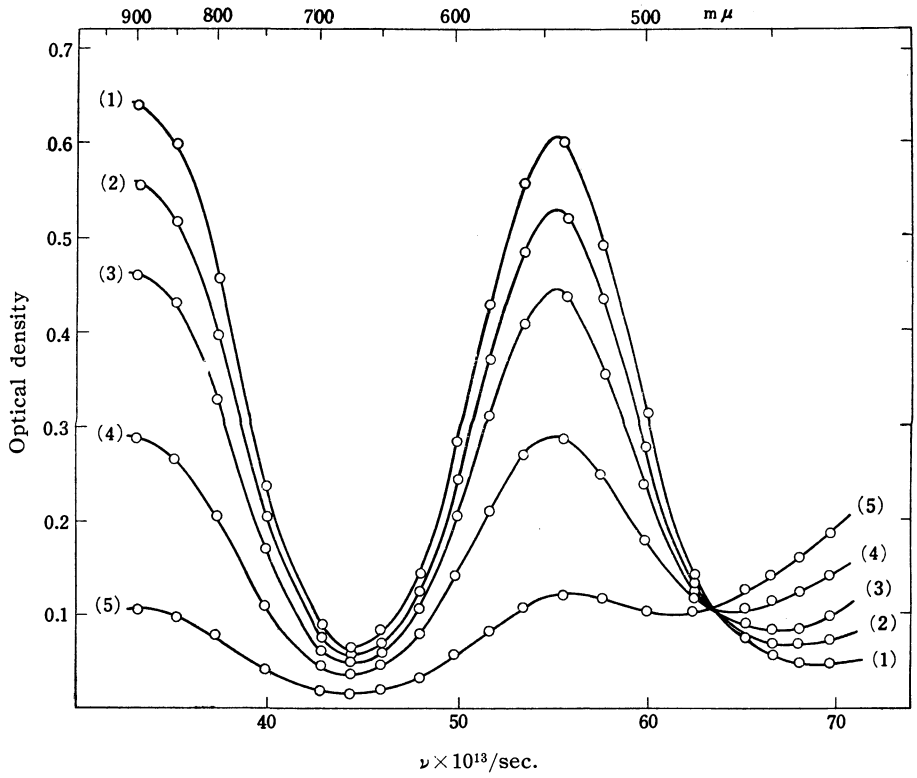

Fig. 1.

by the neighboring ligand; e. g., the strength of the Cu–N bonds are nearly constant in the two complexes, $[Cu\,en_2]^{2+}$ and $[Cu\,en\,C_2O_4]$.

However, it also should be noted that there are many cases in which the formations of the mixed complexes seem not to obey the above-mentioned statistical rule. For instance, the mixed cyano complexes known hitherto are few[7], and difficult to be prepared; this fact would be regarded as suggesting that at least in some cases mixed cyano complexes are not able to be formed or, if it is possibe, they have a strong tendency to be transformed into a complex having only the cyanide ions as ligands. Unfortunately, there is no satisfactory explanation for this phenomenon, since no systematic investigation has ever been made on the conditions leading to the formation of mixed cyano complexes.

This paper will give a report of the investigation which was made for the purpose of getting a clue to this problem.

Results and Discussion

$[Ni\,en_2]^{2+}+CN^-$.—It is well known that the tris-ethylenediamine nickel(II) ion has octahedral configuration, while the tetracyano nickelate(II) ion the planar one. However, it is quite uncertain whether mixed complexes, $[Ni\,en_2(CN)_2]$ and $[Ni\,en(CN)_2]$, which should be closely related to the above-mentioned, can be formed, or not. At first, an attempt, therefore, has been undertaken to clarify this question*.

A sodium cyanide solution was added to a solution of tris-ethylenediamine nickel(II) perchlorate in the ratio as indicated

* Ammine-cyano-nickel(II) compounds, such as $Ni(CN)_2NH_3$, $Ni(CN)_2NH_3H_2O$ and $Ni(CN)_2NH_3C_6H_6$, have been known. [E. E. Aynsley and W. A. Campbell, *J. Chem. Soc.*, **1958**, 1723; K. A. Hofmann and F. Hochtler, *Ber.*, **36**, 1149 (1903)]. However, they are not touched on in this article, since they have complicated structures quite different from that of the mixed complexes in which we are interested here (J. H. Rayner and H. M. Powell, *J. Chem. Soc.*, **1952**, 319).

TABLE II

	(1)	(2)	(3)	(4)	(5)	(6)
([Ni]−1/4[CN])/[Ni]	1.00	0.863	0.726	0.452	0.178	0

for 330 mμ			0.280	0.556	0.816	1.00

Numbers in the first row denote solution numbers in Table I.

in Table I, and extinction measurements were carried out on each of the mixed solutions thus prepared. The results obtained are shown in Fig. 1.

The extinction curves in Fig. 1 tell us that only the tetracyano nickelate(II) and tris-ethylenediamine nickel(II) ions are present, no mixed cyano-amine complex being formed; if any of the mixed complexes were formed, the absorption curve would be more or less subject to deformation, or some new absorption maximum would appear correspondingly.

If we assume all of the added cyanide ion is consumed to form the tetracyano nickelate ion, the calculated values of ([Ni]−1/4[CN])/[Ni] and 1/4[CN]/[Ni] must accord with the experimentally obtainable values, D/D_1 and D/D_6, respectively, where [Ni] and [CN] denote the total concentration of all nickel species and the total concentration of cyanide ion in the solution and D_n is the optical density of the solution, n, shown in Table I and Fig. 1**. Actually, the satisfactory agreement between them can be found as is seen from Table II.

$[Cu\ en_2]^{2+}+CN^-$. — The experiment has been carried out to verify whether the mixed complex such as $[Cu\,en(CN)_2]$ can be formed, or not, when a sodium cyanide solution is added to a solution of bis-ethylenediamine copper(II) perchlorate. Extinction mesurements were made on each of the mixed solutions shown in Table III. The results are shown in Fig. 2.

The extinction curves in Fig. 2 indicate that none of the mixed complexes such as $[Cu\,en(CN)_2]$ is existent in the solutions, because the absorption band (due to $[Cu\,en_2]^{2+}$) does not shift at all, being fixed at 500mμ, and yet none of the new absorption bands appears in the shorter wavelength region.

If we assume that four cyanide ions are consumed to convert a copper amine complex into a cyano complex, the calculated value, ([Cu]−1/4[CN])/[Cu], must accord with the experimentally obtainable value, D/D_7, as in the case of nickel. Actually the accordance can be found in Table IV, though it is not so satisfactory as in the case of nickel. Since cyanide complexes of divalent copper can not exist, the following reaction would have possibly occurred:

$$[Cu(en)_2]^{2+}+4CN^- \rightarrow [Cu(CN)_3]^{2-}{}^{***}+1/2(CN)_2+2\,en$$

Stability constants of copper(I) cyanide complexes were determined by Penneman and Jones[8].

$$k_1k_2=[Cu(CN)_2^-]/[Cu^+]\,[CN^-]^2=1\times10^{24}$$

$$k_3=[Cu(CN)_3^{2-}]/[Cu(CN)_2^-]\,[CN^-]=3.8\times10^4$$

$$k_4=[Cu(CN)_4^{3-}]/[Cu(CN)_3^{2-}]\,[CN^-]=50$$

From these data, it seems quite natural that tricyano copper(I) complex is mainly formed.

It must be noted that the possibility of

** If the reaction, $[Ni\,en_3]^{2+}+4\,CN^-\rightarrow[Ni(CN)_4]^{2-}+3\,en$, takes place quantitatively, optical densities of the mixed solutions can be given as follows:

$$D=\varepsilon_1([Ni]-1/4\,[CN])+\varepsilon_2(1/4[CN]),$$

while, for the solutions (1) and (6), $D_1=\varepsilon_1[Ni]$, and $D_6=\varepsilon_2[Ni]$, where ε_1 and ε_2 are extinction coefficients of $[Ni\,en_3]^{2+}$ and $[Ni\,(CN)_4]^{2-}$, respectively. However, the ratios D/D_1 and D/D_6 may be reduced for some wavelength region: for the region of 900~560 mμ, $D/D_1=[(Ni]-1/4[CN])/[Ni]$ with $\varepsilon_2=0$, and for the region of 400~220 mμ, $D/D_6=1/4[CN]/[Ni]$ since ε_1 is quite small as compared with ε_2.

*** For this complex the 4-coordinated configuration such as $[Cu(CN)_3OH_2]^{2-}$ or $[Cu(CN)_3\,en]^{2-}$, may be also considered. However, this is represented tentatively as $[Cu(CN)_3]^{2-}$, and the discussion of this complex will be done in the next section.

[Cu] is the total concentration of all copper species in solution.

the existence of a complex of coordination number 5 such as $[Cu\,en_2\,CN]^+$ can not be denied; the formation of this complex might be the cause of the unsatisfactory accordance of the calculated value with the experimental one unlike the case of nickel.

$[Cu(CN)_3]^{2-}$ + en.—Absorption spectra of the tricyano copper(I) complex were measured both with and without excess of ethylenediamine, and it was found that both absorption curves completely coincide within the limit of the experimental error. This fact suggests that the tricyano copper(I) complex does not take an ethylenediamine molecule in the solution to form the mixed complex such as $[Cu(CN)_3\,en]^{2-}$, and that the coordination number of the tricyano copper(I) complex may be 3 (perhaps sp^2 hybridization); if the coordintaion number were 4, the tricyanocopper(I) complex would have the configuration such as $[Cu(CN)_3\,OH_2]^{2-}$, and it would become the mixed complex, $[Cu(CN)_3\,en]^{2-}$, when the ethylenediamine is added to the solution.

$[Cu(CN)_2]^-$ + en.—When ethylenediamine is added to a solution of the dicyano copper(I) complex, the solution becomes turbid and light blue, and then slowly changes into a transparent purple blue solution. The absorption spectrum of this solution completely coincides with that of the bis-ethylenediamine copper(II) complex in the visible region.

From the above results, we can easily understand the fact that neither dicyano nor tetracyano copper(I) complex is formed, but tricyano copper(I) complex, when the cyanide solution is added to the

bis-ethylenediamine copper(II) complex solution.

Experimental

Extinction measurements were made by means of the Beckman D. U. spectrophotometer using 1 cm. quartz cells at room temperature.

In the case of $[Cu\,en_2]^{2+}+CN^-$, each of the solutions prepared as shown in Table III was heated just to boiling, and then cooled to the room temperature before extinction measurements were made; without this treatment, extinction data obtained are not reproducible.

$[Ni\,en_3](ClO_4)_2$ and $[Cu\,en_2](ClO_4)_2$. — The metal quantity of the former was analyzed with dimethylglyoxime, and that of the latter was determined by iodometry.

$[Cu(CN)_2]^-$ and $[Cu(CN)_3]^{2-}$ (in solution). —The copper(I) cyanide was dissolved in the potassium cyanide solution at the ratio of 1 : 1 and 1 : 2 to form these complexes, respectively.

Summary

1. Mixed amino-cyano nickel(II) complexes, such as $[Ni\,en_2(CN)_2]$, $[Ni\,en\cdot(CN_4)_4]^{2-}$ and $[Ni\,en(CN)_2]$ in the solution containing the divalent nickel ion, ethylenediamine and cyanide ion, are not formed.

2. In the solution containing the divalent or the monovalent copper ion, ethylenediamine and the cyanide ion, no mixed amine-cyano copper(I) and copper(II) complexes are formed, except the copper(II) complex of coordination number 5.

3. Among cyano copper(I) complexes, tricyano copper(I) ion is the most stable, and its coordination number may be 3.

*Stereoisomers of 2,3-Camphane Diols**

By Tsuneichi TAKESHITA and Masayoshi KITAJIMA

(Received November 21, 1958)

There should exist four possible diastereoisomeric camphane-2,3-diols, which in spite of having been prepared by several authors[1], were mostly obtained as mixtures of isomers, with its single epimer believed to have been isolated in fairly pure state by Rupe and Thommen[2]. Therefore, conformation of each epimer has not been established at all. Only Kwart and Gatos[3,4] recently assigned the structure to the one isomer of the Rupe and Thommen diol with positive evidence of infrared spectra and complex formation. It became then the purpose in these studies to isolate all theoretically possible diols and assign conformation; and, if possible, to correlate the isomeric composition of the diols prepared by various methods with the mode of reaction. Several facts which have been clarified are presented in this report. As the authors have hitherto studied *endo-* and *exo-* isomers of borneols and their epimerization[5,6], the hydrogenation of camphorquinone was similarly followed.

Synthesis of Four Stereoisomers.—Four epimers, namely *exo-exo-* (I), *endo-endo-* (II), *endo-exo-* (III), and *exo-endo-* (IV) may possibly result by reduction of camphorquinone. Effective isolation of pure

isomers can be achieved by selecting the procedure yielding the least number of components, and this would be possible by avoiding the method of reduction which may cause isomerization of the hydroxyl group which was entered. As proved in the epimerization of borneol by the authors, such reducing agents as copper chromite, sodium or aluminum isopropylate are effective catalysts of epimerization[6]. Therefore, these were not used for the present purpose. Reduction with lithium aluminum hydride and Raney nickel were the methods mostly utilized for this purpose.

When camphorquinone absorbs 1 molar hydrogen, it leads to hydroxy-ketone and giving a diol on further reduction. As an analogous mode of reduction of camphor, Raney nickel or lithium aluminum hydride should give *exo-* and *endo-* isomer with a preponderance of the former. Hydroxy-ketone obtained by these methods can now be assumed to be isomeric with "α-hydroxycamphor" (V) and "β-hydroxycamphor" (VI) by zinc- acetic acid reduction. $LiAlH_4$ reduction of camphorquinone is expected to yield one *cis-* and two *trans-* isomers. On the other hand, however, further reduction of V or VI, separated from each other, should lead to one *cis-*, one *trans-*, respectively. A *cis*-diol can thus be easily purified in $LiAlH_4$ reduction, but it must be somewhat hard in the case of *trans*-diol to purify one from another.

cis-Diol I.—Camphorquinone in ether was reduced with lithium aluminum hydride after Trevoy and Brown's method[7] at dry-ice temperature. Crude *cis*-diol was converted to acetonide, rectified over a sodium ribbon till no more O-H absorption is detected in the 3500 cm^{-1} region of infrared spectra**. After regeneration of the diol, it was recrystallized from ligroin and repeatedly sublimed in vacuo.

cis-Diol II.—"β-Hydroxycamphor" VI purified through its dimolecular methyl ether[8] was hydrogenated over Raney nickel at room temperature, a *cis*-diol was separated from one *trans*-isomer and purified similarly as in the case of I.

trans-Diol III.—The *trans*-diol separated from II in the foregoing reduction product was repeatedly treated with acetone to remove any trace of remaining *cis*-diol.

trans-Diol IV.—The *trans*-diol isolated from Raney nickelhydrogenated diols of "α-hydroxycamphor" V was further purified like III.

Assignment of Conformation.—Tentative assignment of *cis*-I, II and *trans*-III, IV were separately performed by comparison with I.R. spectra at O-H region.

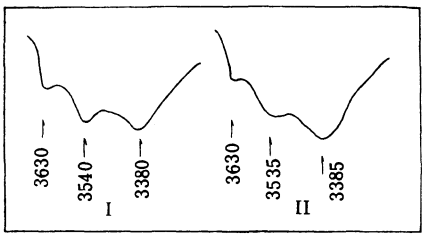

Fig. 2. O-H stretching region (*cis*-diols) CS_2 soln.

The bands at 3540 are intra-molecular O-H; and difference from free O-H, $\Delta\nu=90$, in case of I and 195 in case of II, corresponds to 1.5Å for O-H distance. Concerning the inter-molecular band, intensity of associated O-H/free O-H is a measure of the ease with which solute associates. Thus, as proved in case of borneol[5], the degree of association is far less in *exo-* than that in *endo-*, owing to *gem-* dimethyl hindrance. Of the two *cis*-diols investigated, I can not associate so much as II since the ratio obtained is 291.0 and 416.0%, respectively. Therefore, so far as two *cis*-epimers are concerned, I can be assigned as *exo-*, and II, in turn, as *endo-*. These assigned stuctures of I and II are satisfied with some difference of chemical property,

that is, the difference of saponification velocity of corresponding diacetate, as shown in Table II.

The slower saponification rate of I coincides well with the assignment by I. R. And as will be reported in a later paper[9], epimerization of I resulted in a great preponderance of II over I. This corresponds with the known stability of *endo*-isomer in case of borneol.

trans-Diols, III and IV, were similarly compared on the infrared spectra. Although associated OH can best be compared in CCl_4 or CS_2 because a solvent molecule such as $CHCl_3$ is known to prevent intermolecular association of solute***, spectra were taken in $CHCl_3$ solution on account of sparing solubility of *trans*-diol in CS_2****. Therefore, the difference of ratio of polymeric OH/free OH between III and IV was not one-sided as in the case of *cis*-diols. Table III shows comparison of spectra.

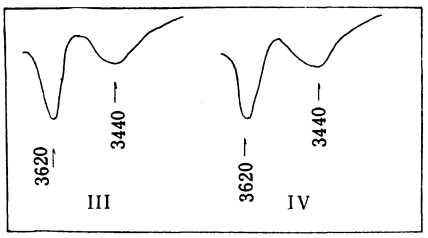

Fig. 3. O-H stretching region (*trans*-diols) $CHCl_3$ soln.

Steric hindrance of *gem*-dimethyl is usually more profound at C_2 than at C_3 because of proximity of adjacent quaternary methyl. That the steric effect of *gem*-dimethyl observed for C_3–OH is not significant has been reported on epi-borneol by Lipp et al.[10] Therefore, an isomer with more bonded OH is suggested to be 2-*endo*-3-*exo*-. This tentative assignment is also supported by the fact that the di-acetate of III is saponified faster than that of IV, as shown in Table IV.

TABLE IV. SAPONIFICATION OF *trans*-DIOL DIACETATES (25±1°C)

Isomer	0.1 N KOH hr.	% Sap'd
III	2	73.1
IV	2	61.3

The properties of four diasteroisomeric diols isolated are summarized in Table V.

TABLE V. PROPERTIES OF DIOLS

Isomer	m. p.(°C)	$[\alpha]_D$	O-H dist.	Conformation
I	262~263	−19.3	1.5 Å	2-*exo*-3-*exo*-
II	224~225	+30.8	1.5	2-*endo*-3-*endo*-

IV	251~252	+ 7.7	(3.3)	2-*exo*-3-*endo*-

Isomeric Composion of Diols by Various Methods of Syntheses.—Diols prepared by direct reduction of camphorquinone and by further reduction of hydroxyketone obtained by zinc-acetic acid reduction of camphorquinone were studied then by infrared spectra. The result of one-step hydrogenation is given in Table VI.

Catalytic hydrogenation affords mainly *cis*-I with some II, *trans*-diols increase with rise of reaction temperature. Therefore, reduction at room temperature easily gives *cis*-diols (I+II) in over 90% yield, though *cis*-I is not easy to purify.

$LiAlH_4$ reduction was much influenced by temperature on the reaction product, *cis*-diol obtained at −70°C being exclusively *exo*-, while that of 0°C was contaminated with *endo*-. Thus, the reduction at dry ice temperature is the procedure employed in this paper for the preparation of uncontaminated *cis-exo*-diol. The Meerwein-Pondorff-Verley type reduction of camphorquinone yielded a characteristic product that consisted of *cis*-diols solely, with very few *trans* isomers. And moreover, II increased considerably, compared with other procedures.

Diols Prepared by Hydrogenation of Hydroxy-camphor. — Camphorquinone

9) T. Takeshita, Presented at the Symposium on Terpenes, held at Hiroshima University, Oct. 10, 1958.

*** The association of ROH in $CHCl_3$ is known to be less than in CS_2. The effect of $CHCl_3$ must be the hydrogen bonding power of CH besides the polarity or molecular size of solvent. (Cf. L. J. Bellamy, "The Infra-Red Spectra of Complex Molecules", Methuen and Co, London (1958), p. 100.

**** Limited solubilty of III in $CHCl_3$, less than 130.0 mg./10 ml., makes possible only narrow concentration range for the present purpose, though IV is more soluble.

yields hydroxy-ketone on zinc-acetic acid reduction, which has been reported to consist of α-hydroxycamphor and β-hydroxycamphor[11]. The configuration of this hydroxycamphor is not clear, but must be *endo*-configuration since β-isomer which was regenerated from sparingly soluble dimolecular methyl ether afforded *cis-endo*-diol. The result of reduction of this hydroxyketone also supports this idea as indicated in Table V.

A point to be noticed is that *cis*-diol obtained from β-hydroxycamphor catalytically or with $LiAlH_4$ was *cis-endo*, while that from α-isomer afforded *endo*- mixed with about one third the amount of *exo*-isomer. This shows the homogenity of β-isomer, *endo*- whereas α-isomer was a mixture of *endo*- and *exo*-, in ratio of 3 to 1. The catalytic hydrogenation of hydroxycamphor presents an interesting problem, since predominant *exo*-addition observed in case of camphor[4] was cut to about half to give *trans*-diol. This indicates steric hindrance in opposing direction by *gem*-dimethyl group to that of *endo*-hydroxyl group. Thus, $LiAlH_4$ reduction gives only 15% of *exo*-reduced product because lithium aluminum salt formed with *endo*-hydroxyl group becomes overwhelmingly bulkier than the *gem*-dimethyl, *exo*-directing radical. Sodium with alcohol gave mostly *trans*-diol as the usual mode of *trans*-addition. Similarity of the reduction product is considered to be isomerization of β-hydroxycamphor to α-isomer as seen in Experiments 13 and 14.

11) β-Hydroxycamphor, so designated, is actually α-hydroxy-epicamphor.

Experimental[12]

I. *exo-exo*-2, 3-Camphane-diol.—A solution of camphorquinone (10 g.) in ether was added dropwise at −60°C to −70°C to an ether solution of $LiAlH_4$ (c=1.6 mol./l.) immersed in a methanol-dry ice bath and kept for 20 hr.[6] After decomposition of excess of reagent with water, the whole was washed with dilute sulfuric acid, saturated sodium chloride solution, dried with anhydrous sodium sulfate and the solvent was evaporated to give the *cis*-diol (9.5 g.). Seven grams of crude product was treated with acetone by the procedure of Rupe et al.[2] to give acetonide (8.4 g.), and vacuum distillation afforded some *trans*-isomer (0.43 g.). Acetonide was purified by rectifying over sodium till it showed no more hydroxyl absorption in 3500 region of its infrared spectra, 4 g. of pure acetonide was saponified to regenerate *cis*-diol (2.7 g.), recrystallized from ligroine, and sublimed in vacuo, m. p. 262~263°C, $[\alpha]_D$−19.3 (c=0.50000 g./5 ml.).

II. *endo*-*endo*-2, 3-Camphane-diol. —" β-Hydroxy-camphor " (27.7 g., m. p. 204~205°C), purified through dimolecular methyl ether (m. p. 147~148°C)[8,13] was hydrogenated in alcohol over Raney nickel at 14~20°C to yield *cis*-diol (28.0 g.) mixed with *trans*-isomer. To isolate *cis*-diol, 20 g. of diol was treated as I with acetone. The solid product (21.0 g.), wet with *cis-endo*-acetonide was extracted with boiling hexane to free it from *trans*-diol. Evaporation of hexane afforded acetonide contaminated with some *trans*-isomer; this was further treated over sodium as I, saponified, recrystallized, and vacuum sublimed.

12) All melting points are uncorrected. All rotations were measured in 1 dm. tube as an alcoholic solution. Infrared spectra were taken with a Perkin Elmer Model 21 Infrared Spectrophotometer equipped with sodium chloride prism.

13) J. L. Simonsen mis-stated the m. p. of the compoud as 37~38°C in " Therpenes ", Vol. II, Cambridge University Press, Cambrige (1949), p. 428.

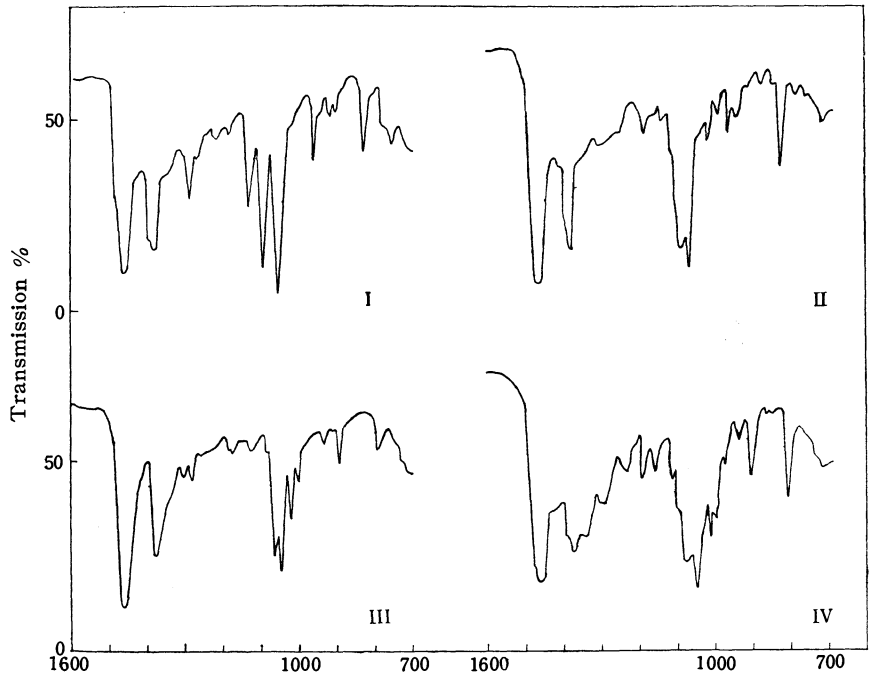

Fig. 4. I. R. of diols (as Nujol mulls)

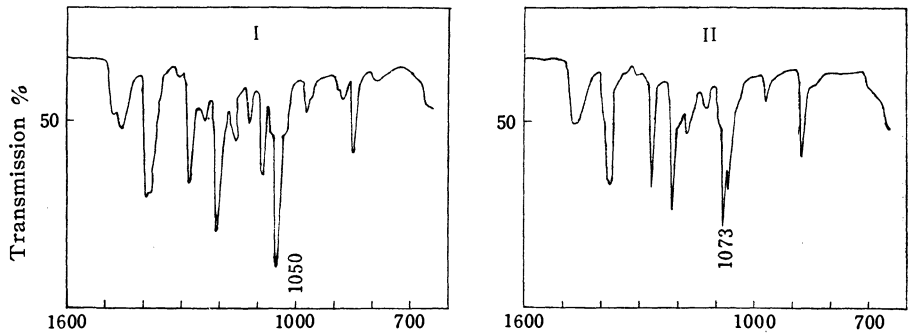

Fig. 5. I. R. of *cis*-acetonide (1600～1650 cm^{-1}) cap.

Yield, 3.6 g., m. p. 224～225°C, $[\alpha]_D$ +30.8 (c= 0.50000 g./5 ml.).

III. *endo*-*exo*-2,3-Camphane-diol. — The *trans*-diol separated (9.2 g.) in isolation of II was further treated with acetone to remove any trace of *cis*-diol present and recrystallized several times from ligroine and sublimed in vacuo. Yield, 7.5 g., m. p. 253～254°C, $[\alpha]_D$+15.0 (c=0.50000 g. /5 ml.).

IV. *exo-endo*-2,3-Camphane-diol.—Similarly as in the case of III, *trans*-isomer separated from hydrogenation of 8.5 g. of "α-hydroxycamphor" was further treated with acetone, to remove *cis*-isomer, recrystallized sublimed in vacuo, m. p. 251～252°C, $[\alpha]_D$ +7.7 (c=0.50000 g./5 ml.).

Infrared Measurement — All the spectra were taken by Perkin Elmer Model 21 with NaCl Optics. The infrared determination of the isomeric composition of diols which resulted as reduction product was developed as follows.

As stereoisomeric cyclic alcohol usually has a characteristic band around the 1000～1100 region like those of *endo*- and *exo*- borneols[5], the spectra of four isomers are distinguishable (Fig. 4) in this region. These are, however, only effective for qualitative analysis because of the overlapping of bands not at the peaks but at the side of absorption maxima. As shown in the preceding discussion, in dilute solution, *cis*-diols absorb both at 3620 and 3520, while *trans*-isomer does so at only 3620 owing to absence of intra-molecular band of 3520. Thus, *cis-trans* composition can be determined by O—H stretching bands. Individual epimers are then determined by C—O stretching region.

1) Intensity of 3620 and 3520 bands measured.

Diols		3620	Average	3520	Average
cis-	I	0.223	0.217	0.166	0.166
	II	0.211		0.165	
trans-	III	0.351	0.354	0.048	0.046
	IV	0.356		0.044	

Concn. 60.0 mg./10 ml. $CHCl_3$
Cell length 1.2 mm. Room temp. 25±2°C

At the concentration indicated, there was not much variation in optical density between isomers within the same geometrical group (*cis-* or *trans-*), and this presents a rapid method of determination of *cis-* and *trans*-isomers. Trial analysis of some synthetic mixtures of known concentration was found to be accomplished with 2% error, this accuracy being sufficient for the present study.

	cis		*trans*		*cis*		*trans*	
Synthetic	II	66.5	IV	33.5	II	33.2	III	66.8
Found		67.2		32.8		34.9		65.1
Synthetic	I	83.2	IV	16.8	III	83.2	III	16.8
Found		85.0		15.0		85.8		14.2

On finding *cis-trans* ratio, determination of each isomer is performed by C—O stretching region.

2) Intensity of C—O stretching region.

Diols	1089	1074	1060
I	0.312	0.095	—
II	0.203	0.282	0.368
III	0.068	0.271	0.168
IV	0.067	0.098	0.401

Concn. 60.0 mg./10 ml. $CHCl_3$
Cell length 0.5 mm.

Fortunately, the 1089 intensity of III and IV does not differ much. *Trans*-contribution at this wave number can be treated as equal in evaluation of *trans* isomers of diols. Compositions III and IV are finally determined after *cis*-diols were removed with acetone as acetonide. Trial analysis was performed with 2% error as follows:

Synthetic	II	66.5	IV	33.5	II	33.2	III	66.8
Found		65.0		35.0		31.0		69.0
Synthetic	I	83.2	IV	16.8	IV	66.5	III	33.5
Found		84.9		15.1		68.3		31.7
Synthetic	III	35.0	IV	65.0				
Found		36.6		64.3				

Thus the ratio of epimers was found to be analyzed on a 2-component system using C—O stretching region with 2% error. However, overall error of analysis amounts to less than 4%, with assay of *cis-trans* ratio combined in analysis of diols. As to *cis*-isomers I and II, characteristic *cis*-acetonide was compared with them. (Fig. 5)

Saponification of Diol Diacetate.—Acetylation of diol was as follows: Each of the diols (3 mmol., 510 mg.) was gently boiled with acetic anhydride (Purity 94.2%, 2.1 g.) and anhydrous sodium acetate (0.4 g.) for 1 hr., settled overnight, the excess of reagent decomposed with 10 ml. of hot water during 2 hr., extracted with ether. After being washed with aqueous solution of sodium chloride, and then sodium bicarbonate, the solution was dried over anhydrous sodium sulfate. Removal of solvent in vacuo, finally by warming at 110°C/7 mmHg afforded slightly colored diacetate oil, in yield ranging from 600 to 700 mg. Purity found. (Theor. Value, Ester Value 441.0 as $(CH_3COO)_2 \cdot C_{10}H_{16}$) Diacetate of I E. V. 427.3, II E. V. 434.5, III E. V. 435.1, IV E. V. 428.1

The diacetate thus prepared was saponified by the usual procedure: Weighed sample, equivalent to 10 ml. of 0.1 N alcoholic KOH, in bottle was immersed in a water bath kept at 25±1°C. To this was added 10 ml. of 0.1 N alcoholic KOH at 25±1°C and maintained at this temperature. Back titration with 0.1 N H_2SO_4 against phenolphthalein gave the amount saponified. (Cf. Table II and IV).

Decomposition Temperature of Urea Adducts

By Naoki YATA

(Received December 16, 1958)

Decomposition temperatures for urea adducts of *n*-hexadecane, *n*-nonadecane, and *n*-paraffins from C_{19}–C_{20} fraction of mineral oil were determined. The results were compared with the data by Redlich et al.[1] and decomposition temperature of *n*-hexadecane by the author was found to be lower than that of Redlich's.

Addition of benzene to the system (adducts and water) results in the lowering of decomposition temperature. This effect becomes remarkable with a decreasing amount of water.

Experimental

Reagents.—Urea (m. p. 132.6°C) was recrystallized from aqueous solution saturated at 30°C. Methanol (b. p. 64~65°C), benzene (b. p. 80~80.5°C) and petroleum ether (b. p. 40~60°C) were redistilled from the commercial product.

n-Hexadecane (commercial) was treated with activated alumina followed by sulfuric acid and sulfur trioxide treatment, m. p. 16.2°C, $n_D^{20}=1.4251$.

n-Nonadecane and *n*-heneicosane were separated from lubricating oil fraction of Yabase crude (b.p. 104~226°C at 3 mmHg) by urea adduction and chemical treatment as mentioned above. Physical constants of these hydrocarbons were compared with the literature values[2,3] and shown in Table I.

Preparation of Adducts.—Adducts from mineral oil (Yabase lubricating oil fraction as described above) were prepared by adding 120 g of urea and 1 cc. of methanol to 150 g. of oil. After the mixed solution being stirred for 50 min., the adduct produced was filtered off and washed with 1500 cc. of benzene. Yield, 150 g. of adducts. Adducts of *n*-paraffins were made from the petroleum ether solution of them. This solution was treated with 3 times of urea to *n*-paraffins, and 0.3 times of methanol, and was stirred for 50 min. The adducts produced were filtered by suction and washed with 30 times the quantity of benzene.

All of these adducts were dried in vacuo until solvent odor was diminished. Analytical data are shown in Table II. Mole ratios in this table were determined by Schiessler's method[4]. Dissociation temperatures were measured by the method of Knight et al.[5]; according to the present author's experiment, dissociation temperatures of *n*-paraffins are quite similar to that of methyl ester which has been measured by Knight et al.

TABLE I. PHYSICAL CONSTANTS OF *n*-NONADECANE AND *n*-HENEICOSANE

Hydrocarbons	Refractive index (n_D^{60})		Melting point (°C)	
	Found	Lit.	Found	Lit.
n-Nonadecane	1.4268	1.4255	31.0	32.0
n-Heneicosane	1.4300	1.4290	40.5	40.5

Procedure.—A small test tube of 2.5 cm. diameter was connected in a large test tube of 4.5 cm. diameter with a rubber stopper. Two

TABLE II. COMPOSITIONS AND DISSOCIATION TEMPERATURES OF ADDUCTS

Hydrocarbons in adducts	Urea/*n*-paraffin Wt. ratio	Urea/*n*-paraffin Mol. ratio	Dissociation temp. (°C)
Lub. oil paraffin	3.5	—	125
n-Hexadecane	3.1	11.7(12)[6]	112
n-Nonadecane	3.2	14.1(13.9)	129
n-Heneicosane	3.1	14.6(14.6)	129

grams of adduct samples and water were put into the small test tube with a thermometer and a stirrer made of iron wire.

The large test tube was placed in a 500 cc. beaker where warm water was filled in, and heated. Constant hand stirring was continued with temperature rise of about 5°C/min. until a paraffin portion was separated on the upper layer, and this point was considered as the decomposition temperature.

Results and Discussion

Decomposition Temperature.—Table III shows the decomposition temperature, the average value taken from the two measurements. Decomposition curve was made according to the method of Redlich et al., as shown in Fig. 1. These curves were extrapolated and the intersection with the saturation curve (dotted line) of urea in water were considered as the decomposition point.

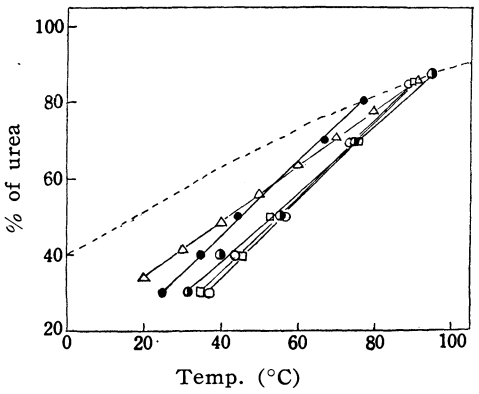

Fig. 1. Decomposition curve of urea adducts.
Dotted line: Urea saturation curve
◑: Mineral oil paraffin adducts
●: *n*-Hexadecane adducts
○: *n*-Nonadecane adducts
□: *n*-Heneicosane adducts
△: *n*-Hexadecane adducts by Redlich

As is shown in Table III, the decomposition point of *n*-hexadecane adduct is 78°C and is lowerthan Redlich's value, 90°C. Schlenk[7] showed that 97.5% of 1 mol. *n*-hexadecane adduct (12 mol. of urea and 1 mol. of *n*-hexadecane) was decomposed in 72 mol. of water at 31°C.

TABLE III. DECOMPOSITION TEMPERATURE OF UREA ADDUCTS

Hydrocarbons in adducts	Decomp. point (°C)	Urea[8] concn. (%)	Decomp. temp. (°C)
Lubricating oil paraffin	95	30	32.0
		40	39.5
		50	55.2
		70	75.0
n-Hexadecane	78	30	24.8
		40	35.0
		50	45.7
		70	67.0
n-Nonadecane	90	30	36.0
		40	43.5
		50	55.2
		70	74.5
n-Heneicosane	90	30	34.5
		40	44.0
		50	53.5
		70	75.0

This result means that 0.975 mol. of *n*-hexadecane adduct is decomposed 72 mol. of water at 31°C and 35.2% aqueous solution of urea is separated. According to the author's result, at the decomposition point of 31°C about 36% aqueous solution of urea is separated, and by Redlich et al. it corresponds to 41%. This deviation of the present result from the data of Redlich et al. was thought to be due to the difference of the determination method.

As *n*-nonadecane and *n*-heneicosane were separated from the same lubricating oil fraction, the decomposition points of these are nearly the same. *n*-Nonadecane sample used in this study is not so pure as is clearly seen from the comparison with the physical properties which have been cited in literature (cf. Table I), but in any case difference of the decomposition point between the carbon number ranges of 1 and 2 seemed to be comparatively small.

Effect of Benzene Addition.—The decomposition of adduct occurs when a sufficient amount of benzene or other hydrocarbon solvents were used at high temperatures. As might be expected, addition of benzene to the system which is composed of adduct and water, lowers the decomposition temperature. Fig. 2 shows the decomposition temperature of adducts containing

6) The values in the brackets were calculated by Redlich's equation[1], $m=0.653n+1.51$, where m is the mole ratio of urea to *n*-paraffin and n is the carbon number.

7) W. Schlenk. Jr., *Ann.*, 565, 204 (1949).

8) Urea concentration means per cent of urea (in adducts) in the urea-water mixture.

43～233% (for urea in adducts) of water and 0～200% (for adducts) of benzene.

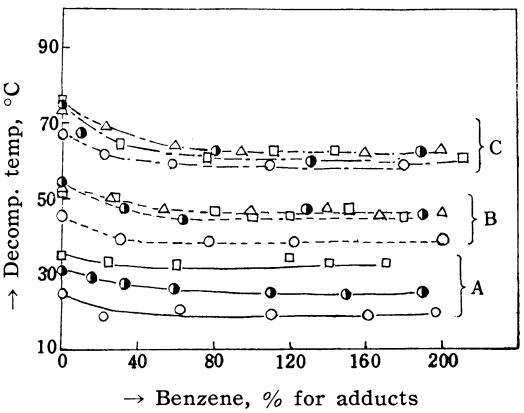

Fig. 2. Effect of benzene addition.
A: 233% water for urea in adducts,
B: 100%, C: 43%
◑: Mineral oil paraffin adducts
○: *n*-Hexadecane adducts
△: *n*-Nonadecane adducts
□: *n*-Heneicosane adducts

When the amount of benzene is increased, the decomposition temperature lowers; but the more the amount of water, the smaller the effect of benzene. The effect of benzene addition of 40～200% for adducts shows almost constant change of decomposition temperature: i. e., on addition of 233% water, temperature change is about 3～5°C, 100% water, 5～8°C, and 43% water, 10～12°C. This unchangeability of the decomposition temperature by the benzene addition may be caused by the limitation of decomposition by benzene itself. Hence, it can be seen that water has greater decomposition velocity than benzene has, and temperature dependence of the benzene decomposition is greater than that of water (Table IV).

Table IV shows the decomposition temperature of *n*-hexadecane adduct by benzene, and complete decomposition is obtained only when the boiling benzene (80°C) is used as 200% for adducts and five hours heating[9].

TABLE IV. DECOMPOSITION OF *n*-HEXADECANE ADDUCT BY BENZENE

Temp. (°C)	Heating time (hr.)	Benzene (% for adduct)	*n*-Hexadecane decomposed (%)
30	4	150	5
50	3	150	19
70	3	150	84
70	6	150	90
80	4	150	93
80	5	150	97.2
30	5	200	7
70	3	200	96
70	5	200	98.7
80	4	200	95
80	5	200	100

Decomposition temperatures of adducts of lower carbon paraffins are lower than those of higher ones, as might be expected from Fig. 2, yet this effect is less striking than water decomposition (Fig. 1).

Thanks are due to Mr. Katsuhiko Ide of this laboratory for many helpful experiments in the course of this work.

Studies on the Vibrated Dropping Mercury Electrode. I. The Theory of the Limiting Current and its Application to the Electrocapillarity

By Hideo IMAI, Senkichi INOUYE and Shōkichi CHAKI

(Received January 8, 1959)

When the dropping mercury electrode is vibrated by the application of an a. c. electric field, the limiting current of a depolarizer is augmented, the convection current being super-induced on the diffusion-controlled one. We called this new technique for improving the sensitivity of polarographic determinations the "VDME" method, and it was briefly reported in the previous communication[1]. Since the increment of the limiting current beyond the diffusion-controlled one depends upon the electric charge of the mercury-solution interface, this technique has a potentiality for the investigation of the electrocapillarity, especially for the determination of the zero-charge potential, i. e., the Lippmann-potential.

In this report, the theory of the limiting current and an accurate method for determining the Lippmann-potential are presented.

The Theory of the Limiting Current

The a. c. electric field exerts a moment of force as great as $q \cdot E \sin(\omega t) \cdot r \cdot \cos\theta$* on the center of the DME, and causes the forced vibration of the DME about the orifice of the capillary electrode (cf. Fig. 1). Counteracting this vibration, there exists the resistance due to the viscosity of the solution and the restoration of the displacement owing to gravity. Supposing that the former obeys Stokes's law, the moment of force is evaluated as great as $6\pi\eta r \cdot r \cdot r\, \mathrm{d}\theta/\mathrm{d}t$. The latter moment of force is equal to $Mg \cdot r \cdot \sin\theta$. Hence, one obtains the following equation of the vibration.

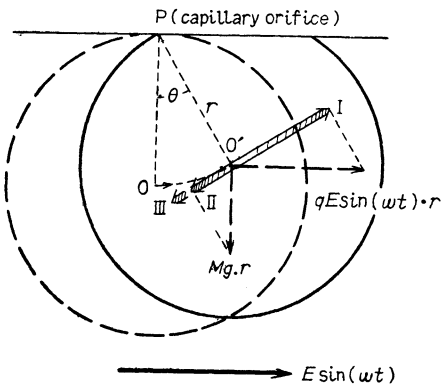

Fig. 1. The schematic representation of the forced vibration of the VDME: The moment of inertia, i, is equal to $q \cdot E \sin(\omega t) \cdot r \cos\theta$, ii is equal to $Mgr \cdot \sin\theta$ and iii is equal to $6\pi\eta r \cdot r \cdot r\, \mathrm{d}\theta/\mathrm{d}t$.

$$I\, \mathrm{d}^2\theta/\mathrm{d}t^2 = q \cdot E \sin(\omega t) \cdot r \cdot \cos\theta - Mg \cdot r \cdot \sin\theta - 6\pi\eta r \cdot r \cdot r\, \mathrm{d}\theta/\mathrm{d}t \quad (1)$$

where the moment of inertia, I, is nearly equal to $2\pi r^2/5$. In Eq. 1, $\cos\theta$ and $\sin\theta$ can be exchanged for one and θ, respectively, provided the amplitude of the vibration is small. It is noteworthy that Eq. 1 holds only in approximation; the reason is that the sphere of the DME may be deformed by the vibration.

The solution of Eq. 1 is given in the following, the term of damped vibration being neglected.

$$\theta = \alpha\{(\beta - \omega^2)\sin\omega t - \gamma\omega\cos\omega t\} / \{(\beta - \omega^2)^2 + \gamma^2\omega^2\} \quad (2)$$

where $\alpha = qEr/I$, $\beta = Mgr/I$

and $\gamma = 6\pi\eta r^3/I$ (3)

Hence, the center of the DME moves at the velocity of

$$r\, \mathrm{d}\theta/\mathrm{d}t = \alpha r\{(\beta - \omega^2)\omega\cos\omega t + \gamma\omega^2\sin\omega t\} / \{(\beta - \omega^2)^2 + \gamma^2\omega^2\} \quad (4)$$

The mean velocity acquired during the motion from the site right under the capillary orifice to the site of the maximum

* The symbols used in this paper are listed below.
q=the surface charge of the DME.
E=the intensity of the a. c. electric field.
ω=the circular frequency of the a. c. electric field.
M=the mass of the DME.
g=the acceleration of gravity.
r=the radius of the DME.
η=the viscosity coefficient of the solution.
I=the moment of inertia of the DME.

amplitude can be evaluated by Eq. 5, i. e.,

$$(r\,\mathrm{d}\theta/\mathrm{d}t)_{\mathrm{mean}}=T/4\cdot\int_0^{\tau/4}(r\,\mathrm{d}\theta/\mathrm{d}t)\,\mathrm{d}t$$
$$=2\omega\alpha r(\beta-\omega^2+\gamma\omega)/\{(\beta-\omega^2)^2+\gamma^2\omega^2\} \quad (5)$$

where T is the period of the vibration.

Assuming that the concentration of the depolarizer at the vicinity of the electrode surface does not vary owing to the successive vibration, the treatment of Okinaka-Kolthoff's theory[2] developed for the limiting current of the rotated dropping mercury electrode can be applied to this case.

Thus, the following equation is given for the mean limiting current of the VDME;

$$\bar{i}_l=\bar{i}_d+knCD^{1/2}(m\tau)^{1/2}(r\mathrm{d}\theta/\mathrm{d}t)^{1/2}{}_{\mathrm{mean}} \quad (6)$$

where $\bar{i}_d$ is the mean diffusion-controlled current in μA, n is the number of electrons transferred per an ion, C is the bulk concentration of the depolarizer in mF, D is the diffusion constant in cm^2/sec., τ is the life-time of the DME in sec. and k is a numerical constant. In Eq. 6, it is assumed that the streaming velocity of the solution on and near the electrode surface is proportional to the velocity of the vibration. It is noteworthy that the actual surface velocity, and accordingly, the constant, k, are unknown.

Combining Eqs. 3, 5 and 6, one can obtain an expression for the relation between the limiting current and the surface charge of the DME;

$$\bar{i}_l=\bar{i}_d+k'(qE)^{1/2} \quad (7)$$

where k' is a proportionality factor.

The surface charge, q, of the DME in Eq. 7 can be evaluated by the following equation. Assuming Helmholtz's electrical double layer, we get

$$q=\varepsilon\varphi/4\pi\delta \quad (8)$$

where ε is the dielectric constant, φ is the potential of the DME and δ is the thickness of the electrical double layer.

Eqs. 7 and 8 lead to the following expression:

$$\bar{i}_l-\bar{i}_d=k''E^{1/2}(\varphi_{\mathrm{DME}}-\varphi_{\mathrm{max}})^{1/2} \quad (9)$$

where k'' is a proportionality factor, φ_{DME} is the potential of the DME and φ_{max} is the potential of the electrocapillary maximum.

From Eq. 9 it can be forecast that $(\bar{i}_l-\bar{i}_d)$ becomes practically zero at the potential of the electrocapillary maximum, and that the current-voltage curve of the VDME consists of two parabolas which intersect at the potential of the electrocapillary maximum. This curvilinear relation of the current and the potential can be transferred to the linear relation by plotting the square of the $(\bar{i}_l-\bar{i}_d)$ versus the potential of the DME.

The accurate determination of the Lippmann-potential will be carried out by evaluating the intersecting point of two straight lines of the $(\bar{i}_l-\bar{i}_d)^2$ versus φ_{DME} plot in the positive polarization and in the negative polarization, respectively.

Experimental

The current-voltage curve was recorded by a Shimadzu Model RP-2 polarograph. The DME used was of an appreciably long life-time and of the slow rate of mercury flow (τ=ca. 10 sec., $m\leq$1 mg./sec.). It is because the mercury flow on the surface of the DME owing to the rapid growth of the mercury droplet presumably affects the ζ-potential of the mercury-solution interface.

The a. c. source was supplied from a C-R oscillater, and was amplified by a power tube (6L6G) and the cathode-follower out-put was applied to the platinum plate electrodes (Fig. 2).

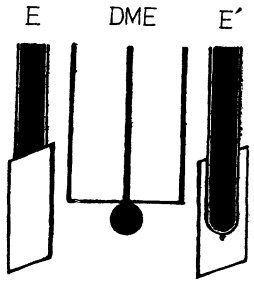

Fig. 2. VDME: E and E' are the platinum plate electrodes to which the a. c. voltage is applied.

Since the impedance of the solution was small, the cathode resistor as small as 30 ohms was used in order to avoid the voltage drop of the out-put. The a. c. voltage was measured by a vacuum tube voltmeter.

All the reagents were of analytical grade. The test solution contained 10^{-3} F Hg^{2+} as the depolarizer. The concentration of the supporting electrolyte ranged from 10^{-3} to 1 F. In the case of the low saline concentration, the depolarizer concentration as small as 10^{-4} F was preferable in order to avoid the migration current. Under these conditions the mercuric ion develops a well-defined wave by a conventional polarograph, and the diffusion-controlled current gives a plateau ranging from -0.1 to -1.7 volts vs. S. C. E. The trace of dissolved oxygen was carefully removed by adding a small quantity of the sodium sulfite solution after the sufficient

2) Y. Okinaka and I. M. Kolthoff, *J. Am. Chem. Soc.*, **79**, 3326 (1957).

bubbling of purified nitrogen. The presence of trace oxygen in the test solution causes the fatal deformation of the current-voltage curve, especially near the potential of the electrocapillary maximum in question.

Results and Discussion

The current-voltage curve of 0.77×10^{-3} F Hg^{2+} in 0.1 F KCl is illustrated in Fig. 3. In Fig. 3 the diffusion-controlled current gives a plateau covering the whole voltage span recorded.

In the region of the positive polarization, the vibration of the DME is gradually retarded as the applied potential is shifted toward more negative potentials, corresponding to the decrease of the surface charge of the DME, and this effect results in the decrease of the limiting current. At the zero-charge potential, that is, the potential of the electrocapillary maximum, the vibration entirely ceases, and accordingly the limiting current will be solely controlled by the diffusion of the depolarizer. Under the appreciably low intensity of the a. c. electric field, the limiting current coincides with the diffusion-controlled one at the potential of the electrocapillary maximum, while it is not so under the sufficiently intense electric field as is illustrated in Fig. 3. This reason is attributable to the fact that the rapid variation of the current at the potential close to the electrocapillary maximum can not be followed by the recorder owing to its damping. In the region of the negative polarization, the limiting current reincreases as the applied potential is shifted toward more negative potentials, corresponding to the increment of the surface charge of the DME. Thus, the limiting current gives a minimum at the potential of the electrocapillary maximum.

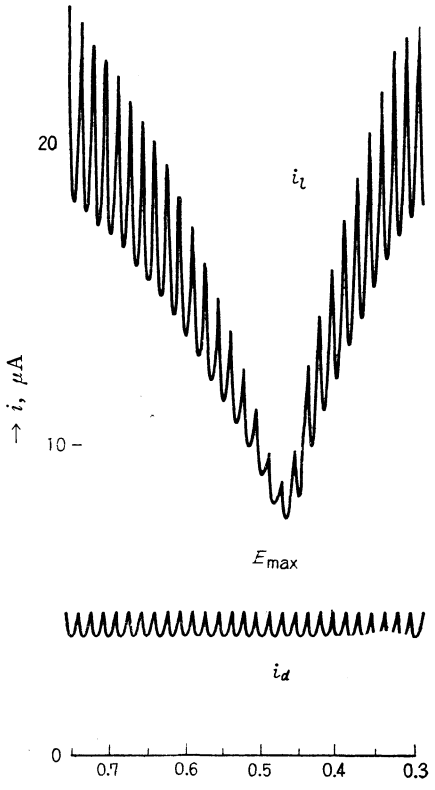

Fig. 3. The VDME current-voltage curve of 0.77×10^{-3} F Hg^{2+} in 0.1 F KCl. The a. c. frequency=25 c. p. s. The intensity of the electric field=0.55 volts/cm. τ= 9.9_4 sec. (open circuit). $m=0.85_5$ mg./sec. Temperature=25°C. (The intensity of the a. c. electric field can be lowered when the trace of surface active materials is removed by adding active charcoal).

The square of $(\bar{i}_l-\bar{i}_d)$ is plotted versus the potential of the DME in Fig. 4. In Fig. 4, the parabolic curvilinear relation of the current-voltage curve in Fig. 3 is transferred to the linear relation as is predicted in Eq. 9. The mean value** of the potential at the intersecting point of

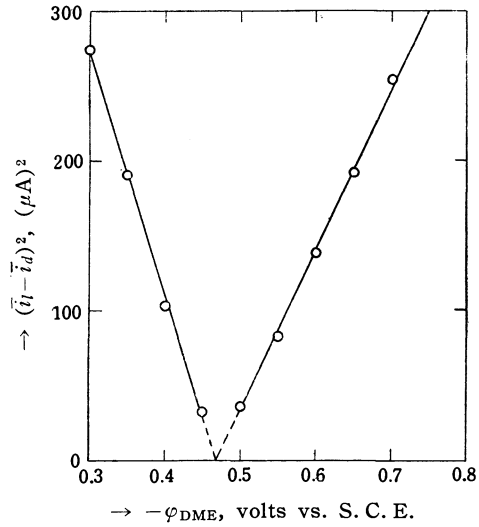

Fig. 4. Variation of the square of $(\bar{i}_l-\bar{i}_d)$ with the potential of the DME. The current was evaluated at the middle point of the saw-tooth oscillation in Fig. 3.

** This value was evaluated as the mean of the data obtained when the applied voltage sweeps toward more negative potentials and when the applied voltage sweeps toward less negative potentials.

two straight lines is -0.467 ± 0.001 volts vs. S. C. E. (in 0.1 F KCl solution). This value shows a very good agreement with the datum obtained by Grahame[3].

This method of determining the Lippmann-potential seems to be better than any other method[4] from the standpoints of the ease and rapidness of the recording, and of its good reproducibility and accuracy.

The authors wish to express their hearty gratitutde to Professor Mutsuaki Shinagawa for his advice and encouragement.

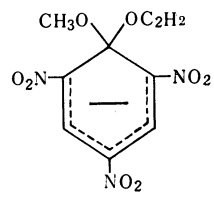
Visible and Ultraviolet Absorption Spectra of Red Complexes of 1,3,5-Trinitrobenzene and its Derivatives with Ammonium Hydroxide



By Takehiro ABE

(Received February 10, 1959)

Trinitrobenzene and its derivatives give red colors with ammonia and with aqueous alkalies. In 1902, Meisenheimer[1] already suggested the following formulae I and II like intermediates in aromatic substitutions, for structures of red products of 1, 3, 5-trinitrobenzene and trinitroanisole with sodium methoxide or sodium ethoxide, respectively.

I

II

By means of the infrared or visible absorption spectra for the red complex of trinitroanisole Meisenheimer's structure II has recently been supported by Hammick and Foster[2,3], by Caldin et al.[4,5], and by Nagakura and Tsubomura[6]. In the previous papers[7,8] the present author also reported the visible absorption spectra of the red colors produced by trinitrobenzene, trinitrotoluene, and tetryl in dilute aqueous solutions of sodium hydroxide. These red colors were reversibly decolorized by addition of weak acids. All the above spectra have been measured directly for the red solutions prepared by adding alkaline solutions into solutions of the nitro compounds, and consequently have been subjected to be influenced by alkalies in the solutions, giving no precise molar absorbancies. In the present study, an attempt has, therefore, been made to determine molar extinction coefficients for the spectra of the red complexes of 1, 3, 5-trinitrobenzene, 2, 4, 6-trinitrotoluene, tetryl, and picryl chloride with ammonium hydroxide without the effect of alkali.

Experimental

Solvents.—All commercial guaranteed solvents were fractionally distilled after usual treatments.

Preparation of the Red Complexes of the Nitro Compounds with Ammonium Hydroxide.—A red-colored solution was prepared by

adding a little of guaranteed ammonia water (28%) into a solution made by dissolving each of the nitro compounds into acetone. This red solution was evaporated slowly at room temperature by a vacuum pump to remove acetone, ammonia and water, and a dark red residue was obtained. However, the red substance obtained

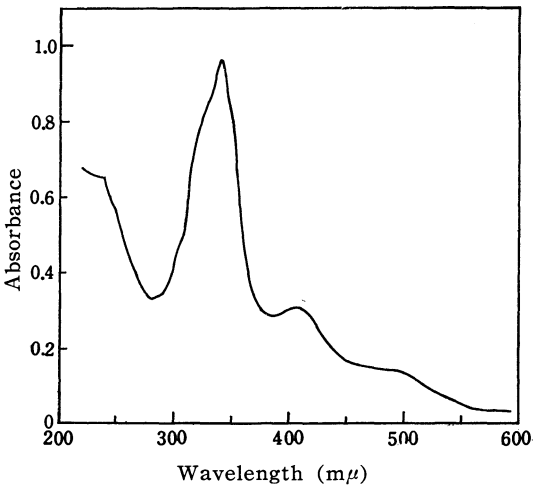

Fig. 1. An absorption spectrum of the red complex of trinitrotoluene with ammonium hydroxide, obtained by evaporation on a water bath, in water.

by evaporation not at room temperature but on a water bath gives an absorption curve illustrated in Fig. 1, which is very different from that indicated in Fig. 2, possibly owing to the further reaction. After being washed with a small quantity of acetone to remove the nitro compound contained, the red substance was dried again at room temperature by a vacuum pump. The powdered dark red product obtained is considered to be the colored complex of the nitro compound with ammonium hydroxide, which is more soluble in water than in acetone, while the nitro compound readily dissolves in acetone but not easily in water. By the above procedure, the red complex of picryl chloride could be obtained easily, although the red color produced by picryl chloride with sodium hydroxide in water disappeared in a few minutes[8].

Spectra.—The spectra of the solutions were measured with a Hitachi quartz spectrophotometer, Model EPU-2 at room temperature. The path length of absorption cells was 1 cm.

Trinitrobenzene forms with sodium methoxide a red product of the empirical composition, trinitrobenzene · CH_3ONa · $1/2H_2O$[9] and with sodium hydroxide a red one having the empirical composition, trinitrobenzene · NaOH[10], respectively. In the present work, the red complexes of the nitro compounds with ammonium hydroxide are assumed to have compositions of nitro compound·NH_4OH in calculating molar extinction coefficients for their spectra. This point is returned to below.

Results and Discussion

The Spectra of the Red Complexes of the Nitro Compounds with Ammonium Hydroxide in Water (Fig. 2).—An absorption spectrum for the red complex of trinitrotoluene is similar to that for the

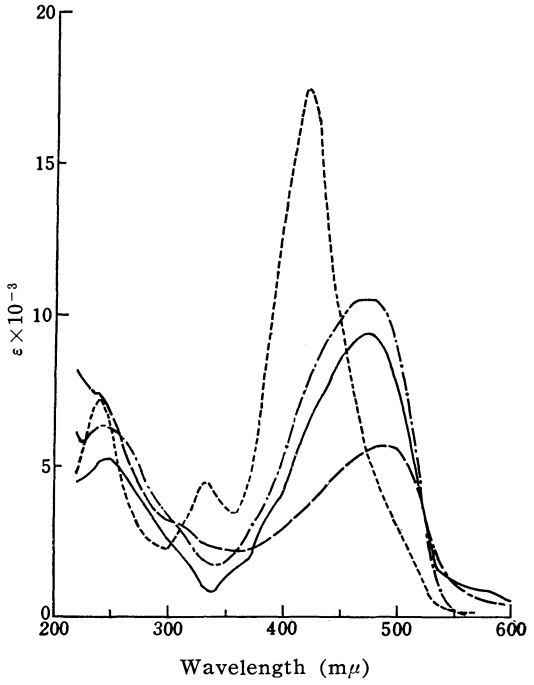

Fig. 2. Absorption spectra of the red complexes of trinitrobenzene (——), trinitrotoluene (—·—), tetryl (— —), and picryl chloride (----) with ammonium hydroxide, all in water.

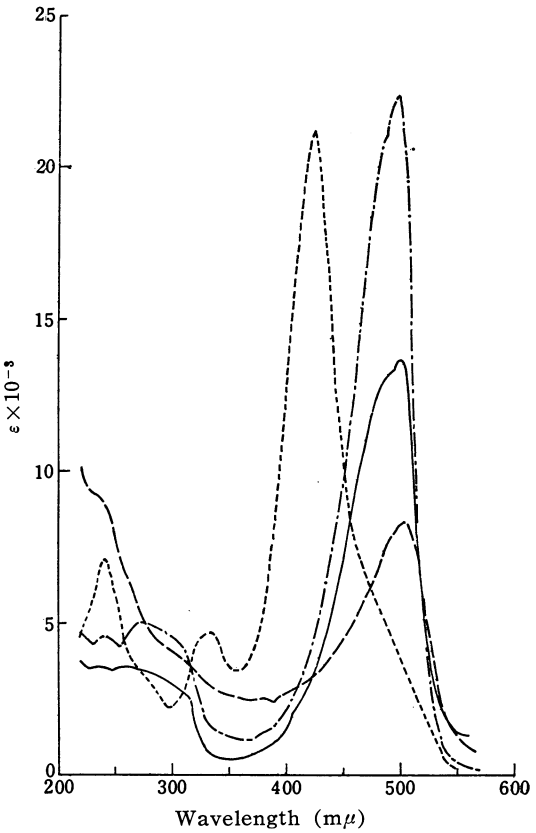
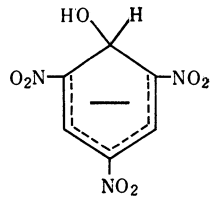
complex of trinitrobenzene, showing an intense absorption maximum band at about 475 mμ, although a whole molar absorbancy for the former is slightly greater than that for the latter. This similarity implies that both the red complexes are structurally analogous. The red complex of tetryl also shows an analogous absorption curve with those of trinitrobenzene and trinitrotoluene, giving a weaker absorption maximum at about 490 mμ as compared with those for the latter. Only the red complex of picryl chloride shows an intense absorption maximum band at about 420 mμ as compared with those for the other complexes, and a weak band clearly at about 330 mμ. The 330 mμ band seems possibly to be attributed to the complex, although it has not been decided whether the band is due

to the complex itself or to picric acid formed by the further reaction[8], because the band lies at the wavelength close to that of the maximum for the picrate ion. All these red complexes give distinct bands at about 240 mμ.

The Spectra of the Red Complexes in Ethanol (Fig. 3).—These red comlexes in ethanol roughly show the similar spectra





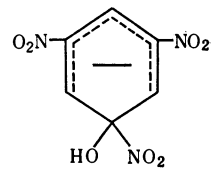


Fig. 3. Absorption spectra of the red complexes of trinitrobenzene (——), trinitrotoluene (—·—), tetryl (—··—), and picryl chloride (----) with ammonium hydroxide, all in ethanol.

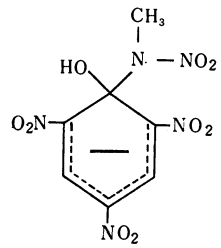
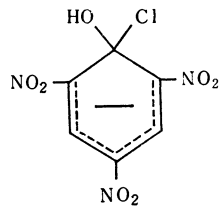
as in water. Both in ethanol and in water, the intense visible absorption bands for these complexes shift to the red in the order of picryl chloride, trinitrotoluene, trinitrobenzene, and tetryl with their molar absorbancies decreasing in the same order, except the molar absorbancy for picryl chloride in ethanol. The molar absorbancies for the 240 mμ bands increase in the order of trinitrobenzene, trinitrotoluene, picryl chloride, and tetryl. All the visible bands shift to the red and have greater molar absorbancies in ethanol as compared with those in water. Each of the wide visible bands for the red complexes of trinitrobenzene, trinitrotoluene, and tetryl in water is expected to consist of more than two absorption bands, because a shoulder is observed for the corresponding one in ethanol.

The red complexes between these nitro compounds and ammonium hydroxide may be regarded as the same complexes as those of the nitro compounds with sodium hydroxide or sodium methoxide. Accordingly, the red complexes with ammonium hydroxide can be presumed to have compositions of nitro compound · NH_4OH by analogy with the empirical compositions of trinitrobenzene · CH_3ONa[9], trinitrobenzene · NaOH[10], and trinitroanisole · CH_3ONa[11], as mentioned above. On standing in the cold with dilute aqueous solution of sodium hydroxide, 1,3,5-trinitrobenzene yields 3,5-dinitrophenol[12] through a red intermediate. Considering only this reaction, the red intermediate seems to be more like the following structure IV than like the structure III presented by Meisenheimer, as mentioned in the previous paper[8].



III

IV



The red color of the complex is certainly owing to transitions of its π-electrons. On the other hand, the complex of tetryl with sodium hydroxide finally produces a product indicating an absorption curve analogous to that for picric acid[8]. The red complex of tetryl with hydroxide anion is, therefore, expected to have Meisenheimer's structure V.

V

11) Jackson, *Am. Chem. J.*, **20**, 448 (1898); **23**, 294 (1901).
12) L. de Bruyn and van Leent, *Rec. trav. chim.*, **13**, 151 (1894).

However, Figs. 2 and 3 indicate that the spectra for the red complex of trinitrobenzene resemble those for the red complex of tetryl, as in the case of the red complexes with sodium hydroxide[8]. This similarity between their spectra can be explained by assuming the structure III for the red complex of trinitrobenzene, since the structure IV is hardly expected to be able to give the similar spectra as those for structure V owing to difference between their π-electron systems. In dilute aqueous solution of sodium hydroxide, picryl chloride finally gives an absorption curve analogous to that of picric acid after the red coloration[8], as in the case of tetryl. The red complex of picryl chloride with ammonium hydroxide is, therefore, expected to have the structure VI such as that for tetryl.

VI

Figs. 2 and 3, though not decisive, appear to be in favor of Meisenheimer's structures such as III, V and VI for all the above red complexes with ammonium hydroxide. Their structures are, however, to be determined hereafter by means of X-rays and infrared spectroscopy.

The difference between the spectra for the red complexes of tetryl and picryl chloride, which both seem to have the same π-electron structures indicated in V and VI, can be interpreted in terms of hyperconjugation of -Cl and $-N(CH_3)NO_2$ to their π-electron systems.

Effect of Sodium Hydroxide on the Spectrum of the Red Complex of 2, 4, 6-Trinitrotoluene with Ammonium Hydroxide in Water (Fig. 4).—As the concentration of sodium hydroxide increases, the molar absorbancy for the spectrum of the red complex of trinitrotoluene with ammonium hydroxide decreases in water, and the decolorization of the red color becomes faster. On the other hand, all these red complexes of the nitro compounds are very stable both in water and in ethanol in absence of alkali. The negative ion OH^- is, therefore, considered

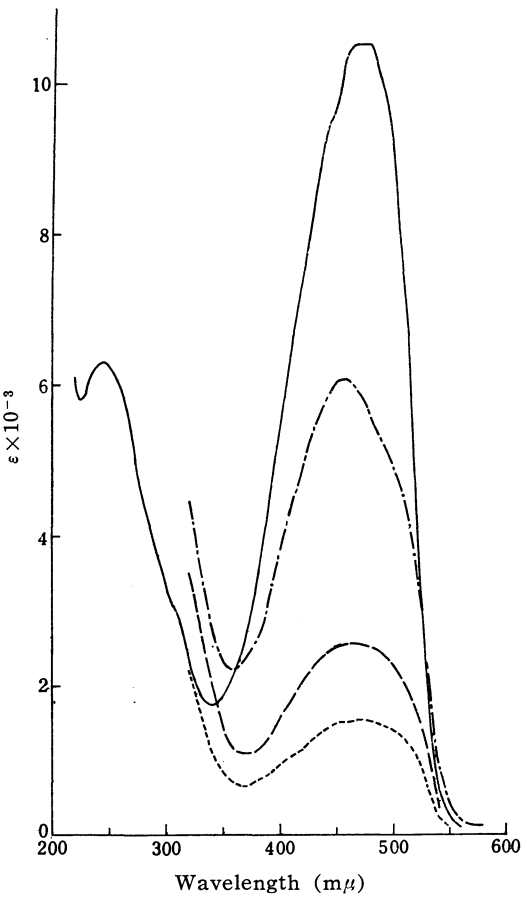


Fig. 4. Absorption spectra of the red complex of trinitroluene with ammonium hydroxide (4.96×10^{-5} M) in water (——) and in aqueous sodium hydroxide solution (0.103 N: —·—, 0.516 N: ——, 1.03 N: ----).

to play an important role for the further decolorization reaction of the red complex. At a low concentration of sodium hydroxide, 0.103 N, the red complex of trinitrotoluene shows an absorption curve similar to that for trinitrotoluene in an aqueous solution of sodium hydroxide[7,8]. This leads to the suggestion that the absorption curves for the red complexes of the nitro compounds, reported in the previous papers[7,8], are somewhat affected by sodium hydroxide.

Summary

The red complexes of trinitrobenzene, trinitrotoluene, tetryl and picryl chloride with ammonium hydroxide, regarded as intermediates in aromatic substitutions, were obtained. Each of these red complexes roughly shows a similar spectrum

both in water and in ethanol. All their visible bands, however, shift to the red and have greater molar absorbancies in ethanol as compared with those in water. The red complex of trinitrobenzene shows an absorption curve analogous to that for the complex of tetryl, although they yield different products after further reactions. As the concentration of sodium hydroxide increases, the molar absorbancy for the spectrum of the red complex of trinitrotoluene decreases in water, probably owing to the action of OH^-.

SHORT COMMUNICATIONS

Infrared Spectroscopic Study on Hydrogen Bond Formation between Acetylene and Donor Solvents

By Shunsuke MURAHASHI*, Bunkichi RYUTANI and Koichi HATADA*

(Received June 5, 1959)

It was previously reported by Copley[1], Huemer[2], and Mckinnis[3] that a donor solvent showed a high solvent power for acetylene. They suggested that this could be attributed to hydrogen bond formation between a hydrogen atom of methine group and a donor group of solvent. Any direct experimental evidence, however, has not been given.

In the course of our studies on the solubility of high pressure acetylene in various solvents at low temperature, some evidences which show the hydrogen bond formation have been accumulated by the measurements of the solubility in mixed solvents and of infrared spectra of acetylene. This communication deals with some results obtained from spectroscopic measurements[4].

The spectra were measured by means of a Perkin-Elmer model 21 double beam spectrophotometer equipped with a rock salt prism. The wave numbers of the absorption bands were corrected by the spectral data of a thin film of polystyrene measured right after each run. The error range of the observed wave numbers was about $\pm 5\,cm^{-1}$ at $3000\,cm^{-1}$ and about $\pm 1\,cm^{-1}$ at $700\,cm^{-1}$. Two cells of 0.1 mm. thickness filled with solution and with pure solvent respectively, were used in order to avoid interference of strong bands of the solvent. All the measurements were carried out at 20~25°C.

The spectral data of the acetylene dissolved in various solvents are given in Table I. As shown in Table I, the C–H stretching bands of acetylene in these solutions shift toward lower frequencies and the C–H deformation bands toward higher frequencies than those of gaseous acetylene. The largest shifts of the C–H stretching and deformation frequencies were found for ethyleneglycol dimethyl ether solution. On the other hand, the solution in *n*-octane, which shows the lowest solubility of acetylene, gives negligibly small shifts of the C–H stretching and deformation bands. The last column of Table I shows that the solubility of acetylene in donor solvents can be related to the magnitudes of the shifts of the C–H stretching and deformation frequencies. Therefore, it appears that a close relationship exists between the solubility of acetylene and the donating power of solvent molecules.

Further evidences of these arguments were also obtained by the absorption

measurement of four monosubstituted acetylene derivatives as shown in Table II. The spectra of these compounds are somewhat complicated on account of an interaction between methine group and substituted group in the molecule. It is, however, of interest to see great differences between the frequencies of their C-H stretching bands in ethyleneglycol dimethyl ether solution and those in carbon tetrachloride solution. In these cases it is seen that the magnitude of the shift of the C-H stretching band depends upon the electronegativity of the substituted groups. All of the above results show that a hydrogen bond is formed between the solute and the donor solvent molecules.

Furthermore some additional evidences of the presence of these intermolecular interaction were also obtained. As shown in Table II, the absorption bands of pure liquid propiolic and cyanoacetylene considerably shift to lower frequencies than those in dilute carbon tetrachloride solution. These shifts may be attributed to the formation of intermolecular hydrogen bond.

Similar shifts were also observed for phenyl acetylene and its deuterated one. The shifts are, however, not so large as those of the above mentioned substances. Therefore, these small shifts may be caused by the "hydrogen-bond-like interaction" between π bonds of benzene nucleus and methine hydrogen[6].

The C-H deformation band was not observed in the rock salt region for the acetylene derivatives except for the case of cyanoacetylene where the frequency of the C-H deformation band was 671 cm^{-1} for the carbon tetrachloride solution and 736 cm^{-1} for the ethyleneglycol dimethyl ether solution. These results of the deformation band may also support the presence of hydrogen bond between the solute and the solvent.

Polarographic Half-Wave Reduction Potentials of Vinyl Compounds and their Molecular Orbital Computation

By Takayuki Fueno, Kameo Asada, Keiji Morokuma and Junji Furukawa

(Received June 25, 1959)

The polarographic half-wave reduction potentials of several vinyl compounds have been determined under essentially identical condition*, and it has been found that these potentials are linearly related to the heights of the lowest vacant π-electronic energy levels of these compounds calculated by the LCAO MO method.

The reduction potentials were determined in a 3 : 1 dioxane-water mixture containing 0.05 M tetra-*n*-butylammonium iodide as a supporting electrolyte. All the compounds were purified by appropriate methods before use. A measured amount of vinyl compound was dissolved into the electrolyte solution so that its concentration was in the region ranging from 10^{-3} to 5×10^{-3} M.

The electrolysis-cell was immersed in a thermostat maintained at 25.0±0.1°C, and any oxygen dissolved in the solution was removed by passing through it a slow stream of oxygen-free and solvent-saturated nitrogen. The dropping-mercury electrode was polarized against a saturated calomel electrode (S. C. E.) connected to the mercury cathode through a pin-hole in the wall of the cell, and the current-voltage curve was recorded. Maxima of the current-voltage curves were suppressed by 10^{-5} M methylene blue incorporated in the sample solution. The half-wave potentials, $E_{1/2}$, were read against S. C. E. and were all corrected for *iR* drop. When tetra-*n*-butylammonium hydroxide was used as the supporting electrolyte, the potentials did not appreciably deviate from those determined in the iodide solution. All the obtained data on $E_{1/2}$ are listed in Table I.

In calculating the energies of the lowest vacant π-levels, the simple LCAO MO method (neglecting overlap integrals) was employed. For each vinyl compound x_{lv}, defined as $\varepsilon_{lv}=\alpha+x_{lv}\beta$, was obtained from the required secular equation. Here α and β are the Coulomb integral of a carbon atom and the resonance integral of a carbon-carbon π-bond, respectively, and ε_{lv} is the energy of the lowest vacant π-level. To empirical integral parameters associated with heteroatoms, were assigned the same values that had previously been used to calculate the localization energies of vinyl compounds[1,2]: $\alpha_O=\alpha+2\beta$ (for carbonyl oxygens), $\alpha_O=\alpha+\beta$ (for ethereal oxygens), $\alpha_N=\alpha+\beta$, $\alpha_{Cl}=\alpha+1.8\beta$, $\alpha_C=\alpha-0.2\beta$ (for carbons bearing a methyl group), $\beta_{CO}=\sqrt{2}\beta$ and $\varepsilon=0.1$**. * Some experimental data determined under different conditions are available, which can not be directly compared.

1) T. Fueno, T. Tsuruta and J. Furukawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 78, 1075 (1957).

2) T. Fueno, T. Tsuruta and J. Furukawa, ibid., 78, 1080 (1957).

** A carbon atom bearing one or more heteroatoms was assumed to have the Coulomb integral of $\alpha+\varepsilon\beta\Sigma k_X$. Here $\alpha+k_X\beta$ is the Coulomb integral of the heteroatom X.

resonance integrals for π-bonds other than carbonyl bonds were all assumed equal to β. The calculated values of x_{lv} are also listed in Table I. Since both α and β are negative quantities, the lowest vacant level ought to be more stable as x_{lv} takes a smaller negative value.

Inspection of the data given in Table I shows that, the smaller the value of x_{lv} for a vinyl compound, the more easily it can be reduced. Phenyl vinyl ether was found to have the highest reduction potential (ca. -3.0 V.) of all the compounds which could be reduced under the present experimental condition. At about -3.0 V. the residual current began to increase markedly owing to reduction of the supporting electrolyte. Vinyl acetate, vinyl chloride, *n*-butyl vinyl ether, *i*-butyl vinyl ether, ethylene, propylene and isobutylene gave no reduction waves in the range of the applied potential less negative than -3.0 V. vs. S. C. E. The situation may reasonably be explained by their relatively large values of $-x_{lv}$.

The half-wave potentials, $E_{1/2}$, determined with the ammonium iodide as the supporting electrolyte were found to be linearly correlated to x_{lv}'s by

$$E_{1/2} = 2.33\, x_{lv} - 0.80$$

the correlation coefficient being 0.995. The linear equation gives $\beta = -2.33$ eV., if it is assumed that, as in the case of unsaturated hydrocarbons[3,4], the electron transfer step from the electrode to vinyl compounds would be potential-determining. This value of β is in reasonable agreement with -2.23 eV.[4] for unsaturated hydrocarbons.

It seems interesting to note that the value of $-x_{lv}$ increases with increasing magnitude of the anionic β-carbon localization energy, L_{β^-} [2], of vinyl compounds, as seen in Table I. Thus, the polarographic reducibility of vinyl compounds may roughly parallel to their anionic polymerizability. This is to be expected, because vinyl compounds probably possess parallel susceptibilities toward an electron as well as basic substances. The detailed discussion on the present results will be published elsewhere.

*The Abnormal Relation between the Viscosities and the Temperatures of Sodium Carbonate Solution**

By Kazuo FUJITA

(Received June 29, 1959)

It has been reported that the ultrasonic velocity and electric conductivity of the dilute solution of sodium sulfate present the abnormalities at the temperatures near the transition points of the saturated solution coexisting with the solid states[1,2].

But the reason why these abnormalities are caused is not fully explained in these reports. Therefore, this communication is to report that the abnormal relation between the viscosities and the temperatures was discovered in sodium carbonate solution.

The author believes that this result is a clue to the behavior of the aqueous solution, containing the inorganic compounds which have the transition-points in the saturated solutions.

In the viscosity measurements was used Ubbelohde suspended level viscometer,

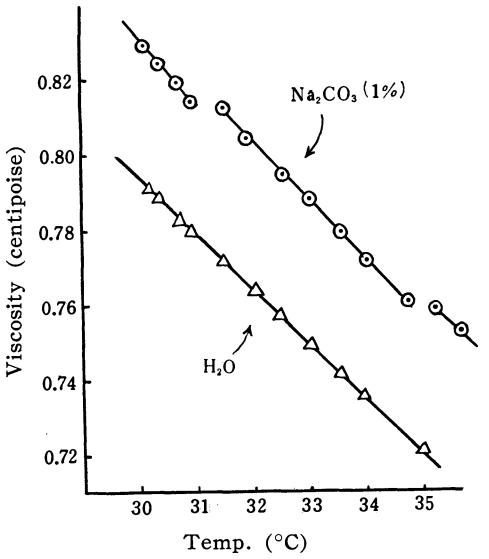

Fig. 1. Plot of viscosity against temperature for 1% Na_2CO_3 aqueous solution and distilled water.

* Presented at 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April 2, 1959.

1) T. Sasaki and T. Yasunaga, *Chem. and Chem. Ind. (Kagaku to Kogyo)*, **7**, 146 (1954).

2) K. Hirano, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **79**, 648 (1958).

the length and diameter of whose capillary are 20 cm. and 0.33 mm., respectively, and this viscometer being used, the flow time of distilled water 7 cc. was 2280 seconds at 25°C, and in this determination a kinetic energy correction was negligible. The temperature measurements were made with accuracy of ±0.01°C. At intervals of 0.5°C from 25 to 40°C, the flow time of 1% sodium carbonate solution and distilled water were measured using a stop watch. The results were shown in Fig. 1. From these results, it is seen that the changes of viscosity with temperatures were not smooth at about 31 and 35°C.

TABLE I. ENTHALPIES OF ACTIVATION FOR VISCOUS FLOW OF Na_2CO_3

Temp. range (°C)	Enthalpy of activation for viscous flow (kcal./mol.)
Below 30.93	5.11
31.43~34.90	3.11
35.29 and over	2.63

These two points of temperature correspond to the two transition points of the saturated sodium carbonate coexisting with the solid.

Eyring and coworkers[3] have applied the theory of absolute reaction rates to viscous flow and obtained following relation

$$\eta = hN/V \cdot \exp \Delta F^*/RT$$

where ΔF^* is the free energy of activation for viscous flow, V is the molar volume and the other constants have the usual significance. By using this relation the enthalpies of activation for viscous flow were calculated. The values of the enthalpies at below 30.9°C, 31.4~34.9°C and above 35.3°C are different from each other, and the data are shown in Table I.

The viscosity measurements are being made on solutions of sodium carbonate with various concentrations and dilute solutions of other compounds (e.g., Na_2HPO_4).

The Syntheses and Exhaustive Methylation of cis- and trans-1, 2, 3, 4, 5, 6, 4a, 4b-Octahydrobenzo [f] quinoline[1]

By Tadashi MASAMUNE
and Masato KOSHI*

(Received July 10, 1959)

A recent paper[2] has described the preparation and also Hofmann's exhaustive methylation of 4-methyl-1, 2, 3, 4, 5, 6, 4a, 4b-octahydrobenzo [f] quinoline (II) R=Me. The stereochemistry of the ring fusion is tentatively assigned as *cis*.

The present paper undertakes to report the syntheses and exhaustive methylation of *cis*- and *trans*-1, 2, 3, 4, 5, 6, 4a, 4b-octahydrobenzo [f] quinoline (II) R=H and (IV). These bases are interesting as 5, 6-benzo-derivatives of decahydroquinoline.

* Present address: Central Research Laboratory of Tōyōkōatsu Industries, Inc., Totsuka-ku, Yokohama.

1) Part X of "The Condensed Polynuclear Perhydrocompounds Containing Nitrogen"; Part IX, T. Masamune, This Bulletin, **30**, 491 (1957).

2) N. A. Nelson, J. E. Ladbury and R. S. Hsi, *J. Am. Chem. Soc.*, **80**, 6633 (1958).

Hydrogenation of benzo[f]quinoline[3] (I) R=A using a catalyst of Raney nickel (150°C) under 100 atm. initial pressure resulted in conversion into the mixture of octahydrobenzo[f]quinoline, consuming four molecular equivalents of hydrogen. From the ethereal solution of oily mixture, *cis*-octahydrobenzo[f]quinoline (II) R=H was isolated as carbonate. *cis*-1,2,3,4,5,6,4a,4b-Octahydrobenzo[f]quinoline[4], which was analyzed as the hydrochloride (Found: C, 64.46; H, 8.09. Calcd. for $C_{13}H_{17}N \cdot HCl \cdot H_2O$; C, 64.65; H, 8.28%.), can be regenerated from the carbonate by adding aqueous caustic alkali. Overall yield, 4.8%. The evaporation of the solvent from mother ethereal solution gave 1,2,3,4,7,8,9,10-octahydrobenzo[f]quinoline (III) in yield of 88%, but no *trans* isomeride could be isolated. On the other hand, hydrogenation of 1,2,3,4-tetrahydrobenzo[f]quinoline[5] (I) R=B in glacial acetic acid with platinum oxide as a catalyst at ordinary pressure, gave the mixture of *cis* and *trans* isomers of octahydrobenzo[f]quinoline in poor yield (*cis* and *trans* 2.4% each). The main product was 1,2,3,4,7,8,9,10-octahydrobenzo[f]quinoline. Yield, 86%. The separation of *cis* and *trans* isomerides was carried out most conveniently by means of the difference between the speed of carbonate formation of the *cis*- and *trans*-bases; thus, on exposing the mixture of *cis* and *trans* isomerides to air for a few hours the *cis* isomeride forms the carbonate preferentially.

Furthermore, the reduction of benzo[f]-quinoline to octahydro-derivatives by sodium and amylalcohol, which has been first described by Bamberger and Müller[3] was reexamined. In this case, *trans*-1,2,-3,4,5,6,4a,4b-octahydrobenzo[f]quinoline (IV) (2.9%) (Found: C, 83.25; H, 9.12; Calcd. for $C_{13}H_{17}N$: C, 83.43; H, 9.08%.), 1,2,3,4,7,8,9,10-octahydrobenzo[f]quinoline (III) (29%) and 1,2,3,4-tetrahydrobenzo-[f]quinoline (V) (39%) were obtained respectively from the reaction mixture.

Though no rigid proof can be given for the configuration of the above isomers,

N-Methylate picrate	m. p. 165~167	m. p. 210~212
Methiodide	m. p. 295[a]	m. p. 238~240

a) N. A. Nelson et al.[2] record m. p. 295°C (decomp.).
b) E. Bamberger et al.[3] record m. p. 91°C.
c) E. Bamberger et al.[3] record m. p. 252°C.

3) E. Bamberger and R. Müller, *Ber.*, **24**, 2648 (1891).
4) Analysis of free base was difficult, owing to rapid absorption of atmospheric carbon dioxide.
5) E. Bamberger and R. Müller, *Ber.*, **24**, 2641 (1891).

in view of the reduction conditions and other considerations[2] there is little doubt that the higher melting product resulting from the reduction with sodium-alcohol system is the *trans* isomeride. The infrared spectra of *cis*- and *trans*-*N*-methyl-octahydrobenzo[f]quinoline are shown in the figure. Physical constants of the *cis* and *trans* isomers and their derivatives are given in Table I.

Exhaustive methylation of *cis*-octahydrobenzo[f]quinoline has been recently carried out by Nelson et al.[2] who found that distillation of *cis*-octahydro-4-methylbenzo[f]quinoline methohydroxide produced 1-(3-dimethylaminopropyl)-3,4-dihydronaphthalene (VI). In the present investigation the Hofmann degradation of *cis*- and *trans*-octahydro-4-methylbenzo[f]-quinoline methohydroxides gave the same oily product in yields of 43% and 32%, respectively, boiling at 150~155°C/4 mm. (picrate m.p. 87~88°C), which was identified as 1-(3-dimethylaminopropyl)-3,4-dihydronaphthalene (VI), and no other compound could be isolated.

Examination of a model of the feasible structures for *cis*- and *trans*-*N*-methyl-octahydrobenzo[f]quinoline shows that in *cis* configuration the necessary conformational requirement for easy Hofmann fission is satisfied by elimination of any one of the equatorial 2-hydrogen, 4b-hydrogen and 5-hydrogen and in *trans* configuration by elimination of the equatorial 2-hydrogen.

Thus, in the exhaustive methylation of both *cis*- and *trans*-octahydrobenzo[f]-quinolines the preferential elimination of a β-proton on C 4b shows vividly that the influence of the electronic character of aromatic substituent at position C 4b is superior to the necessary co-planar *trans*-arrangement for easy Hofmann fission. Several examples[6] of this type of elimination have already been reported. Detailed results of the matters discussed in the present paper will be reported elsewhere.

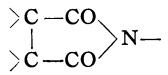
Thermal Homopolymerization of Lysine and Copolymerization with Neutral and Acidic Amino Acids[1]



By Kaoru HARADA

(Received July 15, 1959)

Glutamic acid and aspartic acid characteristically yield copolymers[2,3] with unsubstituted amino acids which fail to form polymers when heated individually. By using an excess of acidic amino acids, it is furthermore possible to copolymerize eighteen common amino acids into a *proteinoid*[4].

The special effects of basic amino acids, particularly lysine, are also interesting. Free DL-lysine was converted to its liquid lactam at 150~170°C with vigorous evolution of water vapor and it homopolymerized at 180~230°C.

The free lysine also copolymerized easily with glycine, alanine and other neutral amino acids, glutamic acid, aspartic acid, caprolactam, succinic acid, terephthalic acid and other carboxylic acids. After acidic hydrolysis, component amino acids were identified by paper chromatography. Infrared absorption spectra of lysine homopolymer, lysine-neutral amino acid copolymers and lysine-glutamic acid copolymer indicated that these are typical polypeptides. The salient maxima at 3080, 3280, 1630 and 1540 cm^{-1}; however, lysine-aspartic acid copolymer shows additional bands at 1720 and 1780 cm^{-1} which indicate the 5 membered cyclic imide structure[5],

Some of the yield and amino acid composition of typical polymers are as follows:

* DL-Lysine (0.01 mol.) was heated for 2 hr.

** DL-Lysine (0.01 mol.) and glycine (0.01 mol.) were heated.

*** Amino acid compositions were determined by DNP method using column chromatography.

**** DL-Lysine (0.01 mol.) and DL-aspartic acid (0.01 mol.) were heated for 2 hr.

Lysine monohydrochloride did not homopolymerize but did copolymerized with glutamic acid, and with other amino acids in the presence of orthophosphoric acid. Lysine homopolymer was water-soluble (it contained some gel-like material), but it was nondiffusible through cellophane tubing. Lysine-glutamic acid and lysine-glycine copolymers were gel-like materials and lysine-aspartic acid copolymer was sponge-like. The amphoteric polymers of lysine-glutamic acid and also lysine-aspartic acid swelled in alkali and acid, and did not dissolve in either alkali or acid. It is likely that these polymers have a high degree of branching and have a quasi three-dimensional structure. α,ω-Linkage studies of lysine and acidic amino acid residues are now in progress. The lactam formation of lysine is very interesting as is copolymerization of glutamic acid with other amino acids[2]. The lactams serve as reactive intermediates, solvents for the reactions and also basic or acidic catalysts for peptide bond formation. At this time, the studies have revealed a new property of lysine and presented an easy way to prepare lysine-containing polymers.

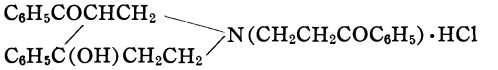
Studies on the Mannich Reaction. I. On the Formation of Piperidine Derivatives (1)

By Norito UCHINO

(Received January 30, 1959)



The Mannich reaction of acetophenone with ammonium chloride and formaldehyde[1-3] gives hydrochlorides of mono-(β-benzoylethyl)-amine (I), bis-(β-benzoylethyl)-amine (II), tris-(β-benzoylethyl)-amine (III) and a small quantity of 4-hydroxy-4-phenyl-5-benzoyl-1-(β-benzoylethyl)-piperidine (IV). The last compound is an isomer of the normal product III·HCl. The melting points of the hydrochlorides are 125, 175, 145 and 199~200°C, respectively.

$$C_6H_5COCH_3 + HCHO + NH_4Cl \longrightarrow$$

$C_6H_5COCH_2CH_2NH_2 \cdot HCl$ (I·HCl)

$(C_6H_5COCH_2CH_2)_2NH \cdot HCl$ (II·HCl)

$(C_6H_5COCH_2CH_2)_3N \cdot HCl$ (III·HCl)

(IV·HCl)

In general, this cyclic by-product, having a piperidine ring, is obtained by treating compound III·HCl with alkali[2]. It is not considered that compound III·HCl may be converted into the piperidine derivative IV·HCl in the acidic medium which is the usual condition of the Mannich reaction. Therefore, we can regard compounds I·HCl, II·HCl and III·HCl as the normal products in the Mannich reaction, but it is considered plausible that the piperidine derivative IV·HCl may be produced in some different reactions.

Compound II·HCl or III·HCl undergoes decomposition readily when it is heated in the presence of water to give phenyl vinyl ketone[2]. Therefore, at least a small portion of the products in this Mannich reaction will decompose to give phenyl vinyl ketone, because the reaction is carried out in an aqueous medium at 100°C.

$$(C_6H_5COCH_2CH_2)_3N \cdot HCl \xrightarrow{\text{in water}} (III \cdot HCl)$$

$$(C_6H_5COCH_2CH_2)_2NH \cdot HCl + C_6H_5COCH : CH_2$$
$$(II \cdot HCl)$$

It is well known that phenyl vinyl ketone has a great reactivity to amines[4]. So, it is probable that the phenyl vinyl ketone produced may take part in this Mannich reaction.

The reaction of phenyl vinyl ketone with compound II·HCl was carried out, on trial, under the same conditions as those in the Mannich reaction to give a good yield of compound III·HCl and a small quantity of piperidine derivative IV·HCl. During the reaction, however, the temperature was kept at 40~45°C to avoid the polymerization of the phenyl vinyl ketone. This result shows that the above reaction gives the same products as those in the usual Mannich reaction. The same result was obtained, when aqueous alcohol was used instead of water as the medium. Phenyl vinyl ketone also reacted with compound I·HCl to give compound III·HCl and a small quantity of an unknown substance. In this case, piperidine derivative IV·HCl failed to be isolated.

In view of these facts, phenyl vinyl ketone may be thought to have some concern with the main reaction. But phenyl vinyl ketone failed to react with ammonium chloride under the same conditions. At a higher temperature, only the phenyl vinyl ketone polymerized. On the other hand, acetophenone and formaldehyde reacted with compound I·HCl, II·HCl or ammonium chloride to give compound III·HCl and a small quantity of compound IV·HCl.

These facts show that the Mannich reaction of acetophenone, formaldehyde and ammonium chloride proceeds step by step to give compounds III·HCl and IV·HCl, and that phenyl vinyl ketone has no concern with the main reaction. But it is thought the phenyl vinyl ketone may have some concern with the side reaction,

and that the benzoylethyl group of compound I·HCl or II·HCl plays an important role in the reaction with phenyl vinyl ketone.

In the reaction between phenyl vinyl ketone and compound II·HCl, IV·HCl was also obtained as in the Mannich reaction. But it was not probable that this IV·HCl was produced by intramolecular aldol-condensation of compound III·HCl, because compound III·HCl did not undergo isomerization, and gave no piperidine derivative IV·HCl, even when it was heated to 45°C in water. Compound III·HCl was recovered quantitatively after the treatment.

Since compound III·HCl or IV·HCl is stable and does not isomerize, it must be considered that neither of them is the secondary product but the primary one. Thus the mechanism of the reaction may be assumed as follows. The primary step of the reaction is the combination of the β-carbon atom of phenyl vinyl ketone with the nitrogen atom of compound II·HCl.

(A)

The intermediate A catches a proton to give compound III·HCl. When the intermediate A undergoes aldol-condensation intramolecularly, it gives compound IV·HCl. More detailed mechanism will be discussed in later papers.

Experimental

Reaction of Phenyl Vinyl Ketone with Bis-(β-benzoylethyl)-amine Hydrochloride (II·HCl).—A mixture of 1.5 g. of compound II·HCl, 1.5 g. of phenyl vinyl ketone and 15 ml. of water was heated with vigorous stirring at 40~45°C for 1.5 hr. A greater part of compound II·HCl dissolved better in the phenyl vinyl ketone than in water, and a crystalline matter was produced as the reaction proceeded. After being cooled for one hour, the crystals were filtered off, washed with water, and dried; yield, 2.0 g.

The crystals were treated with 8 ml. of alcohol with gentle warming, and the soluble matter was extracted. The insoluble residue (about 0.2 g.) was recrystallized from alcohol, giving compound IV·HCl; m. p. and mixed m. p., 199~201°C[5]).

Anal. Found: C, 71.44; H, 6.54; N, 3.07. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

The alcohol extract was evaporated under reduced pressure, and 1.0 g. of compound III·HCl was obtained; m. p. and mixed m. p., 143~144°C (after drying in vacuo at 78°C).

Anal. Found: C, 72.29; H, 6.20; N, 3.39. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

The same result was obtained when aqueous alcohol was used in place of water as the medium.

Reaction of Phenyl Vinyl Ketone with Mono-(β-benzoylethyl)-amine Hydrochloride (I·HCl).—A mixture of 2.1 g. of compound I·HCl, 1.5 g. of phenyl vinyl ketone, 5 ml. of water and 5 ml. of alcohol was heated with stirring at 40~45°C for two hours. The mixture was allowed to stand overnight. The crystals produced were filtered off, washed successively with benzene and alcohol-ether mixture, and dried at room temperature; yield, 1.5 g. The crystals were recrystallized from alcohol, giving compound III·HCl; m. p. and mixed m. p., 142~144°C (after drying in vacuo at 78°C).

Anal. Found: C, 71.84; H, 6.55; N, 3.10. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

The filtrate from compound III·HCl was slightly evaporated to give 0.2 g. of crystals. The crystals were recrystallized from acetone; m. p. 162~164°C. The crystals melted at 174~176°C after repeated recrystallizations. The melting point nearly coincided with that of compound II·HCl (175°C), but the melting point on admixture with an authentic sample depressed exceedingly showing the crystals not to be compound II·HCl. This is further supported by the great solubility of the crystals in alcohol, for the solubility of compound II·HCl is not so great. But it was impossible to make clear whether the crystals were an unknown compound or a mixture of some known compounds, because the yield was too small for the crystals to be identified.

The filtrate from the unknown substance was evaporated under reduced pressure until dry, and 0.5 g. of a residue was obtained. The residue was recrystallized from a mixture of alcohol and acetone; m. p., 121~122°C. The crystals were very soluble in water, and were considered as the starting material I·HCl (m. p., 122~123°C). The melting point on admixture with compound I·HCl did not depress.

Reaction of Bis-(β-benzoylethyl)-amine Hydrochloride (II·HCl) with Acetophenone and Formaldehyde.—A mixture of 3.0 g. of compound II·HCl, 1.2 g. of acetophenone and 1.4 g. of 30% formalin was heated on a steam bath with stirring for 1.5 hr. On cooling, 2.8 g. of crystals were produced. The crystals were filtered off, washed with a mixture of alcohol and ether, and recrystallized from a mixture of alcohol and ether, giving compound III·HCl; m.p. and mixed m. p., 145°C (after drying in vacuo at 78°C).

Anal. Found: C, 71.81; H, 6.18; N, 3.47. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

The residual mother liquor and washings were concentrated to a syrup under reduced pressure and allowed to stand for about two days to give 0.2 g. of crystals. The crystals were recrystallized from alcohol, giving compound IV·HCl;

5) The melting point of β-benzoylethylamine hydrochloride varies with heating speed because of its instability towards heat.

m. p. and mixed m. p. 199～200°C.

Anal. Found: C, 72.01; H, 6.44; N, 3.03. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

Reaction of Mono-(β-benzoylethyl)-amine Hydrochloride (I·HCl) with Acetophenone and Formaldehyde.—A mixture of 1.5 g. of compound I·HCl, 2.0 g. of acetophenone and 1.6 g. of 30% formalin was heated on a steam bath with stirring for 1.5 hr. After being cooled for a while, 1.2 g. of crystals were obtained. The crystals were recrystallized from alcohol, giving compound III·HCl; m. p. and mixed m. p., 145°C (after drying in vacuo at 78°C).

Anal. Found: C, 71.41; H, 6.33; N, 3.33. Calcd for $C_{27}H_{28}O_3NCl$: C, 72,06; H, 6.27; N, 3.11%.

The residual mother liquor was allowed to stand for a few days to give 0.1 g. of crystals. The crystals were recrystallized from alcohol, giving compound IV·HCl; m. p. and mixed m. p., 200～201°C.

Anal. Found: C, 70.71; H, 6.32; N, 2.81. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

Reaction of Phenyl Vinyl Ketone with Ammonium Chloride. — To 10 ml. of water were added 0.25 g. of ammonium chloride and 2.0 g. of phenyl vinyl ketone. The mixture was heated with stirring at 40～45°C for three hours, and was allowed to stand overnight at room temperature to give a resinous matter which was the polymerization product of the phenyl vinyl ketone. The aqueous layer was evaporated until dry under reduced pressure. The residue was confirmed as ammonium chloride by analysis.

Aqueous alcohol (5 : 5 v/v) was used in place of water as the solvent to give the same result. In the case of the higher temperature, the polymerization of phenyl vinyl ketone only was facilitated.

Isomerization of Tris-(β-benzoylethyl)-amine Hydrochloride (III·HCl). — To 7 ml. of water was added 0.5 g. of compound III·HCl, and the mixture was heated with stirring at 45°C for 1.5 hr. On cooling, a crystalline matter was filtered off; yield, 0.5 g. It was recrystallized from alcohol and dried at 78°C in vacuo, giving the starting material III·HCl; m. p., 142～143°C, mixed m. p. on admixture with an authentic sample (143～144°C), 143～144°C.

Summary

1) In the reaction of acetophenone with formaldehyde and ammonium chloride, tris-(β-benzoylethyl)-amine hydrochloride (III·HCl) and 4-hydroxy-4-phenyl-5-benzoyl-1-(β-benzoylethyl)-piperidine hydrochloride (IV·HCl) were produced via bis-(β-benzoylethyl)-amine hydrochloride (II·HCl) after mono-(β-benzoylethyl)-amine hydrochloride (I·HCl).

2) Phenyl vinyl ketone readily reacted with compound I·HCl or II·HCl to give compounds III·HCl and IV·HCl.

The author is particularly indebted to the late Professor Ryuzaburo Nozu and to Professor Ryozo Goto for their discussions and encouragement during this investigation, and also to Professor Seishi Machida for his encouragement.

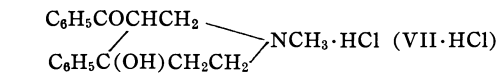
Studies on the Mannich Reaction. II. On the Formation of Piperidine Derivatives (2)

By Norito UCHINO



(Received February 19, 1959)

The Mannich reaction of acetophenone with methylamine hydrochloride and formaldehyde gives hydrochlorides of mono-(β-benzoylethyl)-methylamine (V) and bis-(β-benzoylethyl)-methylamine (VI)[1]. The melting points of the hydrochlorides are 139~141°C and 166~169°C, respectively. 4-Hydroxy-4-phenyl-5-benzoyl-1-methyl-piperidine (VII, m. p., 138~140°C) can be obtained by treating compound VI·HCl with alkali, for its isolation is difficult.

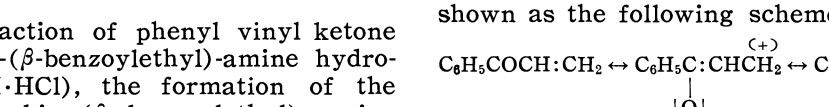
$$C_6H_5COCH_3+HCHO+CH_3NH_2\cdot HCl \rightarrow$$

$C_6H_5COCH_2CH_2NH(CH_3)\cdot HCl$ (V·HCl)

$(C_6H_5COCH_2CH_2)_2NCH_3\cdot HCl$ (VI·HCl)

(VII·HCl)

It has been shown that the reaction of phenyl vinyl ketone with compound V·HCl in aqueous alcohol gives a good yield of VI·HCl together with a small quantity of VII·HCl. When water only was used as the medium, the piperidine base failed to be isolated.



In the reaction of phenyl vinyl ketone with mono-(β-benzoylethyl)-amine hydrochloride (I·HCl), the formation of the isomer of bis-(β-benzoylethyl)-amine hydrochloride (II·HCl) was not certain[2]. But in this case, piperidine derivative VII·HCl could be obtained.

It is necessary to investigate whether or not both of the compounds VI·HCl and VII·HCl were formed at the same time, or whether one of them was formed first and then partly converted into the other. Of course, compound VI·HCl does not isomerize to give compound VII·HCl. Also compound VII·HCl was not converted into compound VI·HCl, under the same conditions as those in the reaction of phenyl vinyl ketone with compound V·HCl.

As the piperidine ring is stable under the above conditions, it is considered that both of the compounds VI·HCl and VII·HCl are primary products of the reaction. The initial step of the reaction may be the combination of the β-carbon atom of phenyl vinyl ketone with the nitrogen atom of compound V·HCl as it has been assumed in the preceding work[2].

If the β-carbon atom of phenyl vinyl ketone can react with the nitrogen atom of β-benzoylethylamine hydrochloride, it seems possible that ammonium chloride or methylamine hydrochloride can also react with phenyl vinyl ketone. Since this is not true, the benzoylethyl group of the amine is likely to play an important role in the reaction.

When a free base of ammonia or methylamine replaced the hydrochloride, it readily reacted with phenyl vinyl ketone to give 4-hydroxy-4-phenyl-5-benzoyl-1-(β-benzoylethyl)-piperidine (IV) or base VII, respectively. The mechanism of this reaction can be considered as follows. The resonance of phenyl vinyl ketone is shown as the following scheme:

This positive carbon atom of phenyl vinyl ketone will combine with ammonia or methylamine by attacking the lone pair of electrons of the nitrogen atom, and give tris-(β-benzoylethyl)-amine (III) or base VI, respectively. As a free base III or VI is very unstable, it isomerizes to give piperidine base IV or VII, respectively[1,3].

From the above, it is concluded that phenyl vinyl ketone can react with a nitrogen atom which has a lone pair of electrons. Here, it is also considered that compound I·HCl, II·HCl or V·HCl may react with phenyl vinyl ketone as the free base which is formed by hydrolysis. To show this, it is necessary for β-benzoylethylamines to be weaker bases than

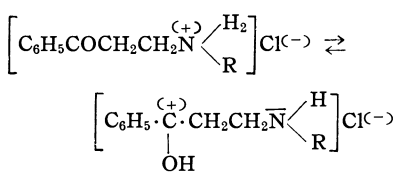
1) C. Mannich and C. Heilner, *Ber.*, **55**, 356 (1922); F. F. Blicke and J. H. Burckhalter, *J. Am. Chem. Soc.*, **64**, 451 (1942); J. T. Plati and W. Wenner, *J. Org. Chem.*, **14**, 543 (1949); cf. C. Mannich and G. Ball, *Arch. Pharm.*, **264**, 65 (1926).

2) N. Uchino, This Bulletin, **32**, 1009 (1959).

3) C. Mannich and S. M. Abdullah, *Ber.*, **68**, 113 (1935).

ammonia or methylamine, and to give sufficient free bases by hydrolysis of the salts. As the free base of β-benzoylethylamines are very unstable, the basicity of them can not be measured directly. Therefore, the dissociation constant was calculated from the hydrogen ion concentration of the aqueous solution of the salt. The hydrogen ion concentration was measured with 0.05 or 0.1 N solution at 20°C.

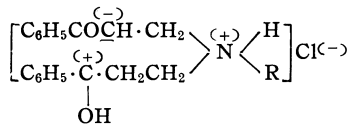
Table I. Degree of hydrolysis of β-benzoylethylamine hydrochloride



Salt	pH	Dissociation constant of base	Degree of hydrolysis (%)
I·HCl	4.8(0.05 N)	2×10^{-6}	3×10^{-2}
II·HCl	5.0(0.05 N)	5×10^{-6}	2×10^{-2}
V·HCl	5.1(0.1 N)	1×10^{-5}	8×10^{-3}
NH_4Cl		1.79×10^{-5}	
$CH_3NH_2\cdot HCl$		4.38×10^{-4}	

The result of the measurement shows that β-benzoylethylamines are weaker bases than ammonia or methylamine, but their differences are not so great as to elucidate the mechanism of the reaction.

β-Chloropropiophenone was able to react with ammonia to give base IV. As it is well known that phenyl vinyl ketone on being added to hydrogen chloride gives β-chloropropiophenone[4], it may be considered that β-chloropropiophenone is an intermediate product of the reaction. But this consideration is not correct, because it is difficult for ammonium chloride to hydrolyze to give enough hydrochloric acid. In fact, ammonium chloride did not react with phenyl vinyl ketone.



Already it was concluded that (i) the benzoylethyl group plays an important role in the reaction of phenyl vinyl ketone with compound I·HCl, II·HCl or V·HCl, and that (ii) phenyl vinyl ketone can react readily with a nitrogen atom which contains a lone pair of electrons.

Now, we will assume the following prototropy for β-benzoylethylamine hydrochloride.

R=H, CH_3, $C_6H_5COCH_2CH_2$

Here, it is reasonably considered that the β-carbon atom of phenyl vinyl ketone can combine with the lone pair of electrons appearing as in the above equation and gives an intermediate B. The hydrogen

(B)

atom of the hydroxyl group moves to the carbanion as a proton to give the normal product. When the intermediate B undergoes aldol-condensation, it gives the piperidine derivative.

In general, it can be considered that the phenyl vinyl ketone formed by decomposition of the products in the Mannich reaction is concerned with the formation of the piperidine bases which are found in that reaction.

Experimental

Reaction of Mono-(β-benzoylethyl)-methylamine Hydrochloride (V·HCl) with Phenyl Vinyl Ketone.—To a mixture of 5 ml. of water and 3 ml. of alcohol were added 0.5 g. of phenyl vinyl ketone and 0.5 g. of compound V·HCl. The mixture was next heated with stirring at 45~50°C for 2.5 hr. Then the mixture was evaporated until dry under reduced pressure, and washed with benzene to remove the polymerized phenyl vinyl ketone. The residue obtained (0.9 g.) was extracted with a small volume of water, and the insoluble matter (0.8 g.) was recrystallized from alcohol giving compound VI·HCl; m.p. and mixed m. p., 165~167°C.

Anal. Found: C, 68.70; H, 6.83; N, 4.16. Calcd. for $C_{19}H_{22}O_2NCl$: C, 68.76; H, 6.68; N, 4.22%.

The extract was evaporated under reduced pressure. The extraction and evaporation were repeated once more, and the solid matter obtained was recrystallized twice from alcohol giving 0.05 g. of compound VII · HCl; m. p. and mixed m. p., 196~198°C.

Anal. Found: C, 68.71; H, 6.79; N, 4.11. Calcd. for $C_{19}H_{22}O_2NCl$: C, 68.76; H, 6.68; N, 4.22%.

Isomerization of 4-Hydroxy-4-phenyl-5-benzoyl-1-methyl-piperidine Hydrochloride (VII · HCl).—In 5 ml. of water was dissolved 0.2 g. of compound VII·HCl, and the solution was heated to 40~45°C for 1.5 hr. If compound VI·HCl is formed by isomerization, some crystalline matter is expected to appear because of its small solubility. But no crystalline matter appeared. The same result was obtained not only when the temperature of the reaction was kept at 55~60°C, but also when three drops of concentrated hydrochloric acid or a small quantity of alkali was added to the solution, respectively. Removal of the solvent

4) E. P. Kohler, *Am. Chem. J.*, **42**, 289 (1909).

under reduced pressure gave the starting material VII·HCl; m. p. and mixed m. p., 196~198°C.

Reaction of Phenyl Vinyl Ketone with Methylamine Hydrochloride.—Two grams of methylamine hydrochloride were dissolved in 3 ml. of water, and about 1 g. of phenyl vinyl ketone was added to the solution. The solution was heated with stirring at 50~55°C for five hours. Almost all the phenyl vinyl ketone polymerized. The aqueous solution was evaporated until dry under reduced pressure. The residue was confirmed to be only methylamine hydrochloride, and no β-benzoylethylamine hydrochloride was detected.

Reaction of Phenyl Vinyl Ketone with Ammonia.—A mixture of 1 g. of phenyl vinyl ketone, 0.5 ml. of aqueous ammonia (28%) and 10 ml. of water was heated with shaking at 40°C for two minutes. The greater part of the phenyl vinyl ketone polymerized to become viscous, and the liquid phase became turbid. After standing overnight at room temperature, the crystals produced were picked up with a pincette, and were washed with alcohol. As it was difficult to separate the crystals from the resinous matter, the yield was only 0.1 g. The crystals were recrystallized from alcohol, giving base IV; m. p. and mixed m. p., 147~148°C.

Anal. Found: C, 77.90; H, 6.52; N, 3.73. Calcd. for $C_{27}H_{27}O_3N$: C, 78.42; H, 6.58; N, 3.38%.

Reaction of Phenyl Vinyl Ketone with Methylamine.—A gas of excessive methylamine was passed into a solution of 4.5 g. of phenyl vinyl ketone in ether with ice cooling. Then the solution was evaporated to a syrup, which solidified after a while; yield, 4.7 g. The product was recrystallized from methanol giving 2.0 g. of base VII; m. p. and mixed. m. p., 139~140°C.

Anal. Found: C, 77.20; H, 7.25; N, 4.73. Calcd. for $C_{19}H_{21}O_2N$: C, 77.25; H, 7.16; N, 4.74%.

Reaction of β-Chloropropiophenone with Ammonia.—To a solution of 5 ml. of water and 5 ml. of alcohol were added 1 g. of β-chloropropiophenone and 1 ml. of aqueous ammonia (25%), and the mixture was heated with stirring at 40~45°C for an hour. One gram of a crystalline substance was formed. On cooling, the crystals were filtered off and recrystallized from alcohol giving base IV; m. p. and mixed m. p., 148~149°C.

Anal. Found: C, 78.48; H, 6.62; N, 3.63. Calcd. for $C_{27}H_{27}O_3N$: C, 78.42; H, 6.58; N, 3.38%.

β-Chloropropiophenone could react with ammonia, but not with ammonium chloride.

Summary

1) The mechanism of the reaction of phenyl vinyl ketone with β-benzoylethylamine hydrochloride was discussed.

It was concluded that the β-carbon atom of phenyl vinyl ketone combined with β-benzoylethylamine hydrochloride on attacking the lone pair of electrons which appeared in consequence of prototropy, and gave the same products as those in the Mannich reaction.

2) In the Mannich reaction, piperidine bases are found to be produced.

It was concluded that the phenyl vinyl ketone, which was produced by decomposition of the products in the Mannich reaction, was concerned with the formation of these piperidine bases.

The author is particularly indebted to the late Professor Ryuzaburo Nozu and to Professor Ryozo Goto for their discussions and encouragement during this investigation, and also to Professor Seishi Machida for his encouragement.

Localization Energy with Electronic Interaction

By Kenichi FUKUI, Keiji MOROKUMA and Teijiro YONEZAWA

(Received January 30, 1959)

The localization method by Wheland[1], in which localization energy is employed as the reactivity index, has achieved successes in interpreting chemical reactivity of conjugated molecules[2]. On the other hand, total π-electron density[3], self-polarizability[4], free valence[5], frontier electron density[6] and superdelocalizability[7] are introduced as good reactivity indexes in the approximation of the simple LCAO treatment. Regarding alternant hydrocarbons (AH's) some mathematical relations have been found between localization energy and other reactivity indexes[8].

In the previous paper[9], utilizing LCAO SCF wave function, namely, the wave function where electronic interaction is explicitly included, we have found that the total π-electron density can not predict the correct reactivity of molecules, while the frontier electron density remains a good index for both ionic and radical reactions in LCAO SCF MO treatment just as well as in usual simple LCAO MO treatment. In the present paper we have defined and calculated the localization energy under an explicit consideration of electronic interaction, and comparison of the results obtained by the present method with those in simple LCAO treatment has been made.

Theoretical

Model of Localized System.—According to Wheland's definition the localized system in the transition state has the configuration in which the attacked carbon atom is sp^3-hybridized, so that the resonance integrals between the attacked atom and the neighboring ones are taken to be zero. More precisely the integral does not completely vanish; however, in order to be faithful to the concept of the term "localization", we assume that the resonance integrals between the attacked atom and the others are always zero. This assumption may be reasonable for our approximate calculation.

Here one more problem arises: Simple treatment naturally allows us to deal with the two parts, the localized electrons and the residue, independently from each other; but when we want to take the electronic interaction into account, the interaction between the two parts, and that between those two and the attacking reagent must be considered, as well as the mutual interaction of electrons inside the residue*. Concerning this point, two approximations would be employed. As the first approximation (Approx. 1) we simply assume the two parts to be independent, that is, the only electronic interaction to be taken into account is that which acts inside the residue*. In the second approximation (Approx. 2) the interaction between the two parts shall be treated as a perturbation. The effects of attacking reagent, which do not seem essential to the localization method, are thoroughly neglected for simplicity in both approximations.

Formulation. — The wave function χ_0 of the "isolated" system consisting of $2n$ carbon atoms and $2n$ π-electrons is given as follows:

$$\chi_0 = \frac{1}{\sqrt{(2n)!}} \begin{vmatrix} (\phi_1\alpha)^1 (\phi_1\beta)^1 (\phi_2\alpha)^1 & \cdots\cdots & (\phi_n\beta)^1 \\ (\phi_1\alpha)^2 (\phi_1\beta)^2 (\phi_2\alpha)^2 & \cdots\cdots & (\phi_n\beta)^2 \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ (\phi_1\alpha)^{2n} (\phi_1\beta)^{2n} (\phi_2\alpha)^{2n} & \cdots\cdots & (\phi_n\beta)^{2n} \end{vmatrix}$$

$$\equiv (1/\sqrt{(2n)!}) [(\phi_1\alpha)^1 (\phi_1\beta)^2 (\phi_2\alpha)^3 \cdots\cdots (\phi_n\beta)^{2n}] \quad (1)$$

* In electrophilic reaction, the interaction between the two localized electrons is also to be included.

where φ_i is the i-th MO, α and β are the spin functions, and the superscripts denote the numbering of electrons. Each MO should be chosen to minimize the electron energy of the system; but so far as the evaluation of localization energy with electronic interaction is concerned, it seems sufficient to use Hückel MO

$$\psi_i=\sum_\mu c_{i\mu}\phi_\mu \qquad (i=1,2,\cdots\cdots,2n) \tag{2}$$

where ϕ_μ denotes the AO on the μ-th carbon atom.

Introducing a SCF-like procedure proposed by Pople[10], we obtain the following expression of the total electronic energy of the system**.

$$\varepsilon_0=2nU+(\gamma_{\mu\mu}/4)\sum_\mu (P_{\mu\mu})^2+2\beta\sum_{\mu<\nu}^{*} P_{\mu\nu} +\sum_{\mu<\nu}\{(P_{\mu\mu}-1)(P_{\nu\nu}-1)-(1/2)(P_{\mu\nu})^2\}\gamma_{\mu\nu} \tag{3}$$

where U is a core matrix element and is put a constant, β is the resonance integral between the nearest neighbors, and $\gamma_{\mu\nu}$ is the coulomb repulsion integral

$$\gamma_{\mu\nu}=\int \phi_\mu^*(1)\phi_\nu^*(2)\frac{e^2}{r_{12}}\phi_\mu(1)\phi_\nu(2)\mathrm{d}v_1\mathrm{d}v_2 \tag{4}$$

and

$$P_{\mu\nu}=2\sum_{i=1}^{n} c_{i\mu}c_{i\nu} \tag{5}$$

Summation Σ and Σ^* should cover all the atoms and the nearest neighboring atoms, respectively. In deriving Eq. 3 the same assumptions as proposed by Pople[10], for instance, of equi-bond-length, of neglecting the coulomb penetration integrals and so on, are employed.

From the assumption made in the preceding section the wave function χ_E of the "localized" system (transition complex) for electrophilic reaction, in which two electrons are localized on the carbon λ, may be written as follows:

$$\chi_E=(1/\sqrt{(2n-2)!})[(\psi'_1\alpha)^1(\psi'_1\beta)^2\cdots\cdots \times(\varphi'_{n-1}\alpha)^{2n-3}(\psi'_{n-1}\beta)^{2n-2}] \times(1/\sqrt{2!})[(\phi_\lambda\alpha)^{2n-1}(\phi_\lambda\beta)^{2n}] \tag{6}$$

where ψ'_i is the i-th Hückel MO for the residue consisting of $(2n-1)$ carbons.

$$\psi'_i=\sum_\mu c'_{i\mu}\phi_\mu \quad (i=1,2,\cdots\cdots,2n-1) \tag{7}$$

Here we refer the superscript "′" to the residue of the molecule. The two parts being treated separately (Approx. 1), the energy of the system, ε_{E0}, is given as follows[11]:

$$\varepsilon_{E0}=2U+\gamma_{\mu\mu}+(2n-2)U+(\gamma_{\mu\mu}/4)\sum_\mu (P^+_{\mu\mu})^2 +2\beta\sum_{\mu<\nu}^{*} P^+_{\mu\nu}+\sum_{\mu<\nu}\{(P^+_{\mu\mu}-1)(P^+_{\nu\nu}-1) -(1/2)(P^+_{\mu\nu})^2\}\gamma_{\mu\nu} \tag{8}$$

where

$$P^+_{\mu\nu}=2\sum_{i=1}^{n-1} c'_{i\mu}c'_{i\nu} \tag{9}$$

The first two terms correspond to the energy of the localized electrons and the others to that of the residue. When the interaction between the parts is taken into account in higher approximation (Approx. 2), the interaction energy ε_{E1}:

$$\varepsilon_{E1}=\sum_\mu (P^+_{\mu\mu}-1)\gamma_{\mu\lambda} \tag{10}$$

is to be added to the energy ε_{E0}.

Also for nucleophilic reaction, through the similar consideration as for electrophilic one, we easily obtain the following formulae.

$$\chi_N=(1/\sqrt{(2n)!})[(\psi'_1\alpha)^1(\psi'_1\beta)^2\cdots\cdots \times(\psi'_n\alpha)^{2n-1}(\psi'_n\beta)^{2n}] \tag{11}$$

$$\varepsilon_{N0}=2nU+(\gamma_{\mu\mu}/4)\sum_\mu (P^-_{\mu\mu})^2 +2\beta\sum_{\mu<\nu}^{*} P^-_{\mu\nu}+\sum_{\mu<\nu}\{(P^-_{\mu\mu}-1) \times(P^-_{\nu\nu}-1)-(1/2)(P^-_{\mu\nu})^2\}\gamma_{\mu\nu} \tag{12}$$

$$\varepsilon_{N1}=\sum_\mu (1-P^-_{\mu\mu})\gamma_{\mu\lambda} \tag{13}$$

$$P^-_{\mu\nu}=2\sum_{i=1}^{n} c'_{i\mu}c'_{i\nu} \tag{14}$$

For radical reaction,

$$\chi_R=(1/\sqrt{(2n-1)!})[(\psi'_1\alpha)^1(\psi'_1\beta)^2\cdots\cdots \times(\psi'_{n-1}\alpha)^{2n-3}(\psi'_{n-1}\beta)^{2n-2} \times(\psi'_n\alpha)^{2n-1}]\cdot(\phi_\lambda\alpha)^{2n} \tag{15}$$

$$\varepsilon_{R0}=U+(2n-1)U+\gamma_{\mu\mu}\sum_\mu P^\alpha{}_{\mu\mu}P^\beta{}_{\mu\mu} +2\beta\sum_{\mu<\nu}^{*} P^0{}_{\mu\nu}+\sum_{\mu<\nu}\{(P^0{}_{\mu\mu}-1)(P^0{}_{\nu\nu}-1) -[(P^\alpha{}_{\mu\nu})^2+(P^\beta{}_{\mu\nu})^2]\}\gamma_{\mu\nu} \tag{16}$$

$$\varepsilon_{R1}=0 \tag{17}$$

$$\left.\begin{aligned} P^\alpha{}_{\mu\nu}&=\sum_{i=1}^{n} c'_{i\mu}c'_{i\nu}=(1/2)P^-{}_{\mu\nu}\\ P^\beta{}_{\mu\nu}&=\sum_{i=1}^{n-1} c'_{i\mu}c'_{i\nu}=(1/2)P^+{}_{\mu\nu}\\ P^0{}_{\mu\nu}&=P^\alpha{}_{\mu\nu}+P^\beta{}_{\mu\nu}\end{aligned}\right\} \tag{18}$$

a) In units of eV.
b) In units of $(-\beta)$.

The first term in Eq. 16 refers to the localized electron and the others to the residue.

As regards the AH, whose MO has special simplifying properties, Eqs. 8, 10, 12, 13 and 16 can be reduced to simpler ones, that is,

$$\varepsilon_{N0}=\varepsilon_{E0}=2nU+(\gamma_{\mu\mu}/4)\,[(n-1)+\sum_{\mu\nu}^{st}\{1+(c'_{n\mu})^2\}^2]+2\beta\sum_{\mu<\nu}^{*}P^0{}_{\mu\nu}-\{-\sum_{\mu<\nu}^{st,\,st}(c'_{n\mu}c'_{n\nu})^2+\sum_{\mu,\nu}^{st,unst}(P^0{}_{\mu\nu})^2\}(\gamma_{\mu\nu}/2) \tag{19}$$

$$\varepsilon_{N1}=\varepsilon_{E1}=-\sum_{\mu}^{st}(c'_{n\mu})^2\gamma_{\mu\lambda} \tag{20}$$

$$\varepsilon_{R0}=2nU+(\gamma_{\mu\mu}/4)\{(2n-1)-\sum_{\mu}^{st}(c'_{n\mu})^4\}+2\beta\sum_{\mu<\nu}^{*}P^0{}_{\mu\nu}-\{\sum_{\mu<\nu}^{st,\,st}(c'_{n\mu}c'_{n\nu})^2+\sum_{\mu,\nu}^{st,\,unst}(P^0{}_{\mu\nu})^2\}(\gamma_{\mu\nu}/2) \tag{21}$$

Summation $\sum^{st}$ and $\sum^{unst}$ should cover all the starred and the unstarred atoms, respectively.

The localization energies, L, of the λ-th carbon atom are, therefore, obtained from the following equations.

$$\left.\begin{array}{ll}\text{Electrophilic Reaction} & \\ \quad\text{(Approx. 1)} & L_E=\varepsilon_{E0}-\varepsilon_0 \\ \quad\text{(Approx. 2)} & L_E=\varepsilon_{E0}+\varepsilon_{E1}-\varepsilon_0 \\ \text{Nucleophilic Reaction} & \\ \quad\text{(Approx. 1)} & L_N=\varepsilon_{N0}-\varepsilon_0 \\ \quad\text{(Approx. 2)} & L_N=\varepsilon_{N0}+\varepsilon_{N1}-\varepsilon_0 \\ \text{Radical Reaction} & \\ \quad\text{(Approxs. 1 \& 2)} & L_R=\varepsilon_{R0}+\varepsilon_0\end{array}\right\} \tag{22}$$

Evaluation of Atomic Integrals. — For numerical evaluation of β and $\gamma_{\mu\nu}$ are utilized the semi-empirical formulae introduced by Pariser and Parr[12]. For simplicity, as partly stated above, all the

12) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).

C–C bond distances are assumed the same, 1.39Å, and all the carbon rings (five- and seven-membered rings for azulene and fulvalene, six-membered rings for the other molecules now considered) are supposed to be regular, and polyenyl bond angles to be 120°.

Results and Discussion

The calculated results of localization energy, which is defined in the preceding section, of seven AH's and two non-AH's are listed in Tables I and II***, together with those obtained by simple LCAO treatment.

As is seen from Eq. 20, the interaction energy between the localized electrons and the residue in nucleophilic and in electrophilic reactions is necessarily negative for the AH, namely, there rises some stabilization of the system from the interaction, this seeming true also for the non-AH (cf. Eqs. 10 and 13); and accordingly the values of the localization energies, L_E and L_N, in Approx. 1 are larger than in Approx. 2. For all that we can see in Tables I and II that in both approximations we obtain nearly the same intramolecular orientation, which will be discussed in the later paragraph in detail. In radical reaction, on the other hand, the interaction energy formally vanishes (cf. Eq. 17), and therefore both approximations give the same value of localization energy.

It will be seen in Tables I and II that the magnitude of L_R is generally much smaller than those of L_N and L_E in both approximations, whereas in the simple LCAO treatment the magnitude of L_R lies between those of L_N and L_E. This by no means admits that the activation energy of radical reaction is smaller than those of the others, because effects of reagents and changes in the σ-system are conventionally set aside from this argument. Especially for the AH Eqs. 19 and 20 show the relation $L_E = L_N$ within each approximation in accordance with the result obtained by the simple treatment.

It may be valuable to notice that both approximations indicate the same intramolecular orientation as the simple treatment for all the reactions of the molecules now concerned, except for the ionic reactions of phenanthrene in Approx. 1. Accordingly, its agreement with experimental results is mostly good, but the facts that azulene reacts at the position 1 in radical reaction[13] (L_R is the smallest at 4) and that the position 4 of biphenyl is more reactive than the position 2 both in radical and electrophilic reactions[14] (L_R and L_E indicate 2-orientation) can not be explained on the basis of the localization energy, whether the electronic interaction is taken into account or not. In fulvalene the position 1 is shown to be the most susceptible to attack by localization energies and the position 2 is so by frontier electron density[15], superdelocalizability[16] and total π-electron density[17],

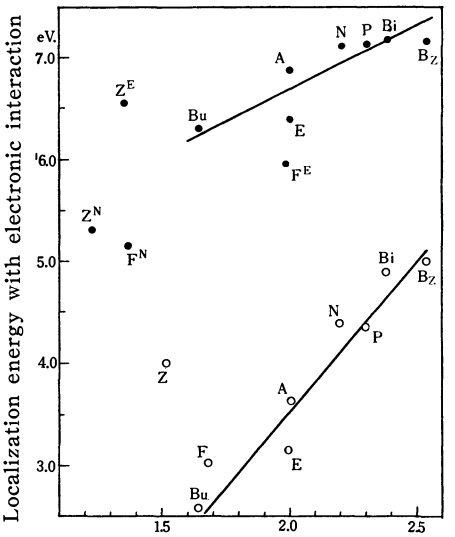

Fig. 1. Relationship between localization energies in simple treatment and with electronic interaction.
○: Radical reaction, ●: Ionic reaction (Approx. 2); E: ethylene, Bu: butadiene, Bz: benzene, N: naphthalene, A: anthracene, P: phenanthrene, F: fulvalene (F^N: nucleophilic, F^E: electrophilic), Z: azulene (Z^N: nucleophilic, Z^E: electrophilic). Only the position of the smallest localization energy of each molecule is plotted. The straight lines are only for AH's.

*** For the position 2 of butadiene, the wave functions of the localized system are expressed in the product of wave functions of three parts, as follows:

$$\chi_E = (1/\sqrt{2})[(\varphi_1'\alpha)^1(\varphi_1'\beta)^2] \times (1/\sqrt{2})[(\phi_2\alpha)^3(\phi_2\beta)^4]$$
$$\chi_R = (1/\sqrt{2})[(\varphi_1'\alpha)^1(\varphi_1'\beta)^2]\cdot(\phi_2\alpha)^3\cdot(\phi_1\alpha)^4$$
$$\chi_N = (1/\sqrt{2})[(\varphi_1'\alpha)^1(\varphi_1'\beta)^2] \times (1/\sqrt{2})[(\phi_1\alpha)^3(\phi_1\beta)^4]$$

In Approx. 1 three parts are treated independently, whereas their mutual interactions are taken into account in Approx. 2.

further experiments being awaited at this point.

It seems also interesting that, except for the mutual coincidence of the most reactive position, the order of reactivity of each position in azulene does not coincide with one another in the three treatments; in electrophilic reaction, for instance, the reactivity of each position decreases in the order $1>5>2>4>6$ in the simple treatment, $1>2>5>6>4$ in Approx. 1, and $1>5>6>2>4$ in Approx. 2.

As it is seen in Fig. 1, agreement of the intermolecular order of reactivity predicted by the simple treatment with that obtained with electronic interaction is not so good in Approx. 2; and in Approx. 1 the agreement is a little worse. Non-AH's, azulene and fulvalene, largely deviate from the linear relationship of Fig. 1, but unfortunately there are no available data to check which result is correct.

From the above discussion it might be concluded that the localization energy, in which the electronic interaction is taken into account, can be a pretty good index of chemical reactivity.

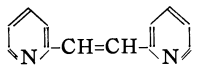
Added in Proof:

It is easily proved that the following wave functions χ'_E and χ'_R, instead of Eqs. 6 and 15, directly lead to the same energy expressions that were derived in Approx. 2, ε'_E and ε'_R respectively.

$$\chi'_E=(1/\sqrt{(2n)!})[(\psi'_1\alpha)^1(\psi'_1\beta)^2\cdots(\psi'_{n-1}\alpha)^{2n-3}\times(\psi'_{n-1}\beta)^{2n-2}(\phi_\lambda\alpha)^{2n-1}(\phi_\lambda\beta)^{2n}]$$

$$\varepsilon'_E=\varepsilon_{E0}+\varepsilon_{E1}$$

$$\chi'_R=(1/\sqrt{(2n)!})[(\psi'_1\alpha)^1(\psi'_1\beta)^2\cdots(\psi'_{n-1}\alpha)^{2n-3}\times(\psi'_{n-1}\beta)^{2n-2}(1/\sqrt{2})\times\{(\psi'_n\alpha)^{2n-1}(\phi_\lambda\beta)^{2n}-(\psi'_n\beta)^{2n-1}(\phi_\lambda\alpha)^{2n}\}]$$



$$\varepsilon_R'=\varepsilon_{R0}$$

Geometrical Isomers of 1,2-Bis-(2-pyridyl)-ethylene

By Takumi KATSUMOTO

(Received February 5, 1959)

1,2-Bis-(2-pyridyl)-ethylene (I) is expected to exhibit geometrical isomerism and to exist in a *cis*- and a *trans*-form. Hitherto, however, only one species has been known. It was first synthesized by Lénárt[1] and melted at 118~119°C. But it has been unknown to which form it belongs. The present author has prepared the other form and concluded from physical properties that the former is the *trans*-isomer and the latter is the *cis*-isomer.

(I)

Experimental

Synthesis of 1,2-Bis-(2-pyridyl)-ethylene. — It was prepared from 2-pyridylformaldehyde, α-picoline and anhydrous zinc chloride. 2-Pyridylformaldehyde, obtained from the Wako Co., was distilled under reduced pressure and the fraction boiling at 76~77°C/17 mmHg was used. α-Picoline, obtained from the Eastman Kodak, was fractionated in an efficient column (b. p., 129.3°C).

A mixture of 2-pyridylformaldehyde (2 g.), α-picoline (3 g.) and anhydrous zinc chloride (2 g.) was heated in a sealed tube at 200°C for 24 hr. After being cooled, the dark brown viscid product was dissolved in aqueous hydrochloric acid. The acid solution was then basified with sodium hydroxide and steam-distilled to remove the unchanged α-picoline. The black oil, which separated on the surface of the solution, was extracted with chloroform and the chloroform extract was dried over anhydrous sodium sulfate and evaporated. The resinous residue was distilled under reduced pressure in a Claisen flask fitted with a wide saber-shaped side tube. A deeply yellow oil distilled out over the interval 150~220°C /15 mmHg and condensed in the side tube. The distillate was extracted with boiling ether, and evaporation of the extract gave 1,2-bis-(2-pyridyl)-ethylene as a brown sticky oil.

Separation of Two Isomers.—The isomers were

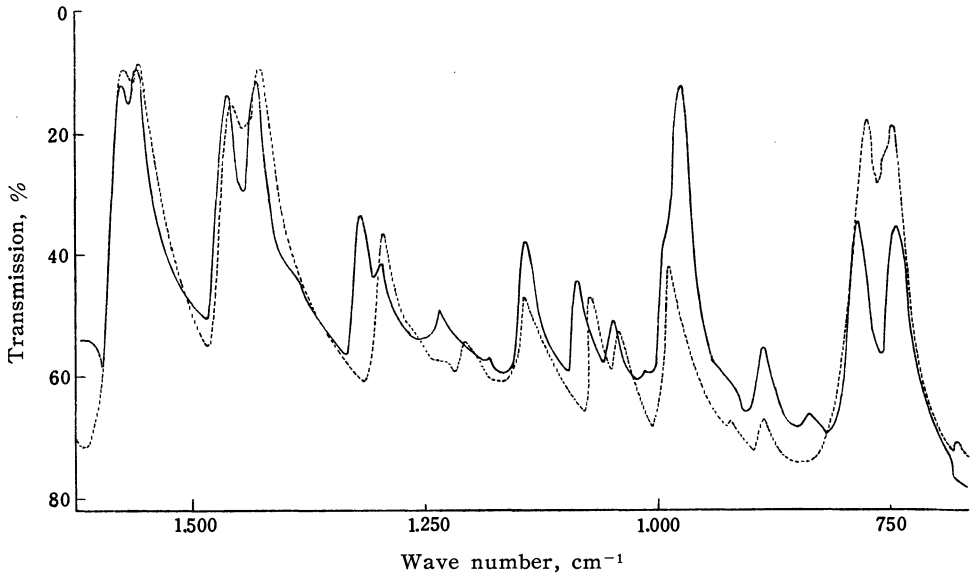

Fig. 1. Infrared spectra of 1,2-bis-(2-pyridyl)-ethylene.
—— compound II (*trans*), ------ compound III (*cis*)

separated by the elution chromatography. The oil was dissolved in chloroform, dried with calcium chloride, and chromatographed on a column (2×13 cm.) of alumina and the column was eluted with the same solvent to give pale brown crystals melting at 70~105°C. Two additional chromatographs on alumina column (2×41 cm.; chloroform) separated them into two parts. One (II), eluted first, forms colorless prisms, m.p. 120~121°C, and corresponds to the compound described by Lénárt. The other (III), contained in the next elute, forms colorless needles and melts sharply at 48.0~48.5°C.

Measurements of Physical Properties. — The boiling points at 15 mmHg pressure were measured by Garcia's method[2]. The pressure was kept constant with a mercury pressure controller fitted with a large buffer bottle (sensitivity, ±0.5 mmHg).

The ultraviolet absorption spectra in cyclohexane were measured with a Shimadzu spectrophotometer. The wavelength of the photometer was calibrated with the absorption band at 301 mμ of an aqueous potassium nitrate solution[3-5]. The infrared spectra in potassium bromide disks were obtained with a Hilger double beam spectrophotometer.

Results and Discussion

The results of the elementary analyses of the two species, II and III, are just the same and consistent with the formula, $C_{12}H_{10}N_2$ (Table I), thus showing that they are isomers.

Configuration	*trans*	*cis*

The infrared spectra of the two isomers, II and III, are given in Fig. 1. All bands of II correspond to those of III, except two strong bands located at 968 and 1318 cm^{-1} as shown in Table II. The band at 986 cm^{-1} of III is not clearly noticed in the spectrum of II, but it seems to be hidden by the very strong band at 968 cm^{-1}, because a shoulder is found in this region. Lunde and Zechmeister[6] also found the absorption band at 980 cm^{-1} as a shoulder on the adjacent and intense band at 960 cm^{-1} in the spectra of many *trans*-diphenylpolyenes including *trans*-stilbene.

* The letters shown in the brackets mean the relative intensities. v=very, s=strong, m=medium and w=weak.

** Py-1,2,3 mean the CH out-of-plane deformation, the CH in-plane deformation, and the ring stretching vibration of 2-substituted pyridine ring, respectively. E means the CH out-of-plane deformation of -CH=CH- (*trans*).

bands show that these two compounds have very similar structures. These bands are assigned to the vibrations arising from the 2-substituted pyridine ring as follows:

The infrared spectra of substituted pyridines are closely similar to those of substituted benzenes, although the effect of the electronegative nitrogen appears regularly. All substituted pyridines exhibit strong and characteristic absorptions in the regions 700~850 cm^{-1} due to the out-of-plane bending vibrations of the ring CH. Shindo[7] suggested that 2-substituted pyridines show intense absorptions in the regions 740~780 cm^{-1}, while 3-derivatives do in the regions 770~820 cm^{-1} (m-s) and 690~730 cm^{-1} (vs), and 4-derivatives in the region 790~850 cm^{-1} (s). The 738 cm^{-1} band of II and the 746 cm^{-1} of III suggest that these compounds are 2-derivatives.

Bellamy[8] suggested that a series of weak absorptions in the regions 990~1200 cm^{-1} shown by substituted benzenes are peculiar to the types of substitution. Randall et al.[9] also found that the absorption near 1020 cm^{-1} in monosubstituted benzenes are independent of the nature of the substituent and assigned it to the in-plane bending vibration of CH. Shindo[7] suggested that a series of weak but sharp absorptions in this region are also found in the case of monosubstituted pyridines and the positions are almost constant regardless of the nature of the substituent and that three absorption bands in the regions 988~998 cm^{-1}, 1041~1050 cm^{-1} and 1140~1151 cm^{-1} are characteristic of 2-substituted pyridines. He also attributed them to the in-plane bending mode of the ring involving a considerable ring vibration. Of the four common bands in the spectra of the present compounds, three bands at 986, 1045 and 1138 cm^{-1} of II and those at 986, 1045 and 1149 cm^{-1} of III are respectively in good agreement with the above bands which are characteristic of 2-substituted pyridines. Now, according to Rasmussen[10] the absorption band due to the bending frequencies of CH or the in-plane vibration of hydrogen in the aromatic ring appears in the vicinity of 1429 cm^{-1}. This band corresponds to the fourth, very strong band at 1428 cm^{-1} (II) and at 1430 cm^{-1} (III).

Aromatics have three highly characteristic absorption bands in the regions 1500~1600 cm^{-1} and these bands are assigned to the C=C stretching vibration of the three double bonds round the ring. Of these bands, Randall et al.[11] regarded a band in the regions 1575~1587 cm^{-1} as a positive indication of conjugation of a double bond with the aromatic ring. Brownlie[12] suggested that heterocyclic aromatics such as pyridine also give a similar pair of bands in the region from the C=C and the C=N links, although in this case the third skeletal vibration is usually at appreciably lower frequencies. According to Shindo[7], 2-substituted pyridines have three bands in the regions 1450~1600 cm^{-1} similar to those of substituted benzenes due to their ring double bond stretching vibrations. Compounds II and III show strong bands in this region. The bands at 1460(vvs), 1559(vvs) and 1574(m) cm^{-1} of compound II and 1460(vs), 1561 (vvs) and 1578 (s) cm^{-1} of compound III seem to arise from the 2-substituted pyridine rings, and especially the band at 1574 and 1578 cm^{-1} may be due to the pyridine ring conjugated with C=C double bond. Thus, it seems to be sure that both compounds II and III are 1,2-bis-(2-pyridyl)-ethylene.

Generally, *trans*-disubstituted ethylenes show intense absorptions near 965 cm^{-1}. Rasmussen and Brattain[13] showed that these absorption bands appear only with *trans* double bond. These absorptions are attributed to the out-of-plane bending vibrations of =CH of the *trans*-disubstituted ethylenes and the absence of these bands can be regarded as conclusive evidence of the absence of *trans* double bond. The strong band at 968 cm^{-1} of II and the lack of this band in the spectrum of III lead to the conclusion that II is the *trans*-form and III is the *cis*-form.

The other sharp band at 1318 cm^{-1} in the spectrum of II is also lacking in the curve of III. According to Lunde et al.[6] *trans*-stilbene gives two weak absorptions at 1312 and 1342 cm^{-1} and these bands are lacking in *cis*-stilbene. Probably, these phenomena have some stereochemical significance which, however, can not be interpreted at the present time.

The melting point of III is lower by about seventy degrees than that of II, as shown in Table I. As the *cis*-isomer always melts at a very much lower temperature than the *trans*-isomer does[14], II and III seem to be a *trans*- and a *cis*-isomer, respectively. Their boiling points at 15 mmHg pressure are also shown in Table I. But it is impossible to distinguish between geometrical isomers from their boiling points, because no general rule as in the case of the melting points holds here.

The ultraviolet spectra of compounds II and III also support the above results as follows: The ultraviolet spectra of geometrical isomers such as those of stilbene[15,16], cinamic acid[16], phenylbutadiene[17] and azobenzene[18] have been investigated. They are composed of the E- (ethylenic) and the K- (conjugated) bands. The absorption intensities of the E-bands of the geometrical isomers are almost equal, while the K-band of the *cis*-form is about half as intense as that of the *trans*-form and lies at somewhat shorter wavelengths. It is well interpreted from the spatial arrangement of groups in these molecules. One of the isomers which approaches more closely to coplanarity exhibits a higher degree of resonance and shows more intense absorption at somewhat longer wavelengths[19]. The ultraviolet absorption curves of II and III are given in Fig. 2. Both have three strong to medium absorption bands in the region of the K-band (Table III). Compound II shows more intense absorption than the compound III and the absorption is located at the longer wavelengths. These curves are typical of geometrical isomers and compound II is a *trans*-isomer and compound III is a *cis*-isomer.

Synthesis of Aspartic and Glutamic Hydrazides and their Chromatographic and Ionophoretic Separation. C-Terminal Groups of Whale Insulin[1]

By Kozo NARITA and Yumiko OHTA

(Received February 11, 1959)

In the hydrazinolysis of peptides and proteins[2], non-C-terminal acidic amino acids or their amides residues in the polypeptide chain will be converted into α-mono- (derived from aspartyl and glutamyl residues) or di-hydrazides (derived from asparaginyl and glutaminyl residues). C-Terminal aspartic and glutamic acids or their amides will be found as free amino acids or as β- or γ-monohydrazides in the hydrazinolysates of proteins, respectively[3].

By quantitative determination of these hydrazides in the hydrazinolysates of proteins, the number of aspartyl, glutamyl, asparaginyl and glutaminyl residues in the original proteins could be estimated[3]. For that purpose, it is desirable to prepare standard substances for the identification and recovery determination by chromatography or ionophoresis.

Glutamic α- and γ-monohydrazides have previously been prepared[4,5], but the other hydrazides of the acidic amino acids have not heretofore been prepared, as far as we are aware. In the present paper, the synthesis of DL-aspartic α-hydrazide from phthaloyl-DL-aspartic α-methylester, of the isomeric β-hydrazide from L-asparagine, and of the dihydrazides of aspartic and glutamic acids from their diesters will be described. The present contribution also includes separation of these hydrazides by chromatography or ionophoresis, and its application to the hydrazinolysates of beef and whale insulins. The separation methods, however, were not satisfactory, since it was observed that appreciable amounts of some hydrazides were decomposed during the operation.

Experimental

Synthesis of DL-Aspartic α-Hydrazide.—A suspension of 14 g. of phthaloyl-DL-aspartic anhydride[6] in 120 ml. of absolute methanol was refluxed for 30 min. and a small amount of insoluble material was filtered off while it was warm. After being kept overnight, phthaloyl-DL-aspartic α-methyl ester crystallized as prisms. It was recrystallized from methanol; yield, 7.9 g., 43.8%, m.p. 181°C (reported[7] m.p. 182°C). The crude β-methyl ester obtained upon evaporation of the filtrate was recrystallized from water; yield, 3.9 g., 24.8%, m.p. 151~152°C (reported[7] m.p. 147~148°C).

A mixture of 4 g. of the α-ester, 50 ml. of methanol and 2.5 g. of 80% hydrazine hydrate was refluxed for 30 min. The precipitate of phthaloylhydrazine which resulted was filtered off and was washed with hot water. The combined solution of the filtrate and the washings

were adjusted to pH 3.5 with 1 N sulfuric acid. Enough amounts of Amberlite XE-58 (weak anion exchanger, free form) were added to the filtrate to remove sulfate ion, and the resin was filtered off after standing for 30 min. and was washed with water. The combined solution was concentrated in vacuo and two volumes of ethanol were added. An oily material solidified after being kept in a refrigerator and it was recrystallized from dilute ethanol; yield, 2.1 g., m.p. 143°C (with decomp.). It was found by paper chromatography and paper ionophoresis that this material was contaminated with a small amount of free aspartic acid. The aqueous solution of the crude material was again treated with Amberlite XE-58 in a similar manner as mentioned above. On evaporation of the filtrate to a small volume in vacuo, DL-aspartic α-hydrazide crystallized as needles. After addition of ethanol to the filtrate, a second crop of the hydrazide was obtained. The two crops combined were recrystallized from water-ethanol; yield, 1.1 g., 44%, m.p. 180°C (with decomp.).

Anal. Found: N, 27.7. Calcd. for $C_4H_9O_3N_3$: N, 28.6%.

Synthesis of L-Aspartic β-Hydrazide.—A mixture of 3 g. of L-asparagine, 2 ml. of ethanol and 2 g. of 80% hydrazine hydrate was refluxed for 30 min. and held overnight at room temperature. Ethanol was added to the syrup which was obtained on evaporation of the reaction mixture in vacuo and the β-hydrazide crystallized upon scratching of the wall of the vessel under ice cooling. The product was recrystallized from water-ethanol; yield, 2.8 g., 74.5%, m. p. 186°C. When the material was dried over phosphorous pentoxide at 100°C in vacuo, analysis indicated loss of 1.5 mol. water of hydration.

Anal. Found: N, 27.9. Calcd. for $C_4H_9O_3N_3$: N, 28.6%.

Synthesis of L-Aspartic and L-Glutamic Dihydrazides.—L-Aspartic and L-glutamic acids were converted into diethyl ester hydrochlorides, respectively, the free ester was extracted with ether as usual, and the solvent was removed after drying over sodium sulfate. Two and a half moles of hydrazine hydrate were added to the ethanolic solution of the ester, the mixture was held overnight at room temperature and the dihydrazide crystallized in needles. Recrystallization from aqueous ethanol gave about 60% yield in both cases. L-Aspartic α,β-dihydrazide, m.p. 164~165°C (with decomp.).

Anal. Found: N, 42.0. Calcd. for $C_4H_{11}O_2N_5$: N, 43.5%.

L-Glutamic α,γ-dihydrazide, m. p. 134~135°C (with decomp.).

Anal. Found: N, 39.2. Calcd. for $C_5H_{13}O_2N_5$: N, 40.0%.

Paper Chromatography.—Chromatography was performed by an ascending method using lutidine-water mixture (5 : 3, vol.) and Toyo No. 3 filter paper. In the case of multiple development the same solvent was repeatedly used. For the detection of both amino acid and hydrazide, 0.2% ninhydrin *n*-butanol solution (saturated with water) was used and for hydrazide only the ammoniacal silver nitrate solution was sprayed[8].

Paper Ionophoresis.—Toyo No. 3 filter paper (18×40 cm.) was generally used. For the separation of amino acids and hydrazides into three groups, namely, acidic, neutral and basic, neutral buffer of pH 6.4 was prepared in a similar manner as suggested by Lockhart and Abraham[9], except lutidine was used in place of collidine. For the mutual separation of neutral substances, 0.5 M acetic acid (pH 2.64) was used. Potential of 500 V. (12.5 V./cm.) was applied in each case. The current was 6 milliamp. in the case of neutral buffer and 2 milliamp. in dilute acetic acid. The ionophoretic rates of the hydrazides varied from experiment to experiment but the order of the rates did not change. Consequently, in the case of the measurements of relative rates of various hydrazides and the corresponding amides, those on the same paper sheet were compared.

Ion Exchange Chromatography.—Elution chromatography on a Dowex 50−X8 (200~400 mesh) column was tested to separate and estimate amino acid monohydrazides according to the procedure of Moore and Stein[10]. C-Terminal amino acids with the exception of terminal basic amino acids must be present as neutral or acidic substances in the hydrazinolysate of proteins. Since basic materials were adsorbed on the top of the resin column which equilibrated with 0.1 or 0.2 M citrate buffer of pH 3.4, neutral substances were eluted with citrate buffers of several pH's from a short column (0.9×15 cm. or 0.9×30 cm.). In the present experiments, the behaviors of alanine, aspartic β- and glutamic α-hydrazides were mainly studied with regard to the study on insulin.

Hydrazinolysis of Insulin and Treatment of the Product.—Beef and whale insulins studied were kindly supplied by Dr. J. Lens, Organon, Oss, and Shimizu Pharmaceutical Co., respectively. Anhydrous hydrazine was prepared in a similar manner as suggested by Ohno[3]. About 30 mg. of insulin was dissolved in 0.5 ml. of anhydrous hydrazine and heated at 100°C for 8 hr. The hydrazinolysate was taken into dryness over calcium chloride in vacuo at room temperature. In paper ionophoresis, the dried residue was dissolved in a minimum volume of water, an aliquot was applied to Toyo No. 50 paper, thick paper (18×40 cm.), along the starting line, and a potential gradient of 500 V. was applied at pH 6.4 in lutidine-acetic acid buffer. After ionophoresis and air drying, strips from both sides of the paper sheet were cut off and treated with the silver nitrate reagent to detect hydrazides. Using these as a guide, the remainder of the sheet containing neutral substances was cut and they were eluted with water by the technique of Sanger and Tuppy[11]. The wetting top of the cut

8) A mixture of one part of 0.1 N $AgNO_3$ and one part of 0.5 N NH_4OH solution.

paper strip was applied to another paper sheet (Toyo No. 3) and subjected to ionophoresis at pH 2.64 or one- or two-dimensional chromatography.

For the characterization of C-terminal amino acid with the exception of the basic one, asparagine and glutamine, the following technique is also applicable. After ionophoresis of the hydrazinolysate at pH 6.4, the area of hydrazides which traveled to cathode was cut off and the remaining area which contained C-terminal amino acid and monohydrazides of acidic amino acids was then developed with phenol and lutidine two-dimensionally. In this case, it is preferable to develop them first with phenol and then lutidine. During the first development, most of the monohydrazides were destroyed and several very faint unidentified spots could be observed near the phenol front. This procedure might be useful to characterize the C-terminal group of polypeptide of a small molecule, and was successfully used for several cytochromes[12] and for insulin shown in Fig. 1.

In the quantitative determination of the C-terminal groups of insulin, the dried hydrazinolysate was dissolved in 0.5 ml. of 0.05~0.1 N hydrochloric acid 0.5 ml. of 0.2 M citrate buffer (pH 3.5) was added and any insoluble material was centrifuged off, if necessary. A half milliliter of the supernatant was applied to the Dowex 50 column (0.9×15 cm.) equilibrated with 0.2 M citrate of pH 4.23 and elution was started.

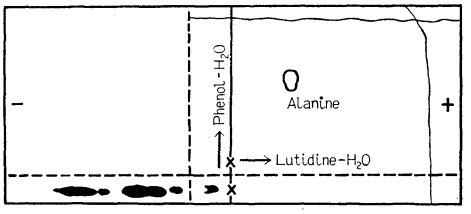

Fig. 1. Ionophoresis at pH 6.40 and subsequent chromatography of the hydrazinolysate of whale insulin. Mark X and broken line indicate original spot and line to be cut before chromatography, respectively. Black and white spots indicate ammoniacal silver nitrate and ninhydrin positive, respectively.

Results and Discussion

Paper Chromatography. — Multiple development technique was used in lutidine-water, since the difference between *Rf* values of the hydrazides was slight in a single development. However, no remarkable effect in resolution of the spots resulted by repeating the development with the same solvent more than twice. *Rf* values of the hydrzaides of acidic amino acids were recorded in Table I.

TABLE I. *Rf* VALUES OF ASPARTIC AND GLUTAMIC HYDRAZIDES*

Number of development	1	2	3
Aspartic α-hydrazide	0.23	0.41	0.48
Aspartic β-hydrazide	0.15	0.33	0.39
Aspartic α,β-dihydrazide	—	0.36	—
Glutamic α-hydrazide	0.24	0.43	0.50
Glutamic γ-hydrazide	0.18	0.37	0.45
Glutamic α,γ-dihydrazide	—	0.44	—

* Lutidine-water (5 : 3, vol.) and the ammoniacal silver nitrate solution were used as the solvent and the reagent, respectively.

Paper Ionophoresis.—Acidic, neutral and basic substances were separated during ionophoresis at pH 6.4, but the acidic amino acid monohydrazides and neutral amino acids could not be separated from each other in this medium. Mutual separation of neutral amino acids has usually been performed in either an acidic or alkaline medium based on the difference of the dissociation constants of their carboxyl or amino group. In the present experiments, acidic pH was used, since amino acid hydrazide seemed to be labile in alkaline medium. The ionophoretic rates of aspartic and glutamic hydrazides to cathode on a paper at pH 2.64 were in the following order:

Glutamic α,γ-dihydrazide>
Aspartic α,β-dihydrazide>
Glutamic α-hydrazide>
Aspartic α-hydrazide>
Glutamic γ-hydrazide>
Aspartic β-hydrazide

The pK'_{COOH} values of aspartic and glutamic monohydrazides are unknown but those of the corresponding amides have been reported[13]. Therefore, the distance that the monohydrazides traveled to cathode during ionophoresis on the

	Hydrazid	Amide	
	Distance	Distance	pK'_{COOH}[13]
Aspartic β-	6.1 cm.	4.4 cm.	2.02
Glutamic γ-	6.7	4.8	2.17
Aspartic α-	7.5	—	2.97
Glutamic α-	8.8	8.3	3.81

* Toyo No. 3 filter paper (18×40 cm.), 0.5 M acetic acid, 500 V., 2 milliamp. and 120 min. were used.

12) K. Titani and H. Ishikura, *J. Biochem.*, **44**, 499 (1957).

13) D. M. Greenberg, "Amino Acids and Proteins", Charles C. Thomas Publishers, Springfield (1951), p. 430.

same paper sheet in acidic medium were compared with those of the corresponding amides, to find relationship between the dissociation constant and behavior on the paper (Table II).

The parallel relationship between the ionophoretic rate and the dissociation constant of the amides was observed. Comparing the rates of the amides with those of the corresponding hydrazides, it is apparent that the dissociation constant of the latter is slightly higher than that of the former, and that the difference between the dissociation constant of the hydrazide of α-position and that of ω-position is smaller than that of the corresponding amides. In the ionophoresis performed under the conditions used, the hydrazides in the following pairs were barely separated from one another: Aspartic α-hydrazide and glutamic γ-hydrazide, and glutamic γ-hydrazide and aspartic β-hydrazide. Futhermore, it was observed that the dihydrazides were partially decomposed into both the isomers of the monohydrazides liberating hydrazine in acidic medium.

Ion Exchange Chromatography.—In the ion exchange chromatography, no hydrazides eluted with 0.1 M citrate of pH 3.45 from the 30 cm. column, although aspartic and glutamic acids and alanine eluted each forming a single sharp peak, respectively. When the pH of the buffer was changed to 4.34, leucine, aspartic β- and glutamic γ-hydrazides successively came out from the column. The recoveries of the hydrazides in effluent were only a small percentage using the ninhydrin color yields of the Table III, in which the ratio of ninhydrin color value per mol. hydrazide to that of leucine is listed[10].

TABLE III. NINHYDRIN COLOR YIELDS OF ACIDIC AMINO ACID HYDRAZIDES

Hydrazide	Color yield
Leucine	1.00
Aspartic α-hydrazide	0.93
Aspartic β-hydrazide	1.05
Aspartic α, β-dihydrazide	0.79
Glutamic α-hydrazide	0.85
Glutamic γ-hydrazide	0.69
Glutamic α, γ-dihydrazide	0.48

It was observed that the recoveries of the hydrazides became lower the more acidic the resin surface and the longer the time of contact with the resin. In order to elute hydrazides more rapidly, the length of the column was halved and the ionic strength of the buffer was doubled. Concerning insulin, alanine, aspartic β- and gultamic α-hydrazides could be separated from one another, but aspartic β- and glutamic γ-hydrazides and leucine overlapped in such a column system. Recoveries of the hydrazides were still low under such conditions and further unknown degradation products of the hydrazides eluted gradually and the base line between the peaks of aspartic β- and glutamic α-hydrazides was relatively high. In the quantitative estimation, the base line behind the peak of glutamic α-hydrazide was used.

C-Terminal Groups of Whale and Beef Insulins.—Characterizations of C-terminal amino acids and free carboxyl groups of whale insulin were carried out by means of hydrazinolysis-ionophoresis method described in the experimental section. Alanine, aspartic β- and glutamic α-hydrazides could be identified. These results indicate that the C-terminal groups of the hormone must be alanine and asparagine and that all of the non-C-terminal carboxyl groups belong to glutamic acid residues.

Quantitative estimation of these groups was done by chromatography on a Dowex 50 column. For this purpose it is necessary to determine to what extent known amounts of amino acids could be recovered after treatment with hydrazine and chromatography. A mixture of alanine, asparagine and isoglutamine was heated with anhydrous hydrazine for 8 hr. at 100°C and the reaction mixture was treated according to the procedures described in the experimental section. The recoveries for those are recorded in Table IV. A typical elution curve of the hydrazinolysate of whale insulin is shown in Fig. 2

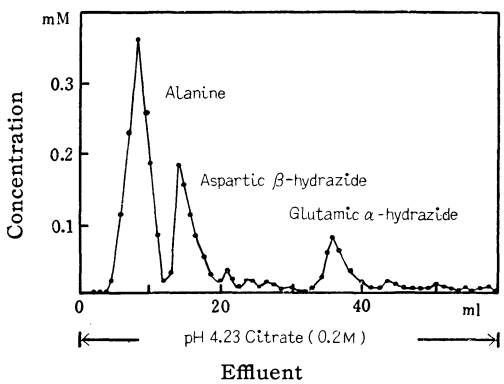

Fig. 2. Elution curve of the hydrazinolysate of whale insulin from Dowex 50 column (0.9×15 cm.).

TABLE IV. RECOVERIES OF AMINO ACIDS AFTER HYDRAZINOLYSIS AND CHROMATOGRAPHY

Material	Product after hydrazinolysis	Recovery after hydrazinolysis and chromatography	Recovery after chromatography	Recovery calculated for hydrazinolysis
Alanine	Alanine	0.48	1.0	0.48
Asparagine	Aspartic β-hydrazide	0.25	0.39	0.64
Isoglutamine	Glutamic α-hydrazide	0.088	0.31	0.29

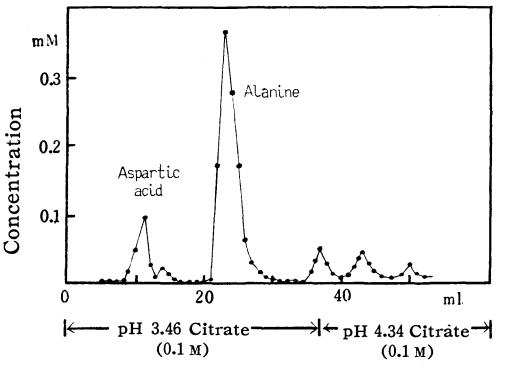
and the analytical data of whale and beef insulins are summarized in Table V.

It appears probable that the C-terminal groups of both the insulins (assumed molecular weight, 6,000) are each one mole alanine and asparagine which are consistent with the results of Sanger et al.[14], Harris et at.[15,16] and Chibnall et al.[17] but differ from our previous results[2], in which we reported an additional C-terminal glycine but missed asparagine which escaped from the detection in the earlier method. The main reason which caused such a difference may be attributed to the drastic conditions used in the previous experiments and non-C-terminal glycine might be erroneously identified.

To confirm the singleness of the peak of alanine in Fig. 2, an aliquot of the hydrazinolysate of whale insulin was chromatographed on a Dowex 50 column (0.9×15 cm.) which equilibrated with 0.1 M citrate of pH 3.46. As is shown in Fig. 3, a small peak appeared before alanine and it corresponded to aspartic acid which might be derived from the hydrazide during chromatography. The amount of alanine found in this system was 0.8 mol. per mol. insulin.

In connection with the number of free



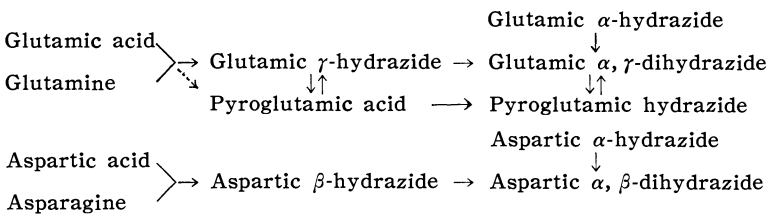


Fig. 3. Chromatogram of the hydrazinolsate of whale insulin on Dowex 50 column (0.9×15 cm.). Concentration and pH of the buffer differ with those in Fig. 2.

carboxyl groups, the present results appear to be of little value, since significant differences were obsereved between the values derived by reduction method and by hydrazinolysis have been obtained with lysozyne[3,18] and the protein of tobacco mosaic virus[19]. As is well known, recoveries of some amino acids, especially aspartic and glutamic acids, after hydrazine treatment are pretty low[20,21]. It was found that one of the main decomposition products was the corresponding hydrazide,

which was identified by paper chromatography. The situation of aspartic and glutamic acids is quite complicated. When glutamic acid alone, for example, was heated with hydrazine and the reaction products were analyzed by chromatography, glutamic acid, glutamic γ-hydrazide, glutamic α, γ-dihydrazide, pyroglutamic acid, pyroglutamic hydrazide and an unknown product were identified. The reaction products of glutamine, glutamic α- and glutamic γ-hydrazides, aspartic acid, asparagine, aspartic α- and aspartic β-hydrazides with hydrazine were analyzed, respectively. Summarizing these results which were obtained, the following reaction scheme could be deduced.

Since free acidic amino acid has never been detected in the reaction mixture of hydrazine with the amide of acidic amino acid, C-terminal asparagine and glutamine can be estimated by hydrazinolysis method by the use of appropriated recovery factors. However, it appears difficult to determine the numbers of non-C-terminal acidic amino acids or their amides residues by hydrazinolysis, owing to the fact that both of them produce the same product, dihydrazide.

In the quantitative determination of C-terminal asparagine or glutamine, elution chromatography described in the present paper seems not to be suitable, since hydrazide derived from the terminal group is decomposed in significant quantity during operation. The dinitrophenyl derivatives of aspartic β- and glutamic γ-hydrazides from the hydrazinolysate of protein by the method III of Akabori et al.[22] or slightly modified method[19], can be separated from one another on two-dimensional paper chromatogram[23,24] developed with Levy's solvent system[25] and this method appears to be more suitable than the present one.

Summary

Aspartic α- and β-monohydrazides and aspartic α, β- and glutamic α, γ-dihydrazides were prepared and their qualitative separation has been performed by means of paper ionophoresis and chromatography. During ionophoresis in acidic medium, the dihydrazide partially decomposed into the isomers of monohydrazides liberating hydrazine. The hydrazinolysis products of whale and beef insulins were analyzed by the aid of elution chromatography on a Dowex 50 column and it was observed that the C-terminal positions were occupied by each one mole of alanine and asparagine in both cases. Furthermore, the present experiments suggested that all of the non-terminal carboxyl groups of the hormone belonged to only glutamic acid residues. Complicated reaction of the acidic amino acids or their amides with hydrazine was discussed.

The present authors are grateful to Professor S. Akabori for his interest and encouragement in these studies, to Shimizu Pharmaceutical Co. and Dr. J. Lens for generous supply of whale and beef insulins, respectively.

*Thermodynamic Studies on Cobalt Complexes. IV. On the Thermal Dissociation and the Solubility of Aquopentamminecobalt(III) Chloride**

By Motoshichi MORI, Ryokichi TSUCHIYA and Yasuhiro OKANO

(Received February 14, 1959)

In the preceding papers the authors determined the standard free energy of formation of hexamminecobalt(III) chloride in the solid state by measuring its solubility in water[1] and employing the known value of the standard free energy of formation of hexamminecobalt(III) ion. The standard free energy of formation of chloropentamminecobalt(III) chloride in the solid state was also determined by measuring the dissociation pressure of hexamminecobalt(III) chloride[2]. In the present report which is a part of the thermodynamic studies on coordination compounds, the standard free energy of formation of aquopentamminecobalt(III) chloride was determined by measuring its dissociation pressure, and its activity coefficient in the saturated aqueous solution by measuring its solubility. On the basis of these experimental results discussions were conducted on the thermodynamic stability of hexamminecobalt(III), aquopentamminecobalt(III) and chloropentamminecobalt(III) chlorides in the solid state and in the aqueous solution.

Experimental

Aquopentamminecobalt(III) chloride was prepared by the method of Jörgensen[3]. The measurement of its dissociation pressure and rate of thermal dissociation was carried out with the same apparatus described in the preceding paper[2].

The solubility of this complex was determined by analyzing the cobalt content of its saturated aqueous solution by iodometry.

Results and Discussion

Dissociation Pressure of Aquopentamminecobalt(III) Chloride.—As we confirmed by the spectrophotometric measurements the fact that the products of thermal dissociation of aquopentamminecobalt(III) chloride were chloropentamminecobalt(III) chloride and water vapour, the dissociation pressure observed is the vapour tension of water formed by the following reaction;

$$[Co(NH_3)_5OH_2]Cl_3(s) = [Co(NH_3)_5Cl]Cl_2(s) + H_2O(g)$$

The results of measurement of the dissociation pressure are given in Table I. The logarithms of the dissociation

TABLE I. DISSOCIATION PRESSURE OF AQUOPENTAMMINECOBALT(III) CHLORIDE

pressure p_{mm} are plotted against the reciprocal of the absolute temperature in Fig. 1, and an almost straight line is obtained. The equation of the straight line calculated by the method of least squares is

$$\log p_{mm} = 7.5888 - 2166.0/T$$

This equation gives the heat of dissociation ΔH as 9908 cal., and the free energy change of dissociation ΔG° as

$$\Delta G^\circ = -RT \ln p_{atm} = 9908 - 21.54T \quad (1)$$

The value of the free energy change of dissociation at 25°C is $\Delta G^\circ_{298} = 3488$ cal. and that of the entropy change is $\Delta S^\circ_{298} = 21.54$ e. u.

In the preceding paper[2] the standard free energy of formation of chloropentamminecobalt(III) chloride was determined by measuring the dissociation pressure of hexamminecobalt(III) chloride as

$$\Delta G^\circ = -254008 + 365.99T \quad (2)$$

By using the standard free energy of formation of $H_2O(g)$ at 25°C, $\Delta G^\circ_{298} = -54636$ cal.[4] and its heat of formation, $\Delta H_{298} = -57798$ cal.[4], the standard free energy of formation of H_2O as a function of temperature is given by

$$\Delta G^\circ = -57798 + 10.607T \quad (3)$$

Combining Eq. 3 with Eqs. 2 and 1, we get the following equation for the standard free energy of formation of aquopentamminecobalt(III) chloride in the solid state,

$$\Delta G^\circ = -321714 + 398.13T \quad (4)$$

The value of ΔG° at 25°C is $\Delta G^\circ_{298} = -203.024$ kcal.

The Rate of Thermal Dissociation of Aquopentamminecobalt(III) Chloride.—The results of the measurement of the rate of thermal dissociation of aquopentamminecobalt(III) chloride are shown in Table II and Fig. 2.

The velocity constant k at the time when the dissociation begins, is assumed to be given by the tangent of the curve at the origin in Fig. 2. When $\log k$ is plotted against the reciprocal of the absolute temperature, $1/T$, an approximately straight line is obtained as shown

TABLE II. RATE OF DISSOCIATION OF AQUOPENTAMMINECOBALT(III) CHLORIDE

in Fig. 3, which gives 21.47 kcal. as the activation energy of the dissociation of aquopentamminecobalt(III) chloride.

Solubility and Activity Coefficient of Aquopentamminecobalt(III) Chloride. — Since the activity coefficient of aquopentamminecobalt(III) chloride has never been found in any literature, the value in the saturated aqueous solution was calculated from the solubility data determined in the present study.

First, by using the standard free energy of formation of aquopentamminecobalt(III) ion in unit activity at 25°C, $\Delta G^\circ_{298} = -104.5$ kcal.[5] and its heat of formation, $\Delta H_{298} = -192.9$ kcal.[6], the standard free energy of formation is obtained as a function of temperature:

$$\Delta G^\circ = -192900 + 296.55T \quad (5)$$

Combining Eq. 5 with Eq. 6 for the standard free energy of formation of chloride ion,

$$\Delta G^\circ = -40023 + 29.1T^{2)} \quad (6)$$

and that of aquopentamminecobalt(III) chloride in the solid state, Eq. 4 obtained above, the free energy change of the solution of aquopentamminecobalt(III) chloride is given by

$$\Delta G^\circ = 8745 - 14.28T \quad (7)$$

The value, 8745 cal. is obtained as the heat of the solution of this complex and $\Delta S^\circ_{298} = 14.28$ e. u. is obtained as the entropy change at 25°C.

On the other hand, the equilibrium constant, K, of the solution of aquopentamminecobalt(III) chloride represented by

$$[Co(NH_3)_5OH_2]Cl_3(s) \rightleftarrows [Co(NH_3)_5OH_2]^{3+}(aq.) + 3Cl^-(aq.)$$

is given by

$$K = \exp(-\Delta G^\circ/RT) \quad (8)$$

If the molality of the solute is expressed by m, the mean activity coefficient, $\gamma_\pm$, in a 1—3 valency type salt[1] is given by

$$\gamma_\pm = \sqrt[4]{K/27}/m \quad (9)$$

Further, if the solubility of aquopentamminecobalt(III) chloride determined by iodometry is expressed by C (mol./l.) and specific gravity of the saturated aqueous solution measured by the hydrometer, d, the molality m is given by

$$m = 1000C/(1000d - MC) \quad (10)$$

where M is the molecular weight of this complex. Thus, the mean activity coefficient $\gamma_\pm$ can be calculated by combining Eqs. 7—10.

The values of the solubility of aquopentamminecobalt(III) chloride and the values of the mean activity coefficient are listed in Table III.

The activity coefficient of aquopentamminecobalt(III) chloride in such concentrated aqueous solutions has never been reported in the past.

Relationship between the Solubility and the Free Energy Change of Solution of Hexamminecobalt(III) and Aquopentamminecobalt(III) Complexes.—From Eqs. 8 and 9, the following equation is derived:

$$\Delta G^\circ = -2.303RT\ (\log 27 + 4\log m + 4\log \gamma_\pm) \quad (11)$$

In the range where $\log \gamma_\pm$ is a linear function of $\log m$ at 25°C, Eq. 11 can be rearranged as

$$\Delta G^\circ_{298} = \alpha + \beta \log m \quad (12)$$

where α and β are constants. Furthermore, if m is approximately proportional to the molar concentration C, Eq. 12 becomes

$$\Delta G^\circ_{298} = \alpha' + \beta' \log C \quad (13)$$

where α' an β' are constants.

When the data of the free energy change, ΔG°_{298}, of the solution of hexamminecobalt(III) chloride, bromide, nitrate and perchlorate reported in the preceding paper[1] as well as that of aquopentamminecobalt(III) chloride listed in Table III are plotted

TABLE III. SOLUBILITY OF AQUOPENTAMMINECOBALT(III) CHLORIDE AND THE RESULTS OF CALCULATION

against the logarithm of their molar concentration C, they all fall on a straight line as shown in Fig. 4. This means that Eq. 13 is applicable to 1—3 valency type complexes described above. Therefore, the free energy change of a solution of a complex of 1—3 valency type can be calculated by using Fig. 4, provided its solubility C is known.

Thermodynamic Stability of Hexamminecobalt(III), Aquopentamminecobalt(III) and Chloropentamminecobalt(III) Chlorides.—The thermodynamic functions in the thermal dissociation and solution of hexamminecobalt(III) and aquopentamminecobalt(III) chlorides at 25°C are summarized in Table IV.

Although the heat of dissociation of hexamminecobalt(III) chloride is close to that of aquopentamminecobalt(III) chloride as shown in Table IV, the entropy change of dissociation of the former is remarkably smaller than that of the latter. Therefore, it is inferred that the difference between the free energy changes of dissociation of the two complexes is due to the difference between the entropy changes. The heat of solution of hexamminecobalt(II) chloride is again close to that of aquopentamminecobalt(III) chloride, and the difference between the free energy changes of solution of these two complexes must be due to the difference between their entropy changes. In other words, it is concluded that the entropy effect plays an important role in those reactions listed in Table IV.

From the solubility data[7] and the activity coefficient[8] of chloropentamminecobalt(III) chloride, its free energy change of solution is calculated as $\Delta G^\circ_{298}=6865$ cal. By using this value and the free energy changes of thermal dissociation and solution of hexamminecobalt(III) and aquopentamminecobalt(III) chlorides, the standard free energy levels of hexamminecobalt(III), aquopentamminecobalt(III) and chloropentamminecobalt(III) chlorides in the solid state and in the aqueous solution in unit activity are computed and shown in Fig. 5. This figure clearly shows the degree of thermodynamic stability of these complexes. The order of the thermodynamic stability is found to coincide with the spectrochemical series[9,10].

Summary

1. The standard free energy of formation of aquopentamminecobalt(III) chloride in the solid state was calculated by measuring its dissociation pressure.

2. From this value and the standard free energy of formation of aquopentamminecobalt(III) ion, the free energy change of the solution of aquopentamminecobalt(III) chloride was calculated. From this value and the solubility data the activity coefficient of aquopentamminecobalt(III) chloride in the saturated aqueous solution was calculated.

The free energy changes of the solutions of hexamminecobalt(III) chloride, bromide, nitrate and perchlorate as well as of aquopentamminecobalt(III) chloride were found to be a linear function of the logarithms of their solubilities.

3. The thermodynamic stability of hexamminecobalt(III), aquopentamminecobalt(III) and chloropentamminecobalt(III) chlorides in the solid state and in the aqueous solution was discussed.

Rheological Properties of Gels. Viscoelasticity of Mercury Sulfosalicylate Solution

By Takaaki DANNO

(Received February 18, 1959)

The study on the visco-elastic properties of agar-agar gel was reported previously[1]. The agar gel shows interesting flow properties superposed on the elastic ones, especially in its softening and melting region. These are interesting from the view point of the relation between the rheological properties and the change of internal structure in the course of the melting of gel. More detailed experiments, however, could not be carried out by reason of the structural limit of our instruments.

On the other hand, mercury sulfosalicylate solution has interesting elasto-viscous properties, as shown by T. Nakagawa[2] who attributed the "Spinnbarkeit" of the solution to its elastic property. The solution is very elastic and also has viscous flow properties. It has been assumed[3] that the structural formula of mercury sulfosalicylate is

It is interesting to seek the origin of strong elasticity of the solution of such a simple substance.

The author measured the visco-elastic parameters of them and studied their dependence on frequency, amplitude, concentration, temperature change, and other factors, by using the coaxial dynamical rheometer.

Experimental

As the experimental procedure for studying the visco-elastic properties of mercury sulfosalicylate solution, the author adopted the method of coaxial type rheometer, which was designed by T. Nakagawa[4].

In this dynamic method for measuring visco-elastic constants, a sinusoidal oscillation is applied at the top of a torsion wire, from which the inner cylinder is suspended, and whose torsion constant is k dyn./cm. Then, the displacement of the top of the torsion wire is given by

$$\Theta = \Theta_0 \sin \omega t \tag{1}$$

and the equation of motion of the inner cylinder is

$$I\ddot{\theta}+R\dot{\theta}+E\theta = k(\Theta-\theta) \tag{2}$$

1) T. Danno, *Bull. Tokyo Gakugei Univ.*, **6**, 103 (1955).
2) T. Nakagawa, This Bulletin, **25**, 93 (1952).
3) Wo. Ostwald and M. Mertens, *Kolloid-Beih.*, **23**, 242 (1926).
4) T. Nakagawa and M. Seno, This Bulletin, **29**, 471 (1956).

where I is the moment of inertia of the inner cylinder, and R and E are the viscous and elastic resistance respectively of the solution between the two cylinders. The stationary solution of this equation is

$$\left.\begin{aligned}\theta &= \frac{k\Theta_0}{\sqrt{\{(E+k)-I\omega^2\}^2+R^2\omega^2}}\sin(\omega t-\phi)\\ &\equiv A\sin(\omega t-\phi)\\ \tan\phi &= \frac{R\omega}{(E+k)-I\omega^2}\end{aligned}\right\} \quad (3)$$

where A is the amplitude of motion of the inner cylinder induced by the sinusoidal torque of the suspension wire, and ϕ is the angle of phase difference between the motion at the top of the suspension wire and the forced oscillation of the inner cylinder. The amplitude ratio m is given by

$$m \equiv \frac{A}{\Theta_0} = \frac{k}{\sqrt{(E+k-I\omega^2)^2+R^2\omega^2}} \quad (4)$$

from Eq. 3, R and E are calculated as

$$\left.\begin{aligned}R &= \frac{kT\sin\phi}{2\pi m}\\ E &= k\left(\frac{\cos\phi}{m}-1\right)+\frac{4\pi^2 I}{T^2}\end{aligned}\right\} \quad (5)$$

where T is the period of oscillation ($\omega=2\pi\nu=2\pi/T$).

When two simple harmonic motions, i.e., the motion at the top of the suspension wire and the forced oscillation of the inner cylinder, whose directions of oscillation are at right angles to each other, are composed, the resulting Lissajous' figure is an ellipse as long as they are of the equal period. Let the area of an ellipse be S_e and that of the rectangle tangent to the ellipse be S_r. Then the next relation is known to hold.

$$\sin\phi = \frac{4}{\pi}\cdot\frac{S_e}{S_r} \quad (6)$$

The scheme of obtaining m and ϕ is realized by a mechanical and optical system. The dynamic viscosity η and the dynamic rigidity G are calculated from the observed R and E by the conventional formulae

$$\left.\begin{aligned}\eta &= \frac{R}{4\pi h}\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\\ G &= \frac{E}{4\pi h}\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\end{aligned}\right\} \quad (7)$$

where h, r_1 and r_2 are the length of the immersed portion of the internal cylinder, the radii of the internal and external cylinder, respectively.

Strictly speaking, the inertia effect of the sample which was discussed by S. Oka[5] can not be neglected. But in our present experiments, in which very low frequencies (long period of oscillation) were applied, the rigorous treatment taking into account the inertia of the sample is not necessary.

5) S. Oka et al., *Bull. Kobayashi Inst. Phys. Res.*, 3, 9, 17 (1953).

The experimental condition was as follows: Three hardened steel wires, whose diameter ranged from 0.29 mm. to 0.90 mm. in accordance with the concentration of the sample solution, were used. Coaxial glass vessels of the outer diameter 9.386 cm., and inner one 5.905 cm., were used.

Mercury sulfosalicylate was prepared as follows[6]: An equivalent mass of yellowish mercuric oxide was mixed into the solution of commercial sulfosalicylic acid. When this mixture is heated in a water bath, flesh-colored mercury sulfosalicylate is obtained. The sample thus prepared, mixed with water, is boiled in a flask with reflux condenser for about an hour. After having been dissolved completely in water, it is poured into the space between the two cylinders, cooled and settled for two days in room temperature for conditioning.

The concentration of the solution was determined by evaporation, and was represented in weight per cent. The temperature of the sample to be tested was controlled at 20~65°C, by a water bath thermostat.

Results

Aging of the Solution.—As is usual in all colloidal solutions[7], the marked effect of aging in the physico-chemical properties is observed in our case. The solution of mercury sulfosalicylate, when it is newly prepared, appears as a transparent solution, but gradually loses its transparency and becomes a visco-elastic fluid. Fig. 1 shows the increase of the viscosity and modulus of the rigidity as a function of time.

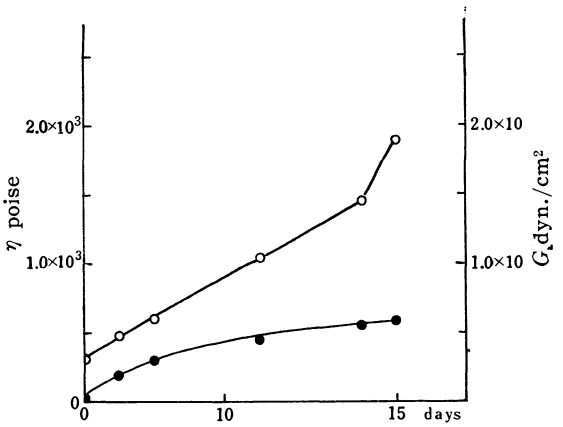

Fig. 1. Viscosity and rigidity of 3.16% mercury sulfosalicylate aq. solution vs. aging time. ○ indicates viscosity and ● rigidity.

6) For instance, J. Samejima, "Koshitsugaku (Colloid Science)", Shokabo, Tokyo (1949), p. 537.

7) For instance, C. Dittmar et al., *J. Poly. Sci.*, 18, 275 (1955).

In our case of mercury sulfosalicylate solution, the viscosity increases rapidly in a few days, while the rigidity increases slowly. In the course of 10 or 15 days, rigidity seems to reach a saturation value, but viscosity continues to increase to a very large value.

Dependence on Frequency. — As is usually observed in the ordinary polymeric solutions, the dynamic viscosity and elasticity of the present system change with frequency.

Fig. 2 shows the viscosity and rigidity of 2.2% mercury sulfosalicylate solution, plotted against the period of oscillation (reciprocal frequency) from 8 sec. to 1286 sec. (about 22 min.). From this figure we see that, in a range of a short period, the viscosity decreases rapidly as the period of oscillation becomes shorter. But, when the period of oscillation is very long, it reaches a constant value.

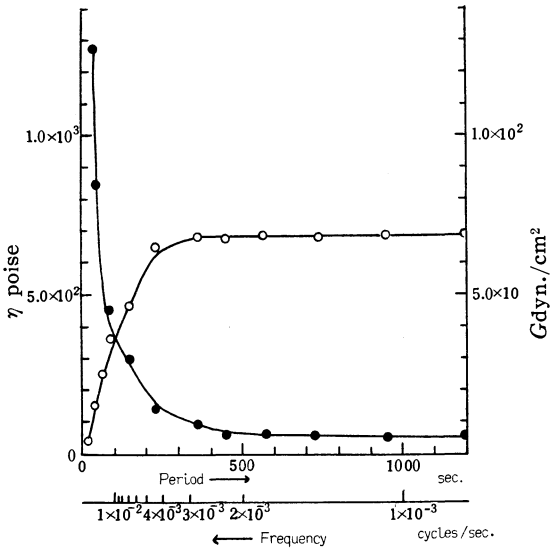

Fig. 2. Frequency dependence of viscosity η and rigidity G of 2.2% mercury sulfosalicylate aq. solution at 24°C. ○ indicates viscosity and ● rigidity.

On the other hand, the rigidity falls steeply in a range of short period. As the viscosity reaches to a certain constant value in a range of a long period, the rigidity also becomes constant. In other words, in a high frequency range, viscosity increases rapidly and rigidity decreases also steeply as the frequency becomes lower. And then, when the frequency is below 2.5×10^{-3} cycl./sec., viz., the period of oscillation is above 400 sec., both viscosity and rigidity are almost constant.

Dependence on Amplitude. — The amplitude effect is shown in Fig. 3, in which $\theta_{\max r=r_1}$ is the amplitude of the shear strain at the wall of the internal cylinder, as given by the following equation,

$$\theta_{\max r=r_1}=\left[\frac{2Ar_1^2r_2^2}{(r_2^2-r_1^2)r^2}\right]_{r=r_1}=\frac{2Ar_2^2}{r_2^2-r_1^2}$$

where A is the amplitude of the oscillation of the internal cylinder and r_1 or r_2 is the radius of the internal and external cylinder, respectively. In the present case, $\theta_{\max r=r}=3.316\ A$ ($r_1=2.953$ cm., $r_2=4.693$ cm.). The concentration of the sample is 1.58 wt. %, and the frequency of oscillation is kept constant. (In the present case, it is 1.29×10^{-1} cycl./sec.).

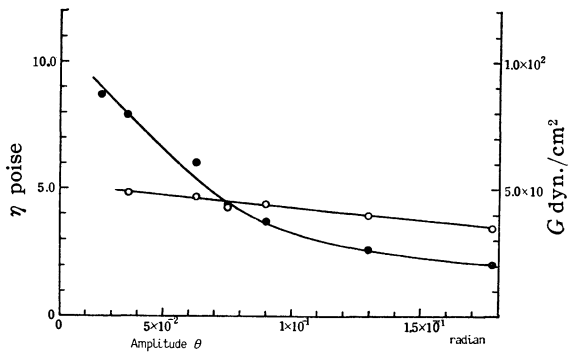

Fig. 3. Amplitude dependence of viscosity η and rigidity G of 1.58% mercury sulfosalicylate aq. solution. ○ indicates viscosity and ● rigidity.

It seems that the viscosity increases as amplitude decreases. But its gradient is fairly slight. As to the rigidity, on the other hand, the situation is somewhat different. It is large in the region of small amplitude, but decreases rapidly as the amplitude increases, and finally tends to a constant value. This is a noticeable experimental result. An explanation of this effect may be given by assuming a sort of structural breakdown by shear strain. An elastic structure breaks into a viscous flow process by a large deformation.

Effect of Concentration of Solution.—So long as we are concerned with dilute solutions, the rigidity seems to be proportional to the third power of concentration as is shown in Fig. 4. This result is in accord with that of agar-agar sol formerly reported[8].

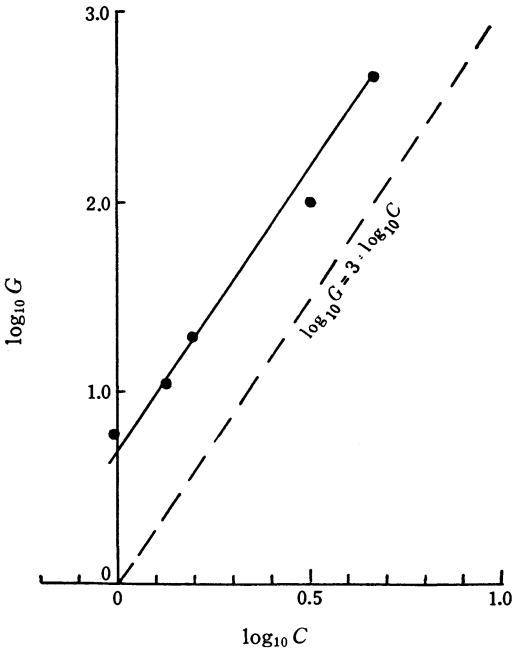

Fig. 4. Effect of concentration of mercury sulfosalicylate aq. solution.

Dependence on Temperature.—Both viscosity and rigidity decrease with the increase of temperature. Fig. 5 shows the results, where viscosity is plotted against the reciprocal of absolute temperature. The author has used the Andrade formula[9]

$$\eta = Ae^{\Delta E/RT}$$

to express the temperature sensitivity of viscosity η; A and ΔE were determined by the method of least square with regard to various periods of oscillation. Results are given in Table I. The apparent heat

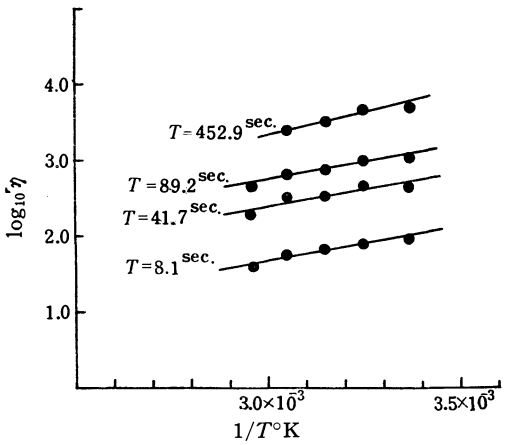

Fig. 5. Temperature dependence of viscosity.

TABLE I. CONSTANTS OF THE ANDRADE FORMULA

Period, sec.	$-\log A$	E, kcal.
8.1	−0.649	4.11
41.7	−0.210	3.96
89.2	−0.0147	4.10
452.9	−0.147	4.79

(For 4.53 wt. % solution).

of activation in relation to the viscous flow process is about 4 kcal./mol. This value makes one assume the existence of the cross-linking due to the weak secondary bonding like a hydrogen bond.

Discussion

From the results of frequency dependence, it is assumed that this solution has two mechanisms of relaxation. A mechanism which relaxes easily finishes its relaxation during the small period. When the period increases to a certain value, both viscosity and rigidity do not change with frequency due to the nearly complete relaxation of the first mechanism (Fig. 2). We have already seen that viscosity increases, while rigidity does not suffer a remarkable change in the course of aging (Fig. 1). An elastic scaffolding structure is formed in the first stage of gelation, and afterwards the gradual growth of suspending particles in a cavity follows. This is shown in the electron-micrograph

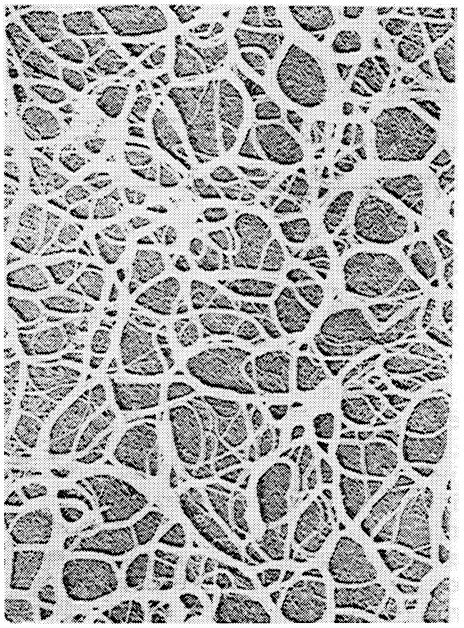

Photo. 1. Electron-micrograph of the aq. solution of mercury sulfosalicylate (×10,000).

(see Photo. 1). This means that the solution of mercury sulfosalicylate has a network structure of two phases.

As to the nature of cross-linking between these submicroscopic network structures, weak secondary bonding, for example, by hydrogenbond, is assumed, because the apparent activation energy of viscosity is calculated to be about 4 kcal./mol.

The author wishes to express his gratitude to Professor H. Akamatsu and Dr. T. Nakagawa both of the University of Tokyo for their leadership and encourgement throughout this investigation. It is also a pleasure to acknowledge the help of the members of Electron-microscope Laboratory of the University of Tokyo.

*Structural Heterogeneity in Viscose Fibers**

By Akiyoshi NAKAI

(Received February 23, 1959)

Though various theories as to the cause and nature of the skin-core effect in viscose fibers have been advanced, none seems to be entirely satisfactory to accout for all the facts so far observed. On the other hand, some observations have been presented which show that the actual structures are far more complicated than the skin-and-core model[1-5], but the results obtained are not yet conclusive.

Dyeing properties of the fiber sections have been studied by various workers, who have dealt almost exclusively with the differential staining of the skin and core. This phenomenon is, as Hermans[6] pointed out, due to a more rapid diffusion of the dye into the core than into the skin.

Generally, dyeing property has two major factors. These are dye diffusion velocity and dye equilibrium absorption. If the picture is oversimplified it would seem that the dye equilibrium absorption is connected with the total spatial per cent of amorphous areas but the dye diffusion velocity is connected with the size and distribution of amorphous areas or the average orientation of the chains in these areas. Then the structural factor which causes the differences in velocity of dye diffusion should not always be identified with that which causes the differences in equilibrium absorption of dye. This suggestion is proved in various experiments.

In addition to the dyeing property of fiber section based on diffusion velocity, therefore, the situation at sorption equilibrium should also be studied. As for this subject, an interesting contribution has been published by Hermans[6], but it seems that there is possibility of further study.

The present investigation is concerned with (1) the observation on the dyeing property of fiber sections and (2) a study of the radial structural gradient by a peeling-off method.

Dyeing Experiment of Fiber Sections

As is well known in ordinary dyeing, the amount of dye absorbed is not sensitively reflected to the depth of color shade beyond the range of fairly low degrees of absorption. In order to distinguish clearly a difference in depth of stained shade on the cross sections prolonged-dyed, dyeing should then be carried out with a diluted dye solution.

Cross sections mounted in the usual way on slides, were dyed for long periods at room temperature with Oxamine Blue 4R which was purified by chromatographing on silica gel.

Müller-bath-type Fiber.—The fiber used here was an ordinary rayon (No. 1) spun in a bath containing sulfuric acid 110 g./l., sodium sulfate 350 g./l., and zinc sulfate 15 g./l.

After half an hour of dyeing in a solution of 0.3% Oxamine Blue 4R to which 1% of sodium sulfate had been added, the cross section exhibited the differential staining of skin-and-core with a selectively stained core, as is well known already. This is shown in Fig. 1.

As the dyeing time increased, the intensity of the color increased over all the parts, especially at both the outer circumference of the skin and the boundary between skin and core. After prolonged dyeing—for example, after dyeing for 6 hr. the section showed a finer staining differentiation than the skin-and-core, as shown in Fig. 2. In the section, a narrow zone of the core next to the skin exhibited a darker shade than the central part and was separated from the latter by a rather sharp boundary, and then showed up as a dark band. Moreover, the outer circumference of the skin was seen to stain deeply, but this zone was so thin that it was difficult to distinguish its existence.

Even after further dyeing the above fine differentiation remained, although it was very difficult to distinguish the differences in depth of color shade because of the intensive staining over the whole section.

When such intensively dyed sections were washed with water, the stain was seen to bleed easily off the outermost thin zone and the core but to remain in the main part of the skin. After short washing, the clearness of the boundaries among the various zones became pronounced and the multilayer-like differential staining came again into view. Fig. 3 is a micrograph of such partially washed-out sections mounted in water. As to the phenomenon that by short washing a narrow zone of the core next to the skin became pronounced, drawing a dividing line from the central part, a similar fact was observed already by Hermans, who did not interpret this narrow zone as the differentiated layer different from the central part, but then explained that during washing the former discolored much later than the latter. On the basis of the above observations on both dyeing and washing, however, it seems rather reasonable to assume that the narrow zone has a much greater dye equilibrium absorption than the central part and that there is, moreover, no remarkable difference in velocity of dye diffusion between the two. In the swollen sections in Fig. 3, a very thin deeply-stained outermost zone seems to be seen, but not yet clearly.

When washing had been carried further, the dye disappeared completely from both the outermost thin zone and the core, and remained only in the main part of the skin. Fig. 4 is a micrograph of such a washed-out section after immersion in water, photographed with a contrasting light filter. There is no doubt that a very thin outermost layer exists actually at the outside of the skin, free from the refraction and diffraction effects associated with the cellulose/water interface, as shown previously by Preston and Joshi[7]. This thin outermost layer has a high velocity of dye diffusion and a great dye equilibrium absorption (proved in the next section) and then exhibits a similar property towards dyes as a narrow zone of the core next to the skin.

The above-mentioned phenomena were also observed in other Müller-bath-type fibers (see Fig. 5) and with other dyestuffs such as Sky Blue FF.

In Müller-bath-type fibers there are apparently four distinct layers which differ in dyeing property. The skin itself is composed of two layers which differ in dye equilibrium absorption, and so does the core. These are summarized in Table I.

TABLE I. DYEING PROPERTIES OF FOUR LAYERS IN MÜLLER-BATH-TYPE FIBER (in cross section)

Layer		Velocity of dye diffusion	Equilibrium dye absorption
Skin	1st layer	rapid	high
	2nd layer*	slow	low
Core	3rd layer	rapid	high
	4th layer	rapid	low

* The main part of the skin.

Skinless-type Fiber.—For a sample "Shintoramomen" (No. H-T) was used, which was a high tenacity rayon staple spun from low-alkali viscose in zinc-free and low-acid bath. Fiber of this type is marked by an all-skin structure, as shown in Fig. 6.

Fig. 7 shows a similar section washed-out after prolonged dyeing. In the section, the stain is seen to bleed completely off the outermost thin layer but to remain

in the inner part, and then two distinct layers are clearly distinguishable. These two layers seem to correspond to the outermost and the second layer in the Müller-bath-type fiber, respectively.

Experiment with Peeling-Off Method

In view of the preceding observations it would seem that the actual structural heterogeneity is far more complicated than that assumed on the basis of the old skin-and-core model. In an investigation with peeling-off technique, therefore, it is necessary to peel the successive layers off as close as possible from the fiber surface toward the center and then to seek the nature of the radial structural gradient existing in fiber to the minutest details.

As a peeling-off technique the heterogeneous nitration presented by Okajima et al.[8] was applied. In a study of this kind, the point is in whether peeling-off is carried on successfully or not. Thereupon, numerous control experiments were carried out carefully.

Experimental Procedure.—A sample of fibers was thoroughly unraveled and vacuum-dried just before use (weight is W). Heterogeneous nitration was carried out at 18°C, and moisture was prevented from entering the reaction vessel. The nitration mixture was made from dry reagents and its composition was as follows:

Nitric acid (1.53) 3 g.
Acetic anhydride 3 g. } per 0.5 g. sample.
Carbon tetrachloride 90 g.

After nitrating the samples to the desired degree, they were washed enough with dry carbon tetrachloride, vacuum-dried and then treated with acetone for removing the nitrate layer.

After applying fresh acetone, they were washed with NH_4SH alcoholic solution recommended by Okajima for the removal of the residual nitrate groups from the fiber surface. Finally they were washed with water, vacuum-dried and weighed (W').

The degree of peeling-off (Pr) was given on the base of the original radius of the filament and obtained by $Pr=1-(W'/W)^{1/2}$.

In order to direct operations properly, microscopical examination of cross sections of the nitrated fibers was carried out using the staining technique. When nitration was carried on much longer, it was seen that the nitrated layer began to show more and more radial flaws, and that nitration proceeded in an irregular fashion. In order to avoid a drawback of this kind, the reaction time was limited to half an hour. If a greater degree of peeling-off was desired, the sample was peeled-off with acetone and then exposed a second time to the nitrating mixture.

Because of the necessity of studying a radial distribution of dye in the dyed fiber—this is the main object in the present investigation — the application of the above peeling-off method to the dyed sample was examined. Fig. 8 shows spectral sorption curves of the dye solutions extracted from the original and peeled-off predyed samples. This figure indicates that, if nitration proceeds under absolutely dry conditions, the dye which remains in the unreacted part has not been decomposed and the acid has not diffused into the inner part beyond the nitrated layer. It was found eventually that the dyed sample was peeled-off satisfactorily as well as the undyed sample. In this case, however, water should not be used for washing, because the dye absorbed in the unreacted part was dissolved away with water.

Samples.—The fibers selected for investigation were "Shintoramomen" (No. H-T) and three ordinary rayons (No. I—III). No. I—III were all spun in the same Müller bath; 1.5, 3.0 and 7.0, deniers, respectively.

Radial Distribution in Dye Equilibrium Absorption.—A sample was dyed to equilibrium at 25°C in a solution of 0.001% Japanol Brilliant Blue 6BKX to which 0.2% of sodium sulfate had been added, and washed briefly with water to remove the mechanically absorbed dye from the fiber surface, vacuum-dried and then peeled-off. In Fig. 9-A is given the amount of dye absorbed as a function of the degree of peeling-off. The radial distribution curves derived therefrom are shown in Fig. 9-B. These are in good agreement with the differential staining based on the differences in equilibrium absorption, irrespective of the differences in dyestuff and even in procedure of dyeing (Ref. Figs. 2, 3 and 7). The fact that a very thin outermost layer has a greater dye equilibrium absorption is experimentally proved here.

Radial Distribution in Crystallinity.—Using the Hessler and Power's method[9], the radial distribution in accessibility was first studied. In Fig. 10-A are given the amount of iodine absorbed on the fibers peeled-off to various degrees. The radial distribution curves derived therefrom are shown in Fig. 10-B, in which a ratio of the absorption value to 412** gives a value for the accessible fraction. Four layers in Müller-bath-type fiber and two in Shintoramomen are clearly distinguished also here.

The accessibility thus obtained is, however, due to the inner surface areas for absorption and seems to be an unsatisfactory measure for crystallinity. In order to seek conclusive evidence on the nature of the fine structure in each layer, the lateral-order (L.O.) distribution of each separated layer was further determined according to the hydrocellulose solubility method presented by Maeda[10]. For example, the L.O. of the outermost layer of No. 1 (P_γ: 0∼about 0.05) was determined by calculation from the L.O. of the original fiber and the observed L.O. of the fiber peeled-off to 0.05 (the outermost layer just about

removed). The results are shown in Figs. 11 and 12.

As is seen in the figures, there is an intrinsic difference in L.O. distribution between a layer with greater dye equilibrium absorption and that with less dye equilibrium absorption. The former has two peaks in its distribution curve and, consequently, lower crystallinity. The latter, on the other hand, gives only one peak in the region of considerably high order and, consequently, higher crystallinity. These are in agreement with the information obtained from the radial distribution in iodine absorption described before.

Discussion

As is seen from the above observations, there are two types of differentiated layers.

One is a layer rich in disordered material which shows a lower crystallinity and a greater dye equilibrium absorption. Cellulose gel of this type, which will be termed here "α-type", is formed by a momentary gelatinizing action, such as that of zinc ions[11].

The other is a highly crystallized layer with relatively limited amorphous regions and shows less dye equilibrium absorption. Cellulose gel of this type, which will be termed "β-type", is formed by a relatively slow gelatinizing action, such as those of sodium or hydrogen ions[11].

Consequently, it seems reasonable to assume that viscose fibers consist of the alternative succession of the α-type and β-type layers. In the Müller-bath-type fiber there are four successive layers, i.e., the α_1-, β_1-, α_2- and β_2-layer; the α_1- and β_1-layer altogether correspond to the skin, and the α_2- and β_2-layer to the core. This seems to be in agreement with the result of Joshi and Preston[4], who observed four zones which differ in transverse orientation.

As to the layer succession, there are some interesting facts as follows: (1) Fiber spun in a zinc-free bath has only one combination of the α-type and β-type layer, but fiber spun in a zinc-containing bath has double combinations. (2) The periods of the layer succession are identical in all fibers spun in the same composition of bath, irrespective of the differences of their deniers. These facts seem to lead to the suggestion that the bath composition is of essential importance for the occurrence of the Liesegang-like periodic coagulation which influences the rate of primary gelatination and, consequently, the degree of crystallization.

Moreover, all types of fiber have the outermost thin α-type layer, which will be designated "the cuticle layer"***, irrespective of the existence of zinc salt in their spinning bath. The formation of this layer seems to connect with some inevitable effect occurring when viscose contacts with bath liquid, — maybe, a momentary dehydration carried out in the

*** The cuticle layer was shown also by Heyn, *Textile Research J.*, **27**. 449 (1957). Heyn's paper had not been published when the present investigation was presented at Spring Meeting of the Fiber Society of Japan, held on May 16, 1957.

order of the relaxation time of the macromolecules in viscose, on the surface of the extruded viscose[11].

The most noticeable conclusion to be drawn from the present study is that the main part of the skin has a good crystallinity as well as the central part. This is opposed to the opinions given in the majority of previous works, which maintain that the degree of crystallinity is less in the skin than in the core[12-14]. On the other hand, a few contributions have been reported which show that there is no remarkable difference in crystallinity between the two[15,16]. Since the actual differentiations are far more complicated as proved here, it is doubtful whether the actual nature of the structural heterogeneity can be sought by the methods used in previous works, for example, by a comparative study of the crystallinity of thick- and thin-skin fibers, or by that of the physical properties of fibers peeled-off to various degrees which kept a relatively long interval between the various ones.

The structural difference based on crystallinity is the major factor which causes the differences in dye equilibrium absorption, but not the major factor which causes the differences in velocity of dye diffusion. This is demonstrated by the following facts: (1) There is a remarkable difference in velocity of dye diffusion between the β_1- and β_2-layer, irrespective of the small difference in their crystallinities. (2) There is no difference in velocity of dye diffusion between the α_2- and β_2-layer, irrespective of the great difference in their crystallinities. Consequently, the skin-core effect is not, as Morehead and others believed, due to the differences in degree of crystallinity between the two.

As already shown by various works, the skin part has a higher degree of axial orientation than the core. Accordingly, the main part of the skin (the author's β_1-layer) seems to have a denser structure with good orientation and good crystallinity. The difficulty of the dye permeating into the main part of the skin, and, more generally, the skin effect seems probably to be due to the interdependence of its higher orientation and higher crystallinity.

The course of fiber formation from viscose seems not to be so simple as to be suggested by previous theories. The present investigation seems to demonstrate that some as yet unknown peculiarity in the process of diffusion of the bath components into the viscose is mainly responsible for skin formation.

The author wishes to express his grateful acknowledgment to Professor I. Tachi of Kyoto University for his kind encouragement. He is also indebted to Messrs. S. Hiraoka and S. Omoto for their valuable assistance.

Some of the work reported here was carried out at the Research Institute of the Mitsubishi Rayon Company.

Infrared Spectrum of α-Aminoisobutyric Acid and the Assignment of the Vibrational Frequencies

By Masamichi TSUBOI and Tadao TAKENISHI

(Received March 3, 1959)

As has been shown in our previous papers[1,2], the infrared absorption measurement is an effective means for detecting differences in the molecular configurations of amino acids in different environments. In order to investigate further in detail such differences in the molecular configurations, it is necessary to know the vibrational mode for each of the bands given by these amino acids. For glycine[3] and DL-alanine[4], complete assignments of the vibrational modes have been made to the bands observed in the NaCl (and also KBr for glycine) region. This paper refers to another simple amino acid, α-aminoisobutyric acid. The vibrational frequencies observed in the solid state infrared spectra of this compound and its deuterated (ND_3^+) one, and also of its hydrochloride will be shown, and then, to all of these observed frequencies, approximate vibrational modes will be assigned on the basis of the results of analyses of normal vibrations made by previous authors for simpler molecules.

It may be worthwhile to point out here that, in these molecules (probably because of their branched-chain structures), the couplings between the skeletal stretching vibrations and the CH_3 or NH_3^+ rocking vibrations are not so strong as in alanine. Therefore, detailed discussions may be made on the couplings between the CH_3 rocking vibrations and the NH_3^+ rocking vibrations.

Experimental

The sample of α-aminoisobutyric acid was purified with active charcoal and repeated recrystallization from water. The deuterated product (ND_3^+) was obtained by dissolving the acid in D_2O and then by evaporating the solvent in vacuum. During the procedure, the D_2O and the acid were kept away from the atmospheric moisture by use of a dry box. By repeating the procedure twice an almost completely deuterated product, practically free from the NDH_2^+ and ND_2H^+ groups, was obtained. α-Aminoisobutyric acid hydrochloride was obtained by dissolving the free acid in concentrated aqueous solution of hydrochloric acid (1.1 equivalents) and was purified by recrystallization from aqueous alcohol.

The infrared absorption measurements were made with Nujol mulls, hexachlorobutadiene mulls, and KBr disks. The instruments used were a Perkin-Elmer 21 spectrometer equipped with an NaCl prism and a Hilger H800 spectrometer equipped with an NaCl prism or with a KBr prism.

Results

Infrared absorption curves obtained for α-aminoisobutyric acid and its deuterated product are shown in Fig. 1, and that for the hydrochloride in Fig. 2. The observed frequencies of the bands are listed in Table I, and are graphically shown in Fig. 3, with their intensities. As to assignments given in the table and Fig. 3, discussions will be given below.

Assignments of the Vibrational Frequencies of Trimethylacetic Acid

Before discussing the vibration frequencies of α-aminoisobutyric acid, considerations will be made on the frequencies of trimethylacetic acid, $(CH_3)_3CCOOH$, which is iso-electronic with α-aminoisobutyric acid cation, $\begin{matrix} NH_3^+ \\ CH_3 \\ CH_3 \end{matrix}\!\!>\!C\text{–}COOH$, the NH_3^+ group of the latter being substituted by the CH_3 group in the former. The frequencies (in the region of 650~1800 cm^{-1}) of $(CH_3)_3CCOOH$, as read from Sadtler Standard Spectrum No. 6355*, are listed in Table II.

For comparison, the frequencies of *tert*-butyl chloride, as observed by Sheppard[5]

* See also reference 7.

are also given in the parallel column. The assignment of the frequencies of *tert*-butyl chloride was made by Nakagawa[6] with the result as given in Table II and Fig. 3.

The vibrational frequencies of trimethylacetic acid can be assigned readily by comparing the frequencies with those of *tert*-butyl chloride and by taking the characteristic frequencies of the carboxyl group[7] into consideration (see Table II and Fig. 3).

The frequencies, 1695, 1408, 1192 and 935 cm^{-1}, (shown in Fig. 3 by thick vertical lines) are assigned to four vibrations of the carboxyl group; i. e., 1695 cm^{-1} to the C=O stretching vibration, 1408 and 1192 cm^{-1} to two vibrations including the C–O stretching and the OH in-plane deformation, and 940 cm^{-1} to the OH out-of-plane deformation vibration. The frequency 865 cm^{-1} is assigned to the C–C (carboxyl) stretching mode, as 895 cm^{-1} in acetic acid dimer[8] or 846 cm^{-1} in acetic acid monomer[8]. All the other frequencies of trimethylacetic acid are correlated (see Fig. 3) with the frequencies of *tert*-butyl chloride, although provisos should be added as follows: The CH_3 degenerate deformation frequency 1460 cm^{-1} in the latter splits into two, 1479 and 1456 cm^{-1}, in trimethylacetic acid. The CH_3 symmetric deformation frequency 1370 cm^{-1} in *tert*-butyl chloride is lowered to 1359 cm^{-1} in trimethylacetic acid; $C\begin{smallmatrix}\diagup C\\ \text{—}C\\ \diagdown C\end{smallmatrix}$ asymmetric stretching frequency 1240 cm^{-1} is raised to 1295 cm^{-1}, and the symmetric stretching frequency 812 cm^{-1} lowered to 766 cm^{-1}. This lowering and raising is explained as the result of interactions of the vibrations of the $(CH_3)_3$–C group with the vibrations of the carboxyl group, interactions between the 1359 and 1408 cm^{-1} vibrations, between 1295 and 1192 cm^{-1} vibrations, and between 766 and 865 cm^{-1} vibrations. The band due to the CH_3 rocking vibration observed at 910 cm^{-1} in *tert*-butyl chloride is probably obscured in trimethylacetic acid by the strong band at 935 cm^{-1}.

Assignments of the Vibrational Frequencies of α-Aminoisobutyric Acid, its Deuterated (ND_3^+) Product, and its Hydrochloride

In the three crystals in question, α-aminoisobutyric acid, its deuterated product, and its hydrochloride, the molecules take the structures expressed by the formulae: $NH_3^+C(CH_3)_2COO^-$, $ND_3^+C(CH_3)_2COO^-$ and $NH_3^+C(CH_3)_2COOH$, respectively. These may be referred to in the following discussions as the zwitterion, the deuterated zwitterion, and the cation, respectively. In all of these three ions there seems to be no strong coupling between the four types of vibrations: the vibrations of the carboxyl group, the skeletal stretching vibrations, the hydrogen deformation vibrations (NH_3^+ and CH_3^+ deformation vibrations), and the hydrogen rocking vibrations. Discussions will, therefore, be presented below of these four types of vibrations in separate paragraphs.

A) Vibrations of the Carboxyl Group (shown in Fig. 3 by thick vertical lines).—In the cation, the carboxyl group takes the form,

$C(=O)OH$ The bands due to the vibrations of this group are picked out on account of their frequencies, intensities, or breadth. These are at 1732 (C=O stretching), 1411 (C-O stretching+OH in-plane deformation), 1183 (C-O stretching + OH in-plane deformation), and 828 cm^{-1} (OH out-of-plane deformation).

The frequency of the last vibration is much lower than that (930 cm^{-1}) of carboxylic acids without the NH_3^+ group. This is also the case for glycine hydrochloride and DL-alanine hydrochloride. This fact may be understood, if we assume that the carboxyl groups in amino acid hydrochlorides are in different hydrogen bondings from those of the carboxylic acids containing no NH_3^+ groups; in the latter the ring dimer is mostly formed through the two OH·····O=C bondings, while in the former the NH_3^+ group, a strong proton donor, interrupts the hydrogen bondings in the ring dimer.

In the zwitterion and the deuterated zwitterion, the carboxyl group takes the form, $C(=O)O$ The antisymmetric and symmetric stretching vibrations of this group are observed around the usual positions, 1600 and 1400 cm^{-1},— 1578 and 1413 cm^{-1} in the undeuterated zwitterion, and 1580 and 1415 cm^{-1} in the deuterated zwitterion.

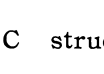
The COO^- rocking vibration has the frequency 504 cm^{-1} in glycine[3], and 540 cm^{-1} in DL-alanine[9]. Therefore, the band at 540 cm^{-1} (doublet with the peaks at 547 and 531 cm^{-1}) in the zwitterion of α-aminoisobutyric acid is assigned to the COO^- rocking vibration. In the deuterated zwitterion, the band at 520 cm^{-1} is picked up as the corresponding one.

The COO^- bending and wagging vibrations have the frequencies 607 and 694 cm^{-1} respectively in glycine[3]. According to the result of the calculation of the normal vibrations in alanine by Fukushima[10], the COO^- bending frequency must be much higher than 607 cm^{-1}, and the band at 746 cm^{-1} was assigned to this vibration. The COO^- wagging vibration in this molecule was assigned to the band at 642 cm^{-1}. α-Aminoisobutyric acid gives two strong bands at 602 cm^{-1} and 790 cm^{-1} (doublet with the peaks at 792 and 787 cm^{-1}) in the region 600~800 cm^{-1}. By analogy with the case of DL-alanine, the band at 602 cm^{-1} is tentatively assigned to the COO^- wagging vibration and that at 790 cm^{-1} to the COO^- bending vibration.

A difficulty of this assignment is due to the fact that, very close to by the band at 790 cm^{-1}, there is another band observed at 805 cm^{-1}, which is later shown to be assigned to the $C-C(-N^+)C$ symmetrical stretching vibration. The two vibrations, COO^- bending and $C-C(-N^+)C$ symmetrical stretching, with dipole oscillations in almost the same direction, would couple strongly, so that the two bands due to these two

9) M. Tsuboi, to be published.

10) K. Fukushima, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **79**, 370 (1958).



vibrations appear much more apart from each other. From this point of view, the band at 790 cm^{-1} is notlikely due to the COO^- bending vibration. Therefore another choice to assign the 790 cm^{-1} to the COO^- wagging and the 602 cm^{-1} to the COO^- bending is not entirely eliminated.

B) Skeletal Stretching Vibrations. — The skeletal stretching frequencies of the  structure are expected to be close to those of the  structure (see above), the symmetrical one being expected to be around 800 cm^{-1} and the asymmetrical one around 1200 cm^{-1}.

Actually, however, a band in the cation that may be assigned to the  symmetrical stretching vibration is observed at 748 cm^{-1}, a little lower than 800 cm^{-1}. This is attributed to a lowering of the frequency of the vibration in question due to its coupling with the C–C (carboxyl) stretching vibration. The band that may be assigned to the C–C (carboxyl) stretching vibration is observed at 875 cm^{-1}, a little higher than usual (835 cm^{-1} in trichloroacetic acid dimer[7]) just as is expected from the above-mentioned coupling of the two vibrations.

In the zwitterion, the C–C (carboxyl) stretching frequency is 895 cm^{-1}, a little higher than in the cation; and the  symmetrical stretching frequency is 803 cm^{-1}, a usual value.

The band of the cation at 1229 cm^{-1} and that of the zwitterion at 1199 cm^{-1} are assigned to one of the  asymmetrical stretching vibrations**.

In the deuterated zwitterion, the three skeletal stretching frequencies, namely, the symmetrical and asymmetrical stretching frequencies of the  structure and the C–C (carboxyl) stretching frequency, are found to be 790, 1206 and 888 cm^{-1}, respectively.

C) NH_3^+, ND_3^+ and CH_3^+ Deformation Vibrations.—As to the assignments of these vibrations, the results of studies on the vibrations of the glycine molecule[3] as well as of some simple molecules with the CH_3 group[11] are to be referred to. In the cation, the NH_3^+ degenerate deformation vibration is assigned to the doublet with the peaks at 1599 and 1587 cm^{-1}, and the NH_3^+ symmetric deformation vibration to the strong band at 1495 cm^{-1}. In the undeuterated zwitterion, the bands corresponding to the above two are at 1635 and at 1544 cm^{-1} respectively, 30~50 cm^{-1} higher than in the cation. This difference in the positions of bands may be explained by considering that the intermolecular (interionic) hydrogen bonding is stronger for the zwitterion than for the cation.

In the deuterated zwitterion, the doublet with peaks at 1237 and 1247 cm^{-1} and the band at 1151 cm^{-1} are interpreted as corresponding to the above two bands. Then, the factors of the shiftings of these bands are respectively 1.32 and 1.34, in agreement with the expected values, 1.37 and 1.31, respectively.

CH_3 degenerate deformation is assigned to a doublet around 1470 cm^{-1} and CH_3 symmetric deformation to a band near 1370 cm^{-1} in any of the cations, the undeuterated zwitterion, and the deuterated zwitterion.

D) NH_3^+, ND_3^+ and CH_3 Rocking Vibrations.—In any of the above three ions now under discussion, six rocking vibrations are expected, two from the NH_3^+ (or ND_3^+) group and four from the two CH_3 groups. In glycine, both of the two NH_3^+ rocking vibrations are observed in the vicinity of 1150 cm^{-1} [3]; and in isopropyl chloride, the four CH_3 rocking vibrations are observed at 1160, 1062, 949 and 932 cm^{-1} [10]. The location of the bands corresponding to the six rocking vibrations may be made around these frequencies.

Actually, in the cation, there are two weak bands observed, at 955 and 945 cm^{-1}, and these may correspond to the above two frequencies at 949 and 932 cm^{-1} of isopropyl chloride. Instead of bands around 1160 and 1062 cm^{-1}, however, three bands are observed at 1277, 1064 and 994 cm^{-1}. This fact may be explained as a result of interactions of the CH_3 rocking and the NH_3^+ rocking vibrations; thus, the two CH_3 rocking frequencies, originally at 1160 and 1062 cm^{-1} are lowered respectively to 1064 and 994 cm^{-1} and the two

** Only one band could be observed though two are theoretically expected.

11) I. Nakagawa and S. Mizushima, This Bulletin, 28, 589 (1955).

NH_3^+ rocking frequencies, originally around 1150 cm^{-1} are both raised to 1277 cm^{-1}.

In the undeuterated zwitterion, a band with a medium intensity is observed at 946 cm^{-1}. This band is considered to be an unresolved doublet and to correspond to the two CH_3 rocking vibrations observed at 949 and 932 cm^{-1} in isopropyl chloride and at 955 and 945 cm^{-1} in the α-amino-isobutyric acid hydrochloride. Besides this, four bands are observed at 1008, 1091, 1273 and 1293 cm^{-1}. These four bands are again explained as resulting from interactions of two of the four CH_3 rocking vibrations with the two NH_3^+ rocking vibrations, all of which are considered to be originally in the vicinities of 1160 and 1062 cm^{-1} (see Fig. 3).

This explanation is supported by what was observed of the rocking vibrations in the deuterated zwitterion. In the deuterated zwitterion, in which the NH_3^+ group is substituted by the ND_3^+ group, the above-mentioned interactions between the CH_3 and NH_3^+ rocking vibrations should be absent, and hence, the almost pure CH_3 rocking vibrations are expected to occur in the vicinities of 1160 and 1062 cm^{-1}. Actually, two bands are observed at 1167 and 1090 cm^{-1} in the deuterated zwitterion. It is also expected from the above explanation, that the two ND_3^+ rocking vibrations occur around $1160/1.32=880$ cm^{-1}. Actually, two bands are observed at 849 and 842 cm^{-1}. The observed frequencies of the bands are sufficiently close to the expected ones to support the above explanation.

Going into detail, however, the observed frequencies of the two CH_3 rocking vibrations are somewhat higher, and those of the two ND_3^+ rocking vibrations are somewhat lower, than the corresponding expected frequencies. This fact suggests that there are interactions of another type between the CH_3 and ND_3^+ rocking vibrations.

Corresponding to the other two CH_3 rocking vibrations in the deuterated zwitterion, expected around the 940 cm^{-1}, two bands are actually observed at 976 and 947 cm^{-1}. That the band at 976 cm^{-1} is situated at a little higher position than the expected position, 940 cm^{-1}, may again be attributed to the interactions of the CH_3 and ND_3^+ rocking vibrations***.

We wish to express our sincere thanks to Professor San-ichiro Mizushima, Dr. Takehiko Shimanouchi and Dr. Haruomi Oeda for their kind encouragement and valuable suggestions and to Miss Chie Yamazaki for helpful assistance.

12) N. Sheppard, *Trans. Faraday Soc.*, **46**, 533 (1950); G. Radinger and H. Wittek, *Z. physik. Chem.*, **B45**, 329 (1940); I. Nakagawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77**, 602 (1956).

*** Under the assumption that all the rocking vibrations are independent of vibrations of other kinds in the zwitterion and in the deuterated zwitterion, the assignment, above made, of the six rocking frequencies is almost consistent with the product rule. Thus, the observed ratio, $1293\times1274\times1091\times1008\times946\times946/849\times842\times1167\times1090\times976\times947=1.93$, is close to the calculated ratio, 1.81. However, it is to be noted that the observed and calculated ratios are not in complete agreement. This is probably to be explained by considering that the assumption is not entirely valid, in other words, that some other vibrations, e. g., CH_3, NH_3^+, or ND_3^+ degenerate deformation vibrations and C-N stretching vibrations are coupling a little with the rocking vibrations.

Infrared Spectra of Salicylaldehyde, Methylsalicylate and their Sodium Compounds

By Haruka YAMADA

(Received April 2, 1959)

Concerning the infrared spectra of conjugated chelate compounds, it is well known that the absorption bands associated with the OH stretching and the C=O stretching vibrations show some peculiarities that are not observed in the spectra of the usual hydrogen-bonded molecules.

The formation of the intramolecular hydrogen bond in conjugated chelate compounds may be mainly due to electrostatic and charge transfer forces. Though some interpretations of the spectra, common to various conjugated chelate compounds, have been given by considering resonance structures, a question as to what structure contributes predominantly to the resonance has not yet been solved completely. The important contribution of ionic structure to the resonance was pointed out by some investigators[1], based on the infrared studies of the C=O bands, while the ionic structure was disregarded by a few others[2] from the measurements of the OH bands. The OH band seems to be inappropriate for accurate measurement because of its broad band width. The intensity measurement of the C=O band has not yet been made. In these circumstances, more experimental knowledge is required to make an analysis of this problem. Salicylaldehyde and methylsalicylate are suitable for the intensity measurements of the C=O bands and for the present analysis.

The sodium compounds of salicylaldehyde and methylsalicylate are very interesting, because they are expected to have an intermediate character between salts and metal chelate compounds and further will be closely related to the hydrogen-bonded compounds. The measurements for these compounds, therefore, will not only make their structures clear but also give a valuable item of knowledge in regard to the hydrogen-bonded chelation.

Experimental

Measurements were made by a Perkin-Elmer Model 112 Infrared Spectrophotometer equipped with CaF_2 and NaCl prisms. For dilute solutions, fixed cells of 0.01, 0.05 and 1 cm. thicknesses were used, and the thicknesses of the thin cells were determined by the interference method. The slit widths for intensity measurements were kept constant and ranged from 0.07 to 0.15 mm. The integrated absorption intensity of a band, A ($mol^{-1}\cdot l.\cdot cm^{-2}$) was calculated by the following formula;

$$A=(K/Cl)\cdot\Delta\nu_{1/2}\cdot\ln(I_0/I)_{max}$$

where C, l, $\Delta\nu_{1/2}$ and $\ln(I_0/I)_{max}$ have their usual meanings and K is obtained from Ramsay's table[3], by use of the spectral slit width calculated by Kudo's equation[4].

The samples used were purified by distillation. The boiling points were as follows; 68.8~69.0°C/10 mmHg for salicylaldehyde, 73.0~73.5°C/5 mmHg for methylsalicylate and 51.0~51.2°C/9 mmHg for benzaldehyde. *o*-Methoxybenzaldehyde was prepared from salicylaldehyde and dimethylsulfate[5]. The boiling point was 37.3~38.0°C.

The sodium compounds of salicylaldehyde and methylsalicylate were prepared by mixing an excess of salicylaldehyde and methylsalicylate with ethylalcoholate[6]. The sodium compound of methylsalicylate was also prepared by throwing metallic sodium into methylsalicylate. Upon heating, the sodium compound of salicylaldehyde chared at ca. 250°C instead of melting and the sodium compound of methylsalicylate at ca. 180°C. From the titration with hydrochloric acid, it was determined that each compound contained two molecules of salicylaldehyde or methylsalicylate for a sodium ion.

Results and Discussion

The results for the C=O bands of salicylaldehyde and methylsalicylate in

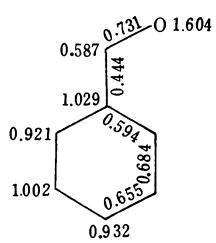
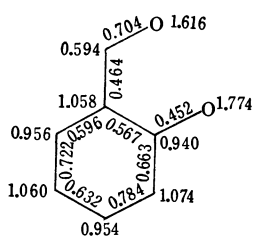
* The intensities are summed up for two ν_{max} assigned to its two isomers, though the intensity of one of them, at 1667 cm^{-1}, is very weak.



carbon tetrachloride solution are tabulated in Table I. In order to know whether or not the intensity of the band alters with chelating, the spectrum of salicylaldehyde should be compared with that of *o*-methoxybenzaldehyde, as the effect of the conjugation with the benzene ring and that of the ortho-substituted oxygen atom on their C=O groups are the same for both compounds. The results of the measurements for *o*-methoxybenzaldehyde[7] are shown in Table II. Because the intensity of the C=O band for salicylaldehyde is nearly equal to that for *o*-methoxybenzaldehyde, it comes out that the chelation effect does not alter the intensity. As the intensity of the C=O band for methylsalicylate shows the normal value of esters[8], it appears that the chelation effect has a large shift for the C=O stretching frequency towards lower frequency region but hardly affects the intensity. The lack of intensity change may indicate that the change in the bond moment is inappreciable.

In Table II are given the results for the conjugated C=O groups forming the intermolecular hydrogen bond with *n*-butanol. Here, the volume percentages of *n*-butanol in carbon tetrachloride range from 30 to 50%. Almost all the C=O groups of the compound in these solutions form the intermolecular hydrogen bond, since the frequency at the maximum absorption and the intensity of the band do not change with the concentration of *n*-butanol. By the formation of the intermolecular hydrogen bond the intensity noticeably increases, while the change in the frequency is very slight. These phenomena are different from those observed in the chelate compounds and can be explained by Tsubomura's theory[2c].



For the conjugated chelate compounds the four possible resonance structures shown below should be taken into account.

7) The ortho-substitution effect can be estimated by the comparison between benzaldehyde and *o*-methoxybenzaldehyde. The decrease of the frequcency and the increase of the intensity for the C=O band were observed by introducing the methoxy group. These changes are due to the migration of the lone pair electrons belonging to the oxygen atom and seem to be explained by the results expected from the molecular diagrams shown below. The molecular diagrams are calculated by a simple LCAO-MO method by use of Orgel's parameters.

* K. Kuratani, *Rept. Inst. Sci. and Technol., Univ. Tokyo*, **6**, 217 (1952).

By the formation of the chelate ring the C and D structures newly contribute to the resonance. The important contribution of the B structure was at first pointed out by Rasmussen et al.[1a] and afterwards by Hadzi et al.[1b] again, while the importance of the C structure was reported by Tsuboi[2a], Josein et al.[2b] and Tsubomura[2c]. As it may be true that for a molecule having the carbonyl group the change in ionic character of C=O bond on chelate bonding contributes to the intensity increase of the C=O band, there seem to be two possibilities to account for the present results. First, if the C structure makes a significant contribution to the structure of the chelating compounds, the bond order of the C=O group will decrease and the appreciable change in the bond moment of the group will not occur, in accord with the results. Secondly, if both the structures of B and D equally contribute to the resonance, an increase in the contribution of the B structure will give rise to a decrease of the bond order and hence to the decrease of the C=O frequency, and the equal contribution of both the structures will not significantly alter the bond moment of the C=O group, because the directions of the polarities of both the resonance structures are opposite, and will result in the unaltered intensity of the C=O band. The second interpretation, however, seems to be less reasonable than the first, because in the second the D structure, in spite of its high energy, must contribute to the resonance to the same extent as the increase of the B structure.

In a molecule having a polar resonance structure the per cent contribution of each structure may vary with the change of solvent. As for such a molecule, a slight change in the per cent contribution gives rise to appreciable changes in the dipole moment and in the intensity of the infrared absorption band. The intensity of the C=O band for salicylaldehyde is the same in carbon tetrachloride, in chloroform and even in acetonitrile. This fact indicates the important contribution of non-ionic structures in this molecule. The chelation in methylsalicylate is not so strong as in salicylaldehyde because of the ester resonance[9]. The contribution of the C structure to methylsalicylate, therefore, will be less important than the contribution to salicylaldehyde. In the case of methylsalicylate, the influence of polar solvent on the intensity of the C=O band was found.

As for β-diketones, conjugated chelate compounds take the enol forms. As the C=O bands of these compounds overlap with their C=C bands, the intensities of the bands appear to be very large. Rasmussen et al. described the fact that a very broad band, estimated to be more than a hundred times as strong as the normal carbonyl band, was observed in the range 1639~1538 cm^{-1}.

As is shown in Table IV, the integrated intensity of the broad band including the C=O and C=C bands measured for the enol form of acetylacetone is only about twice as strong as that of the usual conjugated aliphatic C=O band; e.g., the value for isophorone in chloroform is 4.6×10^4 $mol^{-1}\cdot l.\cdot cm^{-2}$. The interpretation for β-diketones will be essentially the same as that for salicylaldehyde. Since the normal value of the intensity of the C=O band for this molecule is expected, this fact indicates

9) A. E. Martell and M. Calvin, "Chemistry of the Metal Chelate Compounds", Prentice-Hall, Inc., New York (1952), p. 164.

that the intensity of the C=C band increases by the chelation effect.

Concerning the band shapes for the chelate compounds, there can be found a relation between the C=O and the OH band. A compound having a sharp C=O band shows a broad OH band, and conversely a compound having a broad C=O band a sharp OH band. Strong chelation is accompanied by a sharp C=O and a broad OH band. Acetic acid is regarded as a sort of chelate compound. The C=O band measured in carbon tetrachloride solution is shown in Table VI. The association of acetic acid to the dimer is so strong that it dissociates with difficulty to the monomer even in 0.05 mol.·l^{-1} concentration. It is interesting to notice that the intensity of the C=O band seems to be normal, though this band is assigned to the antisymmetric stretching vibration caused by the coupling of the two C=O groups.

The wave numbers of the infrared bands for the sodium compounds of salicylaldehyde and methylsalicylate observed in the solid state are tabulated in Table VII, together with the wave numbers for salicylaldehyde and methylsalicylate in the liquid state.

From the infrared measurements and the titration of sodium ion, it can be seen that a sodium ion links to two salicylaldehyde molecules, one of them being a molecular rest ion of salicylaldehyde and the other a salicylaldehyde molecule. The structures of these compounds will be illustrated in Fig. 1.

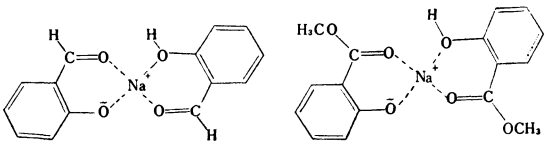

Fig. 1. The sodium compounds of salicylaldehyde and methylsalicylate.

The OH stretching vibrations of the sodium compounds show higher frequencies than those of salicylaldehyde and methylsalicylate. The broad band at 3100 cm^{-1} for salicylaldehyde changes into the sharp band at 3344 cm^{-1} for the sodium compound. The band at 3141 cm^{-1} for methylsalicylate separates into the two bands having their maxima at 3351 cm^{-1} and 3206 cm^{-1} for the sodium compound. The shifts of the OH stretching vibrations caused by changing salicylaldehyde and methylsalicylate into their sodium compounds indicate that the strong intramolecular hydrogen bond in the former varies into the intermolecular hydrogen bond in the latter. The two OH bands for the sodium compound of methylsalicylate may show the existence of the two different types of intermolecular hydrogen bond.

Concerning the sodium compounds, only one band can be assigned to the C=O stretching vibration for each compound. With the vibrations of metal chelate compounds, the couplings between ligand molecules are usually neglected. This approximation may be applied to these

sodium compounds because of the weakness of the metal-oxygen coordinate bonds. The same C=O stretching frequencies for salicylaldehyde and its molecular rest, coordinating to a sodium ion, suggest that the two carbonyl bonds are in the same electronic state. It is deduced that the lone pair electrons on the ionized oxygen in the molecular rest delocalize too little to influence the carbonyl group through the benzene ring. The fact that the carbonyl frequency of the C=O band for sodium compound of salicylaldehyde is higher than that for salicylaldehyde, may be explained by the small value of the electron affinity of sodium ion. As for the electron transfer of the oxygen atom in the carbonyl group, the larger the electron affinity of electron acceptors, the easier the electron transfer. The lone pair electrons on the oxygen atom, therefore, are less drawn by sodium ion than by proton and the frequency of the C=O band is higher for the sodium compound than for salicylaldehyde. The frequency of the C=O band for the sodium compound of methylsalicylate is slightly higher than that for methylsalicylate[10]. Since the coordinate bond between the sodium ion and the carbonyl group is very weak, the carbonyl group of the sodium compound of salicylaldehyde as well as that of *o*-methoxybenzaldehyde will be rather akin to that of virtual non-chelate salicylaldehyde. The difference in the C=O frequency between salicylaldehyde and its sodium compund is 17 cm^{-1}, while that between methylsalicylate and its sodium compound is only 3 cm^{-1}. This fact indicates the strong chelation in salicylaldehyde. This agrees with the results obtained by the solvent effect and the band shapes. The configuration of the sodium compound is probably of a tetrahedral type, since the available orbitals of sodium ion to form the coordinate bond are sp^3 hybrid. However, it has recently been reported[11] that the sodium compound of salicylaldehyde does not form any chelate ring because of the observed high frequency of the C=O band. Based on the present studies this opinion can be left out of consideration.

As regards chelate compounds, the bands assigned to the phenolic C–O stretching vibrations are of considerable interest, because no definite assignment for these bands has yet been made. By comparing the absorption spectrum of salicylaldehyde or methylsalicylate with that of its sodium compound respectively, the phenolic C–O bands are reasonably assigned. The results obtained are listed in Table VIII. The relations between wave numbers of C=O stretching and those of phenolic C–O stretching vibrations are given in Fig. 2.

TABLE VIII. THE WAVE NUMBERS OF C=O AND PHENOLIC C–O STRETCHING VIBRATIONS

	Salicylaldehyde		Methylsalicylate	
	C=O	C–O	C=O	C–O
Na^+	1680	1246	1682	1213
H	1663	1276	1679	1212
Ti^{4+}	1637	1313	1651	1246
Cu^{2+}	1612	1340		

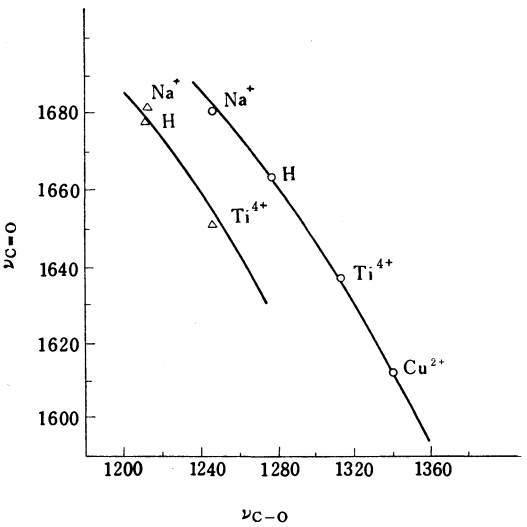

Fig. 2. The relations between the wave numbers of C=O stretching and those of phenolic C–O stretching vibrations. ○ Salicylaldehyde and its metal complexes. △ Methylsalicylate and its metal complexes.

In Table VIII and Fig. 2, copper complex and titanium complexes[12] are shown together. The larger the wave number of C=O stretching vibration, the smaller the wave number of C–O stretching vibration. The reason for this may be as follows. In these chelate compounds, as the double bond character of the C=O bond decreases by the electron migration from the carbon to the oxygen, the electron migration from the oxygen to the benzene ring and the

10) It is supposed that the C=O frequency of the sodium compound of methylsalicylate is hardly affected by the change in the nature of the C–O bond neighboring the C=O bond.

11) P. Chiorboli and P. Mirone, *Ann. chim.*, 48, 363 (1958).

12) A. Yamamoto, to be published.

double bond character of the C–O bond increase. These relations are nearly linear and the curve for salicylaldehyde and its complexes and that for methylsalicylate and its complexes are parallel. From Fig. 2, it follows that the electron affinities of these electron acceptors are probably in the order of $Cu^{2+} > Ti^{4+} > H > Na^{+}$.

The author wishes to express her sincere thanks to Professor K. Kozima for his kind guidance and discussion throughout the course of this study and also to Mr. W. Suetaka for his helpful advice.

Vinyl-polymerization with Alkylboron Derivatives

By Nobuyuki ASHIKARI

(Received October 22, 1958)

The outline of alkylboron derivatives as the catalysts for the polymerization of vinyl compounds was previously reported[1]. In the present paper, the preparation of these catalysts, the polymerization rates, the relation between the conversion and the molecular weight, and the influence of oxygen on the polymerization rate are described in detail. The catalysts studied were dialkylboron chloride (R_2BCl), dialkylboronous ester (R_2BOR'), dialkylborinic acid (R_2BOH), and dialkylboron oxide [$(R_2B)_2O$]. Furukawa[2] reported that dialkylboron oxide was a good catalyst. The present investigation shows that the organoboron compounds employed in this experiment are effective for comparatively polar monomers.

Experimental and Results

Analytical Methods for Organoboron Compounds.—The synthesized catalysts were analyzed by the following methods. In the case of R_2BCl, hydrogen chloride produced by the decomposition of the sample with water was titrated with sodium hydroxide solution under phenolphthalein indicator. In other cases, quantitative analysis of boron was carried out by the modification of Synder's method[3].

A weighed sample (about 0.2 g.) was taken in a 100 cc. Erlenmeyer flask in which air was previously replaced with nitrogen. After 0.1 N sodium hydroxide solution, the amount of which was nearly equivalent to the theoretical value, was poured into the flask; 30% hydrogen peroxide solution was added slowly to it. The flask was shaken for twenty minutes. Then, the content was transferred into a platinum vessel to be heated gently. After the water was mostly vaporized, the vessel was cooled to room temperature, and the content was poured into a 300 cc. beaker with about 70 cc. of distilled water. To the aqueous solution about 5 cc. of glycerin was added and the titration was carried out with 0.1 N sodium hydroxide solution using phenolphthalein indicator. If the excess of alkaline solution is added at the beginning, the solution containing the sample has to be acidified by the addition of the known volume of hydrochloric acid (0.1 N) before the titration with sodium hydroxide solution is carried out.

The Monomers and the Treatments of the Polymers.—The monomers such as styrene (St), methyl methacrylate (MMA), and vinyl acetate (VA) were purified as mentioned below.

St: The "commercial" was washed with 5% alkaline solution, followed by water, dried over calcium chloride, and distilled.

VA: The "commercial" was steam distilled, dried over sodium sulfate, and distilled.

MMA: It was dried with sodium sulfate and distilled.

The distillation of styrene and methyl methacrylate was carried out under reduced pressure. The polymers except for polyvinyl acetate were treated with methanol, filtered, and dried. In the case of polyvinyl acetate, it was separated from its monomer by steam distillation.

Preparation of the Alkylboron Derivatives.—*Alkylboron chloride.*—The alkylboron chlorides were prepared according to Booth's method[4], i. e., by passing dry hydrogen chloride into trialkylboron. The reaction proceeds as follows:

$$R_3B + HCl = R_2BCl + RH$$

Using this method, diisopropylboron chloride,

1) N. Ashikari, *J. Polymer Sci.*, **28**, 641 (1958).
2) J. Furukawa, T. Tsuruta et al., *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **61**, 733 (1958).
3) H. R. Synder, J. A. Kuck and J. R. Johnson, *J. Am. Chem. Soc.*, **60**, 110 (1938).

diisobutylboron chloride and di-*n*-butylboron chloride were prepared.

To a 100 cc. round bottomed flask, were set an inlet of hydrogen chloride, and a condenser to the top of which a calcium tube was connected. Into this flask 36 g. of triisobutylboron was poured, and hydrogen chloride was introduced. The reaction was continued for 15 hr. at 140°C. Then, the content was distilled under reduced pressure, and the fraction of b. p. $_{31}62\sim65$°C was collected. Thus, 28 g. of diisobutylboron chloride was obtained (87% yield).

Analysis.—A weighing bottle containing 0.3116 g. of the sample was put in a 300 cc. flask containing 100 cc. of distilled water. The weighing bottle was tied with wire to the rubber stopper of the flask as shown in Fig. 1. After the rubber

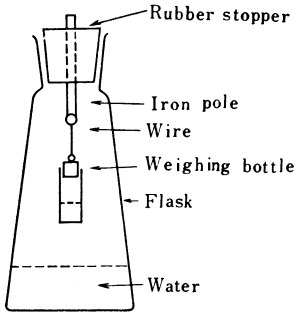

Fig. 1. The vessel for the decomposition of R_2BCl.

stopper was closed, the flask was shaken vigorously to open the stopper of the weighing bottle. The rubber stopper was taken off, and the titration was carried out. The amount of the spent sodium hydroxide solution (0.1 N) was 21.6 cc.

Anal. Found: Cl, 22.42. Calcd. for $(C_4H_9)_2BCl$: Cl, 22.12%.

Similarly, other dialkylboron chlorides were analyzed. The conditions of the preparation and the yields are shown in Table I.

TABLE I. ALKYLBORON CHLORIDE

R in R_2BCl	Temp. °C[a)]	Time hr.	b. p. °C	Yield %
iso-C_3H_7	120	15	125	88
n-C_4H_9	140	15	67/18 mmHg[b)]	82

a) Reaction temperature
b) Booth's value is 173°C[4].

Generally, dialkylboron chloride is rather more unstable to oxygen than the corresponding trialkylboron. For example, diisopropylboron chloride is inflammable in contact with air, but triisopropylboron is not so.

Dialkylboronous ester.—This is easily prepared by the reaction between dialkylboron chloride and alcohol[5]. The reaction formula is as follows:

$$R_2BCl + R'OH = R_2BOR' + HCl$$

Using this method various dialkylboronous esters were prepared. When alcohol was dropped slowly into dialkylboron chloride under nitrogen stream, the reaction took place at once.

The product consisted of two layers. The upper layer was colorless and the lower one, the amount of which was small, was slightly colored. The upper layer was separated from the lower one and distilled. Few studies on the esters of such type as $(iso\text{-}C_3H_7)_2BOR$ have been performed. The yields and the boiling points of these derivatives are shown in Table II.

TABLE II. THE YIELD AND THE BOILING POINT OF $(iso\text{-}C_3H_7)BOR$

R in $(iso\text{-}C_3H_7)_2BOR$	ROH(g.) added	Yield %	b. p. °C
CH_3	3	91.1	117
C_2H_5	4	80.0	132
iso-C_3H_7	5	80.7	51(32 mmHg)
iso-C_4H_9	6	70.1	70(32 mmHg)
tert-C_4H_9	6	35.5	92(30 mmHg)

In Table II, the weigt of the diisopropylboron chloride used was 10 g. in each experiment. Moreover, diisobutylboron isobutyl ester was prepared. This boiled at 97°C/27 mmHg. The yield was 92%.

Analysis of $(iso\text{-}C_3H_7)_2BO(iso\text{-}C_3H_7)$
Sample: 0.1935 g., alkali added: 12.7 cc.
Found B, 7.25%, Calcd. B, 7.05%

Dialkylborinic acid and dialkylboron oxide.—Dialkylborinic acid was prepared according to Eq. 1, but was not always isolated purely because of decomposition by distillation.

$$R_2BCl + H_2O = R_2BOH + HCl \quad (1)$$

Dialkylboron oxide was prepared purely by distillation of the product from dialkylboron chloride and equivalent water. To 28.5 g. of di-*n*-butylboron chloride was added 3.2 g. of pure water under nitrogen stream, and the product was distilled. Thus, 18.5 g. of the product which boiled at 90~92°C/1 mmHg (reported value[6], 136°C/12 mmHg) was obtained (78.3% yield, calculated from di-*n*-butylboron chloride).

Analysis of $[(n\text{-}C_4H_9)_2B]_2O$
Sample: 0.1419 g., alkali added: 10.8 cc.
Found B, 8.41%, Calcd. B, 8.27%

The Rate of the Polymerization of Styrene with these Derivatives.—By observing the polymerization rates, the activities of these catalysts were compared. The catalysts employed in this experiment were isopropylboron derivatives. In

a) The catalyst is diisopropylboron oxide.

every case, the value of catalyst/monomer was 0.188 in mol. %. The weights of the catalysts and the monomer were shown in Table III.

Each reaction was carried out at 50°C under nitrogen stream in a four necked flask to which a stirrer, an inlet of nitrogen, and a thermometer were connected.

At a certain interval of reaction, 10 g. portions of the sample were taken out and poured into methanol. Then, the polymer was filtered, dried, and weighed. These results were represented in Fig. 2.

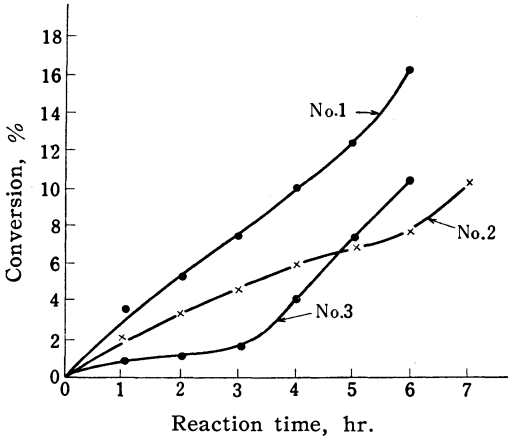

Fig. 2. Polymerization rates of styrene with three types of alkylboron.
No. 1, $(R_2B)_2O$: No. 2, R_2BOR: No. 3, R_2BCl, where, R is iso-C_3H_7.

Usually, in the polymerization with these catalysts, the polymerization rate increased rapidly after a certain reaction time (as shown in Fig. 2).

Relation between the Conversion and the Molecular Weight.—In usual "radical polymerization", the molecular weight is expected to have no relation with the conversion. However, in high conversion, many examples[7] have shown the fact that the former depends on the latter. The same phenomenon was observed, even in low conversion, in the case of the polymerization with alkylboron catalyst. Methyl methacrylate, styrene and vinyl acetate were polymerized in the following conditions (Table IV).

When the reaction was carried out in an ampoule, the apparatus shown in Fig. 4 was used. When a flask was used as a reaction vessel, the reaction was carried out under nitrogen stream, and the sample was taken out after a certain interval of reaction. The relation between the conversion and the intrinsic viscosity was represented in Fig. 3.

In this case, the viscosity of each polymer was measured in the following condition (Table V).

TABLE V. THE CONDITION OF MEASUREMENT OF THE VISCOSITY

Polymer	Solvent	Temp., °C
PMMA	toluene	30
PSt	toluene	30
PVA	benzene	30

Where, "P" means a polymer.

Influence of Oxygen on the Polymerization Rate.—To observe the influence of oxygen on the polymerization rate some monomers were polymerized in the following apparatus (Fig. 4).

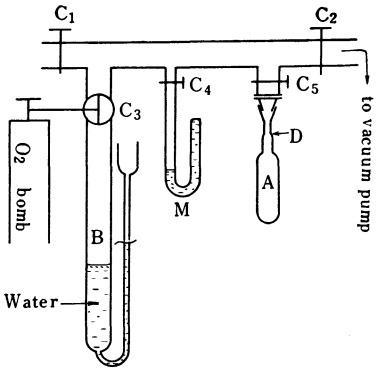

Fig. 4. Apparatus for investigating the influence of oxygen.
M: Manometer
B: Gas burette
A: Polymerization tube

The Explanation of the Apparatus and the Procedure.—The volume of the space enclosed by stopcocks C_1-C_5 is 136 cc., and that of A, polymerization tube, is 70 cc. The volume from C_5 to D is 5 cc.

To tube A in which nitrogen had replaced air, 20 cc. of monomer was introduced and the tube was cooled in dry-ice methanol. After the catalyst, the amount of which was shown in Table VI, was added under a nitrogen stream, the tube was connected to the apparatus. The gas involved in tube A and other spaces enclosed by stopcocks C_1-C_4 was removed by a vacuum pump. After a certain amount of oxygen contained in burette B was introduced to the tube, it was sealed. The sealed tube was transferred into a constant temperature bath. The reaction temperature, the reaction time, etc., were shown in Table VI.

Thus, from the yield obtained after the same reaction time, the influence of oxygen on the polymerization rate was compared. The relation between the amount of oxygen and the conversion was represented in Fig. 5.

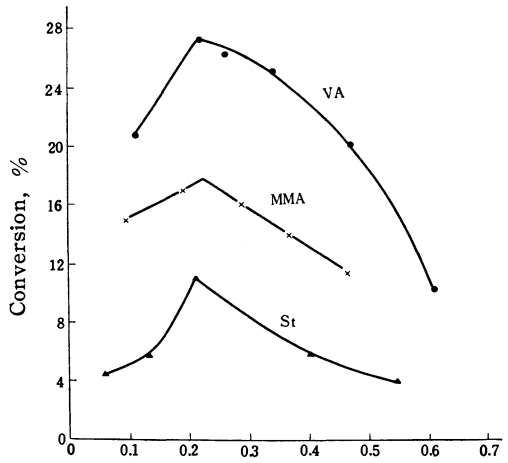

Fig. 5. Diagram of conversion—O_2/catalyst. The influence of oxygen on the polymerization rate.

The viscosity of each sample shown in Fig. 5 was measured to obtain the relation between the molecular weight and the value of O_2/catalyst in mole ratio. These results are represented in Fig. 6. The conditions of measurement of the viscosity and the equations for calculation of the molecular weight are shown in Table VII.

From Fig. 5, it is clear that the polymerization rate is the largest when the value of O_2/catalyst in mole ratio is 0.22. In regard to the molecular weight, the molecular weight at the maximum point of the polymerization rate is minimum except in the case of polyvinyl acetate. The reason why the curve of the molecular weight of PVA against the mole ratio of O_2/catalyst differed from those of polymethyl methacrylate and polystyrene is not clear.

Summary

Such alkylboron derivatives as dialkylboron chloride, dialkylborinic acid, dialkylboronous ester, and dialkylboron oxide as the catalysts for the polymerization of vinyl compounds were studied. Although dialkylborinic acid was a good catalyst, it was pretty difficult to isolate it purely, therefore, only a brief description was made in this paper. Of course, some dialkylborinic acids can be isolated purely under suitable conditions. In regard to this, further investigation will be performed.

The polymerization rates of styrene with these catalysts, the relation between the conversion and the intrinsic viscosity, and the influence of oxygen on the polymerization rate were studied. The polymerization rate of some monomers with dialkylboronous ester is maximum when O_2/catalyst in mole ratio is 0.22.

The author wishes to express his sincere thanks to Mr. T. Iwachido in this laboratory who measured the viscosities.

Polymerization of Olefins with Trialkylboron Catalyst. III. Copolymerization of Butadiene, Isobutylene and 1-Phenylbutadiene

By Nobuyuki ASHIKARI

(Received April 15, 1959)

As is well known, the monomers having comparatively large polarity easily polymerize with alkylboron catalyst, but those having small polarity do not. The polymerizations of the monomers which polymerize alone, and the copolymerizations of those monomers have already been reported[1,2]. In this paper, the copolymerizations of some monomers which exhibit no tendency to polymerize alone, such as butadiene, isobutylene, and 1-phenylbutadiene were studied. In every pair of the monomers treated in this paper, the copolymerization rates were very small. Particularly, the reaction rate of 1-phenylbutadiene with another monomer was so small that the relative reactivity could not be obtained. The relative reactivities of such pairs as isobutylene-acrylonitrile, butadiene-styrene and butadiene-acrylonitrile were obtained.

2) N. Ashikari, *J. Polymer Sci.*, **31**, 249 (1958).

Experimental and Results

1. Monomers.—*1) Isobutylene and butadiene.*—Isobutylene[3] was prepared by dehydration of *tert*-butanol with anhydrous oxalic acid at about 90°C, dried over calcium chloride, and redistilled. Butadiene was prepared according to Blatt's method[4], i.e., thermal decomposition of cyclohexene, dried over calcium chloride, and redistilled.

2) Acrylonitrile, styrene and methyl methacrylate.—The commercial substances were dried and distilled just before use.

3) 1-Phenylbutadiene.—This was synthesized

3) N. Daidan et al., *J. Electrochem. Soc. Japan (Denki Kagaku)*, **13**, 27 (1945).
4) A. H. Blatt et al., "Organic Syntheses", Col. Vol. II, John Wiley & Sons, Inc., New York (1943) p. 655.

from cinnamic aldehyde by the following method[5,6]:

$$\underset{(A)}{RCHO} \xrightarrow{CH_3MgJ} \underset{(B)}{RCH(OMgJ)CH_3} \xrightarrow{NH_4Cl\text{-}H_2O} \underset{(C)}{RCH(OH)CH_3}$$

$$\xrightarrow{HCl} \underset{(D)}{RCHClCH_3} \xrightarrow{-HCl} \underset{(E)}{RCH=CH_2}$$

Where, R is $C_6H_5CH=CH-$.

D was prepared by treating C with dry hydrogen chloride at 0°C, and E was prepared by heating D in pyridin solvent for about one hour. After the reaction was over, unchanged pyridin was distilled off, and the product was washed thoroughly with water to remove the complex of pyridin-hydrogen chloride. Then, the product was dried over calcium chloride and distilled. The yield of pure 1-phenylbutadiene boiling at 56~57°C/3 mmHg was 17~20% of the theoretical amount for cinnamic aldehyde.

II. Procedure of the Copolymerization and the Treatment of the Polymer. — In a polymerization tube, a certain amount of high-boiling monomer such as styrene or acrylonitrile was placed, and the tube was cooled in dry ice-methanol. After the content was thoroughly cooled, the tube was placed on a balance, and a certain amount of second monomer, liquefied by cooling, such as isobutylene or butadiene was poured into the tube. Then, the catalyst, triisobutylboron was added to the tube under nitrogen stream, and the tube was sealed.

The reaction was stopped by cooling the tube in dry ice-methanol. After the tube was opened, the polymer was precipitated by adding the content of the tube into methanol, filtered, dried under reduced pressure at 50°C, and weighed. If the copolymerization was carried out in emulsion system, the polymer was taken out by treating the content with hot water (about 90°C) containing 5% sodium chloride. Thus, the polymer isolated was washed thoroughly with hot water, followed with methanol, dried and weighed.

III. Copolymerization Rates of Butadiene-acrylonitrile in the Bulk and Emulsion Systems. —The copolymerization rate of butadiene-acrylonitrile in emulsion system was compared with that in bulk system.

Generally, the polymerization rate in emulsion system is larger than that in bulk system. In this experiment, the same results were obtained. Moreover, in emulsion system, fairly strong copolymer was obtained.

The total weight of the two monomers in each pair was 11.3 g., and the volume of the catalyst was 0.1 cc. in each experiment. In emulsion system, 12 cc. of distilled water containing 5% emulsifier was used. Each reaction was carried out in a sealed tube at 40°C for five hours. The relation between the conversion and the mole fraction of butadiene in the monomer mixture is shown in Fig. 1.

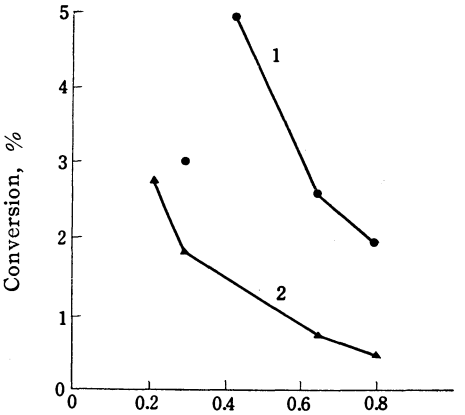

Fig. 1. Copolymerization rates of butadiene-styrene in bulk and emulsion system.
(1) emulsion system
(2) bulk system

IV. Monomer Reactivity Ratios.—The relative reactivities (r_1, r_2) of such pairs as isobutylene-acrylonitrile, butadiene-styrene, and butadiene-acrylonitrile were evaluated graphically using the following equation[7]:

$$r_2 = \frac{\log([M_2]_0/[M_2]) - \frac{1}{p}\log\frac{1-p[M_1]/[M_2]}{1-p[M_1]_0/[M_2]_0}}{\log([M_1]_0/[M_1]) + \log\frac{1-p[M_1]/[M_2]}{1-p[M_1]_0/[M_{02}]}}$$

where $p=(1-r_1)/(1-r_2)$, $[M]_0$ and $[M]$ represent the monomer concentration in the intitial and final states of polymerization, respectively,

V. Infrared Spectra and Turbidity Measurement of 1-Phenylbutadiene—Methyl Methacrylate Copolymer.—It had not been clear whether 1-phenylbutadiene enters into a copolymerization reaction or not. In this respect, the copolymerization of this monomer with methyl methacrylate was carried out to make this point clear. As previously mentioned, 1-phenylbutadiene does not polymerize alone with organo boron catalyst, but does thermally. Therefore, even if the two components are present in the product, it does not always mean a copolymer. For the purpose of looking over the product, infrared spectra and turbidity measurement of the product were employed.

V-1) Copolymerization of 1-phenylbutadiene with methyl methacrylate.—The monomer mixture (feed 1 : 1) consisted of 1-phenylbutadiene and methyl methacrylate (0.0237 mol.) was polymerized with 0.1 cc. of triisobutylboron catalyst in a sealed tube at 50°C for 15 hr. The product precipitated with methanol was redissolved in benzene and precipitated with methanol two times. Thus, 0.0702 g. of the polymer was obtained (conversion: 1.3%).

V-2) Infrared spectra.—The infrared spectrum of the sample obtained above was observed in

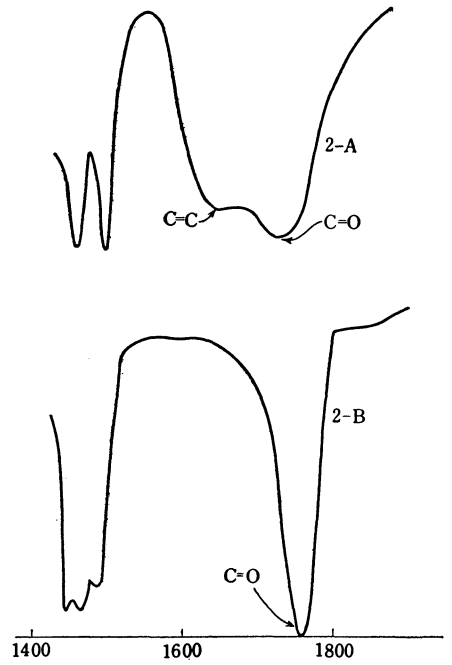

Fig. 2. Infrared spectra of phenylbutadiene-methyl methacrylate copolymer and polymethyl methacrylate.
A, 1-Phenylbutadiene—methyl methacrylate copolymer
B, Polymethyl methacrylate

8) T. Alfrey, J. J. Bohrer and H. Mark, "High Polymers", Vol. VIII, "Copolymerization" Interscience Publishers, Inc., New York (1952), p. 32, 44.

order to confirm the presence of the two components. Fig. 2-A is the spectrum of the sample, and Fig. 2-B is that of polymethyl methacrylate prepared with alkylboron catalyst.

Comparing A with B, it is clear that the product obtained in paragraph V-1 is not identical with polymethyl methacrylate. In Fig. 2-A, the absorption band at about 1650 cm^{-1} owes to C=C, and the band at about 1740 cm^{-1} owes to C=O of methyl methacrylate. Of course, the absorption band of C=C indicates the existence of poly-(1-phenylbutadiene) shown below.

poly(1-phenylbutadiene): $[-CH(C_6H_5)-CH=CH-CH_2-]_n$

V-3) Measurement of turbidity. — The sample obtained in paragraph V-1 was dissolved in 200 cc. of acetone and the turbidity was measured utilizing a nephelo-titrator. The same measurements were carried out with thermally polymerized 1-phenylbutadiene and polymethyl methacrylate prepared with alkylboron catalyst.

In every case, the condition of the measurement was as follows: solvent, acetone; nonsolvent, distilled water; concentration, 0.0070%; temperature, 25°C. These results are represented in Fig. 3.

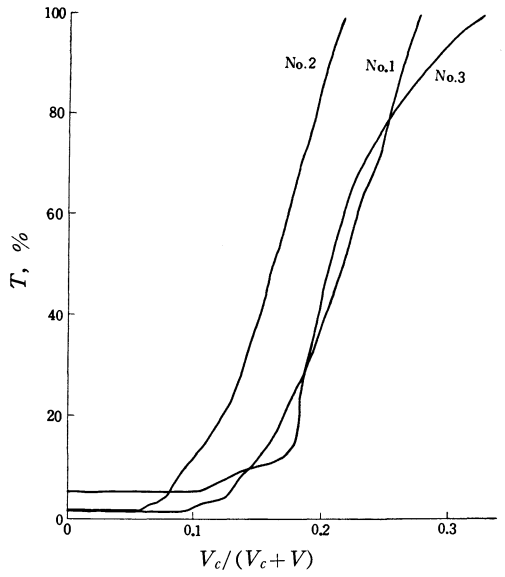

Fig. 3. Diagram of $T-V_c/(V_c+V)$.
T: turbidity, V_c: volume of water,
V: volume of acetone.
No. 1, Copolymer
No. 2, Phenylbutadiene
No. 3, Methyl methacrylate

Comparing No. 1 with No. 2 and 3 in Fig. 3, it may be considered that 1-phenylbutadiene copolymerizes with methyl methacrylate.

Discussion

Diagram of $T-V_c/(V_c+V)$.—If the product (1-phenylbutadiene-methyl methacrylate) is a mixture of the two components, the influence of 1-phenylbutadiene must be more striking around the bottom of No. 1 in Fig. 3. Moreover, the product is a low polymer, so that when it contains the greater part of polymethyl methacrylate, the bottom of No. 1 must be situated on the right side of No. 3. From the viewpoint mentioned above, the product obtained in paragraph V-1 may be considered as a copolymer.

The Relative Reactivities.—The following methods have been employed for obtaining the composition in a copolymer which consists of C and H atoms:

a) from analytical value of C atoms,
b) from refractive index,
c) from ultraviolet absorption.

Any method will contain more or less errors. In this respect, a) is, particularly, apt to contain an error.

Therefore, some questions will be present in the relative reactivity in the copolymerization of butadiene-styrene, reported in this paper. In this respect, the other methods will be employed to the butadiene-styrene copolymer.

As is well known, the mechanism of the polymerization with alkylboron catalyst is a radical type. The propriety of the mechanism is proved in this paper also, comparing the values of the relative reactivities obtained in this experiment with those in the copolymerization with peroxide catalyst.

Summary

The relative reactivities in the copolymerization of some monomers which do not polymerize alone with alkylboron catalyst, with those which polymerize alone, were obtained. The copolymerization rate of 1-phenylbutadiene with another monomer was so small that the relative reactivity could not be obtained. But, from the studies on the reaction product of 1-phenylbutadiene and methyl methacrylate, it was considered that the former copolymerized with the latter.

The author wishes to express his sincere thanks to Messrs. K. Abe and K. Yanagisawa in this laboratory for their kindness observing the infrared spectra.

Analytical Chemistry by Means of Organic Compounds. XXV[1]. *1-Hydroxyacridine as a New Reagent (Neo-oxine) (1)*

By Masayoshi ISHIBASHI, Yuroku YAMAMOTO and Hirohiko YAMADA

(Received February 13, 1959)

It is expected that 1-hydroxyacridine will be useful in analytical chemistry, because it has the same functional group as 8-hydroxyquinoline (oxine) which is one of the most valuable organic reagents in various fields such gravimetry, volumetry, or colorimetry. Irving et al.[2] have investigated the behavior of this compound to some metallic ions such as aluminum, chromium, iron(III), gallium, copper and zinc, concerning the study for the effects of steric hindrance of some oxine derivatives. It was found by them that 1-hydroxyacridine and 2-methyl-oxine did not form precipitate with aluminum, while forming precipitate with other metals, and the reason of the failure of these reagents to react with aluminum was attributed to steric hindrance of the groups in the 2-position of oxine. In the presence of aluminum, 2-methyl-oxine was used by Merrit[3] as a precipitant for zinc, or by Motojima[4] as not only a precipitant but also a coloring reagent for beryllium and titanium.

There is, however, no reference for use of 1-hydroxyacridine in analytical chemistry. It is presumed that this compound is more favorable in gravimetry or colorimetry with solvent extraction because of larger molecular weight than that of oxine or its derivatives. Moreover, this compound has the feature of not reacting to aluminum ion and this selective behavior will be advantageously used in determining some metals in the presence of aluminum without preliminary separation.

It is the purpose of this study to investigate the reaction between 1-hyroxyacridine and numerous cations which are used to be reactive with oxine, and to apply the results for gravimetry or colorimetry with solvent extraction.

The present paper is concerned with the results obtained by spectrophotometric method with solvent extraction. Absorption spectra were taken for the reagent in acidic, neutral and alkaline medium. Both acidic and basic ionization constants were then obtained, according to Stenstrom's method[5]. The basis for solvent extraction with chloroform were investigated for the chelate compounds of the reagent with some metals such as copper, cobalt, nickel and zinc. Reactions with other metals and another aspects of the study, such as formula, solubility and thermal stability of the chelate are under investigation and the results will be reported in the near future.

We propose to name this reagent as "neo-oxine".

Experimental and Results

Apparatus.—Spectrophotometric measurements were made with a Beckman quartz spectrophotometer, Model DU, with 1 cm. silica transmission cells having a tight stopper. A Beckman pH meter with glass electrode, Model H-2, was used for all pH measurements.

Materials.—*1-Hydroxyacridine.*—This compound was synthesized by the method described by Irving and his coworkers[2]. The crude product was recrystallized several times from 75% alcohol and dried in vacuo. The melting point of the dried sample was 115~116°C, identical with that in the literature.

Anal. Found: H, 4.82; C, 79.74; N, 7.17; O, 8.36. Calcd. for $C_{13}H_9ON$, H, 4.64; C, 79.99; N, 7.18; O, 8.22%.

The pure substance obtained is brownish yellow needles and slightly soluble in water but easily soluble in organic solvent such as alcohol, or chloroform. The solution of 1-hydroxyacridine was prepared to concentration of 10^{-3} M with 95% alcohol.

Chloroform.—It was purified by distillation.

Buffer solution.—Borate, phosphate and acetate buffers were prepared using each pure acid. To 1/25 M of each acid solution proper amounts of dilute sodium hydroxide solution were added to obtain the desired pH.

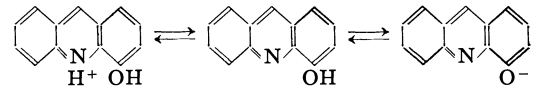
1) Paper XXIV of this series: M. Ishibashi and Y. Yamamoto, *Bulletin of the Institute for Chemical Research, Kyoto University*, **31**, 280 (1953).

2) H. Irving, E. J. Butler and M. F. Ring, *J. Chem. Soc.*, **1949**, 1489.

3) L. L. Meritt, *Record. Chem. Progr. (Kresge-Hooker Sci. Lib.)* **10**, 59 (1949).

4) K. Motojima, This Bulletin **29**, 29, 71, 458 (1956).

5) W. Stenstrom and N. Goldsmith, *J. Phys. Chem.*, **30**, 1683 (1926).



Metal solution.—All of the stock solutions of metals were prepared to concentration of 10^{-3} M. Cupric sulfate which was recrystallized from water and dried in room temperature, was dissolved and then diluted to the desired concentration. Cobaltous sulfate (Merk) was dissolved in water to approximately 10^{-1} M and after the concentration of the metal was checked by electrolysis, the solution was diluted to the desired concentration. Nickel solution was obtained by dissolving pure nickel ammonium sulfate. In the case of zinc the pure metal was dissolved in small amounts of nitric acid and after sulfuric acid was added, the solution was evaporated almost to dryness, and then diluted with water.

All other reagents as ethylenediamine tetraacetic acid, tartaric acid, cuproine (biquinolyl), dimethylglyoxime, etc., were analytical grade ones.

In the preliminary experiments, it was observed that ions such as copper, zinc, nickel, cobalt, iron, etc., were precipitated in slightly acidic (pH 5.1) or in a weak basic (pH 9.5) medium by 1-hydroxyacridine, forming red or reddish orange chelate compounds. It was also confirmed that the compound did not form a precipitate with aluminum in any medium. The filtrate which is obtained by filtrating the precipitate formed in slight excess of reagent, did not react to oxine, and it is presumed that the solubility of the metal chelate of 1-hydroxyacridine may be smaller than that of oxine chelate.

Absorption Spectrum of 1-Hydroxyacridine.—All of the solutions for absorbance measurements were prepared by diluting the required quantity of the stock solution using a buffer solution. The absorbance was measured in the range of 210~450 mμ against the respective buffer solution. Spectra obtained in acidic, neutral and alkaline mediums are shown in Fig. 1.

It is observed that many absorption bands exist in the ultraviolet region, and that the bands in neutral solution shift to longer wavelength with both the decreasing and increasing of pH. The change in absorption spectra with pH may be attributed to structural changes which are due to dissociation of 1-hydroxyacridine as follows, being similar to that of oxine.

Ionization Constant.—To evaluate basic and acidic ionization constants of the reagent, absorbance was then measured for twenty-six solutions having various pH's. In almost all cases, the pH was adjusted using respective buffer solution, but dilute sodium hydroxide or hydrochloric acid solution was used when stronger alkaline or acidic medium was necessary. The absorbance values at four different wavelengths were plotted against pH, as shown in Fig. 2. The phenolic or basic ionization constant was obtained as

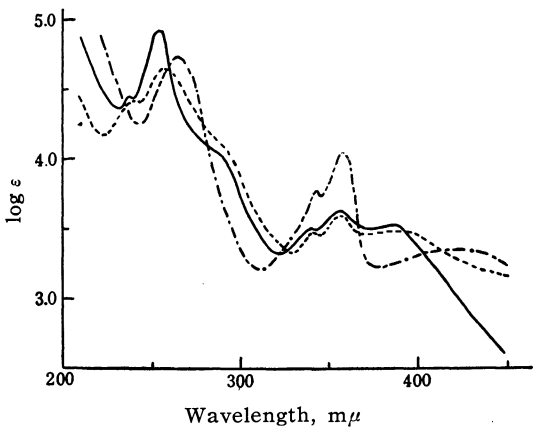


Fig. 1. Absorption spectrum of 1-hydroxyacridine.
—·— pH 4.6, —— pH 7.2, ------ pH 9.5

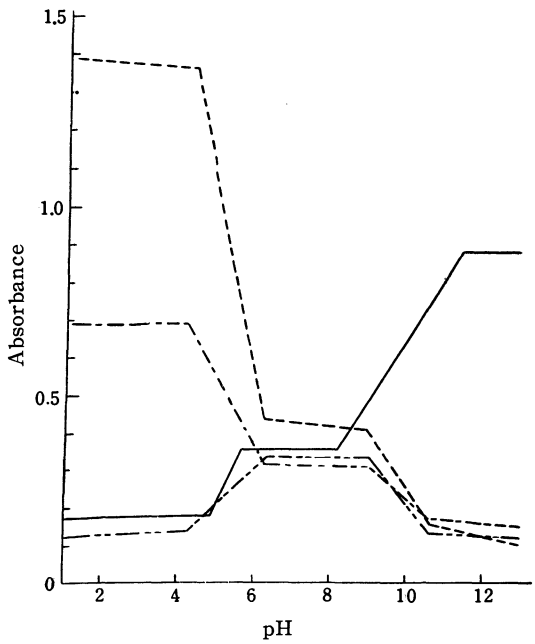

Fig. 2. pK_a and pK_b of 1-hydroxyacridine.
—— at 300 mμ, —·— 343 mμ, ------ 359 mμ, ———— 380 mμ

TABLE I. IONIZATION CONSTANT OF 1-HYDROXYACRIDINE

Wavelength (mμ)	pK_a	pK_b
300	9.85	5.27
343	9.83	5.30
359	9.83	5.31
380	9.86	5.34
Mean	9.84	5.31

pK by a graphical determination of the pH at which the absorbance was half-way between its values in neutral and alkaline or acidic solution. According to Stenstrom and Goldsmith[5], the midpoint pH=pK_a or pK_b. The values obtained are listed in Table I. The pK_a and pK_b of oxine has been reported as 9.70 and 9.08 respectively by Phillips[6]. The pK_a of 1-hydroxyacridine is thus slightly greater than that of oxine, while pK_b is considerably smaller.

Absorption Spectra of 1-Hydroxyacridine and its Chelate in Chloroform. — Procedure of extraction is conducted as follows.
