Surface Chemistry of Synthetic Protein Analogues. VII. Polytyrosine and its Related Polypeptides

By Toshizo ISEMURA and Takuya YAMASHITA

(Received July 22, 1958)

We have previously studied[1-6] the monolayers of synthetic polypeptides with non-electrolytic side chains as well as those with electrolytic side chains at air/water interface. It is well known that tyrosine residue is very specific among other amino acid residues in protein because of the potency of its hydrogen bonding. In the present experiment, poly-L-tyrosine and poly-DL-tyrosine were studied at air/water and oil/water interfaces, in order to investigate the effect of hydrogen bond on the nature of polypeptide monolayer. The monolayer of poly-DL-phenylalanine which lacks only a phenolic OH group per residue was also studied in comparison with polytyrosine. The effect of the phenolic OH group was also investigated by its esterification with benzyl group.

Experimental

Among the samples used in the present investigation, poly-DL-phenylalanine, poly-DL-tyrosine and poly-*o*-benzyl-DL-tyrosine were synthesized by Dr. H. Tani and Dr. H. Yuki of our University, and poly-L-tyrosine by Dr. E. Katchalski and Dr. M. Sela of the Weizmann Institute of Science. The solvents used for the speading solution for each polypeptide are listed in Table I.

Surface pressure and surface potential were measured simultaneously. Surface pressure was measured by Wilhelmy's hanging plate method and surface potential by vibrating air electrode method. The pH of the substrate was adjusted by adding hydrochloric acid or potassium carbonate to any desired pH without buffering. The pH was measured with Beckman's glass electrode or with Toyo pH test paper. Interfacial pressure and interfacial potential were measured by the procedure which was reported previously by Hotta[7-9] of our laboratory, excepting the use of hanging plate instead of detaching ring. At oil/water interface, the interfacial concentration was changed by successive injection method using micrometer syringe. Measurement was carried out five minutes later after every injection. Petroleum ether of boiling point of 90~120°C was used as an oil phase. All the experiments were carried out at room temperature without any temperature regulation. The temperature change never exceeded more than one degree in the course of experiment.

Results and Discussion

Poly-DL-phenylalanine.—We studied at first the film of poly-DL-phenylalanine at air/water and oil/water interfaces as an example of the polypeptide film containing the side chain of benzyl group. In Fig. 1, surface (or interfacial) pressure and surface (or interfacial) moment were plotted per phenylalanyl residue. The surface (or interfacial) moment was calculated from

TABLE I
SOLVENTS USED FOR EACH POLYPEPTIDE

Polypeptide	Solvent	Interface
Poly-DL-phenylalanine	Benzene (9) + Dichloroacetic acid (1)	A/W
	Chloroform	A/W
	Benzene (25) + Dichloroacetic acid (1)	O/W
Poly-L-tyrosine (D. P. 45)	Pyridine (1) + Isopropyl alcohol (1)	A/W, O/W
	Benzene (3) + Dichloroacetic acid (7)	A/W
Poly-DL-tyrosine	Pyridine (1) + Isopropyl alcohol (1)	A/W, O/W
Poly-*o*-benzyl-DL-tyrosine	Benzene (3) + Dichloroacetic acid (2)	A/W, O/W

the observed surface (or interfacial) potential using Helmholtz's formula. $\Delta V = 4\pi n\mu$. The force-area curves of this polypeptide film spread from chloroform solution* and from benzene solution containing a small amount of dichloroacetic acid were exactly identical. A limiting area per residue was found from compressibility-area relation to be 15.8 Å². This area is somewhat larger than that of the typical polypeptide with non-electrolytic paraffine side chains, namely 14.7 Å². Mishuck and Eirich[10] reported that this polypeptide has a small limiting area and attributed this fact to the multilayer formation. On the other hand, Cumper and Alexander[11] found 14.4 Å as the limiting area per residue of this polypeptide from the surface viscosity-area relation. The area found per residue from the force-area relation by them is in rather good agreement with our present result. The surface moment at the area where the film begins to form multilayer is designated by μ_c. μ_c of this polypeptide is 182 mD and is in the same order of magnitude with that of most polypeptide films of non-electrolytic side chains which are spread in β-configuration, whereas Davies[12] reported the surface moment of this polypeptide to be about 100 mD at 30 Å²/residue. At oil/water interface the film is considerably expanded as shown in Fig. 1, because of release of van der Waals force between large side chains such as benzyl groups by oil phase. μ_c was found to be 144 mD and markedly higher than that found by Davies (about 80 mD at 30 Å²).

Poly-L-tyrosine and poly-DL-tyrosine.— The force-area relations of poly-L-tyrosine and poly-DL-tyrosine spread from solutions of respective polypeptide in a mixture of pyridine and isopropyl alcohol (1 : 1) was investigated as a function of pH of the substrate water. The surface pressure-area curves for poly-L-tyrosine and poly-DL-tyrosine are shown in Fig. 2 and Fig. 3, respectively. As shown in these figures on the substrate at pH's less than 9.4 the film considerably condensed. The small area of these polypeptides can not be attributed to partial dissolution of the film as shown in Fig. 4; the presence of salt such as potassium chloride in the substrate water at the concentration of 1.0 mol. per liter scarcely affects the expansion of film. On the other hand, the film is considerably expanded on a substrate at pH's more

than 11.0. However, when the pH of the substrate becomes more than 13, it dissolves rather than expands. In Figs. 2 and 3, the surface moment-area relations of poly-L-tyrosine and poly-DL-tyrosine are also shown, respectively. Surface moment is very small in comparison with that of poly-DL-phenylalanine. The trend of the curve is very different from that of other polymer films. These facts may be caused by the cancellation of dipole by intramolecular hydrogen bond. Several years ago, Masuda and Eda[13] reported the small area per tyrosine residue for poly-DL-tyrosine film. They found a smaller area on acid substrate than on alkaline substrate. This may be caused by partial dissolution of polypeptide because of the smaller degree of polymerization of the polypeptide which they used.

Polytyrosine films spread at air/water interface occupy much less area than the films of other polypeptides such as polyphenylalanine and show much smaller surface moment as mentioned above. These anomalous properties of polytyrosine might come from the hydrogen bonding of phenolic OH group in tyrosine residue. Without this hydroxyl group, polytyrosine may assume exactly a structure of polyphenylalanine. Accordingly, the film would have a limiting area of about 15 Å² per residue. Nevertheless, the limiting area per residue for poly-L-tyrosine was found to be 5.7 Å² and that for poly-DL-tyrosine to be 5.8 Å² both at pH 5.6. These small areas per residue may be attributed to the spreading of these polypeptides in a coiled state, owing to the strong hydrogen bonding of phenolic OH groups. The extremely low value of surface moment supports also this inference. Even on alkaline substrate, the spreading of the film is not complete, although the film expands considerably at pH region between 8.0 and 11.5. As shown in Fig. 5, this finding corresponds to the partial breaking of hydrogen bonds and to the partial dissociation of phenolic OH groups, and to the result of spectrophotometric titration by Katchalski and Sela[14,15]. On the other hand, we obtain the film which seems to assume β-keratin configuration irrespective of the pH of the substrate if we spread it from a solution in dichloroacetic acid which is a strong hydrogen-bond breaking agent. The surface moment of the film thus obtained is about 120~130 mD, as shown in Fig. 6, suggesting the intramolecular cancellation of OH contributions to surface moment

and tending to the value of surface moment of ordinary polypeptide films. In Fig. 7, the surface moment of polytyrosine increases as the film is compressed and passes a maximum and then decreases, whereas most usual well-spread linear polymer shows a constant surface moment, μ_c until the polymer film is closely packed as the film is compressed and further compression causes the decrease of surface moment. The maximum surface moment, μ_{max} and the area where the maximum moment was found, A_μ, are plotted against pH. μ_{max} increases considerably above pH 8.5. This might be caused by the unfolding and reorientation of polypeptide owing to the breaking of some hydrogen bonds. The reason why μ_{max} increases at the extreme acid substrate is not clear but is presumably due to the formation of oxonium ions[16].

In Figs. 8 and 9, the results obtained at petroleum ether/water interface are shown. The film is considerably expanded.

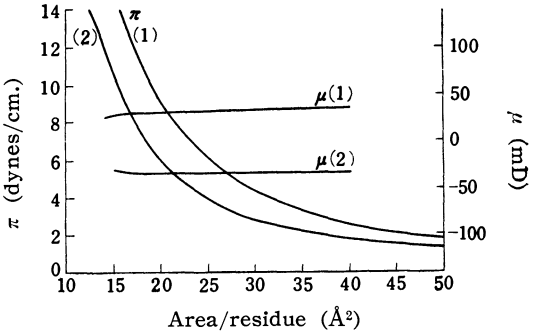

Fig. 9. Interfacial pressure (π)-area and interfacial moment (μ)-area curves of poly-DL-tyrosine. (1) pH 2.0 and (2) pH 11.0. (22°C).

Poly-L-tyrosine film is more expanded at pH 11.0 than at 2.0, whereas poly-DL-tyrosine is more expanded at pH 2.0 than at pH 11.0. The force-area curves are like those of the monolayers of polypeptide with nonpolar side chains such as poly-DL-phenylalanine. At pH 2 all the side chains of *p*-hydroxybenzyl group might be dissolved in the oil phase. Interfacial potential was found to be 60 mD (μ_c) for poly-L-tyrosine and 32 mD at 25 Å²/residue for poly-DL-tyrosine. These values are markedly less than that for poly-DL-phenylalanine (144 mD (μ_c)). This difference might be caused by the contribution of phenolic OH group of tyrosine. Poly-DL-tyrosine is more expanded than poly-L-tyrosine corresponding to the general tendency of expansion of poly-DL-amino acid more than poly-L-amino acid as previously reported[3]. On the other hand, the fact that at air/water interface the film of poly-DL-tyrosine occupies less area than poly-L-tyrosine does at pH 12.5 is due to the general tendency of higher solubility of poly-DL-amino acid than poly-L-amino acid. If the aqueous phase is alkaline, the phenolic OH dissociates and dissolves in the aqueous phase at both air/water and oil/water interfaces. In this case the contribution of dipole is inverse. The negative surface moment was found at oil/water interface, namely −44 mD at 25 Å²/residue for poly-L-tyrosine and −34 mD (μ_c) for poly-DL-tyrosine.

From these results we can conclude that both poly-L-tyrosine and poly-DL-tyrosine spread incompletely at air/water interface and the film is in a partially coiled state because of the hydrogen bonding of phenolic OH group if it is not ionized. However, at oil/water interface by the release of van der Waals force between

side chains due to the intervening of oil, hydrogen bonds are readily broken, and the monolayer which seems to be in β-configuration is obtained. Even at air/water interface, similar monolayer is obtained when we spread the film from a solution in hydrogen bond breaking agent. The obtained force-area curve is very similar to that of poly-DL-phenylalanine. With this monolayer, surface moment of 132 mD (μ_{max}) is found.

Poly-*o*-benzyl-DL-tyrosine. — Force-area and surface (interfacial) moment-area curves of poly-*o*-benzyl-DL-tyrosine at air/water and oil/water interfaces are shown in Fig. 10. Because of lacking of hydrogen bonding agency by esterification of phenolic OH groups, the film is well spread at air/water interface. The area per residue at minimum compressibility is somewhat less than that of poly-DL-phenylalanine and polytyrosine which was spread from the solution containing dichloroacetic acid. The large van der Waals force between side chains seems to cause the condensation of the film. The maximum value of surface moment reached 123 mD. Surface moment increased as the film was compressed, especially when the force-area curve begins to stand steeply at about 20 Å^2 residue. This change is based on the reorientation of large polar side chains. At oil/water interface, poly-*o*-benzyl-DL-tyrosine expanded considerably more than any other polypeptides mentioned above. All large side chains may be in the oil phase, and there is no interaction between the side chain because of the release of van der Waals force between them by intervening of oil. The size and difficulty of packing such large chains may be the cause of the expansion of the film. Interfacial moment was found to be 150 mD

(μ_c) which corresponds namely to the value of poly-DL-phenylalanine.

All the results are summarized in Table II.

Summary

The monolayer properties of synthetic polypeptides which have phenolic OH groups in the side chains such as poly-L-tyrosine and poly-DL-tyrosine were studied to investigate the effect of hydrogen bonding by tyrosyl OH groups. Poly-*o*-benzyl-DL-tyrosine and poly-DL-phenylalanine were also studied for comparison.

At air/water interface, poly-L-tyrosine and poly-DL-tyrosine occupy much smaller area per residue than any other polypeptide films, and have very small surface moment, if they were spread from the solution in pyridine and isopropyl alcohol mixture. These polypeptides might be spread in a strict sense not in an extended monolayer but in a coiled state, suggesting the hydrogen bond between phenolic OH and —CO— or —NH— groups in the main chain. On the alkaline substrate the film expands considerably because of the breaking of hydrogen bonds by the ionization of phenolic OH. At petroleum ether/water interface, the film is also expanded by releasing of van der Waals force. Interfacial moment changes its sign due to whether the aqueous phase is acid or alkaline. It suggests that *p*-hydroxybenzyl groups are in the oil phase at oil/acid solution, whereas they are in the aqueous phase at oil/alkaline solution. Poly-L-tyrosine assumes the configuration very similar to that of poly-DL-phenylalanine, if poly-L-tyrosine is spread from a solution in dichloroacetic acid which is a strong hydrogen bond breaking agent.

Poly-*o*-benzyl-DL-tyrosine gives a monolayer which is somewhat more condensed than poly-DL-phenylalanine at air/water interface, whereas it occupies a larger area per residue than poly-L-tyrosine, poly-DL-tyrosine and poly-DL-phenylalanine at oil/water interface. All these findings are caused by the existence of very large side chains in poly-*o*-benzyl-DL-tyrosine.

The authors express their hearty thanks to Dr. H. Tani and Dr. H. Yuki of the Faculty of Science of Osaka University and Professor E. Katchalski and Dr. M. Sela of the Weizmann Institute of Science in Israel who gave them the valuable samples of synthetic polypeptides. The expense for the experiment was partly defrayed from the grant given by the Ministry of Education, to which the authors' thanks are due.

Catalytic Hydrogenation in Vapor Phase with Urushibara Nickel Catalyst

By Kazuo HATA, Ken-ichi WATANABE and Hamao WATANABE

(Received July 31, 1958)

It has been reported[1] that catalytic hydrogenation in vapor phase with Urushibara nickel catalyst (U-Ni in abbreviation) was carried out for the first time and the experimental results were fairly good. In consequence, it has been proved that U-Ni as a catalyst for hydrogenation is able to be used effectively in vapor phase as well as in liquid phase[2]. It is not as troublesome to use U-Ni as to use other catalysts such as Sabatier's reduced nickel catalyst.

From the previous investigations, we got a suggestion of preparing U-Ni from

1) K. Hata, K. Watanabe and S. Sato, This Bulletin, **30**, 431 (1957).

2) Y. Urushibara and S. Nishimura, ibid., **27**, 480 (1954); Y. Urushibara, S. Nishimura and H. Uehara, ibid., **28**, 446 (1955); K. Hata et al., *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77**, 1405 (1956).

nickel chloride solution and aluminum metal in place of zinc dust. In this paper, we introduce a new study using U-Ni which is made from nickel chloride and aluminum metal. It was found that U-Ni thus made was a more excellent hydrogenation catalyst in vapor phase than any other one because of its activity and convenience in practical use.

At first aluminum powder was used for the precipitating agent, and the precipitated nickel was treated with alkali. The catalyst thus obtained was found to be useful for the reduction of some organic substances. However, aluminum powder did not seem to be entirely suitable for the preparation of the catalyst, although the preparation could be carried out more easily by the addition of some detergent. Then grained aluminum (45 meshes) was chosen instead of aluminum powder. Nickel was precipitated from nickel chloride solution on the surface of aluminum grains, and the precipitated nickel was treated with acetic acid containing inorganic salt such as sodium chloride, whereby the precipitated nickel did not separate from the aluminum grains*. U-Ni catalyst thus prepared, which is called U-Ni-AA** in abbreviation, was proved to be a very convenient catalyst for vapor phase hydrogenation because the grains of aluminum remained undissolved after they were treated with acetic acid, and served as carrier.

A similar catalyst prepared by digesting the precipitated nickel with alkali is called U-Ni-BA**, which is also useful for hydrogenation. U-Ni-BA for the liquid phase hydrogenation must be prepared with grained aluminum[3], but for the vapor phase hydrogenation, it was proved that U-Ni-BA prepared from nickel chloride and commercially available aluminum powder was effective enough. The conditions of preparation of these U-Ni catalysts are shown in Table I.

The results of hydrogenation with these catalysts are summarized in Table II. Nitrobenzene was reduced to aniline, phenol to cyclohexanol. Both styrene and acetophenone were hydrogenated with U-Ni-BA to ethylbenzene (Exp. No. 3 and 4); when U-Ni-AA was used, they were reduced further to ethylcyclohexane (Exp. No. 9 and 10). It is very remarkable that benzene was reduced to cyclohexane[4] with U-Ni-AA, but not with U-Ni-BA (prepared with aluminum powder). Benzonitrile was largely reduced to toluene and ammonia[5], and the result of this cleavage reaction was different from that of previous experiments[1] using U-Ni-A (prepared from nickel chloride and zinc dust).

From these results, it is evident that the aromatic ring is able to be reduced by the use of this new type catalyst U-Ni-AA, while not by U-Ni-A*** or U-Ni-B***. In addition, it is interesting to note that U-Ni-AA can also be used in the hydrogenation in liquid phase under the condition of room temperature and ordinary pressure of hydrogen. For example, nitrobenzene was reduced to aniline in 70% yield in ethanol. Thus U-Ni-AA is shown to be effective for hydrogenation both in vapor and liquid phase as well as reduced nickel catalyst. It may be expected that U-Ni prepared from aluminum will be widely applied in the field of catalytic chemistry.

Experimental

U-Ni-AA.—To 60 g. of grained aluminum (45 meshes), a small amount of water is added. In another vessel, 80 cc. of nickel solution containing 32 g. of $NiCl_2 \cdot 6H_2O$ is heated to 50~60°C, and added to the aluminum with stirring. An exchange reaction occurs and nickel deposits on the surface of the aluminum. The reaction is controlled by cooling with cold water or by heating with hot water. The precipitated nickel is washed with cold water. Then 40% acetic acid solution (385 cc., 70°C) containing 89 g. of sodium chloride is added to the nickel. After 3~7 minutes, the acid solution is decanted, and the residue washed with ca. 2 l. of warm water (50~60°C) and then with methanol. The catalyst thus obtained contains 8 g. of nickel.

U-Ni-BA (for vapor phase hydrogenation).—Ten g. of aluminum powder (200 meshes) is suspended in a small amount of water, and heated on a boiling water bath. Then 10 cc. of warm nickel chloride solution containing 4 g. of $NiCl_2 \cdot 6H_2O$ (ca. 90°C) is added to the aluminum. After a violent exchange reaction ceases, all

* The procedure of preparing the catalyst and of the hydrogenation was quite different unless the salt was used, and the catalyst thus prepared was not suitable for hydrogenation.

** In abbreviation, the last A means aluminum as precipitating agent, and the first A and B mean acid and base as the digesting solution for the precipitated nickel.

1) The temperature of the oil bath.
2) Besides aniline, high molecular amines were obtained as by-products.
3) Grained aluminum (45 meshes) was used, and "Hyflosupercel" was used as carrier.
4) B.p. 80~81.2°C, $n_D^{20}=1.4270$ (lit. 1.4266).
5) B.p. 127~128°C, $n_D^{20}=1.4347$ (lit. 1.4324).
6) B.p. 128~131.8°C, $n_D^{20}=1.4332$ (lit. 1.4324).

the contents are heated to dryness, and 200 cc. of 20% sodium hydroxide solution is added gradually. Since a vigorous exothermic reaction takes place, the contents are stirred well and cooled with running water, and the aluminum is completely dissolved in a short time. Treatment of the nickel precipitate is accomplished by heating for about five minutes. The supernatant solution is decanted, and the residue washed with warm water (50~60°C) until the washing becomes neutral to litmus, and then with methanol thoroughly. The catalyst thus obtained contains about 1 g. of nickel.

Method of hydrogenation.—In the earlier period of these experiments, a special U-tube apparatus was used for hydrogenation reactions, and the reaction tube was heated in an oil bath, as previously reported[1]. In Table II, the experiments, Nos. 1—3, were carried out by the above method.

The U-tube method being somewhat troublesome, the usual hydrogenation method, e.g. with Sabatier's hydrogenation apparatus, has been adopted for convenience. Further experiments, Nos. 4—10, were carried out by such a method in a hard glass reaction tube, 1.8 cm. in diameter and 90 cm. in length, heated in an electric furnace. In experiment No. 4, "Hyflosupercel" (purified kieselguhr) was used as a carrier.

The catalyst was put into the reaction tube, and heated up to an appropriate reaction temperature, while methanol, which was used for washing the catalyst, was expelled by heating. The vaporized sample, together with a large excess of hydrogen, was introduced into the reaction tube. The reaction products flowing out of the tube were collected into the receiver through a condenser, and were isolated by means of fractional distillation. Then each product was identified by preparing an appropriate derivative respectively, except in the case of cyclohexane and ethylcyclohexane.

Summary

Catalytic hydrogenation in vapor phase with new types of Urushibara nickel catalyst was carried out.

1) New types of U-Ni were prepared from nickel chloride and aluminum. U-Ni-BA and U-Ni-AA were respectively obtained by treating the precipitated nickel with alkali or acetic acid.

2) These catalysts are quite easy to prepare and were proved to be useful for hydrogenation. Above all, U-Ni-AA is the most convenient for vapor phase hydrogenation, since it was found to be highly active and the aluminum served as carrier. It was also used in hydrogenation in liquid phase.

The authors express their gratitude to the Ministry of Education for the financial support of this research.

Reactions of Active Methylene Compounds. IV. Synthesis of 2-Hydroxyphenyl Benzyl Ketones and 4-Hydroxy-3-phenylcoumarins (Continued)

By Yoshiyuki KAWASE

(Received August 4, 1958)

In the previous paper[1], 2-hydroxyphenyl benzyl ketones (III) and 4-hydroxy-3-phenylcoumarins (V) were prepared from 2-methoxybenzoyl-phenylacetonitriles (I) and ethyl 2-methoxybenzoyl-phenylacetates (II). Afterwards, it was known that Chatterjea and Roy[2] had reported a preparation of III (R, R′=H) and V (R, R′=H) from I (R, R′=H) by the action of hydrobromic acid in acetic acid.

The present paper describes a preparation of an analogous series of compounds (Ia, IIa, IIIa, IVa, b, b′ and Va, a′, b) by the same procedure described in the previous paper.

By the action of anhydrous aluminum chloride (2 moles) in nitrobenzene, 4-hydroxy-3-phenylcoumarin-2-imides (IVa, b) were obtained from nitriles Ia, b, methoxy groups of which all, except one in the *o*-position of the carbonyl group, were unaffected. 4-Hydroxy-3-phenylcoumarins (Va, b) were obtained from the imides IVa, b by acid hydrolysis, and Va was also obtained from IIa by means of aluminum chloride in nitrobenzene. By the use of an increased amount (4.5 moles) of aluminum chloride, small amounts of IVb′ and Va′ were obtained from Ib and IIa respectively, 4′-methoxy groups of which were demethylated. Attempted preparations of imide IVa′ from Ia, of coumarins Vb, b′ from IIb, and of IVa by ester condensation of methyl salicylate with *p*-methoxyphenylacetonitrile were unsuccessful.

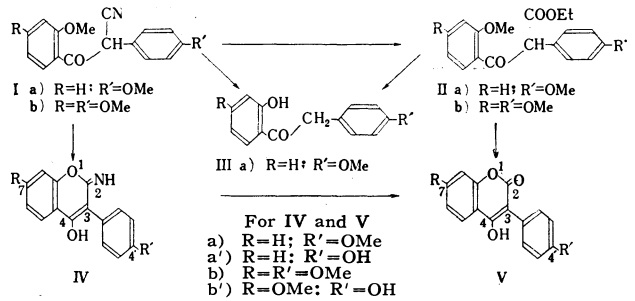
Experimental[3]

2-Methoxybenzoyl-4-methoxyphenylacetonitrile (Ia).—To a solution of methyl 2-methoxybenzoate (5.5 g.) and 4-methoxyphenylacetonitrile (4.5 g.) in anhydrous benzene (100 cc.), sodium hydride (1.5 g., 2 moles) was added and the mixture was heated for 4 hr. on an oil-bath (95~100°), most of the benzene being distilled off in the meantime. The well-cooled mixture was treated with water and extracted with ether. The alkaline aqueous solution was acidified and the solid product separated was collected, washed with aqueous sodium bicarbonate, and recrystallized from ethanol in colorless prisms, m.p. 109~110.5°; yield 6 g. or 70%.



Anal. Found: C, 72.37; H, 5.27; N, 5.05. Calcd. for $C_{17}H_{15}O_3N$: C, 72.58; H, 5.37; N, 4.98%.

Ethyl 2-Methoxybenzoyl-4-methoxyphenylacetate (IIa).—A solution of nitrile Ia (2.2 g.) in anhydrous ethanol (50 cc.) containing one mole of water (0.14 cc.) was saturated with hydrogen chloride with cooling. After three days at room temperature, water was added and ethanol was removed in vacuo. The gummy product separated was taken up in ether, washed with aqueous sodium hydroxide, and distilled to give colorless viscous oil, b. p. 180~200°/0.004mm. (bath-temperature); yield 1.6 g. or 62%.

Anal. Found: C, 69.23; H, 5.90. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

2-Hydroxyphenyl 4-Methoxybenzyl Ketone (IIIa).—(*a*) *From nitrile Ia.*—A solution of Ia (0.5 g.) in acetic acid (10 cc.) containing concentrated hydrochloric acid (5 cc.) was heated on a

3) Melting and boiling points are uncorrected.

steam-bath for 15 hr. The cooled solution was made alkaline with aqueous sodium hydroxide and extracted with ether. The residue obtained from the ether solution was distilled to give colorless oil, b. p. 160~180°/0.003 mm. (bath-temperature); yield 0.2g. 2,4-Dinitrophenylhydrazone, m. p. 198~199° (from ethanol).

Anal. of 2, 4-dinitrophenylhydrazone. Found: C, 59.66; H, 4.11; N, 13.28. Calcd. for $C_{21}H_{18}O_6N_4$: C, 59.71: H, 4.30; N, 13.27%.

(*b*) *From ester IIa.*—By the same procedure described for (a), 0.2 g. of IIIa was obtained from 0.5 g. of IIa; b. p. 160~180°/0.003 mm. (bath-temperature). 2, 4-Dinitrophenylhydrazone, m. p. 197~198°, was identical with the sample from (a).

4-Hydroxy-4'-methoxy-3-phenylcoumarin-2-imide (IVa).—A mixture of Ia (0.5 g.) and anhydrous aluminum chloride (0.5 g., 2.1 moles) in nitrobenzene (5 cc.) was heated on a steam-bath for 1 hr. The cooled solution was treated with water, and nitrobenzene was removed by steam-distillation. The semi-solid product separated from the residue was taken up in ethyl acetate, and extracted with dilute hydrochloric acid. The acid aqueous solution was made alkaline with aqueous sodium bicarbonate, and the precipitates obtained were crystallized from ethanol in colorless microcrystals, m. p. 214.5~215.5°; yield 0.1 g.

Anal. Found: C, 71.75; H, 5.34; N, 5.16. Calcd. for $C_{16}H_{13}O_3N$: C, 71.90; H, 4.90; N, 5.24%.

4-Hydroxy-4'-methoxy-3-phenylcoumarin (Va).—(*a*) *From imide IVa.*—A solution of IVa (ca. 0.05 g.) in 2 cc. of dilute hydrochloric acid (1 : 1) was heated on a steam-bath for 2 hr. The separated crystals were collected and recrystallized from dilute ethanol in colorless microcrystals, m.p. 228~229°; identical with the sample from (b).

(*b*) *From ester IIa.*—A mixture of IIa (0.5 g.) and aluminum chloride (0.5 g., 2.4 moles) in nitrobenzene (5 cc.) was heated for 1 hr. The cooled solution was treated with dilute hydrochloric acid, and nitrobenzene was removed by steam-distillation. The semi-solid product separated from the residue was taken up in ethyl acetate and extracted with aqueous sodium carbonate. The product obtained by acidifying the alkaline solution was recrystallized from dilute ethanol; m. p. 230~231°, yield 0.1 g.

Anal. Found: C, 71.63; H, 4.54. Calcd. for $C_{16}H_{12}O_4$: C, 71.63; H, 4.15%.

4, 4'-Dihydroxy-3-phenylcoumarin (Va').—A mixture of IIa (0.5 g.) and aluminum chloride (0.8 g., 4 moles) in nitrobenzene was worked up as before, and nitrobenzene was removed by steam-distillation. The residual aqueous mixture was filtered while hot, and the crystalline product formed from the filtrate on cooling was recrystallized from dilute ethanol; m. p. 254~255°, yield ca. 0.05 g. It was identical with the sample which will be described in the next paper.

The semi-solid precipitates obtained in the above mentioned filtration were dissolved in ethyl acetate, and treated as before to give Va (ca. 0.05 g.), m. p. 226~227° (from ethyl acetate); identical with the sample described before.

4-Hydroxy-4', 7-dimethoxy-3-phenylcoumarin-2-imide (IVb).—By the same procedure as described before, 0.1 g. of the compound was obtained from 0.5 g. of Ib and 0.5 g. (2.5 moles) of aluminum chloride; m. p. 214~215° (from ethanol).

Anal. Found: C, 68.59; H, 5.33; N, 5.55. Calcd. for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.08; N, 4.71%.

4-Hydroxy-4', 7-dimethoxy-3-phenylcoumarin (Vb).—By hydrolysis of imide IVb with hydrochloric acid, Vb was obtained in colorless needles, m. p. 213~214° (from dilute ethanol). Reported m. p. is 219~220°[4].

Anal. Found: C, 68.10; H, 5.24. Calcd. for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

4, 4'-Dihydroxy-7-methoxy-3-phenylcoumarin-2-imide (IVb').—By the same procedure as described before, a small amount of the compound was obtained from 0.8 g. of Ib and 1.5 g. (4.5 moles) of aluminum chloride; m. p. 287~288° (from ethanol), soluble in acid and in cold aqueous sodium hydroxide.

Anal. Found: C, 67.33; H, 4.66; N, 4.79. Calcd. for $C_{16}H_{13}O_4N$: C, 67.83; H, 4.59; N, 4.94%.

From the ethanolic mother liquor of recrystallization, 0.1 g. of IVb was obtained.

The author wishes to express his hearty thanks to Professor K. Fukui for his helpful advice and encouragement, and to the members of the Agricultural Department of Kyoto University for microanalyses.

*Reactions of Active Methylene Compounds. V. New Synthesis of Hydroxy Substituted 2-Hydroxyphenyl Benzyl Ketones and 4-Hydroxy-3-phenylcoumarins, and Structures of the Latter and Related 2-Imides**

By Yoshiyuki KAWASE

(Received August 4, 1958)

The present paper describes the action of anhydrous pyridine hydrochloride on methoxy substituted ethyl 2-methoxybenzoyl-phenylacetates (II) and 2-methoxybenzoyl-phenylacetonitriles (I) to give hydroxy substituted 2-hydroxyphenyl benzyl ketones (III) and 4-hydroxy-3-phenylcoumarins (V) respectively, and the structures of the latter and the intermediate, 2-imides IV of V are discussed through their infrared spectra.

Anhydrous pyridine hydrochloride is often used for demethylation of methyl ether of phenols[1]; for instances, similar to the present work, 2-methoxybenzal-phenylacetonitriles were transformed into 3-phenylcoumarins[2] and 4-hydroxy-2′-methoxy-3-phenylcoumarins into coumarino (3′, 4′: 3, 2) coumarones[3].

The action of this reagent on nitriles Ia~d[4] under reflux caused demethylation of all the methoxy groups and subsequent cyclization to give the intermediate imides IV, which were readily converted into hydroxy substituted 4-hydroxy-3-phenylcoumarins (Va~d) by acid hydrolysis. Methoxy substituted IV and V had been obtained[5] by the action of aluminum chloride on I and II respectively, methoxy groups of which in the *p*-position of carbonyl group were unaffected. On the other hand, the action of pyridine hydrochloride on esters IIa~d[4] caused at first cleavage of ester group, decarboxylation, and then demethylation of all the methoxy groups to give hydroxy substituted 2-hydroxyphenyl benzyl ketones (IIIa~d). Methoxy substituted III had been obtained[4] by the action of hydrochloric acid on I and II, methoxy groups of which expect one in the *o*-position of the carbonyl group were unaffected.

It is reported that absorptions by carbonyl groups of 4-hydroxycoumarins[6,7] are in a shorter region, and that of chromones[7,8] are in a longer region, than 6 μ.

7) a) C. H. Stammer et al., *J. Am. Chem. Soc.*, **80**, 137, 140 (1958); b) A. Fujino and M. Yamaguchi, *J. Japan. Chem.* (*Kagaku no Ryôiki*), *Extra Voll.* **28**, 124, 126 (1958).

8) H. L. Hergert and E. F. Kurth, *J. Am. Chem. Soc.*, **75**, 1622 (1953); B. L. Shaw and T. H. Simpson, *J. Chem. Soc.*, **1955**, 655; G. E. Inglett, *J. Org. Chem.*, **23**, 93 (1958).

The infrared spectra of IVa, e and Va, b, e were measured in Nujol and compared* with those of related 3-phenylcoumarin-2-imide (VIII), 3-phenylcoumarin (IX), 4-hydroxycoumarin (X) and isoflavones (XIa~c). (see Figs. 1—3). (Preparation of IVa, e and Va, e was reported in the previous paper[5]). It seems that 4-hydroxycoumarin structures of IV and V will rather be replaced by chromone structures, namely 2-amino- (VI) and 2-hydroxy-isoflavones (isoflavonols) (VII) respectively, from the whole shapes of their infrared spectra, and from the absorptions by their carbonyl groups in a longer region than 6 μ.

Experimental[9]

2-Hydroxyphenyl Benzyl Ketone (IIIa).—A mixture of ester IIa (0.3 g.) and anhydrous pyridine hydrochloride (1.5 g.) was refluxed for 20 min. on an oil-bath (ca. 220°). The cooled mixture was treated with dilute hydrochloric acid and heated for several minutes on a steam-bath. After being cooled, the solid product separated was collected and recrystallized from ethanol; m. p. 57~58°, identical with the authentic sample[4]; yield 0.1 g. The three following ketones were prepared in the same way.

2, 4-Dihydroxyphenyl Benzyl Ketone (IIIb).—From 0.3 g. of IIb, 0.1 g. of IIIb was obtained, m. p. 110~113° (from water), identical with the authentic sample[10].

2-Hydroxyphenyl 4-Hydroxybenzyl Ketone (IIIc).—From 0.3 g. of IIc, 0.1 g. of IIIc was obtained, m. p. 106~107° (from oqueous ethanol, and dried at 80°).

Anal. Found: C, 73.58; H, 5.30. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

2, 4-Dihydroxyphenyl 4-Hydroxybenzyl Ketone (IIId).—From 0.3 g. of IId, 0.1 g. of IIId was obtained, m. p. 183~184° (from dilute ethanol, and dried at 120°). Reported m. p. is 191~192°[11].

Anal. Found: C, 68.78; H, 5.20. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%.

2-Hydroxyisoflavone (Isoflavonol) (VIIa).—A mixture of nitrile Ia (0.3 g.) and anhydrous pyridine hydrochloride (1.5 g.) was refluxed for 20 min. on an oil-bath. The cooled mixture was treated with dilute hydrochloric acid and heated on a steam-bath for 1 hr. After being cooled, the deposits were collected and crystallized from ethanol; m. p. 228~229°, yield 0.15 g.; identical with the authentic sample[5]. The following compounds were prepared in the same way.

2, 7-Dihydroxyisoflavone (VIIb).—From 0.3 g. of Ib, 0.15 g. of VIIb was obtained; m. p. 277~278° (from ethanol). Reported m. p. is 284~285°[12] or 285°[13].

Anal. Found: C, 70.68; H, 4.06. Calcd. for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%.

2-Amino-4'-hydroxyisoflavone (VIc) and 2, 4'-Dihydroxyisoflavone (VIIc) —In the case of Ic, intermediate imide VIc was isolated together with VIIc by the same procedure as described before. Ic (0.3 g.) was treated with pyridine hydrochloride and with dilute hydrochloric acid, and the precipitates thus formed were crystallized from ethanol to give VIc in colorless microcrystals, m. p. ca. 330° (decomp.); yield 0.1 g.

Anal. Found: C, 71.15; H, 4.50; N, 5.42. Calcd. for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.37; N. 5.53%.

From the ethanolic mother liquor of crystallization, VIIc (0.1 g.) was obtained; m. p. 255~256° (from dilute ethanol, and dried at 150°).

Anal. Found: C, 70.64; H, 3.98. Calcd. for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%.

VIIc was also obtained from imide VIc by hydrolysis with dilute hydrochloric acid for a longer time; m. p. 252~254°.

2, 4', 7-Trihydroxyisoflavone (VIId).—From Id (0.5 g.) and pyridine hydrochloride (2.5 g.), 0.2 g. of VIId was obtained; m. p. ca. 340° (decomp.) (from methanol, and dried at 150°).

Anal. Found: C, 66.63; H, 3.84. Calcd. for $C_{15}H_{10}O_5$: C, 66.67; H, 3.73%.

The author wishes to express his hearty thanks to Professor K. Fukui for his helpful advice and encouragement, to Professor K. Matsui of Kanazawa University for the sample of 4-hydroxycoumarin, to Mr. M. Yamaguchi of Osaka City University for infrared spectroscopy, and to the members of the Agricultural Department of Kyoto University for microanalyses.

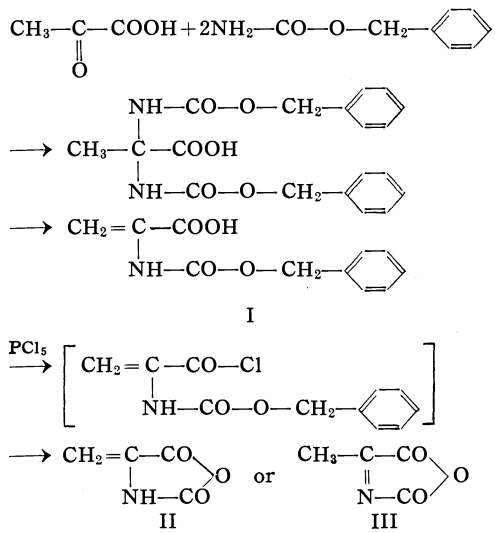
Studies on Dehydroalanine Derivatives. I. Synthesis of N-Carboxy-dehydroalanine Anhydride



By Shumpei SAKAKIBARA

(Received August 5, 1958)

It is supposed that thermal or alkaline decomposition of serine, cysteine and peptides containing those amino acids proceed via dehydroalanine[1], and that dehydroalanine must play an important role as a transient intermediate in the course of enzymatic transformations of those substances[2]. If the synthesis of dehydroalanine were possible, this substance would be hydrolysed immediately into pyruvic acid and ammonia because of the presence of very unstable enamine structure in the molecule[3]. On the other hand, *N*-acyl derivatives of dehydroalanine are comparatively stable toward water, and actually some derivatives have been synthesized previously[4-6]. *N*-acetyl[4], *N*-carboethoxy, *N*-carbobenzoxy and *N*-formyl dehydroalanine[5] have been reported to be polymerized into *N*-acyl derivatives of poly-α-amino acrylic acid through a vinyl type polymerization. However, all efforts to prepare the poly-α-amino acrylic acid from these polymer derivatives remain unsuccessful because of the difficulty of the acid or alkaline hydrolysis of these polymers.

Each of the double bonds of suitable dehydroalanine derivatives is supposed to be reactive toward some reagents such as active hydrogen, hydrogen cyanide, hydrogen sulfide, indole and so on, and poly-dehydroalanine[7], if its synthesis is possible, may be converted into poly-alanine, poly-asparagine, poly-cysteine and poly-tryptophane theoretically by the action of such reagents as described above. In this series of papers, the synthetic studies on poly-dehydroalanine and on poly-α-amino acrylic acid will be described chiefly and the reactivities of the obtained polymers will be discussed.

For the starting material of poly-dehydroalanine and of poly-α-amino acrylic acid, *N*-carboxy dehydroalanine anhydride (II) was prepared from *N*-carbobenzoxy dehydroalanine (I) and phosphorous pentachloride in dry ether. The substance I was first synthesized by Frankel and Reichmann[5] through the procedure resembling that for *N*-acetyl dehydroalanine by Bergmann and Grafe[4].

The reagent, phosphorous pentachloride, and its reacted residuals scarcely affected the double bond of the substance II (or III) in the course of the reaction, but the reaction product crystallized very easily. After recrystallization from ethyl acetate and petroleum ether, colorless prisms with melting point of 111~113° (decomp.) were obtained. This substance sublimed at 80° or higher temperature (0.1 mmHg) accompanied by partial polymerization.

If the structure III is more stable than

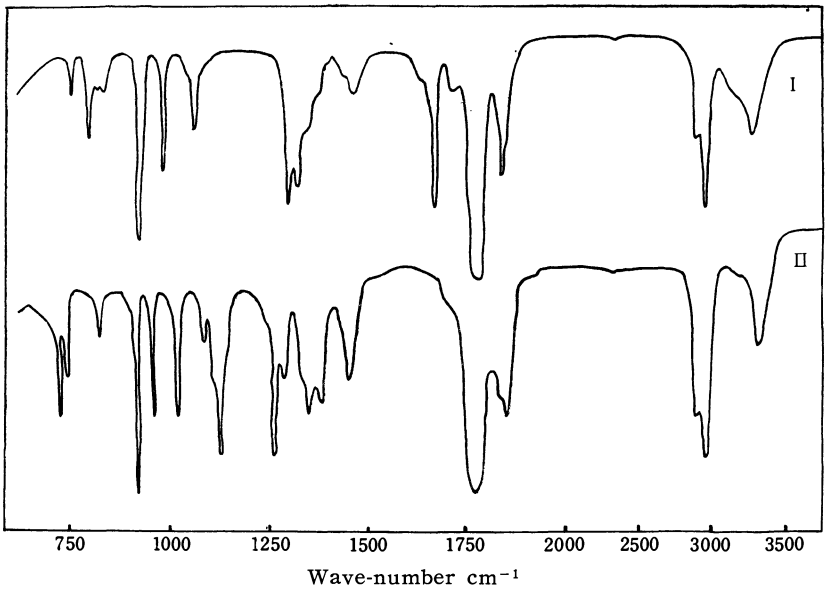
7) This name represents the polypeptide of dehydroalanine in distinction from the vinyl-type polymer of dehydroalanine which is named as poly-α-amino acrylic acid in this series of papers.



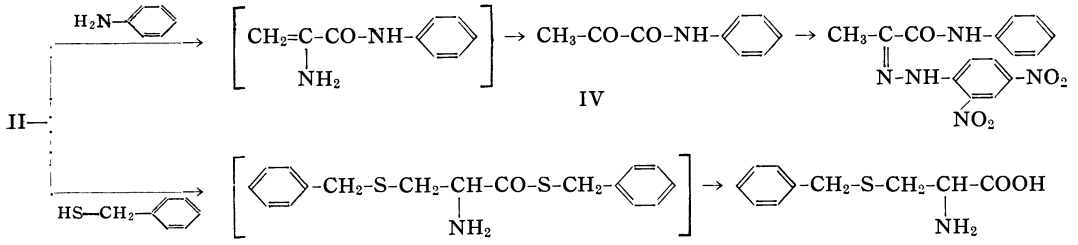


Fig. 1. Infrared spectra recorded on an Adam-Hilger H-80 infrared spectrophotometer: I, *N*-carboxy dehydroalanine anhydride; II, *N*-carboxy DL-alanine anhydride. Nujol suspension.

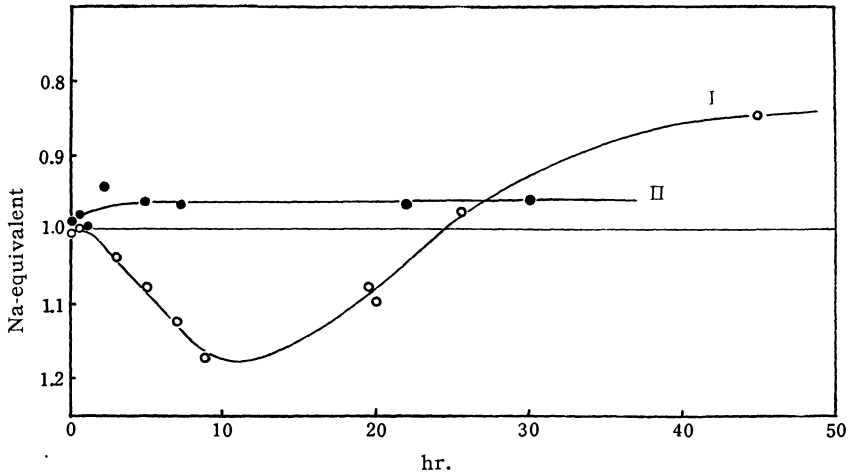
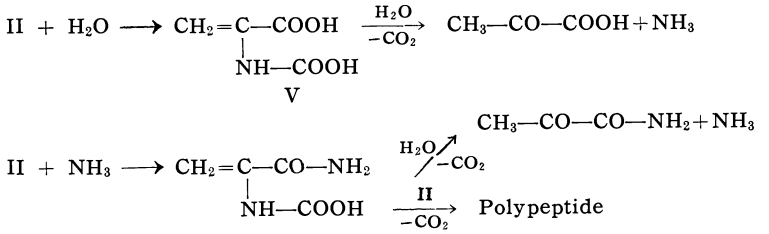
II, the position of the double bond in the molecule may shift from C=C to C=N in the course of the reaction. The infrared spectrum (Fig. 1) of the product, however, showed absorption bands which were all identical with those supposed for the structure II; that is, the absorption bands at 3050~3300 cm^{-1} indicated the presence of —NH— groups in the molecule, and the absorption bands at 1750~1900 cm^{-1} corresponding to carbonyl groups in a five-membered ring were identified completely as those of *N*-carboxy DL-alanine anhydride. The sharp band at 1675 cm^{-1}, which was not observed in the same region of the spectrum of *N*-carboxy DL-alanine anhydride, may be due to the presence of a double bond directly attached to the five-membered ring in the structure II. The absence of δN-H(amide II) band in both the spectra must be explained by the fact that both NH groups exist in five-membered rings of the respective *N*-carboxy anhydride.

In addition, the structure II was confirmed by the reactions with aniline and with benzylmercaptane. In the case of the former, pyruvic acid anilide IV was obtained in a yield of about 60%, and the structure IV was confirmed by the formation of the 2,4-dinitrophenyl hydrazone. In the case of the latter, *S*-benzyl cysteine formed was identified with an authentic sample by paper-chromatography. These results all supported the structure II for the product.

One of the characteristics of the substance II was its relative stability toward water and amines in comparison with ordinary *N*-carboxy anhydrides. For example, the substance II, which had been prepared about half a year ago and stored in a usual desiccator over phosphorous pentoxide without any precautions, indicated almost the same melting point as that of the original one in spite of the fact that almost all of drying agents have already become tarry. Moreover, the





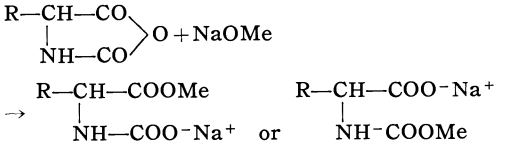


Fig. 2. Time—Na-equivalent curves of *N*-carboxy anhydrides at 30°±0.1° in dioxane containing an equal mole of water: I, *N*-carboxy dehydroalanine anhydride: II, *N*-carboxy DL-alanine anhydride.

substance II immersed in water seemed to be rather stable below 30° and decomposed gradually under evolution of carbon dioxide at 35° or higher temperature.

For clarifying the hydrolytic reaction of the *N*-carboxy anhydride II, it was dissolved in dioxane containing an equal mole of water (against II) and the solution was allowed to react in a bath at 30° ±0.1°. Then, the solution was titrated with sodium methoxide at times according to the procedure of Berger et al.[8] and equivalent values obtained

(the residual amount of the *N*-carboxy anhydride plus acidic material formed, such as pyruvic acid) were plotted against time (curve I on Fig. 2). This curve I was compared with that of *N*-carboxy-DL-alanine anhydride (curve II) under the same condition. In this comparison, it was very interesting to find that the curve I fell down at first, then, recovered gradually and began to rise only after 30 hours, notwithstanding the fact that no practical change of titration values was observed within 30 hours in the case of the *N*-carboxy-DL-alanine anhydride. The reason for the increase in the titration values for the substance II beyond the original line should be explained by the formation of carbamic acid V by hydrolysis. Furthermore, this carbamic acid V would possibly be more stable than those from other ordinary *N*-carboxy amino acid anhydrides at room temperature, since the carbamic acid contains the conjugated double bond in the molecule. If the assumption is reasonable, the considerable stability of the *N*-carboxy anhydride II above mentioned should be explained by the retardation of the chain reactions for polypeptide-forming polymerization. On the other hand, *N*-carboxy-DL-alanine anhydride may be hydrolyzed gradually into carbamic acid of DL-alanine, which is decarboxylated immediately into DL-alanine; then, it will be possible to consider that the titration values

8) A. Berger, M. Sela and E. Katchalski, *Anal. Chem.*, **25**, 1554 (1953).

of the solution should not change practically, since alanine formed is titrated by sodium methoxide in the same manner as *N*-carboxy anhydride under this condition. The upward tendency of the latter part of the titration curve I may also be explained by the gradual formation of the pyruvic acid amide or by the gradual polymerization which was initiated by the formed ammonia.

This material II will be expected to undergo the poly-peptide-forming polymerization and the vinyl type polymerization independently. The details of both cases will be published in later communications.

Experimental

N-Carbobenzoxy dehydroalanine (I). — It was prepared from α,α-dicarbobenzoxyamido propionic acid[9] (m.p. 138.5°) according to the procedure of Frankel and Reichmann[5]. The yield of the low product with m.p. 107° was about 76~83%. After successive recrystallizations from toluene containing a small amount of hydroquinone, colorless plates with m.p. 112~113° (decomp. at 160°) were obtained. Frankel[5] reported m. p. 105° (decomp.) and Wieland[6] m. p. 119° (decomp.).

Anal. Found: C, 59.65; H, 4.50; N, 6.33; No. of double bond, 0.982[10]. Calcd. for $C_{11}H_{11}O_4N$: C, 59.72; H, 5.01; N, 6.33; No. of double bond, 1.00.

N-Carboxy dehydroalanine anhydride (II). —A solution of 10 g. of I in 50 ml. of dry ether was cooled to 0° in an ice water bath and 10.5 g. of powdered phosphorous pentachloride was added in one portion. Then, the suspension was shaken vigorously with intermittent cooling in the bath for about 50 min. The supernatant was decanted quickly into a distillation flask and was concentrated to syrup under reduced pressure at 25~30°. During the course of the treatment, the residual syrup crystallized gradually. After about 30 min., 50 ml. of petroleum ether was added to the residual crystalline mass and the mixture was cooled in an ice water bath for about one hr. Then, the crystalline mass was filtered off and washed with some petroleum ether. The crude crystals were recrystallized from ethyl acetate-petroleum ether after treatment with some active charcoal. The yield of the light yellow prisms with m.p. 105~108° (decomp.) was 3.5 g. (70%). After recrystallization from the same solvents, the colorless prisms of 3.1 g. with m.p. 111° (decomp.) were obtained. After sublimation at 80~90° (0.1 mmHg), this substance melted and decomposed at 111~113°.

Anal. Found: C, 42.56; H, 2.60; N, 12.13. Calcd. for $C_4H_3O_3N$: C, 42.49; H, 2.67; N, 12.39%.

Reaction of II with aniline.—*Formation of pyruvic acid anilide (IV).*—A solution of 1.13 g. of II in 20 ml. of ethyl acetate was cooled to −10° and 5 g. of aniline was added into the solution, then the mixture was allowed to react overnight in a refrigerator at 0~4°. A small amount of yellow precipitate formed was filtered off and the mother liquor was washed successively with 0.5 N hydrochloric acid, water, 0.5% sodium bicarbonate solution and water, dried over anhydrous sodium sulfate and concentrated to dryness under reduced pressure. The residual syrup was transferred into a sublimation vessel with some ethyl acetate. The main product IV was then separated by sublimation at 100° (0.1 mmHg) from yellow by-products. The colorless needles with m.p. 103~105° were obtained in the yield of 1.0 g. (60%); Nef[11] reported m.p. 104°.

Anal. Found: N, 8.65. Calcd. for $C_9H_9O_2N$: N, 8.60%.

2, 4-Dinitrophenyl hydrazone of IV.—To a solution of 50 mg. of IV in 5 ml. of ethanol was added a solution of 100 mg. of 2, 4-dinitrophenyl hydrazine in 5 ml. of 2 N hydrochloric acid, and the mixture was heated for a short time in a boiling water bath and cooled. The voluminous yellow crystals which formed were filtered off, washed with dil. hydrochloric acid and water, and dried. The yield of the yellow crystals was about quantitative and they melted at 245~247° after recrystallizasion from glacial acetic acid.

Anal. Found: C, 52.48; H, 3.82; N, 21.2. Calcd. for $C_{15}H_{13}O_5N_5$: C, 52.49; H, 3.82; N, 20.4%.

Reaction of II with benzyl mercaptane.— A solution of 100 mg. of II and 500 mg. of benzyl mercaptane in 5 ml. of dry acetone was allowed to react overnight at room temperature. The mixture was concentrated to dryness and the residuals were hydrolyzed for one hr. with 6 N hydrochloric acid. The hydrolysate was extracted with ether and the aqueous layer was concentrated to dryness. The residuals were extracted with absolute ethanol and the extract was concentrated. From the residuals, *S*-benzyl cysteine was detected by paper-chromatography, which was identified by comparison with an authentic sample.

Reaction of II with water.—The substance II (350 mg.) was dissolved in 15.00 ml. of freshly distilled dry dioxane containing 56 mg. of water. The solution was divided into 14 test tubes so that each tube contains 1.00 ml. of the solution, and the tubes were sealed. Then, they were allowed to react in a bath at 30°±0.1° simultaneously. Each of the portions was opened successively at times and dry nitrogen was introduced for about one min. into the solution, which was then titrated with a methanol-benzene solution (ca. 0.3 N) of sodium methoxide using thymol blue as an indicator according to the procedure of Berger, et al.[8]. The sodium methoxide solution was standardized every 5 hr.

9) E. Martell and R. M. Herbst, *J. Org. Chem.*, **6**, 878 (1941).

10) This value was determined by back-titration of the bromine using sodium thiosulfate after a sufficient amount of bromine in glacial acetic acid was added to the sample.

11) J. U. Nef, *Ann.*, **270**, 299 (1892).

with purified benzoic acid. After about 8 hr. the reacting solution began to become turbid, and after about 20 hr. yellow precipitates began to form. (Curve I on Fig. 2)

Reaction of *N*-carboxy-DL-alanine anhydride with water.—*N*-Carboxy -DL-alanine anhydride[12] (m.p. 45°) (356 mg.) was subjected to the reaction under the same condition described above. After about 30 hr. the reacting solution remained clear (Curve II on Fig. 2). A suspension of 18.3 mg. of DL-alanine in 1 ml. of dimethyl formamide was titrated with a methanol-benzene solution (0.306 N) of sodium methoxide with an indicator of thymol blue, and 0655 ml. (0.975 equivalent for DL-alanine) of the solution was required for neutralization.

Summary

N-Carboxy dehydroalanine anhydride was first synthesized from carbobenzoxy dehydroalanine. The structure of the *N*-carboxy anhydride was confirmed by the analysis of its infrared spectrum and by the investigation of its chemical behavior. The hydrolytic reaction of the *N*-carboxy anhydride was compared with that of *N*-carboxy DL-alanine anhydride, and it was supposed that dehydroalanine carbamic acid might exist stably in dioxane at ordinary temperature.

Thermal Effects of Some Kaolin Minerals. II. Halloysite

By Hiroshi TAKAHASHI

(Received March 18, 1958)

In the preceding part of this series, studies were made on the structural changes of kaolinite and kaolin mineral of fireclay type with heat-treatment in the relatively low temperature region with respect to the degree of the crystallinity[1].

In the early stage of heat-treatment, the progress of the crystallinity is remarkable. It is mainly due to the loss of the adsorbed water. In the next stage, there occurs the lowering of crystallinity due to the break of the kaolin structure resulting from the loss of the lattice water. In the following stage, the rearrangement of ions for the mullite nucleation becomes remarkable, though the X-ray diagram indicates that this state is an amorphous structure.

Halloysite is composed of the same structural units as those of kaolinite, but the stacking of almino-silicate layers is in almost entirely disorder and generally contains the inter-layer water between unit layers. The crystallinity of halloysite, except a certain type of halloysite[2,5], is lower than that of kaolinite. And, it was also found by Brindley and Robinson that the theory of the reflection for a random layer lattice is applicable to the structure of halloysite[3]. The change in the structure of halloysite owing to the loss of the inter-layer water, was studied in details by Brindley and Goodyear[4].

In this paper, the structural changes of halloysite with heat-treatment in the relatively low temperature region, are presented, through X-ray diffraction method, differential thermal analysis and the density measurement from the point of view of the degree of crystallinity of kaolin minerals and are compared with those of kaolinite.

Experimental

Twelve samples of halloysite with the various degrees of crystallinity were used in this study. From the point of view of the degree of crystallinity in halloysite, the following four samples are generally representative for the structural changes through heat-treatment. Four samples mentioned above are as follows; Halloysite from Spruce Pine, N. C., U. S. A.; Halloysite from Bedford, Ind., U. S. A.; Halloysite from Tintic, Utah, U. S. A. and Shichinoe-clay from Shichinoe, Aomori, Japan.

These samples, except for Shichinoe-clay, are the API Standard Clay Minerals. Of all kinds of halloysite used in this study, Shichinoe-clay has the lowest degree of crystallinity. The structural characteristics of these samples have been discussed in the previous paper[5], and those of Shichinoe-clay was also discussed by Sudo[6]. The method of preparation of the experimental specimens and the experimental conditions of all measurements are the same as those in kaolinite and Kibushi-clay.

Results and Discussion

X-ray Diffraction Studies.—Fig. 1 shows the X-ray diffractometer traces of heat-treated specimens of Tintic halloysite. As shown in these traces, the reflections which correspond to hydrated halloysite disappear owing to the loss of the inter-layer water when heat-treated, and it changes into a dehydrated halloysite. With the rise of the treated temperature, the intensity of all reflections increases and (001) reflection becomes sharp to 400°C. In the 545°C heat-treated specimen, the reflections which are apparent in the original sample are not observable, but only a wedge-like background. In the 700°C heat-treated specimen, only a very diffuse and indistinct band is observable. In Tintic halloysite, it is considered that the crystallinity progresses up to 400°C. This is because the residual inter-layer water which exists sporadically between the kaolin layers is lost with the rise of treated temperature, which causes the arrangement of kaolin unit layers to be ordered. Past 400°C, the structure of halloysite begins to disintegrate due to the gradual disappearance of the lattice water. Then the lattice water completely vanishes. Therefore, its crystallinity drops. The X-ray diagram shows also that the rate of change in the heat-treated specimens of other halloysites is similar to that of Tintic halloysite. The only difference is that the loss of lattice water occurs at a lower temperature according to the order of crystallinity of the original sample. The temperature which eliminates the lattice water is the highest in Spruce Pine halloysite and lowest in Shichinoe-clay. This is quite natural in the light of the thermal data.

It is known by Brindley that halloysite has a pseudo-hexagonal form in symmetry and has a two-dimensional like structure[3]. To the two-dimensional structure, Warren's theory is applicable[7]. This theory has been applied to various kinds of substance[8], particularly to amorphous carbon in the process of graphitization[9]. The structure of halloysite is more complex than that of amorphous carbon in in the chemical composition and the crystal structure. So, it is very dangerous to apply this theory entirely to halloysite. However, the values obtained by the application of this theory should have some relation with the real values to some extent. For this reason, the crystallite dimensions were obtained from the broadening of (001) and (02, 11) reflection lines. There are two elements determining the broadening of the reflection line. One is the crystallite size, and the other is the lattice distortion. Accordingly, to obtain the real crystallite size from the line broadening, the factor of the lattice distortion must be eliminated[10]. However, the

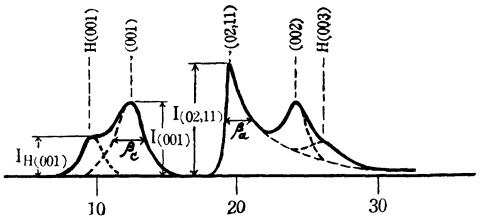
increase of the line breadth correlates the fact that the lattice distortion becomes remarkable and that the crystallite size becomes reduced. These two facts mean a lowering in the crystallinity. Therefore, the crystallite sizes thus obtained indicate the relative degree of crystallinity rather than the real crystallite sizes. Consequently, the crystallite sizes are not the real crystallite sizes, but the values are proportional to the real crystallite sizes. However, the real crystallite sizes of halloysite are not much different from the values thus obtained, which are probably, approximate values. This fact was also described in the separate paper[11]. The crystallite dimension along the direction of the *c*-axis (L_c) was measured by the Bragg's equation[12] and the crystallite dimension parallel to the layer plane (L_a) was measured by Warren's equation[7].

$$L_c = \frac{0.9\,\lambda}{\beta_c \cos\theta} \quad \text{(Bragg's equation)}$$



$$L_a = \frac{1.84\,\lambda}{\beta_a \cos\theta} \quad \text{(Warren's equation)}$$

λ: wave length (Cu K_α: 1.5418 Å)
θ: diffraction angle (degree)
β: half value of breadth (radian)

In these measurements, quartz was used for a correction substance for the instrumental broadening of the reflection line.

Kaolin minerals generally change in their shapes and physico-chemical properties according to the structural characteristics. Kaolin minerals have two kinds of crystallinity; that is, one is the internal crystallinity and the other is the crystallinity in the stacking of layers[5]. Therefore, these two kinds of crystallinity must be considered. So, the ratio of the intensity of (001) reflection to that of (02,11) band is measured. This term seems to indicate somewhat the order of the crystallinity of halloysite samples. The original samples of halloysite, except for Spruce Pine halloysite, are partially hydrated halloysite. In Fig. 2 is shown the schematic drawing of the X-ray diagram of the partially hydrated halloysite. In Fig. 2, the intensity ratio was obtained by the following equation[4].

$$\text{Intensity ratio} = \frac{I_{(001)} + \frac{I_{H(001)}}{4}}{I_{(02,11)}}$$

Degrees 2θ Cu K_α

Fig. 2. Schematic drawing of the X-ray diagram of the partially hydrated halloysite.

Fig. 3 shows the change of the spacings of (001) and (02, 11) reflections, the crystallite dimensions and the intensity ratios with heat-treatment. Figs. 3-A, -B, -C and -D show the data for four samples of halloysite.

On the crystallite dimensions, L_c-dimension increases with the rise of the treated temperature; when the regularity along the direction of *c*-axis disappears, L_c-dimension sharply decreases. L_a-dimension, in the partially hydrated halloysite, reaches a maximum value, it then decreases slowly, and then sharply decreases, In Spruce Pine halloysite, L_a-dimension curve has no maximum point perhaps owing to the original sample being dehydrated halloysite. The increase of L_c-dimension with heat-treatment, is caused by the progress of regularity along the direction of *c*-axis because of the loss of the inter-layer water, while the decrease in L_a-dimension is due to the fracturing of kaolin layers.

As for the change of the intensity ratio, the value increases and reaches a maximum point with the rise of treated temperature, and then sharply decreases. The value of the intensity ratio is larger as the crystallinity is higher. This means that the higher the crystallinity of halloysite is, the higher is the regularity along the direction of *c*-axis. From the value of the intensity ratio, it is understood that Spruce Pine halloysite has very high crystallinity. The maximum value in the change of the intensity ratio is considered to indicate the degree of crystallinity of halloysite. In the hydrated halloysite with very low crystallinity, found in Japan, the results are reverse to those so far described, as far as the intensity ratio is concerned. This is for the reason that there is a remarkable disorderliness in the kaolin layers[6].

As for the changes in spacing, the spacing of (001) reflection slowly reduces

D, Shichinoe halloysite

with the loss of the inter-layer water until it reaches a nearly constant value. This maintained value seems to indicate the order of the crystallinity in halloysite. The spacing of (02,11) band decreases sharply with the loss of lattice water. This corresponds to the disintegration of the kaolin structure.

Differential Thermal Analysis.—The differential thermal analysis curves of some specimens with heat-treatment are shown in Fig. 4, and Table I shows the thermal data obtained from these curves.

In the heat-treated specimens of halloysite except for Spruce Pine halloysite, the endothermic reaction (E_{n1}) associated with the loss of the inter-layer or adsorbed water is observable even in the 400°C heat-treated specimen of halloysite. This might be due to the fact that after the heat-treatment it adsorbs water vapor so rapidly from the atmospheric air. This phenomenon corresponds to the crystallinity of the original sample in the low stage.

In the endothermic reaction (E_{n2}) caused by the loss of the lattice water in Spruce Pine halloysite, the peak height and area of this reaction reduce in the 545°C heat-treated specimen. And in the 700°C heat-treated specimen, this reaction is unobservable. In the 545°C heat-treated specimen of Shichinoe-clay, this reaction disappears. This means that the structure

of Shichinoe-clay disintegrates at a lower temperature as compared with that of Spruce Pine halloysite. This fact corresponds to the fact that the original sample of Shichinoe-clay has the lowest degree of crystallinity of all the halloysite samples used in this study.

In the exothermic reaction (E_x) associated with the mullite nucleation, the features of this reaction are the same as those of kaolinite. That is, the peak temperature tends to lower, though very slightly, and the peak height gradually increases with the rise of treated temperature.

In the 700°C heat-treated specimen, the peak height is large as compared with that of the original sample. This fact seems to indicate that in the metakaolin state, the rearrangement of ions takes place for the mullite nucleation though this state is amorphous from the X-ray diagram. Therefore, the heat-treatment accelerates the rearrangement of ions for the mullite nucleation. As a result, the peak height of the exothermic reaction increases. The peak breadth of this reaction reduces with the rise of the heat-treatment, and attains a minimum value, and then slightly increases again.

Density.—In Fig. 5 are shown the changes of the density of halloysite specimens with heat-treatment. Measurements were made on dried specimens.

The rate of change in the density are very similar to those of kaolinite and Kibushi-clay described in the preceding part of this study. The density increases at first with the rise of treated temperature, and reaches a maximum point; then it falls suddenly and maintains the minimum value. Past the minimum point in the density curve which corresponds to the disappearance of the lattice water, the density increases sharply and straight. The curve is steeper as the crystallinity of the original sample is higher. The same phenomena were also observable in kaolinite and Kibushi-clay.

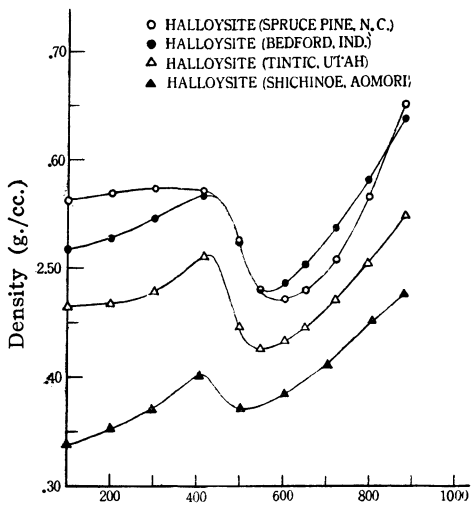

Fig. 5. Curves showing the changes of the density of the halloysite specimens with heat-treated temperature.

When the inclinations in the density curves of kaolinite and ordinary halloysite are compared, that of kaolinite is larger than that of the other.

Therefore, past the minimum point on the density curve, it is considered that the inclination of the density curve of kaolin mineral is corrected to the degree of crystallinity of the kaolin mineral, particularly to the internal degree of crystallinity. This indicates that the rearrangement of ions occurs in the metakaolin state, despite of the fact that the structure is amorphous by the X-ray diagram, and that the stronger the structure of the original sample is, the faster and more perfect is the rearrangement of ions. The mullite nucleation is more remarkable as the crystallinity of the original kaolin mineral is higher.

Mechanism of Structural Change of Halloysite with Heat-treatment.—In the heat-treatment process of halloysite, there are three steps of the structural change with respect to the degree of crystallinity. In the first process, crystallites in one neighborhood aggregate as the inter-layer water vanishes gradually, and so the apparent crystallite size and the value of the density increase and its crystallinity therefore progresses. This tendency is remarkable particularly along the direction of c-axis. In the second process, the hydroxyl ions oriented with the metal ions are cut out and dehydrated, and then kaolin changes into metakaolin. The density decreases suddenly in this stage. As the result, the crystallinity owing to the disintegration of the structure of halloysite. Past this stage, the structure of halloysite becomes amorphous. However, the value of the density of all kinds of halloysite sharply increases with the rise of treated temperature similar to that in kaolinite. The higher the crystallinity is, the larger is the proportion of the increase of the density in all kaolin minerals. This fact shows that even in this amorphous state,

the rearrangement of ions for the mullite nucleation occurs. The higher the original crystallinity is, the more perfect is the rearrangement.

Summery

The structural change of halloysite with heat-treatment in the relatively low temperature region has been studied, and was compared with those of kaolinite and Kibushi-clay. There are three processes, same as in the case of kaolinite. The first process is accompanied by the loss of the inter-layer and adsorbed water, and thə second process by the loss of the lattice water. In the third process, which is an amorphous state corresponding to the metakaolin state, the rearrangement of ions takes place for the mullite nucleation. The rate of the structural change depends on the degree of crystallinity of the original kaolin mineral.

The author wishes to express his hearty thanks to Professor H. Akamatu for his continuous advice and encouragement.

Polarographic Studies of Metallic Complexes. III.[1] *Pentammine Series of Cobalt(III) Complexes*[2]

By Nobufumi MAKI, Yoichi SHIMURA and Ryutaro TSUCHIDA

(Received June 9, 1958)

The relation between the structure of metallic complexes and their half-wave potentials has been studied to some extent[3-12]. For instance, Hall et al.[9] studied several kinds of platinum(IV) complex and found the following facts. Platinum (IV) complexes of halogenopentammine type were reduced irreversibly to platinum (II) complexes in one step and the half-wave potentials were at more positive values for halogenopentammineplatinum (IV) complexes than for hexammineplatinum(IV) ion, $[Pt(NH_3)_6]^{4+}$. The shift, however, was to a more negative value for hydroxypentammineplatinum(IV) complex. Namely the polarographic stability of the pentammineplatinum(IV) complexes, $[Pt(NH_3)_5X]$, increases in the following order of ligand X;

$$Br^- < Cl^- < NH_3 < OH^-$$

They also found that tris(ethylenediamine)-platinum(IV) complex ion was reduced irreversibly to $[Pt\,en_3]^{2+}$, through $[Pt\,en_3]^{3+}$, in two steps at a little more negative potential than the corresponding reduction of hexammineplatinum(IV) ion.

Brigando[11] reported that, on the basis of polarographic measurements and absorption spectra, the following complexes were ranked in order of increasing stability;

$[Co(NH_3)_4(NH_2CH_3)_2]Cl_3$

$[Co(NH_3)_6]Cl_3$, $[Co\,en_3]Cl_3$

$[Co(NH_2CH_2CH_2NHCH_2CH_2NH_2)_2]Cl_3$

The half-wave potentials for these complexes at the dropping mercury electrode in 0.6 F sodium perchlorate were respectively as follows; −0.215 V., −0.297 V., −0.392 V., and −0.420 V. (vs. S. C. E.).

For the same purpose, the present paper deals with the polarography of pentam minecobalt(III) complex ions, $[Co(NH_3)_5X]^{(3-n)+}$.

* Maximum wave.

** The data obtained in the presence of 0.0016% Tween-80.

1) The concentration of the complex; 0.001 gram complex ion per liter.

2) Potential unit; V. vs. S. C. E.

3) Temperature, 25°C.

Experimental

The experimental setup and technique are the same as in the previous work and have been described in the earlier communications[1,12]. The capillary had an m-value of 1.356 mg./sec. and a drop time of 5.82~6.23 sec./drop in 0.1 F potassium chloride or 0.5 F potassium sulfate at a potential of 0.0 V. against the saturated calomel electrode with the mercury head of 96 cm. All the measurements were made at 25±0.1°C, the temperature being maintained by a water thermostat. The reversibilities of the electrode reaction were examined by determining the slope of $\log i/(i_d-i)$ vs. potential. Slopes of the log plots indicated irreversible reaction throughout.

The complex compounds studied were prepared by the method described in previous literature[13-27]. (The references are given in Table I.) Each solution for the electrolysis was made freshly from the dry crystalline cobalt(III) complexes before use and polarographic measurements were made as soon as possible after the removal of oxygen dissolved in solution. No maximum suppressor was used except in the case of azidopentamminecobalt(III) ion. Regarding the complexes of pentammine type, the presence of the maximum suppressor causes the lowering of the diffusion current and the shift of the half-wave potential to negative direction. The supporting electrolytes used were 0.5 F potassium sulfate and 0.1 F potassium chloride.

Results and Discussion

In Table I are shown the half-wave potentials of the cobalt(III) complexes of pentammine series. All the compounds are irreversibly reduced in two steps at the dropping mercury electrode with two exceptions. One of the exceptions is the complexes which contain the ligand reducible by itself, such as chromate ion. The other is the complexes which aquate easily in solution.

From Table I it is seen that the first wave exhibits various half-wave potential

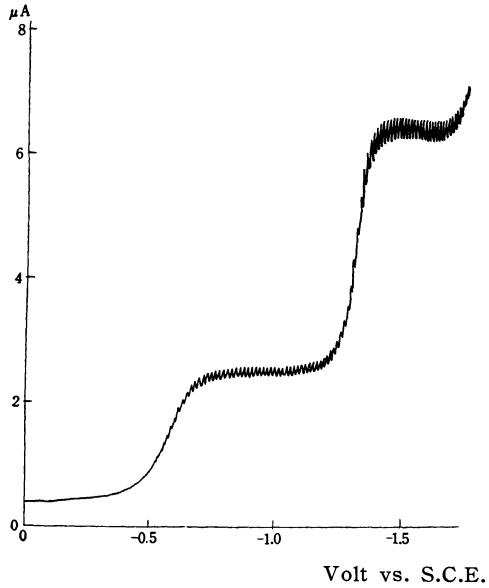

Fig. 1. The polarogram of $[Co(NH_3)_5CO_3]^+$ at the concentration of 0.001 F in the solution of 0.5 F K_2SO_4.
The first wave: $E_{1/2}=-0.50$ V., $i_d=1.52$ μA.
The second wave: $E_{1/2}=-1.28$ V., $i_d=3.04$ μA.

values from compound to compound, while the potentials of the second reduction are always in close proximity to that of hexaquocobalt(III) ion. (−1.428 V. vs. S. C. E. in 0.5 F potassium sulfate solution[4]). Fig. 1 shows the typical polarogram of the pentamminecobalt(III) complexes.

The height of the second wave was very close to twice that of the first wave. The heights of either waves were linearly related with the concentration of the complex ion in the range of $1\times10^{-2}\sim5\times10^{-4}$ F. Accordingly the first wave, corresponding to a one-electron transfer, represents the reduction of cobalt(III) to cobalt(II), and the second, corresponding to a two-electron, represents the reduction of cobalt(II) to metallic state.

As regards the process of the reduction of pentamminecobalt(III) complexes in dilute solution, Willis et al.[4] proposed the following mechanism;

$$[Co(NH_3)_5X]^{n+} + e^- \longrightarrow [Co(NH_3)_5X]^{(n-1)+}$$

$$[Co(NH_3)_5X]^{(n-1)+} + 6\,H_2O \xrightarrow{\text{rapidly}} [Co(OH_2)_6]^{2+} + 5\,NH_3 + X^{-n+3}$$

$$[Co(OH_2)_6]^{2+} + 2e^- \longrightarrow Co + 6\,H_2O$$

From the reduction scheme, it may be seen that the first step in the polarographic reduction of the pentamminecobalt(III) complexes corresponds to the disruption of the complexes, so its half-wave potential of the first wave may be regarded as a measure of the stability against the polarographic reduction.

The polarographic stability of the pentammine series of cobalt(III) complexes increases in the following order of the ligands;

$$I^-, Br^-, Cl^-, CrO_4^{2-}, NCS^- < NO_3^- < SO_4^{2-} < NO_2^- < S_2O_3^{2-} < C_2O_4^{2-} < CH_3COO^- < NH_3 < CO_3^{2-} < OH_2 < OH^-$$

(Supporting electrolyte; 0.1 F potassium chloride).

This order of the stability varied scarcely by the kind of the supporting electrolyte. The reverse of the order is seen between carbonate and water molecule when 0.5 F potassium sulfate was used as a supporting electrolyte.

$$I^-, Br^-, Cl^-, CrO_4^{2-}, NCS^- < NO_3^- < N_3^- < SO_4^{2-} < NO_2^- < C_2O_4^{2-} < CH_3COO^- < NH_3 < OH_2 < OH^- < CO_3^{2-}, HCO_3^-$$

(Supporting electrolyte; 0.5 F potassium sulfate).

No relation between the above order of the polarographic stability and that of the spectrochemical series[29] could be found.

Polarographic Behavior of Individual Complexes.—Some cobalt(III) complexes of pentammine series gave a "prewave" which precedes the actual second

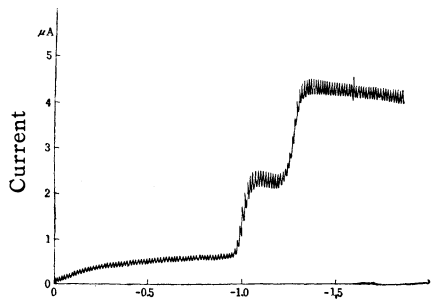

Fig. 2. The polarogram of $[Co(NH_3)_5Br]^{2+}$ at the concentration of 0.001 F in the solution of 0.1 F KCl.
The diffusion current of the second wave: 3.62 μA.
A prewave occurs at around −1.0 V.

29) Y. Shimura and R. Tsuchida, This Bulletin, **29**, 311 (1956).

wave. Brdička[30] explained the prewave as being due to the pentaquomonohydroxocobalt(II) ion formed by hydrolysis, the ion being in slow equilibrium with the hexaquocobalt(II) ion. Fig. 2 shows Brdička's prewave obtained in the reduction of bromopentamminecobalt(III) ion. Similar prewaves were found in the following ions;

$[Co(NH_3)_5I]^{2+}$, $[Co(NH_3)_5Br]^{2+}$

$[Co(NH_3)_5Cl]^{2+}$, $[Co(NH_3)_5SO_4]^{+}$

$[Co(NH_3)_5NO_2]^{2+}$, $[Co(NH_3)_5OH]^{2+}$

$[Co(NH_3)_5OH_2]^{3+}$, $[Co(NH_3)_5OCOCH_3]^{2+}$

On the other hand in the following ions the prewave was completely absent;

$[Co(NH_3)_5S_2O_3]^{+}$, $[Co(NH_3)_5SO_3]^{+}$

$[Co(NH_3)_5HCO_3]^{2+}$, $[Co(NH_3)_5CO_3]^{+}$

$[Co(NH_3)_5C_2O_4]^{+}$

The ion, $[Co(NH_3)_5NO_3]^{2+}$ shows a prewave in 0.1 F potassium chloride, but does not in 0.5 F potassium sulfate.

Thiosulfato- or sulfono-pentamminecobalt(III) ion[31] gave the first wave which had too small a slope at the reduction potential to determine its half-wave potential exactly. This is considered to be due to the aquation of the ion. In 1 F sodium sulfite a well-defined wave of the ion, $[Co(NH_3)_5SO_3]^{+}$ was obtained, because the presence of an overwhelming amount of sulfite ions causes an interruption of the aquation of the complex to some extent (Fig. 3).

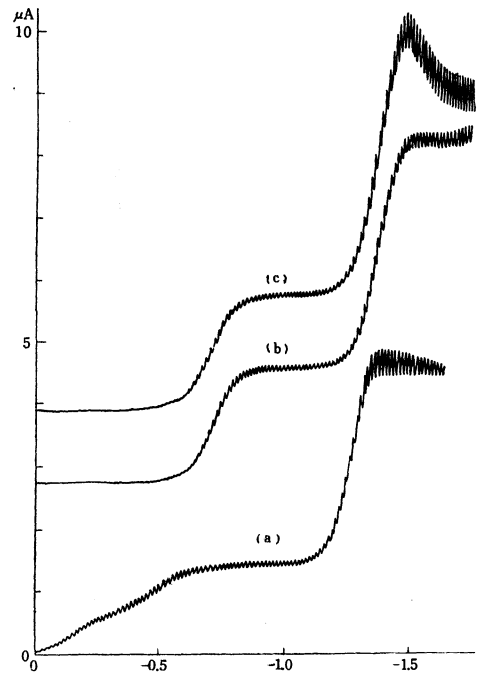

Fig. 3. The polarograms of $[Co(NH_3)_5SO_3]^{+}$ obtained at the concentration of 0.001 F in the solution of 0.5 F K_2SO_4 and of 1 F Na_2SO_3.

b) Current-voltage curve taken in the presence of 0.0032% Tween-80.
c) In the presence of 0.0065% Tween-80.
d) In the presence of 0.0097% Tween-80.

30) R. Brdička, *Collection Czechoslov. Chem. Communs.*, **5**, 113 (1933).

31) The "sulfono group" is SO_3^{2-} radical bound to the central metal ion by the sulfur atom.

The reduction potential of the second step of thiosulfato-pentamminecobalt(III) ion, $[Co(NH_3)_5S_2O_3]^+$, is -0.965 V. vs. S. C. E. in 0.1 F potassium chloride. This value is quite different from that of the other pentamminecobalt(III) complexes. This fact means that through the reduction of the thiosulfatopentamminecobalt (III) ion, a cobalt(II) complex ion was formed, which was reducible more easily than hexaquocobalt(II) ion. The cobalt (II) complex is probably thiosulfatopentaquocobalt(II) ion or a similar one.

The first wave of isothiocyanatocobalt (III) ion has a small maximum wave which can easily be suppressed in the presence of 0.0032% Tween-80.* The effect of the maximum suppressor on the wave form of the ion, $[Co(NH_3)_5NCS]^{2+}$, are shown in Fig. 4. Chromatopentamminecobalt(III) ion shows many complicated waves. This may be an overlap of the waves of the cobalt(III) complexes and of chromate ion (Fig. 5).

In a neutral solution the first wave of aquopentamminecobalt(III) complex ion has always a smaller slope at the half-wave potential than the other pentamminecobalt(III) complexes (Fig. 6). On the other hand, in 1 F perchloric acid, a well-defined wave which had a sharp slope was obtained. One of the reasons for this is considered to be the shift of the equilibrium between the aquopentamminecobalt (III) ion and the hydroxopentamminecobalt(III) ion.

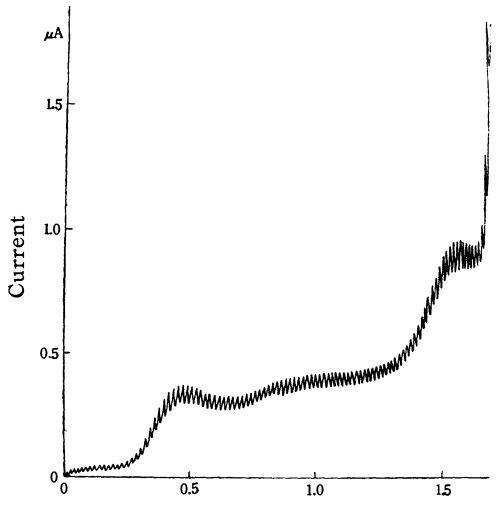

Fig. 5. The polarogram of $[Co(NH_3)_5CrO_4]^+$ obtained at the concentration of 0.001 F in the solution of 0.5 F K_2SO_4.

* Polyoxyethylene sorbitan mono-oleate.

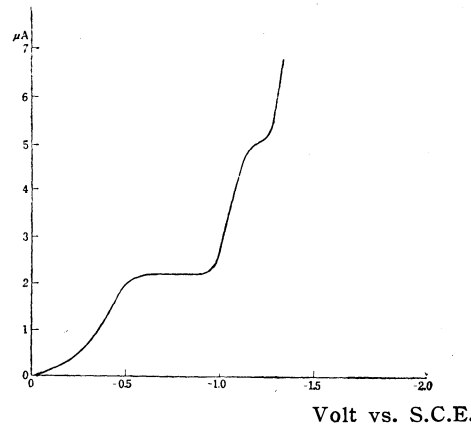

Fig. 6. Current-voltage curve of $[Co(NH_3)_5OH_2]^{3+}$ at the concentration of 0.001 F in the solution of 0.1 F KCl.

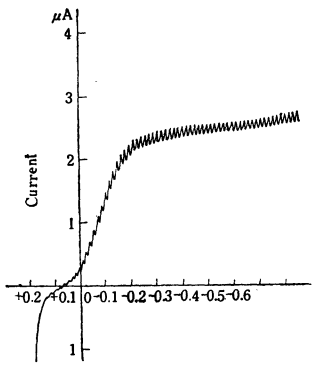

Fig. 7. The polarogram of $[Co(NH_3)_5OH_2]^{3+}$ obtained at 0.001 F in 1 F $HClO_4$. $E_{1/2}$ and i_d, respectively, -0.045 V. and 2.25 μA.

$$[Co(NH_3)_5OH_2]^{3+} \rightleftarrows [Co(NH_3)_5OH]^{2+} + H^+$$

In perchloric acid the above equilibrium is markedly shifted to the left hand. Consequently the well-defined wave of the aquopentamminecobalt(III) ion could be obtained (Fig. 7).

Summary

1. Most of the cobalt(III) complex ions of pentammine series, $[Co(NH_3)_5X]^{(3-n)+}$, are reduced irreversibly in two steps at the dropping mercury electrode. The first diffusion current corresponds to the reduction, cobalt(III) → cobalt(II) and the second to the reduction, cobalt(II) → cobalt (0). The diffusion current and concentration were linearly related.

2. The polarographic stability of cobalt (III) complexes of the pentammine series increases in the following order of the ligands;

I^-, Br^-, Cl^-, CrO_4^{2-}, $NCS^- < NO_3^-$
$< N_3^- < SO_4^{2-} < NO_2^- < C_2O_4^{2-}$
$< CH_3COO^- < NH_3 < OH_2 < OH^-$
$< CO_3^{2-}$, HCO_3^-

(Supporting electrolyte; 0.5 F potassium sulfate).

The reverse of the order was found between carbonate and water molecule when 0.1 F potassium chloride was used as a supporting electrolyte. This order did not agree with that of the spectrochemical series of the pentamminecobalt(III) complexes.

3. In dilute perchloric acid the well-defined wave was obtained for aquopentamminecobalt(III) ion, $[Co(NH_3)_5OH_2]^{3+}$, while the ion gave a modified wave in the first reduction step in neutral supporting electrolyte, potassium chloride or potassium sulfate.

The authors wish to thank Dr. J. Fujita for his kindness in giving them some of the complex compounds used in this study.

Studies on the Cephalin of Escherichia Coli

By Masaharu KUROKAWA, Kyoko HOTTA, Tomoko YOSHIMURA, Mitsuo MAKITA and Ichiro HARA*

(Received June 16, 1958)

To investigate the lipids of gramnegative bacilli two procedures are available. One of these is concerned with the lipids extracted directly from bacilli[1] and the other is carried out on the lipids of lipopolysaccharide protein complxes isolated from bacteria. The lipopolysaccharide-protein complexes of gramnegative bacilli are designated as O-antigen[2]. According to Westphal and Lüderitz[3], lipopolysaccharide-protein complexes are divided into several components as represented in Fig. 1.

Fig. 1
Lipopolysaccharide-lipid-protein complex (Vollantigen)

There were two kinds of lipid in the complex; one of these, designated as lipid B, was separated readily in contrast to the other lipid A, which could be extracted only by treatment with chloroform-ethanol mixture containing hydrochloric acid. The latter was also designated as the bound lipids by Čmelik. Lipid B was regarded as cephalin and like phospholipid, nonantigenic.

This report accounts for the chemical nature of the lipid B(possibly containing some lipid A), which was isolated to investigate the antigenic properties, especially of hapten or testantigen to anti-E. coli rabbit sera. Serological and biological properties of this lipid fraction will be reported later.

Experimental

Preparation of crude toxic substance.—A culture of *E. coli* 0—23 was autolyzed at 37°C for 48 hr. by addition of chloroform. Zinc complex of crude toxic substance was precipitated from the culture by adding 50% solution of zinc chloride in proportion of 20 ml./l. of the culture. The zinc complex was separated by centrifuge, treated with 40% disodium phosphate solution, and centrifuged to remove zinc phosphate. The supernatant was dialyzed against distilled water. The dialyzate was treated with its twothirds

volume of saturated ammonium sulfate solution to precipitate crude toxic substance. The precipitate of crude toxic substance was dialyzed toxic and then lyophilized. Total yield of crude substance was 1 g. per 10 l. culture.

In the paperelectrophoretic pattern (Fig. 2), three peaks were shown by protein staining[4] and two peaks by lipid staining[5], but no further purification was carried out.

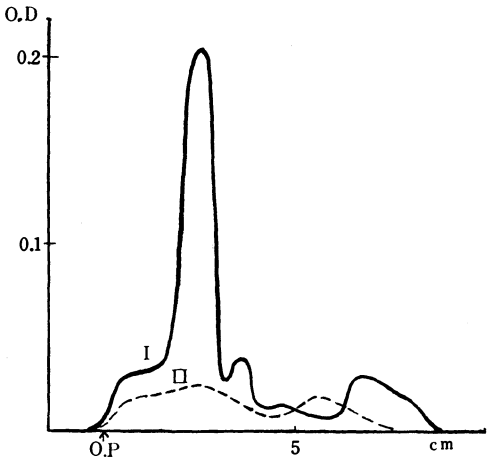

Fig. 2. The paperelectrophoretic pattern. I—Protein, II—Lipid, 0.2 mA/cm; 17 hr's electrophoresis. Veronal buffer pH 8.6, μ 0.05. Filterpaper Tōyō-roshi No. 51

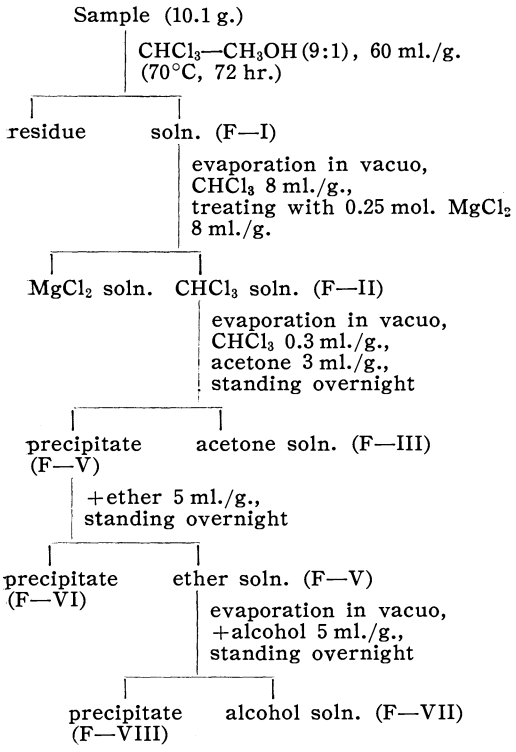
Chemical analysis.—Phosphorus was assayed by King's method[6]. One to two mg. of lipids was digested with 1.2 ml. of perchloric acid, and then colorimetrically determined with 1.0 ml. of 5% ammonium molybdate solution and 0.5 ml. of 1-amino-2-naphthol-4-sulfonic acid solution (0.25 g. of 1-amino-2-naphthol-4-sulfonic acid in 125 ml. of water containing 15 g. of sodium bisulfite and 3 g. of sodium sulfite). Total nitrogen was assayed by the micro Kjeldahl procedure. After hydrolyzing the lipids according to the procedure described in the next section, the main chemical constituents were analyzed respectively. Cholin was assayed by Entenman's method[7]. To the hydrolyzate containing 100 mg. of cholin was added the ammonium reineckate solution (2 g. of ammonium reineckate in 100 ml. of 1.2 N hydrochloric acid). The precipitated cholin reineckate was dissolved in acetone and colorimetrically determined at 500~570 mμ. Serine and ethanolamine were assayed by Axelrod-Reichenthal's method[8]. To the hydrolyzate containing 100 μg of serine and 50 μg ethanolamine was added 0.1 ml. of dinitrofluorobenzene (DNFB) reagent (0.1 ml. of DNFB in 2ml. of absolute ethanol). The dinitrophenyl ethanolamine (DNP-EA) was extracted with chloroform, dinitrophenyl serine (DNP-S) remaining in aqueous solution. DNP-EA and DNP-S were colorimetrically determined at 420 mμ. Total glycerophosphoric acid was determined by Burmaster's method[9]. To the hydrolyzate containing 10~50 μg. of phosphorus were added 1 ml. of 4% sodium sulfite solution, 1 ml. of 10 N sulfuric acid, 1 ml. of 7% sodium molybdate solution and 1 ml. of stannous chloride solution (40 g. of stannous chloride was dissolved in 100 ml. hydrochloric acid and 1 ml. of this solution was diluted with 200 ml. of distilled water). According to this procedure, the inorganic-phosphate phosphorus (Inorg.-P) was colorimetrically determined at 540 mμ. To the hydrolyzate containing 10~50 μg of phosphorus were added 1 ml. of 10 N sulfuric acid and 1 ml. of 0.05 M periodic acid. This solution was immersed in boiling water for 1 hr. and to this were added 1 ml. of 4% sodium bisulfite solution, 0.5 ml. of 10 N sulfuric acid, 1 ml. of 7% sodium molybdate solution and 1 ml. of the diluted stannous chloride solution after cooling. By this procedure the glycerophosphoric acid phosphorus (GPA-P) plus the inorganic phosphate phosphorus were determined. (GPA-P+Inorg-P) $-$ Inorg-P = GPA-P. Sugar was determined with anthrone reagent[10]. Neutralization values of fatty acids were also determined.

Intact lipids and their constituents in the hydrolyzates were qualitatively determined by paper chromatography on Toyo-roshi No. 51 paper with a mixture of *n*-butanol, ethylene glycol and water (4:1:3); phosphorus was identified by spraying Hanes-Isherwood's reagent[11] and amino compounds were by spraying 0.2% ninhydrin in *n*-butanol. In paper chromatography, the ascending method was used at 35°C, for 6 hr.



Fractionation and Hydrolysis.—From lyophilized crude toxic substance (10.1 g.), lipids were extracted with a mixture of chloroform and methanol (9:1 v/v) in a hot-water bath for 72 hr. Extractions were repeated 3 times with new solvents in the same way. Extracted lipids were fractionated according to the following scheme (Fig. 3).

Nitrogen-containing impurities removed from F—I with 0.25 M magnesium chloride solution by McKibbin's method[12]. Six fractions were obtained from F—II (Table I).

F—VII and F—VIII were hydrolyzed as follows, respectively: 50 mg. of lipids was refluxed with 30 ml. of saturated barium hydroxide solution for 5 hr., and then 3.25 ml. of concentrated hydrochloric acid was added. Hydrolysis was continued for 75 min. After cooling, the extraction of fatty acids was carried out thrice with each 15 ml. of chloroform. To the aqueous layer was added 18 ml. of 2 N sulfuric acid to precipitate

Fig. 3

barium sulfate. To remove the residual hydrochloric acid, vacuum distillations were repeated. Both aqueous solutions free from hydrochloric acid, were analyzed according to the procedures described above (Table II).

There was no choline in F—VII, F—VIII, and F—I hydrolyzates. It could not be seen that lecithin and sphingomyelin were contained in these fractions. The results agreed with those of many researches on the bacterial lipids. From Table II it was concluded that F-VII and F—VIII were so-called cephalin fractions. The principal nitrogen-containing constituents of F—VII and F—VIII were ethanolamine and serine respectively. Glycerophosphoric-acid contents in these fractions were 17.7% and 14.6% respectively, but these amounts were less than the calculated amounts (24% for F—VII and 22% for F—VIII), if F—VII and F—VIII consisted of only phosphatidyl ethanolamine and phosphatidyl serine respectively. There was also some inorganic phosphorus in these hydrolyzates, but its origin was obscure. Neutralization values of fatty acids of F—VII and F—VIII were 194 and 239 respectively, but detailed researches on the natures of fatty acids were not satisfactorily completed.

R_f values of paper chromatography of intact lipids and their hydrolyzates indicated similarly that F—VII consisted mainly of phosphatidyl ethanolamine and that F—VIII was a mixture of phosphatidyl ethanolamine and phosphatidyl serine. There were neither free amino acids nor related compounds in F—VII and F—VIII according to the spots of paper chromatography.

Discussion

It could be supposed from the value N/P (0.96) that F—VII contained only monoaminophosphoglyceride. The calculated amounts of phosphatidyl ethanolamine and phosphatidyl serine, based upon Table II, were 88% and 12% respectively. Glycerophosphoric acid amounts calculated from the above estimation were 23.7%, being 6% more than the observed values.

From the value N/P (0.76) it was considered that F-III might contain not only monoaminophosphoglyceride, but also phosphatidic acids. The calculated amounts of phosphatidyl ethanolamine and phosphatidyl serine were 28% and 33% respectivly. The calculated glycerophosphoric acid amount was 18.0%, being 4% more than the observed. The discrepancies of phosphor values in both cases were compensated for by inorganic phosphorus amounts, but the origins of the latter were not ascertained.

Sugars were also contained 6.9% in F—VII and 2.7% in F—VIII. There was no cerebroside because the chloroform-soluble portions of these two hydrolyzates contained no sphingosine-nitrogen. But it was considered that these are probably some sugar containing lipids, such as phosphatidylinosito-dimannoside in *Mycobacterium tuberculosis* reported by Lederer[13].

Summary

The lipids were extracted from the crude toxic substances, isolated from *Escherichia coli* by Hosoya's method[14]. These lipids which were 7.2% of the crude toxic substances by weight, were fractionated by solvents. One of these fractions, that was soluble in diethyl ether and ethanol, contained 7.0% ethanolamine and 1.5% serine, and the other that was soluble in diethyl ether, but insoluble in ethanol contained 2.0% ethanolamine and 4.6% serine. There was no choline in any fraction. Average neutralization values of fatty acids in these two fractions were 194 and 239 respectively.

The authors wish to express their deepest appreciation to Professor Susumu Mitsuhashi, M. D., Gumma University Medical School, for much useful guidance and helpful discussion.

Silica in Water. V. Salt Effect on the Colorimetric Determination of Silica in Concentrated Salt Solution*

By Iwaji IWASAKI and Toshikazu TARUTANI

(Received June 13, 1958)

In a concentrated salt solution, the amount of silica obtained by colorimetric methods (silicomolybdate and molybdenum blue method) is lower than that obtained in the absence of salt**. This phenomenon is called the salt effect or the salt error, and the ratio of the true silica content to the value obtained in the presence of salt is called the salt factor, since it gives a measure of the salt effect. Some salt factors were reported for the colorimetric determination of silica in sea water[1-5], and the salt effect was also investigated for the colorimetric determination of small amounts of silica in alkali[6]. The properties of silicomolybdic acid in a concentrated salt solution have not been studied systematically. The following experiments were carried out to make clear the properties of salt effect and to find the method for correcting the salt effect.

Silicomolybdate Method

Reagents and apparatus. — *Silica solution.*— Portions 0.500 g. of anhydrous silica were fused with 4 g. of sodium carbonate, the melt was dissolved in distilled water, and diluted to 1000 cc. Solutions of a suitable concentration of silica were prepared by diluting this stock solution.

Ammonium molybdate solution.—10%.

Sulfuric acid.—Various normalities.

Salts.—All chemicals were of analytical reagent grade or C. P. purity.

Apparatus.—Hitachi EPU-2 spectrophotometer, 10 mm. cell.

Variations of absorption spectrum of molybdate with acidity and salts.—In the measurement of absorbance of silicomolybdic acid by using a spectrophotometer or a photoelectric colorimeter, distilled water or a solution prepared by adding acid and ammonium molybdate solution to distilled water (or salt solution) is used as the reference. When the latter is used, it must be considered that the absorption spectrum of molybdate in the solution varies with acidity. The absorption spectra of molybdate in the solutions prepared by adding 2 cc. of sulfuric acid of various normalities and 2 cc. of 10% ammonium molybdate solution to 50 cc. of distilled water were measured against distilled water. The results are shown in Fig. 1. The absorption spectra of

molybdate in 0.074 N or 0.15 N sulfuric acid is almost the same as that in 0.11 N. However, in 0.037, 0.11, and 0.22 N sulfuric acid, the spectra are different from one another.

In the concentrated salt solution, the absorption spectrum of molybdate varies with the kind of salt and the concentration of salts, even when quantities of reagents added to the solution are constant. The absorption spectra of molybdate in distilled water, 1 M sodium chloride solution, and 0.5 M sodium sulfate solution, were measured against distilled water (Fig. 2). These solutions contained the same quantity of ammonium molybdate, and the concentration of sulfuric acid was 0.11 N. It can be seen that the absorption spectrum of molybdate varies with the concentration of salts and the kind of salt.

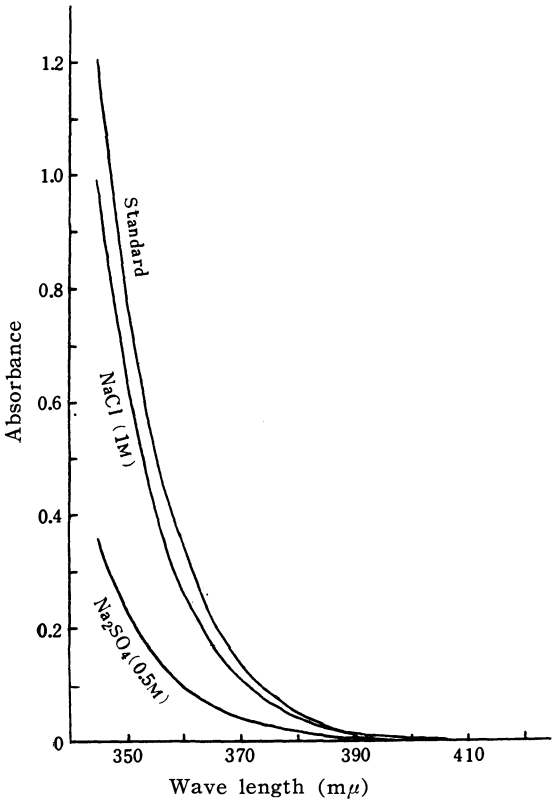

Fig. 2. Variation of absorption spectrum of molybdate with salts.

From the results shown in Figs. 1 and 2, the following conclusions may be drawn. When the solution prepared by adding definite quantities of reagents to distilled water is used for zero standard and the absorbance of silicomolybdic acid in the sample solution containing very small amounts of salt is determined, ultraviolet light can be used.

In the colorimetric determination of silica in the concentrated salt solution, when a wave length above 400 mμ is used, the solution prepared by adding definite quantities of reagents to distilled water can be used as zero standard, but when ultraviolet light is used, the solution of the same concentration of salt as the sample solution has to be used after addition of definite quantities of reagents, because the absorption spectrum of molybdate varies with the concentration of salts.

Time required for the maximum color development of silicomolybdic acid and the stability of color.—The time required for the maximum color development of silicomolybdic acid and the stability of color varies with acidity, temperature, kind of salt, concentration of salts, and quantity of molybdate. The effect of acidity, temperature, and quantity of molybdate on the time required for the maximum color development of silicomolybdic acid were already reported[7]. In a concentrated salt solution, the stability of color is smaller than that in the solution of a negligibly small salt concentration. An example is shown in Fig. 3. These experiments were carried out at 15°C. In Fig. 3, the time necessary for maximum

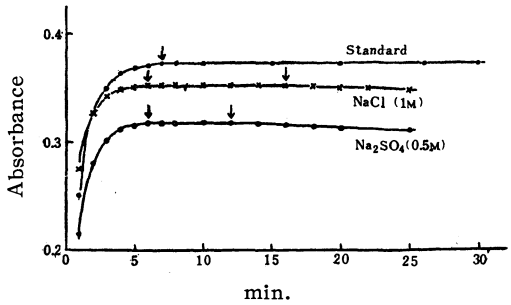

Fig. 3. Stability of color.

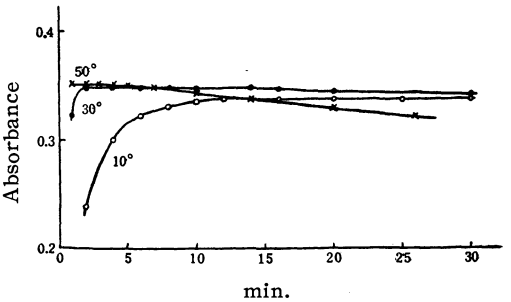

Fig. 4. Color change of silicomolybdic acid with temperature.

color development are shown by the left arrow, and the time when the color intensity begins to decrease is shown by the right arrow. The color change of silicomolybdic acid with temperature are shown in Fig. 4. These experiments were carried out by the following procedure. Fifty cc. of the sample solution containing 10 p.p.m. of silica was taken, and 2 cc. of 3 N sulfuric acid and 2 cc. of 10% ammonium molybdate solution were added, and the absorbance of silicomolybdic acid was measured against distilled water at 400 mμ. From the results shown in Figs. 3 and 4, in the determination of absorbance of silicomolybdic acid, the time required for the maximum color development must be measured to obtain an accurate result.

Salt effect.—In this section, the experiments were carried out by the following procedure. The absorbance of silicomolybdic acid in the solution prepared by adding 2 cc. of 3 N sulfuric acid and 2 cc. of 10% ammonium molybdate solution to 50 cc. of the salt solution was measured against a blank containing the same amounts of salt, molybdate and acid.

Table I summarizes the previous data on the salt factor of sea water. The value reported by Iwasaki and Tarutani is differs from others. These data are supposed to suggest that the salt effect may vary with the wave length used.

TABLE I
SALT FACTOR OF SEA WATER

Author	Apparatus used	Wave length used	Salt factor
Robinson, Chow[1]	Spectro-photometer	430 mμ	1.23
Robinson, Poor[2]	Pulfrich photometer	430 mμ (filter)	1.16
Saeki[3]	Ukena tube	—	1.25
Iwasaki, Tarutani[4]	Duboscq colorimeter	—	1.09
Mullin, Riley[5]	Spectro-photometer	812 mμ (Mo-blue)	1.1

Therefore, the salt effects were measured at various wave lengths (Fig. 5). The concentration of silica in the salt solution was 10 p. p. m. The ordinate in Fig. 5 is the ratio of the absorbance of salt solution to the absorbance of standard silica solution. As will be seen in Fig. 5, the salt effect varies with wave length used and the salt effect at a longer wave length is greater than that at shorter wave length. And also the salt effect varies with the kind of salt, for example, the effect of sulfate is greater than that of chloride. In the salt solution having large salt effect e. g. ammonium sulfate solution, the variation of salt effect with wave length is large, but in the salt solution having smaller salt effect, e. g., sodium chloride solution, this variation is small.

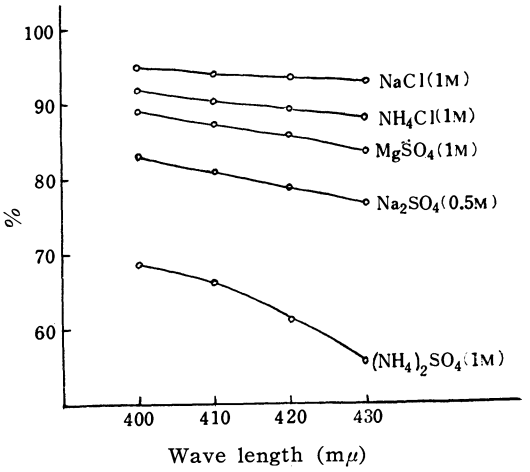

Fig. 5. Salt effect.

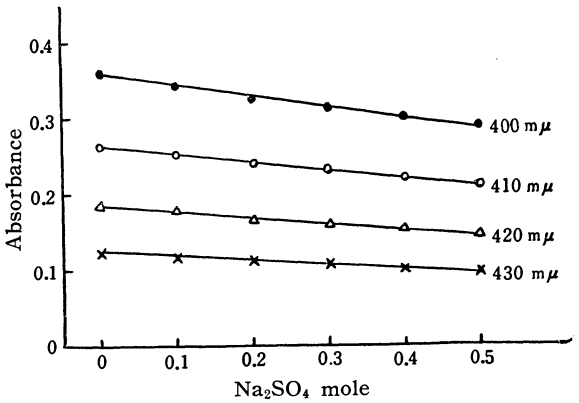
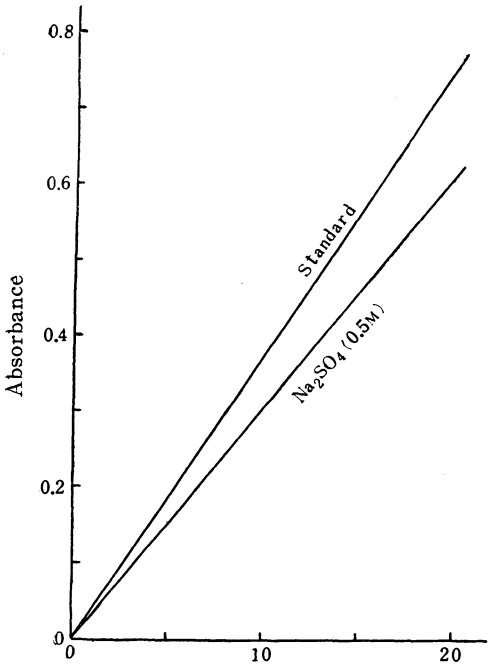
The absorbance was measured for a number of concentrations of sodium sulfate solution containing 10 p. p. m. of silica (Fig. 6). The straight line was obtained and it is shown that the salt effect is proportional to the salt concentration.





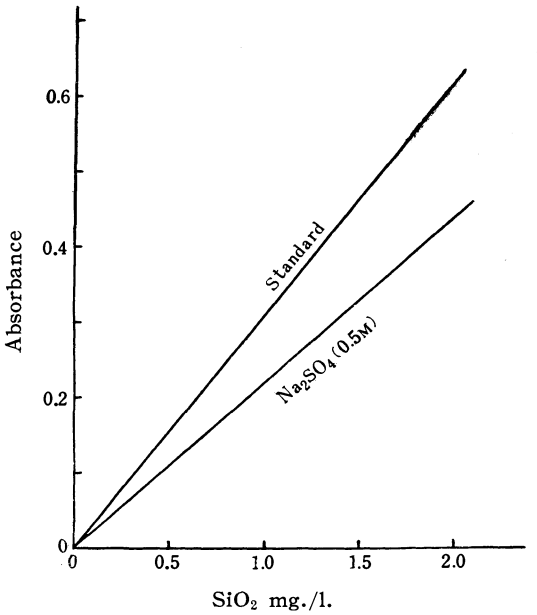


Fig. 6. Relation between absorbance and Na_2SO_4 concentration.

The absorbance was measured for different concentrations of silica in distilled water and in 0.5 M sodium sulfate solution (Fig. 7). Wave length of 400 mμ was used. A straight line was obtained. The absorbance of silicomolybdic acid in the salt solution obeys Beer's law. The ratio of the slopes of the two straight lines obtained for distilled water and salt solution gives the value of salt factor.

SiO_2 mg./l.

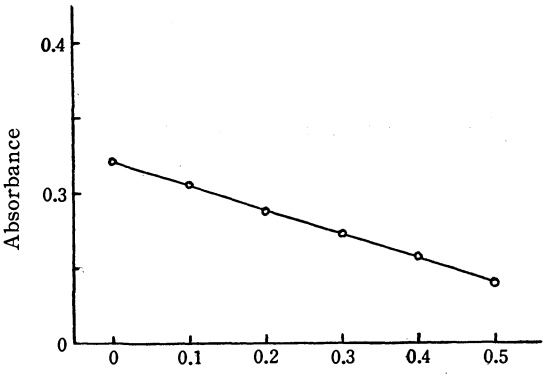
Fig. 7. Calibration curve.

SiO_2 mg./l.

Fig. 8. Calibration curve.

Molybdenum Blue Method

Reagents.—*Sulfuric acid.*—3 N.



Ammonium molybdate solution.—10%.

Reducing agent. — Twenty grams of sodium bisulfite, 2 g. of anhydrous sodium sulfite, and 0.5 g. of 1-amino-2-naphthol-4-sulfonic acid were dissolved in 200 cc. of distilled water, and stored in an amber-colored glass bottle.

Experiments.—Fifty cc. of a sample solution was taken, and 2 cc. of 3 N sulfuric acid and 2 cc. of 10% ammonium molybdate solution were added. After the color of yellow silicomolybdic acid reaches maximum, 5 cc. of reducing agent was added. After the color of molybdenum blue reaches maximum, the absorbance was measured against a blank containing the same amount of reagents at 820 mμ. Fine crystals sometimes separated out from the solution, when the concentration of salts were very high and temperature was low.

The absorbance was measured for different concentrations of silica in distilled water and in 0.5 M sodium sulfate solution, and the results obtained are shown in Fig. 8. Straight lines were obtained—i. e. the absorbance of molybdenum blue complex in the salt solution obeys Beer's law as in silicomolybdate method, and the ratio of the slopes of two straight lines gives the salt factor.

The variation of salt effect with wave length was not measured, but in this method, the salt effect will vary with wave length as in the silicomolybdate method. The absorbance was measured for a number of concentrations of solution containing 1 p.p.m. of silica (Fig. 9). A straight line was obtained. The salt effect is proportional to the salt concentration.

Na_2SO_4 mole

Fig. 9. Relation between absorbance and Na_2SO_4 concentration.

Conclusion

1) Wave length, kind of salt, and concentration of salts are important factors which affect the salt effect in both silicomolybdate method and molybdenum blue method.

2) In the silicomolybdate method, the salt effect is great at a longer wave length. Also, it varies with the kind of salt. The effect of sulfate is greater than that of chloride.

3) The absorbance of both silicomolybdic acid and molybdenum blue complex

in a salt solution obeys Beer's law, when the concentration of salt and reagents are maintained constant, and a definite wave length is used.

4) In the salt solutions containing definite quantities of silica, the absorbance decreases linearly with salt concentration under the conditions described above.

5) From the properties of salt effect mentioned above, it is possible to explain the reasons that several different salt factors were reported for sea water by different authors.

6) In order to obtain the true silica content in the concentrated salt solutions by the colorimetric method, one of the following procedures may be used.

(a) A sample solution is diluted with distilled water to the extent that the salt effect can be neglected, and then absorbance is measured.

(b) The calibration curve is made by using the same concentration of salt as that of the sample solution.

(c) The calibration curve is made by using the standard silica solution, and it is used for the determination of silica in a concentrated salt solution. The concentration (A) of silica in the sample solution is determined and the concentration (B) of silica in the sample solution diluted twice with distilled water is measured. The true silica content (S) can be obtained by the following formula.

$$S = A + 2(2B - A)$$

The cost of this research was defrayed from the Scientific Research Encouragement Grant from the Ministry of Education, to which the authors wish to express their thanks.

Antioxygenic Activity of Lecithin and its Hydrolysis Products. II. α- and β-Glycerophosphoric Acids*

By Chieko URAKAMI, Haru KAMEYAMA and Mitsuko OKADA

(Received May 30, 1958)

Since the last paper on the subject[1] was published, we have observed considerable variations in the activities of α- and β-glycerophosphoric acid with different batches of crude oleic acid obtained from beef tallow. Thus it became necessary to find some means of overcoming this difficulty. In the method of purification by low temperature crystallization, it was found difficult to remove acetone completely and we suspected that some impurities soluble in acetone might have been carried over to the final product to give these varied results. This difficulty was overcome, however, by crystallizing oleic acid as urea complex. The samples of the substrate purified in this way gave rather consistent results.

Further evidences were obtained as to the formation of oil-soluble products from both α- and β-glycerophosphoric acid during autoxidation, as suggested in the previous paper, by applying chromatographic techniques and measuring the ultraviolet absorption of the fractions obtained.

Experimental

Materials.—*Oleic acid.*—Crude oleic acid from beef tallow was supplied by the laboratory of Nihon Yushi Co., Ltd. Olive oil was treated according to the procedure described by Knight, et al.[2] to obtain crude oleic acid. These crude products were purified by the following two methods: *Method A*; The samples were purified by low temperature crystallization from acetone, as described in the previous paper. *Method B*;

* The preceding paper (This Bulletin **29**, 921 (1956).) will be designated as Part I of the series under this new title.

α-Glycerophosphoric acid.—An ethanolic solution of the free acid was prepared from the sodium salt (procured from Daito Seiyaku Co., Ltd.) in the same manner as described in the previous paper[1]. This sample was found to contain about 21% β-glycerophosphoric acid and was used in the experiments with oleic acid. A sample containing 14% β-isomer was prepared by isomerization in an acid medium[4] and used in the runs with methyl oleate.

β-Glycerophosphoric acid.—An ethanolic solution was prepared from its sodium salt (obtained from Yashima Yakuhin Co., Ltd.) as described above. The sample was found to be 100% pure. The concentrations of the ethanolic solutions were determined by Burmaster's method[5].

Autoxidation.—The procedure employed was essentially the same as that described previously, except that the bath temperature was maintained at 45°C for the runs with methyl ester, instead of 50°C used for runs with the acid. The concentration of the glycerophosphoric acids in the substrate was 0.1%.

Peroxide determinations. — The method described in the previous paper was followed, except that the use of nitrogen gas was omitted. As shown in Table III, the values obtained by titration under nitrogen did not significantly differ from those obtained without bubbling nitrogen through the sample solution, as long as one to two drops of a 0.05% solution of hydroquinone in isopropanol had been added to each aliquot taken.

TABLE III

Under nitrogen	0.1824	2.54
	0.2107	2.53
In air	0.2180	2.52
	0.1926	2.58

Recovery test.—The recovery of the water-soluble glycerophosphoric acids from the substrates during autoxidation was examined in the same manner as described previously. The results are shown in Figs. 1 and 2 and Table IV.

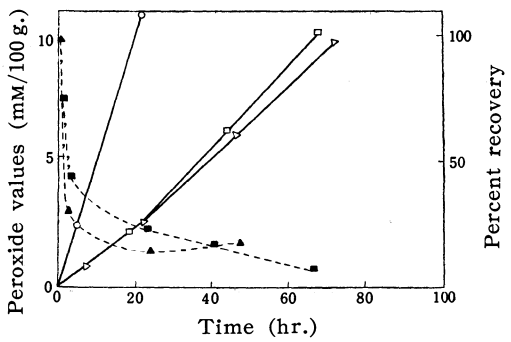

Fig. 1. Peroxide values and percent recovery against time.
○ Oleic acid, O-1, alone. △ Peroxide values for the same sample of oleic acid containing 0.1% α-glycerophosphoric acid (79% purity). □ Peroxide values for the same sample of oleic acid containing 0.1% β-glycerophosphoric acid. ▲ Percent recovery of the α-glycerophosphoric acid. ■ Percent recovery of the β-glycerophosphoric acid.

Chromatography. — Since the method described by Huennekens and his associates[6] affords separation of oleid acid from phosphorus containing substances of biological interest, we utilized the method in removing the substrate from the substance which seemed to be formed from the glycerophosphoric acids added initially. The

a) Methyl oleate obtained from beef tallow containing 7% α-isomer. The ratio of the recovered α:β before and after oxidation remained the same, 70:30. b) Methyl oleate obtained from olive oil containing 0.1% α-isomer. c) Oleic acid from olive oil containing 0.1% β-isomer. The figures in the parentheses represent percent recovery.

last two samples shown in Table IV were subjected to chromatography, after removing any unreacted glycerophosphoric acids by repeated washing with water.

By a trial run with paper, using about 200 mg. each of the samples and a mixture of 1-propanol and water (8:1) as a developing solvent (at 21°C for 15.5 hr.), it was found that a significantly large amount of phosphorus was present in the upper half (toward the solvent front) of the chromatogram. This was somewhat more concentrated in the section 3/4 from the original point of application. Therefore, the upper half of the chromatogram was extracted successively three times with a 50 cc. portion of diethyl ether, twice with 25 cc. of ethanol and finally with 10cc. of a 0.1 N solution of sodium hydroxide. Each extract was tested for the presence of phosphorus and it was found to be present only in the alkaline extract. Therfore, the same sample was subjected to column chromatography in the same manner, using cellulose powder (Toyo-Roshi No. 50), except that a larger amount of diethyl ether was used in place of extracting with ethanol. A blank run was made in exactly the same way. The ultraviolet absorption curves obtained with the ether extract are shown in Fig. 9 and those of the alkaline extracts in Fig. 10 (corrected for the absorption of the blank).

Measurements of ultraviolet absorption.— A Beckman DU-spectrophotometer was used. For the purpose of comparison of the sample obtained from the incorporation of the α- and that from the incorporation of the β-isomer, the extinction coefficients were calculated on the basis of mg. %* of phosphorus since their molecular weights are unknown.

Results

In the present study with oleic acid obtained from two different batches of beef tallow and purified by Method A, both glycerophosphoric acids were found to be active in a comparable strength (see Figs. 1 and 3) but marked differences in activity were observed in the methyl ester prepared from the corresponding sample of oleic acid. In one sample the β-isomer was found to be strongly active, while the α-isomer almost inactive in the early stages of autoxidation as shown in Fig. 2. The activity shown in the later stages is considered to be due to the presence of some 14% β-isomer since the curve obtained by another run with the α-isomer containing 21% β-isomer runs closely parallel to the one shown here, except with an increased activity in the later stages. In

* This expression is used for a matter of convenience instead of the conventional expression, for the products have neither been isolated in pure form nor characterized. However, the estimated values for their molecular extinctions at certain characteristic wave lengths are given in the discussion section.

another sample of the substrate, on the other hand, both acids were found to be active in comparable strength as shown in Fig. 3, although some difference was observed in the later stages. These results are not only in disagreement with our previous finding but also are peculiar in that the activity of the same substance differs in oleic acid and in the methyl ester prepared from the corresponding sample of oleic acid. (Fig. 1 and 2).

The results of the recovery of the glycerophosphoric acids in the aqueous phase during the autoxidation (see Fig. 1 and 2) show, however, that a marked decrease in recovery occurs in the first several hours regardless of whether or not the activity is observed, although a somewhat gradual decrease is shown with the α-isomer during the period in which its activity is depressed. Therefore, it is considered that some minor impurities which could not be removed by low-temperature crystallization from acetone may have interfered so as to give the varied results observed, rather than the difference in the configurations of the glycerophosphoric acids as we suggested in the previous paper.

In the methyl oleate prepared from beef tallow and purified by Method B, both acids were found to be active in an equal strength, (Fig. 4). Comparable results were obtained in oleic acid and its methyl ester prepared from olive oil and purified by the same method, (Figs. 5 and 6). In the latter case, the α-isomer was found to be consistently somewhat more active than the β-isomer. When samples of the substrate obtained from olive oil purified by Method A were used (not presented here), on the other hand, a marked difference in activity was observed, the α-isomer being more strongly active than the β-isomer. It should be pointed out, however, that the β-isomer in methyl oleate did not show activity up to a peroxide value of 10 mM/100 g. but a strong activity in the later stages, Fig. 6. This might have been the case with the β-isomer in the previous report where the experiment was carried out up to this level of peroxide value.

From these results, it is probably certain that α- and β-glycerophosphoric acid are active antioxidants of a comparable strength at a concentration of 0.1%. It is also evident from these results that the purification by low-temperature crystallization from acetone is unsuitable for the study of this nature. Accordingly, those results obtained by using substrates which have been purified by merely repeating distillation of saponified products of fats should be subjected to re-examination.

Fig. 4. Fig. 6. Peroxide values against time. ○ Methyl oleate, M-4, alone. △ The same sample of methyl oleate containing 0.1% α-glycerophosphoric acid (86% purity). □ The same sample of methyl oleate containing 0.1% β-glycerophosphoric acid.

The absorption spectra observed in the region longer than 300 mμ in Fig. 7 are due to the presence of the α-isomer at a concentration of 7% since the E values calculated for the sample of glycerophosphoric acid employed (see Fig. 8) are much greater than those of the substrate before and after autoxidation (see Fig. 9). Therefore, the absorption spectrum observed after 87.5 hours' autoxidation indicates the presence of a substance other than the glycerophosphoric acid itself, probably a substance formed from it during the autoxidation.

With a low concentration of either α- or β-glycerophosphoric acid as actually used (0.1%) for testing their antioxygenic activities, it would be in possible to observe such an absorption in the ultraviolet region before autoxidation but it should be possible after autoxidation, only, however with the sample to which the α-isomer has been incorporated. This is shown in Fig. 9 A where the curve indicated by the solid line represents the absorption due to the presence of an intensely absorbing substance since the substrate isolated from it by the chromatographic means shows a lower intensity of absorption (dotted line). This sort of observation would not be possible with the

The lower curve, β-glycerophosphoric acid.

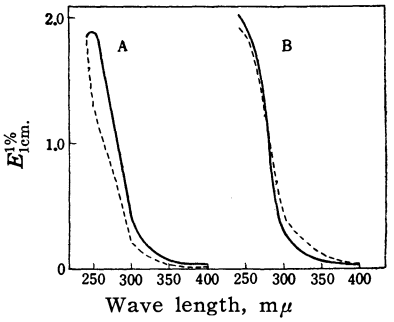

Fig. 9. Absorption curves of the ether solutions of: A, solid line, methyl oleate containing 0.1% α-glycerophosphoric acid (sample b, Table IV); dotted line, the ester isolated by the column chromatography. B, solid line, oleic acid containing 0.1% β-glycerophosphoric acid (sample c, Table IV); dotted line, oleic acid isolated by the column chromatography.

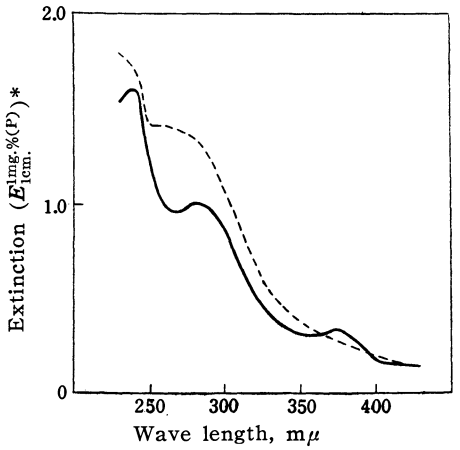

Fig. 10. Absorption curves of 0.1 N sodium hydroxide solutions of the phosphorus containing substances isolated by the column chromatography: dotted line, from the α-glycerophosphoric acid added sample (sample b, Table IV); solid line, from the β-glycerophosphoric acid added sample (sample c, Table IV).

β-isomer since the absorption of its ethanolic solution is much less intense than that of the α-isomer (see Fig. 8), and this found to be the case as shown in Fig. 9B where the absorption curve of the isolated substrate coincides with that of the substrate to which the β-isomer has been added.

Fig. 10 shows the absorption spectra of the phosphorus-containing substances found to be present in the alkaline extracts of the column chromatograms. They differ from those of the glycerophosphoric acids (see Fig. 8). The unknown substance which appears to be formed from β-glycerophosphoric acid shows $E_{1cm}^{1mg\%(P)}$ 1.6 at 240 mμ and 1.0 at 380 mμ and 0.96 at 270 mμ, an inflection. The substance believed to be formed from the α-isomer does not show a sharp maximum but an inflection at 250 mμ with $E_{1cm}^{1mg\%(P)}$ 1.42. This substance is probably a mixture of at least two compounds, one formed from the α- and the other from the β-isomer since the sample incorporated contained some 14% β-isomer and no isomerization is apparent as indicated in Table IV.

Discussion

Although varied reactivities of α- and β-glycerophosphoric acid were observed in different samples of the substrate, both must be active antioxidants since the consistent results could be obtained when highly purified oleic acid and methyl oleate were used. This may reasonably be supported by the isolation of the unknown substances with high intensity of absorption in the ultraviolet region from the substrates to which both α- and β-glycerophosphoric acid have been incorporated.

The antioxygenic activity of the glycerophosphoric acids may, however, be secondary in nature; that is, the unknown substances formed during autoxidation may be responsible for the activity observed, rather than the glycerophosphoric acids themselves. It is unlikely that the involvement of the glycerophosphoric acid molecule is analogous to that of hydroquinone where the molecule itself is ultimately oxidized to quinone after terminating free radical chain reactions by reacting with peroxy radicals[7]. Strong indications for this are that recovery of the glycerophosphoric acids drops sharply in the early stages of autoxidation and that the unknown substances with high intensity of absorption in the ultraviolet region can be isolated from samples which are still exhibiting antioxygenic activity, Table IV and Figs. 7 and 10.

Assuming the molecular weight of the unknown substances to be about 436, (which is the sum of the molecular weight of oleic acid and that of the glycerophosphoric acid minus a mole of water and is considered to be the lowest limit of those oxidized products retaining the original carbon chain length) their molecular extinctions are calculated to be about 42,000 at 270 mμ, at the inflection of the solid line (Fig. 10), and 70,000 at 240 mμ (the maximum). These values are probably higher than those calculated from absorption measured in non-polar solvents but they, nevertheless, indicate that the K-bands are involved. The absorption curve with λ_{max} at 240 and 380 and $\lambda_{infl.}$ at 270 resembles, in its general trend, those reported for oxidized products of ethyl oleate[8] and for the olefinic keto-acids[9]. Therefore, it appears that the glycerophosphoric acids have reacted with some highly conjugated form of compounds produced from the substrate molecule by a free-radical attack during autoxidation.

These results do not reveal, however, whether the phosphoryl group of the glycerophosphoric acid molecule is involved in such a reaction. Because compounds with the same absorption characteristics can possibly be formed, too, if a coordination takes place between a radical of a highly conjugated form (produced from the substrate molecule) and a radical of the glycerophosphoric acid involving the glycerol moiety, or between the former and inorganic phosphoric acid released from the glycerophosphoric acid, as a result of a free radical attack on the glycerol moiety, has been observed to take place in aqueous solutions by irradiation of ionizing radiations[10]. The latter case is least feasible, however, in the system under consideration. Some evidence for this can be provided by the results obtained here. If it had occurred, the absorption band indicated by the solid line in Fig. 9 A or the absorption spectrum observed after 87.5 hours of autoxidation (see Fig. 7) would not have been detected since the *E* value

of orthophosphoric acid in ethanol at λ_{max} 250 mμ is 0.024(measured in our laboratory) and its extinction even at a concentration of 7% is less than 0.167, which is smaller than the E value of β-glycerophosphoric acid, 0.18 at 265 mμ. The β-isomer does not show absorption of the product in the presence of the substrate, (Fig. 9B). The question as to the former case will be treated in a later paper. A highly probable case is, however, participation of the phosphoryl group since phosphoric acid or its alkaline acid salts are known to add readily to ethylene oxide[11] or react with hydroperoxides obtained from lard[12].

Confirmation of the structures of the unknown substances containing phosphorus and exhibiting the high intensity of absorption in the ultraviolet region is of great importance in providing information as to requirements of molecular structures of phosphorus containing compounds of this nature for antioxygenic activity. It also appears to be important from the standpoint of elucidating free radical chain reaction mechanism which is yet obscure and of current interest to a number of workers[8,9,13-15]. The method employed in the present work for the isolation of the unknown substances may find its usefulness in the study of structures of products formed in early stages, if not primary products of a free-radical attack, of autoxidation of ethylenic compounds.

Summary

It has been demonstrated that the method of purification of the substrate by low temperature crystallization is not suitable for the study of antioxidant activity of the glycerophosphoric acids and that further purification by crystallization as the urea complex gives consistent results. In such a highly purified substrate, both acids have been found to be active in a comparable strength.

The study of ultraviolet absorption of the phosphorus-containing substances isolated by the column chromatography has shown that the glycerophosphoric acid molecule acquires a highly conjugated system during autoxidation. Discussions have been presented as to possibilities incurred in the formation of such highly conjugated compounds.

*Rapid Analysis of Gamma-Emitters Using Gamma-Ray Scintillation Spectrometer. II. Determination of ^{137}Cs in Fission Products**

By Fumio AOKI, Seishi YAJIMA** and Toshio KUROSAWA

(Received June 20, 1958)

The rapid and accurate determination of ^{137}Cs in fission products is very important for instance, in the determination of the "fine structure" of the fission yield curve, or in the treatment of the fuel elements and radioactive wastes.

Beta-ray assay, which has been generally used, involves many tedious procedures and requires skill[1], because the object must be isolated prior to the activity measurement. The chemical yield through the procedures is not always highly reliable.

A gamma-ray scintillation spectrometer has been favorably used owing to the speediness of its procedure and

eliability. But when the sample contains nany gamma-emitters, it is, in general, lifficult or impossible to determine the ndividual activity accurately without separation, because of the possible superposition of the spectra of the gamma-rays.

Peirson[2] analysed the fission products from uranium 235 without chemical separations using a two-crystal gamma-ray scintillation spectrometer, which does not give rise to the Compton continua but shows only the photopeaks in the recorded spectrum. Even if such an excellent instrument is available, chemical separations will still be necessary in such cases as:

i) When the gamma-energy of a nuclide in question can not be resolved from superposing spectra of other nuclides.

ii) When the gamma-intensity of the nuclide is weak and overwhelmed by those of others.

Woodhead et al.[3] determined the activity of ^{137}Cs in fission products. They separated ^{137}Cs solely by anion exchange resin using carriers, and measured its gamma-intensity with a gamma-ray scintillation spectrometer. If it were not necessary to separate ^{137}Cs solely, the procedures would become more simple.

The authors have worked out a method for the rapid determination of ^{137}Cs in fission products combining the partial separation of nuclides with anion exchange resin followed by gamma-ray spectrometry.

Method. — *Extraction of Uranium.* — The bulk of the uranium is extracted from the solution of the irradiated fuel elements with a mixture of tributyl phosphate (T. B. P.) and diethyl ether. (1 : 1), together with most of neptunium formed. The residual neptunium is removed by the resin treatment shown below (Table I). In this process the loss of ^{137}Cs is in the order of 10^{-5}, which is negligible in its determination.

Anion Exchange.—In treating the fission product solution, free from uranium, by a mixed bed of carbonate- and oxalate-form anion exchange resin (see section III), alkali metals go completely through the column together with some of alkali earths, while almost all of the other ions are retained in the column[4].

The leakage of alkali earths is reduced by the addition of strontium ions. Tables

40	42	0
60	42	0

I and II show the retention and leakage of some elements.

Measurement.—The fission product solution after the resin treatment will contain ^{140}Ba-^{140}La and ^{137}Cs-^{137m}Ba, when it is short-aged, and ^{137}Cs-^{137m}Ba only, when it is long-aged. (^{133m}Cs and ^{135m}Cs are also formed in fission, but their lives are extremely short. ^{135}Cs, the daughter of ^{135m}Cs, emits no gamma-ray and its life is very long. They are all left out of consideration.)

The activity of ^{137}Cs is represented by the peak height of 0.661 MeV gamma of ^{137m}Ba in equilibrium with ^{137}Cs, the parent. Some of ^{137m}Ba is retained in the resin column, but the parent and daughter soon (about 30 min. after the resin treatment) reach a state of equilibrium. Because of the short half life of ^{137m}Ba (2.6 min.) compared with that of ^{137}Cs (30 y.), the difference between the activities of ^{137m}Ba in equilibrium before and after the resin treatment is negligible.

^{140}La, originally present in the sample, is also removed by the resin treatment, but it grows form ^{140}Ba in the effluent and reaches a state of equilibrium within a week.

When the effluent is measured by a scintillation spectrometer for long-aged samples, the 0.661 MeV peak height gives the activity of ^{137}Cs without correction, because no other nuclides are present. But when the sample is short-aged, the peak is superposed by the Compton pulses of ^{140}Ba-^{140}La gammas, which must be subtracted from the observed peak

2) D. H. Peirson, *Brit. J. Appl. Phys.*, **6**., 444 (1955).

height[5]. The correction factor depends on the crystal dimensions and geometry. In our case pure ^{140}Ba-^{140}La source (in equilibrium) gives Compton pulses of 59% of the 0.82 MeV peak height at the photo-peak of ^{137m}Ba gamma.

Experimental

Chemical Procedures.—Two kinds of sample were prepared, one for the long-aged and the other for the short-aged, which are:

a) F. P. (about 0.4 μC) + uranyl nitrate (several mg.) + pure ^{137}Cs solution (x ml).

b) Sample a) (F. P. and pure ^{137}Cs activities suffered a little change) + ^{140}Ba-^{140}La (about 0.2μC)*.

The cooling time of the fission products, which had been supplied by United State Atomic Energy Commitee, was about 3 years. The quantity of the ^{137}Cs (x) was taken as 0, 0.1, 0.3, 0.5, 0.75, 1.0, 1.25, 1.5, 1.75 and 2.0. One ml. of the pure ^{137}Cs solution corresponded to about 0.01 μC and 0.05 μC in sample a and b, respectively. Other elements of fission products than ^{140}Ba-^{140}La are almost completely retained in the resin column; hence they were left out of consideration. After the samples were dissolved in 50 ml of 5 N nitric acid, uranium was extracted with a mixture of T. B. P. and diethyl ether (1 : 1).

The same quantities of two forms of anion exchange resin (Dowex 1—X7.5, 50—100 mesh, treated by 5% oxalic acid solution and by 10% ammonium carbonate solution) were mixed in a beaker. After carbon dioxide gas was thoroughly removed, a column of about 6 mm. in diameter and 100 mm. in length was set up out of the mixture.

Each fission product sample in nitric acid solution free from uranium was taken in a beaker. After evaporating off most of the nitric acid, the residue was dissolved in 20 ml. of 3 N hydrochloric acid solution and again evaporated to dryness. This process was taken so that the resin column could retain almost all ^{106}Ru, which had been proved empirically. Each of the short-aged samples was dissolved in 20 ml. of 0.5% ammonium chloride solution which contains 30 mg. of strontium ion. The pH value was adjusted to 9 with aqueous ammonia solution. The solution was allowed to run through the resin column followed by a passage of 30 ml. of 1% aqueous ammonia solution. Each effluent was concentrated to 2 ml. and transferred to a polyethylene tube in order to measure the gamma-intensity in the same condition.

Measurements.—The same scintillation spectrometer as that used in the previous study[6] was used. One week after the resin treatment, the samples in polyethylene tubes were placed in the well of the sodium iodide (activated with thallous ions) crystal and the activity was measured. Typical gamma-ray spectra of the samples are shown in Figs. 1 and 2.

The effluents of the long-aged samples contained no other radioactive nuclides than ^{137}Cs-^{137m}Ba,

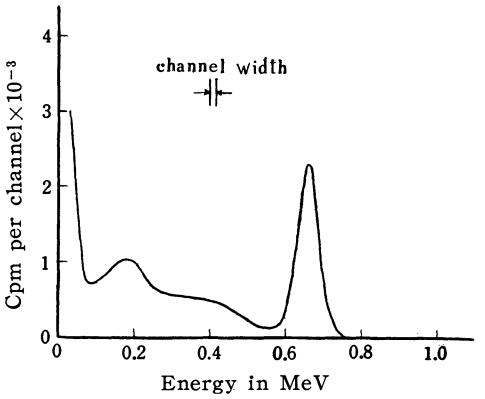

Fig. 1. Gamma-ray spectrum of the long-aged sample treated by the resin column.

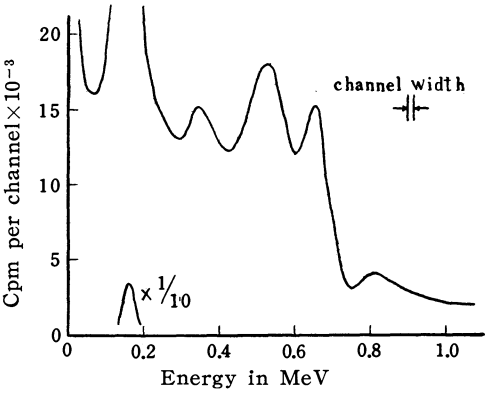

Fig. 2. Gamma-ray spectrum of the short-aged sample treated by the resin column.

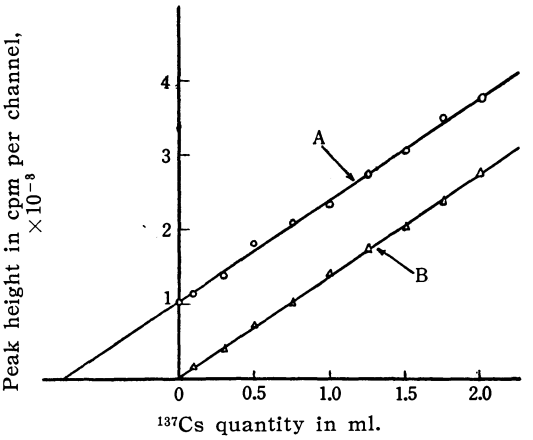

Fig. 3. 0.66 MeV peak heights vs. added ^{137}Cs quantities of the long-aged samples.

5) R. E. Connally M. Leboeuf, *Anal. Chem.*, **25**, 1075 (1953).

* In practice this case was first investigated, but because of the unexpected results, as shown in Fig. 4, the sample a) was next studied. The changes of the activities were due to the shortage of the F. P. and pure ^{137}Cs solution.

6) F. Aoki et al., This Bulletin, **30**, 583 (1957).

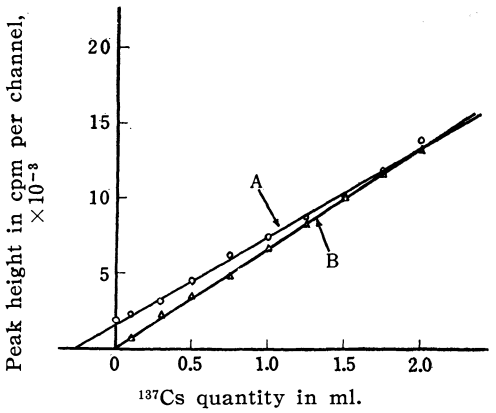

Fig. 4. 0.66 MeV peak heights vs. added ^{137}Cs quantities of the short-aged samples.

but those of the short-aged contained ^{137}Cs-^{137m}Ba and ^{140}Ba-^{140}La, which were identified by the gamma-energies.

The real peak heights of the 0.66 MeV gamma were plotted against the quantities of the added ^{137}Cs solutions (Figs. 3 and 4).

The straight lines, 'A' and 'B' show the 0.66 MeV peak height of the samples and that of pure ^{137}Cs solution added to the fission products, respectively; both have good linearities. In Fig. 3, both lines are parallel, but in Fig. 4 the slope of the straight line 'B' is a little greater than that of 'A'. This fact shows that the peak height, in spite of the correction for the Compton pulses of ^{140}Ba-^{140}La gammas, does not represent the ^{137}Cs quantity, but always gives too low a value. This phenomenon has not yet been sufficiently investigated, but one possible explanation is that some of the 0.66 MeV gamma pulses are summed up with photoelectric or Compton pulses of ^{140}Ba-^{140}La gammas to form higer pulses. However, the length between the origin of the coordinate and the intersection of the straight line 'A' and the abscissa gives the quantity of ^{137}Cs originally present in the fission products, which does not depend on the presence of ^{140}Ba-^{140}La. When the straight line 'A' is determined by the method of least squares, the most probable value of the quantity in question is obtained.

The results are shown in Table III, where N is the 0.66 MeV peak height in counts per minute per channel and x the volume of ^{137}Cs solution in milli litres. The analysed ^{137}Cs quantity corresponds to the absolute value of x at $N=0$, and is given in the same unit as that of the added ^{137}Cs solution whose activity is temporarily shown in milli litres.

TABLE III
ANALYSIS OF ^{137}Cs IN THE FISSION PRODUCTS

Sample	Straight line	^{137}Cs quantity (ml)
Long-aged	$N=1037.44-1370.83x$	0.757
Short-aged	$N=1553.51-5963.95x$	0.260

In this experiment the quantities of ^{137}Cs originally present in the fission products were unkown, so the errors of the measured quantities can not be shown. The maximum deviations of the peak heights from the straight lines determined by the method of least squere are 6% and 10% in the case of the long-aged and the short-aged, respectively.

Summary

A method for the rapid determination of ^{137}Cs in fission products has been studied. Simple and reliable analysis is possible by combining oxalate- and carbonate-form anion exchange resin and a gamma-ray scintillation spectrometer as follows.

Take several samples of equal quantity from a given fission products solution. Add various known quantities of pure ^{137}Cs to them respectively. Extract the bulk of uranium with T. B. P. in diethyl ether. Treat them through a mixed bed of carbonate- and oxalate-form anion exchange resin. Measure each aliquot using a gamma-ray scintillation spectrometer. Plot the real peak height of the 0.66 MeV gamma vs. the added ^{137}Cs quantity, and determine the straight line by the method of least square. Find the intersection of the straight line and the abscissa.

The quantity in question is given by the length of the abscissa between the intersection and the origin.

The authors wish to thank Dr. S. Uchida and Mr. K. Hashimoto for encouraging the prosecution of this work.

Normal Vibrations and Calculated Thermodynamic Properties of Methyltrichlorosilane

By Kazuhiro SHIMIZU and Hiromu MURATA

(Received June 27, 1958)

Methylchlorosilane is the simplest of those methylchlorosilanes which are both industrially important and theoretically interesting. The infrared and the Raman spectrum of this compound have been reported by several investigators[1-5]. But the normal vibrational frequencies have been calculated and assigned only by a method in which a methyl group is regarded as one particle. Therefore, the vibrational frequencies accompanied by the motion of hydrogen atoms have been excluded from the calculations, and the coupling between the skeletal vibrations and the characteristic modes of the methyl group has been ignored. To make all the normal modes clear, it is necessary that the vibrations of hydrogen atoms are taken into account. In this paper, the fundamental frequencies are calculated and assigned, their normal modes are determined, and the thermodynamic properties are calculated.

Normal Coordinate Treatment. — In methyltrichlorosilane, there are two symmetrical groups, CH_3 and $SiCl_3$. Because of the interaction between the CH_3 and the $SiCl_3$ group, the internal rotation is restricted, and it is more correct in the present consideration to treat the relative movement of CH_3 and $SiCl_3$ as torsional oscillation rather than as free internal rotation. This molecule belongs to the point group C_{3v} whether the groups have staggered or eclipsed forms. According to the group theory, it is clearly shown that this molecule has twelve fundamental frequencies of which five belong to species a_1, one to species a_2, and six to species e. All vibrations except the a_2 torsional mode are both infrared and Raman active. If this molecule has the torsional angle about the Si—C axis, it belongs to the point group C_3. The species a_1 and a_2 of the point group C_{3v} correspond to the species a of the point group C_3. Previous work by Collins and Nielsen[6] shows a normal coordinate treatment of the staggered configuration of methyltrifluorosilane having a structure similar to methyltrichlorosilane. But, in this investigation, at first, we undertake to make an attempt to carry out a normal coordinate treatment with an arbitrary torsional angle, and, next, to calculate the normal vibrational frequencies of the point group C_{3v} molecule for which the torsional angle θ is 0° in the eclipsed from, and 180° in the staggered form. We do not calculate the a_2 mode which is both infrared and Raman inactive. A normal coordinate treatment was carried out using the Wilson *FG* matrix method[7]. The *F* matrix elements were formed from the force constants in a Urey-Bradley force field[8].

The various bond distances, the interbond angles, and the distances between nonbonded atoms used to determine the internal coordinates are shown in Fig. 1. From the internal coordinates the following orthonormal symmetry coordinates were found; for the a vibrations,

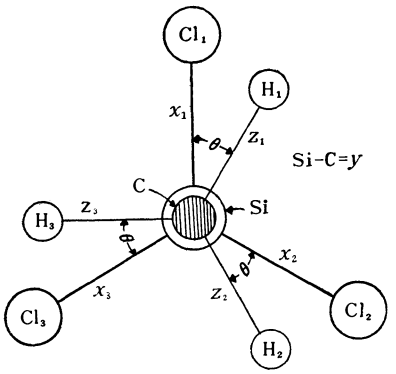

Fig. 1. Internal coordinates of methyltrichlorosilane.

where the following abbreviations are adopted:

$$s_{zz}=4z/3q_{zz} \qquad t_{zz}=2\sqrt{2}\,z/3q_{zz}$$
$$s_{zy}=(3z+y)/3q_{yz} \qquad t_{zy}=2\sqrt{2}\,y/3q_{yz}$$
$$s_{yz}=(3y+z)/3q_{yz} \qquad t_{yz}=2\sqrt{2}\,z/3q_{yz}$$
$$s_{yx}=(3y+x)/3q_{xy} \qquad t_{yx}=2\sqrt{2}\,x/3q_{xy}$$
$$s_{xy}=(3x+y)/3q_{xy} \qquad t_{xy}=2\sqrt{2}\,y/3q_{xy}$$
$$s_{xx}=4x/3q_{xx} \qquad t_{xx}=2\sqrt{2}\,x/3q_{xx}$$

and the symbols used for the equilibrium values of the interatomic distances are x=Si—Cl, y=Si—C, z=C—H, q_{xx}=Cl···Cl, q_{xy}=C···Cl, q_{yz}=Si···H and q_{zz}=H···H.

The G matrix elements are obtained by use of the table of Decius[9]. In terms of the abbreviations ρ_x, ρ_y and ρ_z for the reciprocals of the Si—Cl, Si—C and C—H bond lengths, respectively, and μ_x, μ_y, μ_c and μ_h for the reciprocals of the atomic masses of the Cl, Si, C and H, the following G matrix elements are found, assuming all angles to be tetrahedral:
for the a vibrations,

$$G_{11}=\mu_h+\mu_c/3$$
$$G_{12}=4\rho_z\mu_c/3$$
$$G_{13}=-\mu_c/\sqrt{3}$$
$$G_{22}=2(\mu_h+8\mu_c/3)\rho^2_z$$
$$G_{23}=-4\rho_z\mu_c/\sqrt{3}$$
$$G_{33}=\mu_y+\mu_c$$
$$G_{34}=-\mu_y/\sqrt{3}$$
$$G_{35}=-4\rho_x\mu_y/\sqrt{3}$$
$$G_{44}=\mu_x+\mu_y/3$$
$$G_{45}=4\rho_x\mu_y/3$$
$$G_{55}=2(\mu_x+8\mu_y/3)\rho^2_x$$
$$G_{14}=G_{15}=G_{24}=G_{25}=0,$$

for the e vibrations,

$$G_{66}=\mu_h+4\mu_c/3$$

9) J. C. Decius, ibid., **16**, 1025 (1948).

$$G_{67}=4\sqrt{2}\,\rho_z\mu_c/3$$
$$G_{68}=-\sqrt{2}\,(3\rho_y+\rho_z)\,\mu_c/3$$
$$G_{610}=\sqrt{2}\,\rho_y\mu_c\cos\theta$$
$$G_{77}=(8\mu_c/3+5\mu_h/2)\,\rho^2{}_z$$
$$G_{78}=-2(3\rho_y+\rho_z)\,\rho_z\mu_c/3+\rho^2{}_z\mu_h/2$$
$$G_{710}=2\rho_y\rho_z\mu_c\cos\theta$$
$$G_{88}=3\rho^2{}_y\mu_y/2+(3\rho_y+\rho_z)^2\mu_c/6+\rho^2{}_z\mu_h$$
$$G_{89}=\sqrt{2}\,\rho_y\mu_y\cos\theta$$
$$G_{810}=-[(3\rho_y+\rho_x)\,\mu_y+(3\rho_y+\rho_z)\,\mu_c]\,\rho_y\cos\theta/2$$
$$G_{811}=2\rho_x\rho_y\mu_y\cos\theta$$
$$G_{99}=\mu_x+4\mu_y/3$$
$$G_{910}=-\sqrt{2}\,(3\rho_y+\rho_x)\,\mu_y/3$$
$$G_{911}=4\sqrt{2}\,\rho_x\mu_y/3$$
$$G_{1010}=\rho^2{}_x\mu_x+(3\rho_y+\rho_x)^3\mu_y/6+3\rho^3{}_y\mu_c/2$$
$$G_{1011}=\rho^2{}_x\mu_x/2-2(3\rho_y+\rho_x)\,\rho_x\mu_y/3$$
$$G_{1111}=(5\mu_x/2+8\mu_y/3)\,\rho^2{}_x$$
$$G_{69}=G_{611}=G_{79}=G_{711}=0$$

Since the repulsive force constants between non-bonded atoms are ignored, the F matrix elements of an eclipsed configuration are equal to those of a staggered one. Also, as shown in the G matrix elements, the different point between an eclipsed and a staggered configuration is only the change of the signs of G_{610}, G_{710}, G_{89}, G_{810} and G_{811} elements. However, the calculated values of GF for both the configurations are equivalent.

The C—H stretching vibrations were split off by the method of Wilson. The molecular constants and the potential constants used are listed in Table I. As an aid in determining some of the potential constants, K_x, K_y, K_z, H_{xx}, H_{xy}, H_{zz}, F_{xx}, F_{xy}, F_{zz} and κ, the results from previous investigations of methane[8] and the skeletal vibrations of this molecule[2] were used. But for K_y, a slightly lower value was adopted. We gave -0.05 md/A to the value of κ', taking into consideration the corresponding constants found for methane, monochloromethane, monofluoromethane and methyl alchohol. The values of H_{yz} and F_{yz} were selected so as to give the good agreement with the observed fundamentals. The values of F' are assumed to be $-0.1\,F$.

TABLE I

	κ'($SiCH_3$)	-0.05 A^2

Normal Frequencies.—A normal coordinate treatment of the skeletal vibrations which assumed the methyl group to be one particle was carried out by Goubeau et al.[1] and Shimanouchi et al.[2]. The calculated frequencies of all the normal vibrations are in good agreement with the observed, if the assignment of these frequencies is made adequately as shown in Table II. In it, the results of previous investigations are listed together for comparison.

The L matrices, whose components give the modes of vibrations and the potential energy distribution for each normal vibration were calculated. They are shown in Tables III and IV. Since the ν_1 and ν_6 are considered to have almost pure C—H streching frequencies, their L mairices and potential energy distributions are omitted.

Judging from the values of the contribution of each symmetry coordinate to the normal coordinates Q_{10} and Q_{11} in Table III and the distribution of potential energy in the symmetry coordinates for the normal frequencies ν_{10} and ν_{11} in Table IV, it is reasonable to designate the frequencies 229 cm^{-1} and 164 cm^{-1} respectively as "$SiCl_3$ rocking" and "$SiCl_3$ non-symmetric deformation". Thus, the classification given in Table II is reasonable.

As shown in Tables III and IV, the skeletal vibrations and the vibrations accompanied by the motion of hydrogen atoms are separated to a considerable extent. Therefore, the calculated values of the skeletal vibrations are expected to be in good agreement with their corresponding observed values.

Internal Rotation.—The torsional vibration belongs to the species a_2 and is both infrared and Raman inactive. The frequency can be calculated if the height of the potential barrier hindering the internal rotation is known. However, the

question as to the potential hill has not been definitely settled. Here, the potential barrier of monomethylsilane, methyltrichlorosilane and methyltrifluorosilane are compared with the values of ethane, 1,1,1-trichloroethane and 1,1,1-trifluoroethane, respectively. The heights of ethane[10], 1,1,1-trichloroethane[11] and 1,1,1-trifluoroethane[12] are respectively 2.875±0.125 kcal/mole, 2.97 kcal/mole and 3.25±0.40 kcal/mole. That is to say, the value of 1,1,1-trichloroethane is found between the value of ethane and of 1,1,1-trifluoroethane. On the other hand, the value of monomethylsilane[13] and of methyltrifluorosilane[14] are respectively 1.314±0.229 kcal/mole and 1.20 ±0.16 kcal/mole. Thus it seems that the height of the potential barrier of methyltrichlorosilane is 1.30±0.25 kcal/mole.

In the present investigation, the usual $V=V_0\ (1-\cos 3\theta)/2$ is adopted as the form of the potential barrier. In this formula, V_0 is the height of the potential barrier and θ is the torsional angle. The torsional frequency can now be obtained from V_0. The calculated value $147\pm15\ \mathrm{cm}^{-1}$ is believed to be not far from the real torsional frequency.

Thermodynamic Properties.—The probable values of the wave numbers of the normal frequencies given in Table II were used to calculate values of the heat content, free energy, entropy and heat capacity for the ideal gaseous state at 1 atoms pressure (rigid rotator, harmonic oscillator approximation). The bond distances and the interbond angles given in Table I were used to calculate the product of the principal moments of inertia, using the Hirschfelder formula[15]. The value obtained was $I_aI_bI_b=1.48102\times10^{-112}\ \mathrm{gm}^3\ \mathrm{cm}^6$. The molecular weight used was 149.496 and the symmetry number was 3. In Table V, the contributions of the torsional frequency and the others (translational, rotational and vibrational except torsinal) are listed separately to facilitate revision of the table, if and when a better way is found to calculate the contribution for the former.

The authors wish to thank Professor Y. Morino and Dr. T. Shimanouchi of the University of Tokyo and Dr. H. Shingu of Kyoto University for making many valuable discussions.

*Phase Transition of Lithium Ferrospinel-Lithium Aluminospinel Solid Solution**

By Eizo KATO**

(Received July 8, 1958)

The phase transition of lithium ferrospinel was studied by means of thermal, electric[1] and X-ray measurements[2]. Lithium aluminospinel is a compound in which ferric ion in LFS changes into aluminum ion. Kordes[3], Verwey[4], Braun[5] and Yamaguchi[6] found that the crystal structure of LAS is the same as that of LFS, but its physico-chemical properties are not evident. No information pertaining to a phase transition of LFS-LAS solid solution has ever been presented in the literature. In the present paper, some physico-chemical changes attributed to exchange ferric ion for aluminum ion in LFS-LAS solid solution are systematically investigated by means of X-ray diffraction and differential thermal analysis, besides, formation of LFS-LAS solid solution is discussed.

Experimental

Specimens***.—Hydroxides coprecipitated from mixed aqueous solutions of ferric and aluminum nitrate were mixed with lithium oxalate in acetone, then dried, pressed and calcined in an electric furnace at 1200°C for three days. Specimens in a low temperature form (an ordered phase) were obtained by annealing in the same furnace from ca. 1200°C to the room temperature for a day, while specimens in a high temperature form (a disordered phase) were quenched by immersion into water from ca. 1300°C in 1~2 seconds.

Apparatus and Procedures. — Thermal analyses were carried out up to 1000°C at a heating rate of 10°/min. by the apparatus reported already[7]. The measurements above 1000°C were performed at a rate of 3°/min. by an apparatus with a sample holder of sillimanite. X-ray powder photographs were taken with Co $K\alpha$ radiation by a back-reflection technique, and lattice constants

were accurately determined by an extrapolation method against $1/2(\cos^2\theta/\sin\theta+\cos^2\theta/\theta)$

Results and Discussion

Order-Disorder Transition of Solid Solution.—From spacings and reflection intensities measured by X-ray diffraction, the crystal structures of the low temperature and the high temperature form of LFS–LAS solid solution were found to be an ordered lattice, O^6—$P4_33$, and a disordered lattice, O_h^7—$Fd3m$, respectively. Both lattices are identified by arrangements of cations at octahedral interstices, and have the same structures with those in LFS or LAS alone. The values of the lattice constant as a function of the chemical composition for the ordered and the disordered phase of the solid solution are shown in Table I and Fig. 1. The relation of the lattice constants vs. the composition for disordered phases was calculated by a method of least squares.

$$y=7.912_5+0.4907x-0.0699x^2$$

where x is the mole fraction of LFS in the solid solution, and y thelattice constant of disordered phase.

On the other hand, experimental results for the ordered phase were too few to find an equation similar to the above one. Lattice expansions (Δ) at the transition from the ordered phase to the disordered one is small as is listed in Table I, and these values are in 0.03~0.14% regardless of the composition. If the magnitude of the expansion is estimated at 0.05%, the observed values of lattice constant of the ordered phase will agree with those calculated by the above equation.

Physico-chemical changes of the solid solution in occurrence of the transition were observed by differential thermal analysis. The endothermic reaction due to the transition was already seen in the measurement of LFS, and thermal changes similar to LFS or LAS were found in all specimens of ordered phase of the solid solution*. Though the transition temperature of LFS or LAS** is known, no paper was reported for those of the solid solutions. The exact value of the transition temperature had better be measured by a dilatometry with a considerable slower heating rate. The dilatometry was, however, not carried out, because of difficulty to prepare aluminum-rich specimens by sintering. In place of the relation of the transition temperature vs. the chemical composition, that of the endothermic temperature vs. the composition in a series of specimens was measured and is shown

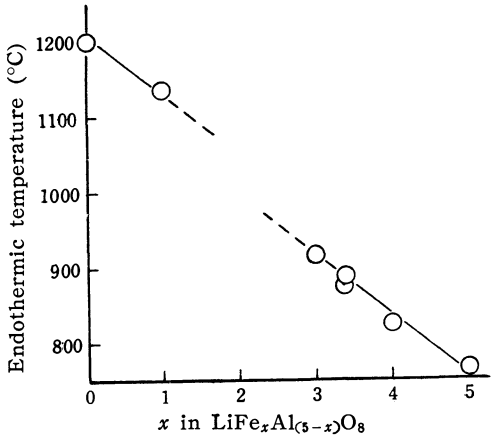

Fig. 2. Relation between the endothermic temperature and the chemical composition in the solid solutions.

in Table I and Fig. 2. The endothermic temperature of LFS is lower than that of any composition of the solid solution, and the more the aluminum content, the higher this temperature. An analogous relation is seen in that of ferromagnetic Curie point vs. chemical composition in nickel-magnesium, cupric-nickel and zinc-nickel ferrospinel solid solution[8]. It is very remarkable that no continuous change of the endothermic temperature against the composition is found in any kinds of specimens of the solid solution but in those of the compositions rich in ferric ion or aluminum ion. This is supposed to be caused by some differences in crystal structure between iron-rich and aluminum-rich compositions. The true transition temperatures, which are provided to be lower than the endothermic temperatures by 10~30° from the result of LFS, will also be given in the similar manner as above-mentioned.

It is concluded that the transition of LFS-LAS solid solution is the order-disorder transition of the same type as that of LFS or LAS from the results on the crystal structure and the endothermic reaction.

Formation of Homogeneous Solid Solution. —In the disordered phase, homogeneous solid solutions were formed at any compositions. In the ordered phase, however, the solid solutions were homogenized in the specimens of iron-rich composition (D and E in Table I) or of aluminum-rich (B). There might be two phases separated in the specimens of intermediate compositions (C, P and R). The compositions of the separated phases were estimated by the measurements of lattice constants and the use of the above equation, and it was determined that in one of these two phases it is of 20 mole per cent LFS, and in the other 68 mole per cent. In thermal analysis, the only endothermic temperature was measured in the case of specimens B, D and E, while two endothermic temperatures corresponded to two phases were revealed in the case of C, P and R. X-ray diffraction results were in conformity with thermal analysis'. The formation of a homogeneous solid solution in the ordered phase of Q, though it was annealed on the same condition as others, is assumed due to a difference in a disordering velocity* from that of the others. Whether the homogeneous solid solution can be formed in the ordered phase at a higher temperature or in the disordered phase quenched at a lower temperature, no knowledge is offered from the present work.

Homogeneous solid solutions were not formed in the region of 20~68 mole per cent LFS, where the discrepancy in the relation of the transition temperature vs. the chemical composition was also observed. The conditions necessary to form a homogeneous solid solution are usually those mentioned below[13]; (1) both phases have the same crystal structure, (2) the values of lattice constants resemble each other, (3) the chemical properties are also similar, (4) the ionic radii of constructing ions are the similar size. Typical examples are revealed in the ferrospinel mentioned above, lead phosphate-lead arsenate and lead phosphate-lead vanadate solid solution[14]. Systematic studies on relations of solid solutions of solid solution with order-disorder transition have hitherto been reported very rarely. The ordered phase of LFS and that of LAS have the same crystal structure and the difference between their lattice constants is small. It is also the case in the disordered phase. These is a considerable agreement between an ionic radius of ferric ion (0.67 Å) and that of aluminum ion (0.55 Å). Though having the conditions necessary to be homogenized, LFS-LAS solid solutions cannot

* From the condition of annealing, the transition velocity of each composition was found to be very rapid as that of LFS.

be formed over all ratios. Such phenomena might be caused by an averaged structure, i. e., a cation arrangement at the octahedral or the tetrahedral interstices in the crystal. Detailed experiments along this line will be discussed in the following paper.

*Experiments on Synthetic Mica Crystal Growing. Crystal Growing with Carbon Granule Resistance Furnace**

By Tokiti NODA and Yoshihiro SUMIYOSHI

(Received July 2, 1958)

In experiments on the growing of synthetic fluor-phlogopite, it is necessary first to melt the mixture of raw materials of fluor-phlogopite composition to a clear liquid by heating it at about 1450°C and then to maintain the resultant melt for many hours at temperatures within a range of several tens of degrees around its crystallizing temperature of about 1350°C. For the growing of large crystals, the melt should be cooled very slowly.

The rate of cooling necessary for the growing of large crystals may be acquired in two ways.

1) For small melts, by precise control of the temperature of the melt; 2) by using a large enough quantity of melt to obtain the necessary rate through natural cooling or by less precise control of temperature. A large mass of melt will provide sufficient space for growing large crystals.

The first way may be carried out by applying the technique originally designed by Stöber[1], Bridgman[2] and Kyropoulos[3] for growing large single crystals, techniques which have been used in the manufacture of optical crystals. The results of experiments done along this line will be reported later; experiments on growing synthetic mica crystals in large melts are described in the present paper.

Experimental

Apparatus.—Among various types, platinum resistance, silicon carbide resistance, carbon resistance and gas-fired furnaces may meet the requirements for the temperature range for synthetic mica crystal growing. In small-scale experiments, the first two types of furnace were used. In large-scale experiments, however, carbon granule resistance furnaces, designed especially for this purpose, were used. Because, the platinum resistance furnace being excluded for its prohibitive expense, a silicon carbide resistance furnace was unexpectedly found to serve only a short time, as heating resistors were attacked by fluorine-containing vapor evolved from the melt.

The first requisite was to design and construct a carbon granule resistance furnace having all the characteristics needed to meet the requirements of temperature control necessary for synthetic mica crystal growing, because this type of furnace is usually considered inadequate for precise temperature control and the furnace is apt to have a reducing atmosphere.

As a preliminary step in designing the furnace, characteristic data, such as electric power input per unit surface area of heating zone, specific resistance of carbon granule heating element, and power input per unit volume of carbon granule heating element, were investigated by a critical examination of several commercial furnaces of the carbon granule resistance type.

A furnace of 2 kg. melting capacity of this type was constructed, employing these characteristic data as a design basis, and used for medium scale experiments on synthetic mica crystal growing. Then based on a close examination of both calculated and observed characteristic data of this furnace, a furnace of carbon granule resistance type having a 30 kg. melting capacity was constructed for large-scale experiments on synthetic mica crystal growing. The furnace

was remodeled several times in the process of the research and a sectional sketch of the furnace in its final form is given in Fig. 1, with its characteristic data.

The power input(P) for heating the furnace up to a certain temperature and the power input (P') for keeping the furnace at that temperature are related to temperature(θ), the effective surface area of heating zone(a), and the time(t) required for heating the furnace up to the temperature by the following equations[4]:

$$P = ca^{0.9}\theta^{1.55}t^{-0.5} \quad (1)$$

$$P' = c'a^{0.9}\theta^{1.55} \quad (2)$$

For this furnace, the values of c and c' were found to be 76 and 7.5 respectively. The power input for keeping the furnace at 1350°C was about 20 kW, the heat loss at the furnace side wall being about 65% of total input, and at the top and the bottom of the furnace, about 35%.

The furnace was harnessed with two voltage regulators in sequence, i.e. a motor-driven induction regulator, controlled by an electronic controller, was used with a saturable reactor combined with a magnetic amplifier and a D.C. voltage stabilizer. With this device, the temperature of the furnace could be controlled within ±2~3°C in the temperature range of 1300° and 1400°C by regulating the terminal voltage within ±0.05%.

A motor-driven lift was attached under the furnace, so that a crucible placed on the lift could be raised to a predetermined height in the furnace.

Raw Materials.—Raw materials, such as quartzite, alumina, magnesia, talc and potassium silicofluoride, were of commercial grade except the poassium carbonate which was of chemical grade. These materials were analysed and were found to have sufficient purity for the present purpose. All gradients of these raw materials were taken into account in calculating the mixing ratio of the raw materials for the preparation of batch mixtures.

Because the loss of fluorine due to decomposition of fluoride in the batch during heating is accelerated by the presence of water vapor[5], the mixture of calculated amounts of silica, magnesia, talc, alumina and potassium carbonate was first calcined at about 1000°C to expel water and carbon dioxide contained in the mixture and then the calculated amout of potassium silicofluroride was added.

Batches of POM 2 composition were used in most of the experiments of the present series because it was found, from results of experiments on the determination of crystallizing

Experimental Procedure.—The evaporation of fluorine in the batch is highest in the course of reaction during heating above 1000°C and is comparably low in the molten state. Therefore, it was planned to melt the batch as quickly as possible to minimize the evaporation of fluorine.

At first it was our plan to follow the melting procedure in this way, viz: the crucible containing the batch is placed in a low position within the furnace (c.f. Fig. 1), heated up to about 1000°C, and then moved to a higher temperature region which had already been heated to 1400°C. After completion of the melting, the crucible is raised or lowered to ensure the required temperature difference between the top and the bottom of the crucible and then cooled slowly by controlling the power input of the furnace. The heating and cooling curve of the experiment carried out in this way is shown in Fig. 2.

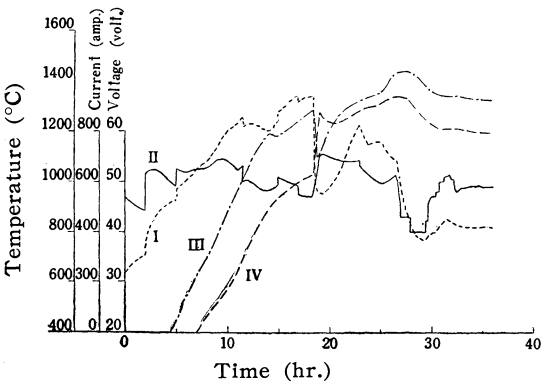

Fig. 2. Heating and cooling curve of experiment No. 1.
I: electric current
II: terminal voltage
III: temperature at the top of the crucible
IV: temperature at the bottom of the crucible

This procedure was abandoned because of operational difficulties, such as failure to get the crucible, buffer plates, thermocouple protecting tube and other furnace furnitures on the lift to raise smoothly, and the increase of undesired updraft of cold air during and after the raising operation. Most of the experiments were carried out in the following way. An unfilled crucible is first placed in the furnace; then the furnace is heated by passing electric current through the resistance element. After the temperature has reached about 1400°C, the crucible is charged several times with the batch until it is filled with the melt. Upon completing the charge, the crucible is covered with a lid, the temperature of the crucible is maintained above 1400°C for 5~6 hours to obtain the clear melt, and then cooled slowly by controlling the power input of the furnace.

Because well-sintered high-aluminous clay crucibles used in the earlier stages of this series of experiments were found to be less resistant to thermal shock, calcined but unsintered high-aluminous clay crucibles were used in later stages of the series. They were first heated in the furnace up to 1650°C to sinter. After the sintering, the temperature of the furnace was lowered to about 1400°C, the crucible was charged with the batch material and after completion of the melting, the melt was cooled slowly, as described above. The heating and cooling curve of a typical experiment of this series is given Fig. 3.

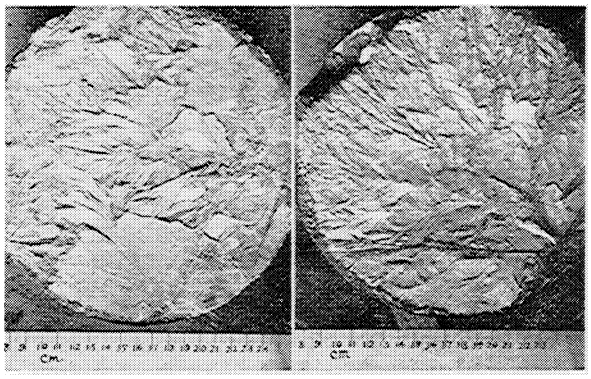
was found to resist the corrosion[8].

Graphite crucibles used were cylindrical in shape, 25 cm. in outer diameter, 50 cm. in height and 46 cm. in depth. The crucible was placed in a sagger made of fire clay, with grog powder packed in the intersticial space between the crucible and the sagger, thus preventing the oxidation of graphite. Buffer plates and cylinders made of fire clay were placed on and under the sagger in the furnace in order to decrease unfavorable convection current in the furnace.

Mica aggregates which crystallized in graphite crucibles were gray, minute carbon particles deposited in interstitial glass between mica crystals discoloring them. Crystals grown in graphite crucibles were generally small, and even when they grew large, they were mostly of mosaic nature.

It seems that one of the causes of small crystal formation is that the wall of graphite crucible is not wetted with the melt and consequently the wall does not initiate the nucleation of mica, so that the melt tends to become supercooled and forms a large number of nuclei when it starts to crystallize at a supercooled temperature.

In one experiment with graphite crucible, the molten state was maintained down to a temperature of about 150°C below the crystallizing temperature and small mica crystals rapidly formed around a steel wire when it was quickly dipped into the melt, while glass adhered to a wire quickly dipped into a melt in a high-aluminous clay crucible.



These observations suggest that the melt in graphite crucible was in a supercooled state or was in a state of easy crystallization with slight stimulus. Another suspected cause for small crystal formation was that a change in chemical composition of the melt was accelerated by the reducing atmosphere, but the change was not verified by chemical analysis. Also, the presence of minute carbon particles might stimulate the nucleation, although no positive assertion can be made.

High-aluminous clay crucibles used in the experiments were of alumina and silica, about 50% each. Crucibles sintered at about 1600°C or below were heavily corroded by the melt, so that the thickness of crucible wall decreased to about one-half of its original thickness, changing the chemical composition of the melt markedly and often leaking the melt completely.

Crucibles sintered at about 1650°C were found to withstand corrosion of the melt. The wall of clay crucibles initiated the nucleation of mica crystals, so that in the earlier stage of crystallization, large numbers of small crystals were formed in the vicinity of the wall. However, in the course of slow cooling, some of these crystals or crystal nuclei which were spontaneously formed in the melt grew to large single crystals of good quality. Mica aggregates crystallized in clay crucibles were slightly colored brown owing to iron contamination coming from crucible material. These aggregates contained a slightly larger amount of glass than those crystallized in the graphite crucible, but contained no carbon.

Result

Temperature Gradient in Melt and Oriented Growing of Crystals.—The formation of large crystals grown horizontally in the surface layer of melt was often observed when the temperature difference between the top and the bottom of the crucible was small during the crystallization period. Crystals grown in this way are shown in Fig. 4a. The crystal in the lower part of the figure measured 7 cm. by 12 cm. and was slightly curved. The evaporation of potassium and fluorine from the surface of the melt must have caused the crystallizing temperature of the surface layer of the melt to become higher and the early-formed crystals in this layer may have been in contact with the melt and may have had a longer time to grow than crystals formed later in the bulk of the melt. This may be the reason for small crystals growing at random in the bulk of the melt in spite of the formation of large crystals in the surface layer. Crystals grew upwards from the bottom of the crucible when the bottom temperature was sufficiently lower than the top temperature to cause the crystal nuclei to form originally at the bottom of the crucible. Edges of basal planes of vertically grown crystals can be seen on the surface of the crystalline mass shown in Fig. 4b. Rapid cooling causes new crystal nuclei to form in a slightly displaced direction from the orientation of

(a) (b)

the original crystals. This type of formation results in curved crystals of mosaic nature and under the most unfavorable conditions in dendritic crystals which are manifested by the branched edges of basal plane, as seen in Fig. 4b.

For the purpose of obtaining the relationship between the temperature gradient in the melt and the oriented growing of crystals, the temperature difference between the top and the bottom of the crucible and the qualitative degree of oriented crystal growing are given in Table II.

Although temperature readings with thermocouples placed at the top and bottom level of the crucible may not always indicate true temperatures of the melt at the same levels, the temperature gradient calculated by dividing the temperature difference by the depth of melt may, for practical purposes, be used for deduction of the experimental result. It can be seen from data of Table II that no oriented growth of crystals was observed when the temperature gradient was 1～2°C /cm. and that the temperature gradient of 4～5°C/cm. may be needed for oriented growth.

Rate of Growth and Quality of Crystal. —In one experiment in which the temperature at the bottom was higher than that at the top, a steel wire was frequently dipped into the charge contained in a graphite crucible to see the start of crystallization. When the temperature was 1230°C at the top and 1375°C at the bottom, the charge was in the molten state; when the temperature was 1205°C at the top and 1335°C at the bottom, a part of the charge began to solidify, the main part being a viscous melt; the crystallization was completed when the temperature was 1185°C at the top and 1325°C at the bottom. Because of the inverted temperature gradient, the convection may have occurred in the melt to equalize the temperature difference, so the real temperature of the upper layer of the melt may have been higher than the measured value. However, a considerable temperature gradient may still have been held, because crystals grew vertically downward from the upper layer. The crystallizing temperature of the melt was estimated to be about 1350°C, while in the above case the actual crystallization began between 1325°C and 1205°C.

This means that a great supercooling took place. It seems that a rapid rate of cooling may favor the occurrence of supercooling. Therefore the melt does not always begin to crystallize when the temperature of the melt is cooled to that corresponding to its crystallizing temperature, and the rate of cooling of the melt, calculated by dividing temperature-drop in the slow cooling period by the duration of slow cooling, does not necessarily correspond to the true rate of cooling during the crystallization. However, in the course of slow cooling, a slow-down of the cooling rate due to the generation of the heat of crystallization* was generally observed, and it can be assumed that the period of the slow-down of the cooling rate corresponds to the duration of crystallization. Therefore the rate of crystal growth of basal plane can be calculated by dividing the size of the largest crystal found in the solidified mass by the duration of crystallization, assuming that the crystal had grown throughout the duration of crystallization, although the solidified mass in the crucible was usually composed of a large number of crystals of various sizes. The rate of crystal growth thus calculated and the quality of crystals produced are given in Table III.

In experiment No. 13, using a well-sintered high-aluminous clay crucible, several clear single crystals measuring about 5 cm. by 5 cm. could be split from the solidified mass, although the yield of crystals of this size was very small. Two of these crystals are shown in Fig. 5. In this experiment, the rate of cooling was 2～5°C/hr.. The quality of these crystals is designated in Table III as "excellent". Crystals which are not perfect

single ones, but are of mosaic nature are designated as "poor" in quality. When they were split from the solidified mass, these crystals separated into many small ones. Crystals grown at a rate higher than 0.1 mm./min. were always imperfect mosaic crystals. It can be deduced then that in order to grow good single crystals which can be split from the solidified mass, the rate of growth should be less than one-tenth of a millimeter per minute.

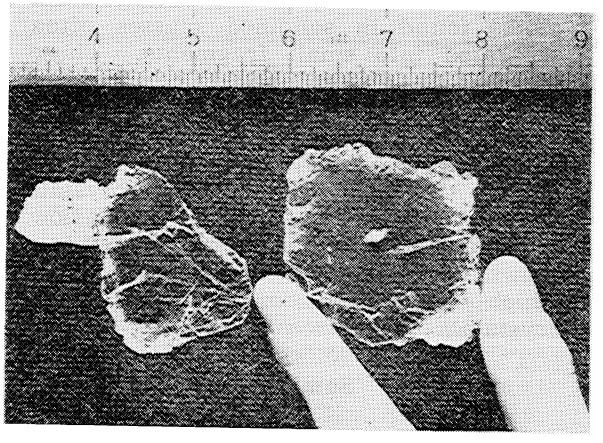

Fig. 5. Single crystals of fluor-phlogopite.

Change in Chemical Composition of Charge during Process.—Chemical compositions of batch mixtures and solidified products of three experiments are given in Table IV.

We used in experiment No. 11, a slightly-sintered high-aluminous clay crucible for melting for a relatively short period, in experiment No. 12, a slightly-sintered high-aluminous clay crucible for a long period and, in experiment No. 13, a well-sintered high aluminous clay crucible for a long period. Changes in individual components of the charge during the melting were calculated on the assumption that the content of magnesia was kept constant because no magnesia came from the crucible and the evaporation of magnesium fluoride was negligible.

In experiment No. 11 where the short period melting and the rapid cooling were used, small crystals resulted without remarkable change in the chemical composition of the melt. In experiment No. 12, the clay crucible was heavily corroded. This resulted in a considerable increase in content of alumina and silica. The loss of fluorine and potassium due to the evaporation was also remarkable. The great shift of the chemical composition and especially a remarkable deficit of fluorine in the melt, may be to blame for the formation of small crystals. The well-sintered clay crucible used in experiment No. 13 strongly resisted the corrosion of melt. The slow-cooling procedure was carried out as planned and the solidified mass contained many large crystals, as described above. The chemical composition

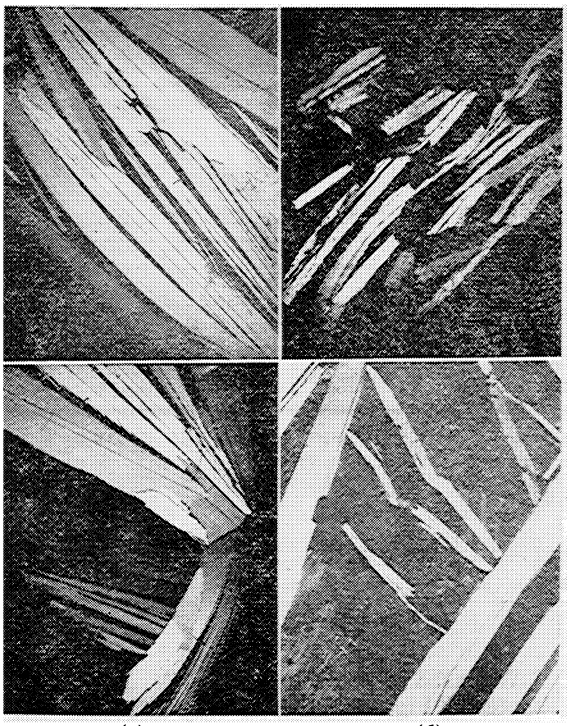

Fig. 6. Microphotograph of fluor-phlogopite (1).

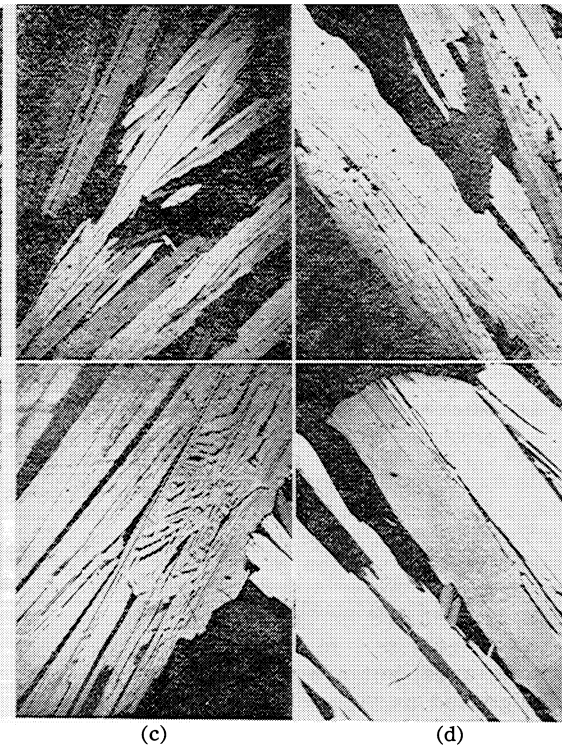

Fig. 7. Microphotograph of fluor-phlogopite (2).

of the product of experiment No. 13, given in Table IV, shows a remarkable increase of silica and alumina content, a slight increase of potassium and a slight decrease of fluorine. Because the excessive potassium of the batch usually concentrates in the glassy part of solidified mass, the analysed sample may have contained a slightly larger amount of glass than average. However, it seems to be essential that in order to obtain good large crystals, the fluorine and potassium content of the melt must not be deficient.

Microscopic Observation.—Curved crystals were often found in solidified masses. Some crystals bent 90° or more. A slightly curved crystal is shown in Fig. 6a. The curved crystals may have been bent by crystals growing from other directions. The curved crystals retain their form after they have been split from the mass. Sometimes the growing pressure of the other crystals was so great that the bent crystal was deformed to become a mosaic crystal, as shown in Fig. 6c. In Fig. 6b there is another example of imperfect curved crystals. Small crystals grown in interstices between large crystals perpendicular to the basal plane of large crystals were bent and ruptured by the pressure of contraction action on the basal planes of large crystals while the temperature was cooling (Fig. 6d).

As was previously described, large basal plates found in solidified masses often separated into small fragments. These plates were almost entirely composed of small crystals grown in the same direction or slightly inclined toward each other or were imperfect skeleton crystals, as shown in Fig. 7a, b, and c. All these crystals were formed by rapid cooling. With slow cooling, we obtained perfect crystals grown parallel to each other (Fig. 7d), which when split made clear single crystals.

Summary

Synthetic mica crystal growing experiments were carried out with a graphite crucible and a well-sintered high-aluminous clay crucible in a carbon granule resistance furnace of 30 kg. melting capacity, specially designed for this purpose. In experiments with a graphite crucible, the

melt often became supercooled and crystallized rapidly, to result in small crystals once crystallization started at the supercooled temperature. With a clay crucible, several experiments failed because of cracks in the crucible or because of corrosion of the crucible by the melt. Only with a well-sintered high-aluminous clay crucible and under the condition of small loss of fluorine and potassium in the melt were perfect large single crystals measuring about 5 cm. by 5 cm. formed even at a mean cooling rate of 2~5°C/hr. in the range of 1360°C to 1300°C. The yield of large single crystals was very small, doubtless because only the few crystals which had formed earlier had enough time and space to be in contact with the melt and thus to grow to large size. If the growing crystals come into contact or collide with other growing crystals, the crystals are either prevented from growing further or become strained or bent. Consequently, for crystals to grow to a large size, they must be in contact with the melt for a long time without being disturbed by other crystals. This can be done when crystals grow in the same direction. It was found that the temperature gradient of 4~5°C/cm. was necessary for crystals to grow in one direction.

Among many factors affecting the growth of crystals, the rate of cooling should be controlled to secure the rate of crystal growth at less than 0.06 mm./min. in order to grow perfect and flawless single crystals of mica.

Needless to say, a sufficient volume of melt is necessary to grow large crystals, i. e. a large quantity of melt gives more opportunity for large crystals to grow. Crystals measuring 5 cm. by 5 cm. were never obtained before the 30 kg. melting experiments were carried out.

This research was carried out during the period from 1946 to 1954 by the cooperation of Messrs. K. Tamura, S. Kanatsu, I. Tate, M. Horiguchi, K. Inagaki, E. Kato, D. Ishii and K. Hata with the aid of the Scientific Research and Development Fund of the Ministry of Education, the Asahi Science Promotion Fund and a special aid by the Electocommunication Laboratory, the Japan Telegram and Telephone Corporation.

Raney Nickel and Platinized Rany Nickel with Higher Catalytic Activities

By Shigeo NISHIMURA

(Received July 8, 1958)

Preparation of Raney Nickel Catalysts. —In a previous paper[1], it was reported that a Raney nickel catalyst with a higher activity can be obtained by adding aqueous sodium hydroxide in portions to the suspension of a Raney alloy in water. To obtain a catalyst of high activity the usual methods of developing the Raney alloy, e. g. the method of Adkins and Billica[2], seemed unfavorable for the following reasons.

a) The reaction of the Raney alloy with sodium hydroxide in an aqueous solution is strongly exothermic and it is very difficult to put the alloy into the solution within a short time. Therefore, a catalyst developed uniformly can not be obtained, because the portion of the alloy added at the beginning is treated with the most concentrated sodium hydroxide for the longest time and that added last with the most dilute sodium hydroxide for the shortest time.

The lack of uniformity can not be neglected in such a catalyst as W-7 of Adkins and Billica[2], which is prepared with a

1) S. Nishimura and Y. Urushibara, This Bulletin, **30**, 199 (1957).
2) H. Adkins and H. R. Billica, *J. Am. Chem. Soc.*, **70**, 695 (1948).

comparatively small quantity of sodium hydroxide and contains a considerable amount of aluminum, or in a catalyst prepared from an alloy containing less nickel.

b) In the preparation of Urushibara nickel catalysts[3,4], which are obtained by treating finely divided nickel, precipitated from a nickel chloride solution by zinc dust, with aqueous caustic alkali or with acetic or propionic acid, it proved harmful to the activity of the catalysts to use a concentrated solution of the developing reagent and mild conditions are favorable so far as the time for the preparation is tolerable. It suggests that use of a strong alkali may be unfavorable also in the preparation of the Raney nickel catalyst.

From this point of view, the author attempted with success to prepare Raney nickel catalyst with a higher activity by adding a sodium hydroxide solution in portions to the suspension of a Raney alloy in water. In the course of this study, it was found that the Raney alloy, after being partly leached with a very dilute sodium hydroxide solution, reacts with, and is developed by, water, forming a large quantity of white aluminum hydroxide, which was confirmed to be bayerite by the X-ray diffraction analysis[5]. After the reaction with water has subsided and the alloy has been covered with grey films of bayerite, the product reacts only very mildly with a concentrated sodium hydroxide solution, which can be added at one time without arousing a violent reaction. Then the digestion is continued to remove the bayerite and to complete the development.

The Raney nickel catalyst prepared in this way (denoted as T-4 when prepared from an alloy containing 40% of nickel) is more active than the W-7 catalyst of Adkins and Billica. The catalyst prepared under the same conditions as W-7 except that a larger quantity of the sodium hydroxide solution of the same concentration was used (denoted as W-7′) was less active than W-7.

It suggests that the W-7′ catalyst was overdeveloped or partly deactivated with the strong alkali in the course of the development. Table I shows the activities of these three catalysts in the hydrogenation of various organic compounds under the ordinary pressure and at 25°C.

TABLE I

TIME (min.) FOR THE HYDROGENATION OF ORGANIC COMPOUNDS WITH RANEY NICKEL CATALYSTS UNDER THE ORDINARY PRESSURE AND AT 25°C

Compound	Amount (g.)	Hydrogen absorbed (mole/mole)	Catalyst T-4	W-7	W-7′
Cyclohexanone	3.93	1	17	21	24
Acetophenone	4.81	1	34	40	50
Cyclohexene	3.29	1	7	9	9
Quinoline	2.58	2	83	84	
Benzonitrile	2.06	2	49	76	80
Cyclohexanone oxime	2.26	2	92	126	

a) The catalyst was prepared from 2 g. of a Raney alloy containing 40% of nickel each time just before the hydrogenation.
b) 20 cc. of 95% ethanol was used as the solvent.

From some apparently similar methods in the literature[6-9] the present method differs in the fact that the Raney alloy is developed mostly with water, but not with an alkali, forming a large quantity of bayerite, which prevents the catalyst from direct contact with a strong alkali and facilitates the later addition of the main portion of the sodium hydroxide solution. The procedure to prepare the T-4 catalyst is given in details in the experimental part.

Preparation of the Platinized Raney Nickel Catalysts. — In many hydrogenations it has been shown that the Raney nickel catalyst is greatly promoted by treatment with chloroplatinic acid. Delépine and Horeau[10,11] showed that a Raney nickel platinized with chloroplatinic acid was effective for the hydrogenation of carbonyl compounds with addition of a little aqueous sodium hydroxide. Lieber, Smith and their co-workers[12-17] showed

that treatment with chloroplatinic acid or with chloroplatinic acid and triethylamine was also effective for many hydrogenations. These methods agree in the fact that the Raney nickel is treated with chloroplatinic acid, and may supposedly have the following disadvantages:

a) The activity of nickel itself may be partly lost on treatment with chloroplatinic acid and the nickel ion then formed may be a catalytic poison[12].

b) The chloride ion and/or the hydrogen ion may be also catalytic poisons[18] and it is not certain if they can be completely removed by mere addition of sodium hydroxide[19] or triethylamine.

Recently Blance and Gibson[20] prepared a platinized Raney nickel from a nickel-aluminum alloy containing 2% of platinum but such an alloy has to be made specially and may not always be readily available.

The present author improved the preparation of the platinized Raney nickel by platinizing and simultaneously leaching the Raney alloy: A chloroplatinic acid solution made alkaline with a little sodium hydroxide is added to the suspension of a Raney alloy in water. The partly leached and platinized Raney alloy reacts with water, forming a large quantity of bayerite, and then can be treated in the same way as in the preparation of the T-4 catalyst. The details of the procedure for the preparation are given in the experimental part.

The platinized T-4 catalyst prepared in this way is more active than the T-4 catalyst platinized by the method of Delépine and Horeau. Table II shows the activities of these two catalysts in the hydrogenation of some organic compounds, T-4-Pt denoting T-4 platinized by the present method and T-4-Pt (D. H.) T-4 platinized by the method of Delépine and Horeau.

TABLE II

TIME (min.) FOR THE HYDROGENATION OF ORGANIC COMPOUNDS WITH THE PLATINIZED RANEY NICKEL CATALYSTS UNDER THE ORDINARY PRESSURE AND AT 25°C

Compound	Amount (g.)	Hydrogen absorbed (mole/mole)	Catalyst	
			T-4-Pt	T-4-Pt (D.H.)
Cyclohexanone	3.93	1	10	13
Acetophenone	4.81	1	13	17
Quinoline	2.58	2	27	38
Benzonitrile	2.06	2	11	14
Cyclohexanone oxime	2.26	2	17	19

a) The catalyst was prepared from 2 g. of a Raney alloy containing 40% of nickel and 50 mg. of chloroplatinic acid, $H_2PtCl_6 \cdot 6H_2O$.

b) 20 cc. of 95% ethanol was used as the solvent.

Experimental

Preparation of T-4 Catalyst.—To a mixture of 2 g. of a Raney nickel-aluminum alloy containing 40% of nickel[21] and 10 cc. of water, contained in a 30 cc. Erlenmeyer flask with a stirrer and heated in a water bath of 50°C, 0.4 cc. of 20% aqueous sodium hydroxide is added with vigorous stirring, care being taken not to let the reaction become violent, and the mixture is stirred. In about one hour, the partly leached Raney alloy begins to react with water and turns grey in color, and the reaction almost subsides in one hour and a half. Then 6 cc. of 40% aqueous sodium hydroxide is added at one time with continued stirring.

The digestion is continued for one additional hour at 50°C with good stirring, until the upper layer becomes snow-white. The catalyst is washed by stirring and decanting four times with 15 cc. of water of 50°C and then three times with the same volume of ethanol. A specimen of the T-4 catalyst thus prepared contained 13.3% of aluminum and a little aluminum hydroxide.

Preparation of W-7 and W-7′ Catalysts.—W-7 catalyst was prepared from 2 g. of the alloy and 12 cc. of a 20 per cent sodium hydroxide solution exactly as described by Adkins and Billica[2] except that the catalyst was washed as described above for the T-4 catalyst. W-7′ catalyst was prepared from 2 g. of the alloy and 24 cc. of 20 per cent aqueous sodium hydroxide. The W-7 and W-7′ catalysts thus prepared contained 13.3 per cent and 12.5 per cent of aluminum, respectively.

Preparation of Platinized T-4 Catalyst.—To a suspension of 2 g. of the Raney alloy in 10 cc. of water, 50 mg. of chloroplatinic acid, $H_2PtCl_6 \cdot 6H_2O$, dissolved in 2 cc. of water made alkaline with 0.4 cc. of 20 per cent aqueous sodium hydroxide, was added with vigorous stirring in a water bath of 50°C.

The procedure hereafter is exactly the same as described above for the T-4 catalyst. Incomplete digestion, which is indicated by the grey

21) A 50-50% alloy can be used with a somewhat lower activity of the resulting catalyst.

color of the upper layer, does not develop the activating effect by platinum.

Platinization of the T-4 Catalyst by the Method of Delépine and Horeau.—To a suspension of the T-4 catalyst, prepared from 2 g. of the Raney alloy, in 10 cc. of water, 50 mg. of chloroplatinic acid, dissolved in 2 cc. of water, is added with vigorous stirring in a water bath of 50°C. In a few minutes, when the reaction is complete, a little sodium hydroxide solution is added with stirring, and then the catalyst is washed.

Hydrogenation. — After the catalyst, suspended in 15 cc. of ethanol, was saturated with hydrogen at 25°C, the substance dissolved in 5 cc. of ethanol was added and the mixture was shaken with hydrogen at 400—500 oscillations per minute.

Identification of Bayerite.—The snow-white precipitate in the upper layer formed during the digestion with alkali was collected by centrifuging and analyzed by means of the X-ray diffraction.

The diffraction pattern shown in Fig. 1 shows that the precipitate is bayerite, one form of aluminum trihydroxide. But the bayerite is different from that formed in the reaction of the alloy with water as shown in Fig. 2. According to Fricke[22], the former is bayerite a and the latter bayerite b.

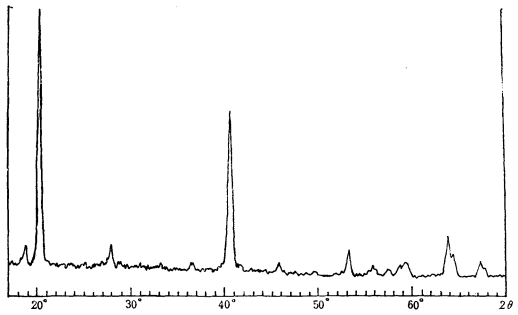

Fig. 1. Diffraction pattern of the precipitate formed during the digestion with alkali.

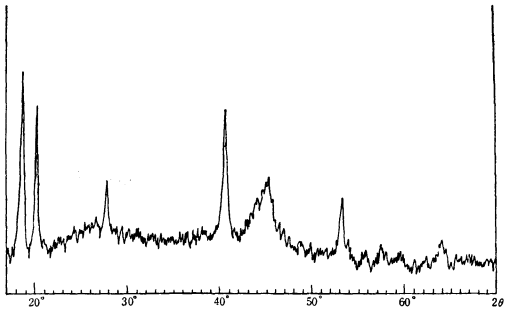

Fig. 2. Diffraction pattern of Raney alloy after the reaction with water.

The patterns were obtained by an X-ray diffractometer with Ni-filtered Cu-K_α radiation.

The author wishes to express his hearty thanks to Professor Yoshiyuki Urushibara for his kind guidance and valuable suggestion given throughout this work. The author is also indebted to Dr. Hiroshi Takahashi and Mr. Haruo Kuroda for their kind help in the measurement of the X-ray diffraction. This study has been supported by the Scientific Research Grant of the Ministry of Education.

The Density of the Polycyclic Aromatic Compounds

By Hiroo INOKUCHI and Masayuki NAKAGAKI

(Received July 16, 1958)

It is already generally known that the physico-chemical properties of the polycyclic aromatic compounds are correlated closely to the number of carbon atoms comprised in the molecule. For instance, it has been found that the inner heat of sublimation of these hydrocarbons possesses a linear function of the number of carbon atoms with an average value of 1.5 kcal./mol. per carbon atom[1] and also that the increment of the number of benzene rings in the molecule of this series shows the increase of the electrical conductivity of these compounds[2].

These compounds belong to typical molecular crystal, in which molecules interact with each other by the van der Waals force. Lattice energies of crystals built up of homopolar molecules such as nitrogen or carbondioxide were first calculated by London[3]. The main object of this paper is to apply similar calculations of computing the density of the polycyclic aromatic compounds in comparison with the number of carbon atoms.

Experimental Procedures

The measurements of density for the polycyclic aromatic compounds were carried out at room temperature by means of the pycnometer as shown in Fig. 1. The total volume of this vessel, made of glass tubing of 15 mm. in diameter, was approximately 5 cc. The addition of the ground-on caps to cover the entrances of the vessel was helpful to prevent the evaporation of the pycnometer liquid.

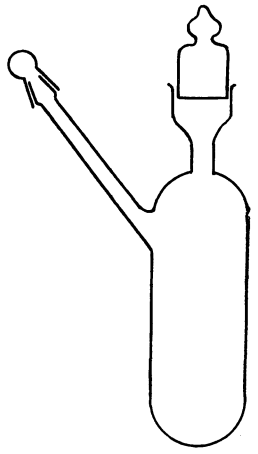

Fig. 1. The pycnometer

Since the solubility of violanthrene and *iso*-violanthrene in organic solvents is negligiblly small at room temperature, ethanol can be used as the pycnometer liquid. The solubilities of anthanthrene and naphthacene were, however, fairly high in the alcohol. Therefore, distilled water mixed with a very small amount of a surface-active agent was employed as the pycnometer liquid for these compounds.

Through a preliminary experiment, it was recognized that the adherence of bubbles of air on a surface of an organic compound was a serious reason for the fluctuation of the observed density values. In order to remove as much of the air as possible, the vessel containing the specimen and liquid had to be attached to a water-pump and to be kept under a reduced pressure.

The polycyclic aromatic compounds used in this experiment were purified thoroughly by the methods already described in previous reports[2].

Results and Discussion

The potential energy of a molecule as

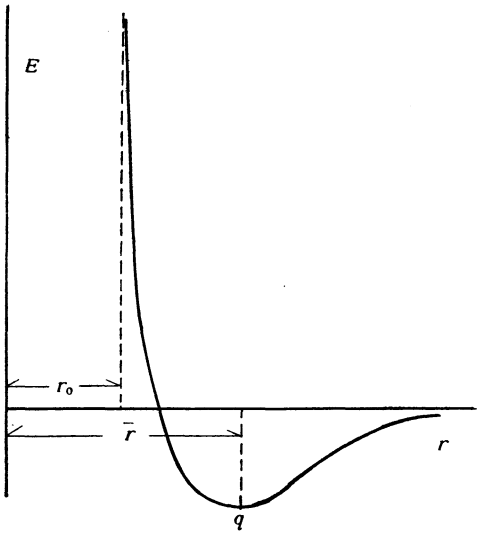

Fig. 2. The potential energy curve for intermolecular force.

1) H. Inokuchi, S. Shiba, T. Handa and H. Akamatu, This Bulletin, **25**, 299 (1952).
2) H. Akamatu and H. Inokuchi, *J. Chem. Phys.*, **18**, 810 (1950); **20**, 1481 (1952). H. Inokuchi, This Bulletin, **24**, 222 (1951); **25**, 28 (1952)
3) F. London, *Z. physik. Chem.*, **B11-12**, 222 (1930-1).

a function of an intermolecular distance, r, is generally expressed by a curve as shown in Fig. 2. This curve is made up of the sum of the dispersion and the repulsive force, the latter arising when the clouds of valence electrons of two molecules interpenetrate each other. These two forces are equal at the minimum point, q, of the potential energy curve. In addition, a strong repulsion due to the interpenetration of inner electron shells is assumed when the intermolecular distance is smaller than r_0. When the molecular weight of the hydrocarbon is very large, that is to say, the interaction between these molecules is very strong, it is reasonable to assume that the equilibrium distance between two molecules, $\bar{r}$, is nearly equal to r_0.

The molecule of the aromatic compound, a member of the series from benzene to graphite, has a plate-like shape, and is packed to make the molecules parallel to one another. Therefore, we can introduce the theory that r_0 corresponds to the interlayer spacing of graphite, 3.35Å, assuming that graphite is a kind of polycyclic aromatic compound having infinitely large molecular weight.

In calculating the sum of the dispersion forces and repulsive forces of atoms in the molecule, the contribution of hydrogen atoms may be neglected. Hence, the interation energy per one molecule $E(r)$ is expressed as,

$$E(r)=\frac{-AN^2}{(r-r_0)^6}+\frac{BN}{(r-r_0)^n} \tag{1}$$

in which N is the number of carbon atoms included in that molecule and A and B are constants.

At the equilibrium condition,

$$\left(\frac{\partial E(r)}{\partial r}\right)_{r=\bar{r}}=0=\frac{6AN^2}{(\bar{r}-r_0)^7}-\frac{nBN}{(\bar{r}-r_0)^{n+1}} \tag{2}$$

Therefore, $(\bar{r}-r_0)$ is represented as

$$(\bar{r}-r_0)^{n-6}=\frac{nB}{6A}\times\frac{1}{N} \tag{3}$$

The density of the aromatic compounds ρ is related to $\bar{r}$ by the equation

$$M/\rho=N_A S\bar{r} \tag{4}$$

in which M and S are the molecular weight and the area of one molecule of the aromatic hydrocarbon respectively, and N_A is Avogadro's number.

Since M and S may be proportional approximately to N, the number of carbon atoms in that molecule, Equation 4 can be rewritten in the form

$$\bar{r}=C/\rho \qquad C=M/N_A S=\text{constant} \tag{5}$$

and also

$$r_0=C/\rho_\infty \tag{6}$$

Equation 3, therefore, becomes

$$\left(\frac{1}{\rho}-\frac{1}{\rho_\infty}\right)^{n-6}=\left(\frac{nB}{6AC^{n-6}}\right)\frac{1}{N} \tag{7}$$

This equation may be reduced to

$$\log\left(\frac{1}{\rho}-\frac{1}{\rho_\infty}\right)=-\frac{1}{n-6}\log N+\log Q \tag{8}$$

Here,

$$Q=nB/6AC^{n-6} \tag{9}$$

When we use the following numerical values

$\rho_\infty=2.26$ (density of graphite)

n=8

$B/AC^2=0.99$

in the above equation,

TABLE I
THE DENSITY OF POLYCYCLIC AROMATIC HYDROCARBONS

Compound	N	Density		Reference
		Observed	Calculated

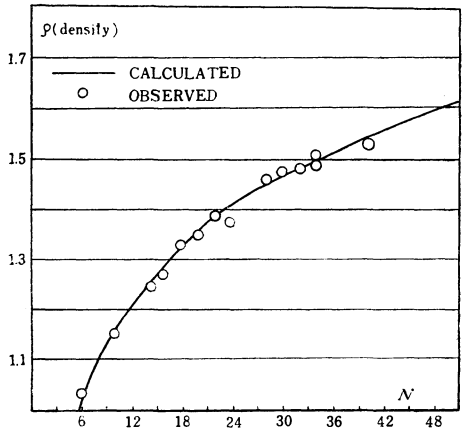

Fig. 3. The density of the polycyclic aromatic compounds.

$$\log\left(\frac{1}{\rho}-\frac{1}{2.26}\right)=-\frac{1}{2}\log N+0.120 \quad (10)$$

can be obtained.

The computed and also observed values of ρ are given in Table I and Fig. 3 for several polycyclic aromatic compounds. The agreement of these values in the table is satisfactory.

Table II
THE DENSITY OF CARBON BLACKS.

Specimen	L_a (Å)[12]	N	Density	
			observed	calculated
Royal Spectra	13.1	66	1.68	1.66
Philblack E	12.0	55	1.76	1.63
Peerless II-A	14.2	77	1.82	1.69
Tokyo Gas Carbon	13.4	69	1.68	1.67
Statex B	16.9	111	1.81	1.76
Philblack O	13.3	67	1.81	1.67

Applying Equation 10 to calculate the density of carbon blacks, we have the result in Table II. By means of the X-ray diffraction analysis, the dimension of a condensed polycyclic aromatic layer of the carbon, L_a, was calculated from the breadth of (10) reflection at half of the maximum intensity, applying Warren's formula for the random layer lattice. The area occupied by a carbon atom in the layer, may be assumed an equilateral triangle, for which b has the value of $a \sin 60°$, as illustrated in Fig. 4. Here, a possesses the distance of C−C bonding, 1.41Å. Thus, the number of carbon atoms in the layer is expressed

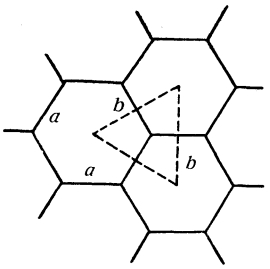

Fig. 4. The area occupied by a carbon atom in graphite layer.

$$N=4L_a^2/3\sqrt{3}\,a^2 \quad (11)$$

On the basis of this table the authors are inclined to think that they have derived a relation between the density and the molecular weight of carbon blacks.

Summary

The density (ρ) of the polycyclic aromatic hydrocarbons, from benzene (C_6H_6) to circumanthracene ($C_{40}H_{16}$), are correlated closely to the number of carbon atoms (N) included in the molecule. We may be expressed the relation as $\log(1/\rho-1/\rho_\infty) = -(1/2)\log N+0.120$, in which ρ_∞ is the density of graphite, 2.26. The agreement of the computed values with the observed results is satisfactory. A trial to apply the equation to calculate the density of carbons is made with some success.

The authors express hearty thanks to Professor H. Akamatu for his kind direction in this work. The cost of this research has been defrayed from the Scientific Research Encouragement Grant from the Ministry of Education to which the authors' thanks are due.

Formation and Aging of Precipitates. X. An Electron Micro-Diffraction Study on Crystal Habit of Barium Sulfate Precipitates*

By Kazuyoshi TAKIYAMA

(Received July 19, 1958)

The shapes of precipitated particles of sparingly soluble salts are usually classified into groups of perfect crystals having simple forms and dendrites having irregular forms. The author has previously reported the relationship between the condition of precipitation and the shape and size of precipitated particles of barium sulfate, by the direct mixing of reagents[1]. The rectangular perfect crystals were prepared from a solution below about 0.0005 M of initial concentration of barium sulfate, and the spindle-shaped dendrites having rugged edges were prepared in a range of initial concentration from about 0.001 to 0.2 M. Above 0.5 M, the precipitate was jelly-like at the beginning, but it changed gradually to the crystalline precipitate. Fischer[2] also studied the morphology of barium sulfate precipitates by electron microscopy and reported that the crystals formed as elevated temperature were somewhat more perfect than those formed at room temperature, and that the fairly perfect crystals were formed when very dilute solutions of reagents were mixed slowly by ionic diffusion through a thin membrane.

An attempt has been made in the present investigation to employ the electron micro-diffraction method for clarifying the crystal habit of barium sulfate.

Sample.—Solutions of 0.001 and 0.1 M barium chloride were placed in small beakers, which were kept at room temperature and at 80°C. Small thin films of Formvar were then floated on the surface of the solutions, and a drop of 0.001 M sulfuric acid was placed on each film. A few minutes were allowed for the reactant ions to diffuse slowly through the thin film and form the precipitates. Then the films with the drops were removed with the aid of a glass slide and refloated on the surface of water in another beaker. About ten minutes were allowed for diffusion of ions from the drop of mother liquid into the water below. Then the films with drops were scooped with specimen grids. After drying the specimen, the precipitates were observed with an electron microscope.

Rectangular perfect crystals were formed from 0.001 M solution independently of the reaction temperature. Dendrites were formed from 0.1 M solution. The growth direction of dendrite was dependent on the reaction temperature as mentioned later. The crystals formed by the diffusion mixing method are generally thin laminae, so they are suitable to study by the electron diffraction method. Crystals precipitated by the direct mixing of reagents have the same morphological characteristics as those precipitated by the diffusion mixing of ions, when the concentration and the reaction temperature are kept at the same condition.

Results

Morphology of Barium Sulfate Precipitates by Electron Microscopy.—A perfect crystal of barium sulfate is a rectangular platelet as shown in Fig. 1a. In a particular case of precipitation in dilute aqueous alcohol, octagonal or hexagonal platelet is formed as shown in Fig. 3a.

The dendrite prepared at room temperature is made of two main stems crossed perpendicularly to each other, which grow from the center of the crystal. Many primary and secondary branches are seen which grow from the main stems parallel to the stems (Fig. 4a). The dendrites prepared at elevated temperature are shown in Figs. 7a and 8a. The primary branches grow obliquely to the main stems crossed perpendicularly with each other (Fig. 7a). The main stems of the crystals shown in Fig. 8a has defects, and the large protuberances of these crystals correspond to the primary branches of the crystals shown in Fig. 7a. The secondary branchings are parallel to the primary branches, that is, they are oblique to the main stems (Figs. 7a and 8a). The relation of the main stems and the branches are shown in Figs. 9a and b.

The dendrite grows generally in two-dimension as shown by a replica of crystal in Fig. 10. The dendrite shown in Fig. 11 is sometimes observed. Here the platelet particle is set perpendicular to the supporting film. The crystal seems to be a twin, and twin planes estimated to be (110) were observed.

Analysis of N-Pattern Obtained by Electron Micro-Diffraction Method. — All electron diffraction patterns obtained from the crystals in the present study are N-patterns. The arrangement for orientation between the electron microscopic image and the electron diffraction pattern as well as the fixing of the index of each reflection spot were made as follows. The image of electron microscope is rotated at a certain angle with respect to the electron diffraction pattern owing to the difference of lens current. The method for an arrangement of these two images is described below, in Fig. 1 as an example. The electron diffraction pattern obtained from a selected crystal in Fig. 1a is shown in Fig. 1c. When the current of the intermediate lens is increased a little more than the value which gives the diffraction pattern, a pattern shown in Fig. 1b is obtained. In Fig. 1b the small bright field image appears at the center of the pattern and many small dark field images appear at the similar positions to the electron diffraction spots. The orientations of the bright and dark field images are the same, so the relative orientation of the electron microscopic image to the electron diffraction pattern can be known. All crystals are, of course, barium sulfate and belong to V_h^{16}. The reciprocal lattice of barium sulfate crystal and the intersection with Ewald sphere are obtained. Then N-pattern constructed is compared with that obtained by experiment (Fig. 1c), and the Miller's indices of reflection spots are fixed as shown in Fig. 2b.

Crystal Habit of Barium Sulfate Precipitates by Electron Micro-Diffraction Method. — All electron micrographs and diffraction patterns shown in this paper are arranged to the same orientation. Electron diffraction patterns obtained from most crystals are N-patterns same as that shown in Fig. 2b. From this, it has been revealed that the platelet crystals have grown along (100) plane. The laminae that give the N-pattern shown in Fig. 2b are perpendicular to the electron beam.

The short- and the long-axes of rectangular crystal shown in Fig. 1a are *b*- and *c*-axes respectively as shown in Fig. 2a. The normal to the platelet is *a*-axis. The normal to the octagonal lamina shown in Fig. 3a is also *a*-axis, and the side planes of that crystal are {010}, {011} and {001} groups.

The main stems of dendrite shown in Fig. 4a have grown to the direction along

(a) (b)

Fig. 2. The direction of axes and the indices of electron diffraction pattern of perfect crystal of barium sulfate shown in Fig. 1.

a: room temperature
b: 80°C

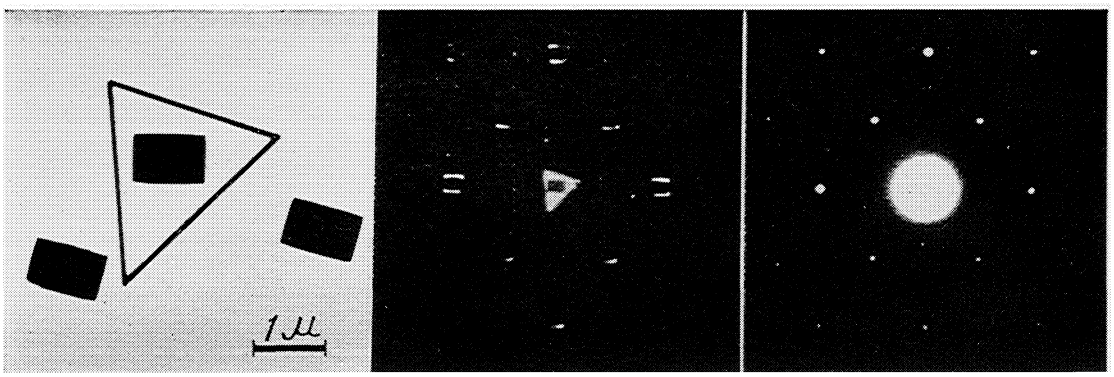
b- and *c*-axes. Small branchings also grow in parallel to these axes (Fig. 9a). The platelet of dendrite shown in Fig. 5a was placed inclined to the electron beam, and the angle between *a*-axis (normal to platelet) and the electron beam was proved 64° from the analysis of N-pattern as shown in Fig. 6. The main stems of the dendrite shown in Fig. 7a have grown along *b*- and *c*-axes, but the branches have grown to the direction perpendicular to the plane of {011} group (Fig. 9b). The dendrites shown in Fig. 8a have grown markedly to the direction perpendicular to the plane of {011} group.

Consideration

Generally speaking, when a crystal grows from a dilute reagent, the growth rate is so small that the perfect crystal is formed. The perfect crystal of barium sulfate is generally a rectangular platelet and the octagonal or hexagonal crystal is formed in a rare case.

Dendrite of barium sulfate crystal is formed in a range of initial concentration from about 0.001 M to 0.2 M. At the concentration above this range, the rate of nucleation is very rapid, so numerous nuclei appear but their growth immediately after mixing of reagents does not proceed. At the concentration below that range, the rate of nucleation is very slow and a small number of nuclei grows slowly to the perfect crystals. In the range of initial concentration mentioned above (0.001 to 0.2 M), both rates of nucleation and growth are a little more rapid than that in the case just mentioned above, and the edge or the corner of a crystal grows preferentially to form the dendrite.

Watson and Freemann[3] believed that the dendrite formed in an iron sol is composed of aggregated small cubic particles. However, the electron diffraction pattern of the dendrite of barium sulfate is N-pattern, which indicates a single crystal and that the crystal has grown from a single nucleus to the dendrite.



Summary

Barium sulfate precipitates in a form of rectangular perfect crystal from a solution of low initial concentration, and in a form of dendrite from a solution of higher initial concentration. They are platelets grown along (100) plane. The short- and long-axes of rectangular crystal are *b*- and *c*-axes respectively. The dendrite grows along *b*- and *c*-axes, or along the direction perpendicular to the plane of {011} group.

Untersuchungen über die Bildung der Proteinase aus einem Aspergillus awamori-Stamm. II. Charakterisierung des Proteinasebildungsvermögens des Mycels im Kultursverlauf durch seinen Stickstoffwechsel

Von Jiro HOSHINO

(Eingegagen am 23. Juli, 1958)

Aus dem ausgewaschenen ruhenden Mycel des Schimmelpilzes, ebenso wie Bakterie sind reichliche Mengen von Enzyme im reinen Zustand leicht zugänglich. Die Enzymbildung wird aber bei diesem experimentalen System durch verschiedene äussere Faktoren stark beeinflusst. Es ist bekannt, wie auch der Verfasser in der vorigen Mitteilung[1] über die Proteinasebildung bestätigt hat, dass sich das Vermögen der Zelle zur Enzymbildung, die eine der Mikroorganismus eigenen biochemischen Aktivitäten darstellt, mit der Züchtungsdauer ändert.

Nach der Angabe von O. Tanabe[2] wurde das Amylasebildungsvermögen des *Asp. oryzae*-Stammes in den früheren Stufen der Züchtung grösser erwiesen. Derselbe Tatbestand wurde von C. P. Hegarty bei der *„adaptiven"* Bildung von Enzyme aus *Streptococcus lactis* festgestellt[3]. Die Bakterien betreffend wurden noch von mehreren Forschern darüber mit den mannigfachen Ergebnisse verfolgt[4-8].

Es liegt nahe anzunehmen, dass verschiedene Stoffe innerhalb des Mycels für die Änderung dieser physiologischen oder biochemischen Aktivitäten verantwortlich sind, von denen die Nucleinsäuren als Spezifität-Donator und die Aminosäuren als Bausteine des Enzymproteins eine entschiedene Rolle spielen sollen.

Da die Ergebnisse über die Änderung des Proteinasebildungsvermögens mit der Züchtungsdauer, die der Verfasser in der vorigen Mitteilung kurz dargelegt hatte, eine sehr Wichtige zu bedeuten scheint, hat der Verfasser nun diese vorige Aufgabe wieder sich aufgestellt, um damit tiefere Übersicht auf die Beziehung des Proteinasebildungsvermögens mit dem Sammelbecken von Aminosäuren des Mycels und seinem Stickstoffwechsel gewinnen zu können.

Arbeitsmethode

Bestimmung des Proteinasebildungsvermögens des Mycels. — Zur Ermittelung des Proteinasebildungsvermögens des Mycels wurde die Aktivität der in die Kulturflüssigkeit sezernierten Proteinase nach dem zwanzigstündigen Schütteln des ausgewaschenen Schüttelmycels (1.0 g feuchtes: ungefähr 0.2 g trocknes), welches aus den verschiedenen Phasen einer Entwicklungskultur abgeerntet worden war, in der 1.0 prozentige Glucose haltigen M/5-Phosphatpufferlösung (pH=6.1) nach der Folinschen Methode bestimmt und mit derselben pro g trocknes Mycels angegeben. Diese Aktivität wird vom Verfasser provisorisch als *„potentiale Aktivität des Proteinasebildungssystems"* (PAPS) bezeichnet.

Züchtung des Pilzes und Gewinnung des ausgewaschenen Schüttelmycels wurden in der vorigen Mitteilung ausführlich dargelgt.

Bestimmung des organischen Stickstoffs des Mycels.—Zur Bestimmung des organischen Stickstoffs des Mycels wurde die semi-mikro Kjeldahlsche Methode nach A. O. A. C. verwendet. Den organischen Gesamtstickstoffgehalt hat der Verfasser experimentell in zwei Gruppen, d. h. Proteine- und non-Proteine-N, eingeteilt, wobei der erstere denjenigen Gesamtstickstoff bedeutet, der sich in der 5.0 prozentigen Trichloressigsäure löslichen Fraktion befindet. Den letztere kann man rechnerisch leicht erreichen. Bestimmung dessen ist wie folgt: Das üblicherweise gut ausgewaschene und abgepresste Mycel (ungefähr 0.2 g trocknes) wurde mit 40 ccm 5 prozentiger Trichloressigsäurelösung 20 Minuten am Rückfluss gekocht. Das Extrahieren wurde in analoger Weise noch zweimal wiederholt. Sodann wurde das rückstehende Mycel getrocknet und zur Ermittelung des Stickstoffs herangezogen.

Ergebnisse

Abhängigkeiten der PAPS und N-Konstitution des Mycels von seinen Entwicklungsphasen. — Das Proteinasebildungsvermögen (PAPS) des Mycels und seine Gehalte am Gesamt-(N_t), Proteine-(N_p) und non-Proteine-N(N_{np}) wurden in den verschiedenen Entwicklungsphasen ermittelt, um damit auf die Frage zu beantworten, welche Bestandteile an die Biosynthese von Proteinase teilnehmen. Die Resultate sind in der Abb. 1 illustriert.

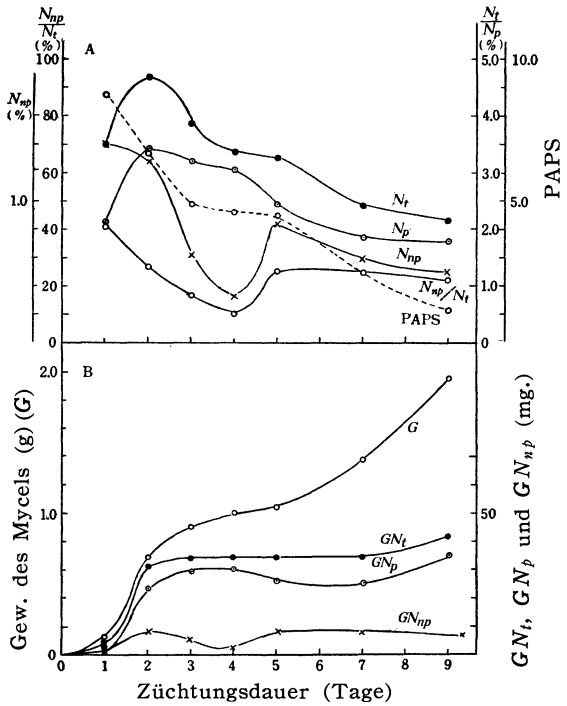

Abb. 1. Abhängigkeiten der PAPS und N-Konstitution des Mycels von seiner Züchtungsdauer.
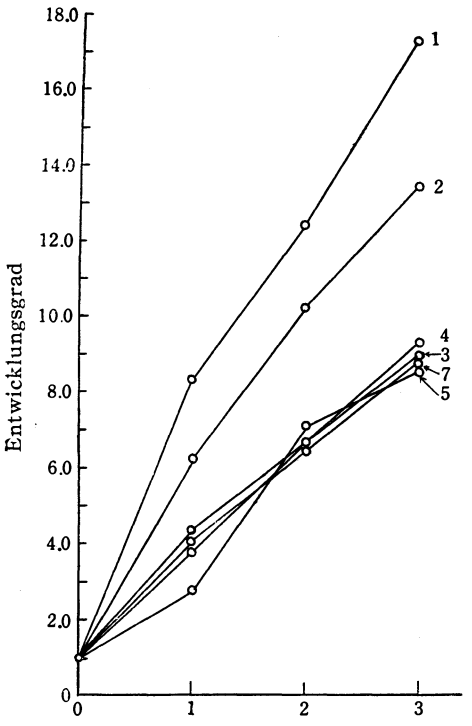
N_t: totaler Stickstoffgehalt des Mycels
N_p: Proteinstickstoffgehalt des Mycels
N_{np}: non-Proteinstickstoffgehalt des Mycels

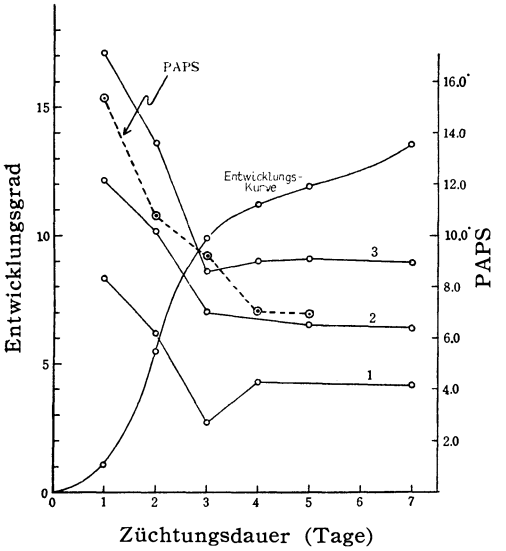
Die Sporen wurden in der vorliegenden Arbeit nicht behandelt, weil die Dauer kurz nach dem Impfen dieselbe der Keimung darstellt und der Stoffwechsel dabei von der Mycelentwicklung recht verschieden sein soll[9].



Vom ersten bis zum zweiten Tagen nach dem Impfen hat sich das Mycel sehr stark entwickelt, und solche Phase wurde 4~5 Tage danach wieder beobachtet. Dass das Mycel in dieser Entwicklungsphase allmählich reicher an N_t und N_p, und im Gegenteil armer an N_{np} geworden ist, ist es nun bedeutungsvoll. Daraus geht es klar hervor, dass in dieser Entwicklungsphase die Myceleiweisskörpern aus den Aminosäuren kräfting synthetisiert werden, wobei also der anabolische Stoffwechsel den Eiweissstoff betreffend eine dominierends Rolle spielt. Vom 4 Tage nach dem Impfen fängt der Amino-N Gehalt des Mycels plötzlich an zuzunehmen und dementsprechend fängt der N_p Gehalt an abzunehmen. In Anbetracht, dass der Gesamt-N inzwischen unveränderlich bleibt, (Abb. 1, B) müssen die Aminosäuren innerhalb des Mycels unter dem Verbrauch von Myceleiweisskörpern anhäufen. In dieser Phase scheint daher der catabolische Stoffwechsel den Eiweisskörper betreffend in analogem Sinne eine dominierende Rolle zu spielen.

Die in der Figur gegebenen Versuche zeigen weiter, dass sich das Proteinasebildungsvermögen (PAPS) in der anabolischen Phase allmählich erschwächt und es gerade mit dem Aminosäuregehalt des Mycels gleichläuft. Daraus folgt es, dass die Proteinasebildung von der Menge der inneren Aminosäuren beschränkt wird, und sich vermindert, wenn die Aminosäuren zur Myceleiweissstoffbildung verbraucht worden sind.

Den Züchtungsverlauf in der Figur kann man in zwei „Lebenskreise" einteilen, von denen das Erste einen typischen Entwicklungs- oder Stoffwechselsprozess bietet: die catabolische Phase entspricht der „*lag*" Phase und die anabolische Phase der „*log*" d.h. kräftig entwickelnden Phase. Das Mycel, das sich zwischen diesen beiden Phasen befindet und also die Aminosäuren am meisten enthält, hat das grösste Proteinasebildungsvermögen in jedem Kreis.



Beziehung der Änderung des Vermögens zur Mycelentwicklung mit der Proteinasebildung. — Da das Mycel, das ein erhebliches Vermögen zur Proteinasebildung besitzt, nicht dasjenige, das ein sich kräftig entwickelendes Mycel, sondern dasjenige ist, das sich in der Vorstufe der „*log*" Phase befindet und damit, wie aus der Abb. 1 ersichtlich ist, uns seine kommende kräftige Entwicklung erwarten liess, hat der Verfasser das potentiale Entwicklungsvermögen des Mycels in den jeden Phase in folgender Weise ermittelt: 1.0 g wie üblich dargestelltes Schüttelmycel wurde in die frische Nährlösung unter sterilen Bedingungen übergetragen und weiter bei

30°C fortgeschüttelt. Je nach 1, 2 und 3 Tagen wurde je ein Kolben abgebrochen und die sich entwickelte Mycel abgeerntet, ausgewaschen, sodann zur Wägung getrocknet.

Als Entwicklungsgrad wurde das Gewichtsverhältnis dieses Mycels zum unterworfenen Mycel ermittelt. In der Abb. 2 werden die Entwicklungsgrade der Mycel verschiedener Züchtungsphasen in Kurvenform gegeben. Dabei ergab es sich, dass das jüngere Mycel ein grösseres Entwicklungsvermögen besitzt, ohne „*lag*" Phase zu zeigen. Die Mycel in den Züchtungsphasen von 3, 4, 5 und 7 Tagen zeigten aber beinahe gleichartige Entwicklungsverläufe. Diese Umstände sind auf der Abb. 3 leicht begreiflich. Hierbei wurde es gezeigt, dass ein deutlicher Parallelismus zwischen dem Proteinasebildungs- und dem Entwicklungsvermögen des Mycels auch in diesem Falle besteht.

Der „*lag*" Phase des zweiten "Lebenskreises" entpricht also die Phase, wovon die Fläche der Kurven des Entwicklungsvermögens beginnt. Während der Prüfung über das Entwicklungsvermögen wurde keine massgebende Bildung der Proteinase beobachtet.

Unter Berücksichtigung dieser Tatsachen wurde es festgestellt, dass das erhebliche Proteinasebildungsvermögen einem Mycel gehört, welches ein kräftiges Entwicklungsvermögen besitzt und reichliche Mengen von Aminosäuren enthält. Diese Erscheinungen stellen daher vermutlich zwei Seiten eines Attributes dar, und sie antagonieren einander gegen ein Sammelbecken von Aminosäuren. Dieser Befund steht in voller Übereinstimmung mit den Untersuchungen von M. Nomura[10], in denen er eine antagonistische Biosynthese von Amylase durch *Bacillus subtilis* gegen dieselbe der Zelleiweissstoffen beobachtet und die Amylasebildung als „*abnorme*" Biosynthese bezeichnet hat.

Beziehung des Proteinasebildungsvermögens der in verschiedenen Bedingungen entwickelten Mycel mit seinem Amino-N Gehalt. — Aus den hierher geschilderten Ergebnisse schien der Aminosäuregehalt des Mycels bei der Proteinasebildung eine dominierende Rolle zu spielen. In Anbetracht dessen wurden die N-Bestandteile desjenigen Mycels in Bezug auf seine Proteinasebildungs- und Entwicklungsvermögen untersucht, das sich unter der

* Entwicklungsvermögen: dies wurde mit dem Entwicklungsgrad der 24-stündigen Prüfung angegeben.

** Proteinasebildungsvermögen: dies steht im Text geschrieben.

variierenden N-Konzentration entwickelt hatte. Die Ergebnisse sind in der Tabelle I zusammengestellt.

Dabei hat es sich ergeben, dass kein wesentlicher Parallelismus zwischen dem Aminosäuregehalt und den beiden Vermögen des Mycels besteht, während es dem Verfasser gelungen ist, auf obige Weise den Aminosäuregehalt des Mycels zu verändern. Daraus darf festgestellt werden, dass der Gehalt des Mycels an Aminosäuren nicht immer für die Proteinasebildung ein entschiedener Faktor ist. Doch ist es so zu deuten, dass das Mycel, das erhebliche Proteinasebildungs- und Entwicklungsvermögen besitzt, stets reichliche Aminosäuren darin enthält.

Die Aufgabe, was für ein Substanz auf die Proteinasebildung in diesem experimentalen System eine dominierende Rolle spielt, bleibt auf Grund der oben dargelegten Resultaten noch unlöslich und bedarf noch weitere Untersuchungen.

In der vorliegenden Arbeit wurde am Schlusse das Proteinasebildungsvermögen des Mycels im Kultursverlauf in Bezug auf das Mycelentwicklung durch seinen Stickstoffwechsel charakterisiert.

Schlusswort

Die Proteinasebildungsvermögen des Pilzmycels wurde in Anbetracht seines Stickstoffwechsels verfolgt. Gleichungen wurden durch die Verfolgungen der Änderung der Stickstoffskonstitution und des Entwicklungsvermögens des Mycels im Kultursverlauf abgeleitet, um damit auf die Frage zu beantworten, ob ein Sammelbecken von Aminosäuren bei der Biosynthese von Proteinase eine dominierende Rolle spielt.

Es wurde gezeigt, dass ein „Lebenskreis" des Mycels in einige metabolische Phasen, d. h. catabolische und anabolische usw. eingeteilt wird und dass Mycel, das sich zwischen diesen beiden Phasen befindet, wo der Vorstufe der gebräuchlichen „*log*" Phase entspricht und Aminosäuren am meisten enthalten sind, das grösste Proteinasebildungsvermögen zeigt.

Das erhebliche Proteinasebildungsvermögen gehört zu einem Mycel, welches neben dem grossen Sammelbecken von Aminosäuren ein kräftiges Entwicklungsvermögen besitzt.

Aus dem Versuch mit dem Mycel, das sich unter der variierenden N-Konzentration entwickelt hatte, wurde es aber festgestellt, dass der Aminosäuregehalt des Mycels nicht immer für die Proteinasebildung ein dominanter Faktor ist.

In der vorliegenden Arbeit konnte der Verfasser zusammenfassend das Proteinasebildungsvermögen des Mycels im Kultursverlauf in Bezug auf das Mycelentwicklung durch seinen Stickstoffwechsel charakterisieren.

Zum Schlusse ist es mir eine angenehme Pflicht, Herrn Professor Dr. N. Taketomi, und Herrn ausserordentlichen Professor H. Suzuki für ihre vielfache Anregungen und Revisionen bei der Anfertigung dieser Arbeit meinen besten Dank auszusprechen.

Dichroism of Dyes in the Stretched PVA Sheet. II[1]. *The Relation between the Optical Density Ratio and the Stretch Ratio, and an Attempt to Analyse Relative Directions of Absorption Bands**

By Yoshié TANIZAKI

(Received July 26, 1958)

Hitherto, dichroic properties have been mainly utilized to investigate dyeing mechanism[2] or the percentage orientation of fibres[3]. A conclusion derived from a number of experimental results shows that almost all dye molecules in dyed state should lie lengthwise along the cellulose chains[4]. In the previous paper[1], this conclusion was applied to presume the relative direction of transition moments of absorption bands of certain direct dyes in the stretched polyvinyl alcohol sheet from their dichroic properties. A similar attempt may not be applied to short molecules which show poor dichroism, and it is still more difficult, as it is not sure that such molecules are adsorbed on a fibre so as to orient parallel to the fibre axis. However, the fact that an observed optical density ratio (to be defined later) depends upon the stretch ratio of the sheet may give a key to analyse the direction of transition moment of the absorption band of the dye molecule. The purpose of this paper is to derive an expression for the density ratio as a function of the stretch ratio, to apply it to absorption bands of certain basic dyes, and to analyse their relative direction.

Experimental

Materials.—Polyvinyl alcohol (abbreviated to PVA) with the polymerization degree of about 1500 was used for preparing sheets by the method described in the previous paper[1].

Dyes used were crystal violet and auramine yellow which were recrystallized twice from ethanol, starting from the pure ones produced in the Laboratory of Hodogaya Kagaku Co., Ltd. The paper chromatography detected no colored impurities in these dyes.

PVA sheets, swollen fully in distilled water, were soaked in the aqueous dye solution at room temperature.

Measurements.—Measurements were carried out with a Shimadzu QB-50 spectrophotometer, in filter hole of which a sheet-polarizer of PVA-iodine[5] was set. To determine the correlation between the electric vector of polarized incident light and the stretching direction of the sample sheet, an apparatus shown in Fig. 1 was used. A colored and an uncolored PVA sheet were respectively pasted on a metal ring to be fixed in R_1 and R_2. The disk D graduated 0° to 360° on its circumference can be rotated at will in concentric with the toothed wheel G_1, and at the same time the rotation is transmitted through G_2, being used as a change gear, to R_1 and R_2. Gear ratios are all the same. This apparatus is set in the cell box of the spectrophotometer in place of

the cell holder. Thus the correlation mentioned above was determined by means of the Malus' law.

Notations.—A circle drawn on the sheet before stretching is deformed into an ellipse after stretching. The ratio of the long axis of the ellipse to the short one is defined as the *stretch ratio* R_s[6]. $D_{\parallel}$ and $D_{\perp}$ are optical densities for completely and linerly polarized lights whose electric vectors are respectively parallel and perpendicular to the stretching direction. An *optical density ratio* R_d is then defined as $D_{\parallel}/D_{\perp}$.

Theoretical

Let us suppose that an imaginary sphere in substrate of PVA sheet is deformed, being kept at a constant volume by stretching into a spheroid. If the optical property around the stretching direction were isotropic and any unit vector with an angle θ_0 against the stretching direction in the sphere were transformed into a unit vector with θ in the spheroid, the distribution of vectors after stretching, $f(\theta)$, would be determined in the following way,

$$f(\theta)=\int_0^{\pi/2} G(\theta,\theta_0)F(\theta_0)\,\mathrm{d}\theta_0 \qquad (1)$$

where $F(\theta_0)$ means a function of distribution before stretching, and $G(\theta,\theta_0)$ is a function of transformation which makes θ_0 transform to θ by stretching. Since it is natural to consider that the distribution of vectors before stretching is quite at random, then $F(\theta_0)$ may be expressed as follows,

$$F(\theta_0)=\sin\theta_0$$

or

$$=\frac{\tan\theta_0}{\sqrt{1+\tan^2\theta_0}} \qquad (2)$$

On the basis of the assumption that the deformation takes place under a constant volume, the relation between θ_0 and θ is expressed as follows,

$$\tan\theta_0=R_s\tan\theta$$

where R_s is the axial ratio of the ellipsoid and is equal to the stretch ratio mentioned above. Then the transformation function may be written as follows

$$G(\theta,\theta_0)=\delta(\tan^{-1}(R_s\tan\theta)-\theta_0)\rho(\theta_0) \qquad (3)$$

where δ is a delta-function and ρ is a surface element, namely

$$\rho(\theta_0)=R_s\frac{\sin\theta_0\cos^2\theta_0}{\sin\theta\cos^2\theta} \qquad (4)$$

By the combination of Eqs. 1, 2, 3 and 4,

$$f(\theta)=\int_0^{\pi/2}\delta(\tan^{-1}(R_s\tan\theta)-\theta_0)\times\frac{R_s}{\sin\theta\cos^2\theta}\frac{\tan^2\theta_0\,\mathrm{d}\theta_0}{(1+\tan^2\theta_0)^2}$$

The interval of this integration involves zero. So that, according to the nature of δ-function[7], this integration becomes equal to the integrand excluding δ-function, in which θ_0 is replaced by $\tan^{-1}(R_s\tan\theta)$, that is,

$$f(\theta)=\frac{R_s^3\tan^2\theta}{\sin\theta\cos^2\theta(1+R_s^2\tan^2\theta)^2}$$

or

$$f(\theta)=\frac{R_s^3\sin\theta}{\{1+(R_s^2-1)\sin^2\theta\}^2} \qquad (5)$$

where $R_s\geq 1$ and $0\leq\theta\leq\pi/2$. Determining $N(R_s)$ so as to make the integration with respect to θ unity, namely,

$$\int_0^{\pi/2}N(R_s)f(\theta)\,\mathrm{d}\theta=1$$

$N(R_s)f(\theta)$ for several values of R_s provides the curves shown in Fig. 2. This figure indicates that for large R_s values, that is, when the PVA sheet is stretched to a high degree, the greater part of vectors becomes able to meet the stretching direction. This

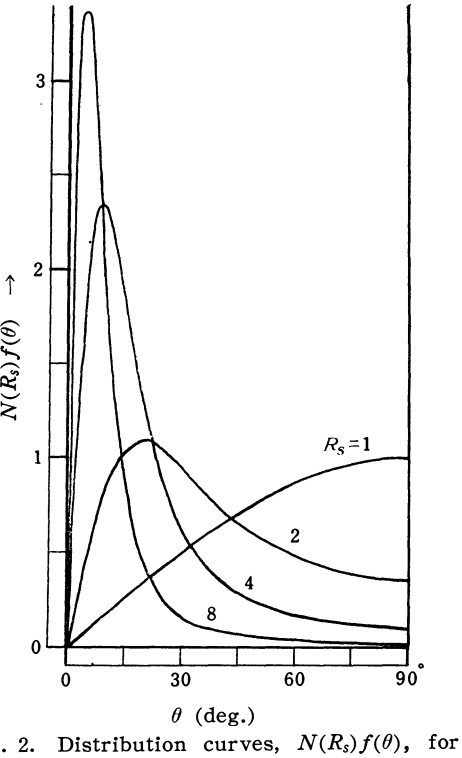

Fig. 2. Distribution curves, $N(R_s)f(\theta)$, for several values of the stretch ratio, R_s.

6) E. H. Land, *J. Opt. Soc. Am.*, **41**, 957 (1951).

7) P. A. M. Dirac, "Quantum Mechanics", Third Edition, Oxford (1947), p. 58.

will correspond to a distribution of a characteristic direction, which is regarded as a vector and is called hereafter an *orientation axis*, of the molecular species. So that, when the direction of the transition moment corresponding to an absorption band is on the orientation axis, the problem is rather easy to be dealt with. For the present purpose, however, it is necessary to consider a general case where transition-directions of dye molecules do not always coincide with orientation axes. Therefore, it will be convenient to introduce here an imaginary plane made of an orientation axis and a direction of transition moment. This plane does not necessarily coincide with the usual molecular plane, and is temporarily called a *light absorption-plane*. The transition moment μ of an absorption band can be decomposed into two components within the light absorption-plane, one of which is normal and the other parallel to the orientation axis, namely μ_b and μ_a respectively. Consequently, if the value of $|\mu_a/\mu_b| = r$ can be obtained, $\cot^{-1} r$ will give the angle of a direction of transition against the orientation axis of a molecule.

Now, if we imagine rectangular coordinates in the PVA substrate, so as to run the Z axis parallel with the stretching direction (see Fig. 3), and if the angle between Z and μ_a is θ, then three components of μ_a can be written as follows,

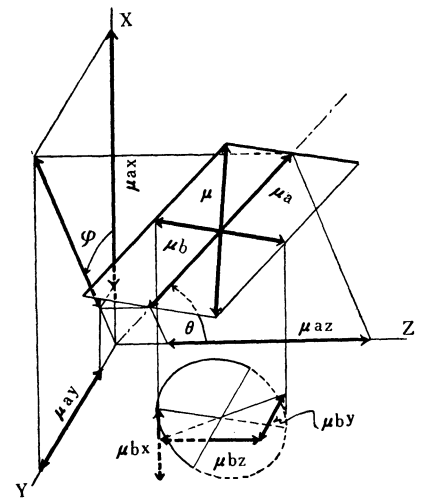

Fig. 3. Rectangular coordinates in the PVA substrate, of which the Z axis is taken parallel to the stretch direction of the PVA sheet. A transition moment μ of a dye molecule is decomposed to a parallel component μ_a and a normal μ_b to the orientation axis in the light absorption-plane.

$$\begin{cases} \mu_{aX} = \mu_a \sin\theta \cos\varphi \\ \mu_{aY} = \mu_a \sin\theta \sin\varphi \\ \mu_{aZ} = \mu_a \cos\theta \end{cases} \tag{6}$$

where φ is the angle between X and the projection of μ_a on the XY-plane. Similarly, corresponding ones for μ_b can be represented by

$$\begin{cases} \mu_{bX} = \mu_b(\cos^2\theta + \sin^2\theta \sin^2\varphi)^{1/2} \cos\phi \\ \mu_{bY} = \mu_b\left(\dfrac{\sin^4\theta \sin^2\varphi \cos^2\varphi \cos^2\phi + \cos^2\theta \sin^2\phi}{\cos^2\theta + \sin^2\theta \sin^2\varphi}\right)^{1/2} \\ \mu_{bZ} = \\ \mu_b\left(\dfrac{\sin^2\theta \cos^2\theta \cos^2\varphi \cos^2\phi + \sin^2\theta \sin^2\varphi \sin^2\phi}{\cos^2\theta + \sin^2\theta \sin^2\varphi}\right)^{1/2} \end{cases} \tag{7}$$

where φ is the angle between the X axis-orientation axis-plane and the light absorption-plane. The angle θ takes values of zero to $\pi/2$, and φ and ϕ values of zero to 2π. Integration with respect to φ and ϕ must be averaged for the region. Thus the components of μ for the X, Y and Z directions should be of the form

$$\begin{cases} \mu_X^2 = \displaystyle\int_{\theta=0}^{\pi/2} \frac{1}{2\pi} \int_{\varphi=0}^{2\pi} \frac{1}{2\pi} \int_{\phi=0}^{2\pi} \\ \qquad \times (\mu_{aX}^2 + \mu_{bX}^2) N(R_s) f(\theta) \mathrm{d}\phi \mathrm{d}\varphi \mathrm{d}\theta \\ \text{etc.} \end{cases} \tag{8}$$

Substitution of Eqs. 6 and 7 for Eq. 8, and integrations with respect to φ and ϕ, give

$$\begin{cases} \mu_X^2 = \mu_Y^2 = \dfrac{1}{4} \displaystyle\int_0^{\pi/2} \{2\mu_a^2 \sin^2\theta \\ \qquad + \mu_b^2(1+\cos^2\theta)\} N(R_s) f(\theta) \mathrm{d}\theta \\ \mu_Z^2 = \dfrac{1}{2} \displaystyle\int_0^{\pi/2} (2\mu_a^2 \cos^2\theta \\ \qquad + \mu_b^2 \sin^2\theta) N(R_s) f(\theta) \mathrm{d}\theta \end{cases} \tag{9}$$

Since the optical density D is proportional to μ^2, it may be possible to write

$$R_d \equiv \frac{D_\parallel}{D_\perp} = \frac{\mu_Z^2}{\frac{1}{2}(\mu_X^2 + \mu_Y^2)} = \frac{\mu_Z^2}{\mu_X^2} \tag{10}$$

For non-stretched state, i. e. $R_s = 1$, integration of Eq. 9 gives $\mu_X^2 = \mu_Y^2 = \mu_Z^2 = \mu^2/3$. Hence the following relation can be obtained by the aid of Eq. 10,

$$R_d = 1 \quad (R_s = 1)$$

For $R_s > 1$, combination of Eqs. 9 and 10, and integration with respect to θ give

$$R_d = \frac{2 + 2(2r^2 - 1) T(R_s)}{(2r^2 + 1) - (2r^2 - 1) T(R_s)} \tag{11}$$

where

$$T(R_s)=\frac{R_s^2}{R_s^2-1}\left\{1-\frac{N(R_s)}{\sqrt{R_s^2-1}}\log(R_s+\sqrt{R_s^2+1})\right\}$$

$$N(R_s)=2\left\{\frac{1}{\sqrt{R_s^2-1}}\log(R_s+\sqrt{R_s^2-1})+R_s\right\}^{-1}$$

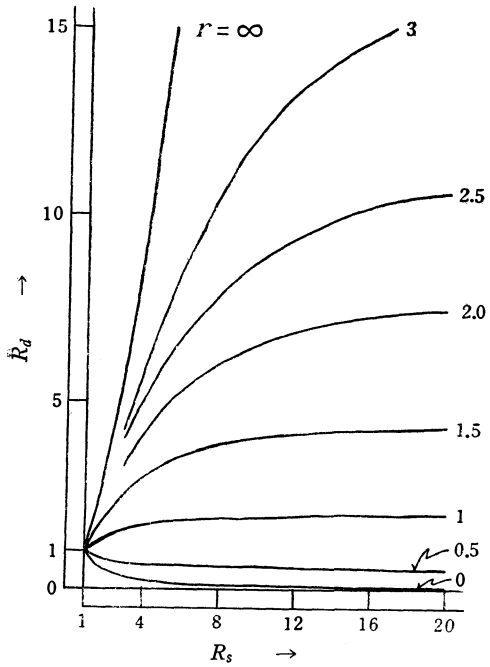

Fig. 4. Relation between R_d and R_s for various values of r.

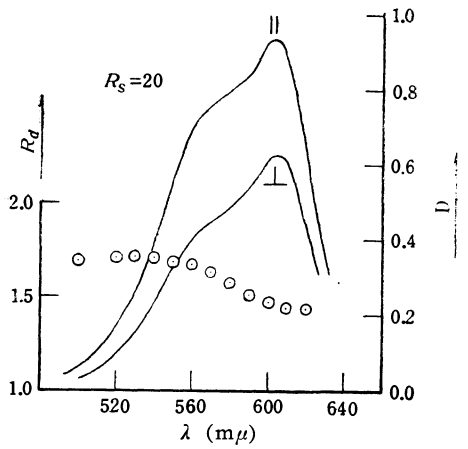

Fig. 5. Absorption spectra by polarized light of the crystal violet ion in the stretched PVA sheet. ∥ means the absorption curve when the electric vector of incident light is parallel and ⊥ means when the vector is normal to the stretch direction. Circles indicate the optical density ratio, R_d.

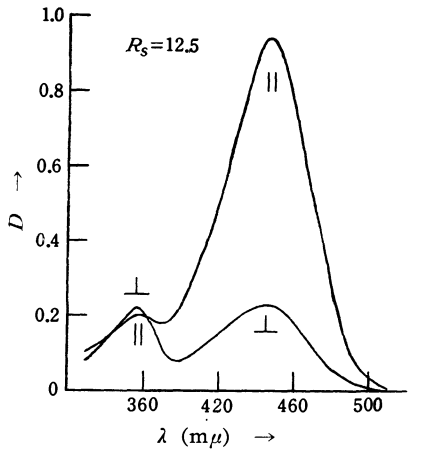

Fig. 6. Absorption spectra by polarized light of the auramine yellow ion in the stretched PVA sheet. The meaning of ∥ and ⊥ is the same as in Fig. 5.

and $R_s>1$.

This is the final expression. Plotting R_d against R_s for various values of a parameter r curves representing Eq. 11 are obtained as shown in Fig. 4.

Results

Absorption spectra by polarized light of the crystal violet and the auramine yellow ion in stretched PVA sheets are shown in Figs. 5 and 6, respectively. Fig. 5 shows that the crystal violet ion has an absorption maximum at about 605 mμ and a shoulder at about 560 mμ, and that R_d values near the shoulder are larger than that at the absorption maximum. Fig. 6 shows that the auramine yellow ion has the first (445 mμ) and the second (~375 mμ) band whose dichroic properties are different from each other. This means that transition moments corresponding to these absorption bands have different directions.

Observed and calculated relations between R_d and R_s of each absorption band are shown in Figs. 7 and 8. Fig. 7 shows the case of the crystal violet ion; the observed values at 605 mμ are represented by the white circles and those of 560 mμ by the half solid circles, and the full lines are the curves obtained from Eq. 11 putting $r=0.86$ for the 605 mμ band and $r=0.90$ and 0.92 for the 560 mμ band. Similarly, Fig. 8 shows the result of the auramine yellow ion; the observed values for the first band are indicated by the white circles and for the second band (375 mμ)

by the half solid circles, and the corresponding full lines are calculated by Eq. 11 putting $r=1.55$ and 1.60 for the first band and $r=0.60$, 0.65 and 0.70 for the second band, respectively. In Fig. 8 it is noticed that, in the small region of R_s, the observed value of R_d are smaller for the first band and larger for the second band than the calculated ones represented by the full lines. This fact may be simply interpreted as the effect due to the overlap of both bands. That is to say, on account of the mutual superposition of the bands the first band with large R_d may apparently increase the small R_d value of the second band and the converse would hold good. For the large R_s value, however, the observed R_d values roughly run along the respective calculated lines. In the case of crystal violet (Fig. 7), the observed R_d values for small R_s values are smaller than the calculated ones, and these differences are larger at 560 mμ than at 605mμ.

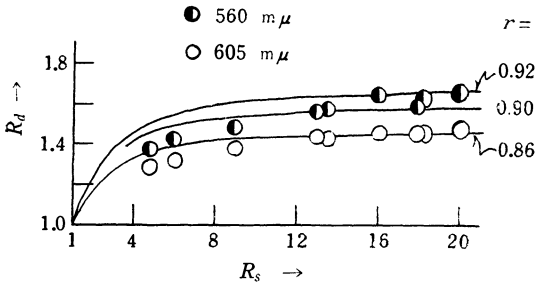

Fig. 7. Observed and calculated relations between R_d and R_s of the crystal violet ion in the stretched PVA sheet.

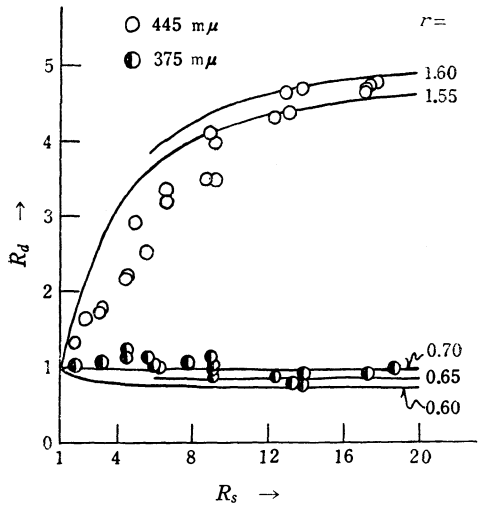

Fig. 8. Observed and calculated relationships between R_d and R_s of the auramine yellow ion in the stretched PVA sheet.

Thus, it can be said that Eq. 11 explains the experimental relation between R_d and R_s except for the smaller region of R_s and accordingly that Eq. 5 represents approximately well the nature of the distribution of such short molecules as the crystal violet ion in the stretched PVA substrate.

Discussion

The crystal violet ion. — Lewis and his coworkers[8] considered that the absorption band in the visible region of the crystal violet ion consists of those of isomers A and B. According to their consideration, the isomer A has a structure like a propeller with three blades (i. e. three benzene rings) and the isomer B has a similar form in which one blade is turned in the opposite direction from the others. As regards the absorption band here discussed, the main band belongs to the A isomer and the shoulder indicates the superposition of two bands A and B. In radially symmetrical molecules such as crystal violet, so-called x and y bands, which are both in the molecular plane[9], coincide with each other. In such a case, the transition moment is equal in all directions of the plane. This should be indeed the case of the A isomer. Furthermore, if we assume that the orientation axis is in the molecular plane, we should expect the value of r to be unity; that is, the angle of the direction of the transition moment against the orientation axis is expected to be 45°. According to our result, however, r equals to 0.86 and the corresponding orientation angle is $\cot^{-1} r=$ 49°. On the other hand, though the B isomer has not the same symmetry as the A isomer, the apparent moment would be regarded to be still equal in all directions of the molecular plane of the B isomer in the statistical sense, because the spacial extent, which may be one principal factor to govern the orientation of the molecule, seems to be passably symmetrical considering its solid thickness. So that, also in the case of the B isomer the angle mentioned above would be expected again to be 45°. But the present result indicates that r equals 0.92~0.90, hence $\cot^{-1} r$ equals to 47.5°~48°.

Fig. 5 indicates that the R_d values near the absorption maximum are always

8) G. N. Lewis, T. T. Magel and D. Lipkin, *J. Am. Chem. Soc.*, **64**, 1774 (1942).
9) G. N. Lewis and J. Bigeleisen, ibid., **65**, 2102 (1943).

smaller than that of the shoulder. According to resolution of the observed band into those of isomers made by Lewis and his coworkers[8], the maximum corresponding to the isomer A is scarcely overlapped by the band of the isomer B, while the slope of the former almost covers the latter. This implies that the observed R_d value at the maximum wavelength gives the true R_d value for the A isomer, but the observed one at the shoulder, gives the smaller than the true value for the B isomer. Accordingly, it is considered that the absorption corresponding to the B isomer has the possibility of taking the r value of unity (i. e. the corresponding angle is 45°). From this fact we should be led to the conclusion that the orientation axis of the molecule deviates from its plane in the A isomer rather than in the B isomer. This seems indeed to be improbable from the point of view of their geometrical shapes. Therefore it seems wise to discard the abovementioned explanation and to adopt the alternative[10] that both bands originate from only one species. That is to say, the light absorption bands originate from two kinds of transition in one molecular species, one of which lies on the molecular plane and the other of which has two components parallel and normal to the plane. The former may correspond to the 560 mμ band and the latter to 605 mμ. Thus we can explain the experimental facts that the 560 mμ band has always the greater R_d value than that at 605 mμ, and the R_d value of the former has the possibility to take the r value of unity.

The auramine yellow ion.—For the first band of the auramine yellow ion, the corresponding r value is 1.55~1.60 (see Fig. 8). Accordingly the angle of the transition-direction against the orientation axis is 32.5°~32°. Similarly, since the most probable value of r for the second band is 0.65, the corresponding angle is obtained as 57°. Since the mutual correlation of the absorption planes of both bands is unfortunately unknown, the angle between two directions of the corresponding transition moments can not be decided directly. Nevertheless, when it is supposed that the absorption planes coincide with each other, namely when both transitions are on the same molecular plane, the angle just mentioned would be 57°+32°=89° or 57°−32°=25°. Here the former value approximates to a right angle. This fact is of interest, because, in such a molecule as the auramine yellow ion, there may exist the x and y bands which are on the molecular plane and at right angles to each other[9].

Summary

1) An expression for the optical density ratio was derived as a function of the stretch ratio.

2) Dichroism of the crystal violet and auramine yellow ion in stretched PVA sheets was observed, and the relation of the optical density ratio to the stretch ratio was plotted. It was shown that the theoretical expression derived here could explain rather well the experimental relation between these two quantities.

3) The analytical results were as follows. The main absorption band and the shoulder of the crystal violet ion did not orginate from the two isomers but were perhaps due to one species. For the auramine yellow ion the angle between the transition directions corresponding to the first and the second band might be approximately a right angle provided that the *absorption-planes* were in a same plane.

The author is indebted to Professor Noboru Ando and Dr. Ikuzo Tanaka for their encouragement to carry out this work and also to Dr. Hideo Yamazaki for his helpful suggestions on the theoretical part. Many thanks are due to Mr. Junzo Ito of Nippon Gosei Kagaku Co., Ltd. who gave polyvinyl alcohol, to Mr. Norio Ikari of Hodogaya Kagaku Co., Ltd. who gave the dye samples, and also to Mr. Toshiro Iijima who helped the author in chromatographical tests.

Studies on Antibiotics and Related Substances. VII. The Structure of Kanamycin

By Sumio UMEZAWA, Yukio ITŌ and Shunzō FUKATSU

(Received August 5, 1958)

Kanamycin has been described by H. Umezawa and coworkers[1] as an antibiotic produced by a strain of *Streptomyces kanamyceticus*. It is low toxic and very active against a variety of Gram-positive and Gram-negative bacteria including streptomycin-resistant strain. Kanamycin was isolated in a pure state as a crystalline monosulfate which was converted into a crystalline free base[2,3]. Analysis and electrometric titrations of the salt and the free base indicated that the antibiotic is a tetra-acidic base of the composition $C_{18}H_{36}O_{11}N_4$. Acetylation of kanamycin with acetic anhydride in methanol gave tetra-*N*-acetyl kanamycin[3,4]. On the other hand, when kanamycin was acetylated with acetic anhydride and pyridine, undeca-acetylkanamycin was obtained[4].

Information about the degradation products of kanamycin was obtained by studying the products formed by acid hydrolysis[3,4]. From the hydrolyzate of kanamycin by 6 N hydrochloric acid, Maeda, et al.[4], isolated two kinds of reducing aminohexoses and diamino-trihydroxycyclohexane which was identical with deoxystreptamine (I) isolated from the vigorous hydrolysis of neomycin[5]. Moreover, Ogawa and Itō[6] obtained deoxystreptamine and two kinds of methylaminohexosides by methanolysis of kanamycin. Recently, we received an information from Hooper and others[7] that they identified the two aminohexose-moieties of kanamycin to be D-6-amino-6-deoxyglucose (pyranose form) (II) and 3-amino-3-deoxyaldohexose (pyranose form) (III).

Therefore, the hydrolytic cleavage of kanamycin could be represented by the following equation:

$$C_{18}H_{36}O_{11}N_4 + 2H_2O \rightarrow C_6H_{14}O_3N_2 + 2C_6H_{13}O_5N$$
(I) (II) and (III)

The present authors[8] recently reported in a short communication that the acid-hydrolysis of exhaustively methylated *N*-acetylkanamycin resulted in the isolation of mono-*O*-methyldeoxystreptamine which presents evidence to show that both of the two aminohexose moieties are directly joined to deoxystreptamine. The situation is different from streptomycin in which streptidine is linked with streptobiosamine, or from neomycin in which deoxystreptamine is linked with neobiosamine.

The present paper deals with the sites of glucosidic linkages occurring between the above-mentioned three moieties in detail.

The tetra-*N*-acetylkanamycin prepared by the method of Cron and others[3] was methylated with dimethyl sulfate and sodium hydroxide by the method of West and Holden[9] to yield a crude methylated product, which was chromatographed through a cellulose powder column to yield a colorless gum. The acetyl determination showed that the methylated product is partially de-*N*-acetylated. When the methylated product was acetylated again to make sure, the tetra-*N*-acetyl-hepta-*O*-methylkanamycin was obtained. It was further ascertained by infrared spectrum that no free hydroxyl group is contained in the methylated product.

The methylated product was hydrolyzed with 6 N hydrochloric acid. Paper chromatography studies of the hydrolyzate showed three ninhydrin positive spots of

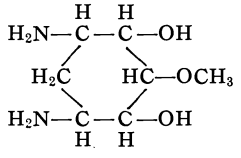
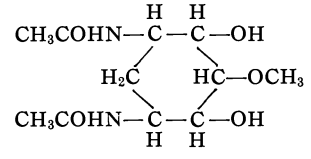
R_f 0.08, 0.32 and 0.41 with a *n*-butanol-ethanol-water mixture. The hydrolyzate was evaporated to dryness, taken up in methanol and treated with ether to yield an amorphous precipitate, which consisted of the product of R_f 0.08, containing a small amount of the product of R_f 0.32. The precipitate was chromatographed through a cellulose powder column to yield the colorless, crystalline hydrochloride of mono-*O*-methyldeoxystreptamine (IV), which was optically inactive and, upon oxidation with periodate, consumed two moles of periodate without the formation of formic acid.

The hydrochloride was acetylated with acetic anhydride in pyridine to yield the colorless prisms of the diacetate (V) of mono-*O*-methyl-di-*N*-acetyldeoxystreptamine.



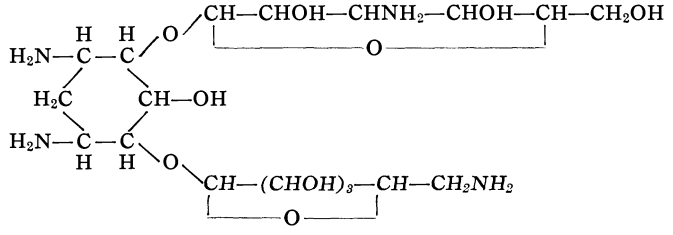
Finally, the diacetate was subjected to de-*O*-acetylation with ammonia in absolute methanol solution at 0°C to yield the colorless prisms of mono-*O*-methyl-di-*N*-acetyldeoxystreptamine (VI). This consumed no periodate and was also optically inactive.

The compounds (IV, VI) with the *O*-methyl group in the 5-position should be optically inactive while the compounds with the *O*-methyl group in the 4- or 6-position should be optically active. The di-*N*-acetyl compound (VI) with the *O*-methyl group in the 5-position should consume no periodate while the corresponding compound with the *O*-methyl group in the 4- or 6-position should consume one mole of periodate. The compound IV with the *O*-methyl group in the 5-position should be oxidized with two moles of periodate without the formation of formic acid while the corresponding compound with the *O*-methyl group in the 4- or 6- position should consume two moles of periodate with the formation of one mole of formic acid.



Therefore, the experimental evidences presented above have led the authors to conclude that the mono-*O*-methyl-deoxystreptamine (IV) is 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane and, considered with the previous findings, permit the assignment of structure VII to kanamycin.

Experimental



Methylation of *N*-Acetylkanamycin.—To a vigorously stirred solution of tetra-*N*-acetylkanamycin (4.0 g.) in water (8 cc.) was added a solution of dimethyl sulfate (52 g.) in carbon tetrachloride (40 cc.). During this and the subsequent addition of alkali the temperature of the reaction was kept at 50~55°C. A solution of sodium hydroxide (108 g.) in water (100 cc.) was then added dropwise over a one-hour period, with vigorous stirring. The temperature was then raised slowly to 70~75°C and dimethyl sulfate (103 g.) was added dropwise over a 30-minute period. Again, a solution of sodium hydroxide (36 g.) in water (30 cc.) was added and then dimethyl sulfate (52 g.) was added gradually in a 15-minute period. After this addition the water-bath was heated to boiling and kept at this temperature for 30 min. The temperature was then lowered to about 50°C and the mixture was stirred vigorously with chloroform (150 cc.) for 15 min. The mixture was filtered and the sodium sulfate precipitate was washed with chloroform. The aqueous portion of the filtrate was re-extracted with chloroform as described above. The chloroform extracts were combined and dried with sodium sulfate. Evaporation of the solvent in vacuo left an amber

(IV)

(VI)

(VII)
Kanamycin

gum (3.22 g.) soluble in methanol, ethanol, chloroform and water. A sample was dried in vacuo at 60~70°C. The determination of methoxyl content gave 27.44% OCH_3.

The crude product (11.17 g.) was dissolved in a solution (30 cc.) of *n*-butanol-ligroin-water (38 : 60 : 2) and chromatographed on a column (2.5×40 cm.) of cellulose powder washed with the same solvent. Sixteen fractions of eluate with the same solvent were limited to 40 cc. each, evaporated in vacuo to dryness and weighed. Fractions 7-14 were combined to yield 7.0 g. of exhaustively methylated *N*-acetyl-kanamycin, m. p. 80°C (sintered at about 65°C). The determinations of methoxyl and acetyl content gave 28.35% OCH_3 and 12.25% $COCH_3$.

It was ascertained by infrared spectrum that no free hydroxyl group is contained in the methylated product.

A portion (2.5 g.) of the methylated product of tetra-*N*-acetylkanamycin was dissolved in absolute methanol (22.5 cc.) and to the solution acetic anhydride (4.3 cc.) was added. After being allowed to stand overnight, the acetylation mixture was filtered and evaporated to dryness. The residue was dissolved in water (20 cc.) and extracted thrice with chloroform (20 cc.). The chloroform extracts were combined and dried with sodium sulfate. Evaporation of the solvent left a colorless gum which resisted attempts to crystallize it (1.17 g.).

Anal. Found: OCH_3, 27.5; $COCH_3$, 21.6. Calcd. for $C_{18}H_{21}O_4(OCH_3)_7(NHCOCH_3)_4$: OCH_3, 28.9; $COCH_3$, 22.9. Calcd. for $C_{18}H_{22}O_5(OCH_3)_6(NHCOCH_3)_4$: OCH_3, 25.3; $COCH_3$, 23.4%.

Isolation of Mono-*O*-methyldeoxystreptamine Hydrochloride (IV) from Hydrolyzed Methylated *N*-acetylkanamycin.—Exhaustively methylated *N*-acetyl-kanamycin (7.0 g.) was refluxed with 6 N hydrochloric acid (100 cc.) for 1.5 hr. The reaction mixture was evaporated to dryness at 60°C in vacuo. The residue was dissolved in water (100 cc.) and evaporated again to dryness. The evaporation to remove hydrogen chloride was repeated thrice. The residue was dissolved in water (100 cc.) and the solution was decolorized with active charcoal (1.0 g.).

Paper chromatography of the hydrolyzate using the top-layer of *n*-butanol-ethanol-water (4 : 1 : 5) gave 3 zones with ninhydrin. The R_f values were 0.08 (brown), 0.32 (orange) and 0.41 (violet), respectively.

The decolorized solution was evaporated at 60°C in vacuo to dryness and dried in a desiccator overnight. The amber residue was dissolved in methanol (20 cc.) and the solution was diluted with ether (50 cc.) to yield a precipitate (1.90 g.). Paper chromatography of the precipitate using the above-mentioned solvent showed the main spot with R_f 0.08 (brown) and a trace with R_f 0.32 (orange).

The precipitate (1.90 g.) was dissolved in the top-layer (10 cc.) of *n*-butanol-ethanol-water (4 : 1 : 5) and chromatographed on a column (1.5×50 cm.) of cellulose powder (18 g.) washed with the same solvent. Twenty fractions of eluate with the same solvent were limited to 20 cc. each, evaporated to dryness in vacuo and weighed. Fractions 6—9 were combined to yield the crude hydrochloride of mono-*O*-methyldeoxystreptamine (1.65 g.).

Three recrystallizations from methanol-ethanol gave colorless needles (350 mg.) of the hydrochloride of 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane (IV), m. p. 207~209°C (decomp.), which was optically inactive.

Anal. Found: C, 34.03; H, 7.17; N, 10.94; OCH_3, 11.65. Calcd. for $C_6H_7(OH)_2(NH_2)_2(OCH_3)\cdot 2HCl$: C, 33.73; H, 7.23; N, 11.24; OCH_3, 12.45%.

Periodate Oxidation. — The accurately weighed sample (20.1 mg.) of 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane hydrochloride was dissolved in 0.023 N sodium periodate solution (20 cc.) and 2 cc. aliquots were titrated with 0.1 N sodium arsenite at the intervals listed in Table I, according to the procedure of Fleury and Lange[10]. Two moles of periodate was consumed without the formation of formic acid.

TABLE I
PERIODATE OXIDATION*

	Time (hr.)					
	0.5	1	2	3	4	6
1, 3-Diamino-4, 6-dihydroxy 5-methoxy-cyclohexane·2HCl	1.91	1.88	—	1.98	—	1.95
1, 3-Diacetamido-4, 6-dihydroxy-5-methoxy-cyclohexane	0.18	0.25	0.14	—	0.23	—

* Expressed in terms of moles of periodate consumed per mole of substance.

1, 3-Diacetamido-4, 6-diacetoxy-5-methoxycyclohexane (V). — The crude hydrochloride (1.2 g.) of 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane was acetylated with acetic anhydride-pyridine (18 cc. : 36 cc.) at 27°C for 24 hr. The acetylation mixture was concentrated to dryness at 40°C in vacuo; the residue was dissolved in water (20 cc.) and decolorized with active charcoal (0.5 g.). The filtrate was again evaporated to dryness in vacuo and dried in a desiccator overnight. The residue was washed with ether (30 cc.), and taken up in chloroform (20 cc.); a small quantity of insoluble part was filtered off and the filtrate was dried with sodium sulfate. Evaporation of the solvent was followed by extraction with hot ethyl acetate. Crystallization from the extract yielded colorless prisms (215 mg.), m. p. 220°C (decomp. sintered at about 170°C).

Anal. Found: C, 52.35; H, 6.65; N, 8.18; OCH_3, 9.22. Calcd. for $C_6H_7(OCH_3)(OCOCH_3)_2\cdot(NHCOCH_3)_2$: C, 52.32; H, 6.98; N, 8.14; OCH_3, 9.01%.

10) P. F. Fleury and J. Lange, *J. pharm. chim.*, [8] **17**, 107, 196 (1933).

The mother liquor was concentrated and allowed to stand at room temperature to yield the second crop of crystals (350 mg.).

1,3-Diacetamido-4,6-dihydroxy-5-methoxycyclohexane (VI). — A solution of 1,3-diacetamido-4,6-diacetoxy-5-methoxycyclohexane (460 mg.) in absolute methanol (130 cc.) was treated with a stream of dry ammonia gas for 1 hr. After being allowed to stand 3 hr. at room temperature, the mixture was evaporated at about 50°C in vacuo to dryness. The residue was dissolved in absolute methanol (50 cc.) and evaporated again to dryness in vacuo. The residue was taken up in absolute ethanol (30 cc.) and the solution was filtered to remove a small quantity of insoluble part. When the filtrate was concentrated and cooled, colorless needles crystallized out. Recrystallization from absolute ethanol yielded 130 mg. of 1,3-diacetamido-4,6-dihydroxy-5-methoxycyclohexane. The product was optically inactive.

Anal. Found: C, 50.94; H, 7.47; N, 10.64; OCH_3, 11.32; *N*-acetyl, 32.99, 33.87. Calcd. for $C_6H_7(OH)_2(OCH_3)(NHCOCH_3)_2$: C, 50.77; H, 7.69; N, 10.77; OCH_3, 11.9. *N*-acetyl, 33.08%.

Periodate Oxidation. — An accurately weighed sample (25.3 mg.) of 1,3-diacetamido-4,6-dihydroxy-5-methoxycyclohexane was dissolved in 0.0287 N sodium periodate (20 cc.) and 2 cc. aliquots were titrated with 0.1 N sodium arsenite at the intervals listed in Table I.

Summary

Evidence is presented to show that both the two aminohexose moieties in kanamycin are directly joined to deoxystreptamine through hydroxyl groups by glucosidic linkages. Proof for the sites of attachment of the two aminohexose moieties rests on the periodate oxidation of the optically inactive 1,3-diamino-4,6-dihydroxy-5-methoxycyclohexane and its *N*-acetyl derivative which were obtained by the degradation of exhaustively methylated *N*-acetylkanamycin by acid hydrolysis followed by acetylation. Kanamycin is therefore represented by formula VII.

The authors wish to express their appreciation to Professor H. Umezawa of National Institute of Health, Dr. I. R. Hooper of Bristol Laboratories and Dr. H. Ogawa of Research Laboratories of Meiji Seika Co. for helpful advice and to Meiji Seika Co. for the generous gift of kanamycin samples.

Vapor Pressure of Molecular Crystals. XIII. Vapor Pressure of α-Glycine Crystal. The Energy of Proton Transfer

By Sadao TAKAGI*, Hideaki CHIHARA and Syûzô SEKI

(Received August 7, 1958)

Glycine is the simplest amino acid, having the zwitterion configuration within the crystal lattice[1]. Three modifications have been reported[2] and the α-form is probably the most stable one at room temperature. The molecular structure of glycine in the vapor phase is not known probably owing to low vapor pressure of the crystal. If glycine sublimes with the molecular configuration (and not the zwitterion configuration), a proton must be transferred from an NH_3^+ group of a zwitterion to a COO^- group of the neighboring zwitterion in the crystalline state. Or, in an alternative way, the proton transfer must occur in the vapor state after the zwitterion has sublimed, and this transfer undoubtedly accompanies greater energy change than it would in the crystalline state[3]. On the other hand, if the sublimation does not accompany the proton transfer, the heat of sublimation would be as great as that of an ionic crystal. The present study aims at the energetics of sublimation, with a hope of obtaining some information about such

proton transfer. The determination of the relative stability of the modifications of glycine crystals by measurements of vapor pressures presents another interesting problem but will not be considered here.

Experimental

Material.—Glycine (Organic Synthetic Chemicals Co., special grade) was recrystallized from aqueous solution repeatedly and dried over phosphorus pentoxide. The more satisfactory method of drying crystals by vacuum sublimation was not applied because it was found that sublimation gave a mixture of α and γ form of glycine. The modifications were identified by use of the X-ray powder diffraction patterns. Occlusion of water within the crystal lattice may cause a serious error in the measurement of vapor pressure[4] and it is highly probable particularly when we deal with crystals of polar molecules. Pieces of glycine crystals, of the same batch as that used for the pressure measurements, were heated in vacuo to see if the occluded water was present, with the result that no water evolution was detected up to the decomposition temperature, ca. 230°C. The constancy of the vapor pressure at a fixed temperature during a fixed length of time, a few hours, was considered to provide another assurance.

Measurements of Vapor Pressures.—The sublimation pressure was measured between 138 and 153°C with an apparatus, the same as the one reported elsewhere[5], based on the Knudsen effusion method.

Results.—The vapor pressures are listed in Table I. These data well fit the vapor pressure equation

$$\log P(\text{mmHg}) = 13.666 - (6816.8/T)$$

obtained by the method of least squares. The heat, entropy and free energy of sublimation derived from the equation are given in Table II.

Table I

Vapor pressure of α-glycine

t°C	P(mmHg) $\times 10^3$	t°C	P(mmHg) $\times 10^3$
138.9_8	1.344	145.9_7	2.459
140.6_6	1.557	147.3_3	2.877
142.0_9	1.789	149.2_6	3.289

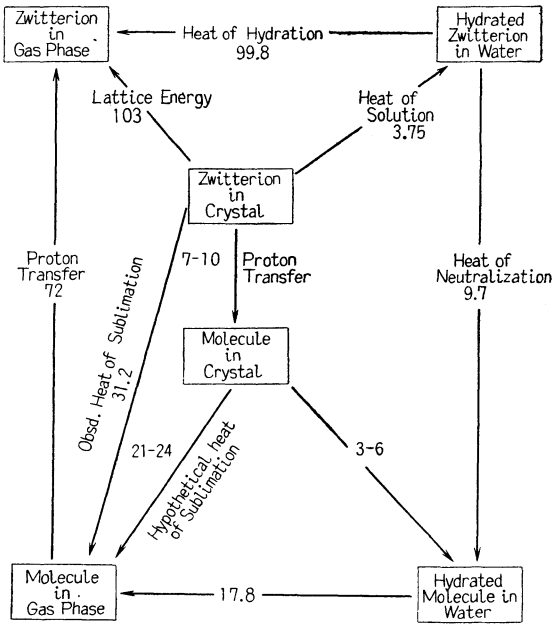

Fig. 1. Energy cycle of glycine (in kcal./mole). Arrows indicate the direction of endothermic changes.

Discussion of the Results

Fig. 1 illustrates an energy-cycle for glycine constructed by use of available thermochemical values. Arrows in Fig. 1 indicate the directions of endothermic changes. This is the final set-up of the energy diagram and we examined other possibilities also, because it was not a priori apparent that the measured heat of sublimation 31.2 kcal./mole corresponds to the change from 'zwitterion in crystal' to 'molecule in gas phase'.

It was first assumed that the observed 31.2 kcal. is the change in heat content in going from the crystal to zwitterions in vapor; in other words this value represents the lattice energy of the crystal if allowance is made for the average kinetic energy of dipolar-ions in vapor. An independent estimate of the lattice energy of glycine has been reported by Shimura from the measured partial molal volume of glycine in aqueous solution by help of Kirkwood's theory on the free energy of hydration[6]. This estimate gives the lattice energy a value as great as 103 kcal./mole. The dipole moment of glycine determined by Buckingham[7] (13.3D) shows

that it is reasonable to assume that unit point charges rest on N and O atoms in a zwitterion so that the electrostatic interaction energy alone in the crystal would amount to about 60 kcal./mole. The total lattice energy including the van der Waals and the hydrogen bond energy will be at least 80 kcal./mole. Therefore our first assumption was wrong and the observed heat of sublimation must correspond not to the lattice energy but to the change in heat content in going from the crystal to molecules in vapor state.

Estimation of the heat of sublimation of a hypothetical crystal composed of glycine molecules, NH_2CH_2COOH.*—The van der Waals energy will contribute about 7.7 kcal. to this hypothetical lattice energy, which is the heat of sublimation[8] of 2-methyl-1-butene, a molecule which is isoelectronic with glycine. The following energy values are assigned to the three hydrogen bonds: 5~6 kcal. for the NH···O 2.76Å long (in diformylhydrazine[9] 2.80Å), 2.5~3.5 kcal. for the bifurcated bonds 2.93 and 3.05Å long (in urea[9] 2.99 and 3.04Å) and 3~4 kcal. for the bond of intermediate length 2.88Å. The sum of all these energy values 20.7~24.7 kcal./mole will be taken as the hypothetical heat of sublimation of molecular crystal of glycine**.

The energies of proton transfer.—By combining the hypothetical heat of sublimation with the observed heat of sublimation 31.2 kcal./mole, we see that the zwitterion crystal is more stable than the molecular crystal by about 7~10 kcal./mole, or in other words a proton transfer in the crystal (a change from $N^+H\cdots O^-$ to $OH\cdots N$) would accompany a heat absorption of 7~10 kcal./mole. If the proton transfer occurred in vapor state, the change

$$NH_2CH_2COOH \rightarrow NH_3^+CH_2COO^-$$

would accompany as much energy absorption as 72 kcal./mole and the "molecular" configuration would be extremely stable in vapor phase in contrast to the situation in the crystalline state. The result that the energy of proton transfer in vapor is about ten times as great as that in a crystal shows that the proton transfer can occur non-adiabatically in the crystal lattice: i.e. as a proton moves along the N···O bond by absorbing the necessary energy, the potential energy curve changes its shape as illustrated schematically in Fig. 2. The strong crystal field may be participating in such a change in the potential

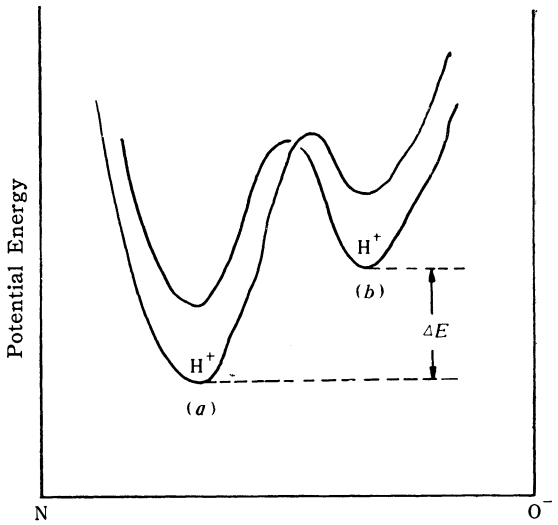

Fig. 2. Change of the potential energy curve in the course of proton transfer. ΔE is the energy of proton transfer (from *a* to *b*) in crystal.

energy diagram. Thus the energy of proton transfer in crystal here obtained does not represent the energy for a single proton to move within a fixed "double minimum" potential field, but the energy required for the overall rearrangement of electronic charges in the entire volume of a crystal is included.

This is a piece of information which we consider to be important in connection with energetics of hydrogen bonding. Participation of hydrogen bonding has often been assumed in various chemical reactions such as in simple hydrogen-deuterium exchange reactions and keto-enol isomerization reactions. Nuclear resonance studies in solution has come to attention of many investigators[10] in relation to the acid-base interaction and they will be one of significant methods of attack against proton transfer in solution.

Glycine is the simplest amino acid constituting complex protein molecules. In

* By hypothetical it is meant that the crystal structure is the same as that of the zwitterion-crystal except for the position of a hydrogen atom; actually the OH···O bonds would be formed if the molecular crystal were more stable.

view of relatively small amount of energy required for a proton jump in a strong crystalline field, it may be reasonably supposed that such proton jumps can frequently occur in many protein systems with or without bound water molecules. Thus a diminishingly small degree of stimulation, given one end of a fibrous nerve protein coiled in a helical arrangement through NH···O hydrogen bonds, may easily be conveyed to the other end of that nerve protein by synchronous proton transfer. Such a mechanism, in fact, has been proposed by several authors[11] and we believe that we could here present some grounds for such speculative discussions.

The energy of proton transfer in vapor state may be very roughly evaluated by the sequence of changes:

$$NH_2CH_2COOH \underset{D}{\rightarrow} NH_2CH_2COO + H \underset{A}{\rightarrow}$$

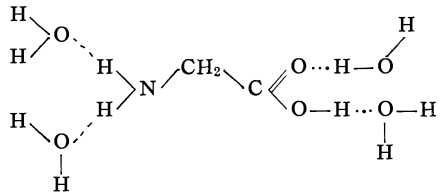
$$NH_2CH_2COO^- + H \underset{I}{\rightarrow} NH_2CH_2COO^- + H^+$$

$$\underset{P}{\rightarrow} NH_3^+CH_2COO^-$$

D, A, I and P may be replaced by the bond dissociation energy of an O—H bond (110.2 kcal./mole), the electron affinity of an O atom (−87.7 kcal./mole), the ionization energy of a hydrogen atom (312.1 kcal./mole) and the proton affinity of an NH_3 molecule (−219 kcal./mole[12]), respectively. The overall change in energy will be 116 kcal./mole in comparison with 72 kcal./mole given in Fig. 1.

Estimation of the heat of self-neutralization in solution and other heats derived therefrom.—The process of self-neutralization in solution may be divided into two steps;

$$H_3N^+CH_2COO^- + H^+ = H_3N^+CH_2COOH - \Delta H_a$$



and

$$H_3N^+CH_2COOH = H_2NCH_2COOH + H^+ + \Delta H_b.$$

ΔH_a can be evaluated from the temperature variation of pK_a, giving 1.16 kcal./mole[13]. ΔH_b may be approximated by the heat (10.8 kcal./mole) associated with the change

$$H_3N^+CH_2COO^- = H_2NCH_2COO^- + H^+.$$

It is believed that this approximation will not cause a significant error since the reaction takes place in aqueous solution having the static dielectric constant larger than 80. The heat of self-neutralization will then be 9.7 kcal./mole (Fig. 1). This value was used to obtain the heat of solution of hypothetical crystals of molecular glycine 3∼6 kcal./mole and the heat of solution of glycine vapor (heat of hydration) 17.8 kcal./mole, both giving a hypothetical solution of molecular glycine*. This is reasonable for a heat of hydration if we assume the hydrogen bond formation scheme like the following one:

The difference 82 kcal./mole between the heat of hydration of zwitterion in vapor and the heat of hydration of molecules in vapor (giving ionic and molecular solutions, respectively) is a rough indication of the effect of ionic charge on N and O atoms when placed in aqueous solution.

Concluding remarks. — The molecular-dipolar ion (zwitterion) relationship now demonstrated for glycine is by no means an exceptional case but may be found in other more familiar systems such as ammonium chloride decomposing into ammonia and hydrogen chloride in the vapor state. Here are apparently the proton jumps occurring in sublimation process, to which a formal analogy of the present treatment may be applicable. It will be interesting to examine the movement of protons or the rôle of hydrogen bonding in more complex amino acids or polypeptides by more-or-less direct means.

Summary

Sublimation pressures of crystalline α-glycine were measured between 138 and 153°C by the effusion method. The pressure equation

$$\log P(\text{mmHg}) = 13.666 - (6816.8/T)$$

11) I. Oshida, Y. Oshika and R. Miyasaka, *J. Phys. Soc. Japan*, **10**, 849 (1955); M. L. Huggins, *Am. Scientist*, **31**, 338 (1943); N. Riel, *Naturwissenshaften*, **43**, 145 (1956).

12) H. Tsubomura, private communication.

13) E. J. Cohn and J. T. Edsall, "Proteins, Amino Acids and Peptides as Ions and Dipolar Ions", Reinhold, New York (1943), p. 80.

* This heat of hydration may be compared with the heat of hydration (7.8 kcal.) of propionic acid corrected for the difference in the interaction energy of a methyl group (3.4 kcal.) and that of an amino group (5.6 kcal.) with water, where it has been assumed that three water molecules accommodate to each of methyl and amino groups (cf. J. A. V. Butler, *General Discussion of the Faraday Soc. on the Structure and Molecular Forces in Pure Liquid and Solution*, 229 (1936));
7.8+(3×5.6)−(3×3.4)=14.4 kcal./mole.

fits well the experimental data. The heat, entropy and free energy (at 25°C) of sublimation were 31.18±0.49 kcal./mole, 49.33 ± 1.17 cal./deg. mole and 16.47 ± 0.60 kcal./mole, respectively. An energy cycle was constructed which correlates zwitterion and molecule in crystal and vapor states, and hydrated zwitterion and molecule in solutions. The observed heat of sublimation corresponds to the change in heat content in going from the zwitterion-crystal to gaseous molecules. The molecular configuration is more stable in vapor state. By using the experimental values of the heat of sublimation, the heat of solution of crystals into water and the temperature dependence of pK_a in solution, with the help of the theoretical values of the lattice energy of the crystal, the following heat values were determined; the heat of proton jump in vapor, $NH_3^+CH_2COO^- \rightarrow NH_2CH_2COOH$, −72 kcal./mole, the heat of proton jump in the crystal 7∼10 kcal./mole, hypothetical heat of sublimation of crystals composed of molecules 21∼24 kcal./mole, the heats of hydration of a zwitterion and a molecule −99.8 and −17.8 kcal./mole, respectively, the heat of solution of the hypothetical crystal to give a solution of molecular glycine 3∼6 kcal./mole, and the heat of self-neutralization in aqueous solution 9.7 kcal./mole. The negative quantities show that the processes are exothermic. It was shown that the proton transfer in a medium of large dielectric constant or in a strong crystalline field requires only a small amount of energy and its significance in chemical reactions and biochemical activities was suggested. Each of the derived heat values was examined by independent checks from different sources, except for the energies of proton transfer.

The authors wish to express their sincere gratitude to Professor I. Nitta for his interest in this research. They are also indebted to the Ministry of Education for the financial support.

*Photometric Study on the Change of Basic Rhodochromium Ion to Basic Erythrochromium Ion in Aqueous Solution**

By Masayasu MORI, Shigeru UESHIBA and Hideo YAMATERA**

(Received August 7, 1958)

The so-called rhodochromium salt has attracted the attention of some investigators in coordination chemistry because of the peculiar reaction of its aqueous solution toward aqueous alkalis. This reaction may be represented by the scheme in Table I.

When Jörgensen discovered these salts, he thought that I and IV were isomers, while II was isomeric to III. Wilmarth, Graff and Gustin[1] investigated this problem using various methods. By careful analyses they denied this isomerism and found the correct formulae of the basic erythro salt and the erythro salt to be as given in Table I.

The reaction II → III may, therefore, be considered as a kind of replacement reaction of the coordinated ammonia molecule. Wilmarth and others called attention to the ease with which this reaction occurs and attributed it to the peculiar structure of the basic rhodo salt with a possible π-bonding as demonstrated by their magnetic measurements. They also found by visual observation that the reaction velocity is not affected by the hydroxide ion concentration ranging from 10^{-4} to 6.0 N in alkali.

It seemed to the present authors that the quantitative study of the kinetics of this reaction II → III would be of value in knowing the energy relation and the

THE RESULT OF ANALYSIS OF DECAMMINE-μ-OL-DICHROMIUM(III) CHLORIDE PERCHLORATE

$[Cr(NH_3)_5OHCr(NH_3)_5]_2Cl_3(ClO_4)_7 \cdot xH_2O$

	Cr	N	Cl	Cl in ClO_4	H_2O
Calcd. $x=0$	15.02	20.22	7.68	17.91	0
Calcd. $x=2$	14.64	19.71	7.49	17.46	2.54
Found in Sample I	15.10	19.56	7.40	16.45	1.74
Found in Sample II	15.22	18.78	7.18	16.78	2.8, 3.4
Found in Sample III	15.07	19.60	6.90	17.15	2.58
Found in Sample IV	15.27	19.82	7.53	17.02	1.57

The poor agreement of the analytical data with the calculated values in some samples is possibly due to the incomplete removal of perchloric acid owing to the fineness of crystals. Special attention has been paid in sample IV to avoid this. It seemed difficult to determine the content of water molecules on account of the slow decomposition of the complex at 100°C.

structure of the related compounds. These salts have characteristic absorption spectra in the visible and ultraviolet region and, therefore, the reaction velocities can be readily pursued by the aid of a spectrophotometer.

Experimental

Materials.—Decammine-μ-ol-dichromium(III) chloride perchlorate, $[Cr(NH_3)_5OHCr(NH_3)_5]_2Cl_3(ClO_4)_7 \cdot xH_2O$ has been used in most of the present research. The chloride prepared as described by Jörgensen was converted into this salt by dissolution in water and addition of perchloric acid. Even recrystallization with perchloric acid did not alter the composition. The preparation of the perchlorate was the first aim, but it was found fairly difficult owing to the high solubility and ready decomposition of the salt. The results of analyses of some chloride perchlorate preparations are given in Table II.

Absorption Measurements.—The absorption mearsurement was carried out with a Beckman DU spectrophotometer. In the kinetic study a solution of rhodo salt (about 0.004 g. ion/l. in 0.1 N perchloric acid) and an equal volume of aqueous ammonia (about 4 N) were first mixed. At the moment of mixing ($t=0$) the whole complex salt should be of the form of basic rhodo salt (II), which will be changed to basic erythro salt (III) as the reaction proceeds. Then at proper intervals the absorbance (A_t) at 392 mμ and the time (t) of the measurement were recorded. Finally the absorbance was measured after the lapse of sufficient time, when the reaction was virtually complete. This absorbance A_∞ should correspond to that of the basic erythro salt (III). It is readily seen that $A_t - A_\infty$ is proportional to the amount of the rhodo salt remaining at time t.

Results and Discussion

When $\log(A_t - A_\infty)$ is plotted against time, the resulting curves are nearly straight lines as shown in Figs. 1a~1d. The slight bending of the curve at the end of each experiment is possibly due to further decomposition of the basic erythro salt produced. A very slow change of absorbance is actually observed in a solution of purified basic erythro salt. However, its velosity is quite low compared with that of the main reaction and its effect seems negligible in the present discussion.

The reaction is, therefore, of the first order and represented by the equation:

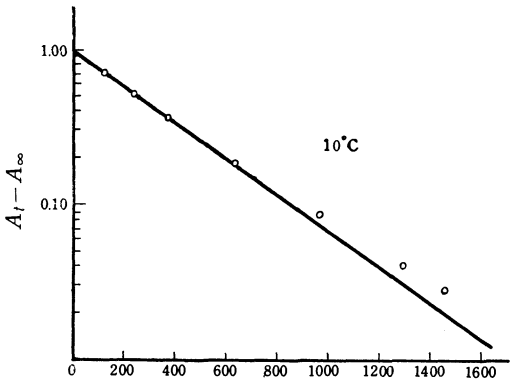

Fig. 1a.

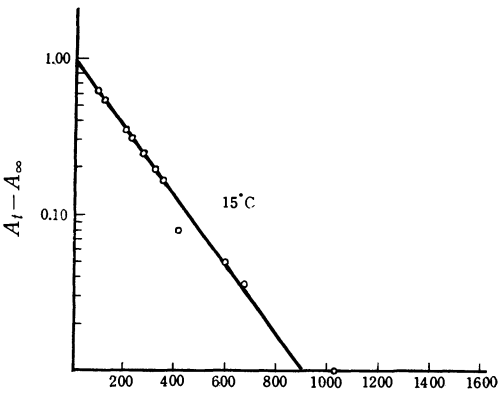

Fig. 1b.

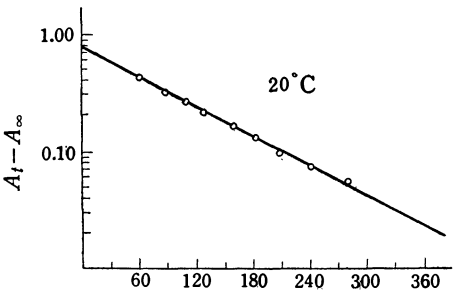

Fig. 1c.

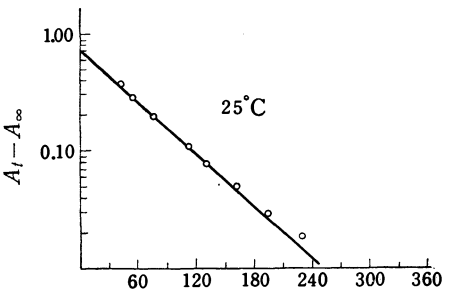

Fig. 1d.

Fig. 1. Change of A_t-A_∞ with time (in a semilog scale).

$$kt=\ln(A_0-A_\infty)-\ln(A_t-A_\infty)$$

where k is the velocity constant and A_0 is absorbance at $t=0$ and corresponds to the absorbance of the basic rhodo salt initially present. These values are readily estimated from the plot in Fig. 1. In Table III are given the velocity constant k and the half-value period $\tau=0.693/k$ obtained in this way.

TABLE III
THE VELOCITY CONSTANT AND HALF-VALUE PERIOD OF THE REACTION

T°C	10	15	20	25
$k\times10^3$	2.64	5.08	9.66	17.3
τ	258	136	72	40

The k values at different temperatures give us the energy of activation E, the frequency factor A and the entropy of activation ΔS^* according to the relations:

$$\ln k = \ln A - E/RT$$

$$\ln A = \ln(kT/h) + \Delta S^*/R - 1$$

The numerical data thus obtained are as follows: $E=21$ kcal/mole, $A=4.5\times10^{13}$ l./mole sec., $\Delta S^*=2$ kcal/deg. mole.

The effect of the hydroxide ion concentration on the reaction velocity was examined by the use of different species and concentration of alkalis. The result, given in Table IV, shows that the increase in

TABLE IV
THE EFFECT OF THE HYDROXIDE ION CONCENTRATION ON THE VELOCITY CONSTANT AT 10°C

Concentration of the complex (In the reacting system)	Concentration of the alkali (In the reacting system)	k
0.00215 g. ion/l.	2.25 N in NH_3	0.00264
0.00107 〃	〃 3.37 N in NH_3	0.00259
0.00107 〃	〃 0.0735 N in NaOH	0.00237
0.00215 〃	〃 0.490 N in NaOH	0.00223
0.00107 〃	〃 0.735 N in NaOH	0.00214

the hydroxide ion concentration caused the decrease in the observed velocity constant. This decrease in the reaction velocity may be due to the increase in the viscosity of the solution; but there is also a possibility that some side reactions or slow deposition of hydrous chromium oxide increased the apparent absorption, and consequently decreased the calculated velocity constant. However, the fact that the reaction is not accelerated by the hydroxide ion excludes the possibility of the S_{N2} mechanism involving a direct attack of the complex by the hydroxide ion.

The addition of sodium perchlorate to the reacting system at 20°C showed that the ionic strength over 0.08 to 1.32 has little effect on the velocity constant. When the concentration of sodium perchlorate exceeded 2.5F, the reaction velocity seemed to decrease, but the fluctuation of the data was significant. This fluctuation may be due to the formation of a fine precipitate of basic rhodo perchlorate even though not visually perceptible.

As seen from the preceeding argument, the aqueous solution of basic rhodo salt is unstable, so that it is difficult to obtain its absorption spectrum directly. When the kinetic data are available, however, the absorbance of the basic rhodo salt (A_0) can be derived from A_t and A_∞ by calculation or on the graph. The curve of the absorption spectrum drawn in this way is shown in Fig. 2. The very characteristic feature of the absorption spectrum probably demonstrates the different electronic structures of the basic rhodo salt from those of other chromium ammines, but the assignment of any electronic transition to each observed absorption band possibly requires a further investigation.

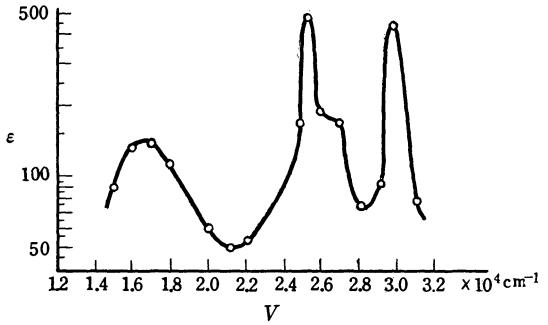

Fig. 2. Absorption spectrum of basic rhodo salt obtained from kinetic data.

Summary

The conversion reaction of the basic rhodo ion to the basic erythro ion in an alkaline solution was found to be of the first order. The velocity constants at 10°, 15°, 20° and 25°C were measured, and the energy of activation, the frequency factor and the entropy of activation calculated. The reaction velocity appeared to be somewhat diminished by higher concentration of sodium hydroxide. The absorption spectrum of unstable basic rhodo salt was derived from the kinetic data.

The authors wish to express their debt of gratitude to Assistant Professor Yukio Kondo of the Rikkyo University for sending them a reprint of his paper concerning the absorption spectra of binuclear ammine complexes.

The Dissociation Constants of Carboxytropone and Carboxytropolones

By Nobuyuki TANAKA, I. T. OIWA*, Toshiko KUROSAWA** and Tetsuo NOZOE

(Received August 4, 1958)

Although tropolones possess the properties characteristic of enols and phenols, they may be regarded, in respect of acidity, as vinylogs of carboxylic acids. Their dissociation constants are closer to the latter than to those of phenols[1-4]. This is attributed to the resonance of the ions A and B. However, the acidity is not so enhanced as would be expected

from the stabilization of the ion species A and B. This fact has been explained by considering the "aromatic" resonance of the species C and D, the former being less favored than the latter[2].

In this study, the dissociation constants of 2-carboxytropone, 3-carboxytropolone and its derivatives have been determined by potentiometric titrations with a glass electrode. From the results obtained, the chelation between the substituted carboxyl group and the hydroxyl group of tropolones is discussed.

Experimental

Materials.—Eight compounds that were investigated in the present study were prepared in this laboratory and had the properties given in Table I. Ten milligrams of each compound was weighed accurately and dissolved in redistilled water ($\kappa < 10^{-6}$ mho/cm.) to prepare a solution of approximately 10^{-3} mole/l. in concentration (Table I). A 0.01 M carbonate-free sodium hydroxide solution was prepared by the usual method[16], and its concentration was standardized against recrystallized oxalic acid. The solution was kept in a bottle with a buret which had an arrangement for protection against carbon dioxide.

Three buffer solutions recommended by the National Bureau of Standards (U. S. A.)[17] were employed for the standard for the pH measurement. They are 0.05 M potassium hydrogen phthalate of pH 4.008 at 25°C, 0.025 M potassium

dihydrogen phosphate and 0.025 M disodium hydrogen phosphate of pH 6.857 at 25°C and 0.05 M borax of pH 9.180 at 25°C.

Apparatus and Procedure.—The cell

Ag-AgCl	0.1 M HCl (inner)	glass membrane		
	sample solution +NaOH (outer)	saturated KCl	Hg_2Cl_2-Hg	

was constructed for the pH measurement. The glass electrode which was designed by one of the authors (I. T. O.) had the shape of a small flask of approximately 30 ml. capacity. A standardized 0.1 M hydrochloric acid was placed inside. A titration cell used is shown in Fig. 1.

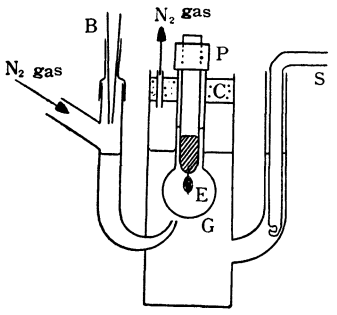

Fig. 1. Schematic diagram of the titration cell: G, glass membrane; E, silver-silver chloride electrode: P, polyethylene seal; C, cork; S, salt bridge; B, buret.

The pH of the solution was determined by the measurement of the electromotive force (e. m. f.) of the above cell. The measurement of e. m. f. was made by means of an instrument which consisted of a potentiometer and the combination of a UX-54 type vacuum tube (corresponding to the FP-54 type vacuum tube in the United States) and a galvanometer[18].

In order to remove the dissolved carbon dioxide and to stir the solution, purified nitrogen gas was passed through the solution before the titration and also after every addition of sodium hydroxide solution during the titration. The e. m. f. was measured with an accuracy of 0.0001 volt; therefore the pH was determined with an accuracy of 0.005 pH-unit. All measurements were carried out in a thermostat of 25.00±0.01°C.

Results

Titration Curves. — Typical titration curves obtained are reproduced in Fig. 2.

Calculation of Dissociation Constants.— (a) *Monobasic acid (HA).*—The dissociation constant of a monobasic acid, K_1, was calculated with the equation

$$K_1=\frac{a_{H^+}\times a_{A^-}}{a_{HA}}=\frac{a_{H^+}\left(b+\frac{a_{H^+}}{f_{H^+}}\right)f_{A^-}}{c-\left(b+\frac{a_{H^+}}{f_{H^+}}\right)} \qquad (1)$$

where c means the total concentration of an acid titrated, b the concentration of sodium hydroxide added, a_{H^+}, a_{HA} and a_{A^-} mean the activities of the hydrogen ion, the undissociated acid and the dissociated acid anion, respectively, and f_{H^+} and f_{A^-} the activity coefficients of the hydrogen ion and the dissociated acid anion, respectively. The activity coefficient of the undissociated acid HA was assumed to be unity, while those of the dissociated acid anion A^- and the hydrogen ion were calculated with the equation

$$\log f_i=-\frac{0.358Z_i^2\sqrt{I}}{1+0.2325a_i\times10^8\sqrt{I}} \qquad (2)$$

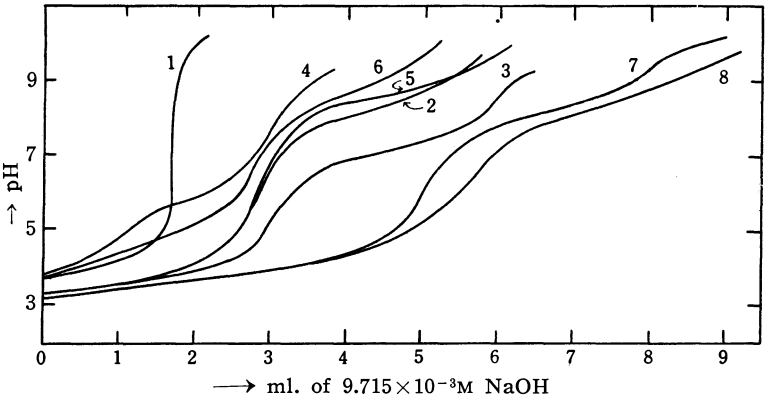

Fig. 2. Titration curves of carboxytropone and carboxytropolones. The curves are given the same number as in Table I.

18) N. Tanaka, I. T. Oiwa and M. Kodama, *Anal. Chem.*, **28**, 1555 (1956).

where Z_i represents the ionic charge, Γ the total ionic concentration, and a_i the ion-size parameter[19]. Because 2-carboxytropone was considered to have a molecular volume similar to that of benzoic acid, its ion-size parameter was assumed to be 6 Å according to Kielland's[19] tables.

(b) *Dibasic acids* (H_2A).—When $K_1/K_2 \geq 10^3$, the first dissociation constant, K_1, was calculated with eq. 1 in which f_{A^-} was replaced by f_{HA^-}, the effect of the second dissociation being neglected. In this calculation, the part of the titration curve before the equivalence point for the first dissociation was used. The second dissociation constant, K_2, was calculated with the equation

$$K_2 = \frac{a_{H^+} \times a_{A^{2-}}}{a_{HA^-}} = \frac{a_{H^+}\left(b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]\right) f_{A^{2-}}}{\left(2c + [OH^-] - \frac{a_{H^+}}{f_{H^+}} - b\right) f_{HA^-}} \quad (3)$$

from the observed values which were obtained between the equivalence points for the first and the second dissociations on the titration curve.

(c) *Tribasic acids* (H_3A).—From the titration curves given in Fig. 2 it was seen that K_1/K_2 is not greater than 10^3, so that K_1 and K_2 were not able to be calculated by the procedure given in (b). In this case they were calculated with the equations

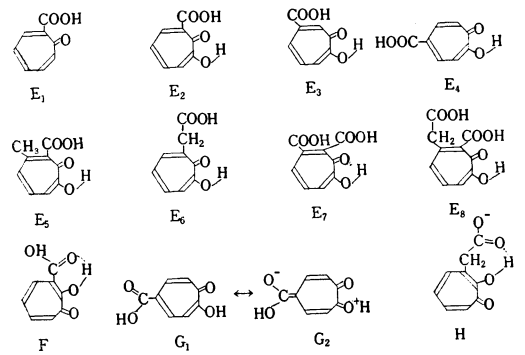
$$K_1K_2 = \frac{a_{H^+}^2 \times a_{HA^{2-}}}{a_{H_3A}} = a_{H^+}^2 \left(\frac{b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]}{2c - b - \frac{a_{H^+}}{f_{H^+}} + [OH^-]} \right) \times \left\{ 1 + \frac{K_1 f_{H^+}}{a_{H^+}} \left(\frac{b - c + \frac{a_{H^+}}{f_{H^+}} - [OH^-]}{b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]} \right) \right\} f_{HA^{2-}} \quad (4)$$

$$K_1 = a_{H^+} \left(\frac{b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]}{c - b - \frac{a_{H^+}}{f_{H^+}} - [OH^-]} \right) \times \left\{ 1 - K_1K_2 \left(\frac{f_{H^+}}{a_{H^+}} \right)^2 \left(\frac{2c - b - \frac{a_{H^+}}{f_{H^+}} + [OH^-]}{b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]} \right) \right\} f_{H_2A^-} \quad (5)$$

from the values obtained before the equivalence point for the second dissociation on the titration curve.

The third dissociation constant, K_3, was calculated with the equation,

$$K_3 = \frac{a_{H^+} \times a_{A^{3-}}}{a_{HA^{2-}}} = \frac{a_{H^+}\left(b + \frac{a_{H^+}}{f_{H^+}} - [OH^-]\right) f_{A^{3-}}}{\left(3c - b - \frac{a_{H^+}}{f_{H^+}} + [OH^-]\right) f_{HA^{2-}}} \quad (6)$$



from the values obtained between the equivalence points for the second and third dissociations on the titration curve.

In Table II are given the typical examples of calculation for the mono- and di-basic acid, and in Table III, the dissociation constants obtained for the compounds investigated. For comparison, the dissociation constants of several substances which have structures similar to the compounds investigated in this study are also given in Table III.

Discussion

2-Carboxytropone (E_1).— This acid is stronger than benzoic acid. This is attributed to the fact that the inductive (electron withdrawal) effect of a tropone ring is stronger than that of a benzene ring.

3-Carboxytropolone (E_2) and 3-carboxy-4-methyltropolone (E_5).— The values of pK_1 are smaller than those of benzoic acid and 2-carboxytropone. This shows the stronger inductive effect of the tropolone ring as well as the existence of chelation

TABLE III

DISSOCIATION CONSTANTS OF CARBOXYTROPONE, CARBOXYTROPOLONES AND THE RELATED COMPOUNDS

Compound	pK_1	pK_2	pK_3
2-Carboxytropone	3.73 ± 0.01		
3-Carboxytropolone	3.20 ± 0.01	7.98 ± 0.01	
4-Carboxytropolone	3.42 ± 0.005	7.03 ± 0.01	
5-Carboxytropolone	4.05 ± 0.01	6.41 ± 0.02	
3-Carboxy-4-methyltropolone	3.15 ± 0.01	8.29 ± 0.01	
3-Carboxymethyltropolone	4.52 ± 0.02	8.77 ± 0.05	
3, 4-Dicarboxytropolone	3.24 ± 0.03	6.26 ± 0.03	8.57 ± 0.01
3-Carboxy-4-carboxymethyltropolone	3.75 ± 0.03	5.90 ± 0.05	8.08 ± 0.02
Acetic acid	4.756[20]		
Benzoic acid	4.201[20]		
Tropolone	6.92[3]		
4-Methyltropolone	7.26[3]		

such as given in structure F. The larger values of pK_2 also show the existence of stable chelation.

4-Carboxytropolone (E_3) and 5-carboxytropolone (E_4). — In these substances the carboxyl group will not be able to form the chelation of type F, which 3-carboxytropolone forms. The magnitudes of pK_1 of these acids, therefore, are expected to be larger than those of 3-carboxytropolone and 3-carboxy-4-methyltropolone, and the magnitudes of pK_2 of the former, smaller than those of the latter. The experimental results agree with this expectation; The pK_1 of 5-carboxytropolone is much greater than that of 4-carboxytropolone, this may be attributed to the contribution of structure G_2. It is also interesting to notice that the difference between pK_1

20) R. A. Robinson and R. H. Stokes, "Electrolytic Solutions," Butterworths Scientific Publications, London, p. 436 (1955).

and pK_2 of 5-carboxytropolone is much smaller than the differences of other monocarboxytropolones (See Table III).

3-Carboxymethyltropolone (E_6). — The methylene group shields the inductive effect of a tropolone ring upon the carboxyl group, and, consequently, the pK_1 value is close to that of acetic acid. The large pK_2 value indicates the existence of the stable chelation (structure H).

3, 4-Dicarboxytropolone (E_7) **and 3-carboxy-4-carboxymethyltropolone** (E_8).— 3, 4-Dicarboxytropolone gives a pK_1 value which is nealy equal to that of 3-carboxytropolone (E_2), while 3-carboxy-4-carboxymethyltropolone gives a somewhat larger pK_1. This seems to be due to the greater steric interference of a carboxymethyl group in the 4-position.

Summary

The thermodynamic dissociation constants of 2-carboxytropone, 3-carboxytropolone, 4-carboxytropolone, 5-carboxytropolone, 3-carboxy-4-methyltropolone, 3-carboxymethyltropolone, 3, 4-dicarboxytropolone and 3-carboxy-4-carboxymethyltropolone have been determined by means of the pH titration with a glass electrode.

The relationships between the magnitudes of the dissociation constants and the structures of these compounds have been discussed.

SHORT COMMUNICATIONS

Absolute Estimation of the Ionic Entropies of Transfer

By Toshio IKEDA

(Received September 9, 1958)

The earlier attempts[1,2] of estimating the absolute ionic entropies of transfer are all based on an artificial assumption. Recently, the first absolute estimation has been carried out successfully by Agar and Breck[3]. The present report would give the second way of estimating these values exclusively from the observed data concerning the "Soret effect" and thermocells without making any assumption except the additivity of the ionic entropies of transfer, which was originally proposed by Eastman[1] and lately has been confirmed by Alexander[4] at low concentrations. For a thermocell of the system, $Ag|AgCl_s$, MCl_{aq}, $AgCl_s|Ag$, we can write, when the Soret effect is hindered, as follows:

$$\boldsymbol{F}\frac{d\varphi}{dT} = -t_+S_+^* + t_-S_-^* - S_{el}^* + S_{Ag} - S_{AgCl} + t_+S_{MCl} \qquad (1)$$

where $\boldsymbol{F}$ is Faraday's constant, $d\varphi$ is the thermopotential difference due to the temperature gradient dT, t_+ and t_- are the transference numbers of positive and negative ions of the salt MCl (here uni-univalent) respectively, S_+^*, S_-^* and S_{el}^* are the entropies of transfer of hydrated positive and negative ions in solution phase and that of electron in metallic phase respectively, S_{Ag} and S_{AgCl} are the molar entropies of metallic silver and solid silver chloride respectively, and S_{MCl} is the molar

Chem.*, **24**, 39 (1897); f, This anomalous value might be due to the fact that Chipman's value of σ here used is incorrect, probably too low; g, I. C. T; B. E. Conway "Electrochemical Data", Elsevier Publ. Co., Amsterdam, (1952).

entropy of MCl in solution phase. Here $S_{MCl}=S_+ + S_-$, S_+ and S_- being the partial molar entropies of hydrated positive and negative ions produced from one molecule of the salt MCl in solution phase.

Coupling the relations[5], $S_+^*=Q_+^*/T+S_+$ and $S_-^*=Q_-^*/T+S_-$, with the approximation formula[6] $\sigma=-(Q_+^*+Q_-^*)/2\boldsymbol{R}T^2$ for the Soret coefficient σ, one may yield the molecular entropy of transfer of the salt MCl as

$$S_+^*+S_-^*=-2\boldsymbol{R}T\sigma+S_{MCl} \qquad (2)$$

where Q_+^* and Q_-^* are the heat of transfer of hydrated positive and negative lons of MCl in solution phase, and $\boldsymbol{R}$ is the gas constant.

Upon solving Eqs. 1 and 2 with respect to S_+^* and S_-^* by the aid of the relation of $t_+ + t_- = 1$, one may yield

$$\left.\begin{aligned} S_-^* &= \boldsymbol{F}\mathrm{d}\varphi/\mathrm{d}T - S_{Ag} + S_{AgCl} \\ &\quad -2t_+\boldsymbol{R}T\sigma + S_{el}^* \\ S_+^* &= -\boldsymbol{F}\mathrm{d}\varphi/\mathrm{d}T + S_{Ag} - S_{AgCl} \\ &\quad -2t_-\boldsymbol{R}T\sigma - S_{el}^* + S_{MCl} \end{aligned}\right\} \qquad (3)$$

Since S_{el}^* is very small as compared with the other terms in Eq. 3, sufficiently correct values of the ionic entropies of transfer may be obtained even by omitting term of S_{el}^* from Eq. 3. Some of the values of S_+^* and S_-^* thus estimated for the 0.05 and 1 molal aqueous solutions of some electrolytes at 25°C are tabulated in Table I. There can be seen some remarkable facts: (1) the values of S_+^* and S_-^* persist their proper values, independent of what system they are originated from; (2) the value of S_-^* is consistently the same, entirely independent of the nature of its conjugate cations present in the chloride solutions; (3) S_i^* is a function of the concentration.

Finally it is very interesting to have a possibility of determing the heats of transfer for positive and negative ions separately, if only the individual ionic activity coefficients are known.

*Studies of the Structure of Bergenin**

By Shin-ichiro FUJISE, Morio SUZUKI, Yasuhiko WATANABE and Sumu MATSUEDA

(Received October 21, 1958)

Two reports on the structure of bergenin were published recently by J. Evelyn Hay et al.[1] and by Posternak et al.[2]. We also wish to report here our results on the structure of bergenin (I) from the bark of *Corylopsis Spicata*[3].

The periodate oxidation of di-*O*-methylbergenin (II) gave 5, 6, 7-trimethoxyisocoumarin-3-aldehyde (III). By careful catalytic hydrogenation of III, 3-hydroxymethyl-5, 6, 7-trimethoxyisocoumarin (IV)

* The paper was read at Annual Meeting of Chemical Society of Japan, April 5, 1958.

(its 3-acetoxymethyl derivative (V)), 3-methyl-5, 6, 7-trimethoxyisocoumarin (VI) and 3-methyl-5, 6, 7-trimethoxy-3, 4-dihydroisocoumarin (VII) were isolated through three steps.

The alkaline treatment of III gave 5, 6, 7-trimethoxy-3, 4-dihydroisocoumarin-3-carboxylic acid (VIII), i. e., an intermolecular Cannizzaro reaction was observed. The values of U. V. spectrum of these compound are given in Tables I and II.

(IX)

From the results shown in Table I, we conclude that bergenin and di-*O*-methylbergenin have dihydroisocoumarin-ring, but not isocoumarin-ring (the absence of 330 mμ absorption). The results also agreed with those in Table II, i. e., I. R. spectrum of 3-methyl-3, 4-dihydroisocoumarin (1716 cm^{-1}) indicated the identical structure with that of bergenin and of di-*O*-methylbergenin.

The catalytic reduction of II, by using Raney catalyst (at 200°, 100 atm.) resulted in obtaining 6-(2, 3, 4-trimethoxyphenyl)-1, 2, 3, 4, 5-heptahydroxyhexane IX, being accompanied by both decarboxylation and hydrogenation. The products was stable to Fehling's solution. The constitution of IX was also confirmed by the oxidation with sodium metaperiodate. In the case that 4 moles of this reagent were consumed, oxidation product was isolated to be prove as 2, 3, 4-trimethoxy phenylacetaldehyde 2, 4-dinitrophenyl hydrazone.

The alkaline hydrogen peroxide oxidation of I gave arabinose (as 2, 4-dinitrophenylhydrazone). II was found to be also stable to Fehling's solution. Deducing from the above-mentioned experimental results, bergenin is concluded to be represented by the formula I.

*Paramagnetic Resonance Absorption in Solution of the Sodium Adducts of Styrene and 1, 1-Diphenylethylene**

By Kozo Hirota, Keiji Kuwata and Kazuo Morigaki

(Received November 21, 1958)

As reported already[1], paramagnetic resonance absorption with hyperfine structure could be observed on the red adduct of styrene with sodium in tetrahydrofuran (THF) solution. Such absorption has been observed by Weissman and his collaborators[2] in caces of polynuclear condensed aromatic hydrocarbons, e. g., naphthalene, anthracene, and naphthacene. Moreover, it is interesting that the adduct of styrene polymerizes easily, turning into a so-called "living polymer". The research, therefore, was continued with an apparatus of higher sensitivity, thus obtaining more interesting and confirmative results. It is the object of the present communication to report them and also a similar research on 1,1-diphenylethylene (DPE), which also forms a living polymer[3].

As shown in Figs. 1a and 1b, two kinds of spectrum were observed in the adduct of styrene, and it was found that they could be observed in the solutions when the adduct of high degree of polymerization was depolymerized with metallic sodium, and after repeated experiment it

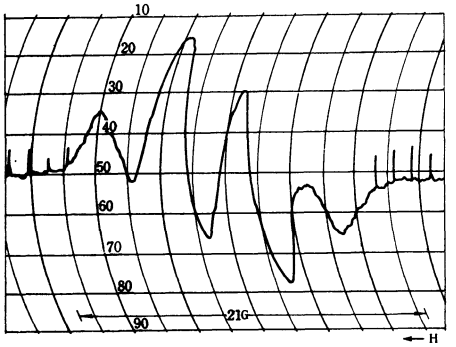

Fig. 1b. Resonance spectrum of styrene radical.

was confirmed that, according as the depolymerization is performed to much extent or not, the spectra observed were composed of about 23 lines or of four lines, as shown in Figs. 1a and 1b, but the reproducibility of the former was not confirmed. It is noteworthy that the spectrum of four lines did not separate into more lines when the measurment was done at such low temperature as about −100°C and when dioxane was used as the solvent, or potassium was substituted for sodium to prepare the adduct.

Similar situation was found on the adduct of DPE whose spectra are shown in Figs. 2a and 2b. The spectrum composed of 32~33 lines (Fig. 2a) could be obtained on the adduct freshly prepared from DPE monomer and sodium in THF. The spectrum, changed into the one composed of nine lines (Fig. 2b), when the sample was kept at 110°C for two days. Now it is clear that solutions of the sodium adducts of styrene and DPE contain some free radicals. Taking such fact into consideration, some discussions on the nature of these adducts were attempted.

These radicals in the adduct of styrene are considered to have the following

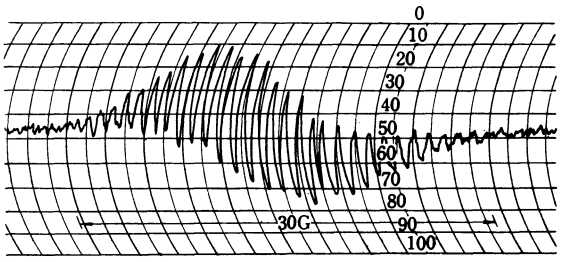

Fig. 2a. Resonance spectrum of DPE radical.

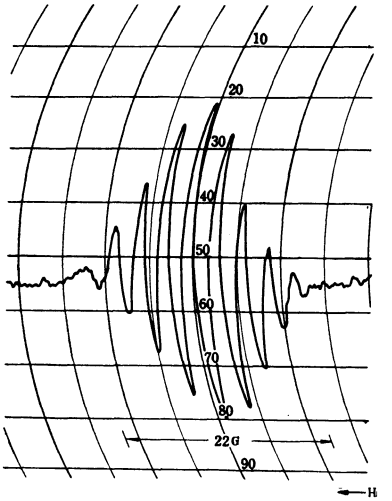

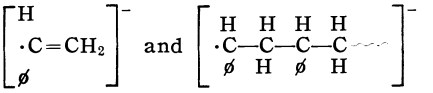

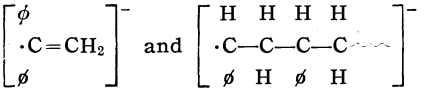

Fig. 2b. Resonance spectrum of DPE radical.

structures on the view of the polymerization reaction, it is believed that these two radicals are the origin of such two resonance spectra*:

In case of DPE the situation is similar, but is more confirmative by the analysis of the spectra. The structures of the radicals corresponding to the spectra shown by Fig. 2a and Fig. 2b are as follows, respectively:

The detailed result and discussion will be published in near future.

* By these formulae all resonace formulae are represented for both adducts.

The writers express sincere thanks to Professor Junkichi Itoh of Osaka University who made the measurement of the paramagnetic resonance absorption possible.

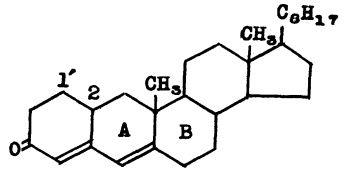
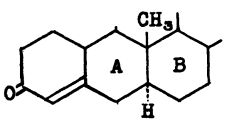
2ξ, 3-(3'-Oxocyclohex-4'-eno)-cholest-4-ene and 2ξ, 3-(3'-Oxocyclohex-4'-eno)-5α-cholestane (Preliminary Note)



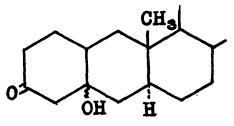
By Yoshiyuki URUSHIBARA and Jihei INOMATA

(Received December 10, 1958)



Chololest-4-en-3-one (I) was condensed with ethyl formate by the action of sodium methoxide to give 2-hydroxymethylene-cholest-4-en-3-one (II), m. p. 110°C[1]. The substance II was then condensed with freshly distilled methyl vinyl ketone in ethyl acetate in the presence of trimethylamine[2], and chromatography of the product on alumina and recrystallization from ethanol-methanol yielded 2ξ-(3'-oxobutyl)-cholest-4-en-3-one (III), m. p. 86~88°, λ_{max} 242 mμ(ethanol) (ε=14500), infrared absorptions 5.813, 5.970, and 6.160 μ (Found: C, 82.11; H, 11.19. Calc. for $C_{31}H_{50}O_2$: C,81.88; H, 11.08%). The diketone (III) gave a dioxime melting at 84°C (Found: N, 5.83. Calcd. for $C_{31}H_{52}O_2N_2$: N, 5.78%).

Treatment of the diketone (III) with alcoholic potash in the stream of nitrogen, chromatography of the product on alumina and recrystallization from ethanol, gave 2ξ,3-(3'-oxocyclohex-4'-eno)-cholest-4-ene (IV), m. p. 149—150° (Found: C, 85.08; H, 11.17. Calcd. for $C_{31}H_{48}O$: C, 85.26; H, 11.08%). The substance IV dissolved in ethanol showed an absorption maximum at 296 mμ (ε=30000) and in Nujol gave infrared absorptions at 6.000, 6.143 and 6.301 μ, which are proofs of the dienone structure IV.



Reaction of 2-hydroxymethylene-cholest-4-en-3-one (II), methanolic sodium methoxide and freshly prepared 4-(diethylamino)-2-butanone methiodide[3], followed by chromatography of the product on alumina and recrystallization from ethanol, gave directly the same dienone (IV), m. p. 141°C, which could be purified with difficulty.

(IV)

(IX)

(VIII)

5α-Cholestan-3-one (V) was transformed into a monohydroxymethylene derivative, m. p. 180~185°C, in the same way as mentioned above(Found: C, 81.14; H, 11.31. Calcd. for $C_{28}H_{46}O_2$: C, 81.13; H, 11.11%). The structure of the product was proved to be 2-hydroxymethylene-5α-cholestan-3-one (VI)[4] by the formation of 2,3-seco-5α-cholestane-2,3-dioic acid, m. p. 193~194°C, on oxidizing the substance with hydrogen peroxide and caustic soda[5]. The dicarboxylic acid was identified with the specimen prepared from 5α-cholestan-3β-ol by the method of Windaus et al.[6]

Reaction of 2-hydroxymethylene-5α-cholestan-3-one (VI), 4-(diethylamino)-2-butanone methiodide and ethanolic potash, followed by chromatography of the product on alumina and recrystallization, gave 2ξ-(3'-oxobutyl)-5α-cholestan-3-one (VII), m. p. 113~114°C, infrared absorption 5.808~5.840μ (Found: C, 81.63; H, 11.52. Calc. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48%), and 2ξ,3-(3'-oxocyclohexano)-5α-cholestan-3ξ-ol (VIII), m. p. 230~231°C, infrared absorptions 2.826 and 5.790 μ (Found: C, 81.80; H, 11.70. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48%).

6) A. Windaus and Cl. Uibrig, *Ber.*, **47**, 2384 (1914).

Compounds VII and VIII yielded the same 2ξ, 3-(3′-oxocyclohex-4′-eno)-5α-cholestane (IX), m. p. 153°C, on treatment with sodium hydroxide in the stream of nitrogen, followed by chromatography of the product on alumina and recrystallization from ethyl acetate (Found: C, 84.75; H, 11.57. Calcd. for $C_{31}H_{50}O$: C, 84.86; H, 11.49%). The substance IX dissolved in ethanol showed an absorption maximum at 243 mμ(ε=15000) and in Nujol infrared absorptions at 5.970 and 6.160μ, which prove the structure IX.

2-Hydroxymethylene-5α-cholestan-3-one (VI) reacted with methyl vinyl ketone on addition of a few drops of 10% ethanolic potash in the heat, and treatment of the product, m. p. 134~135°C, probably the 2-formyl intermediate, with ethanolic potash in the stream of nitrogen gave the same 2ξ-(3′-oxobutyl)-5α-cholestan-3-one (VII).

The 2ξ, 3-(3′-oxocyclohexano)-5α-cholestan-3ξ-ol (VIII), m. p. 231~232°C, and its 3-stereoisomeride, m. p. 217~219°C (Found: C, 81.16; H, 11.42. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48%), were obtained by the action of *N*-ethylanilinomagnesium bromide on 2ξ-(3′-oxobutyl)-5α-cholestan-3-one (VII) followed by hydrolysis of the intermediate product with dilute hydrochloric acid[7].

No experimental evidence has yet been obtained concerning the configuration around the carbon atom 2 in compounds III, IV, VII, VIII and IX[8], but it seems almost certain for these deformylated compounds that carbon atom 1′ is situated at the more stable α-configuration and consequently the hydrogen in position 2 is attached there with the β-bond, axial to both ring A and the added ring.

Details will follow.

High Resolution Proton Magnetic Resonance in Fluorobenzene

By Shizuo Fujiwara, Mikio Katayama and Hiroshi Shimizu

(Received November 11, 1958)

Gutowsky et al. resolved the proton nuclear magnetic resonance spectrum of fluorobenzene into a doublet and interpreted that it would refer to the case where the fluorine was equally coupled through electrons with the ortho-, meta-and paraprotons[1]. Baker also presented the same conclusion[2]. But this conclusion is a quite perplexing one to the chemists, and we continued the efforts to resolve the spectrum further and observed that the components of the doublet were different in the intensity from each other, consistent with the observation by Gutowsky et al.[1], each having the structure as shown in Fig. 1.

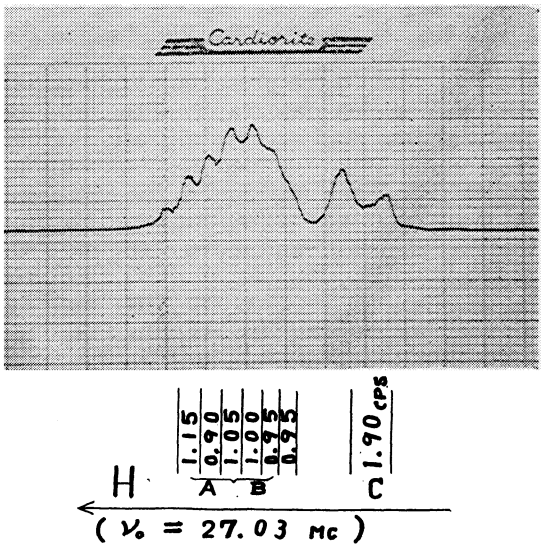

Fig. 1. Proton resonance in fluorobenzene.

The separation between each component of the multiplets is shown in Figure 1. In spite of the argument given by Baker[2] for the fluorine spectrum of this compound, we assume that the proton resonance spectrum of Fig. 1 would refer to the case where the effect of the non-equivalent distribution of electrons participates in

the resonance phenomena. A possible assignment of the line components may be done with the help of the molecular theory[3] by taking the peaks of A, B and C (A is the highest in the resonant field) as referring to meta-, para- and ortho-protons, respectively.

During this experiment, we could know that Bak, Shoolery and Williams[4] reached the same conclusion as ours of unequal H-F couplings, but, in their article, the spectrum of the proton resonance is not shown. Further efforts to make the assignments of each component line and to make measurements at higher field are now being on.

Our thanks are due to Dr. G. A. Williams of Stanford University who sent us the preprint. Thanks are also due to Professor O. Simamura of the University of Tokyo who supplied us the sample.

Hydrogenolysis and Hydrogenation of Some 2, 3-Unsaturated Alcohols with Platinum Oxide and with Platinized Raney Nickel

By Shigeo NISHIMURA and Kazuko MORI

(Received December 10, 1958)

The hydrogenation of cholest-4-ene-3β, 6β-diol (I) in neutral ethanolic solution with platinum oxide as a catalyst gives 5β-cholestane-3β,6β-diol (II)[1]. The present authors carried out the same reaction in the presence of a trace of hydrochloric acid, when a little less than three moles of hydrogen were absorbed and 5α-cholestane (III) was obtained as the main product[2] (Table I). Shoppee et al.[3] obtained similar results in the hydrogenation of cholest-4-en-3-ols and related compounds, but they gave no account on the course of the hydrogenation.

Since it has been found that neither 5α-cholestane-3β, 6β-diol nor 5β-cholestane-3β, 6β-diol can be hydrogenolyzed with platinum oxide and hydrochloric acid, it can be assumed that the cholestenediol (I) underwent for the most part the hydrogenolysis before the saturation of the double bond, giving 5α-cholestane as the main product as illustrated below:

The above assumption is further supported by the fact that the product obtained by an incomplete hydrogenation of the cholestenediol (I) gave coloration with tetranitromethane in chloroform, while the cholestenediol (I) is entirely indifferent to the reagent.

The formation of 5β-cholestane from 3α-acetoxycholest-4-ene[3] can not be explained in a similar way, because, if cholest-4-ene were an intermediate product, then 5α-cholestane should be the main product as in the hydrogenation of the cholestenediol (I).

Similar results have been obtained in the hydrogenation of other 2,3-unsaturated alcohols and phenol, as summarized in Table I.

In the presence of platinum oxide and hydrochloric acid the substances absorbed more hydrogen than is necessary to transform them into the corresponding saturated alcohols. Since none of 3-phenyl-1-propanol, tetrahydrofurfuryl alcohol and

1) V. Prelog and E. Tagmann, *Helv. Chim. Acta*, **27**, 1880 (1944).

2) In ether-acetic acid solution, two moles of hydrogen are absorbed by the diacetate of the diol, and 5α-cholestane-3β,6β-diol, 5α-cholestan-3β-ol and 5α-cholestane are obtained: O. Rosenheim and W. W. Starling, *J. Chem. Soc.*, **1937**, 383.

3) C. W. Shoppee, B. D. Agashe and G. H. R. Summers, ibid., **1957**, 3107.

TABLE I
MOLES OF HYDROGEN ABSORBED IN 95% ETHANOL AT THE ORDINARY TEMPERATURE AND PRESSURE

Compound	Catalyst		
	PtO_2	PtO_2 +HCl	Platinized Raney Ni[5]
Cholest-4-ene-3β,6β-diol	1.0	2.7	1.1
Cinnamyl alcohol	1.0	1.5	0.98
Furfuryl alcohol[4]		3.1	2.1
Phenol		3.4	3.0

cyclohexanol could be hydrogenolyzed under the same conditions, it is concluded that the hydrogenolysis took place prior to the saturation of the double bond. On the other hand, in neutral ethanolic solution cinnamyl alcohol absorbed only 1 mole of hydrogen in the presence of either platinum oxide or platinized Raney nickel prepared in alkaline solution[5], while furfuryl alcohol gave a quantitative yield of tetrahydrofurfuryl alcohol with the latter catalyst.

It has been reported that cinnamyl alcohol gives about equal moles of 3-phenyl-1-propanol and propylbenzene with palladium-charcoal and hydrogen[6]. It is very probable that the catalyst contained a trace of hydrochloric acid.

The authors wish to express their hearty thanks to Professor Yoshiyuki Urushibara for his kind guidance.

Phase Relationship in the System $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$

By Toshiyuki Sata

(Received August 4, 1958)

According to the present writer's published studies[1,2], slowly cooled specimens of fused phosphatic fertilizer and of bone-ash magnesia porcelain are composed of β-tricalcium phosphate, apatite, diopsidic pyroxene, and silica minerals. The equilibrium study of the system composed of these minerals, therefore, must be of great importance for the industrial manufacture of these products. Henceforth the author constructed the phase diagrams of the ternary system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$, on which no paper has ever been presented. This investigation is continued from his preceding report on the system $3CaO \cdot P_2O_5$—$MgO \cdot SiO_2$—SiO_2[3].

Experimental

Of the three-component system concerned, data of the two partial systems, $3CaO \cdot P_2O_5$—SiO_2 and $CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$, were given by other authors, the former by Pierre[4] and Wojciechowska[5], and the latter by Bowen[6]. Another partial system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$ and the three-component system were investigated by usual quenching method in this study.

Powdered batches of selected compositions, prepared by quenching into glass after being kept at above their melting points, were again held at constant temperatures in a silicon carbide resistor furnace and then quenched in water. Thenceforth the equilibrium phases found therein were determined by the optical and the X-ray examination. For measuring the temperature a thermocouple of platinum-platinum rhodium(10%) was used. Details of experimental

procedures are similar to those already described in the author's preceding report[3].

Results

The system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$.—Data on the quenching runs for this two-component system are listed in Table I, from which the equilibrium diagram was constructed as shown in Fig. 1. It is found that this system seems to be perfectly described as a binary one, whose eutectic is located at 39% of $3CaO \cdot P_2O_5$ and 61% of $CaO \cdot MgO \cdot 2SiO_2$, melting point at 1311±4°C. In the region rich in $3CaO \cdot P_2O_5$ (over 80%), the following facts were observed. (1) The crystallization of diopside did not take place when samples were kept for about 1 hr. even under the eutectic temperature. (2) The transition temperature of tricalcium phosphate from

β to α increased with diopside content, 1350 ~1400°C with 5%, 1450~1450°C with 10%, and 1450~1520°C with 20% of diopside (the transition temperature of pure tricalcium phosphate is 1180°C). (3) The spacings for diffraction lines in β-tricalcium phosphate decreased with diopside contents as indicated in Fig. 2, showing apparent formation of solid solution with some diopside (25±2 mol.% or 19±2 wt.%). These facts occurring in the region rich in tricalcium phosphate will be discussed with more data in the near future.

The system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$.—This three-component system is a perfect ternary one, and its eutectic was decided from the quenching data of the 14 samples shown in Table II, whose compositions lie along the tie lines connecting No. 23 (C_3P60—SiO_240) with $CaO \cdot MgO \cdot 2SiO_2$ corner and No. 98 (C_3P40—$CaO \cdot MgO \cdot 2SiO_260$) with No. 197 or No. 199, as

plotted in Fig. 3. The ternary eutectic is located at 36±1% C_3P, 59±1% $CaO \cdot MgO \cdot 2SiO_2$, and 5±1% SiO_2, and at 1277±3°C, which is close to the $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$ join. Accordingly the silica field covers over a very wide area. The isotherms on the liquidus surface were approximately represented in the ternary system.

Summary

The phase relationship in the system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$ was investigated by the usual quenching method. The two partial systems $3CaO \cdot P_2O_5$—SiO_2 and $CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$ have already been reported by previous investigators. Another partial system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$ seems to be approximately binary, whose eutectic is located at 39% of $3CaO \cdot P_2O_5$ and 61% of $CaO \cdot MgO \cdot 2SiO_2$, and at 1311±4°C. In the region rich in $3CaO \cdot P_2O_5$, it was observed that the crystallization velocity of diopside is rather slow under the solidus temperature, that the transition temperature of tricalcium phosphate is considerably increased with diopside content, and that β-tricalicium phosphate apparently makes solid solution with diopside (19 wt.%).

The system $3CaO \cdot P_2O_5$—$CaO \cdot MgO \cdot 2SiO_2$—$SiO_2$ is of a perfect ternary one, whose eutectic is at 36% of $3CaO \cdot P_2O_5$, 59% of $CaO \cdot MgO \cdot 2SiO_2$ and 5% of SiO_2, and at 1277±3°C. Its isotherms of the liquidus surface were approximately represented.

Kinetics of the Acid-Catalyzed Peroxide Oxidation of 4-Hydroxybenzaldehyde in Acetic Acid

By Yoshiro OGATA and Iwao TABUSHI

(Received July 5, 1958)

It is well known that aromatic ketones and aldehydes give on oxidation with peroxides (e. g., hydrogen peroxides or organic peracids) aryl esters or their hydrolysis products, i. e., phenols and carboxylic acids[1-3].

In general, the reaction is acid-catalyzed. It is of interest to note that *o*- or *p*-hydroxyl, amino or mercapto group facilitates the reaction to such an extent that it takes place at a high pH even in aqueous alkaline media[4], where a mechanism involving an initial attack of hydrogen peroxide to the active hydrogen of these groups was postulated[5]. In contrast, the reaction in acidic media occurs without these activating groups[6,7]. In this case, the mechanism has been suggested to be an addition of peroxide to the carbonyl group followed by a rearrangement[2,3].

R: alkyl or H[8] Ar: aryl.

However, few detailed mechanistic studies from the kinetic standpoint have been reported on the hydrogen peroxide oxidation in acidic media. The present study was undertaken to elucidate the mechanism as well as the true oxidizing agent of the acid-catalyzed hydrogen peroxide oxidation of hydroxybenzaldehyde in aqueous acetic acid by estimating the effects of acidity on the rate.

Experimental

Materials.—*p*-Hydroxybenzaldehyde was purified by recrystallization from water, m. p. 116°.

Kinetic Procedures.—*Procedure A. Simultaneous Addition of the Reactants.*—Hydroxybenzaldehyde, acetic acid, sulfuric acid and water were mixed in a flask in the above order, thermostated at 15° or 20°; then hydrogen peroxide was added to the mixture. To avoid the temperature increase during the addition of hydrogen peroxide, a lower concentration of sulfuric acid and relatively high water content should be used. In the procedure, however, the apparent rate constant usually increases during the reaction except at high acidity.

Procedure B. Addition of Aldehyde to an Equilibrium Mixture of Peroxides.—Hydrogen peroxide was added to a cooled mixture of aqueous acetic acid and sulfuric acid in a brown flask, and the mixtue thermostated at 15±0.1 or 20±0.1° until the equilibrium state between hydrogen peroxide and peracetic acid was attained. Then hydroxybenzaldehyde was added to a known amount of the peroxide solution, the oxidation being started here. The reaction temperature was 15±0.1 or 20±0.1°.

In order to ascertain the establishment of the equilibrium and also to estimate hydrogen peroxide and peracetic acid contents in the preliminary equilibrium mixture, permanganate titration for hydrogen peroxide and iodometry for the peracetic acid were employed. Aliquots were taken out at appropriate intervals from the preliminary mixture before the addition of the aldehyde, run into a cooled mixture of ice and sulfuric acid and titrated rapidly at ca. −5° with potassium permanganate to determine the hydrogen peroxide content. An aqueous solution of potassium iodide was then added to the mixture, warmed and titrated with thiosulfate to estimate the peracid content. In general, the aliquot consumes a slight excess of permanganate because of the obscurity of the end point; it was corrected by a separate determination of total peroxides.

When the ratio a/b (where the equivalent amount of hydrogen peroxide present is a, that of peracetic acid b) becomes constant within experimental error, the equilibrium constant K_1 and the forward and the reverse rate constant of peracetic acid formation (k_1 and k_{-1}, respectively) may be calculated by means of equations:

$$K_1 = k_1/k_{-1}, \qquad k+k_{-1} = \frac{2.303}{t}\log\left(\frac{a_0-a_e}{a-a_e}\right)$$

where a_0 is the initial concentration and a_e is the equilibrium concentration of hydrogen peroxide.

In kinetic runs after the addition of hydroxybenzaldehyde, aliquots were withdrawn and their total peroxide content was determined iodometrically. The rate constants were then calculated by means of the usual second-order rate equation. The spontaneous decomposition of the peroxides in the absence of hydroxybenzaldehydes under these conditions is so small that it may be assumed that the amount of consumed peroxides minus the known amount of the spontaneous decomposition is the amount of peroxides reacted.

Reaction Products Criterion.—The reaction mixture gave, on long standing, a product containing hydroquinone or catechol. As mentioned previously, the formates of these phenols are probably produced at an initial stage, since the conversion percentage is not in accord with those of peroxide, when calculated spectrophotometrically on the assumption that hydroquinone is produced directly. These esters could not be isolated in appreciable quantities presumably because of the rapid hydrolysis during isolation procedures, as the hydrolysis was accelerated in the presence of considerable amounts of water and sulfuric acid.

Results and Discussion

The Equilibrium between Hydrogen Peroxide and Peracetic Acid.—When the rate measurements were carried out by adding hydrogen peroxide to an equilibrium mixture of aqueous acetic acid, sulfuric acid and hydroxybenzaldehyde (Procedure A), an induction period was observed at the initial stage and the apparent second-order rate constants increased rapidly at

16.7	0.392	2.4	2.33	—	—

first, and then slowly. This trend was remarkable especially with low concentrations of sulfuric acid and with a relatively high initial concentration of hydroxybenzaldehyde compared with that of hydrogen peroxide. Typical examples are shown in Fig. 1.

On the other hand, when hydrogen peroxide is allowed to reach equilibrium with aqueous acetic and sulfric acid before hydroxybenzaldehyde is added to start the reaction (Procedure B), no such initial suppression of apparent rate constant is observed. The rate constant holds a satisfactory constancy during the reaction except near the end of the reaction where a slight decrease of the constant is appreciable. The constant does not, of course, vary with changing initial concentrations of the reactants. Table I shows the apparent second-order constants with Procedure B.

The facts cited above suggest that an active intermediate is formed by the acid-catalyzed interaction of hydrogen peroxide and acetic acid, the rate of its formation being comparable to that of the main reaction of hydroxybenzaldehyde with the intermediate. The facts that the initial suppression of the rate becomes remarkable by reducing the rate of formation of the intermediate and that the apparent rate constant estimated by Procedure A is much lower at an early stage than that by procedure B, agree well with the assumption of such an active intermediate. For example, a "rate constant" with Procedure A at 10% conversion is ca. 1/12.6 of that with Procedure B in the following condition. $[H_2O]=5.55$ M and $[H_2SO_4]=0.0736$ M at 20°.

It is most probable that the intermediate is peracetic acid, the equilibrium constant of its sulfuric acid-catalyzed formation having been estimated by D'Ans[9].

9) J. D'Ans and W. Frey, O; *Z. anog. Chem.* **84**, 145 *Chem. Abstr.*, **8**, 923 (1914).

$$H_2O_2+CH_3COOH \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} CH_3CO_3H+H_2O \quad (1)$$

$$CH_3CO_3H+\text{hydroxybenzaldehyde} \xrightarrow{k_2} \text{product} \quad (2)$$

In addition to peracetic acid, the formation of Caro's acid may be expected. It seems rational, however, that peracetic acid is the main oxidizing agent, since the acidities used are not very high and the rate of formation of Caro's acid is very low under these conditions, although it may become appreciable at higher acidities[10]. The possibility that the active attacking agent is OH^+ (or $H_3O_2^+$) may be eliminated, since the protonation of hydrogen peroxide should be very rapid.

Approximate rate constants and equilibrium constants of the formation of peracetic acid determined under the same conditions as those of the kinetic experiments are shown in Table II. Both constants increase with increasing acidity in accord with the previous observation in such an equilibrium as hydrogen peroxide-performic acid or hydrogen peroxide-monoperoxysulfuric acid[10].

Since the magnitude of k_1 was moderate in these experiments, conditions where v_1 and v_2 (v's are rates of the subscripted steps) are comparable may easily be attained[11].

Our qualitative observation on the initial suppression of the rate agrees with the above discussion and provides another evidence for the justification of eqs. 1 and 2. Furthermore, the oxidation rate measurements in pure aqueous media of the same acidity show that the rate is too slow to measure, thus indicating that no intermediate is produced by the interaction of hydrogen peroxide and sulfuric acid alone.

Effects of Acidity and Water Content.— A study of the effects of sulfuric acid concentration and water content on the apparent second-order rate constant according to Procedure B (k) shows that the results can not be expressed in a simple form, unless corrections for peracetic acid concentration and acidity are made. (see Figs. 2 and 3).

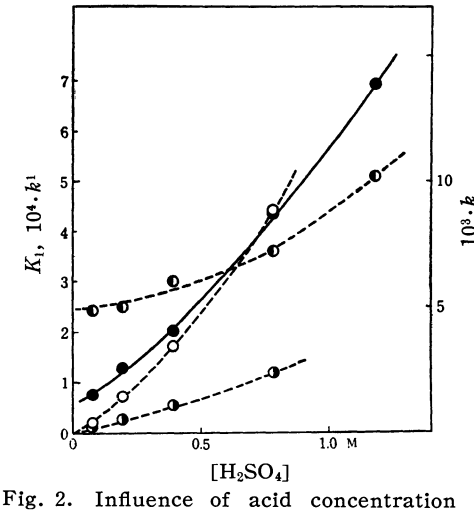

Fig. 2. Influence of acid concentration on the rate and the equilibrium constant for the reaction of peracetic acid formation at 15° and for the oxidation of hydroxybenzaldehyde. $[H_2O]=5.55$ M.
Dotted lines correspond to the peracetic acid formation:
◐, equilibrium constant K_1

$[H_2SO_4]=0.392$ M.

10) J. M. Monger and O. Redlich, *J. Phys. Chem.*, **60**, 797 (1956).

11) Under these conditions the observed initial suppression of the rate in Procedure A becomes remarkable. In the following equations (total peroxide is nearly equal to $[H_2O_2]$ in the early stages of the reaction)

$v_1=k_1[H_2O_2][AcOH]$

$v_2=k_2[CH_3CO_3H][\text{hydroxybenzaldehyde}]$

$=k_2'[\text{total peroxide}][\text{hydroxybenzaldehyde}]$

The observed rate constants with p-hydroxybenzaldehyde at $[H_2O]=5.55$ M, $[AcOH]=15$ M and $[H_2SO_4]=0.392$ M were found to be

$k_1=1.78\times10^{-4}$ l. mole^{-1}sec.$^{-1}$

$k_2'=4.07\times10^{-3}$ l. mole^{-1}sec^{-1}.

Here, k_2' is the apparent rate contant and k is the rate constant of the subscripted step. Therefore,

$v_2/v_1=4.07\times10^{-3}\times[\text{hydroxybenzaldehyde}]/(1.78\times10^{-4}\times15)$

Namely, if the initial concentration of hydroxybenzaldehyde exceeds 10^{-2} M, v_2 appoaches to v_1. This approach should become remarkable as the acidity decreases, since k_1 appreaches to zero with decreasing acidity, while k_2' approaehes to a definite value (see Fig. 2).

The concentration of peracetic acid is obtainable from the concentration of total peroxide [T] as follows.

$$K_1=\frac{[H_3O]\,[CH_3CO_3H]}{[H_3O_3]\,[CH_3CO_2H]} \quad (3)$$

Here, both $[CH_3CO_2H]$ and $[H_3O]$ may be regarded as constant. Since

$$[T] = [H_2O_2] + [CH_3CO_3H] \quad (4)$$

$$[CH_3CO_3H] = \frac{[CH_3CO_2H]\,K_1}{[CH_3CO_3H]\,K_1 + [H_2O]} \cdot [T] \quad (5)$$

$$[H_2O_2] = \frac{[H_2O]}{[CH_3CO_2H]\,K_1 + H_2O} \cdot [T]$$

$$v = k\,[Hy]\,[T] = k_p\,[Hy]\,[CH_3CO_3H] + k_h\,[Hy]\,[H_2O_2] \quad (6)$$

are obtained, where Hy means hydroxybenzaldehyde, k_p and k_h are rate constants for reactions of peracetic acid and hydrogen peroxide, respectively. Therefore,

$$k = k_p\frac{[CH_3CO_2H]\,K_1}{[CH_3CO_2H]\,K_1 + [H_2O]} + k_h\frac{[H_2O]}{[CH_3CO_2H]\,K_1 + [H_2O]} \quad (7)$$

From the above discussion, it may be concluded that the second term of the right hand side of equation 7 expressing hydrogen peroxide oxidation is far less important than the first term. Hence,

$$k = k_p\frac{[CH_3CO_2H]\,K_1}{[CH_3CO_2H]\,K_1 + [H_2O]} \quad (8)$$

The value of k_p calculated by means of equation 8 holds sufficient constancy as noted later; therefore it is confirmed that the second term participation has little effect on the kinetics. This is supported numerically, comparing k in Procedures A and B at the initial stage of reaction, and the ratio of peracid to hydrogen peroxide in the equilibrium state.

For the expression of the acidity of the solutions, the Hammett's acidity function H_0 was used, the indicators being *o*- and *p*-nitranilines and 4-chloro-2-nitraniline. Plots of H_0 vs. log k_p gave no straight line, but a curve whose slope approaches -1 with increasing acidity, while it approaches zero with decreasing acidity. This fact seems to mean that the rate constant k_p may further be separable into the acid-independent (k_n) terms:

$$k_p = k_n + k_a k_0 \quad (9)$$

where h_0 relates to H_0 in expression $\log h_0 = -H_0$.

Plot of k_p vs. h_0 gives a satisfactory straight line as shown in Fig. 4. A slight decrease of k_a at very high acidity or its change in varying water-sulfuric acid ratio at the same acidity is probably due to the unequality of h_0 and proton activity[12].

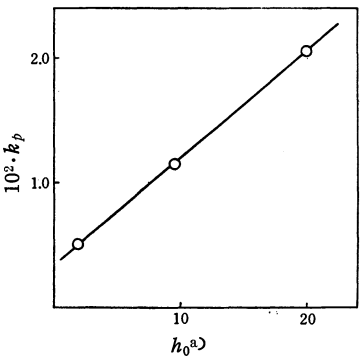

Fig. 4. The plot of k_p vs. h_0 for the reaction of *p*-hydroxybenzaldehyde in moderate acidities at 20°.

Reaction Mechanism.—The above results imply that there is a preliminary, relatively rapid and reversible peracetic acid formation, then acid-catalyzed or uncatalyzed attack of the peracetic acid on the carbonyl group takes place to form an addition complex followed by a rearrangement of the complex to the product. The rearrangement would not perhaps be a rate-determining step, since no stable complex has been isolated, and furthermore, in our preliminary experiments no appreciable difference was observed between the ultraviolet spectrum of the original aldehyde solution and that of the aldehyde solution immediately after mixing it with peracetic acid solution.

On the basis of the observed kinetics, there are two possible mechanisms, i. e., mechanism A involving steps 10, 11, 13, 14 and 16 and mechanism B involving steps 10, 12, 14, 15 and 16.

$$CH_3CO_2H + H_2O_2 + H^+ \rightleftarrows CH_3CO_3H + H_2O + H^+ \quad (10)$$

$$CH_3CO_3H + H^+ \rightleftarrows CH_3CO_3H_2^+ \quad (11)$$

$$ArCHO + H^+ \rightleftarrows ArC^+HOH \quad (12)$$

12) For the ionization and dissociation of sulfuric acid in aqueous acetic acid, see S. Bruckenstein and I. M. Kolthoff, *J. Am. Chem. Soc.*, **78**, 10 (1956).

a) The values of h_0 were calculated from the observed H_0's under these experimental conditions. The values of H_0 were calculated by Hammett's equation $H_0 = pK_a + \log(c_B/c^+_{BH})$ to be -0.28, -0.99 and -1.30 with $[H_2SO_4] = 0.392$ M, 0.784 M and 1.18 M, respectively, where $[H_2O] = 5.55$ M is constant.

$$CH_3CO_3H_2^+ + ArCHO \rightarrow$$
$$ArCHO \cdot CH_3CO_3H_2^+ \text{(complex, } I \cdot H^+) \quad (13)$$
$$CH_3CO_3H + ArCHO \rightarrow$$
$$ArCHO \cdot CH_3CO_3H \text{ (complex, I)} \quad (14)$$
$$CH_3CO_3H + ArC^+HOH \rightarrow I \cdot H^+ \quad (15)$$
$$I \text{ (or } I \cdot H^+) \rightarrow$$
$$ArOCHO + CH_3CO_2H \text{ (or } +H^+) \quad (16)$$

Since the mobile equilibria 11 and 12 probably tend to shift to the left side, step 12 in mechanism A and 11 in B may be neglected except at high acidity. The apparent rate constants k_A and k_B, corresponding to mechanism A and B, respectively, are easily expressed in terms of the equilibrium and rate constants of equations 11—15, where K and k denote equilibrium and rate constants of the subscripted steps, respectively.

$$k_A = k_{13} \cdot \frac{1}{1+K_{12}[H^+]} \cdot \frac{K_{11}[H^+]}{1+K_{11}[H^+]} + k_{14} \cdot \frac{1}{1+K_{11}[H^+]} \cdot \frac{1}{1+K_{12}[H^+]} \quad (17a)$$

$$k_B = k_{15} \cdot \frac{1}{1+K_{11}[H^+]} \cdot \frac{K_{12}[H^+]}{1+K_{12}[H^+]} + k_{14} \cdot \frac{1}{1+K_{11}[H^+]} \cdot \frac{1}{1+K_{12}[H^+]} \quad (17b)$$

Here, k_{13}, k_{14} and k_{15} are acidity-independent constants. At lower acidity, equations 17a and 17b may be simplified in the following way, since both $K_{11}[H^+]$ and $K_{12}[H^+]$ are far smaller than unity.

$$k_A = k_{13}K_{11}[H^+] + k_{14} \quad (18a)$$
$$k_B = k_{15}K_{12}[H^+] + k_{14} \quad (18b)$$

Since both equations 18a and 18b agree with the observed expression 9 and also with the rate-acidity relationship, it seems impossible, on the basis of the kinetics alone, to determine which mechanism is favored in so far as the values of K_{11} and K_{12} are unavailable. However, step 13 is more favorable than step 15, since it involves an attack of a more electrophilic agent $CH_3CO_3H_2^+$.

Summary

The sulfuric acid-catalyzed oxidations of 4-hydroxybenzaldehyde with hydrogen peroxide in aqueous acetic acid were kinetically investigated at 15° and 20° by iodometric estimation of the peroxides. The rates of peroxide consumption were found to be proportional to the product of the concentrations of hydroxybenzaldehyde and peroxide, when the aldehyde was added after the equilibrium between hydrogen peroxide and peracetic acid was attained. The rate constant is a linear function of Hammett acidity function h_0.

Hydrogen peroxide itself reacts slowly with the aldehyde, but it reacts more easily through the formation of peracetic acid. A mechanism involving a ratedetermining attack of protonated and free peracetic acid was postulated and discussed.

Studies on the Interaction of Surface Films with Solute in Solution. IV. Effect of Congo Red Dissolved in Aqueous Substrate upon the Monolayers of Octadecylamine, Cetyl Alcohol, Ethyl n-Hexadecyl Ether, Ethyl Stearate and Cholesterol

By Mitsuo MURAMATSU

(Received August 8, 1958)

In the Part II[1] of this series, the interaction between various dyes in aqueous solutions and stearic acid in the built-up film has been studied. There it was suggested that pH dependence of the amount of dye taken up by the film may be explained by the interaction between dye and stearic acid, involving ionic, dipolar and van der Waals' force. This was generally in agreement with the effect of aqueous dye solution on the monolayer of stearic acid spread on it[2] and has further been supported by the experimental results of a profound effect of aqueous dye on the monolayer of octadecylamine[3]. As has been pointed out in Part II[1], however, there still remained some uncertainty in establishing the mechanism of the interaction between amphoteric dye and the surface film.

Of many amphoteric dyes, Congo red is most familiar to us and the surface-chemical properties of its solution have widely been studied by the measurement of ultrasonic velocity[4], diffusion coefficient[5], viscoelasticity of the adsorbed film[6], and foaming power[7]. Hence Congo red was also adopted in the present work as a representative for the amphoteric dyes and its effect upon the monolayers of several amphipathic compounds has been studied. It may be expected that such a study would also contribute to the understanding of the mechanism of dyeing processes of fibers by so-called direct dyes to which many of the amphoteric dyes belong.

Experimental

Apparatus and procedure were the same as used in the preceding work[3]. The same samples of Congo red[1] and octadecylamine[3] as those which appeared in the preceding reports were used also in of the present experiments. Cetyl alcohol was first grade of Katayama Pure Chemical Co. Ethyl *n*-hexadecyl ether and ethyl stearate were synthesized by the reaction of sodium ethylate with purified hexadecyl bromide and stearyl chloride, respectively. All these amphipathic compounds were purified repeatedly by fractional distillation in vacuo and successive recrystallization from suitable solvents. The highly purified sample of cholesterol was kindly supplied by Dr. E. Kimoto of Kurume Medical College.

Results

Octadecylamine. — It has been suggested[3,8] that the surface pressure, F, of

this film fluctuated considerably for a given molecular area, A. This came from the effects of ageing of the film, carbon dioxide in the substrate, velocity of compression, etc. This tendency disappeared when Congo red was added to the substrate phase. The effect of dye upon $F\sim A$ curve of the monolayer of octadecylamine is shown in Fig. 1 in which the hatched zone is quoted from the preceding report[3]. It can be seen in this figure that the addition of dye results in a remarkable expansion of the monolayer when pH of the substrate is around 5.5. In Fig. 2 curve

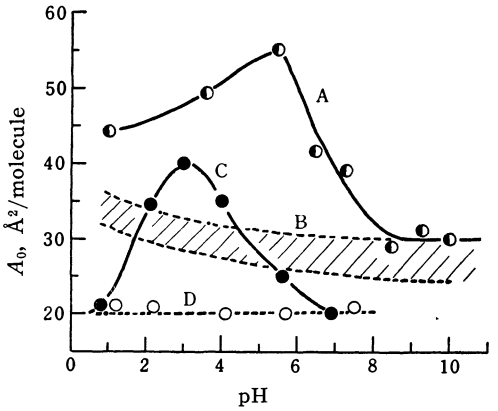

Fig. 2. Effect of Congo red upon A_0 for the monolayer of octadecylamine and cetyl alcohol.
A and B, amine on the substrate with or without dye, respectively; C and D, alcohol on the substrate with or without dye, respectively.

A shows the effect of substrate pH on the area, A_0, of octadecylamine molecule in the monolayer which spread on the solution of dye and is compressed to $F=2$ dyn./cm. In the same figure the hatched zone B expresses the limit of fluctuation of A_0 for a given pH value of the substrate without dye. Maximum expansion of the monolayer was observed at pH 5.5.

Cetyl Alcohol. — No effect of substrate pH was observed upon A_0 for the monolayer spread on the surface of water. When the dye was dissolved in the substrate of pH 2~4, the film expanded considerably. Such an effect of dye is shown in Fig. 2, in which the curve C and D express the pH dependence of A_0 for the monolayer spread on aqueous substrate containing or lacking the dye, respectively. Maximum expansion of the monolayer occurred at pH 3 in this case.

Ethyl *n*-Hexadecyl Ether. — Characteristic kinds of behavior in $F\sim A$ relationship were observed for this film. When the monolayer on the surface of water was compressed, we usually observed an instantaneous rise and subsequent lowering of the surface pressure. A typical example is shown in Fig. 3 (a). The behavior could be reproduced fairly well, though F was determined by means of the vertical plate method which proves to be unsuitable when we measure the decreasing surface pressure. A similar curve was obtained for the film spread on the surface of water of any acidity. The pH dependence of the area, A_0, at $F=2$ dyn./cm. is expressed as curve B in Fig. 4.

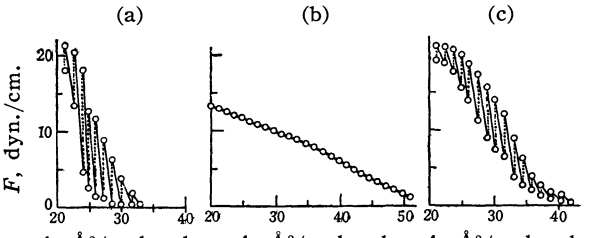

Fig. 3. $F\sim A$ curves for the monolayers of ethyl *n*-hexadecyl ether spread on (a) water of pH 4.0, (b) dye solution of pH 3.8, and (c) dye solution of pH 1.9.

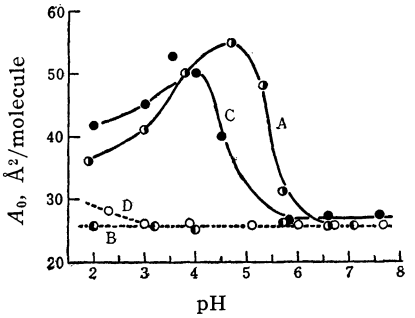

Fig. 4. Effect of Congo red upon A_0 for the monolayer of ethyl *n*-hexadecyl ether and ethyl stearate.
A and B, the ether on the substrate with or without dye, respectively; C and D, the ester on the substrate with or without dye, respectively.

The addition of the dye to the substrate generally resulted in an expansion of the monolayer, as shown in curve A of Fig. 4. The maximum expansion seemed to appear when pH of the dye solution was around 4.4. Precisely speaking, however, there is a difference between the form of $F\sim A$ curve for the region of pH 3.5~5.5 and that for the rest of pH region. In the former region, as illustrated in Fig. 3 (b) for example, dye not only expanded the

monolayer remarkably but also prevented the subsequent lowering of the initial surface pressure. In contrast to this, the effect of surface pressure lowering was evident in the latter region as illustrated in Fig. 3 (c).

Ethyl Stearate.—Effect of substrate pH upon A_0 for the monolayer spread on water is shown by curve D in Fig. 4. Apparently no change in the $F\sim A$ curve was observed throughout pH 3~8. When the monolayer was spread on a substrate water of pH 2.3 and compressed to $F>$ 15 dyn./cm., we usually observed an instantaneous rise and subsequent fall of surface pressure which reached finally an equilibrium value. Such a tendency was most remarkable when the film was compressed fifteen minutes after initial spreading. Any time of elapse longer or shorter than this proved to result in less exaggeration. These phenomena may be due to the hydrolysis of the ester, which was reported for the same film spread on an alkaline substrate[9], and to the change in surface pressure effected by ethanol thereby formed at and ejected from the surface phase. Actually, standing of the monolayer for sixty minutes caused an $F\sim A$ relationship identical with that for stearic acid.

The effect of added dye upon A_0 of the monolayer is shown by curve C in Fig. 4 in which, however, A_0 at pH 1.9 accompanies an inevitable error due to the hydrolysis mentioned above. Even if we took account of this ambiguity, it would be clear that the maximum expansion was observed at pH 3.0.

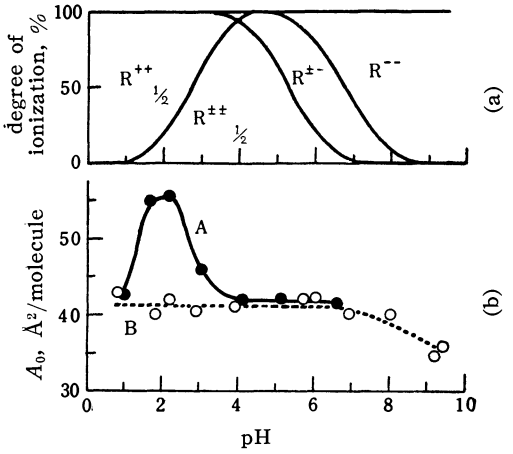

Fig. 5. (a) Effect of pH on the degree of ionization of Congo red. (b) Effect of pH on A_0 for the monolayer of cholesterol spread on the substrate, (A) containing Congo red and (B) lacking it.

Cholesterol.—Curve B in Fig. 5 (b) shows pH dependence of A_0 for the monolayer of cholesterol spread on the surface of water. In conforminity with the results appearing in the other reports[10], the monolayer proved to be of low compressibility and of large area when it was spread on distilled water pH of which was less than 7. In more alkaline region, however, A_0 decreased slighty with increasing pH, while the compressibility was scarcely affected at all by the change of the acidity throughout all pH region investigated. This might be ascribed to the dissolution of cholesterol, as predicted by the experimental results on surface evaporation[11].

For the aqueous substrate containing dye, pH dependence of A_0 is shown by the curve A in Fig. 5 (b). Maximum expansion was observed at pH 2 where A_0 was larger by ca. 15 Å²/molecule than that for the control experiment.

Discussion

In Fig. 5 (a) are shown the ionization curves for each ionizable groups in the molecule of Congo red. They are obtained from respective values of the ionization constants which have been reported in Part I[12] of this series. It should be emphasized that the calculations for the dissociation constants were based on the treatment of the dye as a high-polymer electrolyte. When we compare these curves with $A_0\sim$pH curves shown in Figs. 2 and 4, it can be seen that the interaction of Congo red with various amphipathic compounds is favored in the isoelectric region, irrespective of the types of their polar heads. In Part II[1] of this series, it has been presumed that the conditions for mutual cohesion of dye molecules among themselves would play simultaneously an important rôle in its interation with film materials. Actually the film materials seem to interact with the colloidal aggregates of dye formed in the solution. Remarkable changes both in the ultrasonic velocity in bulk[4] and in the rheological property of the surface[6] of the solution

of Congo red being in the same pH range have also been attributed to the formation of colloidal aggregates of dye. Therefore the present results had better be discussed along this line. Additional support for this suggestion was obtained by Matuura[2] who has reported an expanded film of stearic acid spread on a solution of Congo red, pH of which was ca. 3. Inaba[13] has observed that a surface of paraffin was wetted thoroughly by the same solution. All these phenomena emphasize the importance of the rôle of van der Waals' attraction in the interaction. For the other region of pH, ionic repulsion due to the same sign of the charge of dye molecules would suppress the tendency of forming colloidal aggregates in which the molecules of dye interlink each other by the molecular forces other than ionic.

In Table I is summarized the effect of added Congo red on A_0 for various monolayers spread on the substrates, pH values of which are optimum corresponding to the largest expansion. In this table $(A_0)_{H_2O}$ and $(A_0)_{dye}$ represent values of A_0 on pure water and dye solution respectively. Further, the data on surface potential, ΔV, of the monolayer on water are quoted from other literatures. As is seen in the table the amount of increase, ΔA_0, in the area due to the addition of dye seems to depend on the quantity, $(A_0)_{H_2O}\cdot\Delta V$, which may be expressed as the surface polarity, rather than the molecular weight of the monolayer substance. Noticeable deviation from this is observed only for cholesterol which differs in its molecular structure from the other substances. This suggests the distinct contribution to $A\Delta_0$ of the dipolar attraction, in addition to van der Waals' force. It was pointed out[16] that dipolar attraction acting between each other of dye molecules of zwitterion type enhanced the possibility of forming colloidal aggregates of the dye in aqueous medium. A similar explanation was also made for the mechanism of dyeing of fibers[17].

Let us draw attention to the conspicuous nature of the monolayer of ethyl *n*-hexadecyl ether spread on distilled water. As far as the author is aware, the nature of this film has not been studied before. In the case of the monolayer of octadecyl methyl ether, some investigators[18] reported an intramolar rotation of —O—CH_3 bond when the film was compressed to some extent. There the methyl group was considered to orientate itself toward the bulk of substrate, so that the process resulted in a decrease of resultant dipole. It seems to be probable, however, that such a distortion is accompanied by a strong resistance when the end group is ethyl radical as was the case in the present experiment. In Fig. 3 (a) the instantaneous rise and subsequent lowering in surface pressure due to the compression would be an evidence for this effect. In connection with this, it is of interest to note that such an effect disappears whenever Congo red is added to the substrate of pH 3.5~5.5 where the largest expansion of the film is observed. Intramolecular rotation is evidently hindered by Congo red with which the film substance interacts. It should be further noticed that the molecules of dye are almost in the form of $R^{\pm\pm}{}_{1/2}$, as seen in Fig. 5 (a). This increases the possibility of the dipolar attraction between dye and ethyl *n*-hexadecyl ether, if we take account of the hindrance toward reorientation of ethyl group accompanying the change of resultant dipole moment. Presumably both van der Waals' and dipolar force are

chiefly responsible for the expansion of the monolayer.

Similar kinds of attractive force can also be mentioned to explain the mechanism of the interaction of dye with cetyl alcohol or ethyl stearate. Optimum pH values for the maximum expansion of these films lie in a range of 3~4 where dye molecules are also in the form of zwitterion. On the other hand it is of interest that ΔA_0 for cetyl alcohol is less than that for ethyl *n*-hexadecyl ether. This comes from a decreasing van der Waals' force corresponding to ethyl group. Presumably such a force overwhelms the attraction due to hydrogen bond through the hydroxyl radical of alcohol even if it would be possible. Thus the present result suggests the importance of the rôle of van der Waals' force rather than hydrogen bond in the dyeing process of fibers by the direct dye[17].

Differing from such non-ionic compounds as mentioned above, we may suggest a possibility of ionic interaction in addition to hydrogen bonding, dipole-dipole and van der Waals' force to explain the mechanism of the interaction between Congo red and octadecylamine. The largest expansion of this film is observed when it is spread on the solution of dye of pH 5.5, where a considerable amount of dye molecules are partly ionized, while the molecules of octadecylamine in the film are considered to be perfectly ionized[15]. Therefore we should take account of the additional contribution of ion-ion attraction between dye and octadecylamine to explain the expansion of the monolayer. This is similar to the fact which the present author has pointed out in the case of interaction of basic dye with stearic acid[1] and acid dye with octadecylamine[3]. In connection with this it may be of some values to discuss the effect of dissolved Congo red upon mono- and multilayers of stearic acid and barium stearate. Matuura[2] reported an expansion of the monolayer of stearic acid spread on the dye solution of pH 3. The present author has reported a remarkable increase in thickness of the built-up film of stearic acid and decrease in thickness in the case of barium stearate, when each of them soaks into the dye solution of pH 3.6[1]. In this case both increase have been attributed to the strong interaction. The dye molecules in such a solution are considered to be charged somewhat positively, as shown in Fig. 5 (a). However, no negative charge seems to exist in the molecules of stearic acid in the monolayer spread on pH <6[15,19]. It is probable that the same arguments can also be applied to the case of the multilayers of the same substance. Therefore it would be reasonable to ignore the ion-ion attraction between stearic acid and dye. On the other hand we can not ignore the ion-dipole attraction arising from the positive charge of dye, when dye molecules are allowed to orientate and bind themselves to stearic acid.

Various kinds of behavior of interaction of cholesterol with dye are somewhat erratic. Apparently they are similar to the case of stearic acid rather than cetyl alcohol. This may come from the molecular structure of sterol back-bone being hydrophobic. We can only say at present that the explanation is similar to the case of stearic acid. The detailed discussion may be a future problem.

Summary

Effect of dissolved Congo red upon the monolayers of octadecylamine, cetyl alcohol, ethyl *n*-hexadecyl ether, ethyl stearate and cholesterol spread on the substrate containing the dye has been studied, under varying pH of the solution. It has been observed generally that all monolayers expanded when they were spread on aqueous solution, the pH of which was in such a region that the molecules of dye were almost in zwitterion form. Dipolar and van der Waals' attraction were tentatively postulated to explain the nature of the cohesive force by which the molecules of dye were bond together so that the colloidal aggregates were formed in the solution. The expansion of the monolayer can be accounted for by the binding of the aggregate to film materials. This explanation could successfully be applied to the films of such nonionic substance as cetyl alcohol, ethyl *n*-hexadecyl ether and ethyl stearate.

The largest expansion of the monolayer of octadecylamine was observed when the substrate containing dye showed acidity so that the molecules of dye were partly of negative charge while those of octadecylamine were of positive charge. In this case we had better take account of the possibility of ion-ion attraction between octadecylamine and dye, in addition to the

forces which appeared in the cases of nonionic substances.

The author wishes to express his hearty thanks to Professor T. Sasaki for his kind guidance and encouragement in this work. He is also indebted to Professor R. Matuura of Kyūshū University for his helpful discussion, to Professor H. Saikachi of the same university for the elemental analysis of the samples, and to Mr. H. Ōshima of Fukuoka Gakugei University for his assistance on the synthesis and purification of amphipathic compounds. Absorption Spectra of Dyes. II[1]. *On Non-additivity of Absorption Spectra of Binary Mixtures of a Direct Dye and Some Acid Dyes in Aqueous Solution**

By Yoshié TANIZAKI, Teruaki KOBAYASHI and Noboru ANDO

(Received July 7, 1958)

It has been known that absorption spectra of binary mixtures of dyes in aqueous solution are not always additive[2,3] probably owing to the formation of complexes between dyes in solution, and it is also well known that in dyeing from solutions of mixtures of two dyes, the amounts of dyes adsorbed are frequently non-additive (i. e. a reduction in adsorption)[3]. Moreover in such cases, it seems that there exist some relations between non-additive properties in the amounts of dyes adsorbed and those in absorption spectra. In practical dyeing, mixtures are more frequently used than a single dye in order to produce any desired shade, so that the scientific study on dye mixtures is not only interesting from the physicochemical point of view, but also important practically. For this reason, in our laboratory, the investigation about dye mixtures has been started and the attention is first focused on non-additivity in spectrum.

Hitherto, only a few studies on non-additivity in absorption spectrum of dye mixtures have been carried out[2,3]. Neale and Stringfellow[3] showed that the mixture of Chlorazol Sky Blue FF and an acid dye (*o*-anisidine → H acid) shows non-additive property in absorption spectra, while the mixture of Chlorazol Sky Blue FF and Orange II has an additive spectrum. In this paper, selecting several monoazo acid dyes, the formula of which can be expressed *p*-X-aniline → γ acid with different substituents X, the authors investigated the spectra of pairs of Chlorazol Sky Blue FF and these acid dyes, ranging over the visible and near ultraviolet regions, and found that all of them were more or less different from the sum of the corresponding spectra of their components.

In this paper, a qualitative explanation of non-additivity in spectrum of such mixtures will be given by means of the conventional quantum chemical concept.

Experimental

Materials.—Direct Sky Blue 6B of Mitsubishi-Kasei Co., Ltd. was used as the sample of Chlorazol Sky Blue FF and it was purified by the usual method of Robinson and Mills[4], and the acid dyes made by coupling diazotized *p*-X-aniline with γ acid in acid or alkali solution, were purified by the same method.

Preparation of Samples.—Conductivity water of about 3.5×10^{-7} mho at room temperature was used for the preparation of dye solutions. The

concentrations were 3.59×10^{-6} moles/liter and $1.78\sim1.81\times10^{-5}$ moles/liter for Direct Sky Blue 6B and acid dyes, respectively; these concentrations were determined by the fact that the change in spectrum was the largest when the ratio was about 1 : 5[5].

Dye samples will be conveniently abbreviated in this paper as follows: Direct Sky Blue 6B will be referred to briefly as "Sky Blue". And monoazo acid dyes (p-X-aniline $\rightarrow\gamma$ acid)

(I) (X-α)

(II) (X-β)

will be represented by substituents X, which means here H, CH_3, OCH_3, Cl and NO_2, of diazotized components and their coupling positions α or β; namely dyes of I will be briefly called X-α, or H-α, CH_3-α, etc. according to their substituents, and similarly those of II will be called X-β or H-β, CH_3-β, etc.

Measurements of Absorption Spectra.—For measurements of absorption spectra of dye solutions, the Shimadzu QB-50 and QR-50 spectrophotometers were used at room temperature (14° to 16°C). Absorption cells were 1 cm. and 2 cm. thick, and optical densities are always reduced to values corresponding to 1 cm. thick.

Results

The most marked non-additivity in absorption spectrum was found for the pair, Sky Blue and the acid dye with substituent NO_2, and in the case of Sky Blue and the acid dye with H for X the least non-additivity was found. As examples, spectra of the combinations of Sky Blue with NO_2-α and NO_2-β, whose non-additivity is the most remarkable, are shown in Figs. 1 and 2, respectively, with those of the components. In each figure curves I and II show the observed absorption curves of Sky Blue and the acid dye, respectively, curve III the sum of them,

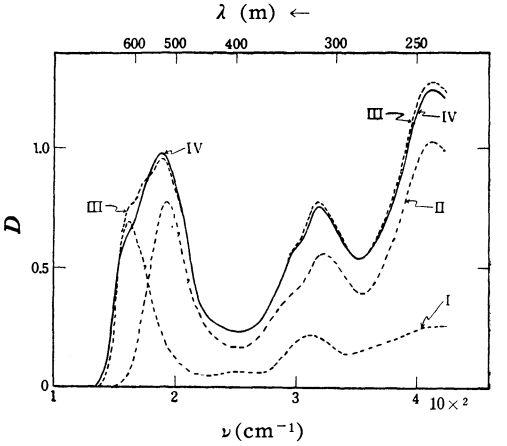

Fig. 1. Absorption spectra of a mixture of Sky Blue and NO_2-α, and its components. Curves I and II show the absorption spectra of Sky Blue and NO_2-α, respectively, curve III shows the resultant of curves I and II, and curve IV observed of the mixture.

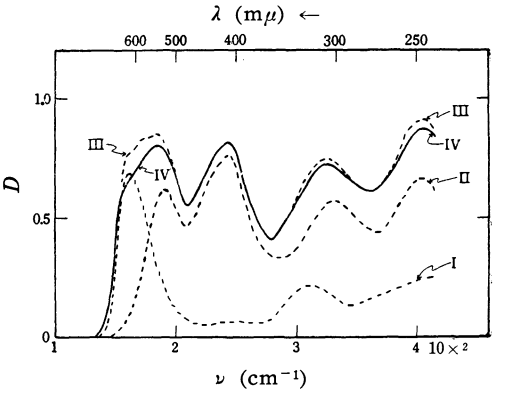

Fig. 2. Absorption spectra of a mixture of Sky Blue and NO_2-β, and its components. Curves show just the same case as in Fig. 1.

and curve IV the observed curve of the mixture. The difference, ΔD, between the sum of optical densities of its components and the observed one of a mixture is the largest in the neighborhood of a wave length of the principal band of Sky Blue ($\sim$620 mμ). And here, it is of interest that the bands corresponding to those of NO_2-β in the range of 400$\sim$460 mμ ($25\sim22\times10^3$ cm^{-1}) are additive, and that

5) T. Kobayashi, Y. Tanizaki and N. Ando, This Bulletin, to be published.

at the position corresponding to the first band of NO_2-α (~530 mμ) the observed absorption is more intense than the resultant one.

Now, observed wave numbers of absorption maxima of each component are shown in Fig. 3, in which values of difference ΔD between maximum densities of the resultant curve and those of the observed one of a mixture are also shown in round brackets at corresponding positions of absorption bands of acid dyes. Values of ΔD at the principal band of Sky Blue (161×10^2 cm^{-1}), however, are shown in the lowest line corresponding to each acid dye component. Fig. 3 shows distinctive facts to be summarized as follows.

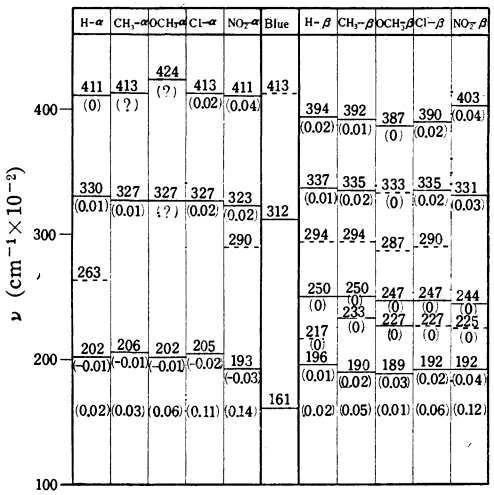

Fig. 3. Observed wave numbers of absorption bands of component dyes. Full and dotted lines mean the maximum positions and shoulders, respectively. Numbers in brackets show the difference between maximum optical densities of the sum of component spectra and observed ones of mixtures.

(1) It can be seen that non-additivity of absorption spectra appears in such positions that the absorption maxima of each component of a mixture are close to each other and there appears such a tendency as that the smaller the difference in wave number between them the larger the difference ΔD.

(2) The observed density near the position corresponding to a wavelength of the first band of each acid dye is smaller than the resultant in the case of Sky Blue and X-β, while it is larger when the acid dye component is X-α, that is to say, ΔD has the negative sign in the latter case.

(3) Absorption bands of the combination with X-β show the additive property in the region of $22\sim25\times10^3$ cm^{-1} (460~400 mμ).

(4) Every mixture shows the largest ΔD at the position corresponding to the wavelength of the principal band of Sky Blue.

Discussion

It may be supposed that such non-additivity in a spectrum comes from the formation of so loose complexes in a solution of dye mixture that the intermolecular charge-transfer does not occur, but some interaction between energy levels of components probably appears provided that their energies are close by. In such a case, for instance, when the excited levels A and B responsible for the absorptions of component dye molecules of a complex interact slightly with each other, it would be assumed that the absorption bands due to the individual transitions change only in wave number, not changing approximately in shape and intensity. Thus, if the spatial configuration of two molecular species were settled, the magnitude of the perturbation would naturally depend upon the difference between energies of A and B, the relative orientation of them in complex or the respective oscillator strength. But if it could be regarded that the effects of the latter two factors were not large and were the same in any complex considered here, the difference between the energies of excited states would become the main factor; namely, the nearer the energies, the larger the perturbation. According to the above consideration, the change in the spectrum of the complex may be approximately discussed by only the difference

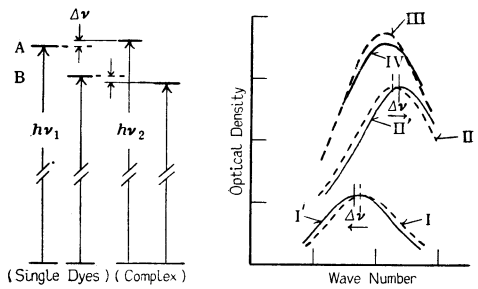

Fig. 4. A schematic illustration of the spectral change in a loose complex. Absorption curves are drawn with a shift of 200 cm^{-1} of each band of the component to the opposite side.

in wave numbers of the corresponding absorption bands of the components. In Fig. 4 the relation between the absorption band of a mixture and those of its components are shown schematically*. In this figure, curves I and II are the absorption bands of the components before interacting, curves I′ and II′ are those after interacting, and curves III and IV are the sums of curves I and II and of curves I′ and II′, respectively. The figure indicates that the intensity of the absorption band composed of those of components after interacting is always smaller than that composed of those before. From studies of dichroism for such dyes as used here, it could be regarded that an apparent single band in the ultraviolet region is the superposition of two, of which the directions of oscillation are orthogonal to each other, originated from the aromatic nucleus of the complicated coupling component[6]. And for this case an explanatory figure also might be given. For example, instead of A mentioned above, $A_{\parallel}$ and $A_{\perp}$ which are orthogonal and close in energy to each other might be considered and the following cases should occur. According to whether $A_{\parallel}$ is directed parallel, normal or inclined to $B_{\parallel}$, the resulting curves will become somewhat different in shape. But practically, the main features of drawn curves for respective cases showed a similar tendency as shown in Fig. 4, indicating a decrease in intensity of the curve after interacting. Anyway, a qualitative and reasonable illustration thus can be obtained for ΔD described in (1) in the foregoing section.

Quite similarly the above consideration will be applied to explain the difference ΔD between the sum of densities of Sky Blue and X-β and the observed one of the mixture at the position corresponding to the first band of X-β. This band is perhaps due to a single absorption and could interact with the first band of Sky Blue in complexes. On the other hand, when a component is X-α the corresponding ΔD has the negative sign. This can be explained, however, if it may be assumed that the first band of X-α consists of two absorption bands, of which one has the same property as the first band of X-β and the other has the different. This assumption is based on the evidence from the dichroic measurement of such dyes in stretched polyvinyl alcohol-sheet[7]. Dichroic properties of some of the dyes used are shown in Fig. 5, in which the curves show absorption spectra when the

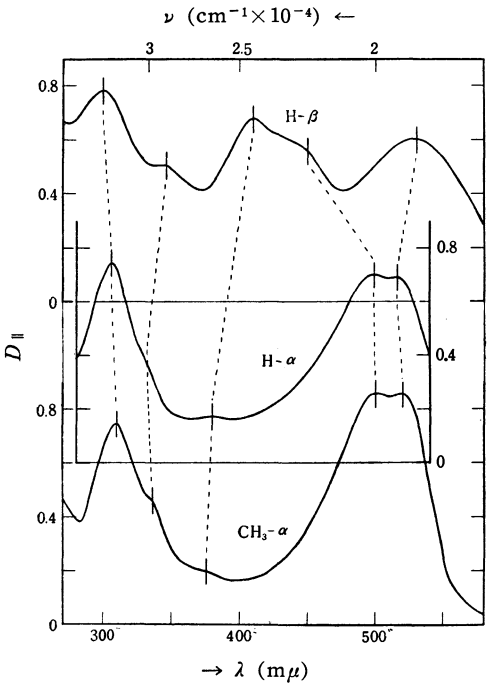

Fig. 5. Absorption spectra for plane polarized light of H-α, CH_3-α and H-β in stretched polyvinyl alcohol sheets when the stretch direction is parallel to the electric vector of incident polarized light.

direction of the electric vector of incident polarized light coincided with the stretch direction. These suggest that respective bands in each curve connected by dotted lines would correspond to each other[7]. It is now possible to assume that the band of the longer wavelength side of two subsidiary bands composing the main band of X-α corresponds to the first band of X-β and is able to interact with the first band of Sky Blue, while the other band of the shorter side has less or no interaction with that of Sky Blue. On the other hand, in Fig. 1 or 2, in which the shoulder of the first band of component Sky Blue ($\sim$580 mμ) becomes more distinctive in the

* The polarizability of such a molecule used here may be more responsible for its excited states than the ground state. Therefore, in a complex the interaction between the excited states of the components may be larger than that between the ground states. In Fig. 4, in order to discuss the relative change in levels, all the ground states are indicated on the same line.

6) Y. Tanizaki and N. Ando, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **78**, 542 (1957).

7) Y. Tanizaki, presented at the 9th Annual Meeting of the Chemical Society of Japan, April 1956.

resultant curve, it may be presumed that the main absorption band of Sky Blue also consists of such two bands as those just mentioned for X-α. Further the subsidiary band of the longer wavelength side of Sky Blue seems to be more sensitive to the change in external condition than that of the shorter side[8]. Consequently, the correlation shown in Fig. 4 may be able to be diverted by the following method to illustrate the facts described in 2 and 4 in the last section, that is, values of ΔD, near the wavelengths of the first bands of the acid dyes, have the positive sign for pairs of Sky Blue and X-β but the negative sign for those of Sky Blue and X-α, and the largest value is found at the wavelength of the principal band of Sky Blue. If it is supposed schematically that the first absorption band of an X-α consists of two bands shown by curves I′ and II′ in Fig. 4 and is expressed by curve IV, it will be changed to curve III, after being perturbed, with the relative shift of the just-mentioned two bands composing it, while for Sky Blue the reverse is the case; that is, curve III means the principal band of Sky Blue before being perturbed and curve IV that after being perturbed.

Now, supposing that the bands of the shorter wavelength side shown by curves I_b and II_b in Fig. 6, which are constituents of the first bands of Sky Blue (I) and NO_2-α (II), respectively, would remain unchanged, and only the bands of the longer side, curves I_a and II_a, interact with each other, there can be obtained curve IV which, corresponding to the observed absorption, is the resultant of the new component bands coming from the shift just mentioned ($I_a \rightarrow I_a'$, $II_a \rightarrow II_a'$). And curve III shows the sum of curves I and II. The case of the mixture of Sky Blue and NO_2-β is shown in Fig. 7, in which the band of NO_2-β indicated by curve II is assumed to be a single band. In these figures the resolution of the main band into subsidiary bands has been properly made. The curve IV in each figure shows the coincidence in character with those observed (see Figs. 1 and 2). In Fig. 7 it is seen that curve IV is also stronger in intensity near a wave number of 20×10^3 cm^{-1} than curve III; in fact observed results showed, though not very clearly, such a tendency.

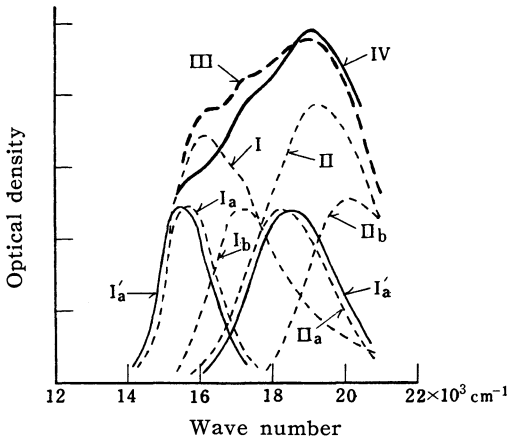

Fig. 6. Absorption curves of a mixture of Sky Blue and NO_2-α, before and after interacting, of the first bands. It is assumed that the interaction occurs only between the bands in the low wave number side, each of which shows a shift of 200 cm^{-1}.

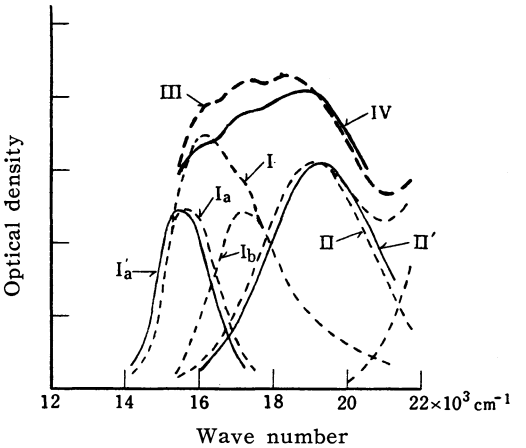

Fig. 7. Absorption curves of a mixture of Sky Blue and NO_2-β, before and after interacting, of the first bands. It is assumed that the interaction occurs between the first band of NO_2-β, which is a single band, and the band of the low wave number side of Sky Blue, each of which shows a shift of 200 cm^{-1}.

It was assumed above that the band of the shorter wavelength side of two constituents of the first band of X-α has less or no interaction with the main band of Sky Blue, corresponding to the second band of X-β (see Fig. 5). If it is true, the second band of X-β should show the

8) Y. Horiki, unpublished. For example, the maximum wavelengths of the first band of Sky Blue in water and in water-pyridine (20% for pyridine) solution were 618 mμ and 630 mμ, respectively, indicating the shift $\Delta\nu$= 310 cm^{-1}. On the other hand, though the determination for the convex parts was not so accurate, it seemed that $\Delta\nu$ was smaller than 290 cm^{-1}, and the shoulder was more distinctive in pyridine solution than in water.

additive spectrum in the combination with Sky Blue. The results observed are indeed in agreement with this expectation. At the same time, the third band also shows the additive property as shown in Figs. 2 and 3. Consequently, it might be considered another reason for the fact described in 3 in the last section that even the band of Sky Blue nearest to the X-β band under consideration lies too far apart for them to interact with each other.

It is well known that the first absorption band of such a dye as used here is quite generally ascribed to the electronic oscillation along the longest conjugated system which includes, as terminal groups, auxochromes characterized by lone-paired electrons in them. That is, the excited state is produced by the migration of an electron on such a terminal group to the inner π-electron system. On the other hand, such frontier electrons may be less protected from the change in the external condition, and are therefore affected easily. It may be, therefore, considered that the first band is more sensitive to the external change than the other bands. Thus, this may be followed by the fact described in (4) in the foregoing section that every mixture shows the largest ΔD at the position corresponding to the principal band of Sky Blue.

Finally, it is interesting to note that ΔD is the largest when X is NO_2 and the smallest when X is H (see Fig. 3). This might be related to the difference in nature of substituents X, but at present there could be found no interpretation for it from these qualitative investigations. As an empirical fact, it can be said that in order to investigate complexes formed in binary mixtures of Sky Blue and the acid dyes used here, NO_2-α or -β will be the most suitable to be selected.

Summary

1. Absorption spectra of mixtures of Direct Sky Blue 6B with p-X-aniline→γ acid, in which the substituent X means H, CH_3, OCH_3, Cl or NO_2, and the components in aqueous solution were observed in the visible and near ultraviolet regions.

2. All the absorption bands showed non-additive property, excepting the bands in the region of 400~460 mμ of the mixtures of Sky Blue and X-β shown in Figs. 2 and 3. And optical densities of observed bands of a mixture were generally smaller than sums of the values of each component, but when the acid dyes made by α coupling were used as other components, increases were seen at the positions corresponding to wave lengths of the first bands of them.

3. An explanation for these non-additive properties was given by means of the interaction between the corresponding bands of components.

4. At the same time, in this connection, it is pointed out that the apparent single band of the first of p-X-aniline→γ acid in α coupling consists of two bands and similarly the first band of Direct Sky Blue 6B may also consist of two bands.

The authors are indebted to Dr. Ikuzo Tanaka for his useful advice, and they also wish to express their sincere thanks to Mr. Toshiro Iijima for his generous offer of purified acid dyes and to Mitsubishi Kasei Co., Ltd. for the kind contribution of a sample of Direct Sky Blue 6B.

Photochemical Reactions between Methylene Blue and Tri-, Di- and Monomethylamine. III. The Behavior of Methylene Blue in the Presence of Oxygen

By Hiroshi OBATA, Kenichi KOGASAKA and Masao KOIZUMI

(Received August 11, 1958)

In the preceding papers[1], the photochemical reactions between methylene blue and three kinds of amine in vacuo were investigated, and the following scheme was proposed.

$$MB^+ + OH^- + Am \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{Intermediate} \xrightarrow{k_3} MBH + AmO \quad (1)$$

Thus, methylene blue when irradiated, reacts with hydroxyl ions and amine and produces a certain type of intermediate with a life time of a few minutes, a part of the intermediate then transforming into leucodye and amine oxide. Now according to a recent paper of Oster[2], methylene blue is photobleached by various kinds of secondary and tertiary amine including ethylenediaminetetraacetic acid, and the reaction which is somewhat similar to ours, was interpreted to take place via the triplet state of dye ion on the ground that the fluorescence of methylene blue is not affected by the added amines. His conclusion will certainly apply to our case, since we have afterwards ascertained that the fluorescence of methylene blue in aqueous solution is practically the same as that of the solution used for the photochemical reaction, both in intensity and in structure.

The objective of the present paper is to elucidate the following three kinetic features which are considered to be important in relation to the above reaction.

(1) *The decision of a species which reacts with oxygen, when the aerobic solution of methylene blue containing amine is irradiated.*—In the studies of photosensitization by methylene blue, Weil[3] observed that amine is oxidized but methylene blue does not practically bleach, and we have also ascertained this fact under our experimental conditions. As to the regeneration of methylene blue in such cases, it seems generally considered especially by biochemists, that the attack of oxygen on leucodye reproduces the original dye. But on the basis of our scheme 1, the possibility of oxygen attack on the intermediate can not be excluded a priori, especially in view of our result that cupric ions react with the intermediate very effectively. The problem must therefore be decided experimentally and for this purpose, a quantitative comparison of the rate of photobleaching in vacuo and that of oxygen absorption by the same solution was undertaken.

(2) *The reactivity of oxygen with a triplet state (T state) of methylene blue.*—Generally, triplet states of dye ions are easily attacked by oxygen[4] as exemplified by the case of eosine studied by Imamura and Koizumi[5]. In the photobleaching of the aqueous solution of eosine under aerobic condition, the reaction takes place chiefly via T state, but most part of the intermediate in the T state is deactivated by oxygen and only a very small fraction of it interacts with oxygen in such an effective way as to lead a bleaching reaction. On this view, the question is raised whether the T state of methylene blue, in the presence of amine, is not attacked altogether by oxygen or alternatively, although attacked by oxygen it is only deprived of its excitation energy, no genuine chemical reaction occurring. This problem is intimately connected with the first one. As a help for the elucidation of this problem, the photobleaching reaction of methylene blue in the aqueous

solution involving no amine was investigated. It turned out that the rate is somewhat slower than that of eosine under similar conditions, and in relation to the above mentioned question, further investigations were undertaken to make clear of the effect of pH and oxygen pressure on the photobleaching rate.

3) *The behavior of T state of methylene blue in the presence of amine and oxygen.*— A quantitative comparison was made between the rate of photobleaching of methylene blue in vacuo by virtue of trimethylamine and that of oxygen absorption by the same system when irradiated, taking into account of the rate with which the aqueous solution of methylene blue is photobleached by oxygen. A conclusion is that T state of methylene blue is very efficiently deactivated by oxygen in the absence of amine, but such a process is practically suppressed by the presence of amine, oxygen only reacting with leucodye.

Experimental and Results

I. Measurement of the rate of oxygen absorption.—*a*) *Apparatus and Procedure.*—For our purpose, the rate of oxygen absorption must be compared with that of photobleaching under as much the same condition as possible. This requirement imposes some severe conditions on the apparatus, and as a result of examination of various methods from this viewpoint, it was decided to adopt Tödt's electrochemical method[6].

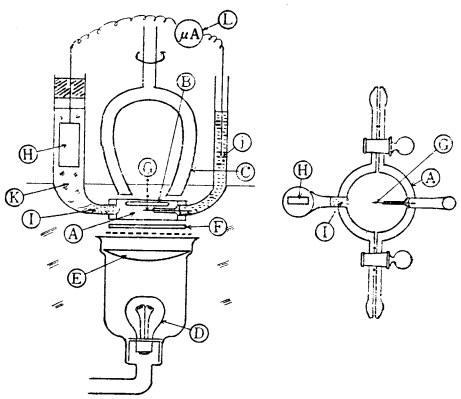

Fig. 1. Apparatus for the measurement of oxygen absorption
A reaction vessel
B magnetic stirrer
C magnet
D light source (automobile head-light lamp 35 w/35 w)
E condensor lens to prepare parallel light
F filter to cut off below 600 mμ
G cathode (platinum wire)
H anode (iron)
I KCl-agar bridge
J mercury
K 0.1 N KCl
L microammeter or galvanometer

The apparatus constructed is shown in Fig. 1. In this figure, A is a reaction vessel with an internal diameter of 28 mm. and a depth of 10 mm., B is a magnetic stirrer, a magnet C being rotated by a phonomotor 80 r.p.m. The cell is irradiated by an automobile head-light lamp 35 w/35 w (D) placed below the cell, E is a condensor lens to prepare parallel light and F is a filter which cuts off below 600 mμ. The intensity of illuminating light is approximately the same as that of the preceding papers[1]. A cathode G., which is polarizable, is a platinum wire 0.3 mm. diameter and 4 mm. length and an anode H, which is unpolarizable, is a piece of iron 30 mm.×10 mm.×4 mm. Tödt's anode contains 2% carbon and 0.6% copper and according to him, the iron rich in carbon and copper generally gives a better stability. Our anode contains 0.18% carbon and 0.98% copper, the specimen being supplied from Osaka Special Steel Ltd. The anode is dipped in 0.1 N potassium (K) solution and is connected to a cell via a potassium chloride-agar bridge I. As shown by Tödt, the amount of current supplied by this cell is determined by the diffusion of oxygen in the neighborhood of platinum electrode, and is given by the following relation after the establishment of a steady state.

$$i = nFDqc/\delta$$

(n=4, F: Faraday, D: diffusion constant, q: area of the cathode surface, c: oxygen concentration in the bulk solution, δ: thickness of diffusion layer).

In our experiment the speed of rotation of the magnet is slower than that in Tödt's experiment, hence the diffusion current is very dependent on the rotating speed and particular caution must be paid to keep constant the speed of rotation. Another thing to be added is that a platinum electrode needs to be dipped in hydrochloric acid to make its surface clean before use. Perhaps a platinum electrode, when exposed in the air, would have its surface covered with a thin film of oxide or the like, which would reduce the current.

b) *Calibration.*—Calibration between the diffusion current and the concentration of dissolved oxygen was made using the same solution for the absorption experiment, the composition being 2.0×10^{-5} M methylene blue, 0.1 N potassium chloride and pH 9.2 controlled by borate buffer. Firstly, the air mixed with a certain amount of nitrogen gas was passed through the solution immersed in a thermostat at 40°C, and the cell was filled quickly with this solution without any gaseous phase left behind. The current was measured in 30°C thermostat by a microammeter

6) F. Tödt, *Z. Elektrochem.*, **54**, 485 (1950); F. Tödt et al., *Biochem. Z.*, **323**, 192 (1952); **325**, 210 (1954); F. Tödt, D. Burk and O. Warburg, *Biochim. et Biophys. Acta*, **12**, 347 (1953).

in higher oxygen concentration or a galvanometer in lower oxygen concentration, while the concentration of oxygen was analyzed by Winkler's method[7] using the remaining solution. Winkler's method, however, when applied directly to the above solution did not give correct results owing to some difficulty in iodometry. Hence the dissolved oxygen was excluded by a flow of nitrogen gas and then redissolved in the mixed solution of manganese chloride and sodium hydroxide which was analyzed by the same method. Between the current and the concentration of oxygen, a good linear relationship holds, as shown in Fig. 2.

7) L. W. Winkler, *Ber.*, **21**, 2843 (1888); F.P. Treadwell and W. T. Hall, "Analytical Chemistry", vol 2. John Wiley of Sons, New York (1942) p. 704.

c) *Results.* — The composition of the solutions employed were usually 2×10^{-5}M methylene blue, 0.1 N potassium chloride pH 9.2 controlled by borate buffer, the amount of trimethylamine being varied from 0.6×10^{-3}M to 2.0×10^{-3}M. In cases of dimethylamine and monomethylamine, the concentration was raised to 4.0×10^{-2}M. A few results obtained for the relation between the concentration of oxygen and time are shown in Fig. 3. As seen from the figure, a linearity holds in all cases. But for a later stage (below about 3×10^{-5}M of oxygen), not shown in the figure, an abnormally rapid decrease of oxygen is observed in cases of trimethyl and monomethylamine, but not in dimethylamine. The origin of the above phenomena is not known at the present stage. It may perhaps be related to the electrode process and different kinds of behavior may partly be due to the mechanism of each reaction in this region. For our present purpose, however, only those regions of the normal behavior were employed and the rate of oxygen absorption was evaluated from its inclination.

The results are summarized in Table I. In this table two kinds of calculated value were obtained as follows.

Calculation A. If one assumes that leucodye, when formed, reacts very rapidly with oxygen according to the following stoichiometric relation

$$MBH+\frac{1}{2}O_2 \longrightarrow MB^+ + OH^-*$$

then, the rate of oxygen consumption will be given by

$$-\frac{d[O_2]}{dt}=\frac{1}{2}\frac{k_1k_3}{k_1+k_2+k_3}[MB]_0$$

where $[MB]_0$ is the analytical concentration of methylene blue.

Figures given under the heading Cal. A are the values by the above formula.

Calculation B. If one assumes that as soon as the intermediate is produced, it is attacked by oxygen immediately according to the following stoichiometric relation,

$$(MB\cdots HO\cdots Am)+\frac{1}{2}O_2 \longrightarrow MB^+ + OH^- + AmO$$

then the rate of oxygen absorption will be given by

* In view of Weil's results that hydrogen peroxide was not detected by an ordinary method though perceptible by pyruvic acid method, the overall reaction in the main would be such as written above.

$$-\frac{d[O_2]}{dt}=\frac{1}{2}k_1[MB]_0$$

Figures given under the heading Cal. B are the values obtained by this formula. k_1, k_2 and k_3 are the constants evaluated from the analysis of the bleaching of the dye ion in vacuo in the same solution used for the oxygen absorption experiment.

II. The photobleaching of the aqueous solution of methylene blue by dint of dissolved oxygen.—*a) Apparatus and procedure.*— The experiment was done in a similar way to that described in Imamura and Koizumi's paper[5]. The concentration of dye was usually 1.6×10^{-5}M. The rate of photobleaching was calculated from the fall of the maximum absorbance. In certain cases the position of maximum absorption showed a slight shift toward a shorter wave length giving rise to some ambiguity to the analysis, although the initial rate generally adopted is quite reliable. The data can be analyzed by Imamura and Koizumi's method and the relation

$$\{\ln(1-e^{-\alpha c_0 d})+\alpha c_0 d)\}-\{\ln(1-e^{-\alpha cd})+\alpha cd\}=k't \quad (2)$$

can express the experimental results satisfactorily. Thus in almost all cases the plot of $\{\ln(1-e^{-D})+D\}$ (D, optical density) against t gives a straight line and from its inclination the value of k' is evaluated, k' is related with the quantum yield k by the following equation

$$k'=\alpha d I_0 k \quad (3)$$

in which α is not a genuine extinction coefficient but is to be considered rather a kind of experimental parameter. By an experiment employing a thermopile, k was determined for a certain solution and the proportionality constant between k and k' thus obtained was utilized for calculating k from k' for all the other solutions.

b) Effect of oxygen pressure on the bleaching rate of the aqueous methylene blue solution.—The aqueous solution of methylene blue was found to bleach gradually when irradiated, but if evacuated there occurs no bleaching perceptible. Thereupon, in order to examine the effect of oxygen concentration on the rate, the experiments were done with the solutions which had been previously brought to equilibrium with the air of various pressures. The concentration of the dissolved oxygen was calculated by use of Ostwald's absorption coefficient of oxygen in water neglecting the effect of a small quantity of dye. The results obtained are summarized in Table II and a plot of $1/k$ against the reciprocal of the oxygen concentration is given in Fig. 4, which shows a good straight line.

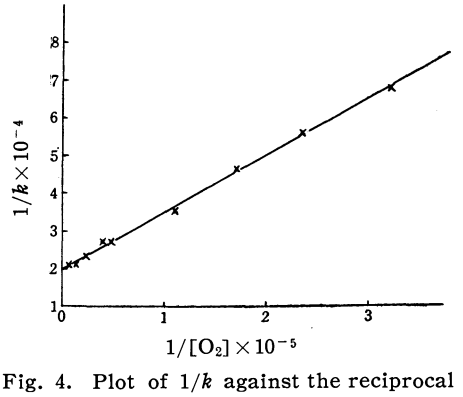

Fig. 4. Plot of $1/k$ against the reciprocal of the oxygen concentration.

TABLE II

Concentration of oxygen mole/l.	k'	k
2.5×10^{-4}	0.0240	4.63×10^{-5}
1.07×10^{-4}	0.0247	4.75×10^{-5}
4.95×10^{-5}	0.0239	4.61×10^{-5}
4.85×10^{-5}	0.0225	4.34×10^{-5}
2.38×10^{-5}	0.0174	3.36×10^{-5}
2.15×10^{-5}	0.0180	3.48×10^{-5}
9.1×10^{-6}	0.0143	2.76×10^{-5}
5.76×10^{-6}	0.0117	2.26×10^{-5}
4.25×10^{-6}	0.00912	1.76×10^{-5}
3.13×10^{-6}	0.00766	1.48×10^{-5}
1.16×10^{-6}	0.00288	5.55×10^{-6}

As the reaction goes via T state, k is to be related with the constants of various steps by the same formula already applied to the case of eosine.

$$k=\varphi_{S\to T}\frac{k^{I}_{D_2}[O_2]}{k^{IS}_{O_2}[O_2]+k^{I}_{H_2O}[H_2O]}\times\frac{k^{II}_{H_2O}}{k^{IIS}_{H_2O}}$$

or $$\frac{1}{k}=\frac{1}{\varphi_{S\to T}}\frac{k^{IS}_{O_2}}{k^{I}_{O_2}}\frac{k^{IIS}_{H_2O}}{k^{II}_{H_2O}}+\frac{1}{\varphi_{S\to T}}\frac{k^{I}_{H_2O}[H_2O]}{k^{I}_{O_2}[O_2]}\frac{k^{IIS}_{H_2O}}{k^{II}_{H_2O}}$$

where $\varphi_{S\to T}$ means transition probability for the suffixes I, II refer respectively to the first and second step and the suffix S means the sum of all the reactions of the related species. Other symbols are evident. From the inclination and the intercept of the plot in Fig. 4,

$$\frac{1}{\varphi_{S\to T}}\times(k^{I}_{H_2O}[H_2O]/k^{I}_{O_2})(k^{IIS}_{H_2O}/k^{II}_{H_2O})=1.55\times10^{-1} \quad (4)$$

$$\frac{1}{\varphi_{S\to T}}\times(k^{IS}_{O_2}/k^{I}_{O_2})(k^{IIS}_{H_2O}/k^{II}_{H_2O})=2.0\times10^{4}$$

or $$\varphi_{S\to T}(k^{I}_{O_2}/k^{IS}_{O_2})(k^{II}_{H_2O}/k^{IIS}_{H_2O})=5\times10^{-5} \quad (5)$$

From 4 and 5

$$k^{I}_{H_2O}[H_2O]/k^{IS}_{O_2}=7.75\times10^{-6} \quad (6)$$

and putting $[H_2O]=55.5$ M

$$k^{I}_{H_2O}/k^{IS}_{O_2}=1.4\times10^{-7}$$

For eosine the above quantities have already been evaluated as follows[8]

$$\varphi_{S\to T}(k^{I}_{O_2}/k^{IS}_{O_2})(k^{II}_{H_2O}/k^{IIS}_{H_2O})=2.8\times10^{-4}$$

$$k^{I}_{H_2O}/k^{IS}_{O_2}=1.3\times10^{-8}$$

Comparing the two sets of values, it may be said that the reactivity (deactivation+genuine reaction) of T state of methylene blue against oxygen is about 1/10 of that of eosine.

c) The effect of pH on the bleaching rate. —The pH effect on the photobleaching was examined only for the solution saturated with air. It is to be noted that absorption spectra of methylene blue change above and below a certain pH value and especially in the strong alkaline region, the dye seems to be quite unstable even in the dark. Hence the effect was examined only in the region where absorption spectra are not affected or affected little. In most experiments the pH values were controlled by the veronal-sodium acetate-hydrochloric acid buffer. All the data could be analyzed by 2, a linearity between $\{\ln(1-e^{-D})+D\}$ and t holding exactly except for a single case of pH 8.59 (the most alkaline solution).

The results are summarized in Table III and are shown in Fig. 5.

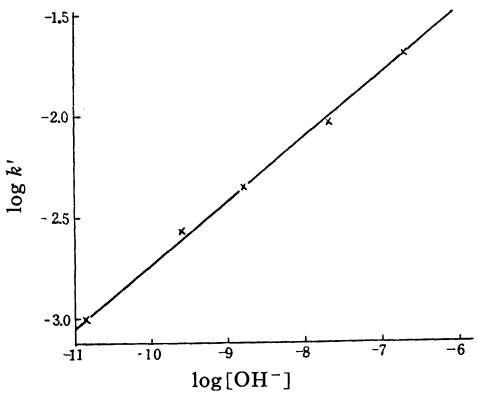

Fig. 5. Relation between $\log k'$ and $\log[OH^-]$.

TABLE III

buffered solution		non-buffered solution	
pH	k'		k'
3.35	0.001	10^{-3}N HCl	0.0019
4.40	0.0027	*pure water	0.024
5.20	0.0043	10^{-3}N NaOH	0.062
6.34	0.0086		
7.30	0.0196		
8.59	0.023		

* pH of the aqueous solution MB 1.6×10^{-5} M was measured by pH meter to be ca. 6.8.

From this figure, it can be said that k is approximately proportional to $[OH^-]^{1/3}$ for the buffered solution and the results for the non-buffered solution are somewhat higher at pH<7.0.

8) M. Imamura, This Bulletin, **30**, 249 (1957).

Discussion

Firstly, the discussion will be given about a species which is attacked by oxygen in the amine added solution of methylene blue. The solution of methylene blue containing trimethylamine does not practically bleach in spite of the presence of oxygen and this fact conforms well with the result that the quantum yield of amine induced photobleaching (reversible photoreduction) in vacuo ($10^{-3}\sim10^{-2}$) is quite larger than that of the oxygen induced photobleaching (irreversible photoöxidation) of the aqueous methylene blue solution ($\sim4.6\times10^{-5}$)***. From the above results the possibility that oxygen attacks T state decomposing methylene blue molecules can be excluded in the amine added solution. And whether oxygen attacks intermediate or leucodye, the rate must be so fast that as soon as the intermediate (or the leucodye) is formed, the consumption of oxygen must immediately take place, because the rate of oxygen absorption is the zeroth order in oxygen concentration. However, there is one thing to be taken into consideration. That is the possibility of deactivation of T state by oxygen. From the results of the irreversible photoöxidation of the aqueous solution, although the value of quantum yield is quite small

$$\varphi_{S\to T}(k^{I}_{O_2}/k^{IS}_{O_2})(k^{II}_{H_2O}/k^{IIS}_{H_2O})=k=5\times10^{-5}$$

the rate constant $k^{IS}_{O_2}$ (for the whole process consisting of deactivation and genuine reaction) is quite larger than $k^{I}_{H_2O}[H_2O]$ ($k^{IS}_{O_2}/k^{I}_{H_2O}[H_2O]=1.3\times10^{5}$). Therefore, there is no reason to deny a priori the posibility of such a deactivation in the solution of methylene blue containing amine. But if this should occur in about the same order as in the aqueous methylene blue solution, the rate of oxygen consumption ought to be exceedingly smaller than the calculated value in Table II. The agreement between the calculated and the observed value in the order of magnitude definitely denies such a possibility, and for the case of trimethylamine, the close agreement between the observed and the calculated value (Cal. A) strongly supports the view that oxygen attacks only on leucodye and not on intermediate. Thus it may be concluded that the behavior of T state toward oxygen is essentially different in two solutions with and without amine. For the solution containing amine, such a view as that competitive reactions of T state with oxygen on the one hand and with amine and OH^- on the other take place, the latter greatly predominating over the former, can not be adopted. Rather, the interpretation that oxygen in the solution containing amine loses the power of deactivating T state or alternatively loses a chance of effective encounter with T state, seems to fit experimental results. This interpretation is further supported from the following argument about the different features of the kinetics already established in the reversible photoreduction and the irreversible photoöxidation. On the basis of a broad outline of the reaction scheme proposed in the previous paper[1], let us asume tentatively a more detailed mechanism which of course must await further studies to confirm it. One plausible scheme would be such as the following

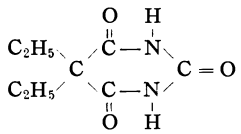
$$\begin{array}{l} MB^+ + h\nu \longrightarrow MB^{+*} \longrightarrow MB^{+t} \\ \qquad\qquad \overrightarrow{k}^{I}_{q} \\ \qquad MB^{+t} \longrightarrow MB^+ \\ \overrightarrow{k}^{I}[OH^-] \Big\downarrow\Big\uparrow \overleftarrow{k}^{II} \qquad \overrightarrow{k}^{II}[Am] \\ \qquad MB\cdots OH \longrightarrow MB\cdots HO\cdots Am \\ \qquad\qquad\qquad\qquad\qquad\quad \downarrow k_2 \\ \qquad\quad k_3 \\ \qquad\longrightarrow \text{Product} \end{array}$$

Applying the stationary state condition to T state and MB $\cdots$OH, k_1 in 1 can be expressed as follows in the above scheme

$$k_1\sim\frac{I_{ab}\varphi_{S\to T}\overrightarrow{k}^{I}\overrightarrow{k}^{II}[OH^-][Am]}{\overrightarrow{k}^{I}_{q}\overleftarrow{k}^{II}+\overrightarrow{k}^{I}[OH^-]\overrightarrow{k}^{II}[Am]+\overrightarrow{k}^{I}_{q}\overrightarrow{k}^{II}[Am]}$$

Although somewhat different relations may result from different mechanisms, the essential point would not be affected. It is that the relation experimentally found, $k_1\propto[OH^-][Am]$ requires a far larger magnitude of $\overrightarrow{k}^{I}_{q}\overleftarrow{k}^{II}$ term or the like compared with other terms involved in the denominator. Thus it is a natural expectation that the reaction of T state with OH^- and amine leading to an intermediate is slower than the deactivation or quenching process of T state by water molecules or itself.

The above situations are in sharp contrast with those of the solution without amine, in which T state is deactivated by



*** To avoid confusion let us designate the two reactions as reversible photoreduction and irreversible photooxidation hereafter.

O_2 far more rapidly than water. Thus the different kinds of behavior in two cases are comprehensive only from the viewpoint mentioned above.

Lastly it is to be added that for the case of monomethylamine, the observed rate of oxygen absorption coincides approximately with the values calculated by A method while it lies near to the values calculated by B method for the case of dimethylamine. But in view of few data and their accuracy being not very good, further studies will be necessary for a decisive conclusion except the case of trimethylamine for which the statement that oxygen attacks leucodye may be beyond doubt.

Next the retarding effect of veronal upon the irreversible photoöxidation may be taken up.

A structural formula of veronal

contains two secondary amino nitrogens, and in view of the results reported by Oster[2], it is a natural expectation that another reaction competing with the irreversible photoöxidation takes place between T state of methylene blue and veronal molecule. To ascertain this conjecture, it was examined whether the evacuated buffered solution displays the photobleaching or not. The result as shown in Fig. 6, is that the photobleaching does really take place and moreover the introduction of oxygen into the bleached solution recovers a greater part of the lost color. Such a bleaching process does not occur in the evacuated dye solution containing 10^{-3}M sodium hydroxide.

Thus, there is no doubt that a reversible photoreduction such as the formation of leucodye is taking place in this case. The retardation of the irreversible photoöxidation caused by the addition of veronal, can be attributed to this competitive reductive reaction, the produced leucodye being recovered by the existent oxygen. Veronal can be said to have amino-like action although to a far lesser extent. It may be worthy of adding here that an enough caution must be paid when the buffer solution is used for such experiments as the present one, since the buffer solutions usually employed often involve such a N-containing compound

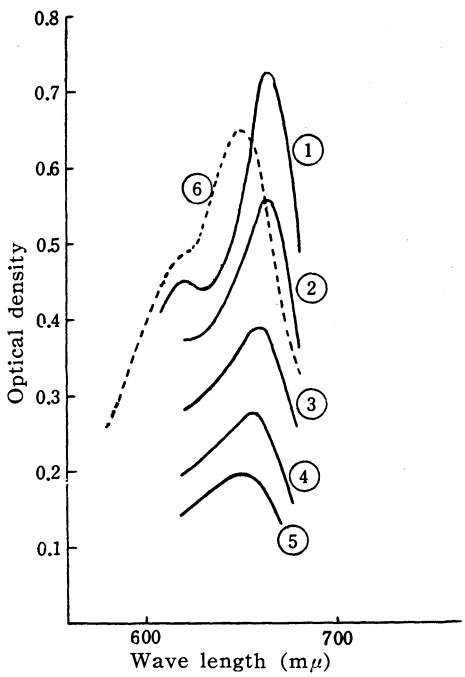


Fig. 6. Photobleaching of the methylene blue solution containing veronal in vacuo.
1 initial
2 after 10 minutes

like veronal.

Studies on the pH dependence of the rate certainly be essential for the elucidation of a detailed mechanism of the irreversible photoöxidation. But the results obtained in this paper are difficult to interpret because of the complexity introduced by the above circumstances and of the lack of experiments for examining the effect of oxygen concentration upon the rate in various pH solutions. A further more careful and extensive study will be necessary in order to make clear a detailed mechanism of the present reaction.

Summary

In connection with the reversible photoreduction of methylene blue in vacuo published already, the rate of the consumption of oxygen in the irradiated solution of methylene blue containing three kinds of amine was measured. In addition, the irreversible photoöxidation of the aqueous methylene blue solution was

studied, particular attention being paid to the effect of oxygen pressure and pH on the rate. The following conclusions were drawn from the above two series of experiments.

1) In the irradiated aqueous solution of methylene blue containing trimethylamine, oxygen does not affect the T state of dye and attacks only the leuco form, reproducing the dye molecule. Oxygen reacts almost instantaneously with the leucodye as soon as the former is produced.

2) In the aqueous solution of methylene blue (with no amine added) the reactivity of T state against oxygen is about one order less than that of eosine in the analogous condition. The deactivation of T state by oxygen in case of methylene blue is about 10^{-7} times greater than that by water.

3) Comparison of the above results 1 and 2 (taking into account of the result that in the evacuated state the reactivity of T state against OH^- and amine is much less than the deactivation by water) leads to the conclusion that the deactivation of T state by oxygen is almost completely suppressed by the addition of amine.

4) The rate of irreversible photoöxidation increases with the alkalinity of the solution. But in the buffer solution containing N-compound like veronal, a competitive reaction somewhat like that between methylene blue and amine occurs. It is pointed out that enough caution must be taken for such a possibility when the buffer solutions are employed.

Photometric Determination of Indicator End Points in Complexometric Titrations

By Sôichirô MUSHA, Makoto MUNEMORI and Kin'ya OGAWA

(Received August 13, 1958)

In photometric titrations with an indicator, the color does not develop linearly with the titrant added. This characteristic has been elucidated by a mathematical treatment of complexometric titration with specific indicator for a certain metal[1].

In a previous communication[2], the present authors proposed a graphical method for determining indicator end point in the complexometric titration by a photometric technique and applied it with success to the titration of magnesium with disodium salt of ethylenediaminetetraacetic acid (Complexon III) using Eriochrome Black T (EBT) as indicator. This method is, however, an approximate one and therefore its utility and limitation will be discussed in the present paper.

Theoretical

List of Principal Symbols.—

m_t, total concentration of metal in titration system
i_t, total concentration of indicator in titration system
c_t, total concentration of titrant in titration system
$\mu = c_t/m_t$, relative concentration of titrant
$\alpha = [I^*]/i_t$, ratio of $[I^*]/([MI] + [I^*])$
$[I^*] = [I] + [HI] + [H_2I] + \cdots\cdots$, sum of the concentrations of metal-free indicator components
$[Y^*] = [Y] + [HY] + [H_2Y] + \cdots\cdots$, sum of the concentrations of metal-free titrant
$K_Y^* = [MY]/[M][Y^*]$, apparent stability constant
$K_I^* = [MI]/[M][I^*]$, apparent indicator constant
A_s, absorbancy during the course of titration

A_{sI}, absorbancy of metal-free indicator
A_{sMI}, absorbancy of metal-indicator complex
V, volume of titrant solution added, in ml.
V_{eq}, volume of titrant solution equivalent to the total concentration of metal, in ml.
V_0, volume of metal ion solution to be titrated, in ml.
C, molarity of titrant

General Expression and Approximate Expression. — In titrating the metal ion with such a reagent as Complexon-III in an aqueous system, there are the following equilibria:

$$M+Y^*=MY \quad \text{and} \quad M+I^*=MI \tag{1}$$

From K_Y^* and K_I^* it follows that:

$$[MY]=K_Y^*[M][Y^*] \tag{2}$$

$$[MI]=K_I^*[M][I^*] \tag{3}$$

On the other hand, m_t, c_t and i_t are expressed by the following equations:

$$m_t=[M]+[MY]+[MI] \tag{4}$$

$$c_t=[MY]+[Y^*] \tag{5}$$

$$i_t=[MI]+[I^*] \tag{6}$$

From Eqs. 2, 3, 4, 5 and 6, the following relationship is derived.

$$c_t=m_t-[MI]\left(1+\frac{1}{K_I^*[I^*]}\right)+[I^*]\frac{K_I^*}{K_Y^*}\left\{\frac{m_t}{[MI]}-\left(1+\frac{1}{K_I^*[I^*]}\right)\right\} \tag{7}$$

By replacing Eq. 7 by the relative values μ and α, comes the following equation:

$$\mu=1-\frac{1}{m_t}(1-\alpha)\left(i_t+\frac{1}{\alpha K_I^*}\right)+\alpha\frac{K_I^*}{K_Y^*}\left\{\frac{1}{1-\alpha}-\frac{1}{m_t}\left(i_t+\frac{1}{\alpha K_I^*}\right)\right\} \tag{8}$$

Eq. 8 is the general expression for the spectrophotometric titration curve and will be called *general equation.*

Now, if $[Y^*]$ and i_t are so small that they can be neglected in the course of titration, Eqs. 4 and 5 are converted into the followings:

$$m_t=[M]+[MY] \tag{9}$$

$$c_t=[MY] \tag{10}$$

From Eqs. 2, 3, 9 and 10 it follows that:

$$c_t=m_t-\frac{1}{K_I^*}\frac{[MI]}{[I^*]} \tag{11}$$

If the dilution of solution by titrant is neglected, Eq. 12 will be obtained by substituting Eq. 11 with V and V_{eq}:

$$V=V_{eq}-\frac{V_0}{C}\frac{1}{K_I^*}\frac{[MI]}{[I^*]} \tag{12}$$

Values of $[MI]/[I^*]$ can be computed from the absorbancy readings by means of the following equation:

$$[MI]/[I^*]=(A_{sI}-A_s)/(A_s-A_{sMI}) \tag{13}$$

If $(A_{sI}-A_s)/(A_s-A_{sMI})$ is plotted against V will result a straight line whose intercept on the V-axis is equal to V_{eq}[2]. By replacing Eq. 11 by μ and α, comes Eq. 14:

$$\mu=1-\frac{1}{m_t}\frac{1}{K_I^*}\frac{1-\alpha}{\alpha} \tag{14}$$

Eq. 14 is the approximate expression for the spectrophotometric titration curve and will be called *approximate equation.*

Discussion

On the basis of general equation, Fortuin et al.[1] discussed the condition to be fulfilled for the accurate determination of indicator end point in complexometric titration by a photometric method. In the present paper, however, we shall discuss the conditions under which the approximate equation is established within experimental errors.

When Eq. 14 is compared with Eq. 8, i_t and K_Y^* are omitted in Eq. 14, and therefore the effects of these variables on the deviation of the approximate equation from the general equation will be mainly examined.

If the magnitudes of m_t, i_t, K_Y^* and K_I^* are assigned in Eq. 8, α and hence $(1-\alpha)/\alpha$ can be evaluated as a function of μ. The curves in Figs. 2 and 4 illustrate the manner in which α changes with μ for the systems defined by Tables I and II, respectively. Corresponding curves in Figs. 1 and 3 illustrate the variation of $(1-\alpha)/\alpha$ with μ. Line A_0 in Fig. 1 and line B_0 in Fig. 3 show the plots obtained by Eq. 14.

1) Effect of i_t.—The effect of the magnitude of i_t was examined when K_I^* is much smaller than K_Y^*. From Fig. 1 it is seen that the deviation of the approximate equation from the general equation becomes greater at higher indicator concentration. Therefore, it may be concluded that in order to estimate μ with precision of 1%, the molarity of the indicator must be ten times smaller than $1/K_I^*$ in numero. Fig. 2, which represents actual behavior of photometric titration curve, shows ambiguous end point at higher indicator concentration.

2) Effect of K_Y^*. — The effect of the magnitude of K_Y^* was examined when the

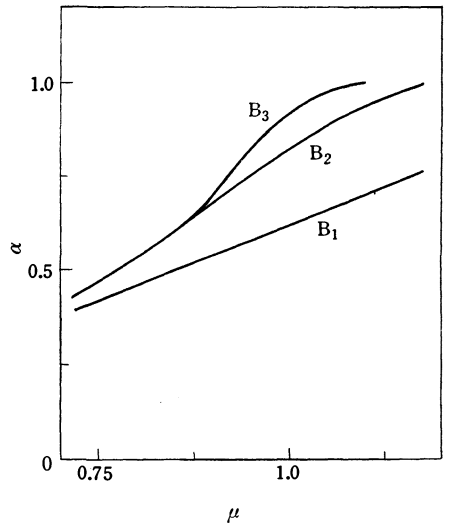

Fig. 4. Variation of α with μ for the systems defined by Table II.

molarity of the indicator was ten times smaller than $1/K_I^*$ in numero. From Fig. 3 it is seen that the deviation of the approximate equation from the general equation becomes larger as the value of $\log(K_Y^*/K_I^*)$ decreases.

In a usual plot of the titration curve (Fig. 4), the end point can be accurately determined only when $\log(K_Y^*/K_I^*)$ is larger than 4. However, if $(1-\alpha)/\alpha$ is plotted against μ (Fig. 3), the end point can be determined through extrapolation even when $\log(K_Y^*/K_I^*)$ is equal to 2 (curve B_2).

3) Slope of the line expressed by the approximate equation.—It is seen from Eq. 14 that the slope of the line expressed by the approximate equation is proportional to the product of m_t and K_I^*. Accordingly, in case of titration where Eq. 12 is well established, the apparent indicator constant can be estimated from the slope of the line expressed by this equation.

Experimental

In order to test the applicability of the linear plot described above, the following titrations were investigated:

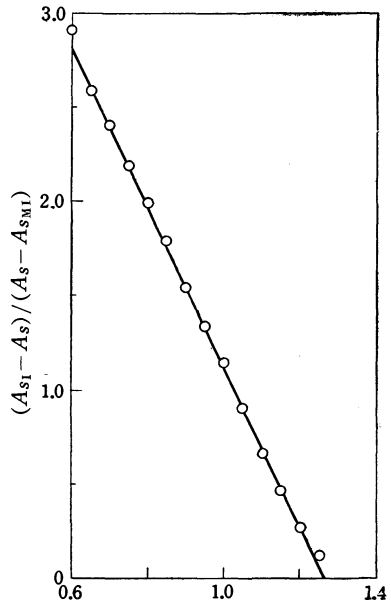
1) Micro-titration of calcium at pH 12 using Murexide indicator, as an example of lower concentration of metal ion.

2) Titration of calcium at pH 10 using EBT indicator, as an example of lower value of K_I^*.

3) Titration of magnesium at pH 10 using EBT indicator, as an example of the case where value of log (K_Y^*/K_I^*) is smaller than 3.

Apparatus.—Yanagimoto Photometric Titrator Model PT-1 and Yanagimoto pH meter were used.

Reagents.—All chemicals used were the reagent grade. Standard solution of calcium was prepared by dissolving calcium carbonate (dried at 110°C), in dilute hydrochloric acid and diluting it with distilled water. Standard solution of magnesium was prepared by dissolving magnesium sulfate heptahydrate in distilled water and its concentration was gravimetrically determined with oxine[3]. Standard solution of Complexon-III was prepared by dissolving disodium ethylenediaminetetraacetate dihydrate in distilled water to produce approximately 0.01 M solution. Murexide indicator solution was prepared by shaking 40 mg. of the dye with 10 ml. of distilled water and 2 ml. of its supernatant was used. This solution was prepared daily. EBT indicator solution was prepared by dissolving 0.5 g. of Eriochrome Black T and 4.5 g. of hydroxylamine hydrochloride in 100 ml. of ethanol and its 0.5 ml. was used. This solution was stable for at least 5 months. For the adjustment of pH of the solution to 10 and 12, 1 N ammonium chloride-ammonia buffer solution and 1 N sodium hydroxide solution were used, respectively.



Procedure.—An aliquot of sample solution and a few ml. of buffer solution were placed in the titration cell and diluted to 50 ml. with distilled water. Appropriate wave-length was set and the absorbancy scale was adjusted to zero with slit. The indicator solution was pipetted into the titration cell and then titration was carried out. Absorbancies were recorded at the beginning of titration and at every 0.05 ml. of the titrant added during the titration, until the constant value of absorbancy was obtained.

Results and Discussion. — *Titration of calcium at pH 12 using Murexide indicator.* —Absorbancy measurement was made at 580 mμ. In this titration system, the values of log K_Y^* and log K_I^* are 10.5 and 5.0, respectively[4]. Although the value of log (K_Y^*/K_I^*) is sufficiently large, the photometric titration curve (Fig. 6) is somewhat round near the equivalence point, owing to the lower concentration of the calcium ion in the titration system. The plot of $(As_1-A_s)/(A_s-As_{MI})$ against the volume of the titrant added (Fig. 5) gives a straight line, the intercept of which corresponds to the equivalence point. The

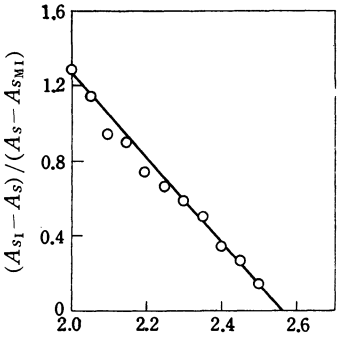
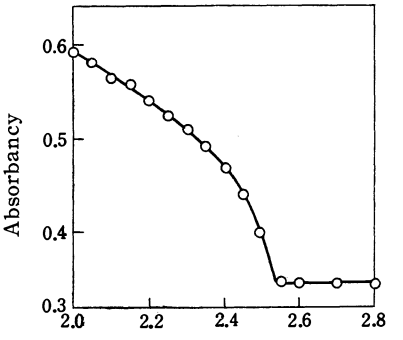
results given in Table III show that the titration can be carried out with high precision.



Titration of calcium at pH 10 using EBT indicator. — In this titration system, the values of $\log K_Y^*$ and $\log K_I^*$ are 10.2 and 4.03, respectively[4]. Visual titration of this system fails owing to the ambiguous color change at the end point. Even by a photometric technique, the titration curve at 545 mμ (Fig. 8) does not give a sharp end point since the value of $\log K_I^*$ is too small. However, the plot of $(A_{sI}-A_s)/(A_s-A_{sMI})$ against the volume of the titrant added (Fig. 7) gives a straight line, the intercept on the V-axis representing the equivalence point. The results given in Table IV show that precisions of the order of a few tenths of one per cent were obtained in most instances.

Titration of magnesium at pH 10 using EBT indicator. — In this titration system, the values of $\log K_Y^*$ and $\log K_I^*$ are 8.5 and 5.44, respectively[4]. The value of $\log (K_Y^*/K_I^*)$ is about 3, so that the photometric titration curve at 545 mμ (Fig. 2 in the previous communication[2]) shows some rounding near the equivalence point. However, the plot of $(A_{sI}-A_s)/(A_s-A_{sMI})$ against the volume of the titrant added gives a straight line, the intercept on the V-axis representing the equivalence point (Fig. 1 in the previous communication[2]). The results (Table I in the previous communication[2]) show that the titration was carried out with precision of about 1%.

TABLE IV



RESULTS OF PHOTOMETRIC TITRATION OF CALCIUM AT pH 10 WITH 0.01 M COMPLEXON-III USING EBT INDICATOR

Fig. 8. Titration curve of the same titration as in Fig. 7.

Apparent indicator constant.—It was previously pointed out that the apparent indicator constant would be estimated from the slope of the linear plot of $(A_{sI}-A_s)/(A_s-A_{sMI})$ against the volume of titrant added. The values of $\log K_I^*$ obtained in the above titrations are given in Table V and compared with those described by Schwarzenbach[4] (given in the fifth column in Table V). It is seen that there are considerable discrepancies between them. These discrepancies may be due to the differences in ionic strength and temperature and also to some unknown factor such as the influence of buffer components in the equilibria.

TABLE V
VALUES OF LOGARITHM OF APPARENT INDICATOR CONSTANT FOR CALCIUM AND MAGNESIUM

Metal ion	pH	Indicator	$\log K_I^*$	
			Values obtained	Values reported
Calcium(II)	12	Murexide	4.3_9	5.0
Calcium(II)	10	EBT	4.0_3	3.84
Magnesium(II)	10	EBT	5.2_8	5.44

Determination of calcium and magnesium in their mixture.—Total amount of calcium and magnesium in their mixture was titrated at pH 10 with standard Complexon-III solution using EBT indicator. Absorbancy measurements were made at 545 mμ. with another aliquot of the sample solution, magnesium was masked by sodium hydroxide and calcium was titrated at pH 12 using Murexide indicator. Absorbancy measurements were made at 580 mμ. The amount of magnesium was calculated by their differences. The linear plots obtained in the titrations of total calcium and magnesium and of calcium give the same pictures as obtained in 3 and 1, respectively. The results are tabulated in Table VI.

Vapor Pressures of Molecular Crystals. XIV[1]. *Sulfamide and Diacetylhydrazine*

By Sadao TAKAGI*, Ryuichi SHINTANI, Hideaki CHIHARA and Syûzô SEKI

(Received August 7, 1958)

The energy of the hydrogen bond can be determined by various methods in vapor, liquid, solution, and crystalline solid. All but one method, that have been reported by the authors and other investigators in cases of liquids and crystals, estimate the energy from the temperature variation of the equilibrium constant for the association-dissociation equilibrium due to hydrogen bonding in vapor or in solution state. Those determinations, however, can not be correlated with the so-called hydrogen bond distances with only one exception for the case of gaseous carboxylic acid dimers, the structure of which could be determined by means of the electron diffraction technique. On the other hand when we deal with crystalline solids, it is possible to determine the hydrogen bond distance by the X-ray investigation although we can not obtain the state, in which only the hydrogen bond ceases to act, other forces such as the dispersion forces and the dipolar forces being unchanged. Usually the compromise has been adopted that the contributions other than the hydrogen bond to be subtracted from the total lattice energy may be estimated by one of the following

1) The Report XIII may be found in This Bulletin, **32**, 84 (1959).

* Present address: The Institute of Polytechnics, Osaka City University, Minami-Ogimachi, Osaka.

2) I. Nitta, S. Seki and K. Suzuki, This Bulletin, **24**, 63 (1951).

two methods: (1) the dispersion energy is calculated by using the interatomic distances and the atomic polarizabilities, and the electrostatic energy by assuming the electron density on each atom; (2) the dispersion and the electrostatic energies of the hydrogen-bonded crystal are substituted by the heat of sublimation of the crystal that is isoelectronic with the crystal in question but that possesses no hydrogen bond between molecules[2].

We have here chosen sulfamide and diacetylhydrazine as compounds having NH···O hydrogen bonds in crystals, whose structures were determined[3,4], and we have applied the former method of obtaining the energies of hydrogen bonds.

Experimental

Materials.—Sulfamide $(NH_2)_2SO_2$ was prepared by Goehring's method from liquid ammonia and sulfuryl chloride[5], and purified by fractional sublimation in high vacuum, m. p. 91.9°C (*Anal.* found S 32.84% and N 28.45%.) Diacetylhydrazine $CH_3COHN\text{-}NHCOCH_3$ was supplied by Miss A. Yamaguchi of the University of Tokyo*. This was recrystallized from aqueous solution and dehydrated** and sublimed in high vacuum; m. p. 123°C. The crystal modifications of both substances were checked against the reported crystal structures by X-ray diffractometer.

Apparatus.—The vapor pressures were measured with the apparatus already reported elsewhere[1] except for minor alterations. In the experiments with diacetylhydrazine, it was found that effused vapor condensed on the quartz helical balance which was kept at room temperature, causing a considerable error in the determination of the weight changes. In order to remove this difficulty the balance container was heated with a ribbon heater from outside the glass tubing to maintain the temperature of the balance at about 70°C. The treatment of the quartz balance with dimethyldichlorosilane vapor was also useful in preventing condensation of diacetylhydrazine.

Results and Discussion

The vapor pressures are listed in Table I for both sulfamide and diacetylhydrazine. The experimental values are well reproduced by the equations,

$$\log P = 11.047 - (5300.4/T) \quad \text{(sulfamide)}$$

and

$$\log P = 12.1947 - (5384.4/T) \quad \text{(diacetylhydrazine)}$$

The heat, entropy and free energy changes of sublimation computed by these equations are given in Table II.

5) M. Goehring, J. Heinke, H. Malz and G. Ross, *Z. anorg. u. allgem. Chem.*, **273**, 200 (1953).

* The authors are indebted to her for her kindness.

** The monohydrate of diacetylhydrazine is more stable than the anhydrous form at room temperature and humidity.

* Association in vapor can be ignored as the vapor pressure is very low.

parameters determined by Trueblood and Mayer[3]. The atomic polarizabilities were calculated from the molecular refractions R_D for O (in a carbonyl), NH_2 (in a primary amine) and SO_2 (in dialkyl sulfate) compiled by Vogel[6]. The static polarizabilities given in Table IV have been corrected for the dispersion effect by subtracting 3% from the values for the NaD light[7]. The dispersion energy was then computed by using the Slater-Kirkwood formula[8] by summation within the 10 Å sphere and by integration outside that sphere. The summation part contributed 13.71 kcal and the integration part contributed 0.014 kcal. to the dispersion energy. The number of terms included in the summation was 1128. The dipolar interaction energy in sulfamide was obtained by summing up the contribution from each pair of molecules in the crystal by using the value of the dipole moment 3.9 D[9]. The dipolar energy contribution within the 10 Å sphere amounted only to 2.87 kcal. and this was taken as the total electrostatic energy as the integration diverges. The hydrogen bond energy was set equal to the difference between the observed lattice energy and the sum of the dispersion and electrostatic energies; $24.25-(12.08+2.9)=9.30$ kcal./mole. There are two NH···O hydrogen bonds per molecule of sulfamide and therefore the energy of a hydrogen bond is 4.6_5 kcal./mole. Omission of the repulsive potential energy in the calculation may be partly justified by the fact that in many molecular crystals the Margenau potential of r^{-8} factor nearly cancels out the repulsive contribution[10].

TABLE IV
STATIC POLARIZABILITIES

b) Diacetylhydrazine. — The summation of r^{-6} and the static polarizabilities are given in Tables V and VI. The dispersion energy is 19.30 kcal./mole for summation within the 10 Å sphere (1064 terms) from "central atoms" and 0.39 kcal./mole for integration outside the sphere. The electrostatic contribtion to the total lattice energy was calculated by point charge model with unbalanced charges on C and O atoms, $\pm2.002\times10^{-10}$ c. g. s. e. s. u., estimated from the bond moment of C=O 2.50 D and the bond length 1.249 Å. The resultant energy was 1.15 kcal./mole, being repulsive. The total hydrogen bond energy is then about 6.06 kcal./mole or 3.03 kcal./mole for each bond.

Comparison of the energy of NH···O hydrogen bond.—In Table VII are summarized the energies of NH···O hydrogen bonds in crystals hitherto reported. In general the NH···O energies fall in a range of values between 3 and 6 kcal. and are in comparable magnitude with the energies of OH···O bands. However, from the point of view that the energy should decrease with increasing length of the bond, it seems hopeless to correlate the energies with the bond lengths in Table VII. This is partly due to the difference of the method of evaluation of the energy and partly due to relatively small contribution of hydrogen bonding forces to the total lattice forces. The situation is in a sense analogous to the evaluation of the resonance energy of conjugated molecules from the experimental heat of formation and the energy of a Kekulé structure.

b: Calculation of the dispersion and the electrostatic energies by use of theoretical formulae (point dipole model).
c: Calculation of the dispersion and electrostatic energies by use of theoretical formulae (point charge model).
* It is uncertain how many bonds there are per molecule.

The method **a** gives the hydrogen bond energy in which the energy required for the rearrangement of molecules from the structure of the isoelectronic crystal to the hydrogen-bonded structure is included. This rearrangement energy is quite analogous to the compression energy[11] and should differ from compound to compound. Thus this type of hydrogen bond energy does not represent the energy localized in the hydrogen bond but includes all the contributions to the change in the lattice energy that would be needed if the hydrogen-bonded structure were transformed into a non-bonded structure, i. e. the energy localized at the hydrogen bonds, the energy of electronic rearrangement within a molecule to make it non-polar within the crystal lattice and the energy for the change of crystal structure[12]. In other words, such "hydrogen bond energy" is a measure of how much gain in stability would result in a crystal as a whole by forming the hydrogen bonds compared with a hypothetical non-bonded structure.

The methods **b** and **c** are less unambiguous than the method **a** in that the former give the energy values in the approximation, the origin of which is less obscure. The estimation of the electrostatic energy is always a hard thing to do correctly; the point dipole model would be a very rough approximation in short-range interaction as in crystals and the charge distribution in crystal is rarely known except in cases of fully refined analysis of the crystal structures. Although the resultant contribution of the electrostatic energy to the total lattice energy is usually small, it is still so large as to affect the hydrogen bond energy value significantly.

The precision with which the dispersion energy is estimated by use of the Slater-Kirkwood formula depends primarily on the choice of the values for the static polarizability of atoms or atomic groups. We have some ground for believing that the calculated dispersion energy is a good measure to the actual interaction energy because we obtained relatively good agreement with the experimental heats of sublimation of nonpolar compounds as is shown in Table VIII. The difference between the calculated and the observed energies still amounts to a few kcal./mole which can not be ignored in comparison with the energy of a hydrogen bond. It may be concluded that the method of evaluating the energy of hydrogen bonds by subtracting contributions of other sources than the hydrogen bonds from the total lattice energy may be applied only to those crystals in which the hydrogen bonding plays an overwhelmingly important role in determining the crystal structure such as ice.

The lattice forces in relation to the crystal structure.—Only one of two hydrogen atoms in each NH_2 group participates in hydrogen bonding in sulfamide crystal. The closest approach between molecules is through the hydrogen bonds but their distance is longer than in diformlyhydrazine. Diformylhydrazine is probably the crystal possessing the shortest NH···O hydrogen bonds (2.788Å) ever known* and its closest approach in the crystal is through hydrogen bonds and not at the contact CH ···O between neighboring molecules (the non-bonded closest distance CH···O is 3.69 Å, which is longer than the sum of the van der Waals radii 3.4 Å). Therefore the equilibrium distance in the system NH···O would be 2.788 Å**. In sulfamide also, there is nothing hindering the neighboring molecules from approaching nearer and nevertheless its hydrogen bond is longer than in diformlyhydrazine. This may be explained by the difference in electronic configuration in these two compounds. In fact the infrared absorption spectrum of sulfamide, recorded with Hilgar Model H800 spectrometer, showed NH stretching absorptions at 3338 and 3248 cm^{-1} by the Daifloil mull method in comparison with about 3100 cm^{-1} in diformylhydrazine[14].

Sulfamide is a polar crystal with parallel orientation of molecular dipoles in the direction of the *c* axis. This may plausibly give rise to the spontaneous polarization of the crystal unless twinning masks the effect. An estimation of the spontaneous polarization gives about 44226 e. s. u. by using the dipole moment 3.9 D. This is surprisingly large polarization being in comparable magnitude with the case of ferroelectric barium titanate $BaTiO_3$ (the saturation polarization 48000 e. s. u.). The measurement of the polarization should give the value of the dipole moment of a molecule in the crystal, and a study along this line is now going on.

The heat of sublimation of diacetylhydrazine is by about one kcal./mole smaller than would be predicted by the additivity of lattice energies; the heat of sublimation of diformylhydrazine is 24.1 kcal./mole and an increment of about one kcal./mole may be predicted for the addition of a CH_2 unit*. The melting point 132°C and the density 1.35 are lower than 158°C and 1.59 of diformylhydrazine. Diacetylhydrazine is very hygroscopic and changes to the monohydrate in air under ordinary condition within an hour. Such properties are reflected on relatively weak hydrogen bonds in diacetylhydrazine. The fact that the electrostatic interaction is acting as repulsive** is somewhat surprising result

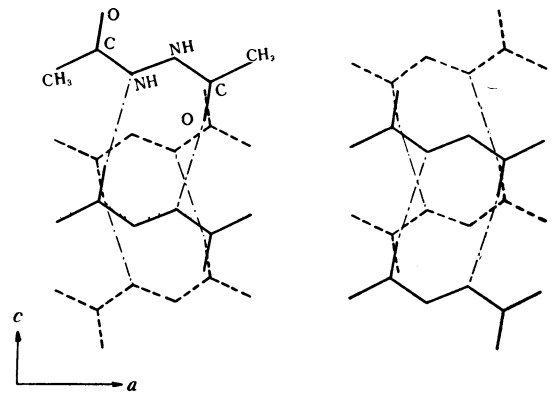

Fig. 1. The arrangement of diacetylhydrazine molecules projected along the *b* axis. Full line shows the molecules lying on *c* plane and dotted line shows molecules displaced halfway in *b*-direction. Hydrogen bonds are represented by chain lines.

13) J. H. de Boer, *Trans. Faraday Soc.*, **32**, 10 (1936).

* 2.75Å for NH···O bond was reported for amino acids or peptides (cf. H. L. Yakel and E. W. Hughes, *Acta Cryst.*, **7**, 291 (1954); R. A. Pasternak, L. Katz and R. B. Corey, Ibid,, **7**, 225 (1954)) but these are the bonds, $N^+H\cdots O^-$, between zwitterions.

** In ice and in solid and gaseous hydrogen fluoride there is nothing that hinders the molecules from getting nearer exceptthe inherent potential energy along the hydrogen bonds, so that the actual distances found 2.76Å and 2.55Å would correspond to the shortest approach in linear OH···O and FH···F systems, respectively, if other effects like conjugation do not greatly modify the electronic structure of the molecules. In other words the single minimum OH···O bond will not exist unless the hydrogen bond is very strongly conjugated with the molecular network.

14) T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec.*, (*Nippon Kagaku Zasshi*), **76**, 341 (1955).

* Mr. Hiroshi Suga of our laboratory has found a lambda-type phase transition of diacetylhydrazine at about 50°C with the heat of transition of probably less than one kcal./mole. In comparing the heats of sublimation of these two compounds the heat of transition must be considered and then the discrepancy would be much smaller. This transition, however, does not affect much the discussion on the hydrogen bond energy.

** Solid carbon dioxide is another example of repulsive electrostatic energy.

in view that the molecules are packed in layers so that C=O bonds are directing antiparallel, one over another (see Fig. 1). This is only a deceptive appearance in the arrangement and actually the lattice is mainly constructed by the dispersion forces.

Summary

The vapor pressures of crystalline sulfamide and diacetylhydrazine were measured between 347°K and 358°K and between 342°K and 353°K, with the results, $\log P = 11.047 - (5300/T)$ and $\log P = 12.195 - (5384/T)$, respectively. The heats of sublimation were found to be 24.25±0.24 kcal./mole and 24.63±0.39 kcal./mole, respectively. The hydrogen bond (NH···O) energies were evaluated by subtracting from the observed heat of sublimation the contribution of the dispersion energy (by Slater-Kirkwood formula) and the contribution of the electrostatic interaction energy. The latter contribution was obtained by adopting the point dipole model with the dipole moment 3.9 D (for sulfamide) and by adopting the point charge model with the charges ±2.002 e.s.u. at C and O atoms diacetylhydrazine). The NH···O energies were 4.7 kcal. and 3.0 kcal., respectively. The electrostatic interaction in diacetylhydrazine is repulsive. Critical discussions are given on the significance of the hydrogen bond energy values obtained by various methods. The inter-relation between the lattice forces and the packing of molecules in the crystals is discussed on the basis of the calculation of separated contributions to the lattice energy and it is shown that the principal forces, acting between diacetylhydrazine molecules are the dispersion forces and the antiparallel arrangement of C=O dipoles in crystal is only a deceptive appearance. It is suggested that the nearest approaches in the linear systems OH···O and FH···F are 2.76 Å and 2.55 Å, respectively, unless very strong conjugation with the molecular network occurs. The NH stretching modes of vibration in sulfamide absorb at 3338 and 3248 cm^{-1}.

The authors wish to express their sincere thanks to Professor I. Nitta for his interest and encouragement during the present series of works. The cost of the research was partly defrayed by the financial support of the Ministry of Education to which their thanks are also due.

Studies on the Graphitization II. Sub-structure and Crystallite Growth of Carbon Black

By Haruo KURODA and Hideo AKAMATU

(Received August 29, 1958)

The Graphitization is a process of crystallite growth and continuous improvement of the crystal structure of carbon to graphite with heat-treatment. The most powerful method of investigation is the X-ray diffraction by which not only the crystallite growth but also the ordering of crystal structure can be well defined[1].

In the previous paper[2], we have examined the graphitization of several kinds of carbon and found that petroleum-coke as well as coal-tar-coke are well graphitized, but carbon blacks are less graphitized with heat-treatment even in the same conditions. With heat-treatment up to 3000°C, the crystallites grow up to 444Å (L_a) for petroleum-coke and their lattice layers are stacked in graphitic orientation, while for Kosmos Carbon Black, for example, the crystallites grow to only

129Å and about 89 per cent of their layers still remains in disordered stacking. The strongest characteristic for carbon blacks is the fact that the crystallite growth does stop. L_a as well as L_c attain to a limited size respectively at about 2500°C, and these values depend on the original particle size of raw carbon blacks. It is widely known that the maximum value of layer diameter, L_a, is about one-third of the original particle size.

The results with both these cases of soft-cokes and carbon blacks, with violanthrone-coke and polyvinyl chloride-coke, show that there is a wide variety in graphitizability, and this should be attributed to the difference in micro-structures or sub-structures of these original cokes or carbons. In this paper, the sub-structures of carbon blacks and their change with heat-treatment will be discussed, from the results of investigation by means of X-ray small-angle scattering and electron microscopy. The sub-structures of soft-cokes will be discussed in the following paper.

Materials and Heat-Treatment.—Three kinds of commercial carbon black were used in the present investigation; Kosmos-15A (LFT, United Carbon Co.), Tokyo Gas Carbon (Tokyo Gas Co.) and Thermax (MT. Thermatomic Co.). The average particle size of Kosmos-15A is 400Å, that of Tokyo Gas Carbon 350Å, and that of Thermax 3000Å. The heat-treatment has been made in vacuo at several temperatures from 1000 to 3000°C. The data for crystallite size, by X-ray diffraction method, are summerized in Table I.

TABLE I
GROWTH OF CRYSTALLITE DIMENSION WITH HEAT-TREATMENT

	Temperature of H.T. (°C)	L_a(Å)	L_c(Å)

	1750	51.3	24.0
	2040	77.5	32.3
	2500	113	36.6
	3000	118	39.4
Thermax	original	38.5	17.0
	1500	47.5	20.2
	1900	78	73
	2500	326	152
	3000	320	177

The crystallite sizes are similar to one another in these original carbon blacks. This is the case even after being heat-treated below 2000°C. However, after being heated over 2000°C, where generally crystallite growth proceeds rapidly, the crystallite size of Thermax becomes much greater than that of the other blacks. The diffractometer records show that, for Kosmos and Tokyo Gas Carbon, (10) and (11)-diffraction still maintain the wedge-like profiles characteristic of the random orientation of layers even after heated to 3000°C, while for Thermax a remarkable modulation of the diffraction profile can be observed after being heated to 3000°C, and the ordering parameter shows that 50 per cent of layers are in the graphitic orientation.

X-Ray Small-Angle Scattering.—*Experimental.*—A X-ray small-angle scattering camera is designed[3] which consists of collimation system, specimen holder and camera body. The collimation system is made of metal tube with two apertures separated by 500 mm.. Several sizes of aperture are prepared; the smallest one is 0.09 mm. in width and 0.1 mm. in length. Each aperture is fixed on a holder which can be fitted to the collimator tube and is easily exchangeable with others without a rearrangement of setting. Thus we can use a selected pair of apertures. The specimen is packed into a circular cavity of 10 mm. diameter in a flat metal plate of 0.5 mm. thickness, and placed immediately behind the second aperture. The camera body is made of a metal tube with a film cassette at one end. The distance from specimen to film is 549 mm.. A beam stopper is placed in front of the film, the thickness of which is controlled so that the image of the direct beam can be registered faintly on the film. The apparatus is evacuated except for the specimen. Cu-K_α radiation filtered with a nickel foil is used.

About twenty diagrams are usually registered for each specimen, with various exposure times from 5 minutes to 20 hours and with different aperture sizes. Of a microphotometer trace, only a restricted range of the photographic density is used for an intensity curve, so that a linear relation can be assumed between the incident energy of X-rays and the corresponding photographic density. A series of intensity curves for each specimen are combined by graphical matching to a complete scattering angle.

Results. — The results for the heat-treated samples of Kosmos and Tokyo Gas Carbon are shown in Fig. 1 and Fig. 2, where the scattering intensity in logarithmic scale is plotted against the scattering angle.

The geometrical condition of our camera, using filtered X-rays, is not applicable to the correct investigation of a very small angle part. We omitted Thermax, since its particle size is too large and the

(A) original, (B) 1350°C, (C) 2100°C, (D) 3000°C.

important part of scattering is presumed to be in such a very small angle part.

It can be seen in Fig. 1 and Fig. 2 that the intensity increases in higher angle part as the heat treatment temperature is higher, while in the lower angle part no remarkable change or slight decrease in intensity is observed. It can be assumed qualitatively that the scattering at a higher angle is due to smaller particles or heterogeneity of smaller dimension, and at lower angle due to larger particles or heterogeneity of larger dimension.

The X-ray small-angle scattering by raw carbon blacks has been discussed in a previous paper[4], where it has been reasonablly interpreted by Porod's theory[5]. According to this theory, a parameter called the distance of heterogeneity, l_c, can be known from the observed intensity curve by means of the following integration,

$$l_c = \pi \int_0^\infty h \cdot I(h) \cdot \mathrm{d}h \Big/ \int_0^\infty h^2 \cdot I(h) \cdot \mathrm{d}h$$

where $h = 4\pi \sin\theta/\lambda$ at scattering angle of 2θ, with X-ray wave length λ, and $I(h)$ is the intensity at h. There is the following relation between the distance of heterogeneity and the average diameter of particle,

$$D = \frac{4}{3} l_c$$

when the system consists of spherical particles and the inter-particle interference is absent.

It has been revealed that in the case of raw carbon blacks, the average diameter of particles estimated from the above relation is in good agreement with the particle size observed by electron microscope. This is the case also for untreated samples of Kosmos and Tokyo Gas Carbon. Therefore, in raw carbon blacks, the structural unit which is responsible for the greater part of the observed scattering is an individual carbon black particle which is observed directly by electron microscope. In consequence, one can assume that each particle is made of homogeneous material density. This is true, however, in the first approximation. According to the theory, the scattering intensity is expected to be proportional to h^{-4} in the higher angle region, when a system consists of particles of homogeneous density. In the case of raw carbon blacks, the region in which $h^4 I(h)$ is nearly constant is observed as seen on curve a in Fig. 3. However, this is realized only in a limited region below a certain scattering angle, and beyond this angle the intensity deviates from the prediction of the theory. This deviation in the higher angle region is presumablly due to the heterogeneity of electron density in a particle.

The change in the parameter l_c with heat-treated temperature is illustrated in Table II. The value of this parameter decreases as heat treated temperature increases. However, the geometrical significance of this parameter is not so simply

TABLE II
CHANGE IN DISTANCE OF HETEROGENEITY WITH HEAT-TREATMENT.

	Temperature of H.T. (°C)	l_c (Å)
Kosmos-15A	original	289
	1325	281
	1570	243
	1950	230
	2500	215
Tokyo Gas	original	261
	1350	232
	2100	216
	3000	208

interpreted as in the case of raw carbon blacks. The decrease in the size parameter can not be attributed to the shrinkage of carbon black particles, since their shape and size do not change appreciably, by electron microscope, below 2000°C, and so also the density even after being heated up to 3000°C.

In Fig. 3 the plot of $h^4I(h)$ versus h is shown. Although a horizontal part is realized for the untreated sample, the deviation from the constancy of $h^4I(h)$ becomes more and more serious as heat treated temperature is higher. This is presumablly due to the advancement of heterogeneity in a particle. Thus, after being heated, the structure unit responsible for the observed scattering is not the individual particle, but the sub-structures which developed in the particle; the substructure made of crystallites which grow in the particle.

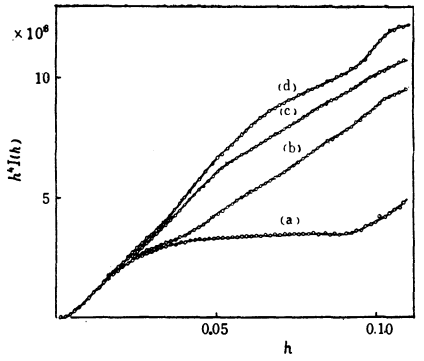

Fig. 3. Plot of $h^4I(h)$ versus h. Tokyo Gas Carbon Black.
(a) original, (b) 1325°C, (c) 2100°C, (d) 3000°C.

The distance of heterogeneity decreases as heat trated temperature is higher, while the crystallite size increases. Thus, at an extreme both these dimensions might approach each other. Neverthless, in reality they do not coincide with each other, since strong interference is likely to be present between crystallites.

In Fig. 4, $\log I(h)$ is plotted against $\log h$. On this curve, the inclination of the curve is illustrated, the value of which is around 2 or 3. This value indicates that the intensity of scattering by heated sample to above 2500°C is nearly proportional to the inverse of the second power of the scattering angle. It can be expected, when a system consists of plate-like particles, that the intensity will be proportional to the inverse of the second power of the scattering angle in a wide

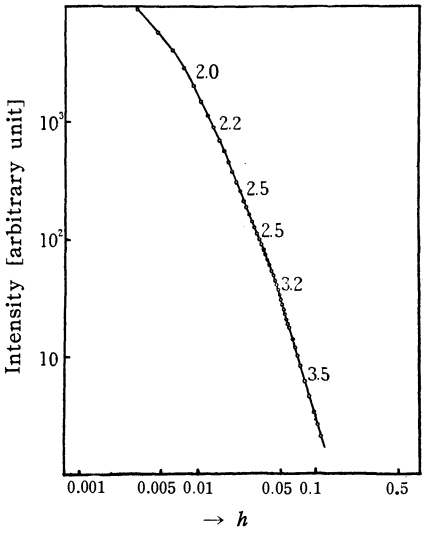

Fig. 4. $\log I(h)$ vs. $\log h$. Kosmos-15A heat-treated to 2500°C.

range[6]. One can conclude that the most part of the observed scattering for a heated sample above 2500°C is caused by crystallites which have a plate-like shape.

The results from X-ray small-angle scattering leads to the following conclusion. A particle of raw carbon black is made of nearly homogeneous density. With heat-treatment, sub-structures develop to plate-like crystallites; at an extreme, however, the carbon black particle does not grow to a large crystalline unit but splits into smaller crystalline units. These small crystallites are quite independent of each other, as each of them can be the center of scattering, but they are still in aggregation so tightly that interference between them is sure to be strong.

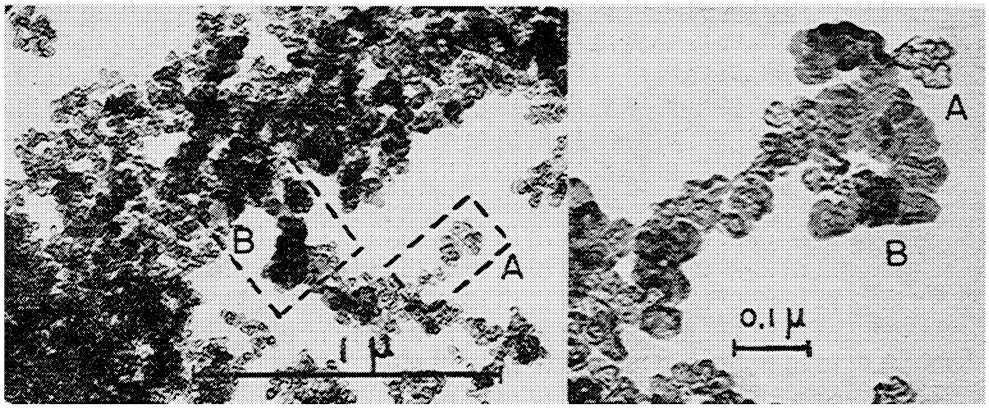

Fig. 5. Electron Micrograph of Tokyo Gas Carbon Black, heated to 3000°C. (Unshadowed).

Electron Microscopic Observation.— *Experimental.* — Electron micrographs were made with Hitachi Electron Microscope, Model-10-A. Special precautions are required to observe the details of structure, with high resolution as well as contrast, of such a minute particle as carbon black. Recently, Sakata[7] in our laboratory has developed a technique of making a collodion grid, whose pore size is one micron or less. This is called micro-grid. One can spread over a micro-grid a very thin collodion film, less than 50A in thickness. The specimen is mounted on this thin film. Thus, the undesirable effects from mounting the film is avoidable to a great extent. Experimental procedures were conducted so as to reduce the effects of contamination[8] to the minimum.

Results.—The electron micrographs show that the appearance of particles does not change appreciably when the heat treated temperature is lower than 2000°C ; particles keep their spherical shape, the average size being similar to those of untreated carbon black. Only a slight change of contrast is seen in the inner part of images of particles. However, after being heated up to 2500°C, the particles suddenly show a completely different appearance. This will be seen in Fig. 5. In these figures, one can see two modes of particle shape. Some particles have very irregular contours and are transparent to an electron beam. These are shown in the region lettered A. Other particles have rather round outlines and are less transparent to an electron beam. These can be seen in the region lettered B. The particles of mode-A have plate-like shape with sharp edges. The particle size is nearly 100 A, which is comparable to the crystallite size determined from X-ray diffraction pattern. Each of these minute particles might be a crystallite. The particles of mode-B show a heterogeneity of density ; the inner part is more transparent than the peripheral part, which suggests a hollow structure of particle. They consist of minute grains whose size is also comparable to the crystallite size. These facts indicate that a particle of mode-B is a shell-like cluster of crystallites, with a loose packing in the inner part. Such a structure is presumably not different from the structure of heat-treated Thermax. It can be easily presumed that particles of mode-A are produced by disintegration from particles of mode-B.

Thermax is most advantageous for electron microscopic observation, for the particle size is very large. The electron micrographs of heat-treated Thermax have been presented by Ragoss, Hoffman and Holst[9], and by Kmetko[10]. Kmetko has given a polyhedron model of graphitized carbon black particles, based on electron microscopic observation by replica technique. In the present investigation, we used a high accelerating potential, 10 kV, in operating the electron microscope. This gives a clear internal structure of particles. Some typical micrographs are illustrated in Fig. 6, 7 and 8.

Below 1500°C of heat treated temperature, no appreciable change can be seen. However, at this temperature, fine contrast is seen in the images. This fine contrast develops to dark radiated strips along the periphery of particle as heat treated temperature is higher. Finally, above 2500°C, the dark strips grow up to trigonal or trapezoidal dark patterns. The

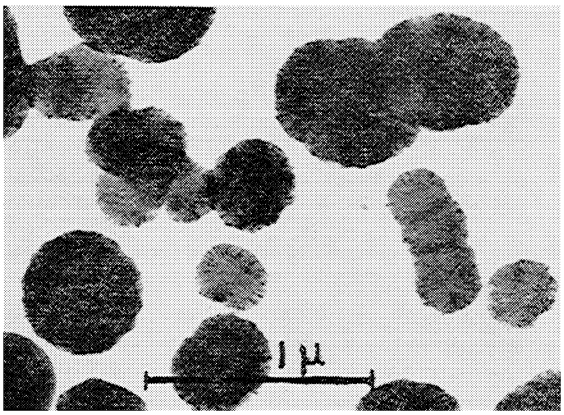

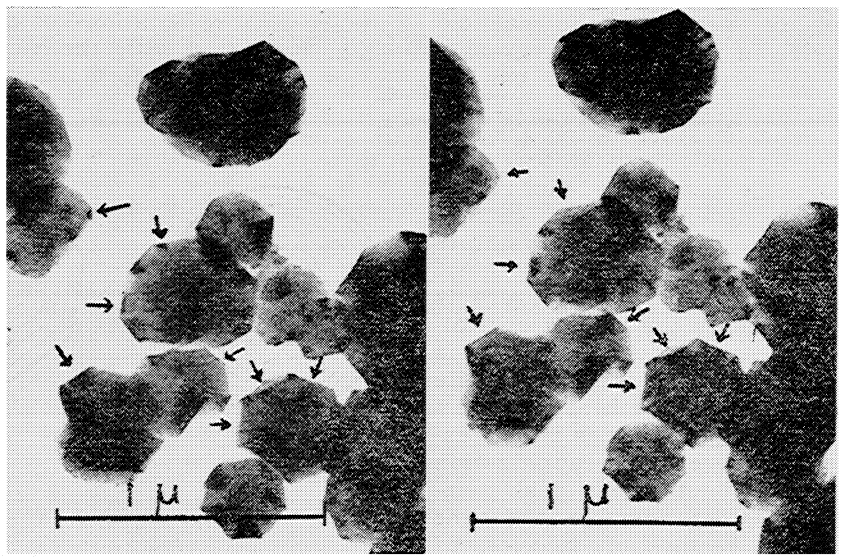

Fig. 7. Thermax heated at 1900°C.

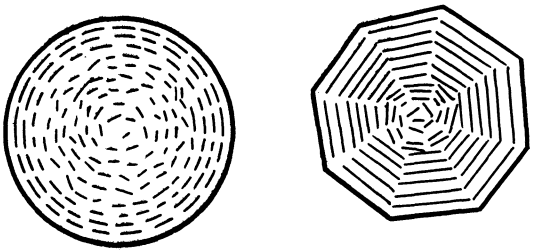
bases of trigons or trapezoids coincide with the edges of the polygonal outlines of the particles. These dark patterns are not due to the difference in thickness of material, but are produced by the diffraction effect. This is illustrated in two micrographs (a) and (b) of Fig. 8. Both the micrographs were made from the same field, but made with different inclination to incident beam by 12°. The dark patterns in each particle change the shape, or disappear, depending sensitively on the direction of incident beam. This is indicated by arrows. It can be easily presumed that these dark patterns are due to (002)-diffractions by the graphite-like crystals. This leads to the conclusion that crystallites are orientated with their c-axes being in the direction normal to the particle surface. The length of edges of the polygonal outlines is in the order of 1000Å, which is only a few times that of L_a-dimension determined by X-ray diffraction. Therefore, the area corresponding to each dark pattern might be a single crystal or a cluster made of a few crystallites with a common direction of their c-axes.

Discussion

Carbon black is deposited from a gas phase in the process of incomplete combustion or thermal decomposition of hydrocarbon gas or vapor. The resulting solid

(a) (b)

Fig. 8. Thermax heated at 3000°C.
(a) and (b) were made from the same field with different directon to incident beam by 12°. The dark patterns in each images are slightly different in (a) and (b).



particles consist mainly of turbostratic carbon crystallites. However, the spheroidal shape suggests that the particles are in a fluid-state when they are produced at a higher temperature. The X-ray small-angle scattering by raw carbon black indicates that the material density is nearly homogeneous in the particle. The minute turbostratic crystallites may be imbedded among heavy hydrocarbon molecules or cross-linkages of disorganized carbon atoms. However, alignment of minute crystallites would not be at random, but may be in a preferential orientation. As this is due to the effective action of surface tension, which is responsible for the spheroidal shape, the preferential orientation should be most effectively conducted along the surface of the particle, with the basal planes of crystallites being tangent to the surface. Hall[11] found indications of such a preferential orientation at the surface of a raw carbon black. The schematic diagram of such a model is illustrated in Fig. 9, A.

In the process of heat-treatment, minute crystallites grow by the condensation process at the expense of the disorganized carbon atoms with liberating hydrogen. Meanwhile, the alignment of crystallites will be further improved. The crystallite growth proceeds mainly in such a way in an early stage of heat-treatment, presumablly below 1500°C. The rate of growth is not different between smaller particles and larger ones. No appreciable change can be seen in the particle shape nor size in electron micrographs, excepting a fine structure which can be seen in images of large particles of Thermax, which indicate rather clearly the preferential orientation of crystallites. The X-ray small-angle scattering can reveal the continuous development of heterogeneity which results from the crystallite growth.

When the heat treated temperature is over 2000°C, suddenly the rate of crystallite growth is greatly advanced. This is so, when the particle size is greater, while in small particles the growth attains very rapidly to a limited size. It is widely experienced that the degree of graphitization is primarily dependent on the peak temperature, but less dependent on the time of soaking. The remarkably accelerated rate of crystallite growth at the higher temperature demands an explanation other than the mechangism mentioned above.

At this stage, the condensation process has been completed, leaving slight defects or distortions between neighboring crystallites. As the crystallites are in such an alignment in that their c-axes are in nearly the same direction among neighbors, they can easily be further rearranged with their c-axes in completely the same direction. This leads to the growth of crystallites, not accompanied by mass transfer nor the work of breaking bonds. The intermediate state is a cluster. The rearrangement would be forced thermally to relax the stresses caused from the distortions.

At a temperature higher than 2000°C, a plastic deformation or creep is known for carbons, therefore, the thermal relaxation would be advanced only at a higher temperature. Mrozowski[12] proposed a driving force of the crystallite growth, which is the anisotropic expansion of crystallites along c-axes. This leads to the creation of local stresses which lead to and become relieved by the growth and rearrangement of crystallites. This process, however, would be practically effective if the crystallites are in alignment in such a manner as mentioned above. The crystallite growth would be accelerated along the surface of the particle in preference to the inner part, as the alignment would be found primarily along the surface. This is what we observed. Thus, the polyhedral particle will result from the preferential orientation of crystallites, which developed with their c-axes being in the direction of normal to the surface. The schematic diagram is given in Fig. 9, B.

A B

Fig. 9. Schematic diagram of alignment of crystallites in a carbon black particle. (A) before heat-treatment, (B) after heat-treatment.

11) C. E. Hall, *J. Appl. Phys.*, **19**, 271 (1948).

12) S. Mrozowski, "Proceeding of 1st. and 2nd. Conferences on Carbon", University of Buffalo, 31 (1956).

As the crystallite growth proceeds in this way, however, the mutual relation between the neighbors becomes different from the alignment mentioned above. This is easily seen when one compares the diagram (A) with (B). Moreover, great stresses would be stored up between crystallites, especially when the anisotropic expansion of crystallites are made at a higher temperature. We observed, for Tokyo Gas Carbon heated to 3000°C, a remarkably asymmetrical profile of (002)-diffraction, which suggests the presence of a large distorsion in lattice.

In this stage, the scheme proposed by Mrozowski must be modified, but becomes rather more important. When the stresses become too great, they are not likely to be relieved practically and the rearrangements of crystallites are not likely to be realized. There is no place for the energy dissipation within the particle, and this is the characteristic for carbon blacks which differ from soft-cokes. This would be so, as the size or the mass of a particle is smaller. Thus, the limited size of crystallite growth would be proportional to the original particle size. The result which would be expected from the further heattreatment is disintegration or rather bursting into individual crystallites, as this is the only way to relieve the stored stresses. This is the case we observed in the case of the small particles of Kosmos-15A and Tokyo Gas Carbon Black.

As the crystallites grow by the mechanism discussed, the turbostratic structures still remain unimproved. It is believed that the crystallite growth proceeds in advance of ordering of crystal structure. The crystal structure will be improved by the rearrangement of layers as pairs of the nearest neighboring layers take on graphitic orientation. The mechanism would not be far from that discussed above. However, this process begins when the layer diameter, L_a reaches a value of about 150Å. For small particies, the growth of crystallites stops for the reason discussed above, even when less than 150Å. In consequence, the crystal structure can not be improved. This is the reason why one can not make graphitization of carbon blacks with small particle size. A similar argument can be extended to hard carbons. The graphitization is primarily dependent on the sub-structures of raw materials.

Summary

The sub-structures of carbon black and its change with heat-treatment have been investigated by means of X-ray small-angle scattering and electron microscopy.

With heat-treatment, the X-ray small-angle scattering intensity increases in the higher angle region, indicating the development of heterogeneous sub-structures to minute crystallites. Above 2000°C, the crystallite growth is rapidly accelerated, and at an extreme, a carbon black particle disintegrated to smaller crystalline units. Electron microscopic observations, especially for Thermax which has a large particle size, revealed that the crystallites are in alignment with their c-axes being in the direction of normal to the particle surface. This alignment leads to the polyhedral shape of the heat-treated particles. From these observations, the sub-structures and the mechanism of crystallite growth in carbon black particles have been discussed.

This investigation is a part of the research project for carbons, which is supported by Committee 117 in Nippon Gakujutsu Shinkokai, and the expense has been defrayed in part from a grant given by the Ministry of Education, for which the authors' thanks are due.

Polarographic Studies of Metallic Complexes. IV.[1] *Bisethylenediamine Series of Cobalt(III) Complexes*[2]

By Nobufumi MAKI, Yoichi SHIMURA and Ryutaro TSUCHIDA

(Received August 13, 1958)

There have been reported, heretofore, some polarographic studies on the ethylenediaminecobalt(III) complexes[3-10]. Holtzclaw et al.[3-5] studied several kinds of *cis*- and *trans*-bisethylenediaminecobalt (III) complex and found that the *trans*-isomer having two negative ligands in its coordination sphere exhibits a little more negative half-wave potential than the corresponding *cis*-isomer. This fact was explained as being due to the stabilization of the complex compound by the trans effect of the two negative ligands. On the other hand the *trans*-isomer containing one or two neutral ligands in its coordination sphere showed almost the same half-wave potential as the corresponding *cis*-isomer.

As regards the reduction wave of tris-ethylenediaminecobalt(III) ion, Kivalo[8] and Laitinen et al.[7] obtained the following results. The ion, $[Co\ en_3]^{3+}$, is reduced reversibly to $[Co\ en_3]^{2+}$ ion in the presence of an excess of 0.1~0.5 F ethylenediamine. ($E_{1/2} = -0.456$ V. vs. S.C.E) However, in the absence of an excess of ethylenediamine the irreversible wave of $[Co\ en_3]^{3+}$ was given. This fact was considered to be due to the following reason. The apparent irreversibility of the reduction is due to the aquation of the reduction product, or to the decrease in the coordination number of cobalt(II) complex ion, though the electron transfer reaction for $[Co\ en_3]^{3+} + e^- \rightarrow [Co\ en_3]^{2+}$ is fast enough to be reversible. While the reversible electrode reaction in the presence of excessive ethylenediamine was explained as being due to the existence of the stable ion, $[Co\ en_3]^{2+}$, which is in equilibrium with an excess of ethylenediamine, being different from the reduction product of hexamminecobalt(III) ion. The latter ion gave an irreversible wave, even if an excess of ammonia was present in solution.

However, Doležal[9] obtained a somewhat different result recently. Namely, his polarographic and oscillopolarographic studies showed that the redox system, $[Co\ en_3]^{3+}/[Co\ en_3]^{2+}$, is not perfectly reversible. It was found that the difference of the half-wave potentials between the anodic and the cathodic wave was 30 mV. under equal conditions. The dependence of the cathodic wave on the pH value of the solution and on the concentration of ethylenediamine and of gelatin was also different from that of the anodic wave. The anodic wave approaches reversibility more perfectly than the cathodic wave.

In the previous work of this series[1] the present authors determined the order of the polarographic stability for the cobalt (III) complexes of pentammine series, $[Co(NH_3)_5X]$. For the same purpose, a comparison of the half-wave potentials of the first waves has been carried out for the cobalt(III) complexes of bis-ethylenediamine series, $[Co\ en_2X_2]$ or $[Co\ en_2Y]$. The polarographic behavior of these complexes has also been dealt with in the present paper.

Experimental

Apparatus.—A Yanagimoto model 104 polarograph with the sensitivity of galvanometer of $2\times10^{-9}\mu$A/mm./m. was used. For the accurate evaluation of curves and half-wave potentials the method described previously was used[10]. As an electrolysis cell an H-type vessel with a saturated calomel electrode was employed. The capillary used had a rate of flow of mercury, 0.615 mg./sec. and a drop time of 7.42~6.98 sec./drop in the solution of 0.5 F potassium sulfate and of 0.1 F potassium chloride at an open circuit with a mercury head of 65.5 cm.. The capillary was

connected to the mercury reservoir by a tube of polyvinylchloride. All the measurements were made at 25±0.1°C, the temperature being maintained by a water thermostat. The reversibility of the electrode reaction was examined by determining the slope of $\log i/(i_d-i)$ vs. potential. Slopes of the log plots indicated irreversible reaction throughout.

Material.—The complex compounds studied were prepared by the method described in literature[11-27,30]. (The references are given in Tables I, II and III.) Each solution for the electrolysis was made freshly from the dry crystalline cobalt(III) complexes before use and the polarographic measurements were made as soon as possible after the removal of oxygen. The concentration of the solution was 0.001 gram complex ion per liter.

In order to remove the dissolved oxygen, a vigorous stream of nitrogen which was purified from oxygen by means of an alkaline solution of pyrogallol, was passed through the cell solution for an hour prior to each electrolysis, preventing the evaporation.

In order to compare the half-wave potentials with each other, no maximum suppressor was used, because its presence at the concentration which is enough to suppress the maxima of the second waves of bisethylenediaminecobalt(III) complxes, causes lowering of the diffusion current, shift of the half-wave potential of the first wave towards negative direction, and sometimes deformation of the wave. The supporting electrolytes used are 0.5 F potassium sulfate and 0.1 F potassium chloride.

Results and Discussion

In Tables I and II are shown the half-wave potentials of the cobalt(III) complexes of bisethylenediamine series.

All the compounds are reduced irreversibly in two steps at the dropping mercury electrode in the solution of 0.1 F potassium chloride or 0.5 F potassium sulfate except the case of the complexes which aquate easily in solution. The complex ions such as $[Co\ en_2S_2O_3]^+$, $[Co\ en_2gly]^{2+}$*, $[Co\ en_2leuc]^{2+}$* show two waves in 0.5 F potassium sulfate at the potential corresponding to the reduction of cobalt(III) → cobalt(II). The height of the second wave was very close to twice that of the first wave in the presence of Tween-80**, a maximum suppressor. The height of the first wave was proportional to the concentration of the complex ion in the range of the concentration $1\times10^{-2}\sim5\times10^{-4}$ F. In the case of the mixed solution of a complex ion and its aquated species, the total height of the waves of the original ion and of the aquated species was roughly proportional to the original concentration of the cobalt(III) complex. Hence, the first wave, corresponding to a gain of one electron, represents the reduction of cobalt(III) to cobalt(II) and the second, corresponding to two electrons, represents the reduction of cobalt(II) to metallic state.

In the solution of a non-complexing supporting electrolyte such as potassium chloride or potassium sulfate, the reduction processes of bisethylenediaminecobalt(III) complexes are considered to be in the following:

$$[Co\ en_2X_2]^{(3-2n)+}+e^-\rightarrow[Co\ en_2X_2]^{(2-2n)+}$$

$$[Co\ en_2X_2]^{(2-2n)+}+mH_2O\rightarrow\begin{cases}[Co\ en_2(OH_2)_2]^{2+}+2X^{n-}\\ [Co\ en_2(OH_2)X]^{(2-n)+}+X^{n-}\\ [Co\ en(OH_2)_4]^{2+}+2X^{n-}+en\\ \text{etc., etc.}\end{cases}$$

$$[Co\ en_2(OH_2)_2]^{2+}+2e^-\rightarrow Co+2H_2O+2en$$

$$[Co\ en_2(OH_2)X]^{(2-n)+}+2e^-\rightarrow Co+H_2O+X^{n-}+2en$$

$$[Co\ en(OH_2)_4]^{2+}+2e^-\rightarrow Co+4H_2O+en\ \text{etc.}$$

From the scheme of the reduction processes, it may be seen that the first step in the polarographic reduction of these cobalt(III) complexes corresponds to the disruption of the cobalt(III) complexes, resulting in the formation of aquo-ethylenediaminecobalt(II) ions such as $[Co\ en_2(OH_2)_2]^{2+}$, $[Co\ en_2(OH_2)X]^{(2-n)+}$ and $[Co\ en(OH_2)_4]^{2+}$, so its half-wave potential may be regarded as a measure of the stability toward polarographic reduction.

* The waves of the original complex ion and of the aquated species are so near located that both the waves cannot be discriminated one another. However, it was noticed that the half-wave potential shifted towards negative direction with the decreasing concentration due to the aquation of the complex ion.
** Maximum wave.
*** The data obtained in the presence of 0.0016% Tween-80.
**** The data obtained in the solution of 1 F $(NH_4)_2C_2O_4$.

The polarographic stability of the cobalt (III) complexes of [Co en_2X_2] type increases in the following order of the ligand X;

$Br^-, Cl^- < NCS^- < NO_2^- < NH_3 < OH_2 < CN^-$

(Supporting electrolyte; 0.5 F K_2SO_4)

The same order was also obtained in 0.1 F potassium chloride. For the complexes of [Co en_2X_2] type the difference of the half-wave potentials between *cis*- and *trans*-isomer is far smaller than that among the other kinds of the complex of this series, hence the difference between *cis*- and *trans*-isomer need not be taken

into consideration in this case.

The order of stability of [Co en_2Y] type complexes was in the following order of the ligands;

$leuc^- < ox^{2-} < gly^- < SO_3^{2-} < CO_3^{2-} < en$

(0.5 F K_2SO_4 or 0.1 F KCl as supporting electrolyte)

No relation between the above orders of the polarographic stability and that of the spectrochemical series[28] could be found in accordance with the result obtained in the previous paper[1].

Polarographic Behavior of Individual Complexes.—The second waves of all the bisethylenediaminecobalt(III) complexes indicated the maxima which could be suppressed by the maximum suppressor, Tween-80, except the case of dicyanobis-

ethylenediaminecobalt(III) ion, [Co $en_2(CN)_2]^+$. Trisethylenediaminecobalt(III) and monoethylenediamine-tetramminecobalt(III) ions have also the maxima in the second step of the reduction, which was reported briefly in an earlier communication[10]. Therefore, it can be said that all the cobalt(III) complexes containing one or more ethylenediamine in their coordination sphere show the maxima at the second wave corresponding to the reduction for Co(II)→Co(0).

Figs. 1 and 2 show the polarograms of *cis*- and *trans*-diisothiocyanato-bisethylenediaminecobalt(III) ions, $[Co\ en_2(NCS)_2]^+$, respectively. It is expected that these ions aquate to some extent in solution. In fact, for *trans*-$[Co\ en_2(NCS)_2]^+$ ion, the small maximum wave was given at around −0.4 V. (vs. S. C. E.), which could be suppressed in the presence of 0.0016% Tween-80. The half-wave potential of this small wave is near to that of diaquobisethylenediamine-cobalt(III) ion, $[Co\ en_2(OH_2)_2]^{3+}$. ($E_{1/2} = -0.44$ V. vs. S. C. E. in 0.1 F KCl) Therefore, this small wave is considered to correspond to the reduction wave of the aquated species such as $[Co\ en_2(NCS)OH_2]^{2+}$ and $[Co\ en_2(OH_2)_2]^{3+}$. Similarly, for *cis*-$[Co\ en_2(NCS)_2]^+$ ion, the small wave of the aquated cobalt(III) ions was given at around −0.51 V. (vs. S. C. E.)

28) Y. Shimura and R. Tsuchida, ibid., **29**, 311 (1956).

in a solution of 0.5 F potassium sulfate. The half-wave potential of $[Co\ en_2(OH_2)_2]^{3+}$ ion is −0.50 V. in 0.5 F potassium sulfate.

In a dilute supporting electrolyte, a similar wave of the aquated cobalt(III) complex ions was found for the following ions;

$[Co\ en_2Cl_2]^+$, $[Co\ en_2Br_2]^+$
$[Co\ en_2(NCS)_2]^+$, $[Co\ en_2ox]^+$
$[Co\ en_2gly]^{2+}$, $[Co\ en_2S_2O_3]^+$
$[Co\ en_2(CN)_2]^+$

Among these ions it was noticed that the height of the wave of the aquated species increases gradually with time for some complex ions, but does not for the others. This is considered to be due to the variety of the rate of the aquation. Namely, the aquation of some ions is comparatively slow, compared with the time of the polarographic measurement, while for the others, the aquation is so rapid that the usual polarographic method can not detect and trace the change of the height of the wave. The ions, $[Co\ en_2(CN)_2]^+$, $[Co\ en_2SO_3]^+$ belong to the former and the ions, $[Co\ en_2Cl_2]^+$, $[Co\ en_2Br_2]^+$ to the latter.

In a solution of 0.1 F potassium chloride dicyano-bisethylenediaminecobalt(III) ion,

b) In the solution of 0.1 F KCl
Sensitivity; 0.04 μA/mm., Damping; 100

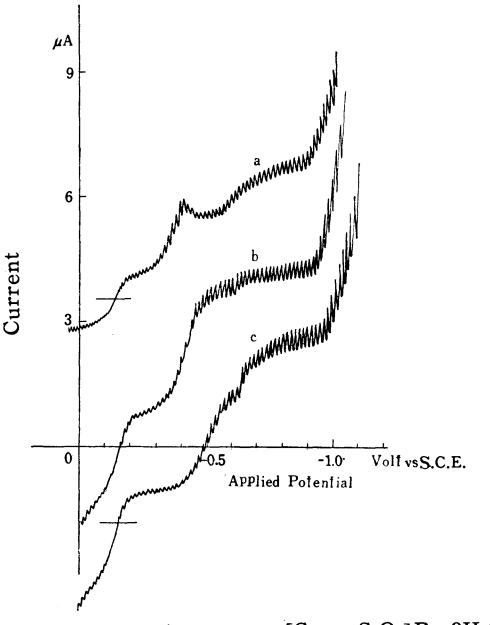

Fig. 4. The polarograms $[Co\ en_2S_2O_3]Br \cdot 3H_2O$.
a) obtained at the concentration of 0.001 F complex ion in the solution of 0.1 F KCl
b) obtained at the concentration of 0.005 F complex ion in the solution of 0.1 F KCl
c) obtained at the concentration of 0.005 F complex ion in the solution of 0.5 F K_2SO_4
Sensitivity; 0.06 μA/mm., Damping; 200

$[Co\ en_2(CN)_2]^+$ showed the wave of the aquated complexes at around −0.80 V., but did not show anything in 0.5 F potassium sulfate. It seemed that the wave of the aquated species was probably covered by the wave of the original ion in the solution of potassium sulfate, because the waves of the original and the aquated ions were located very near to each other. The reduction potential of the aquated ions of $[Co\ en_2(CN)_2]^+$ did not coincide with that of $[Co\ en_2(OH_2)_2]^{3+}$ ion, so it is considered that the main species of the aquated ions is a partly aquated complex ion, $[Co\ en_2(CN)OH_2]^{2+}$. (Fig. 3)

In 0.1 F potassium chloride, thiosulfato-bisethylenediaminecobalt(III) ion, $[Co\ en_2S_2O_3]^+$ has the small maximum wave which could be suppressed in the presence of 0.0016% Tween-80. (Fig. 4) The half-wave potential of the first wave of this ion could not be determined owing to the interference of the anodic wave of the thiosulfate ion liberated from the original complex by the aquation.

Fig. 5 shows the polarogram of the first wave of *cis*-diaquo-bisethylenediaminecobalt(III) ion, $[Co\ en_2(OH_2)_2]^{3+}$ in 0.5 F potassium sulfate. The wave has always

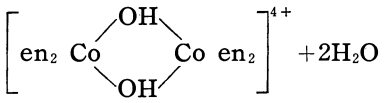
$E_{1/2}=-0.01$ V. (vs. S. C. E.)
$i_d=2.09$ μA.

a slower slope at the half-wave potential than that of the other complex ions of bisethylenediamine series. A gradually rising current near the zero potential was observed. However, it can not necessarily be said that this current is a residual current, since the diffussion current reaches a plateau parallel to the axis of the potential. (Usually, the diffusion current, runs parallel to the residual current, not to the axis of the potential.) Moreover in 1 F perchloric acid, a well-defined wave is obtained, which has a steep slope at the half-wave potential. (Fig. 6) One of the reasons for this is the presence of an equilibrium between the aquo-bisethylenediaminecobalt(III) ion and hydroxo-bisethylenediaminecobalt(III) ion.



$$[Co\ en_2(OH_2)_2]^{3+} \rightleftarrows [Co\ en_2(OH_2)OH]^{2+} + H^+$$

$$[Co\ en_2(OH_2)OH]^{2+} \rightleftarrows [Co\ en_2(OH)_2]^{+} + H^+$$

In perchloric acid the above equilibrium is markedly shifted to the left hand. Consequently, the steep wave of diaquo-bisethylenediaminecobalt(III) ion could be obtained.

Another reason for this is the polymerization of diaquo-bisethylenediaminecobalt (III) ion in neutral solution. Namely, as verified by the spectrochemical studies of Rasmussen et al.[29], various kinds of polynuclear cobalt(III) complex are formed in solution. For instance,

2 *cis*-$[Co\ en_2(OH_2)OH]^{2+} \rightarrow$

It is also considered that in perchloric acid, the polymerization is inhibited due to the presence of an overwhelming

hydrogen ion. Consequently, only the original ion is present in solution. Therefore, the steep well-defined wave of this ion was obtained in perchloric acid.

A similar behavior was observed for the aquo-ammine cobalt(III) complexes, which were shown in Table III.

Summary

1. Most of the cobalt(III) complex ions of bisethylenediamine series, $[Co\ en_2X_2]^{(3-2n)+}$ or $[Co\ en_2Y]^{(3-m)+}$ are reduced irreversibly in two steps at the dropping mercury electrode. The first diffusion current corresponds to the reduction, Co(III)→Co(II) and the second to the reduction, Co(II)→Co(0). The second step always exhibits the maximum wave.

2. The polarographic stability of $[Co\ en_2X_2]$ type complexes increases in the following order of the ligands;

Br^-, $Cl^- < NCS^- < NO_2^- < NH_3 < OH_2 < CN^-$

(Supporting electrolyte; 0.5 F K_2SO_4)

Similarly, the order of the stability of $[Co\ en_2Y]$ type complexes is as follows;

$leuc^- < ox^{2-} < gly^- < SO_3^{2-} < CO_3^{2-} <$ en

(Supporting electrolyte; 0.5 F K_2SO_4)

These orders are independent of the kind of supporting electrolyte such as potassium chloride or potassium sulfate. The orders of the polarographic stability did not agree with that of the spectrochemical series.

3. In perchloric acid the well-defined wave of steep slope was obtained for diaquo-bisethylenediaminecobalt(III) ion, $[Co\ en_2(OH_2)_2]^{3+}$, while the ion gave a modified wave in the neutral solution of 0.1 F potassium chloride and of 0.5 F potassium sulfate. This phenomena was explained as being due to the inhibition of the dissociation and polymerization of the complex in the presence of an overwhelming hydrogen ion. A similar behavior was observed in the aquo-ammine cobalt (III) complexes.

*A Note on the Proton Magnetic Resonance Spectra of Some Thiophene Derivatives**

By Kensuke TAKAHASHI, Yasuo MATSUKI, Tatsuo MASHIKO and Genjiro HAZATO

(Received August 19, 1958)

High resolution magnetic resonance spectra of the aromatic ring protons for a large number of substituted benzenes have at times been studied by several authors[1], but no available data were obtained for substituted thiophenes except for 2-bromo-5-chlorothiophene[2]. Here we present the experimental results and preliminary discussions on the proton magnetic resonance spectra of several thiophene derivatives. With respect to the number of the ring protons, they are less by two than the corresponding benzene derivatives, and so the spectra of mono-, di- and tri-substituted thiophenes are generally expected to show the structure of three quartets, two doublets and one singlet respectively. The analyses are simple for the ring protons of di- and tri-substituted thiophenes but more complicated for mono-substituted ones, and they will be discussed here qualitatively.

Experimental

The basic theory and experimental details of n-m-r measurements have been described by several authors in excellent articles, so they will not be given here.

* Presented partly at the 11th Annual Meeting of the Chemical Society of Japan, held on April 4, 1958, at Tokyo.

Materials.—All thiophene derivatives used in the present observations were synthesized by Y. M. and T. M., the details of the procedure will soon be published in the Journal of the Chemical Society of Japan, Ind. Chem. Sec..

Procedure and Apparatus. — The apparatus used in this research is a Bloch-type high resolution n-m-r spectrometer (Model V-4300B), purchased from Varian Associates, Palo Alto, California. Proton resonances were observed at a fixed frequency of 40 mc./sec. and the corresponding magnetic fields in the neighborhood of 9400 gauss.

The chemical shifts were read from the signals recorded with a Sanborn Model 127 Recorder, comparing with the shift of 227 cps for benzene-cyclohexane mixture, 1 : 1 by volume, as a reference, and the values given here are the averages, usually from about three recordings, and the small values were calibrated by running acetaldehyde, with its known splitting of 2.85 cps.

The values of chemical shift will not be sensitive to the presence of small amounts of impurities, especially in the case of C-H bonds, so that the samples were used after several times distillations or recrystallizations without any other special procedures of purification.

Samples which are solid at room temperature were measured in the super-cooled conditions after being heated above their melting points or dissolved in carbon tetrachloride. In such a case, it should be kept in mind that the occurrence of the additional shift due to the concentration effect or the molecular interaction is possible, so that the measured conditions are given in Table I.

Additional errors do not result from neglecting the bulk diamagnetic susceptibility corrections by using cyclohexane as a internal reference. Another error results from the difference of the reference concentration, but it is assumed that this error is small[3]. In some compounds, especially in 2-bromothiophene and in thiophene itself, it was observed that the line shapes were slightly changed with the variation of the concentration of the reference compound.

The results were reproducible within the deviation of about 4 cps.

Results and Discussion

Table of Chemical Shifts.—The chemical shifts of the ring protons obtained from the twenty-two compounds are given in Table II, in cps, indicating the separations from the cyclohexane signal, the larger value showing the lower field side. In the case where the signal is split by the indirect spin-spin interaction, the shift given here is that for the center of the resonance pattern. As for 2-methyl-, 3-methyl- and 2-bromothiophene, the assignments of their spectra are not given in Table II and they will be discussed in the latter paragraph of monosubstituted thiophenes.

Indirect Spin-Spin Coupling Constants.—The indirect spin-spin coupling constants (J) for disubstituted thiophenes are given in Table III in cps, obtained by reading the scales of their spectra. In monosubstituted thiophenes, however, there are three independent coupling constants, the reasonable values of which can not be determined without theoretical calculations referring to the multiplet structure.

TABLE III

THE COUPLING CONSTANT (J) AND THE CHEMICAL SHIFT (δ) OF TWO RING PROTONS IN DISUBSTITUTED THIOPHENES IN CPS AT 40 mc./sec.

Substituent	J	δ
2,3-$(CH_3)_2$	5.2	5.9

2,5-$(NO_2)_2$		0
2,5-$(SO_2Cl)_2$		0

* from Anderson's value[2].

The mean value (5.4 cps) of the indirect coupling constants between the 4- and 5-positioned protons (J_{45}) for three compounds, i.e. 2,3-dimethyl-, 2-bromo-3-methylthiophene and 3-methylthiophene-2-sulfonylchloride, is greater than the mean value of J_{34} (4.0 cps) for two compounds, 5-methylthiophene-2-sulfonylchloride and 2-bromo-5-chlorothiophene. The values of J_{35} can not be determined from the spectra of 2,4-dimethylthiophene and 2,4-thiophenedisulfonylchloride, for the signals of 3- and 5-positioned protons of these compounds are broad; perhaps they will have the unresolved multiplet structures.

With our results and the help of the values analyzed in detail for selenophene and furan[4], it can be assumed that $J_{45} \simeq J_{23} > J_{34} > J_{25} > J_{24} \simeq J_{35}$ in thiophene derivatives.

And also the methyl resonances for methylthiophenes have the fine structure due to spin-spin coupling with adjacent ring protons, having the approximate coupling constants of 1.0 cps, the signals of which are shown in b and d in Fig. 1.

Monosubstituted Thiophenes.—Nine compounds were measured and the spectra of

4) T. Isobe, Presented at the Symposium on the Structural Chemistry, held on Nov. 21, 1957, at Fukuoka.

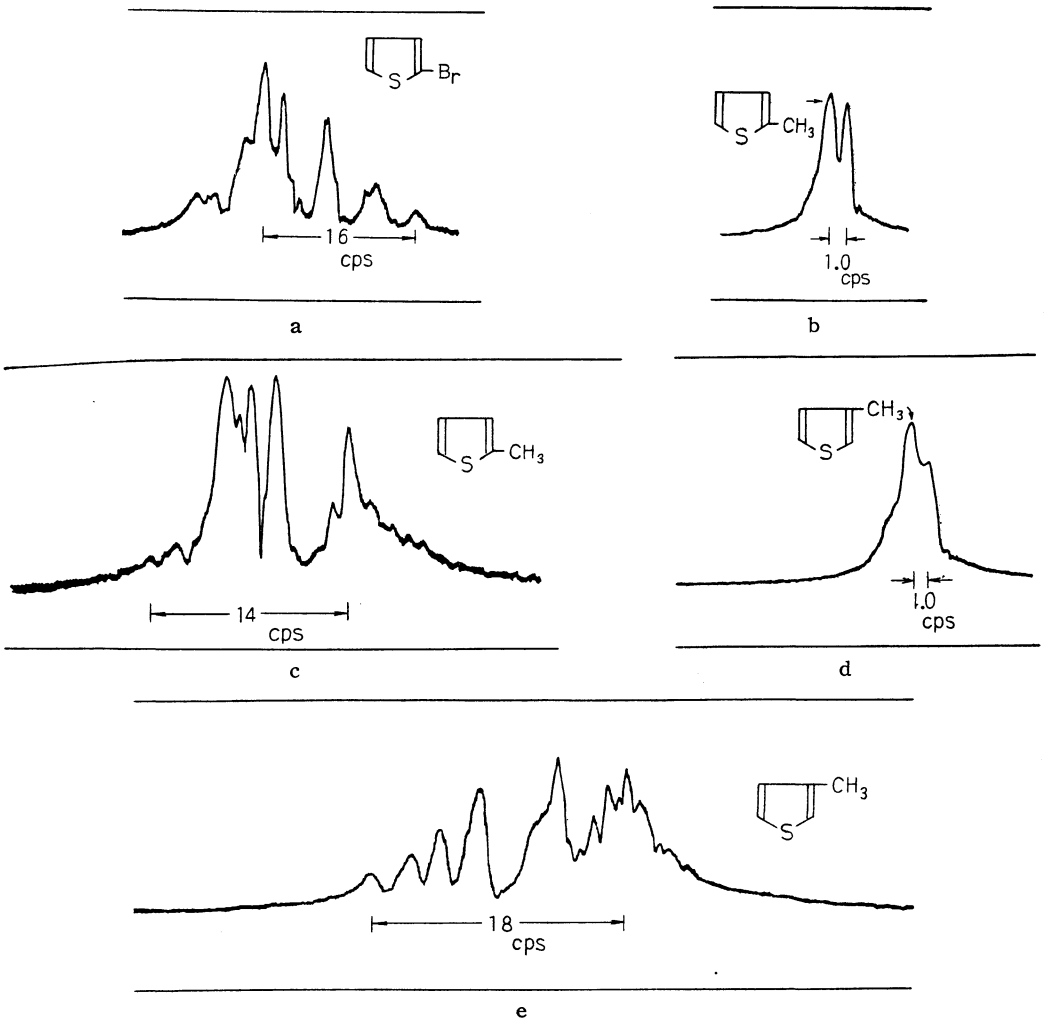

Fig. 1. The proton magnetic resonance spectra showing (a), 2-bromothiophene; (b), methyl group in 2-methylthiophene; (c), ring protons in 2-methylthiophene; (d), methyl group in 3-methylthiophene; (e) ring protons in 3-methylthiophene. Applied magnetic field increasing from left to right.

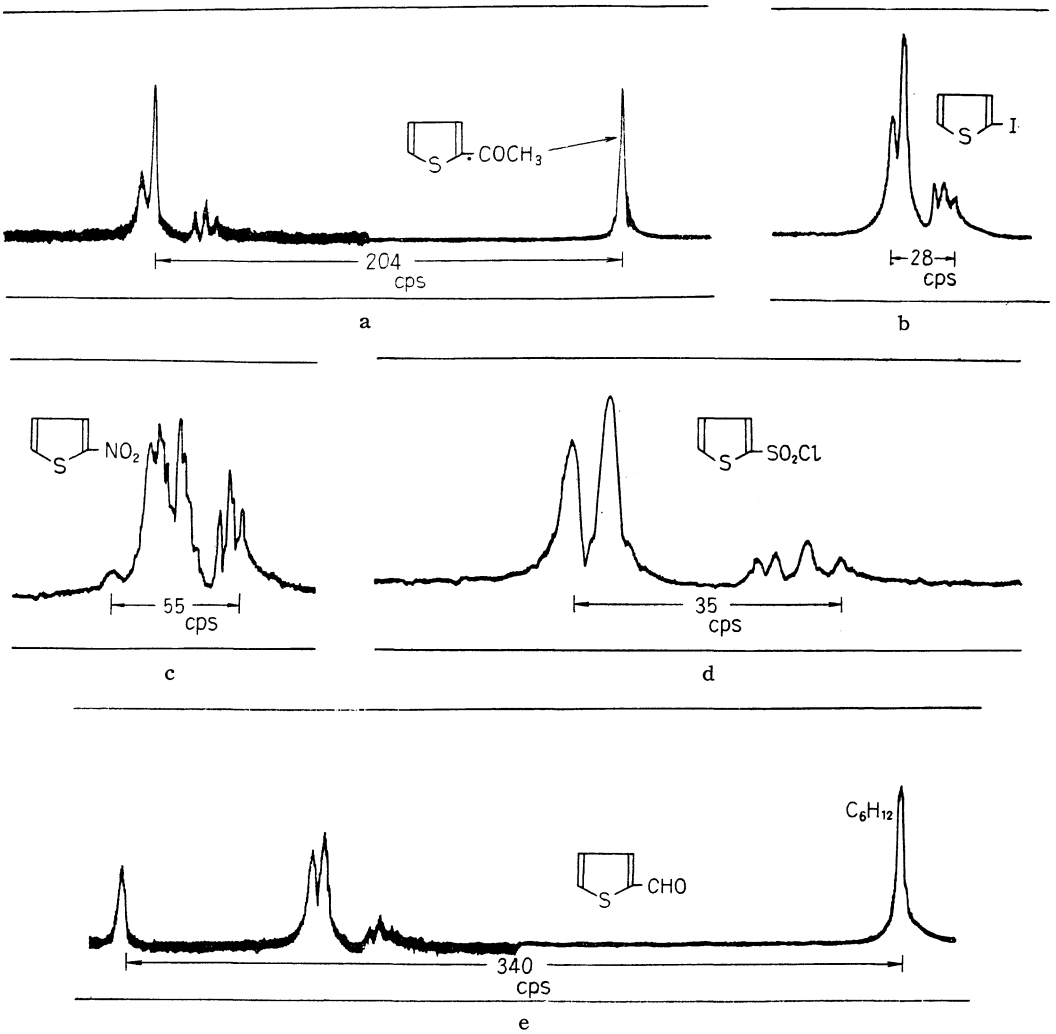
their ring protons can be classified into three types. The spectrum of 2-chlorothiophene is in the first type; it has a broad single line, so that the three protons in the ring are almost magnetically equivalent. The spectra of 2-bromo-, 2-methyl- and 3-methylthiophene are in the second type and they have the most complicated spectra as shown in a, c and e in Fig. 1, but their analyses are difficult for the present, so that they are not given in Table II. As for the others, 2-acetyl-, 2-iodo-, 2-nitrothiophene, 2-thiophenesulfonylchloride and 2-thiophenealdehyde, the spectra are in the third type and they are shown in a, b, c, d and e in Fig. 2. Their signals consist of two main parts separated approximately 20 cps or more. The intensity ratio of the high-field part to the low-field one is 1 : 2, corresponding to one proton and to two protons respectively. At the high-field side of the signal, there are three or four sub-lines. Therefore these sub-lines can be considered as the lines coming from the 4-positioned proton. At the low field side of their signal, there are two sub-lines and they can be assumed to be the lines coming from the 3- and 5-positioned protons, and that both protons have almost the same chemical shifts.

In the spectra of the ring protons in the third group, we can assume that J_{34} and J_{45} have approximately the same value of



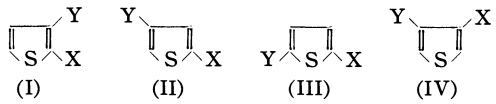


Fig. 2. The proton magnetic resonance spectra showing (a), 2-acetylthiophene; (b), 2-iodothiophene; (c), 2-nitrothiophene; (d), 2-thiophenesulfonylchloride; and (e), 2-thiophenealdehyde. Applied magnetic field increasing from left to right in all figures.

5 cps, closely consistent with the values shown in the preceding paragraph. The spectra of 2-nitrothiophene are more complicated than the others (Fig. 2 c), and in this figure, a signal which appeared at the lowest field side is assumed as coming from 2,5-dinitrothiophene by which the sample is contaminated.

In general, the multiplet structure of the n-m-r spectrum depends upon the ratio of the coupling constant to the chemical shift (J to δ). In monosubstituted thiophenes, it can be supposed that the chemical shifts are small as compared with the coupling constants in the first type, approximately the same in the second type and large in the third type.

Disubstituted Thiophenes. — The disubstituted thiophenes are the typical model of the two-proton system and there are four isomers as follows:

Their spectra consist of two doublets, but if X and Y are the same, the spectra for III and IV should have the single line.

The chemical shifts and coupling constants between the two ring protons are given in Table III; the samples in type IV were not measured. In the near future, we hope to obtain the measurements of this type for the determination of J_{25}, the coupling constant between the two protons

by way of the sulfur atom.

Trisubstituted Thiophenes. — Two compounds were measured and they have a single line.

Substituent Effects to Thiophene Ring. —The nitro, sulfonylchloro, aldehyde and acetyl groups have the strong electron withdrawing power. The introductions of these substituents to the thiophene nuclei should have lessened the electron density of the ring protons, we can see these aspects in the experimental results shown in the seventh column of Table II. In the case of 2-nitrothiophene, the magnitudes of the shifts are large in 3- and 5-H but small in 4-H toward lower field. On the contrary, the shift of the ring proton to the lower frequency in the spectra of methylthiophenes is consistent with the effect of higher electron density in the ring due to methyl substitution.

Also in the halogeno-substituted thiophenes, the similar shifts toward the higher field were observed as shown in Table II. The I-effect of the halogen-substituent withdraws charge from the ring, while the E-effect donated charge to the ring. Therefore, the situation here shows probably a predominance of the E-effect over the I-effect.

It is hoped that the present results will be usefull in determining the structure of unknown thiophene derivatives and in analyzing the spectrum for thiophene in detail.

Summary

1) The chemical shifts of the ring protons for twenty-two kinds of thiophene derivative were measured, and the qualitative discussions on the substituent effects were also given.

2) The coupling constants between the ring protons for thiophene derivatives can be generally assumed to be $J_{45} \simeq J_{23} > J_{34} > J_{25} > J_{24} \simeq J_{35}$.

*The Fundamental Conditions for Countercurrent Distribution Studies of Clupeine**

By Fumio SAWADA

(Received September 5, 1958)

The heterogeneity of some protamines, protein moieties in sperm nuclei of fishes, namely clupeine[1-9] from herring, salmine[3,4] from salmon, iridine[3,4,10] from rainbow-trout, and mugiline[11,12] from mullet, has been reported from German[1-7] and Japanese[8-12] laboratories. Nevertheless, it is still uncertain how the heterogeneity of protamines originates and what the biological activities of different molecules are. Thus, as the first step to resolve the problem, clupeine has been examined

for heterogeneity by means of Craig's countercurrent distribution (C. C. D.) method[13-15].

The usefulness of C.C.D., using a solvent system consisting of lauric acid in butanol and aqueous sodium acetate, for the fractionation of the methyl ester hydrochlorides of clupeine[3-5] and mugiline-β[11,12] has already been described. This solvent system, however, proved to be unsuitable for these protamine sulfates[3,11]. The sulfate is considered to represent more intact protein without any treatment of methyl esterification and to be suitable for the elucidation of the origin of the heterogeneity of clupeine. Thus, a course of study aiming to obtain desirable conditions for the fractionation of clupeine sulfate by means of C.C.D. is described in this paper.

Experimental

Preparation of Clupeine Sulfate[9]. — Dry powder** (50 g.) of the matured milts of herring (*Clupea pallasii*) obtained in 1951 (at Yoichi facing the Japan Sea, Hokkaido, Japan) was stirred with 0.2 N hydrochloric acid (600 ml.) under ice-cooling for 50 minutes, and clupeine was precipitated as picrate (yield 12.3 g.) by the addition of 0.125 M sodium picrate to the first extract. The clupeine picrate (5.29 g.) was then dissolved into 67% (wt./wt.) aqueous acetone, and converted in to the sulfate by adding sulfuric acid (to pH 2) and ethanol under cooling. The aqueous solution of clupeine sulfate reprecipitated once was passed through the Dowex-2 column (sulfate form) to remove the contaminating picric acid. Thus white glittering powder (yield 2.29 g.) of clupeine sulfate was obtained from the eluate after two reprecipitations.

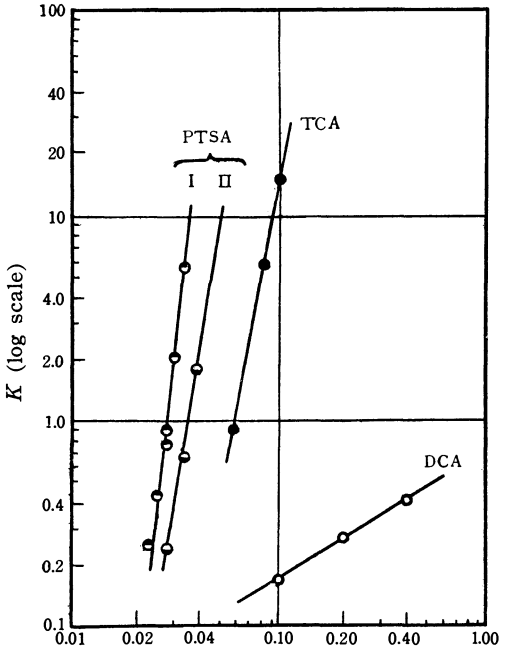
Preparation of Clupeine *p*-Toluenesulfonate.—An aqueous acetone solution of clupeine picrate (253 mg. in 2.5 ml.) and an aqueous solution (6.8 ml.) of 4% *p*-toluenesulfonic acid (see below) were mixed. The liberated picric acid was removed by means of ether extraction (five times with 10 ml. each) and by means of treatment with Amberlite IRA-410 (*p*-toluenesulfonate form). The resultant solution (pH 2) was neutralized with Amberlite IR-4B (OH-form). White amorphous powder of clupeine *p*-toluenesulfonate was obtained by lyophilization (yield 99 mg.)***.

Solvents for the C.C.D.—*n*-Butanol, commercial grade; acetic, dichloroacetic, trichloroacetic and picric acid, commercial grade.

p-Toluenesulfonic acid—The commercial reagent was treated with charcoal and recrystallized from a hot solution in concentrated (1 : 1, by volume) hydrochloric acid, or by saturation of the aqueous solution with gaseous hydrogen chloride. The melting point was 104~105°C (cor.).

Principles of Method. — To the C.C.D. of proteins, only a few types of solvent systems, especially the so-called "butanol systems"[16] are applicable. The author tested, therefore, various systems consisting of *n*-butanol and aqueous solution containing some reagents such as hydrochloric, acetic, dichloroacetic, trichloroacetic, *p*-toluenesulfonic**** or picric acid, sodium *p*-toluenesulfonate and sodium chloride. In every case, the partition coefficients of clupeine in these systems were measured, and the system satisfying the conditions necessary for C. C. D.[14] —no irreversible effects on the solute and a linear partition isotherm***** with a partition coefficient not much shifted from unity—was searched for.

Determination of Partition Coefficient.—A mixture of 1 ml. of *n*-butanol and 1 ml. of an aqueous solution containing the known concentrations of a clupeine sample and a reagent or reagents (see above) were put into a test-tube (1×12 cm.) with a glass stopper, and left to stand at a constant temperature in an incubator for 30 minutes. Then the test-tube was vigorously shaken for about 30 seconds at room temperature, and allowed to stand again in an incubator for 10 minutes. After the phases separated, the amounts of clupeine in both of the phases were measured by the retention analysis using an acidic dye, ponceau 6RF[9]. The average value from three to six measurements was used. The ratio $K=C_1/C_2$, where C_1 and C_2 are the equilibrium concentration of the sample in the upper and the lower phases respectively, was defined as a partition coefficient.



Results and Discussion

Dependence of the Partition Coefficient upon Concentration of the Reagents in the System.—In the systems consisting of *n*-butanol and aqueous solutions of various concentrations of hydrochloric, acetic or picric acid, the *K*-values of clupeine sulfate were found to be almost zero. Therefore these systems were discarded.

In the case of the systems containing

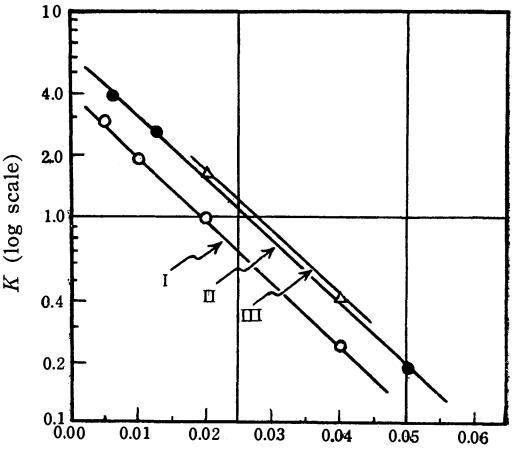
***** A plot of the concentration of solute in one phase in equilibrium with the concentration in the second one is called a partition isotherm. When a partion isotherm remains constant over a wide range of concentration, the isotherm is said to be linear (Ref. 15, p. 277).

dichloroacetic, trichloroacetic or *p*-toluenesulfonic acid, the *K*-values of clupeine sulfate at a definite concentration increased as the concentration of these acids increased (Fig. 1). Because of the low *K*-value for dichloroacetic acid and of the difficult solubility of the sample in trichloroacetic acid, only the system containing *p*-toluenesulfonic acid was found to be favorable for the distribution of clupeine.



Concn. of acids (M in log scale)

Fig. 1. Dependence of *K*-value of clupeine sulfate upon the concn. of acid in the system of *n*-butanol vs. aq. acid (18~23°C).

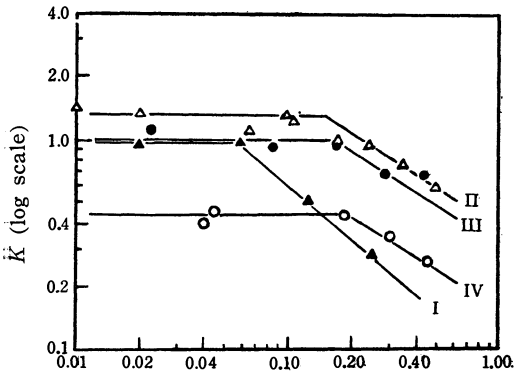
Symbol	Acid	Concn. of clupeine sulfate (%)
○—○	dichloroacetic	0.025
●—●	trichloroacetic	0.025
I ◒—◒	*p*-toluenesulfonic	0.02
II ◒—◒	*p*-toluenesulfonic	0.04

Dependence of the Partition Coefficient upon the Concentration of the Sample.— In the solvent system consisting of *n*-butanol and an aqueous *p*-toluenesulfonic acid at a definite concentration, the partition isotherm was not linear; in other words the *K*-value of clupeine sulfate decreased as its concentration increased (curve I in Fig. 2). The same relation was observed when either clupeine *p*-toluenesulfonate was taken for its sulfate (curve II in Fig. 2) or *p*-toluenesulfonic acid was replaced with its sodium salt (curve III in Fig. 2); only in the last case *n*-butanol in the system was replaced by *n*-butanol-*n*-propanol mixture (3 : 1, v./v.) from the viewpoint of miscibility.

Concn. of clupeine (%)

Fig. 2. Dependence of *K*-value of clupeine salt upon its concn. in the system of *n*-butanol* vs. *p*-toluenesulfonic acid or its Na salt.

Symbol	Concn. of the acid or the salt	Clupeine	Temp. (°C)
I ○—○	0.029 M acid	sulfate	20
II ●—●	0.020 M acid	*p*-toluene-sulfonate	27
III △—△	0.021 M salt	sulfate	30



* In the case of III, *n*-butanol-*n*-propanol (3 : 1).

The non-linearity of an isotherm is generally observed in the partition of inorganic cations, and the favorable partition can be performed by the use of a solvent system containing a large excess of a complexing agent at a constant pH[18]. The same situation is expected in the case of clupeine which is a strongly basic protein.

Thus, the higher concentration of *p*-toluenesulfonic acid may bring a linear isotherm but with an undesirably large *K*-value and a very low pH. However, its salts, for example sodium *p*-toluenesulfonate, would have the same effect at neutral pH as the acid has, and the addition of sodium chloride in the system would make the *K*-value decrease because of its "salting-in" effect. Therefore, in the solvent system consisting of *n*-butanol and an aqueous solution containing a high and suitable concentration of both sodium *p*-toluenesulfonate and sodium chloride, a

18) E. Hecker, "Verteilungsverfahren im Laboratorium", Verlag Chemie, GMBH, Weinheim/Bergstr. (1955), pp. 18, 107.

linear isotherm with a suitable K-value would be obtained at a neutral pH range. In fact, these considerations were proved to be the case as shown in Fig. 3.

Concn. of clupeine sulfate (% in log scale)

Fig. 3. Dependence of K-value of clupeine sulfate upon its concn. in the system of n-butanol vs. aq. salts.

Symbol	Concn. of Na p-toluene-sulfonate	Concn. of NaCl	Temp. (°C)
I ▲—▲	ca. 0.07 M	0.20 M	23~24
II △—△	ca. 0.12 M	0.40 M	ca. 17
III ●—●	0.12 M	0.40 M	22~23
IV ○—○	0.12 M	0.48 M	22~23

The range of the clupeine concentration where the K-value remains constant becomes broader as the concentration of sodium p-toluenesulfonate increases (curves I and II, III or IV in Fig. 3). It seems that the constant K-value ranges depend only upon the concentration of sodium p-toluenesulfonate; temperature (curves II and III in Fig. 3) and concentration of sodium chloride (curves III and IV in Fig. 3) seem not to affect the constant ranges and the gradients of the curves.

Thus, the solvent system consisting of n-butanol and an equal volume of aqueous solution of 0.12 M sodium p-toluenesulfonate and 0.40 or 0.48 M sodium chloride (curve III or IV in Fig. 3) was found to possess at common temperature the linear isotherms with adequate K-values for clupeine sulfate, so far as its concentration was less than 0.2 per cent in the total volume of both phases. In ranges of the higher concentration of clupeine, the K-values suddenly decreased (see also Fig. 3).

Dependency of the Partition Coefficient upon Temperature. — The K-values of clupeine sulfate in the solvent system consisting of n-butanol and aqueous p-toluenesulfonic acid at 0°C and 40°C were equal (Table I). On the other hand, they decreased obviously in the system of n-butanol and an equeous solution containing sodium p-toluenesulfonate and sodium chloride as temperature increased (Table II). Therefore, we must do a C.C.D. procedure with the latter system at a constant temperature.

TABLE I

DEPENDENCE of K-VALUE OF CLUPEINE SULFATE (0.02%) UPON TEMP. IN THE SYSTEM OF n-BUTANOL VS. AQ. 0.029 M p-TOLUENESULFONIC ACID

Temp. (°C)	K-value
0	0.7_5
40	0.7_9

TABLE II

DEPENDENCE OF K-VALUE OF CLUPEINE SULFATE (0.022%) UPON TEMP. IN THE SYSTEM OF n-BUTANOL VS. AQ. 0.14 M Na p-TOLUENESULFONATE—0.40 M NaCl

Temp. (°C)	K-value
1	3.9_2
11~12	2.8_3
19~20	1.5_7
34~35	1.0_3

The solvent system described in the above, well satisfies the conditions necessary for C.C.D. procedure (see principles of the method). In such a system of neutral condition, a danger of secondary transformation of protamines would be minimized. In this system the K-value can be easily controlled by changing the concentration of the components. Moreover, the presence of sodium chloride increases the capacity of the system to dissolve the sample and reduces the time necessary for the separation of phases.

The usefulness of the present system was practically proved by a preliminary experiment of C.C.D., in which the heterogeneity of clupeine sulfate was evidently demonstrated[9], contrary to Rauen's result******[3]. Recently, Scanes and Tozer[19] reported the fractionation of clupeine sulfate by C.C.D. technique, using a unique solvent system, n-propanol-3 M sodium acetate (3 : 2, by volume). The fractionation efficiency of their system seems to be nearly the same as ours.

In connection with the unique effect of p-toluenesulfonate anion in the solvent system, a strange phenomenon was pointed

****** In the Rauen's system, undesirably small K-values were obtained for the sulfates of clupine[3] and mugiline-β[11].

19) F. S. Scanes and B. T. Tozer, *Biochem. J.*, **63**, 565 (1956).

out by Pierce[20] in the case of C.C.D. of an ox pituitary growth hormone. In spite of the fact that the distribution pattern of the hormone protein agreed with the theoretical curve in the solvent system consisting of *sec*-butanol and 0.0044 M aqueous *p*-toluenesulfonic acid, some disagreement was found between the experimental and theoretical curves, when the acid concentration was 0.0022 M. This phenomenon might be explained by such non-linearity of the partition isotherm of the hormone as is shown above in clupeine, though Pierce denied its possibility in his paper.

Summary

The conditions and solvent system suitable for C.C.D. of clupeine sulfate, were systematically studied and the following results were obtained.

1. In the solvent system consisting of *n*-butanol and aqueous hydrochloric, acetic or picric acid, the partition coefficient (K) of clupeine sulfate was almost zero.

2. In the system consisting of *n*-butanol and aqueous dichloroacetic, trichloroacetic or *p*-toluenesulfonic acid, the K-value increased with the increase of the acid concentration at a constant solute concentration. In the last system, at a constant acid concentration, the K-value decreased with the increase of the solute concentration.

3. The system consisting of *n*-butanol and an equal volume of aqueous solution containing 0.12 M sodium *p*-toluenesulfonate and 0.40 or 0.48 M sodium chloride was found to satisfy all the conditions necessary for the C.C.D. of clupeine sulfate.

The author wishes to express his hearty thanks to Professor T. Ando for his guidance and encouragement throughout this work, as well as to Dr. I. Ishii for his helpful discussions and also to Dr. C. Hashimoto for her cooperation in the preparation of clupeine. The present work was supported in part by the Scientific Research Grant from the Ministry of Education given to Professor T. Ando.

Crystal and Molecular Structure of 1-Oxa-azulan-2-one. I. X-ray Determination of Crystal Structure

By Yoshio SASADA

(Received August 18, 1958)

We investigated previously the crystal and molecular structures of sodium salt[1] and hydrochloride of tropolone[2,3] as a part of the serial structural studies of the compounds containing planar seven-membered carbon rings. We have extended our study to the related compounds of azulene. Azulene, a fused five- and seven-membered ring system, is a well-known representative of non-benzenic aromatic compounds. Since Hückel[4] explained the large dipole moment of this compound by molecular orbital treatment, many theoretical and experimental researches especially measurements of dipole moment and absorption spectra, on azulene and its derivatives have been made. These studies were reviewed by several authors[5]. However, there have appeared only a few investigations using diffraction methods which can determine the molecular structures in detail. Even for the mother substance, azulene, it was in 1956 that its structure was reported by Takeuchi and Pepinsky[6] and Robertson and Shearer[7] independently, but no accurate molecular dimension sufficient to discuss in comparison with the theoretical results has

yet been reported. The other few papers on structures of azulene derivatives[8] deal only with crystal data or approximate structures.

Thus the accurate determination of these compounds by means of X-ray analyses will be desirable to the structural chemistry of non-benzenic aromatic compounds. Moreover, the accumulation of knowledge on the molecular orientation in the crystals so determined may contribute to the crystal chemistry of organic compounds, because, for example, azulene is isomer to naphthalene but the electron density distributions in the molecules are more or less different from each other.

Nozoe and his collaborators[9] have obtained, since several years ago, many related compounds of azulene from corresponding derivatives of tropolone, and they kindly supplied us with their valuable products. We have determined the crystallographic data of these compounds[10], some of which were further analysed[11,12]. The present account deals with the structure determination of 1-oxa-azulan-2-one, together with some remarks on the method of X-ray analysis.

Experimental

Crystals are obtained as very fine yellow needles elongated in the c axis direction.

Crystallographic and physical data obtained are as follows:

1-Oxa-azulan-2-one, $C_9H_6O_2$, m. p. 69~70°C; Orthorhombic; $a=21.45\pm0.08$, $b=8.28\pm0.04$, $c=3.96\pm0.02$ Å; Absent spectra, ($h00$), ($0k0$) and ($00l$) when h, k and l are odd respectively; Space group, $P2_12_12_1-D_2^4$; Four molecules per unit cell; Volume of unit cell, 703 Å^3; Density (by floatation); 1.36 g. cm^{-3}; Density (calc.), 1.38 g. cm^{-3}; Linear absorption coefficient for Cu K_α radiation, $\mu=9.45$ cm^{-1}; Total number of electrons per unit cell, $F(000)=304$.

For the structure analysis, a complete set of relative intensities for ($hk0$), ($hk1$) and ($hk2$) was obtained by the integrated Weissenberg procedure. The specimen used has the following maximum and minimum dimensions at right angles to the axis of rotation: 0.01×0.02 cm.

Intensities were estimated by visual comparison with a calibrated scale. The multiple-film technique was used to correlate strong and weak reflexions, ranging in relative intensities from 22000 to 1. Reflexions from only 128 planes were observed out of 232 possible ($hk0$)'s. The corrections for polarization and Lorentz factors were made in the usual way, and that for absorption was neglected.

Results and Discussion

Structure Determination. — Patterson functions[13] have been customarily used in order to obtain some clues to the structure determination problems. However, the two-dimensional Patterson method is generally powerless in the case of the crystals containing no heavy atoms.

For several years, proposals of the so-called direct methods of crystal analysis[14,15] have been made and some of them were applied with success to the actual structure determinations. However, these successful applications are only for the fortunate cases. Some empirical remarks on this point were made by Watase and Nitta[16]. The cause of the inapplicability is due to the fact that the limiting conditions for deriving these analytical forms, such as the non-negativity principle of electron density, are scarcely severe enough. As the actual situations are more complicated, analytical processes based on such rather simple conditions are not enough to solve the crystal structures containing more than, e. g. five independent atoms in the cell.

Therefore the applications of the systematic methods mentioned above may not be effective for the present case. Otherwise information given by individual intensity of each reflexion had to be used carefully as it is.

The very short period of the c axis suggests that the approximate crystal structure can be obtained by the use of the ($hk0$) reflexions alone. The starting-point was very favorable; that is, the shape of the molecule was already known from the preceding studies of the related compounds. Moreover, the shortest axis of the unit cell strongly limited the inclination of the molecular plane to the (001) plane.

As the plane group of this projection is pgg, the structure factors are represented as follows:

For the reflexions with $h+k=2n$

$$F(hk0)=\sum_j f_j \cos 2\pi hx_j \cos 2\pi ky_j$$

and for the reflexions with $h+k=2n+1$

$$F(hk0) = -\sum_j f_j \sin 2\pi hx_j \sin 2\pi ky_j$$

The structure factor maps, graphical representations of the above formulae, were made for all reflexions in the region within $2\sin\theta = 1.2$, the maps being drawn in the scale of 4 cm. = 1 Å.

The planes with very strong or weak intensities in the region with small $2\sin\theta$ severely limit the allowable approximate regions of molecular position and orientation together with symmetry considerations. For example, the value of the unitary structure factor of (400) is 0.36 and that of (200) is very small. As shown in Fig. 1, these facts require that the molecule should be in the regions A or B

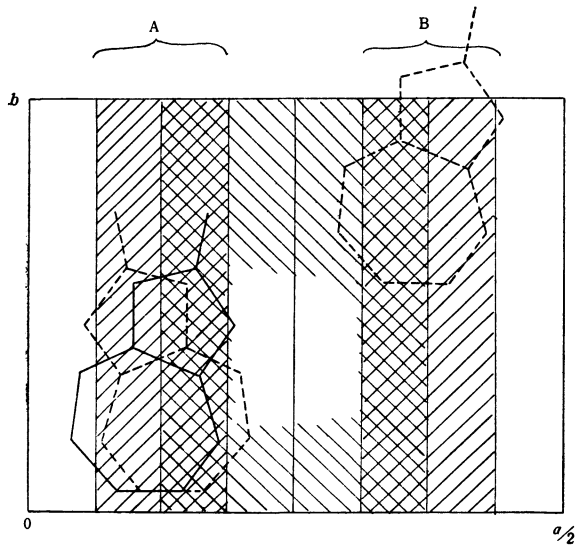

Fig. 1. Example of the determination of the allowable approximate regions using the structure factor maps. The areas shaded with lines obliqued right and left represent the negative regions in the structure factor maps of (400) and (200) respectively.

and the direction of the long axis of the molecule is nearly parallel to the *b* axis. From symmetry considerations, the molecule shown by the dotted line in the region B is equivalent crystallographically to that shown by the dotted line in the region A. Therefore, it was sufficient to apply the trial only to the region A.

The number of possible sets of atomic coordinates in this region which explains the intensities of lower order reflexions was reduced by elimination because of the requirements of the intensities of the higher order reflexions using the structure factor maps. After these successive procedures the structure has been obtained for which the agreement between the observed and the calculated structure factors is fairly good. (After the completion of this structure determination, it was found that the coordinates so obtained deviated from the final positions only by 0.2 Å or less.) Then ordinary Fourier and $(F_o - F_c)$ syntheses followed.

It is noted that the distinction of two structures shown by solid and dotted lines occurs only for the structure factors (*hk*0) with odd *h*. In fact, the structure shown by the dotted line, which was concluded to be false from the detailed trial for (*hk*0) with odd *h*, can also give a Fourier map pretty well to some extent. The detail on this point will be discussed elsewhere.

In the structure-factor calculation, the atomic scattering factors were taken from McWeeny[17], using for oxygen $\overline{f_o} = \frac{1}{3}(f^{\parallel} + 2f^{\perp})$ and for carbon the values for 'valence states'. The corrections were made only for isotropic *B* factors of individual atoms, though it was observed from the $(\rho_o - \rho_c)$ map that thermal motions of some atoms were anisotropic. The best *B* factors were: 6.0 for O_1, C_3, C_4, C_8, C_9 and C_{10}; 7.5 for O_2, C_2, C_5, C_6 and C_7.

The *R* index decreased to 0.134 including the contributions from hydrogen atoms placed radially at a distance of 1.0 Å from the carbon atoms.

TABLE I

ATOMIC COORDINATES (AT ROOM TEMPERATURE)

Atom	*x/a*	*y/b*	*z/c*
O_1	0.100	0.552	0.218
O_2	0.169	0.721	0.470
C_2	0.158	0.588	0.344
C_3	0.194	0.448	0.319
C_4	0.180	0.173	0.110
C_5	0.145	0.051	−0.034
C_6	0.084	0.052	−0.160
C_7	0.042	0.179	−0·168
C_8	0.050	0.335	−0.043
C_9	0.101	0.399	0.115
C_{10}	0.161	0.331	0.168

In Table I are listed the final atomic coordinates. Fig. 2 shows the comparison between observed and calculated structure factors and Fig. 3 the final Fourier projection of the electron density on the (001) plane.

Determination of *z* Coordinates.—As this crystal is a very fine needle in shape, the Weissenberg photographs about the *a* and *b* axes could not be taken. However, the

17) R. McWeeny, *Acta Cryst.*, **4**, 513 (1951).

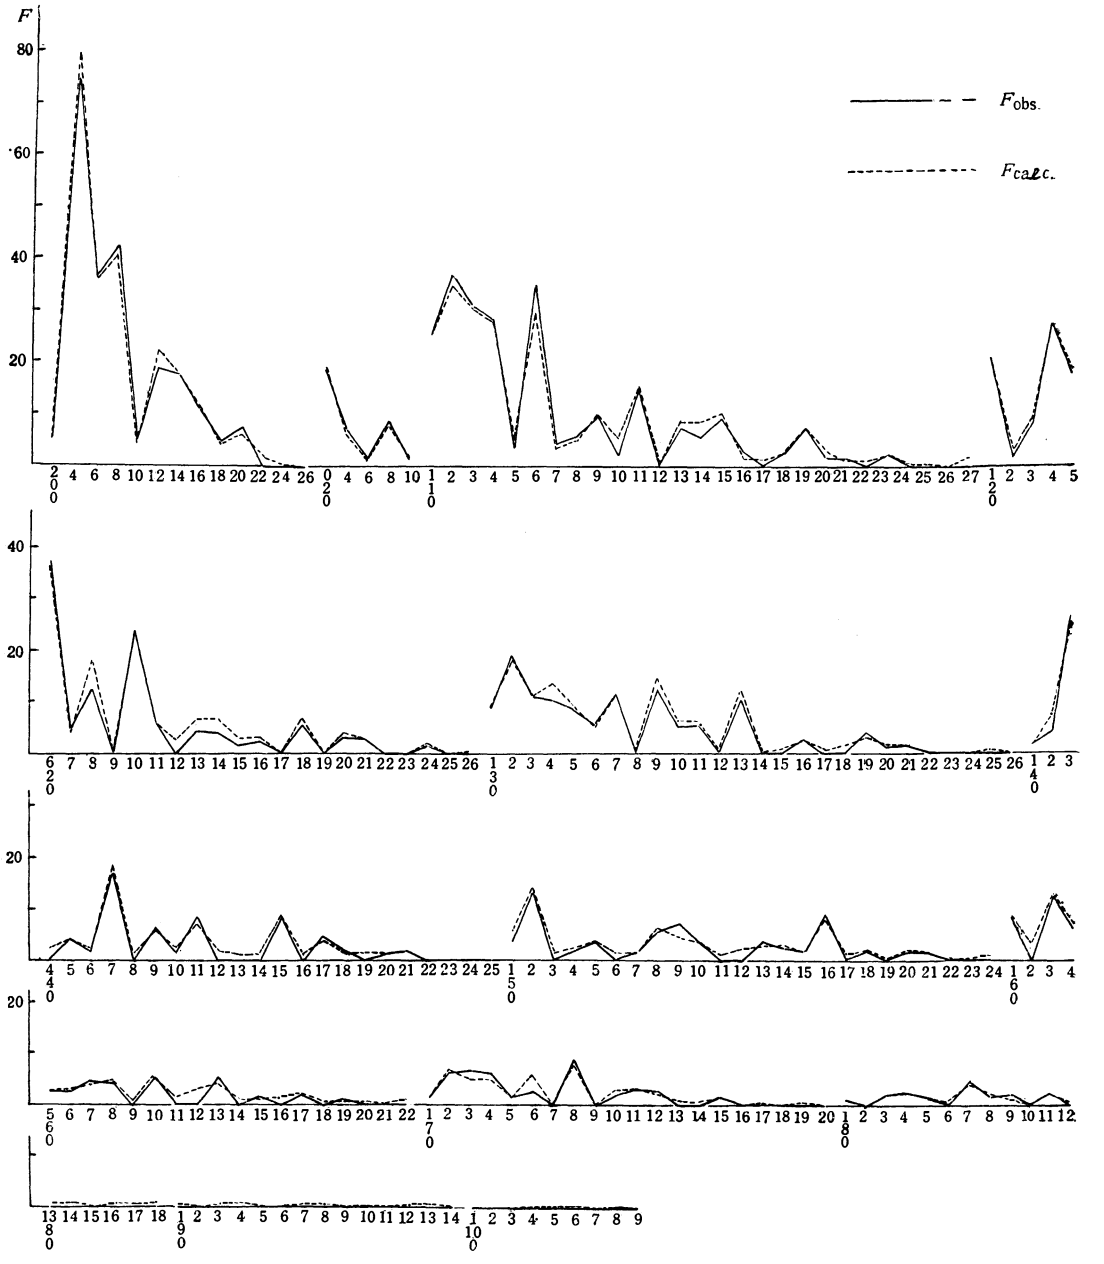

Fig. 2. Observed and calculated structure factors, $F(hk0)$.

very short period of the c axis does not require the full zonal reflexions about the a and b axes in order to estimate z coordinates. The data for $(0kl)$ and $(h0l)$ reflexions were taken from the equi-inclination Weissenberg photographs for the $(hk1)$ and $(hk2)$.

The process of the trial was very simple because the x and y parameters were already known. The coordinates so obtained were refined by the least squares method with suitable weights. For convenience, at the early two cycles, the four parameters, that is, z coordinate of the mass centre of the molecules, angles of the long and short axes of the molecule with the (001) plane and z coordinate of O_2, were corrected assuming the planarity of the fused system of five- and seven-membered rings. In the succeeding two cycles, the z coordinates of eleven atoms were shifted independently.

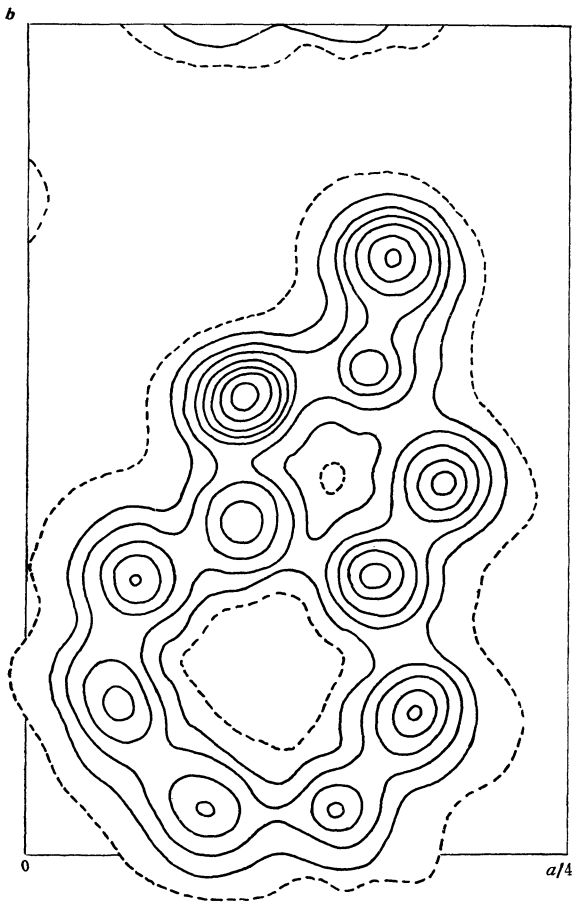

Fig. 3. The final Fourier projection of the electron density on (001). Contours at intervals of 1 e. Å^{-2}. Contour at 1 e. Å^{-2} is broken.

The final z coordinates are listed in Table I and the comparison between observed and calculated structure factors in Fig. 4.

Description of the Structure.—Fig. 5 shows the crystal structure projected on the (001) plane together with intra- and intermolecular distances.

The detailed discussions on the molecular structure are not significant, because the estimated standard deviations of bond lengths reach the values of about 0.04 Å owing to large thermal motions of atoms in the crystal.

There are no intermolecular distances deviating greatly from the sums of normal van der Waals radii.

As seen from Fig. 5, the molecular arrangement is somewhat characteristic. The seven-membered carbon ring, which is supposed to be the electrically positive part of the molecule, has as the first neighbors six five-membered rings, the negative parts, if we include the one within its own molecule. The five-membered ring is also surrounded by six seven-membered rings. Such characteristics of the molecular orientations are in contrast with those of azulene[6,7] and 2-amino azulene[12]. Mutual molecular orientations in these crystals are similar to those in naphthalene[18]. As the basic principles of the packing of molecules in organic crystals are yet to be explored, we shall only point out the parallel relation between molecular orientation and magnitudes of dipole moments of these substances. (According to Kurita and Kubo[19], the values of dipole moments are 5.64, 2.09 and 1.0 D for the present molecule, 2-amino azulene and azulene itself respectively.)

19) Y. Kurita and M. Kubo, to be published.

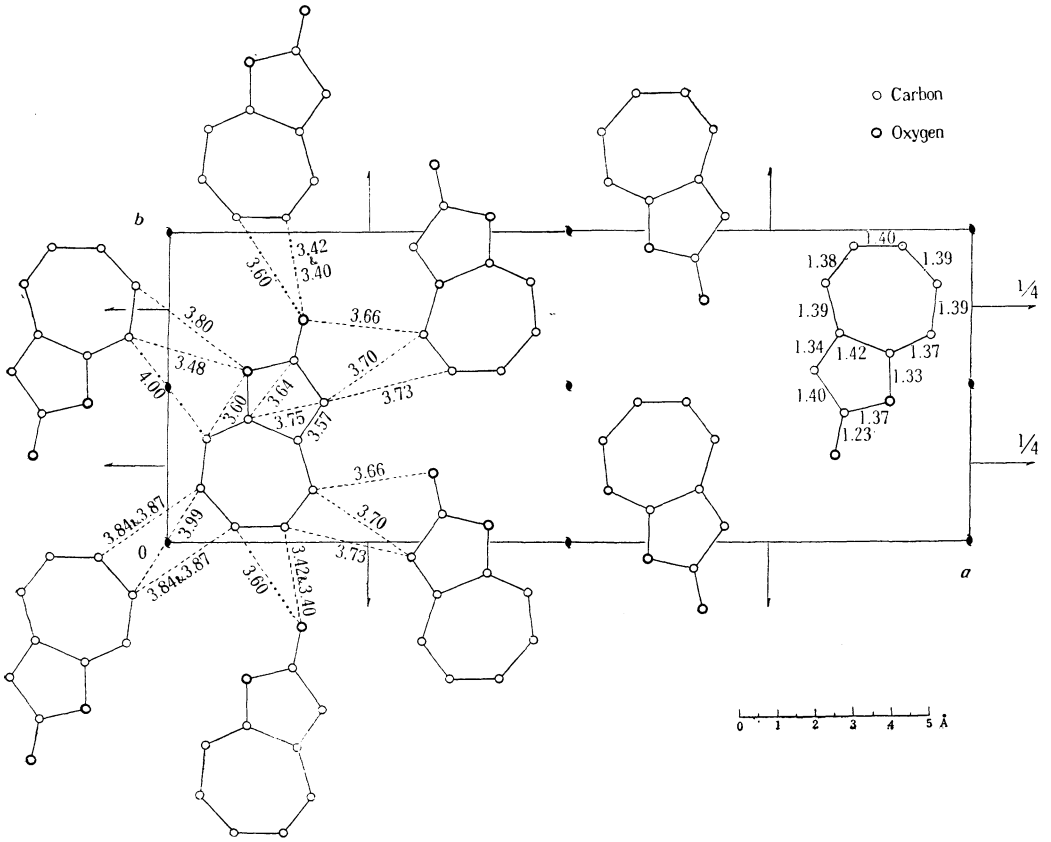

Fig. 5. Crystal structure projected on (001), together with intra- and intermolecular distances (Å).

Finally it was noticed that the B factor of each atom increases with increasing distance of an atom from the mass center of the molecule. This may correspond to the oscillational vibration of the molecule about its mass center.

Further discussion on these points will be given in the following paper which describes the refinement of the structure of this substance by low temperature technique.

The present author wishes to express his sincere thanks to Professor I. Nitta for his guidance and encouragement throughout this work. He is also indebted to Professor T. Nozoe for supplying the sample and also for continued interest.

Crystal and Molecular Structure of 1-Oxa-azulan-2-one. II. A Refinement of the Structure by Low Temperature Technique

By Yoshio SASADA

(Received August 18, 1958)

As a part of the serial investigations of the compounds containing planar seven-membered carbon rings[1-5], the crystal structure of 1-oxa-azulan-2-one was reported in a preceding paper[6]. In that case the great thermal agitation at room temperature did not permit us to give the detailed determination of its crystal structure. The last Fourier projection indicated, moreover, considerably large anisotropic thermal vibrations of some atoms in the molecule. Therefore, it was highly desirable to carry out intensity measurement at low temperature in order to obtain the molecular dimensions with enough accuracy to discuss the molecular structure quantitatively.

Recently Cruickshank has published several papers[7,8] on the method dealing with molecular motions in crystals, which he applied to the cases of naphthalene[9,10] and anthracene[10-12] and compared the molecular vibrations obtained using X-ray data with those from infrared studies. Thus it will also be interesting to examine the thermal vibration of this polar molecule in order to make comparison with naphthalene and anthracene.

For these two main objects, the study of the crystal structure at low temperature was attempted and the present account deals with the analysis of this compound at $-110°C$.

Apparatus.—For several years, low temperature single crystal diffraction techniques have been adopted by several authors[13]. There are two main distinct procedures: one is the cold gas flow and the other the conduction method. The latter method has the advantage that good constancy of temperature is attained. However, for the present purpose, the former procedure is sufficient because fluctuation of temperature less than 5°C is allowable throughout the experiment.

The apparatus used for this work is shown in Fig. 1. This is a modification of the device described by J. H. Robertson. A large Dewar-vessel, 4 liters in volume, is fitted with a wooden cap in which there are holes for a large tube for filling, a level indicator, a vacuum jacketed nozzle and a pair of wires containing the heating element. Careful regulation of the current in this heating element allows sufficiently constant temperature to be maintained. The leakage of cold nitrogen gas, which make precise temperature control impossible, is avoided by the use of rubber packing.

The cold nitrogen stream is directed at the crystal on the goniometer head of a Weissenberg camera. A thermocouple fixed at the tip of the slit was placed between the tip of the nozzle and the crystal, the distance from the crystal being 3 mm. Difference between temperatures at this position and at the crystal was found to be less than 5°C at $-110°C$.

Special care was taken to prevent the frost from condensing on the crystal itself. For this purpose the cold nitrogen stream is surrounded by a supplementary stream of dry nitrogen gas of about 5°C. The velocity of the latter is controlled so as to reduce the frosting. When kept at $-110°C$, 0.7 litre of liquid nitrogen is necessary for one hour.

Experimental

Preliminary tests were made at 0°C, $-45°C$ and $-110°C$. The cell dimensions at these three temperatures show no sign of discontinuous change of considerable magnitude, the values being as follows: $a=21.4_5$, $b=8.28$, at 0°C; $a=21.3_7$, $b=8.28_5$, at $-45°C$; $a=21.2_6$, $b=8.28_5$Å, at $-110°C$. These values were obtained from the reflexions of (20, 0, 0) and (0, 8, 0) recorded on the same film respectively.

The intensity of each reflexion increases continuously with lowering temperature and the change of intensity is more significant with increasing angles. This corresponds to reduction of thermal motion without any phase transitions.

From these preliminary tests, it was expected that a satisfactory result for the present purpose could be obtained from an experiment at $-110°C$.

The final cell dimensions at $-110°C$ and space

group are: $a=21.26\pm0.06$, $b=8.28_5\pm0.04$, $c=3.91\pm0.03$Å and $P2_12_12_1$-D_2^4.

Using Cu K_α radiation, three complete sets of relative intensities for ($hk0$) were obtained by the Weissenberg procedure. Throughout the experiment temperature was kept within the range of ±5°C. The specimens used have the following maximum and minimum dimensions at right angle to the axis of rotation: crystal 1, 0.005×0.023; crystal 2, 0.004×0.018; crystal 3, 0.005×0.020 cm.

Intensities were estimated by visual comparison with a scale, which was prepared by counting the number of times of the repeating reflexion of the crystal 3. The multiple-film technique was used to correlate strong and weak reflexions, ranging in relative intensities from 25000 to 1. The corrections for polarization and Lorentz factors were made in the usual way. The effect due to the shape of the specimen was also allowed for.

The values of structure factors used in the following analysis are the weighted means of the values in the above mentioned three sets. Reflexions from 188 planes were observed out of 229 possible ($hk0$)'s.

Results

Refinement of the (001) Projection and Location of the Hydrogen Atoms. — The structure factors observed at -110°C almost agreed with those observed at room temperature, if the mean temperature factor of 4.0×10^{-16}cm^2 was applied to the former. This implies that the structure at low temperature remains essentially the same as that of room temperature so that the refinement can be made starting from the coordinates reported in the preceding paper[6].

Two successive Fourier and an (F_o-F_c) syntheses on the (001) plane were applied to correct the atomic coordinates. The corrections were estimated from the equation

$$\Delta r=(\mathrm{d}(\rho_o-\rho_c)/\mathrm{d}r)_{r=0}/2p\rho(0)$$

where $\rho(0)$ is the electron density at an atomic centre and p is a constant, whose value was deduced from the second Fourier map assuming the electron density near an atomic centre to be represented by the equation

$$\rho(r)=\rho(0)\ \exp(-pr^2)$$

In the structure-factor calculation, the atomic scattering factors were taken from McWeeny[14], using for oxygen $\bar{f}_o=\frac{1}{3}\times(f^{\parallel}+2f^{\perp})$, and for carbon the values for 'valence states'.

It was observed from the $(\rho_o-\rho_c)$ map that the magnitudes of thermal motions of individual atoms are different from each other and some of them are considerably anisotropic. These thermal

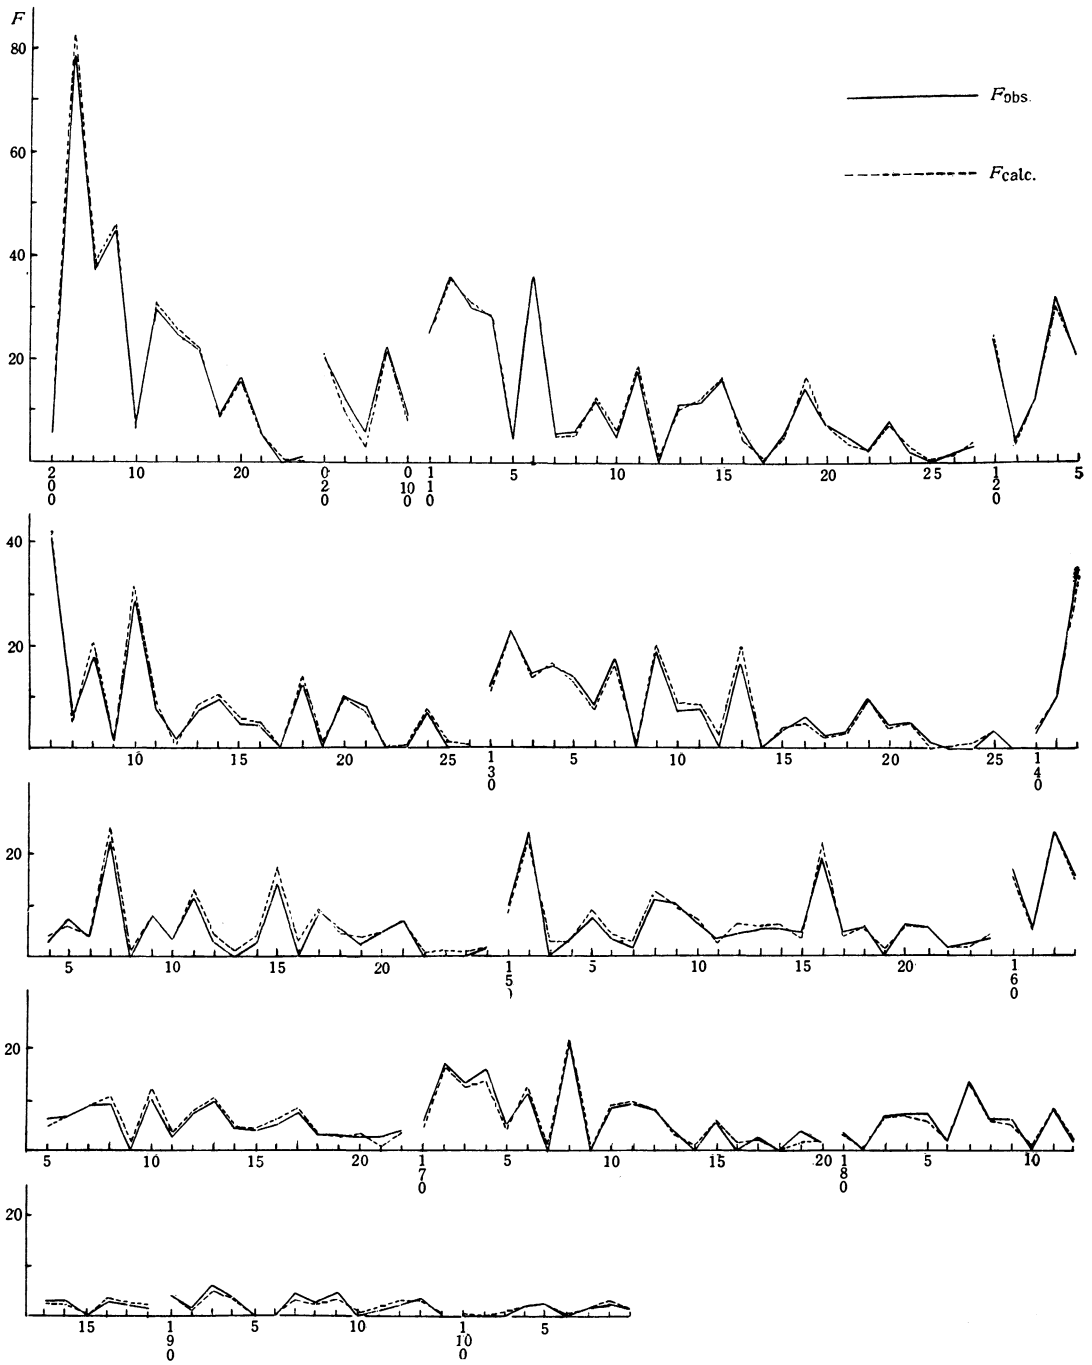

Fig. 2. Observed and calculated structure factors, $F(hk0)$.

factors for individual atoms and their anisotropy were obtained from the successive three (F_o-F_c) syntheses in the following way. The corrections for thermal factors were estimated from the equation[15]

$$\Delta B=\pi^2(\mathrm{d}^2(\rho_o-\rho_c)/\mathrm{d}r^2)_{r=0}/p^2\rho(0)$$

For the atoms vibrating anisotropically, the scattering factors of the form

$$f=f_0\exp[-\{\alpha+\beta\sin^2(\phi-\psi_b)\}(\sin\theta/\lambda)^2]$$

were employed[16,17], where α and β are

constants, ψ_b is the angle between the direction of maximum vibration and the b axis, and $(2\sin\theta, \phi)$ are the polar coordinates of a point in the $(hk0)$ section of the reciprocal lattice, measured from the a^* axis. In the projection it should be noted that only two molecules are equivalent in dealing with the anisotropic vibrations.

Throughout these refinements F_c included the contributions from hydrogen atoms placed radially at a distance of 1.0 Å from the carbon atoms. In Table I are listed the final atomic coordinates and the final thermal parameters. The comparison between observed and calculated structure factors is shown in Fig. 2, where the R index becomes 0.097.

Figs. 3 and 4 show the final Fourier projection on the (001) plane and the fifth $(\rho_o-\rho_c)$ map respectively. In the calculation of the latter, F_c's do not include the contributions from the hydrogen atoms. The significant peaks on this map are evidently due to the hydrogen atoms.

Coordinates and Molecular Dimensions. —The x and y coordinates obtained by the low temperature refinement hardly differ at all from those at room temperature. The z coordinates, the changes of which have scarcely any influence on the intra- and intermolecular distances due to the short c period, were expected to show no significant differences with those at room temperature. In fact, the change of the c period is of the same order as that of the a axis and a few oscillation photographs at low temperature did not show essential differences. Therefore the same z coordinates as those at room temperature are used in the following discussions. The final coordinates of the carbon and oxygen atoms are shown in Table I.

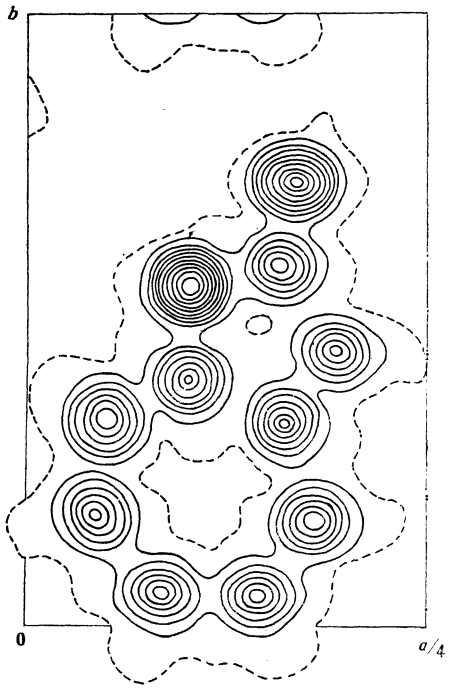

Fig. 3. The final Fourier projection of the electron density on (001). Contours at intervals of 1 e. Å^{-2}. Contour at 1 e. A^{-2} is broken.

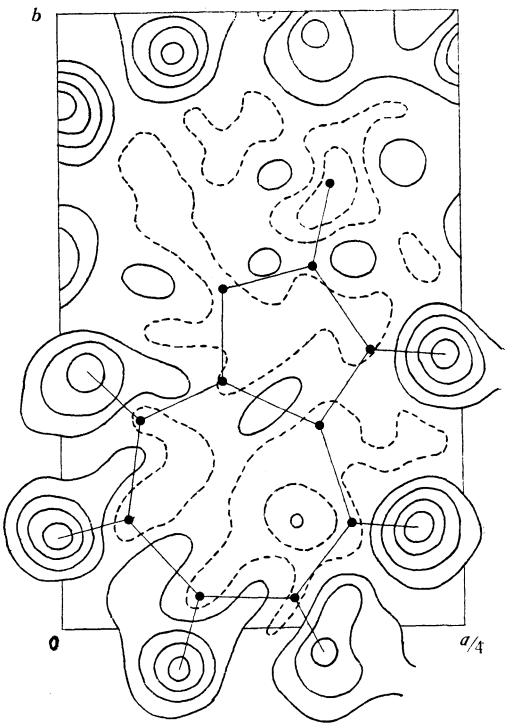

Fig. 4. The final $(\rho_o-\rho_c)$ projection on (001). Contours at intervals of 0.2 e. Å^{-2}. The zero and negative contours are broken.

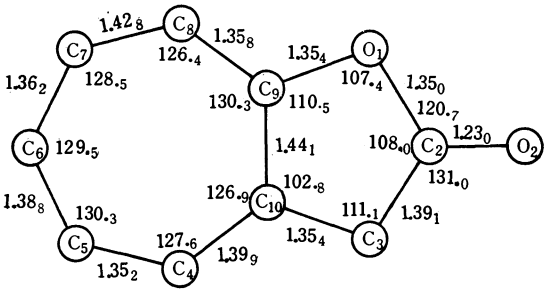
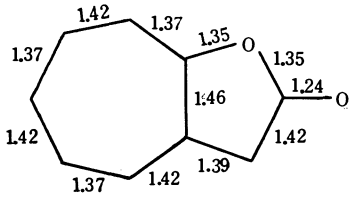


By the use of least squares method the best plane through all carbon and oxygen atoms in the fused ring was determined to be

$$z=0.3634x+0.3192y-1.4186$$



The perpendicular displacements of individual atoms from this mean plane are shown in Table II. The average displacement is 0.02$_4$ Å. The bond lengths and valency angles in the molecule are shown in Fig. 5 (a).

TABLE II

(a)

(b)

Fig. 5. (a) Observed bond lengths (Å) and bond angles (°). (b) Bond lengths calculated by Pauling's relation.

The estimated positions of hydrogen atoms from the fifth ($\rho_o-\rho_c$) map are given in Table III, the z coordinates being obtained by substituting the estimated x and y values in the equation of the mean plane of the molecule, although the assumed positions were used in the calculations of the ($hk0$) structure factors.

TABLE III
HYDROGEN COORDINATES AND BOND LENGTHS OF C—H

Atom	x(Å)	y(Å)	z(Å)
H_3	5.14	3.62	1.61
H_4	4.72	1.33	0.72
H_5	3.40	−0.31	−0.28
H_6	1.53	−0.58	−1.05
H_7	0.04	1.22	−1.02
H_8	0.36	3.46	−0.18

C_3—H_3=1.09, C_4—H_4=0.94, C_5—H_5=0.80, C_6—H_6=1.13, C_7—H_7=0.95, C_8—H_8=0.91 Å

Estimation of Accuracy.—The standard deviations of the atomic coordinates, $\sigma(x)$ and $\sigma(y)$ were estimated by the method of Cruickshank[18-20] as follows: $\sigma(x)$= 0.010−0.012; $\sigma(y)$=0.007−0.009 Å for carbon; $\sigma(x)$=0.007−0.008; $\sigma(y)$=0.005 Å for oxygen.

If the small error introduced by the uncertainty of the molecular orientation is ignored, the standard deviation of a bond length can be shown, in this case, to be

$$\sigma(b)=\sigma(d)\times b/d$$

where b is the length of the bond and d is its length in the projection on (001). From this equation the standard deviation of a C—C bond comes out to be about 0.018Å, and that of a C—O bond about 0.012 Å. The average standard deviation of bond angles was found to be 0.7°, and the standard deviation of electron density was 0.18 e. Å^{-2} for the (001) projection.

Discussion

Molecular Structure. — It is recognized clearly from Fig. 5 (a) that a larger and a

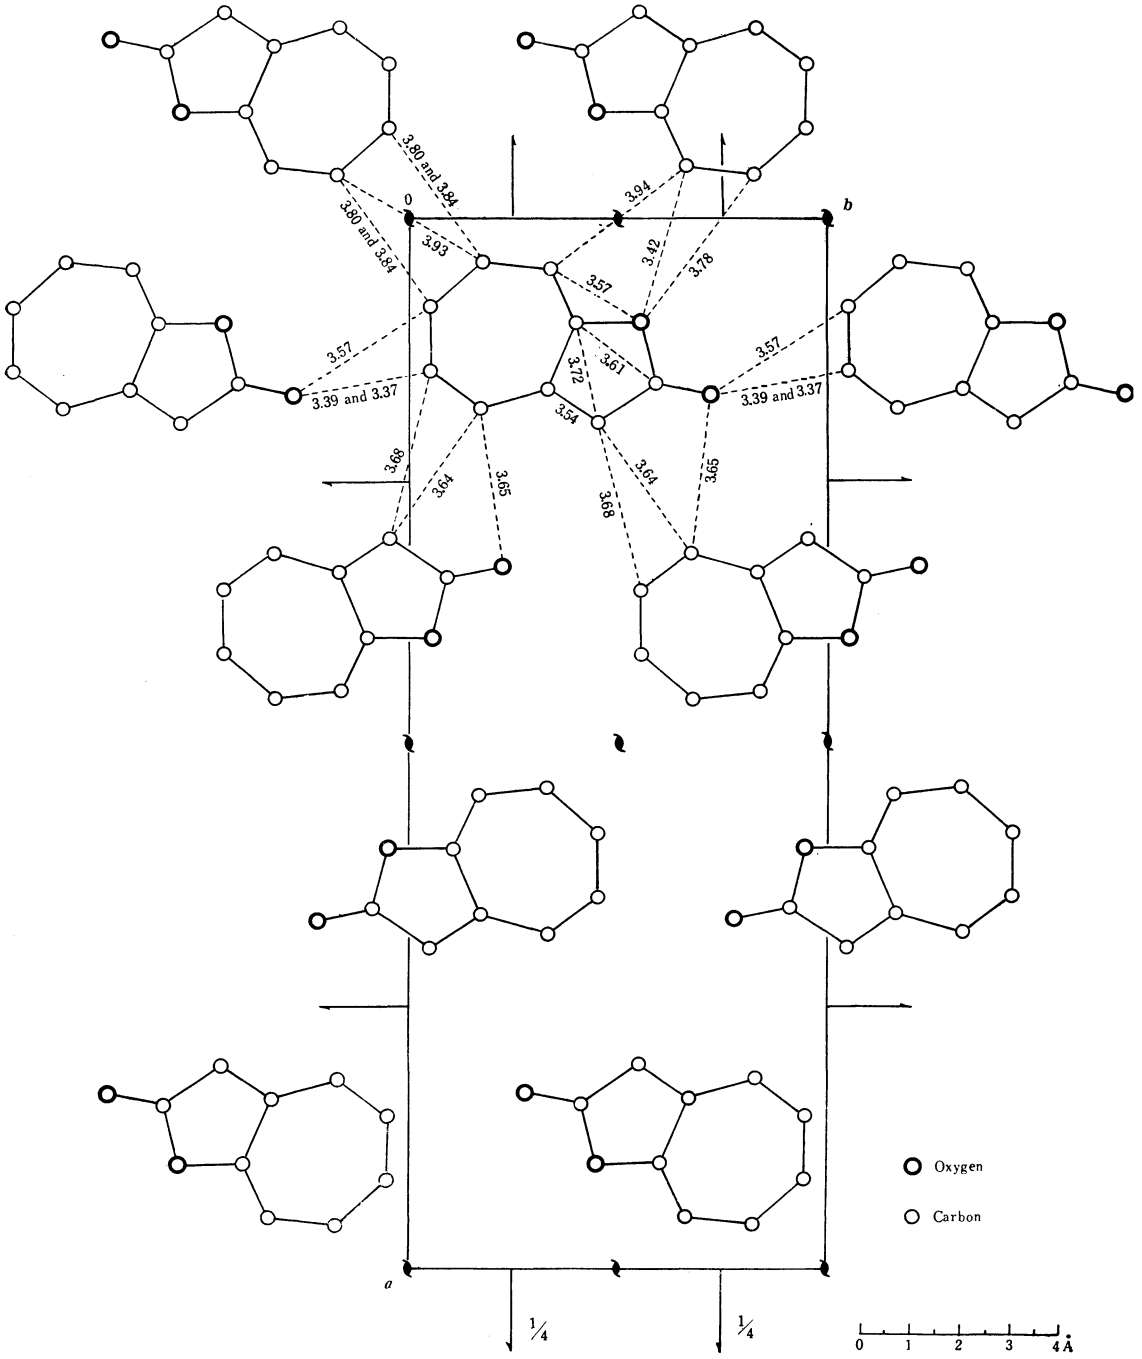

Fig. 7. Arrangement of molecules in the (001) projection with intermolecular distances (Å).

shorter C—C bonds are disposed alternately. The mean values for the larger and shorter C—C bonds are 1.40_9 and 1.35_7Å with estimated standard deviations of 0.01_0 Å respectively. The difference between these two values is highly significant, and this fact favors the conventional chemical formula I shown in Fig. 6.

However, the mean value of the larger C—C bonds and that of two C—O bonds in the five-membered ring (with standard deviation of 0.01_0 Å) are significantly different from their pure single bond lengths respectively. Thus, in order to interpret the bond distances more quantitatively, it becomes necessary to take into account the many resonance structures shown in Fig. 6.

In other words this molecule is not a simple γ-lactone but has the contributions from the structures similar to those in azulene and tropolone. As in the case of tropolone, the carbonyl oxygen is responsible for the drawing out of the ring electron and the lone pair electrons of the oxygen atom in 1-position supply the electron to carbonyl oxygen. The best agreement between measured and calculated bond lengths was obtained taking the following contributions: I, 34%; II (seven structures), each 3%; III (seven structures), each 3%; IV (two structures), each 12%, the relation[21]

$$R=R_1-(R_1-R_2)3x/(2x+1)$$

being used with $R_1=1.54$(C—C), $R_2=1.34$ Å (C=C), $R_1=1.42$ (C—O) and $R_2=1.20$ Å (C=O), (Fig. 5 (b)).

Considering the resonance structures given above, it seems that the seven-membered ring itself is somewhat positively charged. This is justified by the large dipole moment of this molecule[22] and by some chemical evidences[23], and also compatible with characteristic molecular arrangement in the crystal described in Part I of this series[6].

Molecular Arrangement. — The crystal structures projected on the (001) and (010)

23) S. Seto, *Sci. Rep. Tahoku Univ., Ser. I*, **37**, 367 (1953).

planes are shown in Figs. 7 and 8 respectively, together with the intermolecular distances. Intermolecular distances at a low temperature are shorter by about 0.03 Å than those at room temperature. Anisotropy of the change of the intermolecular distances, however, can not be detected owing to the greater standard deviations for them at room temperature.

Although an outline of the crystal structure is the same as that mentioned in Part I, the molecular arrangement can also be described as an assembly of the rods in which the molecules are joined together in a file by the interaction of dipoles in the same directions. The interaction between rods is less than that in the rod.

The thermal expansion coefficient along the *b* axis, which agrees approximately with the direction of the rod, is of negative sign, and those along the *a* and *c* axes are positive and of the same order as those in ordinary organic crystals[24]. This fact can be interpreted well from the point of view mentioned above, and will be further discussed in the following paragraph in connection with the anisotropic thermal vibrations.

Anisotropic Thermal Motion. — Fig. 9 shows the anisotropic thermal vibrations schematically. Dimensions of solid circles and ellipses are proportional to the r.m.s. amplitudes estimated from the *B* factors. These can be understood as the coupling of rigid-body libration of the molecule about its mass centre and the translational vibration whose amplitude along the *a* axis is greatest. The r. m. s. amplitudes of angular oscillation are about 3° and those of the translational vibration along the *a* and *b* axes 0.17 and 0.15 Å respectively. Contrary to the cases of naphthalene[9] and anthracene[11,12], the translational amplitude along the long axis of the molecule is smaller than that along the short axis. This is compatible with the characteristic arrangement of the polar molecules mentioned above.

The present author wishes to express his sincere thanks to Professor I. Nitta for his guidance and encouragement throughout this work. He is also indebted to Professor T. Nozoe for supplying the sample and for his continued interest and to Professor T. Watanabé for his kind advice particularly on the low temperature techniques.

*The Roles of Prolyl Residue in Polypeptide Monolayers. I. On the Chain Configurations Deduced from Surface Pressure and Potential Measurements**

By Toshizo ISEMURA and Shoichi IKEDA

(Received August 25, 1958)

During the last decade, investigations on synthetic polypeptides as model substances of protein have made great progress. Their monolayer properties have also been studied and clarified by the present authors[1] and many other workers[2,3]. In these studies synthetic polypeptides with non-electrolytic or unionized electrolytic side chains are found to spread as condensed monolayers at the air-water interface. Many globular proteins also give condensed monolayers at the same interface. Generally, monolayers of high polymeric substances are of condensed type under the strong interaction between

constituent monomer units and of expanded type under the weak interaction.

Among amino acid residues constituting polypeptide chains in protein, prolyl residue is specific in respect to several properties: (1) it can not be incorporated into the β-configuration of a polypeptide chain because it has a pyrrolidine ring which makes a part of the main chain; (2) it reduces the degree of stertic rigidity because it is inhibited from rotating around some bonds involved; and (3) it can form no hydrogen bond with other carbonyl group because the nitrogen atom of keto-imido bond has no hydrogen atom to participate in the hydrogen bonding.

Synthetic polypeptides, the monolayers of which have so far been studied, contain no prolyl residue. It is of great importance to investigate how these properties of prolyl residue affect the behavior of monolayers of polypeptides and to correlate it with the chain configuration, the chain flexibility and the hydrogen bonding. These studies appear to be useful to interpret monolayer properties of gelatin and collagen.

In this connection, we have investigated the monolayers of synthetic polypetides composed of various proportions and arrangements of prolyl residues, that is, poly-DL-alanine, poly-L-prolyl-L-leucylglycine, copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) and poly-L-proline. Poly-L-hydroxyproline was also examined for comparison with poly-L-proline. In this paper, we will describe the results and some inferences derived from the measurements of surface pressure and potential.

Experimental

Materials.—Poly-DL-alanine is a sample prepared by Dr. Tani[4], the degree of polymerization of which was found to be about 300 by surface pressure measurement. It was spread from the solution in a mixed solvent, dichloroacetic acid-benzene (1 : 9 v/v). Poly-L-prolyl-L-leucylglycine is a sample synthesized by Dr. Sakakibara[5]. Its degree of polymerization was found to be 13 by end-group analysis and surface chemical method. Copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine), poly-L-proline II[6] and poly-L-hydroxy-proline are gifts of Dr. Kurtz through Professor Noguchi. The degree of polymerization of copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) was found to be 129 by surface pressure measurement. Poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) were spread from the solution in a mixed solvent, dichloroaceticacid-benzene (1:4 v/v). The spreading solvent for poly-L-proline II (D. P. 50) and poly-L-hydroxyproline (D. P. unknown) was 50% (v/v) isopropyl alcohol. Because of their hygroscopic nature, poly-L-prolyl-L-leucylglycine, poly-L-proline II and poly-L-hydroxyproline were dried for several hours at the boiling point of toluene in an Abderhalden's pistol, before weighing for preparing the spreading solutions. Poly-L-prolyl-L-leucylglycine contains one molecule of water of crystallization per periodic unit after such drying.

Distilled water was used as aqueous subphases, unless otherwise stated. The pH of subphases was adjusted by 0.01 N hydrochloric acid or by 0.01 M potassium carbonate, if necessary. To certify the minimum solubility of the sample into the aqueous phase, potassium chloride was often added, which was recrystallized from water after removing surface active impurities by using active charcoal as adsorbent and then baked.

Methods.—Surface pressure was measured by a surface balance of float type with a mica float and a double torque system. Its sensitivity was better than 0.01 dyne per cm. Surface potential was measured by the vibrating electrode method. The electrode was made of gold of 2 cm. in diameter. The signal picked up by the electrode was amplified by a three stage A. C. amplifier and detected by an oscilloscope. The potential was determined by the compensation method with a potentiometer. The trough was made of polymethyl methacrylate, the rim of which was coated by a thin paraffin layer to ensure a high contact angle.

All the measurements were carried out at room temperature, but the fluctuation of temperature never exceeded 1° during the experiments. The solution was spread by means of a micrometer syringe. Fifteen minutes after spreading, the compression of film was started. The films of all polypeptides other than poly-L-proline and poly-L-hydroxyproline showed no time effect.

Results

Surface pressure-area (Π-A) and surface potential-area ($\Delta V - A$) curves of poly-DL-alanine, poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) are shown in Figs. 1, 2, and 3, respectively. For comparison with poly-L-prolyl-L-leucylglycine, area of copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) in Fig. 3 was denoted in the unit of A^2 per three amino acid residues. In Fig. 4 the Π-A and ΔV-A curves of poly-L-proline together with the Π-A curve of poly-L-hydroxyproline both on 1 M potassium chloride are shown. The Π-A and ΔV-A curves of all these polypeptides other than the last

$$\Delta V = \frac{4\pi\mu}{A}$$

In the Π-A curve there appears an area, A_Π, where the surface compressibility

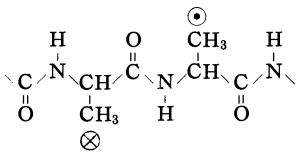
$$\delta = -\frac{1}{A}\frac{\partial A}{\partial \Pi}$$

is a minimum. This area corresponds to that occupied by a repeating unit in the close-packed monolayer. The surface moment is constant, namely, μ_c, over certain regions of area. When the monolayer is compressed, the surface moment begins to decrease at a certain definite area, A_μ. This area is that where the electric dipole of repeating unit begins to change its orientation. Since the dipole is considered to be contributed mainly by the carbonyl groups of peptide bonds in the polypeptides studied (except for poly-L-hydroxyproline), the values of surface moment are concerned with the orientation of carbonyl groups in the monolayer. All these characteristics are summarized in Table I.

TABLE I
MONOLAYER CHARACTERISTICS OF POLYPEPTIDES

Polypeptides	A_Π A² per repeating unit	A_μ A² per repeating unit	μ_c mD
Poly-DL-alanine	14.9	14.8	158
Poly-L-prolyl-L-leucyl-glycine	57	63	162×3
Copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine)	46*	60*	166×3

* A² per three amino acid residues.

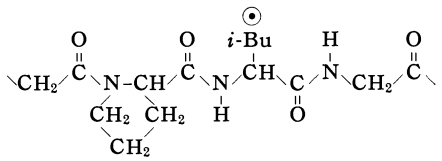


In spite of the marked difference in surface pressure among three polypeptides completely spread as monolayer, that is,

poly-DL-alanine, poly-L-prolyl-L-leucylglycine and copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine), the values of surface moment were found to be nearly equal to one another, μ_c being about 160 mD per amino acid residue, as seen in Table I. This means that the orientation of the carbonyl groups of all these polypeptides are almost the same. Taking the electric moment of carbonyl group to be 360 mD, following Davies[7], it may be directed to 30° downwards to the aqueous surface.

Discussion

Chain Configuration in Polypeptide Films. — *a) Poly-DL-alanine.* — Poly-DL-alanine gives a monolayer of condensed type. Its Π-A and ΔV-A curves have already been reported by Glazer and Dogan[8], and its μ-A curve has been measured by Davies[7]. The Π-A curve in Fig. 1 shifts somewhat to larger area than that of Glazer and Dogan's, but the ΔV-A curve is in good agreement. The A_μ value found from the μ-A curve is much less than Davies'. The monolayer of poly-DL-alanine is much more condensed than some vinyl polymers with side-chains of the same order of length, such as polyvinyl acetate[9-12] and polyethyl acrylate[9]. This is attributed to the fact that the polypeptide chain is held together rigidly by the intrachain hydrogen bonds and is less flexible by the partial double bond nature of peptide bonds. The minor dependence of surface pressure on temperature also supports this view.



From the data in Table I, it appears probable that the β-configuration with the alternation of side-chains, methyl groups, up and down to the surface,

⊙ above the interface
⊗ below the interface

makes most parts of the chain, as Cumper and Alexander[13] and Davies[7,14] suggested from the surface viscosity and surface potential measurements, respectively.

b) Poly-L-prolyl-L-leucylglycine.—Recently, Leung and Marsh[15] determined the crystal structure of the tripeptide, L-leucyl-L-prolylglycine, which is similar to the repeating unit of poly-L-prolyl-L-leucylglycine. They found that all the peptide bonds are planar-*trans* and the tripeptide is in a highly extended configuration. Such a configuration appears to be probable also in this polypeptide. On the basis of these requirements and data in Table I, a possible configuration at the interface may be suggested as follows:

⊙ above the interface

in which the main chain assumes a β-configuration except for the glycyl-L-prolyl bond, and the side-chain of L-leucyl residue stands up out of the aqueous surface. While at the area larger than A_μ all pyrrolidine rings of L-prolyl residues lie flat on the aqueous surface, at the area less than A_μ some of them rise on the surface and at the area equal to A_Π all of them rise and are closely packed.

c) Copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine). — Although copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) has the same proline content as poly-L-prolyl-L-leucylglycine, the arrangements of prolyl and the other residues in the amino acid sequences might be different from each other. As seen in Table I, whereas the values of A_μ are equal for these two polypeptides, A_Π for the former is much less than that of the latter. The former monolayer is more expanded. At the area larger than A_μ, their chain configurations appear to be similar to each other, and they should, however, be different at the area less than A_μ. The amino acid sequence in the former polypeptide cannot, therefore, be entirely periodic as in the latter. On the other hand, if it would contain any successive prolyl residues in some parts of the chain, no prolyl residues could always

exist at the interface in an equivalent manner, orientating the pyrrolidine rings and carbonyl groups irregularly. Then the $A_{//}$ and μ_c values would be less than those observed. Thus the copolypeptide should contain the considerable amounts of L-prolyl-R-L-prolyl sequences, where R is either L-leucyl or DL-alanyl residue. Such parts of the chain will be folded by the steric hindrance and rigidity, submerging a part of the main chain into the aqueous subphase, instead of raising the pyrrolidine rings out of the surface, when the monolayer is compressed to the area less than A_{μ}. The other parts of the chain will remain the same as in poly-L-prolyl-L-leucylglycine. Hence, $A_{//}$ is much less than A_{μ}. It may, therefore, be considered that copoly-1:1:1-(L-proline, L-leucine, DL-alanine) is composed of a polypeptide with no successive but irregular arrangements of prolyl residues.

d) Poly-L-proline. — Poly-L-proline exists in two forms[16]. Poly-L-proline I is prepared by polymerization of N-carboxy-L-proline anhydride in pyridine and precipitated by adding ether to the reaction mixture. It is partly soluble in water and dextro-rotatory, $[\alpha]_D^{25}=+40°$. When it is dissolved in formic acid and precipitated by ether, it is transformed into poly-L-proline II, which is soluble in water and highly levo-rotatory, $[\alpha]_D^{25}=-540°$. But poly-L-proline I is regenerated when poly-L-proline II is dissolved into higher alcohols[17].

The poly-L-proline sample given to us was poly-L-proline II. However, at least, its most part is probably transformed into poly-L-proline I in the present spreading solution, that is, in 50% (v/v) isopropyl alcohol solution. The *Π-A* curves of poly-L-proline on various aqueous subphases are shown in Fig. 5. It is unstable on salt-free subphases, and the higher the pH of the aqueous subphase, the more stable and the more expanded the film. The addition of potassium chloride into the water phase also aids the spreading of film. In any cases examined, films are of expanded type and pressure-soluble.

According to the study of X-ray diffraction by Cowan and McGavin[18], poly-L-proline II in the crystalline state exists in a left-handed helix with 3 residues per

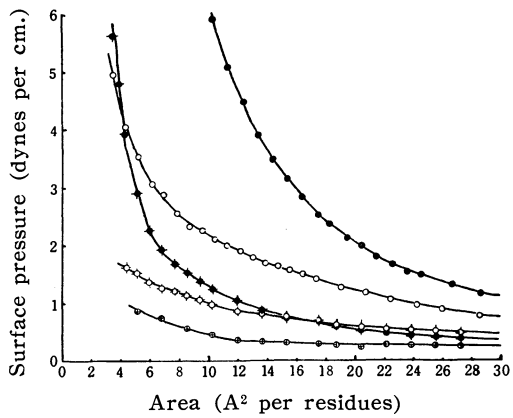

Fig. 5. Surface pressure-area curves of poly-L-proline on various aqueous subphases at 29°C: ⊕, 0.01 N HCl; ◇, H_2O; ○, 1 M KCl; ◆, 0.01 M K_2CO_3; ●, 0.01 M K_2CO_3; 1 M KCl.

turn, the keto-imido bonds being planar-*trans*. On the other hand, though no data on the structure of poly-L-proline I is available, Katchalski[17] inferred it to be a right-handed helix with *cis* bonds, and actually Crick and Rich[19] have deduced it to have approximately $3^1/_8$ residues per turn. Both structures have a high degree of steric rigidities, only permissible to the *cis-trans* transformation. Harrington and Sela[20] have demonstrated this for aqueous solutions. It will be found that no proline residues of poly-L-proline can always exist in an equivalent manner, when it is spread at the interface. Then no carbonyl groups can always orientate to the same direction, and the surface moment is, therefore, relatively low, owing to the intrachain cancellation of dipole moments. In fact, the values of μ_c did not exceed 120 mD in the cases of various subphases examined. The results obtained in the present investigation suggest that the *trans* peptide bonds in poly-L-proline dissolve into the aqueous subphase and the *cis* bonds remain on the surface, after being subjected to the *cis-trans* transformation, as soon as poly-L-proline I is spread. The lower the pH of subphase, the more feasible the transformation will be. The dependence of film behavior on the pH appears to have some correlation with the mutarotation of poly-L-proline I in formic acid, acetic acid or water. The addition of potassium chloride will support the *trans-cis* transformation, reducing the water

activity. The expanded nature of poly-L-proline films may be attributed to their being devoid of hydrogen bond, as shown later.

General Behavior of Polypeptide Monolayers.—From the Π-A curves in Figs. 1, 2, 3 and 4, it can be noticed that the polypeptide films change from the condensed type to the expanded type in the following order:

poly-DL-alanine;

poly-L-prolyl-L-leucylglycine;

copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine);

poly-L-proline.

This order suggests that the higher the prolyl content, the more expanded the film, although the extent of the expansion of film depends also on the arrangement of prolyl residues in the polypeptide sequence. Even poly-DL-alanine, which has the shortest side-chain among polypeptides to be spread as monolayer, gives a very condensed film. The film of poly-L-proline is one of the most expanded.

To distinguish which factor of prolyl residue mentioned earlier is the most responsible for the expansion of film, the film of poly-L-hydroxyproline was studied which differs from poly-L-proline only in the presence of hydroxyl groups on pyrrolidine rings capable of hydrogen bonding. Its Π-A curve on 1 M potassium chloride solution is shown in Fig. 4. The film was unstable and spread incompletely even on such a concentrated salt solution. It is, however, of condensed type. Therefore, the expanded nature of poly-L-proline film may be attributed to the absence of hydrogen bond. The order of expansion of polypeptide films will mainly come from the fact that the prolyl residues involved reduce the number of hydrogen bonds in the film state. The hydrogen bonds in film hold the polypeptide chain together and make it rigid, and, conversely, their decrease in number will make the chain extended and flexible. Accordingly, it is believed that the chain flexibility caused by the reduced number of intrachain hydrogen bonds is generally more effective than the steric rigidity in the monolayer of polypeptide containing prolyl residues.

It is found from Table I that while the condensed poly-DL-alanine monolayer has equal values of A_{Π} and A_{μ}, the expanded monolayer of the other two polypeptides has A_{Π} values less than A_{μ} values. Such a difference between monolayers of condensed and expanded type is extensively observed in other polymers so far reported. Since the condensation and expansion of monolayers of polymers are related to the intrachain interaction, this property depends on the chain configuration in monolayer. The condensed monolayer will collapse if it is compressed beyond the close-packed area, because the molecular chain is held together rigidly. In the expanded monolayer, however, the molecular chain can readily reorientate or fold itself on compression, as it is flexible. The difference in chain configuration or intrachain interaction is considered to be manifested in the monolayer property mentioned above.

Summary

To elucidate the roles of prolyl residue in polypeptide monolayers, the surface films of poly-DL-alanine, poly-L-prolyl-L-leucylglycine, copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine), poly-L-proline and poly-L-hydroxyproline were studied by the surface pressure and potential measurements.

The area of minimum surface compressibility and the smallest area of constant surface moment were assigned to each of the first three polypeptides which were found to form monomolecular films. In the region of large area their surface moments were equal to one another and, therefore, the orientations of carbonyl groups might be the same. From these data their chain configurations at the interface were deduced. Poly-DL-alanine exists in the β-configuration and the other two have the similar configuration except for the bonds attached to prolyl residues. Based on the departure in surface pressure behavior of copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) from that of poly-L-prolyl-L-leucylglycine, the arrangement of prolyl residues in the sequence of the former polypeptides was discussed. In the poly-L-proline film it is likely that the parts of *cis* peptide bond form the film and the parts of *trans* bond dissolve into the aqueous subphase.

The polypeptide films were found to be more expanded as the prolyl content was higher, although the arrangement of prolyl residues also affected the expansion of film. From the comparison of poly-L-proline film with poly-L-hydroxyproline,

the evidence was obtained that the expansion of film comes from the decrease in number of hydrogen bonds because of the presence of prolyl residues. The condensation or expansion and its related properties of the film were interpreted in terms of the chain rigidity or flexibility and the intrachain interaction.

The Electrolytic Reduction of Ketones at a Mercury Cathode.—Preparation of Organomercuric Compounds

By Toshio ARAI

(Received September 1, 1958)

Tafel[1] reported that on an electrolytic reduction, acetone might be reduced to isopropyl alcohol at a mercury cathode, and later he reported[2] that methyl ethyl ketone was reduced to diisobutyl mercury at a mercury cathode, and acetone to diisopropyl lead at a lead cathode. Haggerty[3] investigated the possibility of preparing diisobutyl mercury from acetone in a sulfuric acid solution at a mercury cathode. Dimenthyl mercury[4] was also obtained from menthone in a strong sulfuric acid electrolyte at a mercury cathode at a higher temperature.

It has been thought that on electrolytic reduction of ketones in a sulfuric acid solution at a mercury cathode, organomercury compounds are produced according to the following formula:

$$2\begin{matrix}R\\R\end{matrix}\!\!>\!C{=}O + 6H^+ + 6F + Hg \rightarrow \begin{matrix}R\\R'\end{matrix}\!\!>\!CH{-}Hg{-}CH\!<\!\begin{matrix}R\\R'\end{matrix} \quad (1)$$

and when the organomercury compounds obtained are treated with mercuric halide in an alcoholic solution, organomercuric halides are prepared as follows:

$$R{-}CH_2{-}Hg{-}CH_2{-}R + HgX_2 \rightarrow 2R{-}CH_2{-}HgX \quad (2)$$

It has been also recognized that when they are treated with hydrogen chloride gas in an alcoholic solution, organomercuric chloride and hydrocarbon are obtained:

$$R{-}CH_2{-}Hg{-}CH_2{-}R + HCl \rightarrow R{-}CH_2HgCl + R{-}CH_3 \quad (3)$$

The author has investigated electrolytic reduction of aryl alkyl ketones and cyclic ketones and prepared organomercury compounds from several ketones by using a diluted sulfuric acid solution at a mercury cathode at a higher temperature. Phenylacetone, acetylbenzoyl[5], cyclopentanone, cyclohexanone, and methylcyclohexanone were reduced to organomercury compounds, and their halides were prepared. These organomercury compounds were shown in Table II. The preparation of other ketones, namely, acetophenone, propiophenone, *p*-methylacetophenone, *p*-bromoacetophenone, benzoin, benzil, 1-acetonaphthone, and dibenzyl ketone were tried in this experiment in the same way, but mercury compounds were not obtained, and corresponding pinacol and alcohol were produced.

In general, it is thought that ketones which have carbonyl radical adjacent to phenyl radical are not reduced to mercury compounds.

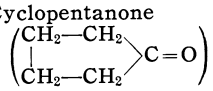
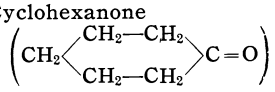
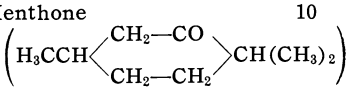
Organomercury compounds were synthesized by many kinds of methods, and dicyclohexyl mercury and its halides were already obtained purely chemically[6,7], but other compounds obtained in this experiment, were not prepared by pure chemical methods. In this experiment the yield of organomercury compounds was not very good; this method, however, seems to be an easy and effective method of syntheses.

Experiment and Discussion







In most cases the cathodic solution consisting of 120 ml. of 5% sulfuric acid in which a ketone was suspended and alcohol was not used as electrolyte. A 5% solution of sulfuric acid served as an anodic solution and cylindrical lead was employed as anode. The anode was separated from the catholyte by means of porous pot. An electrical connection was made with the mercury at the bottom of a cathode by means of platinum wire sealed into a glass narrow tubing. Mercury was purified by washing with nitric acid. The electrolyte was first heated to 50° and during the electrolysis the catholyte was maintained at 50~55° by the reaction heat. The electrolytic chamber was kept upright and the cathodic solution was stirred vigorously. After the current was passed for a short time, a black turbidity appeared in the catholyte. It has been thought[8] that this turbidity seemed to be due to finely divided mercury.

As the electrolysis continued, the cathodic solution gradually cleared up. The amount of electric current passed was about one and a half of the theoretical one. After the electrolysis, a heavy viscous oil floated on the surface of the mercury. The catholyte was placed in a separate funnel, the oil was removed, the residue was extracted with ether, the ether extracts were evaporated under reduced pressure and a solid residue or a viscous oil was obtained. It was mercury compound and the yield of crude product was about 25~30% of the theoretical amount. As the compounds was unstable,

crude product was dissolved in alcohol and the solution was used to prepare organomercuric halides. The product was crystallized from dilute alcohol, but some mercury compounds were difficult to crystallize.

The compound in the product was heated with alcoholic solutions of mercuric chloride, mercuric bromide, or mercuric iodide and white precipitates were formed as shown by Eq. 2. These substances were organomercuric halides; they were recrystallized from alcohol or acetone, and fine crystals were obtained. A quantitative yield was obtained.

The crude products were dissolved in alcohol and hydrogen chloride was passed into the solution and the hot reddish solution was cooled in an ice bath. Precipitates were produced as seen in Eq. 3; they were filtered and recrystallized from dilute alcohol containing charcoal. Fine crystals were obtained. It was organomercuric chloride and was identical with the compound obtained by treating the crude organomercury compound with mercuric chloride.

The analysis of mercury was carried out according to the convenient thiocyanate method recommended by Kharasch and Flenner (cited by Hillebrand and Lundell[8]) and good results were obtained.

The influence of various electrolytic conditions on the reduction of several ketones are shown in Table I. Phenyl acetone was not reduced to mercury compound in 5% sulfuric acid solution at a low temperature; it was recovered almost intact, and was not reduced to secondary alcohol or pinacol. It was mercurised in 30% sulfuric acid or in a mixture of glacial acetic acid and 18% hydrochloric acid solution at a low temperature; however, it was mercurised even in 5% sulfuric acid solution at a high temperature. Cyclohexanone behaves similarly to phenylacetone. Cyclopentanone was easily mercurised at a low temperature in various cathodic solution. By the use of 50 g. of cyclohexanone, in catholyte, pinacol[11] (dihydroxy-dicyclohexyl) was produced by about half the amount.

The ketones mentioned above were reduced to mercury compound even in a mild condition; however, in the case of menthone, it was reported[4] that menthone was reduced to dimenthyl mercury only in a strong sulfuric acid at 77~80° with a high current density and to methone or menthol in a weak sulfuric acid electrolyte at a mercury cathode.

Dibenzyl ketone, which was expected to be reduced to organomercury compound and tried in this experiment, was not reduced to mercury compound.

The formation of these mercury compounds is not a continuation of a secondary-alcohol formation because secondary alcohol was not reduced by electrolytic methods under various conditions; namely, cyclohexanol was reduced under the same conditions as above mentioned, but it was recovered almost as it was.

Dialkyl mercuries are volatile liquids and miscible with organic solvents, practically insoluble in water, decompose on standing at room temperature and are sensitive to light. Diaryl mercuries are solid and stable. The mercury compounds obtained in this experiment were also solid and soluble in ether and hot alcohol, but less soluble in cold alcohol and insoluble in water. Dicyclohexyl mercury was unstable and changed its color from white to gray slowly in several hours after recrystallization. It was reported[6] that dicyclohexyl mercury was unstable and decomposed to black oil after 25 hours in a vacuum desiccator over phosphrous pentoxide. Dicyclopentyl mercury was stable as compared with the former, but both compounds turned from gray to black in a few days and at last they decomposed to yellow liquid and black residue. These compounds, above mentioned, were very unstable in the pure and dried state, but comparatively stable in sulfuric acid, ether, and alcohol. Dicycloalkyl mercury has a strong specific odor like camphor and diisopropylmercury like aromatic hydrocarbon.

It was reported[7] that di-4-methylcyclohexyl mercury was a liquid, but this compound is a crystal and di-3-methyl, and di-2-methylcyclohexyl mercury might be solid; however, they were not obtained crystalline in this experiment and it seems that they have a lower melting point compared with the melting point of its halides, and di-4-methylcyclohexyl mercury and its halide have a high melting point owing to its symmetric structure.

Organomercuric halides are exceedingly stable, and are fine crystals with sharp melting points without odor; they are soluble in pyridine, hot alcohol, and acetone, less soluble in alcohol and insoluble in water. Iodides are white crystals, but their color changes to yellow on standing very slowly.

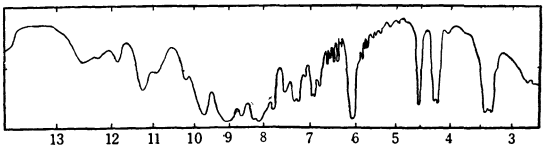
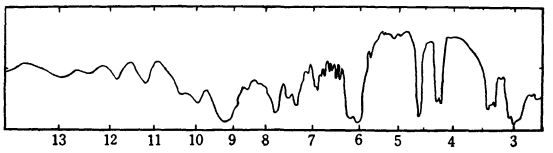
Syntheses of Pyrimidine Derivatives. XVII. On the Reaction Mechanism of Some Pyrimidine Syntheses



By Akira TAKAMIZAWA, Kanji TOKUYAMA and Kazuo TORI

(Received September 3, 1958)

Some interesting reactions have been presented in the previous papers[1-4] dealing with the syntheses of pyrimidine derivatives from 3-alkoxypropionitriles and acetamidine. These reactions can be divided into two types according to their reaction behavior, which are represented by A and B. In the case of reaction A, 2-methyl-4-amino-5-ethoxymethylpyrimidine (II) can be obtained directly by the reaction of 2-methoxymethylene-3-ethoxypropionitrile (I) with acetamidine.



On the other hand, in the case of the reaction of 2-methoxyethoxymethyl-3-ethoxypropionitrile (III) (derived from I) with acetamidine in alcohol, an intermediate IV′ can be detected spectrophotometrically in the reaction mixture (λ_{max} = 275 mμ), without being successfully isolated. Being heated with another one mole of acetamidine, the intermediate IV′ is converted into 2,7-dimethyl-5,6-dihydropyrimido(4,5-d)pyrimidine (V), hydrolysis of which produces 2-methyl-4-amino-5-acetaminomethylpyrimidine (VI), but treatment of IV′ with hydrogen chloride results in II (Reaction B). In view of these facts, the structure of IV′ has reasonably been supposed as 2-acetamidinomethylene-3-ethoxypropionitrile (IV). Besides the above-mentioned facts, it has been shown[5,6] that 2-methyl-4-hydroxy-5-ethoxymethylpyrimidine (VII) could be obtained by the reaction of ethyl 2-methoxymethylene-3-ethoxypropionate (VIII) or ethyl 2-methoxyethoxymethyl-3-ethoxypropionate (IX) with acetamidine in ethanol. One of the important purposes of the present investigations is to identify IV′ with IV, and to present the most reasonable mechanism of these reactions. Another purpose is to check and see if the mechanism of analogous reactions can be explained in a similar manner.

Identification of the Intermediate IV′.— In order to compare the structure of the intermediate IV′ with that of IV, the

Wave length (μ)

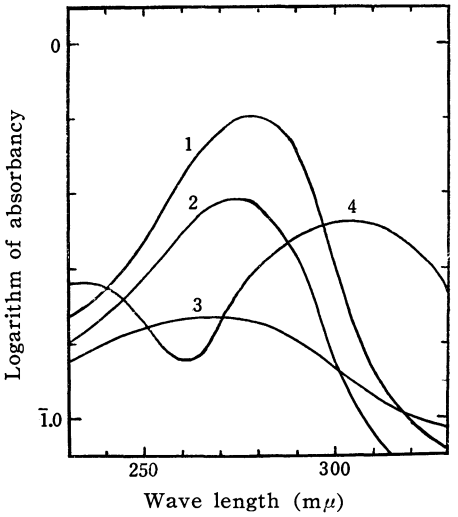
synthesis of the latter from 2-aminomethylene-3-ethoxypropionitrile (XI) and acetiminomethyl ester was undertaken. 2-Ethoxymethylene-3-ethoxypropionitrile (X) was dissolved in liquid ammonia, and after this solution was kept for a long time at room temperature, XI was obtained as a dark brown viscous liquid. The infrared spectra of this product and X were measured. From the results given in Figs. 1 and 2, it is clear that the absorption band due to —C=C—O— group of initial substance X disappears and that of an amino group newly appears. XI thus obtained being unstable, it easily liberated ammonia on heating. Furthermore, its picrate, hydrochloride, etc. could not be derived because of its weak basicity, and the expected derivatives could not be formed by the reactions of XI with acetic

anhydride, methyl iodide and 2,4-dinitrobromobenzene, but acetamide, ammonium iodide and 2,4-dinitroaniline were obtained, respectively.

It is quite natural to expect that IV can be prepared by the reaction of XI with acetiminomethyl ester. The reaction process was traced spectrophotometrically. The result given in Fig. 3 shows that the product has an absorption band (λ_{max}= 275 mμ) identical with that of the intermediate IV′ in the reaction B. The reaction mixture was converted into II by adding hydrochloric acid under cooling and into V by treating with acetamidine under heating. From the above facts, it seems conclusive that the intermediate IV′ is identical with IV.



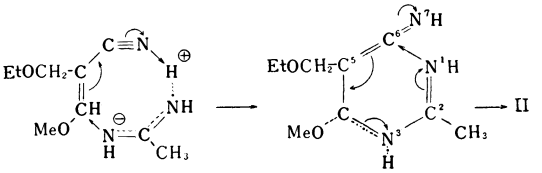


Fig. 3. Changes of ultraviolet absorption spectra of the reaction mixture, XI and acetiminomethyl ester. Curve (1), XI: (2), after 12 hr. at room temperature (IV was formed): (3) after treating IV (curve (2)) with hydrochloric acid gas: (4) after treating IV (curve (2)) with acetamidine. (Beckman DU spectrophotometer).

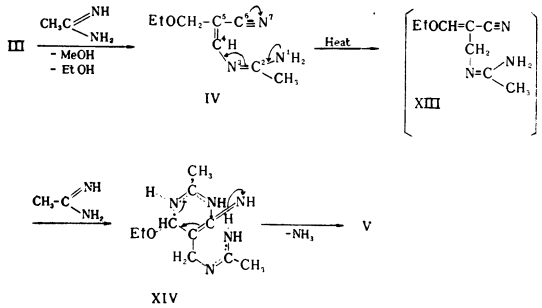
Reaction Mechanism of Pyrimidine Syntheses.—Thus it is easily inferred that there are two reaction processes for pyrimidine syntheses: namely, the first (reaction B) is the reaction of III with acetamidine whose characteristic is to produce the intermediate IV which is converted into V by heating with acetamidine, and the second (reaction A) is that of I with acetamidine in which II is formed directly without passing through any detectable intermediate.

On the basis of all the present data, the mechanisms of these two reactions may be surmised as below. In the first step of reaction A, the Michael type addition of acetamidine to I may conceivably occur. Then, the resulting intermediate XII may be immediately converted into II, since C^6 in $C^5=C^6=N^7H$ group in XII is positively charged to some extent owing to the polarity of C=N bond and N^1 in the acetamidino group has of course some amount of negative charge and therefore C^6 and N^1 can easily be bonded[7].

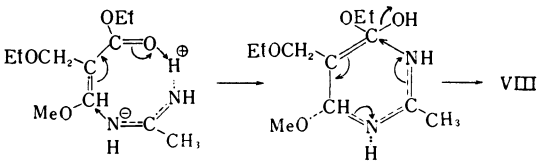


In the case of reaction B, however, the intermediate IV is derived from III by the replacement reaction. The N^1 atom in IV has probably a somewhat positive charge since the electron attracting effect of the $C^2=N^3$ bond and of the nitrile group is considerably large[8]. Moreover, the great dipole moment of $C^6\equiv N^7$ bond (3.5 D) suggests that the C^6 atom is charged positively to a large extent. Therefore, the bond formation between C^6 and N^1 may be very difficult. In addition to this, the intermediate IV can be stabilized by the resonance of the ordinary structure with polar structures where non-bonding electrons in the NH_2 group migrate to C=N and C≡N groups. These are the reasons why IV is fairly stable in the solution and can be detected spectrophotometrically. By heating the solution, the prototropy may occur continually to form the structure XIII, because of the strong electron attracting effect of the nitrile group. Then, another acetamidine molecule may be added to XIII, resulting in XIV which is finally converted into V eliminating an ammonia molecule[9].

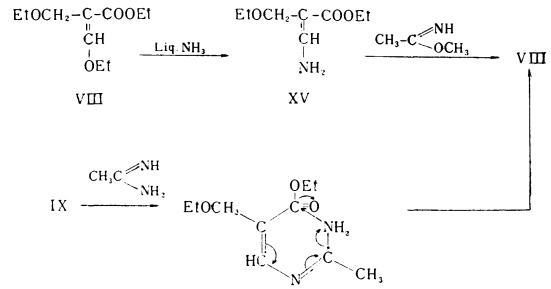
However, by treating IV with a reagent such as hydrochloric acid, the nitrile group

7) In the structure XII, C^6 and N^7 have respectively about 16% positive and negative charges because of the difference in the electronegativity values between C^6 and N^7 of C=NH group. The above value can be evaluated by the aid of the bond moment of C=N. (0.9 D; C. P. Smyth, "Dielectric Behavior and Structure", McGraw Hill, New York, (1955), p. 245).

8) N^1 has a positive charge because of the strong electron attracting power of $C^2=N^3$ bond and of nitrile group affecting through the conjugated system of IV, although N^1 seems to charge negeatively due to the difference of electronegativity between C^2 and N^1 of C^2-N^1H_2 group, the moment of which is only 0.22 D.



9) Further investigation seems to be required for the final conclusion on these reaction mechanisms.



in it may be broken. Thereby the strong electron attracting effect of this group probably decreases and IV is conceivably converted into II[10] through a course similar to that of reaction A mentioned above.

In short, the important difference between these two reactions is that intermediate IV in reaction B has a nitrile group with strong electron attracting power and an amino group with electron donating property at both ends of its conjugated system and between these two groups resonance is possible, whereas the intermediate XII in the reaction A has no longer such a resonating system, since its nitrile group is converted into imino type.

It is quite natural from the above consideration that ethyl 2-methoxymethylene-3-ethoxypropionate (VII) gives 2-methyl-4-hydroxy-5-ethoxymethylpyrimidine (VIII) by the reaction with acetamidine[5,6] in the same manner as in the reaction A.

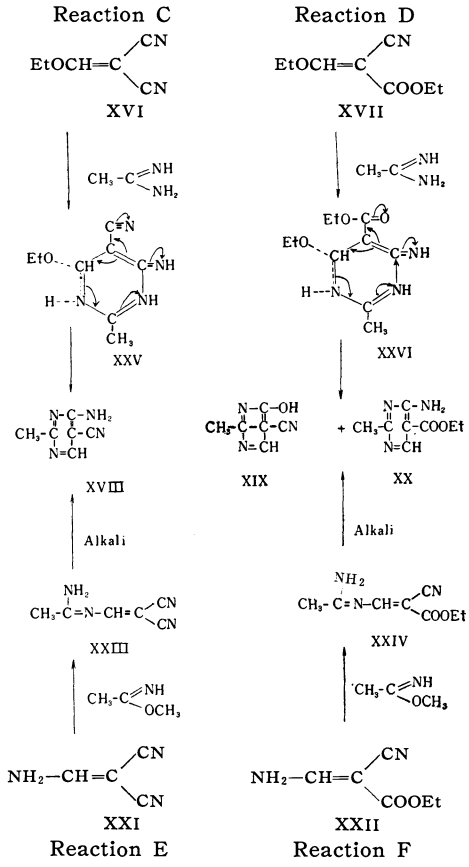
The situation is the same for the reaction of ethyl 2-aminomethylene-3-ethoxypropionate (XV) and acetiminomethyl ester. In this case, VIII was also obtained directly[11]. Now let us consider the reaction of ethyl 2-methoxyethoxymethyl-3-ethoxypropionate (IX) with acetamidine. In the course of this reaction, the intermediate like IV could not be observed spectrophotometrically but the reaction product VIII was obtained directly[5,6]. At the first glance, this fact looks strange because in the intermediate of this reaction, the stabilization due to resonance between the electron attracting (COOEt) and donating (NH_2) groups may be expected. However, this fact may probably be explained by taking account of the small electron attracting power of the carbethoxyl group compared with that of the nitrile group[12]. Further mention on this point will be made below.

According to these two reaction mechanisms for pyrimidine syntheses, it is possible to explain consistently some analogous reactions indicated in the literatures, which have been re-investigated in our laboratory.

The reactions of ethoxymethylenemalondinitrile (XVI) (reaction C) and ethyl ethoxymethylenecyanoacetate (XVII) (reaction D) with acetamidine give 2-methyl-4-amino-5-cyanopyrimidine (XVIII) (reaction C) and 2-methyl-4-hydroxy-5-cyanopyrimidine (XIX) with 2-methyl-4-amino-5-carbethoxypyrimidine (XX) (reaction D), respectively. On the other hand, aminomethylenemalondinitrile (XXI) (reaction E) and ethyl aminomethylenecyanoacetate (XXII) (reaction F) are converted by the reaction with acetiminomethyl ester into acetamidinomethylenemalondinitrile (XXIII) and ethyl acetamidinomethylenecyanoacetate (XXIV), respectively[13-15], yielding the corresponding pyrimidines only by treating with alkali. It is probably that in the cases of the reaction C and D, the intermediates, XXV and XXVI, are led to the corresponding pyrimidines directly in a way similar to that of reaction A, since their nitrile groups disappear, whereas in the cases of the reactions E and F the

10) 2-Methyl-5-carbethoxy-3,4-dihydropyrimidine is also obtained. In this case, it must be considered that the nitrile group is converted into an iminoester group.

11) A. Takamizawa and K. Tokuyama, *J. Pharm. Soc. Japan*, (*Yakugaku Zasshi*), **79**, (1959), in pretss.



12) This is inferred from the fact that the σ vlaue (Hammett's substituent constant) for the nitrile group is apparently larger than that for the carboxyl group.

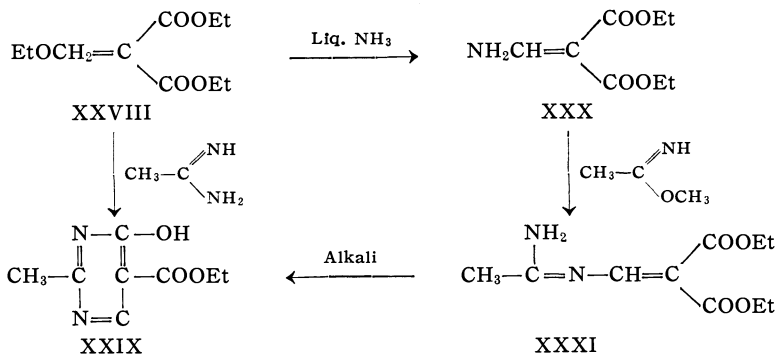
15) Y. Sawa and T. Tsuji, This work was read at the Kinki Congress of Pharmaceutical Society of Japan, Osaka, 1955.



intermediates, XXVII and XXVIII, have still their nitrile groups and therefore do not react further without treating with alkali. That is to say, this mechanism is similar to that of reaction B.

According to Todd[13], the intermediate XXVI was obtainable in the course of the reaction D, but this assertion has been refuted by Sawa and Tsuji[15], who reported that XXVI could not be obtained under the experimental conditions they employed. This result seems to be consistent with the above consideration that the intermediate like XXVI is too unstable to be detected. Moreover, Sykes et al.[16] have reported that XXVII′ was obtained by the reaction of XVII with two moles of acetamidine, but their result is not convincing. It contradicts the present authors' opinion. Inspecting more completely their data on the melting point and elemental analysis, we are led to the conclusion that the compound obtained by Sykes et al. is acetamidinate XXVII[15] of XIX.

As mentioned above, the electron attracting effect of one carbethoxy group is weaker than that of a nitrile group, but the following fact indicates that two carbethoxy groups roughly correspond to one nitrile group in their electron attracting power. While 2-methyl-4-hydroxy-5-carbethoxypyrimidine (XXIX) was obtained at once by the reaction of diethyl ethoxymethylenemalonate(XXVIII) with acetamidine, diethyl aminomethylenemalonate (XXX) was converted with acetiminomethyl ester into diethyl acetamidinomethylenemalonate (XXXI), which gave XXIX on treatment with alkali.

Experimental

2-Aminomethylene-3-ethoxypropionitrile (XI).—A solution of 2-ethoxymethylene-3-ethoxypropionitrile (X) (5.0 g.) dissolved completely in liquid ammonia (20 cc.) was left at room temperature for 45 days. After removal of the liquid ammonia and the alcohol produced under reduced pressure, a dark brown liquid (3.8 g.) was obtained. $n_D^{20.5}$, 1.4759.

Anal. Found: C, 56.62; H, 7.64; N, 22.21; $-OC_2H_5$, 34.66. Calcd. for $C_6H_{10}N_2O$: C, 57.11; H, 7.99; N, 22.21; $-OC_2H_5$, 35.71%.

Reaction of 2-aminomethylene-3-ethoxypropionitrile (XI) with acetiminomethyl ester.—To an ice-cold solution of sodium (0.3 g.) in absolute methanol (50 cc.), was added acetiminomethyl ester hydrochloride (1.5 g.); the mixture was shaken for few minutes and quickly filtered from precipitated sodium chloride. To the cooled filtrate was added 2-aminomethylene-3-ethoxypropionitrile (XI) (1.3 g.) in portions with shaking. After being allowed to stand overnight at room temperature, (i) dry hydrochloric acid was vigorously passed into the solution during three hours at 10~15°C, and the solution was again allowed to stand overnight. After removal of methanol in a vacuum, the residue was neutralized with sodium carbonate, washed with ethyl acetate, made strongly alkaline with sodium hydroxide and extracted with benzene. The benzene layer was dried over sodium sulfate and purified by passing through an alumina column. After evaporation of the solvent, 2-methyl-4-amino-5-ethoxymethylpyrimidine (II) was given; it was crystallized from ethanol in colorless rods, m. p. 89~90°C. Yield, 10 mg., (5.86%). Picrate, m. p. 189~190°C.

Anal. Found: C, 42.44; H, 4.18; N, 21.57. Calcd. for $C_{14}H_{16}N_6O_8$ (as picrate): C, 42.42; H, 4.44; N, 21.21%.

(ii) A mixture of absolute methanol (20 cc.), sodium (0.3 g.) and acetamidine hydrochloride (1.4 g.) was added. After being boiled for three hours, the precipitated sodium chloride was filtered off and the solvent was removed. To the residue was added 10% aqueous solution of sodium hydroxide; the mixture was heated on a water-bath for one hour. After cooling, colorless crystals separated on salting out with 50% aqueous solution of sodium hydroxide. Recrystallization from water gave 2-methyl-4-amino-5-acetaminomethylpyrimidine (VI) of colorless prisms (1.0 g.), m. p. 204~206°C. Picrate was yellow needles, m. p. 200°C.

Anal. Found: N, 23.98. Calcd. for $C_{14}H_{15}N_7O_8$ (as picrate): N, 23.96%.

Reaction of diethyl aminomethylenemalonate (XXX) with acetiminomethyl ester.—To an ice-cold solution of sodium (0.6 g.) in absolute ethanol (50 cc.), was added acetiminomethyl ester hydrochloride (3.2 g.); the mixture was shaken for a few minutes and quickly filtered from precipitated sodium chloride. To the cooled filtrate was added diethyl aminomethylenemalonate (XXX) (3.7 g.) in portions with shaking. After being allowed to stand overnight at room temperature, the solvent was removed in a vacuum. The residue, m. p. ca. 190°C, decomposed by recrystallization. This may be diethyl acetamidinomethylenemalonate (XXXI).

The above product was heated on a water-bath for 15 minutes with an ethanolic sodium ethoxide (0.2 g.; 50 cc.). The yellow solution was cooled, acidified with acetic acid, and concentrated in vacuo to about half the original volume. On standing, 2-methyl-4-hydroxy-5-carbethoxypyrimidine (XXIX) separated; it crystallized from acetone in colorless needles, m. p. 190°C. Yield, 0.1 g.

Anal. Found: N, 15.11. Calcd. for $C_8H_{10}N_3O$: N, 15.38%.

Summary

The mechanism of the reactions of 2-alkoxymethylene-3-alkoxypropionitrile and 2-dialkoxymethyl-3-alkoxypropionitrile with acetamidine was studied. The results show that these two nitriles react with acetamidine in completely different manners. In the case of the reaction of 2-alkoxymethylene-3-alkoxypropionitrile with acetamidine, the final product (2-methyl-4-amino-5-alkoxymethylpyrimidine) can be obtained directly, while in the case of the reaction of the other nitrile with acetamidine, the intermediate with the absorption maximum at 275 mμ can be detected spectrophotometrically. This intermediate could be identified with 2-acetamidinomethylene-3-alkoxypropionitrile. The difference in the mechanism between these two reactions might be explained by taking into consideration the fact that the intermediate in the latter case can be stabilized by the resonance among the usual structure and the polar structures in which non-bonding electrons on the nitrogen atom of the amino group migrate into C≡N or C=N group.

We wish to acknowledge our indebtedness to Professors M. Tomita, University of Kyoto, and S. Uyeo, University of Osaka, and Dr. K. Takeda, Director of our laboratory, for their kind guidance and encouragement and we are also indebted to Assistant Professor S. Nagakura, the University of Tokyo, for his helpful discussion. We are grateful to Messrs. K. Kubota, M. Narisada and H. Miyazaki for the measurements of infrared and ultraviolet spectra and to Messrs. T. Iyeki and K. Miyahara and Misses H. Nakai and K. Numoto for the elemental analyses.

Electron Diffraction Investigation on the Molecular Structure of 1,1,2-Trifluoro-1,2,2-trichloroethane

By Machio IWASAKI

(Received August 5, 1958)

In previous publications[1-3] it has been reported that the energy difference between *trans* and *gauche* isomer for 1,2-difluoro-1,1,2,2-tetrachloroethane is 0~500 cal./mol., and that for 1,1,2,2-tetrafluoro-1,2-dichloroethane is 440±110 cal./mol. In order to compare these results with the data for the well-known series of chlorinated ethanes[4] (CH_2Cl-CH_2Cl, $CHCl_2$-CH_2Cl and $CHCl_2CHCl_2$), it is desirable to elucidate the molecular structure of 1,1,2-trifluoro-1,2,2-trichloroethane. However, the problem of rotational isomerism in this molecule has not yet been studied except when an earlier study was made by Glockler and Sage[5]. Based solely on the number of observed Raman lines, they concluded that two isomers were present, but no attempt was made at the determination of the energy difference between the two isomers.

This report presents the results of studies on the molecular structure of CF_2Cl-$CFCl_2$ carried out by the sector-microphotometer method of electron diffraction mainly to find the effect of fluorine substitution on the energy difference between the two isomers. An attempt was also made at the determination of the equilibrium angle of the stable configuration.

Experimental

The sample was prepared by S. Nagase in this laboratory from hexachloroethane, which was fluorinated with antimony trifluoride under superatmospheric pressures in the presence of antimony pentachloride as a catalyst[6]. The product distilled at 47.8°C. The purity of this sample was tested with an infrared absorption spectrum and there were no absorptions due to impurities.

The diffraction patterns were taken at a room temperature of about 20°C using an apparatus[7] having an r^3-sector, which was rapidly rotated during photographic exposure. The apparatus and the experimental procedures were the same as described in the previous paper[3]. Two nozzle-to-plate distances of 125 mm. and 285 mm. were used: the former was used for large angle scattering and the latter for small angle scattering, which was sensitive to the internal rotation. The wavelength of the electron beam was about 0.055Å. The extraneous scatterings were removed by a beam trap and the spreading of the sample was prevented by a trap cooled with liquid air.

The molecular intensity curve qI_m shown by the top curve in Fig. 5 was obtained by the method similar to that employed by Karle and his coworker[8], the index of resolution being about 1.0.

Analysis

Radial Distribution Curve.—The radial distribution (RD) curve was calculated by the following equation:

$$f(r) = \sum_{q=0}^{q_{\max}} qI_m \exp(-aq^2) \sin(\pi qr/10) \qquad (1)$$

where I_m is the molecular scattering intensity. The artificial damping factor a was chosen so as $\exp(-aq^2)=0.1$ at $q=100$. $q=(40/\lambda)\sin(\theta/2)$, where θ is the angle of scattering and λ is the wavelength of the electron beam.

In the calculation of the RD curve, a theoretical intensity curve which was computed with constant coefficients for the assumed model was substituted in place of the observed intensity below $q=6$. Furthermore, a correction for the effect of non-nuclear scatterings[9] was made. The RD curve shown in Fig. 2 was obtained after several steps of successive

approximations based on Karle's criteria[8].

The RD curve has maxima at 1.34_5, 1.75_5, 2.0~3.7, 3.89_0, and 4.31_3Å. The first two peaks at 1.34_5 and 1.75_5Å are assigned to C—F and C—Cl bond distances, respectively. The unresolved peak at 2.0~3.7Å is due to the superposition of various non-bonded distances, that at 3.89_0Å to the *trans* F···Cl distance, and that at 4.31_3Å to the *trans* Cl···Cl distance.

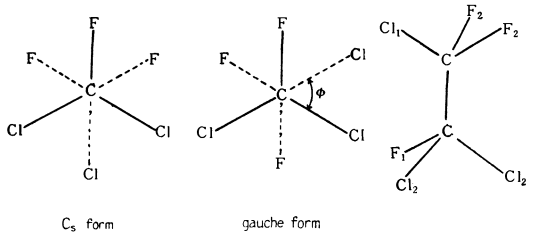

Fig. 1. Rotational isomers of CF_2Cl-$CFCl_2$.

Two configurations are conceivable for this molecule. One of them is a form having the C_s symmetry as shown in Fig. 1. This form will be called the C_s form. The other form having no symmetry is called the *gauche* form. Because the *trans* Cl···Cl distance is characteristic of the *gauche* form, the peak at 4.31_3Å evidently shows the existence of the *gauche* form. On the other hand, the *trans* F···Cl distance appears in both forms, but the number of this distance is three for the C_s form whereas it is one for the *gauche* form. Therefore, the ratio of the areas under these two peaks is expected to depend on whether there exists only the *gauche* form or whether two isomers exist. Because the area under the RD peak is approximately proportional to Z_iZ_j/r_{ij}, the ratio of the two forms, N_{C_s}/N_g, can be calculated from the areas of the two peaks mentioned above by means of the following formula:

$$\frac{N_{C_s}}{N_g} = \frac{Z_{Cl}r_{F\cdots Cl}A_{F\cdots Cl}}{3Z_Fr_{Cl\cdots Cl}A_{Cl\cdots Cl}} - \frac{1}{3} \qquad (2)$$

where Z_F and Z_{Cl} are, respectively, the atomic numbers of fluorine and chlorine, $A_{Cl\cdots Cl}$ and $A_{F\cdots Cl}$ are the areas of the peaks, and $r_{Cl\cdots Cl}$ and $r_{F\cdots Cl}$ are the *trans* Cl···Cl and the *trans* F···Cl distances. The ratio of the areas was hardly affected at all by the assumed value of the abundance ratio of the two isomers, because the correction for non-nuclear scatterings made it possible to use the observed values to such a small q value as 7. In this way, the amount of the *gauche* form was estimated as 80 per cent from the RD curve in applying Eq. 1. This value was further tested by the consideration of theoretical intensity curves described in the next section.

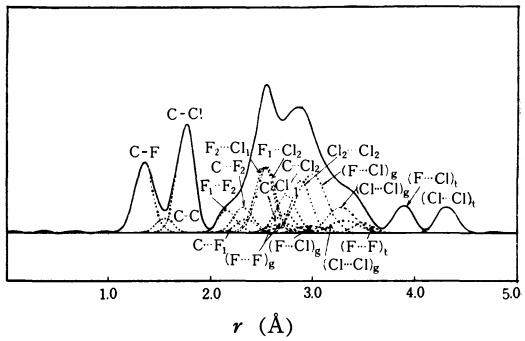

Fig. 2. Radial distribution curve for CF_2Cl-$CFCl_2$.

When the contributions from the C—F and C—Cl distances were subtracted from the composite peak ranging from 1.0 to 2.0Å, the remaining area forms a smooth curve having a maximum at 1.54_5Å which is attributable to the C—C bond distance. These three components of the first composite peak of the RD curve are illustrated in Fig. 2, and the areas under these peaks are in good agreement with the theoretical values shown in Table I.

According to the results of the previous reports[1-3] and many other papers about fluorochloromethane[10], the C—F and the C—Cl bond distances decrease with the number of fluorine atoms bonded with one and the same carbon atom. Therefore, the C—F and the C—Cl bond distances may probably be different for two halves of this molecule. In fact, the values of 1.38Å (C—F) and 1.76Å (C—Cl) in $CFCl_2$-$CFCl_2$, and those of 1.33_0Å (C—F) and 1.74_5Å (C—Cl) in CF_2Cl-CF_2Cl being assumed for the two halves of this molecule, the weighted mean values of the C—F and the C—Cl distances were 1.34_7 and 1.75_5Å, respectively; those values are in good agreement with the observed values of 1.34_5 and 1.75_5Å.

In analyzing the part of the RD curve from 2.0 to 3.7Å, an assumption was made that the bonded distances and the bond angles in two halves of the molecule were equal to those of $CFCl_2$-$CFCl_2$ and CF_2Cl-CF_2Cl, respectively. Furthermore, the

10) The C-F and the C-Cl distances in many organic fluorine compounds have been tabulated in the previous paper, ref. 2.

obtained, the part from 2.4 to 3.7Å of this curve corresponding to the contribution from the *gauche* F···F, the *gauche* F···Cl, the *gauche* Cl···Cl, and the *trans* F···F distances, which change with the azimuthal angle of the *gauche* form and the relative amount of rotational isomers. The fact that the part of the remaining curve from 2.0 to 2.4Å which is attributable to the contribution from the distances that are independent of the internal rotation, is almost equal to zero reflects the correctness of the assumption about the bonded distances and bond angles. When the remaining curve thus obtained was compared with the theoretical one calculated for various azimuthal angles[11], ϕ, of the *gauche* form, the curve for $\phi=60°$ was found to be in good agreement with the observed one as shown in Fig. 3.

The mean amplitudes listed in Table I were obtained by fitting the RD peaks with Gaussian functions, no corrections being made for second order effects, such as a sample spread, multiple scatterings and the failure of Born approximation[12]. The observed mean amplitudes are in good agreement with those calculated by Morino et al.[13] from spectroscopic data.

Theoretical Intensity Curves. — The theoretical intensity curves were calculated using the following equation:

$$qI_m(q)=\sum_{i\neq j}\sum(c_{ij}/r_{ij}) \times\exp(-b_{ij}q^2)\sin(\pi qr_{ij}/10) \qquad (3)$$

where r_{ij} denotes the interatomic distance between i-th and j-th atoms, b_{ij} is the temperature factor, and

$$c_{ij}=Z_iZ_j/\sum_i(Z_i^2+Z_i) \qquad (4)$$

In the region of small q-values the effect of non-nuclear scattering was corrected for the experimental intensity and then the constant coefficient was used over the whole q region in calculating theoretical intensity curves. The summations of Eq. 3 were performed by use of punched cards and a Remington Rand Type-285 Model-2 Tabulating machine[14,15].

In determining the range of uncertainty of 13 structural parameters and 14 mean

11) The azimuthal angle of the *gauche* form is that for the two C-Cl bonds in the molecule.
12) R. Glauber and V. Schomaker, *Phys. Rev.*, **89**, 667 (1953); L. S. Bartell and L. O. Brockway, *Nature*, **171**, 978 (1953); J. A. Ibers and J. A. Hoerni, *Acta Cryst.*, **7**, 405 (1954).
13) Y. Morino, K. Kuchitsu, A. Takahashi and K. Maeda, *J. Chem. Phys.*, **21**, 1927 (1953).
14) Y. Morino and K. Kuchitsu, *X-Ray*, (*X-sen*), **8**, 37 (1954).
15) The calculation by use of punched cards was carried out by K. Kuchitsu of the University of Tokyo.

amplitudes, it was not feasible to exhaust the possible variations in all parameters. Therefore, all the parameters except the ratios, $\rho_{Cl}=C-Cl_2/C-Cl_1$ and $\rho_F=C-F_1/C-F_2$ the azimuthal angle of the *gauche* form, ϕ, and the fraction of the *gauche* form, N_g, were kept constant throughout the analysis. The mean amplitudes used were the same as those in the previous papers[2,3]. The majority of these values listed in Table II were taken from those calculated by Morino et al.[13] from spectroscopic data or obtained by Karle et al.[16,17] from electron diffraction experiments. The C—C distance and all the bond angles were assumed to be equal to those in $CFCl_2$–$CFCl_2$ and CF_2Cl–CF_2Cl, that is, C—C=1.54Å, $\angle CCCl_1=\angle CCCl_2=112°$, $\angle CCF_1=107°05'$, $\angle CCF_2=108°$, $\angle F_1CCl_2=107°30'$, $\angle F_2CCl_1=110°$, $\angle F_1CFl_2=108°44'$ and $\angle Cl_1CCl_2=110°30'$. It was already shown in the RD analysis that this assumption was quite adequate.

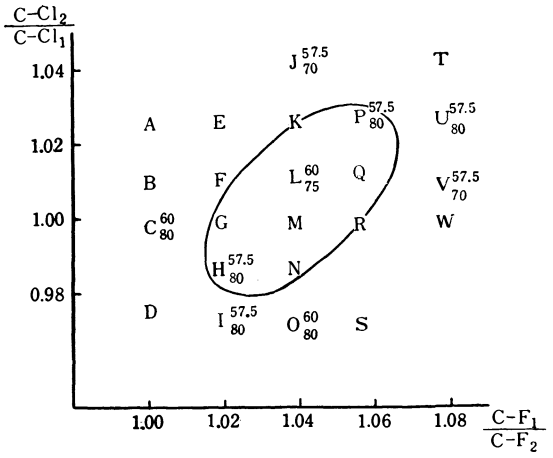

Fig. 4. Parameter chart. The positions of letters indicate the parameters of models for which intensity curves were computed. The values of the superscripts and the subscripts indicate the azimuthal angles and the amounts of the *gauche* form both of which were used in calculating the intensity curves reproduced in Fig. 5.

For each model indicated in a $\rho_{Cl}-\rho_F$ parameter chart (Fig. 4), parameters, ϕ and N_g, were further varied. The projection of the $\rho_{Cl}-\rho_F$ parameter chart on a $\phi-N_g$ plane is shown in Fig. 6. Some of the computed curves are reproduced in Fig. 5. The relative depth of the 5th and the 6th minimum, the position of the 3rd maximum and the 4th minimum and the feature of a shelf on the inner portion of the 4th maximum are very sensitive to small changes in the parameters. The models A–F, J and T in the parameter chart can be ruled out because the relative depth of the 5th and the 6th minimum contradicts with experiments, while the models, O, S, V and W, are unacceptable because the 6th minimum is too deep as compared with experiments. The model I can also be rejected because of the prominence of a shelf on the inner portion of the 4th maximum. The model U is unsatisfactory because the 7th and the 8th maximum are too faint. The models, G, H, L, M, N, P and Q, are regarded as acceptable fits, while the models, K and R, can be accepted as borderline fits. In Table III is given the comparison between the observed and the calculated intensity curve for the best model L. In Table IV

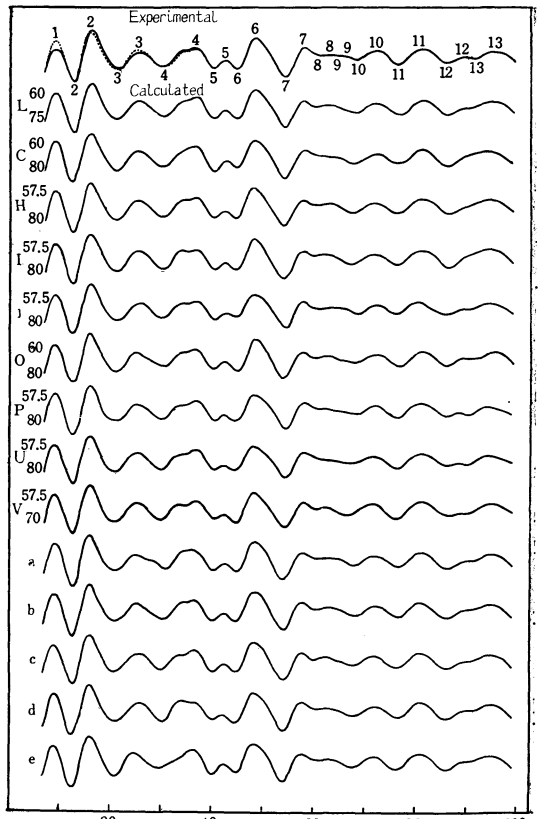

Fig. 5. Experimental and calculated intensity curves. In the experimental curve the dotted line indicates the correction for non-nuclear scatterings.

TABLE IV
DISTANCES OBTAINED FROM q_c/q_o VALUES
(THE DISTANCES ARE GIVEN IN Å UNITS)

Acceptable models	Average q_c/q_o	Average deviation	C—F_1	C—F_2	C—Cl_1	C—Cl_2	C—C
L_{75}^{60}	1.000	0.001	1.38_0	1.33_0	1.74_5	1.76_0	1.54_0
N_{70}^{60}	0.999	0.003	1.37_9	1.32_9	1.76_8	1.74_3	1.53_8
$K_{80}^{57.5}$	1.001	0.003	1.38_1	1.33_1	1.72_6	1.77_1	1.54_1
$G_{80}^{57.5}$	0.999	0.002	1.36_3	1.33_8	1.75_4	1.75_4	1.53_9
$H_{80}^{57.5}$	0.999	0.003	1.36_2	1.33_7	1.76_8	1.74_6	1.53_8
$P_{80}^{57.5}$	1.000	0.003	1.39_5	1.32_0	1.72_5	1.77_0	1.54_0
Q_{75}^{60}	0.999	0.003	1.39_4	1.31_9	1.74_3	1.75_8	1.53_9
Most probable value			1.37_9	1.32_9	1.74_7	1.75_8	1.53_9

are listed the mean values of the q_c/q_o ratio for these acceptable models as well as the molecular parameters calculated therefrom. The accepted values of these parameters and the limits of errors are as follows:

C—F_1=1.37_9±0.02_1Å C—F_2=1.32_9±0.01_4Å

C—Cl_1=1.74_7±0.02_7Å C—Cl_2=1.75_8±0.02_0Å

With respect to the parameter N_g the models for N_g=100 per cent were all unsatisfactory because the positions of the 3rd maximum and the 4th minimum did not agree with experiments. This discrepancy could not be removed without taking into account the coexistence of the C_s form. Therefore, the existence of the C_s form is definitly concluded from the diffraction data. From the acceptable domains estimated for acceptable models

in the $\rho_F - \rho_{Cl}$ parameter chart, the limits of errors for the N_g and ϕ parameters were determined as follows:

$$N_g = 76 \pm 7 \text{ per cent } \phi = 59.5 \pm 3.5^\circ$$

These values coincide with the results from the analysis of the RD curve.

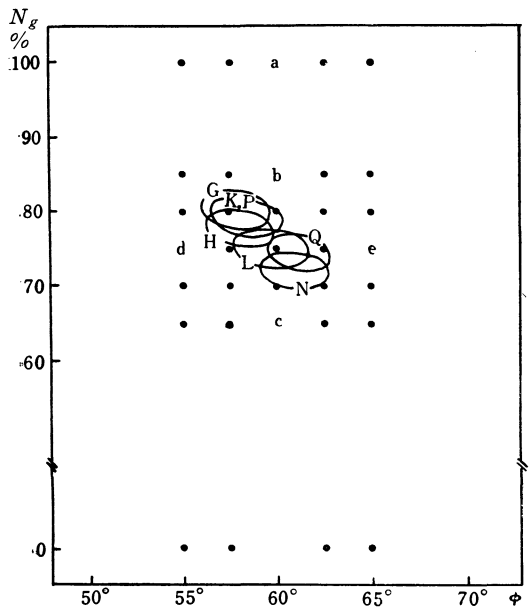

Fig. 6. Parameter chart for N_g and ϕ. The positions of the small letters and dots indicate the parameters of the models for which intensity curves were computed. The areas enclosed in the curved lines roughly indicate the acceptable regions for the models represented by the capital letters, which correspond to the positions in the $\rho_{Cl} - \rho_F$ parameter chart. The theoretical intensity curves corresponding to the positions indicated by the small letters are reproduced in Fig. 5.

Discussion of the Results

The shortening of the C—F bond distance found in $CF_2Cl—CF_2Cl$[3] is also revealed in this molecule. It is concluded that the C—F bond distance in a $-CF_2Cl$ group is different from that in a $-CFCl_2$ group. Moreover, the values of these distances are almost the same as those found in CF_2Cl-CF_2Cl and $CFCl_2-CFCl_2$. It implies that the structure of one half of the molecule scarcely affects the other half of the molecule. With respect to the C—Cl bond distances it appears that the similar difference in two halves of the molecule also exists, although great uncertainties of the data do not permit to draw a definite conclusion. From the analysis described in the preceding section, it was definitly concluded that there exist two rotational isomers, C_s and *gauche* forms for $CF_2Cl-CFCl_2$ molecules in the vapor state, the amount of the *gauche* form being 76 ± 7 per cent. If the ratio of the vibrational and rotational partition functions for the C_s and the *gauche* form is assumed to be equal to unity, the energy difference, ΔE, between the isomers is calculated as 270 ± 250 cal./mol. (the *gauche* form is more stable than the C_s form.) from diffraction data, in remarkable contrast to the value of 2900 cal./mol.[18,19] for $CH_2Cl-CHCl_2$. It appears that this lowering of energy difference arises mainly from the decrease in the difference of electrostatic interactions between the C_s and the *gauche* form due to the fluorine substitution, because the C—Cl bond moment is nearly equal to the C—F bond moment. The decrease in the difference of steric repulsion between the C_s and the *gauche* form, of course, should not be neglected, because the van der Waals' radius of a fluorine atom is larger than that of a hydrogen atom. However, the effect of the change in the steric interaction is less important for this lowering because it was reported[20] that the methyl substitution does not appreciably affect the energy differences in chlorinated ethanes.

In the case of 2-methylbutane, $CH_2(CH_3)-CH(CH_3)_2$, which has a similar skeletal structure to that of $CH_2Cl-CHCl_2$ but has a large difference in electrostatic interaction, the energy difference is reported by Sheppard and Szasz[21] to be almost zero. In this connection, it is interesting to mention that a large energy difference was not observed in a $CF_2Cl-CFCl_2$ molecule, in which the difference of electrostatic interactions decreases.

The azimuthal angle of the *gauche* form was determined to be 59.5° in contrast to the value of 70° in $CH_2Cl-CHCl_2$[22]. This change in the equilibrium position of the *gauche* form seems to have some relation to the lowering of the energy difference.

22) A. Turkevich and J. Y. Beach, *J. Am. Chem. Soc.*, **61**, 3127 (1939).

The result in this investigation is consistent with the conclusion reached by Mizushima, Morino and Shimanouchi[23] that the most important force in dtermining stable configurations of rotational isomers is the steric repulsion and that the electrostatic force plays an important role in determining the energy difference between the rotational isomers because the steric repulsion may become of the same order of magnitude as the electrostatic force in the stable configurations.

Summary

The molecular structure of 1,1,2-trifluoro-1,2,2-trichloroethane was investigated by means of the sector-microphotometer method of electron diffraction. The existence of the two isomeric forms, C_s and *gauche* was ascertained and the amount of the *gauche* form was found to be 76±7 per cent at 20°C. This corresponds to the energy difference of 270±250 cal./mol., the *gauche* form being more stable than the C_s form. The interatomic distances were determined as follows: $C-F_1=1.37_9\pm0.02_1$Å, $C-F_2=1.32_9\pm0.01_4$Å, $C-Cl_1=1.74_7\pm0.02_7$Å, $C-Cl_2=1.75_8\pm0.02_0$Å and the equilibrium angle of the *gauche* form is 59.5±3.5°, where the C—C bond distance and the bond angles were assumed to be equal to the value of CF_2Cl-CF_2Cl and $CFCl_2$-$CFCl_2$ molecules, which have already been investigated by the present author.

The diffraction patterns and the microphotometer traces were taken by using apparatuses in Nagoya University. The author wishes to express his sincere gratitude to Professor M. Kubo, Professor R. Uyeda and Dr. Kimura for giving him facility to use the apparatuses and for their valuable advice. Thanks are also due to Dr. S. Shibata, Mr. H. Morimoto and Mr. K. Kimura of Nagoya University for their friendly assistance, and to Mr. K. Kuchitsu of the University of Tokyo for his help in calculating theoretical intensities by means of a punched card machine. Further, the author is much indebted to Professor Y. Morino of the University of Tokyo for his helpful criticism on this investigation.

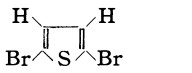
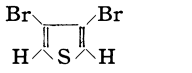
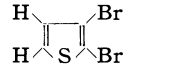
Nuclear Magnetic Resonance Spectra of Dibromothiophene

By Shizuo Fujiwara, Mikio Katayama, Shôichi Hayashi, Hiroshi Shimizu and Shôji Nishimura*







(Received November 17, 1958)

An extensive investigation of nuclear magnetic resonance of substituted thiophenes was carried out recently by Hazato et al.[1], and the results of the measurements of the chemical shifts and of the indirect spin-spin coupling constants J for these molecules were reported. The observed values of the chemical shifts were found in good accord with the values expected from the electronic structures of the substituents, but the chemical shifts due to the difference in the substituent positions were not fully elucidated, since their measurements were not made of 2,3- or 3,4-disubstituted thiophene. We, thus, report here the results of the measurements of these compounds.

The apparatus used is the one constructed in this laboratory of the type of high resolution slow-sweep setup which is composed of oscillator, null-T bridge, pre-amplifier, Collins 51J4 receiver, Sanborn recorder, oscillograph, magnet and saw-tooth generator. The magnet has the same structure as the one previously described by Gutowsky[2]. The field strength of the magnet is about 6200 gauss in 4.8 cm. gap with 12.5 cm. pole face diameter.

The resonance was observed at 27.030 Mc. The disubstituted thiophene and cyclohexane were mixed equally in volume, and sealed in a capillary of about 1 mm. diameter. The shifts were measured as the separations between the spectra of the sample and of cyclohexane. The results are shown in Table I. As the two protons of 2,3-dibromothiophene are not chemically equivalent, multiple resonance lines should be observed. It was, however, unsuccessfull probably owing to the lack of the intensity.

TABLE 1
CHEMICAL SHIFTS OF DIBROMOTHIOPHENE

substance	shift from cyclohexane
 2,5-dibromothiophene	140 cps
 3,4-dibromothiophene	150
 2,3-dibromothiophene	145

We see in Table I that the diamagnetic shieldings for the 3,4-protons in 2,5-dibromothiophene are larger than those for the 2,5-protons in 3,4-dibromothiophene. The shift of 2,3-dibromothiophene falls in the middle of the former two molecules. Our results presented here may be taken as the supplementary data for those of Hazato et al., and all the results will be used for the interpretations of the electronic nature of substituted thiophene.

Our thanks are due to Dr. Yonezô Morino of the University of Tokyo for his suggestion to make measurements on these compound.

Crystal Structure of Pyrazinamide

By Yoshito TAKAKI, Yoshio SASADA and Tokunosuké WATANABÉ

(Received December 9, 1958)

The crystal structure of pyrazinamide*, $C_5H_5N_3O$, (a new potential medicine for tuberculosis[1]) has been examined by X-ray analysis. The crystal data obtained were:

$a=23.07$, $b=6.72$, $c=3.72$Å, $\beta=100.8°$,

space group $P2_1/a$, four molecules per unit cell.

The analysis was carried on by two-dimensional procedures. By considering the molecular packings, all the atoms were roughly located in the projections onto (001) and (010). The atomic coordinates were refined by using structure factor maps and further by successive Fourier projections. At the present stage the discrepancy indices ($R=\sum||F_o|-|F_c||/\sum|F_o|$) are 0.17 for ($hk0$) and 0.20 for ($h0l$).

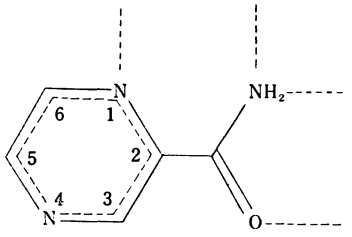

Fig. 1.

The molecule as shown in Fig. 1 is found to be approximately planar. Moreover the bond lengths C—C and C—N in the pyrazine ring show intermediate values between their single and double bonds. These suggest that there is a considerable amount of conjugation between the ring and the amide group.

Two amide groups are linked by a pair of NH—O hydrogen bonds forming a dimer molecule. These dimers are arranged in the direction (011), combining each other by NH—N'_1 hydrogen bonds. This structure explains the cleavage plane parallel to (100).

Further refinement is now going on by $(\rho_o-\rho_c)$ and least squares methods. The details of this work will be shortly published.

The Reaction of Glycine Cobalt Complex with Acetaldehyde

By Yoshikazu IKUTANI, Tôru OKUDA, Mikio SATO and Shiro AKABORI

(Received January 8, 1959)

Considerable progress in the chemical synthesis of threonine has recently been made by Sato, Okawa and Akabori by means of a Knoevenagel-type condensation of acetaldehyde with the active methylene groups of glycine copper complex[1]. As a continuation of their study we have investigated a similar type of reaction using acetaldehyde and glycine cobalt complex. The triglycino-cobalt was reported to occur in two isomeric forms, namely α- and β-form[2]. These two isomers can be obtained separately owing to the difference of their specific gravities.

A 0.02 g. portion of glycine cobalt complex was allowed to react with 0.1 cc. of acetaldehyde in the presence of 0.1 cc. of 6% aq. sodium carbonate as a condensing catalyst in a sealed tube. After suitable periods of time the total yields of products (threonine+allothreonine) and the ratios of threo- to allo-form in the products were determined by the dinitrofluorobenzene method[3] and a simplified ninhydrin method, respectively.

In general, the yields, especially when the β-form complex was used, were poor, while the threo/allo ratios obtained were much higher than those observed in the case of the copper complexes (threo/allo =1.8). The highest ratio was obtained when the condensation was carried out at 70°C for 2 hr. using the α-isomer. Under this condition the total yield (allo+threo) was 32%, (see Table I).

The poor yield may be due to remarkable stability of glycine cobalt complex, and the changes in the threo/allo ratios with reaction temperature and/or time (see Tebles I and II) suggest that the stabilities of cobalt threonine and cobalt

TABLE I

Molecular Structure and Rotational Isomerism of Some Fluorochloroethanes

By Machio IWASAKI

(Received August 15, 1958)

The problem of rotational isomerism in chlorinated ethanes has been well elucidated by a number of investigators from various points of view. In the series of CH_2Cl-CH_2Cl, $CHCl_2$-CH_2Cl and $CHCl_2$-$CHCl_2$, the energy differences between the *trans* (or C_s) and the *gauche* forms are expected to be almost equal, from simple considerations on the interaction between non-bonded atoms. Contrary to this expectation, the experimental evidence shows that there are remarkable variations in the energy differences in these three compounds: the energy difference for CH_2Cl-CH_2Cl is reported to be 1.0~1.3 kcal./mol. by many investigators[1-4], that for $CHCl_2$-CH_2Cl is 2.9kcal./mol.[5,6] and that for $CHCl_2$-$CHCl_2$ is nearly 0 kcal./mol.[5,7], these data being evaluated in the vapor state.

Miyagawa[8] suggested that this variation of the energy difference for these three compounds arises from the induction effect and the difference in bond angles. Kreevoy and Mason gave in their recent paper[9] the same explanation for this experimental result. Miyagawa[10] also reported that the substitution of a hydrogen atom in chloroethanes with a methyl group having a van der Waals' radius almost equal to that of chlorine atom gave no appreciable decrease of the energy difference between the isomers. This fact stimulates the investigation of the effect of fluorine substitution which introduces the C—F bond moment that is almost equal to the C—Cl bond moment in contrast to the methyl substitution which introduces inappreciable change in electrostatic interaction.

Furthermore, the general applicability and the merits of various potential functions[8,9] that have recently been proposed can not be criticized until comprehensive data on the molecular parameters are available. Therefore, it is desirable to carry out a study on the molecular structure and the rotational isomerism of some fluorochloroethanes by electron diffraction which will give the data for the energy difference and the azimuthal angle of the *gauche* form in addition to other molecular parameters.

The present writer has undertaken studies on the molecular structure of CF_2Cl-CF_2Cl, $CFCl_2$-CF_2Cl and $CFCl_2$-$CFCl_2$ in order to find the effect of fluorine substitution on the energy difference between the isomers and on the bond distances.

Apparatus. — In earler investigations, the molecular scattering term required for the analysis of molecular structures was estimated visually from the total scattering which was the supperposition of small oscillation corresponding to the molecular term and the steeply falling background corresponding to atomic and incoherrent scatterings, because the background fell off very rapidly with an increasing scattering angle so that it was difficult to record and measure the pattern accurately. Therefore, the visual method may essentially be free from a large error in the estimation of intensities. As a matter of fact, there is a limit in the accuracy of the molecular parameters determined by the visual method; moreover this method is not sufficiently reliable to provide solutions for such a complicated problem as that of rotational isomerism.

This difficulty has been overcome by the use of a rotating sector to compensate for the sharp drop in intensity by screening electrons appropriately before they reach the photographic emulsion used to record the pattern, and by the measurement of the resulting diffraction patterns with a recording microphotometer. The sector-microphotometer method has been proposed independently by C. Finbak[11] and by P. Debye[12] and has been developed by the

Norwegian school[13]. Several laboratories[13-18] now use this method in electron diffraction investigation on molecular structures. In our country, the first apparatus having a rotating sector was constructed by Ino[19] and applied to thin amorphous films of a high polymer. The apparatus[20] used in this study was designed and constructed after the example of Ino's apparatus and some device was made for the treatment of gaseous samples.

Figs. 1 and 2 show the external appearance and the sectional drawing of the electron diffraction unit, respectively. It consists of four parts: an electron gun, a collimating system, a specimen chamber and a diffraction chamber. Cylinders made of permalloy were used for shielding electron beams from the external magnetic field. The electron gun was of a hot cathode type, consisting of a filament, a Trichter[21] biasing cup and an anode. The divergent beam from the gun was focused on the plane of photographic plates by a single magnetic lens. The direction of the beam was precisely controlled and adjusted to the center of the sector by means of two pairs of Helmholtz coils which are set at a right angle to each other. Two ports are provided for introducing specimens into the electron beam, one at 125 mm. and the other at 285 mm. from the photographic plate. The shorter distance is suitable for studies on moderate and wide-angle scatterings, $20 < q < 105$, and the longer distance

is useful for examination of small angle scattering, $7 < q < 45$. The system of specimen injection is shown in Fig. 3 and the nozzle of a drum type is used. At first sight, it seems likely that in the nozzle of this type the spreading of samples is rather large and so the multiple and extraneous scatterings are serious. However, in practical use, a nozzle of this type makes it possible to take very clean diffraction patterns in lower inlet pressure of gas than that in the case of a nozzle of the ordinary type. Even if the inlet pressure of gas is sufficiently low and the cold trap is used, the diffraction patterns obtained have an index of resolution of 0.95~1.00; that is, the ratio of the amplitude of the molecular scattering terms to the magnitude of the smooth background upon which the molecular terms are superposed is 0.95~1.00 times that given by theory for a perfect pattern. The inlet gas pressure can precisely be controlled by a needle valve having a mildly tapered needle. The spreading gas is caught by using the cold trap which consists of three-fold concentric cylinders. The stop valve which is set behind the magnetic lens permits the electron gun to be isolated from the other parts of the apparatus and to keep it evacuated in placing photographic plates as well as in altering the nozzle-to-plate distance. The wavelength of the electron beam is determined by means of a gold foil attached to the nozzle. The sector which has a spiral form with an angular opening increasing as the square of the radius[22] is provided because this form is somewhat more profitable than the heart form with respect to the accuracy of figuring and finish. The sector is mounted on the inner race of a ball bearing of phosphor bronze, which is rotated by a power supply introduced into the vacuum space through a Wilson seal and transmitted by a pulley and a phosphor bronze wire. The fluorescent screen placed in front of the sector assembly makes it possible to observe the diffraction patterns in their innate state without replacing the sector. Moreover, it serves as a shutter of the electron beam.

The experimental procedure and the method for deriving the molecular scattering intensity from diffraction data has been already described in previous papers[23-25].

Results

The detailed description of the analysis has already been reported in this Bulletin[23-25]. Only the results are briefly described in this paper.

The experimental and the theoretical intensity curves are reproduced in Fig. 4, and the radial distribution curves derived from the experimental intensities are shown in Fig. 5. The molecular parameters obtained by the radial and the correlation method are listed in Tables I and II. In all cases, the analyses were made on the assumption that the structural frame of molecules does not change with rotation about the C—C bond. In the case of a CF_2Cl—$CFCl_2$ molecule, the C—C distance and the bond angles for the two halves of the molecule were assumed to be equal to those of CF_2Cl–CF_2Cl and $CFCl_2$–$CFCl_2$, respectively.

22) At present, an r^3-sector constructed by S. Shibata is available as well as an r^2-sector. S. Shibata, Symposium on the X-ray and electron diffraction held in Osaka City University, Nov. 1956.

TABLE III

THE ENERGY DIFFERENCE BETWEEN THE ROTATIONAL ISOMERS AND THE AZIMUTHAL ANGLE OF THE *GAUCHE* FORM FOR CF_2Cl-CF_2Cl, $CFCl_2$-CF_2Cl AND $CFCl_2$-$CFCl_2$

Molecules	Stable form	N_g(%)	ΔE (cal./mol.)	Azimuthal angle of the *gauche* form
CF_2Cl-CF_2Cl	*trans* (C_{2h})	48± 5 (10°C)	440±110	62.5±3° (Cl-C-C-Cl)
$CFCl_2$-CF_2Cl	*gauche* (C_1)	76± 7 (20°C)	−270±250	59.5±3.5° (Cl-C-C-Cl)
$CFCl_2$-$CFCl_2$	*trans* (C_{2h})	55±10 (15°C)	280±240	59 ±4° (F-C-C-F)

N_g: Amount of the *gauche* form.

ΔE: Energy difference between the isomers. $\Delta E = E_g - E_t$ (or E_{C_s})

the *gauche* form was taken as an unknown parameter. The amounts of the rotational isomers were obtained from the area under the radial distribution peaks by using the successive approximation and further confirmation was made by analyzing the small angle scattering ($20 < q < 40$) that was precisely measured by use of the long camera length. The azimuthal angle of the *gauche* form was also determined by the analysis of the radial distribution curve and the small angle scattering ($20 < q < 40$).

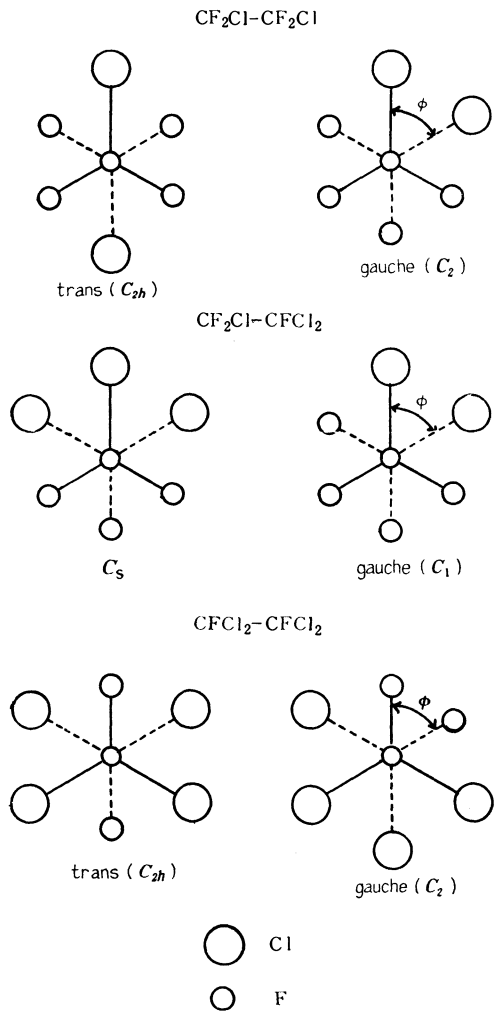

Fig. 6. Stable configurations.

Discussion

Bond Distances and Bond Angles.—The shortening of the C—X bond (X=halogen or carbon atom) by the substitution of hydrogen atoms in H_3C—X compounds with fluorine atoms was a historical problem which has been stimulating many investigators working in the field of electron diffraction and microwave spectroscopy. Brockway and Livingston[26] have first reported this shortening for many fluorinated hydrocarbons from the results of visual electron diffraction. On the other hand, Bauer[27] doubted whether or not this shortening was real, because of the great ambiguity inherent to visual electron diffraction. Thereafter, the development of microwave spectroscopy and the sector-microphotometer method of electron diffraction revealed that this shortening was real in the case of carbon-halogen bonds, although the magnitude of this shortening was somewhat smaller than that reported by Brockway and Livingston.

In the series in question, it was shown that the C—F bond distance decreased with the number of fluorine atoms attached to one and the same carbon atom, i.e., in a —$CFCl_2$ group the C—F bond distance is 1.38Å and in a —CF_2Cl group it is 1.33Å. These results coincide with the results of other organic fluorine compounds as shown in Table IV. The value of 1.38Å for $CFCl_2$-$CFCl_2$ coincides with those of the groups having a single fluorine atom attached to one and the same carbon atom. The value of 1.33$_0$Å for CF_2Cl-CF_2Cl seems to be slightly shorter than that for the group having two fluorine atoms attached to one and the same carbon atom,

but the difference is inappreciable in view of errors involved in experiments.

On the other hand, although the inaccuracies of the data do not permit us to draw a definite conclusion, it appears to be likely that the C—Cl distance also decreases with the number of fluorine atoms. Recently, Livingston and Lyon[28] reported a slightly greater value 1.77_5Å for the C—Cl distance in CF_2Cl_2 in disagreement with the present value, although the difference is within experimental errors. Their result seems to be related to the fact that the ClCCl bond angle 108.5°, obtained by them, is slightly shorter than the tetrahedral value, 109.5°. In this connection, it is desirable to determine the C—Cl distance in CF_2Cl_2 by the sector-microphotometer method or the microwave spectroscopy. The value of the C—Cl distance determined for the extreme case of a $CClF_3$ molecule in which three atoms except one chlorine atom were replaced by fluorine atoms was reported to be 1.748Å[29,30] from the microwave spectroscopy and 1.751Å[30] from the sector-microphotometer method of electron diffraction. In the case of a CF_2Cl-CF_2Cl molecule having two fluorine atoms attached to one and the same carbon atom, the C—Cl bond distance was found to be slightly shorter than the extreme value, the difference being also within experimental errors.

With regard to the C—C bond distance, although a definite conclusion could not be drawn because of the greater ambiguity of the data, experimental results could be explained by the normal distance of the C—C bond. It is not likely that such a

large shortening as reported in earlier investigations was realized in the present molecules.

With respect to bond angles, it is to be noted that the FCF angle is less than the tetrahedral value, in agreement with recent determinations on other fluorinated hydrocarbons. This is interesting together with the fact that the decrease in the FSiF angle from the tetrahedral value was also reported in the case of organosilicon compounds. For example, the FSiF angle is $108°17' \pm 30'$ for $SiHF_3$[31] and $107°56' \pm 6'$ for SiH_2F_2[32]. Other bond angles are also consistent with the values found in other related molecules.

Such a shortening of the carbon-halogen bond was originally explained by Pauling[33] by the assumption of resonance structures of the type

$$X-\overset{\overset{F^-}{|}}{\underset{|}{C}}=X^+ \quad (X=F \text{ or } Cl)$$
$$\quad\quad\; X$$

The fact that the C—F shortening is more marked than the C—Cl shortening is attributed to the great tendency of a fluorine atom to form double bonds. It is conceivable that the structures of this type can also contribute to the slight closing of the FCF angle because of the Coulomb attraction between F^- and F^+.

Rotational Isomerism.—From the present studies, it was definitly confirmed that there exist two isomers, the *trans* (or C_s) and the *gauche* forms, in the vapor state for the series of the molecules in question. As shown in Table III the energy differences were almost of the same magnitude and considerably small compared with the remarkable variation and large values (except $CHCl_2$—$CHCl_2$) observed in the series of chloroethane: CH_2Cl-CH_2Cl (1.2 kcal./mol.), $CHCl_2$-CH_2Cl (2.9 kcal./mol.) and $CHCl_2$-$CHCl_2$ (0 kcal./mol.). It is said that the internal rotation is subject mainly to the steric and electrostatic interactions. According to the replacement of a hydrogen atom with a fluorine atom, the nature of three atoms contained in two groups rotating against each other is more close together in both "steric" and "electrostatic" senses as compared with the case of chloroethanes. As a concequence of this circumstance, it is likely that the potential energy of the *trans* (or C_s) form becomes nearly equal to that of the *gauche* form. It was reported by Miyagawa[10] that the replacement of a hydrogen atom with a methyl group in chloroethanes gave no serious decrease of the energy difference between the isomers and did not affect the tendency of the change in the energy differences with the number of chlorine atoms substituted in the molecules, although a methyl group having almost the same van der Waals' radius as a chlorine atom was introduced. Moreover, a fluorine atom may be closer to a hydrogen atom in the magnitude of the steric interaction than a chlorine atom, because the potential barrier of CF_3-CF_3, 3.92 kcal./mol.[34] is close to that of CH_3-CH_3, 2.875 kcal./mol.[35] as compared with the value in CCl_3-CCl_3, 10.8 kcal./mol.[36]. Accordingly, the main factor contributing to this lowering of energy difference in fluorochloroethane is presumably due to the decrement of the electrostatic interaction rather than the steric interaction. In fact, it is well known that the bond moment of C—F is approximately equal to that of C—Cl.

From a simple assumption of the additivity of interaction energy and the constancy of the bond distances as well as bond angles, it is expected that the energy differences are all the same in the series of 1,2-di-, 1,1,2-tri- and 1,1,2,2-tetrasubstituted ethanes. However, the observed energy differences in chloroethanes were not the same and indicated a remarkable variation which was explained by the induction effect and the opening of the ClCCl bond angle[8] as described in foregoing section. In the series of chlorofluoroethanes, the changes of the energy difference caused by the effect of induction are very small and the ClCCl bond angles are close to the tetrahedral angle. As a result of this circumstance, it appears to be likely that the energy differences in the present series represent almost the same value.

From the theoretical side, many attempts have been made to predict the hindering potential for the internal rotation about single bonds, based on a simple model for interactions between non-bonded atoms or groups. Among a number of attempts, the treatments recently made with tolerable success by Miyagawa[8] and Mason

OBSERVED AND CALCULATED AZIMUTHAL ANGLE OF THE *GAUCHE* FORM

Molecule	ϕ_{obs}	ϕ_{calc}(I)	ϕ_{calc}(II)
CF_2Cl-CF_2Cl	117.5°	118° (119°)	116°
$CFCl_2$-CF_2Cl	122	123 (122)	124
$CFCl_2$-$CFCl_2$	121	120 (120)	118

ϕ_{calc}(I): Lennard-Jones
ϕ_{calc}(II): Buckingham

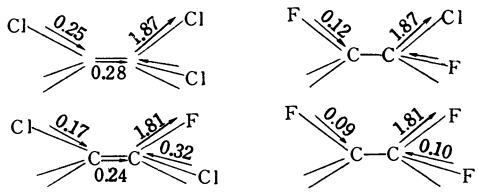
and Kreevoy[9] seem to be most promising. The former author used a Lennard-Jones type potential while the latter a modified Buckingham type potential for interatomic interactions.

In order to estimate quantitatively the energy differences, a similar treatment was applied to the present case. The Lennard-Jones type potential for fluorine-fluorine interaction was approximated by the following formula for neon-neon interaction[37],

$$V(\mathrm{F-F}) = 7.148\times10^4/r^{12} - 143.58\times r^6 \text{ kcal./mol.} \quad (1)$$

The application of this formula leads to the value of 2.4 kcal./mol. for the potential barrier in CF_3-CF_3, minor terms due to dipole interaction being added. Though this value is somewhat smaller than the observed value 3.92 kcal./mol.[34], the two values seem to coincide roughly with each other for such approximate calculation. The formula applied by Miyagawa[8] to chlorinated ethanes with a fair success,

$$V(\mathrm{Cl-Cl}) = 2.332\times10^6/r^{12} - 2.180\times10^3/r^6 \text{ kcal./mol.} \quad (2)$$



was adopted for chlorine-chlorine interaction. The expression for fluorine-chlorine interaction was derived through the method of averages proposed by Miyagawa[8] as follows:

$$V(\mathrm{F-Cl}) = 4.185\times10^5/r^{12} - 5.663\times10^2/r^6 \text{ kcal./mol.} \quad (3)$$

As a result of the application of these formulas, the values listed in the 4th column of Table V were obtained for the energy differences due to steric interaction.

For the sake of comparison, the modified Buckingham type potential given by Mason and Kreevoy[9] was also applied to this problem. The results are listed in the 8th column of Table V.

With respect to the electrostatic interaction, dipole interactions were calculated taking into account of induction effects. For the sake of this computation, the following induced moment were estimated from the observed dipole moments in many chlorofluoroalkanes, assuming a vanishing C—H bond moment and the tetrahedral angle.

The thick and slender arrows indicate original dipoles and induced dipoles, respectively. The dipole moments calculated on the assumption of the additivity of these induced moments were in good agreement with the observed values as shown in Table VII.

The energy differences contributed from the electrostatic interactions were estimated using these dipoles and induced dipoles as shown in the 3rd column of Table V. In this calculation, the center of the dipole moment is located at seven-eighth of the bonded distance from the carbon atom. Total energy differences listed in the 6th and the 9th column of Table V approximately coincide with the observed

values. The modified Buckingham type potential seems to give somewhat better results. However, if two constants in Lennard-Jones type potential are adjusted so as to give observed potential barrier in CF_3-CF_3, the agreement between the calculated and observed energy differences becomes better as shown in the 7th column of Table V. The modified potential functions used in this calculation are as follows:

$$V(\mathrm{F—F}) = 12.729\times10^4/r^{12} - 2.5569\times10^2/r^6 \text{ kcal./mol.} \quad (4)$$

$$V(\mathrm{F—Cl}) = 5.5839\times10^5/r^{12} - 7.5565\times10^2/r^6 \text{ kcal./mol.} \quad (5)$$

It is to be noted that the azimuthal angles of the *gauche* forms calculated from these potential functions are in excellent agreement with observed values as shown in Table VI. In this calculation, the angle was measured from the *trans* (or C_s) position. This agreement may indicate that the potential functions used were fairly adequate.

In the above calculation, the effects of resonance arising from the substitution with fluorine atoms were not included explicitly. However, the changes of the geometry caused by resonance were considered to be implicitly taken into account by using the molecular parameters obtained from the electron diffraction. Furthermore, the changes of the charge distribution were also considered to be implicitly contained in the estimation of the induced moment as a result of ascribing the lowering of the dipole moment caused by resonance to that by induction.

From the foregoing consideration, it is concluded that the substitution of hydrogen atoms in chlorinated ethanes with fluorine atoms decreases the difference of the electrostatic interaction between the *trans* (or C_s) and the *gauche* form, and that as a consequence the energy differences in fluorochloroethanes decrease and become almost equal to one another irrespective of the number of chlorine atoms substituted in the molecules. This fact is consistent with the conclusion reached by Mizushima, Morino and Shimanouchi[38] that the most important force in determining stable configurations of rotational isomers is the steric repulsion, but the electrostatic force plays an important role in determining the energy difference between the rotational isomers, because in the stable configurations the steric repulsive force may become of the same order of magnitude as the electrostatic force.

TABLE VIII
THE ENERGY DIFFERENCES FOR RELATED COMPOUNDS (cal./mol.)

Molecule	X=H	X=F	Difference
CX_2Cl-CX_2Cl	1140	440	700
CX_2Cl-CX_2Br	1460	600	860
CX_2Br-CX_2Br	1700	945	755

As an example of the lowering of the energy difference caused by the fluorine substitution, one can point out the case of bromofluoroethanes studied by Kagarise et al.; that is, the energy difference in CF_2Br-CF_2Br is 945±50 cal./mol.[39] and that in CF_2Cl-CF_2Br is 600±200 cal./mol.[40] as compared with the value of 1700±40 cal./mol. for CH_2Br-CH_2Br[41] and 1460±30 cal./mol. for CH_2Br-CH_2Cl[41]. It is interesting to note that the lowering of energy difference caused by the fluorine substitution shows almost the same value as shown in Table VIII. In other words, this fact indicates that the electrostatic part of the energy difference in these molecules is of almost the same magnitude as 0.7~0.8 kcal./mol. This is caused by the fact that the C—F, C—Cl and C—Br bond moments are of almost the same magnitude. Moreover, the order of the energy differences in the series of CH_2Cl-CH_2Cl, CH_2Cl-CH_2Br and CH_2Br-CH_2Br does not change with the fluorine substitution and a considerable amount of the energy difference exists after the fluorine substitution. This fact indicates that the steric part cannot be neglected and its contribution becomes larger with the number of bromine substitutions.

Summary

In order to investigate the molecular structure and rotational isomerism, the electron diffraction camera having a rotating sector was designed and constructed and its application to some fluorochloroethanes was made successfully. The shortening of the C—F and the C—Cl bond by the substitution of atoms attached to one and the same carbon atom with other fluorine atoms was also revealed in fluorochloroethanes as well as fluorochloromethanes, although in the case of the C—Cl bond distance the inaccuracy of the data does not permit a definite conclusion to be drawn. It was definitly confirmed that there exist two rotational isomers, the *trans* (or C_s) and the *gauche* forms, in the vapor state for the molecules in question. The energy differences between the isomers and the azimuthal angles of the *gauche* form were determined and further discussed from the standpoint of intramolecular potential.

It was found that three fluorochloroethanes in question have almost equal and small energy differences in contrast to the remarkable variation in the case of chloroethanes. This is caused by the fluorine substitution which produces the decrease of the electrostatic part in the energy difference between the isomers.

The author wishes to express his sincere gratitude to Professor M. Kubo, Professor R. Uyeda and Dr. M. Kimura of Nagoya University for their valuable advice and encouragement throughout the course of this work, and to Professor Y. Morino of the University of Tokyo for his helpful criticism on this investigation. The author is also indebted to Dr. I. Miyagawa of the University of Tokyo for his helpful discussion.

Kinetics of the Selenium Dioxide-Catalyzed Hydrogen Peroxide Oxidation of Dimethylaniline in Aqueous Methanol

By Yoshiro OGATA and Iwao TABUSHI

(Received August 23, 1958)

It has been reported that the oxidation of organic compounds with hydrogen peroxide was accelerated by selenium dioxide catalyst[1-3], but the mechanism of these reactions has not yet been clarified satisfactorily.

In general, there seem to be two main types of catalysts in organic oxidations with hydrogen peroxide; i. e., (i) the oxidation-reduction interaction between hydrogen peroxide and catalysts produces OH free radical, (e. g., in Haber-Weiss scheme[4] using Fenton's reagent) which can rapidly oxidize organic substances, and (ii) the combination of hydrogen peroxide with a catalyst gives peroxide as a relatively stable intermediate which is a more active oxidizing agent than hydrogen peroxide itself.

As the latter example, there are many organic and inorganic peroxides which oxidize organic substances without generating free radicals; for example, in the acid-catalyzed hydrogen peroxide oxidation of salicylaldehyde in acetic acid, intermediary peracetic acid reacted faster than hydrogen peroxide itself[5], and also Caro's acid, obtained from the reaction of hydrogen peroxide and sulfuric acid[6], was found to be a far more effective oxidant for tertiary amines than hydrogen peroxide itself[7,8].

As to the selenium dioxide-catalyzed reaction, there seems to be no direct evidence to decide which of these mechanistic types is operating. However, it has been reported that acrolein is oxidized to acrylic acid with neither hydroxylation nor polymerization, suggesting a non-radical mechanism for the reaction. But these peroxide intermediates may react by generating free radicals. For example, it has been considered that osmium, vanadium[9] and tungsten oxide[10] produced intermediary peroxides which could generate an OH radical during their reactions.

The present paper describes the rate data and a probable mechanism of the selenium dioxide-catalyzed hydrogen peroxide oxidation of dimethylaniline (DMA) in aqueous methanol in the presence of perchloric acid.

Experimental

Materials.—DMA and methanol were purified by duplicate fractional distillations.

Kinetic Procedures. — The reaction was carried out in brown flasks with ground-glass stoppers at 40, 50 and 60° (reflux condensers were used for runs at 60°). The solvent used was 50~90 volume % aqueous methanol.

An aqueous methanol solution of DMA was mixed with an aqueous solution of hydrogen peroxide, selenium dioxide and perchloric acid after being thermostated at the reaction temperatures, thus the reaction was started. Aliquots were withdrawn at appropriate intervals of time to estimate the sum of the amount of selenium dioxide and hydrogen peroxide iodimetrically, using ammonium pyrophosphate as accelerator. Since no selenium was precipitated in the course of the reaction and the rate of selenic-acid formation was slow and also equilibrium amounts of intermediate complex were low as stated later, the amount of hydrogen peroxide was obtained as the difference of total oxidizing agents and the selenium dioxide initially present.

The hydrogen-peroxide content in a mixture of hydrogen peroxide and selenium dioxide was determined by introducing it into an aqueous solution of ceric sulfate and then titrating the excessive ceric ion potentiometrically with ferrous sulfate[11,12]. But this method could not be applied

in the presence of DMA, because a rapid oxidation of DMA took place.

Selenate and selenic acid were determined gravimetrically by precipitating lead selenate by the addition of aqueous lead nitrate[13a] or acetate[13b] in aqueous ethanol solution.

Reaction Products.—To examine the reaction products, nearly equimolar amounts of hydrogen peroxide and DMA were used. A mixture of 50 cc. of 1 M methanol solution of DMA, 10 cc. of 0.2 M aqueous solution of selenium dioxide, 6 cc. of 30% aqueous hydrogen peroxide and 2 cc. of concentrated perchloric acid (ca. 10 N) were introduced into a flask with a reflux condenser and heated to 50° for 20 hr. and then at 60° for 5 hr.

After methanol was distilled on a water bath, the residual aqueous solution was treated with potassium hydroxide until it became weakly basic. The solution was cooled and, after filtration of potassium perchlorate, freed from remaining DMA (ca. 1 g.) by extraction with ether.

The residual aqueous layer was neutralized and condensed under a reduced pressure, then poured into a boiling aqueous solution of picric acid (10 g. of picric acid in 200 cc. of water) to precipitate the picrate of DMA oxide[14]. The precipitate consisted of yellow crystals (10.7 g.) and brown amorphous material (2.5 g.); the former, after several recrystalization from ethanol showed no depression of m. p. on admixture with the authentic sample[14]. The brown material was also found to yield the same crystals but with difficulty. The total yield of the oxide amounted to 73% on the basis of the hydrochloride, obtained on the addition of hydrochloric acid into the picrate of DMA oxide.

Vinyl Polymerization. — DMA and peroxide (hydrogen peroxide or benzoyl peroxide) and/or selenium dioxide were added in acrylonitrile, thermostated at 50° in flasks with ground-glass stoppers, to start the reaction. After appropriate time, cold methanol was poured into the reaction mixture to stop the reaction and to precipitate the polymer produced. The precipitates obtained were filtered, dried and weighed. The results are summarized in Table VII.

oxidation of DMA was much faster than the uncatalyzed reaction with selenium dioxide or hydrogen peroxide alone. The rate of consumption of hydrogen peroxide was of first-order with hydrogen peroxide (equation 1) as shown in Fig. 1.

$$-\frac{d[H_2O_2]}{dt} = k_0[H_2O_2] \quad (1)$$

The pseudo first-order rate constant k_0 was found to be proportional to the concentration of selenium dioxide, when the concentrations of DMA and perchloric acid were both kept constant (Fig. 2), while it was linearly related to the concentration of DMA in the range of 5/30~1/45 M, when the concentration of selenium dioxide was constant and the apparent acidity of the solution estimated by pH meter was kept constant by changing the concentration of perchloric acid, where the ionic strength

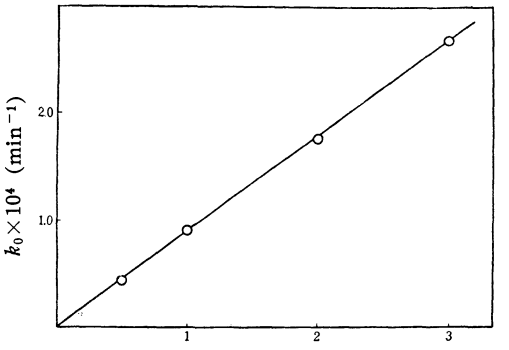

Fig. 2. The effect of concentration of selenium dioxide on the rate; where [DMA] = 5/30 M and [$HClO_4$] = 2/30 M at 50°.

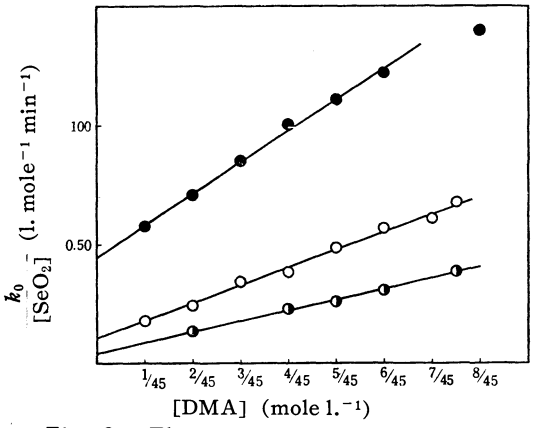

Fig. 3. The effect of concentration of DMA on the rate at various temperature.

was controlled by the addition of neutral salt (sodium perchlorate) (see Fig. 3).

Hence, rate equation 1 can be modified to

$$-\frac{d[H_2O_2]}{dt} = k[H_2O_2][SeO_2][DMA] + k'[H_2O_2][SeO_2] \quad (2)$$

The first term of equation 2 may correspond to the rate-determining attack of an intermediate comples between selenium dioxide and hydrogen peroxide on DMA molecule[15].

The reaction is different from the peracetic acid oxidation[4] in that the main route of complex formation can not be a slow step, since no induction period was observed and the difference between the rates with variation of the time of allowing the mixture of hydrogen peroxide and selenium dioxide to stand before a solution of DMA was added.

The rate of the peroxide consumption in aqueous methanol in the absence of DMA was found to be considerably less than the second term of equation 2 (see Table VIII), thus the second term of equation 2 should mainly express a reaction involving the participation of DMA and only partly a reaction independent of DMA. The former reaction may be a slow reaction between hydrogen peroxide and selenium dioxide to produce an intermediate complex II, which reacts with DMA rapidly.

Hence two complexes I and II may be possible, which respectively react with DMA slowly and rapidly.

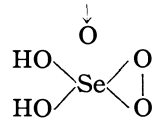
$$H_2O_2 + SeO_2 \underset{\text{mobile equilibrium}}{\rightleftarrows} \text{complex(I)} \xrightarrow[+DMA]{\text{slow } k_3} \text{DMAO (amino oxide)}$$

$$H_2O_2 + SeO_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{complex(II)} \xrightarrow{k_4} \text{DMAO (amino oxide)}$$

where $k_4 \gg k_2 \gg k_1$, so that the formation of the complex II is the rate determining step in the lower reaction.

Active Oxidizing Species.—Hughes[11] assumed the formation of intermediate perselenious acid in the kinetic study of the selenic acid formation, while Smith[1] suggested that the catalytic action of selenium dioxide in hydrogen peroxide oxidation

15) Although the possibilities of the complex formation between H_2O_2 and DMA, or SeO_2 and DMA, followed by the oxidation by the other oxidizing agent may be conceivable, these mechanisms are less probable, since the accelerating effect of selenium dioxide on the H_2O_2 oxidation is not limited to amines but was observed also in aldehydes[1], ketones[2] and olefins[3].



might be due to the formation of selenic acid or its higher peroxides.

To clarify this point, we examined the participation of selenate in the reaction. The reaction with sodium selenate instead of hydrogen peroxide and selenium dioxide or that using sodium selenate and hydrogen peroxide instead of hydrogen peroxide and selenium dioxide was fairly slow (Table III, V), hence selenic acid or a complex of selenic acid and peroxide can not be an active species, I or II. This conclusion is in accord with our observation that the rate of selenic-acid formation estimated cerimetrically was slower than the main reaction, and also with Hughes' data[11].

When besides hydrogen peroxide and selenium dioxide a large amount of sodium selenate was added, a small increase in the rate was observed and the increment was proportional to the concentration of sodium selenate added (Table V). But no salt effect was observed with the addition of sodium perchlorate (Table V). This fact suggests that the increment may be due to the selenium dioxide existing in a selenate solution.

The rate of hydrogen peroxide consumption in the absence of DMA was followed cerimetrically as well as iodimetrically, but no remarkable change in concentration of hydrogen peroxide was observed. This fact suggests that concentrations of I and II are both very small in their equilibrium states.

It may well be assumed that I and II are a kind of peroxide such as HO—Se(=O)—O—O—H (perselenious acid) or

, but no information of I and II could be obtained by us by means of ultraviolet absorption spectroscopy.

Effects of Acidity and Substituents.— Rates of the reaction satisfied equation 2 only at a relatively low concentration of perchloric acid (less than 0.1 M where DMA 5/30 M). In this range, the k_0 values was found to increase with increasing concentration of the acid. But at higher a concentration of the acid (more than 4/30 M where DMA 5/30 M), a tendency of induced reaction was observed in the early stage (before reaching the pseudo-first order kinetics), and it became remarkable as the acidity increased. Typical examples are shown in Fig. 1. This behavior made the quantitative investigation of the effect of acidity difficult, but qualitatively, the rate began to decrease markedly through maximum ($[HClO_4] \fallingdotseq 5/30\ M = [DMA]$) as the acidity increased. This decrease of rate may be ascribed to a decrease in the concentration of DMA by the protonation. The first small increase of the rate, inexplicable by the change of the concentration of DMA, may be due to the suppression of the dissociation of acids I and/or II (equation 4) just as discussed in the case of Caro's acid[16] if I and II have

THE RATE OF DISAPPEARANCE OF HYDROGEN PEROXIDE IN A MIXTURE OF HYDROGEN PEROXIDE AND SELENIUM DIOXIDE BY MEANS OF BACK TITRATION OF EXCESS CERIC ION WITH AN AQUEOUS FERROUS SULFATE SOLUTION: 1 m. mole of H_2O_2, 5 m. mole of SeO_2 and 4 m. mole of $HClO_4$ were mixed with 15 cc. of water and 28 cc. of methanol

Time, min.	0	110	191	∞
$FeSO_4$ required	1.37	1.91	2.53	27.90[a]

a) The theoretical vol. of $FeSO_4$ necessary for the complete disappearance of hydrogen peroxide.

TABLE V

THE EFFECTS OF ADDED MATERIALS ON THE RATE: $[SeO_2] = 1/750$ M, $[DMA] = 5/30$ M and $[HClO_4] = 2/30$ M at 50°

Added material		$k_0 \times 10^3$, min^{-1}
Na_2SeO_4	100 mg. in 30 cc. of solution	1.13
Na_2SeO_4	46 mg. in 30 cc. of solution	1.02
Na_2SeO_4	25 mg. in 30 cc. of solution	0.951
Na_2SeO_4	0 mg.	0.902[b]
$NaClO_4$	1/30 M	0.895
Hydroquinone	2.5 mg. in 30 cc. of solution	0.896
None	time of standing was 0 min.[a]	0.893
None	time of standing was 60 min.	0.898

a) In the other runs, time of standing was 15~30 min.

b) In the absence of selenium dioxide, the rate was considerably low.

16) Y. Ogata and I. Tabushi, This Bulletin, 31, 969 (1958).

their pK_a values near the acidity of maximum rate.

$$DMA + H^+ \overset{\text{mobile}}{\rightleftarrows} DMAH^+ \quad (3)$$

$$HO_2SeOOH \overset{\text{mobile}}{\rightleftarrows} HSeO_4^- + H^+ \quad (4)$$

$$DMA + HO_2SeO_2H \overset{\text{slow}}{\longrightarrow} \text{prod.} \quad (5)$$

The rate of the oxidation of *p*-methyl- and *p*-methoxydimethyl-anilines showed a tendency toward induced reaction even at the low acidity, so that their kinetics could not be followed, but, qualitatively these substituents increased the rate, which supports the above electrophilic substitution mechanism.

Other Factors Influenceing the Rate.—Rate measurements carried out at 40, 50 and 60° gave linear relations of k_0 vs. DMA (Fig. 3) and thus gave the values of k and k' at these temperatures. From these values activation energies and log PZ were calculated, but as to k', Arhenius plot did not give a straight line, probably because the second term of equation 2 contained more than one reaction (for example, selenic acid formation, spontaneous decomposition of hydrogen peroxide and oxidation of methanol). Activation energies and other data were summarized in Table VIII.

TABLE VI

THE EFFECT OF SOLVENT COMPOSITION ON THE RATE. TEMP. 50° $[SeO_2] = 1/750$ M

vol. % of methanol	[DMA], M	k_0, $\text{min}^{-1} \times 10^4$
50	3/30	4.13
66.7	3/30	6.40
66.7	5/30	9.02
80	5/30	14.8
90	5/30	24.2
95	5/30	28.4

20	60	0	0	4.5	86.8
0	60	2 drops	0	2 days	0
0	60	2 drops	2	2 days	0
20	60	0[a]	0	4.0	46.0
0	60	2 drops[b]	0	2 days	0
0	0	2 drops	2	2 days	0
0	0	0	0	Several days	0

a) 0.1 cc. of water was added.
b) 2 drops of conc. $HClO_4$ were added.
c) The solution was slightly turbid.

TABLE VIII

TEMPERATURE COEFFICIENTS, ACTIVATION ENERGY AND ACTIVATION ENTROPY OF k AND k'

$k_{60}/k_{50} = 5.95\,(1.^2\ \text{mole}^{-2}\ \text{min}^{-1})/3.36\,(1.^2\ \text{mole}^{-2}\ \text{min}^{-1}) = 1.74$

$k_{50}/k_{40} = 3.36/1.93 = 1.77$

$\Delta H^{\ddagger}$ (40 and 50°) = 11.50 kcal./mole

$\Delta H^{\ddagger}$ (50 and 60°) = 11.86 kcal./mole

av. $\Delta H^{\ddagger} = 11.68$ kcal./mole

$\Delta S^{\ddagger}(50°) = 11.8$ E. U.

$k'_{60}/k'_{50} = 4.02$ (0.446/0.110)[a]

$k'_{50}/k'_{40} = 2.45$ (0.110/0.045)[a]

a) The unit of the constants is l. mole^{-1} min^{-1}.

The addition of water to methanol markedly decreases the rate (Table VI). This marked solvent effect may partly be attributed to the participation of water in the formation of the intermediate (perselenious acid), since it was reported[11] from the oxygen isotope exchange study that the formation of perselenious acid from selenious acid was attained through dehydration of selenious acid as shown in equations 6 and 7,

$$H_2SeO_3 \rightleftarrows H_2O + SeO_2 \quad (6)$$

$$SeO_2 + H_2O_2 \rightleftarrows HO_2SeOOH \quad (7)$$

and partly to the suppression of the dissociation of the attacking acids I and/or II.

Possibility of Free Radical Mechanism.—The observation that sulfur dioxide and hydroperoxide initiated vinyl polymerization[17]

$$ROOH + SO_2 \rightarrow RO\cdot + \cdot[SO_3H] \quad (8)$$

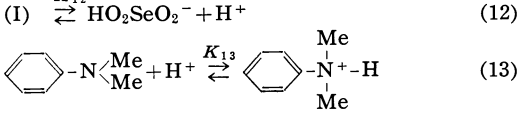
may suggest the possibility of a free radical mechanism of the reaction of selenium dioxide with hydrogen peroxide. But the addition of a small amount of hydroquinone has no appreciable effect on the rate at lower acidity of the solution where no induced reaction has been observed[18].

Furthermore, the tests of the polymerization of acrylonitrile was carried out, indicating that the free radical mechanism was not operating. The polymerization of acrylonitrile was tested in the presence

17) E. I. Thinyakova, B. A. Dolgoplosk and V. N. Reich, *Izvestia A. N. SSSR*, 1957, 851.
18) At higher acidities, hydroquinone markedly consumed hydrogen peroxide under these reaction conditions.

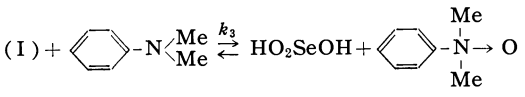
of BPO+DMA, (hydrogen peroxide+DMA), (hydrogen peroxide+selenium dioxide+DMA), (hydrogen peroxide+selenium dioxide), (hydrogen peroxide+selenium dioxide+DMA+perchloric acid) or (BPO+DMA+selenium dioxide), where BPO means benzoyl peroxide. In most of these experiments, no polymerization was observed. But two exception were observed; i. e., the reagent (BPO+DMA) could easily initiate the polymerization in accord with previous investigators[19], and the reagent (BPO+DMA+selenium dioxide) initiated it only with great difficulty.

These observations indicate that (i) the interaction of hydrogen peroxide and DMA can not produce any effective free radical; (ii) selenium dioxide has an effective inhibitory action for the radical polymerization; (iii) I or II can not participate in the radical chain.



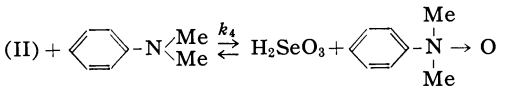
The Over-all Reaction Mechanism.—The results obtained above suggest a set of steps for the over-all reaction.

$$H_2SeO_3 \overset{K_9}{\rightleftarrows} SeO_2+H_2O \tag{9}$$



$$SeO_2+H_2O_2 \overset{K_{10}}{\rightleftarrows} HO_2SeOOH\ (I) \tag{10}$$

$$H_2SeO_3+H_2O_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{complex (II)} \tag{11}$$



$$(I) \overset{K_{12}}{\rightleftarrows} HO_2SeO_2^- + H^+ \tag{12}$$

K's denote mobile equilibrium constants and k's denote rate constants, of which k_1 and k_3 correspond to those of rate-determining steps via complex II and I, respectively.

Summary

The selenium dioxide-catalyzed oxidation of dimethylaniline with hydrogen peroxide was investigated kinetically at 40~60° in 50~95 volume % aqueous methanol. The rate of the consumption of hydrogen peroxide at constant acidity of the reaction mixture was expressed as

$$v=k[H_2O_2][SeO_2][\text{Dimethylaniline}]+k'[H_2O_2][SeO_2]$$

The first term of this equation seems to correspond to the rate of a reaction between dimethylaniline and a complex (I) produced rapidly from selenium dioxide and hydrogen peroxide, while the second term corresponds mainly to a slow reaction between selenium dioxide and hydrogen peroxide to yield the complex (II) followed by a rapid reaction with dimethylaniline. The energy of activation was 11.7 kcal.

When perchloric acid was added to the reaction mixture, the pseudo-first-order rate constant with respect to hydrogen peroxide first increased and then decreased via a maximum, which was explicable by the assumptions of the dissociation of the intermediate and the protonation of dimethylaniline. Electron-releasing groups tended to increase the rate. An increase of the water content in the solvent methanol decreased the rate. There was no evidence for the radical mechanism under these experimental conditions.

Separation and Determination of Microgram Quantities of Molybdenum in Natural Waters

By Ken SUGAWARA, Motoharu TANAKA and Shiro OKABE*

(Received September 4, 1958)

Despite the importance of the role of molybdenum in the biochemical cycle of nitrogen and especially in plant growth, the only accessible datum of the content of this element in an inland water is that of Ter Meulen[1] who reported 0.9 μg. Mo/l. for a canal water in the Netherlands. As for sea water, more data have been reported. However, these data are often discordant, apparently because of defects in some of the methods employed. Thus, while Ishibashi et al.[2] found 10.6 μg./l. for the North Pacific water, Ernst and Hoermann[3] reported 0.3~0.7 μg./l. for the Atlantic.

Considering these facts, the present writers have elaborated a new method of determination, applicable to both sea and fresh waters, by which they plan to conduct an extensive study of the distribution of molybdenum in various kinds of natural water.

The method consists of two steps: 1) the element is co-precipitated together with either hydrated manganese oxide or ferric hydroxide and 2) the molybdenum is then extracted by a solvent consisting of *n*-butanol and chloroform in the form of thiocyanate to be subjected to spectrophotometry. Special care is taken in adjusting the pH of the solution to 3.8 where quantitative co-precipitation of molybdenum is ensured, resulting in a nearly 100% recovery of molybdenum[4].

Of these two different kinds of coprecipitant, manganese oxide is preferred because with this element, a precipitate is obtained which is quickly and easily filtered. This precipitate is more easily soluble in dilute hydrochloric acid containing a small amount of hydrogen peroxide, and the optimal range of pH is wider where a perfect co-precipitation of molybdenum is ensured[4].

Experimental

Reagents. — *Ferrous ammonium sulfate solution.* — Dissolve 0.70 g. of the salt in 100 ml. of 0.2 N sulfuric acid. The solution thus prepared contains 1.0 mg. of ferrous iron per ml. and is good for only one week after being prepared.

Sodium hypochlorite solution. — Neutralize 7.1 ml. of alkaline hypochlorite solution having 7% available chlorine with glacial acetic acid, using *p*-nitrophenol as indicator. Then add 0.6 ml. excess of the same acid and water bringing the solution to 50 ml. The solution is 1% for chlorine and is buffered at pH 3.7.

Potassium permanganate solution. — Dissolve 0.86 g. of potassium permanganate in 100 ml. water. The solution contains about 3 mg. Mn/ml.

Manganous sulfate solution.—Dissolve 1.0 g. of hydrated manganous sulfate in 100 ml. water. The solution contains 2 mg. Mn/ml.

Bromocresol purple. — Ethanolic solution, 0.1% wt./vol.

Potassium iodide solution.—10%, reagent quality.

Sodium sulfite solution.—10%, reagent quality.

Potassium thiocyanate solution. — 10%, reagent quality.

Hydrogen peroxide solution.—1%, 30% reagent is diluted.

Stannous chloride solution.—Ten g. of hydrated salt is dissolved in 100 ml. of 1 N hydrochloric acid. It is recommended that the preparation be made each week.

Solvent mixture of n-butanol and chloroform.—One part of *n*-butanol and four parts of chloroform are mixed. The components must be previously subjected to distillation and those fractions which distil 118°C and 61~63°C respectively are separated.

Standard molybdenum solution. — An amount (0.750 g.) of reagent quality molybdenum trioxide is dissolved in 10 ml. of 0.1 N sodium hydroxide solution and diluted to about 50 ml. After being slightly acidified with hydrochloric acid, the solution is made up to 500 ml. In practice, a dilute solution is prepared each week and used as the standard. The primary standard solution containing 1.0 mg. Mo per ml. is properly diluted

with 0.1 N hydrochloric acid so that one ml. of the dilute solution contains one μg. Mo per ml.

Procedure. — Depending upon the probable content of molybdenum, a sample of 1~5 liters is taken. After being warmed to 70~80°C, the sample is acidified with hydrochloric acid. The solution is neutralized with 4 N sodium hydroxide solution by using bromocresol purple as indicator and is buffered to approximately pH 3.8 by adding 12 ml. of glacial acetic acid and 5 ml. of 4 M sodium acetate solution per liter. Then 2 ml. of the manganous sulfate solution and 2 ml. of the potassium permanganate solution are successively added, while stirring vigorously. The solution is heated to 80°C whereby coagulation of the formed hydrated oxide of manganese is hastened. After cooling, the coagulum is filtered and then dissolved in a small amount of 2 N hydrochloric acid containing 1 ml. of 1% hydrogen peroxide. The solution is transferred into a 100 ml. beaker and boiled gently about 30 minutes until the excess of hydrogen peroxide is expelled. After cooling, 1 ml. of sodium sulfite solution is added whereby the remaining hydrogen peroxide is decomposed and ferric ions are reduced. Further addition of the potassium iodide solution ensures elimination of traces of hydrogen peroxide and the ferric iron. The liberated iodine is driven out by heating the solution for 10 minutes on a water bath. The final volume of the solution is 10~15 ml. Two ml. of concentrated hydrochloric acid, 2 ml. of ferrous ammonium sulfate solution and 3 ml. of potassium thiocyanate solution are successively added. Then the whole is transferred into a 100 ml. separatory funnel. After thoroughly mixing, 3 ml. of the stannous chloride solution is added and then shaken[5].

The next step is the extraction of formed molybdenum thiocyanate by the *n*-butanol—chloroform mixture[6]. After the addition of 7 ml. of the mixture, the contents of the funnel are vigorously shaken for two minutes. When the layers separate, the bottom oil layer is drawn out into a 10 ml. measuring flask and the remaining aqueous fraction is treated with 2 ml. of the solvent mixture. The joint extracts in the flask are made to just 10 ml. Then a few mg. of solid stannous chloride is added to protect the ferrous iron against oxidation. Otherwise, a red coloration by ferric thiocyanate may interfere with the measurement of the coloration. The absorbance measurement is made at 475 mμ. The molybdenum determination is made in reference to the standard curve previously prepared.

Checking the method and application of the method to natural waters.—1) Recovery of molybdenum by the co-precipitation procedure was checked as follows: an amount of molybdenum ranging 5~15 μg. in one liter of water was co-precipitated together with hydrated manganese oxide or ferric oxide, each equivalents to 10 mg. and 100 mg. of Mn and Fe respectively. As shown in Table I, the molybdenum recovery is from 98 to 100% by the use of either manganese or iron.

2) The interferences by ordinary elements and tungsten with the final colorimetry were examined. The results proved that these elements cause no interference at concentrations as are usually found in ordinary natural waters.

3) Examples of the results of the application of the present methods to various natural waters are given in Table II.

Studies on Antibiotics and Related Substances. VIII. Syntheses of the Two Enantiomorphs of 5-Methylenecyclopentanone-3-carboxylic Acid

By Mitsuhiro KINOSHITA and Sumio UMEZAWA

(Received September 5, 1958)

The present authors[1] previously reported the synthesis of 5-methylenecyclopentanone-3-carboxylic acid, an antitumor isomer of sarkomycin[2]. The structure of sarkomycin had been established by Hooper et al.[3] to be 2-methylenecyclopentanone-3-carboxylic acid, the hydrogenated product being (+)-2-methylcyclopentanone-3-carboxylic acid. More recently, Toki[4] reported the synthesis and the resolution of *dl*-sarkomycin.

The present paper describes the syntheses of optically active 5-methylenecyclopentanone-3-carboxylic acids and their antitumor activities. The synthetic routes are analogous to the synthesis of *dl*-5-methylenecyclopentanone-3-carboxylic acid previously described[1].

dl-Cyclopentanone-3-carboxylic acid prepared by the Kay and Perkin's method[5] was resolved into its optically active components (Ia and Ib) by fractionally crystallizing its brucine salt. Both (+)- and (−)-cyclopentanone-3-carboxylic acids were condensed with dimethylamine hydrochloride and paraformaldehyde by means of the Mannich reaction to yield (+)- and (−)-5-(dimethylaminomethyl)-cyclopentanone-3-carboxylic acid hydrochlorides (IIa and IIb), respectively, which were esterified with methanol by the Fischer-Speier method to yield methyl (+)- and methyl (−)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochlorides (IIIa and IIIb), respectively.

Though each of the two products consists of a pair of diastereoisomers differing in the configuration respecting C_5, the separation of components is not required for the preparation of 5-methylenecyclopentanone-3-carboxylic acid. Therefore, each of the two diastereoisomeric mixtures of methyl 5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochloride was directly degraded by vacuum distillation to yield methyl (+)- or methyl (−)-5-methylenecyclopentanone-3-carboxylate (IVa and IVb).

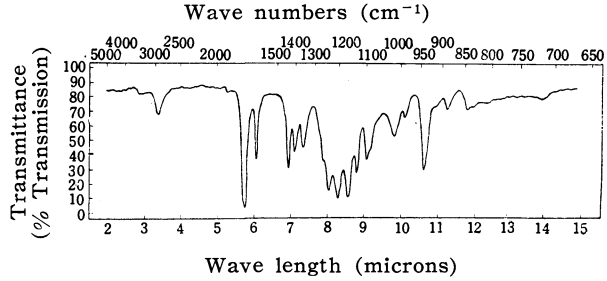

Fig. 1. Infrared absorption spectrum of methyl (+)-5-methylenecyclopentanone-3-carboxylate in carbon tetrachloride.

Mild hydrolysis of IVa and IVb with dilute sulfuric acid, followed by extraction with ethyl acetate and by evaporation of the solvent in vacuo gave (+)- and (−)-5-methylenecyclopentanone-3-carboxylic acid (Va and Vb), respectively.

The ultraviolet absorptions of IVa and IVb in methanol solution showed maxima at 231 and 335~336 mμ, suggesting the presence of an α,β-unsaturated ketone group in each as shown in Fig. 2. The infrared absorption of IVa in carbon tetrachloride showed maxima as follows: 5.74 μ (conjugated carbonyl group), and 6.05 μ

(carbon-carbon double bond) as shown in Fig. 1. The ultraviolet absorptions of Va and Vb in methanol solution showed maxima at 232 and 333 mμ suggesting the presence of an α, β-unsaturated ketone group in each.

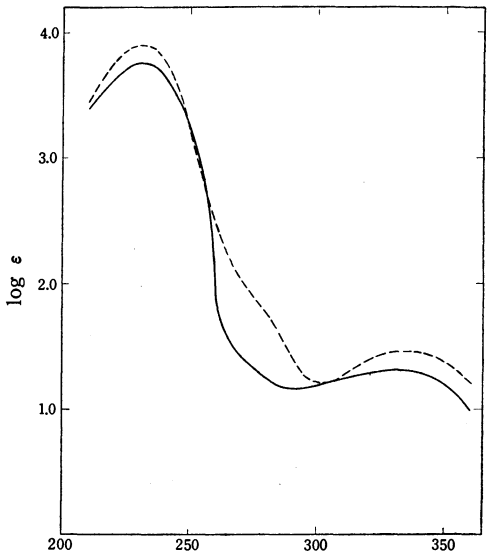

Fig. 2a. Ultraviolet absorption spectra of (+)-5-methylenecyclopentanone-3-carboxylic acid (——) and methyl (+)-5-methylenecyclopentanone-3-carboxylate (------) in methanol.

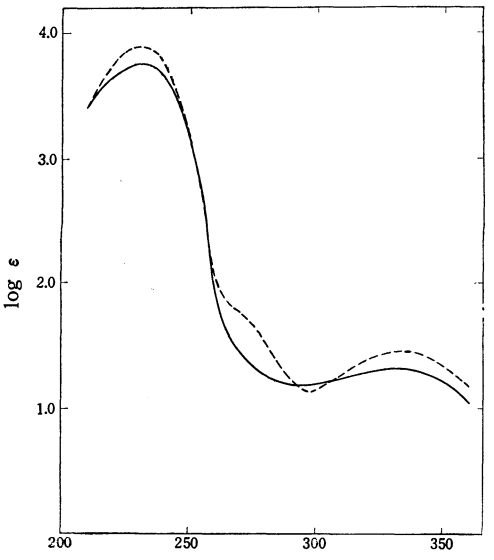

Fig. 2b. Ultraviolet absorption spectra of (−)-5-methylenecyclopentanone-3-carboxylic acid (——) and methyl (−)-5-methylenecyclopentanone-3-carboxylate (------) in methanol.

Moreover, ozonolysis of (−)-5-methylenecyclopentanone-3-carboxylic acid (Vb) gave formaldehyde (isolated as the methone derivative) as one of the products. This established the presence of an exomethylene group in Vb.

Methyl (+)- and methyl (−)-5-methylenecyclopentanone-3-carboxylates (IVa and IVb) possessed significant activities against *Staph. aureus* 209-P. The both enantiomorphs (Va and Vb) of 5-methylenecyclopentanone-3-carboxylic acid possessed strong antitumor activities of the same extent.

Experimental

Resolution of *dl*-Cyclopentanone-3-carboxylic Acid. — (+)-*Cyclopentanone-3-carboxylic Acid* (Ia). — A mixture of *dl*-cyclopentanone-3-carboxylic acid (48 g.), brucine tetrahydrate (178.5 g.) and 90% methanol (380 cc.) was heated until solution was effected. After cooling and storing at 11~12°C for 2 hr., the first crystalline crop was separated, and washed with a small quantity of 90% methanol. The weight of the dried product 103 g. On decomposing a small portion of the crop in the same way as described below, the free acid of $[\alpha]_D^{10}+12.0°$ (c 4, methanol) was obtained. Recrystallization of the crude salt from 90% methanol (120 cc.) gave 80 g. of the purified salt, which, on decomposition, gave the free acid of $[\alpha]_D^{9}+18.5°$ (c 4, methanol).

A second crop (41 g.) was obtained by evaporation of the mother liquor and recrystallized three times from 90% methanol to give 16.7 g. of the salt [free acid: $[\alpha]_D^{10}+19.0$ (c 4, methanol)]. The crops were collected and recrystallized from 90% methanol (1.2 cc./g.) to give 82.5 g. of the nearly pure salt [free acid: $[\alpha]_D^{9}+23.0°$ (c 4, methanol)]. The product was further recrystallized twice from the same solvent and subjected to decomposition.

To a solution of the recrystallized brucine salt (66 g.) of (+)-acid in boiling water (160 cc.) was added dropwise 14% sodium carbonate solution (142 cc.) with stirring. After being cooled in a refrigerator overnight, the brucine was filtered off. The filtrate was acidified with hydrochloric acid to pH 2.4, saturated with ammonium sulfate and extracted with ether repeatedly. After drying the extract, evaporation of ether gave 10.3 g. (43% from *dl*-acid) of (+)-cyclopentanone-3-carboxylic acid (Ia), $[\alpha]_D^{7.5}+27.2°$ (c 2.0, methanol)*. Recrystallization from ether gave colorless plates, m. p. 66~67°C.

Anal. Found: C, 56.49; H, 6.28. Calcd. for $C_6H_8O_3$: C, 56.24; H, 6.29%.

(−)-*Cyclopentanone-3-carboxylic Acid* (Ib). — By concentration of the mother liquor of the above-mentioned second crop, 54.6 g. of the third crop was obtained. The corresponding free acid

* Rotation reported by Toki[4] is $[\alpha]_D^{21}+22.1°$ (c 1.9, methanol).

obtained by decomposition showed $[\alpha]_D^8 -17.5°$ (c 4, methanol). Recrystallization from 85% ethanol (55 cc.) gave 34.5 g. of crystals. The corresponding free acid showed $[\alpha]_D^{9.5} -15.7°$ (c 3.94, methanol). The recrystallized salt was mixed with the crystalline residue obtained by evaporation of the recrystallization mother liquors of the first and the second crops described above and dissolved in hot 85% ethanol. The solution was left at 14°C for 1.5 hr. and the less soluble salt there separated was filtered off. Evaporation of the mother liquor gave 8 g. (crystal A) of the more soluble salt. Evaporation of the mother liquor separated from the third crop and the recrystallization mother liquor of the third crop gave 14 g. (crystal B) and 13 g. (crystal C) of crystalline residues, respectively. Crystals A, B and C correspond to the brucine salt of (−)-cyclopentanone-3-carboxylic acid which is more soluble than the salt of the (+)-acid described above.

For decomposition 14% sodium carbonate solution (76 cc.) was added dropwise to a hot solution of the brucine salt of (−)-acid (35 g., collected crystals A, B and C) and the resulting mixture was processed, in the same manner as described in the preceding paragraph, to yield the crystals of (−)-cyclopentanone-3-carboxylic acid; yield 4.6 g. (19.2% from *dl*-acid), $[\alpha]_D^{10} -23.4°$ (c 2.0, methanol)**. A sample for analysis was prepared by recrystallization from ether, m. p. 65~67°C.

Anal. Found: C, 56.63; H, 6.20. Calcd. for $C_6H_8O_5$: C, 56.24; H, 6.29%.

(+)-*5-(Dimethylaminomethyl)cyclopentanone-3-carboxylic Acid Hydrochloride* (IIa).—A mixture of (+)-cyclopentanone-3-carboxylic acid (9.5 g.) and dimethylamine hydrochloride (6.03 g.) was heated on a water bath. To the resulting melt was added paraformaldehyde (2.22 g.) and the mixture was stirred at 85°C for 1 hr. and then evaporated under reduced pressure to remove moisture. The resulting syrup was dissolved in absolute methanol (13 cc.) and a small amount of insoluble solid was removed by filtration. After addition of acetone (35 cc.) the solution was allowed to stand overnight in a refrigerator to afford the crystalline hydrochloride of (+)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylic acid; yield 3.95 g. (24%), m. p. 136~139°C (dec.). Recrystallization from absolute methanol raised the melting point to 141~142°C (dec.); $[\alpha]_D^{11.5}$ +51.3° (c 1.385, methanol).

Anal. Found: C, 48.81; H, 6.99; N, 6.27. Calcd. for $C_9H_{16}O_3NCl$: C, 48.80; H, 7.28; N, 6.32%.

(−)-*5-(Dimethylaminomethyl)cyclopentanone-3-carboxylic Acid Hydrochloride* (IIb).—A mixture of (−)-cyclopentanone-3-carboxylic acid (4.5 g.) and dimethylamine hydrochloride (2.76 g.) was heated on a water bath. To the resulting melt was added 1.05 g. of paraformaldehyde and the mixture was stirred at 85°C for 1 hr. and then evaporated under reduced pressure. The residue was processed by the same procedure as employed for the preparation of IIa to afford the crystalline hydrochloride of (−)-5-(dimethylaminomethyl)-cyclopentanone-3-carboxylic acid hydrochloride; yield 1.8 g. (23%). The hydrochloride was recrystallized from absolute methanol; m. p. 140~141°C (dec.), $[\alpha]_D^{18} -62.3°$ (c 0.566, methanol).

Anal. Found: C, 48.60; H, 7.16; N, 6.29. Calcd. for $C_9H_{16}O_3NCl$: C, 48.80; H, 7.28; N, 6.32%.

Methyl (+)-5-(Dimethylaminomethyl)cyclopentanone-3-carboxylate Hydrochloride (IIIa).—A mixture of (+)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylic acid hydrochloride (3.3 g.) and absolute methanol (38 cc.) was saturated with dry hydrogen chloride and allowed to stand overnight. The solvent was removed by distillation under reduced pressure. The resulting crystals were dissolved in a small quantity of absolute methanol and the solution was diluted with absolute ether, whereupon there separated colorless, minute plates of methyl(+)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochloride; yield 3 g. (86%). The hydrochloride was recrystallized from absolute methanol, m. p. 144~145.5°C (dec.); $[\alpha]_D^{11} +73.2°$ (c 0.95, methanol).

Anal. Found: C, 50.86; H, 7.42; N, 5.86. Calcd. for $C_{10}H_{18}O_3NCl$: C, 50.95; H, 7.64; N, 5.94%.

Methyl (−)-5-(Dimethylaminomethyl)cyclopentanone-3-carboxylate Hydrochloride (IIIb).—A mixture of (−)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylic acid hydrochloride (1.5 g.) and absolute methanol (22 cc.) was saturated with dry hydrogen chloride and processed in the same manner as described in the preceding paragraph. Yield 1.4 g. (88%). Recrystallization from absolute methanol, m. p. 144~146°C (dec.); $[\alpha]_D^{13} -65.0°$, (c 0.65, methanol).

Anal. Found: C, 50.75; H, 7.46; N, 5.78. Calcd. for $C_{10}H_{18}O_3NCl$: C, 50.95; H, 7.64; N, 5.94%.

Methyl (+)-5-methylenecyclopentanone-3-carboxylate (IVa).—A sample (0.7 g.) of methyl (+)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochloride was placed in a small round-bottom flask and heated at 160~163°C in an oil bath under highly reduced pressure (0.0035mmHg). Colorless crystals of methyl (+)-5-methylenecyclopentanone-3-carboxylate were obtained in a receiver cooled in a dry ice-acetone bath; m. p. 46~48.5°C, $[\alpha]_D^9 +43.3°$ (c 0.82, methanol), yield 0.38 g. (83%). The ultraviolet absorption of the product showed maxima at 231 mμ (ε 7,800) and 335 mμ (ε 29.4) in methanol. The infrared spectrum showed maxima at 5.74, 6.05 and 10.61 μ in carbon tetrachloride as shown in Fig. 1.

Anal. Found: C, 62.42; H, 6.32. Calcd. for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

Methyl (−)-5-Methylenecyclopentanone-3-carboxylate (IVb).—The ester was prepared from 0.7 g. of methyl (−)-5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochloride by the same procedure as described above; yield 0.36 g. (79%), m. p. 46~48°C, $[\alpha]_D^{12} -36.5°$ (c 0.65, methanol). The ultraviolet absorption spectrum

** Rotation reported by Toki[4] is $[\alpha]_D^{21} -22.2°$ (c 2.0, methanol).

of the product showed maxima at 231 mμ (ε 7.780) and 336 mμ (ε 28.6) in methanol (Fig. 2).

Anal. Found: C, 62.40; H, 6.40. Calcd. for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

(+)-*5-Methylenecyclopentanone-3-carboxylic Acid* (Va).—A mixture of freshly prepared methyl (+)-5-methylenecyclopentanone-3-carboxylate (1.44 g.) and 1.5 N sulfuric acid (30 cc.) was stirred at 27~28°C for 2 hr. to give a clear solution, which was kept cold in an ice-bath, adjusted to pH 7.8 with a saturated solution of sodium bicarbonate, and shaken with three 30 cc. portions of ethyl acetate to remove any unchanged ester. The water-layer was adjusted to pH 2.0 with 1.5 N sulfuric acid and extracted with four 25 cc. portions of ethyl acetate. After the extract was dried over sodium sulfate, the ethyl acetate was removed by distillation under reduced pressure at 14°C to yield a crude product of (+)-5-methylenecyclopentanone-3-carboxylic acid, a colorless, viscous oil which rapidly crystallized; yield 0.48 g. (37%), m. p. 46~60°C, $[\alpha]_D^{10}$+34.9° (c 1.0, methanol). The freshly prepared sample was soluble in methanol and in water. However, on standing at room temperature in the absence of polymerization inhibitor, the product gradually polymerized and became much less soluble in methanol or water. It resisted attempts to recrystallize it. The ultraviolet absorption spectrum of the product showed maxima at 232 mμ (ε 5.670) and 333 mμ (ε 20.7) in methanol, showing the presence of α, β-unsaturated ketone group.

(−)-*5-Methylenecyclopentanone-3-carboxylic Acid* (Vb).—This acid was prepared from methyl (−)-5-methylenecyclopentanone-3-carboxylate (0.65 g.) by the same procedure as described above; yield 0.2 g. (34%), m. p. 48~57°C $[\alpha]_D^{12}$−29.3° (c 0.517, methanol). The product polymerized gradually and resisted attempts to recrystallize it. The ultraviolet absorption spectrum of the product showed maxima at 232 mμ (ε 5.650) and 333 mμ (ε 20.5) in methanol, showing the presence of α, β-unsaturated ketone group.

Ozonolysis of Vb.—A solution of 200 mg. of freshly prepared (−)-5-methylenecyclopentanone-3-carboxylic acid (Vb) in ethyl acetate (10 cc.) was treated with an approximately 2% (by weight) ozone-oxygen mixture at 0°C at a rate of 500 cc./min. for 19 min. The resulting solution was mixed with water (10 cc.) and zinc dust (300 mg.) and the mixture was refluxed for 30 min. The reaction mixture was filtered while hot into a solution of methone (300 mg.) in 10 cc. of ethanol. Dilution with 20 cc. of water afforded the needles of formaldehyde methone, m. p. 183~186°C; yield 128 mg. (31%). Recrystallization from 80% ethanol gave pure crystals of m. p. 187~189°C. Admixing with an authentic specimen of formaldehyde methone showed no change of melting point.

Bioassays.—Preliminary results have indicated that methyl (+)-5-methylenecyclopentanone-3-carboxylate (IVa) and the other isomer (IVb) possess potencies of 5.2 and 6.5 unit/mg. (in terms of sarkomycin potency) in 10% ethanol against *Staph. aureus* 209-P respectively. The minimum necessary concentrations of (+)-5-methylenecyclopentanone-3-carboxylic acid (Va) and the other isomer (Vb) for the anti-HeLa-cell effect were 62.5 and 62.5 mcg./cc. respectively. The daily intraperitoneal injections of 0.15 mg. of Va and 0.25 mg. of Vb inhibited the ascites increase and prolonged the survival period of mice bearing ascites type of Ehrlich cartinoma by intraperitoneal route.

A detailed report on the biological activities of IVa, IVb, Va and Vb will be published elswhere.

Summary

1) The two diastereoisomeric mixtures (IIa and IIb) of 5-(dimethylaminomethyl)-cyclopentanone-3-carboxylic acid hydrochloride were synthesized from the two enantiomorphs of cyclopentanone-3-carboxylic acid by means of the Mannich reaction.

2) The two diastereoisomeric mixtures (IIIa and IIIb) of methyl 5-(dimethylaminomethyl)cyclopentanone-3-carboxylate hydrochloride were degraded to give methyl (+)- and methyl (−)-5-methylenecyclopentanone-3-carboxylates (IVa and IVb), which were hydrolyzed into (+)- and (−)-5-methylenecyclopentanone-3-carboxylic acid (Va and Vb), respectively.

3) It was found that IVa and IVb possess high potency against *Staph. aureus* and both Va and Vb show significant antitumor activities of the same extent.

The authors are indebted to Professor H. Umezawa, National Institute of Health, Tokyo, for antitumor assays, and to Mr. S. Nakada of this Laboratory for the microanalytical data.

Selective Oxidation of Allylic Alcohols with Active N-Halogen Compounds. II[1]

By Ken-ichi MORITA*

(Received September 9, 1958)

It was shown in the previous paper[1] that active *N*-halogen compounds are effective reagents for the selective oxidation of allylic alcohols[2]. This article presents examples of selective oxidation of dihydroxylic compounds, each carrying an allylic and a primary or equatorial hydroxyl group, to α,β-unsaturated ketones with the unaffected primary or equatorial hydroxyl group, which may be difficult when manganese dioxide is employed[4,5], and of an allylic alcohol with an isolated ethylenic linkage to an α,β-unsaturated ketone without affecting the isolated double bond.

Reduction of methyl 3-keto-23,24-dinorchol-4-en-22-oate[6] (I) with lithium aluminum hydride gave a product which is presumed a mixture consisting essentially of 23,24-dinorchol-4-en-3β,22-diol and its 3α-epimeride. Oxidation of the mixture III by means of *N*-bromoacetamide in benzene-pyridine gave 23,24-dinorchol-4-en-22-ol-3-one (IVa)[7] in an overall yield of 78% from keto ester I. Similarly, reduction[8] of 3-keto-23,24-dinorchol-4-en-22-al[9] (II) with sodium borohydride to diol mixture III followed by oxidation with *N*-bromoacetamide or with isocyanur bromide[10] yielded 23,24-dinorchol-4-en-22-ol-3-one (IVa)[11].

The lithium aluminum hydride reduction of methyl 3-keto-20-*iso*-23,24-dinorchol-4-en-22-oate (V)[6] to diol mixture VII and the succeeding oxidation with *N*-bromoacetamide furnished 20-*iso*-23,24-dinorchol-4-en-22-ol-3-one (VIIIa) in an overall yield of 72%. The same compound VIIIa was also obtained from 3-keto-20-*iso*-23,24-dinorchol-4-en-22-al[6] (VI) by sodium borohydride reduction followed by the selective oxidation with *N*-bromoacetamide.

Treatment of methyl 3-keto-23,24-dinorchol-4-en-22-oate (I) with ethylene glycol in benzene solution in the presence of *p*-toluenesulfonic acid furnished methyl 3-ethylenedioxy-23,24-dinorchol-5-en-22-oate (IX), m.p. 188~189°C, α_D −46°. The rotatory dispersion curve[14] of this compound (negative plain) is consistent with a 5-ene-ketal. Djerassi et al.[15] have shown that 5-ene-steroids give negative plain dispersion curves. Acid hydrolysis of ketal ester IX regenerated methyl 3-keto-23,24-dinorchol-4-en-22-oate (I). Reduction of ketal ester IX with lithium aluminum hydride gave 3-ethylenedioxy-23,24-dinorchol-5-en-22-ol (Xa), m.p. 181~182°C, α_D −33°. Hydrolysis of ketal alcohol Xa gave 23,24-dinorchol-4-en-22-ol-3-one (IVa), which was identical with the sample derived from compound I or II through diols III.

Addition of hypobromous acid to 3-ethylenedioxy-cholest-5-ene (XI) by means of *N*-bromoacetamide in dioxane containing

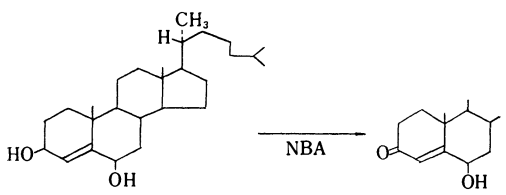
dilute perchloric acid yielded 6β-bromocholestan-5α-ol-3-one (XII) in 50% yield[16]. Treatment of compound XII with sodium hydroxide in methylenechloride-methanol at room temperature gave 6α-hydroxycholest-4-en-3-one (XIV), which was converted into cholest-4-ene-3β,6α-diol (XV)[17] by lithium aluminum hydride reduction. Dehydrobromination of 5α-bromocholestane-3β,6β-diol diacetate (XVI)[18] with boiling pyridine gave cholest-4-ene-3β,6β-diol diacetate (XVII).



Oxidation of cholest-4-ene-3β,6β-diol (XVIII) and cholest-4-ene-3β,6α-diol (XV) by means of about one equivalent of *N*-bromoacetamide gave cholest-4-en-6β-ol-3-one (XIX) and cholest-4-en-6α-ol-3-one (XIV) in good yields, respectively. Proofs for these structures were obtained from their conversion into acetates and into 5α-cholestane-3,6-dione by a reaction with hydrochloric acid[19]. The method may be applica-

ble to a general synthesis of 6β-hydroxy-3-keto-4-ene-steroids[20,21] and of 6α-hydroxy-3-keto-4-ene-steroids[20,22]. Amendolla et al.[5], reported that manganese dioxide oxidation of cholest-4-ene-3β,6β-diol (XVIII) gave cholest-4-en-6β-ol-3-one (XIX) in a good yield while the oxidation of cholest-4-ene-3β,6α-diol (XV), in which $C_{(6)}$-hydroxyl group is equatorial, gave cholest-4-ene-3,6-dione even under mild conditions.

It is noteworthy that on the *N*-bromoacetamide oxidation of compound XVIII 3β-hydroxy group (quassi equatorial) was selectively oxidized whereas 6β-hydroxy group (axial) remained unaffected. This fact is contrary to the general rule for the oxidation by means of *N*-bromoacetamide to the effect that axial hydroxyl groups are more readily oxidized than equatorial ones. Lieberman and Fukushima[23] reported the selective oxidation of cholest-5-ene-3β,4β,7α-triol 3-monoacetate (XX) to cholest-5-ene-3β,4β-diol-7-one 3-monoacetate (XXI), in which quassi axial hydroxyl group 7α was selectively oxidized and axial hydroxyl group 4β remained unaffected. It might be expected that *N*-bromoacetamide oxidation of allylic hydroxyl groups to give s-trans α,β-unsaturated ketones is easier than that of allylic hydroxyl groups to give s-*cis* α,β-unsaturated ketones.

Reduction of stigmasta-4,22-dien-3-one (XXIII)[24] with lithium aluminum hydride gave a mixture of stigmasta-4,22-dien-3β-ol and the corresponding 3α-ol. Oxidation of the mixture XXII by means of about one equivalent of *N*-bromoacetamide gave stigmasta-4,22-dien-3-one (XXIII) in 80% yield. *N*-Halogen compounds may also be effective for the selective oxidation of allylic alcohols containing isolated ethylenic double bonds to α,β-unsaturated ketones without affecting the isolated double bonds.

Experimental[25]

23,24-Dinorchol-4-en-22-ol-3-one (IVa).—*a) From Methyl 3-Keto-23,24-dinorchol-4-en-22-oate (I).*—A mixture of 165 mg. of ketoester I[6] and 100 mg. of lithium aluminum hydride in 15 ml. of anhydrous tetrahydrofuran was heated under reflux for 5 hours. After careful decomposition of excessive lithium aluminum hydride with a small amount of water, tetrahydrofuran was evaporated under a reduced pressure. The solid was collected, dried, and washed well with dioxane. Evaporation of the solvent under a reduced pressure yielded a solid, m.p. 187~204°C, in a quantitative yield.

A solution of the above solid (162.3 mg.) in 2 ml. of benzene and 4 ml. of pyridine was treated with 82 mg. of *N*-bromoacetamide at room temperature (17~18°C) for two and a half hours in the dark. The solution was diluted with benzene and washed successively with 10% aqueous sodium bisulfite, with 10% aqueous sodium hydroxide, with water, with dilute sulfuric acid, and again with water, and dried over anhydrous sodium sulfate. The solvent was evaporated under a reduced pressure, and 165 mg. of a crystalline solid was obtained. The solid was dissolved in 10 ml. of benzene and adsorbed on a column of alumina (5 g.). Elution with ether gave 129 mg. (78% from I) of IVa with m.p. 135~136°C. Recrystallization from aqueous acetone yielded pure IVa, m.p. 137~138°C, $[\alpha]_D^{18}$ +94 (C, 1.125), λ_{max} 241 mμ, log ε, 4.20, ν_{max}^{Nujol} 2.90 (OH), 6.09 (C=O), 6.18 μ (C=C). The melting point was not depressed on admixture with an authentic sample (m.p. 137.5~138°C) kindly provided by Dr. C. Meystre[7].

21) F. Sondheimer et al., *J. Chem. Soc.*, **1954**, 1226; *J. Am. Chem. Soc.*, **76**, 5020 (1954).
22) K. Morita, *Proc. Japan Academy.*, **32**, 588 (1956).
23) S. Lieberman and D. K. Fukushima, *J. Am. Chem. Soc.*, **72**, 5211 (1950).
24) G. Slomp, Jr., et al., ibid., **77**, 1216 (1955). Cf. D. A. Shepherd et al., ibid., **77**, 1212 (1955).
25) All melting points are uncorrected. Rotations are all measured in chloroform solution.

Anal. Found: C, 79.51; H, 10.42. Calcd. for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

b) From 3-Keto-23, 24-dinorchol-4-en-22-al (II) by use of N-Bromoacetamide.—To a suspension of 1.5 g. of keto aldehyde II[9] in 90 ml. of methanol, a solution of 0.3 g. of sodium borohydride in 0.7 ml. of water and 15 ml. of methanol was added with stirring at room temperature. After standing for 2 hours at room temperature excessive sodium borohydride was decomposed by careful addition of a small amount of dilute acetic acid. Then the solution was poured into an excess of water. The solid was collected and well washed with water. The solid melted at 175~190°C. Yield, 1.4 g.

The mixture, dissolved in 15 ml. of benzene and 30 ml. of pyridine, was treated with 700 mg. of *N*-bromoacetamide as described above, and 870 mg. of compound IVa with m.p. 135~138°C was obtained. Identity was established by a mixed melting point determination.

c) From 3-Keto-23, 24-dinorchol-4-en-22-al (II) by use of Isocyanur Bromide[10].—To a solution of 5 g. of keto aldehyde II in 100 ml. of tetrahydrofuran, 2 g. of sodium borohydride in 10 ml. of water was added at room temperature. After allowed to stand overnight at room temperature the solution was poured into an excess of water. The solid was collected by filtration. The solid melted at 196~205°C. Yield, 4.8 g.

A mixture of 404 mg. of the above solid, 25 ml. of *tert*-butyl alcohol, 1 ml. of pyridine and 205 mg. of 83% isocyanur bromide[10] was treated as usual, and 260 mg. of compound IVa with m.p. 134~138°C was obtained.

d) From 3-Ethylenedioxy-23, 24-dinorchol-5-en-22-ol (Xa).—To a suspension of 128 mg. of ketal alcohol Xa in 13 ml. of methanol, 1.3 ml. of 8% (by volume) sulfuric acid was added, and the mixture was refluxed for one hour. A few drops of water were added and the precipitated needles were collected by filtration and recrystallized from aqueous acetone to give 72 mg. of IVa in needles, m.p. 137~138°C. The melting point was not depressed on admixture with the above samples.

23, 24-Dinorchol-4-en-22-ol-3-one acetate (IVb).—The substance was obtained in a usual way, and recrystallized from *n*-hexane, m.p. 131~132°C, $[\alpha]_D^{22}$ +95 (c, 1.248).

Anal. Found: C, 76.89, H, 9.91. Calcd. for $C_{24}H_{36}O_3$: C, 77.37, H, 9.74%.

When a mixture of 21 mg. of the acetate IVb, 3 ml. of methanol and 0.3 ml. of 0.8% (by volume) sulfuric acid was heated under reflux for 45 minutes, compound IVa was obtained.

23, 24-Dinorchol-4-en-22-ol-3-one tosylate (IVc).—To 249 mg. of compound IVa in 2 ml. of pyridine, 0.19 g. of *p*-toluenesulfonyl chloride was added and the mixture was allowed to stand overnight at room temperature. The mixture was poured into an excess of water. The solid was collected, washed with dilute hydrochloric acid and with water, dried, and recrystallized from acetone to give IVc in plates, m.p. 175~177°C (dec.), ν_{max}^{Nujol} 5.99 (C=O), 6.17, 6.24 (C=C), 7.30, 8.51 μ (—O—SO_2—).

Anal. Found: C, 72.66, H, 7.05. Calcd. for $C_{29}H_{36}SO_4$: C, 72.46, H, 7.55%.

Methyl 3-Keto-23,24-dinorchol-4-en-22-oate (I).—To a suspension of 50 mg. of ketal ester IX in 4 ml. of methanol, 0.4 ml. of 8% (by volume) sulfuric acid was added and the mixture was refluxed for 40 minutes. The solid soon disappeared and in about 10 minutes a new crystalline substance began to separate out. The suspension was diluted with water and the solid (m.p. 170~172°C; 45 mg.) was collected and recrystallized from acetone to give I in crystals with m.p. 178~180°C. The identity was established by a mixed[6] melting point determination.

Methyl 3-Keto-20-*iso*-23, 24-dinorchol-4-en-22-oate (V).—3-Keto-20-*iso*-23, 24-dinorchol-4-en-22-al (II)[6] (391 mg.) (m.p. 142~143°C from methylene chloride-isopropyl alcohol; reported m.p. 140~142°C[6], 137.5~139°C[26]), dissolved in 8 ml. of benzene and 8 ml. of glacial acetic acid, was oxidized with 118 mg. of chromic acid in 0.25 ml. of water and 8 ml. of acetic acid according to Herr and Heyl[6].

The ethereal extract was washed twice with 10% sodium carbonate. The sodium salt was collected centrifugally, and washed with ether. Treatment of the salt with 20% sulfuric acid gave 135 mg. of 3-keto-23, 24-dinorchol-4-en-22-oic acid with m.p. 233~243°C, which gave a pure sample, m.p. 265~268°C, on recrystallization from methylene chloride-methanol.

The alkaline solution was neutralized with 20% sulfuric acid and 262 mg. of crude 3-keto-20-*iso*-23, 24- dinorchol-4-en-22-oic acid with m.p. 201~204°C was obtained. Methylation of the crude acid with diazomethane yielded 123 mg. of V with m.p. 118~121°C. Reported m.p. 119~121°C[6].

20-*Iso*-23, 24-dinorchol-4-en-22-ol-3-one (VIIIa).—*a) From Methyl 3-Keto-20-iso-23, 24-dinorchol-4-en-22-oate (V).*—A mixture of 73.7 mg. of keto ester V and 52 mg. of lithium aluminum hydride in 2 ml. of tetrahydrofuran was treated in the same way as described above (reflux for 5 hours) to give 73.4 mg. of a mixture (VII) with m.p. 188~205°C.

The above solid was dissolved in a mixture of 1 ml. of benzene and 3 ml. of pyridine and the solution was treated with 37 mg. of *N*-bromoacetamide (standing for 3 hours at room temperature). After being treated as usual, the crystalline residue (73.6 mg.; m.p. 120~138°C) was dissolved in 10 ml. of benzene and adsorbed on a column of alumina (3 g.). Elution with ether and recrystallization from aqueous acetone gave 53 mg. of VIIIa, m.p. 147~148°C, $[\alpha]_D^{21.5}$ +96 (c, 0.532), λ_{max} 241 mμ, log ε, 4.24, ν_{max}^{Nujol} 2.89 (OH), 6.03 (C=O) 6.20 μ (C=C).

Anal. Found: C, 79.90, H, 10.48. Calcd. for $C_{22}H_{34}O_2$: C, 79.95, H. 10.37%.

b) From 3-Keto-20-iso-23, 24-dinorchol-4-en-22-al (VI).—To a mixture of 1 g. of compound VI[6] in 60 ml. of methanol, a solution of 0.2 g. of sodium borohydride in 1 ml. of water and 5 ml. of methanol was added with stirring at the room

26) K. Tsuda. R. Hayatsu, Y. Kishida and S. Akagi, *J. Am. Chem. Soc.*, **80**, 921 (1958).

temperature. After one hour the reaction mixture was diluted with water and the solid (m. p. 175～195°C) was collected by filtration. Yield, 1 g.

A mixture of 203.7 mg. of the above solid, 2 ml. of benzene, 5 ml. of pyridine and 108.2 mg. of *N*-bromoacetamide was treated in the same way as described above to give 135 mg. of compound VIIIa with m. p. 145～147°C. The melting point was not depressed on admixture with the sample obtained above.

20-*Iso*-23,24-dinorchol-4-en-22-ol-3-one acetate (VIIIb). — The substance was prepared in the usual way from 34 mg. of compound VIIIa. The crude substance showed m. p. 85～91°C, $[\alpha]_D^{22}$ +94 (c, 0.726). No attempt was made to purify it further, because only a few mg. of this substance which is crystallized with difficulty was available.

20-*Iso*-23,24-dinorchol-4-en-22-ol-3-one tosylate (VIIIc).—To 138 mg. of compound VIIIa in 3 ml. of pyridine, 87 mg. of *p*-toluenesulfonyl chloride was added and the mixture was left to stand overnight. Treatment in the usual way gave VIIIc in plates with m. p. 176～178°C (dec.), ν_{max}^{Nujol} 5.99 (C=O), 6.20, 6.26 (C=C), 7.31, 8.51 μ (—O—SO_2—).

Anal. Found: C, 72.35, H, 7.08. Calcd. for $C_{25}H_{36}SO_4$: C, 72.46, H, 7.55%.

Methyl 3-Ethylenedioxy-23,24-dinorchol-5-en-22-oate (IX).—A mixture of 2 g. of compound I[6], 140 ml. of dry benzene, 10 ml. of ethylene glycol and 0.2 g. of *p*-toluenesulfonic acid monohydrate was distilled until 30 ml. of the distillate was azeotropically removed in about 1 hour, and the mixture was refluxed for further 8 hours[27]. After cooling, the mixture was extracted with benzene, and the extract was washed with 10% aqueous potassium carbonate and with water, and dried over anhydrous sodium sulfate. The solvent was evaporated under a reduced pressure, and the crystalline residue was recrystallized from acetone to give 1.4 g. of IX in needles, m. p. 188～189°C, $[\alpha]_D^{20}$ −46 (c, 1.410), ν_{max}^{Nujol} 5.80 (C=O). 7.95 (O=C—O—C), 9.25 μ (ketal)[28].

Anal. Found: C, 74.64, H, 9.86. Calcd for $C_{25}H_{38}O_4$: C, 74.58, H, 9.51%.

3-Ethylenedioxy-23,24-dinorchol-5-en-22-ol (Xa).—A mixture of 748 mg. of ketal ester IX, 170 mg. of lithium aluminum hydride and 20 ml. of anhydrous tetrahydrofuran was treated in the same way as described above (reflux for 4 hours), and recrystallization of the product from methanol gave 610 mg. of Xa in fine needles, m. p. 181～182°C, $[\alpha]_D^{16.5}$ −33 (c, 1.28).

Anal. Found: C, 77.07, H, 9.93. Calcd for $C_{24}H_{38}O_3$: C, 76.96, H, 10.23%.

3-Ethylenedioxy-23,24-dinorchol-5-en-22-ol acetate (Xb). — The substance was prepared in the usual way. Recrystallization from aqueous ethanol gave Xb in long needles, m. p. 122～123°C, $[\alpha]_D^{21.5}$ −32 (c, 1.75).

Anal. Found: C, 74.89, H, 10.00. Calcd. for $C_{26}H_{40}O_4$: C, 74.96, H, 9.68%.

A mixture of 9 mg. of acetate XIb, 3 ml. of methanol and 0.3 ml. of 0.8% (by volume) sulfuric acid was treated in the same way as described above (reflux for 50 min.) to give IVa, m. p. and mixed m. p. 137～138°C.

6β-Bromocholestan-5α-ol-3-one (XII). — A suspension of 1 g. of 3-ethylenedioxy-cholest-5-ene (XI) in 50 ml. of dioxane and 3 ml. of water was mixed with 1 ml. of 60% perchloric acid and 350 mg. of *N*-bromoacetamide, and the mixture was shaken occasionally at room temperature. The whole solid soon went into solution and in a few hours a new solid appeared. After being kept overnight the suspension was diluted with 10 ml. of water and left to stand in a refrigerator for two hours, and the solid was collected, dried, and triturated with hot acetone to give 520 mg. of XII melting at 176～178°C. Recrystallization from acetone raised the melting point to 181～182°C (dec.), which was not depressed on admixture with an authentic sample of XII[29].

Cholest-4-en-6α-ol-3-one (XIV).—To a solution of 59 mg. of bromohydrin XII in 5 ml. of methylene chloride and 10 ml. of methanol, 17 mg. of potassium hydroxide in 8.5 ml. of methanol was added. After being kept at room temperature overnight, the solution was neutralized with acetic acid and concentrated to half the volume under a reduced pressure. Water was added and crystals were collected by filtration to obtain 51 mg. of XIV, m. p. 152～156°C. The melting point was raised to 160～161°C on recrystallization from aqueous ethanol. Identity was established by a mixed[22] melting point determination.

It was shown in a previous paper[22] that sodium bicarbonate hydrolysis of 6β-chlorocholestan-5α-ol-3-one furnished compound XIV in a good yield while sodium bicarbonate hydrolysis of bromohydrin XII in the same manner as described previously furnished compound XIV only in a low yield. When a mixture of bromohydrin XII (0.4 g.) in ethanol (30 ml.) and potassium bicarbonate (0.2 g.) in water (3 ml.) was heated under reflux for 5 hours, 0.35 g. of 5α-cholestane-3,6-dione was obtained, m. p. 169～170°C, $[\alpha]_D^{25}$ +5 (c, 2.50).

Cholest-4-en-3β,6α-diol (XV).—A mixture of 108 mg. of XIV and 50 mg. of lithium aluminum hydride in 3 ml. of tetrahydrofuran was treated in the same manner as described above (reflux for 1 hour). The residue (107 mg.) exhibited m. p. 126～148°C, $[\alpha]_D^{24}$ +47 (c, 1.07). Two recrystallizations from methanol gave 48 mg. of XV in needles, m. p. 178～179°C, $[\alpha]_D^{25}$ +31 (c, 0.388). Reported m. p. 175～178°C, $[\alpha]_D$ +29[30], 176～177°C[17], 178～179°C[31]. Identity was established

by a mixed[17] melting point determination.

Cholest-4-ene-3β,6β-diol (XVIII).—5α-Bromocholestan-3β, 6β-diol diacetate[18] (2 g.) in dry pyridine (15 ml.) was heated under reflux for 8 hours. The mixture was diluted with ice-cold water and extracted with ether. The extract was washed with diluted hydrochloric acid and with water, dried over anhydrous sodium sulfate, and evaporated. Recrystallizations (twice) from methanol gave 1.2 g. of cholest-4-ene-3β, 6β-diol diacetate, m. p. 132~135°C.

Hydrolysis of the diacetate (1 g.) in methanol (20 ml.) with potassium hydroxide (0.3 g.) in methanol (3 ml.) at room temperature gave 0.7 g. of diol XVIII, m. p. 255~258°C. Identity was established by a mixed[32] melting point determination.

Cholest-4-en-6β-ol-3-one (XIX).—A solution of 200 mg. of 3β, 6β-diol XVIII in 3 ml. of benzene and 4 ml. of pyridine was treated with 72 mg. (1.05 equiv.) of *N*-bromoacetamide at room temperature for 18 hours. After being treated as usual, the crystalline residue was recrystallized from acetone—*n*-hexane to give 155mg. of XIX in needles, m. p. 185~189°C. The melting point was raised to 190~191°C by recrystallizations (twice) from acetone—*n*-hexane and was not depressed when mixed with an authentic sample of XIX[22].

The identity was further established by conversion into the acetate, m. p. and mixed m. p. 101~102°C, and into 5α-cholestan-3, 6-dione, m. p. and mixed m. p. 170~171°C, on treating with hydrochloric acid in ethanol.

Cholest-4-en-6α-ol-3-one (XIV).—A solution of 157 mg. of 3β, 6α-diol XV in 3 ml. of benzene and 4 ml. of pyridine was treated with 57 mg. of *N*-bromoacetamide at room temperature overnight. After being treated as usual, the crystalline residue was recrystallized from acetone-*n*-hexane to give 121 mg. of XIV in needles, m. p. 150~155°C. The melting point was raised to 160~161°C when recrystallized from aqueous ethanol. Identity was established by a mixed[22] melting point determination.

The identity was further established by conversion into the acetate, m. p. and mixed[33] m. p. 103~104°C, and into 5α-cholestane-3, 6-dione, m. p. and mixed m. p. 170~171°C, on treating with hydrochloric acid in ethanol.

Stigmasta-4, 22-dien-3-ol (XXII).—A mixture of 0.5 g. of stigmasta-4, 22-dien-3-one (XXIII)[24], m. p. 123~125°C, and 0.2 g. of lithium aluminum hydride in 15 ml. of anhydrous tetrahydrofuran was treated in the same manner as described above (reflux for 1.5 hours) to give a mixture, m. p. 134~163°C, $[\alpha]_D^{24}$ +32 (c, 1.57). It is presumed that the mixture consists essentially of stigmasta-4, 22-dien-3β-ol and the corresponding 3α-ol.

Stigmasta-4, 22-dien-3-one (XXIII).—A solution of 200 mg. of the above mixture (XXII) in 3 ml. of benzene and 4 ml. of pyridine was treated with 70 mg. (1.05 equiv.) of *N*-bromoacetamide at room temperature for 2 hours. After being treated as usual, the crystalline residue was recrystallized from acetone to give 162 mg. of XXIII in needles, m. p. 118~122°C. The melting point was raised to 126~127°C by three recrystallizations from acetone and was not depressed when admixed with an authentic sample of XXIII[24].

Ultraviolet and Infrared Absorption Spectra. — They were measured by use of Hitachi Photoelectric Spectrophotometer Model EPU-2 and ŌYŌ-KŌKEN instrument, respectively. Samples for ultraviolet spectra were dissolved in 95% ethanol. Infrared spectra were kindly measured at Institute of Physical and Chemical Research.

The author is indebted to Professor S. Mori, Tokyo Metropolitan University, Dr. M. Nakamura, Director of this Institute, and Mr. R. Mamine, this Institute, for their encouragement.

Synthesis of Sarkomycin. II.[1] *A New Synthesis of the Alkyl Cyclopentanone-3-carboxylate*

By Katsuyuki TOKI

(Received September 11, 1958)

In the previous report[1], the present author described the synthesis of *dl*-sarkomycin (2-methylenecyclopentanone-3-carboxylic acid) (I) starting from ethyl cyclopentane-3-carboxylate[2] (II).

Though the alkyl cyclopentanone-3-carboxylate (II) is a key substance for the preparation of *dl*-sarkomycin, the hitherto published methods are so complicated for the commercial preparation of alkyl cyclopentanone-3-carboxylate (II) that the present author has studied the synthesis of this intermediate by means of a new convenient route.

It was found that the cyclopentanone-3-carboxylate (II) can be readily obtained by the thermal decomposition of monoester of 1,2,4-butanetricarboxylic acid (3-alkoxycarbonyladipic acid) (VI) which was prepared from butadiene (III) and alkyl acrylate (IV) according to the following new scheme. (See Fig. 1).

Cyclohexene-4-carboxylate[3] (V) was prepared in a good yield (71.4%) by heating butadiene (III) with alkyl acrylate (IV) in an autoclave at 170~180° in the presence of polymerization inhibitors such as hydroquinone.

Monoester of 1,2,4-butanetricarboxylic acid (VI) was obtained by the oxidation[4] of V with potassium permanganate in a 67.2% yield. While cyclopentanone-3-carboxylic acid (X) could be prepared from the triester VII according to Kay's precedure[2], the cyclopentanone-3-carboxylate (II) was formed directly when monoester VI was heated at 200~300° at atmospheric pressure and then distilled under a reduced pressure. The cyclopentanone-3-carboxylate (II), thus obtained, was identical with the specimen prepared by Kay's method[2].

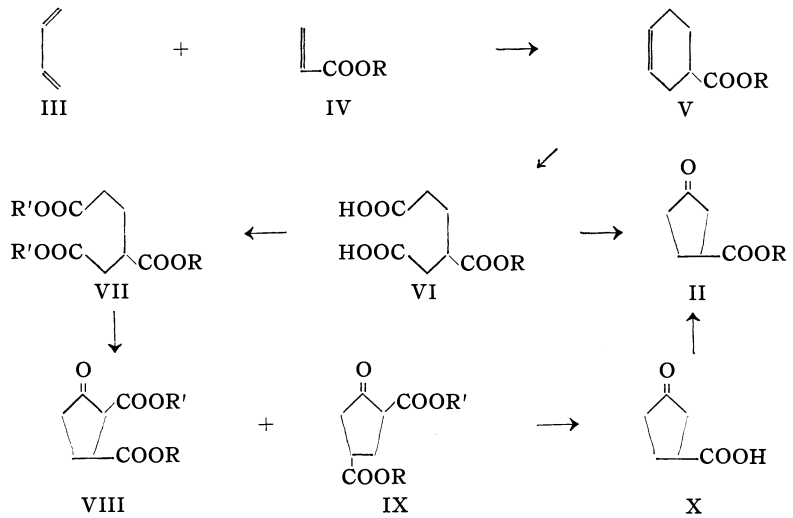

Fig. 1. The new route for the synthesis of alkyl cyclopentanone-3-carboxylate.

Experimental

Methyl cyclohexene-4-carboxylate (V, R=CH_3).—A mixture of 86 g. (1 mole) of methyl acrylate (IV, R=CH_3), 108 g. (2 moles) of butadiene[5] (III) and 1 g. of hydroquinone was heated in an autoclave at 170° for twenty hours. The reaction mixture was distilled in vacuo to remove the polymeric materials and the distillate was fractionated through a Widmer-column. The fraction boiling at 182~185° (99~107°/100 mm.), n_D^{31} 1.4574, was collected. The yield was 90 g. (64.3%).

Anal. Found: C, 68.56; H, 8.58. Calcd. for $C_8H_{12}O_2$: C, 68.57; H, 8.57%.

Ethyl cyclohexene-4-carboxylate (V, R=C_2H_5).—A mixture of 100 g. (1 mole) of ethyl acrylate (IV, R=C_2H_5), 108 g. (2 moles) of butadiene and 1 g. of hydroquinone was treated in the same manner as above. The yield of V (R=C_2H_5), b.p. 105~110°/100 mm., was 110g. (71.4%).

Anal. Found: C, 70.03; H, 8.88. Calcd. for $C_9H_{14}O_2$: C, 70.13, H, 9.09%.

Monoester of 1,2,4-butanetricarboxylic acid (3-Alkoxycarbonyladipic acid (VI)).—*a*) *Methylester.*—Finely powdered potassium permanganate (461 g.) was added in small portions to a mixture of 140 g. (1 mole) of V and 2000 ml. of water with vigorous stirring over a period of five hours at temperatures below 50°. Manganese dioxide was filtered off and the filtrate was acidified with diluted hydrochloric acid and extracted with ether in a large continuous extracter for five days. The ether layer was dried over anhydrous sodium sulfate, the ether was removed and the residue was then distilled in vacuo. The yield of VI, (R=CH_3) b.p. 209~213°/0.4 mm., was 137.1 g. (67.2%). It was recrystallized from a mixture of ethyl acetate and petroleum ether, m.p. 95~97°.

Anal. Found: C, 47.05; H, 5.79. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.88%.

b) *Ethylester.*—A suspension of 154 g. (1.0 mole) of V (R=C_2H_5) in 2000 ml. of water was oxidized with 461 g. of potassium permanganate in the same manner as described above. The yield of VI (R=C_2H_5), b.p. 217~220°/0.5 mm., was 140 g. (64.2%).

Anal. Found: C, 49.48; H, 6.37. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.42%.

Diethyl methyl 1,2,4-butanetricarboxylate (VII, R=CH_3, R'=C_2H_5).—A mixture of 102 g. (0.5 mole) of VI (R=CH_3), 1000 ml. of absolute ethanol and 10 g. of concentrated sulfuric acid was refluxed on a water bath for eight hours. After concentration of the reaction mixture, the residue was poured into ice and water. The oily layer was extracted with ether, washed with 5% aqueous sodium bicarbonate solution and dried over anhydrous sodium sulfate. The ether was removed and the residue was distilled under a reduced pressure. The yield of VII, b.p. 185~190°/28 mm., n_D^{24} 1.4412, was 80 g. (61.5%).

Anal. Found: C, 55.34; H, 7.53. Calcd. for $C_{12}H_{20}O_6$: C, 55.38; H, 7.69%.

5) Butadiene was prepared by the procedure described in "Organic Syntheses", Coll. Vol. II, John Wiley and Sons, Inc., New York (1943), p. 102.

Triethyl 1,2,4-butanetricarboxylate (VII, R=R'=C_2H_5).—A mixture of 109 g. (0.5 mole) of VI (R=C_2H_5), 1000 ml. of absolute ethanol and 10 g. of concentrated sulfuric acid was refluxed on a water bath for eight hours. The reaction mixture was warked up in the same manner as above. The final product, b.p. 190~202°/24 mm., weighed 73 g. (53.3%).

Anal. Found: C, 57.00; H, 8.00. Calcd. for $C_{13}H_{22}O_6$: C, 56.93; H, 8.03%.

Methyl cyclopentanone-3-carboxylate (II, R=CH_3).—After heating 51 g. (0.25 mole) of VI (R=CH_3) with 1 g. of barium oxide at 250~300° for 10~30 minutes, the mixture was distilled under a reduced pressure. The product came over at 122~125°/18 mm. and weighed 10.2 g. (28.7%).

Anal. Found: C, 59.18; H, 7.00. Calcd. for $C_7H_{10}O_3$: C, 59.15; H, 7.04%.

The 2,4-dinitrophenylhydrazone melted at 182~184° (recrystallized from a mixture of ethyl acetate and petroleum ether).

Ethyl cyclopentanone-3-carboxylate (II, R=C_2H_5) from VII (R=R'=C_2H_5).—To a suspension of 13 g. of sodium-sand in 300 ml. of benzene was added 137 g. (0.5 mole) of triethyl 1,2,4-butanetricarboxylate (VII, R=R'=C_2H_5). When the vigorous reaction subsided, the reaction mixture was heated for two hours with stirring and acidified with diluted hydrochloric acid.

The whole mixture was extracted with ether and the ether layer was washed with 5% aqueous solution of sodium bicarbonate and then with water. The ether solution was dried over anhydrous calcium chloride, the ether was removed and the residue was distilled. The yield of diethyl cyclopentanone-2,3- and -2,4-carboxylates, b.p. 131~137°/0.6 mm., was 96 g. (84%).

A solution of 96 g. (0.42 mole) of diethyl cyclopentanone-2,3- and -2,4-carboxylates in 1. of 8% sulfuric acid was boiled for three hours. Cyclopentanone-3-carboxylic acid (X) was extracted from the reaction mixture with ether, the ether layer was dried over anhydrous calcium chloride and the ether was distilled off. The residue was distilled at 138~145°/0.3 mm., m.p. 64~65°, and weighed 45 g. (83%).

A mixture of 45 g. (0.35 mole) of X, 180 ml. of benzene, 75 ml. of 99% alcohol and 4 g. of *p*-phenolsulfonic acid was refluxed for two days, a water separator being used. The ethyl ester (II) was obtained in a yield of 51 g. (93%): b.p. 127~128°/20 mm.

Anal. Found: C, 61.48 H, 7.63. Calcd. for $C_8H_{12}O_3$: C, 61.54; H, 7.69%.

The 2,4-dinitrophenylhydrazone melted at 153~154°.

Anal. Found: C, 49.77; H, 4.65; N, 16.93. Calcd. for $C_{14}H_{16}O_6N_4$: C, 50.00; H, 4.76; N, 16.67%.

Summary

Cyclopentanone-3-carboxylate which is the starting material for the synthesis of *dl*-sarkomycin (2-methylenecyclopentanone-3-carboxylic acid) was obtained by a new

route from butadiene and alkyl acrylate through alkyl cyclohexene-4-carbonylate and thence 3-alkoxycarbonyl adipic acid.

The author wishes to express his deep appreciation to Professor Shiro Akabori, Professor Hamao Umezawa and Professor Masanao Matsui, for their continuous interest in this work. The author is also indebted to Mr. Noboru Nishimura for carrying out micro-analyses and Messrs. Hiroo Wada and Yoshio Suzuki for their kind collaboration.

Effects of Dry Grinding on Kaolin Minerals. I. Kaolinite

By Hiroshi TAKAHASHI

(Received September 10, 1958)

Considerable work has been done on the effects of dry grinding on clay minerals and related minerals, particularly kaolinite[1]. The resolution of the grinding effects on kaolin minerals has proved helpful in the study of the structure of kaolin minerals. It is considered that understanding of the grinding process is useful for the study of weathering processes, soil fertility and the active solid.

It is well known that the grinding of kaolinite increases the base exchange capacity, but there is no consistent explanation of this increase. In the result of study concerning the dry grinding effect of kaolinite, there are two lines of thought, at least. One asserts that the dry grinding of kaolinite brings about only a reduction in particle size of kaolinite owing to cleavage and fracturing of the kaolinite crystal. The cleavage and fracturing of kaolinite crystal increases the specific surface and the broken bond. These facts lead to an increase in the base exchange capacity. The other insists that the dry grinding of kaolinite causes the formation of a zeolitic substance having a structure similar to that of the original kaolinite; that is, it distorts the lattice, and or decomposes kaolinite to alumina and silica gel. It is considered that wet grinding of kaolinite is effective in causing a change on the surface property but not in the structural change.

Studies heretofore of the grinding on kaolin minerals have been made mostly by ball-milling. Incidentally, it was found by Mackenzie and Milne that mechanical mortar is very effective in causing a change in structure of mica[2]. From this point of view, effects of several-hundred-hours mechanical-mortar dry grinding of kaolinite were studied by X-ray diffraction, thermal, electron microscopic and other methods in this study.

The purposes of this study are to obtain the fundamental information of the structure of kaolinite and the correct explanation of the grinding process of kaolinite, and to present the variation of the grinding effects of kaolin minerals with respect to the crystallinity.

Experimental

The following kaolinites were investigated: Kaolinite from Mesa Alta, N. M., U. S. A.; Kaolinite from Drybranch, Geor., U. S. A.. Both clays are the API Standard Clay Minerals. The structural characteristics of these original clays were discussed in the previous paper[3], and from

these results, it is found that Mesa Alta kaolinite is a triclinic in symmetry and so it has the highest degree of crystallinity of all kaolin minerals. The crystallinity of Drybranch kaolinite is somewhat lower than that of Mesa Alta kaolinite.

A 30 g. portion of the original kaolinite was charged and ground by a mechanical mortar (15.2 cm. in diameter and 8.4 cm. in depth). Specimens were taken out at intervals of 24 hour and examined by X-ray, thermal and electron microscopic method. In conjunction with the above measurements, base exchange capacity and density were measured.

X-ray diagrams were recorded by an X-ray diffractometer (Geigerflex). Experimental conditions are as follows: filtered Cu radiation (Cu$K\alpha$: 1.5418 Å) at 35 kV and 15 mA is used; scanning speed is 1° or 1/2° 2θ per minute; time constant is 4 seconds; receiving slit is 0.2 mm. or 0.1 mm.; angular aperture is 1° or 1/2°. The differential thermal analysis curves were obtained by the apparatus described by Sudo et al.[4]. Care was taken to pack a specimen into the sample block in a homogeneous manner and also keep the weight of the specimen constant. The mean heating rate is 12.5°C per minute. The density was measured by pycnometer in carbon tetrachloride. The base exchange capacity was measured by the following procedures. The specimen was treated with hydrochloric acid, thus convert it into "hydrogen-clay", and after being washed with water was titrated with sodium hydroxide solution. The base exchange capacity was expressed as the number of milli-equivalents of cation, per 100 g. of specimen, required to bring the pH to 7. Measurements of the density and the base exchange capacity were made after it had been dried at 110°C to avoid the influence of the adsorbed water. Electron micrographs were obtained by a Hitachi HU-10A type Electron Microscope.

Results and Discussion

X-Ray Diffraction Studies. — X-ray diffractometer traces are shown in Figs. 1 and 2. Figs. 1-a and -b show the X-ray diffractometer traces at various stages of grinding of Mesa Alta kaolinite, and Figs. 2-a and -b show that of Drybranch kaolinite. The data obtained from the X-ray diagrams are shown in Tables I and II.

The following major differences, noted in the X-ray diagrams, were used as criteria to determine the structural characteristics:

(1) Intensity and sharpness of the reflections.
(2) Number of reflections.
(3) Change in the basal spacing.
(4) Resolution between closely spaced reflections.
(5) Absence of certain reflections.
(6) Intensity of the background.

As shown in Fig. 1 and Table 1, the original sample of Mesa Alta kaolinite has the structural characteristics with the highest degree of crystallinity, since the $11\bar{1}$ and $1\bar{1}\bar{1}$ reflections are resolved each other and the $11\bar{2}$, $1\bar{1}\bar{2}$ and 022 reflections are present[5].

Important features of the initial stage of grinding are a decrease in the intensity of 00*l* reflections; however, the breadth of 00*l* reflections are considerably sharper than that of original kaolinite. In the 48-hour-ground specimen, it is found that the intensity of $02\bar{1}$ and 021 reflections decrease and $11\bar{2}$, $1\bar{1}\bar{2}$ and 022 reflections disappear, and that $11\bar{1}$ and $1\bar{1}\bar{1}$ reflections are nearly consistent. These facts show that the grinding causes some displacement of layers parallel with the *b*-axis in the structure of kaolinite. In the 96-hour-ground specimen, all reflections broaden, and the reflections of $1\bar{1}0$, $11\bar{1}$, $02\bar{1}$ and 021 disappear. These facts suggest that the crystalline part of the specimen has a pseudemonoclinic in symmetry similar to that of kaolin mineral of fireclay type, which indicates the displacement of layers by $nb_0/3$ along the *b*-axis[6]. After grinding for 168 hours, the structure of this specimen has the lowest degree of crystallinity among the kaolin minerals with the exception of halloysite which has a two-dimensional structure. That is, the assymmetric 02, 11 band and the broad band similar to that of 20, 13 band on the X-ray diagram of halloysite are observable. These facts mean that the structure of this specimen has a displacement of layers along the *a*-axis in addition to the displacement along the *b*-axis. In other words, it suggests that the two-dimensional kaolinite is formed by dry grinding. As shown in Fig. 1, after 312 hours, only two very broad bands are apparent.

With the grinding progresses, the background increases as the intensity of the reflections weaken. These facts lead to a non-crystalline substance is produced by

dry grinding. To ascertain this fact, the following treatment was made. That is, the 168-hour-ground specimen of Mesa Alta kaolinite was treated with a weak alkali solution. It forms a permutite-like substance. When it is immersed in a weak hydrochloric acid solution to dissolve the gel-like substance, the crystalline portion of the specimen is left. Fig. 1-D shows the X-ray diffractometer trace of the remaining crystalline portion; this diagram closely resembles that of halloysite. X-ray data and the following electron micrograph (Fig. 8-F) reveal that the structure of the kaolinite has changed into a two-dimensional structure.

In Drybranch kaolinite, as shown in Fig. 2 and Table II, it follows just the same process as Mesa Alta kaolinite in dry grinding. The difference is only that the structure of the original sample has a slightly lower degree of crystallinity than that of Mesa Alta kaolinite, so, the time it takes to become amorphous is somewhat shorter than that of Mesa Alta kaolinite.

Differential Thermal Analysis. — Differential thermal analysis curves and data of the grinding process of kaolinite are shown in Figs. 3 and 4 and Tables III and IV.

Measurements which were used are as follows:

(1) The peak temperature, height and area of the first endothermic reaction (E_{n1}) associated with the loss of the adsorbed water. The peak area was measured by planimeter from the base line of the thermal curve.

(2) The peak temperature, height and area of the second endothermic reaction (E_{n2}) associated with the loss of the lattice water.

(3) The peak temperature, height, area and breadth of the final exothermic reaction (E_x) corresponding to the mullite nucleation.

The endothermic reaction (E_{n1}) associated with the loss of adsorbed water, which is not present in the original sample, appears and its height and area increase; These phenomena mean that the substance produced by the dry grinding adsorbs more and more water vapor as grinding progresses. The peak temperature of this reaction gradually rises a little. This fact indicates that the water adsorbed by the ground substance is combined strongly as the grinding progresses.

In the second endothermic reaction (E_{n2}) associated with the loss of the lattice water, are observable a lowering in peak temperature, and a reduction in height and area. Finally this reaction disappears thoroughly. This corresponds with the gradual and complete disintegration of the kaolinite structure due to grinding. In the 96-hour-ground specimen of kaolinite, the X-ray diagram is similar to that of Kibushi-clay, but the height of this reaction is very small as compared with that of Kibushi-clay which is a kaolin mineral of fireclay type. This fact corresponds to the increase of the background of this specimen in its X-ray diagram, that is, a considerable amount of non-crystalline substance is produced by dry grinding.

In the exothermic reaction (E_x), there are some interesting phenomena. The peak temperature falls very slightly. But after 312 hour grinding the peak temperature lowers remarkably although the peak area is relatively unchanged. Except for the 312-hour-ground specimen on which grinding had progressed to an extreme degree, the peak height increases while the breadth decreases. As shown in the X-ray results, the perfectly ordered structure of kaolinite changes to a disordered structure as the grinding progresses. It is well known that the temperature range of the exothermic reaction (E_x) of kaolin with a higher degree of crystallinity is narrower than that of kaolin with a lower degree of crystallinity[7].

It is, therefore, difficult to draw a conclusion on the basis of the most important character of the exothermic reaction. Incidentally, it is known that the exothermic reaction corresponds to the transformation of kaolinite into mullite[8]. This transformation includes two elements of reaction, that is, nucleation of mullite and growth of mullite nuclei. Consequently, it is clear that kaolinite becomes liable to grow into mullite crystal from mullite nuclei produced by dry grinding.

To ascertain the character of the exothermic reaction of the ground specimen, the X-ray diffractometer traces of ground specimens obtained just after the exothermic reaction on the differential thermal analysis curves are recorded, which are given in Fig. 5.

As the grinding progresses, the presence of the reflection line of mullite becomes clear. That is to say, development of the

mullite reflection corresponds to the increasing height of the exothermic peak as grinding progresses.

The features of the exothermic reaction of kaolinite are different from that of halloysite with a lower degree of crystallinity. Results of halloysite are reported in the following part III. From the comparison with the result of the grinding effects of halloysite, it is concluded that a non-crystalline substance produced by dry grinding of kaolinite, even in the 312-hour-ground specimen of Mesa Alta kaolinite or the 384-hour-ground specimen of Drybranch kaolinite, is an allophanic substance rather than the perfectly amorphous substance similar to the silica-alumina mixed gel.

Base Exchange Capacity and Density.— In Fig. 6 are shown the changes in the base exchange capacity at various periods of grinding.

As grinding progresses, the base exchange capacity at first increases. After reaching a maximum value, it gradually decreases until it attains a constant value. These features on the base exchange capacity curve show that the broken bonds of kaolinite increase at first owing to the

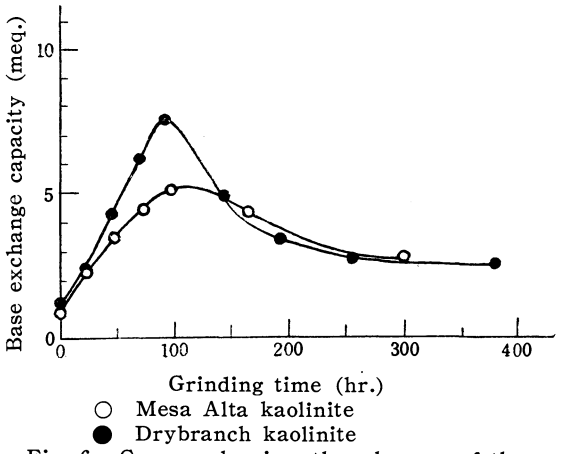

Fig. 6. Curves showing the changes of the base exchange capacity with the time of grinding.

cleavage and fracturing by dry grinding and that a non-crystalline substance gradually increases through dry grinding. These results support the thoughts of Laws and Page in the explanation of the increase on the base exchange capacity through dry grinding of kaolinite[1].

In Fig. 7 are shown the changes in the density at the various stages of grinding. As the grinding progresses, the density sharply decreases, but after reaching a certain point, it is maintained at a constant value. This constant value is nearly equal to the values of a silica-alumina-mixed gel or allophane which is a non-crystalline clay mineral. These facts show also that kaolinite changes to a non-crystalline or an amorphous substance by dry grinding.

The point of bend in the density curve and the maximum point in the base

exchange capacity curve are at nearly identical positions. In the light of the X-ray data, this stage seems to correspond to the point at which kaolinite changes into a zeolitic substance by dry grinding.

Electron Microscopic Studies. — Figs. 8 and 9 show electron micrographs of kaolinite after various periods of grinding. It is observable that, in the early stage of grinding, fine crystallites are produced by cleavage and fracturing of the kaolinite crystal. The fine crystallites reaggregate, and reaggregated particles become radial and the particle size increases, slowly changing into uniformly spherical particles. The specimen with a radial shape has a zeolitic structure and is made of both crystalline and non-crystalline portions. That is, in this specimen, the non-crystalline substance produced by dry grinding falls between the crystalline substance. The crystalline portion in the zeolitic substance is separated by the alkali and acid treatment from the original ground speimen. Fig. 8-F shows the electron micrograph of this crystalline portion. As is clear from these electron micrographs and X-ray data, the crystalline portion which makes a zeolitic substance has a considerably lower degree of crystallinity than that of the original kaolinite. As was presumed from the results of Kibushi-clay and halloysite to be described in the following parts, it seems that these radial particles grow irregularly as the grinding further progresses.

If the mean sizes of the fine particles which are produced through dry grinding and those of the particles which are produced through the reaggregation of such fine particles are plotted against the grinding time, the results are as shown in Fig. 10.

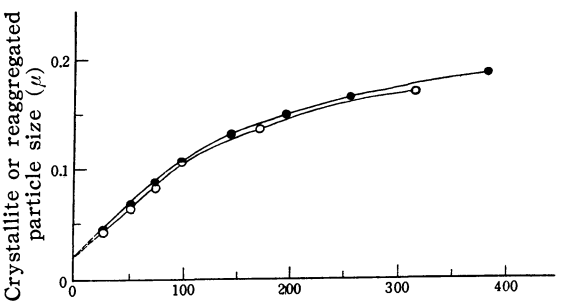

Fig. 10. Crystallite or reaggregated particle size of ground kaolinite plotted against the time of grinding.

The curve, if extrapolated to zero time, indicates almost the same value of about 200 Å for both kaolinites. Judging from this, it seems that the crystallites which separate from the original crystal during the early stage of grinding are about 200 Å in size. This value is consistent with the value in the "most dispersed state" of kaolinite in ball-milling obtained by Gregg et al., through the B. E. T. method[1].

Mechanism of Change in Kaolinite Structure with Dry Grinding. — When kaolinite is ground, kaolinite crystals cleave and fracture and then split into fine crystals that are considered unit crystallites. Such fine crystallites promptly reaggregate in groups of several. The assemblages of the original kaolinite crystallites produced through dry grinding disintegrate partially into allophane or gel-like substances. These substances and crystalline particles promptly reaggregate.

With grinding, the structure of the crystalline part of the reaggregated particle slowly becomes disordered kaolin and as an increase in the amorphous part, the reaggregated particles of the disordered kaolin and the amorphous substance become radial.

At a certain point in the grinding time corresponding to the maximum point on the base exchange capacity curve and the inflection point on the density curve, the particle becomes almost uniformly spherical. The structure of this spherical particle is considered to be zeolitic. This structure, with continued grinding, changes finally into a structure similar to the perfectly amorphous structure as silica-alumina mixed gel and its particle size increases irregularly.

The process of the structural change by dry grinding is the same in both Mesa Alta kaolinite and Drybranch kaolinite, except that the structural change of Drybranch kaolinite occurs slightly faster than that of Mesa Alta kaolinite. This means that the grinding effect on kaolinite is related to the structural perfectness of the original kaolinite. This fact has been ascertained by the study of the dry grinding effect of all kaolin minerals.

Summary

The effects of several-hundred-hour mechanical-mortar dry grinding of kaolinite were studied by X-ray, thermal,

electron microscopic and other methods. It has been found that there are two sorts of structural change in the process of dry grinding of kaolinite. One is the production of a non-crystalline substance attended by the disordering of the crystalline part, and the other is the reaggregation process. The process of the reduction in the particle size and the process of the production of the non-crystalline substance are connected to the process of the reaggregation. In a certain stage of the dry grinding, the reaggregates are spherical particles which have a zeolitic structure. As the grinding further progresses, the structure of the crystalline part in this radial particle becomes disordered due to the mechanical stress, and it changes into an amorphous substance at last. Consequently, the effect of dry grinding of kaolin mineral depends on the structural perfectness of aluminosilicate layers of the kaolin mineral, that is, the internal crystallinity of the kaolin mineral.

Effects of Dry Grinding on Kaolin Minerals. II. Kibushi-clay

By Hiroshi TAKAHASHI

(Received September 29, 1958)

In the preceding part of this series, the effect of dry grinding of kaolinite was discussed.[1] From these results, it was ascertained that the dry grinding by a mechanical-mortar is more effective than that by ball-milling in its structural change, and the mechanism of the process of dry grinding of kaolinite was found. There are two sorts of change in structure. That is, one is the production of a non-crystalline substance resulting from the disordering of a crystalline part. The other is the process of reaggregation. In a certain stage of grinding, a zeolitic structure is formed and it changes finally into an amorphous structure.

A considerable amount of work was done on the grinding effect of kaolinite, but the grinding effects of kaolin minerals with the exception of kaolinite were not studied much. The disordering of kaolinite in the process of dry grinding follows each of the structural variations as reported by Brindley and Robinson[2]. From these facts, the effects of dry grinding of fireclay type kaolin mineral were studied with respect to the degree of crystallinity of the original structure.

Experimental

The sample used in this study is Kibushi-clay from Shidare, Gifu, Japan. This clay is a kaolin mineral of fireclay type and contains a little organic substance[2,3]. The structural characteristics of this clay were discussed in the previous paper[4]. The grinding conditions were the same as those of kaolinite described in the preceding part. The experimental specimens were examined by X-ray diffraction, differential thermal, electron microscopic and other methods. All experimental conditions were the same as those of kaolinite.

Results and Discussion

X-Ray Diffraction Studies.—X-ray diffractometer traces in the process of dry grinding of Kibushi-clay are shown in Fig. 1, and X-ray powder data observed from the X-ray traces are given in Table I. As shown in the X-ray diagram of the original sample, the structure of Kibushi-clay is similar to that of fireclay. That is, in the X-ray diagram, 020 and $1\bar{1}0$ reflections are not resolved to each other and become a wedge-like band, 001 reflection is considerably broad and weak, $13\bar{1}, 1\bar{1}2$ reflections are weak and $20\bar{1}, 130$ reflections are broad.

When Kibushi-clay is ground, its structure gradually becomes more and more disordered. That is, the background increases as the intensity of the reflection weakens. In the X-ray diagrams of the ground specimens during the early stage of grinding, a lowering in the intensity of 001 reflections is remarkable, and the 131, 112, 200 reflections are very indistinct in the ground specimen after 72 hours.

In the X-ray diagrams of the ground specimens after 96 hours, only 02, 11 and 20, 13 bands are observable. When the 144-hour-ground specimen which has an amorphous structure is treated with a weak alkaline solution, it changes into a permutite-like substance. In the next place, it is treated with a weak acid solution to dissolve the amorphous substance produced by dry grinding. The X-ray diagram of the residual part produced by the above treatments is shown in Fig. 1-b-B

and its electron micrograph is shown in Fig. 6-F. The above-mentioned alkali-acid treatment was done for the 192-hour-ground specimen, too. The X-ray diagram of the residual part is shown in Fig. 1-b-D. As shown in this trace, the X-ray diagram is closely similar to that of the silica gel. This fact indicates that the crystalline part is absent in this specimen and it has changed into a gel-like substance. The specimen of Kibushi-clay ground after this stage gives a perfectly amorphous pattern in its X-ray diagram. The above-mentioned alkali-acid treatment of this specimen leaves only the impurities such as quartz.

When the result of X-ray study in Kibushi-clay is compared with that of kaolinite, it is clear that Kibushi-clay takes to become amorphous in far shorter than grinding time the case of kaolinite. On the basis of the X-ray data in the various stages of grinding of Kibushi-clay, it can be concluded that the effects of dry grinding of kaolinite and Kibushi-clay depend on the perfectness of kaolin unit layer, that is, the internal degree of crystallinity.

Differential Thermal Analysis.—Differential thermal analysis curves and data of ground specimens of Kibushi-clay are shown in Fig. 2 and Table II.

The tendency observed from the differential thermal analysis curves are similar to those in the kaolin specimens, but the only difference observable is that all of them have a broad exothermic reaction at about 600°C caused by the presence of some organic substances.

The first endothermic reaction (E_{n1}) associated with the loss of adsorbed or inter-layer water, which is not so remarkable in the original sample, becomes apparent and its height and area grow as the grinding progresses. These phenomena mean that the substance produced by the grinding adsorbs water vapor and its quantity increases with grinding. The peak temperature of this reaction rises slightly. This fact suggests that the substance produced by the grinding adsorbs more and more strongly the water vapor as the grinding progresses.

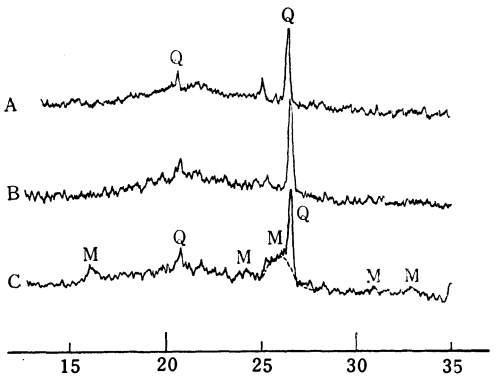
384	—180—	10	1780	—	—	—	960	15	200	14.0



are observable. Finally, this reaction disappears completely. This leads to the disintegration of kaolin structure while it is being ground for long periods.

The final exothermic reaction (E_x) which corresponds to the mullite nucleation, is somewhat different from that of kaolinite. The peak temperature tends to fall, though very slightly, up to 192 hours of grinding. Except for the 384-hour-ground specimen, the peak height and area of the other specimens increase and the peak breadth is reduced. For the 240-hour-ground specimen, the peak temperature is almost the same as that of the 192-hour-ground specimen but the breadth is broader. In the 384-hour-ground specimen, the peak temperature rises above that of all other ground specimens, and the height and the area are smaller than those of the 192-hour-ground or the 240-hour-ground specimens. These facts mean that the structure of a non-crystalline substance produced by dry grinding changes into a more disordered structure as the grinding progresses. In the early stage of grinding, the strcture of a non-crystalline substance becomes to some extent a regular structure which is related to the original kaolin structure, but the structure of the 384-hour-ground specimen is not regular, it is an entirely disordered gel-like substance. From these facts, it might be seen that the temperature for the transformation of kaolin into mullite is high.

As shown in Figs. 2-D and -E, the slight endothermic reaction is observable just before the exothermic reaction. It has been known that the presence of this slight endothermic reaction is observable on the thermal curve of kaolin mineral with the highest degree of crystallinity[6]. The 192-hour-ground specimen of Kibushi-clay has a non-crystalline structure according to the X-ray and other data. Why does this slight exothermic reaction exist in this specimen? It is difficult to draw a conclusion as yet. But it is supposed that this fact is related to the considerable sharpness of the peak of the exothermic reaction and its remarkable height. There are two interpretations of this fact. One is that the way of transformation of kaolin into mullite is different from that of the original sample, and the other is that the tranformation of kaolin into mullite becomes more liable to grow than in the case of the original sample.

5) H. H. Murray, *Am. Mineal.*, **39**, 27 (1954).

To ascertain the character of the final exothermic reaction, X-ray diagrams were taken of some specimens after the exothermic reaction on the differential thermal analysis curve. Their traces are shown in Fig. 3.

B, ground 96 hours
C, ground 192 hours

In this case, too, it is indicated that as the grinding progresses, the reflection line of mullite crystal becomes clear. The final exothermic reaction has two elements, that is, the nucleation of mullite from the original kaolin mineral and the growth of mullite crystal from the mullite nuclei.

This is true because the presence of this weak endothermic reaction in the kaolin mineral with the highest degree of crystallinity corresponds to the nucleation of mullite. In the case of this ground specimen, it is clear that the nucleation of mullite from the kaolin mineral is easy, but the crystal growth of mullite nuclei is hard. But in the case of the ground specimen such as the 192-hour-ground Kibushi-clay, the presence of its endothermic reaction corresponds to the crystal growth of mullite nuclei. That is in the 192-hour-ground specimen or the 384-hour-ground specimen of Kibushi-clay, though the nucleation of mullite from the kaolin mineral is hard, the crystal growth of mullite nuclei is easy. Consequently, in the specimen of Kibushi-clay which is ground for a long period, the temperature of the transformation into mullite rises, because the nucleation of mullite is hard.

But, as the crystal growth of mullite nuclei is easy and rapid, the reflection of mullite is distinctly detected in its X-ray diagram, and so the height of the exothermic peak increases.

Base Exchange Capacity and Density.— In Fig. 4 are shown the changes of the base exchange capacity with the grinding time. Measurements were made on the dried specimens.

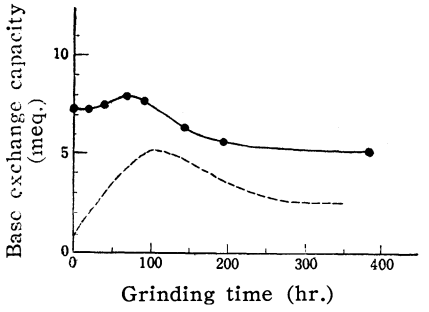

Fig. 4. Curve showing the change of base exchange capacity with the time of grinding.
------: The change in the grinding process of Mesa Alta kaolinite.

In this figure, the change in the grinding process of Mesa Alta kaolinite is drawn for reference.

The features obtained from the curve of base exchange capacity are slightly different from those of kaolinite. The maximum point is observable on the base exchange capacity curve of the grinding process of kaolinite, but it is not distinct on this curve. As shown in the micrograph of the original clay to be noted in the following section, the particle size of the original Kibushi-clay is very fine as compared with that of other kaolin minerals. Therefore, the fracturing into crystallites from the original crystal during the early stage of grinding is not so remarkable as that of kaolinite. In this clay, an increase in the broken bond which results in an increase of the capacity is not remarkable. As the result, it seems that the maximum point on the base exchange capacity curve is unobservable. In this case, the change of the base exchange capacity depends mainly on the production of a non-crystalline substance by dry grinding. This tendency also supports the thought shown by Laws and Page in the explanation for the change of the base exchange capacity due to dry grinding[6].

6) W. D. Laws and J. B. Page, *Soil Sci.*, **62**, 319 (1946).

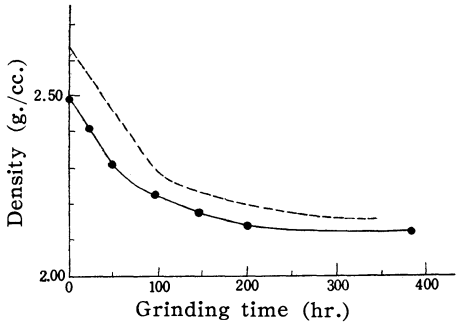

Fig. 5. Curve showing the change of density with the time of grinding.
------: The change in the grinding process of Mesa Alta kaolinite.

In Fig. 5 are shown the changes of the density with the grinding time. Measurements were made on the dried specimens.

In this figure, the change of density in the process of grinding of Mesa Alta kaolinite is drawn for reference. As the original sample of Kibushi-clay contains only a little organic substance, its density value is small.

As the grinding progresses, the density sharply decreases, but after reaching a certain point, it is maintained at a constant value. This constant value is nearly equal to the value of a silica-alumina mixed gel or allophane. These facts mean that Kibushi-clay changes into a non-crystalline substance by dry grinding.

Electron Microscopic Studies. — Fig. 6 shows the electron micrographs in the various periods of grinding of Kibushi-clay. The original clay is very fine and hexagonal platty, and the particle has a considerably sharp edge. In the early stage of grinding, fine crystallites separated from the original crystal are observable. These fine crystallites are nearly hexagonal and platty. As the grinding progresses, the fine crystallites promptly reaggregate, and reaggregated particles become spherical and the particle size increases gradually. As the grinding further progresses, the irregular growth of particles is observable. On the basis of the results obtained through the X-ray and other methods, it is understood that this irregular growth of reaggregated particles indicates that an amorphous substance is produced by dry grinding. The same thing is also found in halloysite as shown latter.

If the mean sizes of the fine particles which are produced through dry grinding and the particles which are produced by

the reaggregation of such particles are plotted against the grinding time, the results are as shown in Fig. 7.

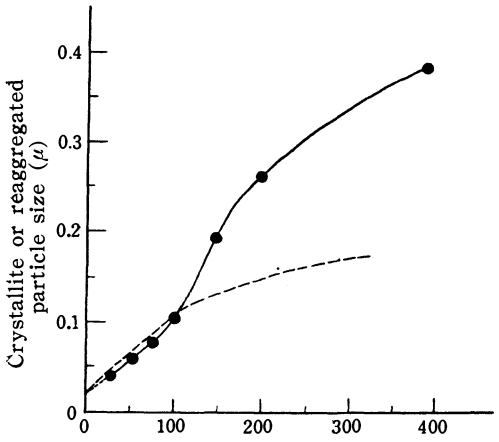

Fig. 7. Crystallite or reaggregated particle size of ground Kibushi-clay plotted against the time of grinding.
------: The change in the grinding process of Mesa Alta kaolinite.

In this figure, the curve showing the change of the crystallite or reaggregated particle with the grinding time in Alta kaolinite is drawn for reference. The curve, if extrapolated to zero time, indicates the value of about 200 Å. This value is the same as that in the case of kaolinite. As in kaolinite, in Kibushi-clay, too, the crystallites produced in the early stage of grinding seem to have about 200 Å in size. It is supposed that the time when the irregular growth begins is related to the degree of crystallinity of the original sample. This tendency is found also in halloysite. That is, the lower the crystallinity, the faster the irregular growth.

Summary

The effects of several-hundred-hour mechanical-mortar dry grinding of Kibushi-clay which is a kaolin mineral of fireclay type were studied by X-ray diffraction, thermal, electron microscopic and other methods and compared with those of kaolinite. It has been found that the process of a production of a non-crystalline substance attended with a disordering of a crystalline part and the process of a reaggregation are present in the dry grinding of Kibushi-clay as in kaolinite. Finally, Kibushi-clay changes into an amorphous substance as the result of dry grinding. In a certain stage of grinding, a zeolitic structure is formed. As the grinding progresses, the particle size increases owing to reaggregation. When an amorphous substance like silica-alumina mixed gel is produced, the particle size grows irregularly. In Kibushi-clay, the time it takes to become amorphous by dry grinding is shorter than in the case of kaolinite. Consequently, the effects of dry grinding of kaolinite and kaolin mineral of fireclay type depend on the structural perfection of unit layers of the original kaolin minerals.

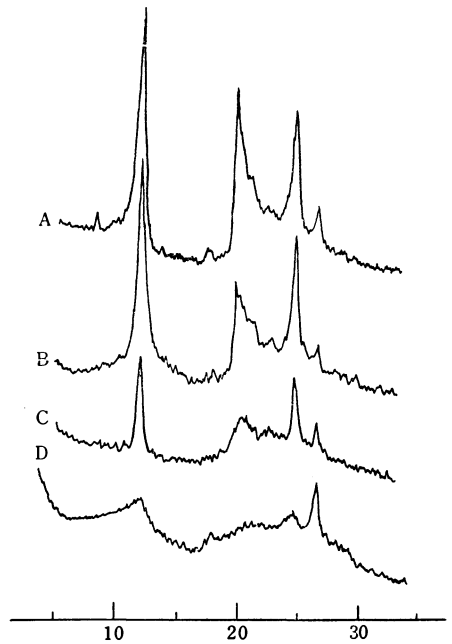
Effects of Dry Grinding on Kaolin Minerals. III. Halloysite

By Hiroshi TAKAHASHI

(Received September 29, 1958)

In the preceding parts of this series, the effects of dry grinding of kaolinite and Kibushi-clay have been studied[1]. From the results, a common mechanism in the structural change of kaolinite and Kibushi-clay by dry grinding was presented. That is, in the process of dry grinding, the separation into unit crystallites from the original crystal, the reaggregation of crystallites, the production of a non-crystalline material, the disordering of the crystallites, the reaggregation of crystallites and a non-crystalline material, the formation of a zeolitic structure in a certain period of grinding and the change into an amorphous substance such as silica-alumina mixed gel are observable. The effects of grinding of halloysite have been little studied so far. In this paper, the effects of dry grinding of halloysite are studied with respect to the degree of crystallinity of kaolin minerals with various degrees of crystallinity.



Experimental

The following samples were used in this study: Halloyste from Spruce Pine, N. C., U. S. A.; Halloysite from Bedford, Ind., U. S. A.; Halloysite from Tintic, Utah, U. S. A. These samples are the API Standard Clay Minerals and their structural characteristics are discussed in the previous paper[2]. As shown in the paper, it is considered that the structural differences among varieties halloysite chiefly depend on the internal variations rather than their stacking variation. Of halloysite, Spruce Pine halloysite has the highest degree of crystallinity. This was ascertained by the electron diffraction method[3]. Bedford halloysite has a lower degree of crystallinity than Spruce Pine halloysite. Tintic hallosite has the lowest degree of crystallinity of all the kinds of halloysite used in this study. Both Bedford and Tintic halloysite are partially hydrated halloysites.

The grinding conditions were the same as for kaolinite described in part I of this series. Experimental specimens were examined by X-ray diffraction, thermal, electron microscopic and other methods. The experimental conditions were the same as for kaolinite. The base exchange capacity and the density in various stages of dry grinding were measured after the specimens had been dried at 110°C in order to avoid the effect of the inter-layer or adsorbed water.

Results and Discussion

X-Ray Diffraction Studies.—X-ray diffractometer traces in the processes of grinding of halloysite are shown in Fig. 1. Figs. 1-a, -b and -c show the X-ray diffractometer traces of Spruce Pine halloysite, Bedford halloysite and Tintic halloysite, respectively. In Tables I-a, -b and -c, the interplanar spacing and the relative intensity measured from their X-ray diagrams are given.

When halloysite is ground, it gradually assumes a more and more disordered structure; that is, the background increases as the intensity of the reflection weakens. In the X-ray diagrams of the original samples of Bedford and Tintic halloysite which are partially hydrated halloysites, the reflection of about 10 Å spacing is present in both original samples. It is known that this reflection indicates the presence of a hydrated halloysite in these samples. This reflection is observable even in the 96-hour-ground specimen of Tintic halloysite and the 144-hour-ground specimen of Bedford halloysite. This fact indicates that the loss of the inter-layer water due to the heat caused by dry grinding does not occur in these specimens. This leads to the theory that the dry grinding does not produce so much local heat. The intensity of all the reflections apparent in the X-ray diagrams decreases as the grinding progresses. The manner of the disappearance of the reflections depends on the degree of crystallinity of original halloysite samples. In the X-ray diagram of the 144-hour-ground specimen of Tintic halloysite which has the lowest degree of crystallinity in the original state, 02,11 bands are not distinct and very diffuse. Whereas, in the X-ray diagram of the 144-hour-ground specimen of Bedford halloysite, the reflection is considerably distinct though its intensity lowers. As the grinding progresses further, the X-ray diagram of this specimen comes to correspond to the amorphous pattern. In Spruce Pine halloysite, which has the highest degree of crystallinity of all the kinds of halloysite, all reflections in the X-ray diagram are considerably distinct even with a 192-hour-ground specimen.

In the early stage of grinding of all halloysite, the lines of basal reflections become sharp as compared with those of the original samples. This tendency is observable also in the case of kaolinite. The structure of halloysite is pseudo-hexagonal in symmetry, and is nearly two-dimensional[4]. The structure of halloysite is not precisely two-dimensional; however, if it is supposed that the theory of the reflection of the two-dimensional lattice is applicable to the structure of halloysite, the crystallite dimension in the process of grinding can be calculated from the breadths of reflection lines[5]. It is

known that the breadth of a reflection line is determined by two factors, that is, the particle size and the distortion of lattice. These factors must be separated for the precise measurement of crystallite dimension[6]. However, the broadening of the line breadth is due to a reduction in crystallite size or a remarkable distortion of lattice. These two elements which correspond to the broadening in the line breadth are related to a lowering in the degree of crystallinity. Therefore, the crystallite dimensions obtained from the line breadth seem to be terms which re-

6) C. R. Houska and B. E. Warren, *J. Appl. Phys.*, **25**, 1503 (1954).

present the relative degree of crystallinity of the specimens rather than the real crystallite sizes. To calculate the crystallite dimension from the line breadth, Bragg's equation was used for the dimension along the c-axis (L_c) from 001 reflection[7], and Warren's equation was used for the dimension of the broadening, parallel to the layer plane of crystallite (L_a) from 02,11 band[5]. Fig. 2 shows the changes of the crystallite dimensions with the grinding time.

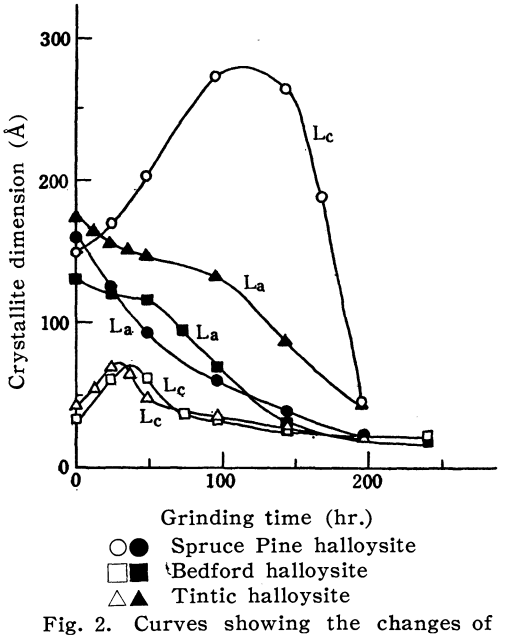

Fig. 2. Curves showing the changes of crystallite dimensions with the time of grinding.

From the curve shown in this figure, it is observable that the breadth of the basal reflection becomes sharper in the early stage of grinding. Of these curves, some features are observable; that is, the maximum point on L_c-dimension curve of Spruce Pine halloysite with the highest degree of crystallinity is apparent when ground for a considerably long time. For the crystallite dimension of Spruce Pine halloysite along a-axis (L_a), it decreases quickly with the grinding, whereas, it does not change in Bedford halloysite and Tintic halloysite up to some extent of grinding. When the grinding passes this stage, the L_a-dimensions of Bedford halloysite and Tintic halloysite decrease as that of Spruce Pine halloysite does. This fact means that Bedford halloysite and Tintic halloysite are more resistant to dry grinding than Spruce Pine halloysite, presumably because of the lubricating action of the water layers between the kaolin layers. This resistant action of the interlayer water is also found in vermiculite[8]. The quick decrease in the L_a-dimension is correlated to the fracturing of the kaolin layer.

The increase of the background in the X-ray diagram of halloysite is similar to those of kaolinite or Kibushi-clay, and is correlated to the production of a non-crystalline material. It is considered that the structure of non-crystalline materials produced by dry grinding of halloysite with lower crystallinity is considerably disordered and is similar to a gel-like structure.

For some ground specimens, the alkali-acid treatment noted in the case of kaolinite was made to ascertain the disordering of the crystallite. Throughout all these specimens, the same tendency is observable as that of kaolinite. The 240-

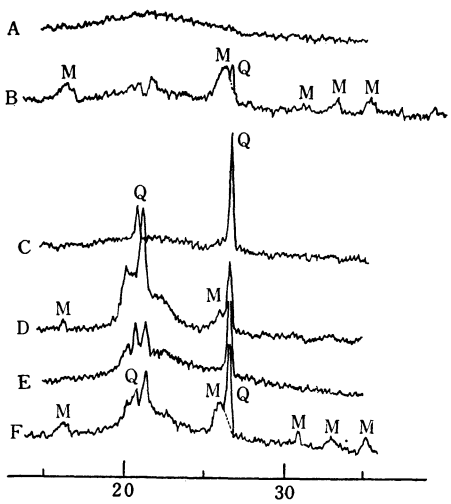
hour-ground specimen of Tintic halloysite which has an amorphous pattern in its X-ray diagram dissolved completely through the alkali-acid treatment and leaves only the impurities such as quartz, felspars and others. When the X-ray diagram of the ground specimen of halloysite is compared with those of kaolinite and Kibushi-clay, it is clear that the dry grinding is not so effective on kaolinite and Spruce Pine halloysite in the structural change, but is most effective on Kibushi-clay and Tintic halloysite. From the X-ray data, it is concluded that the effects of dry grinding of kaolin minerals in the structural change depend on the perfectness of kaolin unit layers, that is, the internal degree of crystallinity.



Differential Thermal Analysis. — Differential thermal analysis curves and data of the grinding process of halloysite are shown in Fig. 3 and Table II.

The first endothermic reaction (E_{n1}) associated with the loss of the inter-layer or adsorbed water, is not present in the original sample of Spruce Pine halloysite, but is present in the original samples of Bedford and Tintic halloysite. It is natural that this reaction is apparent in the original sample of Bedford and Tintic halloysite, because they are partially hydrated halloysite. As the grinding progresses, this reaction appears and its height and area increase. These facts mean that the substance produced by dry grinding adsorbs water vapor and its quantity increases as the grinding progresses. The peak temperature of this reaction gradually rises. This leads to the water adsorbed by the ground substance being combined more strongly as the grinding progresses. In the original sample of Bedford halloysite, a weak endothermic reaction is apparent at about 300°C, probably due to the presence of gibbsite as impurity. This reaction is wholy apparent in the process of grinding. The rates of change in the first endothermic reaction are the same as those in the cases of Spruce Pine and Bedford halloysite. But, in the grinding process of Tintic halloysite, this reaction is slightly different from those of Bedford and Spruce Pine halloysite. On the differential thermal analysis curves of the ground specimens of Tintic halloysite after 48 hours of grinding, the second maximum is apparent in this reaction, and the height and area increase, and the peak temperature gradually rises. In the 240-hour-ground specimen of Tintic halloysite, this reaction increases more, and the second maximum becomes indistinct.

In the second endothermic reaction (E_{n2}) associated with the loss of the lattice water, it is observable that the features of this reaction are similar to those of kaolinite. That is, a lowering in the peak temperature, and a reduction in the peak height and area are observable. When the grinding progresses for a long time, in such specimens as the 144-hour-ground specimen of Tintic halloysite, the 162-hour-ground specimen of Bedford halloysite and the 192-hour-ground specimen of Spruce Pine halloysite, this reaction is unobservable. This fact indicates that the kaolin structure finally disintegrates due to dry grinding. The grinding time in which this reaction disappears is shorter as the crystallinity of the original sample is lower.

In the exothermic reaction (E_n) are found some interesting phenomena. The exothermic reactions of ground specimens of Bedford halloysite and Spruce Pine halloysite are similar to that of kaolinite. The peak temperatures tend to fall very slightly, and in the specimens ground for a long period, the peak temperature falls

remarkably. Except for the 312-hour-ground specimen of Bedford halloysite, the peak height and area of the exothermic reaction increase and the breadth of peak decreases. The exothermic reaction behaves the same as in the case of kaolinite. But, the exothermic reaction of Tintic halloysite behaves very differently from that of kaolinite and the other halloysite. At first the peak temperature tends to be somewhat low, but as the grinding progresses, the temperature rises rapidly. The peak height increases at first, but soon reduces remarkably. The peak height, as the temperature becomes higher, increases again. The peak breadth also becomes narrower at first, but soon increases and then decreases again. To determine whether there is a difference between their exothermic reactions, X-ray diagrams were taken of several specimens just before and after the exothermic reactions on the differential thermal analysis curve. These traces are shown in Fig. 4. It is indicated that as the grinding progresses, the growth of mullite crystal becomes remarkable, but the presence of mullite is unobservable just before the exothermic reaction.

This tendency was also found in the process of grinding of kaolinite. From this fact, it is certain that the exothermic reaction is attributed to the mullite nucleation in halloysite[9]. It is difficult to draw a conclusion from the character of the exothermic reaction as to the grinding effects of halloysite used in the experiment, but it may be interpreted as follows. When the crystallinity of the halloysite is at a considerably low stage, the non-crystalline material produced by dry grinding has a completely amorphous structure, whereas, when the halloysite with a higher degree of crystallinity is ground, the non-crystalline substance produced by grinding has a structure which is somewhat related to that of the original halloysite; that is, it is not a perfectly amorphous substance. This substance is hard to change into a perfectly amorphous substance. The tranformation of kaolin mineral into mullite is closely related to the original structure. In the case of Tintic halloysite, however, the original structure completely disintegrates by dry grinding. The transformation to mullite from kaolin mineral requires much more energy than that of kaolinite, Spruce Pine halloysite and Bedford halloysite. It is considered that the reaction produces a higher temperature. In kaolinite, Spruce Pine and Bedford halloysite, the non-crystalline substance produced by dry grinding may be an allophanic substance rather than gel-like. In all ground specimens of halloysite, the weak endothermic reaction immediately before the exothermic reaction becomes distinct as the grinding progresses. This fact was also found in kaolinite and Kibushi-clay as discussed above. In the transformation of kaolin into mullite, there are two steps of the structural change. The first step is the nucleation of mullite, and the second step is the crystal growth of mullite nuclei. The dry grinding accelerates the reaction of the second step, that is, the crystal growth of mullite nuclei.

Base Exchange Capacity and Density.— In Fig. 5 are shown the changes of the

base exchange capacity with the grinding time.

As the grinding progresses, the base exchange capacity at first increases. After reaching a maximum value, it gradually decreases until it attains the constant value. The maximum value and the constant value vary according to the order of the original sample. The lower the crystallinity of the original sample, the shorter the time in which the base exchange capacity attains its maximum point. The rates of change of base exchange capacity against the grinding time are similar to those of kaolinite. As in kaolinite, these results also support the thought of Laws and Page for the explanation of the change on the base exchange capacity through dry grinding[10].

In Fig. 6 are shown the changes of the density with the grinding time.

As the grinding progresses, the density sharply decreases, but after reaching a certain point, it slowly attains a constant value. This constant value is nearly equal to the value of a silica-alumina mixed gel or allophane. These facts mean that halloysite changes into a non-crystalline substance by dry grinding.

The point of the bend in the density curve and the maximum point in the base exchange curve are at nearly identical positions. This phenomenon was also seen in kaolinite. This stage seems to correspond to the point at which the kaolin structure changes to zeolitic.

Electron Microscopic Studies.—Electron micrographs of halloysite in the process of dry grinding are shown in Fig. 7. Figs. 7-a, -b and -c show those of Spruce Pine halloysite, Bedford halloysite and Tintic halloysite, respectively.

The particles of the original halloysite samples have a tubular shape. It is observable that in the early stage of dry grinding, fine crystallite is produced from the original crystal. The shapes of these crystallites are platty with a considerably sharp edge though the shape of the original halloysite is tabular. As the grinding progresses, the fine crystallites reaggregate, and raggregated particles become spherical and the particle size increases, and then the reaggregated particles slowly change into uniformly spherical particles. As the grinding progresses further, for example in the 240-hour-ground specimen of Tintic halloysite or in the 312-hour-ground specimen of Bedford halloysite,

the remarkable and irregular growth of particles is observable. In the light of X-ray and thermal data, the irregular growth of reaggregated particles corresponds to the fact that an amorphous substance is produced by dry grinding.

If the mean size of the fine particles which are produced through dry grinding and the particles which are produced by the reaggregation of such fine particles are plotted against the grinding time, the results are as shown in Fig. 8.

The curve, if extrapolated to time zero, indicates the value of about 200 Å in all kinds of halloysite, and this value is the same as that in the case of kaolinite. It seems that the crystallites which separate from the original crystal during the early stage of grinding are about 200 Å in size. As shown on these curves, the time in which the reaggregated particles begin to grow irregularly corresponds to the degree of crystallinity of the original samples. The irregular growth of the reaggregated particles is found also in Kibushi-clay. It is considered that the

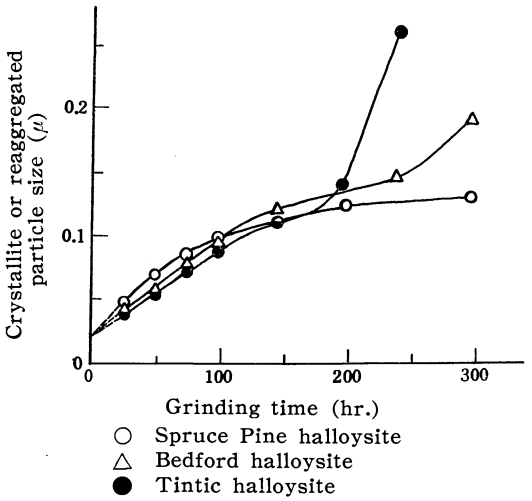

Fig. 8. Crystallite or reaggregated particle size of ground halloysite plotted against the time of grinding.

irregular growth of such particles indicates the change into a perfectly amorphous substance from a non-crystalline substance produced by dry grinding.

Mechanism of Change in Halloysite Structure due to Dry Grinding. — When halloysite is ground, halloysite crystals cleave and fracture and then split into fine crystals which are considered unit crystallites. These crystallites are very similar to those in case of kaolinite in shape and size. Groups of several such fine crystallites promptly reaggregate. The reaggregated crystallites change partially or thoroughly into a non-crystalline material. These non-crystalline substances reaggregate with the crystallites. As the grinding progresses, the crystalline part of the reaggregated particle decreases and the size of the reaggregated particle increases gradually. In a certain stage of grinding, a zeolitic structure is formed. The reaggregated particles which have a zeolitic structure become uniformly spherical. This period in grinding corresponds to the maximum point on the base exchange capacity curve and the inflection point on the density curve. The structure, with the progress of grinding, changes finally to the perfectly amorphous structure as silica-alumina mixed gel and the particle size grows irregularly.

The process of the structural change by dry grinding is the same as in the cases of all kinds of halloysite. The only difference is that Spruce Pine halloysite is less easily subject to the effect of the structural change than Tintic halloysite. This means that the effect of dry grinding of halloysite depends on the structural perfectness of the original halloysite. Generally, the effects of dry grinding on kaolin minerals are related to the internal degree of crystallinity of the original kaolin minerals.

Summary

The effects of several-hundred-hour mechanical-mortar dry grinding of halloysite were studied by X-ray diffraction, differential thermal, electron microscopic and other methods and they were compared with those of kaolinite and Kibushi-clay. It has been found that there are two sorts of structural change caused by dry gringing in halloysite as in the case of kaolinite. One is the production of a non-crystalline material attended with disordering of crystallites, and the other is the process of reaggregation. In a certain stage of grinding, the reaggregates come to have a zeolitic structure. This stage of grinding corresponds to the maximum point on the base exchange capacity curve and the inflection point on the density curve. The particle which has a zeolitic structure is uniformly spherical. As the grinding progresses further, halloysite changes into an amorphous substance, and the particle size increases irregularly. In consequence, it

was found that the effects of dry grinding on kaolin minerals depend strikingly on the structural perfectness of unit layers of the original kaolin minerals, that is, the internal degree of crystallinity.

The author wishes to express his hearty thanks to Professor H. Akamatu for his continuous advice and encouragement. Thanks are due to Professor T. Sudo of the Tokyo University of Education and Professor R. E. Grim of the University of Illinois for their valuable suggestions and discussions.

The Crystal Structure of trans-Dibromo-bisethylenediamine-cobalt(III) Bromide Hydrobromide Dihydrate

By Shun'ichiro Ooi, Yoshimichi Komiyama, Yoshihiko Saito and Hisao Kuroya

(Received September 13, 1958)

The crystal structure of the ethylenediamine-"praseo"-chloride, *trans*-$[Co\ en_2Cl_2]Cl\cdot HCl\cdot 2H_2O$, was determined before by Nakahara and two of us[1]. An attempt has been made now to investigate the crystal structure of the bromine-analogue, namely, the *trans*-dibromo-bisethylenediamine cobalt(III) bromide hydrobromide dihydrate, *trans*-$[Co\ en_2Br_2]Br\cdot HBr\cdot 2H_2O$. This compound has almost the same properties, physical and chemical, as the corresponding chlorine-complex, and, therefore, may be expected to be isotype with the latter. However, the analysis was carried out with caution in consideration of the fact that the configuration of the chloro-dinitro-triammine-cobalt(III), $[Co(NH_3)_3(NO_2)_2Cl]$, is quite different from that of the apparently analogous bromo-compound, $[Co(NH_3)_3(NO_2)_2Br]$[2),3)].

Experimental

The crystals are well-formed dark green tablets, showing predominant (100) faces. This habit is the same as that of $[Co\ en_2Cl_2]Cl\cdot HCl\cdot 2H_2O$. They are monoclinic and belong to the monoclinic holohedral class. Crystals show marked dichroism; in polarized light they appear blue when the electric vector is normal to the *b*-axis and yellowish green when this vector is parallel to the *b*-axis. From oscillation and Weissenberg photographs with Fe $K\alpha$ radiation ($\lambda=1.937$ Å) the unit cell dimension is found to be: $a=10.98$, $b=8.18$, $c=9.46$Å, $\beta=113.2°$. The space group determined from extinctions, is $P2_1/c-C_{2h}^5$.

The cell contains two formula units of $[Co\ en_2Br_2]Br\cdot HBr\cdot 2H_2O$ (density calculated 2.28 g.cm^{-3}; found 2.21 g.cm^{-3}) and cobalt atoms must therefore occur on centers of symmetry.

The intensities of reflections ($h0l$), ($hk0$) were estimated by comparison with a standard scale. The exposures were taken with Fe $K\alpha$ radiation, using multiple film technique. After correction for Lorentz and polarization factors, relative F values were obtained. No correction for absorption was made.

Determination of the Structure

The structure determination is based on the analysis of the ($hk0$) and ($h0l$) reflections, which could be carried out in a rather straightforward fashion. Because of the occurrence of the cobalt atoms at symmetry centers, the Patterson functions were simple and comparison of these results with those obtained for $[Co\ en_2Cl_2]Cl\cdot HCl\cdot 2H_2O$ revealed that both structures were isotype. Therefore, the Patterson function could be solved without difficulty, yielding an approximate position not only for bromine atoms but for most of the lighter atoms as well. The signs of all but weak reflections could be derived on the basis of the sets of parameters thus

deduced. Then the Fourier syntheses of the electron density projected along [001] and [010] were evaluated. In the *c*-axis projection almost every atom was resolved. But it was not the case in the *b*-axis projection. The outlines of the ethylenediamine ligands did not come out clearly, probably due to the diffraction effect of heavy bromine atoms. In order to improve the situation, the contribution of the cobalt and bromine atoms was subtracted from the observed structure factors and trial of computing the residual electron density projections along the *b*-axis was made. (The result is given in Fig. 3).

Fourier refinements were repeated as usual. Final projections shown in Fig. 1—Fig. 4 lead to the structure illustrated in Fig. 5 and Fig. 6. Parameter values are listed in Table I. The parameter of the oxygen atom is less reliable because of poor resolution of the projection. The parameters listed in Table I gave the reliability index $R=\sum||F_o|-|F_c||/\sum|F_c|$ of 0.133 and 0.130 for $(h0l)$ and $(hk0)$ respectively. Calculated and observed structure amplitudes are given in Table II. In the calculation of structure factors,

atomic scattering factors listed in the International Table were employed. Temperature correction of the form $\exp -B(\sin\theta/\lambda)^2$, where $B=0.9$ Å^2, was applied in the final calculation of the structure factors.

Discussion

The structure is isotype with [Co en$_2$ Cl$_2$] Cl·HCl·2H$_2$O. The principal points of stereochemical interest which emerge from this X-ray analysis are as follows.

(1) The structure is essentially ionic and consists of [Co en$_2$Br$_2$]$^+$, [H$_2$O···H···H$_2$O]$^+$ and Br$^-$. Since the structure is isotype with chloro-analogue, a similar consideration of the arrangement of bromine ions leads us to locate a proton midway between the two water molecules. The O···O distance is found to be 2.60 Å. The existence of the group [H$_2$O···H···H$_2$O]$^+$ was suggested by Huggins and this was indeed verified by our investigation on the structures of *trans*-dihalogeno-*iso*-ethylenediamine complexes[4].

4) M. L. Huggins, *J. Phys. Chem.*, **40**, 723 (1936).

(2) The interatomic distances are given in Table III. Co-Br distance is found to be 2.44 Å. This is 0.14 Å larger than the corresponding Co-Cl distance and the difference agrees with that in covalent bond radius of chlorine and bromine atom. Other distances agree well with those found in [Co en_2 Cl_2] Cl·HCl·$2H_2O$.

TABLE III
INTERATOMIC DISTANCES AND BOND ANGLES

Co—Br(1)	2.44 Å
Co—N(1)	2.00
Co—N(2)	2.01

Br(1A)···N(3B)	3.58
Br(2A)···N(3B)	3.46
Br(2)···N(4B)	3.58
Br(3)···N(4B)	3.37
Br(2)···O(2)	3.24
Br(3)···O(2)	3.26
O(1)···O(2)	2.60
N(1)—Co—N(2)	86.5°
Co—N(1)—C(1)	109.2°
Co—N(2)—C(2)	108.3°
N(1)—C(1)—C(2)	107.6°
N(2)—C(2)—C(1)	110.3°

(3) The dichroism of the crystal has been measured by Yamada et al. and their investigation revealed that the general features of the absorption curve are essentially the same as those obtained for [Co en_2 Cl_2] Cl·HCl·$2H_2O$[5]. This is quite feasible since both structures are isotype. The marked dichroism is reasonable since all the Br-Co-Br bonds are nearly parallel to the *c*-crystal axis.

Summary

The structure of *trans*-dibromo-bisethylenediamine cobalt(III) bromide hydrobromide dihydrate has been determined by X-ray analysis.

[Co en_2Br_2] Br·HBr·$2H_2O$ is monoclinic, $a=10.98$, $b=8.18$, $c=9.46$ Å, and $\beta=113.2°$, space group $P2_1/c$, two formula units in the cell. The structure consists of [Co en_2Br_2]$^+$, [H_2O···H···H_2O]$^+$ and Br^-, and is isotype with [Co en_2Cl_2] Cl·HCl·$2H_2O$. The complex ion has a center of symmetry. Two enantiomorphous ethylenediamine molecules, taking "*gauche*" configration, are coordinated to a cobalt atom. A cobalt atom is surrounded in a square coplanar configuration by four nitrogen atoms at distances 2.0 Å, and on a line approximately perpendicular to the plane of nitrogen atoms are two bromine atoms at distances 2.44 Å. The marked dichroism of the crystal is explainable in terms of the characteristic features in the arrangement of the complex ions in the crystal.

Part of the cost of this investigation was defrayed from the Fund for Scientific Research Expenditure of the Ministry of Education to which the authors' thanks are due.

*The Interaction between Dyes and Surfactants. I**

By Tamotsu KONDO and Kenjiro MEGURO

(Received July 7, 1958)

In previous works[1,2], we found the fact that the dye in aqueous solution is flocculated by adding a small amount of ionic surfactant, when the charge of surfactant is opposite to that of the dye.

We also found this flocculate** is dispersed again with further addition of surfactant. We call these phenomena "flocculation and deflocculation of dye by surfactant". To clarify the mechanism of these phenomena, we studied the interaction between anionic surfactants with

* Presented before the 11th Annual Meeting of the Chemical Society of Japan held in Tokyo, April, 1958.

** This flocculate is considered to be a stoichiometric complex salt formed between dye and surfactant. Details of its properties will be described in a later paper.

1) K. Meguro *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagakn Zasshi*), **77**, 72 (1956).

2) T. Kondo et al., ibid., **77**, 1240 (1956).

alkyl chains of different lengths and a cationic dye, and also between cationic surfactants having gegenions of different degrees of hydration and an anionic dye.

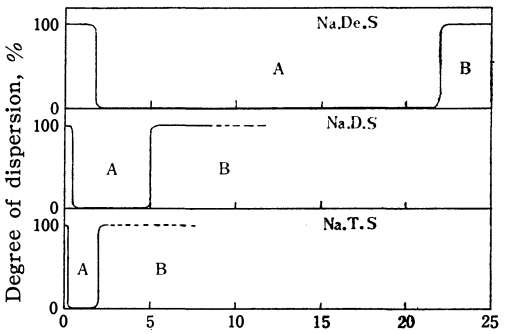
Experimental

Materials.—Rhodamine 6G and Eosine were used as cationic and anionic dyes respectively. Both were commercial samples and were purified by the method described previously[3].

The anionic surfactants employed were sodium decyl (Na. De. S.), dodecyl (Na. D. S.) and tetradecyl sulfates (Na. T. S.). These alkyl sulfates were prepared from the corresponding alcohols by sulfation. The details of the preparation and the purification of these compounds were described already[4].

Dodecylpyridonium chloride (D. Py. Cl.), bromide (D. Py. Br.) and iodide (D. Py. I.) were used as cationic surfactants. These dodecylpyridonium halides were prepared by refluxing the dodecyl halides with pyridine for several hours. The salts were purified by recrystallization from acetone and by extraction with petroleum ether.

Procedure.—As described above, when the surfactant ion has a charge opposite to that of the dye ion, the ionic dye in solution is flocculated by adding surfactant solutions of low concentration. It was also mentioned that the flocculate disperses again in a more concentrated solution of surfactant. In order to treat these phenomena quantitatively, the flocculation value and the deflocculation value were defined as the minimum concentration of surfactants required to cause the complete flocculation and deflocculation of dye in 24 hours at constant temperature after mixing dye and surfactant.



In practice, 2 ml. of dye solution of a constant concentration and equal volume of surfactant solutions of various concentrations were mixed in small test tubes, and these test tubes were permitted to stand at 30°C for 24 hours. At the end of 24 hours, the degree of flocculation was observed visually or spectrophotometrically, if necessary, after centrifuging. The flocculation and deflocculation values correspond to the minimum number of millimoles of surfactant per liter of mixed solution required to cause the complete flocculation and deflocculation. By repeating the same procedure for the dye solutions of various concentrations, the dependence of flocculation and deflocculation values upon the dye concentration was also investigated.

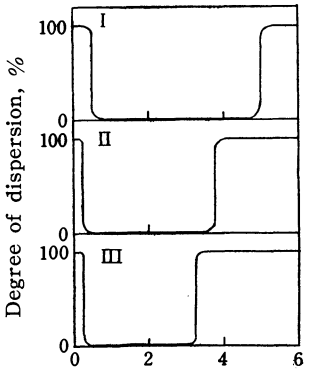
In order to study the properties of the complex formed between dye and surfactant, the transfer of flocculate to nonpolar solvent, such as benzene, was observed by the same procedure described already[5]. That is, 2 ml. of dye-surfactant mixture were shaken with equal volume of benzene in test tubes. After a few hours the degree of coloring of benzene phase was measured photometrically.

Results

The flocculation and deflocculation values varied with the difference in alkyl chain length and gegenion of surfactant, and furthermore with the addition of salt or organic solvent.

Effect of alkyl chain length of surfactant.—Results obtained with the alkyl sulfate—Rhodamine 6G systems in which the dye concentration was kept to be 0.5 mM/l. are shown in Fig. 1.

Concn. of alkyl sulfate, mM/l.
A: flocculation zone, B: deflocculation zone
Fig. 1. Flocculation pattern of Rhodamine 6G by sodium alkyl sulfates.



This figure shows that the minimum amounts of sulfate required to cause the complete flocculation and deflocculation markedly decrease with the increase in alkyl chain length of sulfate. In other words, the width of flocculation zone, i.e., the value obtained by subtracting the flocculation value from the deflocculation value, which is the net amount of surfactant necessary for the complete deflocculation of flocculate, decreases with increasing alkyl chain length.

As the dye concentration decreased, the flocculation and deflocculation values became smaller. Results for Rhodamine-dodecyl sulfate system are shown in Fig. 2. Similar results were obtained with decyl and tetradecyl sulfates.

The plots of the width of flocculation zone against the dye concentration gave a straight line. Results are shown in Fig. 3. It can be seen that the slope of the straight line rises with decreasing alkyl chain length of sulfate.

Effect of gegenion of surfactant.—Fig. 4 shows the flocculation and deflocculation

of Eosine, the concentration of which is 0.5 mM/l., by dodecylpyridonium halides.

In this figure, the chloride gives the largest flocculation and deflocculation values while the iodide gives the smallest ones. That is, the larger the hydration of gegenion of surfactant, the greater the width of flocculation zone.

The linear relation between the width of flocculation zone and the dye concentration for Eosine-dodecyl pyridonium halide systems is as shown in Fig. 5.

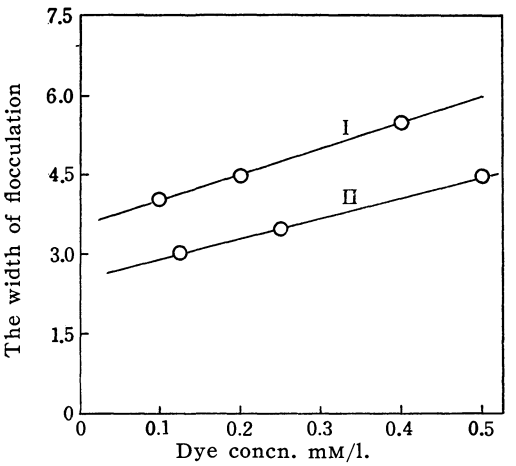
Concn. of Na. D. S., mM/l.
I: no salt, Rhodamine 6G 0.25 mM/l.
II: NaCl 8 mM/l., Rhodamine 6G 0.20 mM/l.
III: NaCl 16 mM/l., Rhodamine 6G 0.20 mM/l.

Fig. 6. Effect of NaCl on the flocculation of Rhodamine 6G by Na. D. S.



I: no salt, II: NaCl 8 mM/l.
III: NaCl 16 mM/l.

Fig. 7. Effect of NaCl on the relation between the width of flocculation zone and the dye concentration in Rhodamine 6G—Na. D. S. system.

Effect of added salt.—Added salt depressed the flocculation to a certain extent but promoted the dispersion of flocculates. A typical result obtained with Rhodamine 6G—Na. D. S.—sodium chloride system is shown in Fig. 6. and 7.

Effect of added alcohol.—The addition of ethanol to Rhodamine 6G – Na. D. S. system did not alter the flocculation value of dodecyl sulfate but exerted a slight influence on its deflocculation value. The width of flocculation zone, therefore, varies slightly as shown in Fig. 8.

I: ethanol 8.1 wt. %, II: no alcohol.

Fig. 8. Relation between the width of flocculation zone and dye concentration for Rhodamine 6G—Na. D. S. system in water-ethanol mixture.

Transfer of dye-surfactant complex into organic solvent.—Results for the transfer of Rhodamine 6G—D. S. complex into benzene are shown in the following table.

TABLE I
TRANSFER OF RHODAMINE 6G—D. S. COMPLEX INTO BENZENE

Dye concn. mM/l.	Na. D. S. concn. mM/l.						
	0.10	0.25	0.50	1.00	2.50	3.75	5.00
0.125	++	+++	++	+	+	−	−
0.25	++	+++	++	++	+	−	−
0.50	+	++	+++	++	++	+	−

In this table, the number of + signs denotes the degree of coloring of benzene phase, and the − sign shows the non-coloring.

It is noticed that the complex has a strong oilphilic property when the concentration of Na. D. S. is equivalent to that of dye. Furthermore, it is remarkable that this oilphilic property decreases again in more concentrated Na. D. S. solutions.

Discussion

The slope of straight lines shown in Figs. 3, 5, 7 and 8 will represent the minimum number of surfactant ions required to cause the complete deflocculation of a dye ion or a dye surfactant complex.

This number is termed "the deflocculation number of surfactant" and denoted by N_d in this series of papers. N_d values for surfactants employed in this work are collected in Table II.

TABLE II
VALUES OF N_d

Dye	Surfactant	N_d
Rhodamine 6G	Na. De. S.	6.7
	Na. D. S.	4.0
	Na. T. S.	2.2
Eosine	D. Py. Cl.	4.2
	D. Py. Br.	2.8
	D. Py. I.	1.9

The plots of $\log N_d$ against the number of carbon atoms of sulfate give a straight line as shown in Fig. 9, which is similar to that found between the C.M.C. and the number of carbon atoms in alkyl chain of surfactant.

On the other hand, with dodecylpyridonium halides, a linear relation between N_d value and lyotropic number of gegen-

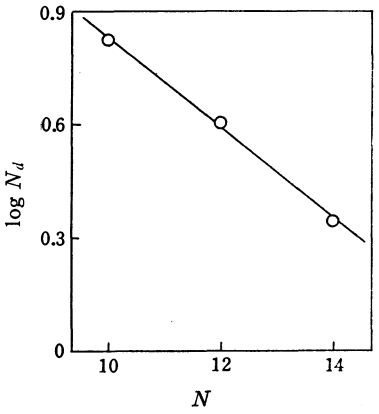


Fig. 9. Relation between log N_d and the number of carbon atoms in alkyl chain of sulfate.

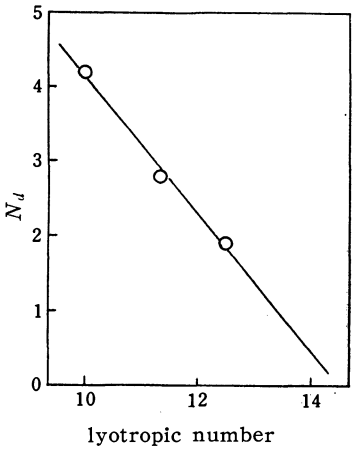

Fig. 10. Relation between N_d values and lyotropic number of gegenions of dodecylpyridonium halides.

ions is obtained as shown in Fig. 10. A similar relation is held between C.M.C. values of these cationic surfactants and lyotropic numbers of their gegenions[6].

It may be suggested that the deflocculation phenomenon of dye is closely related to the association properties of surfactant from the above-mentioned facts. As the magnitude of C.M.C. value measures the ability of micelle formation of surfactant, the N_d value seems to have a close relation with micelle forming ability of surfactant. The facts that the flocculation takes place at the equivalence between dye and surfactant, and that the deflocculation occurs in more concentrated surfactant solutions, and the facts that the flocculate has the oilphilic property, and that the deflocculate loses this oilphilic property, suggest the existence of dye surfactant aggregate composed of a dye surfactant complex, as the nucleus, and few surfactant ions. This dye-surfactant aggregate suggested by the present authors is pictured in Fig. 11.

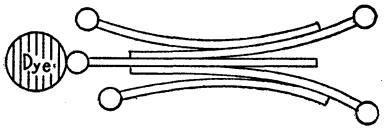

Fig. 11. Schematic representation of a dye-surfactant aggregate.

In connection with these considerations, it will be mentioned that the deflocculation of dye-surfactant complex occurs in surfactant solutions of the concentration below the C.M.C.

If we accept the above argument that a few surfactant ions can combine with a dye—surfactant complex in the deflocculation, we should expect that the surfactant ions themselves can form an aggregate owing to the interaction between their long alkyl chains below the critical concentration for micelle formation[7].

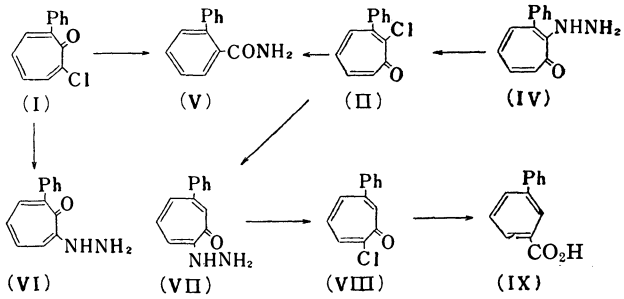
*Reaction of 2-Chloro-3-phenyltropone and 2-Chloro-7-phenyltropone with Ammonia and Amines**



By Toshio MUKAI

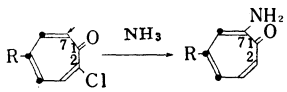
(Received September 19, 1958)

The present writer has been examining the reactivity of 2-phenyltropone[1,2] and taking a great interest in comparing its chemical and physical properties with those of 3- and 4-phenyltropones. As a preliminary step, the synthesis of 3-phenyltropone from 2-phenyltropone was attempted. The objective would be realized if the expected abnormal substitution** could occur in the reaction of ammonia and 2-chloro-3-phenyltropone, easily obtainable from 2-phenyltropone through 3-phenyltropolone. However, such an abnormal substitution of 3- or 7-substituted 2-chlorotropone has not been carried out, although the reaction has been tried often with 4(or 6)- and 5-substituted 2-chlorotropones[3,4]. In the first step of this experiment, therefore, the reaction of not only 2-chloro-3-phenytropone but also 2-chloro-7-phenyltropone with ammonia and amines was examined.

The starting material, the 2-chloro derivatives, were prepared by the reaction of 3-phenyltropolone and thionyl chloride. This afforded a mixture of 2-chloro-7-phenyltropone (I) and 2-chloro-3-phenyltropone(II) in a good yield, in which the quantity of I was 4~5 times as large as that of II. In some cases, a small amount of colorless crystals III, m. p. 86.5°C, was obtained during this reaction. In 1951, Cook and others[5] reported the formation of a *o*-chlorobenzaldehyde, besides 2-chlorotropone, by the reaction of tropolone and thionyl chloride. The analytical values of III also agree with those of the corresponding chlorophenylbenzaldehyde but its infrared spectrum[6] does not exhibit the absorption in the carbonyl region. The ultraviolet absorption spectrum of III, shown in Fig. 1, does not exhibit the absorption in the longer wave length, characteristic of the tropone nucleus[7], so that III must be a compound formed by aromatization, but its structure is still under examination.

The structure of I is proved by the fact that its alkaline hydrolysis affords a biphenyl-2-carboxylic acid and that its hydrogenolysis forms 2-phenyltropone. The structure of II was established by its identity with a compound, obtained by the

decomposition of 2-hydrazino-3-phenyltropone (IV) with copper sulfate in hydrochloric acid solution[8]. IV is derived from the structurally known 2-methoxy-3-phenyltropone[9].



Reaction of 2-chloro-3-phenyltropone (II) by standing in ethanolic solution saturated with ammonia at a room temperature

**) 2-Halotropones react with ammonia to give 2-aminotropones, but it has been found by T. Sato that the replacement of halogen by ammonia does not occur directly, and an abnormal substitution at C_7 rather than at C_2 occurs in the majority of cases (see ref. 3 and 4).

resulted in its rearrangement to biphenyl-2-carboxamide (V) in a good yield, instead of undergoing the expected abnormal substitution. The reaction of 2-chloro-7-phenyltropone (I) and ethanolic ammonia also ended in the same rearrangement.

On heating a mixture of 2-chloro-7-phenyltropone (I) and hydrazine in ethanol, the structurally known 2-hydrazino-7-phenyltropone[2] (VI) was obtained in a good yield. On the other hand, the reaction of 2-chloro-3-phenyltropone (II) and hydrazine afforded yellow crystals VII, m. p. 137°C without the rearrangement. The melting points of IV and VII were very close but their admixture showed them to be different substances. The ultraviolet spectrum of VII, shown in Fig. 2, indicated the absorption of a 2-aminotropone type[10] and its analytical values also agreed with those for a hydrazino compound. The ultraviolet spectra of other hydrazinotropones, IV and VI, are also given in Fig. 2, from which it is seen that the absorption in the longest wavelength region has disappeared in IV alone owing to the steric hindrance of the hydrazino group.

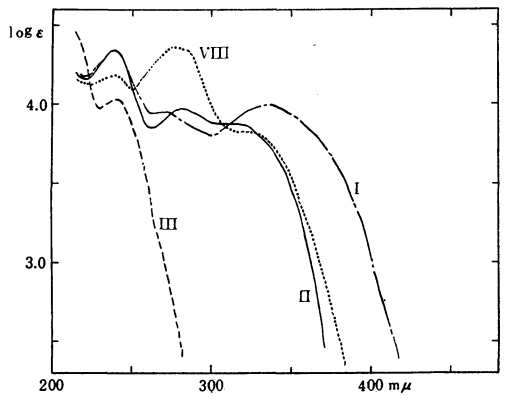

Fig. 1. U. V. Spectra of 2-Chloro-7-phenyltropone (I), 2-Chloro-3-phenyltropone (II), III of m. p. 86.5°C, and 2-Chloro-6-phenyltropone (VIII) in methanol.

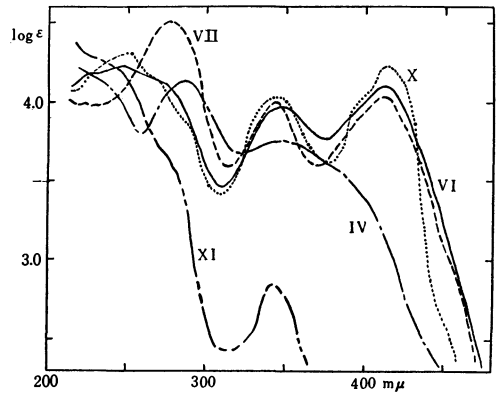

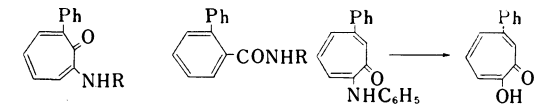

Fig. 2. U. V. Spectra of 2-hydrazino-3-phenyltropone (IV), 2-hydrazino-7-phenyltropone (VI), 2-hydrazino-6-phenyltropone (VII), 2-methylamino-7-phenyltropone (X), and biphenyl-2-carboxymethylamide (XI) in methanol.

Decomposition of VII with copper sulfate in hydrochloric acid medium affords the corresponding chlorotropone VIII which easily undergoes rearrangement on being heated with ethanolic alkali to form biphenyl-3-carboxylic acid (IX)[11]. It follows that VII and VIII are respectively 2-hydrazino- and 2-chloro-6-phenyltropone. The occurrence of an abnormal substitution with hydrazine was observed for the first time in this compound. It is interesting to note that the reaction with hydrazine is so vastly different from that with ammonia. The ultraviolet spectrum of VIII is given in Fig. 1. It is noted that II and VIII are the chlorine derivatives of 3-phenyltropone, their absorption curve shifts to a shorter wave length region than that of 2-phenyltropone derivatives and they have a maximum near 280 mμ.

The reaction of I and II with alkyl- and arylamines was next examined. When I or II was heated with methylamine in ethanol solution, I afforded yellow crystals X, m. p. 159°C and II gave pale yellow crystals XI, m. p. 165°C. The ultraviolet spectra of X and XI are indicated in Fig. 2. The spectrum of X exhibits two peaks of high intensity at above 340 mμ, indicating a typical 2-aminotropone type, while that of XI lacks the corresponding absorption, indicating the possibility of an aromatization. Since the analytical values of X agree with those of 2-methylaminotropones and the hydrolysis of X by heating with alkali in ethanolic solution affords 3-phenyltropolone, X must be 2-methylamino-7-phenyltropone. The structure of

(X): R=CH3 (XI): R=CH3 (XIII) (XIV)

(XV): R=C6H5 (XII): R=C6H5

10) The absorption in the longer region of ultraviolet spectra of 2-amino- and 2-hydrazinotropones splits into two maxima when measured in methanol (cf. Ref. 2).

11) H. Hey, *J. Chem. Soc.*, 1934, 1966.

XI was established by admixture of the methylamide, m. p. 166°C, of biphenyl-2-carboxylic acid, prepared by an unequivocal process.

The reaction with aniline was found to be somewhat more complicated. On heating 2-chloro-3-phenyltropone (II) and aniline in ethanol solution, orange plates XII, m. p. 110°C, were obtained from an easily soluble portion, and yellow crystals XIII, m. p. 173°C, from a sparingly soluble portion. The ultraviolet spectra of XII and XIII are shown in Fig. 3. XII shows absorption of a different type from that of the troponoids while that of XIII is similar to the absorption curve of 2-aminotropones[10]. XII is a neutral substance, is stable to acids and alkalis, and from its analytical values, it is assumed to be the rearrangement anilide of product, biphenyl-2-carboxylic acid. In fact, XII showed no depression of the melting point on admixture with the same anilide, m. p. 110°C, prepared by unequivocal process. Hydrolysis of XIII by heating with alkali in ethanolic solution afforded colorless crystals XIV, m. p. 97°C, an acid substance which gave the coloration with ferric chloride characteristic to tropolones. The ultraviolet spectrum of XIV is also characteristic of that of tropolones[7] as shown in Fig. 3. Previously, Doering and Knox[12] prepared 4-phenyltropolone and gave its melting point at 97°C, and measured its ultraviolet spectrum (in cyclohexane). From the comparison of elemental analytical values and ultraviolet spectra, XIV is undoubtedly 4-phenyltropolone and XIII would then

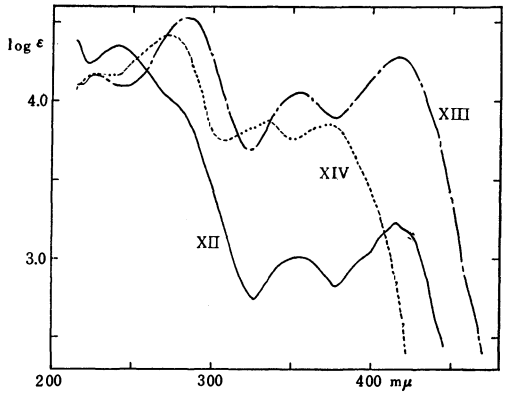

Fig. 3. U. V. Spectra of biphenyl-2-carboxyanilide (XII), 2-anilino-6-phenyltropone (XIII), and 4-phenyltropolone (XIV) in methanol.

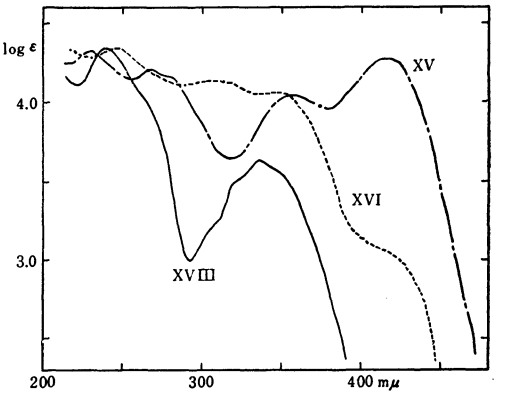
12) W. von E. Doering and L. H. Knox, *J. Am. Chem. Soc.*, 75, 297 (1953).



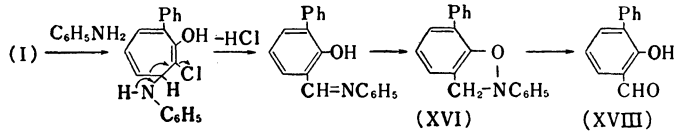


Fig. 4. U. V. Spectra of 2-anilino-7-phenyltropone (XV), the Schiff's Base (XVI), and 2-hydroxy-3-phenylbenzaldehyde (XVIII) in methanol.

be 2-anilino-6-phenyltropone. This fact indicates clearly that an abnormal substitution occurred in the reaction of II and aniline. This is the first example of an abnormal substitution occuring with an arylamine.

In the reaction of 2-chloro-7-phenyltropone (I) and aniline, yellow crystals XV, m. p. 124°C, and colorless crystals XVI, m. p. 103.5°C, are obtained with XVI predominating in yield. The ultraviolet spectra of XV and XVI are indicated in Fig. 4 and from the absorption curve and analytical date, XV was assumed to be 2-anilino-7-phenyltropone. This structure was actually established by the conversion of XV into 3-phenyltropolone (XVII) by alkaline hydrolysis. XVI is a neutral substance and undergoes facile decomposition on being heated in dilute acid or alkali, affording colorless crystals XVIII, m. p. 45.5°C. Although XVIII is an acid substance, it does not dissolve in sodium hydrogen carbonate and exhibits a dark violet coloration with ferric chloride in ethanol, like that of salicylaldehyde. The infrared spectrum of XVIII, exhibits absorptions due to hydroxyl group at 3200 cm^{-1} and that of carbonyl group at 1666 cm^{-1}, which are both displaced to a smaller frequency range. It would be rational to accept this shift by assuming an intramolecular hydrogen bonding between the carbonyl and hydroxyl groups. There is also a C-H stretching vibration of aldehyde group at 2820 and 2730 cm^{-1}. From these facts, the analytical data and ultraviolet absorption in Fig. 4, XVIII is assumed to be 2-hydroxy-3-phenylbenzaldehyde and XVI would then be a Schiff's

Base of XVIII and aniline. This assumption was proved to be correct from the facile formation of XVI by heating XVIII and aniline. However, the infrared spectrum of XVI does not exhibit the O-H stretching vibration and the C=N vibration is not distinct, although there is the aromatic C=C vibration at 1616 cm^{-1} (common with XVIII). Considering the fact that XVI is a neutral substance, it is more likely to have an oxazoline structure than that of Schiff's Base.

The formation of a salicylaldehyde derivative by the nucleophilic attack on tropones has already been observed in the reaction of 2,7-dihalotropone with alkali[13] or ammonia[3]. These reactions all belong to the same type and are assumed to have been instigated by the attack of aniline at 3-position of the tropone ring as suggested by Kitahara[14].

The afore-mentioned reactions are examples of ammonia and amines acting as nucleophilic reagents on 2-halo-3-(or 7)-phenyltropone, and the normal and abnormal substitutions and rearrangement reactions have been observed. These reactions are thought to be brought about in different directions by whether the amines attack the 1-position (C=O) of the tropone ring, or the 2-position (C-Cl) or 3- or the 7-position (C-H). Which of these reactions actually occurs depends on the structure of the reacting tropones to be reacted, the basicity and the size of the reagent used. For example, the reaction of ammonia with 2-chloro-7-phenyltropone (I) is principally directed towards its attack on the 1-position (C=O), resulting in aromatization to form V. With methylamine, which has a larger volume than ammonia, the attack occurs at the 2-position (C-Cl), perhaps due to the steric hindrance of the phenyl group at the 7-position a substitution reaction results, forming X. With further increase in the volume of the reagent to aniline, the attack occurs not only at the 2-position (C-Cl) but also at the 3-position (C-H) and results in the formation of XVI. In 2-chloro-3-phenyltropone (II), the steric hindrance of the phenyl and carbonyl groups toward the 2-position becomes so large that the normal substitution at the 2-position does not occur. In the reaction of II and amines, the attacks on the 1-position (C=O) and the 7-position (C-H) invariably occur competitively so that the attack of ammonia and methylamine, due to their volume and basicity, becomes effective on the 1-position (C=O) and rearrangement reaction is likely to occur in the majority. On the contrary, aniline and hydrazine are more liable to attack the 7-position rather than the 1-position and the result is likely to be an abnormal substitution reaction.

The foregoing experimental evidence (especially formation of VII) offers the possibility of deriving 3-phenyltropone from 2-phenyltropone and the writer expects to carry out the preparation of 3-phenyltropone along line.

Experimental[15]

Reaction of 3-Phenyltropolone and Thionyl Chloride. — To a solution of 1.0 g. of 3-phenyltropolone dissolved in 25 cc. of dehydrated benzene, 0.73 g. (1.2 mol. equiv.) of thionyl chloride was added and the mixture was refluxed for 3 hours on a water bath. Benzene was then distilled off, thionyl chloride was removed under reduced pressure, and the dark brown oily residue was dissolved in a mixture of 5 cc. each of chloroform and carbon tetrachloride. This solution was passed through an alumina column (1 $cm^2 \times 20$ cm.), which was eluted with chloroform, and the effluent was divided into seven fractions. Evaporation of the solvent from each fraction afforded pale yellow to yellow crystals with melting points listed below: (1) m. p. 65~70°C, (2) 72~74°C, and (3) 70~73°C, with a combined yield of 630 mg. (4) 90 mg. of m. p. 55~65°C. (5) Crystalline but its melting point cannot be determined. (6) 50 mg. of m. p. 80~87°C. (7) 110 mg. of m. p. 92~99°C. Fractions 1 to 3 were recrystallized from ethanol to yellow prisms I, m. p. 75°C.

Anal. Found: C, 72.34; H, 4.38. Calcd. for $C_{13}H_9OCl$: C, 72.06; H, 4.14%.

Fractions 6 and 7 were combined and recrystallized from ethanol and afforded pale yellow

14) Y. Kitahara, ibid., **39**, 250 (1956).

15) All m. p. are uncorrected. The microanalyses were carried out by Miss Ayako Iwanaga and Mr. Shinichi Ohyama of this laboratory to whom the author is indebted.

prisms II, m. p. 103~104°C.

Anal. Found: C, 71.88; H, 4.46. Calcd. for $C_{13}H_9OCl$: C, 72.06; H, 4.14%.

The alumina column was finally eluted with ethanol and evaporation of ethanol from the effluent afforded pale yellow crystals. Low-pressure (3 mmHg) sublimation yielded 20 mg. of colorless crystals, m. p. 73~80°C, which recrystallized from cyclohexane to colorless plates III, m. p. 85.5~86.5°C. $\tilde{\nu}$ (in KBr): 3340, 3300~80, 3040, 2915, 2865, 1467, 1412, 1356, 1313, 1240, 1179, 1113, 1085, 1055, 1038, 845, 788, 757, 701 cm^{-1}.

Anal. Found: C, 71.44; H, 4.77. Calcd. for $C_{13}H_9OCl$: C, 72.06; H, 4.14%.

Hydrolysis of 2-Chloro-7-phenyltropone (I) with Alkali. — A solution of 150 mg. of I dissolved in a mixture of 4 cc. each of ethanol and 4 N potassium hydroxide was refluxed for 4 hours on a water bath. Ethanol was then distilled off, the residue was diluted with water, and extracted with benzene to remove a neutral portion. The aqueous layer was neutralized to weak acid and extracted three times with chloroform. The chloroform extract was washed with water and the solvent evaporated, leaving 120 mg. of yellowish brown oil. The residual oil was distilled under reduced pressure (2 mmHg) at a bath temperature of 140°C and the colorless oily distillate crystallized immediately to 90 mg. of crystals melting at 75~85°C. Recrystallization from petroleum ether—benzene mixture afforded colorless crystals, m. p. 107~109°C, undepressed on admixture with biphenyl-2-carboxylic acid, m. p. 109~110°C.

Catalytic Reduction of 2-Chloro-7-phenyltropone (I).—To a solution of 50 mg. of I dissolved in 5 cc. of methanol, 50 mg. of sodium acetate and 20 mg. of 5% palladium-carbon were added and the mixture was hydrogenated at ordinary temperature and pressure. The absorption of hydrogen was quite slow and only 8.1 cc. (1.5 mol. equiv.) was absorbed in 5 hours. The catalyst was filtered off, the residue was diluted with water, and the solution was extracted with benzene. Evaporation of the benzene gave 40 mg. of a pale yellow oil which crystallized on inoculation of 2-phenyltropone crystal. The crystalline mixture was allowed to stand with a small quantity of methanol and afforded needles, m. p. 81~83°C. The mixed m. p. 82~84°C on admixture with 2-phenyltropone, m. p. 84°C. Similar catalytic reduction of 2-chloro-3-phenyltropone (II) ended in the recovery of II and no product was obtained that would form a hydrochloride or a picrate.

Formation of 2-Hydrazino-3-phenyltropone (IV).—To a solution of 120 mg. of 2-methoxy-3-phenyltropone[9], m. p. 77~78°C, dissolved in a mixture of 4 cc. of ether and 1 cc. of methanol, 0.1 cc. of 80% aqueous solution of hydrazine hydrate was added and the mixture was allowed to stand overnight in a refrigerator. This solution was treated with water and the separated ether layer was evaporated at room temperature from which 120 mg. of orange yellow crystals were obtained. Recrystallization from ethanol afforded 70 mg. of deep yellow prisms IV, m. p. 140°C.

Anal. Found: N, 12.97. Calcd. for $C_{13}H_{12}NO_2$: N, 13.20%.

Formation of 2-Chloro-3-phenyltropone (II) from 2-Hydrazino-3-phenyltropone (IV). —A solution of 300 mg. of IV dissolved in 4 cc. of concentrated hydrochloric acid was added in a few minutes into a heated solution of 3 g. of copper sulfate dissolved in 3 cc. of water. Some evolution of nitrogen was observed but a fair amount of tarry substance separated out. After boiling for 5 minutes, the solution was cooled and extracted with chloroform. The chloroform extract was washed with water, passed through an alumina column, and the column was eluted with chloroform. The pale yellow crystals, m.p. 93~95°C, obtained on evaporation of chloroform, were recrystallized from ethanol to pale yellow plates, m. p. 104~105°C, undepressed on admixture with 2-chloro-3-phenyltropone (II), m. p. 104°C, as described above.

Reaction of 2-Chloro-3-phenyltropone (II) and Ammonia.—A solution of 100 mg. of II dissolved in 3 cc. of ethanol saturated with ammonia at room temperature was placed in a vessel, sealed tightly, and left to stand at room temperature for 50 hours. The color of the solution changed from yellow through brown to pale yellow. Ethanol was evaporated under reduced pressure at room temperature and 60 mg. of pale yellow crystals, m. p. 173~174°C, so obtained were recrystallized from benzene to colorless needles V, m. p. 174~174.5°C, undepressed on admixture with an authentic sample of biphenyl-2-carboxamide, m. p. 174°C.

Reaction of 2-Chloro-7-phenyltropone (I) and Ammonia. — A mixture of 120 mg. of I in 3.7 cc. of ethanol saturated with ammonia was allowed to stand in a sealed vessel for 50 hours. Ethanol was evaporated under a reduced pressure at room temperature and 80 mg. of brown crystals, m. p. 148~160°C (sint. 120°C), were recrystallized from benzene to 50 mg. of colorless needles V, m. p. 174~174.5°C, undepressed on admixture with biphenyl-2-carboxamide.

Reaction of 2-Chloro-7-phenyltropone (I) and Hydrazine. — To a solution of 50 mg. of I dissolved in 1.5 cc. of ethanol, 0.06 cc. of 80% hydrazine hydrate solution was added and the mixture was refluxed for 30 minutes on a water bath. The ethanolic solution was concentrated to about one-half and cooled. From this 45 mg. of golden yellow needles, m. p. 195~197°C, separated out. The crystals were recrystallized from ethanol to VI, m. p. 199~200°C[16], which showed no depression on admixture with the structurally known 2-hydrazino-7-phenyltropone, m. p. 192°C (decomp.)[16]. Benzylidene compound[2] of VI: m. p. 150°C.

λ_{max}^{MeOH} mμ (log ε): 240(4.38), 273(4.20), 280(4.14), 442(4.56).

16) VI was reported as melting at 192°C (cf. Ref. 2), but it is corrected to m. p. 200°C.

Reaction of 2-Chloro-3-phenyltropone (II) and Hydrazine.—To a solution of 100 mg. of II dissolved in 3 cc. of ethanol, 0.10 cc. of 80% hydrazine hydrate solution was added and the mixture was refluxed for 30 minutes on a water bath. Evaporation of ethanol and cooling of the residue separated 80 mg. of golden yellow crystals, m. p. 100~130°C, which were recrystallized from cyclohexane to 60 mg. of orange scales VII, m.p. 136~137°C.

Anal. Found: N, 13.28. Calcd. for $C_{13}H_{12}ON_2$: N, 13.20%.

Benzylidene compound of VII: Yellow needles, m. p. 203°C.

Anal. Found: N, 9.52. Calcd. for $C_{20}H_{16}ON_2$: N, 9.33%.

λ_{max}^{MeOH} mμ (log ε): 238(4.25), 285(4.42), 377(4.26), 438(4.59).

Formation of 2-Chloro-6-phenyltropone (VIII) from 2-Hydrazino-6-phenyltropone (VII) and its Aromatization. — A suspension of 80 mg. of VII and 1.5 cc. of concentrated hydrochloric acid was added to a heated solution of 1.5 g. of copper sulfate dissolved in 1.5 cc. of water. After boiling 30 minutes, the solution was diluted with water and extracted with benzene. The benzene extract was washed with water and passed through an alumina column. Evaporation of benzene eluate afforded 45 mg. of a yellowish crystals m. p. 110~112°C, which were recrystallized from ethanol to pale yellow needles VIII, m. p. 113~114°C.

Anal. Found: C, 71.72; H, 4.39. Calcd. for $C_{13}H_9OCl$: 72.06; H, 4.14%.

A solution of 40 mg. of VIII in 2 cc. of 10% ethanolic potassium hydroxide solution was refluxed for 30 minutes, ethanol was distilled off, 2 cc. of water was added to the residue, and the mixture was heated for a further 10 minutes. A small amount of brown precipitate that separated out was filtered off, the filtrate was acidified with 6 N sulfuric acid, and the white precipitate so formed was collected by filtration, yielding 20 mg. of colorless crystals, m. p. 145~153°C. The crystals were recrystallized from benzene-petroleum ether to colorless plates IX, m. p. 162~163°C. The reported melting point for biphenyl-3-carboxylic acid is 162~164°C[11].

Reaction of 2-Chloro-7-phenyltropone (I) and Methylamine.—To a solution of 100 mg. of potassium hydroxide dissolved in 2.5 cc. of ethanol, 180 mg. of methylamine hydrochloride was added and potassium chloride that separated out was removed by filtration. To this filtrate, 100 mg. of I was added and the mixture was refluxed for 3 hours on a water bath. The residue obtained on evaporation of ethanol was recrystallized from ethanol to 45 mg. of yellow plates X, m. p. 159°C.

Anal. Found: N, 6.97. Calcd. for $C_{14}H_{13}ON$: N, 6.63%.

Ethanol was evaporated from the recrystallization mother liquor, the residue was dissolved in benzene, and the solution was passed through an alumina column. From the benzene eluate, 30 mg. of yellow crystals, m. p. 75°C, was obtained and this was identified to be I by mixed fusion.

Hydrolysis of 2-Methylamino-7-phenyltropone (X) with Alkali.—A solution of 25 mg. of X dissolved in a mixture of 1.5 cc. of ethanol and 4 N potassium hydroxide was refluxed for 6 hours on a water bath, ethanol was evaporated, and the residue was diluted with water. This was extracted with benzene and 20 mg. of pale brown crystals, m. p. 105~110°C, obtained on evaporation of benzene were recrystallized from ethanol to crystals of m. p. 113°C, undepressed on admixture with an authentic sample of 3-phenyltropone, m. p. 118°C[2].

Reaction of 2-Chloro-3-phenyltropone (II) and Methylamine.—A solution of 100 mg. of II dissolved in a solution of 130 mg. of methylamine hydrochloride and 100 mg. of potassium hydroxide dissolved in 2.5 cc. of ethanol was sealed in a glass tube and heated for 3 hours at 100°C. The ethanol was evaporated from the mixture, the residue was extracted with benzene and the solid residue obtained on evaporation of benzene was recrystallized from ethanol to pale yellow needles XI, m. p. 162~164°C.

The oily acid chloride obtained on refluxing biphenyl-2-carboxylic acid with thionyl chloride in benzene was added to ethanolic solution of methylamine and the mixture was warmed on a water bath, from which biphenyl-2-carboxymethylamide was obtained as colorless crystals, m. p. 165~167°C. This showed no depression of the melting point on admixture with XI.

Reaction of 2-Chloro-3-phenyltropone (II) and Aniline. — A solution of 180 mg. of II and 400 mg. of aniline dissolved in 5 cc. of ethanol was refluxed for 3 hours on a water bath. Ethanol was then evaporated, the residue cooled, and 40 mg. of yellow crystals, m. p. 165~167°C, obtained from it were recrystallized from benzene to XIII, m. p. 172~173°C.

Anal. Found: C, 83.79; H, 5.42; N, 5.53. Calcd. for $C_{19}H_{15}ON$: C, 83.49; H, 5.53; N, 5.13%.

The ethanolic solution left after separation of the crystals was extracted with benzene, the benzene extract was shaken with 1 N hydrochloric acid solution to remove remaining aniline, and washed with water. The benzene solution was then passed through an alumina column and the column was eluted with benzene. The effluent was divided into two fractions and evaporation of benzene from the initial fraction left 100 mg. of pale orange oil. The latter fraction afforded 40 mg. of similar oil. Both oils crystallized immediately and respectively afforded crystals of m. p. 97~101°C and 102~105°C. These were combined and recrystallized from cyclohexane to 90 mg. of colorless prisms XII, m. p. 109~110°C.

Anal. Found: C, 83.14; H, 5.46; N, 5.38. Calcd. for $C_{19}H_{15}ON$: C, 83.49; H, 5.53; N, 5.13%.

The alumina column was further eluted with ethanol and 10 mg. of yellow crystals, m. p. 165~167°C, were obtained, which showed no depression of the melting point on admixture with XIII.

Biphenyl-2-carboxylic acid chloride was refluxed with aniline in benzene and colorless crystals

(from ethanol), m. p. 110°C, thereby obtained showed no depression of the melting point on admixture with XII.

Hydrolysis of 2-Anilino-6-phenyltropone (XIII).—To a solution of 30 mg. of XIII dissolved in 2.5 cc. of ethanol, 2.5 cc. of 3 N potassium hydroxide solution was added and the mixture was refluxed for 8 hours on a water bath. Ethanol was evaporated from the mixture, water was added to the residue, and this was extracted with benzene.

Alkaline aqueous solution was neutralized with dilute hydrochloric acid and the turbid solution that resulted was extracted three times with chloroform. The extract was washed with water and the solvent was evaporated, leaving 20 mg. of brown oil which crystallized immediately. Its recrystallization from ethanol afforded colorless needles XIV, m. p. 97°C.

Anal. Found: C, 78.23; H, 5.38. Calcd. for $C_{13}H_{10}O_2$: C, 78.77: H, 5.09%.

This substance colors red with aqueous solution of ferric chloride and the color transits to the chloroform layer. The reported melting point of 4-phenyltropolone is 97°C[12].

Reaction of 2-Chloro-7-phenyltropone (I) with Aniline. — A solution of 600 mg. of I and 1.8 g. of aniline dissolved in 6 cc. of ethanol was refluxed for 6 hours on a water bath. Evaporation of the solvent left 250 mg. of yellow crystals, m. p. 97~98°C. Ethanol was added to the filtrate, which was further refluxed for 3 hours, and 100 mg. of yellow crystals, m. p. 97~98°C, was obtained. The mother liquor left here will be designated as A. The two crops of the above crystals were combined, dissolved in carbon tetrachloride and passed through a short alumina column. Evaporation of carbon tetrachloride from the effluent afforded 250 mg. of orange plates, m. p. 101~102°C, and its recrystallization from ethanol gave XVI, m. p. 103~103.5°C. $\tilde{\nu}$ (in KBr): 3030, 1616, 1583, 1488, 1455, 1427, 1372, 1293, 1280, 1202, 1173, 1100, 1075, 1023, 1000, 980, 940, 906, 849, 830, 757, 692, 650 cm^{-1}.

Anal. Found: N, 5.29. Calcd. for $C_{19}H_{15}ON$: N, 5.13%.

XVI is insoluble in either dilute acid or alkali. The mother liquor (A) was dissolved in benzene, shaken with 1 N hydrochloric acid to remove excessive aniline, the benzene layer was washed thoroughly with water, and the benzene evaporated, leaving 190 mg. of yellow crystals, m. p. 89~106°C. The crystals were dissolved in a mixture of 5 cc. each of ethanol and 2 N hydrochloric acid and the mixture was refluxed for 30 minutes on a water bath. Ethanol was evaporated, residual solution was extracted with benzene after addition of water, and the benzene extract was shaken with dilute sodium hydroxide solution to remove an acid portion. The alkaline extract will be designated as B. The benzene extract was washed with water and the solvent evaporated, giving 150 mg. of yellow crystals, m. p. 110~113°C. Recrystallization from ethanol afforded 90 mg. of yellow prisms XV, m. p. 122~124°C.

Anal. Found: N, 5.22. Calcd. for $C_{19}H_{15}ON$: N, 5.13%.

The extract B was neutralized, acidified and extracted with chloroform. The extract was washed thoroughly with water; and evaporation of the solvent left 20 mg. of pale brown oil which soon solidified to colorless crystals, m. p. 38~40°C. This substance is probably identical with XVIII described below.

Hydrolysis of 2-Anilino-7-phenyltropone (XV) with Alkali.—A solution of 50 mg. of XV dissolved in a mixture of 4 cc. of ethanol and 2 cc. of 6 N potassium hydroxide was refluxed for 6 hours on a water bath. Ethanol was evaporated from this mixture, water was added to the residual solution, and extracted with benzene to remove a neutral portion. The aqueous alkali solution was acidified with dilute hydrochloric acid and extracted with chloroform. The extract was washed with water; evaporation of hlorcoform afforded 30 mg. of pale yellow crystals, m. p. 97~100°C. Its recrystallization from ethanol gave yellowish prisms, m. p. 114~116.5°C, which showed no depression with authentic 3-phenyltropolone, m. p. 118°C[2].

Hydrolysis of Schiff's Base (XVI).—A solution of 110 mg. of XVI dissolved in a mixture of 4 cc. of ethanol and 2 cc. of 6 N potassium hydroxide was refluxed for 1 hour. Ethanol was evaporated from this solution, water was added and then extracted with benzene to remove a neutral portion. The aqueous alkali solution was acidified and extracted with chloroform. The extract was washed with water, the chloroform evaporated, and 80 mg. of pale brown oily residue crystallized immediately, showing m. p. 40~42°C. Recrystallization from ethanol afforded colorless plates XVIII, m. p. 45.5~46°C. $\tilde{\nu}$ (in KBr) 3200, 3040, 2820, 2730, 1666, 1611, 1495, 1472, 1453, 1433, 1384, 1303, 1264, 1214, 1167, 1097, 1065, 1026, 911, 829, 794, 761, 720, 693 cm^{-1}.

Anal. Found: C, 78.33; H. 5.11. Calcd. for $C_{13}H_{10}O_2$: C, 77.98; H, 5.09%.

The halogen test is negative with XVIII and it does not transit to an alkali layer on shaking its benzene solution with saturated solution of sodium hydrogen carbonate. Ethanolic solution of XVIII becomes dark violet with ferric chloride.

Hydrolysis of 80 mg. of XVI by heating in a mixture of 2 cc. of each of ethanol and 2 N hydrochloric acid for 30 minutes also affords 50 mg. of XVIII, m. p. 45°C.

Reaction of 2-Hydroxy-3-phenylbenzaldehyde (XVIII) and Aniline. — A mixture of 80 mg. of XVIII and 200 mg. of aniline was heated on a water bath for 20 minutes and the resulting dark red oil separated crystals on being cooled. The addition of a small amount of ethanol afforded 90 mg. of almost colorless scales, m. p. 103°C, undepressed on admixture with XVI, m.p. 103.5°C.

The author takes this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this work, to Professor Shuichi Seto and Assistant

Professor Yoshio Kitahara for much helpful advice, and to Mr. Mutsuo Ishii for his cooperation in carrying out the experiments.

Spectrophotometric Determination of Uranium with Neo-thorone

By Shozo SHIBATA and Teiichi MATSUMAE

(Received July 7, 1958)

In an earlier communication[1] a photometric method for the determination of uranium with Neo-thorone (*o*-arsonophenylazo-chromotropic acid) was briefly described. The purpose of this paper is to treat the same subject in detail. Several colorimetric methods recently reported for the determination of uranium were based on the complex formation with such a reagent as dibenzoylmethane[2], 2-acetoacetylmethane[3], diethyldithiocarbamate[4], potassium ferrocyanide[5], potassium thiocyanate[6], or on the formation of peroxide with hydrogen peroxide[7].

Hydrogen peroxide is the common reagent used for the colorimetric determination of uranium, but it is not very sensitive. Kuznetsov[8] has reported a qualitative test; a very sensitive color reaction of uranium with *o*-arsonophenylazo-chromotropic acid. Neo-thorone in a solution of pH 1 or 2 has been used as a chromogenic reagent to determine thorium[9] and fluoride[10].

Experimental

Apparatus.—A Hitachi Model EPV-2 Spectrophotometer with 1 cm. cells was used for all absorbance measurements.

Reagents.—Neo-thorone (0.1%): dissolve 0.1 g. of reagent grade chemical (Hayashi Chemical Works, Osaka) in water and dilute to 100 ml.

Standard uranium nitrate solution: Dissolve 1.20 g. of reagent grade uranyl nitrate in water and dilute to 1 liter to prepare a stock solution. It was standardized gravimetrically by the oxine method. An aliquot of this solution was diluted to give a solution containing 5 μg. of uranium per ml.

Sodium ethylenediaminetetra-acetate (2%): Dissolve 20 g. of disodiumdihydrogen ethylenediaminetetra-acetate dihydrate in water and dilute to 1 liter.

Sodium acetate-acetic acid buffer: Dissolve 12 g. of sodium acetate in water and dilute to 1 liter. A 0.1 N acetic acid solution was used to make a buffer solution.

Other reagents were analytical grade chemicals.

General Procedure.—The following procedure was used to determine uranium in aqueous solution. The sample solution was adjusted to contain from 2 to 10 μg. of uranium per ml. One ml. aliquot was pipetted into 25 ml. glass stoppered volumetric flask. One ml. of 0.1% solution of Neo-thorone and 5 ml. of buffer solution of pH 6.0 were added, and then the solution was made up to 25 ml. with water. The solution was allowed to stand for five minutes, and then the absorbance was measured at 600 mμ, against a reference solution. The amount of uranium was determined by comparison with a previously prepared absorbance-uranium concentration curve.

Results and Discussion

Spectral Properties. — The absorption spectrum of an aqueous solution of Neothorone was obtained with water as the reference. The absorption peak of Neothorone in a buffered solution of pH 1.0~6.0 was found at 510 mμ. (Fig. 1). The absorption spectra of the aqueous solution of uranium—Neo-thorone complex at pH 2.0, 3.0 and 6.0 are shown in Fig. 2. Correction was applied for the reagent blank.

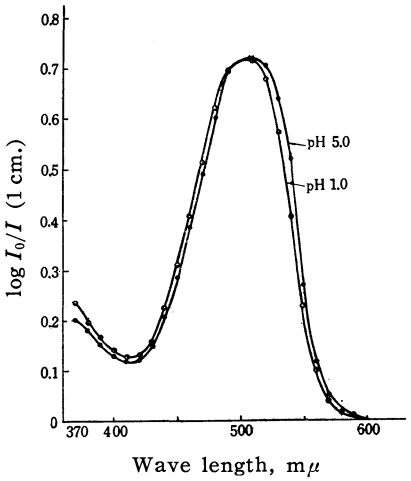

Fig. 1. Absorption spectra of Neo-thorone.

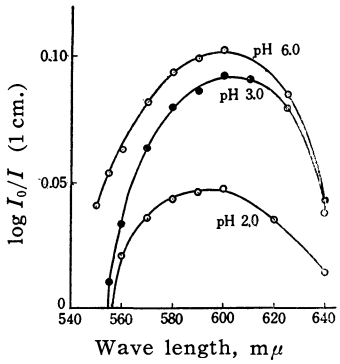

Fig. 2. Absorption spectra of uranium—Neo-thorone complex.

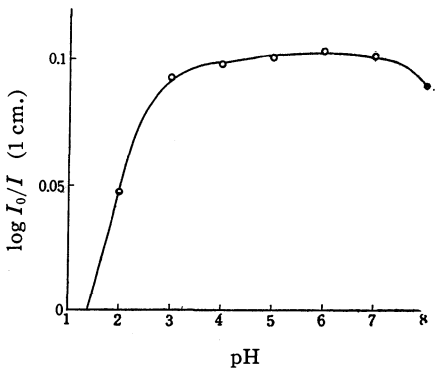

Fig. 3. Effect of pH on the color intensity.

Effect of pH. — Solutions of pH range 1.0~8.0 were prepared as previously described. The complex provides maximum intensity over a pH range of 5.0 to 7.0 (Fig. 3), the absorbance being constant over this range. With increasing pH values above 7.0, the color intensity decreased. All absorbance measurements were performed at 600 mμ.

Effect of Reagent Concentration. — The optimum amount of Neo-thorone was sought by adding various amounts of 0.1% solution of Neo-thorone to a solution containing 20 μg. of uranium, and the result is shown in Fig. 4. Corrections were made for reagent blank. In all cases the pH values were maintained constant. When more than 0.5 ml. of 0.1% Neo-thorone solution per 25 ml. was added, the absorbance become practically constant. The reagent blank increased slightly with increasing Neo-thorone concentration. Therefore, 1 ml. of 0.1% Neo-thorone solution was taken each time in the present work.

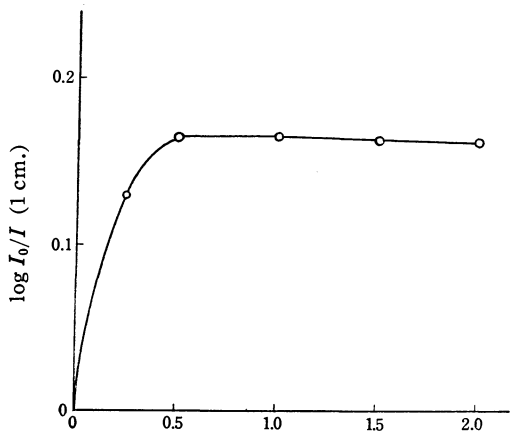

Fig. 4. Effect of Neo-thorone concentration. (20 μg. U taken, pH 6.0)

Temperature Effect. — Throughout the present investigation the experiments were carried out at room temperature which ranged from 10 to 25°C. In this range the temperature had no remarkable influence on the absorbance of uranium-Neo-thorone complex.

Stability of Color. — The color of the uranium—Neo-thorone complex in aqueous medium seemed to develop fully after a few minutes, and its intensity did not change for at least 4 hours, as shown in Table I.

TABLE I
STABILITY OF COLOR

Time after color developed.	Absorbancy (at 600 mμ)	
min.	20 μg.U/25 ml.	120 μg.U/25 ml.
5	0.081	0.429
15	0.080	0.429
60	0.081	0.429
120	0.082	0.428
240	0.081	0.429

Calibration Curve. — The calibration curve is shown in Fig. 5. It was found that the system conformed to Beer's law in the concentration range from 0 to 40 μg. of uranium per 25 ml.

Composition of Complex.—The composition of uranium—Neo-thorone complex was determined by the continuous variation method. The results obtained are shown in Fig. 6. From these results, the ratio of uranium to Neo-thorone would be 1 : 1*.

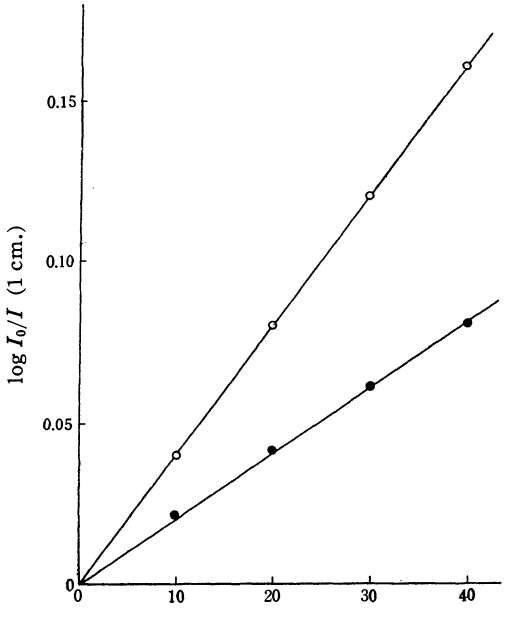

Fig. 5. Calibration curve, ○ pH 6.5, ● 1.0 ml. 1% sodium ethylenediaminetetra-acetate present.

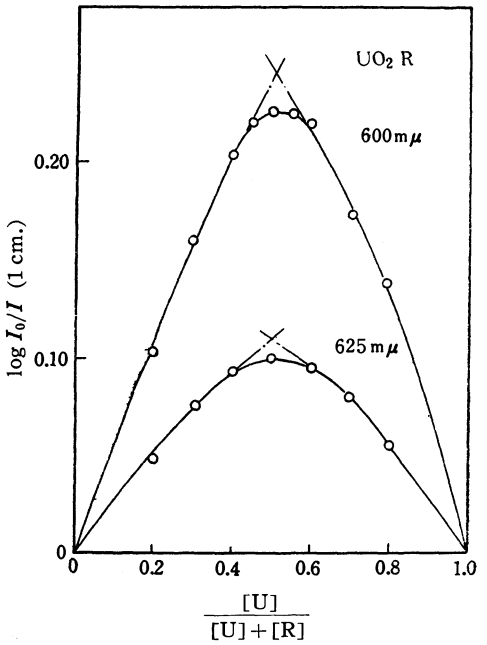

Fig. 6. Continuous variation method.

Effects of Foreign Ions.—A study was made on the effects of several anions and cations. Oxalate, fluoride, and phosphate interfered. A few grams of sodium, potassium, and ammonium which were present in the solution as acetate, sulfate, chloride, and nitrate did not interfere. Many of the cations, for example, aluminum, copper, iron(III), indium, titanium, zinc, thorium, cerium, and zirconium interfered because they formed respective complexes with Neo-thorone. But a proper amount of such metals as aluminum, iron(III), zinc, zirconium, thorium and lead can be masked by the use of sodium ethylenediaminetetra-acetate. For example absorbance measurements when using the ethylenediaminetetra-acetate as masking agents, were made for solutions containing aluminum, iron(III), zinc and thorium. The results are presented in Table II.

TABLE II
DETERMINATION OF URANIUM IN THE PRESENCE OF Al, Fe, Zn AND Th

U taken	Metals added (mg.)				U found	Error
(μg.)	Al	Fe	Zn	Tn	(μg.)	(μg.)
0.0	0.4				0.3	+0.3
10.0	0.4				10.2	+0.2
20.0	0.4				20.0	±0.0

20.0	0.2	0.5	0.1		20.4	+0.4

As shown Table II; aluminum, zinc, iron(III) and thorium do not interfere.

Summary

The spectrophotometric method for the determination of microquantities of uranium with Neo-thorone was established. By this method 5 to 40 μg. of uranium in

* In preparing this paper, H. Matsuyama, T. Hara and K. Koyama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **79**, 958 (1958). have reported independently a similar method for the determination of uranium by Neo-thorone. However they have stated that the complex was composed of 2 moles of uranium to 3 moles of Neo-thorone.

25 ml. solution can be determined easily and accurately. Interference by a small amount of aluminum, zinc, lead, thorium and iron could be avoided by using sodium ethylenediaminetetra-acetate. Therefore, complete separation of iron, thorium, and aluminum is not necessary.

The authors wish to express their heartfelt thanks to Professor Dr. Masayoshi Ishibashi for his encouragement and numerous suggestions throughout the investigation. Also the authors express hearty thanks to Mr. S. Higashi who kindly supplied Neo-thorone to them.

Studies on Meso-ionic Compounds. IX[1]*. *Sydnone-4-carboxylic acid via Lithium Compound*

By Hiroshi KATO and Masaki OHTA

(Received September 24, 1958)

Although a large number of sydnone derivatives have been obtained, attempts to prepare sydnone-4-carboxylic acid (III) have not yet been successful. 3-Phenyl-4-bromosydnone (I) did not react with potassium cyanide[2], nor did the Grignard reagent derived from the bromo-compound I react with carbon dioxide[3]. On the other hand, many attempts to prepare III by oxidizing the methyl group of 3-phenyl-4-methylsydnone have not been promising[4]. After many trials, the authors have finally succeeded in preparing III via lithium compound.

Among many methods proposed for the preparation of organolithium compounds, the authors have tried halogen-metal interconversion method, because it has been known that the ease of interconversion depends on the degree of positive polarization of the halogen atom[5], and it has been reported that the bromine atom of 4-bromosydnone (I) has the tendency to be removed as positive ion[2]. In accordance with the above consideration, 3-phenyl-4-bromosydnone (I) reacted smoothly with *n*-butyl-lithium to give the corresponding lithium compound (II), which in turn,

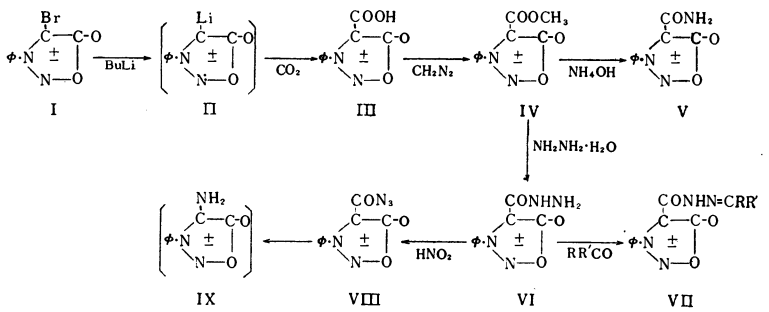

Fig. 1. Sydnone-4-carboxylic acid and its derivatives.

* Presented in part at the 11th Annual Meeting of the Chemical Society of Japan held in Tokyo, April, 1958.

reacted with carbon dioxide to give the expected 3-phenylsydnone-4-carboxylic acid (III). The acid gave the ester IV by reaction with diazomethane, and the ester gave the corresponding amide (V) or hydrazide (VI) by the action of ammonia or hydrazine hydrate, respectively. The hydrazide is rather unstable and is converted, by warming, into an unidentified compound. This compound is negative to Liebermann's nitroso test, but turns positive to it after being warmed with 5% sodium hydroxide solution, which suggests the maintenance of sydnone nucleus in that compound[6].

The hydrazide VI is characterized by its ready formation of hydrazones VII by reaction with ketones (see Table 1). When the hydrazide was treated with sodium nitrite in acetic acid, the corresponding azide VIII was obtained, but the authors succeeded in preparing neither aminosydnone IX nor its derivatives by Curtius or its modified reactions. As a considerable number of attempts to prepare aminosydnone IX by reduction of 4-nitrosydnone have been unsuccessful[4,7], the stability of this supposed compound might be called in question.

Experimental

3-Phenyl-4-bromosydnone (I).—The method of preparation of this compound is a little different from those reported earlier[8]. Into a solution of 50 g. of 3-phenylsydnone and 50 g. of fused sodium acetate in 400 cc. of glacial acetic acid was added dropwise 50 g. of bromine under cooling and stirring. After a few minutes, the solution was diluted with a large quantity of water and the precipitate which separated out was filtered off. Recrystallization from ethanol gave 57 g. of white needles, m.p. 141°C.

3-Phenylsydnone-4-carboxylic acid (III).—A solution of *n*-butyl-lithium in 100 cc. of ether prepared from 3.1 g. of lithium metal and 35 g. of *n*-butyl bromide[9] was added dropwise to a suspension of 35 g. of 3-phenyl-4-bromosydnone in 70 cc. of anhydrous ether under a stream of nitrogen and under stirring and cooling to −50°C. After thirty minutes, the reaction mixture was poured over 50 g. of powdered dry ice. When all the dry ice had been evaporated, the mixture was decomposed with water and the aqueous layer was washed three times with benzene and acidified with hydrochloric acid. The precipitate which separated out was collected and recrystallized from ethanol giving 25 g. of white needles, m.p. 193°C (decomp.).

Anal. Found: C, 52.16; H, 3.19; N, 13.68. Calcd. for $C_9H_6O_4N_2$ (III): C, 52.43; H, 2.93; N, 13.59%.

Methyl 3-phenylsydnone-4-carboxylate (IV).—Diazomethane prepared from 2 g. of *N*-nitroso-*N*-methyl-*p*-toluenesulfonamide was absorbed into a suspension of 0.5 g. of III in 20 cc. of ether. After a few minutes, the solution was concentrated and the crystals which separated out were collected and recrystallized from methanol giving 0.47 g. of colorless leaflets, m.p. 142°C (decomp.)

Anal. Found: N, 12.44. Calcd. for $C_{10}H_8O_4N_2$ (IV): N, 12.72%.

3-Phenylsydnone-4-carboxamide (V).—In 5 cc. of concentrated aqueous ammonia was suspended 0.2 g. of III. After being kept standing for three days under room temperature, the precipitate was collected and recrystallized from ethanol giving 0.13 g. of colorless needles, m.p. 227°C (decomp.).

Anal. Found: N, 20.50. Calcd. for $C_9H_7O_3N_3$ (V): N, 20.48%.

3-Phenylsydnone-4-carboxylic acid hydrazide (VI).—Into a solution of 10 cc. of hydrazine hydrate and 4 cc. of methanol was added 10 g. of IV. After three hours, the crystals which separated out were collected, dissolved in chloroform, and reprecipitated by addition of ligroin, giving 9 g. of yellow needles. This compound was turned into a dark red substance by warming; the latter decomposed at 303°C.

Anal. Found: C, 49.05; H, 3.99; N, 25.07. Calcd. for $C_9H_8O_3N_4$ (VI): C, 49.09; H, 3.66; N, 25.45%.

When VI was warmed in methanol or in xylene, a dark red substance of m.p. 303°C (decomp.) separated out, which is insoluble in most solvents.

Anal. Found: C, 45.92; H, 3.12; N, 25.36%.

This compound was negative to Liebermann's nitroso test, but turned positive to it after warming two hours with 5% sodium hydroxide solution.

When VI was treated with carbonyl compounds at room temperature, the corresponding hydrazones VII were obtained. Some of the derivatives of this type are listed in Table I.

Example: To 0.1 g. of VI was added a few drops of acetone. After a few minutes, petroleum ether was added and the crystals which separated out were collected, dissolved in acetone and reprecipitated by addition of petroleum ether giving 0.08 g. of white fine needles, m.p. 144~146°C (decomp.).

3-Phenylsydnone-4-carboxylic acid azide (VIII).—Into a solution of 0.6 g. of VI in 10 cc. of 50% aqueous acid, was added 0.2 g. of sodium nitrite under cooling. After thirty minutes, water was added and the crystals which separated out were collected, dissolved in acetic acid and reprecipitated by addition of water affording 0.52 g. of white needles, m.p. 102°C (decomp.).

Anal. Found: C, 46.78; H, 2.54; N, 30.37. Calcd. for $C_9H_5O_3N_5$ (VIII): C, 46.75; H, 2.18; N, 30.30%.

When VIII was heated in ethanol, water or a

Study on Zinc Oxide-Chromium Oxide Catalyst. III. Promoting Effect of Chromium Oxide on Catalytic Activities for Methanol Synthesis and Decomposition

By Yoshisada OGINO, Masaaki OBA and Hiroshi UCHIDA

(Received September 19, 1958)

Several papers have appeared dealing with the promoting effect of chromium oxide in zinc oxide-chromium oxide catalysts on the catalytic activities for the methanol synthesis and decomposition. However only Natta's paper has been able to discuss the subject from the kinetic view point, since there had not been any rate equation of the methanol synthesis before the one given by Natta[1,2]. Recently the authors of this paper have proposed a rate equation that gives the rate constant of the synthesis from a relatively small number of measurements[3]. By the aid of this rate equation a quantitative expression of the activity becomes available more easily. This leads us to a further understanding of the promoting effect of chromium oxide.

Our previous paper[4] described the activity for the methanol decomposition in connection with the catalyst composition along with its structural dependence, but the catalyst used in the study proved to have such a poor activity that an accurate determination on the synthesis was somewhat difficult. In the present study the catalyst has been prepared by a procedure different from the previous one, and necessary attention has been paid to obtain homogeneous structure of the catalyst.

Experimental Procedure

Catalyst Preparation.—The catalysts were made by treating a commercial zinc oxide powder (grade, pure) with an appropriate chromic acid solution. The mixture was kneaded into a paste, which was divided into two portions. One of them was allowed to dry immediately at room temperature, while the other was washed with acetone before drying. According to the

paper by Feitknecht et al.,[5] the washing furnished a means for separating a solid product from a liquid product in the paste without decomposition. The dried cakes were powdered and pressed into tablets, which were crushed and screened to 2 to 3 mm. particles. The catalyst produced directly from the paste is denoted catalyst A, while the one from the separated solid is denoted catalyst B.

Further, another catalyst, denoted catalyst S, was prepared. A preparation of the catalyst B-9 whose chromic acid content was equivalent to Cr/Zn ratio of 0.5 was reduced in hydrogen at 350°C, and was leached with nitric acid at room temperature till any dissolution of uncombined oxide of zinc or chromium was hardly detectable. The remainder, according to the statement by T. Sato[6], was to give the crystal structure of zinc chromite spinel with no sign of either zinc oxide or chromium oxide. It was then treated in the same way as described above. The Cr/Zn ratio in the catalyst S was determined 1.6 by chemical analysis.

Catalytic Activities for Synthesis and Decomposition of Methanol. — A reactor as described in our previous paper[3] was used for the determination of catalytic activity for the methanol synthesis. The syntheses were conducted at several different temperatures from 300 to 360°C at a constant pressure (150 kg./cm^2 of $2H_2+1CO$ gas) and space velocity (about $1\cdot10^4$). Methanol concentration in the exit gas from the reactor gave a measure of the activity. On the other hand, activity for the methanol decomposition was given by a rate of carbon monoxide evolution, or percent of methanol decomposition, during a constant feed through a catalyst bed. The measurements were made at several different temperatures from 300 to 400°C. By-products in the synthesis as well as in the decomposition were determined by analytical methods as usually employed*1.

Specific Surface Area.—The specific surface area was determined from nitrogen adsorption data plotted according to the BET theory.

Results

Chemical Composition of Catalysts B.— In order to determine the time of kneading necessary for completion of the reaction between zinc oxide and chromic acid solution, change in chemical composition of the solid in the paste with kneading times was pursued. It appeared that after only one hour of the kneading both Cr/Zn ratio and the crystallisation-water in the solid attained respective values which were held approximately constant during the prolonged kneading extending twenty hours. The results clearly show that to the utmost two hours of the kneading are sufficient for completion of the reaction considered, and for producing a solid of homogeneous structure.

In Fig. 1, the Cr/Zn ratio in the catalysts B is plotted against the ratio in the original pastes after kneading for two hours. The full line in Fig. 1 illustrates the fact that the quantity of chromic acid which is removable from the paste by

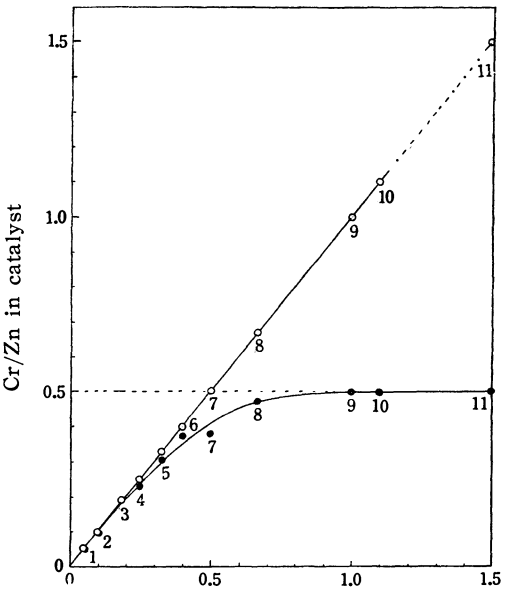

Fig. 1. Catalyst composition.

○ catalysts A; ● catalysts B

washing with acetone becomes larger according to the increasing ratio of Cr/Zn in the paste. The catalyst B, or the solid in the paste, can thus contain no more chromic acid than that equivalent to the Cr/Zn ratio of 0.5. The results also show that the solid is in equilibrium with the liquid of a higher chromic acid concentration, the amount of which becomes larger according to the increase in chromic acid content in the paste*2.

catalysts A gives the straight line in the figure.

Catalytic Activity for Methanol Synthesis and Decomposition.—Part of the results is shown in Fig. 2 presenting the methanol concentration as a function of the reaction temperature. From the data available, rate constants, k, have been calculated by the aid of the following rate equation proposed by us[3],

$$r = k(p_{CO}p^2_{H_2})^{0.7} - p_{CH_3OH}\cdot(p_{CO}p^2_{H_2})^{-0.3}/K$$

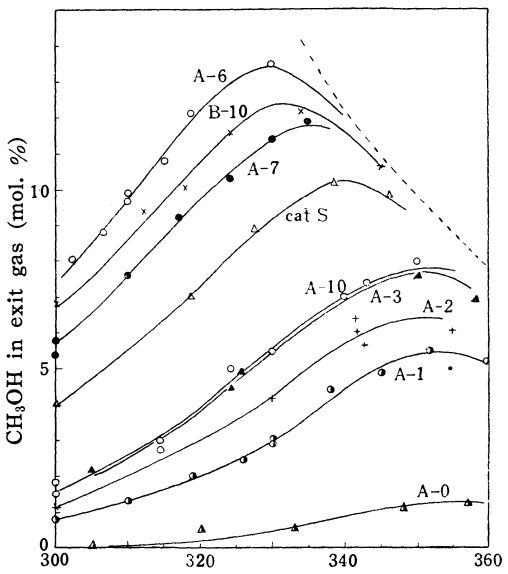

Fig. 2. Methanol concentration as a function of reaction temperature at 150 kg./cm² and S. V. of 0.95—1.05·10⁴.

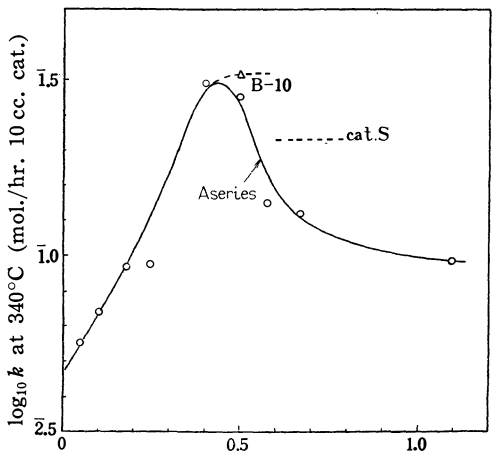

Fig. 3. Relation of Cr/Zn ratio to catalytic activity for synthesis.
k's were evaluated from the data in Fig. 2 after the corrected values at S. V. of 1·10⁴ had been estimated.

where K is the equilibrium constant of the synthesis, and are given in Fig. 3 as a function of Cr/Zn ratio in the catalysts. The figure reveals that the series of catalysts A exhibits maximum activity at the Cr/Zn ratio which is a little less than 0.5, whereas catalyst B-10 of Cr/Zn ratio of 0.5 gives activity higher than the catalyst A-7 of the same Cr/Zn ratio.

Molstad et al.,[8] and Frolich et al.[9] have done comprehensive work on the activity correlated to the Cr/Zn ratio in a wider range. The present results give a maximum activity at the same Cr/Zn ratio as pointed out by the former, but differ from the work of the latter in giving the maximum activity at a somewhat higher Cr/Zn ratio. The difference may mainly be due to our mode of catalyst preparation which is different from theirs.

Catalyst S is of intermediate activity between catalyst B-10 and catalyst A-10. Catalytic activity for the methanol decomposition is shown in Fig. 4 as a function

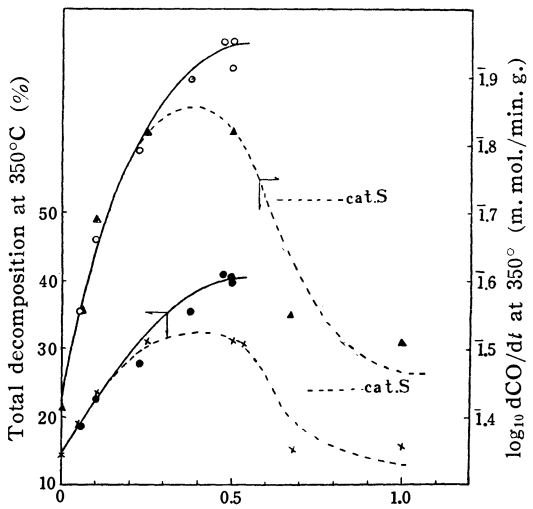

Fig. 4. Relation of Cr/Zn ratio to catalytic activity for decomposition.
dotted lines, A series; full lines, B series.

of Cr/Zn ratio in the catalyst. Tendencies similar to those found in the synthesis are found in the decomposition. Furthermore an asymptotic rise of the activities of catalysts B with the increasing Cr/Zn ratios up to 0.5 can be seen more clearly. The similarity between the changes in activity for the synthesis and for the

a), numerals listed, except b), show the specific surface areas determined on the catalysts after having been used in the synthesis: b) is the area determined on the catalyst A-O before the synthesis. c), the specific surface areas of catalysts B were determined on the specimens reduced in hydrogen at 320~350°C.

decomposition with the Cr/Zn ratios was once reported by Frolich et al..*3

Selectivity in Synthesis and Decomposition.—In the synthesis, gaseous products such as carbon dioxide and methane were produced in extremely small amounts: increase in carbon dioxide concentration in the gas after the synthesis did not exceed one percent, and hardly any methane was detectable. Among the liquid products both formaldehyde and methylformate were usually found to be very small in amount (0.1% and 0.5% respectively), and because of the too small quantity of dimethylether produced, no accurate determination was probable by the method employed in this work. On the other hand, the zinc oxide catalyst gave the highest yield of water, which diminished rapidly with the increasing Cr/Zn ratios in the catalysts (refer to Fig. 5). Anyhow, hardly any kind of effect of chromic acid addition undesirable to the selectivity of the synthesis has been found.

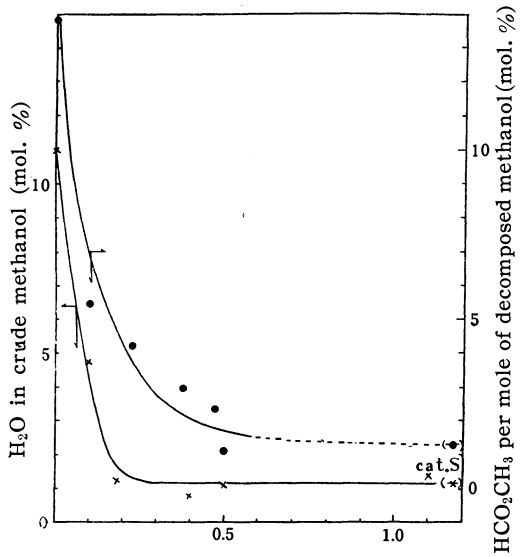

Fig. 5. Cr/Zn ratio in catalyst and selectivity in reactions.

*3 In this respect any similarity was hardly found by Storch (*J. Phys. Chem.*, 32, 1743 (1928)).

In the methanol decomposition, small quantities of carbon dioxide and formaldehyde were produced, independent of the Cr/Zn ratios in the catalysts, whereas the production of methylformate seemed closely correlated to the ratio (refer to Fig. 5). The correlation appeared remarkable on the series B of the catalysts: the yield was the greatest on the zinc oxide catalyst, and tended to decline regularly with the increasing Cr/Zn ratios. As for the series of the catalysts, a slight minimum of the yield appeared at a relatively small Cr/Zn ratio.

Specific Surface Area. — The specific surface areas which were determined on the catalysts after the synthesis are listed in Table I. With respect to the series A the area passes through a maximum at the Cr/Zn ratio of 0.4. The individual catalysts of the B series show a larger specific surface area than the corresponding ones of the series A.

Discussion

Catalyst Composition and Catalytic Activity.—In the course of our manufacturing the catalysts A, the liquid which contained chromic acid more abundantly than the solid in the paste left after drying the surface layer of higher chromic acid content at the back of the original solid particle, and the particle surface became more enriched with chromic acid than the particle interior. Therefore the chemical composition of the catalysts A can not indicate the real surface concentration of chromic acid. On the other hand, the chemical composition of the catalysts B can directly predict the concentration considered, since the catalyst was produced from the solid, free of the liquid. Only the B series of the catalysts thus gives a correct relation of the catalytic activity to the chemical composition.

For the reason mentioned above, a maximum of the activity appearing at the Cr/Zn ratio shortly before 0.5, which was usual in the previous work, is not the necessary relation between the activity and the chemical composition. An excessive addition of chromic acid may certainly cause decrease in the activity, since chromic acid alone is no more an active catalyst than zinc oxide alone, but an exact representation of the activity change in the intermediate range of the Cr/Zn ratio has not been established as yet*4.

Catalyst Composition and Specific Catalytic Activity per Unit Surface Area.—By dividing the activity per gram of the catalyst by the specific surface area, the specific catalytic activity per unit surface area is obtained, and is plotted against the Cr/Zn ratio of the catalyst in Fig. 6. Over a wide range of the relatively high ratios, the specific activities for both the synthesis and the decomposition vary a little, gradually approaching either one of catalyst S. However, in the range of the low Cr/Zn ratio the specific activity for the synthesis rises with the increasing Cr/Zn ratios, whereas the one for the decomposition indicates the opposite.

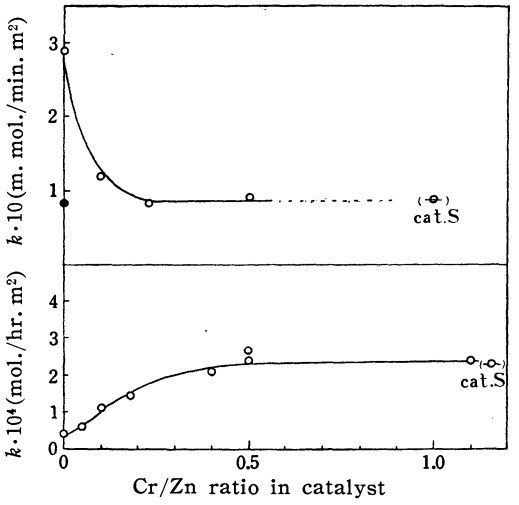

Fig. 6. Relation between Cr/Zn ratio in catalyst and specific activity per unit surface area.
above, decomposition; below, synthesis.
● shows the specific activity determined on catalyst A-0 after having been used in the synthesis.

*4 In this respect a catalyst prepared by coprecipitation of hydroxides of zinc and chromium from a mixed solution of the nitrates was at first expected to give information, however it has proved difficult to obtain a catalyst of homogeneous structure as well as one of moderate activity by this procedure of preparation.

It was at first sight apparently difficult to explain the results thus seemingly inconsistent with each other, but soon the following fact could shed some light upon the subject: the catalysts without and with a little chromic acid content turned gray after having been used in the synthesis for a few days, and came to give far lower activity for the decomposition than the original one having the clean surface, while regarding the catalyst of the higher chromic acid content neither darkening of the catalyst nor decrease in the activity for the decomposition occurred. This shows easier contamination of the surface of the former catalyst with carbon from carbon monoxide decomposition during the synthesis. If the catalyst surface remained clean, the series of catalysts with none and with a little chromic acid content should show the downward tendency of the activity for the synthesis with the increasing chromic acid contents.

At any rate change in the activity based on unit surface area is far smaller than that in the activity based on unit mass (volume) of the catalyst. This suggests an apparent proportionality of the catalytic activity to the extent of the specific surface area, and furthermore, when combined with the relation of the specific surface area to the Cr/Zn ratio, an intercrystalline promoting effect of chromic acid.

Relation of Catalyst Composition to Activation Energy and Frequency Factor in Methanol Synthesis and Decomposition.—From Arrhenius' plots of the rate constants of the synthesis and the decomposition, the constants being based on unit specific surface area, the activation energy and frequency factor have been evaluated*5. Fig. 7 shows the plots of the energy and factor vs. the Cr/Zn ratio in the catalyst. Both of the plots similarly fall with the increasing Cr/Zn ratio rapidly at first, and then asymptotically approach respective minimum values of catalyst S*6.

The addition of chromic acid thus causes decreases in both the frequency factor and the activation energy. The decrease in the former necessarily results in the fall

*5 In our previous paper the plots on the rate of decomposition were given on the catalysts of a different procedure of preparation, and were found intersecting with each other at a definite $1/T$. In the present results the plots certainly show different slopes, but no intersection appears in the temperature range which is far lower than that in the previous paper.

*6 Although the syntheses were not always conducted on the clean catalyst surface, the present tendency may be considered still inherent to the clean one.

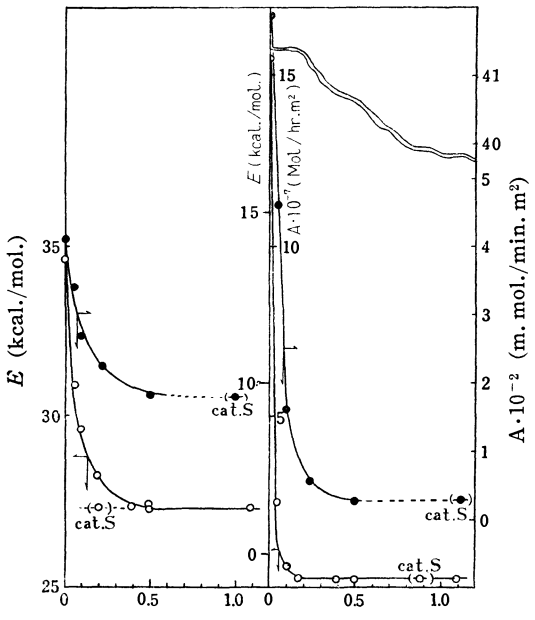

Fig. 7. Relation of Cr/Zn ratio in catalyst to activation energies and frequency factors of reactions.
○, synthesis: ●, decomposition.

of the specific activity per unit surface area, which is simultaneously compensated with decrease in the latter. Consequently the specific activity per unit specific surface area can be maintained at the level of catalyst S, presumably a zinc chromite spinel, of moderate activity.

At first sight one may be apt to consider chromic acid simply an intercrystalline promoter, namely a structural promoter responsible for production of high-area structure, but closer investigation as mentioned above leads us to the conclusion that chromic acid behaves not only as an intercrystalline but also as an intracrystalline promoter, namely a promoter modifying the structure of the catalyst advantageously for preservation of the specific activity*7. Moreover, we should like to emphasize the effect of chromic acid addition upon the improvement of the selectivity and prevention of carbon monoxide decomposition on the catalyst surface, which are suggestive rather of a intracrystalline than an intercrystalline promoting effect.

*7 Natta stated that chromium oxide was an intercrystalline promoter because of there being little change in the activation energy of the synthesis by the addition.

Summary

The catalysts have been prepared from pastes of zinc oxide powder kneaded with chromic acid solutions of different concentrations. From the pastes two series of the catalysts have been produced, namely the one directly from the paste and the other from the solid, free of the liquid, in the paste. Only the results on the latter series can give the correct relation of the catalyst composition to the catalytic activity, which indicates the activity rising with the higher chromic acid contents to an asymptotic maximum at the Cr/Zn ratio of 0.5.

The catalytic activity on the catalysts of different Cr/Zn ratios almost parallels the specific surface area of the catalysts, while the specific activity based on unit specific surface area of the catalysts changes in a far less degree than the change in activity per unit gram of the catalyst. These suggest an intercrystalline promoting effect of chromic acid. Moreover the closer investigation on the activity reveals that both the activation energy and the frequency factor of the reactions which are based on unit surface area show a downward tendency with the increasing Cr/Zn ratios asymptotically to their respective minimums of presumable zinc chromite spinel. This shows besides an intracrystalline promoting effect of chromic acid.

Within the range of the present study, hardly any effect of chromic acid addition undesirable to the selectivity in the synthesis has been found.

Non-exchange of Sulfur Atoms between Sulfate and Sulfonate Ions

By Mitsuo MURAMATSU

(Received October 3, 1958)

Many works have been undertaken to determine whether the sulfur atoms in an organic molecule can exchange themselves with those in a molecule of another compound[1]. According to the reports published up to the present, a measurable rate was observed in the exchange reactions between alkyl disulfides and trisulfides[2], elementary sulfur and organic substances containing S-S or C=S bond[3], sulfite and alkylthiosulfates[4], and alkylpolysulfides and alkylmercaptides[5]. These facts may be explained by the easiness of opening and subsequent closing of sulfur bond in organic compounds. However, no exchange seemed to be reported between other sulfur-containing compounds[1].

In order to obtain further information regarding the lability of sulfur bond and to study the possibility of introducing radioactive sulfur atoms into the molecules of organic compounds, the present author has attempted to study the exchangeability of sulfur atom in sulfate with that in sulfanilate, naphthionate, β-naphthalenesulfonate, *o*-nitrophenolsulfonate, *o*-carboxybenzenesulfonate, *m*-nitrobenzenesulfonate and taurine.

Experimental

Sodium salts of taurine, sulfanilic acid and naphthionic acid were of reagent grade. Ammonium *o*-carboxybenzenesulfonate, sodium *m*-nitrobenzenesulfonate, *o*-nitrophenolsulfonate and β-naphthalenesulfonate were synthesized. All these sulfonates were recrystallized repeatedly and were dissolved to make a stock solution of 0.25 M. The solution of radioactive sulfate having specific activity of 10 mC/mol. was prepared by dissolving purified sodium sulfate into a solution of carrier-free $^{35}SO_4^{2-}$, to make a solution of 0.25 M.

Four cc. portions of sulfonate and sulfate solutions were transferred into a measuring flask and made up exactly to 10 cc. and to a desired acidity with distilled water and dilute hydrochloric acid or aqueous ammonia. The reaction mixture was then transferred into a reaction flask to which a reflux condenser was attached and was kept at desired temperature.

After the supposed exchange reaction, inorganic sulfate was separated as barium salt and the specific activity of the precipitate and the remaining sulfonate in the filtrate was determined separately after purification. In the case of naphthionate, another method of separation was also adopted; hydrochloric acid was added to the reaction mixture and the specific activity of naphthionic acid formed was determined.

Radioactivity of each sample was measured by means of an end-window type GM counter. The quantity of the sample to be counted was little enough to ignore the self absorption of soft β-ray of sulfur-35.

Results and Discussion

It was observed that no measurable exchange of sulfur took place between sulfate and any organic sulfonates during a few decades of hours at temperature up to 91±2°C or during six months at room temperature. This was indeed the case at any pH from 2 to 10. Separation-induced exchange did not take place for any compounds studied, irrespective of the method of separation. Typical examples are shown in Table I.

Such a difficulty of exchange may be ascribed to the firm C–S bond in the sulfonate ion, rather than the S=O bond in the sulfate. Actually, a slow rate of exchange of the oxygen atom in the reaction of sulfate ion with $H_2{}^{18}O$[6] is not sufficient to explain the present results. Such a conclusion is in accord with what is familiar in organic chemistry.

The author wishes to thank Professor T. Sasaki for his criticism and many helpful suggestions. The cost of this research was defrayed from the Scientific Research Expenditure of the Ministry of Education.

Ion-Exchange Separation of Cerium and Thorium with Lead-EDTA Complex as Eluting Agent

By Tomitsugu TAKETATSU

(Received October 11, 1958)

Vickery[1] reported that when EDTA was used as eluant, separation of two metal ions by ion-exchange resin became more effective by introducing a third metal ion having a peak position of elution between those of the two ions, than the separation without the third metal ion. The method, using a third metal-EDTA complex solution as eluant was studied in this paper, instead of adding the third metal ion to the sample solution. Schwarzenbach et al.[2] determined the formation constants of cerium(III)-, lead(II)- and thorium(IV)-EDTA complexes and gave values $10^{16.0}$, $10^{18.0}$ and $10^{23.2}$, respectively. The separation of cerium and thorium ions was tried here by cation exchange resin with lead-EDTA.

Experimental

Reagents and apparatus.—Solution of lead-EDTA complex in various concentrations was prepared by adding a measured volume of a 0.1 mole solution of disodium salt of ethylenediaminetetraacetic acid to a 0.1 mole lead nitrate solution of the same volume, the pH controlled with aqueous ammonia and nitric acid and filled up to 1000 ml. with distilled water. Thorium or cerium standard solutions were prepared by dissolving their nitrate in distilled water and the concentrations were determined gravimetrically as their oxides. The results were 5.38 mg./ml. (ThO_2) and 12.00 mg./ml. (CeO_2).

The cation exchange resin Dowex 50 of ammonium form and of 50×100 mesh was used in a column of 5 cm.×0.6 cm^2.

General procedure.—The following procedure was recommended. A slightly acidic mixed solution of cerium and thorium ions was poured over the top of the column and the ions were adsorbed on the resin bed. After the resin bed was washed with 100 ml. of water, 250 ml. of a 0.015 M solution of lead-EDTA complex (pH 3.0) was passed through the column at a flow rate of 1.0~1.5 ml./min. in order to elute thorium ions. It was again washed with 100 ml. of water and cerium ions were eluted with 3 N hydrochloric acid. Lead ions remaining in the column were

1) R. C. Vickery, *J. Chem. Soc.*, **1952**, 4357.
2) G. Schwarzenbach, R. Gut and G. Anderegg, *Helv. Chim. Acta*, **37**, 937 (1954).

precipitated as lead chloride but gradually redissolved in hydrochloric acid and eluted from the resin bed.

Analytical method.—The first effluent containing thorium and lead ions was dried up, and treated with concentrated sulfuric and nitric acid to decompose EDTA[3]. Lead ions were thus removed as lead sulfate. The second effluent containing cerium and lead ions was similarly treated. Cerium and thorium ions were precipitated with aqueous ammonia and their concentrations determined gravimetrically as oxides.

Results and Discussion

The quantities of thorium and cerium used were 26.9 mg. (ThO_2) and 44.1 mg. (CeO_2), respectively. The effects of various conditions of the eluant on the rate of separation were examined, i.e., the concentration of lead-EDTA complex solution, the pH and the flow rate.

Effect of the concentration.—Lead-EDTA complex solution with concentrations varying from 0.010 to 0.020 mole was used as eluants. The pH value was fixed at 3.0 and the flow rate at 1.5 ml./min. Each 100 ml. of the effluents was collected and the concentration of thorium or cerium ions was determined. The data obtained are given in Fig. 1.

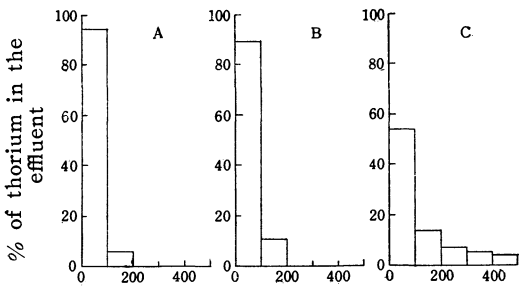

Fig. 1. Elution of thorium ion at different concentrations of eluants.
A: 0.020 mol. lead-EDTA complex solution.
B: 0.015 mol. lead-EDTA complex solution.
C: 0.010 mol. lead-EDTA complex solution.

It can be seen that thorium ions were completely eluted with 200 ml. of 0.020 and 0.015 mole eluants but incompletely with 500 ml. of 0.010 mole eluants. On the other hand, cerium ions were not eluted with the eluants under the same conditions.

Effect of pH.—In order to determine the optimum pH, 0.015 mole eluants of pH 2.4, 3.0 and 4.7 were used. The elution graphs for thorium ions are shown in Fig. 2.

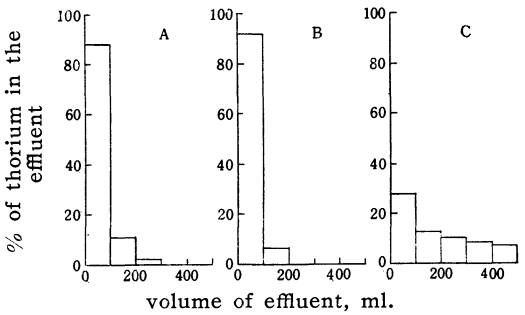

Fig. 2. Elution of thorium ion at different pH values of eluants.
A: pH 2.4 B: pH 3.0 C: pH 4.7

The data indicate that thorium ions were most effectively eluted at pH 3.0, whereas cerium ions were not eluted in the range of pH between 2.4 and 4.7.

Effect of flow rate.—The flow rate studied was 0.6, 1.2 and 2.0 ml./min. Each 50 ml. of the effluent was collected and the concentration of thorium ions was determined. The results are shown in Fig. 3.

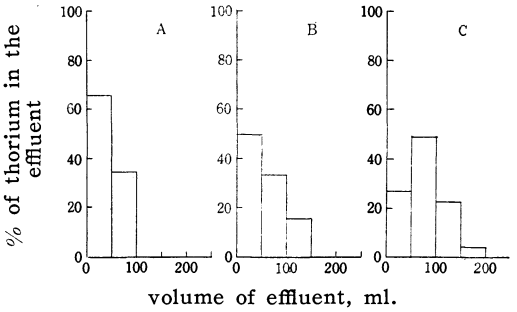

Fig. 3. Elution of thorium ion at different flow rates.
A: 0.6 ml./min. B: 1.5 ml./min.
C: 2.0 ml./min.

From the elution graphs it can be seen that the amount of thorium ions in the effluent increases with decrease of the flow rate. However, a flow rate of 1.0~1.5 ml./min. was employed to make the time taken for an experiment reasonable. Cerium ions were not eluted at any flow rate of the eluant.

The optimum conditions for the separation were as follows: the concentration of the lead-EDTA complex solution was 0.015 mole, pH 3.0 and the flow rate 1.0~1.5 ml./min. Fig. 4 shows that cerium ions

3) W. F. Hillebrand and G. E. F. Lundell, "Applied Inorganic Analysis" (1929), John Wiley & Sons, Inc., New York, p. 61.

were not eluted even with 1000 ml. of the lead-EDTA solution at the optimum conditions.

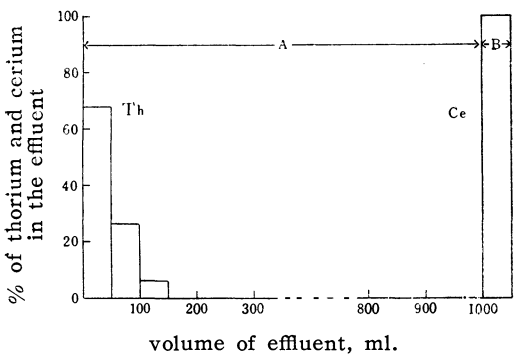

Fig. 4. Elution graph of thorium and cerium.
eluant { A: 0.015 ml. lead-EDTA complex solution.
B: 3 N HCl solution.

On the other hand, when only an EDTA solution of the concentration of 0.015 mole was used as eluant at pH 3.0 and at a flow rate 1.0~1.5 ml./min. instead of the lead-EDTA complex solution, cerium ions began to flow out even in the first fraction of the volume of 50 ml. This shows that lead ions as the third element in the lead-EDTA complex gave a remarkable effect on the efficiency of the separation.

The results of analyses for various quantities of the two ions by this procedure are shown in Table 1.

TABLE I
SEPARATION OF CERIUM AND THORIUM IONS

Taken. (mg.)		Found. (mg.)			
ThO_2	CeO_2	ThO_2	Error	CeO_2	Error
39.5	19.6	39.7	+0.2	19.6	±0.0
26.9	12.0	26.9	±0.0	11.7	−0.3
53.8	12.0	53.6	−0.2	11.9	−0.1

A qualitative detection by the fluorescent X-ray spectrometer "Norelco" showed that there was neither cerium in the thorium oxide fraction nor thorium in the cerium fraction. Thus, it was concluded that the separation of cerium and thorium ions was quantitatively carried out.

At the optimum conditions of the separation of cerium and thorium ions, the behavior of other rare earth ions was examined. Rare earth ions, i.e., lanthanum, cerium, praseodymium, neodymium, dysprosium and yttrium and a trace of thorium were extracted from allanite and adsorbed on the resin bed. The total weight of their oxides was about 123.2 mg. After 250 ml. of the 0.015 mole lead-EDTA solution (pH 3.0) was passed through the resin bed, the rare earth and thorium ions in the effluent and in the resin bed were separately determined gravimetrically as oxides. Each rare earth oxide was qualitatively detected by the fluorescent X-ray spectrometer. Heavy lanthanons, gadolinium, dysprosium and yttrium and thorium (total oxides 11.1 mg.) were detected in the effluent; on the other hand, light lanthanons, lanthanum, cerium, praseodymium, neodymium, samarium and gadolinium (total oxides 112.0 mg.) were found to remain in the resin bed.

Further studies are under way on the separation of the rare earths with the lead- and other-EDTA complex solutions as eluants.

Summary

The separation of cerium and thorium ions was studied with a lead-EDTA complex solution as eluant. The optimum conditions were determined as the following: the concentration of the lead-EDTA solution was 0.015 mole, pH 3.0 and the flow rate 1.0~1.5 ml./min. Thorium ions were completely eluted with 200 ml. of the eluant at the optimum conditions, while no cerium ions were detected in the effluent with 1000 ml. of the eluant. Thus the use of a lead-EDTA complex solution as eluant was concluded to be effective for separation of cerium and thorium ions.

The author wishes to express his gratitude to Professor S. Misumi for his valuable discussion and encouragement.

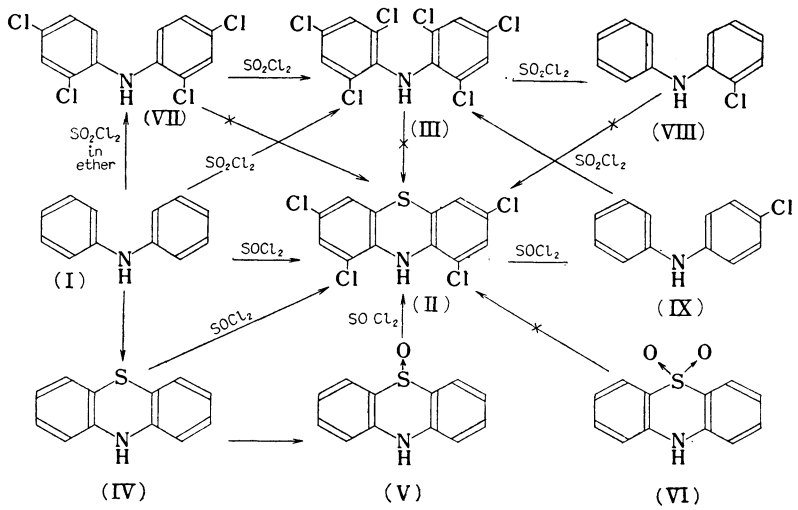
Phenothiazine Derivatives. III[1]. *Mechanism of the Reaction of Diphenylamine with Thionyl Chloride*

By Manabu FUJIMOTO

(Received September 24, 1958)

In the preceding paper[1] of this series, it was reported that diphenylamine (I) reacts violently with thionyl chloride, thionyl bromide and sulfuryl chloride, and that thionyl chloride transforms diphenylamine (I) into 1,3,7,9-tetrachlorophenothiazine (II), while thionyl bromide and sulfuryl chloride transforms it merely into 2,4,6,2′,4′,6′-hexabromodiphenylamine and the corresponding hexachlorodiphenylamine (III), respectively, as shown schematically in Chart I, where arrows with crosses indicate that the expected changes do not take place by the action of thionyl chloride.

Thionyl bromide is less stable than thionyl chloride, decomposing slowly even at room temperature as follows:



$$4SOBr_2 \rightarrow S_2Br_2 + 3Br_2 + 2SO_2$$

Therefore, in its reaction with diphenylamine (I) it gives an extensively brominated product, hexabromodiphenylamine. On the other hand, the sulfonyl group in sulfuryl chloride is so stable that the reagent can react with diphenylamine (I) only as a chlorinating agent (Chart I).

The present paper deals with the characteristic reaction of thionyl chloride with diphenylamine which has been further studied closely. The reaction involves at least two processes, namely, phenothiazine ring formation and chlorination of the benzene nuclei, but the sequence of the two processes is to be determined.

As already reported[1], phenothiazine (IV) and its 5-oxide (V) react with thionyl chloride to form the same tetrachlorophenothiazine (II). Nevertheless, it has now been found that the hexachlorodiphenylamine (III), 2,4,2′,4′-tetrachlorodiphenylamine (VII)[2], 2-chlorodiphenylamine (VIII) and phenothiazine 5,5-dioxide (VI) do not react with thionyl chloride. On the other hand, the tetrachlorophenothiazine (II) was obtained from the reaction of 4-chlorodiphenylamine (IX) and thionyl chloride. Therefore, it may be concluded that the first process of the reaction giving the chlorinated phenothiazine is the sulfur-bridge formation to

CHART I

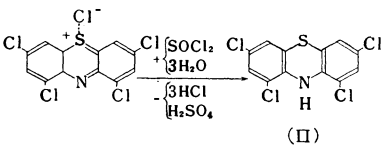
TABLE I



Solvent	Thionyl chloride (g.)	Volume of solvent (ml.)	Time of reflux	Recovered diphenylamine (%)	Diphenylamine hydrochloride (%)	Tetrachlorophenothiazine (%)
Benzene	0.7	30	1 hr.	71	26	2
	4.2	〃	〃	78	—	10
Carbon tetrachloride	0.7	20	〃	80	13	—
	4.2	〃	30 min.	58	33	—
	〃	〃	8 hr.	57	—	28

give the phenothiazine ring system, followed by the chlorination to yield the final product II.

It was expected that dilution with an inert solvent, such as benzene or carbon tetrachloride, might moderate the reaction and make it possible to catch an intermediate of the phenothiazine type, such as phenothiazine (IV), its 5-oxide (V), phenazathionium chloride or hydroxide. But moderation of the reaction gave mainly diphenylamine hydrochloride along with a small amount of the final product II (Table I). This result can be interpreted by assuming that the dilution with an inert solvent retards greatly the first process of phenothiazine formation, but the chlorination of the phenothiazine once formed is relatively rapid.

In the reaction of diphenylamine to give the tetrachlorophenothiazine (II), color development of brown to dark green and the presence of sulfur monochloride or dichloride in the thionyl chloride in reflux are always observed, which facts suggest intermediate formation of phenazathionium chloride, because it is known that penazathionium chloride and hydroxide form dark brown needles[3]. Thus the reaction mechanism may be represented as follows:

As phenothiazine 5,5-dioxide is a sulfone, so it would not be transformed into a phenazathionium compound, and thus it can reasonably be expected that it will resist the attack by thionyl chloride.

Experimental

Treatment with Thionyl Chloride. — The general procedure for the treatment with thionyl chloride was as follows. To a diphenylamine or a phenothiazine derivative (1 g.), 10 ml. of thionyl chloride was added dropwise, and the mixture was heated gently under reflux for 5 min. Hydrogen chloride and sulfur dioxide were evolved when a reaction took place. The cooled solution was poured onto crushed ice. 1,3,7,9-Tetrachlorophenothiazine (II) was obtained yellow crystals from diphenylamine (I), phenothiazine (IV), the 5-oxide (V) and 4-chlorodiphenylamine (IX). Recrystallized from benzene, it showed m.p. 235 ~236°C. The yield was nearly quantitative. 2,4,6,2',4',6'-Hexachlorodiphenylamine (III), 2,4,2',4'-tetrachlorodiphenylamine (VII), 2-chlorodiphenylamine (VIII) and phenothiazine 5,5-dioxide (VI) were recovered intact.

Treatment of Diphenylamine with Thionyl Chloride in Solution. — Diphenylamine (1 g.) was dissolved in a solvent, and thionyl chloride dissolved in the same solvent was added drop by drop. The mixture was refluxed, cooled, and poured on ice. After filtration, the organic layer was separated, dehydrated over sodium sulfate, and passed through a column of alumina. Elution first with the same solvent and then with a mixture of the solvent and acetone gave the results listed in Table I.

Diphenylamine Hydrochloride. — Recrystallized from methanol-ethyl acetate. Colorless needles, m.p. 195~196°C (decomp.).

Anal. Found: C, 69.80; H, 5.96; N, 6.75. Calcd. for $C_{12}H_{12}NCl$: C, 70.04; H, 5.88; N, 6.81 %.

Treatment with Sulfuryl Chloride. — One gram of each of diphenylamine (I), and chlorinated diphenylamines, VII, VIII and IX, was treated with 10 ml. of sulfuryl chloride. When the initial violent reaction ceased, the solution was refluxed for 30 min., and poured onto crushed ice. The precipitate was collected, dried, and recrystallized from ethanol. The product was always 2,4,6,2',4',6'-hexachlorodiphenylamine (III) which was obtained in colorless needles, m.p. 138~139°C. The yield was quantitative. 2,4,2',4'-Tetrachlorodiphenylamine (VII) was prepared from diphenylamine by the action of sulfuryl chloride in ethyl ether[2]. Colorless needles, m.p. 141~142°C (from acetic acid). Yield, 74%.

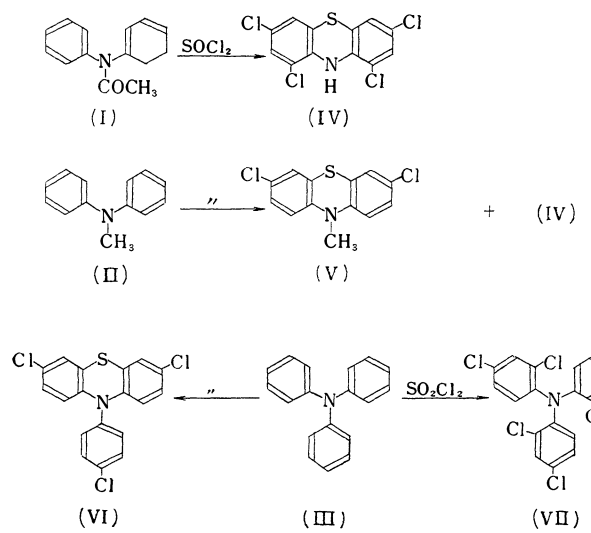
Phenothiazine Derivatives. IV[1]*. Reactions of Thionyl Chloride with Some Substituted Diphenylamines and with Naphthylphenylamines*



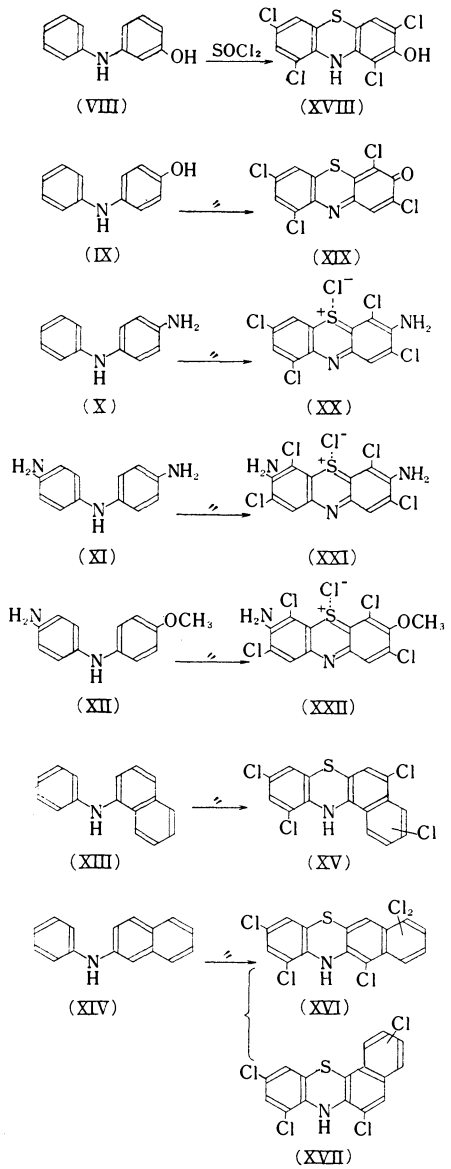
By Manabu FUJIMOTO

(Received September 24, 1958)

In part III[1] of this series, the reaction of thionyl chloride with diphenylamine was investigated in detail. The present paper describes similar reactions of thionyl chloride with some substituted diphenylamines and with naphthylphenylamines.

***N*-Substituted Diphenylamines.** — *N*-Acetyldiphenylamine (I), methyldiphenylamine (II), and triphenylamine (III) were treated with thionyl chloride with results represented schematically in Chart I. While *N*-acetyldiphenylamine (I) was completely transformed into 1,3,7,9-tetrachlorophenothiazine (IV), methyldiphenylamine (II) gave 7% of 3,7-dichloro-10-methylphenothiazine (V)[2] besides 89% of the same tetrachlorophenothiazine (IV). It appears that the substituents on the nitrogen atom exerted some steric hindrance on the *ortho* positions to the nitrogen atom, and they were either removed to give way to chlorine atoms entering these positions or retained to hinder chlorination in these positions. With thionyl chloride, triphenylamine (III) gave a nearly quantitative yield of a product $C_{18}H_{10}NCl_3S$, which is probably 3,7-dichloro-10-(4′-chlorophenyl)phenothiazine (VI) considered on the basis of the orienting and the steric effects, but with sulfuryl chloride it gave a hexachlorotriphenylamine in a high yield, which is supposed to be 2,4,2′,4′,2″,4″-hexachlorotriphenylamine (VII) from a similar consideration.

CHART I



1) Part III: This Bulletin, **32**, 294 (1959).

2) A. C. Schmalz and Burger, *J. Am. Chem. Soc.*, **76**, 5458 (1954).

Diphenylamines Substituted in the Benzene Nuclei.—2-, 3- and 4-nitrodiphenylamines were found inert to thionyl chloride, and likewise, phenyl-(2-, 3-, and 4-)tolylamines did not give the corresponding phenothiazines. On the other hand, 3-hydroxy- (VIII), 4-hydroxy- (IX), 4-amino- (X), 4,4'-diamino- (XI) and 4-amino-4'-methoxy- (XII) diphenylamines reacted normally, as shown in Chart II. Assign-

CHART II

ment of the structures to the products is discussed below.

As observed previously[1], the reaction of unsubstituted diphenylamine with thionyl chloride proceeds through the formation of the intermediate phenazationium chloride and subsequent chlorination to give 1,3,7,9-tetrachlorophenothiazine, which shows that positions 1,3,7 and 9 of the intermediate phenazathionium chloride are rendered reactive in the chlorination by the effect of the nitrogen atom (position 10). 3-Hydroxydiphenylamine (VIII) is expected to produce 2-hydroxyphenazathionium chloride as the intermediate, in which the hydroxyl group will favor chlorination in positions 1 and 3. Thus, the product $C_{12}H_5ONCl_4S$ from 3-hydroxydiphenylamine (VIII) and thionyl chloride is assumed to be 1,3,7,9-tetrachloro-2-hydroxyphenothiazine (XVIII). Nevertheless, in the redundant 3-substituted phenazathionium intermediates from 4-hydroxy- (IX) and 4-amino- (X) diphenylamines, the hydroxyl group and the amino group in position 3 will orient chlorination to positions 2 and 4. As the hydroxyl group and the amino group have stronger orienting effects than the imino group, it is expected that positions 2, 4, 7 and 9 of the 3-substituted phenazathionium intermediates are reactive toward chlorination. Thus, the phenothiazone $C_{12}H_3ONCl_4S$ obtained from 4-hydroxydiphenylamine (IX) is assumed to be 2,4,7,9-tetrachloro-3-phenothiazone (XIX), and the phenazathionium chloride $C_{12}H_5N_2Cl_5S$ obtained from 4-aminodiphenylamine (X) to be 3-amino-2,4,7,9-tetrachlorophenazathionium chloride (XX). For similar reasons, the product $C_{12}H_6N_3Cl_5S$ from 4,4'-diaminodiphenylamine (XI) and thionyl chloride is supposed to be 3,7-diamino-2,4,6,8-tetrachlorophenazathionium chloride (XXI), and the product $C_{13}H_7ON_2Cl_5S$ from 4-amino-4'-methoxydiphenylamine (XII) and thionyl chloride to be 3-amino-2,4,6,8-tetrachloro-7-methoxyphenazathionium chloride (XXII). 2-Hydroxydiphenylamine gave exceptionally only an unpurifiable black tarry mass.

Naphthylphenylamines. — α-Naphthylamine (XIII) reacted normally with thionyl chloride to form a single product $C_{16}H_7NCl_4S$, probably x,5,9,11-tetrachlorobenzo[a]phenothiazine[3] (XV). There are two possibilities for the positions of cyclization in β-naphthylphenylamine (XIV), and in fact two products with formulae $C_{16}H_6NCl_5S$ and $C_{16}H_7NCl_4S$, respectively, were separated chromatographically from the reaction mixture of β-naphthylphenylamine (XIV) and thionyl chloride (Chart II). The product $C_{16}H_6NCl_5S$ obtained in a larger amount is supposed to be the

linearly cyclized compound, 1,3,x,x',11-pentachlorobenzo[b]phenothiazine[3] (XVI). It melts at 147~149°C, and gives dark blue coloration with sulfuric acid. Then the minor product $C_{16}H_7NCl_4S$ may be x,6,8,10-tetrachlorobenzo[c]phenothiazine[3] (XVII). It melts at 217~219°C (decomp.) and produces dark green color with sulfuric acid. These two benzophenothiazines could not be distinguished from each other in the ultraviolet and infrared absorption spectra.

Experimental

Thionyl chloride (10 ml.) was added dropwise to 1.0 g. of the compound to be treated with the reagent, and the mixture was gently heated under reflux for 30 min., when hydrogen chloride and sulfur dioxide were evolved. The cooled mixture was poured onto ice, and the product was collected and dried. The following substances were obtained, depending upon the starting materials.

1,3,7,9-Tetrachlorophenothiazine (IV) and 3,7-Dichloro-10-methylphenothiazine (V).—The mixed product, obtained from methyldiphenylamine (II) as the starting material, was recrystallized from a mixture of ethanol and benzene. 1,3,7,9-Tetrachlorophenothiazine (IV), m.p. 235~236°C, crystallized out in yellow needles in a yield of 89%. The mother liquor was evaporated, and the residue was recrystallized from 50% aqueous ethanol. 3,7-Dichloro-10-methylphenothiazine (V), m.p. 129~130°C, was obtained in yellowish-green needles in a yield of 7%. The two substances were identified with authentic samples[1,2], respectively. The former IV was also obtained quantitatively from *N*-acetyldiphenylamine (I).

3,7-Dichloro-10-(4'-chlorophenyl)phenothiazine (VI).—Obtained from triphenylamine (III). Yellow fine crystals from benzene, m.p. 131~132°C. Yield, 91%. The substance shows indigo-blue coloration with sulfuric acid.

Anal. Found: C, 57.54; H, 2.89; N, 4.16. Calcd. for $C_{18}H_{10}NCl_3S$: C, 57.09; H, 2.66; N, 3.70%.

1,3,7,9-Tetrachloro-2-hydroxyphenothiazine (XVIII).—Obtained from pure 3-hydroxydiphenylamine (VIII), and recrystallized from chloroform-ethanol. Fine powder with chocolate color, m.p. 202~203°C (decomp.). Yield, 92%. The substance is soluble in 10% aqueous caustic soda, and produces blue-violet color with sulfuric acid.

Anal. Found: C, 40.49; H, 1.54; N, 4.03. Calcd. for $C_{12}H_5ONCl_4S$: C, 40.82; H, 1.43; N, 3.97%.

2,4,7,9-Tetrachloro-3-phenothiazone (XIX).—Derived from freshly distilled 4-hydroxydiphenylamine (IX). White crystals with pinkish tinge from ethanol-benzene, m.p. 145~146°C. Yield, nearly quantitative. It gives cobalt-blue coloration with sulfuric acid.

Anal. Found: C, 41.11; H, 1.01; N, 4.00. Calcd. for $C_{12}H_3ONCl_4S$: C, 41.06; H, 0.86; N, 3.99%.

3-Amino-2,4,7,9-tetrachlorophenazathionium Chloride (XX).—Obtained from freshly rectified 4-aminodiphenylamine (X). Reddish-violet fine powder from chloroform, m.p. 185~186°C. Yield, 86%. It gives reddish-violet coloration with sulfuric acid.

Anal. Found: C, 37.40; H, 1.10; N, 7.30. Calcd. for $C_{12}H_5N_2Cl_5S$: C, 37.28; H, 1.30; N, 7.25%.

3,7-Diamino-2,4,6,8-tetrachlorophenazathionium Chloride (Tetrachlorothionine) (XXI).—From pure 4,4'-diaminodiphenylamine. Bluish-purple fine powder from methanol, m.p. over 360°C. Yield, 94%. It gives dark green coloration with sulfuric acid.

Anal. Found: C, 36.13; H, 1.78; N, 10.46. Calcd. for $C_{12}H_6N_3Cl_5S$: C, 35.90; H, 1.51; N, 10.47%.

3-Amino-2,4,6,8-tetrachloro-7-methoxyphenazathionium Chloride (XXII).—Obtained from 4-amino-4'-methoxydiphenylamine (XII). Bluish-violet fine powder from methanol, m.p. 281~284°C (decomp.). Yield, 82%. Its color in sulfuric acid is bluish violet.

Anal. Found: C, 37.22; H, 1.41; N, 6.97. Calcd. for $C_{13}H_7ON_2Cl_5S$: C, 37.47; H, 1.69; N, 6.73%.

x,5,9,11-Tetrachlorobenzo[a]phenothiazine (XV).—One gram of α-naphthylphenylamine (XIII) gave 1.7 g. (96%) of this compound (XV) in reddish-violet fine crystals, which was purified chromatographically, and then recrystallized from benzene, m.p. 266~268°C. Its coloration with sulfuric acid is bluish violet.

Anal. Found: C, 49.43; H, 2.19; N, 3.15. Calcd. for $C_{16}H_7NCl_4S$: C, 49.65; H, 1.82; N, 3.62%.

1,3,x,x',11-Pentachlorobenzo[b]phenothiazine (XVI) and x,6,8,10-Tetrachlorobenzo[c]phenothiazine (XVII).—One gram of β-naphthylphenylamine (XIV) gave 1.8 g. of a crude crystalline mixture. The mixture was dissolved in 20 ml. of benzene, and passed through a column of alumina. The chromatogram was eluted first with the same solvent and then developed with a mixture of chloroform and ethanol. The first fraction gave a substance in yellow fine crystals, which was assumed to be 1,3,x,x',11-pentachlorobenzo[b]phenothiazine (XVI). Recrystallized from chloroform-ethanol, it melts at 147~149°C and gives dark blue coloration with sulfuric acid, Yield, 1.2 g. (62%).

Anal. Found: C, 45.32; H, 1.88; N, 3.07. Calcd. for $C_{16}H_6NCl_5S$: C, 45.57; H, 1.43; N, 3.32%.

The second fraction, which was strongly fluorescent in solution, gave another substance in fine yellow crystals, which was assumed to be the other possible product, x,6,8,10-tetrachlorobenzo[c]phenothiazine (XVII). Recrystallized from chloroform-ethanol, it melts at 217~219°C (decomp.). Yield, 0.5 g. (28%). It gives dark green coloration with sulfuric acid.

Anal. Found: C, 49.70; H, 2.04; N, 3.57. Calcd. for $C_{16}H_7NCl_4S$: C, 49.65; H, 1.82; N, 3.62%.

Reaction of Triphenylamine (III) with Sulfuryl Chloride.—Sulfuryl chloride (10 ml.) was added to 1.0 g. of triphenylamine (III), and the mixture was gently refluxed for 30 min., and

3) The nomenclature of these benzophenothiazines conforms to the "Ring Index" (1940).

poured onto crushed ice. The precipitate was collected, dried, and recrystallized from ethanol. 2,4,2',4',2'',4''-Hexachlorotriphenylamine (VII) was obtained in colorless crystals, m.p. 78~79°C. Yield, 92% of the theory. It remains colorless with sulfuric acid.

Anal. Found: C, 47.66; H, 2.44; N, 3.17. Calcd. for $C_{18}H_9NCl_6$: C, 47.83; H, 2.01; N, 3.10%.

Summary

Reactions of thionyl chloride with some substituted diphenylamines and with naphthylphenylamines were studied. *N*-Acetyldiphenylamine gave the known 1,3,7,9-tetrachlorophenothiazine. Methyldiphenylamine gave a small yield of the known 3,7-dichloro-10-methylphenothiazine besides the same tetrachlorophenothiazine as the main product. The following new compounds were obtained from respective starting materials and their structures were deduced: 3,7-dichloro-10-(4'-chlorophenyl)-phenothiazine from triphenylamine, 1,3,7,9-tetrachloro-2-hydroxyphenothiazine from 3-hydroxydiphenylamine, 2,4,7,9-tetrachloro-3-phenothiazone from 4-hydroxydiphenylamine, 3-amino-2,4,7,9-tetrachlorophenazathionium chloride from 4-aminodiphenylamine, 3,7-diamino-2,4,6,8-tetrachlorophenazathionium chloride from 4,4'-diaminodiphenylamine, 3-amino-2,4,6,8-tetrachloro-7-methoxyphenazathionium chloride from 4-amino-4'-methoxydiphenylamine, x,5,9,11-tetrachlorobenzo[a]phenothiazine from α-naphthylphenylamine, and 1,3,x,x',11-pentachlorobenzo[b]phenothiazine and x,6,8,10-tetrachlorobenzo[c]phenothiazine from β-naphthylphenylamine.

The author expresses his thanks to Professor Y. Urushibara, the University of Tokyo, for his helpful guidance throughout this work, to Dr. K. Takeda, Director of the Laboratory, for his permission to undertake this research, and also to the members of the Center of Microanalytical Services, Shionogi & Co., Ltd., for the elementary analyses.

Studies on Organic Reagents for Inorganic Analysis. V. m-Nitrophenylfluorone for the Spectrophotometric Determination of Zirconium

By Hirotoshi SANO

(Received September 17, 1958)

For the determination of zirconium, the phenylfluorone (abbreviation for 2,3,7-trihydroxy-9-phenylfluorone) method was recommended previously by the present author and Kimura[1]. The reactions between phenylfluorone and several metals were also studied[2,3]. The method, which is about forty times more sensitive than the alizarin red S method[4], is the most sensitive method for the colorimetric determination of zirconium, but the absorbance of the chelate decreases with increasing acidity in the solution. On the other hand, several derivatives of phenylfluorone were synthesized by the author, and the effect of the substituent on the utility of the derivative as a spectrophotometric reagent was studied[5,6]. The results suggested that *m*-nitrophenylfluorone (abbreviation for 2,3,7-trihydroxy-9-(3′-nitrophenyl)fluorone) was one of the most excellent reagents in view of the sensitivity, stability, and other characteristics. In this paper, detailed procedure for the spectrophotometric determination of zirconium using this reagent is described.

Experimental and Results

Apparatus and Reagents Used. — The absorbance measurements were made with a UVISPEK spectrophotometer using a 10 mm. glass cell. The reference cell contained distilled water for all the measurements, except for the measurement of the absorption spectrum of the chelate, in which the blank solution was used as a reference solution.

Ethanolic solution of m-nitrophenylfluorone was made up in the following way: *m*-nitrophenylfluorone was synthesized from hydroxyhydroquinone triacetate and *m*-nitrobenzaldehyde according to the prescription reported previously[2,3], and 0.120 g. of this reagent was dissolved in 150 ml. of ethanol and 1 ml. of 5 N hydrochloric acid by warming. After being cooled, the solution was diluted to 200 ml. with ethanol.

Ethanolic solution of phenylfluorone was prepared dy dissolving 120 mg. of phenylfluorone in 150 ml. and 1 ml. of 5 N hydrochloric acid, and diluting to 200 ml. with ethanol.

Zirconyl chloride stock solution was prepared by dissolving analytical grade zirconyl chloride octahydrate in 1 N hydrochloric acid, and standardized gravimetrically using distilled aducous ammona. This solution contains 2.07 mg. of zirconium per ml. A working solution was prepared from the stock solution by dilution with dilute hydrochloric acid, every time an experiment was made,

Cyclohexanol.—Reagent grade cyclohexanol was used without further purification.

Ethanol: Reagent grade 99% ethanol was used.

Fundamental Reaction.—The treatment of slightly acidic solution of zirconyl ions with an excess of a standard *m*-nitrophenylfluorone solution results in a color change from yellow to red; an orange-red colored precipitate appears, aftar it is allowed to stand. Various organic solvents, such as acetic acid anhydride, acetone, benzene, carbon disulfide, carbon tetrachloride, chloroform, cyclohexane, cyclohexanol, dioxane, ethanol, ethyl acetate, diethyl ether, ethyl *iso*propyl ketone, *iso*butanol, *iso*propanol, di*iso*propyl ether, methanol, *n*-pentanol, *n*-butanol and petroleum ether were tried to dissolve the precipitate of zirconium *m*-nitrophenylfluoronate, with little success. Then an attempt was made to keep the complex in the supersaturated or colloidal solution with the addition of a suitable stabilizer. A cyclohexanol-ethanol mixed solution was found to be the most favorable stabilizer. In the experiments described below, all the solutions were made to a total volume of 25 ml. The order of the addition of the reagents was always the same. The zirconium solution was added first; and acid, ethanol, cyclohexanol, and ethanolic solution of *m*-nitrophenylfluorone were added in this order.

Spectral absorbance data for the reagent blank and 20.7 μg. of zirconium (following the standard procedure mentioned later) are given in Fig. 1. The absorption maximum of the dye and the chelate was found at 475 mμ and 550 mμ, respectively. The optimum wavelength was taken as 550 mμ because at this point the absorption caused by the blank solution is small and that by zirconium *m*-nitrophenylfluoronate is the greatest.

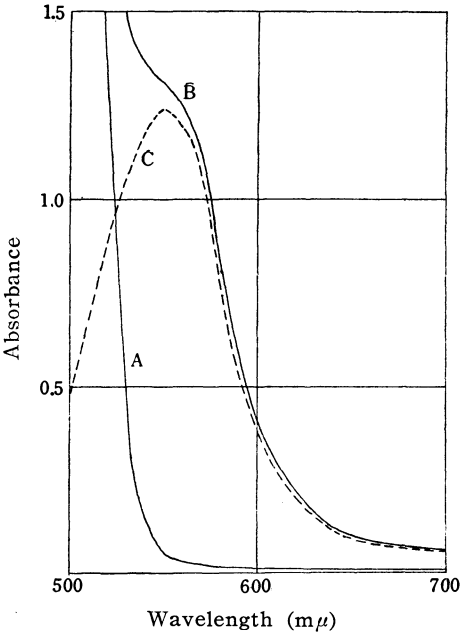

Fig. 1. Absorption spectra.

Curve A: Reagent blank (Reference solution: water)
Curve B: 20.7 μg. Zirconium (Reference solution: water)
Curve C: 20.7 μg. Zirconium (Reference solution: reagent blank solution)

Effect of Cyclohexanol and Ethanol Concentration.—A precipitate of zirconium *m*-nitrophenylfluoronate is obtained after a while from a solution containing no cyclohexanol and less than 5 ml. of ethanol. The colored solution becomes stable as an increasing amount of cyclohexanol is added, but cyclohexanol layer separates from ethanolic water layer when the amount of cyclohexanol becomes relatively great in comparison with that of ethanol. The solution shows no difference in the position of absorption maximum when the amount of cyclohexanol or ethanol added is changed, although there was a slight difference in the detailed shape of the absorption curve. From these results, 2.5 ml. of cyclohexanol, 5 ml. ethanol, and 5 ml. ethanolic solution of *m*-nitrophenylfluorone were taken as the optimum. In this condition, the solution gives no visible precipitate of *m*-nitrophenylfluoronate in zirconium concentration below 3 μg. per 25ml. by being allowed to stand for a day or more.

Effect of Acidity.—The effect of acid concentration upon the absorbance given by 20.7 μg. of zirconium and 3 mg. of *m*-nitrophenylfluorone is illustrated in Fig. 2, together with the case given by 20.7 μg. of zirconium and 3 mg. of

phenylfluorone* for the purpose of comparison. The absorbances shown in Fig. 2, are the values observed thirty minutes after the preparation of the solution. In the acidity range higher than 1.5 N hydrochloric acid concentration, the absorbances increase slowly with increasing digestion time, so the plateau range of the curve extends a little. In the case of *m*-nitrophenylfluoronate the absorbance is almost independent of hydrochloric acid concentration in the region below 0.1 N, whereas no plateau range is found above 0.05 N acid concentration in the case of phenylfluoronate.

Effect of Digestion Time. — The effect of digestion time on the absorbance given by 5.0 μg. of zirconium and 3 mg. *m*-nitrophenylfluorone in 0.1 N hydrochloric acid solution is shown in Fig. 3. In a solution containing zirconium above 4 μg., a precipitate of zirconium *m*-nitrophenylfluoronate is obtained after the solution is allowed to stand for a day, but the stable suspension can regenerate with a short shaking by hand. The absorbance remains nearly constant for forty minutes after the preparation.

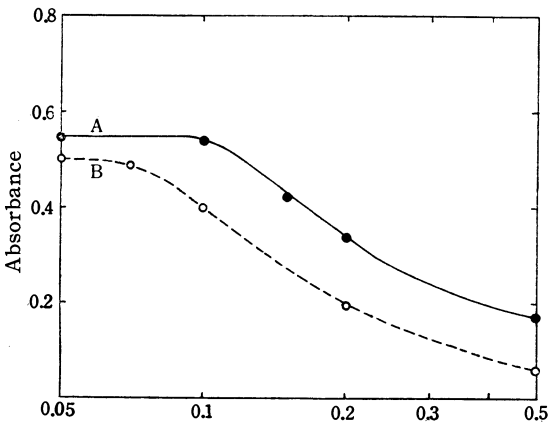

Fig. 2. Effect of acidity.
Curve A: Zirconium *m*-nitrophenylfluoronate (Reference solution: water)
Curve B: Zirconium phenylfluoronate (Reference solution: water)

Standard Procedure.—From the results above mentioned, the following was recommended as the optimum procedure.

Transfer the sample solution (less than 10 ml.) to a 25 ml. volumetric flask. When the sample contains more than 20 to 25 μg. zirconium, an aliquot portion of the sample solution containing the desired amount of zirconium in final volume is pipetted into a 25 ml. volumetric flask. Additional acid will then be required to bring the acidity up to 0.10 N hydrochloric acid used in the determination of zirconium with *m*-nitrophenylfluorone. Adjust the volume to about 10 to 12 ml. with distilled water. Add 5 ml. of ethanol, 2.5 ml. of cyclohexanol, and 5 ml. of ethanolic solution containing 3 mg. of *m*-nitrophenylfluorone in this order. Make up the solution to the mark with distilled water, mix with shaking by hand, allow to stand for an hour, and obtain the absorbance of the solution in the spectrophotometer at 550 mμ using a 10 mm. glass cell and distilled water as a control solution. Determine the amount of zirconium by reference to the standard working curve prepared previously.

Working Curve.—Data for the working curve are given in Fig. 4. These data were obtained following the standard procedure. A straight-line relationship between the absorbance and the amount of zirconium is shown up to 0.6 p. p. m. Solutions containing from 0.6 to 1.0 p. p. m.

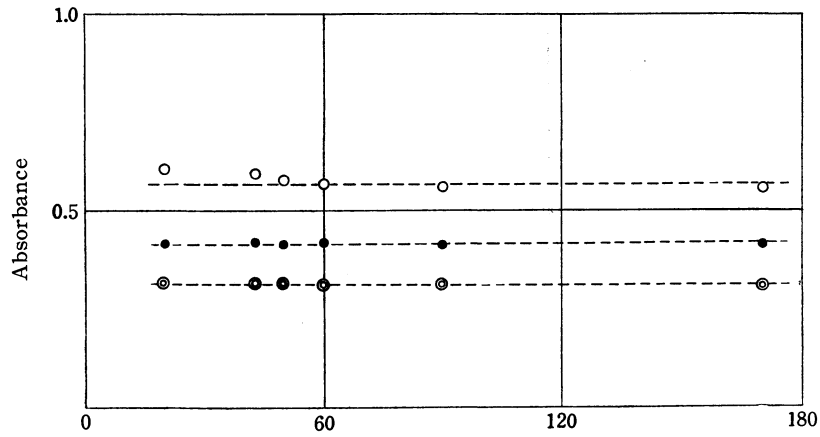

Fig. 3. Effect of digestion time.
-○- 540 mμ (Reference solution: water)
-●- 550 mμ (〃)
-◎- 560 mμ (〃)

* The absorbance measurements were made by a procedure similar to that of *m*-nitrophenylfluoronate.

deviate slightly from Beer's law but their absorbances are reproducible. The region from 0 to 0.10 p. p. m. of zirconium was examined in detail for any deviation from the straight-line relationship, but none was found. In Fig. 4, the working curves used in the Alizarin Red S method[4] and in the Phenylfluorone mothod[1] are shown for the comparison of the sensitivities of the methods.

Effect of Diverse Ions.—The effect of various ions was studied using 0.3 p. p. m. of zirconium. The standard procedure was employed, with the exception that the desired amount of the diverse ion was added into a volumetric flask prior to the addition of the zirconium solution. The concentrations of zirconium and diverse ion are expressed on the basis of the final volume 25 ml. The change in absorbance was then measured at 550 mμ. Errors of less than 3% of the zirconium present were considered to be negligible. A negligible error was obtained with the following maximum about;

2000 p. p. m. of: sodium, potassium, ammonium and magnesium ions.

1000 p. p. m. of: calcium, barium, strontium and mercuric ions.

500 p. p. m. of: lanthanum, neodymium, cerrous, cadmium and zinc ions.

100 p. p. m. of: aluminum and thorium ions.

Chloride, bromide, nitrate (2000 p. p. m.) and sulfate (1000 p. p. m.) ion do not interfere with the reaction. Some elements give interference by increasing the color intensity. Some elements quench the color due to zirconium *m*-nitrophenylfluoronate. Table I lists the interfering ions and their effect. Serious interference is given by the following ions: titanium, germanium, tin, iron (III), antimony, oxalate, phosphate and fluoride.

HPO_4^{2-}	5	20	0.7

Discussion

The color change arising from the reaction of *m*-nitrophenylfluorone with zirconium closely resembles the case of phenylfluorone, namely the shift of the absorption maximum caused by chelate formation is 75 mμ in *m*-nitrophenylfluorone, and 72 mμ in phenylfluorone[2], whereas the differences of the absorption maximum between the phenylfluorone or its zirconium chelate and *m*-nitrophenylfluorone or its zirconium chelate are 7 and 10 mμ, respetively. The trend in the effect of the acidity of the solution on the absorbance is, however, considerably different. In the *m*-nitrophenylfluorone method recommended here the constancy of the absorbance is obtained at the region of the acidity below 0.10 N hydrochloric acid concentration, whereas there is no such constancy in the phenylfluorone method. This will be caused by the effect of the *m*-nitro group attracting the electron of the —OH group at 3 position and increasing the electronegativity of the oxygen atom. Furthermore, it was fortunately found that the absorbance of *m*-nitrophenylfluoronate was greater than that of the corresponding phenylfluoronate. The comparison of the sensitivities by several methods is shown in Fig. 4. The sensitivity of this method, given by the inclination of the working curve, is nearly fifty times as great as that the alizarin red S method[4], about five times that of the quercetin method[7], and about 1.2 times for the phenylfluorone method[1]. In

7) F. S. Grimaldi and C. E. White, *Anal. Chem.*, 25, 1886 (1953).

the region from zero to 0.15 p. p. m. of zirconium, the solution remains without any visible precipitation for three days or more, so the stability of the absorbance seems to be greater than that in the phenylfluorone method. These facts show the method is excellent for the determination of a micro amount of zirconium.

Summary

The spectrophotometric determination of a micro amount zirconium, using *m*-nitrophenylfluorone, has been described. The method recommended here, which is carried out in 0.1 N hydrochloric acid solution, shows nearly fifty times the sensitivity of the alizarin red S method, about five times that of the quercetin method, and about 1.2 times that of the phenylfluorone method reported previously as the most sensitive reagent by the author and K. Kimura. The solution becomes stable enough to carry on the spectrophotometric determination by adding some cyclohexanol and ethanol, and no precipitation is found for the small amount of zirconium. Furthermore, the stability for increasing acidity in the solution is greater than that of the phenylfluorone method. The method is found to be suitable for the determination of 0 to 0.5 p. p. m. of zirconium. Transfer the sample solution (less than 10 ml.) to a 25 ml. volumetric flask. Then add additional acid to bring the acidity up to 1.0 N hydrochloric acid and 7.5 ml. cyclohexanol-ethanol (1 : 2) mixed solution, and 5 ml. ethanolic solution containing 3 mg. *m*-nitrophenylfluorone in that order. Adjust the volume to 25 ml., shake the solution, allow to stand for one hour, and read the absorbance of the solution with a spectrophotometer at 550 mμ with 1-cm. glass cells and distilled water as a control solution. Oxalate, fluoride, phosphate, titanium, germanium, iron(III) and antimony cause serious interference.

The author is indebted to Professor Emeritus Kenjiro Kimura and Professor Nobufusa Saito for their encouragement in carrying out this study. The author is also grateful for a grant from the Ministry of Education.

SHORT COMMUNICATIONS

*Synthesis of Trimethylboron from Boric Anhydride or Borate**

By Jun IYODA and Isao SHIIHARA

(Received November 26, 1958)

Many organoboron compounds have been prepared by the action of Grignard reagents[1] on boron trihalides or esters of boric acid. But so far as is known, there is no report** on the synthesis of organoboron compounds from naturally occuring materials such as boric anhydride or sodium borate directly. Related reactions are concerned only with sodium hydride[2] at a temperature as high as 330°C in an autoclave. Recently, with progress in the study of organoaluminum compounds, many attempts have been made to utilize organoaluminum compounds in related reactions in place of Grignard reagents[3,4]. Previously we[5] found that the silicon-oxygen bond in polymeric form was cleaved and alkylated simultaneously with organoaluminum compounds. In the present communication, this reaction was applied to boron-oxygen compounds and it was found that organoboron compound was obtained directly from inorganic boric anhydride or its salts in a good yield.

The reaction was carried out as follows. Methylaluminum sesquichloride[6] $(CH_3)_3Al_2Cl_3$ was added to a boron compound in an inert atmosphere and the reactant was refluxed at 150 to 170°C for several hours, and trimethylboron (b. p. −21.8°C) generated was caught by a dry-ice acetone trap.

The results obtained are shown in Table I. In the case of boric anhydride the yield of trimethylboron is especially good and almost quantitative but it is somewhat low in the case of borate. It is interesting to note that when the reaction was carried out in isoamyl ether solution, no trimethylboron was produced. Also, by the use of methylmagnesium chloride in the same ethereal solution, no methyl-boron

Coexistence of Two Different Molecular Forms within a Single Crystal of L-Valine

By Masamichi Tsuboi, Tadao Takenishi* and Yoichi Iitaka

(Received December 25, 1958)

In the course of our work on the infrared absorption spectra of amino acids, we found that a crystal of L-valine gives a spectrum quite different from that of a crystal of DL-valine (Fig. 1). The number of the bands observed for the DL-valine crystal is that expected from one valine molecule[1], and almost every band has been assigned to one of the vibrational modes expected for the molecule[2]. While, the L-valine crystal shows much more bands than the DL-valine crystal does. For example, instead of the band at 680 cm^{-1} of the DL-crystal, which is assigned to the COO^- scissoring mode, the L-crystal shows two bands at 715 and 663 cm^{-1}. These are situated too far apart to be considered as arising from one molecular vibration due to the splitting in the crystalline force field. A pair of bands is also observed in the spectrum of the L-crystal, instead of each of the bands of the DL-crystal at 774, 818, 890, 925, 948, 1035, 1105, 1181, 1320, 1355, 1406, 1593 and 1629 cm^{-1}. These observations may lead us to a view that the L-valine crystal belongs to an unusual type of crystal composed of molecules of one species of two different forms.

This view is supported by an X-ray examination. From the oscillation- and Weissenberg-photographs of the L-valine crystal the following data were obtained: monoclinic, $a=9.71$ Å, $b=5.32$ Å, $c=12.08$ Å, $\beta=90.8°$. Its density was reported by Cohn et al.[3] to be 1.230 g. cm^{-3}, which shows that there are four molecules per one unit cell, its density calculated being 1.247 g. cm^{-3}. Systematic extinctions on the photographs indicate the space group to be either C_2^2–$P2_1$ or C_{2h}^2–$P2_1/m$. The piezoelectricity is detected of this crystal; accordingly, the possibility of C_{2h}^2–$P2_1/m$ is eliminated, and the space group is determined to be C_2^2–$P2_1$. This space group requires only two crystallographically similar units (related by the twofold screw axis) within one unit cell. This requirement is fulfilled by supposing that the four molecules in one unit cell are in two sets of two molecules of different forms[1].

The question may now be raised, what is the difference between these two forms. Considered on the basis of what are at present known on the internal rotation around the C–C single bond[4], three rotational isomers are possible for the valine molecule, i. e., *trans*, *gauche I*, and *gauche II* isomers (Fig. 2; A, B, and C). The energy differences among these three isomers may be very small as are the energy differences between the *trans* and *gauche* isomers of symmetric tetrachloroethane[5] and between those of symmetric tetrabromoethane[6,7] (Fig. 2; D and E). The two molecules of different forms, composing the L-valine crystal, are probably two of these three isomers.

Similar rotational isomers with the small energy differences are also possible for the isoleucine molecule, in which one of the two methyl groups of the valine molecule is substituted by the ethyl group. Then, the existence of isoleucine crystals composed of two rotational isomers may

* Central Research Laboratory, Ajinomoto Co., Inc. Kawasaki, Kanagawa.

1) That the DL-valine crystal is composed of molecules of one form is evident from the space group (C_i^1–P_1), the unit cell dimensions ($a=5.25$Å, $b=5.43$Å, $c=11.05$Å, $\alpha=91°$, $\beta=92.4°$, $\gamma=109.4°$), and the the density (1.315 g. $cm.^{-3}$) of this crystal; this space group requiring two crystallographically similar units within one unit cell, and the unit cell dimensions and the density requiring two molecules (D and L) in each unit cell. Details will be shown elsewhere (M. Tsuboi, T. Takenishi and Y. Iitaka, to be published).

ν_{O-H} *Absorption of Cholesterol and Epicholesterol*[1]*

By Michinori Ōki and Hiizu Iwamura

(Received January 6, 1959)

The authors observed two ν_{O-H} absorptions with 3-buten-1-ol[2], and attributed

* Added in proof: While this paper was in press, P. von R. Schleyer, D. S. Trifan and R. Bacskai (*J. Am. Chem. Soc.*, **80**, 6691 (1958)) reported the same phenomenon for these compounds without noticing the unsymmetry of the O-H stretching band of cholesterol.

1) Part III of intramolecular interaction between hydroxyl group and π-electrons.

2) M. Ōki and H. Iwamura, This Bulletin, in press.

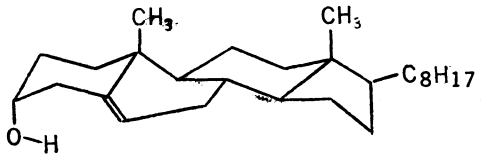

TABLE I

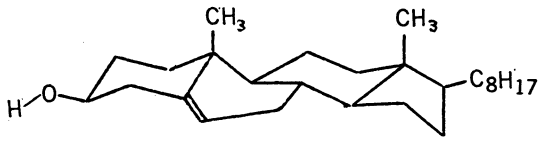
ν_{O-H} ABSORPTION OF CHOLESTEROL AND EPICHOLESTEROL



Compound	ν_{O-H} band	ν_{max} (cm^{-1})	$\Delta\nu_{1/2}$ (cm^{-1})	$A\times10^{-3}$ ($mole^{-1}\cdot liter\cdot cm^{-2}$)	$\Delta\nu_{max}$ (cm^{-1})
cholesterol	I	(3613.0)	(18.4)	(1.05)	10
	II	3623.0	16.4	3.47	
epicholesterol	I	3589.6	32.0	2.67	34.1
	II	3623.7	16.8	0.85	

one at the lower wave number (3596.1 cm^{-1}) to the intramolecular interaction between hydroxyl group and π-electrons of the double bond. Then it was naturally expected that the concept would be applicable to more complex molecules, such as steroids.

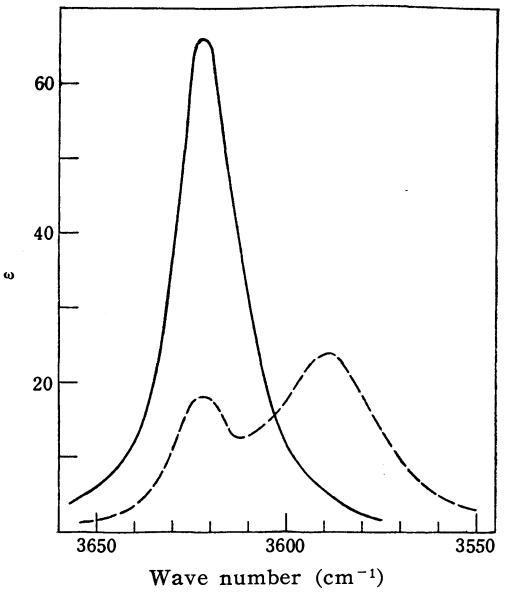
The molecular scale models indicate that the steric requirement is fulfilled for such a kind of interaction to take place in epicholesterol[3] (I), but not in cholesterol[3] (II).

I

II

Measurements of the O-H stretching absorption in the fundamental region showed that it is really the case. As shown in Fig. 1, epicholesterol gave two distinct maxima, while cholesterol a normal band for secondary alcohols, although the band can be divided into two as in the cases of other secondary alcohols[4] (Table I). The measurements and the calculation were carried out similarly as reported previously[2,5].

Comparison of the integrated intensities of band I (interacted form) and of band II (free) of epicholesterol with the corresponding values of 3-buten-1-ol shows that the number of molecules with internal interaction between hydroxyl group and the π-electrons of the double bond is much



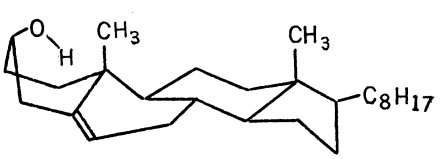


Fig. 1. ν_{O-H} absorption of cholesterol (——) and of epicholesterol (----).

greater in epicholesterol than in 3-buten-1-ol, since the integrated intensity of band I of epicholesterol is greater than that of 3-buten-1-ol (1.93×10^3 $mole^{-1}\cdot liter\cdot cm^{-2}$) and the A_I/A_{II} value is 3.1 for epicholesterol and 0.6 for 3-buten-1-ol. The reverse in the intensities of the two bands in these compounds can be attributed to the more favorable conformation of epicholesterol than that of 3-buten-1-ol. Namely, when the interaction takes place, the conformation of C–C–C–O must be a *gauche* form which will cause greater unstability in term of energy and unfavorable entropy change in 3-buten-1-ol, while the conformation favorable for the interaction is fixed in epicholesterol.

III

3) Pure samples of these substances were kindly donated by Miss K. Mori of this laboratory, to whom the authors' thanks are due.

4) M. Ōki and H. Iwamura, This Bulletin, in press.

5) M. Ōki, H. Iwamura and Y. Urushibara, ibid., **30**, 769 (1958).

The possibility for A ring of cholesterol to take a boat form (III) to some extent is denied, as far as the present data concern, because no absorption band was observed that would have been expected if cholesterol had possessed structure III favorable for the interaction.

This finding may be utilized for the analysis of epicholesterol in a mixture and similar phenomena will be observed in many other compounds of the same type. Examination of the scale models reveals that only the axial hydroxyl group is capable of forming this kind of interaction in steroids. Possibility for use in the diagnosis of the hydroxyl group is under investigation.

Asymmetric Synthesis of Threonine by Optically Active Complex Ions of Cobalt

By Masuo MURAKAMI and Kozo TAKAHASHI*

(Received January 8, 1959)

The structure of an octahedral complex containing two or three molecules of an optically active bidentate coordinating agent is defined by the configuration of these bidentate molecules, and the number of stable isomers of these complexes is limited by asymmetric effect of these bidentate molecules[1]. For example, the reaction of dextro-1,2-*trans*-diaminocyclopentane with dichloro-bis(levo-cyclopentadiamine)cobalt(III) chloride gives only D[Co(*l*-cptdin)$_3$]Cl$_3$ and L[Co(*d*-cptdin)$_3$]·Cl$_3$[2].

On the basis of these results, Bailar et al. attempted to resolve some of racemic coordinating substances by the aid of an optically active complex. They failed to obtain optically active alanine, leucine, phenylalanine and propylenediamine[3], but succeeded in the case of tartaric, α-chloropropionic acid and lactic acids by this method[4]. These facts suggest possibility that an effective asymmetric synthesis may be brought about by a reaction whereby a new asymmetric carbon atom is formed through the coordinating molecule of an optically active octahedral complex.

Recently, Akabori et al. reported an excellent method for the synthesis of threonine by means of a Knoevenagel type condensation of acetaldehyde with the active methylene group of glycine copper complex[5]. We have attempted to synthesize optically active threonine by means of the reaction mentioned above from optically active complexes of the type [Co B$_2$ glycine].

One gram of levo-glycino-bis(ethylenediamine)cobalt(III) iodide, which was prepared according to the direction of Meisenheimer[6], was allowed to react at room temperature with 0.34 cc. of acetaldehyde in 5 cc. of 4% sodium carbonate aqueous solution. After 90 hr., 0.5 g. of sodium sulfide nonahydrate was added and cobalt(II) sulfide was removed and then the filtrate was flowed through a cation exchange resin column (H form Amberlite IR-120). The amino acids adsorbed on the resin were eluted with 2 N aqueous ammonia. The crude crystalline product (190 mg., 80% yield) obtained from the above eluate showed dextro rotation, $[\alpha]_D^{13}$ +3.84 (c 2.345, in water), m. p. 223~224°C. The paper chromatogram, obtained by developing with *n*-butanol-methylethylketone-concentrated aqueous ammonia-water (5 : 3 : 1 : 1), indicated that the crude product consisted of threonine, allothreonine and glycine with the relative ratio of the spot area of 7 : 2 : 1. The crude 2,4-dinitrophenylthreonine obtained from the reaction product showed levo rotation, $[\alpha]_D^{11}$ −8.22 (c 2.34, in 4% aq. sodium hydrogen carbonate), (asymmetric yield ca. 8%), m. p. 125~132°C[7].

Glycino-bis(levo-propylenediamine)-cobalt(III) chloride[8], which is considered to

7) The specific rotation and m. p. of dinitrophenyl-L-threonine are described to be +107 and 145°C, respectively, by K. R. Rao and H. A. Sober, *J. Am. Chem. Soc.*, 76, 1328 (1954).

8) *Anal.* Found: C, 27.51; H, 6.75; N, 19.28. Calcd. for $C_8H_{24}O_2N_5Cl_2Co$: C, 27.21; H, 6.86; N. 19.88%.

be preferable to L[Co en_2 glycine] I_2, was prepared and treated with acetaldehyde in a similar manner described above. The threonine thus obtained was a syrup and probably contaminated with levo propylenediamine. The paper chromatogram showed that this crude threonine consisted of threonine, allothreonine and glycine with the approximate ratio of 6.5 : 3 : 0.5. This crude threonine was converted into dinitrophenyl derivative (75% yield), which showed a slight levo rotation, $[\alpha]_D^{11}$ −1.2 (c 5.822 in 4% aq. sodium hydrogen curbonate), (asymmetric yield ca. 1%).

These varied yields for the asymmetric product may depend largely on the stability of the complex ions.

*The Crystal Structure of Phenylarsonic Acid**

By Akira SHIMADA

(Received December 28, 1958)

In the attempt to determine the molecular configuration of an organoarsenic compound and at the same time to compare the structure of this acid with that of other organic acids, this study was undertaken. Small needle crystals of phenylarsonic acid, $C_6H_5AsO(OH)_2$, were easily obtained by the slow evaporation of a water-ethanol solution. Oscillation and Weissenberg photographs prepared with Cu K_α radiation gave the following unit-cell dimensions:

$$a=10.42, \quad b=14.92, \quad c=4.70\ \text{Å}$$

Schröder et al.[1] already showed that this crystal was orthorhombic with the axial ratios 0.7048 : 1 : 0.203, and also that perfect cleavages were found along the (110) plane, and imperfect ones along the (100) plane. The axial ratios given by these authors can be compared with the values derived by the X-ray measurement, 0.698 : 1 : 0.315 = 0.698 : 1 : 0.210×3/2. With assumption of four chemical units in the unit cell with the dimension given above, one can calculate the density to be 1.84 g./cc., which agrees satisfactorily with the observed value, 1.804 g./cc., reported by Schröder[2]. The systematic absence of (h00) reflections for h=odd, (0k0) ones for k=odd, (00l) ones for l=odd, and nothing else lead to the space group D^4_{42}–$P2_12_12_1$. Intensities were estimated visually with a calibrated scale, by making use of the multiple-film technique. The corrections for polarization and Lorentz factors were made in the usual way and that for absorption was neglected.

Since the c axis is shorter and each projection has the center of symmetry with plane group P_{gg}, the Patterson projection onto the (001) plane was first synthesized, which revealed clearly interatomic vectors between arsenic atoms owing to their greater scattering powers. The first electron-density projection was then synthesized, the Fourier coefficients being the observed structure amplitudes $|F_{hk0}|$'s with the signs determined by the arsenic atoms alone, and the successive refinement of the electron-density projection made clearer all of the atomic positions except hydrogen atoms. The electro-density projection is shown in Fig. 1. The reliability index for (hk0) spectra is, at the present stage of refinement, 20% with a temperature factor $B=4.2\ \text{Å}^{-2}$ for all. Preliminary studies of electron-density projections along other axes with the same method of analyses were sufficient to give an approximate z coordinate of each atom, from which the outline of the molecular configuration as well as their orientation were derived.

Although the result given above is preliminary and not very accurate, some interesting features of crystal structure were revealed. The interatomic distances within a molecule as well as between nearest molecules were found to be plausible. Three As–O bonds, with a mean length of 1.6_9 Å, and an As–C_1 bond, with a length of 1.9_1 Å, are arranged in a distorted tetrahedron. Long chains are formed along the two-fold screw axis perpendicular to the (001) plane by two sets of non-equivalent hydrogen bonds $-OH_1\cdots O_3\cdots HO_2-$. One set of hydrogen bonds with

* The major part of this paper was read at the Autumnal Joint Meeting of Chemical Societies of Japan, Tokyo, 1958.

2) Schröder, *Ber.*, 12, 562 (1879).

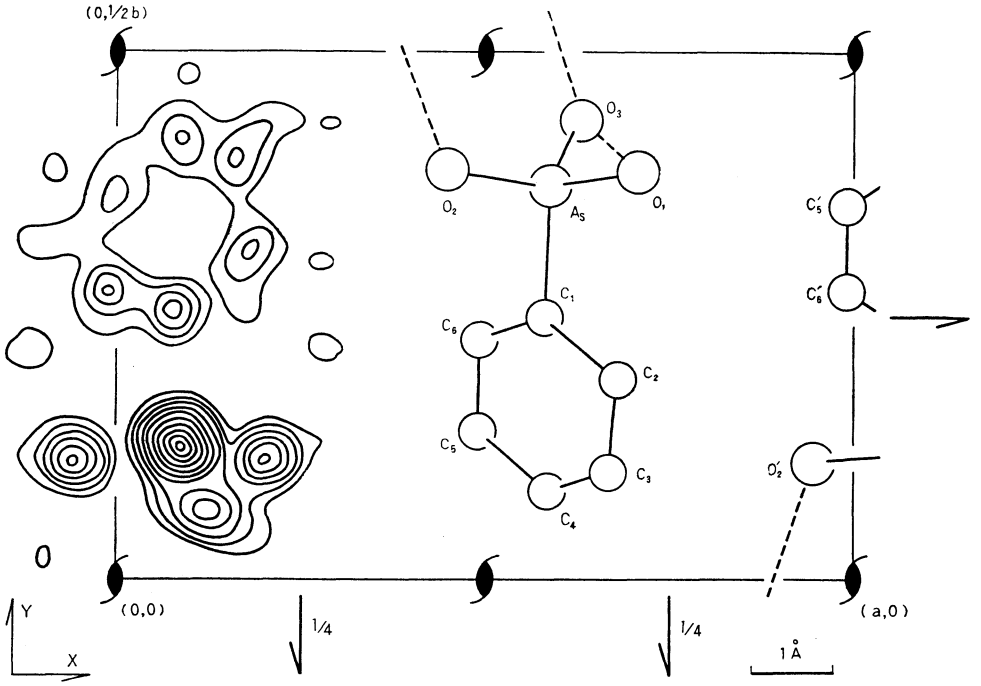

Fig. 1. Projection of the structure on (001). Contours are drawn at arbitrary intervals. Dashed line indicates the hydrogen bond between the molecules.

a distance 2.7_3 Å unites the oxygens, O_2 and O_3, of adjacent molecules around the screw axis, while the other set with a distance 2.5_6 Å unites the oxygens, O_3 and O_1, of adjacent molecules both along the *c* axis. The benzene rings are connected through the arsenic atoms to these chains and, hence, there might be no intermolecular forces other than those of the van der Waals type between these chains. This mode of packing of the molecules would explain the cleavages along the planes parallel to the (110) and (100) planes. Further refinement of the structure is now in progress.

The author wishes to express his sincere thanks to Professor I. Nitta and Professor T. Watanabé of Osaka University for their helpful advice, to Professor H. Nakata of Konan University for supplying the specimen, and to the other members of this University for their encouragement.

Effect of Antioxidants on Polyethylene

By Shigeharu Okamoto and
Keisaku Takeuchi*

(Received January 9, 1959)

It is well known that oxidized polyethylene contains some amount of oxygen. Infrared spectrophotometric studies[1] have shown that during oxidation carbonyl groups are formed. The presence of these polar groups should be readily detected by measurements of the dielectric losses which imply the existence of the rotation of the polar groups under the influence of an externally applied alternating electric field. The oxidation resistance of polyethylene can be improved by the use of certain inhibitors and it is to be expected that increased knowledge of the effect of antioxidants on polyethylene will contribute toward this improvement.

* Present Address, Kijima Communication Wire Co., 6-1252, Kamimeguro, Meguro-ku, Tokyo.

1) F. M. Rugg, J. J. Smith and R. C. Bacon, *J. Polymer Sci.*, 13, 535 (1954).

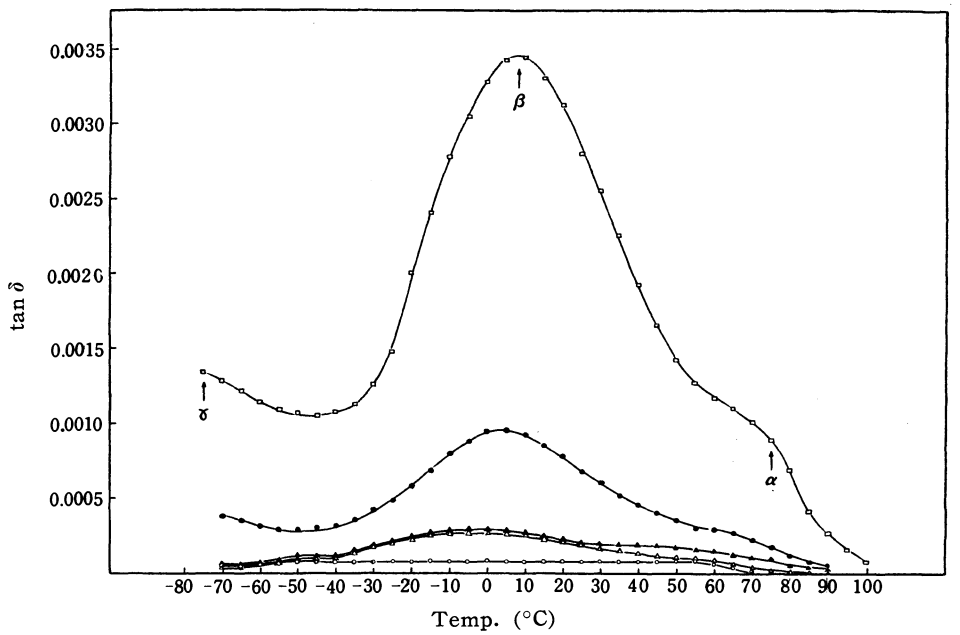

Fig. 1. The dissipation factor as a function of temperature for polyethylene exposed to ultraviolet radiation. Frequency 10 kc./sec. ○ before exposure; △ (20 hr.) and ▲ (40 hr.) exposure, with an antioxidant; ● (20 hr.) and □ (40 hr.) exposure, without antioxidant.

In this view we have studied the effect of an antioxidant on the change of the dielectric losses of polyethylene during aging. The polyethylene examined was Alathon 10-NC10-Natural and the antioxidant chosen was α-naphthylamine. A small amount of the antioxidant (1% by weight) was added on an open mill into the polyethylene sample. The photo-oxidation of polyethylene specimens has been carried out by exposure to the ultraviolet radiation from a mercury quartz lamp during 20 and 40 hr. Dielectric measurements were made over a temperature range of -75 to $+100$°C at a frequency of 10 kilocycles per sec. The results are given in Fig. 1.

As shown by the graph, for polyethylene samples containing no antioxidant, there exist three loss peaks and the maximum heights of the peaks increase as the time of exposure is increased. It is customary to label these peaks as α, β and γ descending from higher temperatures. On the other hand, far polyethylene samples containing a small amount of antioxidant, the α and β loss peaks which are attributed to the carbonyl activity in the crystalline regions and to that in the amorphous regions respectively, are markedly small and remain almost unchanged in intensity, independent of increasing exposure time. Furthermore, the γ peaks are missing as does that of original polyethylene sample before exposure.

It is concluded from the results that dielectric measurement is a sensitive method to estimate the degree of polarity of oxidation products and α-naphthylamine can be established to be an effective oxidation inhibitor for polyethylene by the use of dielectric method too.

DNP-amino acids are unstable toward light, and Akabori et al.[3] have previously reported a semiquantitative investigation on the photochemical decompsition of the DNP-amino acids.

In the present investigation, photochemical decomposition of DNP-dipeptides, DNP-L-leucyl-glycine and DNP-glycyl-L-leucine, was examined. It was thus confirmed that the *N*-terminal amino acid residues of these peptides, together with the attached DNP-group, were completely decomposed under suitable conditions, resulting in the liberation of the *C*-terminal residues, glycine and leucine, in the form of free amino acids. The starting materials, DNP-L-leucyl-glycine and DNP-glycyl-L-leucine, were prepared from L-leucyl-glycine[4] and glycyl-L-leucine[5] according to Sanger's method[6] and their purity was confirmed by nitrogen analysis and two-dimensional paper chromatography under improved Levy's condition[7].

Anal. Found: N, 15.68**; N, 15.78***. Calcd. for $C_{14}H_{18}O_7N_4$: N, 15.81%. Found: N, 15.40****. Calcd. for $C_{14}H_{18}O_7N_4 \cdot 1/2\,H_2O$: N, 15.42%. Two milligrams of DNP-L-leucyl-glycine (m.p. 154~157°) on a glass dish (9 cm. in diameter) were dissolved in a small amount of ethanol or ether and then diluted with 20 ml. of suitable solvent such as distilled water, 1 N-hydrochloric acid, ether, benzene, chloroform and carbon tetrachloride. The solution was covered with cellophane sheet (0.02 mm. thick) and exposed to a 15 W. Mazda UV-sterilizing lamp for about 20 hr. at a distance of 20 cm., the principal line of the lamp being 2537 Å. The exposed solution was evaporated to dryness in a vacuum desiccator at room temperature and the residue was extracted as completely as possible with 1 ml. of water. One tenth milliliter of the extract was subjected to paper chromatography using a mixture of butanol, acetic acid and water (4:1:1) as solvent in order to detect the ninhydrin-positive products. The water-insoluble part of the photodecomposed residue was extracted with ethyl acetate and the extract was similarly analyzed by two-dimensional paper chromatography under improved Levy's condition (Fig. 1, Table I). When water or 1 N-hydrochloric acid was used as the solvent during irradiation, rather complicated results were obtained; dinitroaniline, dinitrophenol, glycine and other ninhydrin-positive materials, though small in amount, being detected as the products. In the case of benzene as the solvent,

** DNP-L-leucyl-glycine (dried in vacuo at room temperature)

*** DNP-glycyl-L-leucine (dried in vacuo at 80° for 3hr.)

**** DNP-glycyl-L-leucine (dried in vacuo at room temperature)

especially when saturated with 1N-hydrochloric acid, only one faint but clear spot corresponding to glycine was obtained as ninhydrin-positive substance, but greater part of the starting material remained unchanged. More promising results were obtained in the case of chloroform and of carbon tetrachloride saturated with 1 N-hydrochloric acid. In both cases only one deep spot due to glycine (almost in the same density) was obtained, but a distinct difference was observed in the ethyl acetate soluble by-products.

Two milligrams of DNP-glycyl-L-leucine (sintered at 75~78°, resolidified and then decomposed at 110~115°) were dissolved in a small amount of ether and diluted with 20 ml. of chloroform or carbon tetrachloride, and treated exactly as in the case of DNP-leucyl-glycine. As expected, a clear single leucine spot was obtained in both solvents.

Application of these results to DNP-tri or higher peptides would be more interesting and the method may be utilizable as a new route for step-wise degradation of peptides from their *N*-terminal amino acid residues. Studies along this line are being pursued in this laboratory.

Infrared Absorption Bands Possibly Associated with the Helical Structure of Polystyrene, Poly-p-methylstyrene and Poly-m-methylstyrene Prepared with Ziegler Catalyst

By Hiroyuki TADOKORO, Shun'ichi NOZAKURA, Tohru KITAZAWA*, Yutaka YASUHARA and Shunsuke MURAHASHI

(Received February 5, 1959)

In a previous paper[1] we have briefly suggested the possibility that the several bands of the spectrum of isotactic polystyrene might be associated with the threefold screw-axis of this polymer. On carrying out further studies in relation to this problem, we have found some experimental facts which supports this possibility as well as the inference that poly-*p*-methylstyrene and poly-*m*-methylstyrene prepared with Ziegler catalyst might have the isotactic structure, although they did not show distinct crystallinity.

Fig. 1 partly reproduces the spectra of of the films of crystallized and quenched

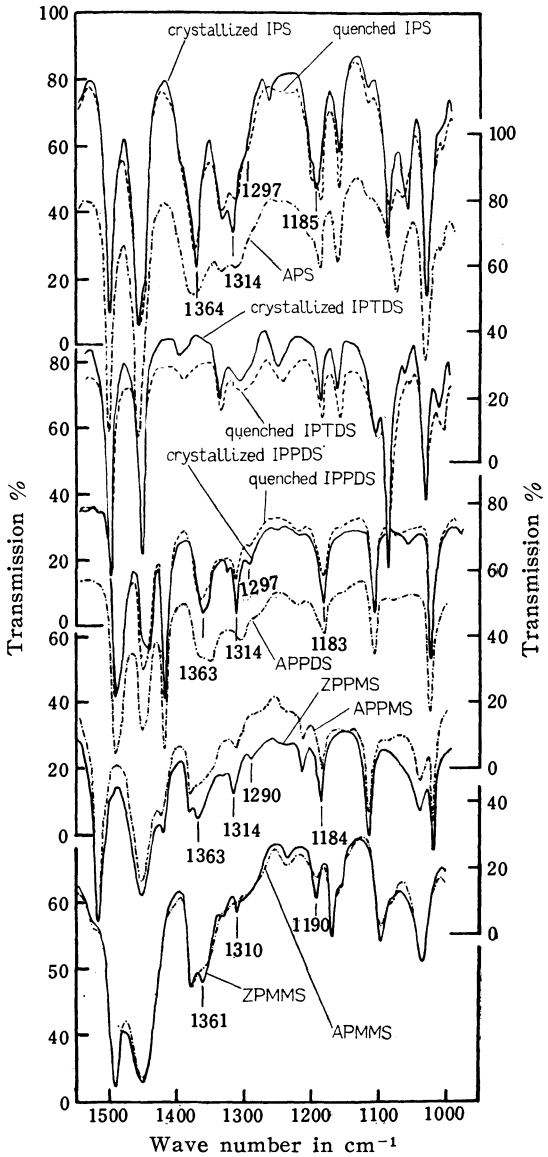

Fig. 1. Infrared spectra of crystallized and quenched IPS, APS, crystallized and quenched IPTDS, crystallized and quenched IPPDS, APPDS, ZPPMS, APPMS, ZPMMS and APMMS.

isotactic polystyrene (IPS)[2,3] atactic polystyrene (APS), crystallized' and quenched isotactic poly-α, β, β-trideuterostyrene (IPTDS)[1], $-(-CD_2-\underset{\underset{C_6H_5}{|}}{CD}-)_p-$, crystallized and quenched isotactic poly-*p*-deuterostyrene (IPPDS), $-(-CH_2-\underset{\underset{D}{|}}{CH}-)_p-$, atactic poly-*p*-deuterostyrene (APPDS), poly-*p*-methylstyrene prepared with Ziegler catalyst (ZPPMS), atactic poly-*p*-methylstyrene (APPMS), poly-*m*-methylstyrene prepared with Ziegler catalyst (ZPMMS) and atactic poly-*m*-methylstyrene (APMMS). Fig. 2 shows the polarized spectra of the oriented-and-crystallized IPS, IPTDS and IPPDS samples. The spectra of IPS and IPPDS exhibit several bands showing the same dichroism and the similar behavior on crystallization at nearly the same wave numbers; 1364 (⊥), 1314 (⊥), 1297 (∥) and 1185 cm^{-1} (∥). These four bands appear in weak intensity even in the spectra of quenched samples of IPS and IPPDS which give amorphous X-ray patterns, while they do not appear in the spectra of APS and APPDS. As these four bands are absent in the spectrum of IPTDS, these bands are considered to be not directly associated with the vibrations of the phenyl group, but with that of main chain. The first three bands at 1364, 1314 and 1297 cm^{-1} may be in the region assignable to CH_2 and CH wagging and CH_2 twisting, and the fourth at 1185 cm^{-1} in the region of CH_2 twisting and C–C stretching[4]. Hence the bands in these regions may be expected to be easily affected by the changes of the skeletal configurations. We could therefore consider that those bands are closely associated with the intramolecular interactions in the helical chain having the three-fold screw-axis (alternate sequence of *gauche* and *trans* conformation)[2,5]. The occurrence of these bands in the spectra of the quenched samples of IPS and IPPDS may be interpreted as indicating the existence of the locally remained helical structure in the amorphous region.

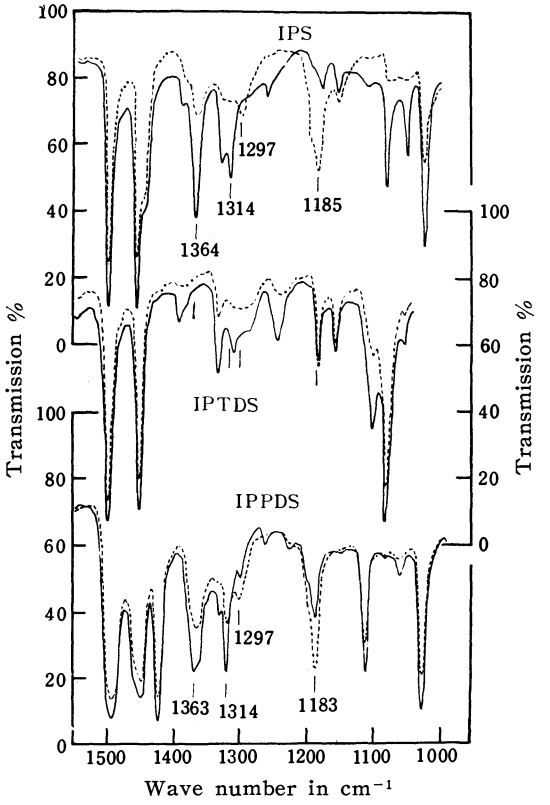

Fig. 2. Polarized infrared spectra of IPS, IPTDS and IPPDS.
—— electric vector perpendicular to elongation
------ electric vector parallel to elongation

It is interesting to note that the difference between the spectra of ZPPMS and APPMS as well as that between those of ZPMMS and APMMS are closely analogous to that between the spectra of quenched IPS and APS. Similar bands appear also at nearly the same positions in the spectra of ZPPMS (1363, 1314 and 1290 cm^{-1}) and ZPMMS (1361, 1310 and 1190 cm^{-1}) prepared with Ziegler catalyst, although these polymers are not appreciably crystalline. On the other hand, these bands are absent in the spectra of ordinary APPMS and APMMS. In view of the similarity pointed above, it can be inferred that ZPPMS and ZPMMS may have also isotactic and local helical structure just as quenched IPS has. Now the tentative explanation for the reason why these polymers are difficult to be crystallized in spite of their possible isotactic structure, would be that the packing of the neighboring molecular

3) S. Murahashi, S. Nozakura, M. Sumi and K. Hatada, This Bulletin, to be published.
4) For example, Fig. 4 of the paper by Nielsen et al. J. R. Nielsen and A. H. Woollett, *J. Chem. Phys.*, **26**, 1391 (1957).
5) C. W. Bunn and E. R. Howells, *J. Polymer Sci.*, **18**, 307 (1955).

chains in hypothetical crystalline lattices of these polymers may be considered to be not so close on account of the existence of the *p*- or the *m*-substituent methyl groups.

The inference of the existence of local helical structure is strongly supported by the experimental results that the densities of several samples of ZPPMS ($1.015_2 \pm 0.0008$ g./cc.) were always higher than those of APPMS ($1.011_0 \pm 0.0008$ g./cc.). These density values were measured by the flotation method using aqueous sodium chloride solution at 25°C.

Thus, it may be considered that ZPPMS and ZPMMS might be crystallized if some adequate conditions of orientation and thermal treatments were found. In this standpoint of view, we are now going to study the crystallization of these polymers by use of X-ray-, infrared- and density measurements.

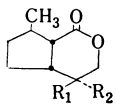
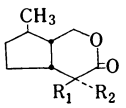
On the Structure of Actinidine and Matatabilactone, the Effective Components of Actinidia polygama

By Takeo SAKAN, Akira FUJINO, Fujio MURAI, Yasuo BUTSUGAN and Akio SUZUI



(Received February 10, 1959)

Deep interest has been held in Japan in *Actinidia polygama* Miq., a plant especially liked by the Felidae animals. The authors isolated two substances that excite cats from the leaves and gall of this plant. One is a base, named actinidine, $C_{10}H_{13}N$, b.p. 100~103°C/9 mm., $[\alpha]_D^{11}$ −7.2° (c 17.54, chloroform) (picrate: m.p. 143°C; *Anal.* Found: C, 51.45; H, 4.09; N, 14.97. Calcd. for $C_{16}H_{16}O_7N_4$: C, 51.06; H, 4.29; N, 14.89%), and the other, a neutral substance, named matatabilactone, $C_{10}H_{16}O_2$, b.p. 106~109°C/2 mm., $[\alpha]_D^{28}$ +31.9° (c 1.82, chloroform) (3,5-dinitrobenzoate of the methyl ester of the corresponding hydroxy acid: m.p. 78~79°C; *Anal.* Found: C, 54.88; H, 5.77; N, 7.09. Calcd. for $C_{18}H_{22}O_8N_2$: C, 54.82; H, 5.62; N, 7.10%).



Permanganate oxidation of the hydroxy acid, obtained by alkali hydrolysis of matatabilactone, afforded two isomeric dicarboxylic acids, $C_{10}H_{16}O_4$, of m.p. 84~85°C, $[\alpha]_D^{13}$ +32.5° (c 0.63. chloroform), (*Anal.* Found: C, 60.32; H, 8.08. Calcd.: C, 59.98; H, 8.05%), and of m.p. 117~118°C, $[\alpha]_D^{12}$ +15.6° (c 0.93, chloroform), (*Anal.* Found: C, 60.32; H, 8.08.), which were found, through the good offices of Dr. McElvain, to be respectively identical with nepetalinic acids[1,2] of m.p. 85°C (Ia*) and of m.p. 117°C (Ib), obtained from nepetalactone by him.**

Ia $R_1=CH_3, R_2=H$
Ib $R_1=H, R_2=CH_3$

IIa $R_1=CH_3, R_2=H$
IIb $R_1=H, R_2=CH_3$

IIIa $R_1=CH_3, R_2=H$
IIIb $R_1=H, R_2=CH_3$

It follows, therefore, that the structure of matatabilactone may be represented by either II or III. In the inrared spectrum of matatabilactone, the value of $\nu_{C=O}$ (5.76 μ in carbon tetrachloride) differs from that[3] of isoiridomyrmecin[4] (iridolactone)[3,5,6](IIIa) and of iridomyrmecin[3,5-9] (IIIb), but is very similar to that of the dihydro derivative of nepetalactone*. Thus, matatabilactone is II, i.e. dihydronepetalactone[10]. Examination are now

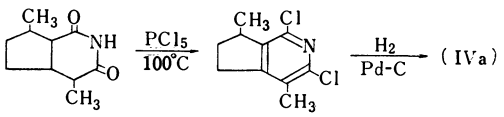
being made to see whether this lactone is a mixture of IIa and IIb or not.



Actinidine was assumed to be a pyridine base from its color reaction (violet to 2,4-dinitrochlorobenzene and alkali) and from ultraviolet and infrared absorption spectra, λ_{max} 262 mμ (ethanol) (ε=2,400) and $\nu_{C=N}$ 6.30 μ (liquid). Several pyridine derivatives were actually isolated as the permanganate-oxidation products. One melting at 255°C with decomposition (*Anal.* Found: C, 53.19; H, 4.24; N, 8.00. Calcd. for $C_8H_7O_4N$: C, 53.04; H, 3.90; N, 7.73%), was found to be identical with 5-methylpyridine-3,4-dicarboxylic acid obtained by similar oxidation of 4-methylisoquinoline. Consideration of the natures of other oxidation products, a hydroxy compound, m.p. 132~133°C (*Anal.* Found: C, 73.11; H, 8.23; N, 8.48. Calcd. for $C_{10}H_{13}ON$: C, 73.59; H, 8.03; N, 8.58%) and a lactone, m.p. 92.5~93°C (*Anal.* Found: C, 66.33; H, 5.61; N, 8.28. Calcd. for $C_9H_9O_2N$: C, 66.24; H, 5.56; N, 8.58%), suggests formula IVa for actinidine.

The alternative formula IVb is excluded by the fact that a ketone, m.p. 47~49°C, $\nu_{C=O}$ 5.85 μ (liquid), (*Anal.* Found: C, 74.42; H, 6.92; N, 8.49. Calcd. for $C_{10}H_{11}ON$: C, 74.51; H, 6.88; N, 8.69%), was derived from actinidine-*N*-oxide, m.p. 123.5~124.5°C (*Anal.* Found: C, 73.94; H, 8.04; N, 8.45. Calcd. for $C_{10}H_{13}ON$: C, 73.59; H, 8.03; N, 8.58%) through rearrangement, hydrolysis and oxidation.

IVa $R_1=CH_3, R_2=H$
IVb $R_1=H, R_2=CH_3$

The structure IVa is closely related to that of II. Actually, actinidine was synthesized from nepetalinic acid imide as shown below.

It is very interesting to note that a monoterpene and an alkaloid having the same carbon skeleton following the isoprene rule have been found in one and the same plant.

The authors wish to express their sincere gratitude to Dr. S. M. McElvain for the identification of their samples with his nepetalinic acids.

Rapid Gas Chromatographic Analysis of a Mixture of Oxygen, Nitrogen, Methane, Carbon Monoxide, and Carbon Dioxide

By Yûichi Murakami

(Received February 10, 1959)

Gas chromatography has been widely used as method for separation or analysis of many complex mixtures of gases or liquids. However, a mixture of oxygen, nitrogen, methane, carbon monoxide, and carbon dioxide has not been separated successfully. "Molecular Sieves 5-A" is effective in separating hydrogen, carbon monoxide, oxygen, nitrogen, and methane but it adsorbs irreversibly carbon dioxide[1].

Activated charcoal can separate hydrogen, carbon monoxide, oxygen, methane, and other hydrocarbons, but for practical use carbon dioxide shows too long a retention time as well as too widely a diffuse band and nitrogen can not be separated from oxygen[2,3]. Silica gel is very poor in separating hydrogen, oxygen, and methane[2] but for some rather complex procedure[4], and gives longer retention time for carbon dioxide than that for the above gases. Alumina is also very poor in separating the above gases[2] and adsorbs irreversibly carbon dioxide.

The present author will propose a new method of gas chromatography, with which the above mixture can be completely analyzed within a few minutes. The principle and the procedure of the method are rather simple as follows.

1) G. Kyryacos, and C. E. Boord, *Anal. Chem.*, **29**, 787 (1957).

5. Sensitivity cell
6. Outlet

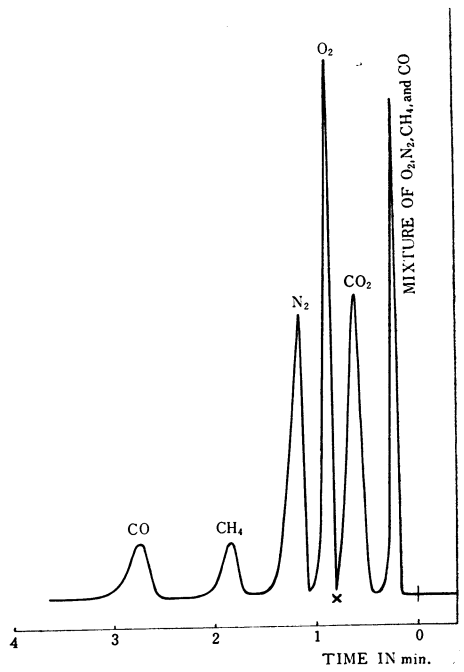

Fig. 3. Gas chromatogram.
× Switching the poles of recorder.

Apparatus.—The flow diagrams of the present new method and the usual one are illustrated in Figs. 1 and 2 respectively. In the usual method the carrier gas passes through successively a thermal-conductivity cell, a sample inlet, a column, and the other cell. The former cell works as a reference cell while the latter as a sensitivity cell. On the other hand, in the present method the carrier gas passes through successively a sample inlet, column I, thermal-conductivity cell I, column II, and cell II. The two cells are the same in construction. The electrical circuit comprises a Wheatstone bridge, the two arms of which are the platinium wires of the thermal-conductivity cells. In order to measure both positive and negative deflections, it is necessary either to adjust the base line to the middle of the chart or to be able to switch the poles of the recorder.

Columns.—*Column I*: A spiral copper column used was 40 cm. long and 4 mm. in inner diameter. Silica gel supplied by Chiyoda & Co. was used as the adsorbent. It was comminuted into 50~80 mesh and heated for one hour at 350°C. *Column II*: A spiral copper column used was 200 cm. long and 4 mm. in inner diameter, and "Molecular Sieves 5-A", comminuted into 50~80 mesh and heated for one hour at 400°C was used.

Procedure and Principle of the present method.—The test gas is separated firstly into carbon dioxide and a mixture of remaining gases by means of column I: they pass through thermal-conductivity cell I. During this period, in cell II the carrier gas alone is flowing, and then cell I is working as a sensitivity cell while cell II as a reference cell. Successively the mixture of remaining gases is separated further into oxygen, nitrogen, methane and carbon monoxide through column II and they pass through cell II. The situation in the second period is entirely changed, so that the role of each cell is interchanged and the direction of deflection is reversed.

The columns were operated at 80°C. The inlet pressure was 0.63 kg./cm^2 gage, the outlet atmospheric. The flow rate of hydrogen as carrier gas was 70 cc./min. Fig. 3. is an example of the gas chromatogram thus obtained and it shows that a mixture of oxygen, nitrogen, methane, carbon monoxide, and carbon dioxide has been completely separated. The time required for analysis is not more than four minutes.

The author wishes to express his sincere thanks to Dr. T. Keii and Mr. S. Terasawa for their kind encouragement.

Changes of Dynamic Properties of Some Kaolin Minerals by Heat-treatment

By Shigeru MOCHIDA, Isao KAWASAKI and Yoichi NISHIMURA

(Received July 18, 1958)

In general, ceramic products are made by heating clay mineral at a high temperature in order to utilize its strength and hardness. In some cases, however, moderate abrasion as well as strength and hardness are required where clay mineral is used at the meta-stable state in the process of its structural changes, different from the general conception of ceramic products. It is therefore, important to study changes of dynamic properties of clay mineral when it is heated at a relatively low temperature region, and this study aims at clarifying the characteristics of the results of heat-treatment in air-tight and carbon dioxide atmosphere.

Mutual relationship between changes of dynamic properties, densities and structures of some kaolin minerals was investigated when they were heated in a closed vessel. On the dynamic properties, the Young's modulus and bending strength, and on the physical properties, bulk density and density were measured.

At the same time, the relationship between changes of dynamic properties and structures was partly tested by X-ray diffraction method. The results of Kibushi-clay heated in a closed vessel were compared with the results when it was heated in the open air.

Samples.—The following kaolin minerals were used in this study: Shidare-Kibushi clay from Shidare, Gifu, Japan; Yagusa-Kibushi clay from Yagusa, Aichi, Japan; Naegi-Kaolin from Naegi, Gifu, Japan; and Hongkong-Kaolin from Hongkong.

By the X-ray diffraction method, any of them excepting Hongkong-Kaolin is a kaolin mineral of fireclay type[1] and contains a small quantity of quartz in spite of being elutriated. Shidare-Kibushi clay contains a small quantity of organic matter as an impurity. Hongkong-Kaolin is halloysite with a high crystallinity[2]. The results of chemical analysis of the four samples which have been elutriated are shown in Table I.

In differential thermal analysis curves of all samples, the endothermic peak was reached due to the loss of inter-layer water between 100 and 200°C and to the loss of structural water between 400 and 500°C. The exothermic peak was reached at about 950°C corresponding to the structural change to mullite.

TABLE I
CHEMICAL ANALYSIS OF SOME KAOLIN MINERALS

Component	Shidare-Kibushi	Yagusa-Kibushi	Naegi-Kaolin	Hongkong-Kaolin
SiO_2	48.76	50.29	47.48	46.78
TiO_2	0.77	0.23	0.01	tr.
Al_2O_3	34.53	33.13	37.59	35.62
Fe_2O_3	1.50	2.10	0.40	0.46
MnO	0.00	tr.	0.00	tr.
CaO	0.27	0.24	0.11	0.81
MgO	0.20	0.64	0.02	0.63
K_2O	0.34	1.51	1.61	1.16
Na_2O	0.19	0.58	0.16	1.11
Ig·Loss	13.43	11.40	12.45	13.27
Total	99.99	99.82	99.83	99.84

All samples were elutriated, roll-milled with a proper amount of water and extruded into rods of about 3.5 mm. in diameter by a press. Each sample prepared as mentioned above was dried at 100°C in a drying oven for 24 hours. The samples were heated in an air-tight graphite crucible, the temperature of which is raised by 5°C per minute in an electric furnace with siliconit heaters, and then they were cooled down naturally in the crucible taken out of the furnace after having constantly been heated therein at a given temperature for an hour. In the case of heat-treatment in the open air, samples were heated in a porcelain crucible with many holes under the same conditions as in the case of the air-tight crucible. The temperatures of heat-treatment in both cases were 500, 800, 900, 1000, 1050, 1100, 1150, 1200 and 1250°C.

Experimental

Young's Modulus. — Young's modulus was measured in a cramp-free state by loading at a non-fixed end. It was calculated by the following equation[3]:

$$\text{Young's modulus} = (4l^3/\pi a^4 e)P/3$$

where l, distance between the fixed point and the loaded point = 10 cm.; P, load = 980 dynes; a, radius of sample (cm.); and e, length of strain (cm.).

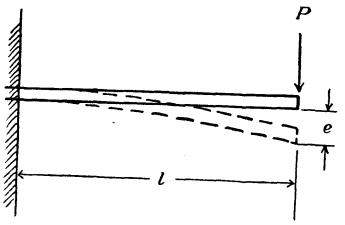

Fig. 1. Measuring procedure of Young's modulus.

Bending Strength. — Although a bending strength does, in an exact sense, not always mean a physical value, it is practically used as a breaking strength in industries. By supporting a sample on two knife edges, continuously loading on the middle of the sample and reading the weight of the load just breaking the sample the bending strength was calculated by the following equation[4]:

$$\text{bending strength} = 8Pl/\pi d^3$$

where P, weight of load just breaking the sample (g.); l, distance between two supporters 60 mm. and d, diameter of sample (mm.).

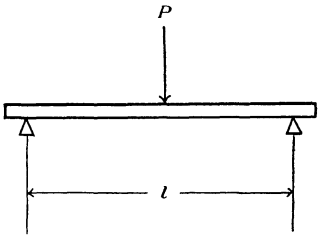

Fig. 2. Measuring procedure of bending strength.

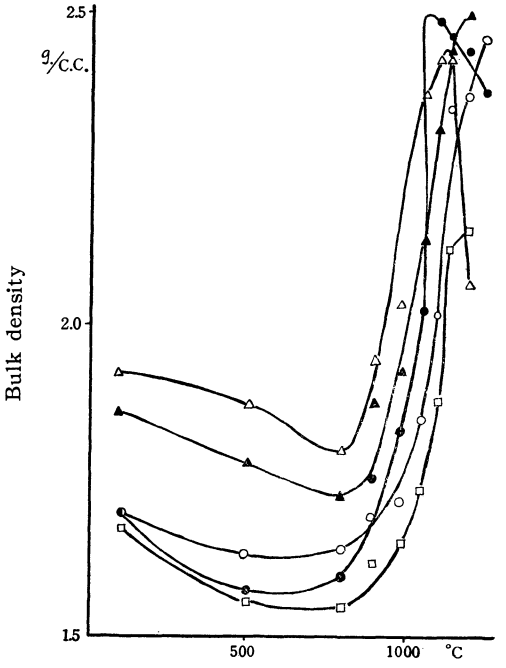
Density. — The sample was ground into a powder finer than 200-mesh and its density was measured by a picnometer in mono-chlorbenzene at 25°C.

Results



Bulk Density.—The value of bulk density is shown in Table II and Fig. 3, and there is the minimum point at about 800°C in each curve, except that the temperature corresponding to the minimum point of bulk density of Shidare-Kibushi clay heated in the open air moves down to about 500°C and its maximum point appears at about 1150°C.

Density.—As shown in Table III and Fig. 4, there is a minimum point between 500 and 800°C and a maximum point at about 1000°C in each curve of the density. Beyond 1000°C the density decreases gradually.

Young's Modulus.—As shown in Table IV and Fig. 5, the Young's modulus increases rapidly beyond 800°C and a maximum value is shown between 1100 and 1200°C.

Bending Strength.—As shown in Table V and Fig. 6, beyond 800°C the bending strength increases gradually and beyond 1000°C, it increases

rapidly. In both cases, there are maximum values and, after reaching the maximum values, it decreases rapidly.

Discussion

Even clay minerals, which belong to the same "kaolin" group, differ from one another according to their kinds in regard to the bending strength and Young's modulus. There are many factors, for example, particle sizes, structural characteristics, impurities, etc., which influence the dynamic properties of kaolin minerals.

As only four samples were experimented with in regard to their dynamic properties, it is difficult to discuss and to relate the results of their dynamic properties with the results of chemical analysis. The effects of the impurity contained in kaolin mineral on the dynamic properties are studied now and their results will be reported in future.

In this paper, some relationships between the dynamic properties and the structural characteristics are discussed. The changes of the dynamic properties by heat-treatment beyond a certain temperature are not continuative but are abrupt.

In the heat-treated specimens of Yagusa-Kibushi clay, for example, the bending strength increases to only 2000 g./mm² between 800 and 1000°C and as much as 8000 g./mm² between 1000 and 1100°C, but decreases rapidly between 1100 and 1200°C. Also, the Young's modulus and even density take a similar tendency. These phenomena seem to be attributed to the changes of crystal structures in clay minerals. Therefore, those causes which affect the changes of dynamic properties may be due to the following:

1. Change of plasticity of kaolin mineral by heating at an early stage.
2. Change of crystal structure of kaolin mineral and transformation of its macrostructure caused by the change of crystal structure by heating at a later stage.
3. Sintering.

Now, the value expressed by percentage which is obtained by dividing a bulk density by a density is called "filling ratio". The dynamic properties and the filling ratio will be discussed. As shown in Table VI and Fig. 7, the minimum value of filling ratio appears, generally speaking at the temperatures between 500 and 800°C. The changes of the filling ratio

TABLE VI

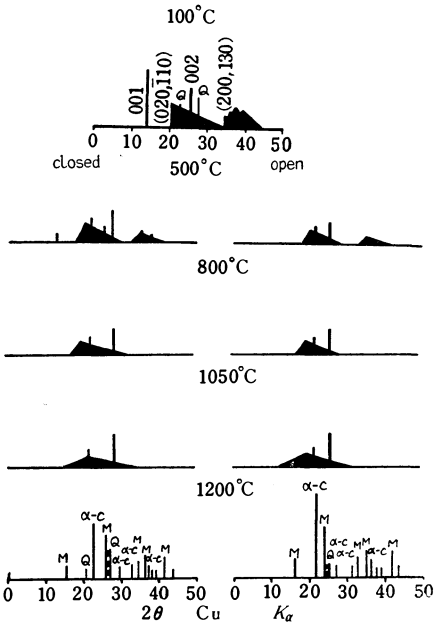
may be due to the following. In the early stage of heating, the sample loses interlayer water. At the temperatures between 500 and 800°C, it has the minimum filling ratio, because it becomes porous owing to the loss of structural water while the shrinkage caused by sintering does not keep pace with it. Beyond 800°C, it is in the state of "meta-kaolin" and its filling ratio is recovered gradually between 800 and 1000°C, because the shrinkage by sintering is larger than the loss of structural water.



The Young's modulus changes a little until it reaches 800°C, but as soon as the temperature exceeds 800°C, the Young's modulus begins to increase in company with filling ratio. This indicates that the Young's modulus increase is accompanied by the sintering. The filling ratio increases rapidly beyond 1000°C which may be due not only to the sintering but also to the commencement of the structural changes of the kaolin minerals[5]. This rapid increase of the filling ratio has influence on the bending strength and the Young's modulus.

The temperature at which crystallization begins varies a little according to the kinds of kaolin mineral. That is to say, in the case of Yagusa-Kibushi clay, the Young's modulus begins to increase just beyond 1000°C, but in the case of Shidare-Kibushi clay and Naegi-Kaolin, it does at higher temperature. In the case of Hongkong-Kaolin, it begins to increase rapidly beyond 1050°C. However, when the temperature of heat-treatment rises up to a certain point along with the development of crystallization, the filling ratio does not increase but begins to decrease and, at the same time, the bending strength and the Young's modulus also are inclined to decrease. This may be explained as follows.

In the case of Shidare-Kibushi clay, the filling ratio continues to increase until 1250°C together with the bending strength and Young's modulus, which may be caused, to a great extent, by the sintering and the commencement of crystallization. Crystals of mullite and α-cristobalite do not yet grow at 1050°C, but they appear at 1200°C. In the case of Yagusa-Kibushi clay, the Young's modulus increases rapidly beyond 1000°C, and reaches the maximum value between 1100 and 1200°C. However, at 1200°C the Young's modulus apparently starts to decrease according to the decrease of the filling ratio. Moreover, the characteristics of the sample heated at 1200°C shows a distinguished expansion in diameter.

X-ray diffraction data will be discussed below. As shown in Fig. 8, in the case of Shidare-Kibushi clay, mullite begins to

M: mullite, α-c: α-cristobalite, Q: quartz

Fig. 8. Schematic drawings of the X-ray diffractometer traces of heat-treated specimens of Shidare-Kibushi clay.

grow at about 1050°C. At about 1200°C, the crystallization to mullite is distinguishable and the quartz of impurity changes to α-cristobalite. Therefore, it is considered that when this clay begins to crystallize and its filling ratio increases rapidly owing to sintering, both the bending strength and the Young's modulus increase together. However, when the crysrallizations to mullite and α-cristobalite are remarkable, cracks grow along the crystals, and therefore, the filling ratio and bending strength together with the Young's modulus are reduced.

The difference between the heat-treatment in a closed vessel and in the open air will be discussed. In general, Kibushi clay changes at the lower temperature when heated in the open air. This may be clearly seen from the X-ray diffraction diagrams of the heat-treated specimens of Shidare-Kibushi clay shown in Fig. 8. That is, in the heat-treatment in a closed vessel, two reflections, (001) and (002), are clearly left at 500°C although their intensities are weaker, while in the heat-treatment in the open air, the reflections are thoroughly extinguished at the same temperature. The X-ray diffraction diagram of the 1100°C heat-treated specimen in the open air is almost exactly similar to that of the specimen heated at 1200°C in a closed vessel.

Summary

When kaolin mineral is heat-treated at a relatively low temperature region, its density has the minimum value between 500 and 800°C and the maximum at about 1000°C.

The value of dynamic properties of kaolin mineral increases slightly until about 800°C but increases rapidly beyond 1000°C to reach the maximum value. Then, the value is inclined to decrease rapidly beyond the temperatures, at which the maximum value is yielded. Similarly, the filling ratio also has the minimum value at about 800°C and increases rapidly beyond 1000°C to reach the maximum value. This indicates that when kaolin mineral is heat-treated at a relatively low temperature region, its dynamic properties have a close relation with its filling ratio. It is considered that these phenomena are due not only to the sintering of clay mineral by heat-treatment but also to the structural changes as shown in X-ray diffraction data.

The changes of dynamic and physical properties and of the structures of kaolin mineral heated in a closed vessel take place later than those heated in the open air. It may be due to the fact that the oxidation of the organic matters contained in kaolin mineral is oppressed in a closed vessel.

The writers wish to express their sincere thanks to Dr. Hiroshi Takahashi of the University of Tokyo for his valuable advice and assistance throughout this work.

*Crystal Structure and Lattice Energy of i-Erythritol. I. Crystal Structure of i-Erythritol**

By Akira SHIMADA

(Received August 13, 1958)

i-Erythritol ($CH_2OH \cdot C^*HOH \cdot C^*HOH \cdot CH_2OH$) is one of the polyalcohols, which has a close relationship with carbohydrates. Hence a knowledge of its stereochemical configuration would be of great interest and importance to the chemistry of carbohydrates. The molecule of this compound is built up of two and, in a sense, identical groups, each of which has an asymmetric carbon atom, C*, as indicated in the above chemical formula. It has already been reported that in the crystal of this substance these two identical groups are related to each other by a center of symmetry[1,2]. However, the detailed spatial configuration of this molecule still remains unexplored.

Interesting roles of the hydrogen bond have been elucidated for pentaerythritol in connection with its thermal and electrical properties[3-8]. Therefore, it seems highly promising to make an attempt to find out what types of hydrogen bond are linking molecules together in the crystal of *i*-erythritol, in order to understand some physical properties of this crystal.

Experimental

i-Erythritol crystallizes in the tetragonal bipyramidal class. Crystals were prepared by the slow evaporation of the solution in a mixture of ethyl alcohol and water. They were ground to cylindrical rods, elongated parallel to the [001] or [010] axis; their diameters are less than 0.4 mm. All photographs were taken with Cu K_α radiation. The crystal has been shown by the previous workers[1,2] to possess the space group symmetry $C_{4h}^6-I4_1/a$, with eight molecules in the unit cell. This assignment of the space group was verified by oscillation and Weissenberg photographs in the present experiment, and a redetermination of the unit cell dimensions gave the following values.

$$a=12.81\pm0.03\ \text{Å} \qquad c=6.81\pm0.02\ \text{Å}$$

The axial ratio $c/a=0.532\pm0.003$ as deduced from these lattice constants will give $c/\sqrt{2}\ a=0.376\pm0.002$ if we refer to the old choice of the crystallographic axes*, which is in excellent agreement with the goniometric value 0.3762[9]. Assuming eight molecules in the unit cell with the dimensions given above, the density is calculated to be 1.45 ± 0.01 g./cc., which is in good harmony with the value, 1.450 g./cc., reported by Schröder[10].

The ($hk0$) and ($h0l$) intensity data were estimated visually from multiple-film Weissenberg photographs. They were corrected for the Lorentz and polarization factors, using Cochran's chart[11]. Correction was applied to the absorption in the usual way, although this was found to be very small (absorption coefficient $\mu=12.7$ cm^{-1}). The observed structure ampliudes were first set on to an absolute scale using Wilson's method[12] which were further improved during the later stages of refinement.

Structure Determination

The unit cell contains only eight molecules, that is, sixteen C, sixteen C*, sixteen O_1 and sixteen O_2 atoms, suggesting that the center of gravity of each molecule must occupy a special position in the unit cell. In accord with the conclusion[1,2] already derived from a preliminary consideration of intensities of certain principal planes, it was confirmed that each molecule was situated at a center of symmetry. Hence each atom occupies the general positions given by,

* The major part of this paper was read at the 7th Annual Meeting of the Chemical Society of Japan, April, 1954. A short communication is now in press in Acta Crystallographica, and the present account describes the structure analysis in detail.

Because of the short c axis, it was expected that an approximate structure might appear in an electron density projection on the (001) plane, without complication due to overlappings of atoms. Since a molecule contains only lighter atoms, a Patterson projection $P(uv)$ on the (100) plane, shown in Fig. 1, did not give any useful information about the location of each atom. Hence, an attempt was made to solve the structure with a minimum function[13] derived from this Patterson projection. In order to get a minimum function, a location of rotation peaks must be determined and various minimum functions were tried, regarding acceptable peaks in the Patterson function as the possible image-seeking vectors. The location of rotation peaks, marked by a cross in the Patterson function, gave the most promising minimum function $M_4(xy)$ as shown in Fig. 2. Another approarch to the clue to an approximate structure was obtained by the inequality method[14] using Sakurai's chart[15], and the signs of five out of fifty-two observed reflections could be determined. The first Fourier map prepared with these terms, given in Fig. 3, shows a good resemblance to the minimum function $M_4(xy)$.

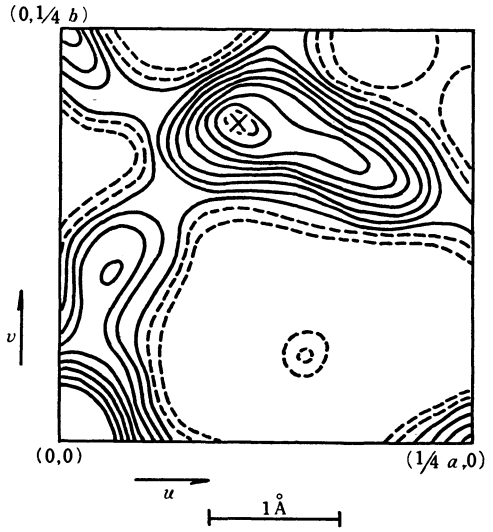

Fig. 1. Patterson projection $P(uv)$ onto (001) with contours at arbitrary intervals.

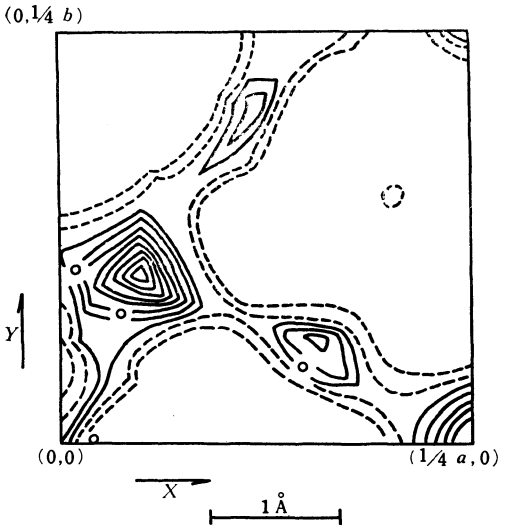

Fig. 2. Minimum function $M_4(xy)$ with contours at arbitrary intervals. Circles indicate the location of atoms corresponding to Fig. 4.

Based on these two promising figures, an effort was made to locate each atom at each peak by trial and error method. Starting from the approximate structure projected on the (001) plane, the structure was refined by successive Fourier syntheses with the aid of difference syntheses at later stages. The final Fourier

projection on the (001) plane is shown in Fig. 4. The reliability index $R=(\sum||F_o|-|F_c||)/\sum|F_o|$ for $(hk0)$ spectra is reduced to 16.5%, the contributions from hydrogen atoms being excluded. Several plausible configurations of the molecule were derived from the Fourier projection on the (001) plane with the aid of the Patterson projection $P(uw)$ on the (010) plane, which is shown in Fig. 5. They were put to the test by the comparison of observed and calculated structure factors for $(h0l)$ spectra. One of these configurations led to an approximately good agreement between the observed and the calculated structure factors, so as to give an approximate value of z for each atom. Since the symmetry of the crystal is high, there are considerable overlappings of atoms in the (010) projection which make it difficult to refine x,y and z values by successive Fourier syntheses alone. We were able to overcome this difficulty by preparing difference syntheses with the coefficients F_o-F_c', where F_c' stands for the structure factor calculated by means of the coordinates of the atoms, the peaks of which were well resolved but equivalent peaks were overlapped by other atoms by the symmetry operations. The usual difference syntheses were also tried at later stages to refine the structure. The electron density projection on the (010) plane is shown in Fig. 6. The reliability index R for $(h0l)$ spectra is found to be 13.3%*, the contributions from

hydrogen atoms being excluded. The atomic coordinates detemined in this way are listed in Table I. The observed and the calculated structure factors for (*hk*0) and (*h*0*l*) spectra are given in Table II. In the above calculation of structure factors, McWeeny's[16] scattering curves of "valence states" for carbon atom and of $f=1/3(f^{\parallel}+2f^{\perp})$ for oxygen atom were used with the isotropic temperature factor $B=2.17$ Å^2.

Discussion of the Structure

Since the molecule lies at the center of symmetry, two identical $CH_2OH\cdot C^*HOH$ groups constituting each half of the molecule are in the *trans*-position to each other, and the zig-zag chain of the four carbon atoms lies exactly in a plane, one of the C* atoms being of the nature *d* and the other *l*. All the valency angles for the carbon atoms are found to be approximately tetrahedral. Hence the configuration of the molecule as a whole can be described, only if we refer to the relative orientation of the outer C–O_2 bond with regard to the outer C*–C bond in each half of the molecule. The configuration of the molecule can be easily understood from Fig. 7, which shows the perspective view of a molecule in the C*–C bond direction. Intramolecular bond distances and bond angles are also listed in Table III. The plane of the C*–C–O_2

16) R. McWeeny, ibid., 4, 513 (1951).

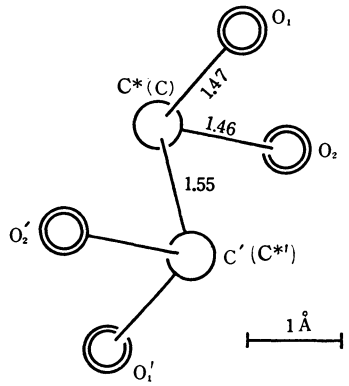

Fig. 7. *i*-Erythritol molecule projected on a plane at right angles to the C*-C bond. Intramolecular bond distances are given in Ångstrom units.

TABLE III
INTRAMOLECULAR BOND DISTANCES AND BOND ANGLES

C*-C	1.54 Å	∠C*'-C*-C	110°
C*-C*'	1.55 Å	∠C*'-C*-O_1	110°
C*-O_1	1.47 Å	∠C-C*-O_1	113°
C-O_2	1.46 Å	∠C*-C-O_2	108°

group forms a dihedral angle of 59° with the plane of the C-C*-O_1 group and an angle of 65° with that of the zig-zag chain of carbon atoms. In other words, the directions of the outer C-O_2 bond and the C*-C*' bond make the *gauche*-configuration with respect to the C*-C bond, and the two hydroxyl oxygen atoms in each half of the molecule are also in the *gauche*-positions around the C*-C bond. It is interesting to note that this relative configuration of the two hydroxyl groups with respect to the C*-C bond agrees with that found in tartaric acid and tartrate ion[17-21]. This mode of linkage is known to exist in carbohydrates. It must also be added that this configuration should be compared with the molecular configurations reported on ethylene glycol and glycerol on the basis of an electron diffraction study[22].

Fig. 8 gives the view of the crystal

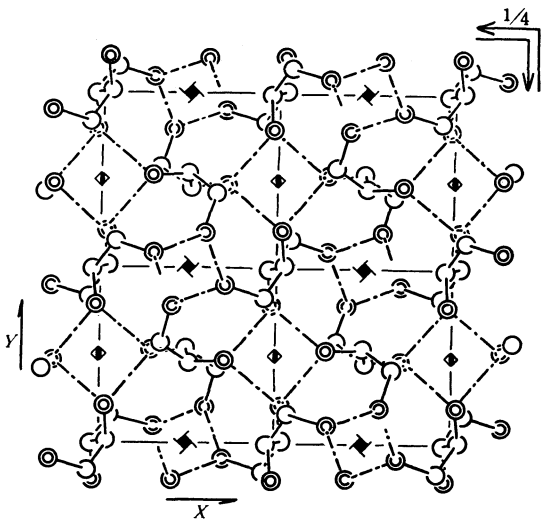

Fig. 8. A projection of the structure along the *c* axis of the crystal.

structure along the *c* axis. In this structure, important roles of two types of hydrogen bonds in the cohesion of the crystal can not be overlooked. The outer hydroxyl oxygen atom is linked to two oxygen atoms of the outer hydroxyl groups of the neighboring molecules, above and below, with a distance 2.66 Å forming a spiral chain arrangement of hydrogen bonds along the *c* axis. The inner hydroxyl oxygen atom, on the other hand, is linked to two oxygen atoms of the inner hydroxyl groups of the neighboring molecules. They form a distorted square of the side length 2.77 Å around the position given by the symmetry $\bar{4}$. They are making a lateral linkage, in a way, but at the same time they are uniting molecules within the same chain mentioned above. Thus, the crystal structure is held together by a three-dimensional net work of these hydrogen bonds, in which all the available hydrogen atoms and all the oxygen atoms also are joining, in agreement with the fact that this crystal has no cleavage.

The author is indebted to Professor I. Nitta, and Professor T. Watanabé for their helpful advice.

Crystal Structure and Lattice Energy of i-Erythritol. II. Lattice and Hydrogen Bond Energies for i-Erythritol

By Akira SHIMADA

(Received August 13, 1958)

There have been already reported many studies on the lattice energy of crystalline substances, but most of them are dealing with crystals which are composed of ions. Viewed from the standpoint of the fact that the most powerful force capable of holding ions together is the electrostatic one, this situation seems to be very natural. On the other hand, there have been reported few studies on the lattice energy of crystals composed of more or less complicated molecules. Among these studies, a detailed calculation of the lattice energy has been already carried out for pentaerythritol[1], which gave a satisfactory result in comparison with the observed heat of sublimation. Of *i*-erythritol ($CH_2OH \cdot C^*HOH \cdot C^*HOH \cdot CH_2OH$), which is also a member of tetrahydric alcohols, various physical properties have been already reported and related to those of pentaerythritol[2,3]. Now that the crystal structure of *i*-erythritol has recently been determined by X-ray analysis[4], it was attempted to calculate the lattice energy and compare it with the observed heat of sublimation[2].

Calculation of the Lattice Energy.—The crystal of *i*-erythritol was found to belong to the tetragonal system with $a=12.81$ Å, $c=6.81$ Å and the space group $C_{4h}^6-I4_1/a$[5]. There are eight centro-symmetrical molecules in the unit cell. The structure projected on the (001) plane is shown in Fig. 1, in which the Roman numerals are given for the sake of convenience in the following calculations. The interesting feature of this structure is that two different types of hydrogen bonds, as shown in Fig. 1, link all the molecules firmly in a three-dimensional way*. One of these two types of the hydrogen bond, with a distance 2.77 Å, connects two CHOH groups of adjoining molecules while the other, with a distance 2.66 Å, connects two CH_2OH groups of adjoining molecules. The coordinates of atoms determined by X-ray analysis[4] were used in the following calculations.

The calculations of the lattice energy was carried out in the same way as in the case of pentaerythritol. This energy was supposed to be composed mainly of the van der Waals and electrostatic energies. Slater-Kirkwood's formula was applied to get the former energy, splitting the molecule into three kinds of force center; they are the CH, the CH_2 and the OH group. The polarizability α of each atomic group used in Slater-Kirkwood's formula is shown in Table I. They were

TABLE I
MOLECULAR REFRACTION AND POLARIZABILITY

esimated from the molecular refractions M_∞ at infinite wave length[1]. As for the molecules the centers of which lie within about 10 Å from the molecule 0 at the origin, the minus sixth power of distance between force centers was computed one by one and summed up. As for the molecules lying apart beyond 10 Å from the molecule 0, the summation was replaced by integration, assuming the uniform distribution of the force centers. The result of calculation is given in Table II, showing that the contribution of the integral part is found to be very small. The obtained value 20.42 kcal./mol. is somewhat greater than that of pentaerythritol (17.62 kcal./mol.) and this is possibly related to the

* A preliminary infrared study on *i*-erythritol crystal shows that there is no marked band at the frequency of the unbonded OH stretching mode (3700 cm^{-1}), but at 3210cm^{-1} is observed a broad band which can be ascribed to the stretching modes of the hydrogen-bonded OH. Further study is now in progress.

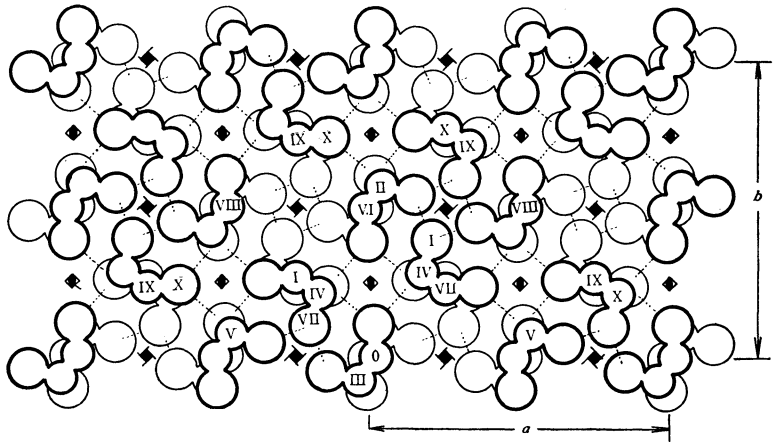

Fig. 1. View of molecular arrangement projected on (001) plane. The upper half of the centro-symmetrical molecule is shown by the broad outline, the large circle standing for OH group and the small one for CH and CH_2 groups. Dashed line indicates the hydrogen bond between the molecules.

difference of the packing in the two compounds (molecular volume: *i*-erythritol 84.2 cc./mol. and pentaerythritol 97.5 cc./mol. at room temperature).

In the calculation of electrostatic energy for this crystal, the point charge model was adopted, putting a net charge ε on the nuclear positions of the carbon atoms in CH and CH_2 groups, ε' on the hydrogen atoms in OH groups and $-(\varepsilon+\varepsilon')$ on the oxygen atoms. The positions of hydrogen atoms in OH groups were assumed to lie approximately on the line connecting two oxygen atoms at a distance 0.96 Å from the oxygen atom. A value 0.551×10^{-10} e. s. u. was assigned to the charge ε, and values 1.726 (Case A), 1.870 (Case B) and 2.015 (Case C) $\times10^{-10}$ e. s. u. were given for the charge ε', as in the case of pentaerythritol. These three cases correspond respectively to the three degrees of ionic characters 36, 39 and 42% of the OH bonds. The result of calculation is shown in Table III. In this calculation, the summation is taken over a sphere with its origin at the center of the molecule 0 and a radius of about 11 Å. The contribution of the outer part is neglected, in consideration of a possibility that it will decrease at least with the third power of distance. In fact, it can be shown by the Taylor's theorem that the electrostatic energy between each pair of molecules with no resultant permanent dipole moment will decrease at least with the fifth power of distance, and the number of pairs of molecules will increase with the second power of distance. Summing up the van der Waals and the electrostatic energies, the following three values are obtained, 32.23, 34.94 and 36.97 kcal./mol., corresponding respectively to the case A, B and C. The first value is in good agreement with the experimental value: 32.3± 0.2 kcal./mol[2]. It will be seen that for *i*-erythritol a good agreement is obtained for the case A, whereas the case B or C stands good for the case of pentaerythritol.

Estimation of the Hydrogen Bond Energy.—A part of the lattice energy may be attributed to the four hydrogen bonds, which are formed between a molecule of *i*-erythritol and its nearest neighbors. However, it is not easy to define and calculate that part of energy in this case, because in this complicated structure are appreciable the contributions of distant neighbors especially to the electrostatic energy and, furthermore, there is a rather even distribution of the hydrogen bonds, in contrast to the case of pentaerythritol where the hydrogen bonds connect the molecules to construct a typical layer lattice. Hence, in this case, the hydrogen bond energy is tentatively defined as the interaction energy between two OH groups directly linked together by the hydrogen bond. The van der Waals energies for the hydrogen bonds between two CHOH and two CH_2OH groups come out to be 1.35 and 1.65 kcal./mol. respectively. The corresponding electrostatic energies are computed, for the case A, to be 2.90 and 4.73 kcal./mol. Summing up these values, the hydrogen bond energies are to be 4.3 and 6.4 kcal./mol. The average value of these energies (5.4 kcal./mol.) seems to be somewhat larger than that of pentaerythritol (4.68 kcal./mol. for the case B or 5.16 kcal./mol. for the case C), although the definition of the hydrogen bond is somewhat different between these two compounds[1]. However, it is noteworthy to point out that a reasonable correlation of hydrogen bond energies (4.3 and 6.4 kcal./mol.) with hydrogen bond distances (2.77 and 2.66 Å) has been found in this calculation on the ground of rather simple model, while the model suggested by Lippincott[6] gives the values of hydrogen bond energies, 4.2 and 6.7 kcal./mol., corresponding to these two hydrogen bond distances.

Suzuki et al.[7] suggested another way for estimating hydrogen bond energy. This is to compare the heat of sublimation of the hydrogen-bonded substance with that of a reference substance, which is composed of isoelectronic molecules having similar configuration but no ability of hydrogen-bonding. This method was also applied to the cases of *i*-erythritol and pentaerythritol. The suitable reference substance chosen were 3, 4-dimethylhexane and 3, 3-diethylpentane each for these two compounds. The heat of sublimation of the reference substance was obtained by adding the heat of fusion[8] and that of vaporization. Since the heat of fusion of 3, 4-dimethylhexane is not yet known, it was estimated by adding the difference between the heat of fusion of 2, 3-dimethylbutane (0.194 kcal./mol.) and that of

n-butane (1.114 kcal./mol.) to that of *n*-hexane (3.114 kcal./mol.). The heat of vaporization was calculated from the temperature variation of vapor pressure[8] near the melting point. Table IV gives the latent heats associated with the phase

TABLE IV
HEAT OF PHASE CHANGE FOR THE REFERENCE SUBSTANCE (kcal./mol.)

	Reference substance	
	3,4-Dimethyl-hexane	3,3-Diethyl-pentane
Heat of fusion	2.19	2.35
Heat of vaporization	9.53	10.50
Heat of sublimation	11.7	12.9

changes for the reference substances. From these values, the hydrogen bond energies of 5.2 and 4.6 kcal./mol. have been estimated for *i*-erythritol and pentaerythritol respctively. These values are found to be in good agreement with the average values mentioned in the preceding paragraph.

At any rate, it seems likely that the average hydrogen bond energy for *i*-erythritol is larger than that for pentaerythritol, since the two methods of calculation gave parallel results. The values obtained above can be compared with those obtained on other alcohols[9]. Although in the calculation of the lattice energy mentioned above certain assumptions are involved, and the repulsive and other higher terms are ignored[10], it is noteworthy that the reasonable values for the lattice and hydrogen bond energies are obtained, based on the crystal structure.

The author wish to thank Professor I. Nitta, Professor T. Watanabé and Dr. S. Seki for their continued encouragement and Dr. K. Suzuki for his helpful discussion on the calculation of the lattice energy.

10) In the case of iodine crystal, these two terms were found to cancel out with each other. The agreement of the observed heat of sublimation with the lattice energy calculated by the use of Slater-Kirkwood's formula in many examples seems to indicate that these two terms cancel out with each other. See, I. Nitta and S. Seki, ibid., **64**, 475 (1943).

Electrical Conductance of Concentrated Aqueous Solutions of Copper Sulfate

By C. V. Suryanarayana and S. Alamelu

(Received September 19, 1958)

Numerous attempts have been made to extend the Debye-Hückel theory to electrolyte solutions of higher concentrations than 0.1 N. The attempts of Falkenhagen and Leist[1], Robinson and Stokes[2], Wishaw and Stokes[3], and Leist[4], are the most notable contributions in recent times in this direction.

Suryanarayana and Venkatesan[5,6] recently formulated the equation,

$$\Lambda_c = \Lambda_s + A\frac{(1-c_p)}{\eta_p} \qquad (1)$$

where

$$\Lambda_c = \frac{\text{specific conductance } (K_c)\times 1000}{c_p}$$

Λ_s = specific conductance at saturation $(K_s)\times 1000$

$$c_p = \frac{\text{mole fraction at a given concn.}}{\text{mole fraction at saturation at the same temp.}}$$

of course, at saturation $c_p = 1$

$$\eta_p = \frac{\text{viscosity at a given concn.}}{\text{viscosity at saturation}}$$

A = a constant whose value is a function of temperature and dielectric constant of the medium.

The basis of the formulation of the concepts c_p and η_p has already been given[7].

In the present investigations the data collected for copper sulfate solutions are sought to be fitted into equation 1. We hoped to verify the equation of Wishaw and Stokes (loc. cit.) with the same data. Unfortunately, copper sulfate being an "intermediate electrolyte" and a bi-bivalent salt with complications regarding ionic hydration in solution, and owing to uncertainty regarding the actual value of the mean distance of closest approach '$\mathring{a}$', we could not test Wishaw and Stokes' equation or even that of Falkenhagen and Leist (loc. cit.). Equation 1 involves no such uncertain parameters since the very

approach in its derivation was from a new angle (loc. cit.). Hence, equation 1 is now tested with the data of copper sulfate.

Experimental

All solutions were made by weight using "Analar" (British Drag House) variety of copper sulfate ($CuSO_4 \cdot 5H_2O$). A Jones and Bollinger type cell[8] of cell constant 0.6723 was used for conductivity determinations for all concentrations at different temperatures. The measurement of conductance was made by a Philip's GM 4249/01 bridge at a frequency of 1000 cycles/sec. Owing to the high concentration range in which measurements were made, the correction for conductance of pure solvent was quite negligible owing to high specific conductance in all the solutions and the correction was ignored. All connecting wires were heavily insulated, rigid, and well separated so that errors of poor insulation and induction effect were avoided. In the

range of measurement of resistance the instrumental error was ±2.00%. The conductivity cell was immersed in a Gallenkamp b-12210 thermostat giving an accuracy of ±0.05°C.

The viscosities were determined using an Ostwald viscometer immersed in the same thermostat. After attainment of equilibrium the saturated solution was sucked through a tube plugged with cotton wool into a pipette which was kept at the same temperature as the thermostat to avoid crystallization of the saturated solution and transferred into the viscometer. The densities of all the solutions were also measured. Solubility data were obtained from Seidell[9].

Results obtained are given in the tables.

Discussion

A test of equation 1 consists in obtaining a linear plot when Λ_c is plotted against $(1-c_p)/\eta_p$. Fig. 1 shows that such a plot is a straight line at all the temperatures betweem 30° and 60°C, with a few points (right hand side)toward low concentrations going off the straight line at each temperature. This indicates that equation 1 is valid in the range of concentrations from 0.3862 M to saturation (1.5 to 2.5 M). Since the actual resistance measured at saturation at different temperatures happened to be small, attempt is not made here to compare the extrapolated value of Λ_s with that found experimentally owing to the limitations of the instrument used. This aspect is postponed to a future date.

Pearce and Pumplin[10] found out the partial molal volumes of copper sulfate in aqueous solutions upto saturation at 25°C. They observed that the data on copper sulfate solutions are especially interesting because of the negative values of the partial molal volumes in dilute aqueous solutions, quite similar to the phenomenon observed for lithium hydroxide, sodium hydroxide and magnesium sulfate solutions. The very low values in general for copper sulfate indicate a very large amount of electrostriction of the solvent produced by the cupric ion, the water dipoles being compressed around the cupric ion by the intense electrostatic field produced by the high charge density of the ion. Absence of any discontinuity in the curve and a constancy of the law of variation throughout the curve upto saturation indicate that no sudden changes occur either in the total number of water molecules surrounding the ion or the type of bonding between the ion and the water molecules. Stewart[11] observed that the variation of the partial molal volume of ions with concentration is closely linked with the change in structure of water in the same solutions, as revealed by X-ray studies.

Fig. 2 shows the temperature variation of Λ_c for all the sixteen concentrations of copper sulfate solutions investigated upon. The curves are not perfect straight lines but are slightly bent convex toward the X-axis. Usually the two factors that determine the form of the temperature conductance curve are: (1) the increase in the viscosity of the solution, and the corresponding decrease in the mobility of the ions, with decreasing temperature; and (2) the effect of temperature on association of ions. With complications of ionic hydration and uncertainties regarding the predominance of one or the other of the above two factors, it is difficult to explain the non-linear variation of Λ_c against temperature.

Equation 1 was originially derived for fully dissociated strong electrolytes based on the principle that the difference in the mobilities of an ion at two different concentrations is a function of the difference in the respective internal pressures at the two concentrations. Copper sulfate is known to be an intermediate electrolyte[12] and the above mentioned observations show that equation 1 holds well even with a bibivalent electrolyte like copper sulfate.

Summary

The electrical conductance of aqueous solutions of copper sulfate has been measured over a wide range of concentrations up to saturation. The equation connecting conductance and concentration in the range of high concentrations recently formulated by Suryanarayana and Venkatesan has been tested with the data obtained for copper sulfate solutions. The equation is found to be valid over a wide range of concentration from 0.3862 M to saturation at temperatures ranging from 30° to 60°C. Slight deviations have been observed at lower concentrations.

Substituent Effects on the Ultraviolet Absorption Spectrum of 1,3,5-Trinitrobenzene in Some Solvents

By Takehiro ABE

(Received August 22, 1958)

The near ultraviolet absorption spectrum of 1,3,5-trinitrobenzene shows an intense band at 223 mμ and two shoulders at about 300 and 340 mμ in ethanol[1,2]. The maximum absorption band has a shorter wavelength of 223 mμ and a greater molar absorbancy than that of nitrobenzene[2], which has been interpreted by Nagakura and Tanaka[3], in terms of the intramolecular charge transfer.

In the present paper, an attempt has been made to investigate the effects of four substituents on the spectra of 1,3,5-trinitrobenzene in some solvents. The ultraviolet absorption spectra of 1,3,5-trinitrobenzene (TNB), 2,4,6-trinitrotoluene (TNT), picryl chloride (PC), 2,4,6-trinitrophenylmethylnitramine (Tetryl) and picric acid (PA) have been compared in solvents like water, water-sodium hydroxide, ethanol, benzene and acetone, together with the solvent effects upon the spectra of PC, Tetryl and PA. The spectra of TNB and TNT, measured in the previous work[2], have been used here.

Experimental

Materials.—Trinitrobenzenes of commercial extra pure grade were purified by recrystallizing several times. PC: m. p. 82.5°C, Tetryl: m. p. 129.9°C, PA: m. p. 122.6°C. Commercial guaranteed solvents were fractionally distillated after usual treatments.

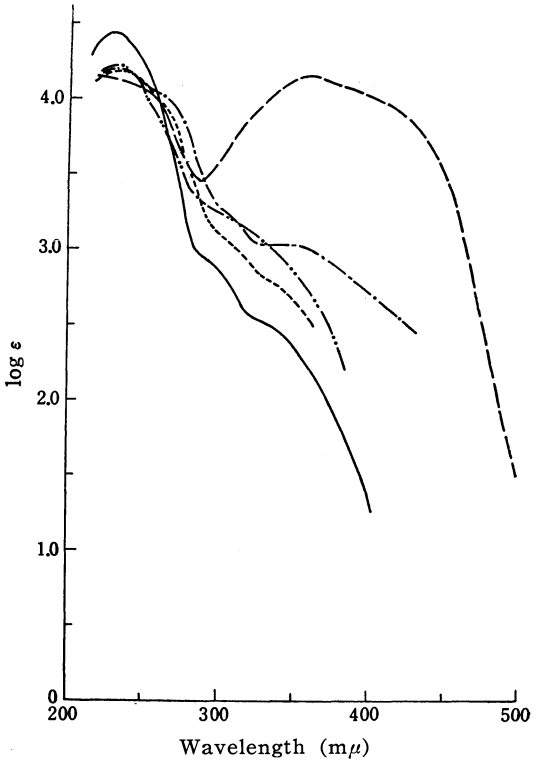

Fig. 2. Absorption spectra of TNB (——), TNT (------), PC (—·—), Tetryl (—··—) and PA (— —), all in water.

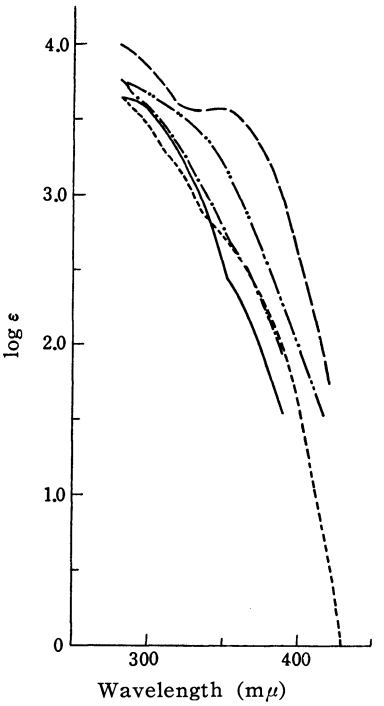

Fig. 3. Absorption spectra of TNB (——), TNT (------), PC (—·—), Tetryl (—··—) and PA (— —), all in benzene.

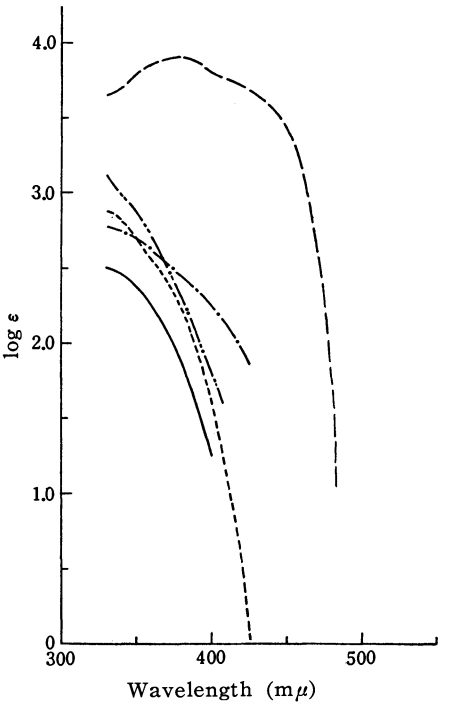

Fig. 4. Absorption spectra of TNB (——), TNT (------), PC (—·—), Tetryl (—··—) and PA (— —), all in acetone.

Spectra.—The spectra of the solution were measured with a Hitachi Model EPU-2 spectrophotometer at room temperature. Path length of absorption cells was 1 cm.

Results and Discussion

Spectra of Trinitrobenzenes in Some Solvents.—*In ethanol* (Fig. 1).—By substituting a group like $-CH_3$, $-Cl$, $-N(CH_3)NO_2$ or $-OH$, the 223 mμ band of TNB shifts to the red and its molar absorbancy decreases in the following order: TNB> Tetryl> TNT> PC> PA. Molar extinction coefficients of 300 and 340 mμ bands of the substituted trinitrobenzenes are greater than those of TNB, except those of PA that gives intense absorption bands at 350~450 mμ.

In the previous paper[2], it has been described that a benzene nucleus of polynitro-substituted benzene possesses some positive charge owing to the strong electron-attracting nature of nitro groups, and that the greater this positive charge, the greater becomes the blue shift of the maximum absorption band of the nitro compound. A benzene nucleus of each derivative of TNB possesses a less positive charge than that of TNB, because the electron of the $-CH_3$, $-Cl$, $-N(CH_3)NO_2$ or $-OH$ substituent can migrate to some extent toward the benzene nucleus in the direction opposite to the electron migration of the nitro groups, as indicated in Fig. 5. It is, therefore, known that the maximum absorption bands of the substituted trinitrobenzenes, benzene nuclei of which possess less positive charges than that of TNB, shift to the red with decreasing molar absorbancies, compared with the band of TNB.

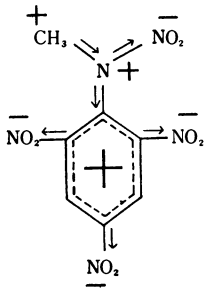

Fig. 5. Charge distribution of Tetryl.

In water (Fig. 2).—The substituted trinitrobenzenes show similar spectra as in ethanol, but give their maximum absorption bands at longer wavelengths and the smaller molar absorbancies in water than in ethanol. Both in ethanol and in water the molar absorbancies of their maximum absorptions are in the following order: TNB> Tetryl> TNT> PC> PA.

In benzene (Fig. 3).—The molar absorbancy of the 350 mμ shoulder of each substituted TNB is greater than that of TNB. Especially PA shows intense bands in this region.

In acetone (Fig. 4).—The molar absorbancies of the 340 mμ shoulders of the substituted trinitrobenzenes are greater than that of TNB. In addition to this shoulder, PA shows intense bands at 370~440 mμ. In all solvents the molar absorbancies of the 340 mμ bands of the trinitrobenzenes increase in the order of TNB, TNT, PC, Tetryl and PA, except the absorbancies of PC in water and in acetone.

It has been found that the visible absorption bands of TNB in acetone, indicated in the previous paper[2], are owing to the action of visible light on the trinitrobenzene used, because TNB that gives no visible absorption bands in acetone as shown in Fig. 4, shows such visible absorption spectra as indicated in the previous paper, after being irradiated by an usual incandescent lamp for a long time.

Solvent Effects on the Spectra of PC, Tetryl and PA (Figs. 1~4).—PC, Tetryl and PA give greater molar absorbancies of absorption bands near 300 mμ in benzene than in ethanol or in water. These great absorbancies in benzene seem probably to be due to formations of molecular complexes between the trinitrobenzenes and benzene, as TNB and TNT form complexes with benzene[2,4].

The absorption curves of PC and Tetryl in ethanol are not so closely resemble those in water as the curves of TNB and TNT. Only the 350 mμ band of PC exceptionally gives a greater molar absorbancy in water than in ethanol.

PA shows similar absorption curves in all three solvents like ethanol, water and acetone. This similarity seems to show that PA dissociates in negative ion not only in water, but also in ethanol and in acetone, losing a proton, because PA is known to be strongly acidic in water.

Spectra of Trinitrobenzenes in Aqueous Sodium Hydroxide Solution (Figs. 6~8).—In Fig. 6, visible absorption spectra of

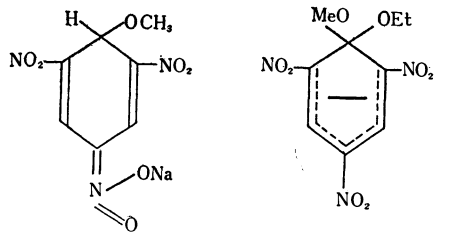
1. An aqueous solution of PC;
2. A solution in which a red color produced by adding a little of dilute sodium hydroxide solution into the solution (1), already discolored;
3. An aqueous solution of PA;
4. A solution obtained by adding a concentrated sodium hydroxide solution into the solution (3).

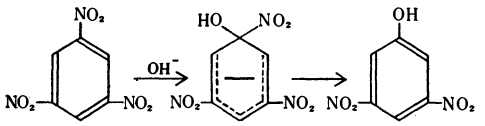


sodium hydroxide solutions of TNB, TNT and Tetryl are compared one another, and the absorption curves of the rather stable alkaline solutions of TNB and TNT, boiled to accelerate the rates of reactions between the trinitrobenzenes and alkali, are also indicated. The spectrum of TNB (curve 2) in sodium hydroxide solution closely resembles to that of Tetryl (curve 7). The spectrum of TNT (curve 5) in this solution also resembles them. These red colors are reversively decolorized by addition of weak acids.

On standing for two hours, the red color of the sodium hydroxide solution of Tetryl changes slowly to yellow, as described in Fig. 7. A spectrum of the yellow solution (curve 5) that yields no red color again by adding alkali, closely resembles that of PA (curve 6).

On treating an aqueous solution of PC with sodium hydroxide solution, a red color is produced and fades in a few minutes. By adding a concentrated solution of sodium hydroxide, a solution of PA at once gives a brownish orange color, which disappears in a moment. Absorption curves of yellow solutions to which these alkaline solutions of PC and PA change finally through red solutions, are given in Fig. 8. In a concentrated solution of sodium hydroxide, PA shifts a position of its maximum absorption band to the red by about 30 mμ, and shows a weak shoulder at about 500 mμ (curve 4).

From the above results, the red colors of the aqueous sodium hydroxide solutions of the substituted trinitrobenzenes are stable at room temperature in the following order: TNB and TNT> Tetryl> PC> PA. It is noticed that the substituted trinitrobenzenes that form the labile colors with sodium hydroxide, contain electron-donating substituents like $-N(CH_3)NO_2$, -Cl and -OH.

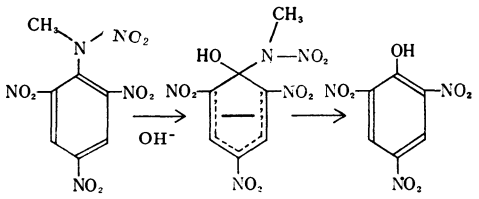


On boiling with dilute sodium hydroxide solution, TNB yields 3,3′,5,5′-tetranitroazoxybenzene and 3,5-dinitrophenol[5]. On standing in the cold with methanolic sodium methylate, TNB yields 3,5-dinitroanisol[6] and on boiling with alcoholic soda solution, it undergoes a partial reduction to form 3,3′,5,5′-tetranitroazoxybenzene[7]. The first product of the reaction of methanolic caustic alkali on TNB is a red crystalline addition product having the experimental composition, $TNB \cdot CH_3ONa \cdot 1/2H_2O$, isolated by Bruyn and Leent[8]. From these experimental results, the red product between TNB and sodium hydroxide seems probably to be an intermediate in the reaction of TNB to 3,5-dinitrophenol. The red products of TNT and Tetryl with sodium hydroxide may be also intermediates in their reactions. The transient colors of the sodium hydroxide solutions of PC and PA, absorption spectra of which have not been determined owing to their rapid discolorations, seem to be due to the same complexes as those of TNB, TNT and Tetryl. Actually, it has been reported that a methanol solution of TNT, treated with potassium methylate, yields a red product of an empirical composition, $TNT \cdot CH_3OK \cdot H_2O$[9]. A methanol solution of picryl chloride, treated with an excess of sodium methylate or of strong sodium hydroxide solution, also turns dark red and deposits red crystals of the empirical composition, $trinitroanisol \cdot NaOCH_3$[10]. The color reaction of sodium ethoxide with TNT and TNB in ethanol has been interpreted by Caldin and his co-workers[1,11] in terms of a proton-transfer reaction for TNT and in terms of an addition reaction for TNB.

(a) (b)

Fig. 9. Meisenheimer's structure for $TNB \cdot CH_3ONa$(a) and $TNA \cdot OEt^-$(b).

A structure of the red product of $TNB \cdot CH_3ONa$ was presented by Meisenheimer[12], as indicated in Fig. 9 (a). His structure seems to be doubtful in the following point. If the red product between TNB and sodium hydroxide has such a structure as given in Fig. 9 (a), PA may be produced from it at the end of the reaction, while 3,5-dinitrophenol is experimentally obtained as mentioned above. The absorption band of PA is not found also in the spectrum (curve 3) of the boiled alkaline solution of TNB in Fig. 6. It has been, by Nagakura[13], suggested to the present author that TNB should react with sodium hydroxide as follows:



Pale yellow Red Yellow

It was suggested also by Meisenheimer[14] that a red product between 2,4,6-trinitroanisol (TNA) and sodium ethoxide had the probable constitution indicated in Fig. 9(b). In this case, he isolated as solids the products of the reaction of TNA with potassium ethoxide and of 2,4,6-trinitrophenetole with potassium methoxide, obtained a mixture containing trinitrophenetole on decomposing each of these solids with dilute sulfuric acid, and concluded that both red products consisted of the potassium salt of the anion (Fig. 9(b)). The structure presented by Meisenheimer for the complex between TNA and ethoxide ion, has been recently supported by Hamick and Foster[15,16], and by Nagakura and Tsubomura[13,17], who

have succeeded in measuring an energy of activation for a decomposition reaction of a red complex of 2,4-dinitroanisol and hydroxyl ion to dinitrophenol.

In the reaction of Tetryl with sodium hydroxide PA seems to be finally produced through an intermediate, as indicated below, because the final absorption curve (5) of the reaction closely resembles that of PA (6) in Fig. 7. Although the red

products of TNB and Tetryl with alkali finally yield the different substances, that is, 3,5-dinitrophenol and PA, respectively, the resemblance between their spectra (curves 2 and 7 in Fig. 6) suggests that the structure of the red product of TNB may be similar to that of the red product of Tetryl. This is, thus, considered to support Meisenheimer's structure, since the resemblance of their spectra can be interpreted by assuming his structures in Fig. 9 (a), although the question pointed out above remains still.

Summary

(1) In ethanol and in water the maximum absorption bands of the substituted trinitrobenzenes are observed at longer wavelengths and possess smaller molar absorbancies than 1,3,5-trinitrobenzene, a benzene nucleus of which possesses some greater positive charge than those of the derivatives.

(2) Picric acid shows similar absorption curves in solvents like ethanol, water and acetone. This similarity seems to show that picric acid dissociates in all solvents.

(3) On treating the trinitrobenzenes with aqueous sodium hydroxide solution, the red colors are produced. The colors given by the trinitrobenzenes having substituents like $-N(CH_3)NO_2$, -Cl and -OH, are labile, while those produced from trinitrobenzene and 2,4,6-trinitrotoluene are rather stable. The spectrum of the red color of trinitrobenzene closely resembles that of Tetryl.

The author is particularly indebted to Professor Y. Nomura for his suggestion and encouragement of the present work. Thanks are also due to Associate Professor S. Maeda for use of the spectrophotometer.

*Penetration of Liquids into Filter Paper Used in Paper Chromatography**

By Masayuki NAKAGAKI and Kyoko OSAGAWA

(Received August 21, 1958)

The velocity of liquids ascending in filter paper, which is hung in a closed vessel and whose lower end is dipped in a liquid, is interesting from two viewpoints. The one is as the basis of the paper chromatography, in which the knowledge on the mechanism of the ascending of the developer liquid in a filter paper and on the properties of the filter paper seems to be fundamental to understand the physico-chemical details in the process of paper chromatography. The other standpoint is as a part of the studies of the penetration of liquids into porous materials. The latter, for example, the penetration of detergent solutions into clothes, is important when we consider the treatment of textiles in water.

The phenomenon can be treated by assuming that the penetration of liquids is due to the capillary force under the

* Presented before the Himeji Meeting held by the Chemical Society of Japan on May 31, 1958.

resistance by the viscosity and the hydrostatic pressure. Many theoretical and experimental investigations have already been made from this standpoint. Brittin[1] and Ikeda and Soeya[2] studied the ascending of liquids in capillary tubes. Lucas[3], Peek and McLean[4] and Fujita[5] studied the penetration into filter paper. Wolkowa[6] studied the penetration of liquids into a tube packed with powdered material. Carman[7] also studied the layer of powders on the basis of Kozeny's theory.

According to these investigations, the velocity of ascending, dh/dt, is given by[3,4]

$$dh/dt = (1/8\eta h)(2r\gamma \cos\theta - r^2 h\rho g) \quad (1)$$

and the equation for the initial stage of penetration is[3,4,6]

$$h^2 = kt \quad (2)$$

with $$k = r\gamma \cos\theta/2\eta \quad (2a)$$

In the present paper, a model of laminar capillary gaps will be used besides the model of tubular gaps already used by investigators cited above. Moreover, parameters will be used to take into account the winding of the gaps and the adsorption of liquids by the fibre. Finally, the penetration of liquids into the filter paper actually used in the paper chromatography will be studied.

Experimental

Organic Liquids.—Ethanol was boiled for 4 hours on a water bath with calcium oxide and distilled. The fraction distilled out at 78°C was dehydrated with sodium metal and distilled to collect the fraction at 78°C. Finally, it was again distilled on calcium oxide and the fraction of 78°C was used.

Benzene of the guaranteed reagent grade was distilled and the fraction at 80°C was used.

Acetone of the extra pure reagent grade was distilled and the fraction at 56.3°C was used.

Carbon tetrachloride of the extra pure reagent grade was treated with potassium hydroxide solution in an alcohol water mixture (KOH: H_2O:Alcohol=1:1:2) and shaken on a water bath for 30 min. at 50~60°C. Then it was washed with water, dehydrated with sodium metal and distilled to collect the fraction at 76.7°C.

Method of the Measurement. — Toyo filter paper No. 50 (for chromatography) was cut in pieces of 1 cm. in width and 25 cm. in length, and marked every 1 cm. with a pencil to show the distance from one end. A piece of the filter paper was hung in a measuring cylinder of 200 cc. closed with a cork stopper. In the cylinder, 10 cc. of liquid for study was placed in advance. The filter paper was hung so that its lower end was just 1 cm. below the surface of the liquid. The time when the front of the liquid passed every pencil mark was measured by a stop watch. All measurements were made in a thermostat held at 20°, 30° or 40°±0.02°C.

Theoretical Consideration of the Penetration

It may be natural to assume that liquid goes up in a piece of filter paper owing to the capillary force, under the resistance by the viscosity and the hydrostatic pressure. The shape of the capillary gap may be assumed to be one dimensional (tube like) or two dimensional (laminar).

In the case of the one dimensional gap, the amount of the liquid which penetrates into the gap per unit time, Q (cc./sec.), is given by Poiseuille's law,

$$Q = (\pi r^4/8\eta l)p \quad (3)$$

where η is the viscosity of the liquid, r the radius of the gap, p the pressure difference and l the length of the capillary filled with the liquid. The value of l may be different from the height of the liquid penetrated, because the capillary may be curved or wound. Therefore, the factor f is introduced here to indicate the degree of winding of the capillary by the equation,

$$f = l/h \quad (4)$$

where h is the height to which the liquid has gone up.

Now, the pressure difference p is the difference of the pressure by the surface tension and the hydrostatic pressure by the gravity,

$$p = (2\gamma \cos\theta)/r - h\rho g \quad (5)$$

where γ is the surface tension of the liquid, θ is the advancing contact angle and ρ is the density of the liquid and g is the constant of the gravity. At the equilibrium, $h=h_\infty$ and $p=0$, so that

$$h_\infty = 2\gamma \cos\theta/r\rho g \quad (6)$$

Then, another factor must be introduced here. If it is assumed that a fraction of the liquid which penetrates into the filter paper, α, is absorbed in fiber and $(1-\alpha)$ remains in the capillary gap, then,

$$(1-\alpha)Q = \pi r^2(dl/dt) = \pi r^2 f(dh/dt) \quad (7)$$

4) R. L. Peek and D. A. McLean, *Ind. Eng. Chem., Anal. Ed.*, **6**, 85 (1934).
5) H. Fujita, *J. Phys. Chem.*, **56**, 625 (1952).
6) Z. W. Wolkowa, *Kolloid-Z.*, **67**, 280 (1934).
7) P. C. Carman, *J. Soc. Chem. Ind.*, **57**, 225 (1938); **58**, 1 (1939).

Integrating this equation with Eqs. 2 and 4,

$$t/\tau = -h/h_\infty - \ln(1-h/h_\infty) \quad (8)$$

is obtained, where

$$\tau = 8\eta f^2 h_\infty/(1-\alpha)r^2\rho g \quad (9)$$

On the other hand, if the gap is two dimensional and its width is w and the half distance of the gap is a, $(w \gg a)$, then Eqs. 3, 5, 6, 7 and 9 should be replaced by

$$Q = (2wa^3/3\eta l)p \quad (3a)$$

$$p = \gamma\cos\theta/a - h\rho g \quad (5a)$$

$$h_\infty = \gamma\cos\theta/a\rho g \quad (6a)$$

$$(1-\alpha)Q = 2awf\mathrm{d}h/\mathrm{d}t \quad (7a)$$

and

$$\tau = 3\eta f^2 h_\infty/(1-\alpha)a^2\rho g \quad (9a)$$

respectively. However, the final equation 8 holds also in this case, although the interpretation of the constants h_∞ and τ is different from the former case. The assumption of two-dimensional gaps seems to be more reasonable than the one-dimensional gaps in the case of the filter paper.

On the basis of Eq. 8, it is easily seen that h^2 is proportional to the time, t, at the initial stage of the penetration,

$$h^2/t = 2h_\infty{}^2/\tau \quad (h/h_\infty \ll 1) \quad (9)$$

which agrees with Eq. 2 if $2h_\infty{}^2/\tau$ is equal to k.

According to the experimental data, the h^2-t curve is, however, straight only in the very initial range. The curve is not straight in the later stage. It is, therefore, desirable to expand Eq. 8 in a power series. It can be done in two ways:

$$h^2/t = (2h_\infty{}^2/\tau)\{1-(2/3)(h/h_\infty) - (1/18)(h/h_\infty)^2 - \cdots\cdots\} \quad (11a)$$

and

$$t/h^2 = (\tau/2h_\infty{}^2)\{1+(2/3)(h/h_\infty) + (1/2)(h/h_\infty)^2 + \cdots\cdots\} \quad (11b)$$

These equations show that the plot of h^2/t or t/h^2 against h should be almost linear if h is sufficiently small compared to h_∞. These equations also show that the deviation from the linearity should be smaller in h^2/t than in t/h_2, because the coefficient of the term of $(h/h_\infty)^2$ is smaller in Eq. 11a than in Eq. 11b. This is shown in Fig. 1, where curve I shows Eq. 11a and curve II shows Eq. 11b. The straight lines I′ and II′ are the initial slope of these curves. The symbols a and b show the deviation of curves I or II from the linearity by 1% and 5%, respectively.

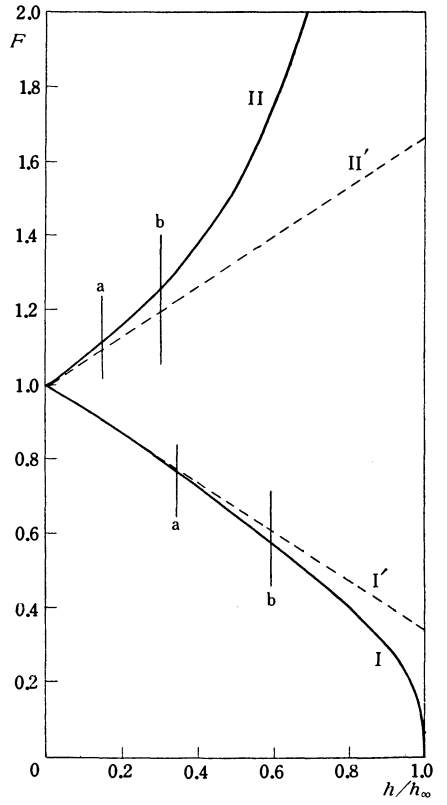

Fig. 1. Theoretical curves and their deviation from the linearity.

I: $F = (\tau/2h_\infty{}^2)(h^2/t)$
I′: $F = 1-(2/3)(h/h_\infty)$
II: $F = (2h_\infty{}^2/\tau)(t/h^2)$
II′: $F = 1+(2/3)(h/h_\infty)$
a: 1% deviation
b: 5% deviation

On the basis of the fact that curve I can be approximated by a straight line I′ in a fairly wide range of (h/h_∞), it is proposed to plote experimental values of (h^2/t) against h. The initial slope of this plot will give the values of A and B in the equation

$$h^2/t = A - Bh \quad (12)$$

and A and B are related to h_∞ and τ by the relations:

$$h_\infty = 2A/3B \quad (13)$$

and

$$\tau = 8A/9B^2 \quad (14)$$

as easily derived from Eq. 11a.

Results and Discussion

The height of the ascent of water and ethanol against time is shown in Fig. 2. The curves in this figure are the theoretical curves by Eq. 8, using the values of h_∞ and τ obtained by (h^2/t) vs. h plots on the basis of Eqs. 12, 13 and 14. These values are shown in Table I together with the

f ($\alpha=0$)	3.64	4.10	4.54	3.96	4.70

values of A and B of Eq. 12.

In order to eliminate the factors depending on the properties of the liquid penetrating and in order to obtain the parameters depending mostly on the properties of the filter paper, two quantities, x and y, are introduced, both of which are proportional to the half distance, a, in the case of two-dimensional gap and are proportional to the radius, r, of the gap in the case of the one-dimensional gap. That is,

$$x=\gamma/\rho gh_\infty=a/\cos\theta \text{ or } r/2\cos\theta \qquad (15)$$

and

$$y=(3/2)(\eta B/\rho g)^{1/2}=(1-\alpha)^{1/2}a/f \text{ or } (3/8)^{1/2}(1-\alpha)^{1/2}r/f \qquad (16)$$

The values of x and y are cited in Table I. The values of x for water and ethanol are different from each other, while the values of y are approximately the same for both water and ethanol.

The relationship between (h^2/t) and h are shown in Fig. 3 for acetone, benzene, water, carbon tetrachloride and ethanol at 20°C. The linearity expected from Eq. 12 is satisfied. The values of A and B obtained from this linearity are listed in Table II. Using the values of the viscosity, surface tension and density of these liquids listed also in Table II, the values of x and y are calculated and shown in the same table. It is seen that the value x varies widely depending on the nature of the liquid, while the value of y is roughly the same.

According to Eq. 15, the difference of the value of x should be due to the difference of the contact angle. If the contact angle is assumed to be zero in the case of the smallest value of x, that is the case of ethanol (this corresponds to the assumption that $a=6.09\,\mu$ or $r=12.2\,\mu$), then, the largest possible values of $\cos\theta$ and the smallest possible values of the advancing contact angle, θ, are calculated as shown in Table II. For fat-free filter paper, it is said that the value of θ was zero for many liquids[4], but it is not so for the filter paper used in the actual paper chromatography.

In order to make further estimation, the value of α is assumed to be as follows. In the case of water, the amount of water contained in 1 cm^2 of the filter paper was 0.0165 g./cm^2, and the weight of the dried filter paper was 0.0133 g./cm^2. Therefore, the amount of water contained in 1 g. of the filter paper was 1.24 g. On the other hand, the amount of water adsorbed by 1 g. of the fiber of the filter paper may be about 0.2 g., referring to the data by Marshall and Peters[8]. Therefore, the value of α is assumed to be 0.16. If a liquid other than water is adsorbed less in the fiber, the value of α should be smaller than this. The values of f calculated under this assumption were listed in Table II. Assuming the value of $a=6.09\,\mu$ in the case of two-dimensional gap model, the mean value of f is 3.12 if $\alpha=0.16$ and 3.41 if $\alpha=0$. In the case of one-dimensional gap model of $r=12.2\,\mu$, the mean value of f is 3.85 if $\alpha=0.16$ and 4.21 if $\alpha=0$. Therefore, the length of the gap is three to four times larger than the length of the filter paper.

The value of $6.09\,\mu$ for the half distance of the gap seems to be reasonable, because the diameter of fibers of the filter paper measured under a microscope was about $15\,\mu$. In this connection, it may be good to point out the generally accepted fact that the dimension of the gap obtained by the measurement of the permeability of liquid is usually five to fifteen times greater than the value obtained by the measurement of the permeability of particles.

Summary

The penetration of liquid into a piece of filter paper hung vertically above a liquid is studied theoretically and experimentally. The height of the ascent of the liquid is proportional to the square root of the time at the initial stage of the penetration, but the proportionality does not hold in a wide range of time. The equation which describes this relationship between the height and time has been derived. The values of the parameters in the equation have been determined for acetone, benzene, water, carbon tetrachloride and ethanol. It is concluded that the capillary gap in the filter paper is about $6\,\mu$ in the half distance and the length of the gap is about 3 times larger than the length of the filter paper, if the gap is assumed to be two dimensional.

The Aconite Alkaloids. XXIV. Oxidation of Miyaconitine and Miyaconitinone*

By Shichiro KAKIMOTO

(Received September 4, 1958)

Miyaconitine (I) $C_{23}H_{29}O_6N$ and miyaconitinone (II) $C_{23}H_{27}O_6N$ were isolated from *Aconitum miyabei*, Nakai, and the following extended formulae were given to them, respectively, in Part XVI[1].

$C_{16}H_{20}$ { $OCOCH_3$, OH, $(CO)_3$, $N\text{-}C_2H_5$ } I

$C_{15}H_{19}$ { $OCOCH_3$, $(CO)_4$, $N\text{-}C_2H_5$ } II

Since these alkaloids were relatively unstable to oxidation with either potassium permanganate or nitric acid, no crystalline oxidation product could be isolated even by the best method[2] found for the aconite alkaloids by H. Suginome. But, when miyaconitinone was oxidized with potassium permanganate under milder conditions, oxomiyaconitinone (III) $C_{20}H_{20}O_6$ ($-CO-N-C_2H_5$) was obtained only in a small yield.

In Part XVI[1] it was shown that an α-diketone group exists in these two alkaloids, and it seemed that oxidation with hydrogen peroxide would be successful. But all attemps of oxidative ring opening under the vigorous conditions described, for instance, by Holleman[3] and by Boeseken[4], to open the ring of *o*-camphorquinone, were unsuccessful. The present author has established a milder method to oxidize *o*-camphorquinone almost quantitatively to camphoric acid and these alkaloids have been oxidized successfully to dibasic acids by this method.

Namely, oxidation of miyaconitine with dilute alkaline hydrogen peroxide gave a basic substance, oxymiyaconitine (IV) $C_{23}H_{29}O_7N$, and an acid, miyaconinic acid (V) $C_{21}H_{29}O_7N$. It was determined that miyaconinic acid retains the original ethylimino group but not the acetyl group. It was titrated as a monobasic acid and gave a monomethyl ester (VI) $C_{22}H_{31}O_7N$ by esterification with diazomethane, while the dimethyl ester (VII) $C_{23}H_{33}O_7N$ could be derived with dimethyl sulfate in a concentrated potassium hydroxide solution. Acetylation of the dimethyl ester afforded a diacetyl compound (VIII) $C_{27}H_{37}O_9N$. Miyaconinic acid as well as these derivatives could not be hydrogenated by the method[1] described as a method for comparison of miyaconitine with miyaconitinone. These experiments showed that miyaconitine was hydrolyzed and then oxidized at the α-diketone group to give a dibasic acid V and its transformations into the above-mentioned derivatives are represented by the following schema:

I → $C_{16}H_{20}$ { $(OH)_2$, CO, $(COOH)_2$, $N\text{-}C_2H_5$ } V → $C_{16}H_{20}$ { $(OH)_2$, CO, COOH, $COOCH_3$, $N\text{-}C_2H_5$ } VI →

$C_{16}H_{20}$ { $(OH)_2$, CO, $(COOCH_3)_2$, $N\text{-}C_2H_5$ } VII → $C_{16}H_{20}$ { $(OCOCH_3)_2$, CO, $(COOCH_3)_2$, $N\text{-}C_2H_5$ } VIII

Oxidation of miyaconitinone by the same method gave miyaconinic acid and miyaconitinonic acid (IX) $C_{23}H_{29}O_8N$. The formation of miyaconinic acid from miyaconitinone is analogous to the alkaline hydrolysis of miyaconitine and miyaconitinone to miyaconine. Miyaconitinonic acid had an acetyl group and absorbed 1 mole of hydrogen, so that its relation to miyaconinic acid may be similar to the relation of miyaconitinone to miyaconine. Accordingly, formula IX is given to miyaconitinonic acid.

$C_{15}H_{19}$ { $OCOCH_3$, $(CO)_2$, $(COOH)_2$, $N\text{-}C_2H_5$ } IX

* This constitutes a part of a series entitled "The Aconite Alkaloids" by H. Suginome. The report, "On Lucaconine" presented in *Proc. Japan Acad.*, **22**, 122(1946) will be called Part XXIII. Part XXII is H. Suginome and S. Umezawa, *J. Fac. Sci. Hokkaido Univ., Ser. III Chem.*, **4**, 44 (1950).

1) H. Suginome, S. Furusawa, Y. Chiba and S. Kakimoto, ibid., **4**, 1 (1950).

2) H. Suginome, ibid., **2**, 95 (1937); *Ann.*, **533**, 172 (1931).

3) M. A. F. Holleman, *Rec. trav. chim.*, **23**, 169 (1904).

4) M. J. Boeseken, ibid., **30**, 142 (1911).

Miyaconinone that had been obtained by acid hydrolysis of miyaconitinone was oxidized to miyaconinic acid. This relation also had the same resemblance as observed previously. Miyaconine was oxidized to isomiyaconinic acid (X) differing from miyaconinic acid in melting point, optical rotation and crystalline form, but possessing the same formula $C_{21}H_{29}O_7N$ and the same chemical properties.

When miyaconitinonic acid was treated with acetic anhydride or heated under a reduced pressure, carbon dioxide and water were split off, producing a weak base, anhydrodecarboxymiyaconitinonic acid (XI) $C_{22}H_{27}O_5N$. It absorbed 1 mole of hydrogen, and had still an acetyl group. It could be distilled in high vacuum and it corresponded to a base resulting from original miyaconitinone by loss of one carbonyl group. It would be the most useful substance for succeeding degradation to clarify the constitution of the original alkaloid. The same treatment of miyaconinic acid with acetic anhydride afforded a weak base, diacetyldecarboxymiyaconinic acid (XII) $C_{24}H_{33}O_7N$. From isomiyaconinic acid, diacetyldecarboxyisomiyaconinic acid (XIII) $C_{24}H_{33}O_7N$ was obtained.

These acids and derivatives were produced by opening of one ring containing the α-diketone group just as expected. Further, anhydrodecarboxy compound XI was derived by closing the ring and splitting off carbon dioxide and water.

As the acids were titrated as monobasic, the ring opening might have occurred in the neighborhood of the ethylimino group. Accordingly, it was expected that the ethylimino group would be changed in its chemical properties and attacked in the ordinary degradation process. But, methiodides of their esters returned readily with alkali to the original substances such as miyaconitine and miyaconitinone.

Experimental

Oxomiyaconitinone (III).—Two g. of miyaconitinone was added to a solution of 0.15 g. of potassium permanganate and 5 cc. of glacial acetic acid in 30 cc. of acetone and the solution was allowed to stand for 24 hr. After filtration to remove manganese dioxide, the solution was evaporated to dryness and the residue was dissolved in water. The crude oxomiyaconitinone was extracted from the aqueous solution with chloroform and recrystallized from ethanol. Yield, 0.2 g. White needles, m. p. 210°.

Anal. Found: C, 64.86; H, 6.10; (N)-C_2H_5, 7.49. Calcd. for $C_{21}H_{20}O_7N$-C_2H_5: C, 64.62; H, 5.90; (N)-C_2H_5, 6.80%.

A Modified Method for Preparation of Camphoric Acid.—To a mixture of 2.5 cc. of 3 percent hydrogen peroxide, 2.5 cc. of N potassium hydroxide solution and 5 cc. of water, 0.2 g. of *o*-camphorquinone was added and the mixture was shaken for 24 hr. The reaction mixture was acidified and concentrated to give 0.2 g. of camphoric acid. m. p. 186~187°. $[\alpha]_D^{10}$ +57.3° (acetone).

Anal. Found: C, 59.90; H, 7.99. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.06%.

Oxidation of Miyaconitine with Hydrogen Peroxide.—*a) Oxymiyaconitine (IV).*—A suspension of 1.7 g. of powdered miyaconitine in a mixture of 8 cc. of 3 percent hydrogen peroxide, 10 cc. of N potassium hydroxide solution and 20 cc. of water, was shaken for 24 hr. The mixture of unchanged miyaconitine and oxymiyaconitine was collected and fractionally recrystallized from ethanol; 0.25 g. of oxymiyaconitine was obtained. m. p. 244~245° (decomp.). $[\alpha]_D^{9.5}$ +44.6° (N acetic acid).

Anal. Found: C, 64.33; H, 6.69. Calcd. for $C_{23}H_{29}O_7N$: C, 64.02; H, 6.78%.

b) Miyaconinic acid (V).—The basic filtrate from miyaconitine and oxymiyaconitine, was acidified with dilute hydrochloric acid and dried up under a reduced pressure. The residue was extracted with ethanol, the extract was evaporated to dryness and the residue was treated with dilute acetic acid. The crude acid thus obtained was dissolved in dilute ammonia water and reprecipitated with dilute acetic acid. Yield, 0.17 g. Needles, m. p. 295° (decomp.). $[\alpha]_D^{18}$ +17.7° (N ammonia). It contained 1 mole of water of crystallization.

Anal. Found: H_2O, 4.18. Calcd. for $C_{21}H_{29}O_7N$-H_2O: H_2O, 4.25. Found: C, 61.79; H, 6.96; N, 3.65; COOH*, 12.41. Calcd. for $C_{21}H_{29}O_7N$: C, 61.90; H, 7.18; H, 3.44; COOH, 11.08%.

c) Monomethyl ester of miyaconinic acid (VI).—To a suspension of 0.1 g. of miyaconinic acid in 25 cc. of ether, 0.1 g. of diazomethane was added and the mixture was allowed to stand for 24 hr. The precipitate was dissolved in dilute acetic acid and reprecipitated with dilute ammonia water. The precipitate was recrystallized from methanol. Yield, 0.1 g., m. p. 285° (decomp.). It contained 2 moles of water of crystallization.

Anal. Found: H_2O, 7.52. Calcd. for $C_{22}H_{31}O_7N \cdot 2H_2O$: H_2O, 7.88. Found: C, 62.73; H, 7.41; OCH_3, 7.76. Calcd. for $C_{22}H_{31}O_7N$: C, 62.69; H, 7.41; OCH_3 7.36%.

Its perchlorate melted at 210° with decomposition.

Anal. Found: Cl, 6.49. Calcd. for $C_{22}H_{31}O_7N \cdot HClO_4$: Cl, 6.80%.

Its methiodide melted at 271~272° with decomposition.

Anal. Found: C, 48.50; H, 5.51; I, 23.87. Calcd. for $C_{22}H_{31}O_7N \cdot CH_3I$: C, 48.90; H, 6.03; I, 23.53%.

d) Dimethyl ester (VII).—To a solution of 0.2 g. of miyaconinic acid in 1.3 cc. of 15 percent

* Titrated with 0.01 N potassium hydroxide (Indicator: Phenolphthalein).

potassium hydroxide solution, 1 cc. of dimethyl sulfate was added and the mixture was warmed at 60°. The reaction mixture was acidified with dilute sulfuric acid and filtered. The solution was alkalized with dilute ammonia water, producing 0.19 g. of the dimethyl ester. It melted at 296~297° with decomposition and formed a perchlorate and a methiodide.

Anal. Found: C, 63.58; H, 7.10; OCH_3, 14.08; (N)-C_2H_5, 7.18. Calcd. for $C_{23}H_{33}O_7N$: C, 63.41; H, 7.41; OCH_3, 14.24; (N)-C_2H_5, 6.67%. Found: Cl, 6.47. Calcd. for $C_{23}H_{33}O_7N\ HClO_4$; Cl, 6.62%.

e) Diacetyl dimethyl ester (VIII).—To a solution of 0.2 g. of dimethyl ester in 2 cc. of glacial acetic acid, 2 cc. of acetic anhydride and 2 cc. of pyridine were added. After 24 hr., the solvent was distilled off under a reduced pressure. The residue was dissolved in water, and dilute ammonia water was added to give 0.2 g. of diacetyl dimethyl ester. It was recrystallized from methanol. m. p. 167~168°.

Anal. Found: C, 62.65; H, 7.34; OCH_3, 11.12; (N)-C_2H_5, 5.43; $COCH_3$, 16.39. Calcd. for $C_{27}H_{37}O_9N$: C, 62.41; H, 7.18; OCH_3, 11.94; (N)-C_2H_5, 5.59; $COCH_3$, 16.57%.

Oxidation of Miyaconitinone. — Three g. of miyaconitinone was oxidized by the above-described method. After the separation of 0.32 g. of crude miyaconinic acid from the reaction mixture, chloroform was added to the filtrate and the mixture was stirred for several minutes. The semicrystalline product, presumably containing chloroform, was separated and warmed in water to remove the contained chloroform. From the concentrated solution, 0.17 g. of crude miyaconitinonic acid crystallized out in white needles. It was recrystallized from ethanol, m. p. 259° (decomp.). $[\alpha]_D^{10}$ −84.7° (N ammonia water).

Aanl. Found: C, 61.28; H, 6.57; COOH, 10.16; $COCH_3$, 9.83. Calcd. for $C_{23}H_{29}O_8N$: C, 61.73; H, 6.54; COOH, 10.05; $COCH_3$, 9.62%. 8.120 Mg. of sample absorbed 0.442 cc. of hydrogen (1.04 mol.).

Oxidation of Miyaconine. — Oxidation of 0.7 g. of miyaconine afforded 0.2 g. of isomiyaconinic acid. It melted at 268° with decomposition. White plates, $[\alpha]_D^{9.3}$ +27.3° (N ammonia water).

Anal. Found: H_2O, 4.55; C, 59.53; H, 7.06; COOH, 10.53. Calcd. for $C_{21}H_{29}O_7N\cdot H_2O$: H_2O, 4.25; C, 59.28; H, 7.35; COOH, 10.53%.

Oxidation of Miyaconinone. — From 0.45 g. of miyaconinone, 0.05 g. of miyaconinic acid was obtained, m. p. 295°.

Anal. Found: C, 62.69; H, 6.88. Calcd. for $C_{21}H_{29}O_7N$: C, 61.90; H, 7.18%.

Anhydrodecarboxymiyaconitinonic Acid (XI).—Miyaconitinonic acid (0.2 g.) was heated at 259° in a high vacuum for a few minutes. After cooling, the residue was recrystallized from ethanol to give anhydrodecarboxymiyaconitinonic acid. Yield, 0.13 g., m. p. 164~165°, $[\alpha]_D^{10}$ −117.0° (chloroform). XI was soluble in dilute hydrochloric acid, but almost insoluble in dilute acetic acid, and it was precipitated with ammonia water from the acidic solution. XI was also obtained from 0.1 g. of the original acid by heating with a mixture of 0.5 cc. of glacial acetic acid and 3 cc. of acetic anhydride for 1 hr., evaporating the solvent and adding water. XI was recrystallized from ethanol. Yield, 0.04 g.

Anal. Found: C, 67.43; H, 6.77; N, 3.74; $COCH_3$, 11.54. Calcd. for $C_{22}H_{27}O_6N$: C, 68.55; H, 7.06; N, 3.63; $COCH_3$, 11.09%. 8.533 Mg. of sample absorbed 0.442 cc. of hydrogen (1.15 mol.).

When this base was heated with 45 per cent ethanol for 2 hr., it was converted into a weak base, m. p. 194~195°, $[\alpha]_D^{10}$ −142.4° (chloroform). The latter base corresponded to decarboxymiyaconitinonic acid.

Anal. Found: C, 65.63; H, 6.94; $COCH_3$; 10.63. Calcd. for $C_{22}H_{29}O_6N$: C, 65.50; H, 7.25; $COCH_3$, 10.67%. 8.637 Mg. of sample absorbed 0.446 cc. of hydrogen (0.93 mol.).

Diacetyldecarboxymiyaconinic Acid (XII).—When 0.22 g. of miyaconinic acid was treated with acetic anhydride as mentioned above, 0.11 g. of diacetyldecarboxymiyaconinic acid was obtained in white prisms, m. p. 215~216°.

Anal. Found: C. 63.57; H, 6.39; $COCH_3$, 18.98. Calcd. for $C_{24}H_{33}O_7N$: C, 64.41; H, 7.43; $COCH_3$, 19.68%.

Diacetyldecarboxyisomiyaconinic Acid (XIII).—From 0.1 g. of isomiyaconinic acid, 0.01 g. of diacetyldecarboxyisomiyaconinic acid was obtained in white needles, m. p. 200~202°.

Anal. Found: C, 63.73; H, 6.50; $COCH_3$, 19.80. Calcd. for $C_{24}H_{33}O_7N$: C, 64.41; H, 7.43; $COCH_3$, 19.68%.

The author wishes to express his thanks to Professor Harusada Suginome, President of Hokkaido University, for his exceedingly kind direction throughout this work.

The Aconite Alkaloids. XXV. Selenium Dehydrogenation of Miyaconitinone and Lucidusculine*

By Harusada SUGINOME and Shichiro KAKIMOTO

(Received September 4, 1958)

Miyaconitinone[1], $C_{23}H_{27}O_6N$, which has been isolated from *Aconitum miyabei*, Nakai, belongs to the aconine group that may be derived from the fundamental base, $C_{19}H_{29}N$; while lucidusculine[2], $C_{24}H_{35}O_4N$, which has been isolated from *Aconitum lucidusculum*, Nakai, may be derived from the fundamental base, $C_{20}H_{31}N$, similar to atisine. These two aconite alkaloids, belonging to different fundamental bases, were subjected to dehydrogenation by selenium, producing the following results:

Miyaconitinone → $C_{21}H_{38}$ (unsure), phenanthrene, anthracene

Lucidusculine → phenanthrene, 3-methylphenanthrene, pimanthrene (unsure)

Hetisine, atisine, napelline and staphisine all yielded neutral fractions consisting of complex mixtures of phenanthrene hydrocarbons, some of which were identified to be phenathrene, 1-methyl-, 1,7-dimethyl-, 1-methyl-6-ethylphenanthrene, 3-methylretene, and $C_{17}H_{16}$ or $C_{18}H_{18}$[3].

The conditions, employed at first, to dehydrogenate miyaconitinone were rather more vigorous than Lowson's procedure, but a good result was not obtained. Only an oily mixture of unsaturated hydrocarbons and a saturated hydrocarbon, which melted at 60° and seemed not to be pure but near to $C_{21}H_{38}$, were obtained.

When miyaconitinone was dehydrogenated under more drastic conditions, e. g., heated in a sealed tube at 300~320° for 24 hr. and then at 370~380° for 24 hr., an oily mixture of unsaturated hydrocarbons was yielded. High vacuum distillation of the mixture afforded crystalline hydrocarbons from which pure phenanthrene and anthracene were separated by means of recrystallization. Each of them was determined by observation of ultraviolet absorption spectrum and preparation of quinone and picrate.

Under the same condition, giving phenanthrene and anthracene from miyaconitinone, lucidusculine was dehydrogenated. The main part of mixture of crystalline hydrocarbons was phenanthrene, and two other hydrocarbons were obtained in small quantities. One of them was determined to be a methylphenanthrene by elementary analysis. It melted at 62° and was converted into the picrate, bright yellow needles, m. p. 130°, and into the quinone, orange plates, m. p. 204°. Therefore, it was decided to be a 3-methylphenanthrene[4]. The other hydrocarbon melted at 80° and was converted into the picrate, yellow needles, m. p. 125°, and into the quinone, reddish needles, m. p. 182°. It seemed to be 1,7-dimethylphenanthrene (pimanthrene)[5]. From lucidusculine no anthracene derivative was yielded, but only the derivatives of phenanthrene.

It has not yet been reported that anthracene is obtained from other aconite alkaloids. The authors have been able to obtain anthracene from miyaconitinone. But it may be too early to conclude that the aconite alkaloid, having the fundamental base, $C_{20}H_{31}N$, has a constitution with a skeleton that yields both phenanthrene and anthracene, because miyaconitinone has so many oxygen atoms that it is very unstable to oxidation (cf. Part XXIV) and because it requires a drastic condition for dehydrogenation. It is of interest that some cholestanediols can be converted readily into anthracene ring system[6].

Experimental

Dehydrogenation of Miyaconitinone. — A mixture of 3 g. of miyaconitinone and 15 g. of selenium was divided into four portions. Each of them was sealed in a hard glass tube and heated at 320° for 35 hr. The reaction mixtures were combined and extracted with ether, and from the extract, basic substances from which no crystalline substance could be isolated, were removed by extraction with dilute hydrochloric acid. After ether was distilled off, the residue was fractionated by high vacuum distillation (over 10^{-3} mm.). Three hundred mg. of first fraction, distilled at 80~130°, was treated with glacial acetic acid. The insoluble part was recrystallized three times from methanol to give 13 mg. of white leaflets, m. p. 60°. The material has no color reaction with tetranitromethane and may be $C_{21}H_{38}$ or hydrocarbon near $C_{21}H_{38}$.

Anal. Found: C, 85.36; H, 14.38. Mol. Wt. 294 (Rast's method). Calcd. for $C_{21}H_{38}$: C, 86.79; H, 13.21%. Mol. Wt. 290.

When water was added to the solution of unsaturated hydrocarbon in glacial acetic acid, oil was separated. It was distilled to give 230 mg. of oil which was colored by tetranitromethane. It seemed to be a mixture of unsaturated hydrocarbons.

Anal. Found: C, 89.64; H, 7.98%.

Since it was not possible to isolate the pure substance in the above described experiment, more drastic conditions were employed as the following.

A mixture of 20 g. of miyaconitinone and 80 g. of selenium was divided into ten portions. Each of them was heated at 300~320° for 24 hr., and then at 370~380° for the same period in a sealed tube. The reaction mixtures were combined and extracted with ether. Ethereal extract was washed with dilute hydrochloric acid, next with dilute sodium bicarbonate solution and then with water. After removal of the ether, the residue was distilled under a high vacuum to give one part of oil and 460 mg. of crystalline part. The latter was fractionally recrystallized from methanol into three parts, i) melted at 90~100°, ii) melted at 190~200°, iii) melted at 120~150°. Recrystallization through picrate and chromatographic separation of crude substance was not effective to obtain pure compounds. The part i thus separated was able to be purified through the picrate which was recrystallized from ethanol, and then the derived free hydrocarbon was recrystallized from methanol again to yield 25 mg. of phenanthrene, m. p. 99~100°. The substance was characterized by the observation of ultraviolet absorption spectrum and by preparing the picrate, m. p. 144° and phenanthrenequinone, m. p. 205°, which was derived by oxidation with chromic trioxide in glacial acetic acid. These derivatives gave no depression of the melting points on admixture with the corresponding derivatives of pure phenanthrene.

Anal. Found: C, 94.33; H, 5.24. Calcd. for $C_{14}H_{10}$: C, 94.34; H, 5.66. Found: C, 80.70; H, 3.66. Calcd. for $C_{14}H_8O_2$: C, 80.69; H, 3.87%. Found: C, 59.37; H, 2.71. Calcd. for $C_{14}H_{10}$. $C_6H_3O_7N$: C, 58.97; H, 2.80%.

The part ii, mentioned above, was recrystallized from methanol to yield 20 mg. of an anthracene, m. p. 215°. The derived anthraquinone melted at 283°.

Anal. Found: C, 94.35; H, 5.65. Calcd. for $C_{14}H_{10}$: C, 94.34; H, 5.66. Found: C, 80.41; H, 3.62. Calcd. for $C_{14}H_8O_2$: C, 80.69; H, 3.87%.

The part iii was found to be a mixture of i and ii. Recrystallization through picrate and chromatographic separation afforded no good result. Therefore, the mixture was oxidized with chromic trioxide in glacial acetic acid. The oxidized substance was dissolved in alcohol and the product was adsorbed on neutral alummina and eluted with benzene; 20 mg. of pure phenanthrenequinone and 15 mg. of anthraquinone could be separated.

Dehydrogenation of Lucidusculine. — The conditions of dehydrogenation were the same as those used for miyaconitinone to obtain phenanthrene and anthracene. Neutral oil in an amount of 1.731 g. was obtained from 20 g. of lucidusculine. From the oil, 426 mg. of crystalline hydrocarbon mixture was separated by high vacuum distillation. The mixture was repeatedly recrystallized from methanol, but only 45 mg. of phenanthrene, m. p. 98°, (its picrate, m. p. 142°, the quinone, m. p. 204°) was isolated and no anthracene could be obtained. Other parts of hydrocarbon mixture were converted into picrate. The recrystallization was repeated again to give phenanthrene picrate and two other picrates. One of them was in the form of bright yellow needles, m. p. 130° and the other of yellow needles, m. p. 125°. From the former, 38 mg. of 3-methylphenanthrene, m. p. 62° was obtained and it was oxidized to the quinone, m. p. 204°. Orange plates.

Anal. Found: C, 93.58; H, 6.06. Calcd. for $C_{15}H_{12}$: C, 93.71; H, 6.26%. Found: C, 80.92; H, 4.79. Calcd. for $C_{15}H_{10}O_2$: C, 81.10; H, 4.54%.

From the latter, 9 mg. of hydrocarbon, m. p. 80° was obtained. Five mg. of this substance was oxidized to quinone which was recrystallized from methanol and melted at 182°. Reddish needles. But its yield was too small to be recrystallized repeatedly for analysis. It seemed to be pimanthrene (1,7-dimethylphenanthrene).

The Aconite Alkaloids. XXVI. On Lucaconine and Monoacetyllucaconine*

By Harusada SUGINOME and Sijô FURUSAWA**

(Received September 4, 1958)

In Part XXIII[1] of this series, it was reported that a new alkaloid, lucaconine, $C_{21}H_{33}O_6N$, was isolated from the roots of *Aconitum luciduscul*um, Nakai and it was suggested that it had two methoxyl, four hydroxyl, and a secondary amino group. One of the present authors with Amiya[2] found that diacetyllucaconine had two active hydrogens. Therefore, *N*-alkyl and other functional groups had to be determined more precisely. As the results of repeated examinations, it was found that the base had an *N*-ethyl and three methoxyl groups, and, therefore, the older molecular formula of lucaconine, $C_{21}H_{33}O_6N$, should be revised to $C_{24}H_{39}O_7N$***.

On the other hand, a new alkaloid was isolated from the roots of the above mentioned *Aconitum* species, viz., on the basis of the difference of solubility in benzene from the crude bases containing lucaconine. The content of the base was about one-tenth of that of lucaconine and was about 0.012 per cent that of dried roots. The new alkaloid was purified through a perchlorate, from which the free base was liberated and recrystallized from ethanol. The purified base had m.p. 187°, $[\alpha]_D^{18}+42.7°$, and molecular formula $C_{26}H_{41}O_8N$. On hydrolysis with alcoholic potassium hydroxide it split off one mole of acetic acid and produced the alkamine, lucaconine.

$$C_{26}H_{41}O_8N+H_2O\rightarrow CH_3COOH+C_{24}H_{39}O_7N$$

Therefore, this new base was named monoacetyllucaconine.

Acetylation of lucaconine I and monoacetyllucaconine II with acetic anhydride gave the same diacetyl compound, diacetyllucaconine III, $C_{28}H_{43}O_9N$, m. p. 124°, $[\alpha]_D^{16}+15.3°$, which afforded lucaconine on hydrolysis with alcoholic potassium hydroxide.

From these results the formulae of lucaconine I and monoacetyllucaconine II may be extended as follows:

$C_{19}H_{21}$ { $(OCH_3)_3$, $(OH)_4$, $N\text{-}C_2H_5$ } Lucaconine (I)

$C_{19}H_{21}$ { $(OCH_3)_3$, $OCOCH_3$, $(OH)_3$, $N\text{-}C_2H_5$ } Monoacetyllucaconine (II)

Lucaconine and monoacetyllucaconine are assumed to have hexacyclic structure based on the skeletal formula, $C_{19}H_{29}N$[3].

Experimental

Isolation of Lucaconine.—As described in the previous reports[1,4], 293.6 kg. of dried roots of *Aconitum luciduscul*um, Nakai was treated. The percolate thus obtained was divided into three fractions, which were named fraction I, fraction II, and fraction III as previously described[4]. The yield of fraction III was 1,062 g. (0.36% of dried roots). Treatment of fraction II with acetone gave 357 g. of crystalline material, which was recrystallized from ethanol to give 210 g. of crude lucaconine, melting at 197°.

From 5.5 g. of this crude lucaconine, 6.8 g. of crystalline perchlorate was prepared, which was recrystallized from ethanol to give 5.1 g. of pure perchlorate, m. p. 210° (decomp.). From this salt, 3.9 g. of a free base melting at 198° was liberated; on three recrystallizations from ethanol, the base melted at 200°, and showed no depression of the melting point on admixture with an authentic sample of lucaconine[1]. $[\alpha]_D^{14}+57.1°$ (chloroform).

Anal. Found: C, 63.48; H, 8.39; N, 3.55; OCH_3, 20.86; (N)-C_2H_5, 6.59. Calcd. for $C_{24}H_{39}O_7N$: C, 63.55; H, 8.45; N, 3.09; 3-OCH_3, 20.53; (N)-C_2H_5, 6.19%.

Determination of N-ethyl group[5].—Lucaconine was treated in the usual manner for Willstätter's *N*-alkyl determination. Trimethyl ethyl ammonium iodide thus obtained was analyzed.

Anal. Found: I, 60.38. Calcd. for $(CH_3)_3(C_2H_5)NI$: I, 59.02%.

The pure lucaconine was also obtained by treatment of the crude base melting at 197° with ethanolic potassium hydroxide, followed by recrystallization from ethanol.

Perchlorate.—m. p. 210° (decomp.).

Anal. Found: C, 51.68; H, 7.08; Cl, 6.39. Calcd. for $C_{24}H_{39}O_7N \cdot HClO_4$: C, 52.01; H, 7.75; Cl, 6.36%.

Hydrochloride.—m. p. 216~217° (decomp.) (from abs. ethanol).

Anal. Found: C, 58.81; H, 8.31; Cl, 7.32. Calcd. for $C_{24}H_{39}O_7N \cdot HCl$: C, 58.80; H, 8.22; Cl, 7.24%.

Hydrobromide.—m. p. 223° (decomp.) (from abs. ethanol).

Anal. Found: C, 54.30; H, 7.54; Br, 14.81. Calcd. for $C_{24}H_{39}O_7N \cdot HBr$: C, 53.91; H, 7.54; Br, 14.93%.

Methiodide.—m. p. 174° (from water).

Anal. Found: C, 49.23; H, 7.29; OCH_3, 16.36; I, 19.51. Calcd. for $C_{24}H_{39}O_7N \cdot CH_3I$: C, 50.40; H, 7.11; 3-$OCH_3$, 15.91; I, 21.32%.

The methiodide readily returned to the original base by means of alkali.

Isolation of Monoacetyllucaconine. — On being left to stand in a refrigerator, the mother liquor, obtained by removal of the lucaconine-rich base, gave 90 g. of crystalline substance melting at 168~172°. This substance was recrystallized from benzene and then from ethanol to give a crystalline base melting at 186°. Yield 12.8 g. From this base perchlorate was obtained, which after three recrystallizations from ethanol showed m. p. 202~202.5° (decomp.). Yield, 9.0 g. Free base, obtained from this perchlorate, showed m. p. 187°, $[\alpha]_D^{18}$+42.7° (ethanol) after recrystallization from ethanol. Yield, 3.75 g.

Anal. Found: C, 63.11; H, 8.22; N, 2.85; OCH_3, 18.90; (N)-C_2H_5, 5.05; $COCH_3$, 10.80. Calcd. for $C_{26}H_{41}O_8N$: C, 63.07; H, 8.34; N, 2.83; 3-OCH_3, 18.79; (N)-C_2H_5, 5.86; $COCH_3$, 8.68%.

This base, monoacetyllucaconine, was easily soluble in methanol and in ethanol and moderately so in benzene but sparingly so in water and in petroleum ether.

Perchlorate.—m. p. 202~202.5° (decomp.).

Anal. Found: Cl, 5.85. Calcd. for $C_{26}H_{41}O_8N \cdot HClO_4$: Cl, 5.95%.

Hydrobromide.—m. p. 190~191° (decomp.).

Anal. Found: H_2O, 2.42. Calcd. for $C_{26}H_{41}O_8N \cdot HBr \cdot 3/4H_2O$: H_2O: 2.29%.

Anal. (anhydrous) Found: Br, 13.21. Calcd. for $C_{26}H_{41}O_8N \cdot HBr$: Br, 13.85%.

Hydrolysis of Monoacetyllucaconine.— After monoacetyllucaconine was hydrolyzed with 0.5 N ethanolic potassium hydroxide, a crystalline substance was obtained. After recrystallization from ethanol, it was identified as lucaconine by the mixed melting point test.

Anal. Found: C, 63.34; H, 8.77. Calcd. for $C_{24}H_{39}O_7N$: C, 63.55; H, 8.45%.

Acetic acid produced on hydrolysis of monoacetyllucaconine was identified as silver salt.

Anal. Found: Ag, 64.67. Calcd. for CH_3CO_2Ag: Ag, 64.64%.

Diacetyllucaconine (III). — *a) From Lucaconine (I).*—Lucaconine was heated in acetic anhydride for 30 min., and the reaction mixture was treated in the usual manner. After recrystallization from dilute ethanol, diacetyllucaconine was obtained in colorless needles, m. p. 124°, $[\alpha]_D^{16}$+15.3° (94% ethanol).

Anal. Found: C, 62.40; H, 8.01; N, 2.69; $COCH_3$, 15.93. Calcd. for $C_{28}H_{43}O_9N$: C, 62.55; H, 8.05; N, 2.61; 2-$COCH_3$, 15.9%.

b) From Monoacetyllucaconine (II).—Upon the same treatment as in the case of lucaconine described above, monoacetyllucaconine afforded the same diacetyllucaconine, m. p. and mixed m. p. 124°.

After being heated at 145° for 10 min. under reduced pressure (1×10^{-5} mmHg), diacetyllucaconine was recovered unchanged.

Hydrolysis of Diacetyllucaconine (III).— Diacetyllucaconine was hydrolyzed by heating with 0.5 N ethanolic potassium hydroxide. After removal of most of the ethanol, the reaction mixture was extracted with chloroform and then the chloroform extract was evaporated to give lucaconine, which melted at 198° after recrystallization.

Anal. Found: C, 63.58; H, 8.67; N, 3.44. Calcd. for $C_{24}H_{39}O_7N$: C, 63.55; H, 8.45; N, 3.09%.

The Molecular Cross-sectional Areas for the Determination of Specific Surface Areas of Solids. I. Carbon Black

By Kumasaburo KODERA and Yoshito ONISHI

(Received September 11, 1958)

Various methods have been developed to estimate the specific surface areas of solids from the theory of physical adsorption. Among them, most widely used is the Brunauer-Emmett-Teller, or B. E. T. method[1]. In this method, the number of adsorbed molecules necessary to cover the surface of 1 g. of a solid completely with a monomolecular layer is evaluated by so-called B. E. T. equation, i. e.,

$$\frac{P}{V(P_s-P)} = \frac{1}{V_mC} + \frac{(C-1)}{V_mC}\cdot\frac{P}{P_s} \qquad (1)$$

where P is the equilibrium pressure, P_s the saturation pressure of the adsorbate gas, V the volume of the gas adsorbed at S. T. P., V_m that necessary to cover the surface with a monomolecular layer, and C a constant.

Specific surface area is then obtained by multiplying V_m with the molecular cross-sectional area, σ, which is given by the following equation:

$$\sigma = 1.091(M/N\rho)^{2/3} \qquad (2)$$

where M is the molecular weight, ρ the density in the liquid (or solid) state of the adsorbate, and N Avogadro number. If the number of molecules in a monomolecular layer and the cross-section obtained above were correct, the calculation would give an absolute surface area, and the values obtained by different adsorbates should agree. But it is well known, generally, that this is not the case. For instance, Jacobs and Tompkins[2] stated that most adsorbates yield surface areas that require multiplication by a factor of between 1.2 and 1.5, and in extreme cases 2 or 3, to give areas agreeing with those calculated from the nitrogen isotherms. This disagreement may arise from either of two reasons: (1) the B. E. T. equation cannot be applied satisfactorily for the isotherms; and (2) equation 2 for σ fails to give a correct cross-section of an adsorbate molecule on the surface. Existence of chemisorption, active spots, and pores or cracks on the surface mainly affects the type of isotherm while packing of adsorbate molecules on the surface affects σ because the factor 1.091 in equation 2 is calculated from the assumption that the adsorbate molecules on the surface is spherical closest packing, i. e., three dimensionally 12 co-ordination and two dimensionally 6 co-ordination. Therefore, it is very difficult to know the absolute value of the surface area by this method. Thus, to compare surface areas using different gases, relative values of cross-sections should be determined beforehand.

On the other hand, Harkins and Jura[3] have developed the absolute calorimetric method to measure the absolute surface area without the knowledge of the cross-section of the adsorbate molecule. But this method has not been employed generally, because it can not be applied to solids which have pores and cracks and the method of measurement is so difficult that its applicability is rather limited.

Livingston[4] examined published data about the measurements of the specific surface areas of oxides by the B. E. T. method and assigned the cross-sections of adsorbate molecules which might give the consistent areas for oxides. He took the case of adsorption of nitrogen at $-195°$ as a standard process and assigned the value 15.4 Å^2 for the cross-section of a nitrogen molecule instead of widely used value, 16.2 Å^2, obtained from equation 2 using liquid density of nitrogen. Cross-sections of the other gas molecules were, then, determined so as to give equal surface area with nitrogen. These values are shown in Table V, column 5. These values, however, can not necessarily give consistent surface areas for other solids than oxides. In the experiments described below, adsorption of several gases on carbon black samples was measured by the same

apparatus under similar experimental conditions. The specific surface areas of the adsorbents were then calculated and by comparing them with each other and with the values obtained from the electron microscopy, and taking into consideration of the two dimensional van der Waals' constant of argon, the molecular cross-section for each adsorbate gas which would give consistent surface area was determined. Gases were also examined to discover whether they were suitable for this purpose or not.

Experimental Method and Results

A series of 8 commercial carbon blacks listed in column 2, Table I, were used in this experiment. Nitrogen, argon, oxygen, carbon dioxide and *n*-butane were chosen as adsorbate gases.

The apparatus for the adsorption measurement was an ordinary volumetrical type. Temperatures of the adsorbents were measured by a vapor-pressure thermometer with suitable vapors. Samples of carbon black were heated at 200°C in the apparatus and evacuated until pressure in the apparatus reached 1×10^{-5} mmHg every time before the adsorption was measured. In most cases adsorption isotherms were taken between the relative pressures of 0.02 to 0.35, and in some cases up to 0.90. Measured values of $P/V(P_s-P)$ were plotted as a function of P/P_s, according to equation 1. Curves obtained were classified in 7 types as shown in Fig. 1.

Curves I and III have similar forms, but the former has a longer linear portion which extends over 0.35 of P/P_s. Curve II is the most general form which has the linear part from 0.05 to 0.2 or more, and below 0.5 deflects downwards. Curves IV to VII are of special types which appear in a few cases.

In Table I, types of curves obtained are listed together with the appearance of the hysteresis in the measured pressure range.

V_m was calculated from the linear parts of these curves and shown in Table II. From these values of V_m, specific surface areas of the adsorbent were calculated using molecular cross-sections in column 4, Table V, which were calculated by equation 2 using the liquid density of each gas at measured temperatures[5]. The values are shown in Table III. The ratio S_{N_2}/S is that between surface area measured by nitrogen and that of the other gas. Surface areas measured by the absolute method by Okuda and Tanaka[6] and from electron microscopy by Suito and Arakawa[7] are shown for comparison. It should be remembered that the latter values were calculated from average particle diameter $d_1=\sum nd/\sum n$, assuming the density of carbon black to be 1.8, whereas values from the adsorption correspond to $S=K(\sum nd^2/\sum nd^3)$, where K is a shape factor.

Discussion

As are shown in Table III, the ratios of surface area by nitrogen adsorption to that by argon adsorption (S_{N_2}/S), for both adsorption temperatures are 1.14 and their standard deviations are small. For oxygen and *n*-butane, the standard deviations in area ratios are greater and for carbon dioxide the greatest, even with the exclusion of No. 6.

Applicability of the B.E.T. isotherm can be judged from the range of the linear part on the curve. From Fig. 1 and Table I, it is seen that argon (−183°C) and oxygen show largest range of linear part and then follow nitrogen and argon (−196°C). Of

these two, argon (−196°C) has longer linear portions though not listed in the table. By *n*-butane, linear parts are also large but in most cases isotherms show hysteresis. Carbon dioxide is inferior to the other gases. Among the adsorbents used, No. 7 exhibits anomalous isotherms for all gases.

From the above facts, nitrogen and argon turned out to be the most suitable adsorbates for the surface area measurement of carbon black, while oxygen and *n*-butane are seen to be somewhat inferior to the former two. Carbon dioxide is not suitable for this purpose. From the surface ratio values in Table III, except for No. 6 by carbon dioxide, it is possible to eliminate the differences in surface areas measured by different gases by assigning a proper molecular cross-section for each gas. In doing this, a gas which might be considered to give the specific surface area nearest to the absolute surface should be chosen as a standard gas; then, the cross-section of other gases could be determined to give the equal surface area as the standard gas. Generally, nitrogen is used for the B. E. T. method with the cross-section of 16.2 Å^2, but it generally gives a larger surface area when compared with that by the other gases and also with the value obtained by electron microscopy or the absolute method. To compare surface area values by the B. E. T. method with those by electron microscopy, ratio of the values by the two methods was calculated for each carbon black with various gases and listed in Table IV*. It is seen from the table that the agreement of values between the two methods is best for argon, whereas nitrogen adsorption gives somewhat greater values. The molecular cross-section of each gas used for the evaluation of the surface area was divided by the respective average ratio and shown in the bottom of the table. These are cross-sections which will give surface areas in agreement with those from electron microscopy. For carbon black, Anderson and Emmett[8] concluded that 16.2 Å^2 is better than 13.8 Å^2 calculated from the solid density. On the other hand, Arnell and Henneberry[9] compared the surface areas of carbon blacks measured by permeability, electron microscopy, and the B. E. T. method using nitrogen cross-section of 16.2Å^2. The results revealed that the surface areas measured by the B. E. T. method was 30% larger in average than those by the other methods (except for samples which had pores and cracks as mentioned by Arnell et al.).

From the above considerations, the value 16.2 Å^2 for nitrogen cross-section would be too large. The concept of two dimensional gas of adsorbed molecules suggests that the molecular cross-section should be nearly equal to the two-dimensional van der Waals' constant[10]. For nitrogen this value is 15.4 Å^2; Livingston used this value as a standard and estimated the cross-section of other gases from this value. In the above experiment both nitrogen and argon proved to be suitable for this method, but from Table IV, it is seen that argon gives surface areas more consistent with those by electron microscopy than nitrogen does. In addition, the following facts point to the superiority of argon to nitrogen, i. e., in the plot of equation 1, generally, the former has longer linear part than the latter. Moreover, argon shows no chemisorption and exhibits more ideal packing state on the surface as it consists of monoatomic molecules and has no quadruple moment which nitrogen has to some extent[11]. The fact that the agreement between the two dimensional van der Waals' constant and the value from the equation 2 is better in argon than in nitrogen, seems to show that the former exhibits more ideal packing state on the surface than the latter does. Therefore, argon was taken as a standard. For the molecular cross-section of argon, three values were obtained, i. e., 13.5 Å^2 from comparison with electron microscopy, 13.8 Å^2 from equation 2 using liquid density at −195°C, and 13.6 Å^2 from the van der Waals' constant. Among these three values, 13.8 Å^2 from equation 2 was employed as a standard, because the differences among these values are rather small and there is no serious reason to change the generally employed value from equation 2. The molecular cross-section thus determined, those given by Livingston,

* Values in parentheses are the largest and the smallest ratios for each gas and are excluded from the average, because corresponding samples might have some undesirable surface states or particle size distributions for this comparison.

ordinary values from equation 2 and the two dimensional van der Waals' constants are shown in Table V. It is seen that the values agree surprisingly well with those in Table IV except oxygen. The value for oxygen agrees with that of van der Waals' constant. The value for nitrogen becomes smaller than that from equation 2 and of Livingston. Livingston said that according to the results of Arnell and Henneberry for 9 carbon blacks, nitrogen adsorption surfaces are about 12% higher than the values by permeability and electron microscopy. It is not clear how Livingston estimated the value of 12%, but if nitrogen cross-section 16.2 Å² used by Arnell and Henneberry is reduced by 12%, it gives 14.5 Å² which nearly agrees with the present value.

The specific surface areas calculated by these cross-sections are listed in Table VI. Comparison with the values by the absolute method shows good agreement in case of No. 8, while in No. 3, the absolute method gives a far smaller value. The electron microscopy also gives a smaller value for the latter sample. If there were small pores and cracks on the surface of the latter, unobservable by the electron microscope, these would be covered by the adsorbate in the case of the absolute method, so that both methods might give lower values than the B. E. T. method does. Other small values by electron microscopy are also explainable by the existence of pores and cracks. Thus, Nos. 1, 3 and 8 show somewhat lower values also by n-butane adsorption which suggest the existence of small pores, into which rather large n-butane molecules can not penetrate.

In electron microscopy, as is described above, the surface areas were calculated from $d_1=\sum nd/\sum n$, assuming all the particles to be spherical. Calculation from d_1 gives correct surface area only when all the particles have the same size. Generally, this is not the case, and owing to the particle size distribution, this calculation gives too large a surface area. Moreover, as was pointed out by Arnell and Henneberry, if a small number of large particles were overlooked in measuring particle size by the electron microscope, surface area estimated from the results would give also higher value. Therefore, larger values than those by the B. E. T. method are not unexplainable.

No. 6 shows a remarkably small surface for carbon dioxide. The surface area of this sample for carbon dioxide increased as the temperature of heating before the adsorption rose above 200°C, although it remained constant for nitrogen and argon. This effect of heating temperature was seen only in this sample. This might be explained as the heat treatment above 200°C changed surface state of this sample, and also changed the state of adsorption of carbon dioxide molecules, but the

adsorption of nitrogen and argon, which should be purely physical, would not be affected.

Conclusions

For the measurement of the specific surface areas of solid adsorbents, argon and nitrogen are most suitable for adsorbate gases. Oxygen and *n*-butane are also applicable but carbon dioxide may give unreliable results in some cases. The cross-sectional areas of adsorbed molecules listed in Table V, column 6, were determined to give consistent surface areas for different gases. The anomaly for carbon dioxide may be explained by the surface state of the carbon black.

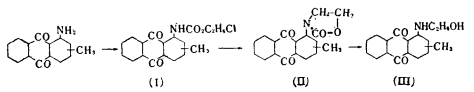
*Studies on 3-(Anthraquinon-1-yl)oxazolidin-2-ones. I. 3-(Methylanthraquinon-1-yl)oxazolidin-2-ones and Their Related Compounds**

By Kō NAIKI

(Received September 18, 1958)

In a previous paper[1], it was reported that 1-aminoanthraquinone reacted with 2-chloroethyl chloroformate and formed 2-chloroethyl anthraquinon-1-yl carbamate. The chloroethyl anthraquinonyl carbamate was converted into 1-*N*-2-hydroxyethylaminoanthraquinone by the action of potassium hydroxide, and 3-(anthraquinon-1-yl)oxazolidin-2-one could not be separated from reaction mixture by fractional recrystallization. The reactions are explained as follows (Scheme I).

Sheme 1



In another paper[2], it was found that 2-chloroethyl anthraquinon-1-yl carbamates which contain 2-substituent in anthraquinone nucleus were converted into 2′-substituted 3-(anthraquinon-1-yl)oxazolidin-2-ones by the action of potassium hydroxide.

The result of these investigations suggests the existence of a steric hindrance of 2′-substituent in the anthraquinonyl-oxazolidinones which plays an important part in the stability of the anthraquinonyl-oxazolidinones in aqueous solution of potassium hydroxide. Similarly, an electronic effect of substituent should be considered to be important and this is being investigated in the author's laboratory.

In the present study, 3-(methylanthraquinon-1-yl)-oxazolidin-2-ones, 1-*N*-2-hydroxyethylaminomethylanthraquinones and 2-chloroethyl methylanthraquinon-1-yl carbamates were synthesized and the effect of the methyl group by its position on the stability of the anthraquinonyloxazolidinones was investigated. None of them has yet been prepared, so far as is known.

Preparation and Results

The syntheses of the compounds were carried out according to the following processes (Scheme II).

Scheme II

2-Chloroethyl 2-methylanthraquinon-1-yl carbamate(Ia), 3-methylanthraquinon-1-yl carbamate(Ib) and 4-methylanthraquinon-1-yl carbamate(Ic) were obtained from the corresponding 1-aminomethylanthraquinones by the action of 2-chloroethyl

The proportion of the constituents of the reaction mixtures was determined by spectrophotometry. These results are shown in Table I. Each of the constituents was separated from the reaction mixtures by column chromatography from benzene on alumina.

Absorption spectra of the compounds obtained above are shown in Figs. 1, 2 and 3, respectively. Absorption maxima and extinction coefficients are given in Table III.

Discussion

Effects of the Methyl Group According to its Position on the Stability of the Methylanthraquinonyloxazolidinones.— On account of aqueous dispersion of solid materials, various difficulties may be introduced in the discussion when their stabilities are compared with one another. Nevertheless, it may probably be considered that there exists some close relation between the stability and the factors such as electronic and steric effects of groups. Table I shows clearly that the 2′-methyl group increases the stability of

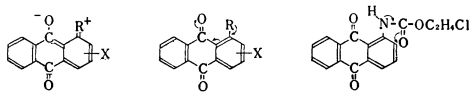
* Determined by the spectrophotometry.

the anthraquinonyloxazolidinone in aqueous solution of potassium hydroxide. In other words, it shows the existence of steric hindrance of the methyl group in the hydrolysis process (cf. Scheme I).

The reaction mixture obtained from the chloroethyl methylanthraquinonyl carbamates and potassium hydroxide can be separated into the constituents by the column chromatography from benzene on alumina. It is observed, however, that the unreacted 2-chloroethyl methylanthraquinonyl carbamates are gradually converted into the corresponding methylanthraquinonyloxazolidinones on alumina in the column. For this reason, the use of the column chromatography to determine exactly the proportion of the constituents is not desirable in a strict sense. Thus, the determination of the proportion of the constituents was attempted by the spectrophotometry. Since the principal absorption bands of the constituents are apart from one another as shown in Figs. 1, 2 and 3, the determination of the proportion of the constituents was carried out exactly.

The Effect of the 2-Methyl Group on Absorption Spectra.—A marked difference in intensity of light absorption between mono- and dimethylated 1-aminoanthraquinones was explained by the steric hindrance of the *N*-methyl group with the adjacent carbonyl group[3]. Accordingly, it may be expected that another substituent at 2-position provides a further steric effect. This expectation agrees with the experimental result of the 1-amino-2-methoxyanthraquinones shown in Table II[4].

TABLE II
ABSORPTION SPECTRA OF 1-AMINO-2-METHOXYANTHRAQUINONES



Compound	Principal absorption band (in ethanol)
1-Amino-2-methoxyanthraquinone	478 mμ
1-Methylamino-2-methoxyanthraquinone	520 mμ
1-Dimethylamino-2-methoxyanthraquinone	506 mμ

It is now apparent that the steric hindrance of the methyl group of the compounds discussed here plays an important part. It has been known that the first absorption band of the 1-substituted anthraquinones can be attributed to resonance hybrid of the normal and the extreme ionic form (IV). The explanation of the formation of the ionic form is given by the well-known mechanism (V) which shows a mesomeric shift of the electrons from the 1-substituted group to the carbonyl oxygen atom. Thus, the contribution of the ionic form will be further increased by the 1-substituent with the greater electron-donating ability, resulting in the stronger the donating power, the longer the wave length of absorption maxima. This is illustrated in the case of the hydroxyethylaminoanthraquinones (Table III). However, in the 2-chloroethyl anthraquinonyl carbamates, another electron shift may be introduced in the opposite sense(VI). This alternative effect will counter the shift of the electrons to the anthraquinone ring and lower the wave length of absorption.

TABLE III
ABSORPTION SPECTRA OF 1-AMINOMETHYLANTHRAQUINONES*

Compound	$\lambda_{max.}$ (mμ)		$\varepsilon_{max.} \times 10^{-4}$

** Concn. 1×10^{-3} mol./l.

The further effect will come into play if such a group as methyl is introduced in the 2-position, for the steric hindrance from both the carbonyl and the methyl group forces atoms attached to the substituting group out of the plane of the anthraquinone nucleus. Consequently, in the case of the spectrum of 2-chloroethyl 2-methylanthraquinon-1-yl carbamate, the intensity of the corresponding absorption band (336 mμ) to that of anthraqinone becomes stronger and the primary band (378 mμ)

3) R. H. Peters et al., *J. Chem. Soc.*, **1953**, 2101.

becomes weaker than the other methylanthraquinonyl carbamates. If a more bulky group such as the oxazolidinonyl group is at the 1-position of the anthraquinone nucleus, the steric effect inhibits the shift of the electrons from the nitrogen atom to the anthraquinone nucleus, and spectra of the anthraquinonyloxazolidinones are very similar to that of anthraquinone itself.

In the case of the methylanthraquinonyloxazolidinones, it seems that the 2-methyl group in the anthraquinone nucleus increases the steric inhibition and the absorption intensity at about 400 mμ becomes weaker than the other methylanthraquinonyloxazolidinones.

Experimental

2-Chloroethyl 2-Methylanthraquinon-1-yl carbamate (Ia).—The synthesis of the compound was reported in the previous paper[2]. The product was recrystallized from ethanol, giving yellow needles, m. p. 173~174°.

2-Chloroethyl 3-Methlanthraquinon-1-yl carbamate (Ib). — A mixture of 1.08 g. of 1-amino-3-methylanthraquinone (m. p. 185~189°), 0.76 g. of 2-chloroethyl chloroformate, 0.54 g. of sodium carbonate and 70 ml. of xylene was refluxed with stirring for 2 hours. Insoluble substance was removed by hot filtration and the filtrate was evaporated to a volume of about 20 ml. for crystallization. Yield, 1.27 g. (83% of the theory) of yellow needles, m. p. 198~200°. The product was recrytallized from ethanol, giving yellow needles, m. p. 201~202°. *Anal.* Found: N, 4.34. Calcd. for $C_{18}H_{14}O_4NCl$: N, 4.07%.

2-Chloroethyl 4-Methylanthraquinon-1-yl carbamate (Ic). — A mixture of 1.88 g. of 1-amino-4-methylanthraquinone (m. p. 180~182°), 1.24 g. of 2-chloroethyl chloroformate, 0.95 g. of sodium carbonate and 18 ml. of xylene was refluxed with stirring for 6 hours. The insoluble substance was removed by hot filtration and the filtrate was cooled. The crystal formed was collected and dried. Yield, 2.45 g. (90% of the theory) of yellow needles, m. p. 187~188°. It was recrystallized from ethanol, giving yellow needles, m. p. 190~191°. *Anal.* Found: N, 4.25. Calcd. for $C_{18}H_{14}O_4NCl$: N, 4.07%.

Behavior of 2-Chloroethylmethylanthraquinon-1-yl carbamates on Alumina.—2-Chloroethyl 3-methylanthraquinon-1-yl carbamate (0.40g., m. p. 198~199°) was dissolved in benzene, then adsorbed on alumina, stood overnight and eluted by the use of ethanol. The substance (0.30 g., m. p. 213~215°), consisting of 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one and unchanged 2-chloroethyl 3-methylanthraquinon-1-yl carbamate, was obtained. It was separated into the constituents by means of chromatography on alumina from benzene. 2-Chloroethyl 3-methylanthraquinon-1-yl carbamate passed through the column; 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one was eluted by the use of ethanol. Pure 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one was obtained.

Similar treatment of 2-chloroethyl 2-methylanthraquinon-1-yl carbamate and 4-methylanthraquinon-1-yl carbamate gave 3-(2-methylanthraquinon-1-yl) oxazolidin-2-one and 3-(4-methylanthraquinon-1-yl) oxazolidin-2-one, respectively.

3-(2-Methylanthraquinon-1-yl)oxazolidin-2-one (IIa).—The synthesis was reported in the previous paper[2]. Pale yellow needles, m. p. 226~227°.

3-(3-Methylanthraquinon-1-yl) oxazolidin-2-one (IIb).—A mixture of 1.00 g. of finely powdered 2-chloroethyl 3-methylanthraquinon-1-yl carbamate (m. p. 198~199°) and 30 g. of 20% aqueous solution of potassium hydroxide was heated in a boiling water bath with vigorous stirring for 1 hour. After being diluted with water, the precipitate was collected, washed with water and dried. Yield, 0.82 g. of reddish powder. The product, consisting of unchanged 2-chloroethyl 3-methylanthraquinon-1-yl carbamate, 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one and 1-*N*-2-hydroxyethylamino-3-methylanthraquinone, was dissolved in benzene and chromatographed on alumina. 1-*N*-2-Hydroxyethylamino-3-methylanthraquinone is most strongly adsorbed and 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one is more strongly adsorbed than 2-chloroethyl 3-methylanthraquinon-1-yl carbamate. The red band, containing 1-*N*-2-hydroxyethylamino-3-methylanthraquinone, was eluted by the use of ethanol. Yield, 0.38 g. of red needles, m. p. 234~235°. The pale orange band, containing 3-(3-methylanthraquinon-1-yl) oxazolidin-2-one, was eluted by the use of ethanol. Yield, 0.18 g. of pale orange needles, m. p. 235~236°. It was recrystallized from ethanol, giving pale orange needles, m. p. 235~236°. *Anal.* Found: N, 4.50. Calcd. for $C_{18}H_{13}O_4N$: N, 4.56%. The yellow eluate, containing 2-chloroethyl 3-methylanthraquinon-1-yl carbamate, was evaporated for crystallization. Yield, 0.14 g. of yellow needles, m. p. 198~199°

3-(4-Methylanthraquinon-1-yl) oxazolidin-2-one (IIc).—A mixture of 0.50 g. of finely powdered 2-chloroethyl 4-methylanthraquinon-1-yl carbamate (m. p. 187~188°) and 15 g. of 20% aqueous solution of potassium hydroxide was heated with vigorous stirring in a boiling water bath for 1 hour. After being diluted with water, the precipitate was collected, washed with water and dried. Yield, 0.33 g. of reddish brown powder. It was fractionally recrystallized from ethanol, giving pale brown needles, m. p. 201~202°. *Anal.* Found: N, 4.58. Calcd. for $C_{18}H_{13}O_4N$: N, 4.56%.

The chromatographic separation of the reaction product obtained above, consisting of 1-*N*-2-hydroxyethylamino-4-methylanthraquinone, 3-(4-methylanthraquinon-1-yl) oxazolidin-2-one and unchanged 2-chloroethyl 4-methylanthraquinon-1-yl carbamate, was carried out in the same with the 3-methyl derivative. Yield, 0.100 g. of 1-*N*-2-hydroxyethylamino-4-methylanthraquinone, m. p. 153~154°, 0.130 g. of 3-(4-methylanthraquinon-1-yl) oxazolidin-2-one, m. p. 201~202°, and 0.060 g. of

2-chloroethyl 4-methylanthraquinon-1-yl carbamate, m. p. 189~190°.

Determination of the Proportion of the Constituents of the Reaction Product Obtained from the 2-Chloroethyl Methylanthraquinon-1-yl Carbamates and 20% Aqueous Solution of Potassium Hydroxide.—A mixture of 0.20 g. of finely powdered 2-chloroethyl methylanthraquinon-1-yl carbamate and 6.00 g. of 20% aqueous solution of potassium hydroxide was heated with vigorous stirring in a boiling water bath for 1 hour. After being diluted with water, the precipitate was collected, washed with water and dried. Yield, 0.16 g. of pale red powder, m. p. 192~201°, from 2-chloroethyl 2-methylanthraquinon-1-yl carbamate; 0.15 g. of brownish red powder, m. p. 139~149°, from 2-chloroethyl 3-methylanthraquinon-1-yl carbamate; 0.16 g. of reddish brown powder, m. p. 148~167°, from 2-chloroethyl 4-methylanthraquinon-1-yl carbamate.

The proportion of the constituents of the products obtained above were determined by the use of a Shimadzu QB-50 Electrophotometer. Optical densities (D) of the benzene solutions of the products are shown in Tables IV, V and VI. It was found by simple caluculation that the reaction product obtained from 2-chloroethyl 2-methylanthraquinon-1-yl carbamate contains 21 mg. of 1-*N*-2-hydroxyethylamino-2-methylanthraquinone, 124 mg. of 3-(2-methylanthraquinon-1-yl) oxazolidin-2-one and 12 mg. of 2-chloroethyl 2-methylanthraquinon-1-yl carbamate; the product obtained from 2-chloroethyl 3-methylanthraquinon-1-yl carbamate contains 91 mg. of 1-*N*-2-hydroxyethylamino-3-methylanthraquinone, 33 mg. of

Polyterpenes. II[1]. *Oxidation of Thujopsene with Lead Tetra-acetate**

By Shizuo NAGAHAMA, Hiroshi KOBAYASHI and Saburo AKIYOSHI

(Received September 19, 1958)

It has been reported by Kawamura[2] and recently by Nozoe et al.[3], that thujopsene, the main constituent of Hiba (*Thujopsis dolabrata Sieb. et Zucc.*) wood oil, affords a glycol, m. p. 91°, by the oxidation with permanganate in acetone containing water. On the other hand, the authors obtained a ketonic acid, m. p. 165° as a main product and no glycol was found when the oxidation was carried out in acetone solution without addition of water[1].

To obtain the glycol by an alternate route, oxidation of this sesquiterpene with lead tetra-acetate was attempted. However, contrary to the expectation, a ketone and its enol acetate were found to be the main products.

It is well known that the olefines, when oxidized with lead tetra-acetate, usually give a mixture of acetates produced partly by the addition of acetoxyl group to the double bond and partly by the substitution to the alpha position of the double bond or simultaneous occurrence of these cases[4]. As a single example of ketone formation, there are some reports concerning the formation of R-homocamphenylone from camphene[5,6], which accompanied by ring-enlargement**. In the present case, however, the oxidation was considered to be accompanied by ring-contraction, a novel reaction which seems not to have appeared in literature. The reaction was carried out in two ways. (1) To the benzene solution of the terpene was added solid lead tetra-acetate in portions. (2) The minium was added to the mixture of the terpene and acetic acid. The reaction product was fractionated by distillation under reduced pressure, and the main fraction was found to be the same in both cases. As an example, one of the results obtained by method 1 is shown in Table I.

TABLE I

* Ester value. Calcd. for $C_{17}H_{26}O_2$: 214

The infrared spectra were examined concerning all fractions, and no appreciable band was found in 3400 cm^{-1} region. Fraction 5 had an infrared band at 1708 cm^{-1} (cf. Fig. 1) and its greater part proved to be a ketone I which gave a semicarbazone m. p. 214° (decomp.) and a 2, 4-dinitrophenylhydrazone m. p. 170°. The highest boiling fraction showed a band at 1745 cm^{-1} suggesting that it was probably a mixture of normal ester (1735~1740 cm^{-1}) and enol ester (1755 cm^{-1}). This was confirmed by the fact that the saponification product of this fraction showed bands at 3450 and 1708 cm^{-1} and gave a 2, 4-dinitrophenylhydrazone, m. p. 168°, which was identified with that of ketone I by mixed melting-point test and infrared spectrum. In the spectra of fractions 6 and 7, rather weak bands were observed at 1825 and 1666 cm^{-1}.

Since ketone I, $C_{15}H_{24}O$ gave an acid $C_{14}H_{22}O_2$, m. p. 102° (II) by hypohalite oxidation, it was presumed to be a methyl ketone. Alkaline permanganate oxidation

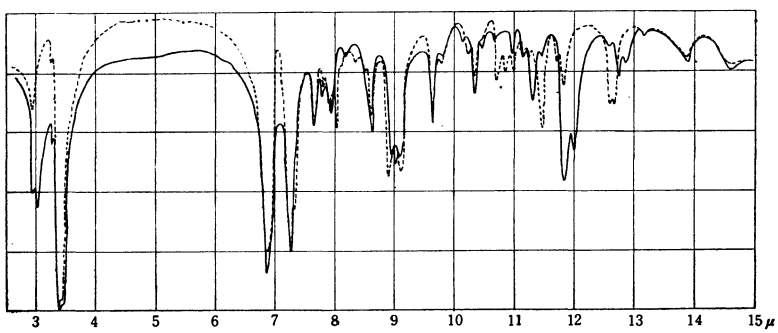

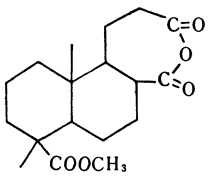

Fig. 4. —— Peroxide X, ------ Peroxide XI (Nujol).

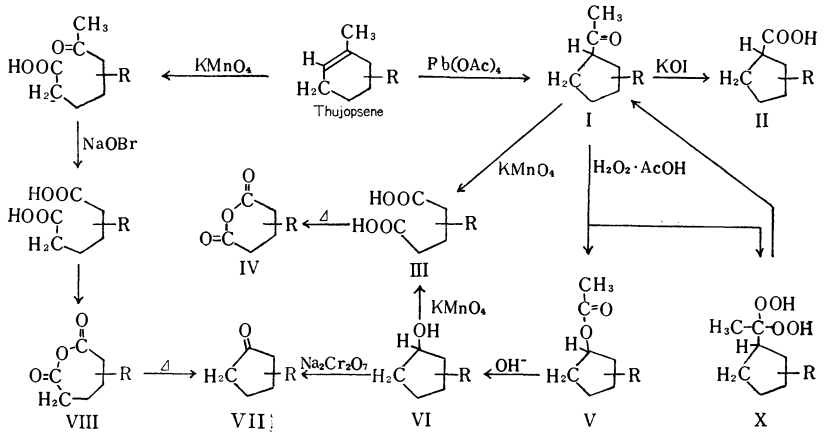
of I gave mainly a dicarboxylic acid $C_{13}H_{20}O_4$ (III) accompanied by a small amount of acid II. Acid III was readily converted into an anhydride, m. p. 211~212° (IV) by heating or treating with acetic anhydride. Since this anhydride shows infrared absorption at 1799 and 1754 cm^{-1} (in carbon tetrachloride) and is stable toward heating, it may be considered to be of glutaric anhydride type.

Peracetic acid oxidation of ketone I followed by saponification and alumina chromatography gave an alcohol $C_{13}H_{22}O$, m.p. 78° (VI), and a ketone $C_{13}H_{20}O$, m.p. 118.5~121° (VII) (Fig. 2). When chromatographic separation was performed prior to the saponification, an ester V (Fig. 3) was obtained. Saponification of ester V gave alcohol VI, which in turn gave ketone VII by the chromic acid oxidation***. It is noticeable that ketone VII shows infrared absorption at 1727 cm^{-1} (in carbon tetrachloride) which is intermediate value of cyclopentanone (1745 cm^{-1}) and cyclohexanone (1715 cm^{-1}). Alcohol VI was oxidized with permanganate under a condition similar to the oxidation of ketone I, giving the same dicarboxylic acid III.



It has been reported[1] that the dicarboxylic acid obtained from thujopsene by permanganate oxidation followed by hypobromite treatment, gave an anhydride VIII, m. p. 110°, to which a glutaric anhydride was suggested from the infrared spectrum. However, an adipic anhydride IX from methyl vouacapenate showed anhydride bands at 1808 and 1764 cm^{-1} (in chloroform)[7]. Furthermore, Ozeki, Seto and Nozoe[3] obtained the "pyroketone" m. p. 121° by treating the dicarboxylic acid with acetic anhydride, followed by heating to 310°. On reexamining the experiment, it was confirmed that the pyroketone was identical with the above-mentioned ketone VII. Therefore, it must be considered that the anhydride VIII is of an adipic anhydride type, and the ring containing double bond in thujopsene is of a six-member type.

IX

The result mentioned above is formulated as Scheme I, assuming the cyclopentyl methyl ketone structure I for ketone I. Infrared absorption at 1708 cm^{-1} supports the validity of this inference.

In the case of the peracetic acid oxidation of ketone I, two kinds of crystalline ketone peroxide were separated. One of them $C_{15}H_{26}O_4$ (X) was obtained in 47% yield when the reaction was carried out below 20°. By means of iodometric titration, it was proved that two -OOH groups are present in X. When the acetic acid solution of X was warmed, the peroxide was decomposed and the original ketone I was regenerated. When the oxidation

Scheme I. R=C_8H_{18}

*** The same ketone VII was separated from the neutral parts of permanganate oxidation products of thujopsene.

7) M. Arakawa, Private communication.

was conducted at about 25°, another peroxide XI was obtained in a poor yield. It decomposed at 135~138°, but it was not studied further owing to lack of material. The infrared spectra of X and XI are shown in Fig. 4.

Further investigations on the structure of thujopsene are being carried on.

Experimental

Thujopsene was obtained by the fractionation of Hiba wood oil as previously described[1].

Reaction of Thujopsene with Lead Tetra-acetate.—(a) Thujopsene (35 g.) was dissolved in 165 cc. of dry benzene, and lead tetra-acetate (prepared from 305 g. of acetic acid, 105 g. of minium, and recrystallized from acetic acid) was added portionwise with stirring for half an hour. The flask was immersed now and then in the water bath to keep the temperature below 40°. Stirring was continued for an additional one and a half hours. The reaction mixture was filtered, sodium bicarbonate solution was added to the filtrate and the organic layer was separated. This was washed twice with water, again with diluted sodium bicarbonate solution and finally with water and dried over sodium sulfate. Solvent was removed and the residue was fractionated. The result of a typical run is shown in Table I. Fraction 5 which boiled mainly at 125~127°/7 mm., gave a yellow 2,4-dinitrophenylhydrazone m. p. 170~170.5°, and a semicarbazone, m. p. 213~214°C (decomp.).

Anal. Found: C, 69.53; H, 9.83; N, 15.41. Calcd. for $C_{16}H_{27}ON_3$: C, 69.27; H, 9.81; N, 15.15%.

Regenerated ketone from the semicarbazone showed the following constants. B. p. 132~133°/9 mm. n_D^{20} 1.4920, d_4^{20} 0.979, M. R. 65.1. Calcd. for $C_{15}H_{24}O$, 64.91. Infrared spectrum, Fig. 1. The ketone separated in another run on the second distillations gave the following constants. B. p. 125°/5 mm. n_D^{26} 1.4897, d_4^{26} 0.9762, $[\alpha]_D^{30}$ +1.23°.

(b) To a mixture of 35 g. of thujopsene, 305 g. of acetic acid and 105 g. of acetic anhydride, was added 160 g. of minium in portions for 1.5 hours, the temperature being kept below 60°. Stirring was continued for one additional hour. Water was added, and the solution was neutralized with sodium carbonate, filtered and extracted with benzene. Fractionation gave 13.3 g. of ketone I, b. p. 125~127°/7 mm.

Hypohalite Oxidation of Ketone I.—The ketone (1 g.) was dissolved in 10 cc. of dioxane and oxidized with the hypobromite solution prepared from 4.8 g. of sodium hydroxide, 75 cc. of water and 2.1 cc. of bromine. When the mixture was warmed gradually, the reaction set in at about 80°. The crude acid II was precipitated by acidification of the alkaline solution, yield 850 mg. Repeated crystallization from methanol-water and final sublimation under reduced pressure gave a sample of m. p. 101~102°. The same acid was obtained by potassium hypoiodite oxidation according to the procedure of Heer and Miescher[8].

Anal. Found: C, 75.72; H, 10.10. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

Permanganate Oxidation of I.—The ketone (1 g.) was suspended in 40 cc. of 5% sodium hydroxide solution and 100 cc. of 4% potassium permanganate solution was added portionwise with stirring at 50~60°. Permanganate was consumed in 7 hours. On dissolving manganese dioxide with sodium bisulfite and hydrochloric acid, an acid mixture was precipitated, which was collected and dissolved in benzene. The benzene solution was extracted with sodium bicarbonate and sodium hydroxide solution successively. Acid III (122 mg.) was obtained from the former extract and recrystallized from methanol-water.

Anal. Found: C, 65.37; H, 8.05. Calcd. for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

The sodium hydroxide extract gave 4 mg. of crude acid II m. p. 98~99°.

Anhydride IV.—Acid III (192 mg.) was heated with 5 cc. of acetic anhydride for 3 hours and acetic anhydride was removed under reduced pressure. The residue was crystallized by rubbing and recrystallized from acetic anhydride, m. p. 211~212°, yield 80 mg. When acid III was heated in a small tube, dehydration occurred at about 190° and melted at 211°. After being cooled, the contents solidified, and this solid also melted at 211°. The infrared spectrum coincided with that of the anhydride obtained by acetic anhydride treatment. Mixed melting point of III and IV showed no appreciable depression. Though the anhydride was heated to 450°, evolution of carbon dioxide was not observed practically and the anhydride could be recovered.

Peracetic Acid Oxidation of Ketone I.—(a) Ketone I (3.0 g.) was dissolved in 30 cc. of acetic acid (treated with chromium trioxide) and 24 cc. of hydrogen peroxide (30%) was added with swirling. After being kept at room temperature (about 25°) for 38 hours, the mixture was diluted with water and extracted with ether, and the ether extract was washed three times with sodium bicarbonate solution and then twice with water. On evaporation of ether, 1.95 g. of reaction product was obtained. This was dissolved in 5 cc. of methanol, and sodium hydroxide solution (1 g. in 5 cc. of water) was added to it and the mixture was allowed to stand overnight; then it was poured into water, and extracted with ether. Ether was removed and the residue was dissolved in petroleum ether and chromatographed with alumina column of 1.8×10 cm. The petroleum ether eluate was an oil (0.5 g. n_D^{20} 1.4965) and the infrared spectrum suggested the presence of unchanged I. The benzene and ethyl acetate eluates gave a crystalline alcohol, 0.42 g., m. p. 74~76°. An analytical sample was prepared by purification with the aid of sublimation under reduced pressure, m. p. 78°.

8) J. Heer and K. Miescher, *Helv. Chim. Acta*, 28, 156 (1945).

Anal. Found: C, 80.10; 11.64. Calcd. for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

In another run where the reaction mixture was allowed to stand for 3 days, the product was distilled under reduced pressure, saponified and chromatographed; the petroleum ether eluate gave crystalline ketone, m. p. 113~114° (100 mg. from 2.9 g. of I) and its infrared spectrum was identical with that of ketone VII obtained by chromic acid oxidation of alcohol VI.

(b) The ketone (5.4 g.) was oxidized for 5 days as before and a solid substance XI (195 mg.) was separated from the reaction mixture. This was filtered and recrystallized from benzene-petroleum ether mixture, which decomposed at 135~138°. The infrared spectrum is shown in Fig. 4. The attempted elementary analysis failed because of an explosion. The filtrate was treated as before (without distillation and saponification) and the product was chromatographed. Petroleum ether eluate (0.4 g. n_D^{26} 1.4863, d_4^{22} 0.9957) and benzene eluate (1.3 g. n_D^{20} 1.4858, d_4^{22} 1.044, infrared spectrum Fig. 3) were combined and saponified with methanolic sodium hydroxide solution, and alcohol VI was obtained in quantitative yield. Although ethyl acetate eluate (0.5 g. n_D^{22} 1.5000) did not crystallize, its infrared spectrum was essentially identical with that of VI.

(c) The ketone (3.67 g.) was dissolved in 45 cc. of acetic acid, to which 30 cc. of hydrogen peroxide (30%) was added. When the reaction mixture being kept below 20° overnight, a large quantity of crystalline substance X separated out. This was collected on a glass filter, recrystallized from benzene, yield 2.11 g. (47%), decomposed at about 120°.

Anal. Found: C, 66.78; H, 9.69. Calcd. for $C_{15}H_{26}O_4$: C, 66.63; H, 9.69%.

A 13.2 mg. and a 15.0 mg. portion of the sample required 1.98 cc. and 2.19 cc. of 0.1 N sodium thiosulfate solution (f=1.008). Calcd. for $C_{15}H_{24}\cdot 2OOH$: 1.93 and 2.19 cc.

Acetic acid solution of X was warmed and water was added. On cooling there separated out an oil, from which a semicarbazone of m. p. 214° (decomp.) was obtained. The infrared spectrum of this semicarbazone was identical with that of semicarbazone of I.

Chromic Acid Oxidation of VI.—Sodium dichromate (100 mg.) was dissolved in 0.5 cc. of acetic acid and alcohol VI (194 mg.) in 0.5 cc. of acetic acid was added. The mixture was warmed for a few minutes and allowed to stand for one day. Water was added and the oil which separated was extracted with ether. Ether was evaporated and residue was crystallized by rubbing. Yield 148 mg. Recrystallization from methanol-water and sublimation under reduced pressure gave a sample of m. p. 118.5~121°C.

Anal. Found: C, 81.46; H, 10.37. Calcd. for $C_{13}H_{20}O$: C, 81.20; H, 10.48%.

2, 4-Dinitrophenylhydrazone orange m. p. 215~216°.

Permanganate Oxidation of VI. — Alcohol VI (1.0 g.) was suspended in 40 cc. of 5% sodium hydroxide solution and 50 cc. of 4% permanganate solution was added to it dropwise with vigorous stirring. The temperature was kept below 55° by cooling with a water bath. After being stirred for 4 hours, the reaction mixture was acidified with hydrochloric acid and sodium bisulfite was added to it. The precipitate which separated was dissolved in sodium bicarbonate solution, filtered and reprecipitated with hydrochloric acid; yield 647 mg. The infrared spectrum of it was identical with that of III obtained from ketone I. It gave the anhydride of m. p. 211~212°.

The authors wish to express their gratitude to Professor M. Hamana and Professor H. Saikachi of the Pharmaceutical Department of this University for elementary analysis and measurement of rotation. They are also indebted to Mr. M. Shido for elementary analysis.

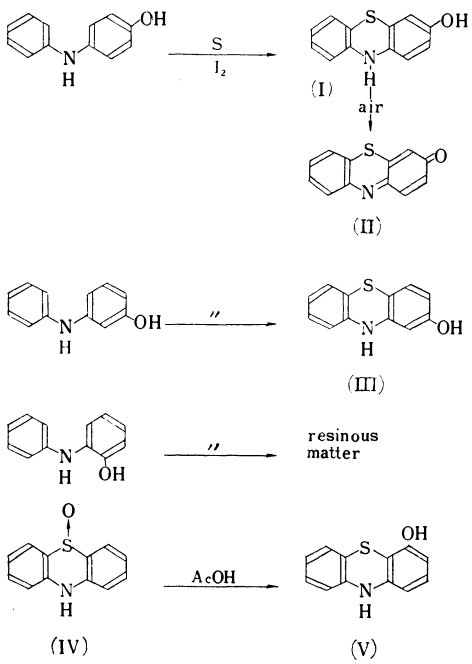
Phenothiazine Derivatives. V[1]*. Synthesis of Hydroxyphenothiazines*



By Manabu FUJIMOTO

(Received September 24, 1958)

Of the theoretically possible four hydroxyphenothiazines, the 3-hydroxy compound I only has been reported[2,3]. By treating 4-hydroxydiphenylamine with sulfur and iodine, Houston et al.[2] prepared the compound as a dark greenish brown solid with m. p. 170~175°C and with a tendency to be easily oxidized in air to 3-phenothiazone (II) (Chart I).

Before Houston et al., Hilditch and Smiles already prepared the supposed 3-hydroxyphenothiazine[3] by an intramolecular rearrangement of phenothiazine 5-oxide in acetic acid. It was a purple crystalline mass that defied purification. They submitted it to reduction with zinc and hot acetic acid and obtained a colorless soft crystalline substance which rapidly recovered purple color in the presence of air.

Chart I

The present author repeated the experiment of Hilditch and Smiles and obtained a reddish-violet substance in fine powder melting at 141~143°C. It showed a distinct depression of the melting point on admixture either with 3-hydroxyphenothiazine (I) or with 3-phenothiazone (II), prepared according to the method of Houston et al[2]. Although the rearranged product was chromatographically pure and phenolic in nature, it was evidently different from the substances of Houston et al.

The investigation described below presents a contribution to the solution of the problem concerned. In the first place, an attempt was made to synthesize all of the unknown hydroxyphenothiazines.

It was reported by Charpentier et al.[4] that the reaction of a *meta* substituted diphenylamine with sulfur and a small amount of iodine as a catalyst gives a mixture of a 2-substituted phenothiazine and its 4-isomer, although the 2-substituted product is formed in a greater yield, and that 3-methoxydiphenylamine gives only 2-methoxyphenothiazine.

The present author obtained one hydroxyphenothiazine by thionation of 3-hydroxydiphenylamine, but could not isolate the expected isomeric product. Therefore, the hydroxyphenothiazine is supposed to be 2-hydroxyphenothiazine (III). As a very unstable compound, 2-hydroxydiphenylamine gave only a black resinous matter by a similar treatment. If 1-hydroxyphenothiazine, were obtained by the reaction of 2-hydroxydiphenylamine it would have a tendency to form 1-phenothiazone similarly to the 3-hydroxy isomer I.

As an alkaline solution of the substance, obtained by the intramolecular rearrangement of phenothiazine 5-oxide IV with acetic acid according to Hilditch and Smiles resists aeration, it is considered to be a phenol with the hydroxyl group in a *meta* position to the nitrogen atom. Two such hydroxyphenothiazine are possible,

1) Part IV: This Bulletin, **32**, 296 (1959).
2) D. F. Houston et al., *J. Am. Chem. Soc.*, **71**, 3818 (1949).
3) T. P. Hilditch and S. Smiles, *J. Chem. Soc.*, **101**, 2295 (1912).
4) P. Charpentier et al.: *Compt. rend.*, **235**, 59 (1952).

namely, 2-hydroxy- and 4-hydroxy-phenothiazines. As the substance from the rearrangement of the 5-oxide (IV) differs conspicuously from 2-hydroxyphenothiazine (III) described above, it must be 4-hydroxyphenothiazine (V). The position 4 is quite a reasonable place where the sulfoxide oxygen atom may migrate.

Experimental

3-Hydroxyphenothiazine (I) and 3-Phenothiazone (II). — Essentially the method of Houston et al.[2] was followed.

2-Hydroxyphenothiazine (III). — A mixture of 3.7 g. of 3-hydroxydiphenylamine and 1.4 g. of sulfur was ground in a mortar and placed in a 100 ml. flask. Then 0.04 g. of iodine was added, and the flask was stoppered and placed in a metal bath preheated to 190°C. The bath temperature was kept at 190~200°C during 30 min., while hydrogen sulfide was evolved, and then for additional 10 min. The reaction mass was poured into a porcelain dish and allowed to cool. It solidified to a greenish-yellow cake. Yield, 4.2 g. Fractional recrystallization from benzene gave 3.2 g. of the pure substance III in dark yellow powder, m. p. 270~272°C. It gives cobalt-blue coloration with sulfuric acid.

Anal. Found: C, 67.11; H, 4.09; N, 6.40. Calcd. for $C_{12}H_9ONS$: C, 66.85; H, 4.21; N, 6.50%.

4-Hydroxyphenothiazine (V). — Acetic acid (20 ml.) was added to phenothiazine 5-oxide (IV) (1.0 g.), and the reddish-violet solution was refluxed for 3 hr. Acetic acid was evaporated in vacuo, and the residue was recrystallized from absolute ethanol. The yield was quantitative. It forms reddish-violet fine powder, m. p. 141~143°C, and gives sepia-brown coloration with sulfuric acid. It is soluble in 10% aqueous caustic soda. The benzene solution showed a single adsorption band in the chromatogram on alumina.

Anal. Found: C, 67.01; H, 4.08; N, 6.45. Calcd. for $C_{12}H_9ONS$: C, 66.85; H, 4.21; N, 6.50%.

Summary

The phenolic compound resulting from the rearrangement of phenothiazine 5-oxide in acetic acid was found to be 4-hydroxyphenothiazine, and to be different from 2- and 3-hydroxyphenothiazines which were derived from 3- and 4-hydroxydiphenylamines, respectively, by fusion with sulfur and iodine.

*Heat of Solution of Methanolized Cellulose**

By Yoshizo TSUDA

(Received September 19, 1958)

In our previous papers[1,2], the lateral order distribution of cellulose was determined and discussed. In our laboratory the lateral order distribution has been determined from the solubility data of methanolized cellulose in aqueous sodium hydroxide solution of various concentrations.

Recently it has been shown that the solubility of methanolized cellulose depends on the degree of polymerization of the methanolized cellulose and that distribution obtained by such a method gives rather a longitudinal order distribution of crystallites. On the other hand, it has been shown that the effect of the degree of polymerization of hydrolyzed cellulose on its solubility is smaller than that of the lateral order[3].

The present investigation of heat of solution of methanolized cellulose was undertaken to obtain some informations

* This paper was presented at the 11th Annual Meeting of the Chemical Society of Japan, April, 1958.

1) Y. Tsuda and S. Mukoyama, This Bulletin, **29**, 748 (1956).

2) Y. Tsuda and S. Mukoyama, *Textile Research J.*, **27**, 945 (1957).

about the dependency of the solubility of methanolized cellulose on the cohesive energy of crystallites.

Experimental

Cellulose Samples. — Cuprammonium rayon, Shin-toramomen, BX-yarn[4], viscose rayon, tire-cord rayon A (conventional) and tire-cord rayon B (all-skin type) were used.

Methanolysis. — Methanolysis of the samples was performed at 40° for 24 hours with 1 N hydrogen chloride in absolute methyl alcohol. After methanolysis, the residue was filtered, washed with methanol until it became chloride-free and then dried.

Measurement of Heat of Solution. — The apparatus was a simple non-adiabatic calorimeter composed of a 100 ml. pyrex vacuum bottle, a Beckmann thermometer (in 0.01° division), a stirring rod and a sample inlet tube, as shown in Fig. 1.

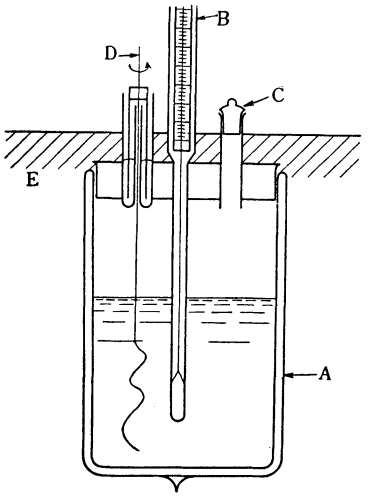

Fig. 1. Calorimeter.
A, 100 ml. pyrex vacuum bottle
B, Beckmann thermometer
C, Sample inlet tube
D, Stirrer
E, Thermostat

The apparatus was immersed in a thermostat kept at 20°. Methanolized sample (50 mg.) was bone-dried and kept at 20°. The solvent was 50 ml. of 11% aqueous sodium hydroxide solution, which was kept at 20° in the calorimeter. The stirring was done at a constant speed because constancy of the mechanical generation of heat was necessary for the measurement of small heat change. Under these experimental conditions observed temperature rise was about 0.05°, which was estimated to 0.001°. The dissolution of methanolized cellulose in the alkaline solution was a relatively rapid reaction. The heat capacity of calorimeter was determined experimentally under working conditions by measuring the heat of solution of potassium chloride in water.

Degree of polymerization was measured using cuprammonium solvent. Lateral order distribution was obtained by the same method as described in a previous paper[2].

Results

In Table I are shown the values of the heat of solution together with the statistical quantities which indicate their reliability. Degree of polymerization of methanolized cellulose is also shown in Table I. It is evident from Table I that the heats of solution of samples I, II and III are smaller than the others and those of samples V and VI are larger than the rest. The lateral order distribution of these samples is shown in Fig. 2.

TABLE I
HEAT OF SOLUTION

	Methanolized	Heat of solution cal./g.	95% Confidence limit	Degree of polymerization
I	Cuprammonium Rayon	27.6	±1.3	50
II	Shin-toramomen	27.8	±1.2	45
III	BX-yarn	29.2	±1.3	40
IV	Viscose Rayon	31.4	±1.2	33
V	Tire-cord Rayon A	33.4	±1.3	28
VI	Tire-cord Rayon B	34.3	±1.1	25

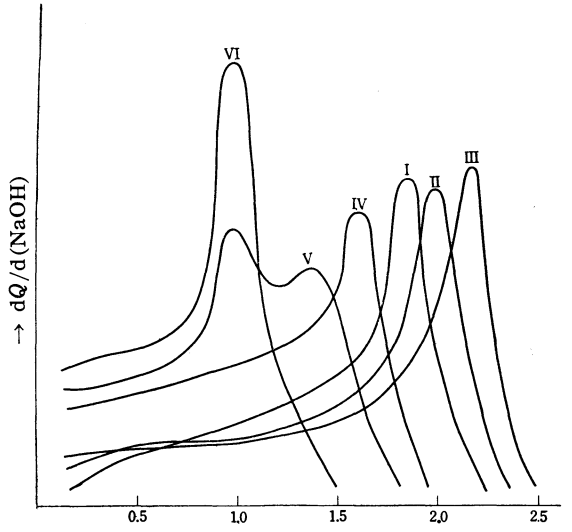

Fig. 2. Lateral order distribution (types identified in Table I).

Discussion

The heat of solution of the cellulose sample, H_s, can be separated in two parts as follows;

4) N. Drisch and L. Soep, *Textile Research J.*, 23, 513 (1953).

$$H_s = H_a - E_c$$

where H_a is the heat of solution of amorphous cellulose in the alkaline solvent and E_c is the cohesive energy of the cellulose sample. H_a is a constant value with respect to all cellulose samples under a given experimental condition. Therefore the difference in the heat of solution of two samples can be regarded as the difference in their cohesive energies; that is, the larger the heat of solution, the smaller the cohesive energy. It will be seen from the results in Table I that the methanolysis residue of Shin-toramomen, Bx-yarn and cuprammonium rayon have large cohesive energy values and tire-cord rayons have rather low values. On the other hand, as shown in Fig. 2, the former shows high lateral order distributions and the latter shows low lateral order distributions. These relationships indicate that the distribution obtained from the fractional dissolution of methanolized cellulose corresponds to the distribution of cohesive energy. Although the degree of polymerization can be regarded as another factor of the fractional dissolution, its effect would be relatively small in comparison with the effect of cohesive energy.

It may be accepted from these relationships that the length of crystallite depends on the lateral order of crystallite and a portion of high lateral order can form a long crystallite, and therefore the dependency of lateral order distribution on the degree of polymerization has been observed.

If it is assumed that methanolysis destroys only the aggregated portion of very low cohesive energy, the cohesive energy of the methanolysis residue would be almost identical with that of the original cellulose.

Summary

The heat of solution of methanolysis residue of cellulose fibers was measured and then the difference in the cohesive energy of different samples was estimated. It was elucidated that the cohesive energy of methanolized cellulose corresponds to the experimentally evaluated lateral order.

Effects of Dry Grinding on Talc

By Hiroshi TAKAHASHI

(Received October 2, 1958)

In the previous papers, the effects of dry grinding on kaolin minerals were studied, and the mechanism of the structural change caused by dry grinding was presented[1]. That is, there are two ways of change in structure. One is the production of a non-crystalline material attended with disordering of a crystalline portion, and the other is the reaggregation process. Finally, the kaolin mineral changes into a completely amorphous substance through a formation of a zeolitic substance. The mechanism of the dry grinding on kaolin minerals must be common somewhat to any substances with layered structure. In the ball-milling of graphite, too, a remarkable disordering in structure was observed by Bacon[2]. However, the effects of grinding for substances with the layered structure have not been studied very much heretofore, with the exceptions of kaolinite and mica[3]. The mechanism of dry grinding on kaolin minerals is somewhat common to that of other clay and related minerals, for example, such as montmorillonite, mica, attapulgite, pyrophyllite, serpentine and chrysotile. The results of the grinding

1) H. Takahashi, "Proc. Sixth Natl. Conference on Clay and Clay Minerals", Natl. Res. Council-Natl. Acad. Sci., (in press); H. Takahashi, This Bulletin, **32**, 235, 245, 252 (1959).

2) G. E. Bacon, *Acta Cryst.*, **5**, 392 (1952).

3) M. L. Jackson and E. Truog, *Soil Sci. Soc. Am., Proc.*, **4**, 136 (1939); R. C. Mackenzie and A. A. Milne, *Min. Mag.*, **32**, 178 (1953); R. C. Mackenzie and A. A. Milne, *Clay Min. Bull.*, **2**, 57 (1953).

effects on these clay and related minerals are reported in the following papers. Talc is an end-member of clay mineral with three-layered structure. In this study, the effects of a mechanical-mortar dry grinding on talc are discussed in the structural change, and compared with those of kaolin minerals.

Experimental

The sample used in this study is talc from Kanjun, China. The dry grinding was done in the same manner as for kaolin minerals. That is, 30 g. of original sample was charged and ground by a mechanical-mortar (15.2 cm. in dia. and 8.4 cm. in depth). Experimental specimens were taken out at intervals of 48 hours and examined by X-ray diffraction, differential thermal and electron microscopic methods. The density was also measured.

X-ray powder diagrams were recorded by an X-ray diffractometer (Geigerflex). Experimental conditions are as follows. Filtered Cu radiation (Cu $K\alpha$: 1.5418Å), at 35 kV and 15 mA is used, scanning speed is 1° or 1/4° 2θ per minute, time constant is 4 seconds, receiving slit is 0.2 mm. or 0.1 mm., angular aperture is 1° or 1/2° were used. The differential thermal analysis curves were recorded by the apparatus described by Sudo et al.[4]. Care was taken to pack a specimen into the sample block in the homogeneous manner and also to keep the weight of specimen constant. The mean heating rate is 12.5°C per minute. The density was measured by pycnometer in carbon tetrachloride. It was done after it had been dried at 110°C in order to avoid the effect of the adsorbed water. Electron micrographs were obtained by the Hitachi HU-10A type Electron Microscope.

Results and Discussion

X-Ray Diffraction Studies.—X-ray diffractometer traces and data are given in Fig. 1 and Table I. In this table, the interplaner spacing and the relative intensity measured from the X-ray trace are shown and the values described in ASTM Card are given for reference.

Generally, as the grinding progresses, even though the X-ray diagram is similar to that of the original sample, a decrease in the intensity of reflections except for some reflections and an increase in the background are observable. The intensity of reflections belonging to the basal reflections come to decrease sharply as compared with that of the original sample during the early stage of grinding. Another distinct feature observable in the X-ray

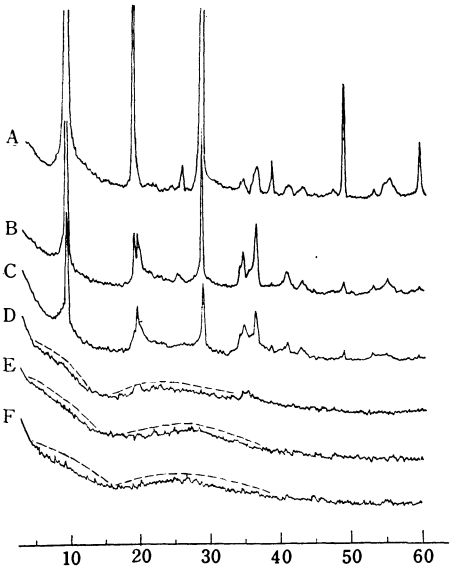

Fig. 1. X-ray diffractometer traces of ground specimens of talc.
A, original talc
B, ground 96 hours
C, ground 192 hours
D, ground 240 hours
E, ground 384 hours
F, ground 528 hours

diagram is that the reflection of 4.60Å spacing comes to be remarkably distinctive as the reflection of 4.69Å spacing weakens due to the progress of grinding. The profile of this reflection becomes an assymmetric broad band which is similar to the (02,11) band found in the X-ray diagram of halloysite. It seems that this reflection is related to the structure of talc and has (020) index rather than a spurious line[5]. The above-mentioned two characteristics with respect to the intensities of reflection line and background observed in the early stage of grinding become more and more distinct as the grinding progresses up to 192 hours. After 192 hours in grinding, the change of the interplaner spacing is not so remarkable. When the grinding progresses further, the X-ray diagram changes remarkably in contrast with that observed thus far. In the 240-hour-ground specimen, the X-ray diagram scarcely has any distinct reflection, but only two very diffuse bands. It is clear that a non-crystalline substance is produced by dry grinding. In the process of the grinding of talc, a remarkable change

occurs in the structure at the period between 192 hours and 240 hours under the experimental condition of this experiment. In the 384-hour-ground specimen, the X-ray diagram is nearly similar to that of the 240-hour-ground specimen. As the grinding progresses, the maximum points of diffuse bands in the X-ray diagram gradually become more and more indistinct, and the intensity of the background at the small angle part of a scattering angle increases progressively.

That a zeolitic substance is formed in the dry grinding of kaolin minerals can be supported on the basis of the X-ray diagram of the ground specimen treated with a weak alkali- and acid-solution as described in the previous papers[1]. These procedures were used for some ground specimens of talc. A part of these X-ray traces are shown in Fig. 2.

From a comparison of these X-ray traces with those of the original ground specimen, the following conclusions are drawn. In the alkali-treated specimen of 192-hour-ground talc, only a slight increase in the intensity of background is observable in the X-ray diagram, as compared with that of the original ground specimen. The X-ray pattern of the acid-treated specimen after being treated with the above weak alkaline solution is almost similar to that of

528	—140—	15	825	1	—	—

the original ground specimen, however, the pattern becomes somewhat distinct owing to a dissolution of an amorphous substance produced by dry grinding. In the X-ray diagram of the weak alkali-treated 240-hour-ground specimen, two very diffuse bands are noticeable as is clear by comparison of Fig. 1-D and Fig. 2-B. The positions of the maximum points of these bands are about 14.7Å and 3.5Å in the interplaner spacings. In addition to these diffuse bands, a very remarkable scattering is also observable in the region of a scattering angle as low as six degrees. To dissolve the amorphous substance produced by dry grinding, acid treatement was given. The X-ray diagram of the residual part has a broad band with a maximum of 3.86Å in spacing. The background decreases below that before acid treatment. This fact indicates that in the 192-hour-ground specimen, the disordering in the talc structure is observable but the production of an amorphous substance is yet remarkable. In this stage, a zeolitic substance is not to be formed. In the 240-hour-ground specimen, the crystalline substance is not present. This fact is ascertained by the X-ray diagram of a residual substance treated with alkali and acid. Therefore, it is considered that the structure of this specimen is not perfectly amorphous, but it is related somewhat to the original structure though the original talc structure disintegrates due to dry grinding. In the light of the X-ray data, the structure of the 384-hour-ground specimen is considerably similar to that of the 240-hour-ground specimen. In the 528-hour-ground specimen, the amorphous substance dissoluble by the alkali-acid treatment considerably increases. This means an increase of the amorphous substance by dry grinding.

Consequently, it is concluded that in the dry grinding of talc, the disordering of structure is remarkable up to a certain stage of grinding, and past this stage, the specimen changes wholly into a non-crystalline substance and then gradually changes into a completely amorphous substance. Therefore, the formation of a zeolitic substance is not remarkable as compared with that of kaolin mineral.

Differential Thermal Analysis. — Differential thermal analysis curves of the specimens in the various periods of grinding are shown in Fig. 3, and thermal data measured from these curves are given in Table II.

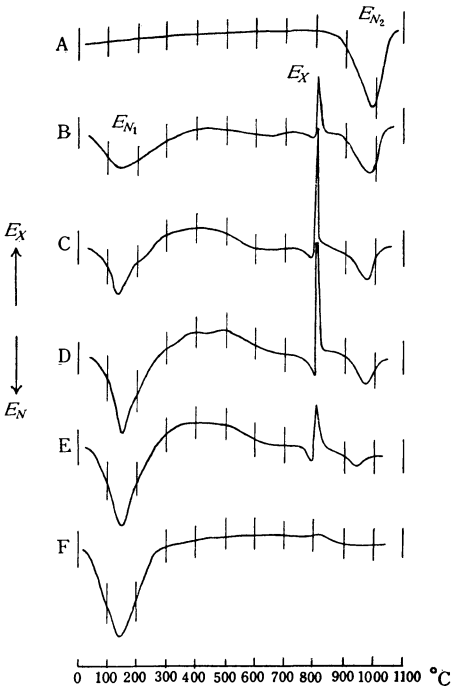

Fig. 3. Differential thermal analysis curves of ground talc.

E, ground 240 hours
F, ground 528 hours

The original sample has only an endothermic reaction (E_{n2}) associated with the loss of lattice water. The peak temperature of the endothermic reaction is 990°C, which is nearly equal to the value given in literature[6]. In the 96-hour-ground specimen, the first endothermic reaction (E_{n1}) associated with the loss of adsorbed water is apparent. This fact means that a non-crystalline substance is produced by dry grinding. As that of a kaolin mineral, a lowering in the peak temperature and a decrease in the height are observable in the second endothermic reaction (E_{n2}). It seems that these characteristics are related to the partial disintegration of the original structure. In the differential thermal analysis curve of this specimen, another important characteristic is observable. That is, a sharp exothermic reaction (E_X) is apparent at about 800°C, and there is the presence of a slight but distinct endothermic reaction immediately before this reaction. In the 192-hour-ground specimen, all features observed in the differential thermal analysis curves of the 48- and 96-hour-ground specimens become all the more distinct. An increase in the height of the first endothermic reaction, a remarkable increase in the intensity of the exothermic reaction, a lowering in the peak temperature and a decrease in the height of the second endothermic reaction are observable. Moreover the endothermic reaction just before the exothermic reaction becomes more distinct. The first endothermic reaction of ground specimens up to 192 hours is considered to be caused by a non-crystalline substance produced by grinding rather than by the water which gets into the inter-layers of talc as an inter-layer water, because the basal spacing of these specimens does not change much. In the 240-hour-ground specimen, the height of the exothermic reaction sharply decreases and the height of the second endothermic reaction decreases remarkably as compared with those of the 192-hour-ground specimen. In a many-hour-ground specimen, for example, the 528-hour-ground specimen, the reaction which is present in the original specimen is absent. Only the first endothermic reaction associated with the loss of the adsorbed water, and the weak and broad exothermic reaction at 825°C are observable. Then the endothermic reaction just before the exothermic reaction has already disappeared.

On the differential thermal analysis curves of the ground specimens, an important and interesting phenomenon is observable. That is, a new phase different from the original structure is apparent in the course of dry grinding. To ascertain this new phase, the X-ray traces of the 192-hour-ground specimen taken out just before and after the exothermic reaction on the differential thermal analysis curve are compared. A difference is observable in that only a reflection of 2.885Å spacing is apparent. From the facts that all reflections of the original 192-hour-ground specimen remain in the X-ray diagram of the specimen taken out just after the exothermic reaction and that a new reflection appears, it is supposed that the exothermic reaction on the differential thermal analysis curve is not based on the structural change of original talc. And from the fact that this exothermic reaction disappears again in many-hour-ground specimens, it is supposed that this exothermic reaction is not also based on the structural change of a perfectly amorphous substance produced by dry grinding. Therefore, it is clear that this exothermic reaction is based on crystallization from the new phase formed by dry grinding which is not the talc structure and is not a perfectly amorphous structure. This sort of structural change is not found at all in the case of kaolin minerals. The appearance of a new phase

by dry grinding is an important characteristic of talc.

Density.—A curve showing the change of the density in the process of the dry grinding on talc is shown in Fig. 4.

The density sharply decreases up to about 200 hours in the grinding, but thereafter it reaches a nearly constant value. This constant value is nearly equal to that of a gel-like substance. The point of the bend in the density curve is existent between the points of 192 hours and 240 hours. In the light of the X-ray and thermal data, this point corresponds to the point where the structure of talc changes wholly into a new structure by dry grinding. In talc, grinding takes a longer time for the density to reach the constant value than that of kaolin minerals. This means that talc suffers the effects of dry grinding less than kaolin minerals do, for the structure of talc is stronger than that of kaolin minerals.

Electron Microscopic Studies. — Fig. 5 shows the electron micrographs in the process of grinding on talc.

The original sample is an irregular and platty particle with a sharp edge, and the particle has several microns in size. In the 48-hour-ground specimen, it is observed that the particles are fine as compared with those of the original particle, while considerably large particles are also observable. It seems that the fine particles do not aggregate unlike the fine particles in the grinding process of kaolin minerals, and the edge of this particle is not sharp. The shape of the considerably large particle is spherical. As the grinding progresses, number of large particles decreases and that of fine particles increases, but the size of the fine particles remains almost unchanged. This means that the reaggregation process is not very remarkable in this case. In the 240-hour-ground specimen, the shape of the particle is almost uniformly spherical as compared with that of the 192-hour-ground specimen but it is not so spherical as the shape of particles found in the process of dry grinding of kaolin minerals. The mean value of the particle size of this specimen is about 0.1 micron. Past this stage in grinding, the particle size increases as compared with that of the 240-hour-ground specimen. As the grinding further progresses, an irregular growth of the particle is observable. This corresponds to the fact that the completely amorphous substance has been produced by grinding.

Summary

The several-hundred-hour mechanical-mortar dry grinding on talc was examined by X-ray diffraction method, differential thermal analysis, electron microscopy and density measurements, and they were compared with those of kaolin minerals. In the dry grinding on talc, some characteristics in the structural changes by dry grinding were found. As the grinding progresses, the original crystals cleave and fracture and then split into fine crystals. Disordering in structure of these fine crystals is observable before the talc structure disintegrates completely. In talc, a new substance is produced by dry grinding, which is somewhat related to but different from the original talc structure. The appearance of this new phase is most remarkable in the stage of grinding where the crystalline pattern of talc entirely disappears in the X-ray diagram. This new phase has a non-crystalline structure, but the strurcture is not completely amorphous. It crystallizes into a new crystal at about 800°C. As the grinding progresses, the structure of this new phase gradually disintegrates to a completely amorphous structure similar to that of a silica-magnesia mixed gel. The formation of a zeolitic structure is not so remarkable; also, even if this structure is formed, the period of its stage is very short. It is an important characteristic that talc wholly changes into a new non-crystalline substance by dry grinding. It is generally supposed that talc does not easily suffer the effects of dry grinding because the structure is stronger than that of kaolin minerals.

The author wishes to express his hearty thanks to Professor H. Akamatu for his continuous advice and encouragement. Thanks are due to Professor T. Sudo of the Tokyo University of Education and Professor R. E. Grim of the University of Illinois for their valuable suggestions and discussions.

Wet Grinding on Kaolin Minerals

By Hiroshi TAKAHASHI

(Received October 2, 1958)

In the previous studies, the effects of dry grinding on the structural change of kaolin minerals have been presented[1]. It was concluded that the effect of dry grinding depends on the internal degree of crystallinity of the original kaolin mineral, and there are two processes in the structural change. One is the production of a non-crystalline material attended by disordering of the crystalline portion, and the other is the reaggregation process. At a certain period in the grinding, a zeolitic structure is formed; then finally, kaolin mineral changes into a completely amorphous substance like a silica-alumina mixed gel.

Considerable work has been done on the dry grinding of kaolinite, but comparatively little is known on the wet grinding. It was found by Shaw that the wet grinding of kaolinite causes a shearing along the cleavage plane[2]. This will lead to weakening the stacking force between kaolin unit layers. The wet grinding of kaolinite has been made heretofore using ball-mill with water or organic liquid such as benzene. Judging from the fact that wet grinding causes a shearing stress, it is obvious that a higher viscous liquid is more effective in the grinding process than the lower one. Therefore, glycerol was used in the present experiment, combined with a mechanical-mortar as it is very effective in causing a change in structure as discussed in the previous papers[1].

The purpose of this study is to know the correlation between the effect of the wet grinding and that of the dry grinding from the point of view of the degree of the crystallinity of kaolin minerals. It is hoped that this will lead to the fundamental information concerning kaolin minerals.

Experimental

The following kaolin minerals were investigated: Kaolinite from Mesa Alta, N. M., U. S. A.; Halloysite from Spruce Pine, N. C., U. S. A.; Halloysite from Tintic, Utah, U. S. A.. These specimens are API Standard Clay Minerals. The structural characteristics of these specimens were discussed in the previous paper[3]. Of all kaolin minerals, Mesa Alta kaolinite has the highest degree of crystallinity, of all halloysites, Spruce Pine halloysite has the highest degree of crystallinity, and Tintic halloysite has a lower degree of crystallinity than Spruce Pine halloysite.

30 g. of each original kaolin mineral was charged, mixed with 100 cc. glycerol. The mixture was wet-ground by a mechanical-mortar (15.2 cm. dia. and 8.4 cm. in depth). The specimen was taken out at intervals of 48 hours and washed with water throughly and then air-dried. The experimental specimen thus prepared was examined by X-ray, thermal and electron microscopic methods. In parallel with these examinations, its density was measured.

X-ray powder diagrams were recorded by an X-ray diffractometer (Geigerflex). Experimental conditions are as follows. Filtered Cu radiation (Cu K_α: 1.5418 Å) at 35 kV and 15 mA is used, scanning speed is 1° or 1/4° 2θ per minute, time constant is 4 seconds, receiving slit is 0.2 mm. or 0.1 mm., angular aperture 1° or 1/2° were used. The differential thermal analysis curves were recorded by the apparatus described by Sudo et al.[4]. Care was taken to pack the specimen into the sample block in a homogeneous manner and also to keep the weight of the specimen constant. The mean heating rate is 12.5°C per minute. The density was measured by pycnometer in carbon tetrachloride. The electron micrographs were obtained by the Hitachi HU-10A type Electron Microscope.

Results and Discussion

X-Ray Diffraction Studies. — X-ray diffractometer traces in the wet grinding process of kaolin minerals are given in Fig. 1. Fig. 1-a and Table I show the X-ray traces and the data of Mesa Alta kaolinite in their various stages of the wet grinding.

As the grinding progresses, the intensities of all reflections decrease and those of the background increase slowly. The X-ray diffraction diagram of the 48-hour-ground kaolinite is not much different from that of the original kaolinite. However, all the reflection lines become broad, $(1\bar{1}\bar{1})$ reflection becomes weak and the resolution of $(20\bar{1}, 130, 1\bar{3}0)$ reflection and $(13\bar{1}, 1\bar{1}2)$ reflection slightly fall. In the 96-hour-ground specimen, $(11\bar{1})$ and $(1\bar{1}\bar{1})$ reflections become broad, and they are hardly resolved at all with each other. The intensities of $(02\bar{1})$ and (021) reflections decrease and $(11\bar{2})$, $(1\bar{1}\bar{2})$ and (022) reflections disappear. These facts mean that the unit layers are displaced slightly in parallel to *b*-axis. In the 192-hour-ground specimen, a decrease in the intensity and a broadening of (020) and $(1\bar{1}0)$ reflections are observable, but $(02\bar{1})$ reflection can scarcely be detected. From these phenomena, it can be seen that a displacement occurs in this specimen, which is more random than the displacement by $b_0/3$ in parallel to *b*-axis. In the X-ray diagram of the 288-hour-ground specimen, the lowering in the resolution of (020) and (110) reflections is observable, but the broad $(1\bar{1}\bar{1})$ line can not be seen. In the X-ray diagram of the 384-hour-ground specimen, a wedge-like (02, 11) band is observable, but (003), $(20\bar{2}, 1\bar{3}1, 11\bar{3})$ and $(1\bar{1}3, 131)$ reflections resolve distinctly with one another. The structure of the 384-hour-ground specimen becomes similar to that of fireclay[5]; however, it has still more regular displacement comparing with that of fireclay. As shown in Table I, in the process of wet grinding, the value of the basal spacing grows gradually, though slightly, as the grinding progresses. This means that the local water gets into the space between the kaolin unit layers as the inter-layer water, or that the stacking of the unit layers becomes looser owing to the shearing stress. From the above results, it is clear that the structural change of kaolinite caused by wet grinding results from cleavages in the kaolin crystal.

In the case of halloysite, however, the features observed in kaolinite are not so remarkable. Figs. 1-b and -c show the X-ray traces in various stages of wet grinding of Spruce Pine halloysite and Tintic halloysite, respectively. As seen in these figures, the X-ray traces for various stages of wet grinding are only slightly different from one another. In the wet-ground specimen of Spruce Pine halloysite, all reflections become slightly broad; only the intensity of (00*l*) reflection decreases and the background increases, as the grinding progresses. In Tintic halloysite, the changes in X-ray traces due to wet grinding are similar to that of Spruce Pine halloysite. In the 528-hour-ground specimen, it is observable that the halloysite-glycerol complex is formed.

The reflection lines generally become slightly broad by wet grinding. To ascertain the broadening of the reflections, crystallite dimensions in the wet grinding process of Tintic halloysite are measured from (001) reflection and (02, 11) band[6], as reported in the previous papers[1,7]. Their values are shown in Table II.

The crysatllite dimensions thus obtained

TABLE II
CRYSTALLITE DIMENSIONS IN THE VARIOUS STAGES OF WET GRINDING OF TINTIC HALLOYSITE

Grinding time (hr.)	Crystallite dimension (Å)	
	L_c (from 001 reflection)	L_a (from 02, 11 band)
0	80	155
192	76	141
288	70	118
384	66	110
528	58	105

are, of course, not accurately real crystallite sizes but relative values. The change of the basal spacing in the process of wet grinding of halloysite is not so remarkable as that of kaolinite. This indicates that the cleavage caused by wet grinding is not very remarkable in halloysite compared with that of kaolinite. The dry grinding is in general more effective than the wet grinding in causing the structural change. However, it is observable that there is a great difference in the wet grinding effects between kaolinite and halloysite. As clearly shown in X-ray data, kaolinite is subjected to its effects more than halloysite though its degree of crystallinity is originally higher. In kaolinite, the shearing stress acts in parallel to the layer planes, as kaolinite is made of stacking of parallel unit layers. On the other hand, in halloysite, its crystal has a tubular shape, resulting from the rolling up of the unit layers[8]. So, it is hard to make cleavage by shearing stress through wet grinding. Furthermore, as halloysite has originally a two-dimensional structure; even if a small displacement takes place along the unit layers, it does not affect its X-ray diagram.

Differential Thermal Analysis.—Differential thermal analysis curves and data in the process of wet grinding of kaolin minerals are shown in Fig. 2 and Table III.

In ground specimens of kaolinite, the the first endothermic reaction (E_{n1}) associated with the loss of the inter-layer or adsorbed water becomes apparent and its height increases as the grinding progresses. This means that the water gets locally into the increased spaces between kaolin layers because of cleavages through wet grinding, and it becomes the inter-layer water, and/or that the non-crystalline material which adsorbs some amounts of water is produced by wet grinding. For the second endothermic reaction (E_{n2}) associated with the loss of the lattice water, as the grinding progresses, the lowering in its peak temperature and the decrease in its peak height and area are observable. In the final exothermic reaction (E_x) due to the mullite nucleation, as the grinding progresses, the lowering in the peak temperature, the increase in the peak breadth and the decrease in the peak height and area are observable. However, in halloysite, these features observed in this reaction are not so remarkable compared with that of kaolinite. This fact corresponds to the fact that kaolinite is more liable to suffer the effects of wet grinding than halloysite as shown in X-ray data. That is, in halloysite, although a lowering in the peak temperature is observable, the peak breadth decreases and the peak height is either invariable or increases. These phenomena indicate that the effect of wet grinding of halloysite is nearly the same as the effect at the early stage of dry grinding[1].

Density.—In Fig. 3 is shown the density at various periods of grinding. Measurements were made after the specimens had been dried at 110°C in order to avoid the effect of the adsorbed water.

In halloysite, the density gradually decreases at first; after reaching a certain point of grinding, it rapidly decreases. On

the other hand, in kaolinite, the decrease in the density is remarkable in the early stage of grinding, then the density slowly decreases, and finally it attains a nearly constant value. The rate of change in the density corresponds to the fact that kaolinite is more liable to suffer the effect of wet grinding than halloysite, at least in the early stage of grinding as indicated in previous sections.

The structure of kaolinite changes into a disordered structure due to cleavage caused by the wet grinding, while halloysite scarcely suffers the effect in the early stage of grinding. In a considerably long time of grinding, the structure of halloysite gradually decomposes due to fracturing and cleavage caused by grinding. This corresponds to the somewhat rapid decrease in the density.

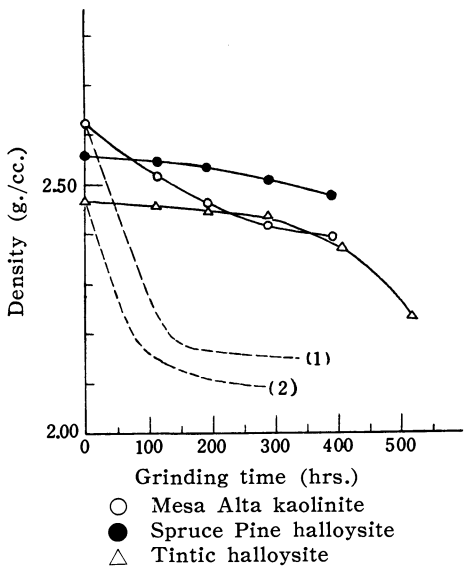

Fig. 3. Curves showing the changes of the density of wet-ground specimens of kaolin minerals with the time of grinding. (1), (2): Curves showing the changes in the process of dry grinding of Mesa Alta kaolinite and Tintic halloysite, respectively.

Electron Microscopic Studies.—The electron micrographs of some ground specimens are shown in Fig. 4.

In the early stage of grinding of kaolinite, it is seen that the edge of a kaolin crystal tends to curl. This tendency is interpreted in the light of the characteristic of the shape of kaolin unit layer by Bates et al.[8]. That is, kaolin mineral with a random displacement has generally the tubular shape like halloysite. The relation between the degree of crystallinity of a kaolin mineral and the shape of the crystal was presented in the previous paper[3]. As the grinding progresses, the shape of the kaolin crystal gradually change into a circular but platty shape. The particle size does not change remarkably. Finally, it changes into spherical aggregates of fine platty particles.

In halloysite, various shapes such as split tubular, platty, lath-shaped, cabbage-like and other variations are observable in the wet grinding process. From these phenomena, it seems that the force of wet grinding causes fracturing rather than shearing.

Mechanism of Structural Change of Kaolin Mineral due to Wet Grinding.—When kaolinite is wet-ground, the crystal

cleaves along the layer plane owing to shearing stress. In consequence, displacement of layers takes place in parallel to *b*-axis. As the grinding progresses for a long time, the structure of the original kaolinite with a triclinic in symmetry change into the more disordered structure. These displacements are remarkable in the early stage of grinding. The change of the particle shape due to wet grinding is observable as the gradual formation of fine and radial platty particles though it is not so remarkable in the early stage. When the grinding further progresses, kaolinite with a higher degree of crystallinity gradually changes into kaolin with a random displacement similar to that of halloysite.

In the early stage of grinding of halloysite, the original crystal splits and fractures owing to the fracturing force. Therefore, the change on the X-ray diagram is not so remarkable and the thermal data also indicate the same tendency. From the electron micrographs, too, it can be concluded that the force of wet grinding acts as a fracturing force, which results in splitting tubular crystal. The process of the structural change through wet grinding for the platty particle of halloysite produced by splitting is similar to that of kaolinite.

Summary

The effects of wet grinding on kaolin minerals were examined by X-ray diffraction method, differential thermal analysis, electron microscopy and density measurement. The effects of wet grinding of kaolin minerals are different from those of dry grinding, particularly at the early stage of grinding. It has been considered that the force of dry grinding acts as fracturing and cleaving forces, while the force of wet grinding acts as a weak cleaving force for kaolinite and as a weak fracturing force for halloysite in the early stage of grinding. It has been revealed that the effects of wet grinding depend on the shape of crystal in the original kaolin mineral in the early stage of grinding, and beyond a certain stage of grinding, they depend on the structural perfectness of the kaolin layer, that is, the internal degree of crystallinity of the original kaolin mineral.

Formation and Aging of Precipitates. XI. An Electron Micro-Diffraction Study on Nucleation of Barium Sulfate Precipitate from Homogeneous Solution*

By Kazuyoshi TAKIYAMA

(Received October 6, 1958)

In the course of precipitate formation, the nucleation process is the idea generally accepted. The nucleation involves a process of formation of embryo, which is an unstable intermediate, and a process of the nucleus formation. When the precipitate is formed with direct mixing of ions, the growth of the nuclei formed in small numbers plays a predominant part in the region of the lower concentration, and the nucleation plays a predominant part in the higher concentration region[1,2]. When the precipitate is formed from a homogeneous solution, the nucleation occurs when a certain degree of supersaturation is attained[3]. During the

* The tenth paper of this series, This Bulletin, 32, 68 (1959).

2) K. Takiyama, ibid., 32, 68 (1959).
3) V. K. LaMer and R. H. Dinegar, *J. Am. Chem. Soc.*, 73, 380 (1951).

precipitation process the crystal property of particles seems to appear after nucleation.

An attempt has been made in the present investigation to employ the electron micro-diffraction method with a view to observe the nucleation process during the formation of barium sulfate precipitate according to LaMer and Dinegar's method[3].

Experimental

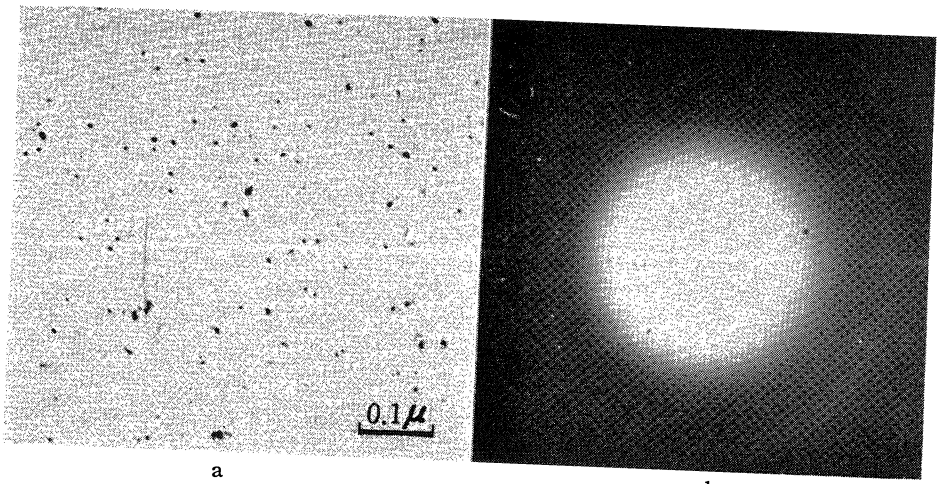
Procedure.—Fifty ml. of 0.02 M ammonium persulfate solution was added to a 200 ml. beaker containing 50 ml. of 0.02 M barium nitrate solution. Barium sulfate formed from the sulfate in persulfate was filtered with a glass filter. Ten ml. of 0.1 M sodium thiosulfate solution was then added to the clear filtrate and the reaction solution thoroughly mixed was kept in a thermostat at 25°C. The precipitate, when examined with a beam of white light, exhibited Tyndal beam 7 minutes after the addition of thiosulfate.

The reaction mixture was poured into a spray bottle which was kept in the thermostat, and was sprayed on tiny Formvar films floating on the surface of distilled water 5, 6, 7, 8, 9 and 10 minutes after the addition of thiosulfate. A few minutes were allowed for diffusion of soluble salts from the drop of reaction mixture into the water below. The films were scooped with specimen grids for observation with an electron microscope.

Calculation of Size of Crystalline Nucleus.—From the Thomson's equation[4] on nucleation in the supersaturated vapor, the size of nucleus formed in the supersaturated sparingly soluble salt solution is expressed by the following equation,

$$r=\frac{2M\sigma}{iRT\rho \ln S/S_\infty} \qquad (1)$$

where r is the radius of spherical nucleus, M the molecular weight, σ and ρ are the surface tension and the density of the crystal, R is the gas constant, T the absolute temperature, S the supersaturation concentration, S_∞ the solubility of the salt and i the van't Hoff factor. According to LaMer and Dinegar[3], the value of the supersaturation ratio, $\sqrt{K^\circ_{SS}/K^\circ_{SP}}$ (K°_{SS} and K°_{SP} are the activity products of both supersaturated and saturated solutions), is a constant and is 22 on an average at 25°C. The value of r is calculated in the present case, as 100 Å from the equation 1, when this limiting value, 22, is substituted for S/S_∞. On the other hand, the condition of concentration of reacting ions at the time that the precipitate begins to appear in the case of homogeneous solution method, seems to correspond to the limiting supersaturation concentration at which the precipitate appears without an induction period in the case of direct mixing method. This limiting supersaturation concentration is about 0.002 M[1]. The size of nucleus, r, is calculated as 60 Å according to the equation 1, when this value of 0.002 is substituted for S. It seems that the size of crystalline nucleus formed under the experimental condition mentioned above is in the range of 100 to 200 Å in diameter.



Results

The image of particles began to be observed with the electron microscope after 6 minutes and the particles grew gradually as the time passed. An electron micrograph and an electron diffraction pattern obtained from the six minutes' specimen are shown in Figs. 1 a and b. The diameter of particles shown in Fig. 1 a measures 30 to 80 Å and the particles looked like unstable embryos formed by aggregation of monomers. As the crystal structure of these particles is not perfect, the diffraction pattern is composed of a few broad rings. The particles in the seven minutes' specimen are nearly spherical and measure 100 to 200 Å in diameter as shown in Fig. 2 a. The size of these particles coincides with that obtained by the calculation from equation 1. The electron diffraction pattern obtained from these particles is composed of indistinct coarse rings as shown in Fig. 2 b. But the rings indicate that the crystal structure of particles is more perfect than that of particles shown in Fig. 1 a. The size of particles in the eight minutes' specimen is 300 to 400 Å in diameter as shown in Fig. 3 a. The electron diffraction pattern is composed of distinct coarse Debye-Scherrer rings as shown in Fig. 3 b. The crystal structure of particles seems to have been completed in this stage. The particles in the ten minutes' specimen are spindle-shaped and the length of the long axis is about 1000 Å as shown in Fig. 4 a. The electron diffraction pattern obtained from one of the particles arrow is N-pattern as shown in Fig. 4 b. Each particle is obviously a single crystal, and the long axis proves to be b-axis from the analysis of the pattern shown in Fig. 4 b. The shape of the particle grown completely is oval. The oval particle of barium sulfate seems to be formed through dendritic growth in every direction from a crystal nucleus and the particle has a single crystal structure. The growth along b-axis seems to be more or less marked.

The particles of barium sulfate began

to appear after 6 minutes and grew up continuously into large crystals. During the precipitation process, the existence of the nucleus with a certain size can be logically proved from the standpoint of thermodynamics[3,4], but in fact only the continuous growth of a particle is observed by electron microscopy and the particle appears to form a distinct crystal structure when it has attained the size as large as that of the nucleus calculated thermodynamically.

Summary

The nucleation process of the precipitation of barium sulfate from the homogeneous solution of persulfate-thiosulfate system was observed by the electron micro-diffraction method. The particles grew continuously, but the distinct crystal structure began to appear in the particles having the length of 100 to 200 Å in diameter, corresponding to the nucleus calculated thermodynamically.

Studies on the Interaction of Surface Films with Solute in Solution. V Deposition of Monolayers of Several Amphipathic Compounds from Surfaces of Aqueous Solutions of Congo Red and Crystal Violet

By Mitsuo MURAMATSU

(Received September 18, 1958)

It has been shown by several investigators that useful knowledge could frequently be obtained for the surface interaction of the insoluble monolayer formed at air-water interface with the other additives, by investigating the nature of the built-up film obtained from the surface of aqueous substrate. Thus, the nature of the mixed monolayer of stearic acid and normal paraffin[1] or cetyl alcohol[2] has been studied by means of this method. In the latter case, formation of a stoichiometric complex of 1:1 ratio was suggested by the measurement of the surface potential, which was in agreement with the experimental result on the mixed monolayer of the same materials spread on the surface of water[3]. Such a method could sometimes be applied to study the interaction between the insoluble monolayer and the aqueous solute in the solution underlying the film. The present author[4] obtained the built-up film of stearic acid of low refractive index by transferring the monolayer from the surface of aqueous solutions containing copper, aluminum and thorium ions and discussed the structure of metal soap formed at the solution-air interface. A similar method could successfully be applied to the case of interaction between dicarboxyacids in aqueous phase and octadecylamine in the monolayer spread on it[5].

In the preceding reports[6,7] it has been shown that the addition of dye to aqueous substrate resulted in a remarkable expansion of the monolayer of amphipathic compound spread on it, when pH of the substrate was in a proper range where the binding of dye to the film material as well as the aggregation of the former

was remarkable. This could be ascribed to the interaction between the dye and the amphipathic compound, involving ionic, dipolar and van der Waals' forces. A similar conclusion was obtained by Matuura[8] in the case of the monolayer of stearic acid. To obtain further confirmations for such an interaction, the present author has intended to study the nature of the built-up films of several amphipathic compounds transferred from the surfaces of aqueous solutions of Congo red and Crystal violet.

Experimental

Materials. — Amphipathic compounds and dyes were purified thoroughly by the methods similar to those used in the former experiments[6,7]. Oleic acid and castor oil as piston oils were pure grade commercial products of Kahlbaum and Takeda, respectively, which were used without any further purification. Tri-*p*-cresyl phosphate was synthesized by the reaction of *p*-cresol and phosphorus pentachloride[9] and was distilled three times in vacuo.

Method.—Monolayers were spread from the benzene solutions of amphipathic compounds onto the aqueous substrates, containing or lacking the dyes. They were built up onto the base echelon of successive Y-multilayers of barium stearate deposited on a highly polished slide of stainless steel, by means of Langmuir-Blodgett technique[10] under the spreading pressure, F, of either of tri-*p*-cresyl phosphate ($F=10$ dyn./cm.), castor oil (15 dyn./cm.) or oleic acid (30 dyn./cm.), unless otherwise mentioned. The spacing of the built-up film was determined by means of the simplified optical method[11], assuming the same refractive index of 1.462 for the film as that of the base echelon, spacing of which was reported to be 24.4Å[10].

Concentration of the dye solution was kept to 10^{-4}mol./l. The acidity of the substrate was adjusted simply by twice-distilled hydrochloric acid and ammonia using the Beckman glass electrode. In the case of dye solution, experiments were conducted under the pH of largest expansion of each monolayer[7,8].

Results

Ease of Building-up of the Films.— Successive Y-multilayer of stearic acid could easily be obtained in pH range of 4～7 by transferring the monolayer under the spreading pressure of oleic acid or castor oil from the surface of water containing no dye. When pH of water was less than 4, however, the monolayer adherred neither to the bare surface of the slide nor to the base echelon of barium stearate. These facts are in agreement with what was reported[10]. In contrast with this, the successive Y-multilayer was obtained from the surface of the aqueous solution of Congo red the pH of which was 3.2. Deposition of the monolayer was clearly favored by the addition of the dye at least in the region of low pH, presumably owing to an increased stability of the film. From the surface of the solution of Crystal violet, we could obtain the Y-multilayer only when the monolayer was compressed by oleic acid and the slide was dried thoroughly after each transfer of the film.

Attempts were made to build the multilayers of cholesterol from the substrates of water and solution of Congo red. In the former case the substrate water of pH 5.8 proved to be favorable for obtaining the successive Y-layer for any piston oil used, while deposition of the monolayer was unsuccessful on the substrate of pH 2.0. Here, the addition of Congo red to the substrate resulted in promoting the easiness of building-up of the film even at pH 2.0. In this case the use of oleic acid and castor oil as piston oil effected Y-layer and occasionally X-layer.

The monolayers of cetyl alcohol, ethyl *n*-hexadecyl ether and ethyl stearate adhered neither to the bare surface of the slide nor to the base echelon, irrespective of the addition of Congo red to the substrate. This was indeed the fact under the spreading pressure of any piston oil used. Further efforts were also made to build up the multilayers under the spreading pressure of benzene solutions of film material placed near the slide covered with the base echelon. This method proved to be suitable for the deposition of such monolayers as copper, aluminum and thorium stearate, to which the ordinary technique of Langmuir-Blodgett method failed to apply[4]. However, it was unsuccessful in the present case even with this method.

The monolayer of octadecylamine could be deposited onto the base echelon only when the fiilm was compressed by tri-*p*-cresyl phosphate, under the substrate pH of 5～9. This was in agreement with the results reported in a former paper[5]. When Crystal violet was added to the aqueous substrate, no monolayer could be deposited in many cases onto the solid surface. Even when it could be built up,

we merely obtained optically heterogeneous films, irrespective of the nature of the piston oil and of the substrate pH. In contrast with this, homogeneous Y-multilayer was obtained successively from the surface of the solution of Congo red of pH 5.5, when the monolayer was compressed by tri-*p*-cresyl phosphate and the built-up film was dried after each transfer of the film.

The conditions for the successful deposition of the film were summarized in the columns of Table I from the first to the fourth columns. In this table the fifth column expresses the types of the multilayers thus obtained.

Spacing of the Built-up Films. — In Table I, the sixth column shows the spacing of the built-up films of stearic acid, cholesterol and octadecylamine, transferred from the surfaces of aqueous substrates containing or lacking dye. They are expressed in average values of 5—12 independent experiments. When the monolayer was deposited from the surface of water, the spacing depended only a little on the acidity of substrate throughout the whole region of pH investigated and on the choice of piston oil. The latter condition was valid also in the case of the solution of dye as substrate. This might come from the low compressibility of these films[7].

Wettability of the Films. — As is cited in the seventh column of Table I, all built-up films were of hydrophobic character when they were once dried. Of these films, the film of stearic acid was reported to be wetted profoundly by aqueous solutions of copper, aluminum and thorium ions[4,12]. Such an effect of metal ions was observed in the present experiments for the built-up films of stearic acid transferred from the surfaces of water, solution of Congo red and of Crystal violet. However, there were some differences between the three films in their behaviors towards the subsequent procedure. For the first film, the solid surface remained in its hydrophilic condition for at least two minutes after final rinsing with water. For the second and the third films, the procedure under the same condition resulted in peeling-back of rinsing water. After the films were once dried, the subsequent conditioning by aqueous metal ions gave rise to no wetting of the first film, while it rendered the remaining two films wettable.

The last column of Table I represents the wettability of these films toward a drop of benzene placed on them. Though the test was merely qualitative, the result was sufficient to classify the film into two groups with respect to their wetting characters. Benzene showed a large contact angle toward the films of stearic acid and of octadecylamine both transferred from the surface of water. When the slide was tilted, the drop slid on the film on which less color change was observed at the track. On the contrary, the contact angle was very small for the rest of the films and the sliding of the drop resulted in a remarkable change in color, showing the profound dissolution of film materials into the benzene drop.

Discussion

As mentioned in the preceding section, the monolayers of cetyl alcohol, ethyl *n*-hexadecyl ether and ethyl stearate spread on the surfaces of water adhered neither to the metal surface nor to the base echelon of barium stearate. Isemura

12) I. Langmuir, *Science*, **87**, 493 (1938); A. Inaba, This Bulletin, **26**, 43 (1953).

and Nakagawa[2] have obtained a similar result for the case of cetyl alcohol. In the case of ethyl stearate it was reported[13] that the monolayer could be deposited successively only under the delicate control of substrate pH, speed of down- and up-trip of the slide. The built-up film thus obtained however seems to consist of large crystals transferred heterogeneously on the slide, as was pointed out by the microscopic observation[14]. All these phenomena, as well as the present results, seem to show the difficulty of building up a non-ionic monolayer spread on water. A similar result was obtained for the monolayers of these compounds spread on aqueous solutions of Congo red. Under the present conditions of pH of substrate, the majority of dye molecules were considered to be in a zwitterion form as pointed out in a preceding report[7]. Therefore, there is no net charge in the molecules either of film materials or of dye.

On the other hand, building-up was successful in the cases of the monolayers of stearic acid, cholesterol and octadecylamine spread on the solutions of Congo red, and of stearic acid on the solution of Crystal violet. Of these films, it is noticeable that the building-up of the monolayers of stearic acid and cholesterol is facilitated by an addition of Congo red to the substrate. Here, because of Congo red being in the region more acidic than the isoelectric point, the molecules of the dye have a positive charge while the monolayers are not in a charged state[7]. In the remaining two cases, dye and film materials are charged oppositely to each other, as pointed out in the preceding reports[7,15]. These facts lead us to a presumption that a suitable attachment of charged dye to the film material does not decrease the easiness of obtaining a built-up film of its own.

As seen in Table I, the apparent spacing of the built-up film of stearic acid or octadecylamine is decreased by an addition of Congo red to the substrate of the monolayer. It has been reported that the monolayers of stearic acid[8] and octadecylamine[7] expanded remarkably when they were spread on aqueous solution of Congo red and were compressed to a surface pressure of piston oil used in the present experiment. This could be explained by an attachment of colloidal aggregates of dye to the monolayer. Therefore the attachment of Congo red to the film may cause an increase in film thickness, while it may result in a decrease in surface density of *n*-hydrocarbon chain of the amphipathic compound and consequently a decrease of refractive index of the film. These two effects contribute oppositely to each other to the apparent spacing which we actually measured assuming the same refractive index of the upper layer as that of the base echelon. In the present case, the effect of the former seems to be overwhelmed by that of the latter. A similar effect of solute was observed in the case of the built-up film of stearic acid obtained from the surface of aqueous solutions of copper, aluminum and thorium ions[4]. In contrast with this, an overwhelming contribution of the former is observed for the film of cholesterol spread on the solution of Congo red and for the film of stearic acid on the solution of Congo red and for the film of stearic acid on the solution of Crystal violet.

It is of interest to show that, though all the films studied exhibit hydrophobic property, they are wettable toward benzene, except for the films of stearic acid and octadecylamine transferred from the surface of water which proved to be oleophobic. Zisman et al.[16] obtained the oleophobic monolayers of methyl-rich surface being non-wettable toward methylene liquid such as *n*-hexadecane, benzene, etc. They explained the phenomenon by a difference between methyl-methyl and methylene-methylene attractions[17]. As was pointed out by several investigators[18], the oleophobic character toward methylene liquid seems to suggest the existence of the methyl-rich surface, in which the molecules are closely packed and orientate towards the contacting phase. In Table I the built-up films of stearic acid and octadecylamine show an oleophobic property while the cholesterol film proves to be oleophilic, when they are transferred from the surface of water. This can be explained by the greater difficulty of packing of methyl head for the case of cholesterol, as would be expected from the special structure of

cholesterol. Similarly, the oleophilic nature of the films taking up the dye can reasonably be explained by the structure of built-up film consisting of widely spaced *n*-hydrocarbon chain. We can find that this is also in a conformity with the effect of added dyes upon the limiting area of the monolayers of stearic acid, cholesterol and octadecylamine[7,8].

Summary

Attempts were made to obtain the built-up films of stearic acid, cholesterol, cetyl alcohol, ethyl *n*-hexadecyl ether, ethyl stearate and octadecylamine, by transferring each monolayer from the surfaces of water and aqueous solutions of Congo red and Crystal violet. Deposition of the monolayers of cetyl alcohol, ethyl *n*-hexadecyl ether and ethyl stearate was unsuccessful, irrespective of whether the substrate contained dye or not. On the other hand, the monolayers of the remaining compounds could easily be deposited onto the solid phase from the surfaces of water and dye solution.

The effect of added dye upon the apparent spacing of the film thus obtained seems to show an attachment of dye to the film substance, though the spacing varied from one case to another. This variation could be explained taking account of the balance of two contributing factors mutually opposite to the apparent spacing: one, increase of the film thickness due to the attachment of dye, and the other, decrease of the refractive index of the film due to the wide separation of *n*-hydrocarbon chain. Such a consideration was supported by the data on the wettability toward benzene. All these phenomena are in agreement with the data on the effect of dissolved dye upon the limiting area of the monolayer spread on it.

In conclusion the author expresses his hearty thanks to Professor T. Sasaki for his kind guidance in the course of this study. The cost of this research has been defrayed from the grant of the Ministry of Education given to the Professor.

Remarks on the Molecular Calculation of Naphthalene and Anthracene

By Noboru MATAGA, Kichisuke NISHIMOTO and Shizuyo MATAGA

(Received September 22, 1958)

The calculations made by Pariser and Parr[1,2] and also by Pople[3] in terms of semi-empirical molecular orbital (MO) method, have made a remarkable progress in the interpretation of the spectra of π-eletron systems. However, the agreement between the experimental and the theoretical results on the spectra of naphthalene which should come to our attention naturally next to benzene, does not seem to be satisfactory as yet. Although the results of Pople's SCF calculation[3] and Pariser's ASMOCI calculation[2] seem to be fairly well founded experimentally, the results of SCF and ASMOCI calculations of Moser and Lefebvre[4] in various degrees of approximations are in rather an unfortunate disagreement with experimental observations. Such an undesired circumstance is not restricted only to the case of electronic spectra, but, for example, the calculated bond orders of naphthalene and anthracene seem to agree hardly at all with observed values. The bond orders of naphthalene calculated with naive MO's are in a serious discrepancy with experimental values, but those of anthracene calculated in the same way are in good cor-

respondence with experiment. The application of the semiempirical SCFMO method of Pople to these molecules leads to a nice agreement with experiment in the case of naphthalene[5] but at the same time to a wrong prediction in the case of anthracene[6]. However, employing the values of molecular integrals which we have been using for studying the electronic structures of nitrogen heterocycles[7], the electronic spectra and other properties of naphthalene and anthracene seem to be satisfactorily interpreted. In the present report, the results of our calculation on the aromatic hydrocarbons will be described with some critical discussions comparing our results with those of other authors.

I. Electronic Spectra.—As indicated in Tables I and II, the calculated spectra of naphthalene and anthracene employing our parameters[7] are in a satisfactory agreement with experimental values. In these tables the results obtained by Pople and Pariser, respectively, are also given for the purpose of comparison. In both of these tables, "i" is the result of the ordinary Hartree-Fock SCF calculation with the approximation of zero differential overlap, and "ii" is obtained by an approximate SCF calculation in which $F_{\mu\nu}$'s for the neighbors more distant than the nearest are neglected, and in "iii" the naive MO's are used for the calculation of excitation energies and oscillator strengths. The calculated results in "iii" are close to those "i" or "ii", and the agreement with the observed values is satisfactory. This fact is in accordance with the circumstance that, as pointed out by Dewar and Longuet-Higgins[8], owing to the uniform charge distribution in aromatic hydrocarbons, their naive MO's themselves are fairly close to SCFMO's.

Now, the results obtained by Lefebvre and Moser are collected in Table III. In this table, A is the result of the calculation which involves the penetration integrals to hydrogen atoms, in addition to other parameters which are the same as used by Pariser and Parr. Accordingly, the pairing property between the bonding and the antibonding orbitals is lost in this

case. In B, $F_{\mu\mu}$, the diagonal element of Fock's Hamiltonian in terms of AO, has been assumed to be constant regardless of the position of carbon atoms, resulting in the pairing property, and all the off-diagonal elements, $F_{\mu\nu}$'s for nearest neighbors have been assumed to be equal to each other. For more distant neighbors, $F_{\mu\nu}$ is calculated by $F_{\mu\nu}=H_{\mu\nu}-1/2\ P_{\mu\nu}\gamma_{\mu\nu}$, where $H_{\mu\nu}$ is the off-diagonal element of core Hamiltonian, $P_{\mu\nu}$ is the bond order and $\gamma_{\mu\nu}$ is the electronic Coulomb repulsion integral. In C, it has been assumed that all values of $H_{\mu\nu}$ for nearest neighbors are equal.

The most important difference of our calculation from Lefebvre's and Moser's is in the choice of parameters, especially of $\gamma_{\mu\nu}$ values. In this respect, some discussions will be given in the latter part of this paper.

II. Bond Orders.—As mentioned in the introductory part of the present paper, Pople's self-consistent treatment as applied to the calculation of bond orders gave good agreement with the experiment for naphthalene, but not for anthracene, whereas with the simple treatment without the inclusion of electronic interaction, the situation was reversed. In view of this circumstance, Pritchard and Sumner[9] tried to hit the experimental values calculating the bond orders of naphthalene and anthracene by various approximations. This was, however, a rather hard task. Among various approximations (six approximations), only one (their approximation 5) gave results for both molecules free from significant error. In this approximation, Pople's self-consistent MO method was used with variation of α, the diagonal element of core Hamiltonian in terms of μth AO; the correction used was $\Delta\alpha=\beta$ in the sense that atoms labelled 3 in Fig. 1 are more electronegative than other atoms in the system.

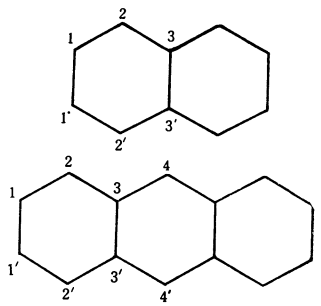

Fig. 1. Numbering of atoms in naphthalene and anthracene.

Now, as indicated in Table IV, the bond lengths calculated by the self-consistent field MO method using our parameters, are in good correspondence with experiment, where the results of Pritchard and Sumner by approximation 5 (abbreviated as P.S.) are also indicated for the purpose of comparison. In this table, the calculated

TABLE IV
CALCULATED AND EXPERIMENTAL BOND LENGTHS OF NAPHTHALENE AND ANTHRACENE (IN A)

Naphthalene

bond	Calcd. (i)*	(ii)*	P.S.	Expt.
1—2	1.374	1.369	1.369	1.365±0.006
2—3	1.414	1.417	1.420	1.425±0.005
3—3'	1.412	1.406	1.409	1.393±0.010
1—1'	1.405	1.412	1.413	1.404±0.009

Anthracene

bond	Calcd. (i)*	P.S.	Expt.

2—3	1.423	1.430	1.424±0.005
3—4	1.396	1.403	1.396±0.004
3—3'	1.436	1.432	1.436±0.007
1—1'	1.408	1.422	1.408±0.010

* The meaning of i and ii is the same as those in Tables I and II.

9) H. O. Pritchard and F. H. Sumner, *Trans. Faraday Soc.*, 51, 457 (1955).

bond lengths were obtained from the bond orders using the equation

$$R_{\mu\nu}=S-\frac{S-D}{1+\kappa\left(\frac{1-P_{\mu\nu}}{P_{\mu\nu}}\right)}$$

where S is taken to be 1.54 Å, D=1.33 Å and κ=0.765.

None of the calculated values using our parameters differs from the experimental mean by more than two and a quater times the "estimated standard deviation," and may be regarded as correct.

III. Ionization Potentials and Electron Affinities.—The ionization potentials and electron affinities are important quantities for studying the molecular sturctures. We have examined whether our calculation can predict correctly the ionization potentials and electron affinities of naphthalene and anthracene. The calculated values have been standardized to the observed values of benzene, i.e., after adding $\Delta I=I^{\text{obs.}}_{\text{benz.}}-I^{\text{calc.}}_{\text{benz.}}$ or $\Delta A=A^{\text{obs.}}_{\text{benz.}}-A^{\text{calc.}}_{\text{benz.}}$ to the calculated ionization potentials or electron affinities, respectively; the theoretical values have been compared with experiment. As shown in Table V, the calculated values agree satisfactorily with observed values.

Discussion

As has been described so far, the electronic spectra, bond lengths, ionization potentials and electron affinities calculated with our parameters are in an excellent agreement with experimental values, and the main difference of our calculation from that of other authors' is in the choice of $\gamma_{\mu\nu}$ values. Our values are somewhat smaller than those used by Pariser and Parr and by Pople. The procedure employed by Pariser and Parr for evaluating $\gamma_{\mu\mu}$ is analogous to the Moffitt's method of "atoms in molecules"[10] which takes into account accurately the energy difference between the separated pairs of ions and neutral atoms. In other words, it may also be regarded as an appropriate consideration of the effect of electronic correlation for the one-center interaction integral $\gamma_{\mu\mu}$, by the use of the experimental values of atomic valence state ionization potential and electron affinity[11]. In Moffitt's method, $\gamma_{\mu\nu}$'s where $\mu\neq\nu$, are calculated theoretically using, for example, Slater type AO's. In the procedure used by Pariser and Parr, $\gamma_{\mu\nu}$'s for neighbors more distant than the nearest are calculated in terms of Slater type AO's or by uniform charge sphere approximation. $\gamma_{\mu\nu}$'s for nearest neighbors are evaluated by interpolation formula of the type: ar^2+br+c, where r is the interatomic distance and $c=\gamma_{\mu\mu}$. When atoms are combined to form a molecule, however, the effective charges for σ-electrons may be rather increased compared with the case of isolated atoms and the electron clouds associated with σ-bonds may somewhat contract.

In contrast to this, the effective changes for π-electrons may by decreased. Owing to this circumstance, one should use a little smaller values of $\gamma_{\mu\nu}$'s than those used by Pariser and Parr and by Pople, which may be a cause of the excellent agreement of our calculated results with experiment. In addition, our procedure for evaluating $\gamma_{\mu\nu}$'s is very simple and straightforward. One can easily obtain them if one can only know the values of valence state ionization potentials and electron affinities of the atoms involved. Another reason for the use of our $\gamma_{\mu\nu}$ values may be as follows, although it might be essentially the same as described above. When applied to some simple molecules such as hydrogen[12,13] and lithium molecules[14], the method of Moffitt gives

10) W. Moffitt, *Proc. Roy. Soc.*, **A210**, 245 (1951); *Report Progr. Phsics*, **17**, 173 (1954).
11) W. Kotos, *Acta Phys. Polon.*, **16**, 299 (1957).
12) C. W. Scherr, *J. Chem. Phys.*, **22**, 149 (1954).

14) A. Rahman, *Physica*, **20**, 623 (1954).

rather unsatisfactory results. For example, it leads to the conclusion that the ground state of the hydrogen molecule is almost completely ionic[13]. A similar conclusion is also reached in the case of the diamond[15]. In the latter case, however, if one calculate non-empirically the energies and wave functions employing Slater AO's, one can obtain the result that the ground state is homopolar even if the agreement between the calculated and the observed cohesive energy is very unsatisfactory.

Then, one may be able to improve the results in the following way. For example, if $\gamma_{\mu\mu}$ calculated with Slater AO's is κ times the $\gamma_{\mu\mu}$ evaluated by Moffitt's method, one divides by κ all $\gamma_{\mu\nu}$'s calculated with Slater AO's and one uses $\gamma_{\mu\nu}=(1/\kappa)\gamma_{\mu\nu}$ (Slater) in the calculation of molecular energy and wave function. Actually, in the case of the diamond, a satisfactory improvement has been brought about in this way[15]. Although the real theoretical ground for doing it in this way is not very clear, the physically unsatisfactory results at which Moffitt's method arrives originate from the inconsistent use of, for example, $\gamma_{\mu\mu}$ values which are obtained empirically on the one hand and $\gamma_{\mu\nu}$ $(\mu\neq\nu)$ values which are calculated with ordinary orbital functions on the other hand. Thus, even if the interatomic part of energy is very small compared with its intra-atomic part, the former still affects the calculated results to such an extent as described above.

When studing the π-electronic structures, such a circumstance may not be very serious as in the case of σ-electronic structures. Nevertheless, our calculation in the present paper seems to indicate that such a circumstance still exists in the case of π-electronic structures. Actually, the ratio $\gamma_{\mu\nu}$ (Slater)$/\gamma_{\mu\nu}$, where $\gamma_{\mu\nu}$ is the value we have used, is approximately constant and close to κ when μ-th and ν-th atoms are one or two bond distances apart from each other and approaches gradually to unity as they become more distant.

15) T. Yamaguchi, Private communication.

Summary

Electronic structures of naphthalene and anthracene have been studied by the self-consistent field MO method employing our semiempirical parameters. The calculated electronic spectra, bond lengths, ionization potentials and electron affinities are in a good agreement with expriment. Some discussions have been given in connection with the method of "atoms in molecules" and others.

We are grateful to Professor R. Fujishiro for his encouragement. One of the authors (N.M.) expresses with pleasure his cordial thanks to Mr. T. Yamaguchi of Osaka University for his helpful discussions.

The Aconite Alkaloids. XXVII. On Lucaconine*

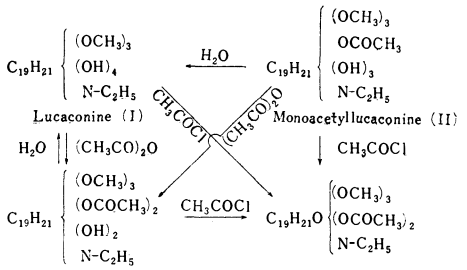
By Sijô FURUSAWA**

(Received September 4, 1958)

In the previous paper[1] the extended formulae of lucaconine (I), $C_{24}H_{39}O_7N$, and monoacetyllucaconine (II), $C_{26}H_{41}O_8N$, were given as follows:

$C_{19}H_{21}\begin{cases}(OCH_3)_3\\(OH)_4\\N\text{-}C_2H_5\end{cases}$ $C_{19}H_{21}\begin{cases}(OCH_3)_3\\OCOCH_3\\(OH)_3\\N\text{-}C_2H_5\end{cases}$

Lucaconine (I) Monoacetyllucaconine (II)

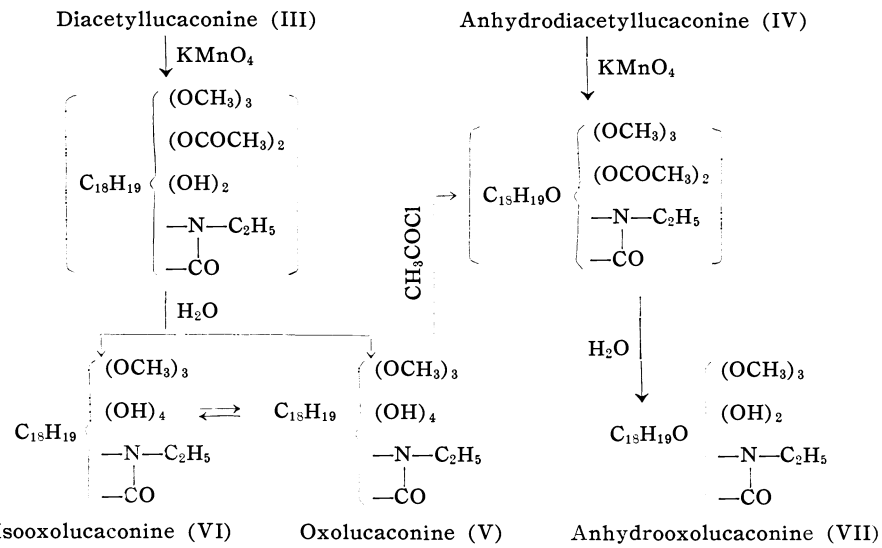


The present paper describes further experiments, undertaken with the object of characterizing the hydroxyl groups of lucaconine. Acetylation of lucaconine (I)

* This constitutes a part of a series entitled "The Aconite Alkaloids" by H. Suginome. Part XXVI, cf. foot note 1).

** Present address, Faculty of Technology, Chû-ô University, Tokyo, Japan.

1) H. Suginome and S. Furusawa, This Bulletin, **32**, 354.

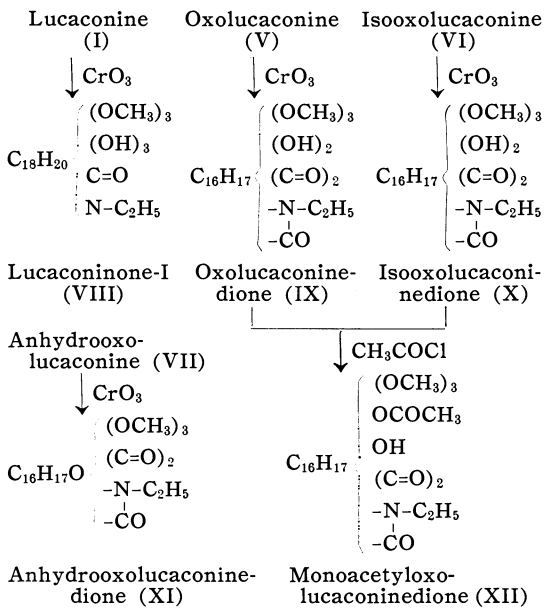


with acetic anhydride gave diacetyllucaconine(III), $C_{28}H_{43}O_9N$[1], while, on treatment with acetyl chloride, lucaconine (I) yielded anhydrodiacetyllucaconine(IV), $C_{28}H_{41}O_8N$, m. p. 156°, $[\alpha]_D^{27}+20.0°$. This anhydrodiacetyl-compound IV was obtained also from monoacetyllucaconine (II) and diacetyllucaconine (III) by the similar treatment. Anhydrodiacetyllucaconine (IV) decolorized bromine in acetic acid and absorbed one mole of hydrogen over platinum catalyst, showing the presence of a double bond. A small quantity of isodiacetyllucaconine, $C_{28}H_{43}O_9N$, m. p. 188° (decomp.), $[\alpha]_D$ 0°, was isolated as a by-product when lucaconine (I) was treated with a large quantity of acetyl chloride.

Oxidation of diacetyllucaconine (III) with potassium permanganate in acetone, followed by hydrolysis, gave two neutral products, oxolucaconine (V), $C_{24}H_{37}O_8N\cdot 1\,3/4\ H_2O$, m. p. 132°, $[\alpha]_D^{16.2}+24.2°$, as a main product and isooxolucaconine (VI), $C_{24}H_{37}O_8N$, m. p. 242°, $[\alpha]_D^{22.6}+44.8°$, as a by-product. The latter compound VI was also obtained by heating V at about 150° for 10 minutes under reduced pressure (1×10^{-5} mmHg) and VI was partly converted reversely into V on action of methanolic hydrogen chloride or alcoholic sodium hydroxide in a sealed tube. Treatment of oxolucaconine V with acetyl chloride, followed by hydrolysis, gave anhydrooxolucaconine (VII), m. p. 256°, $[\alpha]_D^{27}-25.0°$. This compound VII was also obtained directly from anhydrodiacetyllucaconine(IV)by oxidation with potassium permanganate, followed by hydrolysis.

Acetylation of isooxolucaconine(VI) and of anhydrooxolucaconine (VII) by acetic anhydride gave no crystalline product, but the determination of acetyl groups of these amorphous products showed the production of diacetyl-compounds by these reactions.

On treatment with chromic acid in glacial acetic acid lucaconine (I) was converted into lucaconinone-I (VIII), $C_{24}H_{37}O_7N$, m. p. 210°, $[\alpha]_D^{27}+15.0°$, which showed bands in the infrared spectrum at 2.99 and 5.72 μ, corresponding to hydroxyl and five-membered ring ketone group[2], and formed a monoxime melting at 223~224° (decomp.). Oxolucaconine(V)was converted by the same procedure into a diketo-compound, oxolucaconinedione(IX), $C_{24}H_{33}O_8N$, m. p. 209°, $[\alpha]_D^{26.7}+139°$, which showed bands in the infrared spectrum at 2.90, 5.72, 5.83 and 6.08 μ, characteristic of hydroxyl, five-membered ring ketone, six-membered ring ketone and lactam carbonyl group, respectively[2], and further furnished



2) H. Suginome, T. Amiya and T. Shima, unpublished work.

a monoxime melting at 246~248° (decomp.). In this case, a by-product, isooxolucaconinedione (X), $C_{24}H_{33}O_8N \cdot H_2O$, m. p. 136° (decomp.), $[\alpha]_D^{26}$ +33.7°, which formed the same monoxime (m. p. 246~248°) as described above, was obtained***. Isooxolucaconine (VI) gave only isooxolucaconinedione (X) by similar procedure. Anhydrooxolucaconine (VII) was similarly oxidized into a diketo-compound, anhydrooxolucaconinedione (XI), $C_{24}H_{31}O_7N$, m. p. 272°, $[\alpha]_D^{26.5}$ −84.2°, which showed bands in the infrared spectrum at 5.72 and 5.83 μ [2], and gave a monoxime melting at 268° under decomposition.

Upon treatment with acetyl chloride, both oxolucaconinedione (IX) and isooxolucaconinedione (X) gave the same monoacetyloxolucaconinedione (XII), $C_{26}H_{35}O_9N$, m. p. 269° (decomp.), $[\alpha]_D^{26.7}$ +113°. On hydrolysis with methanolic sodium hydroxide, this compound XII afforded nearly an equal amounts of IX and X.

Selenium was liberated on heating lucaconinone-I (VIII) and oxolucaconinedione (IX) with selenium dioxide in glacial acetic acid. On the contrary, lucaconine (I) and oxolucaconine (V) did not give selenium under similar conditions. That may probably be due to the presence of a methylene group adjacent to a keto group in VIII and IX.

On the basis of these facts, it may be reasonably concluded that, of four hydroxyl groups of lucaconine, two can be acetylated or oxidized to oxo groups, one being attached to a five-membered ring and the other to a six-membered ring, but the remaining two hydroxyl groups can be neither acetylated nor oxidized under usual conditions. Furthermore, it is to be noted that the latter two hydroxyl groups split off one mole of water on treatment with acetyl chloride. These observations will be discussed in a later paper.

In conclusion mention will be made of the action of nitric acid on lucaconine. Upon treatment with concentrated nitric acid, lucaconine (I) was converted into nitronitrosolucaconinic acid (XIII), $C_{16}H_{19}O_9N_3$, m. p. 214° (decomp.), $[\alpha]_D^{27}$ −117°. This compound contained two methoxyl groups but no *N*-ethyl group and was soluble in alkali with a pale yellowish green color.

Experimental

Anhydrodiacetyllucaconine (IV).—*a) From Lucaconine.*—A mixture of 2.0 g. of lucaconine and 10 cc. of acetyl chloride was allowed to stand in a sealed tube for ten days. After removal of the excess of acetyl chloride, the residue was treated with ice-water and made alkaline with aqueous ammonia to give a white precipitate. This material was recrystallized from ethanol to obtain anhydrodiacetyllucaconine in colorless plates, m. p. 156°, $[\alpha]_D^{27}$ +20.0° (94% ethanol). Yield 1.5 g.

Anal. Found: C, 64.63; H, 7.83; N, 2.90; OCH_3, 19.73; $COCH_3$, 18.14. Calcd. for $C_{28}H_{41}O_8N$: C, 64.72; H, 7.95; N, 2.70; OCH_3, 17.90; 2-$COCH_3$, 16.56%. 6.459 mg. of the substance absorbed 2.84 cc. of hydrogen (1.04 mol.).

When a mixture of 1.0 g. of lucaconine and 10 cc. of acetyl chloride was refluxed for 40 min., and treated in the usual manner, it yielded 0.4 g. of anhydrodiacetyllucaconine and a small quantity (ca. 0.01 g.) of a crystalline substance, isodiacetyllucaconine, m. p. 188° (decomp.), $[\alpha]_D$ 0°.

Anal. Found: C, 62.69; H, 8.37; N, 2.80; OCH_3, 16.84; $COCH_3$, 16.81. Calcd. for $C_{28}H_{43}O_9N$: C, 62.55; H, 8.05; N, 2.61; 3-OCH_3, 17.31; 2-$COCH_3$, 16.02%.

b) From Monoacetyllucaconine (II).—A mixture of 0.5 g. of monoacetyllucaconine and 4.5 cc. of acetyl chloride was refluxed for 40 min. The reaction mixture was treated in the usual manner to give 0.38 g. of anhydrodiacetyllucaconine.

c) From Diacetyllucaconine (III).—A mixture of 0.25 g. of diacetyllucaconine and 5 cc. of acetyl chloride was allowed to stand at room temperature for a week. After treatment as described above, 0.2 g. of anhydrodiacetyllucaconine was obtained.

Oxolucaconine (V).—To a solution of 3.2 g. of diacetyllucaconine in 100 cc. of acetone, 3.5 g. of powdered potassium permanganat was gradually added under stirring and chilling. Manganese

*** There is a possibility that isooxolucaconinedione (X) is a hydrate of oxolucaconinedione (IX), but it is preferable to call it an "iso-" compound because of difference in optical activities.

dioxide was filtered off and the filtrate was evaporated to dryness. The residue was treated with boiling ethanolic potassium hydroxide for 30 min. After cooling, the solution was made slightly acidic with hydrochloric acid and was evaporated up. The residue was then extracted with absolute ethanol and the ethanolic extract was evaporated to give ca. 1.8 g. of colorless crystals which were recrystallized from ethanol. Oxolucaconine was obtained in colorless crystals, m. p. 132°, $[\alpha]_D^{16.2}$+24.2° (94% ethanol). This material was insoluble in water, diluted hydrochloric acid and diluted aqueous ammonia, and it seemed to be neutral.

Anal. Found: C, 57.54; H, 7.96; N, 2.72; H_2O, 6.06; (N)-C_2H_5, 4.32. Calcd. for $C_{24}H_{37}O_8N$. 1¾ H_2O: C, 57.75; H, 8.18; N, 2.81; H_2O, 6.32; (N)-C_2H_5, 5.82%.

From the mother liquor of the above recrystallization, a small quantity of a crystalline substance, m. p. 242°, identical with isooxolucaconine mentioned next, was obtained.

Isooxolucaconine (VI). — When 0.2 g. of oxolucaconine was heated at 150° for 5 min. under reduced pressure (1×10^{-5} mmHg), it decomposed under foaming, became glassy and crystallized on cooling. On recrystallization from ethanol, isooxolucaconine was obtained in colorless needles, melting at 242°, $[\alpha]_D^{22.6}$+44.8° (94% ethanol).

Anal. Found: C, 61.17; H, 8.16; OCH_3, 20.73. Calcd. for $C_{24}H_{37}O_8N$: C, 61.65; H, 7.98; 3-OCH_3, 19.93%.

Upon heating with methyl iodide in a sealed tube, isooxolucaconine could not be methylated but yielded oxolucaconine. The same substance was also produced when isooxolucaconine was heated in a sealed tube with ethanolic potassium hydroxide or with methanolic hydrogen chloride.

Acetylation of Isooxolucaconine (VI).—A solution of isooxolucaconine in a mixture of pyridine and acetic anhydride (1:1) was allowed to stand at room temperature overnight. After removal of the solvents, an amorphous product was treated with aqueous ammonia and extracted with ether. An amorphous residue, obtained on evaporating the ethereal extracts, was purified by repeated precipitation from dilute ethanol.

Anal. Found: $COCH_3$, 16.85. Calcd. for $C_{24}H_{35}O_8N(COCH_3)_2$: 2-$COCH_3$, 15.60%.

Anhydrooxolucaconine (VII). — *a) From Anhydrodiacetyllucaconine (IV).*—To a solution of 0.6 g. of anhydrodiacetyllucaconine in 20 cc. of acetone, 0.4 g. of powdered potassium permanganate was added. After being kept for 24 hr. manganese dioxide was filtered off and the filtrate was evaporated to give 0.5 g. of an amorphous residue. This product was treated with ethanolic potassium hydroxide and then crystallized from ethanol. On repeated recrystallization from ethanol, anhydrooxolucaconine, m. p. 256°, $[\alpha]_D^{27}$−25.0° (94% ethanol) was obtained. It was soluble in methanol and slightly so in acetone, ether and water.

Anal. Found: C, 64.32; H, 7.91; N, 3.27; OCH_3, 20.69; (N)-C_2H_5, 4.72. Calcd. for $C_{24}H_{35}O_7N$: C, 64.17; H, 7.85; N, 3.12; 3-OCH_3, 20.72; (N)-C_2H_5, 6.46%.

b) From Oxolucaconine (V).—A mixture of 2.0 g. of oxolucaconine and 20 cc. of acetyl chloride was refluxed for 30 min. After removal of the excess of acetyl chloride, the residue was treated with alkali to give 1.0 g. of a crystalline substance. On recrystallization from ethanol, anhydrooxolucaconine, m. p. 257°, was obtained.

Acetylation of Anhydrooxolucaconine (VII).—A mixture of 0.05 g. of anhydrooxolucaconine, 0.5 cc. of pyridine and 0.2 cc. of acetyl chloride was allowed to stand at room temperature overnight. After removal of the solvent, the residue was treated with aqueous ammonia to give a white precipitate. This precipitate was dissolved in ethanol and was reprecipitated by addition of water. After repetition of this treatment, the precipitate was dried and analyzed.

Anal. Found: $COCH_3$, 17.64. Calcd. for $C_{24}H_{33}O_7N(COCH_3)_2$: 2-$COCH_3$, 16.15%.

Lucaconinone-I (VIII).—To a solution of 2.0 g. of lucaconine in 25 cc. of glacial acetic acid, a solution of 0.7 g. (2 mol.) of chromic trioxide in 15 cc. of acetic acid was dropped in under stirring and coolling. After standing overnight and after the removal of the solvent, a glassy substance was obtained. This material was dissolved in water; the solution was made alkaline and was extracted with chloroform. On evaporation of the chloroform solution, 0.64 g. of a crystalline residue was yielded, which was recrystallized from 99% ethanol to give crystals melting at 200~201°. Yield 0.4 g. This substance was converted into perchlorate, melting at 236° after being recrystallized from ethanol. It was transformed into the free base by the usual method. The base, lucaconinone-I, thus obtained melted at 210°, $[\alpha]_D^{27}$+15.0° (94% ethanol).

Anal. Found: C, 63.82; H, 8.31; N, 3.18. Calcd. for $C_{24}H_{37}O_7N$: C, 63.83; H, 8.26; N, 3.11%.

Perchlorate. — m. p. 236° (decomp.) (from ethanol).

Anal. Found: Cl, 6.92. Calcd. for $C_{24}H_{37}O_7N\cdot HClO_4$: Cl, 6.79%.

Oxime. — m. p. 223~224° (decomp.) (from ethanol).

Anal. Found: N, 6.12. Calcd. for $C_{24}H_{38}O_7N_2$: N, 6.01%.

Oxolucaconinedione (IX).—To a solution of 0.8 g. of oxolucaconine in 10 cc. of glacial acetic acid, a solution of 0.28 g. (2.2 mol.) of chromic anhydride in 10 cc. of the same solvent was added slowly under stirring and cooling. After the mixture was set aside overnight, it was treated in the usual manner to give 0.3 g. of a crystalline product which was recrystallized from ethanol. Oxolucaconinedione was obtained as colorless needles melting at 209°, $[\alpha]_D^{26.7}$+139° (94% ethanol).

Anal. Found: C, 62.10; H, 7.40; N, 3.11. Calcd. for $C_{24}H_{33}O_8N$: C, 62.13; H, 7.18; N, 3.02%.

Oxime. — m. p. 246~248° (decomp.) (from ethanol).

Anal. Found: N, 5.91. Calcd. for $C_{24}H_{34}O_8N_2$: N, 5.86%.

The mother liquor from which the above mentioned crystals were separated was extracted with chloroform and the chloroform extracts were evaporated to dryness. The residue was crystallized from ethanol to give 0.1 g. of a colorless crystalline substance, m. p. 136~137° (decomp.), which was identified with isooxolucaconinedione mentioned below.

Isooxolucaconinedione (X).—Isooxolucaconine was oxidized with chromic anhydride in glacial acetic acid by the method described above to give isooxolucaconinedione, colorless crystals melting at 136~137° (decomp.), $[\alpha]_D^{26}+33.7°$ (94% ethanol).

Anal. Found: C, 59.77; H, 7.43; N, 3.17; H_2O, 3.62. Calcd. for $C_{24}H_{33}O_8N\cdot H_2O$: C, 59.82; H, 7.34; N, 2.91; H_2O, 3.75%.

The oxime prepared from isooxolucaconinedione melted at 246~248° (decomp.) and showed no depression of the melting point on admixture with the above-mentioned oxolucaconinedione oxime.

When isooxolucaconinedione was heated in an oil bath at 160~170° for 10 min. under reduced pressure (1×10^{-5} mmHg), it melted under foaming and crystallized on cooling. Recrystallization from ethanol gave a crystalline substance, m. p. 136° (decomp.), which showed no depression of the melting point on admixture with the starting material.

Anhydrooxolucaconinedione (XI).—With 0.08 g. of chromic anhydride in acetic acid, 0.25 g. of anhydrooxolucaconine was oxidized as described above to give 0.2 g. of anhydrooxolucaconinedione, which was recrystallized from ethanol, m. p. 272°, $[\alpha]_D^{26.5}-84.2°$. It was sluble in methanol, ethanol and acetone and sparingly soluble in ether and benzene.

Anal. Found: C, 64.30; H, 7.50; N, 3.27. Calcd. for $C_{24}H_{31}O_7N$: C, 64.70; H, 7.01; N, 3.14%.

Oxime.—m. p. 268° (decomp.).

Anal. Found: N, 6.52. Calcd. for $C_{24}H_{32}O_7N_2$: N, 6.08%.

Monoacetyloxolucaconinedione (XII).—A mixture of 0.26 g. of oxolucaconinedione and 3 cc. of acetyl chloride was heated under reflux for 30 min. After removal of the solvent, the residue was treated with aqueous ammonia to give white precipitate which was crystallized from ethanol. Monoacetyloxolucaconinedione melted at 269° (decomp.), $[\alpha]_D^{26.7}+113°$ (ethanol). It was soluble in methanol and ethanol and sparingly soluble in acetone, benzene and water.

Anal. Found: C, 62.62; H, 7.56; $COCH_3$, 8.79. Calcd. for $C_{24}H_{32}O_8N(COCH_3)$: C, 61.80; H, 6.98; $COCH_3$, 8.51%.

This substance was also obtained from isooxolucaconinedione by the same procedure as described above.

Hydrolysis of Monoacetyloxolucaconinedione (XII).—A solution of 0.1 g. of monoacetyloxolucaconinedione in 2 cc. of N-methanolic sodium hydroxide was heated for 20 min. After removal of the solvent, the residue was treated with water and the precipitate was fractionally recrystallized from ethanol. Isooxolucaconinedione melting at 132° (decomp.) and oxolucaconinedione melting at 207° were yielded in nearly equal amounts.

Nitronitrosolucaconinic Acid (XIII).—A mixture of 3.0 g. of lucaconine and 20 cc. of nitric acid (*d*: 1.43) was heated on a water bath at 80° for 1 hr. with stirring. After cooling, 30 cc. of water was added and yellow precipitate was collected, which was repeatedly precipitated from diluted ethanol and finally crystallized from diluted acetone. Nitronitrosolucaconinic acid was obtained in pale yellow plates, melting at 214°, $[\alpha]_D^{27}-117°$. It was easily soluble in acetone and sparingly so in water, methanol, ethanol, ether and chloroform.

Anal. Found: C, 48.60; H, 4.81; N, 10.83; OCH_3, 15.32; COO-, 24.64; (N)-C_2H_5, neg. Calcd. for $C_{12}H_{13}O_3N_3(OCH_3)-(COO)_2$: C, 48.47; H, 4.78; N, 10.57; 2-OCH_3, 15.62; 2-COO-, 22.66%.

The author wishes to express his sincere thanks to Professor Harusada Suginome, President of Hokkaido University, for his kind guidance throughout this work.

The Study of Adsorption of Detergents at a Solution-Air Interface by Radiotracer Method. II. The Kinetics of Adsorption of Sodium Alkyl Sulfates

By Ryohei MATUURA, Hideo KIMIZUKA, Shigeru MIYAMOTO, Ryosuke SHIMOZAWA and Katsumasa YATSUNAMI

(Received September 24, 1958)

It is usual in the case of the solution of detergents that a considerable time is required to attain true equilibrium of adsorption at the solution-air interface. The process has been studied chiefly from the measurement of the change in surface tension with time. The suggestion that the diffusion of solute to the surface is a cause of the alteration of surface tension with time was first made by Milner[1], and equations to describe the phenomena in terms of diffusion have been deduced by Bond and Puls[2], Ross[3], Ward and Tordai[4], Bartholomé and Schäfer[5], Lange[6] and Fordham[7]. However, it has been proved that there are many cases in which the process can not be explained in terms of simple diffusion alone, and the factors governing the adsorption rate other than diffusion have been proposed. For example, the concept of energy barrier has been introduced by Doss[8], Blair[9] and Addison[10].

In the preceding paper[11] the Gibbs adsorption equation has been checked in the case of sodium dodecyl sulfate, tetradecyl sulfate and hexadecyl sulfate at the solution-air interface. It is perfectly clear that the Gibbs equation refers only to the adsorption equilibrium. It has nothing to do with the process of reaching the equilibrium, and so to calculate the surface excess at the stage of non-equilibrium from surface tension by using the Gibbs equation is incorrect. In order to study the kinetics of adsorption, therefore, it is preferable to measure the change in the adsorbed amount with time directly. By using radioisotopes this can easily be done. The method is simple and accurate, and is most suitable since the adsorption can be measured at a liquid surface without any mechanical disturbances. It is the purpose of the present experiment to measure the rate of adsorption of sodium alkyl sulfates at the solution-air interface by radiotracer method and to make discussions as to the theories of the adsorption rate presented by earlier authors.

Experimental

Surface active substances used in the present experiment were the same as those in the preceding paper[11], i.e., sodium dodecyl sulfate (SDS), sodium tetradecyl sulfate (STS), and sodium hexadecyl sulfate (SHS). Labelling these compounds with S-35 was described earlier[11].

The counting apparatus was also the same as that used in the preceding paper[11]. After the formation of a fresh plane surface of a detergent

solution, the measuring arrangement was quickly set in and the count from the solution was measured with time. An example is shown in Fig. 1 (curve A). The curve B in the same figure shows a change in the counting with time of a sulfuric acid solution with the same concentration and specific activity as the detergent solution. The two series of measurements should be done under exactly the same conditions. t_0 in Fig. 1 is the starting time of counting. The tangent of the curve at any time t is clearly the intensity of radiation from the bulk of the solution, I_i, plus that from the adsorbed layer at that time, $I_{s(t)}$. The intensity of radiation from sulfuric acid solution does not show any change with time and it can be regarded as equal to I_i since no surface adsorption will take place with sulfuric acid solution of so low a concentration as in the present experiment. Then,

$$I_{s(t)} = (I_i + I_{s(t)}) - I_i \quad (1)$$

i.e., the counting rate at time t of the surface layer can be obtained from the difference between the counting rate of the detergent solution at that time and that of sulfuric acid solution. The surface excess at time t, Γ_t, is calculated from $I_{s(t)}$ by using the following relation;

$$\Gamma_t = I_{s(t)}/SA \quad (2)$$

where S is the specific activity of the radioactive substance and A is the surface area of the solution. S can be determined as in the preceding paper[11].

Results

The change in adsorption with time of SDS, STS and SHS at the solution-air interface is plotted in Figs. 2, 3 and 4, respectively. The abscissa is represented as the square root of time for the convenience of discussions.

Discussions

It is seen from Figs. 2, 3 and 4 that at the initial stage of adsorption the surface excess of the detergents is proportional to the square root of time, i.e., the adsorption at constant temperature can be expressed by the relation,

$$\Gamma_t = Kt^{1/2} \quad (3)$$

were, t is the time of aging and K is a constant independent of time but dependent on the concentration of the detergent solution. When K is plotted against concentration, C, approximately linear relation can be found as shown in Fig. 5, i.e.,

$$K = K_0C \quad (4)$$

where K_0 is a constant characteristic of each detergent. From Eqs. 3 and 4 the

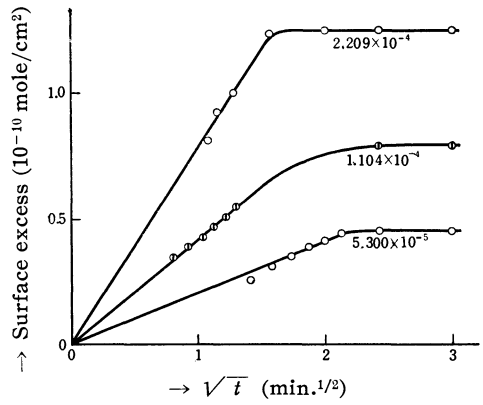

Fig. 2. Surface excess vs. time curves of SDS, at 28±1°C. Numericals of each curve represent the concentration of the detergent solution in mole/l.

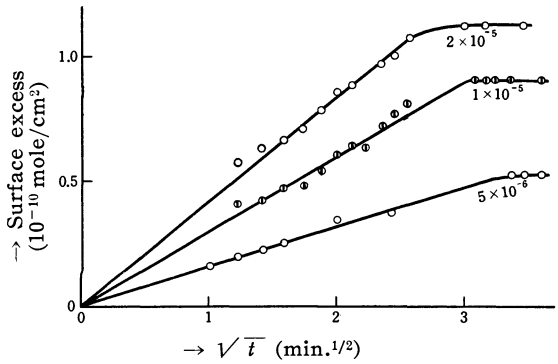

Fig. 3. Surface excess vs. time curves of STS, at 28±1°C. Numericals of each curve represent the concentration of the detergent solution in mole/l.

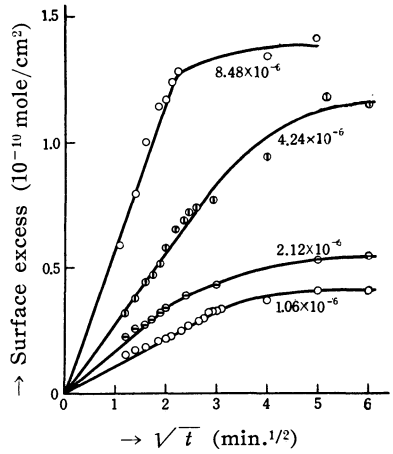

Fig. 4. Surface excess vs. time curves of SHS, at 28±1°C. Numericals of each curve represent the concentration of the detergent solution in mole/l.

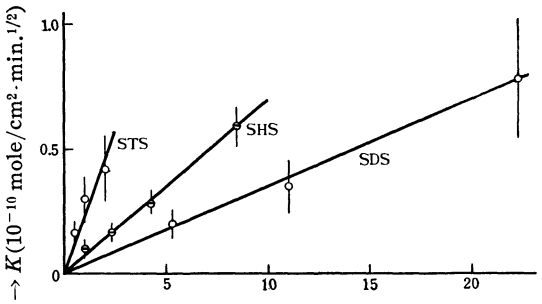

Fig. 5. K vs. concentration of detergents at 28±1°C.

following relation is obtained;

$$\Gamma_t = K_0 C t^{1/2} \tag{5}$$

Now the simple diffusion theory[4] tells us that the surface excess at time t, Γ_t, is given by the relation,

$$\Gamma_t = 2C(Dt/\pi)^{1/2} \tag{6}$$

where D is the diffusion coefficient of the solute molecules. At first sight it is seen that Eq. 6 is similar in form to Eq. 5, and this similarity of the two equations may seem to lead to the conclusion that the rate of adsorption is determined solely by the diffusion of solute molecules from the bulk phase to the surface layer. But further insight makes it clear that discrepancy is involved in the simple diffusion theory. If the simple diffusion theory could be applied to the present case, K_0 in Eq. 5 should be equal to $2(D/\pi)^{1/2}$ in Eq. 6. Then we should be able to calculate the diffusion coefficient from the experimental values of K_0. The calculated values of diffusion coefficient of three alkyl sulfates used are shown in Table I as D_{calc}. In order to check the diffusion theory it is necessary to compare these values of D_{calc} with the observed values of diffusion coefficient. We could not find in any literature the experimental values of diffusion coefficient of sodium alkyl sulfates in aqueous solutions, but we can estimate the values from conductivity data of Lottermoser and Püschel[12] by using the Nernst's equation,

$$D = \Lambda_0 RT/|Z|F^2 \tag{7}$$

where Λ_0 is the conductivity at infinite dilution of surface active ion with the valency Z and F, R and T are Faraday constant, gas constant and absolute temperature, respectively. The estimated values of diffusion coefficient for three alkyl sulfate ions used are shown in Table I as D_{est}. These values are, of course, diffusion coefficients at infinite dilution, but the concentrations so small as in the present experiment would not alter the values appreciably.

TABLE I
COMPARISON OF DIFFUSION COEFFICIENTS

Detergents	SDS	STS	SHS
Temp. (°C)	28±1	28±1	28±1
D_{calc}(cm^2/sec.)	1.60×10^{-9}	7.69×10^{-6}	6.32×10^{-7}
D_{est}(cm^2/sec.)	6.80×10^{-6}	4.54×10^{-6}	4.01×10^{-6}

As seen from Table I the calculated values of the diffusion coefficient are in general much smaller than the estimated ones. Moreover, the most embarrassing point is that the diffusion coefficient calculated by the simple diffusion theory decreases considerably with decrease in the chain length of the detergent molecule. This is quite unreasonable. Therefore, we can conclude that the simple diffusion theory can not explain the rate of adsorption of sodium alkyl sulfates at the solution-air interface under the conditions of the present experiment.

Salley et al.[13] measured the rate of adsorption of Aerosol OTN at the solution-air interface by radiotracer method and obtained the rate equation,

$$\Gamma_t = kt^n \tag{8}$$

where k and n are constants. They found that n is nearly 1/2. They calculated the diffusion coefficient of sulfosuccinate ion from the experimental values of k by making use of the simple diffusion equation. The calculated diffusion coefficient was $0.7\sim2.2\times10^{-4}$ cm^2/min., which was, according to them, comparable to the observed value, $3\sim4\times10^{-4}$ cm^2/min. However, we suppose that the agreement is not so good as to confirm the validity of the simple diffusion theory, and various surface active compounds, especially with varying chain length, should be examined in order to check the diffusion theory.

In the case of the adsorption of surface active electrolytes, such as those used in the present experiment, it is reasonable to take the energy barrier idea into consideration. Let λ be the energy barrier to the adsorption, then the rate equation[9] may be given by

$$\Gamma_t = 2C(Dt/\pi)^{1/2} \exp(-\lambda/RT) \tag{9}$$

12) A. Lottermoser and F. Püschel, *Kolloid-Z.*, **63**, 175 (1933).

13) D. J. Salley, A. J. Weith, Jr., A. A. Argyle and J. K. Dixon, *Proc. Roy. Soc.*, **A203**, 42 (1950).

in which the simple diffusion equation is combined with the idea of energy barrier. Tentatively we applied Eq. 9 to the present case and calculated the energy barrier to the adsorption of three alkyl sulfates used in the present experiment. That is, from Eqs. 5 and 9

$$K_0 = 2(D/\pi)^{1/2} \exp(-\lambda/RT) \qquad (10)$$

Using the value of D, estimated from the conductivity data of Lottermoser and Püschel, and K_0, obtained in the present experiment, the values of energy barrier were calculated*. They are shown in Table II.

TABLE II

ENERGY BARRIER, λ, TO THE ADSORPTION

Detergents	SDS	STS	SHS
Temp. (°C)	28±1	28±1	28±1
Energy barrier, λ, (kcal./mole)	2.5	1.2	0.6

We could not compare the calculated energy barrier with the observed one, and therefore the validity of the energy barrier theory has not been established. This point will be discussed by further study of the adsorption rate, especially in the presence of inorganic electrolytes.

* Strictly speaking, we should calculate λ from the slope of $\ln K_0/2(D/\pi)^{1/2}$ vs. $1/T$ plot.

Summary

The rate of adsorption of sodium dodecyl sulfate, sodium tetradecyl sulfate and sodium hexadecyl sulfate at the solution-air interface has been measured by radiotracer method. It has been found that the surface excess of a detergent is proportional to the concentration of the solution and the square root of time of aging at the initial stage of adsorption. The simple diffusion theory has been checked and it has been found that the results of the present experiment can not be explained by the simple diffusion theory. The idea of energy barrier has tentatively been applied and the values of energy barrier have been calculated.

The authors wish to express their thanks to Professor Tunetaka Sasaki of Tokyo Metropolitan University for his kind advice and encouragement throughout this study. The expenses of this research were defrayed from the Scientific Research Grant of the Ministry of Education, to which the authors' thanks are also due.

The Different Distribution of Rubidium and Cesium in Natural Plants

By Noboru YAMAGATA, Toshiko YAMAGATA and Shunji MATSUDA

(Received October 9, 1958)

The uptake of rubidium and cesium by plants in relation to potassium absorption was studied by several investigators. Collander[1] found that the differences between the plant species, the eleven phanerogams studied, were only moderate for potassium, rubidium and cesium contents; all plants absorbed rubidium and cesium with almost the same rapidity as for potassium. The data of Collander and the experiments of other investigators[2-4] suggested the possible use of radioactive rubidium-86 as a tracer for potassium in plant growth experiments, since an isotope of potassium having a suitable half-life was not readily available. On the other hand, cesium-137 is one of the principal long-lived products of nuclear fission and its absorption by cultured plants is a matter of keen interest.

If cesium is hardly differentiated in uptake by plants as in the case of rubidium, and its translocation up to the aerial part is similar to that of rubidium, the distribution of these elements in the leaves of natural plants must be of the same nature. The present paper points

out the different distribution of rubidium and cesium in natural plants and deals with the discussion of the different nature of these elements in the biological cycle from soil to plant.

Distribution of Rubidium and Cesium in Natural Plants.—The distribution studies on the rare alkali elements in soil, plants, and waters have been carried out and reported by one of the authors[5]. Sixty-one samples of natural plants consisting of fifty different species were collected from various districts in Japan and analyzed for leaves by a spectrographic method by use of cathode-layer arc excitation. The plant species consist of two mosses, seven ferns, five gymnosperms, and eleven monocotyledons, the rest being dicotyledons. The analytical data are summarized in Table I. Rubidium varied from 0.6 to 50 p.p.m. and cesium from 0.002 to 1 p.p.m. on the dried material.

The determination of rubidium and cesium in plants has been reported by G. Bertrand and D. Bertrand[6]. The values for land plants examined by them ranged from 2.1 to 81 (average, 20.3) p.p.m. of rubidium and from 3 to 88.5 (average, 22) p.p.m. of cesium for phanerogams on the dried material. The values for rubidium are in good agreement with those given by the authors; however, the values for cesium given by Bertrand et al. are an order similar to the values for rubidium, showing surprisingly high values. Recently, Smales and Salmon analysed seaweed and the ratios of $0.55\sim1.4\times10^{-2}$ (average, 1.0×10^{-2}) were given for the ratio Cs/Rb[7]. Rubidium is more abundant than cesium by factors of approximately 100 in rocks, soils, seaweeds, and other natural materials; the land plants could not be the only exception. The result of the authors' determination indicates the variation of the Cs/Rb ratio from 2×10^{-4} to 2×10^{-1} and the average 3×10^{-2}.

Relationships between the potassium content and the rubidium or the cesium content of natural plants were examined;

$Rb=5.3\times K^{0.94}$, $r=0.72$

the Rb/K ratio varied from 1.2×10^{-4} to 3.2×10^{-3} and the average was 7.3×10^{-4} for sixty-one samples. The variation of Cs/K ratio was greater than that of Rb/K and covered from 2×10^{-6} to 1×10^{-3}. Fig. 1 is a plot in logarithmic scale of the potassium content in percent versus the rubidium content in p.p.m. The existence of a linear relationship between rubidium and potassium contents can easily be seen; the coefficient of correlation (r) is 0.72. Fig. 2 is a plot in logarithmic scale of the potassium versus the cesium content. In this case, the existence of a linear relationship is doubtful ($r=0.18$). The coefficient of correlation between rubidium and cesium contents was also calculated and the value of 0.0073 appears to indicate no relation between the contents of these elements in the examined plants.

The variation of the Cs/K ratio greater than the Rb/K ratio and the doubtful existence of correlation between cesium and potassium contents may be accounted for by one or several reasons as under described.

(1) The variation of total cesium content of the soils on which the plants were growing is greater than that of rubidium.

(2) The uptake of cesium into the aerial portions of the plants is irregular as compared with that of rubidium; for example, the uptake tends to increase at the higher concentrations of cesium in soil solution.

(3) The ion-exchange or adsorption mechanism between soil and solution that makes the release of cesium and rubidium for soil colloids and minerals is different.

Distribution of Rubidium and Cesium in Soil.—Soils usually contain 20~500[8] or 5~100 (average, 60[9] or 100[10]) p.p.m. of total rubidium and only less than 1 to 25.7 (max.) p.p.m.[8] of total cesium in contrast with 1.36% of total potassium on the average[9]. Although the data for cesium are too incomplete to guess the average content, Vinogradov gave a value of approximately 5 p.p.m.[9,10]. The average ratio of Rb/K is $4\sim7\times10^{-3}$ and the average Cs/K is approximately 4×10^{-4}. Those data appear to be reasonable in accordance with Horstman's recent work[11]. He gave 240~460 for the average ratios K/Rb of various rocks ($Rb/K=2.2\sim4.2\times10^{-3}$) and 6700 for K/Cs of granitic rocks ($Cs/K=1.5\times10^{-4}$). On the weathering of rocks, absolute loss of the three elements occurs with the fastest leaching and the least adsorption of potassium, as the result, the ratios of Rb/K and Cs/K increase. However, the above-mentioned data indicate that soils differ not so much from fresh rocks in the averaged ratios of Rb/K and Cs/K.

No biological activities can ever extend to the complete decomposition of soil forming silicate minerals, although the total elements existing in soil are reserved

for living matter to be utilized in far future. In this respect, we often consider the amount of elements extractable with mineral acid as a measure for the availability by plants in the near future.

Fifteen representative Japanese soils were extracted with hot hydrochloric acid (31%) and analyzed; the result[12] has been recalculated and summarized in Table II. The variation of rubidium and cesium covered from 0.3 to 80 and from 0.01 to 3 p.p.m. respectively when potassium varied from 0.01 to 0.13%. The Rb/K ratio varied from 1.5×10^{-3} to 7×10^{-2} and the Cs/K ratio varied from 4×10^{-5} to 1×10^{-3}. These values indicate that the variations of levels of rubidium and cesium in soil are of the same order and it appears to us that the first reason (1) for the different distribution of these elements in natural plants fails to elucidate the fact.

Culture Experiment.—Many investigators carried out the culture experiments with solutions of various concentrations of rubidium and cesium; an example is shown in Table III. When the uptake by natural or cultivated plants growing in soil comes into question, we must consider the natural levels of rubidium and cesium concentrations in soil. Indeed, the culture experiment with higher concentrations may serve for certain physiological purposes, however, for the present purpose, it will be desirable to make the levels of these elements in culture solution as close as possible to those in natural soil conditions.

TABLE III
RUBIDIUM, CESIUM AND POTASSIUM LEVELS IN CULTURE SOLUTION USED BY SEVERAL INVESTIGATORS

	Rb meq./l.	Cs meq./l.	K meq./l.
Collander[1]	0.1 2	0.1	2
Menzel and Heald[13]	0.054 0.0054	0.054 0.0054	0.54
Murphy et al.[14]	Rb/K (weight) 1/1, 1/2, 1/5, 1/10		

It is not the total or acid soluble but only a fraction of the elements that the root of a plant can readily absorb. It is well known that rubidium and cesium are more firmly held by the clay fraction of soil than potassium, probably on account of their greater ionic polarizability. We can therefore assume that the Rb/K and the Cs/K ratios in the neutral ammonium acetate extract of soil or in the actual soil solution are probably smaller respectively than the ratios of the total or strong acid soluble elements in soil.

As the concentrations of available or active rubidium and cesium in soil had not been estimated when the present cultue experiment was undertaken, the standard ratios of Rb/K and Cs/K were temporarily fixed to approximately 10^{-2} and 2×10^{-4} respectively except where varied as an experimental condition.

Experimental

The experiment was conducted in a greenhouse and cucumber, rice-plant, and soy-bean were chosen for the experiment plants. The seedlings were grown in nutrient solutions in 3 liter porcelain pots from 3rd July to 11th July when tracer isotopes were added. After that, a long period experiment was carried on for thirty days with occasional renewal of nutrient solution and radio isotopes.

The culture solution was prepared with extra pure chemicals and distilled water; the elementary composition was as follows[15]: (p.p.m. in solution)

NO_3-N: 130, NH_4-N: 23, K: 200, Ca: 200, Na: 20, Mg: 40, Si: 20, P: 50, Cl: 20, S: 50, Fe: 2, Mn: 0.4, B: 0.4, Zn: 0.4, Cu: 0.04, Mo: 0.002.

Two isotopes ^{137}Cs and ^{86}Rb were added together in a concentration of about 10 μc/l. each of nutrient solution. Another experiment to determine the uptake velocity of these elements by plants in a short period was conducted with higher concentrations of isotopes.

The harvested plant leaves were incinerated and counted for the total activity of ^{137}Cs and ^{86}Rb. After thirty-nine days the sample was recounted for the activity. As the difference was to be ascribed to the decay of a short-lived isotope ^{86}Rb (half-life: 19.5 days), each of the activities of these isotopes could be calculated. After the activity determination, the plant ash was analyzed for potassium by a chemical method. The ratio of counts from ^{137}Cs (or ^{86}Rb) and concentration of potassium in the plant were compared with the same ratio in the culture solution. The distribution factors between plant and solution were calculated by dividing the two ratios: (^{86}Rb/K in plant)/(^{86}Rb/K in solution) for rubidium, and (^{137}Cs/K in plant)/(^{137}Cs/K in solution) for cesium.

Results

A short period experiment was performed to examine whether there were any differences between rubidium and cesium of the transport velocity into the aerial part. The result of the experiment is shown for rice-plant (Fig. 3). The transport velocity is represented by plotting the increase of distribution factors against time, consequently, it does represent an increase of rubidium or cesium in the plant not absolutely but relatively to potassium. Rapid absorption is observed in several early hours and steeper slope for rubidium appears to indicate faster transport in the plant or rubidium than of cesium at the early stage of absorption, although the difference between these elements will have no connection with the absorption during the prolonged period.

A long period experiment was conducted with the three crop plants over a range of concentrations of rubidium and cesium from 0.02 to 20 and about 0.0001 to 4 p.p.m. respectively. The results are shown in Table IV. The effect of concentration was not clear except for rubidium in the case of soy-bean. The relatively small variation of distribution factors with concentration in nutrient solution indicates that the effect of concentration on rubidium and cesium uptake relative to potassium is small, by a factor of two or three at most. The results also indicate that a difference exists between plant species. It can be seen that the distribution factor for cesium is greater in leaves than roots only in the case of soy-bean. The rice-plant accumulates less cesium relative to potassium than the other plants. These results are in good agreement with Rediske and Selders' experiement with several other crop plants[16].

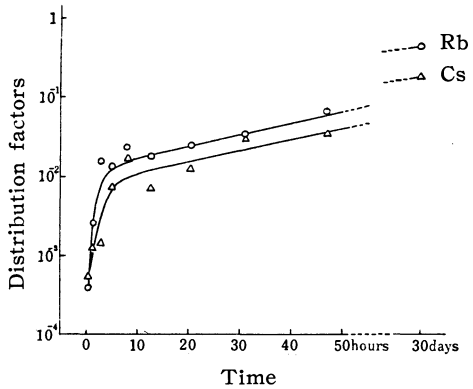

Fig. 3. Uptake velocity of cesium and rubidium by rice-plant as represented by distribution factor between solution and plant leaf.

Distribution of Rubidium and Cesium in Tobacco Leaf.—The analytical data for the distribution of the alkali elements in cultivated tobacco leaves were previously presented by one of the authors[17]. The recorded value for rubidium varied from 5 to 90 p.p.m. on the dried material and the average was 30 p.p.m. The Rb/K ratio varied from 5×10^{-4} to 3×10^{-3} and the average was 1×10^{-3}; these values are in good agreement with those of the natural plants.

On the other hand, the concentration of cesium in tobacco leaves was very low and for this reason it was only successfully determined quantitatively for one sample among seventeen (No. 10a in the original paper). This sample contained 0.17 p.p.m. cesium in ash or 0.02 p.p.m. in the dried material, and the Cs/K ratio for the whole leaf was 1.2×10^{-6}. The Cs/K ratios for the rest of the sample are considered to be less than this value. It can thus be concluded that the Cs/K ratios for cultivated tobacco leaves are surprisingly low as compared with those for the natural plants ($2\times10^{-6}\sim1\times10^{-3}$).

According to the experiment conducted by Menzel[18], the uptake of rubidium and cesium by plants was inversely proportional to the available potassium in the soil, and the uptake of cesium was more affected than that of rubidium by the increase in available potassium. Thus, the remarkable discrimination in the cultivated tobacco plant of cesium from potassium will be accounted for by the possible existence of a greater quantity of available potassium in the soil as compared with the case of natural plants.

Another interesting phenomenon should be pointed out, that of the different distribution with in the tobacco leaf of cesium from rubidium and potassium. The tobacco leaf was divided into two portions, the principal vein and the remaining part, and separately analyzed. Qualitative examination indicated in every sample of tobacco leaves the considerable enrichment of potassium and rubidium in the vein and the inverse trend for cesium. Quantitative determinaion was made with the tobacco leaf No. 10a and the result is

TABLE V

THE DIFFERENT DISTRIBUTION IN TOBACCO LEAF OF CESIUM FROM RUBIDIUM AND POTASSIUM

(Sample No. 10a, recalculated from the previous report[17])

	K %	Rb p.p.m.	Cs p.p.m.	Rb/K	Cs/K
Whole leaf	1.77	40	0.02	2×10^{-3}	1.2×10^{-6}
Principal vein	3.70	90	0.006	2.5×10^{-3}	1.5×10^{-7}
The remaining part	1.35	20	0.02	1.5×10^{-3}	1.5×10^{-6}

shown in Table V. The Rb/K ratio is similar in the principal vein and in the rest. On the other hand, the Cs/K ratio in the former is approximately one tenth of the ratio in the latter, that is to say, the cesium is relatively enriched in the latter as compared with potassium and rubidium. These results appear to be inconsistent with the conclusions by Glueckauf[19] who considered the possible enrichment of cesium and strontium occurring in flowers, leaf veins and root substrate.

Conclusion

1. The greater variation of cesium in natural plants than that of rubidium could not be attributed to the variations of total or acid soluble elements in the soil.

2. The relative uptake by plants of rubidium and cesium to potassium was only slightly affected by the concentrations of these elements in nutrient solution. It appears that a difference does exist between plant species in their ability to accumulate cesium and rubidium relative to potassium.

3. The greater variation of the Cs/K ratio and the doubtful existence of correlation between cesium and potassium contents of natural plants may be principally attributed to the complicated mechanisms of ion-exchange or adsorption between soil and solution.

Fixation by soils and uptake by plants of cesium have been investigated by several authors[20-22] in connection with the problems of radioactive contamination from nuclear fission explosions and also with a view to the ultimate disposal of fission products. The fate of cesium-137 in the biogeochemical cycle from soil to plant has usually been considered likely to follow that of potassium. This appears not to be true after both the results ascertained by us and other investigators. When consideration is taken of the difference of the ionic radii between rubidium (1.49Å) and cesium (1.63Å), we can not expect that cesium can replace potassium (1.33Å) as freely as rubidium does. In this regard, the concept of the "Cesium Unit" temporarily adopted by U.N. authorities to evaluate the concentration of cesium-137 in natural

materials relatively to potassium has little meaning. We believe that the future burden of mankind with radioactive cesium-137 will properly be estimated on the basis of the concept of isotopic dilution.

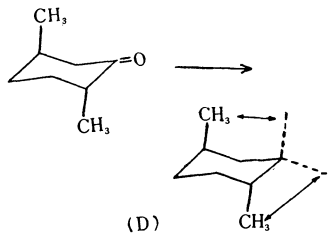
Stereochemistry of Some Steroidal Ketones



By Ken-ichi MORITA

(Received November 12, 1958)

According to Barton's rule[1a] for calculating the relative degrees of steric hindrance of carbonyl groups, the degree of steric hindrance of a $C_{(6)}$-carbonyl group must be the same whether it is in a 5α-steroid or in a 5β-steroid[2]. However, the fact that reduction of a $C_{(6)}$-carbonyl group in a 5α-steroid (I) with lithium aluminum hydride gives exclusively an axial isomer[3] whereas reduction of a $C_{(6)}$-carbonyl group in a 5β-steroid (II) with the same reagent gives a considerable amount of an equatorial isomer[4] suggests[1b,5] that the degrees of steric hindrance of the two carbonyl groups may be different. In the two compounds, the geometrical circumstances around the carbonyl groups are equal except the $C_{(4)}$-methylene groups (see I and II). The expressions A and B show the views[6] looking down the $C_{(5)}$-$C_{(6)}$-axes of a 5α-6-ketone (I) and a 5β-6-ketone (II), respectively. The angle between the $C_{(6)}$-oxo-group and the $C_{(4)}$-methylene group is much greater in II than in I. The interaction between the oxo-group and the $C_{(4)}$-methylene group may be smaller in II than in I. Thus the oxo-group in II must be less hindered[7]. This postulation is well in line with the results of the hydride reduction, if we accept the generalization[1b,5] that the more hindered ketone gives the more axial hydroxyl group by lithium aluminum hydride reduction.

This view may be extended to carbonyl groups in other positions. As far as the steroid nucleus of 5α-series is concerned, the angular methyl groups at positions $C_{(10)}$ and $C_{(13)}$ are axial with respect to A and C ring, respectively. Therefore the degrees of steric hindrance of the carbonyl groups at positions $C_{(1)}$ and $C_{(12)}$ may be less[8] than Barton's degree[1a]. If we

* In 5α-steroids unless otherwise stated

arbitrarily indicate the degree of the steric effect by an axial substituent attached at α-carbon atom by the + sign, indicating a positive magnitude less than one unit, Barton's degrees may be modified as shown in IV (see also Table I). The results of reduction of steroidal ketones with lithium aluminum hydride (Cf. Table I) suggest[20] that the sum (indicated by the + + sign)

IV

of the steric effect by the γ-carbon atom which is bent round so as to hinder the carbonyl group and the steric effect by the axial substituent attached at α-carbon atom may be smaller than one unit in magnitude. If it is true, the order of relative degrees of steric hindrance of the $C_{(1)}$- or $C_{(12)}$-carbonyl group and of those of the $C_{(4)}$- or $C_{(6)}$-carbonyl group reverses in the two estimations.

Becker et al.[1,6] and Jones et al.[15] recorded that reduction of cholest-4-en-6-one with lithium aluminum hydride gave mainly cholest-4-en-6α-ol. Urushibara and Mori[17] reported that reduction of cholest-4-en-3β-ol-6-one acetate with lithium aluminum hydride gave mainly cholest-4-en-3β, 6α-diol. These facts are of interest in connection with the foregoing discussion.

20) It may be necessary to study the relative degrees of steric hindrance of these carbonyl groups by using carbonyl reagents such as ethyleneglycol, ethanedithiol, semicarbazide and the phenylhydrazines, etc., since the degrees of steric hindrance of the carbonyl groups may not exactly be reflected redution with lithium aluminum hydride[21].
21) Cf. K. D. Hardy and R. J. Wicker, ibid., **80**, 640 (1958).

Cholest-4-en-6-one and cholest-4-en-3β-ol-6-one acetate exhibit the maximum absorption bands at 243 mμ (ε=6,360)[22] and 236 mμ (ε=6,300)[23] in the ultraviolet region, respectively. A method of calculating the principal absorption band of α,β-unsaturated ketones was devised by Woodward[24] and was extended by Fieser and Fieser[25]. The calculated value of the absorption maximum for the 4-ene-6-ketone system is 242mμ, which is in agreement with the observed wavelengths within 6 mμ. In Woodward-Fieser-Fieser's method of calculation no steric factor is considered. We may thus assume[26] that the steric hindrance involved in the system does not cause an abnormal change in wavelength but causes a decrease in absorption intensity and is associated with the transition between the non-planar ground state and the near-planar excited state[27]. Hence, the interplanar angle θ between the $C_{(6)}$-carbonyl double bond and the 4,5-ethylenic bond in the ground state may be calculated[30] from Braude-Sondheimer's equation[26] as roughly 55°[31], if the value of intensity for the unhindered system is arbitrarily taken as 18,000[33]. The expression C shows the view looking down the $C_{(5)}$-$C_{(6)}$-axis of the 4-ene-6-ketone (III). The interaction between the carbonyl group and the $C_{(4)}$-methylene group may be smaller in III than in I; it means that the carbonyl group in III is less hindered, and then may be reduced to the stable form in a more proportion. The result of the hydride reduction corroborates the assumption. Jones et al.[15] reported that reduction of cholest-5-en-4-one, λ_{max} 242 mμ (calculated value; 242 mμ), ε=5,900, with lithium aluminum hydride gave mainly the 4α (equatorial)-hydroxy compound. This phenomenon may also be explained in a similar way ($\theta \simeq 55°$). Another example was recorded by Shapiro et al.[34] who reduced 5,16-pregnadien-3β-ol-20-one acetate with lithium aluminum hydride, obtaining the 20α-hydroxy compound (stable form). 16,17-Saturated $C_{(20)}$-ketones are exclusively reduced to 20β-isomers[35].

The author is indebted to Professor S. Mori, Tokyo Metropolitan University, Dr. M. Nakamura, Director of the Institute, and Mr. R. Mamine, the Institute, for their interest in the present study.

27) It should be noted that the wavelengths of the absorption maxima of the semicarbazone (253 mμ; ε, 7,050) and of the 2, 4-dinitrophenylhydrazone (375 mμ; ε, 24,900) of cholest-4-en-6-one are abnormally low[22,28,29] with low intensity. Steric hindrance involved in the systems seems to be strong, because of bulkiness of =NNHCONH$_2$ and =NNHC$_6$H$_3$(NO$_2$)-2,4 moieties, and to be associated with transitions between non-planar ground states and non-planar excited states.

Crystal Structures of Silicon Nitride

By Kiichi NARITA and Kenji MORI

(Received September 28, 1958)

Leslie, Carrol and Fisher[1] separated silicon nitride from nitrided silicon steel and, by studying the X-ray and the electron diffractions of the nitride, proposed an orthorhombic cell for Si_3N_4. More recently Turkdogan and Ignatowiez[2] reported that non-metallic inclusions extracted from the nitrided Iron-Silicon alloys are identical with one of the two silicon nitrides synthesized.

It has been established[2-5] that when silicon is nitrided at high temperatures varying from 1200 to 1400°C, a mixture of two phases (α and β) of nitrides is formed. Vassiliou and Wilde[3] mentioned that these two phases were regarded as orthorhombic (α) and hexagonal (β), respectively. But Popper and Ruddlesden[4] reported that one of them (β) can be indexed as rhombohedral, while both of the two phases were claimed to be hexagonal by Hardie and Jack[6]. More recently Forgeng and Decker[5] have come to the same view as Hardie and Jack's. The spacings, however, calculated by the various investigators are in good agreement with one another, notwithstanding that they differ in opinions on these two phases. Thus, it may not yet be concluded that the behavior of silicon nitride in steel is unequivocally solved.

The present authors prepared silicon nitrides in the following way and made a study on their X-ray and electron diffractions, using an electron microscope also at the same time. As it was difficult to obtain the appropriately large single crystal of silicon nitride for X-ray diffraction, the N-pattern obtained with a selected area electron diffraction was used for a study of the crystal structure of this material, in the place of the precession diagram in the X-ray diffraction study. This paper is to present a brief report of the results obtained.

The samples of silicon nitrides were prepared by heating the powdered elementary silicon in a current of ammonia* in the temperature range 1200° to 1500°C. Caution, however, was paid: at every several hours' interval the reaction product was taken out, ground into particles of about 150 mesh in size, and then submitted to the repeated reactions.

The final product is composed of the two specimens; the major part is grayish white powder, and the other of less quantity white mould growing on the former. When the mould-form product is ground, it changes into grayish white powder similar to that of the major part. It is to be noted that there is no distinguishable difference between these two specimens, as far as the X-ray diffraction spectra obtained with a diffractometer are concerned. This leads the present authors to a suggestion that both of these two specimens can be regarded as a mixture of α and β silicon nitride and others, as described below.

Table I shows the results from our studies of the X-ray diffraction (on both two specimens) and the selected area electron diffraction (on the material shown in Fig. 1). The spacings are in good agreement with those given by other investigators. One of the substances, which is more frequently found in the mould-form portion, is in the form of the flat needle as shown in Fig. 1. Its pattern of the selected area electron diffraction in the form of rectangle-shaped N-pattern is illustrated in Fig. 2. It is regarded that this pattern corresponds to the reciprocal lattice of $(11\bar{2}0)$ plane of hexagonal α-silicon nitride

1.72	1.75_4	9	302	1.75_4	301	1.75_3	132	1.77_9

mentioned by the other investigators[5,6]. And it can not be indexed according to Leslie's[1] orthorhombic lattice.

In view of the above, the crystal structure of α-silicon nitride is regarded more likely as hexagonal. The selected area electron diffraction could not be applied to β-silicon nitride; however, considering the structure of β silicon nitride as hexagonal, as mentioned by the other investigators[5,6], the X-ray diffraction data shown in Table I can be explained as resulting from the mixture of α and β nitrides.

The parameters of these hexagonal cells of α and β silicon nitrides which are yielded from the X-ray diffraction data are as follows:

α-silicon nitride $a_0=7.76\pm0.05$ Å

$c_0=5.64\pm0.006$ Å $\quad c/a=0.727$

β-silicon nitride $a_0=7.59\pm0.06$ Å

$c_0=2.92\pm0.008$ Å $\quad c/a=0.385$

There are some discrepancies between the observed values for spacings obtained with the diffractometer and the calculated values. One of such discrepancies is also found in Leslie's data[1]. These discrepant spacings coincide with those of silicon oxynitride determined by Forgeng and Decker[5] as shown in Table I.

Chemical Shifts of Proton Resonance and Mesomeric Effects in Substituted Benzene

By Hiroshi SHIMIZU, Mikio KATAYAMA and Shizuo FUJIWARA

(Received December, 8, 1958)

In regard to the chemical shift phenomena of nuclear magnetic resonance, efforts have been made to correlate the observed values with the bond characters of the compounds including the resonating nuclei, and successful results have been obtained with the fluorine resonances in binary systems[1]. Further study for the dependence of the chemical shifts on the substituents in polyatomic molecules were made by Gutowsky et al. and showed that *mata* and *para* substituents in substituted fluorobenzenes produced fluorine shifts proportional, respectively, to the inductive and the resonance effects of the substituents as is inferred from chemical reactivities. They showed also that the substituent effects in polysubstituted fluorobenzenes are reasonably additive[2]. Since these results offer most valuable informations for the investigations of the reactions of simple organic molecules, further study of the problem has been made by Corio and Dailey for the proton shifts in monosubstituted benzenes[3], but the results are rather complicated and have been interpreted in terms of the polarization effects in aromatic substitution reactions.

As the last results are complicated by the electron coupling of the proton spins, we have planned here to make measurements of proton resonance in substituted benzenes at a moderate resolution, where the ring protons will give a sharp line, and to investigate the proton shifts in relation with the characters of the substituent groups. The apparatus used is the one constructed in this laboratory, being operated at 27.030 Mc and using a permanent magnet.

In the actual experiments of the measurements, each sample was mixed with cyclohexane at the ratio of 1 : 1 by volume and the shift was measured as the average of the separations between the sample and cyclohexane in several records. Then, as shown in Table I, the shift values were

calculated taking benzene as the reference.

It is noted in Table I that there are observed very small but definite shifts for both bromo and chlorobenzene from benzene and, furthermore, our results in the table show a fine proportionality with the ability of each group to cause mesomeric effect[4].

Authors are very grateful to Professor Osamu Simamura of the University of Tokyo for valuable discussions. Our thanks are also due to Miss M. Nakahara who has made the purification of some of the samples.

The Poisoning Effect of Lead Acetate and Quinoline

By Tosao FUKUDA

(Received February 23, 1959)

As previously reported[1], when palladium-calcium carbonate catalyst was poisoned by lead acetate, the activity for the hydrogenation of 1,4-butenediol decreased with increasing amount of lead acetate. It seems likely that, when it is poisoned by a large amount of lead acetate, the activity for the hydrogenation of 1,4-butynediol as well as 1,4-butenediol disappears completely. On the other hand, when palladium-calcium carbonate catalyst was poisoned by quinoline, the activity for the hydrogenation of 1,4-butenediol disappeared almost completely, while that for the hydrogenation of 1,4-butynediol decreased to about a half. Accordingly, it was suggested that the partial hydrogenation of 1,4-butynediol can be achieved by using quinoline as a poison, but not by using lead acetate.

It is a well known fact that the catalyst properties may be changed complicatedly by the adsorption of the poisons[2]. It seems that the properties of palladium-calcium carbonate catalyst are also affected by the adsorption of lead acetate or quinoline. The effect of quinoline might be different from that of lead acetate. Accordingly, the partial hydrogenation of 1,4-butynediol takes place as observed.

However, it seems that the difference in the poisoning effect of lead acetate and quinoline originated also in the difference of the adsorbability between lead acetate and quinoline.

The experiments were carried out by using the aqueous solution of 1,4-butynediol and 1,4-butenediol, at 25°C. The concentration of 1,4-butynediol and 1,4-butene-

1) T. Fukuda and T. Kusama, This Bulletin, 31, 339 (1958).
2) R. Suhrman and K. Schultz, *Z. Phys. Chem. N. F.*, 1, 69 (1954); W. H. Sachtler, *J. Chem. Phys.*, 25, 751 (1956); L. E. Moore and P. W. Selwood, *J. Am. Chem. Soc.*, 78, 697 (1956).

diol was 175 μ mol./cc. The results are shown in Fig. 1 and Fig. 2.

When lead acetate was added to the reactant, the activity of palladium-calcium carbonate catalyst disappeared almost completely with 0.4 μ mol./cc. of lead acetate. When quinoline was used with 0.4 μ mol./cc., the activity for the hydrogenation remained almost unchanged. When it was used 40 μ mol./cc. the activity for the hydrogenation of 1,4-butynediol decreased only a little, but that for the hydrogenation of 1,4-butenediol disappeared almost completely. It is interesting to note that, when the catalyst was poisoned by a small amount of quinoline, the activity for the hydrogenation of 1,4-butynediol increased at first and then decreased with increasing amount of quinoline.

When palladium-calcium carbonate catalyst was poisoned by the larger amount of lead acetate, the activity for the hydrogenation of 1,4-butynediol as well as 1,4-butenediol disappered completely. But, when it was poisoned by quinoline, the activity for the hydrogenation of 1,4-butenediol disappeared completely, while that for the hydrogenation of 1,4-butynediol decreased only a little. These results may explain clearly that lead acetate is adsorbed much more strongly than 1,4-butynediol, but quinoline is not. The catalyst properties are affected by quinoline. Quinoline might be adsorbed competitively with 1,4-butynediol and 1,4-butenediol. As a result, the hydrogenation of 1,4-butenediol is stopped by quinoline, while that of 1,4-butynediol is only retarded.

It may be concluded that the difference in the poisoning effect of lead acetate and quinoline originates also in the difference of the adsorbability between lead acetate and quinoline.

*Isomerization of Luciculine**

By Takashi Amiya

(Received February 25, 1959)

Lucidusculine (I) ($C_{24}H_{35}O_4N$) is one of the aconite alkaloids; upon hydrolysis it gives a trihydric amino alcohol, luciculine (II) ($C_{22}H_{33}O_3N \cdot H_2O$)[1]. In contact with palladium-carbon in the presence of hydrogen and methanol, compound II was found to isomerize to a ketone base, isoluciculine (III), m. p. 131~136C°, λ_{max} in MeOH 302 mμ, logε1.4 (*Anal.* Found: C, 71.22; H, 9.33; N, 332; H_2O, 2.33. Calcd. for $C_{22}H_{33}O_3N \cdot {}^1/_2H_2O$: C, 71.71; H, 9.30; N, 3.80; H_2O, 2.44%). Compound III showed a band at 5.82 μ in the infared spectrum, and was considered therefore to be a cyclic six-membered ketone. Since it was shown previously that a terminal methylene group exists in compound II[1], this isomerization seems to proceed similarly to that of Shimoburo base I[2], hypognavine[3] or napellonine[4,**] as follows:

(II) (III)

On the basis of these observations, the presence of an allyl alcohol moiety in the structure of compound II may be claimed.

Preparation of Chromium-51 of a High Specific Activity by the Szilard-Chalmers Process

By Nagao SHIBATA and Kenji YOSHIHARA

(Received January 16, 1959)

High specific activity ^{51}Cr has been prepared by neutron irradiation of electromagnetically enriched ^{50}Cr in a pile[1]; but this method offered only a small enrichment factor (about 23). The Szilard-Chalmers process of chromate or dichromate was investigated by Green and Maddock[2], and by Kahn, Freedman and Bryant[3], and it was found that about 30% and 8% tervalent chromium were formed from chromate, and dichromate, respectively (crystalline in both cases). This effect is applicable to the enrichment of ^{51}Cr but the yield is not very high.

In this paper, the authors studied the preparation of high specific activity ^{51}Cr by the Szilard-Chalmers process of neutron-irradiated, highly stable dye, Palatine Fast Blue GGN (Fig. 1), and succeeded in preparing highly enriched ^{51}Cr with a high yield.

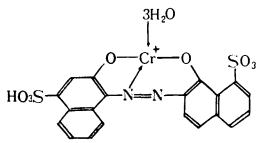

Fig. 1. Palative Fast Blue GGN.

This dye is water-soluble and slightly acid. It has an affinity to an anion- but not to a cation- exchange resin, whilst tervalent chromium is caught by the latter. The present separation is based on this difference.

The dye which was irradiated in the reactor, JRR-1 (neutron flux: 4×10^{11} n/cm^2 sec.), was dissolved in 0.01 N hydrochloric acid, passed through a resin column (10 mm. $\phi\times100$ mm. of Diaion SK#1, 100—200 mesh), and the column was washed with a sufficient volume of distilled water till the effluent became colorless. Then hydrochloric acid of various concentrations was passed through the column. The ^{51}Cr on the resin was eluted dy this procedure. Elution curve is shown in Fig. 2 in which many peaks appear. As the sample is dissolved in hydrochloric acid, complicated chloro-complexes of chromium may be formed. When the histogram is compared with the elution curves of a few chloro-aquo chromium ions, the first peak in Fig. 2 seems to be ascribed to the dichloro-tetra-aquo, the second to the monochloro-penta-aquo, and the third to the hexa-aquo chromium ion. It is not clear to which chemical forms the fourth and the fifth portion are to be assigned, but they were co-precipitated together with tervalent chromium. Thus 77~83% of the total activity was eluted from the resin in cationic forms.

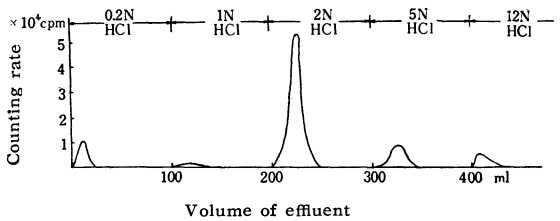

Fig. 2. Elution curve of chromium-51 formed in Palative Fast Blue GGN by hydrochloric acid.

Harbottle[4] investigated the Szilard-Chalmers process of some tervalent chromium salts, and found that about 10% of the neutron-captured atoms are present in sexivalent form. In the present case, whether tervalent chromium of Palatine Fast Blue GGN is oxidized to sexivalent or not was investigated as follows. Pottasium chromate carrier was added to the dye solution which had passed through the cation exchanger, as well as tervalent chromium as hold-back carrier. Lead acetate solution was added to this mixture to precipitate chromate as lead chromate. The activity observed in the procipitates was about 6 to 8% of the total activity. It is considered that this quantity corresponds to that of chromate formed on the present nuclear transformations.

For the preparation of high specific activity ^{51}Cr, it is considered to be convenient to utilize tervalent chromium which is caught by the cation exchanger, because it is difficult to separate the anionic part of chromium from the dye and from the contaminating activities (^{35}S and ^{32}P formed from the sulfonic sulfur).

3) M. Kahn, A. J. Freedman and E. A. Bryant, AECU-2329 (1949).

4) G. Harbbottle, *J. Chem. Phys.*, **22**, 1038 (1954).

The solution of neutron irradiated dye is passed through the cation exchanger column, and the column is washed with distilled water sufficiently. Tervalent chromium absorbed on the column is eluted by 200 ml. of 5N hydrochloric acid. Then, sulfric acid is added to the effluent and the mixture is dried up. This must be repeated decompose of micro quantities of organic substances. Then the sample is treated with silver peroxide to oxidise tervalent chromium to chromate. The product is sufficiently pure and impure activities were not detected by the inspection of its γ-ray spectrum and decay curve (by the Geiger tube). The yield is 69 to 75%, and the enrichment factor is 915 for 15 hr. irradiation and is 1150 for 5 hr. irradiation. This preparation method of enriched ^{51}Cr is considered to be useful. And the hot-atom chemistry of chromium complexes of diazo-compounds in detail is to be published at hand.

The authors wish to express their acknowledgement to Dr. K. Kimura for his kind encouragement and to Dr. T. Ishimori for his valuable suggestions and to Mr. I. Okubo for his helpful opinions.

Self-diffusion of Benzene under Pressure

By Hiroyuki HIRAOKA

(Received February 9, 1959)

Most of the works on diffusion in liquids have been made at atmospheric pressure. At atmospheric pressure, however, both the temperature and the density are varying simultaneously and so it is impossible to separate the effects of these two factors on diffusion. There has been no attempt to separate the two effects on self-diffusion of organic liquids except carbon tetrachloride[1] and carbon disulfide[2]. In advance of the present work, diffusion of iodine and sulfur in benzene under pressure was studied[3]. In this communication a study on the self-diffusion of benzene under pressure is presented.

Diffusion was measured by the capillary-cell method. The diffusion cells were accurately calibrated capillaries about 4 cm. in length and 0.02 ml. in volume and were filled with benzene containing carbon-14 sufficient to give 1900 counts per minute in a counting system used. The cells were immersed in a reservoir of pure inactive benzene in a thermostat constant to ± 0.01 °C. Diffusion was allowed to proceed for about 3 days, after which benzen in the cell was transferred into a combustion apparatus by a gas-phase sampling technique and was converted into barium carbonate by wet combustion method. The activity was measured by an α-β-γ proportional counter. Three to six determinations were carried out at each experimental conditions and the maximum deviation occurred was as large as 3.5 per cent from the mean. The results were presented in Table I with Graupner's data[4] at atmospheric pressure.

According to Eyring's theory[5], if the mechanism of activation in diffusion can be assumed identical with that of viscous flow, the relation between self-diffusion coefficient and viscosity in liquids is given by

$$D\eta/\boldsymbol{k}T = \lambda_1/(\lambda_2\lambda_3) \qquad (1)$$

where the common notation is used. The constancy of the values of $D\eta/\boldsymbol{k}T$ is shown in Table I, where at 35°C the values of λ_1 and $(\lambda_2\lambda_3)^{1/2}$, obtained on the assumption that $\lambda_1\lambda_2\lambda_3$ is equal to the mean molecular volume, are also given. The distance between two adjacent layers of graphite is 3.40 Å and the molecular diameter of benzene is 4.96 Å, and thus the values of λ_1 and $(\lambda_2\lambda_3)^{1,2}$ agree fairly well with the known dimensions of the molecule. From the self-diffusion coefficient of carbon-tetrachloloride determined by Hildebrand et al., $\lambda_1 = 2.24$ Å and $(\lambda_2\lambda_3)^{1,2} = 8.48$ Å at 25°C is obtained with the same assumption as used above. Although benzene is particularly amenable to Eyring's theory, because its geometry should lead to diffusion preferentially in the direction of benzene ring plane, it is strange that in the case

of carbontetrachloride λ_1 is much smaller than $(\lambda_2\lambda_3)^{1/2}$. It can not be concluded that the valuse of λ_1 and $(\lambda_2\lambda_3)^{1/2}$ thus calculated are true dimensions in liquid state, as Partington et al.[6] and other investigators did.

The relation between the experimental activation energy of diffusion at a constant volume, E_v, and the experimental activation energy at a constant pressure, E_p, is given by

$$E_v = E_p + (RT^2)(\alpha/\beta)(\partial \ln D/\partial P)_T \quad (2)$$

where α is the isobaric expansion coefficient and β the isothermal compressibility. From the values in Table I the following results are obtained: E_p=2,780 cal./mole, $(RT^2)(\alpha/\beta)(\partial P \ln D/\partial)_T$=2,000 cal./mole, E_r =780 cal./mole. According to Eyring, the increase of internal energy for the activation process, ΔE^*, is given by

$$\Delta E^* = E_v - RT \quad (3)$$

This gives the value ΔE^*=170 cal./mole, which is so small that it is difficult to consider any high potential barrier for diffusion in benzene.

The author wishes to express his appreciation to Dr. Jiro Osugi for his interst in this work.

*Studies on Explosion Reaction of Ethylene Mixed with Oxygen or Air. II. On the Explosion Peninsula**

By Masao SUGA

(Received September 22, 1958)

In a previous paper[1], it has been shown that the explosion boundaries of ethylene mixed with oxygen and with air was determined by the "admission method" i. e., by sudden introduction of the premixed gases into a heated and previously evacuated vessel. Also, it has been noticed that the explosion, like that of the other combustible gases[2,3], occurred in a certain region of the pressure, temperature and composition of mixed gases. In this case, there are the first (the lower), the second (the upper) and the third (the thermal) limit in the definite composition and temperature range. The explosion peninsula lies in the range bounded by the first and the second pressure limit of explosion within which pale blue ignitions occurred. On the other hand, the explosion occurred normally with a blue flame which rapidly built up into a bright flash filling the reaction vessel and accompanied by a pulse in pressure. Also, it was apparent that the induction period of the explosion, the color of flame and the propagation velocity of flame were different in the two cases described.

Now the experiment has been made between 550°C and 700°C for mainly 20% ethylene with oxygen in order to observe in detail explosion phenomena in the explosion peninsula and to compare this with normal thermal explosion. The effects of nitrogen and vessel diameter on the explosion limit were studied. They will be briefly discussed.

Experimental

Materials. — The ethylene employed in this experiment was prepared by the dehydration of absolute ethanol and purified by the method described in the previous paper. The oxygen employed was obtained from a commercial cylinder (purity: 99.4%). The oxygen and the air were employed after being purified through a train consisting of two bottles containing a concentrated aqueous solution of sodium hydroxide and concentrated sulfuric acid. Before use, the gases were dried with phosphorus pentoxide.

Apparatus and Procedure. — The apparatus used and the procedure adopted were of the types described in the previous paper. This consisted of an electrically heated reaction vessel into which a gas mixture could be admitted from a separate mixing vessel. Subsequent explosion of the mixture could be observed visually through a small window of mica in the dark room, and a blue filter of 1 mm. thickness whose transmission curve** is shown in Fig. 1 was used to eliminate the red glow of the furnace so that an ignition could be detected. Cylindrical reaction vessels of quartz 15 cm. long and 3 cm. in standard diameter, were used, but the diameter was varied to 4 cm., 2 cm. or 1 cm. as required. The apparatus was evacuated down to $10^{-4}\sim10^{-5}$ mmHg (tested by Gaisler tube) with rotary and "Hücksman's diffusion" pump.

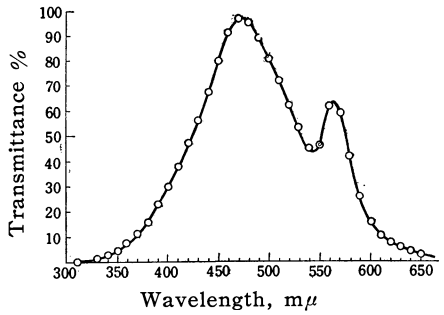

Fig. 1. The transmission curve of a filter.

Results and Consideration

The Explosion Limit.—Isochors for the explosion limits of 20% ethylene with oxygen and of 5% ethylene with air are shown respectively in Fig. 2 and Fig. 3. The evidence of an explosion was judged by observing the appearance of ignition, and usually the observation was continued for twenty minutes in the dark room.

* A part of this investigation was reported at the Annual Meeting of the Chûgoku-Shikoku Branch of the Chemical Society of Japan in Niihama, October 19, 1956.

1) M. Suga, This Bulletin, 31, 515 (1958).

2) B. Lewis and N. von Elbe, "Combustion, Flames and Explosions of Gases", Academic Press, New York (1951), p. 29.

3) K. J. Laidler, "Chemical Kinetics", McGraw-Hill Book Co., Inc., New York (1950), p. 319.

** It was measured with a HITACHI Model EPB-U photo-electric spectrophotometer.

The results of observation were classified as follows:

(1) After the lapse of various induction periods (usually less than 10 sec.), luminous blue flames were observed.

(2) After the lapse of the relatively long induction periods (6 sec.~20 min.), pale blue flames were observed in the dark room.

(3) No flame could be found even in the dark room.

Case 1, 2 and 3 are indicated respectively by ◎, ○ and × in Figs. 2 and 3. Also ⊕ in Fig. 2 indicates the case of the luminous flame propagating into the storage bulb owing to the shorter induction period than 0.8 sec. and the large propagation velocity of flames.

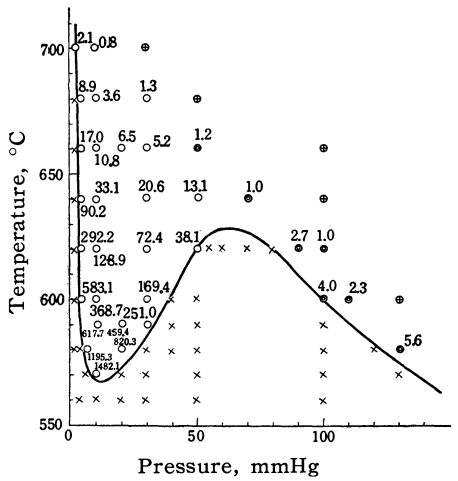

Fig. 2. Explosion limit of 20% ethylene with oxygen. (Induction periods in seconds are indicated by numbers beside observation points.)

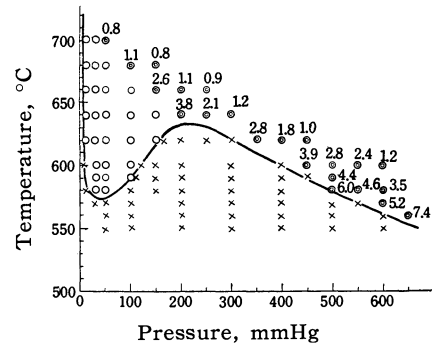

Fig. 3. Explosion limit of 5% ethylene with air. (Induction periods in seconds are indicated by numbers beside observation points and the results of longer induction period will be indicated in Fig. 6).

It is evident from the isochors that the first, the second and the third pressure limit of explosion exist in the explosion limit of ethylene-oxygen and -air mixtures. The first pressure limit of explosion does not seem to depend to a great extent on temperature, but the observation was more or less obscure because of the low admission pressure. The boundary of the first and the second pressure limit of explosion, i. e., the tip of the explosion peninsula, was determined from the results of observation for thirty minutes. The second pressure limit of explosion increases abruptly with increasing temperature, and, on the other hand, the third pressure limit of explosion decreases with increasing temperature.

Fig. 4 shows the isochors for the explosion limits of ethylene-oxygen mixtures. In this case, the explosion peninsula results in various shapes according to the composition of gas mixtures. That is to say, the composition of gas mixture affects the explosion limit considerably, and particularly it was noticed that the explosion peninsula disappears at over 25% ethylene with oxygen.

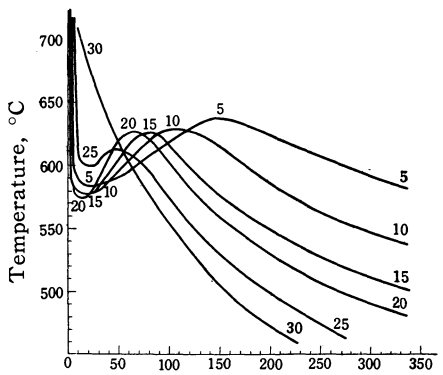

Fig. 4. Isochors for explosion limit of ethylene-oxygen mixtures. curve 5=5%, 10=10%, 15=15%, 20=20%, 30=30% ethylene.

The Effect of Nitrogen in the Air.—As shown in the previous paper, the third pressure limits of explosion for ethylene with oxygen and with air were equivalent to each other in spite of the differences of the propagation velocity of flame, the induction period, etc., so far as the partial pressure of nitrogen was neglected. Also, in order to elucidate the effect of nitrogen, an isochor for explosion limit of 20% ethylene with oxygen is shown and this is plotted with the corresponding points

of the results for explosion limit of 5% ethylene with air, by calculation, subtracting the partial pressure of nitrogen.

This plot is shown by the broken line in Fig. 5. It is concluded that the first and the third pressure limit of explosion are slightly lower, and, the on other hand, the second pressure limit of explosion considerably lower, than the corresponding full line. In other words, nitrogen affects the second pressure limit of explosion, but does not affect the first and the third pressure limit of explosion.

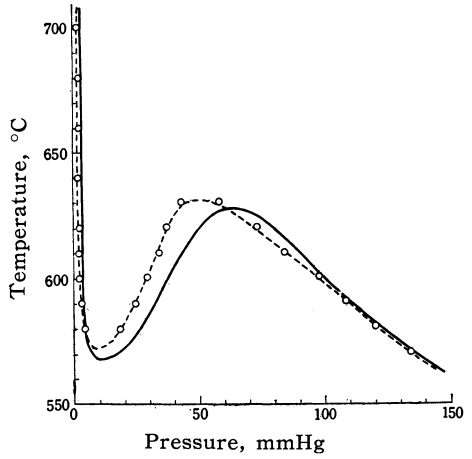

Fig. 5. Effect of nitrogen on isochor for explosion limit of 20% ethylene with oxygen. (Broken line represents the data calculated from the limit of 5% ethylene with air, Fig. 3.)

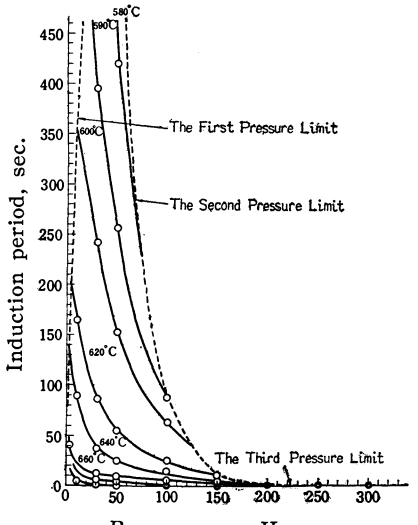

Fig. 6. Relationship between explosion limit pressure and induction period at definite temperatures for 5% ethylene with air.

The Explosion Limit and Induction Period. — The results of the experiment with regard to the induction period are shown by numbers beside the observation points in Figs. 2 and 3. The induction period was measured by a stopwatch. But in cases where the admission time required more than 0.6 sec., the induction period could not always be measured by a stopwatch with high accuracy. Fortunately, induction period is fairly long in the region

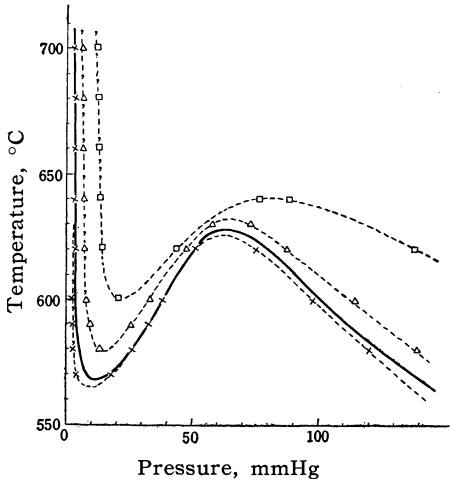

Fig. 7. Effect of reaction vessel diameter on isochor for explosion limit of 20% ethylene with oxygen. Diameter: Full line, 3 cm.; □, 1 cm.; △, 2 cm.; ×, 4 cm.

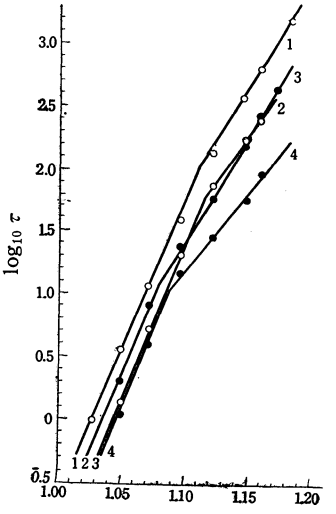

Fig. 8. $\log_{10}\tau$ against $1/T$ curves for the explosion of 20% ethylene with oxygen and 5% ethylene with air.
○; 20% C_2H_4 with O_2, curve 1=10, 2=30 mmHg admission pressure, ●; 5% C_2H_4 with air, curve 3=50, 4=10 mmHg admission pressure.

of the explosion peninsula and is reproducible so far as precautions are taken in accord with standard procedure[1]. Fig. 6 shows the relationship between explosion limit pressure and induction period at various different temperatures for 5% ethylene with air.

The Effect of Reaction Vessel. — For reaction vessels, quartz cylinders of 3 cm. in diameter and 15 cm. in length were usually employed. Quartz cylinders of 4, 2 and 1 cm. in diameter of the same length were also employed in order to compare the effects of the diameter of reaction vessels. The results are indicated in Fig. 7. The decrease of the vessel diameter increaed the first and the third pressure limit, and, on the other hand, lowered the second pressure limit of explosion; i. e., the decrease of the vessel diameter serves invariably to retard the explosion. It is noticed that the second pressure limit of explosion suffers the effect of the surface of the vessel only slightly, and in consequence, the explosion peninsula tends to disappear when the specific surface of the vessel is increased.

The Activation Energy of the Reaction. —In Fig. 8 is shown the relationship between the absolute temperature T and the induction period τ in relation to the results of Fig. 2 and Fig. 6. Every curve bends at the neighborhood of ca. 620°C, but is essentially linear and holds the relationship $\log_{10}\tau = A/T + B$. On the other hand, while this result has no direct relationship with the meaning of kinetics and the adaptability of the former's formula to the latter is questionable, nevertheless the gradient of these lines, A, is thought to be equal to $E/2.303\times R$[4,5]. Thus, values for E, the apparent activation energy, may be as in Table I.

TABLE I. ACTIVATION ENERGIES ESTIMATED FROM THE INDUCTION PERIOD

5) N. Semenoff, *Z. Physik*, **48**, 57 (1928).

Summary

In the previous paper, the explosion limit of ethylene mixed with oxygen and with air by the "admission method" was presented. It was pointed out that the explosion peninsula lies in the region between the first and the second pressure limit of explosion. The results of observation in this region differ from those in thermal explosion.

In the present experiment, the following results have been obtained.

(1) The explosion peninsulas of ethylene-oxygen and ethylene-air mixtures lie approximately in the range of the same temperature and pressure limits as that of carbon monoxide-oxygen mixture[6].

(2) If ethylene concentration exceeds ca. 25% ethylene with oxygen, the explosion peninsula disappears.

(3) The induction period of explosion in the explosion peninsula is relatively longer than those of other thermal explosions.

(4) In the explosion within the explosion peninsula, the apparent activation energy estimated in accordance with Semenoff's theory is of abnormally high value. Merely from these facts, it is difficult to determine the explosion mechanism of ethylene-oxygen mixture, but it is possible for one to assume that the explosion within the explosion peninsula has a different mechanism from other thermal explosions.

If one refers to the studies of Neumann and Serbinoff[7], Norrish and Food[8], and Lewis[2] on the explosion of methane-oxygen mixture, he will find that the explosion peninsula which is observed in the explosion limit of ethylene-oxygen or -air mixtures is not always related to the nature of ethylene itself. In other words, ethylene-oxygen mixture is decomposed into carbon monoxide first in the definite range of temperature and pressure. Furthermore, it is considered that carbon monoxide which is produced and accumulated in slow oxidation of ethylene, i. e., slow reaction, is ignited in the definite condition. Thus, if ethylene concentration is greater than the stoichiometric value crresponding to $C_2H_4+3O_2=2CO+2H_2O$, the oxygen which is required to oxidate this carbon monoxide is insufficient, and therefore the

8) R. G. W. Norrish and S. G. Food, *Proc. Roy. Soc.*, **A 157**, 503 (1936).

explosion peninsula disappears. The conclusion is a little too speculative, but it is considered that the explosion peninsula of ethylene-oxygen or -air mixtures originates in the oxidation of carbon monoxide which is accumulated in slow reaction.

The author wishes to express his gratitude to the late Professor R. Kiyama and Dr. J. Ôsugi of the Kyôto University and Professor T. Kôzu for their kind advice and encouragement throughout this work. Dissociation Constants of Some Carboxylic Acids in Mixed Aqueous Solvents

By Motoo YASUDA

(Received October 9, 1958)

The dissociation constants of carboxylic acids were determined by various authors in mixed solvents, such as water-methanol, water-ethanol and water-dioxane mixtures and the relationship between the dissociation constants of the acids and the dielectric constants of the mixed solvents was discussed. As the dissociation of an acid is influenced by the dielectric constant of the solvent, it may be reasonable to suppose that an acid has almost the same acidity, i. e., almost the same dissociation constant in mixed solvents having the same dielectric constant. However, both Speakman[1] and Dondon[2] observed that aqueous dioxane acted as if it had a higher effective dielectric constant than aqueous alcohol of the same bulk dielectric constant. In other words, the values of dissociation constants of several acids in aqueous dioxane were reported to be higher than those determined in aqueous alcohol with the same dielectric constant. The present paper deals with the problem whether a carboxylic acid has really different acidity in various mixed solvents having the same dielectric constant.

Calculation of the Dissociation Constants. — The dissociation of a carboxylic acid in mixed solvents is an equilibrium reaction of the type

$$HA + S \rightleftarrows SH^+ + A^- \qquad (1)$$

where HA is a monobasic acid and S is one of the components of the mixed solvent. Since water has an exceptionally high proton affinity, Eq. 1 may be written as Eq. 2, if the mixed solvent contains a sufficient quantity of water and the concentration of the acid is small.

$$HA + H_2O \rightleftarrows H_3O^+ + A^- \qquad (2)$$

The equilibrium constant of this dissociation, or the dissociation constant of an acid in aqueous mixed solvents should be given by Eq. 3:

$$K = [A^-]\,[H_3O^+] / [HA]\,[H_2O] \qquad (3)$$

where square brackets indicate activity. On the other hand, the strength of an acid in water is usually expressed in terms of the constant K_a, instead of K defined by Eq. 3,

$$K_a = [A^-]\,[H^+] / [HA] \qquad (4)$$

In aqueous solution K_a may be used, for $[H_2O]$ is nearly constant. But this is not true in mixed solvents containing a limited amount of water. Due consideration should be paid to the fact that the activity of water in mixed solvents changes with the molar fraction of organic solvents. Therefore, the constant K defined by Eq. 3 should be used for the estimation of the dissociation of an acid in mixed solvents, in place of K_a defined by Eq. 4.

Furthermore, K_a has a different numerical value in accordance with the unit of concentration used in calculation, whereas

1) J. C. Speakman, *J. Chem. Soc.*, **1943**, 270.
2) M. -L. Dondon, *J. chim. phys.*, **54**, 290, 304 (1957).

K does not depend on the unit of concentration. The present author calculated the values of K from the values of K_a reported by previous workers. But, as the activity of water in mixed solvents containing electrolytes is not known, it was replaced by the concentration of water.

Results and Discussion

1) Benzoic, Adipic and Succinic Acids.— Speakman determined the dissociation constant K_a defined by Eq. 4 of some carboxylic acids in aqueous alcohols and dioxane by using a glass electrode in conjunction with a cell involving liquid-liquid potentials. Some of his results are listed in Table I together with the dielectric constants ε reported by him. As seen in Table I, the values of $pK_a(=-\log K_a)$ in aqueous dioxane are lower than those of pK_a in aqueous alcohol having the same dielectric constant. The present author calculated the values of pK defined by Eq. 3 considering the change in the amount of water in mixed solvents. The values of the first and the second dissociation constant, pK_1 and pK_2, recalculated in this way are listed in Table II.

The values of pK are plotted against $1/\varepsilon$ in Fig. 1. It is seen that all points fall on a straight line. This means that an acid has nearly the same acidity in the medium having the same dielectric constant, at least in the range of the dielectric constant studied.

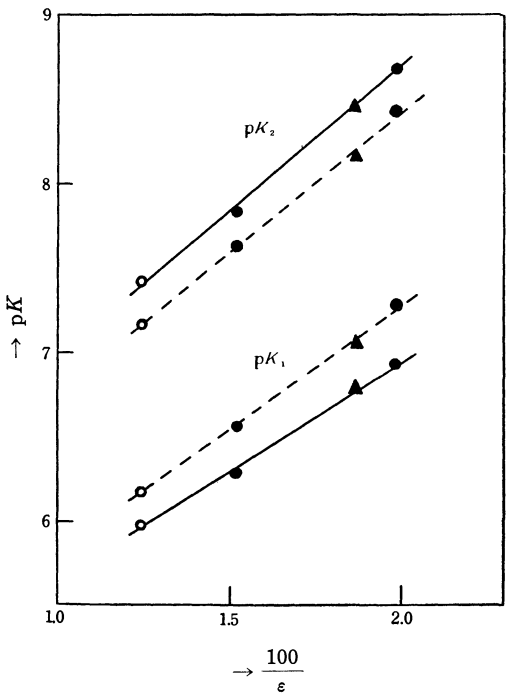

Fig. 1. Variation of pK values with the dielectric constant of the solution. Solid and broken lines indicate succinic and adipic acids, respectively. White and black circles and triangles show values in water, water-alcohol and water-dioxane mixtures, respectively.

TABLE I. VALUES OF pK_a AT 20°C REPORTED BY SPEAKMAN

Solvent % by wt.	ε	Adipic acid		Succinic acid		Benzoic acid
		pK_{a1}	pK_{a2}	pK_{a1}	pK_{a2}	pK_a
Water	80.4	4.43	5.42	4.22	5.67	4.24
25% Ethanol	65.7	4.93	6·00	4.65	6.19	4.83
50% Ethanol	50.4	5.83	6.98	5.48	7.24	5.87
30% Dioxane	53.3	5.45	6.55	5.19	6.84	5.35

25% Ethanol	6.55	7.62	6.27	7.81	6.45
50% Ethanol	7.27	8.42	6.92	8.68	7.31
30% Dioxane	7.04	8.14	6.78	8.43	6.94

2) Succinic and Azelaic Acids. — In addition to the work of Speakman, Dondon reported recently the values of dissociation constants of several dibasic acids in water-methanol, water-ethanol and water-dioxane mixtures. A part of her results is shown in Fig. 2. She also reported that the dissociation of acids in aqueous dioxane is larger than in aqueous alcohols with the same dielectric constant. The values of pK_a determined by her in water-dioxane and in water-alcohol mixtures fall on two separate curves when they are plotted against $1/\varepsilon$. The range of the solvent composition studied for succinic acid by Dondon is wider than that by Speakman. She used the molarity basis for the calculation, but Speakman used the molality basis.

Now Dondon's values of pK_a are recalculated to give those of pK_1 and pK_2, which are listed in Table III. The values of density of the aqueous mixed solvents used for calculation were taken from Landolt-Börnstein's Tables[3] and the data

reported by Dunsmore and Speakman[4]. When the values of pK_1 and pK_2 are plotted against $1/\varepsilon$ (Fig. 3), all points of pK fall on a curve, except the points of pK_2 of succinic acid in the range of ε smaller than 40.

TABLE III. RECALCULATED VALUES OF pK_1 AND pK_2 AT 20°C

Solvent % by vol.	ε	Succinic acid		Azelaic acid	
		pK_1	pK_2	pK_1	pK_2
Water	80.4	5.88	7.41	6.29	7.24

4) H. S. Dunsmore and J. C. Speakman, *Trans. Faraday Soc.*, **50**, 236 (1954).

For the irregularity of pK_2 of succinic acid, it is difficult to find the cause. One cause now suspected is the change of the distance between the secondly dissociating proton and the previously dissociated carboxyl group in different mixed solvents.

Although Dondon reported dissociation constants determined in 100% methanol, 100% ethanol and 80% dioxane, these data were not used in the calculation, for the dissociation of an acid in pure organic liquids is different from that shown by Eq. 2 and she reported that the data for 80% dioxane were least reliable.

3) Acetic Acid. — The dissociation constant of acetic acid in mixed aqueous solvents was determined by several authors[5-7]. The same situation as mentioned above was also found for acetic acid. The values of pK_a originally reported and those of pK recalculated for acetic acid are listed in Table IV and

6) A. L. Bacarella, E. Grunwald and H. P. Marshall, *J. Org. Chem.*, **20**, 747 (1955).

7) H. S. Harned and G. L. Kazanjian, *J. Am. Chem. Soc.*, **58**, 1912 (1936).

these values of pK are plotted against $1/\varepsilon$ in Fig. 4. The dielectric constants, ε, of the mixed solvents were calculated by interpolation using the data of Gosting and Albright[8].

As shown in Tables II, III and IV, all the values of pK for acetic, benzoic, succinic, azelaic and adipic acids were calculated using the concentration of water instead of its activity. Nevertheless a carboxylic acid has almost the same dissociation constant in various mixed solvents having the same dielectric constant. The apparently greater acidity of a carboxylic acid in the water-dioxane mixture reported previously is due to the greater concentration of water in this mixture than in the water-alcohol mixture having the same dielectric constant.

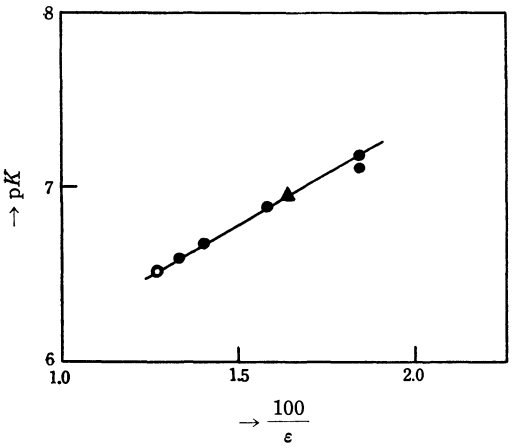

Fig. 4. Variation of pK values of acetic acid with the dielectric constant of the solution. White and black circles and triangle show values in water, water-alcohol and water-dioxane mixtures, respectively.

TABLE IV. THE DISSOCIATION CONSTANT OF ACETIC ACID AT 25°C

Solvent	ε	pK_a	pK

40% Methanol (by vol.)	63.2	5.34[5]	6.88
60% Methanol (by vol.)	54.4	5.74[5] 5.81[6]	7.10 7.17
20% Dioxane (by wt.)	60.8	5.29[7]	6.94

Summary

Several authors determined dissociation constants of acids such as benzoic, succinic and azelaic acids in mixed solvents and reported that the dissociation constants determined in aqueous dioxane were higher than those determined in aqueous alcohols having the same dielectric constants. However, if the variation of the amount of water in mixed solvents is taken into consideration in calculating the dissociation constant, an acid has almost the same dissociation constant in various mixed solvents with the same dielectric constant.

The author is greateful to Professor K. Yamasaki and Professor H. Kakihana, who read the manuscript and made helpful comments and criticism.

Interaction Polarization of the Hydrogen Bonded Complexes

By Ko KIMURA and Ryoichi FUJISHIRO

(Received October 20, 1958)

A strong intermolecular interaction such as hydrogen bonding will be expected to give rise to some variation in the charge distribution of the interacting molecules[1]. Hence the dielectric measurement for the system containing hydrogen bonds will give some useful information about the intermolecular association through hydrogen bonding. Hammic, Norris and Sutton[2] investigated the polarization of molecular complexes from this point of view and pointed out[3] that it was not generally practicable to derive both the association constant and the dipole moment of a complex from polarization data alone. Few and Smith[4] also studied this problem, and proposed a method by which both values for a complex were obtained from the dielectric measurement alone. The association constant of a complex derived by them, however, was much lower than the value obtained by other methods such as infrared absorption spectroscopy. Although their analysis is correct, in principle, such a discrepancy may probably result from the difficulty in estimating polarization owing to the solvent effect within the accuracy of 0.1 cc. If an accurate correction for the solvent effect is possible, the method proposed by them will be applied extensively.

This report describes a somewhat different approach from those above mentioned to the interaction polarization of hydrogen bonded complexes such as benzyl alcohol-dioxane and phenol-dioxane in benzene.

Experimental

All materials used in this work were purified by the standard method[5], and dried carefully. The solvent used throughout this work was benzene which was a very "*good solvent*" compared with other non-polar solvents such as cyclohexane or carbon tetrachloride.

Molecular polarizations were determined by measuring dielectric constants ε, refractive indexes n and specific volumes v of the binary or the ternary solutions. The apparatus for the dielectric measurement is almost the same as that generally used; that is to say, the heterodyne beat method. A very stable oscillator is necessary in order to obtain high accuracy, so the circuits devised by Gouriet[6] are employed without any improvement. The beat frequency of both tank circuits was again coupled with a standard tuning fork by making use of the cathode-ray oscilloscope. The dielectric cell was made of nickel and has three coaxial cylindrical electrodes[7], the outer side of which are connected to the ground. The capacity of the cell is about 100 pF. The cell constant was determined by carefully purified and dried benzene. An oil bath was used as a thermostat to minimize the error due to stray capacity. The temperature was kept at 25 ± 0.05°C throughout this work. The refractive index of the solution was measured by a Pulfrich refractometer, and a sodium lamp was used as the light source. The density of the solution was determined by a Lipkin pycnometer.

The calculation of molecular polarization was performed according to Halvelstadt and Kumler's method. For the ternary systems, the amount of the proton acceptor, that is dioxane, was kept constant and the polarization was extrapolated to zero concentration with regard to the proton donor.

Results

The results of the measurements of ε, n^2 and v for the two ternary systems, i.e., benzyl alcohol-dioxane-benzene and phenol-dioxane-benzene, are summarized in Table I together with those for the corresponding binary systems, i.e., benzyl alcohol-benzene and phenol-benzene. Experimentally determined formulae relating ε, n^2 and v to w, respectively, are also included in Table I for each system, where w represents the weight fraction of the proton donor.

1.44	2.3131	2.2450	1.1411	

Polarization values calculated from these experimental data are shown in Table II, where p or P is the specific or the molecular polarization, and r or R the corresponding refraction. The values of dipole moment were evaluated on the assumption that $P_{E+A}=[R_D]$ or $P_{E+A}=1.05$ $[R_D]$ and shown in the same table as μ or μ'.

TABLE II. POLARIZATIONS AND DIPOLE MOMENTS OF THE HYDROGEN BONDED COMPLEXES AND THE FREE PROTON DONORS

	Benzyl alcohol -Dioxane	Benzyl alcohol	Phenol-Dioxane	Phenol
p	0.9039 cc.	0.8674	1.0264	0.8993
r	0.2074 cc.	0.3005	0.3009	0.2931
P	97.7 cc.	93.8	96.6	84.9
R_D	32.1 cc.	32.5	28.3	27.6
μ	1.79 D	1.73	1.84	1.67
μ'	1.76 D	1.70	1.82	1.65

Attention was called especially to the association among the proton donors. For example, when the dipole moment of benzyl alcohol was measured in cyclohexane, the value obtained was 1.55 D or so which was a little smaller than 1.70 D[8] of methanol measured in the vapor phase. This fact seems attributable probably to the association of benzyl alcohol in this solvent. On the other hand, we used benzene as a solvent for benzyl alcohol and could obtain almost the same dipole moment as that of methanol in the vapor phase. Infrared absorption spectroscopy showed that the bridged bands were not perceived at concentrations less than ca. 0.01 mol./l. in carbon tetrachloride. Although the dielectric measurements in such a dilute solution are desirable, the change in the dielectric constants within the range of concentrations where the bridged bands are not observed, is not detected by the present apparatus and technique. But it seems probable that the fraction of solutes capable of existing as free molecules without association is more or less altered from one solvent to another. Although we have not ascertained it, it seems appropriate to use benzene as the dispersing solvent to minimize the effect of association of solutes.

For the ternary systems a few remarks must be added. The dielectric constant of the mixed solvent composed of ca. 0.7 benzene and 0.3 dioxane in weight fraction is about 2.26 compared with 2.27 of bezene. Even such a small change in the dielectric constant of the medium may cause the change in polarization due to the solvent effect. Generally speaking, the following factors are considered to contribute to the solvent effect: (1) dielectric constant of the medium, (2) anisotropy of solvent molecules, (3) polarizability of solute molecule and (4) geometrical shape of the solute molecule. The change in polarization by the first factor was estimated as the order of magnitude of 0.1 cc.[9] Contributions of the other factors are difficult to estimate, but will probably lie within the limit of experimental errors. The experiemntal data for the ternary systems were, therefore, employed without any correction for the solvent effect. Molecular polarization obtained by the usual method of extrapolating to zero concentration contains, however, the contributions of both the free molecules and the molecular complexes. In order to divide the observed value into polarization of the free

8) A. A. Maryott and F. Bucklay, *N. B. S. Circular*, **537**, 13 (1953).
9) K. Shogenji, *J. Phys. Soc. Japan*, **12**, 166 (1958).

molecules and that of the molecular complexes, the following procedure was adopted.

Let us consider the equilibrium for the complex formation between molecules A and B. We assume the interaction between A and B to be one to one. The equilibrium constant of this system is

$$K=\frac{x}{(a-x)(b-x)}=\frac{1}{(a-x)(b/x-1)} \quad (1)$$

where a and b are concentrations of molecular species A and B, respectively, in the initial state and x is that of the molecular complex. A is dioxane and B is benzyl alcohol or phenol in the present work. When b is reduced smaller, x also diminishes, and the ratio $f_x=x/b$, i.e., the fraction of the complex in the system approaches to a definite value,

$$\lim_{b\to 0} f_x=\lim_{b\to 0} x/b=aK/(aK+1) \quad (2)$$

since x becomes negligible against a in the denominator of Eq. 1. The formation constants are reported to be about 5,000[10] and 9,400[11] for benzyl alcohol-dioxane and phenol-dioxane complexes, respectively, using mol./cc. as the unit of concentration. Hence f_x is calculated to be 0.942 for the former, and 0.976 for the latter. The contribution of the free proton donor to the observed polarization is, therefore, estimated as $93.8\times 0.058=5.4$ in the former, and $84.6\times 0.024=2.0$ in the latter. If the difference between the observed polarization and the above one is divided by the fraction of the complex, then the value for the true polarization of the complex is obtained as 97.9 cc. for benzyl alcohol-dioxane, and 96.9 cc. for phenol-dioxane. These values are almost the same as those without any correction. It can therefore be concluded that there is no need for this correction when the equilibrium constant is comparatively large and, moreover, the nonpolar proton acceptors exist in large quantities.

Discussion

Perturbation of the proton donor by the proton acceptor and vice versa will be relatively small since the energy of hydrogen bonding is generally about 5 kcal./mol. or so. Hence, the deformation of σ-orbitals or even that of lone pair orbitals not participating in the hydrogen bond but existing in its neighborhood, is completely out of the question in the present treatment as generally believed, whereas in the case of the polarizable π-orbitals their deformation is comparatively large even by a small perturbation. It seems probable therefore that the change in the distribution of π-electrons may be induced by the access of lone pair electrons of a proton acceptor within the range of van der Waals radius. Coulson and Sutton[12] already discussed the hyperpolarizability of benzene and pointed out the importance of this effect in the vicinity of an ion or a dipole. The system of benzyl alcohol-dioxane will not need consideration of the hyperpolarizability as already stated. Contrary to this, the system of phenol-dioxane is supposed to receive a comparatively large effect. It will, therefore, be necessary first to consider the polarizability of the π-electrons of phenol due to the lone pair field of the proton acceptor. To estimate this effect, we try at first to determine the simple molecular orbitals of phenol and those of dimethyl ether, the molecular size of which is presumed to be half as great as a dioxane molecule, and then to evaluate the induced polarization of the π-orbitals of phenol. Then a brief discussion on the delocalization due to hydrogen bonding will be given.

Molecular Orbitals of the π-Electrons of Phenol.—Molecular orbitals of π-electrons of phenol were determined by the use of Matsen's parameter[13]. All the notations used in this section are the same as those of Matsen's paper. According to the molecular symmetry the secular determinant of the seventh order was factored into one of the second and one of the fifth order. All the orbitals obtained by solving these secular determinats are shown in Table III. Orbitals belonging to the symmetry group B_1 are the same as those of benzene, whereas those of A_1 receive a modification as shown in this table. An energy and a moment of each molecular orbital are also tabulated. The calculated π-moment is 1.46 D and its direction is directed toward the benzene ring from the

position of the oxygen atom, the positive pole lying at the oxygen nucleus.

Equivalent Orbitals of Dimethyl Ether. —The LCAO SCF MO method developed by Roothaan[14] will give the most reliable results for the electronic structure of a molecule. However, the low symmetry of the molecule of dimethyl ether prevents us from following this procedure. On the other hand, the unique treatment by Pople[15] of some simple molecules with lone pair electrons, such as water or ammonia, seems to express the electronic structures of these molecules quite well, though the results obtained by his method show that the lone pair moment may be overestimated. For example, in the case of water the lone pair moment obtained by Pople's method is about twice as large as that obtained by the LCAO SCF MO method[16]. This defect will be overcome by considering properly the apparent nuclear charge of oxygen as seen later.

Our treatment is similar to that by Pople and the values of the dipole moment used in our calculation are 1.30 D[8] and 0.30 D[2] for an ether molecule and a C–H bond, respectively. For the latter, its direction is assumed to be along the direction of the C–H bond with the negative center at the hydrogen atom. Outer electrons of $2s$ and $2p$ alone were considered explicitly and $1s$ inner electrons of the oxygen atom and the two carbon atoms were treated together with the nucleus as the rigid cores. Thus the nuclear charge of oxygen becomes 6 and that of carbon 1.059 upon the following approximations. For the orbitals of each carbon atom the sp^3 hybridization was a priori assumed. Moreover, to avoid complexity arising from the existence of methyl groups, each methyl group was replaced by a single C–H bond and its charge distribution was assumed to be expressed by point charges located at each nucleus with the distance of 1.09 Å. On these assumptions, the hybridization parameters at the oxygen atom and the coefficients in each bonding orbital were adjusted so as to be reconciled with the observed resultant moment. Such a simplification does not seem to be accompanied by any serious error within the limit of the approximation used here in the determination of wave functions.

TABLE IV. MOLECULAR CONSTANTS AND ATOMIC ORBITALS USED IN THE CALCULATION OF EQUIVALENT ORBITALS OF DIMETHYL ETHER, AND THEIR CALCULATED RESULTS

Molecular constants: Bond distance O-C 1.43Å; Bond angle 111°

Atomic orbitals:

$\phi(2s)=(Z^5/3\pi)^{1/2}\ r\exp(-Zr)$

$\phi(2p)=(Z^5/\pi)^{1/2}\ r\cos\theta\ \exp(-Zr)$

where $Z=2.275$ for the oxygen atom

$Z=1.625$ for the carbon atom

Equivalent orbitals

$\chi(l_1)=\cos\varepsilon_l\phi(O_{2s})+\sin\varepsilon_l\phi(O_{2p_1})$

$\chi(l_2)=\cos\varepsilon_l\phi(O_{2s})+\sin\varepsilon_l\phi(O_{2p_2})$

$\chi(b_1)=\lambda\{\cos\varepsilon_b\phi(O_{2s})+\sin\varepsilon_b\phi(O_{2p_1})\}+\mu\psi(c_1)$

$\chi(b_2)=\lambda\{\cos\varepsilon_b\phi(O_{2s})+\sin\varepsilon_b\phi(O_{2p_2})\}+\mu\psi(c_2)$

where

$\psi(c_i)=1/2\{\phi(c_{i2s})+\sqrt{3}\,\phi(c_{i2p})\}$

Acceptable values for the parameters:

$\lambda=0.665$ $\cos\varepsilon_b=0.367$ $\cos\varepsilon_l=0.508$

$\mu=0.475$ $\sin\varepsilon_b=0.929$ $\sin\varepsilon_l=0.860$

15) A. B. F. Duncan and J. A. Pople, *Trans. Faraday Soc.*, **49**, 218 (1953). See also, *Proc. Roy. Soc.*, **A202**, 323 (1950).

16) F. O. Ellison and H. Shull, *J. Chem. Phys.*, **23**, 2348 (1955); L. Burnelle and C. A. Coulson, *Trans. Faraday Soc.*, **53**, 403 (1957).; W. C. Hamilton, *J. Chem. Phys.*, **26**, 345 (1957).

The molecular constants and the atomic orbitals used in evaluating the necessary integrals are tabulated in Table IV together with the final results thus obtained, where the symbols used are the same as those employed by Pople, et al.[15] Necessary overlap integrals and dipole moment integrals are all found in the tables or the formulae given by Mulliken, et al.[17]

The distinction between the present results shown in Table IV and those by Duncan and Pople lies in the hybridization parameters at the oxygen atom. As pointed out by Pople, this discrepancy originates from the small overlap integral between $\psi(c_1)$ and $\psi(c_2)$ because of the comparatively long distance between the two carbon atoms of an ether molecule, and the larger Z-value of Slater's atomic orbital of carbon.

The Induced Polarization of the π-Electrons of Phenol.—The induced polarization due to the lone pair field was easily calculated by means of the first order perturbation theory based on the equivalent and the molecular orbitals already given. The geometrical configuration of the complex between a proton donating molecule and an accepting one is not clear enough for the present case. However, it is well known that in ice a tetrahedral arrangement prevails and its arrangement has the large electrostatic energy[18] and the large overlap integral which is concerned largely with the delocalization energy[19]. It seems, therefore, probable to assume that the three atoms, O–H···O lie on a straight line, though the thermal motion will, in fact, induce some deviation. Moreover the distance between the oxygen atom of phenol and that of ether is not measured in solution. But according to the relationship proposed by Nakamoto, Margoshes and Rundle[20] between the atomic distance and the shift of the infrared absorption, the distance between the two oxygen atoms was estimated as being about 2.9 Å which is larger than that of ice. For the purpose of comparison, the perturbed wave functions of phenol were calculated in the case of three O···O internuclear distances of 2.7, 2.8 and 2.9 Å, respectively. The following two approximations were employed for this calculation. Firstly, only the interaction between the lone pair electrons of ether and the π-electrons of the oxygen atom of phenol was considered, and the interaction of the lone pair electrons with other π-electrons in the benzene ring of phenol was neglected. Molecular integrals required in this computation were obtained by making use of the formulae described in Roothaan's paper[21]. Secondly, an apparent nuclear charge of the oxygen atom of ether was determined by the point charge approximation. The apparent nuclear charges obtained at the three interatomic distances are as follows:

O···O distance, R	2.7	2.8	2.9
Z'	2.200	2.196	2.192

These large values of the apparent charges look curious, and may probably be due, as already stated, to the effect of overestimation of lone pair moments. It is believed that such a defect will be excluded if the same treatment as that of water by Ellison and Shull[16] is carried out. The extent of the interaction between the apparent nuclear charge of the oxygen atom of ether and the π-electrons of the oxygen atom of phenol was also estimated by Roothaan's formulae as before.

Finally we formulate the calculating procedure for the perturbed wave functions of phenol. The perturbation H' is given by

$$H' = 2\int \frac{\chi(l_i)\chi(l_i)}{r} d\tau - \frac{Z'}{r'}$$

The first term represents a coulombic potential due to the lone pair electrons of ether in the orbital, $\chi(l_i)$ which participates in the hydrogen bond, and the second is that due to the apparent nuclear charge Z' of the oxygen atom of ether. The first-order perturbed wave functions of phenol will then be expressed as

$$\chi_i^{(1)} = \chi_i + \sum_{j \neq i} \frac{H'_{ij}}{E_i - E_j}\chi_j, \quad \begin{pmatrix} i=1,7,3 \\ j=1,7,3,5,6 \end{pmatrix}$$

Values of the π-moments calculated from these orbitals are tabulated in Table V at each internuclear separation.

This table shows that the polarization of the π-orbitals arising from the lone pair field is the order of a magnitude of 0.1 D compared with the value of about 0.2 D given by Hampson and Weissberger[22], who

TABLE V. MOMENTS OF THE PERTURBED π-ORBITALS OF PHENOL

At 2.7 Å $\mu=\mu_1+\mu_7+\mu_2+\mu_3+\mu_c$
$=3.704+9.946+10.632+8.250-31.896$
$=0.637$ a.u.$=1.62$ D

At 2.8 Å $\mu=3.647+9.970+10.632+8.277-31.896$
$=0.630$ a.u.$=1.60$ D

At 2.9 Å $\mu=3.615+9.980+10.632+8.92-31.896$
$=0.624$ a.u.$=1.58$ D

The increment of π-moment, $\Delta\mu_\pi$

R in Å	2.7	2.8	2.9
μ in D	0.16	0.14	0.12

estimated the induced moment of the π-electrons due to a polar substituent group by making use of the average polarizability of the molecule. The induced moment decreases almost linearly with the increase of the interatomic distance from 2.7 to 2.9 Å. When we extrapolate it to the distance of 3.5 Å which corresponds to the sum of the van der Waals radii of both the oxygen atom of ether and the O–H of phenol, then the value obtained will be zero. These results show quite well that the theoretical treatment already described is reasonable. But it must be noted that the numerical values thus obtained are those of the interacting molecules which are placed mutually in the fixed configuration.

The Increment of the Dipole Moment Arising from Delocalization.—As is well known, the structures largely contributing to hydrogen bonding are considered as the following three:

[I] O–H O

[II] O^-H^+O

[III] O^-H-O^+

If we suppose that the ratio of the weights of structures I and II is of the same as that in a free state, then the increase of the dipole moment due to hydrogen bonding will be attributable only to the participation of the structure III. Strictly speaking, the transitional structures also must be taken into account. But it is difficult to treat them without making more precise quantum mechanical calculations. Neglecting these transitional structures, we can easily estimate the weight of the structure III from the additional moment observed.

One obstacle remains as yet. That is the direction of the resultant moment of the molecule in the free state. However, in view of the result[16] that the O–H bond moment in a water molecule is not so large as hitherto believed, it is assumed that only the lone pair dipoles make a contribution to the molecular dipole moment of benzyl alcohol. In the case of phenol, the direction of the resultant moment, as usually done, is determined by vectorial combination of dipole moments of both phenol itself and some of *p*-substituted phenols. The result[3] obtained shows that the direction of the resultant vector of phenol makes an obtuse angle of 91° with the O–C bond.

Once the direction of the resultant moment in the free state for benzyl alcohol and phenol, respectively, and the value of the induced moment of phenol in the bonded state are determined, then it is possible to calculate the increment of dipole moment, $\Delta\mu_D$ only due to delocalization.

Firstly, let us discuss the system of benzyl alcohol-dioxane. The bond angle about the oxygen atom of benzyl alcohol was taken to be 110°. Then, the value of $\Delta\mu_D$ obtained from the method mentioned above amounts to 0.10 D. When the interatomic distance between the two oxygen atoms is taken to be 3.0 Å from the shift of the infrared absorption[10], we obtain 14.41 D as the moment referring to the structure III, and its weight is estimated as about 0.7%.

Next, let us consider the system of phenol-dioxane. As the sp^2 hybridization was assumed for the orbitals of the oxygen atom, the bond angle about it was taken to be 120°. The interatomic distance between the two oxygen atoms was estimated as 2.9 Å as already stated. If the value of 0.12 D is used for the induced polarization of the π-electrons as already tabulated, $\Delta\mu_D$ is calculated as 0.21 D. This value corresponds to 1.5% as the weight of the structure III. Although it is qualitatively understood from the viewpoint of acidity that the contribution of the structure III in the latter system is about twice as large as that in the former, further discussion on this point will be given in the forthcoming report together with other data.

Summary

The dielectric measurements for the system of benzyl alcohol-dioxane and that of phenol-dioxane, respectively, were carried out by using benzene as the solvent.

The induced polarization of the π-electrons in the latter system was evaluated based on some assumptions. From these,

the additional moments due to delocalization were estimated and the weights of the structure III were evaluated for both systems.

The authors wish to express their thanks to Professor S. Kawaguchi for his kind inspection and revision of this manuscript, and also Messrs. N. Mataga and K. Nishimoto for their helpful discussions. The cost of this work has been partly defrayed by a Grant from the Ministry of Education.

γ-Hydroxyarginine, a New Guanidino Compound from a Sea-cucumber. I. Isolation and Identification

By Yoshimasa FUJITA

(Received October 28, 1958)

In the course of studies[1] on the extractable naturally occurring guanidino compounds by means of paper chromatography using Makisumi's method[2], the author found an unknown guanidino compound from the extract of a sea-cucumber, *Polycheira rufescens*, and isolated it as a hydrochloride. It was hydrolyzed, though somewhat more slowly than arginine, but completely by the action of arginase, into urea and an unknown amino compound. In 1953, Robin[3] oxidatively prepared γ-guanidinobutyric acid from L-arginine with the action of a homogenate obtained from the hepatopancreas of *Mytilus edulis*. The homogenate from this species appears to contain L-amino acid oxidase only as amino acid oxidase[4]. The isolated compound could also be converted enzymically and chemically into its oxidation products whcih were positive for the Sakaguchi reaction. Further characterizations of the isolated compound and its degradation products led the author to assume the unknown guanidino compound to be γ-hydroxyarginine. Consequently, the unknown amino compound produced from the isolated compound by the action of arginase should be γ-hydroxyornithine.

On the other hand, γ-hydroxyornithine was synthesized according to Tomita's method[5] which was somewhat modified by the author and then transformed into γ-hydroxyarginine by guanidization with S-methylisothiourea. The provisional structures of the isolated guanidino compound and the amino compound produced therefrom were proved to be correct by comparing them on a paper chromatogram with the synthetic γ-hydroxyarginine and γ-hydroxyornithine, respectively.

Experimental

Isolation of the Unknown Guanidino Compound.—The sea-cucumbers used as the material were collected at the tidal zone near the Amakusa Marine Laboratory, the Faculty of Science, Kyushu University. The washed materials (43.5 kg.) removed from their internal organs were chopped in a meat-chopper and introduced into hot water (45 l., 70~80°C) for the purpose of extraction for 2 hr. with stirring. The residue separated from the extract was re-extracted in the same manner. The combined extract, deproteinized with a hot saturated basic lead acetate solution and freed from the lead, was passed through a column of Amberlite IR-120 (H- form). After washing the column with water, the adsorbed fraction was eluted with 2 N aqueous ammonia. The eluate, after removal of the ammonia by evaporation in vacuo, was again passed through a column of Amberlite IR-120 (ammonium form) to adsorb basic substances only. The elution from the washed column was carried out by using the same aqueous ammonia. The eluate freed from the ammonia was made up to 300 ml. with water and neutralized with 6 N hydrochloric acid. The solution, after addition of flavianic acid (50 g.), was heated for 30 min. on a boiling water bath. When the resulting solution was allowed to stand overnight in an

ice-box, a flavianate crystallized out. The flavianate was separated and washed with a small amount of cold water. It consisted almost entirely of the unknown guanidino compound, except for slight contamination with arginine. The product was recrystallized from hot water, until its paper chromatogram showed only one spot with the Sakaguchi or ninhydrin reaction. The purified flavianate was dissolved in hot water (100 ml.), and it was treated with a barium hydroxide solution to remove the flavianic acid moiety in the usual manner. The filtrate freed from the excessive barium was evaporated up to dryness in vacuo. The residue was extracted repeatedly with 50% hot ethanol. The extract, after evaporation to dryness, was dissolved in water (50 ml.), and the resulting solution was brought to pH 6~7 with 1 N hydrochloric acid. It was decolorized with charcoal and concentrated to a syrup in vacuo. The syrup was dissolved in 50% hot ethanol (10 ml.), and then absolute ethanol was added to it until the solution became opalescent. When the solution was kept overnight in a refrigerator, colorless plate crystals of the guanidino compound appeared. The compound was dissolved in a minute amount of 70% hot ethanol and then recrystallized with the addition of absolute ethanol. The yield was about 2.7 g.; m.p. 190~191°C (decomp.); $[\alpha]_D^{23}$ +5.4° (c 2, in 5 N hydrochloric acid).

Anal. Found: C, 31.75; H, 6.95; N, 24.65; Cl, 15.68. Calcd. for $C_6H_{14}N_4O_3 \cdot HCl$: C, 31.79; H, 6.67; N, 24.72; Cl, 15.64%.

It gave the Sakaguchi, the Lieben (iodoform), and ninhydrin reaction, indicating the presence of guanidino, alcoholic hydroxy (on the basis of the hydrogen content, alcoholic hydroxy group is superior to ketonic), and amino groups, respectively.

Enzyme Actions on the Guanidino Compound.—*1. Arginase.*—The arginase used in this experiment was a partially purified beef liver preparation of Step D according to Greenberg[6]. The guanidino compound was incubated to hydrolyze with arginase at pH 9.5 and 35°C for 24 hr. The incubate, after deproteinization with basic lead acetate, was fractionally purified by using Amberlite IR-120 (H- and ammonium forms). Since the purified fraction obtained here showed only one spot on a paper chromatogram with ninhydrin reaction, it was not necessary to carry out further purification. The fraction was decolorized with charcoal and crystallized similarly as in the case of isolation of the guanidino compound. The yield of the recrystallized compound was 280 mg. from 500 mg. of the guanidino compound; m.p. 183°C (decomp.); $[\alpha]_D^{32}$ +21.0° (c 2, in water).

Anal. Found: C, 32.65; H, 6.86; N, 15.2.1 Calcd. for $C_5H_{12}N_2O_3 \cdot HCl$: C, 32.58; H, 7.10; N, 15.17%.

This gave ninhydrin- and iodoform reaction but not the Sakaguchi reaction. The effluent passed through a column of Amberlite IR-120 (H^+ form) was again passed through a column of Amberlite (OH^- form), and from this effluent urea was identified as dixanthylurea and urea nitrate.

2. L-Amino acid oxidase.—The guanidino compound was incubated with the enzyme preparation obtained from the hepatopancreas of *Mytilus edulis* according to Robin's method[3] at pH 6.2 and 35°C for 24 hr. under aeration. The incubate acidified with acetic acid to pH 3~4 was boiled for 10 min. and filtered. To the filtrate (200 ml.) was added 30% hydrogen peroxide (1 ml.) for further oxidation of the keto acid to be produced by oxidative deamination from the guanidino compound, and it was allowed to stand for 15 hr. at room temperature. In this condition the guanidino compound itself is not oxidized at all with hydrogen peroxide. The resulting solution was passed through a column of Amberlite IR-120 (H-form), the column was washed with water, and then the adsorbed oxidation product was eluted from it by using 2 N aqueous ammonia. The eluate was evaporated up to dryness, and the residue was dissolved in 50% hot ethanol. When the solution was cooled in an ice-box, colorless needle crystals of the product appeared. The yield was 100 mg. from 300 mg. of the material; m.p. 238~240°C (decomp.); $[\alpha]_D^{22}$ −15.5° (c 2, in 5 N hydrochloric acid).

Anal. Found: C, 37.26; H, 6.88; N, 26.08. Calcd. for $C_5H_{11}N_3O_3$: C, 37.25; H, 7.11; N, 26.25%.

This compound gave the Sakaguchi and iodoform reaction, but not ninhydrin reaction.

Identification of the Oxidation Product.—*1. Reduction with hydroiodic acid.*—The oxidation product (10 mg.) was heated with hydroiodic acid (d=1.7, 0.5 ml.) for 2 hr. at 140°C in a sealed tube. After removal of the hydroiodic acid, the solution was tested by paper chromatography. On the basis of the result, it was found that the product was reduced to a compound which was identified as γ-guanidinobutyric acid (Table I).

The R_f values shown in Tables II and III were also obtained by using the same procedures.

2. Comparison with the synthetic γ-guanidino-β-hydroxybutyric acid.—In a preliminary experiment, it was observed paper-chromatographically

6) D. M. Greenberg, "The Enzymes", vol. I, edited by J. B. Sumner and K. Myrbäck, Academic Press Inc., New York (1951), p. 905.

that the naturally occurring guanidino compound was oxidatively degraded with barium permanganate to guanidine and glycocyamine by way of an intermediate which was later proved to be identical with the oxidation product formed by the action of L-amino acid oxidase. The production of glycocyamine led to the conclusion that the alcoholic hydroxy group should situate in β- or γ-, probably γ-position, but not δ-position of the guanidino compound; accordingly, the structure of the enzymatic oxidation product before reduction by hydroiodic acid is to be γ-guanidino-β-hydroxybutyric acid. The conclusion was supported satisfactorily by comparing the paper chromatographic behaviors of the oxidation product with those of the synthetic γ-guanidino-β-hydroxybutyric acid[7,8] (Table II).

TABLE II. R_f VALUES OF OXIDATION PRODUCT WITH OXIDASE AND γ-GUANIDINO-β-HYDROXYBUTYRIC ACID

	Solvent			
	I	II	III	IV
Oxidation product	0.40	0.38	0.48	0.35
γ-Guanidino-β-hydroxybutyric acid	0.40	0.38	0.48	0.35

Synthesis of γ-Hydroxyornithine.—Finely powdered sodium ethyl acetylaminomalonate (24 g.) and γ-phthalimido-β-hydroxypropyl chloride (24 g.) were thoroughly mixed, and the mixture was heated at 140~150°C for 5 hr. with vigorous stirring. To the extremely viscous reaction mixture was added concentrated hydrochloric acid (100 ml.), and it was refluxed for 10 hr. and then allowed to stand overnight. The filtrate removed from the phthalic acid was concentrated in vacuo. Dilution with water and evaporation in vacuo were repeated three times to remove the excess of hydrochloric acid as much as possible. The syrup obtained thus was dissolved in water (200 ml.), and from this solution a basic fraction was separated by using Amberlite IR-120 (H- and ammonium form) in the same manner as described in the isolation procedures for the guanidino compound. The basic fraction, after being passed through a column of finely powdered Amberlite IR-120 (ammonium form, 100~200 mesh, 3 cm. ×40 cm.), was fractionally eluted and collected as follows. The column was washed with water, and the adsorbed substances were developed and eluted with 0.2 N aqueous ammonia. The eluate collected between 350 and 650 ml. was concentrated to a syrup in vacuo. The syrup was dissolved in a small amount of water, and the solution was adjusted to pH 6~7 with 1 N hydrochloric acid, decolorized with charcoal, and again concentrated to a syrup in vacuo. The syrup dissolved in a small amount of 50% hot ethanol was subjected to crystallization in an ice-box with the addition of absolute ethanol. After 2 days, the crystals of γ-hydroxyornithine hydrochloride were obtained. Yield, 8%; m. p. 181~183°C (decomp.).

Anal. Found: C, 32.72; H, 7.30; N, 15.65. Calcd. for $C_5H_{12}N_2O_3 \cdot HCl$: C, 32.53; H, 7.10; N, 15.17%.

Synthesis of γ-Hydroxyarginine.—γ-Hydroxyornithine hydrochloride (370 mg.) and S-methylisothiourea (280 mg.) were dissolved in 1 N sodium hydroxide (5 ml.). The solution which had been left to stand for 5 days at room temperature was passed through a column of Amberlite IR-120 (H- form). After washing the column with water, the adsorbed compounds were eluted with 2 N ammonia. The eluate was evaporated up to dryness in vacuo and the residue was dissolved in water (10 ml.). The solution was heated on a boiling water bath for 30 min. with the addition of flavianic acid (2 g.). On keeping the solution for 2 days in an ice-box, a flavianate of γ-hydroxyarginine crystallized out. The flavianate, after removal of the flavianic acid moiety in the usual manner, was converted into γ-hydroxyarginine hydrochloride. Yield, 57%; m. p. 189~190°C (decomp.).

Anal. Found: C, 31.88; H, 6.76; N, 24.83. Calcd. for $C_6H_{14}N_4O_3 \cdot HCl$: C, 31.79; H, 6.67; N, 24.72%.

Comparison of the Naturally Occurring Guanidino and Amino Compounds with the Synthetic Ones.—The synthetic γ-hydroxyarginine and γ-hydroxyornithine showed the same paper chromatographic behaviors as those of the naturally occurring guanidino compound and the amino compound produced therefrom by the action of arginase as shown in Table III.

TABLE III. R_f VALUES OF NATURALLY OCCURRING GUANIDINO AND AMINO COMPOUNDS AND SYNTHETIC ONES

	Solvent			
	I	II	III	IV
Guanidino compound	0.16	0.19	0.20	0.17
γ-Hydroxyarginine	0.16	0.19	0.20	0.17
Amino compound	0.12	0.15	0.17	0.13
γ-Hydroxyornithine	0.12	0.15	0.18	0.13

Summary

A new guanidino compound was isolated from a sea-cucumber, *Polycheira rufescens*, and identified as γ-hydroxyarginine. γ-Hydroxyornithine and γ-guanidino-β-hydroxybutyric acid produced enzymically from the guanidino compound were also isolated and identified. It was, further, concluded that the new guanidino compound susceptible to arginase and L-amino acid oxidase should be γ-hydroxy-L-arginine, although the configuration of the γ-hydroxy group was not yet decided.

Formation and Aging of Precipitates. XII. Studies on Types of Crystal Growth of Barium Sulfate by Dissolution in Water*

By Kazuyoshi TAKIYAMA

(Received November 4, 1958)

Barium sulfate is one of the sparingly soluble salts and it gradually dissolves in water. The investigation of dissolution of barium sulfate in EDTA solution was reported[1], but hitherto no morphological study has been made. The author previously reported the investigation of growth process of barium sulfate precipitate[2]. The precipitate was purified by the diffusion washing, that is, a drop containing the precipitate was placed on a Formvar film floating on the surface of distilled water for about ten minutes and the soluble matter was made to diffuse through the film into the water below. About ten minutes were suitable for the washing process while, under too long time of washing, the precipitate tended to dissolve in water. The present investigation is intended to study the type of crystal growth of barium sulfate by the dissolution of the crystal under the diffusion washing for a long period.

Sample.—Two kinds of barium sulfate precipitates were used in the dissolution by diffusion washing. One was the oval particles prepared by the method described in the previous paper[3], and the other was the thin rectangular particles prepared by direct mixing of dilute reagents[4].

Experimental.—A drop of the suspension containing the precipitate mentioned above was placed on a thin Formvar film floating on the surface of distilled water. The drop was left for several hours or one day to let ions diffuse from the drop into the water below. The film was then scooped up with a specimen grid for electron microscopy. Both the fresh and the aged precipitates were examined.

Experimental Results and Consideration

Oval Crystal. — The freshly prepared oval particles as shown in Fig. 1a changed to those as shown in Figs. 1b and c after they were treated with water for three hours. The radial arrangement of small particles are observed in each oval particles. It seems that the oval particles, subjected to dissolution, have been formed by the repetition of dendritic growth, the rate of which is rapid and slow alternately, and that the weakly oriented parts around the particles dissolve in water easily while the comparatively stable parts are not easily soluble, thus the radially arranged particles can be observed. Several hours after, the oval particles dissolved in water and changed in appearance as shown in Figs. 2a and c. The particle shown in Fig. 2a has still the original orientation of crystal structure and the orientation of crystal shown in Fig. 2c was disordered, as was proved by electron diffraction pattern shown in Figs. 2b and d.

Oval particles which were aged for about one day in the mother liquid changed in appearance as shown in Figs. 3a and b. In the aging process, the crystal structure of particles, especially that of the surface of particles, seems to become perfect gradually. Thus in the case of an aged particle, the inner part

of particle dissolved faster than the surface part which remained undissolved as shown in Fig. 3b.

Rectangular Thin Crystal.—Freshly prepared rectangular particles dissolved from the corner of particles as shown in Fig. 4. The corner of the slightly dissolved particles has many steps as shown in Figs. 4b and c. The rectangular particles are the perfect single crystal as described in the previous paper[4] and their growth seems to agree with the perfect crystal growth theory proposed by Kossel and Stranski[5]. Thus the particles seem to have grown stepwise and to have many steps which are large in some parts. Then weak parts at the surface of particles dissolved quickly and many of these large steps appeared around the particles.

The aged rectangular perfect crystals dissolved in water and gave the figure as shown in Fig. 5. The particles began to dissolve from the side of crystals, that is, from (0 1 0) plane (Fig. 5a), and the inner parts dissolved faster than the surface parts of particles (Fig. 5c). The surface of aged particles seems to become stable by complete orientation of crystal structure during digestion in mother liquid as in the case of oval particles. The particle shown in Fig. 5a (arrow) has a perfect single crystal structure (Fig. 5b) and the single crystal structure of the particle shown in Fig. 5c has begun to decompose (Fig. 5d) as examined by electron diffraction method. The crystal structure of the surface part remained almost perfect even after one day's treatment with water.

5) I. M. Stranski, *Z. phys. Chem.*, **136**, 259 (1928).

Summary

The oval and rectangular crystals of barium sulfate precipitates seem to grow through the dendritic and perfect crystal growth processes, respectively. These particles dissolve in the process of diffusion washing. The oval particles dissolved slightly show the dendrite structure in them, and the rectangular particles dissolved slightly show the large steps around the particles. Thus these particles proved to have grown through dendritic and perfect crystal growth processes, respectively. The surface of the aged particles of both oval and rectangular crystals become stable by digestion in mother liquid; hereby the dissolution rate of inner parts of particles is faster than that of surface parts of them.

The author desires to thank Professor Eiji Suito of Kyoto University for his guidance. He also wishes to express his hearty thanks particularly to Professor Masayoshi Ishibashi of Kyoto University for his continuous advice and encouragement.

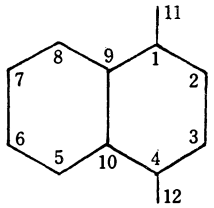
Electronic Structures of Naphthalenediols. I. α, α'-*Naphthalenediols*

By Kichisuke NISHIMOTO and Ryoichi FUJISHIRO



(Received November 4, 1958)

While the electronic structures of substituted benzenes have been studied by many authors, the theoretical investigations of those of substituted naphthalenes have been scarcely ever made[1-4], because of difficulties of the calculation due to low symmetry of these molecules and the presence of many π-electrons to be considered. The spectra of naphthalene mono-derivatives show[5] in general two kinds of characteristic picture depending upon the position of substitution, either β or α positions. In the di-derivatives, two substituents are bonded with rings in two ways, that is, both with the same

ring and each with the different rings. This seems to lead additional effects on their molecular properties. De Laszlo[6] showed that fourteen isomeric dichloronaphthalenes could be classified spectroscopically as aa, ab and bb compounds. But as pointed out by Daglish[7] in the case of naphthalene di-derivatives having strongly conjugating substituents, such as hydroxyl, amine etc., this classification is an over-simplification of the problem. In the present paper theoretical treatments based on the simple MO theory will be applied to the electronic structures of α,α'-naphthalenediols, such as 1-4, 1-5 and 1-8 diols, in order to establish the effects of substituents on their molecular properties. The electronic structures of β,β'-naphthalenediols will be considered in the next paper.

Method of Calculation.—The method is based on the simple LCAO MO theory with only fourteen $2p\pi$ electrons considered explicitly. The Coulomb and the exchange integrals used are the same as those in the previous paper[8], where the electronic structure of phenol was discussed. All the Coulomb integrals for carbon atoms are taken as equal to α. When the non-uniformity of charge distribution is small, the above assumption may be approximately held. In order to simplify the calculation we make this approximation. The numbering of atoms and the symmetry orbitals for the moleclues are shown in Fig. 1. A, B, A_2 and B_1 in the figure express the irreducible representations, to which each symmetry orbital belongs.

Results and Discussion

(A) MO's and their Polarization.—The calculated MO's and their energies for the naphthalenediols are summarized in Table I.

The comparison of the MO's of the naphthalene[9] and those of diols obtained here makes it clear that the signs of the coefficients at each carbon AO in each MO are unchanged by the introduction of the hydroxy groups. Thus, so far as the mono- and di-derivatives are concerned, it is not too much to say that the effect of substitution brings about some modification of the MO's of parent hydrocarbon, but the extent of these modifications is not so large as to destroy their orbital characteristics. This situation will give a basis to the assumption that in many cases the perturbation theory supplies qualitatively useful results, even if the effect of the substitution amounts to considerable extent. In the naphthalene molecule, φ_1 is totally symmetric for the symmetry operation with respects to the principal axis and has no node of the wave function. For the naphthalenediols, φ_1's of them have still no node, but they are strongly polarized along the direction toward the substituents in a regular manner. If we try to measure the degree of polarization by the value of $C_{1\mu}/C_{1\mu_0}$, where the $C_{1\mu}$ is the square of coefficient at μ-th carbon AO in φ_1 of the diol and the $C_{1\mu_0}$ is that of naphthalene, these values are the greatest at the carbon atoms bonded with a hydroxy group and decrease with the increase in the distance between the μ-th carbon atom and the substituent. For the case of 1-8 diol, the values at the carbon atoms numbered by 1, 2, 3 and 4 in Fig. 1 are 1.367, 0.925, 0.656 and 0.591, respectively. This polarization is similar to the inductive effect which is usually regarded as the polarization of σ-cores

caused by the introduction of the polar group into the molecule. But, when we take $\beta_{CO}=0$, this polarization is absent, so far as invoking the simple theory, since the interactions between the $2p\pi$ electrons of the substituents and of the naphthalene ring are impossible in this case. If the polarizations of φ_1's are inductive, it is expected that the value of C_{11}/C_{11_0} for 1-8-diols is the greatest and the smallest for 1-5-diol. Actually, their values are 1,367, 1,319 and 1.251 for 1-8, 1-4 and 1-5-diols, respectively. Although the all MO's for the diols have the same numbers of nodes as those for the corresponding naphthalene MO's, the regular polarizations are not recognized in them except φ_1's. In the light of the above fact, we may except that when the overlap between the electronic cloud of conjugated molecule and that of the attacking molecule is present, the lowest π-orbital of the former will be most sensitive to the influence of the latter. The occupied lowest π-orbital will, therefore, play the most important role for the rearrangement of charge distribution of the molecule produced by the approach of the reagent.

(B) Absorption Spectra. — It is well known that the introduction of the hydroxy group into the α-position of naphthalene causes a very large bathochromic shift in the p-band with some distortion of the fine structure and a rather small shift in the α-band. As mentioned by Daglish[7] and Spruit[10], the spectra of α, α'-diols also have those characteristic features, but these bathochromic shifts in the p-bands are larger in 1–4 derivative and slightly larger in 1–5 compound than that in α-naphthol. Comparison of the energy level diagrams given in Fig. 2

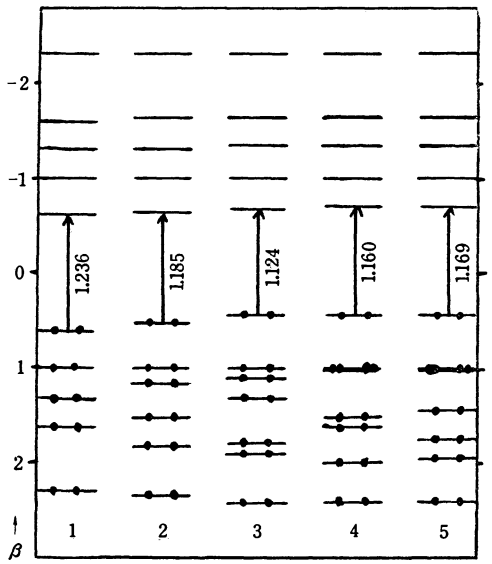

Fig. 2. Energy level diagrams.
1. naphthalene
2. α-naphthol
3. 1-4 naphthalenediol
4. 1-5 naphthalenediol
5. 1-8 naphthalenediol

makes it possible to expect that the spectra of 1–8 diol may be very close to that of 1–5 diol, since the spacing of their levels concerned with the electronic transitions in the near ultraviolet region are very similar to each other. This is the case of Hochstein et al.[11], who reported that the spectroscopic distinction between them was difficult. The energy level diagram of α-naphthol which is calculated by using the same parameters for diols is also given in Fig. 2. The numerical values given in Fig. 2 express the orbital energy differences between φ_7 and φ_8 for the corresponding compounds in the units of β, respectively. The comparison of these values suggests that the wave lengths of absorption corresponding to the $\varphi_7 \rightarrow \varphi_8$ transitions which are closely related to the p-band are in following order; 1–4 diol > 1–5 diol $\simeq$ 1–8 diol $\simeq$ α-naphthol.

The fact that the orbitals having orbital energies of $\pm\beta$ are not affected by the substitution in the α-positions of naphthalene may provide a determining factor for the discussion of electronic transitions concerned with α-bands of α-compounds, because these orbitals are closely connected with them. Experimentally observed distortion of the fine-structure in the p-band will be reasonably attributable to the anharmonicity produced by the ununiform charge distribution and the alteration of the bond orders. The full discussion about the electronic transitions on the ground of the method involving the electronic interaction will be desirable. Here, we will try no further discussion about this problem.

(C) Extra Delocalization Energies and Molecular Diagrams.—Delocalization of the $2p\pi$-electrons of substituents into the naphthalene ring brings the excess of stabilization energies (extra delocalization energies) for the molecule as a whole. These values per one hydroxy group are evaluated to be 0.1807, 0.1851 and 0.1866β for the 1–4, 1–5 and 1–8 diols, respectively. A naive consideration will give larger extra delocalization energy for greater charge migration. Actually, if we plot these values against the magnitudes of the charge migrations from the hydroxy

10) C. J. P. Spruit, *Rec. trav. chim.*, **68**, 309 (1949).
11) F. A. Hochstein et al., *J. Am. Chem. Soc.*, **75**, 5457 (1953).

group into the naphthalene ring, a linear relationship is obtained as shown in Fig. 3. It is surprising that a point corresponding to the phenol, which is obtained from our previous paper[9], is also located on this line. This fact gives us an interesting suggestion that the degree of charge migration will be estimated by only the calculation of orbital energies of the molecule. This seems to give a theoretical background to a well-known conception of the electronic theory in organic chemistry that the acidity of the aromatic hydroxy derivatives is closely connected with the magnitude of charge migration. In the case of α-naphthol, the value of extra-delocalization energy is $0.1862\,\beta$. Its magnitude of charge density at the hydroxy group will be, therefore, expected to be comparable with that of 1–8 diol.

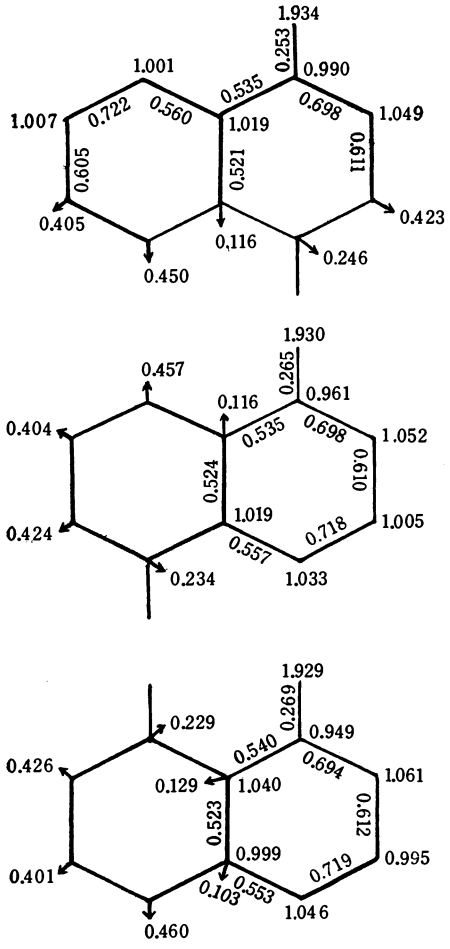

Fig. 4. Molecular diagram.

As seen from the molecular diagrams given in Fig. 4 the charge distributions in the molecules show a sharp difference according to the type of substitution, either two hydroxy groups bonded with the same ring or not. Namely, in the case of 1–4 diol the migrated charges are, for the most part, localized within one ring whereas in those of 1–5 and 1–8 diols they are equally distributed into both rings. In the discussion of the molecular properties, such as reactivity, of the naphthalene di-derivatives this characteristic charge distribution will supply a useful information.

Summary

The simple LCAO MO method was applied to the electronic structures of α,α'-naphthalenediols, using the same parameters as those of phenol based on the ASPMO calculation. The theory proved that

(a) the lowest π-orbital of the molecule would be the most sensitive to the influence of the external molecular field,

(b) the absorption spectra of diols were satisfactorily correlated with their energy level diagrams, and

(c) the extra delocalization energies produced by the charge migrations from the hydroxy groups into the naphthalene ring increased linearly with the increment of the magnitude of charge migrations.

The authors express their gratitude to Mr. N. Mataga for his helpful discussions.

Expansion Formulae of Secular Determinant in Simple LCAO MO Treatment of Aromatic Hydrocarbons

By Kenichi FUKUI, Chikayoshi NAGATA, Teijiro YONEZAWA and Akira IMAMURA

(Received November 17, 1958)

In the LCAO MO treatment of conjugated molecules, it goes without saying that the secular determinant must be known in its expanded form in order to solve it numerically. The use of secular determinant is not necessarily restricted to finding its roots. Coulson and Longuet-Higgins[1] obtained the integral formulae for electronic energy, bond order and various kinds of polarizability in which the integrands were expressed in terms of secular determinants. Also Baba[2] and the present authors[3] pointed out the importance of the coefficients in the expansion of minors of secular determinant for predicting the reactivity of alternant hydrocarbons.

In this paper, we derive several formulae which are useful for expanding the secular determinant of aromatic hydrocarbons. By using these formulae, the secular determinant can be expressed in terms of that of a smaller molecule and the laborious calculation for large molecules can be considerably simplified.

The Expansion Formulae of Secular Determinant for the Aromatic Hydrocarbon.—In the first, the types of "growth" of aromatic hydrocarbons are classified into five as shown in Fig. 1. The first, the third, and the fifth are tentatively named "even growth", and the second, and the fourth "odd growth". Then, an even molecule is formed either by an even growth of an even molecule, or otherwise by an odd growth of an odd molecule, and the formation of an odd molecule results from an odd growth of an even molecule or from an even growth of an odd molecule.

If we put the secular determinants of a molecule before and after the growth as $\Delta(\lambda)$ and $D(\lambda)$, respectively, the expansion formulae for each type are obtained

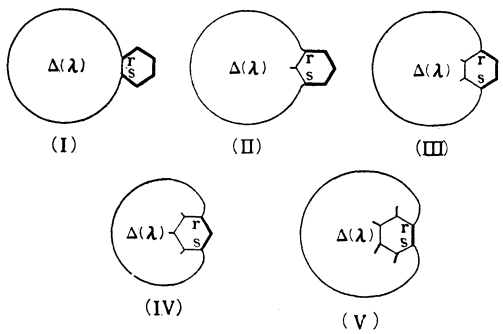

Fig. 1. The types of "growth" of aromatic hydrocarbons are shown. (I) is the first type of growth and (II) is the second type of growth and so on. The thick lines indicate the bonds formed as a result of "growth".

as follows:

For the first type of growth,

$$D(\lambda)=(\lambda^4-3\lambda^2+1)\Delta(\lambda)+\lambda(\lambda^2-2)\{\Delta_{rr}(\lambda)+\Delta_{ss}(\lambda)\}+(\lambda^2-1)\Delta_{rrss}(\lambda)-2(-1)^{r+s+1}\Delta_{rs}(\lambda) \quad (1)$$

For the second type of growth,

$$D(\lambda)=-\lambda(\lambda^2-2)\Delta(\lambda)-(\lambda^2-1)\{\Delta_{rr}(\lambda)+\Delta_{ss}(\lambda)\}-\lambda\Delta_{rrss}(\lambda)+2(-1)^{r+s+1}\Delta_{rs}(\lambda) \quad (2)$$

For the third type of growth,

$$D(\lambda)=(\lambda^2-1)\Delta(\lambda)+\lambda\{\Delta_{rr}(\lambda)+\Delta_{ss}(\lambda)\}+\Delta_{rrss}(\lambda)-2(-1)^{r+s+1}\Delta_{rs}(\lambda) \quad (3)$$

For the fourth type of growth,

$$D(\lambda)=-\lambda\Delta(\lambda)-\Delta_{rr}(\lambda)-\Delta_{ss}(\lambda)+2(-1)^{r+s+1}\Delta_{rs}(\lambda) \quad (4)$$

For the fifth type of growth,

$$D(\lambda)=\Delta(\lambda)-\Delta_{rrss}(\lambda)-2(-1)^{r+s+1}\Delta_{rs}(\lambda) \quad (5)$$

Besides the above types of nuclear growth, the types of branching and bridging also exist in conjugated systems.

1) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, **A191**, 39 (1947).
2) H. Baba, This Bulletin, **30**, 147 (1957).
3) K. Fukui, T. Yonezawa, and C. Nagata, *J. Chem. Phys.*, **26**, 831 (1957).

They are shown in Fig. 2 and are tentatively designated as type 1, 2, ····· , 9. The expansion formulae for them are given as:

For the type 1,

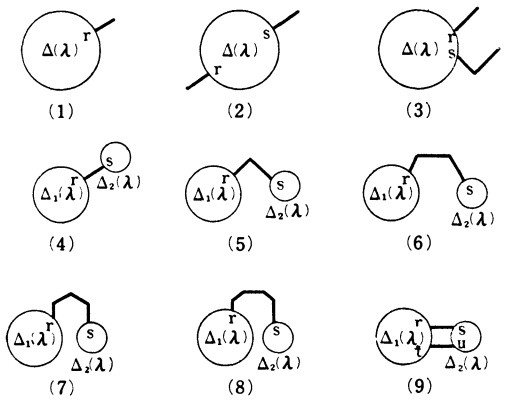

Fig. 2. The types of branching and bridging in conjugated molecules are shown. The thick lines indicate the branches {(1), (2) and (3)} and bridges {(4), (5), (6)·····, (9)} respectively.

$$D(\lambda) = -\lambda\Delta(\lambda) - \Delta_{rr}(\lambda) \tag{6}$$

For the type 2,

$$D(\lambda) = \lambda^2\Delta(\lambda) + \lambda\{\Delta_{rr}(\lambda) + \Delta_{ss}(\lambda)\} + \Delta_{rrss}(\lambda) \tag{7}$$

For the type 3,

$$D(\lambda) = (\lambda^2-1)\{-\lambda\Delta(\lambda) - \Delta_{rr}(\lambda)\} - \lambda^2\Delta_{ss}(\lambda) - \lambda\Delta_{rrss}(\lambda) \tag{8}$$

For the type 4,

$$D(\lambda) = \Delta_1(\lambda)\Delta_2(\lambda) - \Delta_{1rr}(\lambda)\Delta_{2ss}(\lambda) \tag{9}$$

For the type 5,

$$D(\lambda) = -\lambda\Delta_1(\lambda)\Delta_2(\lambda) - \Delta_{1rr}(\lambda)\Delta_2(\lambda) - \Delta_{2ss}(\lambda)\Delta_1(\lambda) \tag{10}$$

For the type 6,

$$D(\lambda) = (\lambda^2-1)\Delta_1(\lambda)\Delta_2(\lambda) + \lambda\{\Delta_{1rr}(\lambda)\Delta_2(\lambda) + \Delta_{2ss}(\lambda)\Delta_1(\lambda)\} + \Delta_{1rr}(\lambda)\Delta_{2ss}(\lambda) \tag{11}$$

For the type 7,

$$D(\lambda) = -\lambda(\lambda^2-2)\Delta_1(\lambda)\Delta_2(\lambda) - (\lambda^2-1)\{\Delta_{1rr}(\lambda)\Delta_2(\lambda) + \Delta_{2ss}(\lambda)\Delta_1(\lambda)\} - \lambda\Delta_{1rr}(\lambda)\Delta_{2ss}(\lambda) \tag{12}$$

For the type 8,

$$D(\lambda) = (\lambda^4-3\lambda^2+1)\Delta_1(\lambda)\Delta_2(\lambda) + \lambda(\lambda^2-2) \times\{\Delta_{1rr}(\lambda)\Delta_2(\lambda) + \Delta_{2ss}(\lambda)\Delta_1(\lambda)\} + (\lambda^2-1)\Delta_{1rr}(\lambda)\Delta_{2ss}(\lambda) \tag{13}$$

For the type 9,

$$D(\lambda) = \Delta_1(\lambda)\Delta_2(\lambda) - \Delta_{1rr}(\lambda)\Delta_{2ss}(\lambda) - \Delta_{1tt}(\lambda)\Delta_{2uu}(\lambda) + \Delta_{1rrtt}(\lambda)\Delta_{2ssuu}(\lambda) - 2(-1)^{r+t+1}\Delta_{1rt}(\lambda)(-1)^{s+u+1}\Delta_{2su}(\lambda) \tag{14}$$

where $\Delta(\lambda)$, $\Delta_1(\lambda)$ and $\Delta_2(\lambda)$ may be secular determinants of any conjugated system. $\Delta_{rr}(\lambda)$, or $\Delta_{ss}(\lambda)$ is the (r, r), or the (s, s) minor and $\Delta_{rrss}(\lambda)$ is the (rs, rs) minor of $\Delta(\lambda)$, and these are obtained by striking off the indicated rows and columns of $\Delta(\lambda)$. The equation of $\Delta_{rs}(\lambda)$ can be obtained according to the theorem proposed by Coulson and Longuet-Higgins[1].

The expansion formulae derived above, are very useful for obtaining secular equations of conjugated molecules, especially of large molecules.

Density Matrix in Simple LCAO MO Method

By Kenichi FUKUI, Chikayoshi NAGATA, Teijiro YONEZAWA and Akira IMAMURA

(Received November 17, 1958)

The LCAO MO method has been applied extensively to the explanation of the facts in organic chemical reaction. That is to say, the static method by Coulson and Longuet-Higgins[1], the localization method by Wheland[2] and the frontier electron method by Fukui et al.[3-7] and many other similar methods have been used successfully to explain the reactivity of a number of conjugated molecules.

In this article, the present authors indicate that the theoretical indexes such as electron density, bond order, and various polarizabilities derived by Coulson and Longuet-Higgins[1], can be given also by a novel method which is entirely different from that of the previous authors.

Partial Density Matrix and Hamiltonian Matrix. — First, we define the following two matrices which are most fundamental in the theory. They are referred to as partial density matrix $\mathbf{D}_j$ and Hamiltonian matrix $\boldsymbol{\alpha}$, and are defined respectively as follows:

$$\mathbf{D}_j \equiv \begin{pmatrix} (C_1^j)^2 & C_1^jC_2^j & \cdots\cdots & C_1^jC_n^j \\ C_2^jC_1^j & (C_2^j)^2 & \cdots\cdots & C_2^jC_n^j \\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots \\ C_n^jC_1^j & C_n^jC_2^j & \cdots\cdots & (C_n^j)^2 \end{pmatrix} \quad (1)$$

$$\boldsymbol{\alpha} \equiv \begin{pmatrix} \alpha_1 & \beta_{12} & \cdots\cdots & \beta_{1n} \\ \beta_{21} & \alpha_2 & \cdots\cdots & \beta_{2n} \\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \beta_{n1} & \beta_{n2} & \cdots\cdots & \alpha_n \end{pmatrix} \quad (2)$$

$$(\beta_{rs}=\beta_{sr})$$

where C_r^j is the coefficient of atomic orbital, ϕ_r, in molecular orbital ψ_j, that is, according to the usual LCAO MO method, ψ_j is expressed as a linear combination of atomic orbitals whose number is n; $\psi_j=\sum_{r=1}^{n} C_r^j\phi_r$. α and β are the Coulomb and the resonance integral, respectively. From Eqs. 1 and 2 the following formulae are easily obtained:

$$\boldsymbol{\alpha}\mathbf{D}_j = \varepsilon_j\mathbf{D}_j \quad (3)$$

$$\boldsymbol{\alpha}\mathbf{D}_j = \mathbf{D}_j\boldsymbol{\alpha} \quad (4)$$

The partial density matrices have the following relations with each other;

$$\mathbf{D}_j=\mathbf{D}_j^2=\mathbf{D}_j^3=\cdots\cdots \quad (5)$$

$$\mathbf{D}_j\mathbf{D}_k = 0 \quad (j\neq k) \quad (6)$$

$$\mathbf{D}_j=\frac{\mathbf{D}_j\boldsymbol{\alpha}\mathbf{D}_j}{\varepsilon_j} \quad (7)$$

$$\mathbf{D}_k\boldsymbol{\alpha}\mathbf{D}_j = 0 \quad (k\neq j) \quad (8)$$

$$\sum_{j=1}^{n}\mathbf{D}_j = \mathbf{E} \quad (9)$$

where $\mathbf{E}$ is unit matrix.

Variation of $\mathbf{D}_j$ leads us to the following relations,

$$\mathbf{D}_j\cdot\delta\mathbf{D}_j+\delta\mathbf{D}_j\cdot\mathbf{D}_j=\delta\mathbf{D}_j \quad (10)$$

$$\mathbf{D}_j\cdot\delta\mathbf{D}_k+\delta\mathbf{D}_j\cdot\mathbf{D}_k=0 \quad (k\neq j) \quad (11)$$

$$\mathbf{D}_j\cdot\delta\mathbf{D}_j\cdot\mathbf{D}_j = 0 \quad (12)$$

$$\mathbf{D}_k\cdot\delta\mathbf{D}_j\cdot\mathbf{D}_k = 0 \quad (k\neq j) \quad (13)$$

$$\mathbf{D}_k\cdot\delta\mathbf{D}_j\cdot\mathbf{D}_l = 0 \quad (l\neq j,\ k\neq j) \quad (14)$$

Perturbation Theory in Density Matrix. — The perturbation theory in density matrix can be constructed in just the same way as in LCAO MO method. When the Hamiltonian matrix $\boldsymbol{\alpha}$ is subjected to perturbation by the amount of $\delta\boldsymbol{\alpha}$, $\mathbf{D}_j$ and ε_j are assumed to become $\mathbf{D}_j+\delta\mathbf{D}_j$ and $\varepsilon_j+\delta\varepsilon_j$, respectively. Then from Eq. 3, the following formulae are obtained.

$$\mathbf{D}_j\cdot\delta\varepsilon_j=\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j+(\boldsymbol{\alpha}-\varepsilon_j)\delta\mathbf{D}_j \quad (15)$$

Multiplying Eq. 15 by $\mathbf{D}_k$ $(k\neq j)$ from the left-hand side, we gain the following relation,

1) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, **A191**, 39 (1947).
2) G. W. Wheland, *J. Am. Chem. Soc.*, **64**, 900 (1942).
3) K. Fukui, T. Yonezawa and H. Shingu, *J. Chem. Phys.*, **20**, 722 (1952).
4) K. Fukui, T. Yonezawa, C. Nagata and H. Shingu, ibid., **22**, 1433 (1954).
5) K. Fukui, T. Yonezawa and C. Nagata, This Bulletin, **27**, 423 (1954).
6) K. Fukui, T. Yonezawa and C. Nagata, *J. Chem. Phys.*, **26**, 831 (1957).
7) K. Fukui, T. Yonezawa and C. Nagata, ibid., **27** 1247 (1957).

$$\mathbf{D}_k\cdot\delta\mathbf{D}_j=\frac{\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k} \tag{16}$$

Similarly, from Eqs. 11 and 16,

$$\delta\mathbf{D}_j\cdot\mathbf{D}_k=\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k}{\varepsilon_j-\varepsilon_k} \tag{17}$$

From Eqs. 16 and 17, using the idempotent nature of $\mathbf{D}_j$ we easily obtain the following formulae:

$$\mathbf{D}_k\cdot\delta\mathbf{D}_j\cdot\mathbf{D}_j=\frac{\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k}\quad(k\neq j) \tag{18}$$

$$\mathbf{D}_j\cdot\delta\mathbf{D}_j\cdot\mathbf{D}_k=\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k}{\varepsilon_j-\varepsilon_k}\quad(k\neq j) \tag{19}$$

From Eqs. 9, 16 and 17,

$$(\mathbf{E}-\mathbf{D}_j)\delta\mathbf{D}_j=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k} \tag{20}$$

$$\delta\mathbf{D}_j(\mathbf{E}-\mathbf{D}_j)=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k}{\varepsilon_j-\varepsilon_k} \tag{21}$$

are obtained. These formulae can be transformed to the following formulae by the aid of Eq. 10, that is

$$\delta\mathbf{D}_j\cdot\mathbf{D}_j=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k} \tag{22}$$

$$\mathbf{D}_j\cdot\delta\mathbf{D}_j=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k}{\varepsilon_j-\varepsilon_k} \tag{23}$$

After adding Eqs. 22 and 23, we use the relation in Eq. 10, then $\delta\mathbf{D}_j$ is expressed as

$$\delta\mathbf{D}_j=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k+\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k} \tag{24}$$

If Eq. 15 is multiplied by $\mathbf{D}_j$ from the left-hand side, the following equation is obtained, that is

$$\mathbf{D}_j\cdot\delta\varepsilon_j=\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j \tag{25}$$

Taking the (r, r) element of Eq. 24, we obtain

$$\delta C_r^j=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{C_r^k\sum_t\sum_u C_t^jC_u^k(\delta\alpha)_{tu}}{\varepsilon_j-\varepsilon_k} \tag{26}$$

Similarly, the (r, r) element of Eq. 25 becomes

$$\delta\varepsilon_j=\sum_t\sum_u C_t^jC_u^j(\delta\alpha)_{tu} \tag{27}$$

Now, we define the density matrix $\mathbf{Q}$ as the sum of the partial density matrices, namely,

$$\mathbf{Q}=\sum_{j=1}^{n}\nu_j\mathbf{D}_j=\begin{pmatrix}q_1 & p_{12} & \cdots\cdots & p_{1n}\\ p_{21} & q_2 & \cdots\cdots & p_{2n}\\ \cdots & \cdots & \cdots & \cdots\\ p_{n1} & p_{n2} & \cdots\cdots & q_n\end{pmatrix} \tag{28}$$

where q and p stand for the electron density and the bond order defined by Coulson and Longuet-Higgins and ν_j is the number of electrons in the jth molecular orbital. Then the variation of density matrix is written as

$$\delta\mathbf{Q}=\sum_{j=1}^{n}\nu_j\delta\mathbf{D}_j=\sum_{j=1}^{n}\nu_j\sum_{\substack{k=1\\k\neq j}}^{n}\frac{\mathbf{D}_j\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_k+\mathbf{D}_k\cdot\delta\boldsymbol{\alpha}\cdot\mathbf{D}_j}{\varepsilon_j-\varepsilon_k} \tag{29}$$

If we take the (r, r) and the (r, s) elements of Eq. 29, δq_r and δp_{rs} are obtained respectively.

$$\delta q_r=\sum_{j=1}^{n}\nu_j\sum_{\substack{k=1\\k\neq j}}^{n}\frac{2C_r^jC_r^k\sum_t\sum_u C_t^jC_u^k(\delta\alpha)_{tu}}{\varepsilon_j-\varepsilon_k} \tag{30}$$

$$\delta p_{rs}=\sum_{j=1}^{n}\nu_j\sum_{\substack{k=1\\k\neq j}}^{n}\frac{(C_r^jC_s^k+C_s^jC_r^k)\sum_t\sum_u C_t^jC_u^k(\delta\alpha)_{tu}}{\varepsilon_j-\varepsilon_k} \tag{31}$$

The total π-electron energy E is the sum of the orbital energy ε_j, that is

$$E=\sum_{j=1}^{n}\nu_j\varepsilon_j \tag{32}$$

then, from Eq. 27, is expressed as

$$\delta E=\sum_{j=1}^{n}\nu_j\delta\varepsilon_j=\sum_{j=1}^{n}\nu_j\sum_t\sum_u C_t^jC_u^j(\delta\alpha)_{tu} \tag{33}$$

Relations among Theoretical Indexes.— Differentiating $\delta\varepsilon_j$, δE, and δC_r^j with respect to α and β, we obtain the following relations:

$$\frac{\partial\varepsilon_j}{\partial\alpha_r}=(C_r^j)^2 \tag{34}$$

$$\frac{\partial\varepsilon_j}{\partial\beta_{rs}}=2C_r^jC_s^j \tag{35}$$

$$\frac{\partial E}{\partial\alpha_s}=\sum_{j=1}^{n}\nu_j(C_r^j)^2=q_r \tag{36}$$

$$\frac{\partial E}{\partial\beta_{rs}}=2\sum_{j=1}^{n}\nu_jC_r^jC_s^j=2p_{rs} \tag{37}$$

$$\frac{\partial C_r^j}{\partial\alpha_s}=C_s^j\sum_{\substack{k=1\\k\neq j}}^{n}\frac{C_r^kC_s^k}{\varepsilon_j-\varepsilon_k} \tag{38}$$

$$\frac{\partial C_r^j}{\partial\beta_{st}}=\sum_{\substack{k=1\\k\neq j}}^{n}\frac{C_r^k(C_s^jC_t^k+C_t^jC_s^k)}{\varepsilon_j-\varepsilon_k} \tag{39}$$

These equations coincide with those

derived by Coulson and Longuet-Higgins[1]. Similarly, from Eqs. 30 and 31, the following formulae are obtained and these are nothing but the polarizabilities defined by Coulson and Longuet-Higgins[1].

$$\frac{\partial q_r}{\partial \alpha_s} = \sum_{j=1}^{n} \nu_j \sum_{\substack{k=1 \\ k \neq j}}^{n} \frac{2C_r^j C_r^k C_s^j C_s^k}{\varepsilon_j - \varepsilon_k} \tag{40}$$

$$\frac{\partial q_r}{\partial \beta_{st}} = \sum_{j=1}^{n} \nu_j \sum_{\substack{k=1 \\ k \neq j}}^{n} \frac{2C_r^j C_r^k (C_s^j C_t^k + C_t^j C_s^k)}{\varepsilon_j - \varepsilon_k} \tag{41}$$

$$\frac{\partial p_{rs}}{\partial \alpha_t} = \sum_{j=1}^{n} \nu_j \sum_{\substack{k=1 \\ k \neq j}}^{n} \frac{C_t^j C_t^k (C_r^j C_s^k + C_s^j C_r^k)}{\varepsilon_j - \varepsilon_k} \tag{42}$$

$$\frac{\partial p_{rs}}{\partial \beta_{tu}} = \sum_{j=1}^{n} \nu_j \sum_{\substack{k=1 \\ k \neq j}}^{n} \frac{(C_r^j C_s^k + C_s^j C_r^k)(C_t^j C_u^k + C_u^j C_t^k)}{\varepsilon_j - \varepsilon_k} \tag{43}$$

Rapid Colorimetric Determination of Selenium by the Tin(II)-Strong Phosphoric Acid Reduction Method

By Toshiyasu KIBA, Ikuko AKAZA and Hiroaki HACHINO

(Received November 18, 1958)

With the increasing demand of the electronic industry for selenium, the element has become critically important, and a rapid and accurate method of detecting and determining the element is badly wanted in the field and in the laboratory. Although selenium occurs widely in many geological formations frequently accompanied with minerals containing sulfur, the amount is so small that chemical analysis of the element is one of the most difficult of techniques. The procedures which have been presented by most investigators are of two parts: decomposition of samples with oxidizing acids, and estimation of the selenium in the solution. However, it is really regrettable that in all the methods the decomposition of the samples is time-consuming and loss of the element is likely to occur during the evaporation of the solution or filtration of the undissolved residue.

Previously the authors devised a new powerful decomposing and reducing agent, tin(II)-strong phosphoric acid[1], by which sulfur in inorganic substances such as ores[2] as well as in organic compounds[3,4] could be taken out as hydrogen sulfide and readily estimated iodimetrically or colorimetrically. A further attempt was made by the present authors to reduce selenates, selenites, and elementary selenium to hydrogen selenide by treatment with the same reagent. As the result of the preliminary experiments it was found that selenium in various forms could be reduced to hydrogen selenide at somewhat higher temperatures than in the case of sulfur. By the powerful decomposing power of the reagent even pyrite can readily and completely be decomposed without any other treatment, and the selenium can be separated as gaseous hydrogen selenide from the sample. The present paper describes the investigation by which a new method for quantitative analysis of selenium is established.

Experimental

Apparatus —The apparatus used in this study is shown in Fig. 1. It is composed of two parts, a reaction vessel (A) and an absorbing part (B). The reaction vessel (A) is a round-bottomed flask of hard glass having a glass cap fitted to its top and provided with inlet and outlet tubes for hydrogen gas. The absorbing part (B) is composed of two test-tubes 3 cm. in diameter. A gas delivery tube (G) is connected with a piece of rubber tubing (R) to the outlet arm of the reaction vessel (A) and inserted into the absorbing solution. A Kipp's apparatus is employed for the production of hydrogen, which is purified by four gas-washing bottles (not shown in the figure) and introduced in the reaction vessel

R: Short piece of rubber tubing

through the inlet arm. The solution used for the purification of hydrogen is described below.

Reagents. — *Strong phosphoric acid.* — Four hundred grams of commercial orthophosphoric acid of extra pure grade (d=1.7) is placed in a 300 ml. conical beaker, and dehydrated by heating on a 500 W hot plate until a thermometer dipped in the liquid indicates 300°C. If the heating takes too long the liquid will become turbid and viscous and useless for the purpose in view. During the heating, the water vapor and the mist of phosphoric acid coming off should be rapidly removed from the neighborhood of the liquid surface through a glass tube, one end of which is held near the liquid surface, the other end being connected to a suction pump. It saves much time in the dehydration.

Tin(II)-strong phosphoric acid.—Fifty grams of tin(II)-chloride dihydrate of extra pure grade is placed in a 300 ml. conical beaker and on it is poured 250 g. of the strong phosphoric acid prepared as described above. The content is heated to 300°C within about 30 min. in the manner of preparation of strong phosphoric acid. After cooling, the tin(II)-strong phosphoric acid thus obtained, a very viscous and possibly slightly turbid liquid, may be stored in a closed vessel.

Tin(II)-chloride solution.—15% in 9 N hydrochloric acid.

Gum arabic solution.—1% aqueous solution.

Hydrogen gas.—Hydrogen gas produced in the Kipp's apparatus is purified by passing through four gas washing bottles containing respectively, water, 1% potassium permanganate in 10% sodium carbonate solution, 2% vanadium(II) sulfate in 6 N sulfuric acid solution, and 5% barium chloride, and is introduced into the reaction vessel through a glass tube in which a copper net is placed to prevent accidental explosion of the gas.

Standard selenious acid solution. — Elementary selenium is dissolved in concentrated nitric acid and evaporated to dryness, and the selenious acid thus formed is sublimed by gentle heating in another vessel. The sublimate is collected and dissolved in water to make a solution containing 3 mg. of selenium in 1 ml. The solution is diluted to a suitable concentration for the following experiments.

Pyrite ore. — Natural pyrite from the Ogoya Mine near Kanazawa City was ground to 200 mesh size and used as a sample to test the procedure established by the present authors.

Other reagents were all of the pure chemical grade and the utensils were of the ordinary kind for the laboratory.

Procedure.—(1) *Decomposition of samples and evolution of hydrogen selenide.*—Take an accurately measured sample—pipet a solution; weigh a solid—containing selenium and put it into the reaction vessel (A, in Fig. 1). The volume of the vessel should be varied according to the amount of the sample to be analyzed. Evaporate to dryness if the sample is a solution. Pour about 10 to 50 g. of tin(II)-strong phosphoric acid over the sample. Put 5 to 10 ml. of 5 N sodium hydroxide solution into each of the absorbing apparatuses as shown in Fig. 1. Connect all the apparatuses. Pass hydrogen gas very rapidly through the apparatus for five minutes to expel the air from the apparatus. Then reduce the flow of the gas to rate of one bubble per second. Cover the top of the reaction vessel with a block of diatomaceous earth (D) as shown in Fig. 1. Heat the bottom and the sides of the reaction vessel by passing an electric current through nichrome wires placed in the diatomaceous earth blocks (C). The voltage of the current should be regulated by a variable transformer. It is unnecessary to keep the reaction temperature constant, but it should be high enough that the content of the reaction vessel seems to be solidified when cooled after the reaction. After about twenty or thirty minutes the heating is stopped.

Disconnect the absorbing vessels from the gas-outlet arm of the reaction vessel, and transfer the contentin to a 100 ml. Erlenmeyer flask with sufficient washings of the gas-delivery tube. Add 30% hydrogen peroxide solution carefully, drop by drop, since when a relatively large amount of sulfur is present the oxidation takes place explosively. By the above treatment hydrogen selenide is oxidized to selenic acid, and hydrogen sulfide to sulfuric acid. Boil the solution for about ten minutes to decompose the residual hydrogen peroxide completely, and cool the solution by dipping the vessel in running water. Add enough concentrated hydrochloric acid to neutralize the sodium hydroxide and 20 ml. in excess to the solution. Boil the contents for about twenty minutes

with a reflux. By this treatment the selenic acid is reduced to selenious acid, whereas the sulfuric acid remains unchanged.

(2) *Photometric determination of selenium.*—Transfer the content of the flask into a 100 ml. measuring flask, put 4 ml. of gum arabic solution in it, and add water to make the total volume about 95 ml. Place the vessel in a thermostat kept at 45°C, and when the temperature of the liquid has become constant, add 5 ml. of the tin(II) chloride solution and leave the vessel in the thermostat for about twenty minutes. Then, the selenious acid will have been reduced to colloidal elementary selenium having a red color. Add more water till the liquid level comes to the mark, and measure the absorbancy of the solution with a photoelectric colorimeter using a 372 mμ-filter and 10 mm.-cells.

A working curve for the colorimetric measurement should be prepared by carrying out the same procedure with known amounts of selenious acid.

Results and Discussion

Reduction of Selenious Acid by the Tin(II)-Strong Phosphoric Acid.—A definite volume of the standard selenious acid solution was placed in the reaction vessel and the reduction of the acid and the evolution of hydrogen selenide were carried out by the procedure. The recovery of the selenium is satisfactory as shown in Table I, 0.1 to 2.5 mg. of selenium being recovered with relative deviation not exceeding 5%.

0.8	0.508	0.508	100.0

Determination of Selenium in Presence of Sulfur.—As selenium is often accompanied with a larger amount of sulfur, it was deemed necessary that the effect of sulfur on this method be first examined. A mixed solution of sodium sulfate and sodium selenite in various ratios was employed for the test, and the determination of the selenium was done according to the procedure described above. The results are shown in Table II, from which it is confirmed that the presence of forty to two hundred parts of sulfur for one part of selenium does not interfere with the determination of the latter. When still larger amounts of sulfur are present in the sample, larger amounts of the tin(II)-strong phosphoric acid should be employed to decompose the sample and to remove the sulfur as hydrogen sulfide. In such cases, a larger amount of the absorbing solution of sodium hydroxide should be used.

Determination of Selenium in Presence of Sulfur and Iron.—Before the method is applied to the determination of selenium in a sulfur-containing ore such as pyrite, the effect of iron should be first examined by carrying out the procedure with a synthetic sample. The analysis was performed with a mixed solution of iron(III) sulfate and sodium selenite for this purpose. As shown in Table III, iron has no influence on the determination of selenium. So the procedure presented above may safely be applied to the determination of selenium in pyrite.

0.4	0.508	0.504

Determination of Selenium in Pyrite.—As all the sulfur and the selenium in the ore could be removed as hydrogen sulfide and hydrogen selenide, respectively, all troublesome treatments such as the dissolving of the ore in nitric and hydrochloric acids and the evaporation of the solution were dispensed with by a single treatment with the tin(II)-strong phosphoric acid. The results obtained by this method are tabulated in Table IV, which are in good agreement with the results obtained by the ordinary acid-dissolving

method. This method takes about two hours, while the usual method takes five or more hours.

Color System of Selenium. — Many methods have been described for the colorimetric determination of minute amounts of selenium, e.g., coloration of elementary selenium by reduction with tin(II) chloride or other reducing agents[5], colorization by pyrrol[6], and by diaminobenzidine[7], but the tin(II) chloride method is considered the simplest. So the method was preferred in this study. To determine the optimum operating wavelength for absorption spectrometry of selenium, an absorbancy-wavelength curve was plotted by means of a spectrophotometer (Hitachi Ltd., Model EPU-2). covering the range between 320 and 500 mμ. The conditions of the experiment were the same as those described in the procedure, The curves obtained are shown in Fig. 2, in which it is seen that remarkable absorption takes place in the ultraviolet region, but the absorbancy of the blank, the solution containing no selenium, increases also in the same region. The authors chose 372 mμ as the optimum wavelength, at which the absorbancy of the blank is scarcely perceptible, and the absorbancy obeys Beer's law when the selenium concentration is from 0.1 to 0.25 mg. in 100 ml. The relation between the amount of the

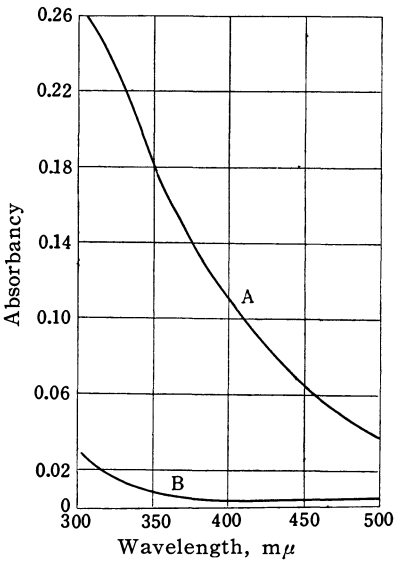

Fig. 2. Spectral absorbance of colloidal selenium.

B: The same solution without the selenium.

selenium taken and the absorbancy measured is expressed by the following equation which was computed from twenty-five measurements by the method of least squares

$$x = 3.558\,I$$

where, x is the amount of selenium taken and I the absorbancy measured. A working curve involves a standard deviation of about 1.5%.

Summary

A new procedure for a rapid determination of selenium has been devised by the present authors. Tin(II)-strong phosphoric acid, previously prepared by the authors, has a remarkable decomposing and reducing power, and selenium in various forms can be reduced to hydrogen selenide which is evolved as a gas from samples. Sulfur in various forms is reduced to hydrogen sulfide at the same time. Solid samples such as pyrite can be allowed to decompose rapidly by simple heating with the reagent in an atmosphere of hydrogen. The gas evolved is introduced into an absorbing solution of 5 N sodium hydroxide. Then, a small

8) H. Goto et al., *Sci. Repts. Research Inst. Tohoku Univ.*, **A, 4**, 28 (1952);**4**, 121 (1952);**5**, 34 (1953); **7**, 23 (1955).

volume of 30% hydrogen peroxide solution is added. Thus sodium selenate and sodium sulfate are formed in the solution. After adding an excess of concentrated hydrochloric acid and boiling for about twenty minutes with a reflux condenser, the selenic acid is reduced to selenious acid, while the sulfuric acid remains unchanged. The solution is kept at 45°C for several minutes, and solutions of gum arabic and tin(II) chloride are added successively. The red color of the elementary selenium is measured at 372 mμ by a photoelectric colorimeter. The recovery of selenium is uniform even in the presence of large amounts of sulfur and iron. The analysis of selenium in pyrite was carried out by this procedure, and the results were in good agreement with those obtained by other methods.

The expense of the present research was met in part by a Grant for Scientific Research from the Ministry of Education, to which the authors' thanks are due.

Crystal Structure of 2-Chloro-1-aza-azulene

By Chihiro TAMURA*, Yoshio SASADA and Isamu NITTA

(Received December 2, 1958)

We have studied several crystal structures of the molecules containing a seven-membered carbon ring, such as tropolone hydrochloride, sodium tropolonate and 1-oxa-azulan-2-one[1-7]. As a part of these serial investigation, the present account deals with the crystal structure of 2-chloro-1-aza-azulene, which Professor T. Nozoe and his collaborators kindly supplied us.

Experimental

Crystal and physical data obtained are: 2-Chloro-1-aza-azulene, C_9H_6NCl, m.p. 72~73°C. Monoclinic, $a=16.00\pm0.07$, $b=7.50\pm0.04$, $c=7.03\pm0.03$ Å, $\beta=113.8\pm0.5$°C.

Absent spectra; $(h\,0\,l)$ when h is odd, $(0\,k\,0)$ when k is odd. Space group; $P2_1/a-{}^5_2C_h$. Four molecules per unit cell. Volume of unit cell; 771.9 Å^3. Density (by flotation); 1.40 g.cm^{-3}. Density (calculated); 1.41 g.cm^{-3}. Linear absorption coefficient for Cu K_α radiation,

$$\mu = 37.5\ \text{cm}^{-1}$$

Total number of electrons per unit cell, $F(0\,0\,0)=336$.

Weissenberg photographs were taken at room temperature around the b and c axes, using Cu K_α radiation. The crystals used, which were cut from a large brown block, were square in cross section with rectangular dimensions:

0.05×0.06 cm. for the b axis rotation,

0.06×0.08 cm. for the c axis rotation.

Intensities were estimated by visual comparison with a calibrated scale. The multiple-film technique was used to correlate strong and weak reflexions, ranging in relative intensities from 8000 to 1 for $(h\,0\,l)$ and from 6000 to 1 for $(h\,k\,0)$ reflexions. Reflexions from 102 and 76 planes were observed out of 135 possible $(h\,0\,l)$'s and 143 $(h\,k\,0)$'s respectively. The corrections for polarization and Lorentz factors were made in the usual way, and that for absorption was omitted.

Results

Structure Determination. — The initial step was intended to locate the chlorine atom by computing Patterson functions $P(uw)$ and $P(uv)$. $P(uw)$ showed three broad peaks, of which two overlapped each other. While the possibility that the one peak is due to the interatomic vector between two chlorines can be excluded by the comparison with $P(uv)$, it was impossible to decide which of the remaining two corresponds to the actual

Cl–Cl vector. Therefore, the trial method was applied to $(h\,0\,l)$ first, in order to obtain the x and z coordinates of all atoms. After satisfactory x and z coordinates were determined, y coordinates were estimated by the trial for $(h\,k\,0)$. Refinements of these atomic coordinates were made by successive two-dimensional Fourier and the least square method. The final atomic coordinates of the chlorine, nitrogen and carbon are listed in Table I. Calculated structure factors $F(h\,0\,l)$ and $F(h\,k\,0)$ are shown with broken lines in comparison with observed values (full lines) in Figs. 1 and 2 respectively. In the structure-factor calculations the atomic scattering factors were taken from McWeeny's paper[8], the values for "valence states" being used for carbon. The best B factors were 3.5 and 4.5 Å^2 for $(h\,0\,l)$ and $(h\,k\,0)$

8) R. McWeeny, *Acta Cryst.*, **4**, 513 (1951).

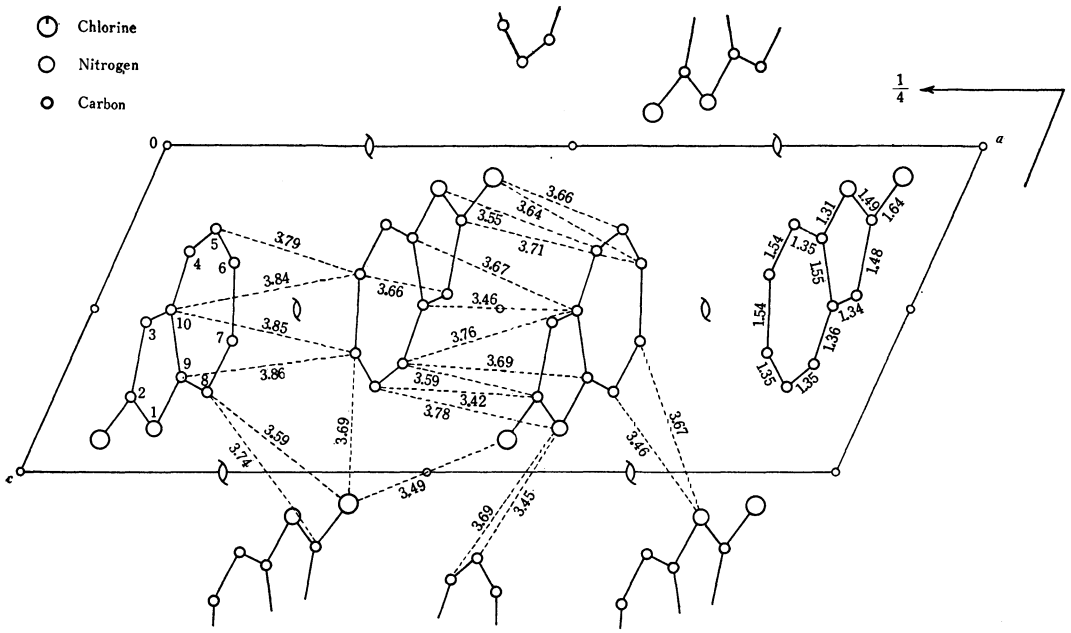

Fig. 5. Arrangement of molecules in the (010) projection, with intra- and intermolecular distances (Å).

respectively. At this stage, R indices become 0.176 for (h 0 l) and 0.231 for (h k 0), if non-observed reflexions are omitted. The electron density projections along the b and c axes are shown in Figs. 3 and 4 respectively.

Description of the Structure.—As the scattering factors modified by thermal coefficients for nitrogen and carbon are hardly different, it is difficult at the earlier stage of analysis to decide which of the atoms, 1 or 3 numbered as shown in Fig. 5 corresponds to the nitrogen. If the atom at 3-position is nitrogen, the R index for (h 0 l) becomes 0.185. On the other hand, if the atom at 1-position is nitrogen, the R index is 0.176 as described in the preceding paragraph. Moreover, the intermolecular distances show that the atom at 1-position has the near approaches to neighboring molecules such as 3.45 and 3.46 Å, which seem unreasonable for the CH–CH contacts. Thus it may be concluded that the atom at the 1-position is nitrogen.

Molecular dimensions (shown in Fig. 5) can not be discussed in detail in view of the rather large standard deviations of the coordinates.

Crystal structure projected along the b axis is shown in Fig. 5. There are no large discrepancies from the ordinarily accepted range of values for the intermolecular approaches. The long and short axes of the molecule make angles of about 50° and 30° with the (0 1 0) plane respectively. An outline of the molecular arrangement in this crystal seems to be of the intermediate type between those in azulene[9] and 1-oxa-azulan-2-one[4,5].

The authors wish to express their sincere thanks to Professor T. Nozoe for supplying the sample and for his continued interest.

*Thermodynamic Studies on Cobalt Complexes. II. Solubility and Standard Free Energy of Formation of $[CoA_6]$-type Salts**

By Motoshichi MORI, Ryokichi TSUCHIYA and Yasuhiro OKANO

(Received August 8, 1958)

Although there are numerous investigations on the cobalt complexes, very few reports[1] have been published on the solubility of these complexes determined at different temperatures, and consequently neither the calculations of the heat of solution have been made nor the discussions from the view point of thermodynamics have been carried on.

In the present study the solubilities of hexamminecobalt(III) complexes in water were determined at various temperatures, and on the basis of these data and from the activity coefficient of hexamminecobalt(III) chloride reported in the preceding paper[2] the heat of solution and the free energy change of the solution were calculated. By using the latter and the standard free energy of formation of the hexamminecobalt(III) ion already known, the standard free energy of formation was calculated for solid hexamminecobalt(III) chloride, bromide, nitrate and perchlorate.

Experimental

Hexamminecobalt(III) chloride was prepared by Bjerrum's method[3]. Hexamminecobalt(III) bromide, nitrate and perchlorate were precipitated from the aqueous solution of the chloride by adding ammonium bromide, nitric acid and perchloric acid, respectively.

Sufficient amount of the sample and water to form the saturated solution was poured into a flask, which was dipped into the thermostat at the desired constant temperature. After the equilibrium of the solution was attained, an aliquot of the solution was taken out through asbestos by a measuring pipette and the solubility was calculated by analyzing the cobalt content of the solution by iodometry[4].

By measuring the specific gravity of the saturated solution by a hydrometer at each temperature the molality m was calculated by means of the following formula,

$$m = 1000C/(1000d - CM)$$

where C is the molar concentration, d, the specific gravity of saturated solution and M, the molecular weight of the solute.

Results

The results obtained for the hexamminecobalt(III) chloride, bromide, nitrate and perchlorate are summarized in Tables I, II, III and IV, respectively.

In the Tables I—IV, $\gamma_\pm$ is the mean activity coefficient of the complex and K is the equilibrium constant of the solution. The methods of the calculation of them are given in the following discussion.

Discussion

Hexamminecobalt(III) Chloride.—When the hexamminecobalt(III) chloride is dissolved into water the change is expressed by,

$$[Co(NH_3)_6]Cl_3(s) = [Co(NH_3)_6]Cl_3(aq.\ a)$$
$$= [Co(NH_3)_6]^{3+}(aq.) + 3Cl^-(aq.)$$

If the activities of the complex salt, the complex cation and the anion in the solution are expressed by $a_{[Co(NH_3)_6Cl_3]}$, $a_{[Co(NH_3)_6]^{3+}}$ and a_{Cl^-} respectively, and the activity coefficients of the complex cation and the anion by $\gamma_{[Co(NH_3)_6]^{3+}}$ and γ_{Cl^-}, the equilibrium constant of the solution, K, is given as follows:

$$K = a_{[Co(NH_3)_6]Cl_3} = a_{[Co(NH_3)_6]^{3+}} \cdot a^3_{Cl^-}$$
$$= (m\gamma_{[Co(NH_3)_6]^{3+}})(3m\gamma_{Cl^-})^3$$
$$= 27m^4\gamma_{[Co(NH_3)_6]^{3+}} \cdot \gamma^3_{Cl^-} \quad (1)$$

When the mean activity coefficient of the salt is expressed by $\gamma_\pm$, the formula 1 is replaced by

$$K = 27m^4\gamma^4_\pm \quad (1')$$

In order to calculate K, it is necessary to know the mean activity coefficient of the hexamminecobalt(III) chloride in each molality. It was obtained by interpolation

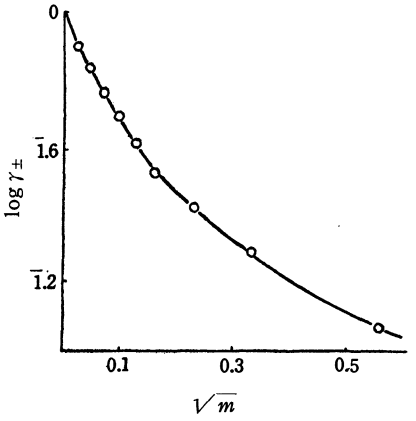

Fig. 1. The mean activity coefficient of hexamminecobalt(III) chloride.

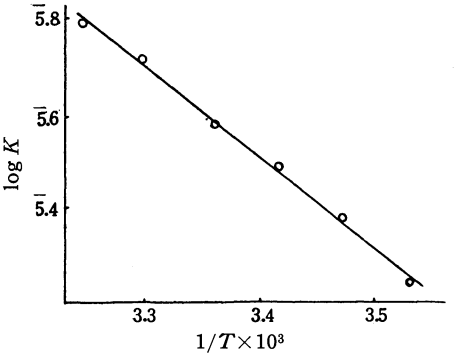

Fig. 2. The relationship between the equilibrium constant and the temperature for hexamminecobalt(III) chloride.

and extrapolation of the curve in Fig. 1 obtained in the preceding paper[2] which gave the relationship between the mean activity coefficient and the molality for hexamminecobalt(III) chloride. The logarithm of K calculated by the formula 1 and given in Table I is plotted against the reciprocal of the absolute temperature in Fig. 2, which shows an almost straight line. By the least square method the equation of this straight line is computed as follows:

$$\log K = 1.8823 - 1873/T \qquad (2)$$

From the inclination of this straight

line or the coefficient of $1/T$, the heat of solution is obtained as $\Delta H=8567$ cal.

As the heat of solution, the value of 9.0 kcal. was determined calorimetrically[5]; this value is in good agreement with our value.

By Kapustinskiĭ[6], the lattice energy of a complex salt was given by,

$$U_{ca}=287.2\frac{\Sigma n\cdot z_1\cdot z_2}{r_1+r_2}\left(1-\frac{0.345}{r_1+r_2}\right) \quad (3)$$

where n is the number of ions dissociated, z_1 and z_2 are the charges of cation and anion, and r_1 and r_2 are the radii of cation and anion, respectively. By Fajans[7], the heat of solution, L, was given by,

$$L = L_1 + L_2 - U_{ca} \quad (4)$$

in which L_1 and L_2 are the heat of hydration of cation and anion. By using these two formulae 3 and 4, the heat of solution of hexamminecobalt(III) chloride is calculated as $\Delta H=13.53$ kcal., which is a little larger than the value, 8567 cal., calculated from the solubility data.

From the heat of formation of solid hexamminecobalt (III) chloride, $\Delta H=-274.1$ kcal.[5], that of the hexamminecobalt(III) ion in unit activity, $\Delta H=-146$ kcal.[8], and that of chloride ion in unit activity, $\Delta H=-40.023$ kcal.[9], given in the literature, the heat of solution of this complex salt can also be calculated as $\Delta H=8031$ cal., which is again in agreement with the value 8567 cal. calculated above.

The standard free energy change of the solution, $\Delta G°$, is computed by the following formula using the value of K given in formula 2,

$$\Delta G° = -RT\ln K = 8567 - 8.61T \quad (5)$$

Values of the standard free energy change of solution at 25°C (298°K), $\Delta G°_{298}=6003$ cal. and the entropy change of solution at 25°C, $\Delta S°_{298}=8.61$ e. u. are obtained; these formulae have never before been found in the literature.

As the standard free energy of formation of the hexamminecobalt(III) ion at 25°C the value of $\Delta G°_{298}=-54.5$ kcal.[10] was already known. By using this value and the heat of formation of this ion, $\Delta H=-146$ kcal.[8], the standard free energy of formation of the ion as the function of temperature is calculated as,

$$\Delta G° = -146000 + 307T \quad (6)$$

From the formulae 5 and 6 and the standard free energy of formation of chloride ion in unit activity, that of hexamminecobalt(III) chloride in the solid state is calculated as

$$\Delta G° = -274660 + 402.9T$$

and the value of $\Delta G°_{293}=-154.55$ kcal. is obtained.

Hexammincobalt(III) Bromide. — The change when the hexamminecobalt(III) bromide was dissolved into water is expressed by,

$$[Co(NH_3)_6]Br_3(s) = [Co(NH_3)_6]Br_3(aq.\ a)$$
$$= [Co(NH_3)_6]^{3+}(aq.) + 3Br^-(aq.)$$

The equilibrium constant of the solution, K, is deduced in the same manner as in the formula 1, if m and $\gamma_\pm$ are replaced by those of the bromide.

If the activity coefficients of the above cation and anion are expressed by γ_+ and γ_-, the mean activity coefficient of the salt, $\gamma_\pm$, is given by $\gamma_\pm=\sqrt[4]{\gamma_+\cdot\gamma_-^3}$. As the activity coefficient of the bromide ion is the same as that of the chloride ion according to Kielland's table[11], the mean activity coefficient of the hexamminecobalt-(III) bromide is assumed to be the same as that of the chloride. Then the value in each molality was obtained by the interpolation of the curve for hexamminecobalt(III) chloride shown in Fig. 1. By using this $\gamma_\pm$ and the molality determined

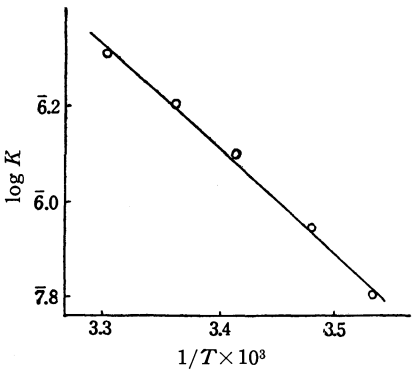

Fig. 3. The relationship between the equilibrium constant and the temperature for hexamminecobalt(III) bromide.

10) A. B. Lamb and A. T. Larson, *J. Am. Chem. Soc.*, 42, 2038 (1920).
11) J. Kielland, ibid., 59, 1675 (1937).

from the solubility measurement, the equilibrium constant K given in Table II was calculated.

The plots of $\log K$ against the reciprocal of the absolute temperature are shown as a straight line in Fig. 3, and the equation of the straight line is calculated by the least square method as

$$\log K = 2.1911 - 2378/T \qquad (7)$$

From this equation the heat of solution is obtained as $\Delta H = 10.026$ kcal.

The heat of solution determined calorimetrically is 12.7 kcal.[5] and that calculated by Kapustinskiĭ's formula 3 and Fajans' one 4, is 13.90 kcal., both of which are a little higher than our value, 10.026 kcal. From the heat of formation of hexamminecobalt(III) bromide in the solid state, $\Delta H = -244.5$ kcal.[5], that of the hexamminecobalt(III) ion in unit activity[8] already given and that of the bromide ion in unit activity, $\Delta H = -28.90$ kcal.[12], the heat of solution of the complex bromide is calculated as 11.8 kcal., which is closer to our value 10.026 kcal. than the two former ones, 12.7 and 13.90 kcal.

The standard free energy change of solution is calculated by the formula 7 as

$$\Delta G^\circ = 10026 - 7.56T \qquad (8)$$

and the value of $\Delta G^\circ_{298} = 7772$ cal. and $\Delta S^\circ_{298} = 7.56$ e. u. are obtained.

From the formulae 8 and 6 and the standard free energy of formation of the bromide ion in unit activity, that of hexamminecobalt(III) bromide in the solid state is calculated as

$$\Delta G^\circ = -242726 + 358.09T$$

and the value of $\Delta G^\circ_{298} = -136.12$ kcal. is obtained.

Hexamminecobalt(III) Nitrate.—As the activity coefficient of the nitrate ion is the same as that of the chloride ion according to Kielland's table[11], the mean activity coefficient of the hexamminecobalt(III) nitrate in each molality is obtained in the same way as that for the bromide from Fig. 1, and the equilibrium constant, K, listed in Table III was calculated by the formula 1′.

The plots of $\log K$ against the reciprocal of the absolute temperature are shown in Fig. 4 as a straight line and the equation of the straight line is calculated as

$$\log K = 3.3797 - 2774/T \qquad (9)$$

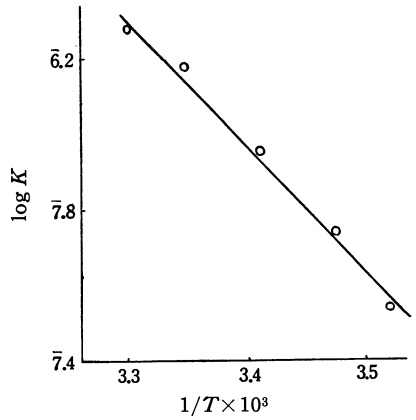

Fig. 4. The relationship between the equilibrium constant and the temperature for hexamminecobalt(III) nitrate.

From this equation, the heat of solution is obtained as $\Delta H = 15.558$ kcal. The value found in the literature[5] is 17.9 kcal. and that which was calculated from the heat of formation of hexamminecobalt(III) nitrate in the solid state, $\Delta H = -311.5$ kcal.[5], that of the hexamminecobalt(III) ion in unit activity[8] already given and that of the nitrate ion in unit activity, $\Delta H = -49.372$ kcal.[13], is 17.384 kcal., both of which are a little higher than our value, 15.558 kcal.

The standard free energy change of solution is calculated by the formula 9 as

$$\Delta G^\circ = 15558 - 25.63T \qquad (10)$$

and the value of $\Delta G^\circ_{298} = 7918$ cal. and $\Delta S^\circ_{298} = 25.63$ e. u. are obtained.

From the formulae 10 and 6 and the standard free energy of formation of the nitrate ion in unit activity, that of hexamminecobalt(III) nitrate in the solid state is calculated as

$$\Delta G^\circ = -309674 + 563.72T$$

and the value of $\Delta G^\circ_{298} = 141.68$ kcal. is obtained.

Hexamminecobalt(III) Perchlorate.—According to Kielland's table[11] the activity coefficient of perchlorate ion is different no more than 0.4% even in the molality of 0.01 from that of the chloride ion. Therefore, the activity coefficient of the hexamminecobalt(III) chloride shown in Fig. 1 was used in the place of that of the perchlorate to calculate the equilibrium constant, K. The values of $\log K$ are plotted against $1/T$ in Fig. 5, and the straight line obtained can be represented by the following equation:

12) F. D. Rossini et al., "Selected Values of Chemical Thermodynamic Properties", United States Government Printing Office, Washington, D. C. (1952), p. 27.

13) F. D. Riossini et al., ibid., (1952), p. 53.

TABLE V. THERMODYNAMIC FUNCTIONS FOR HEXAMMINECOBALT (III) COMPLEXES

Complex salts	Heat of solution	Free energy change of solution	Standard free energy of formation
$[Co(NH_3)_6]Cl_3$	8.567 kcal.	6.003 kcal.	−154.55 kcal.
$[Co(NH_3)_6]Br_3$	10.026	7.772	−136.12
$[Co(NH_3)_6](NO_3)_3$	15.558	7.918	−141.68
$[Co(NH_3)_6](ClO_4)_3$	18.533	9.080	− 71.40

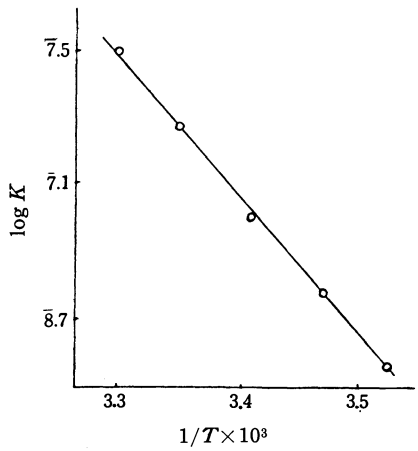

Fig. 5. The relationship between the equilibrium constant and the temperature for hexamminecobalt(III) perchlorate.

$$\log K = 4.0396 - 3226/T \qquad (11)$$

The heat of solution is obtained as $\Delta H=$ 18.53 kcal. The value found in the literature, 22.5 kcal.[14], and that calculated by the equations 3 and 4, 21.54 kcal., are both higher than our value, 18.53 kcal.

The standard free energy change of solution is calculated from 11 as

$$\Delta G^\circ = 18533 - 31.71T \qquad (12)$$

and the value of $\Delta G^\circ_{298}=9080$ cal., and $\Delta S^\circ_{298}=31.71$ e. u. are obtained.

From the formulae 12 and 6 and the standard free energy of formation of the perchlorate ion, that of hexamminecobalt-(III) perchlorate in the solid state is calculated as

$$\Delta G^\circ = - 258763 + 628.96T$$

and the value of $\Delta G^\circ_{298}=-71.46$ kcal. is obtained.

The thermodynamic values obtained for the above four hexamminecobalt(III) salts are summarized in Table V.

As shown in this table, both the heat of solution and the free energy change of the solution become greater in the order of hexamminecobalt(III) chloride, bromide, nitrate and perchlorate. This means that the affinity of these complexes toward water becomes greater in this order. However, the standard free energy of their formation increases in the order of chloride, nitrate, bromide and perchlorate and this means that the thermodynamic stability becomes lower in this order; that is, chloride is the most stable among the above four salts in the solid state.

Summary

The solubilities of hexamminecobalt(III) chloride, bromide, nitrate and perchlorate were measured at 10~35°C. From the solubility measurements the relationships between the equilibrium constant of the solution and the temperature were calculated. The heats of solution calculated from these data agreed approximately with the values given in the literature and those calculated by using formulae of Kapustinskiĭ and Fajans.

The free energy changes of formation of these complexes in the solid state were calculated for the first time. It is concluded from the results that the stability of these salts decreases in the following order:

$[Co(NH_3)_6]Cl_3 > [Co(NH_3)_6](NO_3)_3 > [Co(NH_3)_6]Br_3 > [Co(NH_3)_6](ClO_4)_3$

*Thermodynamic Studies on Cobalt Complexes. III. Thermal Dissociation of Hexamminecobalt(III) Chloride and Chloropentamminecobalt(III) Chloride**

By Motoshichi MORI and Ryokichi TSUCHIYA

(Received September 17, 1958)

Compared with a great number of studies on the reaction of complex salts in the aqueous solution, the investigations on the thermal decomposition of complexes in the solid state are few. These include studies on ammines of cobalt[1,2], nickel[3], platinum[4] and indium[5] and on nitroammines of platinum[6] and cobalt[7,8]. Among these studies the data on dissociation pressure were reported only for cobalt- and nickelammine complexes[1,3] and thermodynamic discussion of them has never been made. For this reason we started the present study and determined the dissociation pressure of hexamminecobalt-(III) chloride and chloropentamminecobalt-(III) chloride. The free energy change of dissociation of the former complex was calculated and the standard free energy of formation of the latter complex was obtained.

Experimental

Hexamminecobalt(III) chloride was prepared by Bjerrum's method[9] and chloropentamminecobalt-(III) chloride, by the method of Jörgensen[10]. The apparatus used for the determination of the dissociation pressure is shown in Fig. 1.

After the sample was put into the reaction vessel, made of heat resistant borosilicate glass, A, the whole apparatus was evacuated. The cocks B and C were closed and the temperature of the electric furnace F was held at the desired constant temperature by an automatic regulator. The dissociation pressure was determined by the manometer M.

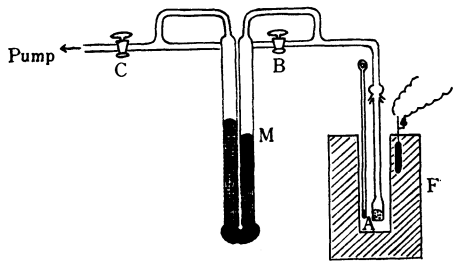

Fig. 1. Apparatus.

Results and Discussion

Dissociation Pressure of Hexamminecobalt(III) Chloride. — The dissociation pressure of hexamminecobalt(III) chloride was measured at several temperatures in the range of 83~173°C. As we found that the decomposition products consist of chloropentamminecobalt(III) chloride and ammonia, but not of cobaltous chloride, the decomposition reaction can be expressed by the following equation,

$$[Co(NH_3)_6]Cl_3(s) = [Co(NH_3)_5Cl]Cl_2(s) + NH_3(g)$$

The values of dissociation pressure determined for hexamminecobalt(III) chloride are listed in Table I.

Biltz[1] reported that the decomposition of hexamminecobalt(III) chloride began at 175~180°C and chloropentamminecobalt-(III) chloride was formed at 216~220°C. Clark et al[2]. reported that the decomposition began at 173°C and ammonium chloride appeared at 181°C. However, we detected the evolution of ammonia at 160°C by passing the decomposition gas into water containing phenolphthalein, and could determine the dissociation pressure at a temperature lower than that pointed out by Biltz[1] and Clark[2].

TABLE I. DISSOCIATION PRESSURE OF HEXAMMINECOBALT(III) CHLORIDE

Temp.(°C)	$1/T\times10^3$	Dissociation pressure (mmHg)	$\log p_{mm}$
83	2.808	0.70	−0.1549
92	2.739	1.15	0.0607
102	2.666	1.45	0.1614
114	2.583	2.19	0.3404
124	2.518	2.89	0.4609
129	2.487	3.49	0.5428
133	2.462	3.94	0.5955
138	2.432	4.59	0.6618
143	2.403	5.33	0.7267
149	2.369	6.04	0.7810
153	2.347	6.98	0.8439
158	2.320	7.73	0.8882
162	2.298	8.87	0.9479
168	2.267	10.33	1.0141
173	2.242	12.21	1.0867
176	2.227	14.26	1.1541

Biltz[1] observed 14 mmHg as the dissociation pressure of hexamminecobalt(III) chloride at 174°C, which is relatively close to our value, but he did not measure it at a temperature lower than 174°C. On the other hand, it was found by us that ammonium chloride began to form at about 170°C and the decomposition pressure rapidly increased at higher temperatures.

The logarithm of the dissociation pressure was plotted against the reciprocal of the absolute temperature (Curve a in Fig. 2). The obtained curve is approximately linear except the two points at 173 and 176°C. The equation of the straight line is calculated by the least square method as follows:

$$\log p_{mm} = 5.7705 - 2101.40/T \qquad (1)$$

From this equation the heat of dissociation is obtained as $\Delta H = 9612$ cal.

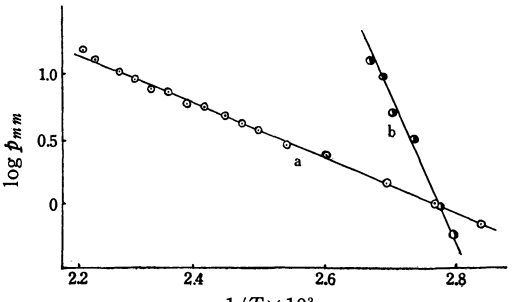

Fig. 2. The relationship between the dissociation pressure and the temperature for
a: hexamminecobalt(III) chloride
b: chloropentamminecobalt(III) chloride.

Biltz[1] obtained the value of about 18 kcal. as the heat of dissociation from his data determined at 174~216°C by means of the Nernst formula, but we recalculated the value of 28 kcal. from his data.

If the value of $\Delta H = 9612$ cal. determined above at the temperature in the range of 83~173°C is assumed to be approximately equal to that at 25°C, it agrees fairly well with the value of 8.56 kcal. calculated from the heats of formation of $[Co(NH_3)_6]Cl_3(s)$, (−274.1 kcal.[11]), $[Co(NH_3)_6Cl]Cl_2(s)$, (−254.5 kcal.[12]) and $NH_3(g)$ (−11.04 kcal.[13]).

The standard free energy change of decomposition calculated by the formula 1 is:

$$\Delta G^\circ = -RT\ln p = 9612 - 13.218T \qquad (2)$$

The values of $\Delta G^\circ_{298} = 5672$ cal. and $\Delta S^\circ_{298} = 13.22$ e. u. are obtained.

The standard free energy of formation of complex salts in the solid state has never been known except that of $[Co(NH_3)_6]Cl_3(s)$, which was calculated by the present authors from the solubility data in the preceding paper[14]. By using this value and the equation 2 the standard free energy of formation of $[Co(NH_3)_5Cl]Cl_2(s)$ in the solid state is calculated to be:

$$\Delta G^\circ = -254008 + 365.99T$$

and the value of $\Delta G^\circ_{298} = -144.90$ kcal. is obtained.

Dissociation Pressure of Chloropentamminecobalt(III) Chloride. — The dissociation pressure of chloropentamminecobalt-(III) chloride was measured by the same apparatus as that shown in Fig. 1. The results are given in Table II.

TABLE II. DISSOCIATION PRESSURE OF CHLOROPENTAMMINECOBALT(III) CHLORIDE

Temp.(°C)	$1/T\times10^3$	Dissociation pressure (mmHg)	$\log p_{mm}$
88	2.769	0.50	−0.3010
93	2.732	1.49	0.1732
96	2.709	3.08	0.4886
99	2.687	5.93	0.7731
101	2.673	9.51	0.9782
103	2.659	12.15	1.0846

11) K. B. Yatsimirskiĭ and L. L. Pankowa, *Zhur. Obshchei Khim.*, **19**, 617 (1949); K. B. Yatsimirskiĭ, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), p. 162.
12) A. B. Lamb and J. P. Simmons, *J. Am. Chem. Soc.*, **43**, 2188 (1921).
13) F. R. Bichowsky and F. D. Rossini, "Thermochemistry of the Chemical Substances", Reinhold Publishing Corp., New York, N. Y. (1936).
14) M. Mori, R. Tsuchiya and Y. Okano, This Bulletin, **32**, 462 (1959).

Biltz[1] found that chloropentamminecobalt(III) chloride decomposed at 180~220°C, but our results show that the decomposition takes place at a lower temperature. In contrast to hexamminecobalt(III) chloride, the increase of the dissociation pressure of chloropentamminecobalt(III) chloride with the rise of temperature is quite large. In other words, although the dissociation pressure of chloropentamminecobalt(III) chloride is less than that of hexamminecobalt(III) chloride at a temperature lower than 90°C, the thermal dissociation of the former exceeds that of the latter at a temperature higher than 92°C, and the dissociation pressure of the former at 103°C is nearly the same as that of the latter at 173°C. It is concluded from these facts that chloropentamminecobalt(III) chloride is stable at a temperature below 90°C and becomes suddenly unstable at a temperature above 192°C.

The plots of the logarithm of the dissociation pressure against the reciprocal of the absolute temperature give a straight line as shown by the line b in Fig. 2. The equation of the straight line is calculated as follows:

$$\log p_{mm} = 36.4869 - 13288.3/T$$

From this equation as the heat of dissociation the value of $\Delta H = 60.78$ kcal. is obtained. It is in good agreement with the value, 60.84 kcal., which is calculated from the heats of formation of components of the following dissociation reaction,

$$[Co(NH_3)_5Cl]Cl_2(s) = CoCl_2(s) + 1/6\ N_2(g) + NH_4Cl(s) + 11/3\ NH_3(g)$$

$\Delta H_{f[Co(NH_3)_5Cl]Cl_2} = -254.5$ kcal.[12]

$\Delta H_{fCoCl_2} = -77.8$ kcal.[15]

$\Delta H_{fNH_4Cl} = -75.38$ kcal.[13] and

$\Delta H_{fNH_3} = -11.04$ kcal.[13]

The Rate of Thermal Dissociation of Hexamminecobalt(III) Chloride.—The rate of the thermal dissociation of this complex was determined by tracing the pressure change of ammonia produced in the decomposition by the apparatus shown in Fig. 1. The results are shown in Table III and Fig. 3.

The velocity constant k at the time when the dissociation begins to take place is given by the tangent of the velocity curve at zero point in Fig. 3. The plots of logarithm of the velocity constant against the reciprocal of the absolute temperature give a straight line as shown in Fig. 4, from which the value of 17.98

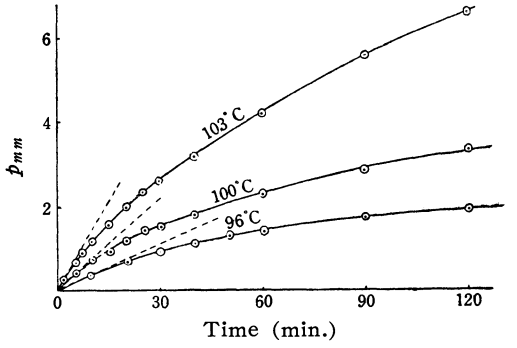

Fig. 5. Rate of dissociation of chloropentamminecobalt(III) chloride.

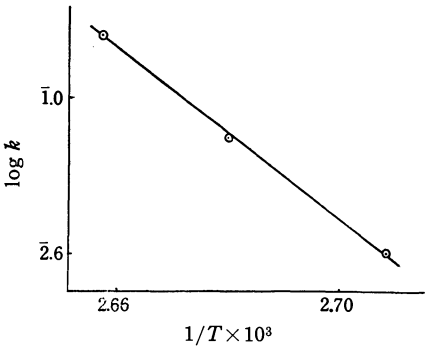

Fig. 6. The relationship between the velocity constant and the temperature for chloropentamminecobalt(III) chloride.

As shown above, the heat of dissociation and the activation energy of chloropentamminecobalt(III) chloride are very high compared with those of hexamminecobalt(III) chloride. These data give an explanation for the fact that chloropentamminecobalt(III) chloride produced in the thermal dissociation of hexamminecobalt(III) chloride does not suffer from further decomposition so far as the latter is present, even if the dissociation pressure of the former is very high.

Summary

1. The thermal dissociation of hexamminecobalt(III) and chloropentamminecobalt(III) chlorides was studied. The heats of dissociation calculated from the the data of dissociation pressure determined are in good agreement with the values calculated from other sources.

2. The free energy change of dissociation of hexamminecobalt(III) chloride was calculated and by combining this value with the standard free energy of formation of that complex previously obtained, the standard free energy of formation of chloropentamminecobalt(III) chloride in the solid state was determined.

3. The rate of the thermal dissociation of hexamminecobalt(III) and chloropentamminecobalt(III) chlorides was determined and the activation energies of the dissociation were calculated.

Normal Stress Effects in Polymer Solutions. I. Measurements in a Parallel Plate Instrument

By Mikio TAMURA, Michio KURATA and Tadao KOTAKA

(Received November, 6, 1958)

It is well noted that a visco-elastic fluid under steady shear flow usually generates not only shearing stress but also normal stresses. Thus, the essential requirement for obtaining the complete information for flow behavior of such a fluid is the development of the *goniometry of flow*, or in other words, the development of experimental procedures for the determination of all stress components, i.e., shearing stress and normal stresses[1,2].

In this report, as the first step of the stress-goniometry of flow, we will describe some findings on the normal stress measurements in a parallel plate instrument. Correlations between observed normal pressure and dimension of the instrument, and influences of secondary effects which inevitably arise in the course of measurements will be discussed at some length[3]. Detailed descriptions of the data and their physical interpretations will be published in a subsequent paper[4].

Padden and DeWitt[5], and recently Markovitz and Williamson[6] have suggested that the concentration and temperature dependencies of normal stress should be expressible in terms of "*reduced variables*". These suggestions are tested with the data obtained in our measurements.

Experimental

Instrument and Principles.—A parallel plate instrument used in this study is shown in Fig. 1. The figure itself is self-explanatory. An outer cup containing a test fluid is rotated at a steady speed within the range of 5 to 170 rpm by driving through a pulley and belt system by a 1/2 H. P. induction motor. The rotating bob is held at a distance of one centimeter or less above the cup. The dimensions of two outer cups and three inner bobs used in this study are listed in Table I. When the cup is rotated, the fluid, if it shows the normal stress effect, rises in the manometer tubes mounted on the stationary bob and reaches equilibrium levels. Equilibrium heights of the fluid were read by a travelling microscope. The non-parallelism and the non-concentricity of two plates, especially the former, largely affect the pressure distribution and disturb the quantitative measurements. A con-

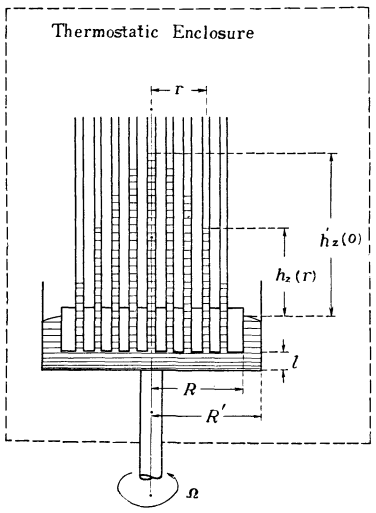

Fig. 1. Schematic diagram of the parallel plate instrument.

3) Works of similar nature were developed by Greensmith and Rivlin, but they are different from ours in the standpoint and the approach to the problem. H. W. Greensmith and R. S. Rivlin, *Phil. Trans. Roy. Soc. (London)*, **245**, 399 (1953).

4) T. Kotaka, M. Kurata and M. Tamura, in preparation.

5) F. J. Padden and T. W. DeWitt, *J. Appl. Phys.*, **25**, 1086 (1954).

6) H. Markovitz and R. B. Williamson, *Trans. Soc. Rheology*, **1**, 25 (1957).

dition free from such disturbances is easily attained by making sure that the symmetry in pressure distribution is established and that the pressure values are kept unchanged by clockwise and counterclockwise rotations at the same speed. The temperature at which the measurements were run was roughly controlled within ±1.0°C by a simple thermostatic enclosure.

The normal pressure is correlated to the normal stresses by the relation of force equilibrium in torsional shear flow as follows:

$$-\frac{\partial P_z(r)}{\partial \ln r}=\sigma_{11}-\sigma_{33}+\frac{\partial(\sigma_{22}-\sigma_{33})}{\sigma \ln r} \tag{1}$$

or in the integral form

$$\Delta P_z(r)=P_z(0)-P_z(r)$$
$$=\int_0^r(\sigma_{11}-\sigma_{33})\frac{dr}{r}+\sigma_{22}-\sigma_{33} \tag{2}$$

and

$$P_z(0)-P'=\int_0^R(\sigma_{11}-\sigma_{33})\frac{dr}{r} \tag{3}$$

where $P_z(r)$ denotes the pressure exerted on the stationary bob of radius R at the distance r from the rotating axis, P' denotes the pressure exerted on the fluid in the gap from the outside, σ_{ii} ($i=1,2,3$) denotes the normal stress component parallel to the direction of flow ($i=1$), and perpendicular to the shearing surface ($i=2$), and perpendicular to both ($i=3$), respectively. It should be noted here that in the derivation of the above equations the influences of the centrifugal force, and of disturbances of flow arising from edge effects were all neglected. It is readily seen that, if the state of flow were ideally torsional shear and undesirable disturbances were depressed within the experimental error, the left hand sides of the equations from 1 to 3 should be dependent on the rate of shear, $D=r\Omega/l$, alone. Here r is the distance from the axis, Ω is the angular velocity of rotation and l is the gap between two plates.

Materials.—Solutions of a commercial sodium carboxymethylcellulose (Na-CMC; Harcules, Cellulose Gum Type 70 sp-High) obtained through the courtesy of Dr. H. Inagaki of this University were mainly used in this study. Its molecular weight was about 10^5, and the range of degree of carboxymethylation was from 0.65 to 0.95. The data obtained on the solutions of commercial methylcellulose* (Interchemical, Methocell 4000 cp: $\bar{M}_v\sim10^5$, $D.S.\sim0.92$) in water and polystyrene* (Lustrex Hi-Flow 77, $\bar{M}_v\sim10^5$) in decalin are also described for the sake of comparison.

Results and Discussion

Some Geometrical Studies in a Parallel Plate Instrument.—*$h_z(0)$ vs. Ω Relations: the Centrifugal Force Effect*:—With the combination of bob A and cup 1, we first read $h_z(0)$ against the rotational velocity, Ω, with various gaps, l, on solution of 2g. Na-CMC in 100 ml. water (1.97 wt.%). The results are shown by solid lines in Fig. 2. If the curves of $h_z(0)$ vs. Ω with different l are replotted against the rate of torsion, Ω/l, they fall on a single reduced curve as shown by a broken line in Fig. 2. Close inspection, however, reveals that $h_z(0)$ value begins to deviate below the reduced curve when the rotational speed exceeds about 70~80 rpm irrespective of the gap, l. This tendency should be attributed mainly to the influence of the centrifugal force which repels the fluid outward in a radial direction and also acts as a rotational couple in r-z plane. The exact mathematical treatment of this effect is quite difficult, but in any case, the action of the centrifugal force may lower the $h_z(0)$ values, especially may lower them remarkably at a high velocity. Thus we may conclude that, to eliminate the effect of the centrifugal force, it is preferable to keep the rotational speed below about 70~80 rpm with a cup of this dimension ($R'=6.0$ cm.).

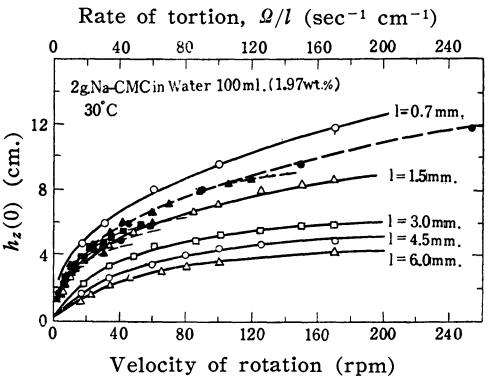

Fig. 2. $h_z(0)$ vs. velocity of rotation (solid lines) and $h_z(0)$ vs. rate of torsion, Ω/l (broken lines); Na-carboxymethylcellulose in water 1.97% at 20°C.

Pressure Distribution on a Stationary Bob: the Edge Effect:—In the derivation of Eqs. from 1 to 3, the influence arising from the side gap was simply replaced by an isotropic term P'. To check the validity of this assumption, measurements were performed with two different combinations of bob A ($R=5.0$ cm.) with cup 1 ($R'=6.0$ cm.), and bob A with cup 2 ($R'=8.0$ cm.) on solutions of Na-CMC-water, and the pressure distributions on the bob were compared. Fig. 3 indicates the pressure distributions, $h_z(r)$, with various velocities.

* Samples of methylcellulose and polystyrene were obtained through the courtesy of Toyo Ink Mfg. Co., Ltd., and Nagase and Co., respectively.

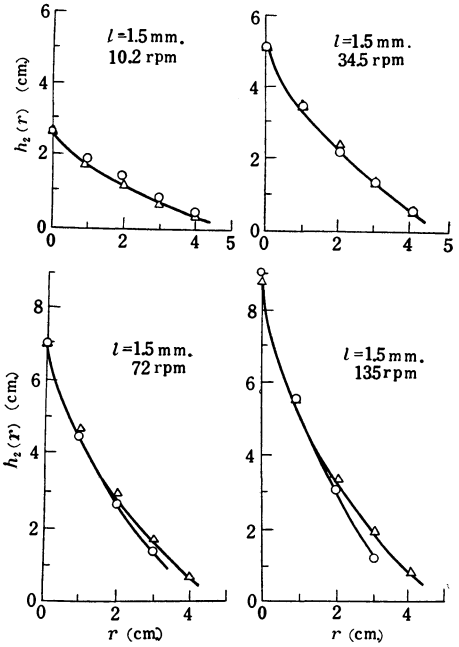

Fig. 3. Pressure distributions on a stationary plate (R=5.0 cm.) with cup 1 (R'=6.0 cm.)···Δ, and cup 2 (R'=8.0 cm.)···0. 1.97wt.%-CMC-water.

It is seen that when the rotational velocity is not so high the pressure distribution, $h_z(r)$, is practically unaffected by the difference in the side gap, but, the higher the velocity becomes (above 70 rpm), the more significant the deviation becomes. The pressure falls more rapidly in the larger cup. The plots of $h_z(0)$ vs. Ω/l, though the data are not shown here, are reduced on a single curve except at high speed and show no indication of edge effect.

Effect Arising from the Finite Size of Accesses of Manometer Tubes.—It might be expected that the presence of holes of manometer tubes on the base of a bob would disturb the flow pattern in their neighbor. Also for the finite size of accesses of manometers, the observed pressure does not represent a value at its center but the average over the area. That the quantitative estimation of this average with a parallel plate instrument is impracticable without the dependence of $h_z(r)$ on r (namely on the rate of shear) has been known. It can be said, however, that when the diameter of holes is larger, their influence is also greater. Actually, in our measurements, for the bob A (diameter of holes is 5 mm.) a slight but appreciable deviation was observed, while for the bob with smaller holes (diameter 2 mm.) no appreciable disturbance was observed. This had also been observed by Greensmith and Rivlin[3]. It is desirable to keep the size of holes as small as possible, but if too small, it becomes time-consuming for the fluid to attain equilibrium positions in each manometer.

The Normal Pressure Gradient $-\partial P_z(r)/\partial \ln r$ *vs. Rate of Shear* D.—Eqs. 1 and 2 indicate that the normal pressure difference, $\Delta P_z(r)$, or the normal pressure

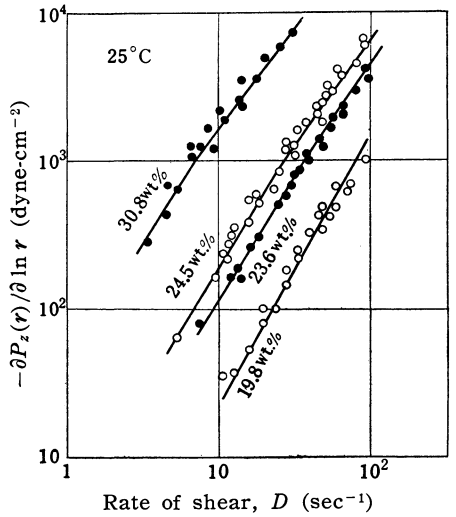

Fig. 4 (a). Normal pressure gradient, $-\partial P_z(r)/\partial \ln r$, as a function of rate of shear, D. Solutions of polystyrene in decalin.

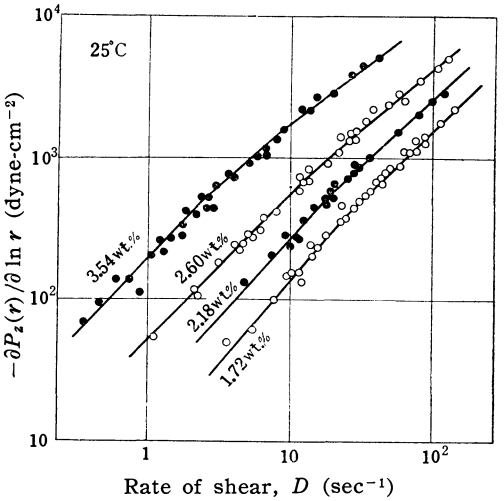

Fig. 4 (b). Normal pressure gradient, $-\partial P_z(r)/\partial \ln r$, as a function of rate of shear, D. Solutions of methylcellulose in water.

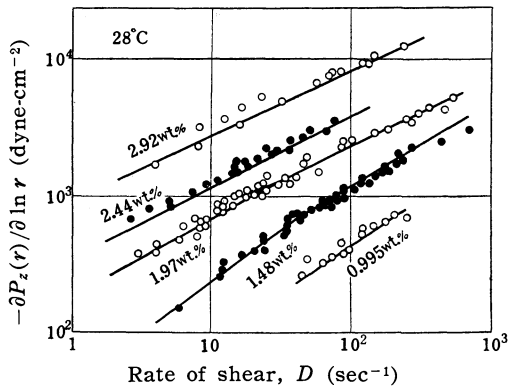

Fig. 4 (c). Normal pressure gradient, $-\partial P_z(r)/\partial \ln r$, as a function of rate of shear, D. Solutions of Na-carboxymethylcellulose in water.

gradient, $-(\partial P_z(r)/\partial \ln r)$**, should be a function of the rate of shear, $D=r\Omega/l$. Fig. 4 indicates the curves of $-\partial P_z(r)/\partial \ln r$ vs. D for three different polymer species, all of which show that the expected relations safely hold. Of course, the data which were beyond the limitations mentioned in the previous subsections were eliminated in the plots.

It should be noticed that the dependences of normal stresses on the rate of shear differ remarkably in each polymer species, which reflect the essential difference in characteristic rheological properties of those polymers. The detailed discussions will be given in our subsequent paper[4].

The Applicability of the Superposition Principle.—It has been suggested that from the normal stress data obtained on solutions of various concentrations and temperatures, a single reduced curve should be obtained by applying the superposition procedure which is currently used for the dynamic data[5,6]. In this case, reduced quantities are defined such as

$$[-\partial P_z(r)/\partial \ln r]_r = [-\partial P_z(r)/\partial \ln r] \cdot [T_0/Tf(c)]$$

and $$D_r = D\eta\, T_0/Tf(c)$$

where T is the absolute temperature, T_0 is a reference temperature, and η is the *zero shear* viscosity of the solution. $f(c)$ is a function of concentration, and was chosen by Padden and DeWitt[5] as $f(c)=c$ and by Markovitz and Williamson[6] as $f(c)=c/c_0$ for $c<c_0$ and $f(c)=c^2/c_0^2$ for $c\geq c_0$. The reduced plot of the data with solutions of methylcellulose in water is shown in Fig. 5, in which $T_0=298$°K and $f(c)=c$. It is seen that the reduction is not so satisfactory, but rather a systematic deviation is observed. Although results are not shown here, another choice of $f(c)$ improves the situation slightly. For another two polymer species, polystyrene in decalin and Na-CMC in water, the reductions are a little better than for methylcellulose in water, but again not so satisfactory.

On the basis of the cross-elasticity theory[4], the normal stresses and the apparent viscosity (=shearing stress/rate of shear) are given as follows:

$$-\frac{\partial P_z(r)}{\partial \ln r} = \sigma_{11}-\sigma_{33} = G\tau^2 D^2 \tag{4}$$

$$\eta = \sigma_{12}/D = G\tau \tag{5}$$

where G and τ are the shear modulus and the relaxation time of the solution, respectively. The superposition procedures are based on the following assumptions: the shear modulus and the relaxation time of the solution are dependent on such concentration and temperature that $G=G_0[Tf(c)/T_0f(c_0)]$ and $\tau=a_Ta_c\tau_0$. Here G_0 and τ_0 are the values of G and τ, respectively, at the reference temperature T_0 and concentration c_0. Introducing these assumptions into Eqs. 4 and 5, we obtain

$$-\frac{\partial P_z(r)}{\partial \ln r} = \frac{Tf(c)}{T_0f(c_0)} G_0\tau_0^2(a_Ta_cD)^2 \tag{6}$$

$$D\eta = \frac{Tf(c)}{T_0f(c_0)} G_0\tau_0(a_Ta_cD) \tag{7}$$

and

$$a_Ta_c = \frac{T_0f(c_0)}{Tf(c)}\frac{\eta}{\eta_0} \tag{8}$$

With the choice of such a reference state that η_0 and $f(c_0)$ are unity and a *zero shear* value for η, the reduced variables indicated before are determined.

It should be mentioned, however, that the above-mentioned definitions of reduced variables implicitly include such a further assumption namely that the reducing factors, $f(c)/f(c_0)$ and a_Ta_c, are independent of the rate of shear. This assumption may be valid in the case of a dynamic measurement if the amplitudes of vibrational motion are sufficiently small. On the other hand, in the steady flow measurements over wide range of rates of shear, this assumption may be improper, or valid only within a limited range of rates of shear, or of concentrations. Actually, the flow curves of polymer solutions

** Many experimental evidences show that the difference of σ_{22} and σ_{33} is nearly zero so it may be considered taht $[-\partial P_z(r)/\partial \ln r]=\sigma_{11}-\sigma_{33}$. See references 1), 2) and 4).

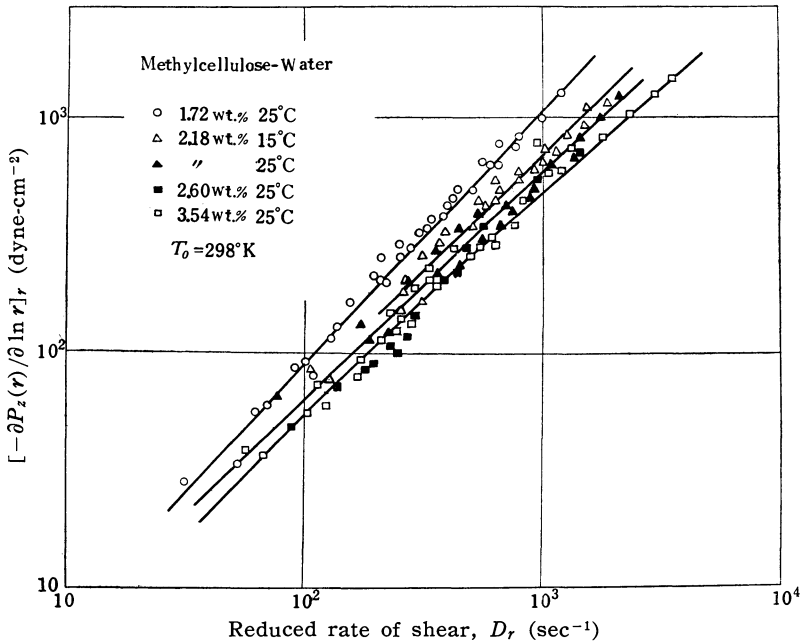

Fig. 5. Reduced normal pressure gradient, $[-\partial P_z(r)/\partial \ln r]_r = -[\partial P_z(r)/\partial \ln r][T_0/Tf(c)]$ vs. reduced rate of shear, $D_r=\eta T_0/Tf(c)$, where $f(c)=c$, T_0=298°K, solutions of methylcellulose in water.

have a distinct S shape[7], which indicates the presence of two different Newtonian regions at low rate of shear and at high rate of shear. In concentrated solutions the initial viscosity, $\eta_{D=0}$, at a low rate of shear increases more rapidly than the fifth or tenth power of the concentration[8], and the final viscosity, $\eta_{D=\infty}$, at a high rate of shear is proportional to the concentration itself[7]. These facts suggest that the whole feature of the flow curve can not be determined by their initial branch. This situation probably reflects also on the normal stresses, therefore, the above-mentioned superposition procedures should be valid only for the data obtained within the limited range of rates of shear and concentrations.

One more remark should be added to the factor T/T_0 of the shear modulus. This factor was derived from the conception of the entropy elasticity of the flexible chain polymer system. But in the case of concentrated solutions, in which the presence of transient junctions due to entanglements or interactions between polymer chains plays an important role and their number itself varies with temperature, the temperature dependence of the modulus of the solution is perhaps more complicated. A correct choice of this factor is a problem for further investigation.

Summary

Results of some geometrical studies of normal stress effects in a parallel plate instrument have been discussed. The parallelism and the concentricity of two plates are necessary conditions for the quantitative measurement. The rotational velocity of a cup should be kept below about 70 rpm for the apparatus with the cup radii about 6~8 cm. to avoid the influence of the centrifugal force. Accesses of manometer tubes with the diameter about 2 mm. cause no appreciable disturbances. The influence of side gap may also be neglected. With these experimental remarks, the normal stresses are obtained as a function of the rate of shear.

The applicability of the concentration-temperature superposition procedures has been tested with the data obtained here. They are partly valid in some limited range of variables.

Studies on the Sapogenins of Dioscorea tokoro Makino. I.[1]* *The Structure of Tokorogenic Acid*

By Katsura MORITA

(Received November 4, 1958)

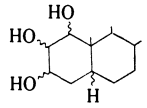
Steroidal sapogenin from plants belonging to the family *Dioscoreaceae* in Japan was first reported in detail by Tsukamoto et al.[2] Nevertheless, until we reported the isolation of a new sapogenin from *Dioscorea tokoro* Makino, diosgenin had been the sole sapogenin from these plants. In a previous paper[1] we made clear the following points on the new sapogenin: (1) The elementary analyses of the sapogenin and its acetate coincide with those of trihydroxysapogenin and its triacetate. (2) The infrared absorption spectrum (980, 917, 895 and 862 cm^{-1}) shows that the sapogenin has iso-configuration of ring F[3]. (3) Chloroform solution of the sapogenin rapidly consumes bromine and evolves hydrogen bromide fume. (4) 16-Pregnene-x, y, z-triol-20-one triacetate, U.V.λ_{max}^{EtOH}: 240 mμ (ε: 1120), can be derived from the sapogenin by the isomerization to the pseudosapogenin followed by oxidation, hydrolysis and re-acetylation.

Since no trihydroxysapogenin possessing the same physical constants with this had so far been announced, we named this sapogenin "tokorogenin" and started to investigate its chemical structure.

Tokorogenin undergoes oxidation with chromic anhydride in acetic acid to give a dibasic acid "tokorogenic acid" and a small amount of a lactone-like substance, the structure of which has not yet been elucidated. Tokorogenin also undergoes oxidation with periodic acid in an ethanol solution giving a crystalline substance, $C_{34}H_{60}O_6$, which tends to become tokorogenic acid by treatment with aqueous acetic acid and subsequent oxidation with chromic anhydride in the same solvent. The I.R.-absorption spectrum of the periodic-acid oxidation product, however, showed that the substance possessed neither a hydroxyl group nor aldehyde functions, and therefore an acetal structure must be necessarily assigned to this substance.

Lead tetra-acetate also affects tokorogenin in 80% acetic acid, but no crystalline substance could be obtained. Quantitative estimation, however, showed that the oxidizing agent consumed in the reaction was almost equivalent to the value calculated for a glycerol structure.

In view of these results, it is quite reasonable to presume that tokorogenin possesses a glycerol moiety in ring A of steroid nucleus and that the chromic anhydride oxidation of this triol possibly causes elimination of one of its carbon atoms giving tokorogenic acid. It is, therefore, almost certain that tokorogenin must be defined as either spirostan-1, 2, 3-triol (I) or spirostan-2, 3, 4-triol (I') and



* This is a full paper of the previous communication (K. Morita, *Pharm. Bull.*, **5**, 496 (1957)), and constitutes Part VIII of Nishikawa's paper entitled "Studies in Steroids".

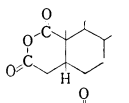
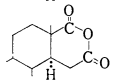
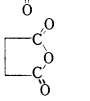
tokorogenic acid as either 1,3-seco-2-nor-spirostane-1,3-dioic acid (II) or 2,4-seco-3-nor-spirostane-2,4-dioic acid (II′).

(I)

(I′)



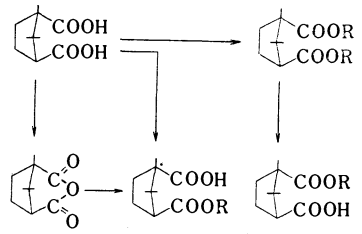




(II)

(II′)

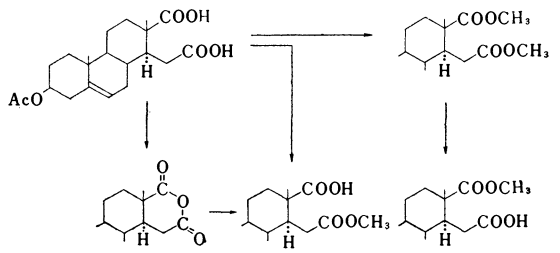
These assumptions are further supported by the fact that tokorogenic acid, on heating with acetic anhydride, forms an anhydride (I.R. λ_{max}^{Nujol}: 5.51, 5.71 μ), for according to the Blanc rule[4] no seven-membered ring anhydride can be formed from the corresponding 1,6-dibasic acids under these conditions. Moreover, the elementary analytical values of tokorogenic acid, its dimethyl ester and the anhydride favor the values calculated for $C_{26}H_{40}O_6$, $C_{28}H_{44}O_6$ and $C_{26}H_{38}O_5$, respectively.



Evidence is also given by the fact that the infrared carbonyl bands of tokorogenic anhydride are typical of the 6-membered ring anhydride as shown in Table I.

TABLE I

Substance	Structure	I.R. max.	Ref. No.
Tokorogenic anhydride (III)		Nujol 5.55, 5.71	5)
3β-Acetoxy-5-etiobilienic anhydride		Nujol 5.55, 5.70	5)
Glutaric anhydride		$CHCl_3$ 5.55, 5.68	6)
Succinic anhydride		Nujol 5.36, 5.61	7)

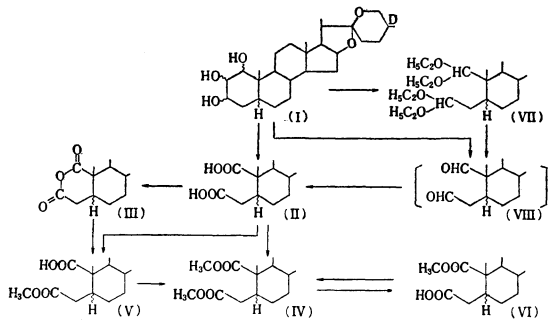


For the determination of the structure of tokorogenic acid, the following facts provide evidence in support of formula II rather than II′: (1) on treatment with methanol and hydrogen chloride tokorogenic acid affords a monomethyl ester (α-monomethyl ester); (2) alkaline hydrolysis of the dimethyl ester gives a different monomethyl ester (β-monomethylester); (3) treatment of the anhydride with one mole of sodium methoxide furnishes the α-monomethyl ester. These results are in complete accord with the earlier observations in the camphoric acid series (Chart 1)[8], where one of the carboxyl groups of the acid is attached to a tertiary carbon atom.

CHART 1

Since the structure II is closely similar to that of etiobilienic acid, which was first prepared from cholesterol by Kuwada[9] in our Laboratories, it can be presumed that etiobilienic acid and its derivatives will undergo reactions similar to those demonstrated in the camphoric acid series (Chart 1). We confirmed that this was true with etiobilienic acid, prepared from 5,16-pregnadien-3β-ol-20-one acetate according to Adams et al.[10]

CHART 2



On the basis of these findings and the aforementioned discussion, one is led to conclude that the reactions in the tokorogenic acid series can be best represented by Chart 3; that is, tokorogenic acid must have the structure II, and tokorogenic anhydride III, the α-monoester V, and the β-monoester VI, respectively.

9) S. Kuwada, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), **56**, 78 (1936).

It is also evident that the periodic acid oxidation product ($C_{34}H_{60}O_6$) must have a dialdehyde diacetal structure VII and that the structure I has to be assigned to tokorogenin.

CHART 3

Experimental

All melting points are corrected.

Tokorogenic Acid (II). — To a solution of 1.0 g. of tokorogenin I in 90 ml. of glacial acetic acid was added with vigorous stirring a solution of 2.0 g. of chromium trioxide in 20 ml. of 80% acetic acid at room temperature over a period of one hour. The solution was then allowed to stand overnight and the excess of the reagent was destroyed with sodium bisulfite. Partial evaporation gave a difficultly soluble crystalline substance of the solution (135 mg., m.p. 241°C (decomp.); I.R.λ_{max}^{Nujol}: 5.60 μ).

Anal. Found: C, 70.06; H, 8.74. Calcd. for $C_{27}H_{40}O_7$: C, 70.40; H, 8.75%.

The mother liquor was diluted with a large volume of water and extracted with ether, and the ethereal solution was repeatedly washed with water. The ethereal solution was then extracted with alkali and the alkaline solution was acidified and re-extracted with ether. Thorough washing of the solution followed by drying and evaporation furnished a solid residue (II, 470 mg.), which was recrystallized from acetic acid containing water yielding 400 mg. of colorless needles; m.p. 255°C (decomp.), $[\alpha]_D^{23}$ −26.3° (in acetone).

Anal. Found: C, 69.65; H, 9.13. Calcd. for $C_{26}H_{40}O_6$: C, 69.61; H, 8.99%.

Tokorogenic Acid Dimethyl Ester (IV).—A solution of tokorogenic acid II in ether was treated with a slight excess of diazomethane in the same solvent and the solution was immediately evaporated to dryness to give a crystalline dimethyl ester IV. Crystallization from methanol raised the melting point to 158~159°C.

Anal. Found: C, 70.75; H, 9.31. Calcd. for $C_{28}H_{44}O_6$: C, 70.55; H, 9.31%.

Tokorogenic Anhydride (III).—Tokorogenic acid II was heated with acetic anhydride for twenty minutes. After evaporation to a small volume the solution was cooled to give colorless needles of the anhydride III; m.p. 270~273°C, I.R.λ_{max}^{Nujol}: 5.55, 5.71 μ.

Anal. Found: C, 72.47; H, 9.09. Calcd. for $C_{26}H_{38}O_5$: C, 72.52; H, 8.90%.

A small portion of the anhydride III dissolved in methanol containing water and potassium hydroxide was digested for one hour, cooled, and neutralized with hydrochloric acid. Tokorogenic acid (II) was recovered in a good yield.

Tokorogenic Acid α-Monomethyl Ester (V). — a) To a mixture of 80 mg. of tokorogenic acid II and 3 ml. of absolute methanol was added 0.01 ml. of chlorosulfonic acid and the mixture was warmed on a steam bath to ensure complete solution. After being kept at room temperature for two hours the fine needles, which precipitated in the solution, were collected. Recrystallization from methanol afforded the analytical sample, which first melted at 141°C, then soon solidified and finally melted at 184~187°C (sintering 140°C).

Anal. Found: C, 69.88; H, 9.26. Calcd. for $C_{27}H_{42}O_6$: C, 70.10; H, 9.15%.

By the action of diazomethane V gave the dimethyl ester IV.

b) To a solution comprising 5 ml. of methanol and 6 mg. of sodium metal was added 100 mg. of the anhydride III and the mixture warmed on a steam bath for several minutes. The solution was then allowed to stand at room temperature for forty-five minutes. A small quantity of acetic acid was added to this and the solution was evaporated to dryness to give fine needles; m.p. 184~187°C (pre-sintering at 140°C). The sample here obtained did not show depression of melting point on admixture with a specimen prepared according to (a).

Tokorogenic Acid β-Monomethyl Ester (VI).—To a solution of 50 mg. of dimethyl ester IV in 4 ml. of methanol was added 100 mg. of sodium hydroxide dissolved in 1 ml. of water and the solution was refluxed for fifteen minutes on a steam bath and then allowed to stand at room temperature for one hour. The solution was diluted with a large volume of water, extracted with ether and the ethereal solution was discarded. After acidification, the aqueous layer was again extracted with ether and the ethereal solution was washed, dried and evaporated to give a solid substance VI. Recrystallization from methanol afforded colorless thin plates of the β-monomethyl ester VI; m.p. 208~210°C.

Anal. Found: C, 70.18; H, 9.04. Calcd. for $C_{27}H_{42}O_6$: C, 70.10, H, 9.15%.

By the action of diazomethane, the β-monomethyl ester VI gave the dimethyl ester IV melting at 158~159°C, which did not show depression of the melting point on admixture with the sample obtained by the other method.

Periodic Acid Oxidation of Tokorogenin (I).—To a suspension of 500 mg. of tokorogenin I in 10 ml. of absolute ethanol was added 1 g. of periodic acid dissolved in 1 ml. of water. The mixture was stirred vigorously for fifteen minutes and the resulting solution was allowed to stand

10) W. J. Adams et al., *J. Chem. Soc.*, **1956**, 297.

at room temperature for twenty-four hours to give colorless prisms. Recrytallization from methanol afforded 200 mg. of the diacetal VII; m.p. 150~151°C.

Anal. Found: C, 72.86; H, 10.55. Calcd. for $C_{34}H_{60}O_6$; C, 72.80; H, 10.71%.

Three hundred mg. of the diacetal dissolved in 80% acetic acid (40 ml.) was gently warmed on a steam bath for thirty minutes and cooled. To this was added a solution of 0.5 g. of chromic anhydride in 5 ml. of 80% acetic acid in small portions. Working up of the reaction mixture as in the case of tokorogenic acid II led to needles melting at 255°C; yield 190 mg., mixture m.p. with tokorogenic acid II, 255°C.

Lead Tetra-acetate Oxidation of Tokorogenin (I).—To a solution of lead tetra-acetate in 90% acetic acid (40 ml., 0.71 M) was added 444 mg. (1 mmol.) of tokorogenin I and the mixture was stirred vigorously to ensure complete solution. The solution was then allowed to stand at 20°C for two hours and a half. During this time, one ml. of the reaction mixture was taken out at regular intervals, a solution of potassium iodide was added to each of the solutions, and the solution was titrated with 0.1 N sodium thiosulfate with results shown in Table II, which show that tokorogenin consumed about two moles of the reagent.

3β-Hydroxy-Δ^5-etiobilienic Acid α-Monomethyl Ester.—a) A solution of 500 mg. of 3β-acetoxy-Δ^5-etiobilienic acid[9] in 30 ml. of methanol containing 0.5 ml. of chlorosulfonic acid was allowed to stand overnight at room temperature. After partial evaporation of the solution in vacuo water was added in small portions to give needles of the α-monomethyl ester. Recrystallization from acetone and water afforded the analytical sample melting at 175~178°C.

b) A solution of 350 mg. of 3β-acetoxy-Δ^5-etiobilienic anhydride[9] in 20 ml. of methanol containing 300 mg. of potassium hydroxide was refluxed on a steam bath for fifteen minutes. After standing at room temperature for thirty minutes a small quantity of acetic acid was added and the solution was evaporated in vacuo to a small volume. Water was added to this and the mixture was extracted with ether and the ethereal solution was extracted with alkali.

After acidification of the alkaline solution, it was extracted with ether, and then ethereal solution washed with water, dried and evaporated to give a syrup. Recrystallization from acetone and water afforded colorless needles melting at 175~178°C; mixed m. p. with the sample prepared according to (a), 175~178°C.

3β-Hydroxy-Δ^5-etiobilienic Acid β-Monomethyl Ester.—A solution of 500 mg. of 3β-acetoxy-Δ^5-etiobilienic acid dimethyl ester[10] in 30 ml. of methanol containing 300 mg. of patassium hydroxide was refluxed on a steam bath for four hours. After evaporation in vacuo a large volume of water was added to this and the mixture was extracted with ether. From the ether solution, 200 mg. of the material melting at 110~112°C was recovered. The aqueous solution, after acidification with diluted hydrochloric acid, was extracted with ether, and the ethereal solution was washed with water, dried and evaporated to give fine needles melting at 214~215°C*.

The β-monomethyl ester, on treatment with diazomethane, gave the dimethyl ester.

Summary

(1) Oxidation of tokorogenin by means of chromic anhydride in acetic acid, periodic acid in ethanol and lead tetra-acetate in aqueous acetic acid led to the conclusion that tokorogenin must have a glycerol moiety in ring A of the steroid nucleus.

(2) Tokorogenic acid, an oxidation product from tokorogenin, forms an anhydride by heating with acetic anhydride and gives rise to a monomethyl ester (α-monoester) by treatment with methanol and hydrogen chloride, while alkaline hydrolysis of the dimethyl ester of the acid furnishes a different monomethyl ester (β-monoester). The same α-monoester also results from tokorogenic anhydride by the action of alkali in a methanol solution.

(3) On the basis of the theoretical considerations and the afore-mentioned observations in the tokorogenic acid series compared with those in the camphoric acid and etiobilienic acid series, it is concluded that tokorogenic acid has to be defined as 1,3-seco-2-nor-spirostan-1,3-dioic acid (II) and hence tokorogenin as spirostan-1,2,3-triol (I).

The author wishes to express his grateful thanks to Dr. Y. Asahina of the University of Tokyo, Dr. S. Kuwada and Dr. T. Matsukawa in our Research Laboratories for their encouragement throughout the work. Thanks are also due to Mr. H. Kamio

* Kuwada[9] assigned the m. p. 176~177°C (sinter. at 169°C) to the same monomethyl ester. Discrepancy between the melting points may would be attributed to the solvents ethanol being used by Kuwada.

for infrared- and ultraviolet-spectral measurements and to Mr. M. Kan for elementary analyses.

Phenothiazine Derivatives. VI[1]*. Reactions of Some Substituted Phenothiazines with Thionyl Chloride*

By Manabu FUJIMOTO

(Received October 9, 1958)

In Part II[2] of the present series, it was reported that thionyl chloride transforms phenothiazine and its 5-oxide into 1,3,7,9-tetrachlorophenothiazine. Besides the present series, two reports have been published on the nuclear substitutions of phenothiazine derivatives with thionyl chloride. Namely, phenothiazine-1-carboxylic acid gave 3,7,9-trichlorophenothiazine-1-carbonyl chloride[3], and phenothiazine-2-carboxylic acid 1,3,7,9-tetrachlorophenothiazine-2-carbonyl chloride[4].

CHART I

The present paper describes similar substitution reactions of some other phenothiazine derivatives with thionyl chloride.

Mono-substituted Phenothiazines. — As shown in Chart I, the action of thionyl chloride gave 1,3,7,9-tetrachloro-2-hydroxyphenothiazine (II) from 2-hydroxyphenothiazine (I), 2,4,7,9-tetrachloro-3-phenothiazone (VII) from 3-hydroxyphenothiazine (V) and from 3-phenothiazone (VI), and 3-amino-2,4,7,9-tetrachlorophenazathionium chloride (X) from 3-aminophenothiazine (VIII) and from 3-phenothiazime (IX). These three products, II, VII and X, had been obtained by the action of thionyl chloride on 3-hydroxydiphenylamine, 4-hydroxydiphenylamine and 4-aminodiphenylamine, respectively[5]. In Part III[6] of this series it was observed that the reaction of thionyl chloride with diphenylamine to form 1,3,7,9-tetrachlorophenothiazine proceeds through the intermediate formation of phenazathionium chloride and subsequent chlorination. The fact that the substituted phenothiazines and the corresponding diphenylamines gave the same products by the action of thionyl chloride affords support to the above mechanism of the reaction of thionyl chloride with diphenylamine. Thionyl chloride and 4-hydroxyphenothiazine (III) gave a new tetrachloro-4-hydroxyphenothiazine. As it is expected that the hydroxyl group in position 4 of 4-hydroxyphenothiazine will strengthen the 1,3-orienting effect by the imino group, the

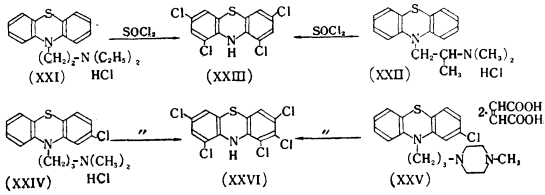
4) A. Burger and J. B. Clements, *J. Org. Chem.*, **19**, 1113 (1954).
5) This Bulletin, **32**, 298 (1959).
6) Ibid., **32**, 294 (1959).

product is assumed with great certainty to be 1,3,7,9-tetrachloro-4-hydroxyphenothiazine (IV).

2-Acetylphenothiazine (XI) gave a pentachloro derivative. A part of the chlorine atoms was found labile giving easily the chloride anion, and thus was present in the side chain. The positions of the chlorine atoms in the ring with the chlorinated acetyl group can not be presumed unequivocally, because the orienting effect by the acetyl group and that by the imino group do not fall on the same positions, but the product can be assumed to be 1,3,7,9-tetrachloro-2-(chloroacetyl)-phenothiazine (XII) in analogy to 1,3,7,9-tetrachlorophenothiazine-2-carbonyl chloride from phenothiazine-2-carboxylic acid[4].

Phenothiazine Dyes[7]. — From among many known phenothiazine dyes, thionine (XIII), methylene blue (XIV), toluidine blue (XV) and methylene green B (XVI) were chosen for the reactions with thionyl chloride.

CHART II



In the order of mention, they gave 3,7-diamino-2,4,6,8-tetrachlorophenazathionium chloride (XVII), 3,7-bis(dimethylamino)-2,4,6,8-tetrachlorophenazathionium chloride (XVIII), 3-amino-1,4,6,8-tetrachloro-2-(chloromethyl)-7-(dimethylamino)-phenazathionium chloride (XIX), and 2,6,8-trichloro-3,7-bis(dimethylamino)-4-nitrophenazathionium chloride (XX), respectively.

7) These dyes are expediently expressed in phenazathionium formulae.

As it is reasonably expected that the amino group and the dimethylamino group in positions 3 and 7 are stronger in the orienting effect than the competing nitrogen atom of position 10, substitution took place presumably in all the positions 2, 4, 6 and 8, unless already substituted. Toluidine blue (XV) gave a pentachloro derivative. It can be assumed by the same reason as stated above that three of the five chlorine atoms are situated at positions 4, 6, and 8. As substitution in position 1 is favored by both the nitrogen atom of position 10 and the methyl group in position 2, one is probably in position 1, and the remaining one in the methyl group to make chloromethyl group. Thus the pentachloro product is considered 3-amino-1,4,6,8-tetrachloro-2-(chloromethyl)-7-(dimethylamino)phenazathionium chloride (XIX).

Phenothiazine Drugs.—Four of the most important phenothiazine drugs were treated with thionyl chloride with results shown in Chart III. The same 1,3,7,9-tetrachlorophenothiazine (XXIII)[2] was obtained from either diethazine (XXI) (2987 R.P.) or promethazine (XXII) (3389 R.P.). In a similar manner, 1,2,3,7,9-pentachlorophenothiazine[2] (XXVI) was derived from chlorpromazine (XXIV) (4560 R.P.) and from prochlorperazine

CHART III

(XXV) (6140 R.P.). As the yields were nearly quantitative, the reaction with thionyl chloride may be useful to the qualitative and quantitative analyses of various phenothiazine drugs.

Experimental

General Procedure of Treatment with Thionyl Chloride.— Thionyl chloride (10 ml.) was added dropwise to 1.0 g. of the compound to be treated, and the mixture was heated gently under reflux for 30 min., when hydrogen chloride and sulfur dioxide were evolved. The cooled mixture was poured onto crushed ice, and the product was collected, dried, and recrystallized.

1,3,7,9-Tetrachloro-2-hydroxyphenothiazine (II) from 2-Hydroxyphenothiazine (I). —Fine powder of chocolate color from chloroform-ethanol, m.p. 202~203°C (decomp.). Yield,

93%. The substance was identified with an authentic sample[5].

1, 3, 7, 9-Tetrachloro-4-hydroxyphenothiazine (IV) from 4-Hydroxyphenothiazine (III).—Fine powder with chocolate color from benzene, m.p. 168~170°C. Yield, 94%. The product IV gives bluish-violet color with sulfuric acid.

Anal. Found: C, 40.67; H, 1.10; N, 4.01. Calcd. for $C_{12}H_5ONCl_4S$: C, 40.82; H, 1.43; N, 3.97%.

2,4,7,9-Tetrachloro-3-phenothiazone (VII) from 3-Hydroxyphenothiazine (V) and from 3-Phenothiazone (VI).—Fine crystals with pinkish tinge from ethanol-benzene, m.p. 145~146°C. Yields, 92% from V and 97% from VI. The product VII gives cobalt-blue coloration with sulfuric acid. The substance showed no depression of the melting point on admixture with an authentic sample[5].

3-Amino-2, 4, 7, 9-tetrachlorophenazathionium Chloride (X) from 3-Aminophenothiazine (VIII) and from 3-Phenothiazime (IX).—Reddish-violet fine powder from chloroform, m.p. 185~186°C. Yields, 89% from VIII and 99% from IX. The substance showed no depression of the melting point on admixture with an authentic sample[5].

1,3,7,9-Tetrachloro-2-(chloroacetyl)phenothiazine (XII) from 2-Acetylphenothiazine (XI).—Green powder, m.p. 145~146°C. Yield, quantitative. Coloration with sulfuric acid is violet. Silver chloride was precipitated on adding silver nitrate to an alcoholic solution of the substance XII.

Anal. Found: C, 37.19; H, 1.93; N, 3.15. Calcd. for $C_{14}H_6ONCl_5S \cdot 2H_2O$: C, 37.37; H, 2.24; N, 3.11%.

3, 7-Diamino-2, 4, 6, 8-tetrachlorophenazathionium Chloride (XVII) from Thionine (XIII).—Bluish-purple fine powder from methanol, m.p. over 360°C. Yield, 99%. The substance gives dark green color with sulfuric acid.

Anal. Found: C, 35.99; H, 1.83; N, 10.54. Calcd. for $C_{12}H_6N_3Cl_5S$: C, 35.90; H, 1.51; N, 10.47%.

2,4,6,8-Tetrachloro-3,7-bis(dimethylamino)-phenazathionium Chloride (XVIII) from Methylene Blue (XIV).—Greenish-blue fine crystals, m.p. over 360°C. Yield, 94%. The substance gives green color with sulfuric acid. When recrystallized from a mixture of dimethylformamide and water, it was transformed into the corresponding phenazathionium hydroxide, which was analyzed.

Anal. Found: C, 43.66; H, 3.28; N, 10.06. Calcd. for $C_{16}H_{15}ON_3Cl_4S$: C, 43.75; H, 3.44; N, 9.57%.

3-Amino-1, 4, 6, 8-tetrachloro-2-(chloromethyl)-7-(dimethylamino)phenazathionium Chloride (XIX) from Toluidine Blue (XV).—Purplish-blue fine powder from acetic acid, m.p. over 360°C. Yield, 96%. It gives reddish-brown color with sulfuric acid.

Anal. Found: C, 37.90; H, 2.72; N, 8.48. Calcd. for $C_{15}H_{11}N_3Cl_6S$: C, 37.68; H, 2.32; N, 8.79%.

2,6,8-Trichloro-3, 7-bis(dimethylamino)-4-nitrophenazathionium Chloride (XX) from Methylene Green B (XVI).—Green fine powder from methanol, m.p. 234~237°C (decomp.). Yield, quantitative. Coloration with sulfuric acid is violet.

Anal. Found: C, 40.88; H, 3.40; N, 12.09. Calcd. for $C_{16}H_{14}O_2N_4Cl_4S$: C, 41.05; H, 3.01; N, 11.97%.

1, 3, 7, 9-Tetrachlorophenothiazine (XXI) from Diethazine (XIX) and from Promethazine (XX).—Yellow needles from benzene, m.p. 234~235°C. Yields, 99% from XIX and 96% from XX. It was identified with an authentic sample[2].

1,2,3,7,9-Pentachlorophenothiazine (XXVI) from Chlorpromazine (XXIV) and from Prochlorperazine (XXV).—Faint-yellow or colorless needles from benzene, m.p. 204~205°C. Yields, 96% from XXIV and 90% from XXV. It was identified with an authentic sample[2].

Summary

Some phenothiazine derivatives including dyes and drugs were treated with thionyl chloride and five new polychlorinated products and six known were obtained.

The author expresses his thanks to Professor Y. Urushibara, the Tokyo, for his helpful guidance throughout this work, to Dr. K. Takeda, Director of the Laboratory, for his permission to conduct this research, and also to the members of the Center of Microanalytical Services, Shionogi and Co., Ltd., for the elementary analyses.

Phenothiazine Derivatives. VII[1]. *Reactions of Phenothiazines with Sulfuryl Chloride and with Chlorosulfonic Acid*

By Manabu FUJIMOTO

(Received October 9, 1958)

In the previous papers of this series, reactions of diphenylamines and phenothiazines with thionyl halides, and of diphenylamine with sulfuryl chloride were described[2]. The present paper deals with the reactions of phenothiazines with sulfuryl chloride and with chlorosulfonic acid.

CHART I

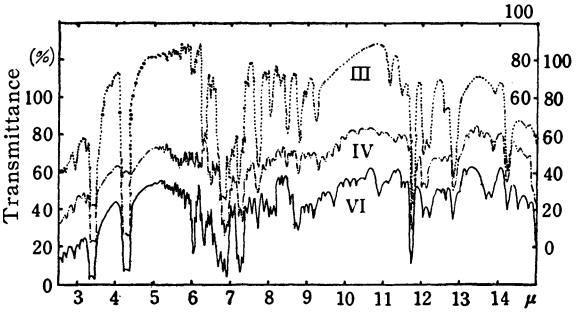
The action of sulfuryl chloride on phenothiazine (I), on phenothiazine 5-oxide (II), and on 1,3,7,9-tetrachlorophenothiazine (III) produced chocolate-colored mixtures which, on treatment with water, gave a highly chlorinated product. The molecular weight of the purified product was found to be 309, and it was analyzed as $C_{12}H_5ONCl_4S$, corresponding to 1,3,7,9-tetrachlorophenazathionium hydroxide (VI).

Brady and Smiles[3] obtained 1,3,7,9-tetrachlorophenazathionium hydroxide(VI) by treating 1,3,7,9-tetrachlorophenothiazine 5-oxide (V) with aqueous sulfuric acid, and they described the substance as a brownish-red powder, decomposing somewhat gradually at 200°C and giving a purple solution in sulfuric acid. The substance obtained by the present author is a fine powder of chocolate color melting at 210~211°C (decomp.) and giving violet coloration with sulfuric acid. We may well be justified in regarding the present substance as identical with the substance of Brady and Smiles.

1) Part VI, This Bulletin, **32**, 480 (1959).
2) Part II, *Pharm. Bull. (Japan)*, **5**, 395 (1957); Part III, IV and VI, This Bulletin, **32**, 294, 296, 480 (1959).
3) O. L. Brady and S. Smiles, *J. Chem. Soc.*, **97**, 1562 (1910).

Without treatment with water, 1,3,7,9-tetrachlorophenazathionium chloride (IV) was obtained as the precursor of the hydroxide VI. Hydrolysis of the purified chloride IV with aqueous sulfuric acid or with ethanolic potassium hydroxide gave the phenazathionium hydroxide VI. Therefore, it was concluded that the treatment of the primary reaction mixtures with water caused a hydrolysis by sulfuric acid which was generated from water and the remaining sulfuryl chloride.

Mutual transformations of the four 1,3,7,9-tetrachlorophenothiazine derivatives, III, IV, V and VI, were further investigated. Reduction of 1,3,7,9-tetrachlorophenathionium chloride (IV) and of the hydroxide VI with stannous chloride gave 1,3,7,9-tetrachlorophenothiazine (III), while the hydroxide VI was produced either by oxidation of the phenothiazine III with chromic anhydride in benzene or by intramolecular rearrangement of 1,3,7,9-tetrachlorophenothiazine 5-oxide (V) in acetic acid. Action of dry hydrogen chloride on the 5-oxide (V) and on the



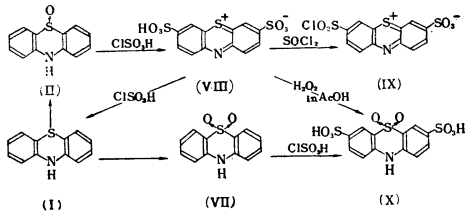


Fig. 1. Infrared spectra in Nujol of 1,3,7,9-tetrachlorophenothiazine (III), 1,3,7,9-tetrachlorophenazathionium chloride (IV), and the hydroxide VI.

phenazathionium hydroxide VI yielded the phenazathionium chloride IV. These transformations demonstrate that the four chlorine atoms are situated at the corresponding positions in the four compounds concerned. The infrared absorptions of

three (III, IV and VI) of the four compounds also indicate that they are similarly substituted (Fig. 1).

Phenothiazine 5,5-dioxide (VII) did not react with sulfuryl chloride, but chlorosulfonic acid transformed it into a disulfonic acid, probably 3,7-disulfophenothiazine 5,5-dioxide (X), as shown in Chart II.

CHART II

The action of chlorosulfonic acid on phenothiazine (I) and on its 5-oxide (II) gave an inner salt VIII of 3,7-disulfophenazathionium hydroxide. The inner salt VIII has converted into the disulfonic acid X by oxidation with 30% hydrogen peroxide in acetic acid, and into the inner salt IX of 3-sulfo-7-(chlorosulfonyl)phenazathionium hydroxide on treatment with thionyl chloride. Thus the sulfo groups and the chlorosulfonyl group in these inner salts are situated at the same positions as in the disulfophenothiazine 5,5-dioxide (X), which were assumed to be 3 and 7 as mentioned above.

Experimental

Reduction of 1,3,7,9-Tetrachlorophenazathionium Chloride (IV) and of 1,3,7,9-Tetrachlorophenazathionium Hydroxide (VI) with Stannous Chloride. — a) A mixture of 1.0 g. of 1,3,7,9-tetrachlorophenazathionium chloride (IV), described below, and 0.8 g. of stannous chloride was dissolved in 20 ml. of acetic acid, and then 1.0 g. of 35% hydrochloric acid was added. The solution was refluxed during 3 hr., and the cooled mass was poured into water. The yellow precipitate was collected, dried, and recrystallized from dioxane. Yellow needles, m. p. 235~236°C. Yield, 96%. The substance was identified with 1,3,7,9-tetrachlorophenothiazine (III) by a mixed melting point determination with an authentic sample[2].

b) Similarly, 1,3,7,9-tetrachlorophenazathionium hydroxide (VI), described below, gave the same tetrachlorophenothiazine (III) in a yield of 94%.

1,3,7,9-Tetrachlorophenazathionium Chloride (IV). — a) Sulfuryl chloride (10 ml.) was added to 1.0 g. of phenothiazine (I), and the mixture was gently refluxed for 30 min. Then the excess of sulfuryl chloride was evaporated under reduced pressure. The product was recrystallized from benzene. 1,3,7,9-Tetrachlorophenazathionium chloride (IV) was obtained in chocolate-colored needles, m. p. 223~224°C (decomp.). Yield, nearly quantitative. It gives purple coloration with sulfuric acid.

Anal. Found: C, 38.95; H, 1.43; N, 3.98. Calcd. for $C_{12}H_4NCl_5S$: C, 38.79; H, 1.09; N, 3.77%.

On treatment with sulfuryl chloride in a similar manner, phenothiazine 5-oxide (II) and 1,3,7,9-tetrachlorophenothiazine (III) gave the same product IV also in nearly quantitative yields.

b) A carbon tetrachloride solution of 1,3,7,9-tetrachlorophenothiazine 5-oxide (V) was saturated with dry hydrogen chloride, the chocolate-colored solution was refluxed for 1 hr., and then the solvent was distilled off. The residue was recrystallized from benzene. 1,3,7,9-Tetrachlorophenazathionium chloride (IV) was obtained quantitatively.

1,3,7,9-Tetrachlorophenazathionium Hydroxide (VI).—a) The reaction mixture resulting from phenothiazine (I) and sulfuryl chloride as described above, was poured into water, and the chocolate-colored product was collected, dried and recrystallized from benzene. 1,3,7,9-Tetrachlorophenazathionium hydroxide (VI) was obtained in chocolate-colored needles, m. p. 210~211°C. Yield, quantitative. It gives violet coloration with sulfuric acid.

Anal. Found: C, 40.49; H, 1.54; N, 4.03; mol. wt. (Rast), 309. Calcd. for $C_{12}H_5ONCl_4S$: C, 40.82; H, 1.43; N, 3.97%; mol. wt., 353.

b) 1,3,7,9-Tetrachlorophenazathionium chloride (IV) (0.2 g.) was dissolved in 5 ml. of sulfuric acid, and then the mixture was poured into 50 ml. of water. A nearly quantitative yield of the same hydroxide VI was obtained.

c) The chloride IV (0.2 g.) was dissolved in 50 ml. of hot ethanol, and a solution of 0.1 g. of potassium hydroxide in 5 ml. of hot ethanol was added. After reflux during 1 hr., the solvent was distilled off, and then the residue was neutralized with 10% hydrochloric acid. Recrystallization of the insoluble part from benzene gave 1,3,7,9-tetrachlorophenazathionium hydroxide (VI).

d) To a solution of 1.0 g. of 1,3,7,9-tetrachlorophenothiazine (III) in 50 ml. of benzene, 1.0 g. of chromic anhydride was added little by little. The mixture was refluxed on a water bath during 3 hr. The solvent was distilled off, and the residue was poured onto crushed ice. The same hydroxide VI was obtained in a quantitative yield.

e) A solution of 1.0 g. of 1,3,7,9-tetrachlorophenothiazine 5-oxide (V) in 30 ml. of acetic acid was refluxed for 1 hr., and the chocolate-colored solution was evaporated in vacuo. The residue was recrystallized from benzene, and 1,3,7,9-tetrachlorophenazathionium hydroxide (VI) was obtained in chocolate-colored fine needles.

Inner Salt VIII of 3,7-Disulfophenazathionium Hydroxide. — Chlorosulfonic acid (10 ml.) was added dropwise to phenothiazine (I),

and the mixture was heated gently under reflux for 30 min., and then the cooled mass was poured onto crushed ice. The precipitate was collected, dried, and recrystallized from benzene. The inner salt VIII of 3,7-disulfophenazathionium hydroxide was obtained in dark reddish-violet powder, m.p. 225~226°C. Yield, 93%. It gives bluish-violet coloration with sulfuric acid.

Anal. Found: C, 36.56; H, 2.39; N, 3.85. Calcd. for $C_{12}H_7O_6NS_3 \cdot 2H_2O$: C, 36.64; H, 2.82; N, 3.56%.

Treatment of phenothiazine 5-oxide (II) with chlorosulfonic acid in a similar manner gave the same product in a yield of 97%.

Inner Salt IX of 3-Sulfo-7-(chlorosulfonyl)phenazathionium Hydroxide.—Thionyl chloride (10 ml.) was added drop by drop to 1.0 g. of the inner salt VIII of 3,7-disulfophenazathionium hydroxide, when hydrogen chloride and sulfur dioxide was evolved. After reflux during 30 min., the mixture was poured into water. The precipitate was collected, dried, and recrystallized from ethyl acetate. The inner salt IX of 3-sulfo-7-(chlorosulfonyl)phenazathionium hydroxide was obtained in dark-violet powder, m.p. 163~164°C. Yield, 0.9 g. (94%). It gives cobalt-blue coloration with sulfuric acid.

Anal. Found: C, 38.70; H, 1.80; N, 3.66. Calcd. for $C_{12}H_6O_5NClS_3$: C, 38.35; H, 1.61; N, 3.73%.

3,7-Disulfophenothiazine 5,5-Dioxide (X).—a) The reaction of phenothiazine 5,5-dioxide (VII) and sulfuryl chloride gave 3,7-disulfophenothiazine 5,5-dioxide (X) as a hygroscopic, dark-green substance. Yield, over 86% of the theory. The substance X is soluble in water, in ethanol, and in methanol. The sodium, potassium, calcium and barium salts are easily soluble in water. Coloration with sulfuric acid is reddish-purple.

b) To a solution of substance VIII in 40 ml. of acetic acid, 1.0 ml. of 30% hydrogen peroxide was added, and the solution was heated on a water bath during 3 hr. Evaporation of the solvent gave the same disulfonic acid X. Yield of the crude product, quantitative.

Summary

Reactions of some phenothiazines with sulfuryl chloride and with chlorosulfonic acid were investigated. With sulfuryl chloride, phenothiazine (I), its 5-oxide (II), and 1,3,7,9-tetrachlorophenothiazine (III) gave the same product, 1,3,7,9-tetrachlorophenazathionium chloride (IV), which yielded the corresponding hydroxide VI by the action of aqueous sulfuric acid and of ethanolic potassium hydroxide. To establish the structural relationship of these substances, mutual transformations were carried out. Treatment of phenothiazine and of its 5-oxide with chlorosulfonic acid gave the inner salt VIII of 3,7-disulfophenazathionium hydroxide, which yielded the inner salt IX of 3-sulfo-7-(chlorosulfonyl)phenazathionium hydroxide by the action of thionyl chloride. Chlorosulfonic acid converted phenothiazine 5,5-dioxide into 3,7-disulfophenothiazine 5,5-dioxide which was obtained also by the oxidation of the inner salt VIII with 30% hydrogen peroxide in acetic acid.

Analysis of Organic Compounds by Flame Spectrometry. I. Determination of Chlorine in Organic Compounds by Band Spectra of Cuprous Chloride*

By Masao MARUYAMA and Setsuya SENO

(Received September 1, 1958)

Analysis by flame spectrometric method has developed around metal elements with low excitation energy and recently its application has gradually been extended to heavy metals. On the other hand, determination of nonmetallic elements has been reported only in a few instances, such as the determination of phosphorus[1] and halogen[2] by indirect method, that of the chloride ion in sea water by band spectrum of cuprous chloride[3], that of organophosphorus compounds[4], and semi-quantitative determination of the fluoride ion by photographic measurement[5].

The present writers re-examined the determination of the chloride ion by the band spectrum of cuprous chloride, based on the so-called Beilstein's reaction, developed by Honma and others[3].

It was thereby learned that a stable band spectrum of cuprous chloride can be obtained similarly even in the case of non-ionized chloride and a rapid determination of chlorine in organic compounds was carried out successfully by the use of an organic solvent, *N*, *N*-dimethylformamide (DMF).

Experimental

Apparatus and Reagents.—Measurement of flame spectrum was made with Beckman Model DU spectrophotometer (with 4300 photomultiplier accessory), with 9200 flame attachment, 4020 atomizer burner, and 92300 spectral energy recording adapter. Hydrogen and oxygen were used for excitation. To obtain a stable low pressure hydrogen flow, a combination of a flow meter, a hydraulic pressure governor, and a damper was placed between the burner and the gas regulator. Brief outline of this apparatus is shown in Fig. 1.

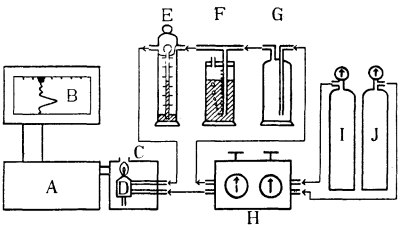

Fig. 1. Schematic diagram of the apparatus.

The reagents used were all commercial reagents of special grade (G.R. grade). The solvent, DMF was dehydrated and distilled, collecting the fraction of b.p. 152~153°C. Standard substance for chloride was the γ-isomer of BHC (hexachlorocyclohexane) of standard quality for polarographic analysis.

Experimental Procedure.—*Preparation of the solvent* (Cu, 0.05 M).—In dehydrated DMF, 12.08 g. of cupric nitrate (trihydrate) was dissolved and 1 cc. of nitric acid was added into this solution to prevent the precipitation of cupric hydroxide or basic cupric chloride and the solution was brought up to 1000 cc.

Preparation of standard chloride solution and sample solution.—In a 100 cc. volumetric flask, 4.848 g. of standard BHC (chloride equivalent, 48.48) was accurately weighed and dissolved in DMF containing 0.05 M of copper to prepare standard 1 M chloride solution. The solution was diluted as required to a concentration of 0.05~0.1 M chloride. Test solutions were prepared by placing a quantity of the sample corresponding to 0.2~1.0 mM of chloride in a 20 cc. volumetric flask and dissolved in DMF containing copper.

Procedure of flame photometric analysis.—For the analysis, a peak of the band spectrum of cuprous chloride at 435.4 mμ was used and the calibration curve was made from the height of the base line to the peak of the spectral curve.

* The gist of this work was presented at the 6th Annual Meeting of the Japan Society for Analytical Chemistry in October, 1957.

Conditions of the measurement were as follows: wavelength, 442 to 428 mμ; slit width, 0.05 mm.; sensitivity, full; oxygen pressure, 1.76 kg./cm² (25 lb./in²) on the fuel pressure gauge; hydrogen pressure, 1st, 0.035 kg./cm² (0.5 lb./in²) on the fuel pressure gauge, 2nd, 10 cm. water column; hydrogen flow rate, 450 cc./min.; scanning speed, 10, on the scale of the instrument; chart speed, 7.62 cm./min. (3 in./min.).

Experimental Results and Discussion

Exeitation of Cuprous Chloride Band Spectrum.—The band spectrum of cuprous chloride emitted in oxy-hydrogen flame has bands at the wave lengths listed in Table I[6].

TABLE I. BAND SPECTRA OF CUPROUS CHLORIDE

Wavelength (mμ)	Relative intensity	Wavelength (mμ)	Relative intensity
526.2_3	6	443.3_8	9
498.2_2	2	441.2_4	8
494.6_2	1	435.3_9	10
488.1_5	4	433.3_2	9
484.6_4	3	428.0_9	9
478.8_5	2	425.8_9	7
475.5_7	1	418.7_9	3
449.3_8	5		

The brightest of these is the band at 435.4 mμ, followed by bands at 443.4, 433.3 and 428.1 mμ; 435.4 mμ was taken as the analytical wavelength.

Honma and others have already examined the cuprous chloride band spectrum of a sample in aqueous solution and found that its measured intensity is low and the slit width must be so wide that hardly any fine structures were observed. It was also pointed out that, in this wavelength region, the cuprous chloride band spectrum is interfered by C_2-Swan band owing to the presence of carbon compounds, and does not make quantitative estimation possible.

The present writers, however, were able to overcome these difficulties by weakening the interfering action of C_2-Swan band by careful adjustment of the fuel gas pressure even in the presence of organic compounds and by markedly increasing the intensity of cuprous chloride band spectrum by the use of a suitable organic solvent in place of water.

In general, organic compounds are sparingly soluble in water and the use of an organic solvent will be the only means of preparing a sample solution for flame photometric analysis.

Dimethylformamide as Solvent for Flame Photometric Analysis and Establishment of Measurement Conditions.—Dimethylformamide (DMF) was chosen as the solvent, which dissolves not only many organic compounds, but also copper compounds to an extent of over 17.5% of cupric nitrate (trihydrate), over 15% of cupric chloride (dihydrate), 1.8% of cupric sulfate, and even a small amount of cupric acetate.

When DMF is used as solvent, the fuel gas pressure, especially the pressure and the flow rate of hydrogen, greatly affect the excitation of the objective cuprous chloride and the interfering C_2- Swan band and cupric oxide spectra. At hydrogen pressure of more than 0.14 kg./cm² (2 lb./in² gauge) the flame becomes very large by inflammation of DMF, attaining a height of over 10 cm., and the emission becomes unstable. The spectral curve obtained in such a case is covered by the C_2-Swan band, cupric oxide and cuprous hydride spectra, and cuprous chloride spectrum are hardly ever distinguishable.

With the decrease of hydrogen pressure, the flame becomes smaller and the effect of interfering spectra lessens gradually, with the appearance of a peak of cuprous chloride band spectrum.

When oxygen pressure is elevated, such as to 1.76 kg./cm² (25 lb./in² gauge), in order to strengthen the spraying of the sample,

and hydrogen pressure is adjusted to about 10 cm. water column, cuprous chloride band spectrum gives a distinguished peak, as indicated in Fig. 2.

The slit width was fixed at 0.05 mm., at which the fine structure of cuprous chloride band spectrum can be observed, and the sensitivity was adjusted accordingly. The relationship between the slit width and the cuprous chloride band spectrum is indicated in Fig. 3.

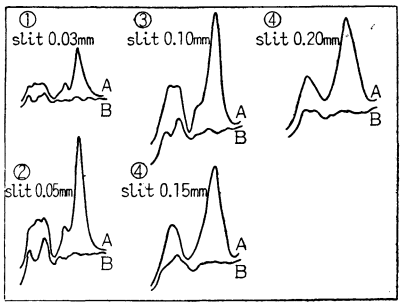

Fig. 3. Effect of slit width on cuprous chloride spectrum.

Preparation of Calibration Curves and Stability of Intensity.—As shown in Fig. 2, a base-line connecting two minima, 431 mμ and 439 mμ, was drawn on a recorded spectral curve, and the height from this line to the top of the peak was taken as the intensity of the cuprous chloride band, whose values were used for preparing the calibration curve.

The concentration of copper affects the stability of the flame and the intensity of the cuprous chloride band and the background. At a low concentration, sufficient intensity can not be obtained; at a high concentration, the background intensity increases and the flame becomes unstable. Examination with various concentrations of copper showed the optimal concentration to be 0.05 M of copper.

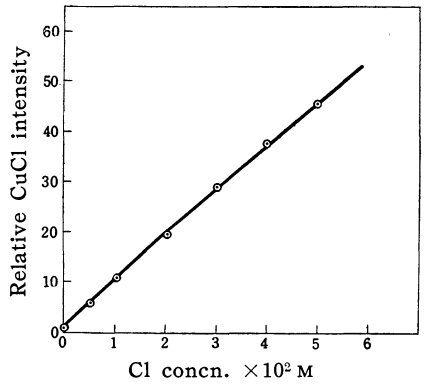

Fig. 4. Calibration curve of chloride.

An example of calibration curve at 0.05 M of copper is indicated in Fig. 4.

In the range of this calibration curve, the intensity becomes most stable in a chloride concentration of 0.02~0.05 M and is available for determination.

Table II gives the stability of cuprous chloride intensity of 0.02 M and 0.05 M chloride concentration.

will diminish. Hence the determination should be carried out as rapidly as possible after the sample has been transferred to a beaker. The effect of moisture on the spectral curve is shown in Fig. 5.

Determination of Chlorine in Organic Compounds.—Results obtained by the application of the present method to 11 kinds of organic chlorine compounds are shown in Table III.

These results indicate that the amount of chlorine found in solid organic chlorine compounds is approximately 98~102% of the theoretical value, while the value differs greatly from that calculated for liquid organic chlorine compounds, chloramine-T, and procaine hydrochloride. The values are higer by approximately 30% for carbon tetrachloride, and 10% for chloroform, and very arbitrary for chloramine-T.

Such a discrepancy may be due to the change in the intensity of the cuprous chloride band by the characteristic effect of evaporation rate for carbon tetrachloride and chloroform, by the ionic nature of chlorine of procaine hydrochloride, and by the sodium that forms a salt for chloramine-T. However, further detailed examination is still required.

Range of Application.—It is possible to carry out the qualitative and the quantitative determination of chlorine by dissolving organic chlorine compounds in DMF in a chlorine concentration of over 0.005 M and using 2~5 cc. of this solution. It is considered possible that this method can be used as a simple procedure for organic elementary analysis.

Organic compounds containing bromine or iodine can also be determined as in the case of chlorine at approximately the same wavelength region but the band spectra of cuprous bromide or cuprous iodide present less intensity than that of chloride under the same condition.

It is hoped that further research will be made on the determination of compounds containing bromine or iodine.

Summary

Examinations were made on the band spectrum of cuprous chloride based on the Beilstein's reaction in oxy-hydrogen flame. Determination of chlorine in organic chlorine compounds was attempted by using dimethylformamide containing

copper as a solvent and a band peak of 435.4 mμ of cuprous chloride.

In order to decrease the effect of C_2-Swan band that is produced on combustion of organic compounds, and to increase the sensitivity of cuprous chloride band spectrum, combustion gas was maintained at high oxygen pressure; 1.76 kg./cm^2 (25 lb./in^2 gauge), and low hydrogen pressure; 1st, 0.035 kg./cm^2 (0.5 lb./in^2 gauge), 2nd, 10 cm. water column.

γ-BHC was used as the standard and determination was carried out on 11 kinds of organic chlorine compounds, and good results were obtained with samples other than liquid, metal salts, and hydrochlorides. The determinable range for chlorine is 0.005~0.1 M concentration.

Confirmation of the Formation of Colloidal Particles in Aqueous Cobalt Salt Solution by Radiotracer Electrodialysis

By Tsunetaka SASAKI and Katsuyoshi OSAKA*

(Received October 16, 1958)

It has been pointed out by a series of our experiments[1] as well as of others[1], that polyvalent metallic ions such as aluminum, iron, copper and thorium exhibit remarkable effects in regard to surface-chemical properties, for instance, wettability of paraffin by water and the nature of monomolecular films of fatty acids. Such effects were explained by the assumption that these ions when dissolved in water mainly exist as hydrated polynuclear ions in a region of suitable pH, rather than as simple monomeric ions, as in the case of alkali and alkaline earth metal ions which show no remarkable effects in regard to the surface-chemical properties. Such an assumption of the existence of aggregated ions has also been proposed by Haissinsky[2] to explain a large fluctuation in the published data on the solubility product of one and the same insoluble compound. McGee, Kraus, Milburn and Kohlschütter[3] also offered similar opinions. Thus the existence of the polynuclear structure becomes increasingly convincing. However, all of these experimental evidences are rather indirect in nature. As a more direct evidence of the existence of such polynulear ions, we can also refer to a number of studies upon radiocolloid formation which proved the existence of colloidal particles in extremely dilute solutions of polonium, bismuth, lead, thorium, yttrium, etc.[4] In more concentrated solutions, the formation of aggregated particles were also observed in cobalt salt solution, for instance, by a self-diffusion method[5].

The present authors have also carried out the experiment of radiotracer electrodialysis[6], coupled with an ordinary filtration, to obtain a direct evidence of the formation of colloidal particles in an aqueous cobalt salt solution.

Experimental

(1) Radiotracer Electrodialysis.—The apparatus employed in the experiment was shown in Fig. 1. In this figure, A is a glass U-tube with one end somewhat wider than the other.

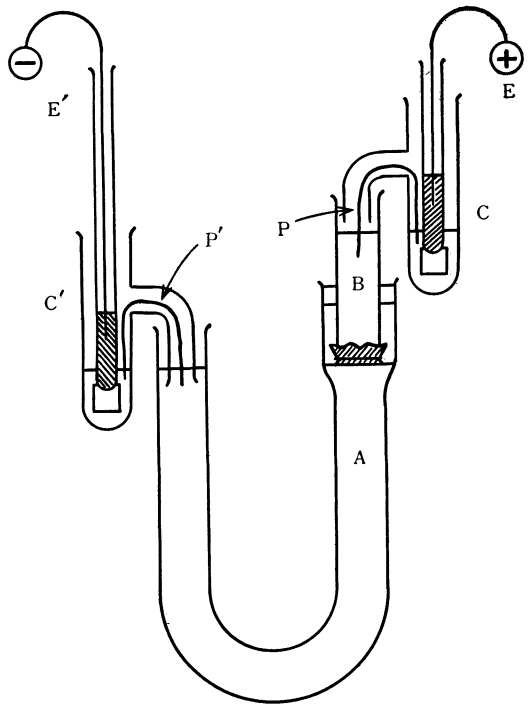

Fig. 1. Electrodialysis cell.

B is a glass cylinder, to the bottom of which a semipermeable cellophane membrane is tightly attached as shown in the figure, with the aid of a rubber ring. The electrode cells C and C' consist of two platinum electrodes E, E' and filter paper bridges P, P'. To carry out an experiment, the tubes A, B and cells C, C' are all filled with the same solution to be studied, that is 10^{-3} mol./l. aqueous solution of cobaltous chloride, with the exception that the solution in B alone is especially tagged with a suitable amount of radioisotope cobalt-60 as a tracer. Hereby, care should be taken that the lower end of the tube B is so placed that it just touches the surface of the solution in A. Now, when we apply D. C. voltage to the electrodes as indicated in Fig. 1, the cobalt ions will move from C to C'. So they will pass through the cellophane membrane downwards, if they are in a state of single ions or relatively small aggregates, while they will not be able to pass through the membrane if they exist as colloidal particles or even larger particles. Thus we can confirm the formation of particles larger than a colloidal size, when we trace the change in concentration of the solution in A.

Now, we have determined a suitable condition for practice from a preliminary experiment. It was evident that the amount dialyzed increased with the increase of applied potential gradient, as well as with the duration of electric current passed, but we performed a 50 volt and 15 minute dialysis*, since prolonged dialysis disturbed the steady condition of the solution to be dialyzed**. After the dialysis, the tube B was removed, 1 cc. of solution in the tube A just below the tube B was taken, heated to dryness in a stainless steel dish, and the radioactivity due to cobalt-60 was measured by a GM counter, as in the usual manner. The permeability was then expressed in c.p.m. Hereby, the GM tube was masked against β-ray and counting was taken only for that due to γ-ray, since the counting due to β-ray fluctuated sensitively for apparently identical geometry of counting arrangement. The cellophane used was a commercial product of a suitable thickness, which was cut in 5×5 cm^2 pieces, and was kept in distilled water for a long time in order to swell the sheets sufficiently for use.

In the course of experiments we found that the permeability of cellophane fluctuated from one sample to another, and also that one and the same sample gradually lost its permeability when used repeatedly. To overcome these undesirable conditions, we used the same membrane only for a couple of measurements, that is, for the permeability measurement of the reference solution containing 10^{-3} mol./l. cobaltous chloride, kept at pH 1, and for the subsequent measurement of the solution to be studied, which was of the same concentration but varying in pH. The control of pH was made using hydrochloric acid and sodium hydroxide.

From the measured permeability, we calculated the relative permeabilty, by the following formula,

$$P_r=\frac{\text{Permeability at pH}=x}{\text{Permeability at pH}=1}$$

The value P_r was used for further discussion. The change of pH due to the electrodialysis was about 0.5 at most.

Before use, cellophane membrane was also examined against pin holes by measuring a leak of Congo red solution through the membrane into pure water for 24 hours, from which we could confirm the fact that the membrane was free from eventual large pores, and also that the

TABLE I. PERMEABILITY OF AQUEOUS COBALT IONS THROUGH CELLOPHANE MEMBRANE

Permeability P_1 at pH=1	Permeability P' at pH=x	P	$P_r=P/P'$

* The distance between the two electrodes is 22 cm.

** The flow of water due to the hydrostatic pressure of water in the tube B was negligible during the period of experiment.

membrane acted as a sieve for particles at least larger than the Congo red molecule. Stock aqueous solution was kept at pH=1 and made up to a desired pH immediately before use. Permeability at varying pH and corresponding P_r values were listed in Table I.

(2) **Filtration.**—Ordinary filtration was carried out to detect the formation of particles coarser than colloidal ones in aqeous solution of cobalt salt. Radioactive cobalt salt solution of the same origin as used in the electrodialysis was filtered under varying pH using fine pore filter paper (Tôyô 5C) and a cobalt content in the filtrate was analyzed by measuring radioactivity due to the aliquot of the filtrate in the same manner as in the preceding experiment. The results were shown in Table II. In this table we showed the amounts of the cobalt ion in solution before and after the filtration by an arbitrary unit of radioactivity of 1 cc. of respective solution which was considered to be proportional to the concentration of cobalt ion. The degree of permeability of cobalt ion was expressed by the ratio F_r of radioactivities in a solution before and after the filtrations as shown in the last column of Table II.

TABLE II. PERMEABILITY OF AQUEOUS COBALT ION THROUGH FILTER PAPER (TÔYÔ 5 C)

pH	Amount of cobalt (cpm) before filtr. (A)	after filtr. (B)	$F_r=(B)/(A)$

9.4	874	336	0.38
10.1	846	15	0.017

* Geometry of the counting arrangement was accidentally different from the rest of the measurements.

Discussion

From Tables I and II, we prepared a diagram showing a pH dependence of permeability of cobalt ions through cellophane membrane and filter paper as shown in Fig. 2. In constructing this diagram, we first plotted P_r against pH, excluding the value at pH 1 which showed an extreme deviation, and obtained a curve which as a whole gave a plateau in the region of pH from 2 to 6. Next, we plotted F_r against pH and a similar curve was obtained. Then we adjusted the units of P_r and F_r axes so that both curves coincided at their plateau portions, assuming that there the complete passage of solute took place for both operations.

Now, in Fig. 2, we can readily recognize that the cobalt ions in the region A pass through both cellophane membrane and

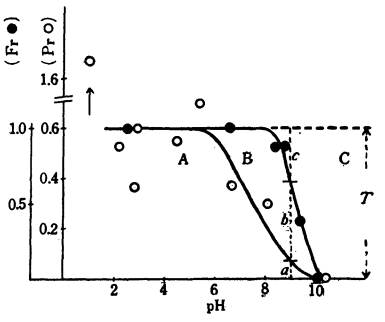

Fig. 2. State of dispersion of aqueous cobalt ion.
A, simple ionic dispersion
B, colloidal dispersion
C, macroscopic aggregation
T, total amount of cobalt in water

filter paper, while those belonging to the region B pass through the filter paper but are retained by the cellophane membrane, and those belonging to the region C are retained both by cellophane membrane and filter paper. Therefore, when we draw an ordinate at a certain pH, a portion a of the ordinate belonging to the region A represents a fraction of an amount of cobalt in the state of A region (simple ionic state), and so on. Thus, in the region of pH from 6 to 10, we confirm the formation of colloidal cobalt particles as those permeable to filter paper but not to cellophane membrane. We can also see the initiation of macroscopic agglomerate formation at pH 8 and precipitation of practically all cobalt ions at pH larger than 10, in the aqueous cobalt salt solution.

Now, from the published data of the solubility product[7], we calculated the minimum pH required to initiate cobaltous hydroxide precipitate in 10^{-3} molar aqueous cobalt salt solution. It was about 6.8, which happened to be situated between pH values of the initiation of colloidal particle formation and macroscopic agglomerate formation. We can conclude from these facts that in the solution studied, there exists a pH region of colloidal particle formation somewhere near the pH, beyond which solubility is exceeded. This conclusion is consistent with the results of a series of our former investigations already mentioned[1].

It must be added that the dissolved state of cobalt ion in aqueous solution changes gradually in the course of time, in a higher pH region as seen from the

7) Landolt-Börnstein, "Physikalisch-chemische Tabellen". I. Erg., Verlag J. Springer, Berlin, (1927), p. 662.

change of color of the solution. So we may expect that the boundary between the A regions and B of Fig. 2 will gradually shift presumably to the left in the course of time. The boundary may also shift according to the nature of the semipermeable membrane used.

Summary

(1) Dissolved state of cobalt ions in 10^{-3} molar aqueous solution of cobaltous chloride, varying in pH, was studied by a radiotracer electrodialysis coupled with an ordinary filtration.

(2) Formation of colloidal particles permeable to filter paper but not permeable to cellophane membrane were confirmed in the solution, in the region of pH from 6 to 10.

(3) Macroscopic precipitates of cobaltous hydroxide began to form at about pH 8 and practically all cobalt ions were precipitated at a pH greater than 10.

(4) The value of pH of insoluble cobaltous hydroxide formation in aqueous 10^{-3} molar cobalt salt solution calculated from the solubility product of cobaltous hydroxide was found to be situated between the pH of the initiation of colloidal particle formation and the pH of the initiation of macroscopic agglomerate formation.

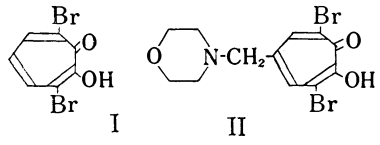
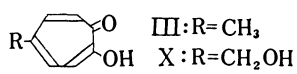
The Mannich Base of Troponoid and its Application. I. Synthesis of 5-Hydroxymethyl and 5-Formyltropolone Derivatives



By Shuichi SETO and Kyozo OGURA

(Received October 16, 1958)

Hartwig[1] reported morpholinomethyl derivatives of tropolone, 3-bromotropolone and 5-bromotropolone, and Pauson[2] also gave a brief description on piperidino methyltropolone in his review. However, Mannich reaction of 3,7-dibromotropolone (I) has not been reported. The present authors applied Mannich reaction to I in order to introduce a carbon chain to the 5-position of the tropolone nucleus and obtained 3,7-dibromo-5-morpholinomethyltropolone (II) in a good yield, from which 5-hydroxymethyl and 5-formyl compounds were derived. This paper describes these results.



When I was treated with morpholine and formalin in acetic acid, II was obtained as yellow powder. II is sparingly soluble in water and usual organic solvents, produces a hydrochloride difficultly soluble in water when treated with hydrochloric acid and gives a green color to the water layer with ferric chloride. Catalytic hydrogenolysis of II in the presence of palladium-carbon gave 5-methyltropolone (III)[3]. This indicates that the morpholinomethyl group of II has taken 5-position in the tropolone nucleus. 3,7-Dibromo-5-acetoxymethyltropolone (V) was obtained when II was heated with a large excess of acetic acid. If a small quantity of acetic acid is used, bis-(3,7-dibromotropololon-5-yl) methane (IV) is formed as a by-product. IV was also formed when II was treated with formalin and dimethylamine in acetic acid or V was heated in aqueous hydrobromic acid. V was easily hydrolyzed by alkali to give 3,7-dibromo-5-hydroxymethyltropolone (VI). The hydroxymethyl group of VI is readily displaced by other groups. For example, 5-nitro (VII)[4], 5-bromo (VIII)[5]

and 5-azo (IX)[6] compounds were yielded by the reactions of VI with dinitrogen tetroxide, *N*-bromosuccinimide and diazonium salt respectively.

Sebe and Matsumoto[7] obtained the formyl derivative by oxidizing 3-hydroxymethyltropolone derivatives with activated manganese dioxide. The application of this method to VI gave 3,7-dibromo-5-formyltropolone (XI). Catalytic hydrogenolysis of VI afforded 5-hydroxymethyltropolone (X) which was an unstable substance. Oxidation of X with manganese dioxide gave 5-formyltropolone[8].

3,7-Dibromo-5-formyltropolone (XI) gives an acetal, reacts with various ketonic reagents and produces Schiff's base with aniline. Furthermore, the reactions of XI with acetone, acetophenone, 2-hydroxyacetophenone, malonic acid and 4-acetyltropolone[9] gave 3,7-dibromo-5-(γ-oxobutenyl)tropolone (XII), 3,7-dibromo-5-(γ-phenyl-γ-oxopropenyl)tropolone (XIII), 3,7-dibromo-5-[γ-(2'-hydroxyphenyl)-γ-oxopropenyl]tropolone (XIV), 3,7-dibromo-5-(β-carboxyethenyl)tropolone (XV), and 3,7-dibromo-5-[γ-(tropolone-4'-yl)-γ-oxopropenyl]tropolone (XVI) respectively.

Further experiments of 5-hydroxymethyl and 5-formyltropolone derivatives are in progress.

Experimental[10]

3,7-Dibromo-5-morpholinomethyltropolone (II).—To a stirred mixture of 2 g. of 3,7-dibromotropolone (I), 3 ml. of acetic acid and 2 ml. of morpholine was added 1 ml. of formalin at 70°. The mixture became a clear orange solution and after a few min. a yellow precipitate began to deposit. Thereafter, stirring was continued at 80~90°C for 2 hr. Then 5 ml. of water was added to the cooled reaction mixture. The precipitate, 3,7-dibromo-5-morpholinomethyltropolone (II) was collected and washed with water. Yield, 2.6 g., m. p. 198~200°C.

Anal. Found: C, 38.40; H, 3.55; N, 3.82. Calcd. for $C_{12}H_{13}O_3NBr_2$: C, 38.00; H, 3.43; N, 3.70%. U. V. λ_{max}^{MeOH} (log ε): 268 mμ (4.32), 344 mμ (4.00), 427 mμ (3.92).

Hydrochloride of II; m. p. 225°C (decomp.).

Anal. Found: C, 34.65; H, 3.57; N, 3.35. Calcd. for $C_{12}H_{14}O_3NBr_2Cl$: C, 34.61; H, 3.61; N, 3.36%.

5-Methyltropolone (III).—When 500 mg. of II in aqueous sodium hydroxide was shaken with hydrogen at room temperature in the presence of palladium-carbon, 3 molar equivalents of hydrogen were absorbed. The catalyst was removed by filtration and the filtrate was acidified. A precipitate thereby formed was crystallized from benzene to give 5-methyltropolone (III) as colorless crystals, m. p. 109~110°C, undepressed by admixture with an authentic specimen.

Bis-(3,7-dibromotropolone-5-yl)methane (IV).—To a mixture of 500 mg. of I, 400 mg. of aqueous dimethylamine (40%) and 2 ml. of acetic acid was added 320 mg. of formalin (37%) at 90°C with stirring. After 40 min. the reaction mixture was cooled. Yellow crystals thereby formed

10) Melting points are not corrected.

were collected and washed with a small quantity of methanol. Yield 450 mg., m. p. 225°C (decomp.).

Anal. Found: C, 31.37; H, 1.23. Calcd. for $C_{15}H_8O_4Br_4$: C, 31.48; H, 1.40%. U. V. λ_{max}^{MeOH} (log ε): 272 mμ (4.48), 345 mμ (4.16), 430 mμ (4.07).

When an aqueous solution of ferric chloride was added to a suspension of IV in benzene, a black solid formed at the interface of the benzene and aqueous layers.

Heating of 5-acetoxymethyl compound (V) in aqueous hydrobromic acid under reflux also gave IV.

3,7-Dibromo-5-acetoxymethyltropolone(V). —A suspension of 1 g. of II in 35 ml. of acetic acid was heated at 100°C for 1 hr. and then at 120° for 3 hr. with stirring. The mixture became a yellow solution. When it was cooled, pale yellow needles separated out. The crystals (0.5 g.) were collected. Concentration of the filtrate at 60°C under reduced pressure gave a further crop (0.2 g.). Recrystallization of the combined crystals from ethyl acetate afforded 3,7-dibromo-5-acetoxymethyltropolone (V), m. p. 184~185°C.

Anal. Found: C, 34.66; H, 2.64. Calcd. for $C_{10}H_8O_4Br_2$: C, 34.09; H, 2.27%. U. V. λ_{max}^{MeOH} (log ε): 265 mμ (4.64), 345 mμ (4.14), 425 mμ (4.06).

3,7-Dibromo-5-alkoxymethyltropolone. — Heating of V in methanol under reflux gave 3,7-dibromo-5-methoxymethyltropolone as pale yellow crystals, m. p. 135°C.

Anal. Found: C, 34.08; H, 2.64. Calcd. for $C_9H_8O_3Br_2$: C, 33.33; H, 2.47%.

3,7-Dibromo-5-ethoxymethyltropolone, m. p. 100 °C, was similarly obtained.

Anal. Found: C, 35.19; H, 3.33. Calcd. for $C_{10}H_{10}O_3Br_2$: C, 35.54; H, 2.96%.

3,7-Dibromo-5-hydroxymethyltropolone (VI).—A mixture of 1 g. of V, 5 ml. of 3 N sodium hydroxide and 0.5 ml. of ethanol was heated on a water bath for 5 min. with stirring. After being cooled, the reaction mixture was acidified with 6 N hydrochloric acid and a precipitate thereby formed was collected, washed with water and crystallized from methanol to give 3,7-dibromo-5-hydroxymethyltropolone (VI) as pale yellow needles, m. p. 164~165°C. Yield, 0.8 g.

Anal. Found: C, 31.35; H, 1.79. Calcd. for $C_8H_6O_3Br_2$: C, 30.97; H, 1.93%. U. V. λ_{max}^{MeOH} (log ε): 266 mμ (4.47), 345 mμ (4.12), 425 mμ (4.09).

Reaction of VI with Dinitrogen Tetroxide. —To a solution of 0.1 g. of VI in 40 ml. of chloroform was added 0.5 g. of dinitrogen tetroxide with ice-cooling. After being kept for 30 min. at room temperature, the solvent and excess reagent were removed under reduced pressure. Yellow crystals thereby formed failed to show any depression of m. p. on admixture with an authentic 3,7-dibromo-5-nitrotropolone (VII), m.p. 145~146°C.

Reaction of VI with *N*-Bromosuccinimide. —A mixture of 50 mg. of VI, 30 mg. of *N*-bromosuccinimide and 6 ml. of chloroform was boiled for 2 hr. After removal of succinimide by filtration, the filtrate was evaporated to give 50 mg. of colorless crystals, m. p. 124~125°C, undepressed by admixture with 3,5,7-tribromotropolone (VIII).

Reaction of VI with Diazonium Salt. — To a pyridine solution of 50 mg. of VI was added a solution of diazonium salt prepared from 30 mg. of *p*-toluidine. A red precipitate thereby formed was collected, washed with methanol and crystallized from methanol to give red prisms, m. p. 190~191°C, undepressed by admixture with 3,7-dibromo-(*p*-tolylazo)tropolone (IX).

5-Hydroxymethyltropolone (X). — A suspension of 350 mg. of VI in aqueous sodium hydroxide was shaken with hydrogen at room temperature in the presence of palladium carbon. After absorption of 2 molar equivalents of hydrogen and removal of the catalyst by filtration the filtrate was acidified. A small amount of yellowish brown precipitate thereby formed was removed by filtration and the filtrate was extracted with ethyl acetate. Evaporation of the solvent from the extract afforded 5-hydroxymethyltropolone (X) as colorless needles, m. p. 131~132°C. Yield, 100 mg.

Anal. Found: C, 62.82; H, 5.32: Calcd. for $C_8H_8O_3$: C, 63.15; H, 5.27%. U. V. λ_{max}^{MeOH} (log ε): 233 mμ (4.40), 323 mμ (4.01).

5-Formyltropolone.—A mixture of 50 mg. of X, 5 ml. of acetone and 200 mg. of activated manganese dioxide was stirred for 2 days at room temperature. After removal of excessive manganese dioxide by filtration, the filtrate was concentrated to give a yellow manganese salt which was treated with 6 N hydrochloric acid and extracted with ethyl acetate. Evaporation of the extract left 20 mg. of 5-formyltropolone, m. p. 181°C.

3,7-Dibromo-5-formyltropolone (XI). — A mixture of 1 g. of X, 40 ml. of acetone and 4 g. of manganese dioxide was stirred for 20 hr. at room temperature. The mixture was then separated into a solid A and a filtrate B. Removal of the solvent from filtrate B under reduced pressure afforded a yellowish brown manganese salt. Treatment of the salt with 6 N sulfuric acid yielded a yellow precipitate which was crystallized from benzene to give 3,7-dibromo-5-formyltropolone (XI) as yellow prisms, m. p. 175~176°C. Extraction of solid A with acetone by means of a Soxhlet extractor gave a further crop of manganese salt which was also treated similarly to give XI. Yield, 0.95 g.

Anal. Found: C, 31.39; H, 1.43. Calcd. for $C_8H_4O_3Br_2$: C, 31.17; H, 1.30%. U. V. λ_{max}^{MeOH} (log ε): 260 mμ (4.21), 382 mμ (4.31), 410 mμ (4.33).

Heating of XI with methanol gave the acetal as colorless needles, m. p. 135°C.

Anal. Found: C, 33.58; H, 2.79. Calcd. for $C_{10}H_{10}O_4Br_2$: C, 33.90; H, 2.82%. U. V. λ_{max}^{MeOH} (log ε): 265 mμ (4.43), 350 mμ (4.02), 430 mμ (4.21).

Oxime of XI, yellow needles, m. p. 212~213°C.

Anal. Found: N, 4.21. Calcd. for $C_8H_5O_3NBr_2$: N, 4.35%. U. V. λ_{max}^{MeOH} (log ε): 270 mμ (4.42), 372 mμ (4.43), 433 mμ (4.10).

Semicarbazone of XI, yellow granular crystals, m. p. 249~250°C.

Anal. Found: C, 29.24; H, 2.18; N, 10.72. Calcd. for $C_9H_7O_3N_3Br_2$: C, 29.59; H, 1.92; N, 11.51%. U. V. λ_{max}^{MeOH} (log ε): 273 mμ (4.42), 378

mμ (4.55).

Thiosemicarbazone of XI, orange crystals, m.p. 280~288°C (decomp.).

Anal. Found: C, 28.79; H, 2.13. Calcd. for $C_9H_7O_2N_3SBr_2$: C, 28.35; H, 1.84%. U. V. λ_{max}^{MeOH} (log ε): 289 mμ (4.28), 395 mμ (4.47).

Phenylhydrazone of XI, red needles, m. p. 209~210°C.

Anal. Found: N, 6.97. Calcd. for $C_{14}H_{10}O_2N_2Br_2$: N, 7.04%. U. V. λ_{max}^{MeOH} (log ε): 265 mμ (4.42), 410 mμ (4.58).

2,4-Dinitrophenylhydrazone of XI, red needles, m. p. 257~258°C.

Anal. Found: N, 11.78. Calcd. for $C_{14}H_8O_6N_4Br_2$: N, 11.48%. U. V. λ_{max}^{MeOH} (log ε): 260 mμ (4.41), 440 mμ (4.61).

Schiff's Base of XI. — A mixture of 100 mg. of XI, 1 ml. of aniline and 0.5 ml. of acetic acid was heated on a water bath for 10 min. Deep red crystals thereby formed were recrystallized from methanol. Yield 100 mg., m. p. 209~210°.

Anal. Found: C, 43.61; H, 2.55; N, 3.81. Calcd. for $C_{14}H_9O_2NBr_2$: C, 43.98; H, 2.36; N, 3.67%. U. V. λ_{max}^{MeOH} (log ε): 270 mμ (4.37), 390 mμ (4.40).

Condensation of XI with Acetone. — To a solution of 100 mg. of XI in 1 ml. of acetone was added 0.3 ml. of aqueous sodium hydroxide (10%) with stirring at room temperature. After 2 days, an orange precipitate was collected and acidified with 6 N hydrochloric acid to give a yellow precipitate. Its recrystallization from acetone afforded 100 mg. of 3,7-dibromo-5-(γ-oxobutenyl)tropolone (XII), m. p. 195°C.

Anal. Found: C, 38.19; H, 2.61. Calcd. for $C_{11}H_8O_3Br_2$: C, 37.93; H, 2.30%. U. V. λ_{max}^{MeOH} (log ε): 280 mμ (4.38), 405 mμ (4.56).

Condensation of XI with Acetophenone.— A mixture of 100 mg. of XI, 0.3 ml. of acetophenone and 0.3 ml. of aqueous sodium hydroxide (10%) was stirred for 2 hr. at room temperature. A deep red precipitate thereby formed was collected and acidified with 6 N hydrochloric acid to give a yellow precipitate. Its crystallization from methanol yielded 120 mg. of 3,7-dibromo-5-(γ-phenyl-γ-oxopropenyl)tropolone (XIII), m. p. 200 °C.

Anal. Found: C, 46.16; H, 2.40. Calcd. for $C_{16}H_{10}O_3Br_2$: C, 46.83; H, 2.44%. U. V. λ_{max}^{MeOH} (log ε): 260 mμ (4.14), 288 mμ (4.16), 418 mμ (4.38).

Condensation of XI with 2-Hydroxyacetophenone. — A mixture of 100 mg. of XI, 80 mg. of 2-hydroxyacetophenone, 1 ml. of ethanol, and 0.5 ml. of 6 N sodium hydroxide was stirred on a water bath for 30 min. The mixture became dark red and formed a small quantity of precipitate C. Precipitate C was removed by filtration. Acidification of the filtrate with 6 N hydrochloric acid gave a brown solid. Recrystallization of the solid from methanol afforded 50 mg. of 3, 7-dibromo-5-[γ-(2'-hydroxyphenyl)-γ-oxopropenyl]tropolone (XIV), m. p. 215°C (decomp.).

Anal. Found: C, 45.02; H, 2.60. Calcd. for $C_{16}H_{10}O_4Br_2$: C, 45.11; H, 2.35%. U. V. λ_{max}^{MeOH} (log ε): 260 mμ (4.20), 295 mμ (4.20), 440 mμ (4.54).

Acidification of precipitate C gave XI recovered.

Reaction of XI with Malonic Acid.—A mixture of 100 mg. of XI, 100 mg. of malonic acid, 1 ml. of pyridine and 3 drops of piperidine was heated for 1 hr. at 90°C, for 2 hr. at 100°C and finally for 2 hr. at 120°C. During this time, evolution of carbon dioxide was observed and the mixture turned brown in color. Then the mixture was poured into a mixture of 0.5 g. of ice and 1 ml. of concentrated hydrochloric acid. A brown precipitate thereby formed was crystallized from methanol after decolorization with carbon to give 50 mg. of 3,7-dibromo-5-(β-carboxyethenyl)tropolone (XV), m. p. 195°C.

Anal. Found: C, 34.92; H, 2.01. Calcd. for $C_{10}H_6O_4Br_2$: C, 34.29; H, 1.71%. U. V. λ_{max}^{MeOH} (log ε): 268 mμ (4.39), 380 mμ (4.40).

Condensation of XI with 4-Acetyltropolone.—A mixture of 50 mg. of XI, 40 mg. of 4-acetyltropolone, 0.5 ml. of methanol and 0.5 ml. of aqueous sodium hydroxide (10%) was stirred for 30 min. at room temperature. The mixture turned red in color and deposited a deep red precipitate. The precipitate was collected, acidified with 6 N hydrochloric acid and recrystallized from methanol to give 50 mg. of 3,7-dibromo-5-[γ-(tropolone-4'-yl)-γ-oxopropenyl]tropolone (XVI), m. p. 220°C (decomp.).

Anal. Found: C, 42.93; H, 2.23. Calcd. for $C_{17}H_{10}O_5Br_2 \cdot H_2O$: C, 43.01; H, 2.54%. U. V. λ_{max}^{MeOH} (log ε): 255 mμ (4.24), 430 mμ (4.25).

Summary

Application of the Mannich reaction to 3,7-dibromotropolone gave 3,7-dibromo-5-morpholinomethyltropolone, from which 5-hydroxymethyl and 5-formyl derivatives were derived. It was found that the hydroxymethyl group of 3,7-dibromo-5-hydroxymethyltropolone can be easily displaced, and that 3,7-dibromo-5-formyltropolone has the characteristics of an ordinary aldehyde and reacts with ketones and malonic acid.

For the purpose of this work, 4-acetyltropolone was graciously furnished by Mr. K. Takase (Professor Nozoe's Laboratory, Faculty of Science, Tohoku University). A part of the expenses for the present research was defrayed by Sankyo Co., Ltd. The microanalyses were carried out by Messrs. S. Oyama and S. Azumi and Miss A. Iwanaga. The authors wish to express their sincere gratitude to the above mentioned people.

Cesium-137 in the Coastal Waters of Japan

By Noboru YAMAGATA and Shunji MATSUDA

(Received October 20, 1958)

The levels of radioactive cesium-137 in various materials have been analyzed by the authors and their colleagues since May 1957. A part of the results was compiled by Hiyama and presented to the Scientific Committee on the Effects of Atomic Radiation[1]; the full report is to be published in near future. The analytical data from other countries for cesium-137 in various materials are also available in the U.N. Report[2]. However, we have received no information on the level of cesium-137 in sea-water although that of strontium-90 was presented by Bowen in 1957[3]. It is necessary to know the level of the concentration of cesium-137 in oceanic water caused by nuclear fission explosions and also to guess a tolerable discharge rate of radioactive waste, especially for the Japanese people for whom marine products are the principal sources of proteins.

The cumulative ground deposit in Japan of strontium-90 has been shown by Miyake to be about 8 mc/km^2 in June 1957[4], and perhaps this value is also valid for cesium-137, of which the fission yield and the half-life are almost the same. If we consider temporarily that the sea-water is uniformly mixed to the depth of 100 m., then about 80 $\mu\mu$c of cesium-137 is expected to be present in one kilo-liter of sea-water. The sensitivity for cesium-137 measurement was about 100 $\mu\mu$c, and so it was a matter of actual difficulty to deal with kilo-liters of sea-water in the laboratory. Fortunately, domestic salt is commonly produced directly from sea-water in Japan; hence bittern or carnallite of industrial origin could be chosen as the starting material.

The Behavior of Cesium during the Evaporation of Sea-water. — It is a well known fact that cesium and rubidium are enriched in carnallite as compared in sea-water. Jander and Busch found 0.0002% of cesium chloride in Stassfurt carnallite on the average[5]. In the manufacturing process by solar and vacuum evaporation, cesium and rubidium have also been expected to be enriched in bittern and carnallite. The authors performed several experiments by the use of radioactive tracers ^{86}Rb and ^{137}Cs. Small fractions of sodium chloride and potassium chloride were crystallized respectively from their saturated aqueous solution by the isothermal evaporation. Both the activities of the crystal and of the evaporation residue of the initial solution were measured and the logarithmic distribution coefficient λ was calculated from the equation:

$$\lambda \log \frac{\text{NaCl (Total)}}{\text{NaCl(Total)-NaCl(Crystal)}} = \frac{^{137}\text{Cs (Total)}}{^{137}\text{Cs(Total)-}^{137}\text{Cs(Crystal)}}$$

In case of carnallite crystallization, activities were measured for both the initial solution and the mother liquor. The

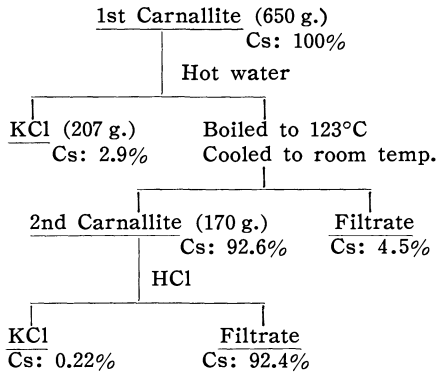

Fig. 3. Loss of cesium in the process of recrystallization of carnallite.

results summarized in Fig. 1[6] are in accord with the fact that cesium and rubidium have been naturally enriched in carnallite, and this nature will be useful for the practical concentration aimed at cesium-137 determination in sea-water. However, as the industrial conditions of carnallite formation greatly differ from the natural, the authors attempted to check the concentration procedure for cesium with a tracer experiment. The procedure and the loss of cesium is schematically shown in Fig. 2; the recovery of cesium is satisfactory.

Recrystallization of Carnallite.—Further enrichment of cesium can be accomplished by fractional recrystallization of carnallite. Halperin and Sambursky applied this method to the determination of rubidium in Dead-Sea carnallites[7]. As easily conceivable from the well-known phase diagram of the system KCl-$MgCl_2$-H_2O, on evaporation of the solution of artificial carnallite which contains a few per cent of sodium chloride, first only sodium and potassium chloride are deposited until the so-called "carnallite point" is reached, where the deposition of carnallite begins. The authors have modified this method for the practical convenience as described below.

A quantity of hot water less than that sufficient for complete dissolving is added to the primary carnallite (CI) and the suspension is cooled with vigorous agitation. Undissolved sodium and potassium chloride are filtered off and the filtrate is boiled until the boiling point reaches 123°C and then cooled to room temperature. The second carnallite (CII) thus obtained is only about one fourth the weight of the primary carnallite and contained 92.6% of the original cesium, so that a fourfold enrichment in concentration of this element can be obtained (Fig. 3).

Another recrystallization of CII resulted in the formation of the third carnallite (CIII) weighing about 600~800 g. which was expected to contain 70~80% of the total cesium originally existing in 50 kg. of bittern. When started from 2.5 kg. of the industrial carnallite sample, only one recrystallization was required to make the mass suitable for the further treatment of cesium separation. The chemical composition of several samples of bittern and carnallite is shown in Table I. An early experiment revealed that only 20 kg. of bittern or 1 kg. of carnallite was sufficient for cesium-137 determination and the later determination were made on this scale.

Separation and Determination of Cesium in Carnallite.—An aliquot of the saturated solution of the final carnallite was reserved for the flame photometric determination of natural cesium and the remainder was made 2.5 N acid with hydrochloric acid after the addition of carrier cesium chloride (100 mg. as Cs). Precipitated potassium chloride was filtered off and to the filtrate was added sodium silicomolybdate solution*) at 60~70°C with constant agitation. After cooling, the precipitate of cesium silicomolybdate was filtered off and washed with 2.5 N hydrochloric acid and then with water. The precipitate was dissolved with the least possible amount of hot 10% solution of sodium hydroxide. The undissolved silica was filtered off and

* B indicates bittern and C indicates carnallite sample.

** Computed for the basis of 50 kg. bittern.

after the filtrate was made up to about 300 ml. with water, 10% aqueous solution of chloroplatinic acid was added to precipitate the cesium. The precipitate was washed with water and then with ethyl alcohol, dried at 110°C, weighed and mounted for counting.

Radioassay was performed by β-counting by the use of a shielded GM-tube of the mica end-window type and the result was corrected for the absorption and the scattering of cesium chloroplatinate and the chemical yield. Details of the later steps of separation and radiochemical

determination have already been described[8,9]. Contamination of the final precipitate of cesium chloroplatinate with other fission activities, potassium-40, and rubidium-87 is negligibly small[9].

In the determination of natural cesium, it is necessary to take care, not to introduce contamination resulting from the reagents to be used. As there is no evidence of the absence of a trace of cesium in sodium salt, the dipicrylamine has been chosen as the precipitant for potassium. The reagent can easily be purified and a tracer experiment has proved that potassium dipicrylaminate effectively carries down traces of cesium.

An aliquot of the saturated solution of the final carnallite containing approximately 0.1 g. of potassium was diluted to about 50 ml. and treated with magnesium dipicrylaminate solution. The separation of potassium and cesium from the precipitated dipicrylaminate was accomplished in the simple way by the methyl isobutyl ketone extraction, of which the principle was previously reported[10]. The intensity of cesium 852.1 mμ line was measured in the usual way.

Materials and Results

Fifteen samples of bittern and eight samples of carnallite manufactured during June 1956 and April 1958 were collected around Japan. The location and the date of manufacture are shown in Table II and Fig. 4. The outline of manufacture of salt in Japan must be described to serve for the later discussion. The modern system of manufacture is entirely artificial, driven by electric power. Sea-water is pumped up directly into a vacuum evaporator and is never exposed to the open air, so the consideration about atmospheric contamination during the whole production process is unnecessary. The samples of bittern manufactured by this system are B-1, 2, 3, 4, 14 and 15 in Table II. On the other hand, the other samples have been manufactured by the usual salt-field system. In this case, sea-water is exposed to the open air, so that, we must consider the influence of fall-out during production.

The results are shown in Table II. Four

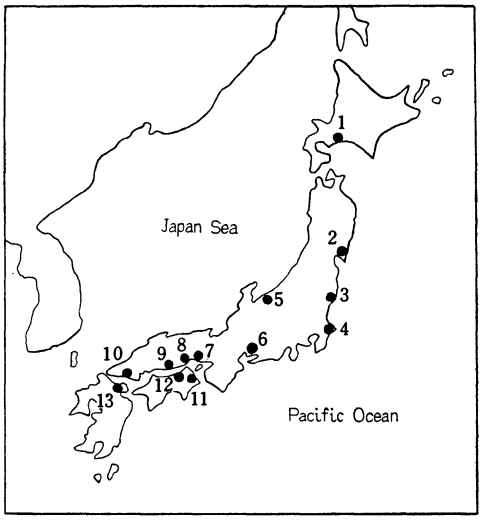

Fig. 4. Locations materials obtained.

kilo-liters of sea-water will produce about 50 kg. of bittern which are equivalent to about 2.7 kg. of carnallite. Values in Table II have been computed on the basis of 50 kg. of bittern. The analytical data for the natural cesium content of several samples are shown in Table III in which the isotopic ratios of cesium-137 and -133 have also been calculated.

The Natural Cesium Content of Sea-water.—Several authors have given surprisingly different values for the cesium content of sea-water. The maximum value is 4.3 μg. whereas the minimum is only 0.002 μg. per liter. The earliest estimate was given by Goldschmidt et al. as 2 μg.[11], although it was not based on actual determination in sea-water. Harada reported values from 0.002 to 0.01 μg.[12] Minami et al. started from about 50 ml. of

sea-water, by use of the cathode layer emission spectroscopy and gave the value of 0.1~1 μg. per liter[13]. Ishibashi and Hara reported values from 3.4 to 4.3 μg.[14] Recently, the most sensitive radioactivation analysis was applied by Smales and Salmon and the value of 0.5 μg. (±10%) per liter was reported[15]. The relative proportions of the major constituents in sea-water are practically constant, although some of the micro-elements of biological activities may fluctuate with time and space. On account of the strongly ionic nature of this element and its biological insignificancy, we can not guess any proper reason for real fluctuations of the concentration of cesium in the open oceans. In fact, the levels of cesium given by Smales and Salmon have been fixed within narrow limits for sea-water from the Atlantic Ocean including a sample of coastal water. The circumstance is considered also valid for the Pacific Ocean and the coastal waters of Japan. On the assumption that the value of 0.5 μg. is correct for the sea waters around Japan, we should like to proceed with the discussions in the following section.

Discussion

The concentration of cesium-137 in samples other than Location No. 1, 3 and 5 is considerably higher by factors of 5 to 10 or more than that in the latter locations; the trend is clear also in the isotopic ratio. The difference may be attributed principally to the contamination by fall-out during production. We can guess the possible contamination as follows. One of the salt-field systems of obtaining the brine from sea-water is the oldest, called the "Irihama" system and the evaporation is effected principally by the sun. For instance, in March 1958, at Watanoha, Miyagi Prefecture (Loc. No. 2), 12 kl. of brine of specific gravity (d_4^{15}=1.125) 16.0° Bé was produced per hectare in two days. Another plan to obtain the brine is a combination of the system of evaporation by the sun and air called the "flowing-down" system. For instance, 120 kl. of sea water is treated per day per hectare by this system. From these figures we can guess the possible contamination of 50 kg. of bittern approximately as 0.3~6 mμc when the fall-out rate of cesium is temporarily assumed to be 0.03~0.3 mc/km^2/month in early 1958.

The above computation indicates that the bittern and the carnallite obtained at the locations other than No. 1, 3 and 5 where salt is produced by the salt-field system are possibly contaminated by fall-out during production to a great extent. Only the results obtained for the bitterns from the locations No. 1, 3 and 5 are reliable to enable us to guess the levels of concentration of cesium-137 in sea-water. On the basis of the approximate figure of the weight of bittern equivalent to the volume of sea water, viz., 50 kg. to 4kl. and of 70% of the over-all yield of cesium, we can compute the concentration of cesium-137 in sea-water approximately to be 70~150 $\mu\mu$c/kl. The values of 160 and 310 $\mu\mu$c/kl. are also derived on the basis that the isotopic ratio of cesium-137 to -133 is 4.1 and 7.7×10^{-9} (Table III) and the cesium-133 content of sea-water is 0.5 μg./l.

The greater part of the domestic salt consumed in Japan comes from sea-salt and an average person takes approximately 15 g. of sodium chloride every day. The average daily intake of cesium-137 by a Japanese in the period from Aug. 1957 to Aug. 1958 is determined by the authors to be 22~56 $\mu\mu$c. The contribution of sea-salt to the total intake of cesium-137 by a person may be roughly computed if the assumption is admitted that the cesium in sea-water moves into the salt during manufacture following the distribution law by the coefficient of 0.03 (Fig. 1). Thus, the weight ratio of Cs/Na in the salt shall be 1.5×10^{-9} as compared with the ratio of 5×10^{-8} in sea-water (calculated from the values, 0.5 μg. of cesium and 10 g. of sodium in one liter). When we take the ratio of cesium-137 to -133 in sea water approximately to be 10^{-8} or 1 mμc of cesium-137 per 1 mg. of cesium-133, 15 g. of sodium chloride shall contain 0.01 $\mu\mu$c of cesium-137. It means that the contribution of sea-salt to the total intake of radioactive cesium-137 by a person is only 10^{-3} or less.

The β-counting equipment used by the authors was a usual mica end-window type GM-counter shielded by lead blocks. Natural background was 10~12 c.p.m. and counting efficiency was 5.3% for cesium-137 by our experimental conditions. About 100 $\mu\mu$c was the minimum amount of cesium-137 to be measured with a standard error of ±10%. Our present program includes the arrangement of a low-level β-counting equipment. With this, only 50~100 liters of sea-water

are sufficient for cesium-137 determination. With a slight modification of the separation method direct separation from sea-water will be possible.

The authors thank those who co-operated or assisted in the collection of bittern and carnallite samples, especially Dr. Jirō Sugi and Dr. Kazuo Shimizu at the Central Research Institute, Japan Monopoly Corporation. The authors also thank Mrs. T. Yamagata and Mr. E. Tajima for advice and assistance in the laboratory. Finacially, this work was partly supported by the Ministry of Education.

Action of Reducing Agents on Copper Phthalocyanine and its Chlorinated Derivatives

By Masahiro SHIGEMITSU

(Received September 19, 1958)

Although copper phthalocyanine is a very stable organic pigment, it is decomposed by oxidizing agents in its dissolved state in strongly acid solvents. However, it has been considered so far that copper phthalocyanine is stable toward reducing agents. The author examined the action of reducing agents on copper phthalocyanines containing chlorine in the range of naught to sixteen atoms per molecule and found that they were easily attacked by reducing agents, while copper phthalocyanine containing no chlorine was not. When copper phthalocyanine is chlorinated into "copper phthalocyanine green", its color is darkened from bright green to dark green. The cleavage of phthalocyanine nucleus was not caused by reducing agents, although it was caused by oxidizing agents.

Experimental

Materials.—Syntheses of copper phthalocyanine and chlorinated copper phthalocyanines were carried out as follows.

Copper phthalocyanine.—A mixture of phthalic anhydride, urea and cuprous chloride was heated at about 190°C for 3 hr.[1] The reaction product was treated with 5% hydrochloric acid and 2% sodium hydroxide The precipitate was filtered off, washed with water and ethanol, and dried.

Chlorinated copper phthalocyanines.—One part of copper phthalocyanine was dissolved in 6 parts of a eutectic mixture of aluminum chloride and sodium chloride (9:2, by weight, m. p. 145°C) at 150~160°C, and chlorine gas was introduced at a given flow rate and samples were taken out at regular intervals. These samples were washed with 5% hydrochloric acid, 2% sodium hydroxide, water and ethanol, and nine kinds of chlorinated copper phthalocyanine with chlorine content ranging from 2.91% to 44.97% as the degrees of chlorination were prepared. Copper hexadecachlorophthalocyanine (sample XI in Table I) was prepared by chlorinating copper octa-(3,6)-chlorophthalocyanine[2].

The results of chlorine analysis (micro-Carius method) for eleven samples thus prepared are given in Table I.

Methods.—*Particle size reduction.*—The particle size of these samples prepared as above were too large to be used as pigments. Therefore, the particle size of these samples was reduced

by the acid pasting method[3]. One part of the sample (I~V) was dissolved in 5 parts of 98% sulfuric acid, while 1 part of the sample (VI~XI) was dissolved in 3 parts of chlorosulfonic acid. Each solution was poured into 70 parts of ice water with stirring. Fine crystals precipitated were filtered off, washed free from acid with water and dried at about 60°C.

*Treatment by reducing agent, rongalit**. — A mixture of 1 g. of the sample treated as in the above section and 30 cc. of 20% aqueous solution of rongalit was heated at 150~155°C for 20 min. in a stainless steel autoclave equipped with a stirrer. The product obtaind was filtered off, washed with water and dried at about 60°C.

Measurement of the spectral reflectance curves. —One part of the sample treated as in the above section and 1.5 parts of polymerized linseed oil were mixed, made into paste by grinding 400 rounds in a Hoover automatic muller. To one part of this paste were added 70 parts of zinc white paste obtained by grinding 2 parts of zinc oxide with 1.5 parts of polymerized linseed oil. Then the mixed paste was applied 0.5 mm. thick on a coated paper with a "bladeoapplicator" (Gardner Laboratory), and the specimen was dried at room temperature. The spectral reflectance of the specimen prepared thus was measured with a General Electric recording spectrophotometer.

Electron microscopic observation of particle forms and measurement of particle size distributions.—To the samples (VI, VII, VIII, IX and X treated as in the above section was added 0.1% aqueous solution of a non-ionic surface active agent and the pigment was thoroughly dispersed with agitation. A drop of the dispersed solution was placed on a collodion film and dried. The electron microphotographs were taken at 2,000 magnification with an electron microscope of Hitachi Works, and the 20,000 magnification was obtained by enlarging photographs ten times. Three hundreds particles photographed were taken out at random, and particle size distributions were calculated by measuring their shorter and longer diameters.

Results

Variation in Chlorine Content.—Chlorine contents of the samples heated in the aqueous solution of rongalit are given in Table II.

As is clear from Table II, samples I to V do not vary in their chlorine content. But samples VI to X, which have greater chlorine contents, show some decrease in chlorine content by the treatment in rongalit. The greater the chlorine content of the sample, the greater the decrease in the chlorine content by the treatment. However, copper hexadecachlorophthalocyanine (XI) shows somewhat smaller decrease in chlorine content.

TABLE II. VARIATION IN CHLORINE CONTENT

Sample	Cl %: Original sample	Cl %: Sample treated by rongalit
I	0.11	0.12
II	2.91	2.86
III	15.15	15.09
IV	24.05	24.12
V	25.44	25.38
VI	33.71	33.32
VII	39.57	39.15
VIII	42.86	42.41
IX	43.63	43.10
X	44.97	44.30
XI	50.32	49.76

Variation in Color.—The luminosity Y, purity P_e and dominant wavelength λ_D calculated after the C. I. E. coordinate system from the spectral reflectance data are given in Table III.

TABLE III. LUMINOSITY, PURITY AND DOMINANT WAVELENGTH OF THE PIGMENTS

Sample		Y %	P_e %	λ_D mμ
I	original	24.80	48.7	479.0
	treated	22.78	40.3	478.8
II	original	19.07	54.2	478.5
	treated	24.13	48.0	479.4
III	original	18.45	56.0	478.2
	treated	21.62	53.7	478.9
IV	original	19.75	58.3	481.0
	treated	21.87	56.0	481.2
V	original	21.77	54.0	482.2
	treated	23.08	52.0	482.0
VI	original	25.13	49.5	484.8
	treated	23.90	47.3	483.3
VII	original	25.63	46.0	486.9
	treated	21.75	45.5	485.2
VIII	original	26.83	40.3	489.8
	treated	20.48	37.0	486.8
IX	original	26.80	41.0	490.8
	treated	20.07	38.5	487.4
X	original	30.33	37.0	491.4
	treated	20.15	39.0	487.5
XI	original	30.34	36.8	492.6
	treated	22.18	39.1	488.9

It is evident from Table III that the variation of color becomes greater with the increase in the chlorine content and diminishes again in copper hexadecachlorophthalocyanine (XI). The relationship between the luminosity change (ΔY%)

* addition compound of formalin and sodium hydrosulfite.

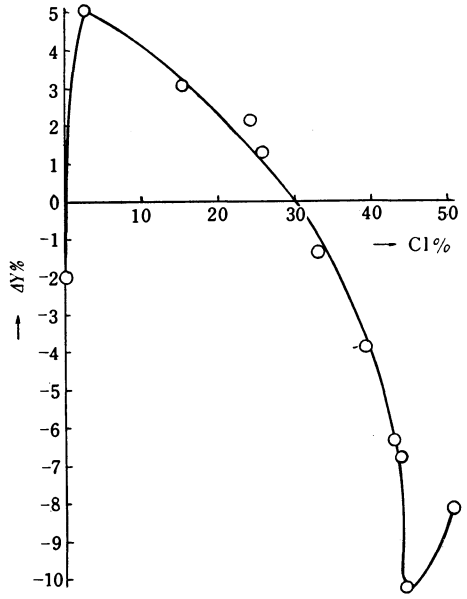

Fig. 1. Relationship between luminosity change and chlorine content.

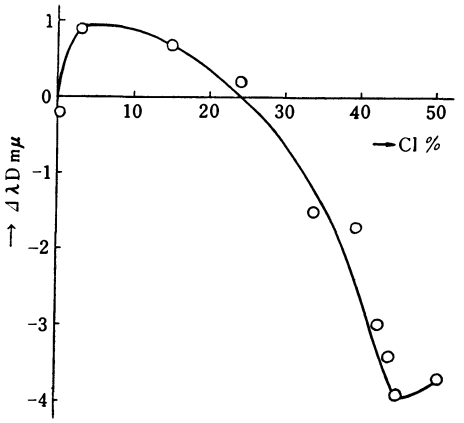

Fig. 2. Relationship between the shift of dominant wavelength and chlorine content.

or shift of dominant wavelength ($\Delta\lambda_D$ mμ) and the chlorine content are shown in Figs. 1 and 2.

It is to be noted that the sample with a greater chlorine content shows a lower brightness in color and shorter dominant wavelength.

Particle Size Distribution of Samples Subject to Remarkable Discoloration.—It is inferred from the above results that darkening of the color of samples treated with reducing agents is accompanied with the change in chemical composition of pigments. However, as the color of pigments, unlike dyes, is largely influenced by the form and the size of particles. particle size distribution of samples subject to remarkable discoloration (VI, VII, VIII, IX and X) was measured. The results are given in Table IV in which d_{mp} denotes the most probable value and d_m the average particle diameter. The value of d_m was calculated from

TABLE IV. PARTICLE SIZE DISTRIBUTION

		220~450	330	313	54	
X	treated	110~302	208	217	38	〃
		243~448	315	331	39	

$$d_m = 1/100 \sum_i f_i d_i$$ [4)]

where f is frequency and d particle diameter. "$\pm\delta$" in Table IV denotes deviation, that is, average deviation value from d_m, which was calculated from

$$\Delta = 1/100 \sum_i (d_m - d_i)^2 f_i$$ [4)]

It is obvious from Table IV that variation in form or aggregation of pigment particles did not occur by the treatment of pigments in the aqueous solution of rongalit. Namely, as already described, it was confirmed that the variation of color was due to the change of chemical composition.

Summary

Action of reducing agents on copper phthalocyanine and its chlorinated derivatives was studied, and it was found that, while copper phthalocyanine containing no chlorine did not suffer from discoloration, the color of its polychlorinated derivatives darkened. The discoloration, was most conspicuous when 13 to 14 chlorine atoms per phthalocyanine molecule were contained. The chlorinated copper phthalocyanine become stable towared reducing agents when it was exhaustively chlorinated.

It was confirmed that the darkening of the color of pigments was caused by the change of chemical composition, not by the change of size and form of particles.

The author extends his sincere thanks to Dr. Ryozo Goto, Professor of Kyoto University, for his kind guidance throughout the present study. The author's grateful thanks are also due to Dr. Takahisa Nakamura and Dr. Wataru Ishikawa, Toyo Ink Manufacturing Company, for the valuable advice and much help during the experiments.

Hydrogen Peroxide Oxidation. I. A New Selenium Dioxide-Catalyzed Synthesis of Carboxylic Acids from Aliphatic Ketones Accompanied by Rearrangement of Alkyl Groups

By Noboru SONODA and Shigeru TSUTSUMI

(Received November 6, 1958)

In the selenium dioxide oxidation of aliphatic carbonyl compounds, α-dicarbonyl compounds are generally obtained, whereas in the presence of hydrogen peroxide the oxidative reaction proceeds quite differently. For instance, selenium dioxide was used as catalyst for hydroxylation of olefins[1,2], and recently the use of selenium dioxide catalyst for the hydrogen peroxide oxidation of acrolein to acrylic acid has been reported by Smith and Holm[3], and the ring contraction of cycloalkanones to cycloalkanecarboxylic acids has also been confirmed by Payne and Smith[4].

We had tried to hydroxylate olefins with hydrogen peroxide in the presence of selenium dioxide catalyst and by using a mixed solvent of *tert*-butyl alcohol and a ketone. It was interesting to note that the oxidation of the ketone, used as solvent, proceeded mainly to form carboxylic acid accompanied by a migration of an alkyl group of the ketone.

For the purpose of elucidating the new reaction mode, acetone, methyl ethyl ketone, methyl *n*-propyl ketone and diethyl ketone were chosen as the starting materials. In the presence of a catalytic

1) M. Mugdan and D. P. Young, *J. Chem. Soc.*, **1949**, 2988.
2) P. Seguin, *Compt. rend.*, **216**, 667 (1943).
3) C. W. Smith and R. T. Holm, *J. Org. Chem.*, **22**, 746 (1957).
4) G. B. Payne and C. W. Smith, ibid., **22**, 1680 (1957).

amount of selenium dioxide, the oxidation of ketones was carried out with a slight excess of hydrogen peroxide in *tert*-butyl alcohol in gentle reflux condition (78~82 °C) for 5~6 hr. At the end of the oxidation the deposition of metallic selenium was observed by which the reaction mixture was colored brownish red, while the hydrogen peroxide completely disappeared. The oxidation products were separated by fractional distillation and analyzed.

When acetone was treated according to the above method, propionic acid, which arose by the shift of either of the methyl carbons to another, was isolated in a yield of 40.7% based on the acetone used. The oxidation of methyl ethyl ketone under similar conditions gave isobutyric acid as the main product in a 27.3% yield and *n*-butyric acid in a 4.8% yield. Both products were formed by the respective migration of the methyl and ethyl groups to the α-carbon atom of the carbonyl group.

$$(CH_3)_2C{=}O \xrightarrow[\textit{tert}\text{-butyl alcohol}]{SeO_2-H_2O_2} CH_3CH_2COOH \quad (1)$$

$$CH_3CH_2(CH_3)C{=}O \longrightarrow CH_3CH_2(CH_3)CHCOOH + CH_3CH_2CH_2COOH \quad (2)$$

All the acids obtained were identified by their physical properties, preparation of the derivatives (*p*-bromophenacyl esters), and their infrared spectra.

When methyl *n*-propyl ketone and diethyl ketone were oxidized under similar conditions to those described above, methyl ethyl acetic acid, which was formed by the respective migration of methyl and ethyl groups to the α-carbon atoms of the carbonyl groups, was isolated in a yield of 22.8% and 32.4%, respectively. The migration of *n*-propyl group of methyl *n*-propyl ketone was also observed, producing *n*-valeric acid in a 5.7% yield.

$$CH_3CH_2CH_2(CH_3)C{=}O \xrightarrow{SeO_2-H_2O_2} CH_3CH_2(CH_3)CHCOOH + CH_3CH_2CH_2CH_2COOH \quad (3)$$

$$CH_3CH_2(CH_3CH_2)C{=}O \longrightarrow CH_3CH_2(CH_3)CHCOOH \quad (4)$$

The above results suggest that similar treatments can be applied to other dialkyl ketones. Thus, the oxidative reactions may be generalized as follows;

$$R{-}CH_2(R')C{=}O \xrightarrow[\textit{tert}\text{-butyl alcohol}]{SeO_2-H_2O_2} R(R')CHCOOH \quad (5)$$

R=H or alkyl R'=alkyl

It is inferable that the main rearrangement in these oxidative reactions is due to the migration of the alkyl group having a smaller number of carbon atoms to the α-carbon atom of the larger alkyl group, and, in consequence, the generated acids have the same number of carbon atoms as the original ketones. On the other hand, the migration of the alkyl group with a larger number of carbon atoms to the smaller one occurs simultaneously in some degree, so that the corresponding isomers are obtainable when unsymmetrical dialkyl ketones are used.

Small amounts of cleavage products were obtained as by-products in all cases. These are listed in Table I.

TABLE I. CLEAVAGE PRODUCTS FROM OXIDATIVE REACTION OF KETONES

Reactants	Products confirmed	Yield
acetone	acetic acid[a]	trace
methyl ethyl ketone	acetic acid	trace
	propionic acid	trace
methyl *n*-propyl ketone	acetic acid[b]	trace
diethyl ketone	acetic acid[a]	trace
	propionic acid	4.1%

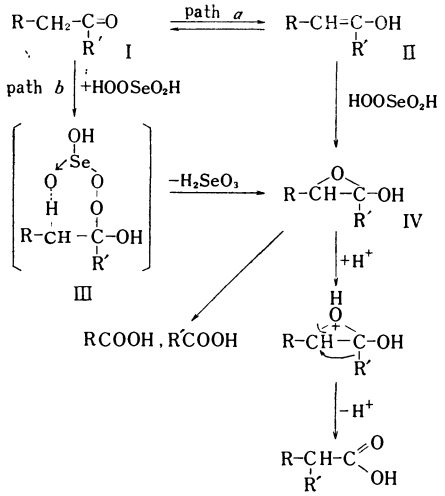
(a) The presence of acetic acid was confirmed by the boiling point, the refractive index and the value of neutral equivalent, and the other acids were identified in the form of *p*-bromophenacyl esters.
(b) Propionic acid and *n*-butyric acid are assumed to be present, but were not detected.

These products have apparently formed by the cleavage of the bond between the α-carbon atom and the carbonyl group, although, propionic acid can partly be furnished from oxidation of the solvent; because acetone and methyl alcohol are presumed to be generated from the decomposition of *tert*-butyl hydroperoxide and di-*tert*-butyl peroxide which are produced by the reaction of *tert*-butyl alcohol, used as solvent, with hydrogen peroxide. Actually, the formation of a small amount of aceton was observed (identified as its 2, 4-dinitrophenylhydrazone; the melting point and mixed melting point with authentic sample were 123°C[5]) when the

5) W. Dirscherl and H. Nahm, *Ber.*, **73**, 448 (1940).

selenium dioxide-hydrogen peroxide solution used above was heated without ketones.

The presence of acetic acid and propionic acid in the oxidation products of diethyl ketone indicates that both of the cleavaged groups from one ketone can be oxidized to acids in these reaction systems. In addition, the occurrence of formic acid due to the cleavage of methyl alkyl ketones or oxidation of methyl alcohol produced from solvent may be possible, but it was not detectable.



Synthesis of carboxylic acids from ketones by the use of aqueous ammonium polysulfide or a mixture of sulfur and water has been known as Willgerodt-reaction[6], in which aromatic-aliphatic ketones are mainly used as the starting materials, and no change of the carbon skeleton has been observed because of the consecutive reduction and oxidation of the carbon atoms in the aliphatic carbon chain. In the reaction described here the rearrangement of alkyl group occurs apparently and therefore the reaction mode is different from the Willgerodt-reaction. On the other hand, oxidation of ketones accompanying the rearrangement of alkyl group, by peracids or hydrogen peroxide in the presence of acidic catalyst, has been well known as Baeyer-Villiger reaction[7], but in this case the migrating alkyl group becomes the ester group of the resulting carboxylic acid so that the carbon numbers of the generated carboxylic acid are less than those of the starting ketone used. It is of interest to note that the rearrangement by the selenium dioxide-hydrogen peroxide system is applicable to such lower ketones as acetone and methyl ethyl ketone which produce monomeric or polymeric ketone-peroxides under the conditions of Baeyer-Villiger reaction. The ring contraction of cycloalkanones reported by Payne and Smith[4] may be interpreted as one of the rearrangement reactions described here.

Although little evidence was obtained about the mechanism of the rearrangement, the reaction would obviously proceed owing to the peculiar action of the catalyst. It seems to us that selenium dioxide may not affect the reaction directly but a further oxidized form of selenium dioxide by hydrogen peroxide may be the most probable catalytic form. Because α-dicarbonyl compound is not the intermediate[4]; for example, diacetyl was cloven into two molecules of acetic acid under the same reaction conditions and C_4-acid was not obtained.

The oxidation of selenium dioxide with hydrogen peroxide has been reported by several workers[8-10]. Hughes and Martin[9] proposed the formation of peroxyselenious acid in the course of the oxidation of selenium dioxide to selenic acid as shown below.

$$SeO_2 + H_2O_2 \rightleftarrows HOOSeO_2H$$

We investigated[11] previously the fact that the hydroxylation of a double bond was possible by applying the same oxidative method to olefins, and this fact would be elucidated by considering the formation of some kind of peracid in the reaction system. In the present case, the peroxyselenious acid may be formed in *tert*-butyl alcohol solution and may attack ketones in an ionic fashion; thus the following mechanism will be presumed.

Path a indicates that the epoxidation of *enol*-form II by the peroxyselenious acid may occur and addition of proton to the resulting epoxyalcohol IV may cause the migration of an alkyl group. Formation of epoxyalcohol IV will be also expected

from path b which may include the combination between the α-hydrogen and the oxygen of peroxyselenious acid at the same time of addition of peroxyselenious acid to the carbonyl group. The former path would be more favorable to the latter because of the difficulty of such ring formation III. After the epoxidation, the peroxyselenious acid may become selenious acid which is in equilibrium with selenium dioxide and water (equation 7)[9],

$$H_2SeO_3 \rightleftarrows SeO_2 + H_2O \qquad (7)$$

and the reproduced selenium dioxide will be again oxidized to peroxyselenious acid with hydrogen peroxide (equation 6).

Experimental[12]

Starting Materials.—The ketones and the solvent used in this study were commercial products. Acetone and methyl ethyl ketone were carefully purified by treatment with potassium permanganate solution according to the usual method[13]. The other ketones and *tert*-butyl alcohol, used as the solvent, were purified by fractional distillation prior to their uses. Hydrogen peroxide (30%) and selenium dioxide were from Wako Pure Chemical Industries, Ltd.

Reagent for Oxidation.—A solution containing 150 ml. of 30% hydrogen peroxide and 600 ml. of *tert*-butyl alcohol was dried over 200 g. of anhydrous sodium sulfate overnight. After separating the sodium sulfate, the concentration of hydrogen peroxide in the solution was determined by iodometry. A solution containing 68~69 mg. of hydrogen peroxide per 1 ml. was obtained, and 2 g. of selenium dioxide was dissolved in 500 ml. of the solution (corresponding to about 1 mol. of hydrogen peroxide) with stirring. Selenium dioxide-hydrogen peroxide reagent thus obtained was used in all experiments.

Oxidation of Acetone.—A 1 l. round bottomed flask was charged with 500 ml. of the selenium dioxide-hydrogen peroxide reagent (2 g. of selenium dioxide and 1 mol. of hydrogen peroxide), and 50 g. (0.86 mol.) of acetone was added slowly with stirring. The flask was then fitted with an efficient reflux condenser and was heated on a steam bath. After refluxing (79~81°C) the mixture gently for about 5 hr., the solution became brownish red owing to the deposition of metallic selenium, and the hydrogen peroxide had been completely consumed at this stage. The reaction mixture was allowed to cool to room temperature, the reflux condenser was exchanged for a Widmer-spiral and the distillation was then carried out to remove the remaining acetone-*tert*-butyl alcohol azeotropic mixture. When about 400 ml. of the azeotropic mixture was distilled off, the residue was cooled and the precipitated metallic selenium was filtered off. Ten g. of anhydrous sodium sulfate and 50 ml. of ether were added to the filtrate. After the solution was allowed to stand overnight, it was transferred to a separatory funnel and the water layer was removed and dried over anhydrous sodium sulfate. The ether and the products boiling up to 83°C were distilled off and materials of higher boiling point were fractionated through a 1×40 cm. packed column. The fraction boiling at 139.5~141°C was collected, and 26.0 g. of propionic acid was obtained (40.7% of the theoretical amount based on the quantity of acetone used); n_D^{25} 1.3852, neut. equiv. 74.8; lit.[14] b. p. 140.3°C, n_D^{25} 1.3848. Calcd. for $C_3H_6O_2$: neut. equiv. 74.1.

The infrared spectrum of the acid coincided with that of an authentic sample. *p*-Bromophenacyl ester of the acid was prepared by an usual method[15], m. p. 63.5~64°C, reported[16] 63°C. The mixed melting point with an authentic sample (63.5~64°C) was not depressed.

Anal. Found: C, 48.64; H, 4.23%. Calcd. for $C_{11}H_{11}O_3Br$: C, 48.74; H, 4.09%.

The results of fractional distillation and the characterization of each fraction were listed in Table II.

Table II. Distillation of oxidation products from acetone

Fraction	B. p. °C	Vol. ml.	Characterization n_D^{25}	neut. equiv.
a-1	82~108	6.0	1.3738	90.2
a-2	108~115	2.0	1.3721	69.2
a-3	115~125	0.5	1.3781	78.5
a-4	125~135	0.6	1.3810	83.7
a-5	135~138	o.5	1.3822	80.0
a-6	138~139.5	0.9	1.3844	78.9
a-7	139.5~141	26.0	1.3852	74.8
	residue	1.7(g.)		

Fraction a-1 contained small amount of azeotropic mixture of acids and water. From the value of neutral equivalent, fraction a-2 seemed to contain the carboxylic acid lower than propionic acid. The *p*-bromophenacyl ester of fraction a-2 had melting point of 79~105°C, which indicated presumably the presence of formic acid and acetic acid: reported melting point of *p*-bromophenacyl ester of acetic acid, 85°C[16]; *p*-bromophenacyl ester of formic acid, 135°C[15]. It was presumed from the value of neutral equivalent that fraction a-3 was acetic acid which was contaminated by impurities other than carboxylic acid. Fraction a-4 was also an acid component but was contaminated by impurities. *p*-Bromophenacyl ester of fractions a-5 and a-6 were confirmed to be that of propionic acid

12) The boiling and melting points are uncorrected.

respectively from their melting points and mixed melting points with an authentic sample. Fraction a-7 was propionic acid, and the residue in the distilling flask consisted mainly of metallic selenium.

Oxidation of Methyl Ethyl Ketone. — To a 500 ml. of the selenium dioxide-hydrogen peroxide reagent (2 g. of selenium dioxide and 1 mol. of hydrogen peroxide) was added 62g. (0.86 mol.) of a methyl ethyl ketone, and the reaction was carried out under gentle reflux condition for 5.5 hr. The reaction mixture was concentrated through a Widmer-spiral to about 150 ml., and conducted in the same manner as described for the oxidation of acetone. The results of the fractional distillation were listed in Table III.

TABLE III. DISTILLATION OF OXIDATION PRODUCTS FROM METHYL ETHYL KETONE

Fraction	B. p. °C	Vol. ml.	Characterization n_D^{25}	neut. equiv.
b-1	102~115	1.0	1.3715	80.7
b-2	115~121	1.0	1.3756	67.7
b-3	121~137	0.4	1.3799	73.0
b-4	137~142	0.5	1.3838	77.4
b-5	142~152	1.2	1.3904	85.5
b-6	152~153.5	1.8	1.3923	88.1
b-7	153.5~156.5	21.2	1.3928	88.9
b-8	156.5~162	2.3	1.3950	89.2
b-9	162~164	4.1	1.3965	88.3
	residue	1.8(g.)		

Fraction b-1 consisted principally of the azeotropic mixture between lower carboxylic acids and water from the standpoint of the values of neutral equivalent and the refractive idex. Fraction b-2 was acetic acid which was identified, from its *p*-bromophenacyl ester m. p. 84~84.5°C; reported[16] m. p. 85°C; the depression of melting point was not shown when the ester was mixed with an authentic sample (m. p. 84.5°C).

Fraction b-3 would be possibly a mixture of acids. Fraction b-4 was identified to be propionic acid from the melting point of its *p*-bromophenacyl ester, m. p. 62.5~63°C, reported[16] m. p. 63°C; the mixed melting point with an authentic sample was not depressed. Fraction b-5 would be a mixture of acids. Fractions b-6 and b-7 were isobutyric acid, 23 g. (27.3% yield of the theoretical amont based on the quantity of methyl ethyl ketone used); the infrared spectrum of the acid coincided with that of an authentic sample; lit.[14] b. p. 154.6°C, n_D^{20} 1.3930; Calcd. for $C_4H_8O_2$, neut. equiv. 88.1.

p-Bromophenacyl ester of the acid was prepared, m. p. 75~75.5C°, reported[16] m. p. 76.2°C. The mixed melting point with an authentic sample (m. p. 75.5°C) was not depressed.

Anal. Found: C, 50.68; H, 4.59. Calcd. for $C_{12}H_{13}O_3Br$: C, 50.55; H, 4.60%.

Fraction b-8 would be obviously a mixture of isobutyric acid and *n*-butyric acid.

Fraction b-9 was *n*-butyric acid, 4.1 g. (4.8% yield based on the quantity of methyl ethyl ketone used); the infrared spectrum of the acid coincided with that of an authentic sample; lit.[14] b. p, 164°C, n_D^{20} 1.3979; Calcd. for $C_4H_8O_2$, neut. equiv. 88.1.

p-Bromophenacyl ester of the acid was prepared, m. p. 62.5°C reported[16] m. p. 63°C. The mixed melting point with an authentic sample (62.5°C) was not depressed.

Anal. Found: C, 50.39; H, 4.70. Calcd. for $C_{12}H_{13}O_3Br$: C, 50.55; H, 4.60%.

Oxidation of Methyl *n*-Propyl Ketone. — To a 250 ml. (1 g. of selenium dioxide and 0.5 mol. of hydrogen peroxide of the selenium dioxide-hydrogen peroxide reagent was added 37 g. (0.43 mol.) of a methyl *n*-propyl ketone, and the mixture was treated under the gentle reflux condition for 6 hr. The reaction mixture was concentrated through a Widmer-spiral to about 70 ml. (when aqueous layer had separated) followed by addition of 5 g. of anhydrous sodium sulfate to saturate the aqueous layer. After separation, the aqueous layer was extracted with 20 ml. of ether. A mixture of the ether extract and the separated organic layer was dried over anhydrous sodium sulfate, and fractional distillation was carried out through the same column described as in the case of acetone. The results of the fractional distillation were listed in Table IV.

TABLE IV. DISTILLATION OF OXIDATION PRODUCTS FROM METHYL *n*-PROPYL KETONE

Fraction	B. p. °C	Vol. ml.	Characterization n_D^{25}	neut. equiv.
c-1	110~117	0.9	1.3733	67.5
c-2	117~122	0.3	1.3752	—
c-3	122~160	1.3	1.3875	81.3
c-4	160~166	0.4	1.3977	97.2
c-5	166~172	1.0	1.4008	101.3
c-6	172~175	3.1	1.4030	103.0
c-7	175~177	7.5	1.4044	103.7
c-8	177~182	1.1	1.4059	102.8
c-9	182~186	2.7	1.4074	104.0
	residue	2.2(g.)		

Fraction c-1 would be a mixture of lower carboxylic acids which consisted mostly of acetic acid. Fraction c-2 was identified as acetic acid from its *p*-bromophenacyl ester, m. p. 84.5°C, reported[16] 85°C; the mixed melting point with an authentic sample was not depressed. Fractions c-3 and c-4 would be a mixture of acids, and a detectable amount of *n*-butyric acid was not obtained. The greater part of fraction c-5 would consist of methyl ethyl acetic acid similar to the next fraction.

Fractions c-6 and c-7 were identified to be methyl ethyl acetic acid, 10.0 g. (22.8% yield of the theoretical amount based on the methyl *n*-propyl ketone used), the infrared spectrum of the acid coincided with that of an authentic sample; lit.[14] b. p. 174°C (reported[15] 176°C), n_D^{20} 1.4051; Calcd. for $C_5H_{10}O_2$, neut. equiv. 102.1.

17) O. T. Schmidt, *Ann.*, *483*, 115 (1930).

p-Bromophenacyl ester of the acid was prepared from the fraction c-7, m. p. 54.5~55°C, reported[15] 55°C; mixed melting point with an authentic sample was not depressed.

Anal. Found: C, 52.34; H, 5.36. Calcd. for $C_{13}H_{15}O_3Br$: C, 52.19; H, 5.06%.

Fraction c-9 was confirmed to be *n*-valeric acid, 2.5 g. (5.7% yield based on the ketone used); the infrared spectrum of the acid coincided with that of an authentic sample; lit.[14] b. p. 186.4°C, n_D^{20} 1.4086; Calcd. for $C_5H_{10}O_2$, neut. equiv. 102.1.

p-Bromophenacyl ester of the acid was prepared; m. p. 73.5~74°C, reported[17] m. p. 74°C; the mixed melting point with an authentic sample was not depressed.

Anal. Found: C, 52.01; H, 5.33. Calcd. for $C_{13}H_{15}O_3Br$: C, 52.19; H, 5.06%.

Oxidation of Diethyl Ketone.—To a 150 ml. (0.6 g. of selenium dioxide and 0.3 mol. of hydrogen peroxide) of selenium dioxide-hydrogen peroxide reagent was added 22.4 g. (0.26 mol.) of diethyl ketone, and the mixture was gently refluxed for 5.5 hr. The resulting reaction mixture was concentrated through a Widmer-spiral to about 50 ml. and was treated according to the same method as described in the case of methyl *n*-propyl ketone. The results of the fractional distillation were listed in Table V.

TABLE V. DISTILLATION OF OXIDATION PRODUCTS FROM DIETHYL KETONE

Fraction	B. p. °C	Vol. ml.	Characterization n_D^{25}	neut. equiv.
d-1	103~112	1.2	—	—
d-2	112~124	0.5	1.3770	68.4
d-3	124~135	0.3	—	—
d-4	135~142	0.8	1.3860	75.4
d-5	142~160	0.6	1.3891	82.8
d-6	160~170	0.5	1.3960	91.0
d-7	170~174	0.8	1.4033	101.5
d-8	174~177	8.0	1.4040	103.1
d-9	177~179	0.3	1.4051	104.8
	residue	1.1(g.)		

Fraction d-1 was an azeotropic mixture of acids and water. Fraction d-2 was a mixture of acids which would consist mainly of acetic acid from the standpoint of the boiling range, the refractive index and the value of neutral equivalent, but the *p*-bromophenacyl ester did not give the constant melting point owing to the presence of the ester of the other acids. Fraction d-3 would be a mixture of acetic acid and propionic acid.

Fraction d-4 was identified to be propionic acid (4.1% yield based on the ketone used); *p*-bromophenacyl ester, m. p. 62.5~63.5°C, reported[16] m. p. 63°C, the mixed melting point with an authentic sample was not depressed. Fractions d-5 and d-6 would be a mixture of acids which were not identified.

Fractions d-7 and d-8 were identified to be methyl ethyl acetic acid, 8.6 g. (32.4% yield based on the quantity of diethyl ketone used); the infrared spectra of these fractions coincided with that of an authentic sample; lit.[14] b. p. 174°C (reported[15] 176°C); n_D^{20} 1.4051; Calcd. for $C_5H_{10}O_2$, neut. equiv. 102.1.

p-Bromophenacyl ester was prepared from the fraction d-8, m. p. 55°C, reported[15] m. p. 55°C; the mixture melting point with an authentic sample was not depressed.

Anal. Found: C, 51.94; H, 5.06. Calcd. for $C_{13}H_{15}O_3Br$: C, 52.19; H, 5.06%.

Oxidation of Diacetyl.—To a 130 ml. (0.52 g. selenium dioxide and 0.26 mol. hydrogen peroxide) of the selenium dioxide-hydrogen peroxide reagent was added 21.5 g. (0.25 mol.) of diacetyl. The mixture was refluxed for 6.5 hr. and then was treated in the same manner as described for the oxidation of acetone. Acetic acid (b. p. 117~119°C) was isolated by distillation and the yield was 10.8 g. (36.0% based on diacetyl used).

Summary

1) Selenium dioxide catalyzed oxidation of aliphatic ketones with hydrogen peroxide gave carboxylic acids which were produced by the rearrangement of the alkyl group as shown by equation 5.

2) Acetone, methyl ethyl ketone, methyl *n*-propyl ketone and diethyl ketone were selected as starting materials. The main rearrangement observed is due to the migration of the alkyl group having a smaller number of carbon atoms to the α-carbon atom of the larger alkyl group, and the migration of the alkyl group with a larger number of carbon atoms to the smaller one also occurs in some degree.

3) The yield of the generated acids were about 30~40% of the theoretical amounts based on the ketones used. Small amounts of cleavage products were obtained as the by-products in all cases. Both of the cleavaged groups from a ketone were oxidized to acids in these reaction systems.

4) The most probable catalytic form seems to be peroxyselenious acid which may be produced by the oxidation of selenium dioxide with hydrogen peroxide (equation 6). Inferential reaction mechanism was discussed.

Protonation Effects on the Electronic Spectra of Pyrazine

By Shizuyo MATAGA and Noboru MATAGA

(Received October 21, 1958)

In our previous reports[1,2], we have tried to interpret theoretically the characteristics of electronic spectra of hydrogen bonded or protonated nitrogen heterocycles, especially in the case of pyridine. In these reports, semiempirical Hartree-Fock SCF MO's for pyridine interacting with proton have been computed assuming extreme models: (1), there is no transfer of non-bonding electrons on nitrogen toward proton, but bare proton or somewhat shielded proton is located near the nitrogen atom of neutral molecules. In the latter case, the effective charge of proton has been introduced in theory (model I); (2), there is considerable charge transfer from nitrogen atom to proton, leading to covalent binding between them (model II).

The calculated sepectra with model I were in a very good agreement with the experiment. The calculation with model II, however, led to a result which gave rather poor agreement with the experimental values. These results were examined carefully and some discussions on the cause of the superiority of model I and the unsatisfactory result obtained with model II were given.

In the present paper, we shall report another example of our calculations, i.e., the study of the electronic spectra of pyrazinium diion. In this case, the features of spectral change produced by protonation are somewhat different from the case of pyridine.

Method of Calculation

Our method of calculation has already been described in detail elsewhere[2]. Accordingly, the outline of our method will be given briefly as follows.

Model I.—In this case, the complete electronic Hamiltonian may be written as,

$$H=\sum_i H_i^{c\ rel}+\sum_{i<j}^{2m}(e^2/r_{ij}) \tag{1}$$

$$H_i^{core\prime}=H_i^{core}+H_i^P \tag{2}$$

where H_i^P is the electrostatic potential due to proton

$$H_i^P=-\sum_P\frac{Z_{H^+}e^2}{r_{Pi}} \tag{3}$$

In Eq. 2, r_{Pi} is the distance between proton and i-th electron and $Z_{H^+}e$ is the effective charge of proton. In the present calculation it has been assumed to be $Z_{H^+}=1$. The i-th MO may be written in the LCAO form as,

$$\phi_i=\sum_\mu C_{i\mu}\phi_\mu \tag{4}$$

and the eigenvalue equations become as follows in terms of Hartree-Fock SCF MO with neglect of differential overlap,

$$\sum_\nu F_{\mu\nu}C_{i\nu}=\varepsilon C_{i\mu} \tag{5}$$

where

$$F_{\mu\mu}=\alpha_\mu{}'+\frac{1}{2}P_{\mu\mu}\gamma_{\mu\mu}+\sum_{\kappa(\neq\mu)}(P_{\kappa\kappa}-1)\gamma_{\mu\kappa} \tag{6}$$

$$F_{\mu\nu}=B_{\mu\nu}-\frac{1}{2}P_{\mu\nu}\gamma_{\mu\nu} \tag{7}$$

$$\alpha_\mu{}'=\alpha_\mu+V_\mu{}^P \tag{8}$$

$$V_\mu=-\sum Z_{H^+}e^2\int\frac{\phi_\mu{}^2(i)}{r_{Pi}}\mathrm{d}v(i) \tag{9}$$

The meaning of the quantities in these equations other than $V_\mu{}^P$ is the same as before[3-5]. Among the molecular integrals that arise, $V_\mu{}^P$ has been computed theoretically employing the usual Slater $2p\pi$ AO's of nitrogen and carbon atoms, and the others have been evaluated by the same procedure as before[3-5]. Because the interatomic distances in pyrazinium diion necessary for the evaluation of molecular integrals are uncertain, C–C and C–N distances have been assumed to be the same as in neutral molecules and the N–H$^+$ distance has been put to be 1.032 Å, which is the value determined by Bersohn and Gutowsky[6] by means of nuclear

magnetic resonance in the case of ammonium chloride.

Model II.—For the calculation to be made by this by this model, the values of the valence state ionization potential I_{N^+} and electron affinity A_{N^+} of N^+ ion are needed. Using the values of valence state energies above the ground state, which have been taken from Pritchard and Skinner[7], the values of I_{N^+} and A_{N^+} are easily obtained considering the processes,

$N^+(sp_xp_yp_z,\ V_4) \rightarrow N^{++}(sp_xp_y,\ V_3)$ and

$N(sp_xp_yp_z^2,\ V_3) \rightarrow N^+(sp_xp_yp_z,\ V_4)$,

respectively.

With these values the evaluation of molecular integrals has been made in the same manner as before[1-5], and the salf-consistent field calculation has been worked out.

Results and Discussion

The calculated SCF MO's, MO energies, charge and bond orders are collected in Table I.

TABLE I. SCF MO's, MO ENERGIES, CHARGE AND BOND ORDERS OF PYRAZINIUM DIION

As shown in Table I, the charge density at nitrogen is increased remarkably by protonation and the features of charge distribution in neutral pyrazine molecule[3] which can be practically regarded as slightly perturbed benzene[5] are lost. With these MO's and MO energies, the electronic spectra of pyrazinium diion are easily calculated. In Table II the calculated spectra are indicated together with the experimental values.

(a) F. Halverson and R. C. Hirt, *J. Chem. Phys.*, **19**, 712 (1951) and S. Mataga, unpublished.

(b) There is no indication of the existence of other electronic band than ^1L_b below 45 *kK*.

* The observed oscillator strength of pyrazinium diion is uncertain. The oscillator strength of ^1L_b band, however, seems to be two or three times as large as that of neutral molecule.

In contradistinction to the case of protonated pyridine, ^1L_b band is somewhat strengthened as well as shifted to red, while the wave length of ^1L_a band seems to remain almost invariable by double protonation. As shown in Table II, the calculated excitation energy with model I is in good agreement with the experiment. In addition to this, since the calculated oscillator strength of ^1L_b band in neutral pyrazine molecule is 0.162[3], the calculated value in Table II, 0.489, is correct in its order of magnitude in comparison with the calculated value of the neutral molecule. In contrast with the satisfactory results obtained by model I, the calculation with model II leads to the result which is in rather poor agreement with the experiment, that is, the calculated red shift and increase of intensity in the case of ^1L_b band are too great compared with the experiment.

As has already been pointed out in the case of protonated pyridine[1,2], the most predominant factor which leads to the unsatisfactory results with model II may be the neglect of the inductive charge displacement in the σ-core, caused by the transfer of non-bonding electrons on the nitrogen atom toward proton. In the case of model II, the core potential is very deep at nitrogen and is the same as

7) H. O. Pritchard and H. A. Skinner, *Chem. Revs.*, **55**, 745 (1955).

that in the neutral molecule at the carbon atoms. In the case of model I, however, the difference between the core energies at nitrogen and carbon is not so great as in model II and the displacement in σ-core may be appropriately taken into consideration by the formal use of the electrostatic proton potential.

Moreover, the values of $F_{\mu\mu}$'s which may be regarded as an effective electronegativity of μ atom in the molecule[2,3], show the same tendency as the core energies. They are collected in Table III.

TABLE III. VALUES OF α_μ's AND $F_{\mu\mu}$'s

Model	F_{11}	F_{22}	α_1'	α_2'
I	−22.3721	−16.2897	−29.0877	−21.9661
II	−18.3705	−5.0689	−28.72	−11.42

Although the observed spectra can be satisfactorily reproduced by model I as described above, one should not regard model I as the real state of protonated pyrazine. This model represents the electric interaction between proton and π-electrons rather than the electronic interaction between proton and pyrazine. The strong charge transfer interaction between the nitrogen atom in pyrazine and proton may lead to a fairly strong covalent binding between them. Then, the changes in the core energies produced by protonation may be almost completely contributed by the inductive displacement in σ-core. If this is the case, in view of the short range character of the interactions in σ-core, the $(\alpha_\mu' - \alpha_\mu)$ values used in the calculation with model I may be too large. It seems probable that the protonation effect on the core energies may be almost negligible at the nitrogen atom in the opposite side of that proton. However, if we use $(V_\mu^P - 2V_0^P)$'s instead of V_μ^P's of Eq. 9, where V_0^P is the potential energy due to proton at the nitrogen atom in the opposite side of that proton, it is evident that the MO's calculated by model I stay unchanged although the MO energies are lifted by $2|V_0^P|$ uniformly. Thus, the calculation with model I may still be correct even in this case. One might be able to say that the real changes in core energies due to inductive displacement are approximately represented by $(V_\mu^P - 2V_0^P)$ in the case of doubly protonated pyrazine. We shall give a detailed and critical discussion in a later report[8] about such a statement comparing the results obtained with model I with those obtained by an improved model II which employs the self-consistent electronegativity method as developed by Brown and Heffernan[9].

Summary

The protonation effect on the electronic structure and spectra of pyrazine has been studied theoretically employing quantum mechanical calculation. Semi-empirical Hartree-Fock SCF MO's for pyrazine interacting with two protons have been computed with two different methods, respectively.

i) Electrostatic potential due to proton has been added to the core potential in the total electronic Hamiltonian and nuclear attraction integrals which arise owing to the proton potential have been computed theoretically employing the usual Slater $2p\pi$ AO's.

ii) The doubly protonated pyrazine has been replaced by doubly charged pyrazinium ion and molecular integrals have been evaluated semi-empirically using valence state ionization potential and electron affinity of the N^+ atom.

The calculated spectra with method i are in a very good agreement with the experiment. The calculation with method ii has led to a result which is in rather poor agreement with the experimental observation. On the basis of these results, some discussions about the protonation effect on the electronic structure of this molecule have been given.

We are grateful to Professor R. Fujishiro for his encouragement throughout the present study. We also express our appreciation to Mr. T. Kubota of Shionogi Co., Ltd. for his helpful discussions.

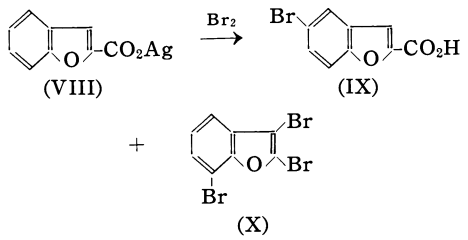
Intramolecular Cyclization of o,o'-Dihydroxydiphenyldiacetylene

By Fumio TODA and Masazumi NAKAGAWA



(Received October 21, 1958)

Recently the reactivity of acetylenic bond to the variety of nucleophilic reagents is well recognized, and the formation of furane ring by the intramolecular cyclization of acetylenic glycol[1] and acetylenic phenol[2] has been reported by several investigators. In the course of the studies concerning the synthesis of cyclic acetylenic compounds, the authors found that the nucleophilic addition of the hydroxyl groups in *o,o'*-dihydroxydiphenyldiacetylene (III) to the triple bonds in the same molecule yields benzofurane derivatives. The present paper reports the formation and the structure determination of the benzofurane derivatives thus obtained.

o-Hydroxyphenylacetylene (II) was prepared according to the method of Prey[3] cleaving the furane ring in coumarone I with sodium in pyridine. Oxidative coupling of II was carried out according to the procedure of Sörensen[4] yielding *o,o'*-dihydroxydiphenyldiacetylene (III) in good yield. The physical properties of III were identical with those of the previously reported values[5]. III was heated on a water bath for a few hours with diluted ethanolic sodium ethoxide solution or with aqueous sodium hydroxide solution forming a neutral material in quantitative yield. The U. V. and I. R. spectra of this substance indicate the absence of any acetylenic linkage and hydroxyl group. The presence of ether linkage was recognized from the characteristic absorption at 1250 cm^{-1}. The neutral material yielded III and an unidentified phenolic polymerized material on the treatment with sodium in pyridine at 160~170°C. From these findings the structure of 2,2'-dibenzofuranyl (IV) was assigned to the neutral material. This assignment was confirmed by the mixed melting point determination of the neutral material with a synthetic specimen which was obtained by the Ullmann reaction of 2-bromobenzofurane (VII). VII was prepared by the pyrolytic distillation of 2,3-dibromocoumarane (VI)[6]. The attempt to prepare VII by the Hunsdiecker reaction of silver coumarilate VIII gave an unsatisfactory result. The products were found to be 5-bromocoumarilic acid (IX)[7] and so-called 2,3,7(?)-tribromocoumarone (X)[8].

A phenolic substance and IV was obtained when III in ethanol was refluxed for 1.5 hr. with a small amount of sodium ethoxide. The I. R. spectrum of the phenolic substance showed the characteristic absorption bands of acetylenic bond and hydroxyl group at 2207 cm^{-1} and 3380 cm^{-1} respectively. This substance was converted into IV quantitatively by the action of alkali. It is reasonable to conclude that the structure of the phenolic substance is 2-(*o*-hydroxyphenylethynyl)-benzofurane (V) formed by the half ring closure of III.

Experimental*

o, o'-Dihydroxydiphenyldiacetylene (III).—*o*-Hydroxyphenylacetylene[3] (II, 23.6 g.) was mixed with cuprous chloride (14.5 g.), ammonium chloride (225 g.), concentrated aqueous ammonia 4.0 cc.) and water (572 cc.). The mixture was vigorously stirred at room temperature under an atomosphere of oxygen. The exothermic reaction was completed during the period of 6 hr. with the absorption of theoretical amount of oxygen. The reaction mixture was extracted with ether, washed with water and dried over anhydrous magnesium sulfate. The crude crystals obtained by the evaporation of the solvent were recrystallized from carbon tetrachloride yielding 23 g. (86%) of III, m. p. 142~143°C, colorless needles.

Anal. Found: C, 81.99; H, 4.30. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

U. V. max., 258, 276, 316 and 346 mμ (log ε = 4.13, 3.85, 4.55 and 4.39). I. R. max., 3300, 2180 and 1190 cm^{-1}.

Reaction of III with benzoyl chloride gave dibenzoyl derivative, m. p. 126~126.5°C (from ethanol), colorless needles.

Anal. Found: C, 81.58; H, 4.30. Calcd. for $C_{30}H_{18}O_4$: C, 81.43; H, 4.10%.

U. V. max., 230, 275, 311 and 332 mμ (log ε = 4.91, 4.36, 4.54 and 4.48). I. R. max., 2200, 1744, 1260 and 1240 cm^{-1}.

2, 2'-Dibenzofuranyl (IV) —III (1.0 g.) was dissolved in 30 cc. of 10~20% solution of sodium ethoxide in ethanol or of sodium hydroxide in water. No change was observed after keeping the solution overnight at room temperature. The solution was heated on a water bath for 1~2 hr. causing deposition of crystals. The cooled reaction mixture was filtered. Recrystallization from benzene or ethanol gave IV as colorless needles, m. p. 194.5~195.5°C in quantitative yield.

Anal. Found: C, 81.94; H, 4.47. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

U. V. max., 320 and 338 mμ (log ε = 4.77 and 4.77). I. R. max., 1250 and 1170 cm^{-1}.

Synthesis of 2, 2'-Dibenzofuranyl (IV).—An intimate mixture of 2-bromocoumarone (VII, 1.0 g.) and activated copper bronze (2.5 g.) was heated to 225~240°C in an oil bath for 5 hr. The cooled reaction mixture was transferred to a sublimation apparatus, and was heated to 160~180°C at 20 mmHg. Colorless crystals were obtained as sublimate after removal of the unreacted VII. The crystals were recrystallized from ethanol giving 0.2 g. (40%) of colorless needles, m. p. 194.5~195.5°C. The mixed melting point determination with IV which was derived from III showed no depression.

Anal. Found: C, 82.25; H, 4.33. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%. I. R. max., 1250 and 1170 cm^{-1}. The I. R. spectra of these two specimens were found as superimposable over the entire region of wave length.

2-(*o*-Hydroxyphenylethynyl)-benzofurane (V).—Heating of III (1.2 g.) in 60 cc. of very diluted ethanolic sodium ethoxide for 1.5 hr. on a boiling water bath resulted in crystallization. Recrystallization from benzene yielded 0.4 g. (33%) of IV, m. p. 194.5~195.5°C. The mother liquor of the recrystallization was concentrated to form crude crystals, which were recrystallized from light petroleum (b. p. 55~75°C) employing active charcoal to give 0.5 g. (41%) of V as colorless needles, m. p. 102.5°C.

Anal. Found: C, 82.24; H, 4.33. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

U. V. max., 250, 298, 318 and 340 mμ (log ε = 3.83, 4.38, 4.44 and 4.45). I. R. max., 3380, 2207 and 1269 cm^{-1}.

V is slightly soluble in aqueous sodium hydroxide. Reaction of V with benzoyl chloride gave monobenzoate, colorless needles, m. p. 117°C.

Anal. Found: C, 81.62; H, 4.27. Calcd. for $C_{23}H_{14}O_3$: C, 81.64; H, 4.17%.

The solution of V (0.1 g.) in ethanolic sodium ethoxide was refluxed for 3 hr., forming colorless crystals in quantitative yield. This was identified as IV by mixed melting point determination with previously obtained IV.

Ring Cleavage of 2, 2'-Dibenzofuranyl (IV).—A mixture of IV (0.4 g.), pyridine (4.0 g.) and sodium (0.3 g.) was refluxed for 3.5 hr. under nitrogen atomosphere. Water was added cautiously to the reaction mixture to decompose the unreacted sodium, and the mixture was extracted with ether. The aqueous layer was acidified with 2 N hydrochloric acid, and extracted with ether. The ethereal extract was washed with 2 N hydrochloric acid and water successively. The dried ether solution was evaporated, and the residue was repeatedly recrystallized from carbon tetrachloride affording a small amount of

* Melting points were not corrected. All U. V. and I. R. spectra were measured employing ethanolic solution and nujol mull respectively.

crystals, m. p. 140~141°C. The mixed melting point of this substance with III showed no depression.

Hunsdiecker Reaction of Silver Coumarilate (VIII). — Bromine (7.5 g.) in dry carbon tetrachloride (20 cc.) was added in one portion on well dried VIII (10.0 g.) at room temperature. Vigorous evolution of gas was observed, and the color of bromine disappeared during the period of 2 hr. The mixture was kept for 3 hr. to complete the reaction. The reaction mixture was extracted with ether, and the extract was washed with aqueous solution of sodium hydrogen carbonate to remove acidic materials. The alkaline solution was neutralized with 2 N hydrochloric acid, and extracted with ether. The ether solution was washed with water and dried. The solvent was removed by distillation and the recrystallization of the residue from aqueous ethanol gave 5 g. (56%) of 5-bromocoumarilic acid (IX), m. p. 256°C as colorless needles. (lit. value m. p. 253°C)[7].

Anal. Found: Br, 33.40. Calcd. for $C_9H_5O_3Br$: Br, 33.19%.

The ether layer which was washed with sodium hydrogen carbonate solution was washed with water and dried. The crude neutral crystals obtained by the evaporation of the solvent were recrystallized from aqueous ethanol yielding 2.0 g. (15%) of colorless needles, m. p. 81~83.5°C.

Anal. Found: Br, 67.07. Calcd. for $C_8H_3OBr_3$: Br, 67.60%.

This would be identical with so-called 2,3,7(?)-tribromocoumarone (X, m. p. 84~85°C) prepared by Stoermer[7,8].

Grateful acknowledgments for supplying coumalin are made to Shiono Perfume Industry Co., Osaka. The authors also wish to express their appreciation to Messrs. T. Shiba and M. Okumiya and Miss K. Koike for performing the elementary analyses.

The Formation Constants of Metal Acetate Complexes. I. Polarographic Determination of the Formation Constants of Acetatonickel(II) Complexes

By Nobuyuki TANAKA and Kiyoko KATO

(Received October 20, 1958)

In the course of our studies on the inorganic reactions involving metal complexes[1,2], the necessity for the use of the formation constants of various acetato complexes has been realized. Although many of those constants have been reported[3], they were not determined under the conditions which satisfy our present requirements. They were obtained by various researchers by various methods under various conditions.

In order to determine the formation constants of various acetato complexes under the given conditions, a systematic study has been carried out. The careful considerations of various methods which can be applied to the determination of the formation constants led to the conclusion that none of the methods is satisfactory for the present purpose. The potentiometric methods, which are considered to have the widest applicability, generally include uncertainties due to the estimation of the liquid junction potential and that of the activity coefficients of the ions present. The solubility studies have only a limited applicability. The polarographic method which was applied by Hume and his co-workers[4,5] to their study on the acetatolead(II) complexes is available only when the electrode processes are reversible at the dropping mercury electrode.

In the present paper, the principle of a new method for the determination of the

5) E. A. Burns and D. N. Hume, ibid., **78**, 3958 (1956).

formation constants and the application of the method to acetatonickel(II) complexes are presented. The method is similar to that proposed by Schwarzenbach and his co-workers[6-8], but applicable without data of the dissociation and the formation constants concerning the auxiliary complex-forming substance, which Schwarzenbach's method requires.

Theoretical

Let us consider the acetate buffer solution which contains nickel(II) and nitrilotriacetate (NTA) ions[9]. There exist the following equilibria:

$$Ni^{2+} + n\,OAc^- \rightleftarrows Ni(OAc)_n^{(2-n)+} \quad (1)$$

$$Ni^{2+} + X^{3-} \rightleftarrows NiX^- \quad (2)$$

$$NiX^- + H^+ \rightleftarrows NiHX \quad (3)$$

where X^{3-} denotes a tervalent NTA anion. The total concentration of nickel, $\sum[Ni]$, and that of NTA, $\sum[NTA]$, in the solution are given in terms of the ionic and molecular species as follows:

$$\sum[Ni] = [Ni^{2+}] + \sum_1^n [Ni(OAc)_n^{(2-n)+}] + [NiX^-] + [NiHX] \quad (4)$$

$$\sum[NTA] = [NTA]_f + [NiX^-] + [NiHX] \quad (5)$$

where $[Ni^{2+}]$ represents the concentration of hydrated nickel ions and $[NTA]_f$, the sum of the concentrations of uncomplexed NTA. In the polarographic measurement it is impossible to measure separately either the concentration of hydrated nickel ions or that of acetatonickel(II) complexes in an acetate medium. On the contrary, the polarographic diffusion current of nickel corresponds to the sum of the diffusion current due to the hydrated nickel ions and that due to the acetatonickel(II) complexes. If the hydrated nickel ion and the acetatonickel(II) complexes have nearly the same diffusion current constants, the sum of their concentrations can be determined from the polarographic diffusion current, if necessary, after correction.

Then, we write the equation as,

$$[Ni^{2+}]_{app.} = [Ni^{2+}] + \sum_1^n [Ni(OAc)_n^{(2-n)+}] \quad (6)$$

where $[Ni^{2+}]_{app.}$ is the concentration that can be determined from the polarographic diffusion current. Eq. 4 is rewritten as,

$$\sum[Ni] = [Ni^{2+}]_{app.} + [NiX^-] + [NiHX] \quad (7)$$

The concentrations of NiX^-, Ni^{2+} and X^{3-} are given by

$$[NiX^-] = (\sum[Ni] - [Ni^{2+}]_{app.})/\beta \quad (8)$$

$$[Ni^{2+}] = [Ni^{2+}]_{app.}/(1 + \sum_1^n K_{Ni(OAc)_n}[OAc^-]^n) \quad (9)$$

$$[X^{3-}] = [NTA]_f/\alpha \quad (10)$$

$$\alpha = 1 + \frac{[H^+]}{K_{HX}} + \frac{[H^+]^2}{K_{H_2X}K_{HX}} + \frac{[H^+]^3}{K_{H_3X}K_{H_2X}K_{HX}}$$

and $$\beta = 1 + K^H_{NiHX}[H^+]$$

where K_{H_3X}, K_{H_2X} and K_{HX} represent the first, the second and the third dissociation constant of nitrilotriacetic acid, respectively, and $K_{Ni(OAc)_n}$ and K^H_{NiHX} represent the overall formation constant of $Ni(OAc)_n^{(2-n)+}$ and the equilibrium constant of the reaction given by Eq. 3, respectively. The formation constant of NiX^-, consequently, is given as

$$K_{NiX} = \frac{[NiX^-]}{[Ni^{2+}][X^{3-}]} = \frac{\alpha\{\sum[Ni] - [Ni^{2+}]_{app.}\}\{1 + \sum_1^n K_{Ni(OAc)_n}[OAc^-]^n\}}{\beta[Ni^{2+}]_{app.}[NTA]^f} \quad (11)$$

From Eqs. 5 and 7, the concentration of uncomplexed NTA is given as,

$$[NTA]_f = [Ni^{2+}]_{app.} - \sum[Ni] + \sum[NTA] \quad (12)$$

Introducing Eq. 12 into Eq. 11, the relation

$$\frac{\{[Ni^{2+}]_{app.} - \sum[Ni] + \sum[NTA]\}[Ni^{2+}]_{app.}}{\sum[Ni] - [Ni^{2+}]_{app.}} = \frac{\alpha}{\beta K_{NiX}} + \frac{\alpha}{\beta K_{NiX}} \sum_1^n K_{Ni(OAc)_n}[OAc^-]^n \quad (13)$$

is obtained.

When the values of K_{H_3X}, K_{H_2X}, K_{HX}, K_{NiX} and K^H_{NiHX} are known, the formation constants of acetatonickel(II) complexes can be determined with Eq. 13 from the measurements of $[Ni^{2+}]_{app.}$ at n different concentrations of acetate. However, the equilibrium constant K^H_{NiHX} has not been reported and the other constants K_{H_3X},

6) G. Schwarzenbach and E. Freitag, *Helv. Chim. Acta*, **34**, 1492 (1951).
7) G. Schwarzenbach and E. Freitag, ibid., **34**, 1503 (1951).
8) H. Ackermann and G. Schwarzenbach, ibid., **32**, 1543 (1949).
9) Nickel(II) and nitrilotriacetate may be replaced by other metal ions and complex-forming substances.

K_{H_2X}, K_{HX} and K_{NiX} have been determined[6,10,11] in conditions not convenient for our study.

An alternative and better procedure for determining the formation constants of acetatonickel(II) complexes was developed. It is obvious that both α and β in Eq. 13 are constant in the solution of the given pH and the given ionic strength. The values of $[Ni^{2+}]_{app.}$ are determined by the polarographic method at the given pH and ionic strength, but at varied concentrations of acetate. The left-hand side of Eq. 13 is calculated and plotted against the concentration of acetate. If the left-hand side of Eq. 13 is denoted with F_0, it is expressed as,

$$F_0 = \frac{\alpha}{\beta K_{NiX}} + \frac{\alpha}{\beta K_{NiX}} K_{NiOAc}[OAc^-] + \frac{\alpha}{\beta K_{NiX}} K_{Ni(OAc)_2}[OAc^-]^2 + \cdots\cdots \quad (13')$$

From extrapolation of the plot to zero acetate concentration, $\alpha/\beta K_{NiX}$ is obtained. Then we obtain,

$$F_1 = \frac{F_0 - \frac{\alpha}{\beta K_{NiX}}}{\frac{\alpha}{\beta K_{NiX}}[OAc^-]} = K_{NiOAc} + K_{Ni(OAc)_2}[OAc^-] + \cdots\cdots \quad (14)$$

$$F_2 = \frac{F_1 - K_{NiOAc}}{[OAc^-]} = K_{Ni(OAc)_2} + K_{Ni(OAc)_3}[OAc^-] + \cdots\cdots \quad (15)$$

F_1 is plotted against $[OAc^-]$ and the K_{NiOAc} is determined by extrapolating the plot to zero acetate concentration. The further treatment leads to the determinations of $K_{Ni(OAc)_n}$, if higher acetato complexes are present in the solution.

Experimental

Reagents. — The solution of disodium nitrilotriacetate was prepared from the commercial nitrilotriacetic acid (DOTITE NTA), and standardized against the standard solution of copper(II) nitrate by amperometric titration with the same procedure for ethylenediaminetetraacetate[12,13]. The standard solution of nickel nitrate was prepared by dissolving a known amount of pure nickel metal in reagent-grade nitric acid. Commercial guaranteed reagents were used for buffers and supporting electrolytes without further purification.

Apparatus and Procedure. — A Shimadzu RP-2 pen-recording polarograph was used for the measurement of the current-voltage curves. The dropping mercury electrode used had an m value of 1.27 mg./sec. and a drop time t of 3.69 sec. in an air-free 0.1 M potassium chloride solution at 25°C with open circuit.

The sum of the diffusion currents of hydrated nickel ions and acetatonickel(II) complexes were determined in the acetate buffer of pH 3.83±0.01 containing nickel(II) and a slight excess of NTA at 15, 25 and 35°C. The concentration of acetate in the acetate buffer was varied from 0.05 M to 0.20 M. The ionic strength of the solution was adjusted to be 0.2 with potassium nitrate, unless otherwise stated. Polyoxyethylene lauryl ether (LEO) was added as a maximum suppressor by 1×10^{-6} M (at 15°C) or 2×10^{-6} M (at 25° and 35°C) in concentration. The pH of the solution was measured accurately, after the polarographic measurement, with a Hitachi Model EHP-1 pH meter with a glass electrode.

In the preliminary experiment, it was observed that the formation of nickel-NTA complexes nearly completed within 30 minutes under the experimental condition. Therefore, all reaction mixtures were kept in a thermostat for 3 hours to reach the completely equilibrated condition before being subjected to the polarographic measurement.

Results

The polarograms were recorded with the solutions of the same pH containing 1.00×10^{-3} M nickel nitrate, 1.12×10^{-3} M

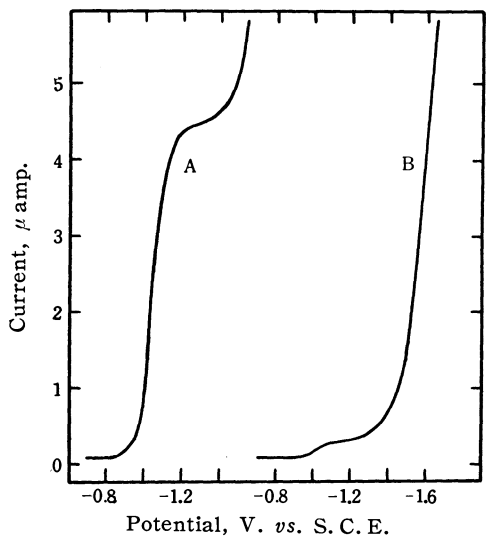

Fig. 1. Polarograms of 1.00×10^{-3} M nickel (II) obtained in the acetate-nitrate media of pH 3.83 at 25°C in the absence (curve A) and in the presence of 1.12×10^{-3} M NTA (curve B). The residual current is not corrected.

NTA and various concentrations of acetate. Fig. 1 shows the polarograms obtained in the absence and the presence of a slight excess of NTA. Nickel(II) gives an irreversible wave with the half-wave potential of about −1.05 volts *vs.* S. C. E. in the acetate-nitrate media. (Curve A in Fig. 1). This wave is due to the reductions of the hydrated nickel(II) ions and the acetatonickel(II) complexes. The presence of a slight excess of NTA decreases to a great extent the height of the nickel wave, but does not obliterate the wave completely. A small wave which was followed by the depolarization of the supporting electrolyte is clearly seen in Fig. 1 (Curve B). The limiting current of the wave was found to be proportional to the square root of the effective height of mercury column on the dropping mercury electrode. This clearly showed that the limiting current is diffusion-controlled and is proportional to the concentration of the electroactive species.

The apparent diffusion current constants were determined from the measurement of the diffusion current of nickel(II) at various acetate concentrations at the given ionic strength. In Fig. 2, typical examples

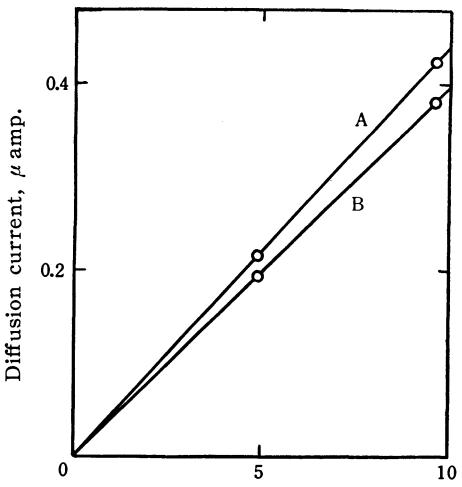

Fig. 2. Relation between diffusion current and concentration of nickel nitrate in acetate buffer solutions of pH 3.83 at 25°C. Acetate concentrations are: A, 0.05 M; B, 0.20 M.

of those measurements are given. The values of $[Ni^{2+}]_{app.}$ of Eq. 6 were calculated with the aid of those diffusion current constants from the limiting currents obtained with reaction mixtures. The results are given in Table I, which indicate that $[Ni^{2+}]_{app.}$ increases with increasing concentration of acetate.

The left-hand side of Eq. 13 was calculated with the values of $[Ni^{2+}]_{app.}$ given in Table I, and was plotted against the acetate concentration. The results are

shown in Fig. 3, where it is clearly seen that there is a linear relation between the values of the left-hand side of Eq. 13 and the concentration of acetate. This indicates conclusively that only one type of acetato complex, $NiOAc^+$, exists in the solution under the experimental condition. From the plots in Fig. 3, the values of

$\alpha/\beta K_{NiX}$ and $\alpha K_{NiOAc}/\beta K_{NiX}$ in Eq. 13′ were determined, the former being given by the intersept at $[OAc^-]=0$ and the latter, by the slope. The experimental results obtained at 25°C were also treated by the least square method, with the result that the probable errors of $\alpha/\beta K_{NiX}$ and $\alpha K_{NiOAc}/\beta K_{NiX}$ were ±1.5% and ±4.1%, respectively. The formation constants of the monoacetatonickel(II) complex at 15°, 25° and 35°C were obtained by dividing the values of $\alpha K_{NiOAc}/\beta K_{NiX}$ by those of $\alpha/\beta K_{NiX}$. These are given in Table II.

TABLE II. FORMATION CONSTANTS OF MONOACETATONICKEL(II) COMPLEX AT VARIOUS TEMPERATURES

Temp., °C	K_{NiOAc}

Discussions

The formation constants of monoacetatonickel(II) complex, K_{NiOAc}, are found to be almost independent of temperature in the range from 15° to 35°C. Jena, Aditya and Prasad[14] studied the acetatonickel(II) complex by the e.m.f. method and reported the thermodynamic formation constant of the monoacetatonickel(II) complex to be 13.5 at 30°C. The formation constant at ionic strength 0.2 was calculated from this value to be 4.5, when the activity coefficient of acetate ions was assumed to be equal to that of monoacetatonickel(II) ions and the activity coefficient of nickel ions was estimated to be 0.33[15]. The resulting value of 4.5 seemed to be in good agreement with the formation constant obtained in this study. Both values were determined by completely different methods and the value obtained by the e. m. f. method involves the uncertainty due to the estimation of the activity coefficient. Fronaeus[16] studied the formation of the complex by means of the ion-exchanger and also by means of the measurement with a quinhydrone electrode and obtained the formation constants of 4.7 and 5.5, respectively, at ionic strength 1.0 (sodium perchlorate) at 20°C. They also seem to support the value obtained in this study.

The experimental solution contained a certain quantity of potassium nitrate, which was added to adjust the ionic strength of the solution. It is expected that the nitrate ion has such a small tendency to form a complex with the nickel(II) ion that it seems unnecessary to consider the effect of the nitrate ion in the present calculation. The confirmation of this was attained in the comparison of the experimental results observed in nitrate and perchlorate media. The perchlorate has been known to have the least complex-forming ability. If an appreciable amount of nitrato complex is formed in the nitrate media, the values of the left-hand side of Eq. 13 obtained at the same concentration of acetate are expected to be larger in the nitrate media than in the perchlorate media. The measurement of $[Ni^{2+}]_{app.}$ was carried out in the solution of which the ionic strength was adjusted with sodium perchlorate instead of potassium nitrate. The value of $[Ni^{2+}]_{app.}$ agreed completely with that obtained in the solution containing nitrate. From this fact it may be concluded that the nitrate ions show least complex-forming tendency and, consequently, the use of nitrate ions requires no correction on the present calculation.

In conclusion it should be noted here that the method for the determination of the formation constant given in this paper may be applicable to the study of other metal complexes of relatively small formation constants. The method is more rigorous than the e. m. f. method, because the latter method requires the estimations of the liquid junction potential and the activity coefficient. The determination of the sum of the concentration of hydrated nickel ions and that of acetatonickel(II) complexes may be carried out by other methods.

Summary

A new method for the determination of the formation constants of metal acetate complexes has been developed. The method is based on the polarographic measurement of the sum of the equilibrium concentrations of hydrated metal ions and metal acetate complexes in the presence of an appropriate auxiliary complex-forming substance. One of the advantages of the method is that no estimation is required in the course of the calculation. The other is that no information of the dissociation and formation constants is

required concerning the auxiliary complex-forming substance.

The method is applied to the study of acetatonickel(II) complexes using nitrilotriacetate as an auxiliary ccmplex-forming substance. The results reveal that only monoacetatonickel(II) ions, $NiOAc^+$, exist in the solution containing acetate up to 0.2 M in concentration. The formation constants K_{NiOAc} at ionic strength 0.2 are calculated to be 2.6 at 15°C, 2.6 at 25°C and 2.4 at 35°C.

Effects of Protonation on the Electronic Structure and Spectra of Nitrogen Heterocycles

By Shizuyo MATAGA and Noboru MATAGA

(Received October 21, 1958)

In the previous papers[1-3], we have reported detailed theoretical studies about the protonation effects on the electronic spectra of some nitrogen heterocycles. In these reports, the interaction between proton and a nitrogen heterocycle has been treated by various approximations. Among these, the following two are most representative.

i) It has been assumed that there is no transfer of non-bonding electrons on nitrogen toward proton but bare proton is located near the nitrogen atom of neutral molecule. Thus, the electrostatic potential due to proton has been added to the core potential in the total π-electronic Hamiltonian and nuclear attraction integrals which arise owing to this potential have been computed theoretically employing the usual Slater $2p\pi$ AO's.

ii) It has been considered that there is a strong charge transfer from nitrogen atom to proton leading to covalent binding between them and molecular integrals have been evaluated semi-empirically using valence-state ionization potential and electron affinity of N^+ atom.

By means of the semi-empirical Hartree-Fock SCF MO's obtained with these integrals, the electronic spectra of protonated nitrogen heterocycles have been calculated. The calculated spectra by the method i have been in very good agreement with those experimentally obtained. However, the calculation with the method ii has led to a result which is in rather poor agreement with the experimental values. A careful examination of these results has led to the following conclusion. In the case of the later method, the inductive charge displacement in σ-core caused by the charge transfer of non-bonding electrons from nitrogen atom toward proton may not be appropriately accounted, where the core potential is very deep at nitrogen and the same as that in the neutral molecule, at the carbon atoms. In the case of the method i), however, the displacement in σ-core may be appropriately taken into consideration by the formal use of the electrostatic proton potential, which may be the cause of the superiority of this method.

If the unsatisfactory results obtained with the method ii originates from the neglect of the inductive charge displacement in σ-core caused by protonation as described above, one may be able to improve the results by taking into consideration the inductive displacement in σ-core in some appropriate manner. In this respect, we have calculated the electronic structures and spectra of pyridinium ion and pyrazinium diion employing

the self-consistent electronegativity method proposed by Brown and Heffernan[4] which may be regarded as an improvement of the method ii. Our calculation procedure is essentially the same as that of Brown and Heffernan but a little different from theirs in some details of actual compution procedures. In the present paper, we shall report the results of this calculation with some discussions. In addition, results of some critical studies about the effects of protonation on the core energies and diagonal elements of Fock's Hamiltonian, $F_{\mu\mu}$'s, will be given comparing the present results with previous ones.

Application of Self-Consistent Electronegativity (SCE) Method

In SCE method, it is assumed that Slater's rules for effective charges of atoms are applicable for continuous variation in electron density. Accordingly, for atoms in the first row of the periodic table the relationship is

$$Z_\mu = N_\mu - 1.35 - 0.35\ (\sigma_\mu + P_{\mu\mu}) \qquad (1)$$

where N_μ is the atomic number of μ atom and σ_μ is the number of σ-electrons associated with μ atom in the molecular framework, e.g. 3 for carbon and positively charged nitrogen in pyridinium ion. $P_{\mu\mu}$ is the π-electron density on μ atom. If this variation of Z_μ with $P_{\mu\mu}$ is included in the SCF MO procedure, in addition to the usual functional dependence of the SCF matrix elements upon the charge distribution, the various molecular integrals become functions of $P_{\mu\mu}$ from their dependence on Z_μ. The methods of allowing for this variation are as follows.

Firstly, the form of the relationship between the valence state ionization potential I_μ and Z_μ should be established.

Various valence-state ionization potentials have been calculated from the experimental term values of atomic spectra. If I_μ's are plotted against Z_μ's for the (sp^3, V_4) valence state of the iso-electronic series, C, N^+, O^{2+} and for the (sp^4, V_3) valence state of the iso-electronic series, C^-, N, O^+, respectively, the curves are accurately parabolic:

$$I_\mu(sp^3, V_4) = 3.490\, Z_\mu^2 - 8.541\, Z_\mu + 2.446 \qquad (2)$$

$$I_\mu(sp^4, V_3) = A_\mu(sp^3, V_4) = 3.730\, Z_\mu^2 - 16.285\, Z_\mu + 14.108 \qquad (3)$$

where A_μ is the valence state electron affinity. These equations are used for evaluating I_{C^-} and I_{N^+}. Then, from these eqs., the mono-centric inter-electronic coulomb repulsion integral, $\gamma_{\mu\mu}$, is easily obtained as,

$$\gamma_{\mu\mu}(sp^3, V_4) = I_\mu(sp^3, V_4) - A_\mu(sp^3, V_4) = -0.240\, Z_\mu^2 + 7.743\, Z_\mu - 11.662 \qquad (4)$$

The two-center electronic coulomb repulsion integral, $\gamma_{\mu\nu}$, was evaluated as in our previous works[2,5-7] from the formula,

$$\gamma_{\mu\nu} = e^2/(a_{\mu\nu} + r_{\mu\nu}) \qquad (5)$$

where parameter $a_{\mu\nu}$ has been determined by the equations:

$$a_{\mu\nu} = 2a_{\mu\mu}\cdot a_{\nu\nu}/(a_{\mu\mu} + a_{\nu\nu}) \qquad (6)$$

$$a_{\mu\mu} = 14.3949/\gamma_{\mu\mu} \qquad (7)$$

The other quantities necessary for the calculation are the values of off-diagonal matrix elements of core Hamiltonian, $\beta_{\mu\nu}$. We have used the same values as before[2] for these quantities.

With the parameters described above, SCE LCAO MO's of pyridinium ion and pyrazinium diion have been obtained by the iterative process in which all integrals except $\beta_{\mu\nu}$ depend on the π-electron distribution.

The results are collected in Table I and

* F. Halverson and R. C. Hirt, *J. Chem. Phys.*, **19**, 712 (1951) and S. Mataga, unpublished.

** The observed oscillator strength of pyrazinium diion is uncertain. The oscillator strength of ^1L_b band, however, seems to be two or three times as large as that of a neutral molecule. (The calculated oscillator strength of ^1L_b band in the case of pyrazine molecule is 0.162[5]).

The agreement of the calculated spectra with observed values as given in Table II, is not satisfactory. There is not such nice agreement with experiment as seen in the previous calculation[1-3] with method i as described in the introductory part of this paper, and the present result seems to be only a small improvement of the previous calculation[1-3] with the method ii. Accordingly, the present unsatisfactory results may originate from the same circumstance as in the case of the previous calculation with the method ii, i.e., from the insufficient consideration of the inductive charge displacement in the σ-core caused by the transfer of nonbonding electrons on nitrogen atom toward proton. In this respect, some critical discussions about the effects of protonation on the electronic structure of these nitrogen heterocycles will be given in the next section.

On the Inductive Charge Displacement in the σ-Core Caused by the Protonation

In the method i, the electrostatic potential due to proton is simply added to the core Hamiltonian and the diagonal element of Fock's Hamiltonian in terms of AO's has the following form:

$$F_{\mu\mu}=\alpha_\mu+V_\mu^P+\frac{1}{2}P_{\mu\mu}\gamma_{\mu\mu}+\sum_{\kappa(\neq\mu)}(P_{\kappa\kappa}-1)\gamma_{\mu\kappa} \quad (8)$$

where

$$\alpha_\mu=\int\phi_\mu(i)\left\{-\frac{1}{2}\Delta_i^2-V_\mu(i)\right\}\phi_\mu(i)\mathrm{d}v(i)=-I_\mu$$

$V_\mu^P=-e^2\int\sum_P\frac{\phi_\mu^2(i)}{r_{Pi}}\mathrm{d}v(i)$ and r_{Pi} is the distance between proton and i-th electron.

As pointed out before[2,3], the changes in the core energies produced by protonation may be almost completely contributed by the inductive displacement in σ-core. Then, in view of the short range character of the interactions in σ-core, the additional core energy, i.e., V_μ^P, used in the method i may be too large. It seems probable $V_\mu^P=0$ at the atom in the opposite side of proton. However, if we use $(V_\mu^P-V_0^P)$'s instead of V_μ^P's where V_0^P is the additional core energy at the atom in the opposite side of proton, it is evident that, in our approximation, the MO's calculated by method i stay unchanged although the MO energies are lifted by $|V_0^P|$ uniformly. Accordingly, one may be allowed to say that the real changes in core energies due to inductive displacement are represented by $(V_\mu^P-V_0^P)$, because the calculated spectra with method

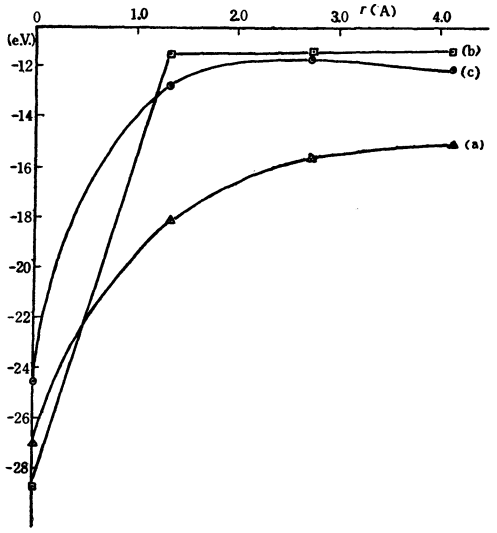

Fig. 2. α_μ's or $(\alpha_\mu+V_\mu{}^P)$ plotted against the distance r along the bonds between the protonated nitrogen and μ-th atom in the case of pyridine. (a) method i, (b) method ii, (c) SCE method.

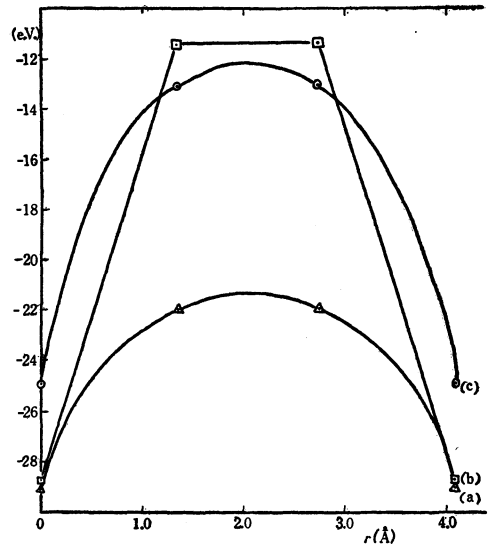

Fig. 3. α_μ's or $(\alpha_\mu+V_\mu{}^P)$ plotted against the distance r along the bonds in the case of pyrazine. (a) method i, (b) method ii, (c) SCE method.

i are in a very good agreement with experiment[1-3].

Now, the circumstance mentioned at the end of the last section is evident from Figs. 2 and 3 where α_μ's in the method ii and SCE method, and $(\alpha_\mu+V_\mu{}^P)$'s in the method i are plotted against the distance along the bonds between protonated atom and μ atom. Moreover, $F_{\mu\mu}$'s which may be regarded as a kind of effective electro-

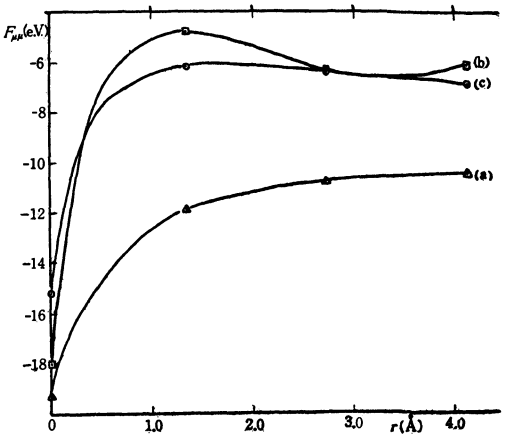

Fig. 4. $F_{\mu\mu}$'s plotted against the distance r along the bonds between the protonated nitrogen and μ-th atom in the case of pyridine. (a) method i, (b) method ii, (c) SCE method.

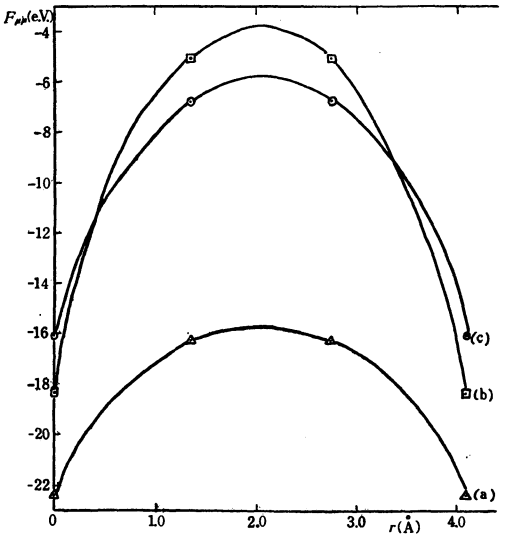

Fig. 5. $F_{\mu\mu}$'s plotted against the distance r along the bonds in the case of pyrazine. (a) method i, (b) method ii, (c) SCE method.

negativity of μ atom in the molecule[2,5] show the same tendencies as α_μ's and $(\alpha_\mu+V_\mu{}^P)$'s, respectively, in Figs. 4 and 5.

In these figures, the results obtained by the SCE method are rather close to the results obtained by the method ii, which may be the most predominant factor that leads to the unsatisfactory prediction of electronic spectra by the former method.

Now, in the case of protonated pyridine, if we put:

$$\alpha_\mu{}'-\theta=(\alpha_4{}'-\theta)/\nu^n \qquad (9)$$

where $\alpha_\mu' = (\alpha_\mu + V_\mu^P)$, θ and ν are parameters to be determined semiempirically and n is the number of bonds between nitrogen and μ atom, then the values of α_μ' plotted in Fig. 2 are well reproduced by this equation putting $\theta = 14.86$ eV. and $\nu = 4$.

If we approximate the distances from nitrogen along the bonds by $r = n \cdot \lambda$ where λ is the average bond distance of pyridine, i.e., 1.38 Å, then Eq. 9 becomes

$$\alpha_\mu' - \theta = (\alpha_4' - \theta)/\nu^{r/\lambda} \quad (10)$$

Actually, Eq. 10 is valid.

Similar equations have been obtained also for $F_{\mu\mu}$'s as follows:

$$(F_{\mu\mu} - 10.50) = (F_{44} - 10.50)/6^n \quad (11)$$

$$\text{or} \quad = (F_{44} - 10.50)/6^{r/1.38} \quad (12)$$

The value of θ in Eqs. 9 and 10 and the corresponding quantity in Eqs. 11 and 12 are very close to α_1' and F_{11}, respectively.

Therefore, these equations may be regarded as representing the inductive displacement caused by protonation and also that the inductive effect due to protonation is practically negligible on the atom which is more than two-bond distance apart from the protonated nitrogen atom.

Then, Eqs. 9 and 10 may be useful in general for the study of the protonation effect on the electronic structure of nitrogen heterocycles, although the behaviour of $F_{\mu\mu}$ may be characteristic of each molecule and Eqs. 11 and 12 can not be used in general. It is customary in the simple MO theory to take into consideration the inductive effect assuming the form of coulomb integral as $\alpha_\mu = \alpha + \delta_\mu \beta$ It has been pointed out[2] that the SCF MO's and charge distributions calculated by the method i are well reproduced with simple MO's obtained using the values of coulomb integrals $\alpha_4 = \alpha + 2.4\,\beta$, $\alpha_3 = \alpha_5 = \alpha + 0.4\,\beta$ and assuming the all resonance integrals are equal to β. Then $\delta_3 = \delta_5 = \delta_4/6$, which is the same relationship as in the case of $F_{\mu\mu}$, i.e., by Eq. 11 $\Delta F_{33} = \Delta F_{55} = \Delta F_{44}/6$, where $\Delta F_{\mu\mu} = (F_{\mu\mu} - 10.50)$

Although, in the case of the protonated pyrazine, we can not obtain the relationship as Eqs. 9—12, because of the higher symmetry of the molecule, the circumstance may be analogous to the case of protonated pyridine.

Summary

The self-consistent electronegativity method has been applied to calculate the electronic structure and spectra of some protonated nitrogen heterocycles. This method may be regarded as an improvement of our method ii which has led to poor agreement with experiment because of the neglect of the inductive displacement in σ-core caused by protonation. The calculated results with the present method, however, are in rather poor agreement with experiment, and it is only a small improvement of the method ii.

Comparing the present results with the previous ones obtained with method i and ii, some discussions about the nature of the protonation effect on the electronic structure of these molecules have been given. In addition, formulae which represent the magnitude of inductive effect on each atom as a function of the distance or number of bonds from the protonated atom have been given.

(Received February 9, 1959)

The unstability of dinitrophenyl amino acids to sunlight was already described by Sanger[1], Mills[2], and Blackburn[3]. Akabori et al.[4] also studied the rate of the photochemical decomposition of various dinitrophenyl amino acids by exposure to a tungsten lamp.

Trinitrophenyl (TNP) amino acids and peptides, synthesis of which is going to be published elsewhere, have similar properties to dinitrophenyl derivatives and are also labile photochemically.

A saturated solution of TNP-amino acid in 1 N hydrochloric acid was prepared 20 ml. of the solution was placed in a petri dish (8 cm. in diameter) and exposed to ultraviolet light (Mazda UV-sterilizing lamp) or sunlight. The absorption spectrum of the solution changed gradually to that of picramide. It suggests the formation of picramide by the photochemical decomposition of TNP-amino acids. When the solution showed the absorption spectrum of picramide, it was concentrated to dryness under reduced pressure. The residue was dissolved in a small amount of ethanol and applied to filter paper. The presence of picramide and the absence of free amino acids were verified by means of one-dimensional paper chromatography on Toyo No. 51 filter paper. The solvent systems used were phenol-water (4 : 1, v/v), 1.5 M phosphate buffer (pH 5.6) or butanol saturated with 2 N ammonia.

By further exposure to light (after 24 ~44 hr.), no ninhydrin positive substance was detected by two-dimensional paper chromatography of the concentrated samples, although the decoloration of the solution was observed, indicating the complete decomposition of the TNP-amino acid. A yellow substance, probably resulting from picramide, was then precipitated. Conditions of the two-dimensional paper chromatography were as follows: ascending method, on Toyo No. 51 filter

TABLE I. PHOTODECOMPOSITION OF TNP-AMINO ACIDS AND -PEPTIDES

paper, using butanol-acetic acid-water (4 : 1 : 1, v/v) as the first developer and phenol-water (4 : 1, v/v) as the second.

In the cases of TNP-peptides, the similar photochemical decomposition was observed. Only the trinitrophenylated amino-terminal amino acid residue was decomposed photochemically, while the second residue was liberated in a free state.

The liberated amino acid was estimated by the TNP-method, which was composed of the trinitrophenylation of amino acids with picryl sulfonate, followed by the colorimetry at 340 mμ[5]. The recoveries of amino acids were listed on Table I. The amino acid liberation was caused exclusively by the photochemical decomposition of the TNP-amino-terminal amino acid residue, since no amino acid was released by the similar treatment of TNP-peptide without exposure to light, or of free dipeptide with exposure to light.

In the case of TNP-triglycine, glycylglycine was liberated, but no release of glycine could be observed.

These results suggest a probable application for a new method of the stepwise degradation of peptide from the amino terminal. Detail of these studies will be the subject of the future communication.

Ionic Character and Hybridization of Ammonia Molecule

By Yoshifumi KATO*, Utaro FURUKANE and Haruo TAKEYAMA

(Received February 9, 1959)

Townes and Dailey[1] have determined the electronic structure of molecules from the nuclear quadrupole coupling constants. In the present paper, this theory has been applied to the ammonia molecule. On the basis of the theoretical results, together with the experimental value of the dipole moment, some discussion has been made on the ionic character of the N–H bond and the s–p hybridization of the nitrogen atom. The following VB function has been assumed to the ground state of the molecule,

$$\Psi_T = A\left[\Psi_{\mathrm{cov}} + 3\lambda\Psi_{\mathrm{ion1}} + 3\lambda^2\Psi_{\mathrm{ion2}} + \lambda^3\Psi_{\mathrm{ion3}}\right] \quad (1)$$

Here A represents the normalization factor, the coefficient λ is concerned with the magnitude of the ionic character of the N–H bond and the wavefunctions Ψ_{ion1}, Ψ_{ion2}, and Ψ_{ion3} respectively refer to the singly, doubly and triply ionized structure. To each configuration the following electron pair bond functions are assumed:

$$\left.\begin{aligned}
\Psi_{\mathrm{cov}} &= (\mathrm{N}_l)^2(\mathrm{N}_1\mathrm{H}_1)^2(\mathrm{N}_2\mathrm{H}_2)^2(\mathrm{N}_3\mathrm{H}_3)^2 \\
\Psi_{\mathrm{ion1}} &= (\mathrm{N}_l)^2(\mathrm{N}_1)^2(\mathrm{N}_2\mathrm{H}_2)^2(\mathrm{N}_3\mathrm{H}_3)^2 \\
\Psi_{\mathrm{ion2}} &= (\mathrm{N}_l)^2(\mathrm{N}_1)^2(\mathrm{N}_2)^2(\mathrm{N}_3\mathrm{H}_3)^2 \\
\Psi_{\mathrm{ion3}} &= (\mathrm{N}_l)^2(\mathrm{N}_1)^2(\mathrm{N}_2)^2(\mathrm{N}_3)^2
\end{aligned}\right\} \quad (2)$$

Here N_l and N_i ($i=1$, 2 and 3) are the lone pair orbital and the equivalent orbitals on the nitrogen atom and $(\mathrm{N}_i\mathrm{H}_i)^2$ is the normalized bond orbital of the Heitler-London type. When the structure of the ammonia molecule is considered to belong to the symmetry species C_{3v}, N_l and N_i orbitals are expressed as follows:

$$\left.\begin{aligned}
\mathrm{H}_l &= \alpha\mathrm{S} + \sqrt{3}\beta\mathrm{P}_z \\
\mathrm{N}_1 &= \gamma\mathrm{S} + \sqrt{\frac{1}{6}}\delta\mathrm{P}_x + \sqrt{\frac{1}{2}}\delta\mathrm{P}_y + \sqrt{\frac{1}{3}}\varepsilon\mathrm{P}_z \\
\mathrm{N}_2 &= \gamma\mathrm{S} + \sqrt{\frac{1}{6}}\delta\mathrm{P}_x - \sqrt{\frac{1}{2}}\delta\mathrm{P}_y + \sqrt{\frac{1}{3}}\varepsilon\mathrm{P}_z \\
\mathrm{N}_3 &= \gamma\mathrm{S} - \sqrt{\frac{2}{3}}\delta\mathrm{P}_x + \sqrt{\frac{1}{3}}\varepsilon\mathrm{P}_z
\end{aligned}\right\} \quad (3)$$

Here S, P_x, P_y and P_z represent the Slater AO's and the coordinate system was taken as shown in Fig. 1. By considering the orthonormalization conditions for Eq. 3, the number of coefficients to be determined is reduced to only one ε.

The dipole moment and the quadrupole coupling constant are expressed as follows:

$$\mu = e\left(\sum_{i=1}^{3} r_i - \sum_{j=1}^{8} \bar{Z}_j\right), \quad \bar{Z}_j = \int |\Psi_T|^2 Z_j \mathrm{d}v \quad (4)$$

$$eQq = -e^2Q\int |\Psi_T|^2 (3\cos^2\theta_z - 1) r^{-3}\mathrm{d}v \quad (5)$$

$$\approx eQq_{pz}f(\lambda, \varepsilon) \quad (5')$$

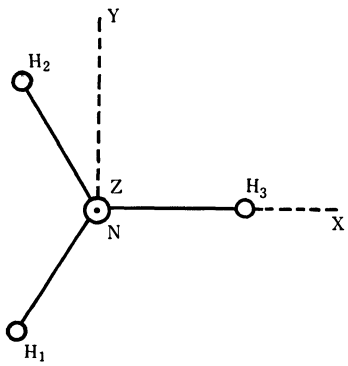

Fig. 1. The coordinate system of NH_3 molecule. Length N-H=1.014 Å. Angle H_i-N-H_j=106° 47' [11].

$$q_{pz} = -e\int|\Psi_{n:2pz}|^2(3\cos^2\theta_z - 1)r^{-3}dv \qquad (6)$$

(e: protonic charge, 4.802×10^{-10} e.s.u.)

We followed the theory of Townes and Dailey that the contribution to the field gradient at the nitrogen nucleus depends exclusively upon the p electrons of the nitrogen atom. Moreover, since we have had no experimental value for eQq_{pz} of the nitrogen atom, we used a value $-11.12\,Mc.$ calculated with the aid of the $2pz$ SCF AO of the ground state ^4S of the nitrogen atom, which was obtained to fit to Hartree-Fock field by Hartree and Hartree[2]. We used the microwave data for the experimental values, $\mu=1.468\,D$ and $eQq=-4.0842\,Mc.$[3], and all the overlap integrals and the dipole moment matrix integrals were evaluated by the ordinary method[4]. These values are tabulated in Table I.

TABLE I. OVERLAP INTEGRAL: $S_{ab}=\int\chi_a\chi_b dv$

DIPOLE MOMENT MATRIX INTEGRAL:

$$M_{ab}=\int\chi_a Z\chi_b dv \text{ (in } a.u.\text{)}.$$

The following abbreviated notations for AO's are used: h_i=(H: 1s), s=(N: 2s), x=(N: 2px), y=(N: 2py) and z=(N: 2pz).

S_{his}	0.510836	M_{hihi}	0.718747
S_{hiz}	0.151483	M_{his}	0.168502
S_{h_1x}	−0.187118	M_{hiz}	0.461132
S_{h_2x}	−0.187118	M_{sz}	0.0866768
S_{h_3x}	0.374235	M_{h_1x}	0.0640552
		M_{h_2x}	0.0640552
		M_{h_3x}	0.128110
		M_{h_1y}	0.111230
		M_{h_2y}	0.111230
		M_{h_3y}	0

The parameters ε and λ were determined as 0.9465 and −0.38, respectively, by the aid of Eqs. 4 and 5′, and the observed values of μ and eQq. The normalized hybrid orbitals of the nitrogen atom then become,

$$\left.\begin{aligned} N_l &= 0.8395S - 0.5434P_z \\ N_1 &= 0.3137S - 0.4082P_x - 0.7071P_y \\ &\quad + 0.4847P_z \\ N_2 &= 0.3137S - 0.4082P_x + 0.7071P_y \\ &\quad + 0.4847P_z \\ N_3 &= 0.3137S + 0.8165P_x + 0.4847P_z \end{aligned}\right\} \qquad (2)$$

TABLE II. RELATIVE WEIGHTS OF VALENCE STRUCTURE IN NH_3 AND S CHARACTER OF THE HYBRID ORBITAL OF N ATOM

Structure		Weight of structure %	
		Present	Syrkin et al.
Covalent form	(I)	14.5	16
Single ionic form	(II)	18.8	13.5
Double ionic form	(III)	2.7	3.9
Triple ionic form	(IV)	0.1	0.3
Transitional	(I)—(II)	33.0	27.3
〃	(I)—(III)	12.5	15
〃	(I)—(IV)	1.6	3
〃	(II)—(III)	14.3	15
〃	(II)—(IV)	1.8	4
〃	(III)—(IV)	0.7	2

	S character %		
	Present	Duncan & Pople	Higuchi
For lone pair orb.	70.5	38.9	71.4
For equivalent orb. (each)	9.8	4.1	3.2

Thus we get the estimates of the ionic character and the s-p hybridization of NH_3 molecule. These are given in Table II, together with the estimated values by other authors. Several views for the orbitals of NH_3[5-8] has been already reported, however we can not always compare those with the present results since those orbitals are almost described in

2) D. R. Hartree and W. Hartree, *Proc. Roy. Soc.* (*London*), **A193**, 299 (1948). This result for $2pz$ function can be approximated in the following analytical form:

$$(3/4\pi)^{1/2}\cos\theta_z r[1.809\,e^{-1.387r}+6.620\,e^{-2.950r}]$$

We calculated q_{pz} by this function.

MO and not in Heitler-London type. When we dare to compare, they have some differences from ours as above mentioned. Here Duncan and Pople's orbitals[5] are determined in such a way as the parameters in orbitals are well fitted to the experimental value of the dipole moment of NH_3, and Higuchi's ones[6] are obtained following Roothaan's SCF procedure[9], in which all the electrons in molecule take part in setting up MO, so that the orbitals are considered more accurate than the present and Duncan and Pople's ones. Also, Syrkin et al.[10] have estimated the ionic character of the structure from the base of the additivity of bond moment. On the other hand, our estimations are made taking into consideration the nuclear quadrupole coupling constant besides the dipole moment. However these both estimates may be said to be equal substantially.

Two Crystalline Forms of DL-α-*Amino-n-butyric Acid*

By Masamichi Tsuboi, Yoichi Iitaka, Shigeko Suzuki and San-ichiro Mizushima

(Received March 19, 1959)

In the course of our infrared studies on amino acids, we have found that there are at least two crystalline modifications in DL-α-amino-*n*-butyric acid,—one of which corresponds to the form already known (hereafter designated as A-form), while the other is a new form (B-form).

A-form is obtained as tabular crystals from the saturated aqueous solution on cooling. While, B-form is obtained as fibrous crystals from the aqueous solution (not necessarily saturated) by adding ethanol. The two forms give different

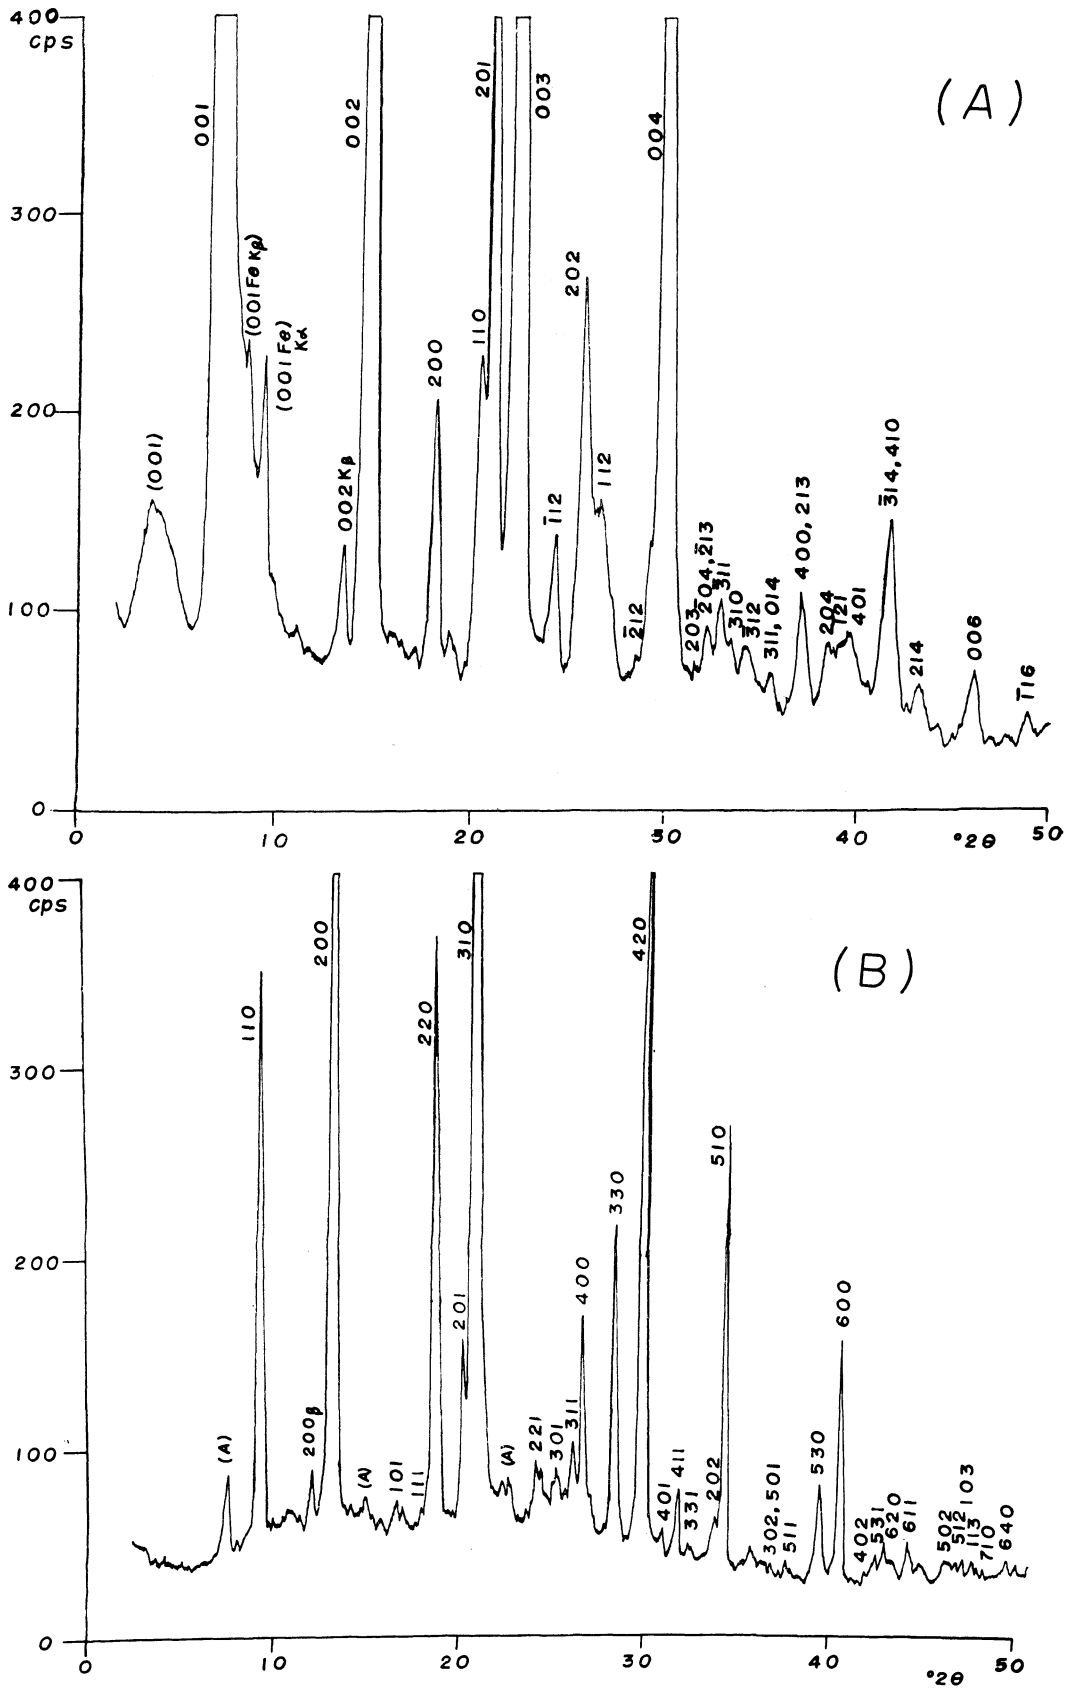

Fig. 2. X-ray powder patterns of A- and B-forms of DL-α-amino-n-butyric acid. Radiation used: CuK, 30 kV., 15 mA., Ni-filtered. (The diffused peak indicated as (0 0 1) for A-form is the continuous spectrum of the X-ray diffracted by the (0 0 1) plane.)

infrared spectra and X-ray powder patterns as shown in Figs. 1 and 2. From the measurements at different temperatures it was found that B-form is transformed into A-form at 195°C, whereas A-form remains unchanged from room temperature to 200°C. Therefore, at room temperature B-form is stable and A-form is metastable, but above 195°C this form becomes stable.

By our X-ray and infrared investigations, A-form is identified as the one, for which Dawson and Mathieson[1] gave the following constants: $P2_1/a$, $a=9.87$ Å, $b=4.80$ Å, $c=12.10$ Å, $\beta=101°$, $Z=4$, and Koegel et al.[2] observed infrared spectrum.

For B-form, it was found, from oscillation and Weissenberg photographs about the axis of the elongation (c-axis) and the axis perpendicular to it (a-axis), that the crystal is tetragonal, with the Laue symmetry of $4/m$, and with the unit cell dimensions: $a=13.38$ Å, and $c=5.85$ Å. Analysis of the photographs showed systematic absence of the reflections for ($h\,k\,0$) planes when $h+k$ is odd, and for ($0\,0\,l$) planes when l is odd; indicating the space group of $P4_2/n$.

As to the molecular configurations of A- and B-forms, it was found probable, from our infrared measurements with plane polarized radiation, that the two forms are rotational isomers to each other[3]. Furhther analysis of the X-ray photographs is now in progress, from which it is hoped to determine accurately the configurations of these isomers.

We wish to thank Sister Mary Marina, for her sending us the infrared spectra of a crystalline DL-α-amino-n-butyric acid which now turned out to be A-form.

A New Very Large Long-period in the X-ray Small-angle Diffraction of Polyethylene Filaments

By Takani Mochizuki

(Received March 25, 1959)

The meridional long-period X-ray diffraction in polyethylene was measured by several authors[1-4]. However the reported long-period spacings are divergent. For instance, a spacing given by Kiessig[2] is 98 Å, whereas that by Statton[3] is 240 Å. These discrepancies might be due to the difference in polyethylene specimens and also their preparations.

This communication is to report that a further large long-period spacing has been observed recently in the meridional small-angle scattering for low-pressure polyethylene filaments.

Polyethylene ("Fortiflex A" of Celanese Corp. of America; Melt index: 0.7) filament specimens were prepared with an extruder at 210°C (Sample A), and stretched at 140°C up to 100% (Sample B), 200% (Sample C) and 300% (Sample D). From the X-ray diffraction photographs, a fairly high orientation of the crystallites was seen for Sample A and a typical uniaxial orientation of the crystallites was observed for Sample D. The small-angle scatterings of X-rays from these samples were

measured in the direction parallel to the fiber axis with an X-ray diffractometer having the following slit system, shown in Fig. 1, Cu $K\alpha$ radiation (38 KV. 15 mA) filtered with nickel foil being used.

Curves of the diffracted X-ray intensity are shown Fig. 2. All samples show a very strong and distinct peak of intensity. The center of the peak for Samples A and D is found using Bragg's law to correspond to a spacing of the order of 260 Å and 460 Å, respectively. Such a large long-period of about 460 Å has not been observed previously for synthetic polymers. From the intensity curves of Samples B and C, it seems that two kinds of long-period (260 Å and 460 Å) coexist in these samples.

Further, high-pressure polyethylene ("Tenite #864" of Eastman Chem. Products; Melt index: 0.3) was examined for comparision. Filaments were prepared in the same way as above, and stretched up to 270% at 100°C (Sample E). The intensity curve of the meridional small-angle interference of Sample E is given by the dotted line in Fig. 2, which shows a broad and low intensity peak. The Bragg distance of this peak is calculated to be 177 Å,

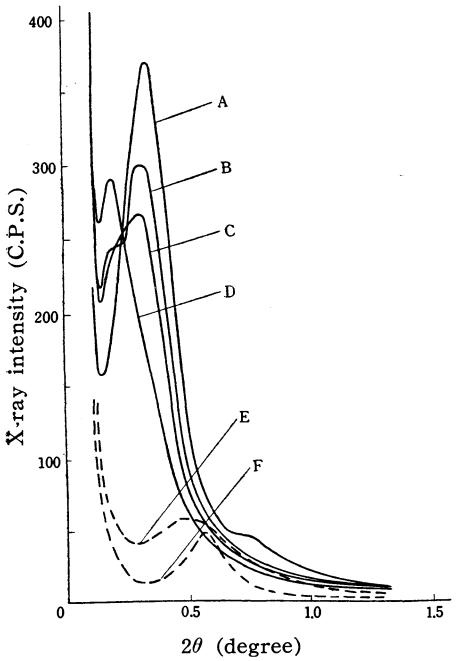

Fig. 2. Intensity curves of small-angle X-ray scattering.
A: original filament
B: 100% stretched filament
C: 200% stretched filament
D: 300% stretched filament
E: high-pressure polyethylene filament
F: polyvinyl alcohol fiber

which is in agreement with the value given by Meibohm and Smith[1] and Sakurada, Nukushina and Tanaka[4].

Some points of interest come to light in this experiment. In the low-pressure polyethylene, a very strong small-angle interference was observed as compared with the intensities obtained for high-pressure polyethylene and polyvinyl alcohol fibers[5]. It seems likely that this marked difference in the intensities might be partly due to the difference between the mean electron densities of the crystalline and amorphous parts, and has something to do with similar difference, shown in Fig. 3, in intensities of the meridional reflections (0 2 0) from both samples[5].

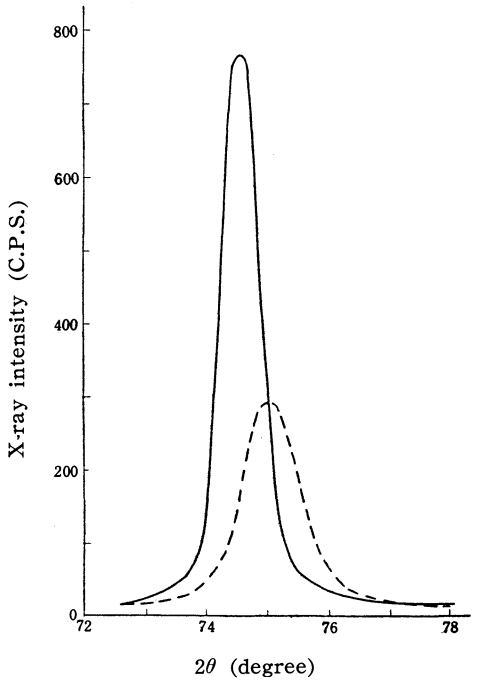

Fig. 3. Intensity curves of (0 2 0) reflection —— polyethylene ------ polyvinyl alcohol

Besides, it is to be noted that the curve A shows a second intensity hump. It corresponds to the second order reflection of the spacing of 260 Å. Such small intensity hump has not been observed in the curves B, C and D, and hence, it seems that the regular fine texture is destroyed by stretching process.

The author expresses his sincere thanks to Professor I. Nitta, Osaka Univercity, for his kind guidance and encouragement

5) The detailed results of polyvinyl alcohol fibers will be reported elsewhere.

throughout this experiments. He is also indebted to Mr. S. Miyazaki for supplying the samples.

Isotopic Exchange of Zinc Chelate Compounds in an Anhydrous Organic Solvent

By Kazuo Saito and Michiko Tamura

(Received March 31, 1959)

Isotopic exchange of zinc in its complexes has been studied by a few workers with various chelate compounds[1-3]. It is generally agreed that the exchange is rapid, except that of zinc phthalocyanine complex, which has a "fused ring" structure. All these experiments, however, involve the use of water, either as solvent or as separating agent for the two compounds between which the isotopic exchange is to be examined. The present authors are of the opinion that the exchange might be accelerated by water, as is in the case of other metal complexes, and that, when the experiment is carried out in the absence of water, a measurably slow exchange might be expected even for those ions having filled inner *d*-orbitals.

Attempts have been extensively made to separate two chelate compounds of zinc in an anhydrous organic solvent. It was eventually found that pure zinc oxinate is precipitated, when dioxane solution of zinc oxinate and acetylacetonate is treated with a large excess of *iso*-propylether, trichloroethylene or chloroform. The yellow precipitate was spectrophotometrically examined in methanol and found to be free from acetylacetonate. The isotopic exchange was examined with inactive oxinate and acetylacetonate labelled with radioactive zinc-65. A linear relationship was observed, when the counting rate of the photo-multiplier pulse due to photo-electric peak of the γ-ray spectrum (1.114 MeV.) of zinc-65 is plotted against the amount of the labelled compound. In order to avoid the influence of water, all procedures were carried out in a dry box (relative humidity, less than 10%; dew point, below $-14°C$).

It was elucidated that the exchange proceeds instantaneously, even under an anhydrous condition. Since the exchange between zinc acetylacetonate in solution and solid zinc oxinate proceeds slowly, it appears evident that the rapid exchange took place in the homogeneous solution rather than between the solute and the precipitate in the nascent state.

Further work with other chelate compounds is in progress. Details of the study will be published later.

Experimental.—The chelate compounds were prepared by the usual methods and dried at 110°C immediately before use. The organic solvents were refluxed with sodium and distilled with dry apparatus. The presence of water was tested with various reagents, including anhydrous copper sulfate and cobalt chloride, but the results were all negative. It appears as if the water content is less than 0.01%.

mol. in 15 ml.) and that of zinc acetylacetonate (0.000125 mol. in 25 ml.) were mixed (at room temperature, 18°C) and, after 30 sec., *iso*-propylether (ca. 300 ml.) was added. The precipitate was filtered off with a detachable sintered glass filter plate, thoroughly washed with *iso*-propylether, weighed and submitted to γ-ray counting. Precipitation of the oxinate was completed within one hour. (No. 1 and 2 in the table).

Exchange between solid oxinate and acetylacetonate in solution was examined in a mixture (100 ml.) of dioxane and *iso*-propylether (1+3, by volume). About 7 and 75 per cent exchange were observed after one hour and 12 hours, respectively. Since the mixed solvent assumed yellow, the exchange appears to proceed through partial dissolution of the oxinate.

*Crystalline Polymers of Some Nuclear-substituted Styrenes**

By Shunsuke Murahashi, Shun'ichi Nozakura and Hiroyuki Tadokoro

(Received April 9, 1959)

In the preceding paper we pointed out the possible crystallization of poly(*p*-methylstyrene) and poly(*m*-methylstyrene) prepared by Ziegler's catalyst from the observation of infrared spectra and density-measurements[1]. In the present communication, we wish to report that this expectation has been realized by the suitable heat-treatment in both cases and also a newly prepared poly(*p*-trimethylsilylstyrene) has been found to crystallize easily by the same treatment.

These results stand in contrast with the recent observation by Natta that the polymers of *p*-substituted styrene obtained with Ziegler's catalysts are generally amorphous, except for *p*-fluorostyrene, because of a steric hindrance caused by the *p*-substituent in crystallization[2].

Table I. Polymerization of nuclear-substituted styrenes with Ziegler's catalyst at 70°C in 20 ml. of *n*-heptane

Monomer g.	$TiCl_4$ mmol.	$AlEt_3$ mmol.	$AlEt_3$ added after washing mmol.	Time hr.	Conversion %	$[\eta]$[a]	Softening point °C[b]

Fig. 1. Fiber diagrams of X-ray diffraction patterns.
(a) Poly(*p*-methylstyrene). An extruded filament was drawn at 135°C to about 20 times of the original length and heated for 6 hr. at the same temperature.
(b) Poly(*m*-methylstyrene). Drawn at 90°C to about 20 times and heated for 3 hr. at 100°C.
(c) Poly(*p*-trimethylsilylstyrene). Drawn at 150°C to about 20 times and heated for 0.5 hr. at 200°C.

All the polymerization procedure in this paper was performed by the use of Ziegler's catalysts according to the modified method described in the previous paper[3], i. e., the catalystic solid mass was washed with *n*-heptane prior to polymerization (Table I). The fractional extraction of the crude polymer was carried out in the case of poly(*p*-trimethylsilylstyrene) as shown in Table II.

The fiber diagrams of X-ray diffraction patterns with these polymers are shown in Fig. 1. Poly(*p*-methylstyrene) could be crystallized by the heat-treatment in a stretched state, although its crystallinity was rather low as shown in Fig. 1 (a). On the contrary, the benzene-fraction (Table II) of poly(*p*-trimethylsilylstyrene) was found to be crystallized easily and highly crystalline even in an unoriented state. Poly(*m*-methylstyrene) was more reluctant to crystallize than poly(*p*-trimethylsilylstyrene) in an unoriented sample.

Fiber periods observed are 12.9, 57.0 and 60.4 Å for the polymers of *p*-methyl-, *m*-methyl- and *p*-trimethylsilyl-styrene, respectively. The large values of identity periods of these polymers suggest some complicated nature of the helical structures of these isotactic polymers. The detailed X-ray analysis will be published elsewhere by Nitta and others.

These three polymers are all considered to be isotactic and to have the helical structure of trans-gauche alternate sequence from the inspection of the following infrared data. (1) The 2849 cm^{-1} CH_2 symmetric stretching band has almost no dichroism (or rather weak parallel dichroism), though the 2924 cm^{-1} CH_2 antisymmetric stretching band shows distinguished perpendicular nature, as is in the case of isotactic polystyrene[4]. This dichroic behavior indicates such an inclination of the triangle of the methylene group that the direction of H—H is nearly perpendicular to the fiber axis and the angle between the bisector of the angle H—C—H and the fiber axis is about 54°44′. (2) The four bands in the region of 1400~1100 cm^{-1}, which are considered to be closely associated with the helical structure in the previous paper[1], are also found in the polarized spectra of these three polymers, showing the same dichroic natures as the corresponding bands of the oriented isotactic polystyrene: 1364 (⊥), 1314 (⊥), 1297 (∥) and 1185 cm^{-1} (∥).

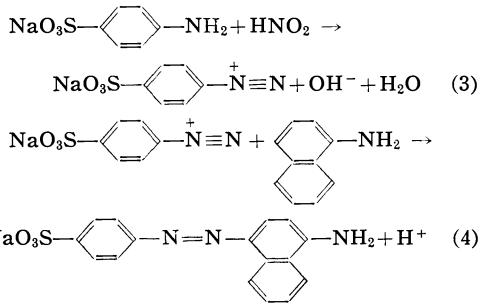
*Organic Spot Tests. I. Detection of Acidic Compounds**



By Yujiro NOMURA

(Received April 11, 1959)

The familiar and sensitive Griess test for nitrites has been found to be used conversely for the detection of very small quantities of acidic compounds. Thus, the mixed solution of sodium sulfanilate, sodium nitrite and α-naphthylamine in dilute alcohol or dioxan produces intense red color on adding a tiny quantity of various acidic compounds. This color reaction depends on the formation of the red azo dye through the following successive reactions:

$$HA \rightleftarrows H^+ + A^- \quad (1)$$

$$NaNO_2 + H^+ \rightleftarrows HNO_2 + Na^+ \quad (2)$$

$$NaO_3S-C_6H_4-NH_2 + HNO_2 \rightarrow NaO_3S-C_6H_4-\overset{+}{N}\equiv N + OH^- + H_2O \quad (3)$$

$$NaO_3S-C_6H_4-\overset{+}{N}\equiv N + C_{10}H_6-NH_2 \rightarrow NaO_3S-C_6H_4-N=N-C_{10}H_6-NH_2 + H^+ \quad (4)$$

The reactions 3 and 4 proceed so rapidly and completely that the equilibria 2 and 1 are shifted toward the right successively. Accordingly, by virtue of the equilibrium disturbance it is possible to detect many organic acids which are not very soluble and are so weak that they do not affect usual dyestuff indicators at all or do indecisively at most.

Reagents.—1) 2.9 g. of sodium sulfanilate $NH_2C_6H_4SO_3Na \cdot 2H_2O$ and 0.7 g. of sodium nitrite are dissolved in 30 cc. of distilled water.

2) 1.8 g. of α-naphthylamine is dissolved in 40 cc. of ethanol or dioxane.

The reagent solution is prepared by mixing two solutions 1) and 2) just prior to use.

Procedure.—A few drops of the reagent solution are placed in a depression of a spot plate. A small amount of the test material (a few crystals or the residue after evaporating a drop of a test solution) is added. Depending on the acidity and solubility of the acid present, a red or orange color appears at once or after a few minutes. A comparison blank test is advisable when dealing with a slight amount of the sample.

Results.—The limits of detection attained with various acids were 25~40 γ. The following compounds were tested.

Immediate intense red color reaction.—Formic acid, acetic acid, propionic acid, butyric acid, isovaleric acid, caproic acid, oxalic acid, malonic acid, succinic acid, adipic acid, fumaric acid, maleic acid, lactic acid, thioglycolic acid, malic acid, citric acid, tartaric acid, benzoic acid, salicylic acid, anthranilic acid, sulfanilic acid, benzenearsonic acid, hippuric acid and picric acid.

Immediate orange to orange-red color reaction.—Caprylic acid, pelargonic acid, capric acid, palmitic acid, stearic acid, oleic acid, elaidic acid, erucic acid, cholic acid, aspartic acid and glutamic acid.

Orange color reaction within a few minutes.—Lauric acid, myristic acid and 12-hydroxyoleic acid.

Negative reaction.—Phenol, cresol, catechol, resorcinol, hydroquinone, ethyl acetate, ethyl benzoate, diethyl malonate, benzoylacetone, ethyl acetoacetate, acetanilide, succinimide and ammonium salts or metal salts of carboxylic and sulfonic acids.

α-Amino acids except aspartic acid and glutamic acid gave no response to the reagent solution. But after digesting with two or three drops of formaline they showed positive reactions. The following amino acids could be detected in this manner: glycine, alanine, cystine, valine, methionine, leucine, isoleucine, phenylalanine, tyrosine, histidine and asparagine.

Purification of Silicontetraiodide by Zone-refining Process

By Hideo BABA, Tadashi NOZAKI and Hidemaro ARAKI

(Received July 12, 1958)

In spite of the superior properties of silicon as a semiconductor material, the electronic devices such as silicon transistors or power rectifiers have not been fully developed. One of the causes of this comes from the fact that the techniques of purification of this material are more difficult than those of germanium. The refining process of silicon would have to choose another direction from that of germanium especially in its chemical purification steps. Moreover, elementary silicon is so chemically active in its molten state that the zone refining can not be carried out in the same way as in the case of germanium. For these reasons, chemical purification is important to obtain a highly pure silicon.

Several methods have been presented for obtaining transistor grade silicon[1-4], but among them, the so called du Pont method is the most predominant in the industrial aspect at present. On the other hand, we expect that the silicon iodide method will be one of the promising ones for improving the purification processes. First of all, the most important problem is the methods of removing impurities in silicontetraiodide. Of course, the usual refining processes such as recrystallization, distillation and sublimation are also applicable in this case, but in addition to them, the zone-refining process, which has been proved excellent for the purification of germanium[5], may be applied to this compound. But the behavior of impurity elements in the iodide during this process has not been made clear. As some elements such as boron, phosphorus and arsenic are removed with difficulty by the zone-refining of elementary silicon[6], it is preferable to remove them from it beforehand. For this reason, we studied the behavior of a trace of boron and phosphorus in silicontetraiodide during the normal freezing and zone-melting of the material.

Recently, Rubin et al. studied the zone-melting of silicontetraiodide and they determined the segregation coefficients of several elements by spectrographic analysis[7]. But as they pointed out, the concentrations of impurities at the top of the charge were too far below the limits of spectrographic detection for some elements to make clear the details of the impurity distribution through the charge.

Experimental Results

Behavior of Phosphorus in Silicontetraiodide.—*a) Preparation of radioactive phosphorus-iodide.*—Radio isotope ^{32}P is conveniently used to trace the behavior of phosphorus during the zone melting process of silicontetraiodide. Phosphorus in silicontetraiodide will not be present in its elemental state but will exist as some iodine compounds such as diphosphorus tetraiodide or phosphorus triiodide. Radio isotope ^{32}P can easily be produced by deuteron radiation. But neither kind of phosphorus, red or yellow, can be irradiated in the cyclotron because of its high vapor pressure. In order to avoid these difficulties, it is preferable to use some phosphorus alloy. Pure copper foil with 99.96% purity and 0.2 mm. thick was vacuum-sealed with red phosphorus in a quartz tube, and was heated at 300°C for about ten hours in a furnace. During this heat treatment, the phosphorus diffused into copper and the surface of the foil turned silver white in color. This alloy was irradiated by deuteron in cyclotron to make it radioactive.

The thus activated Cu—P alloy was treated with toluene containing iodine at its boiling point for about two hours to dissolve out the activated phosphorus, and labeled phosphorusiodide could be obtained. A little portion of activated copper was accompanied with phosphorusiodide in solution forming copper iodide, but the influence of γ rays emitted from ^{64}Cu could be neglected in measuring β rays emitted from ^{32}P using a Geiger counter. Toluene solution containing radioactive phosphorusiodide was added to crystalline siliconiodide and it was dissolved completely by the addition of boiling toluene. Then it was cooled at 0°C for several hours to crystallize out

the silicon iodide contaminated with radioactive phosphorus.

b) Measurement of phosphorus distribution by the radiochemical method. — Segregation Experiments. — The thus prepared silicon iodide was sealed in a quartz tube of 15 mm. diameter and 30 cm. length under reduced pressure. The content was melted by heating uniformly and cooled rapidly so that no segregation of the impurity would occur and was followed by the measurement of the initial distribution of ^{32}P. As shown in Fig. 1, the tracer was distributed uniformly throughout the rod. The content was melted again completely in a furnace which was long enough to melt it uniformly, then the quartz tube was moved down with a speed of 2.2 mm. per minute. The melted silicon iodide was solidified from the top portion outside of the furnace gradually. As a little part of the silicontetraiodide was hydrolyzed by atmospheric moisture, the melted portion of silicon iodide became somewhat turbid. But hydrolyzed products were easily segregated and transferred toward the upper part of the rod.

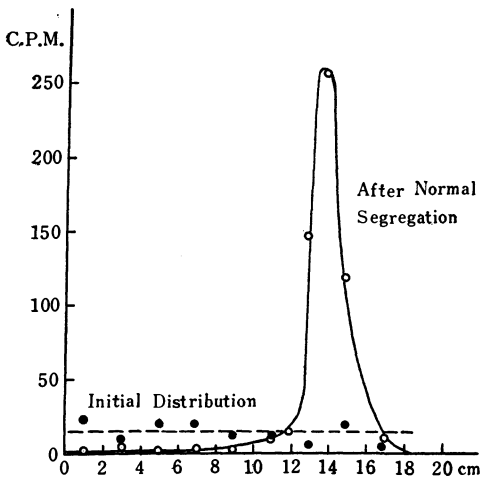

Fig. 1. Distribution of phosphorus after normal freezing.

The distribution of phosphorus after normal segregation could be found by measuring the radioactivity of β-rays emitted from ^{32}P at every 10 mm. length of the rod using a sealing device. The results are shown by curve 2 in Fig. 1 by plotting the counting rate against the distances from the top of the rod.

This method was convenient to carry out the experiment of segregation or zone melting processes, because repetition using the same sample was possible. But the selfabsorption by silicontetraiodide and the absorption by quartz wall made the counting rate less, and when the iodide changed its phase, liquid to solid and vice versa, local strong strength sometimes broke the quartz tube.

These troubles could be avoided by using a quartz boat instead of a tube as shown in Fig. 2. In this case, dried argon gas was introduced gently from the top of the boat to carry the evaporated iodide toward the end of the boat. After normal segregation or zone refining processes, the rod of silicon iodide was taken off from the boat and cut into about ten segments, and each

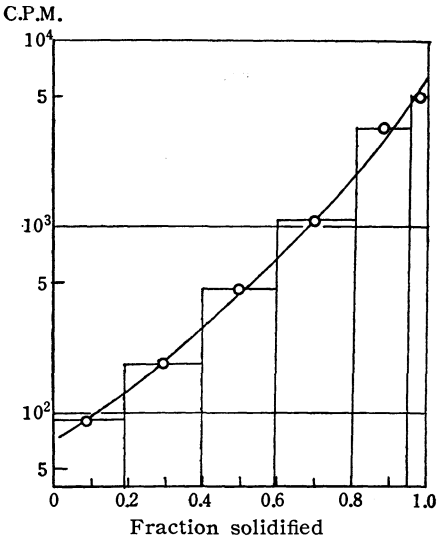

Fig. 4. Distribution of phosphorus after three passes of molten zone.

of them was weighed quickly avoiding the hydrolysis by the atmospheric moisture. Then they were hydrolyzed in a quartz evaporating dish by adding distilled water and dried up on a hot plate. The radioactivity of the samples thus obtained was measured by a Geiger counter.

The results are shown in Fig. 3. Curve 1 indicates the distribution of phosphorus after normal segregation with a velocity of 2.5 mm./min., and Fig. 4 shows the result of zone refining of three passes with a velocity of 0.83 mm./min. In both cases the counts of one gram of hydrolyzed products per five minutes were plotted against a solidified fraction of the iodide bar.

Behavior of Boron in Silicontetraiodide.—*Determination of boron by colorimetric method using curcumin.*—As it is impossible to trace the behavior of boron by using its radioisotope because of its short half life, there is no way but chemical analysis for this purpose. The colorimetric method using curcumin seemed to be the most satisfactory.

Several reports have been published on the determination of boron by this method[8-11]. But some of them have poor reproducibility, because coloring conditions, such as the concentration of the reagents, the time of treating, the evaporation temperature and the dissolving method of formed curcumin-boron complex, affect the results significantly.

Reagents.—*a*) *Curcumin-oxalic acid solution.*—Dissolve 5.0 mg. of crystalline curcumin and 0.5 g. of recrystallized oxalic acid in 50 ml. of redistilled ethanol. This solution was prepared freshly immediately before use and kept cold.

b) *Boron standard solution.*—Dissolve 0.1430 g. of boric acid (extra pure grade) in 500 ml. of redistilled water. Dilute 5.0 ml. portion of this stock solution to 500 ml. (the boron content will be 0.5 γ per ml.).

Standard Reference Curves.—Taking zero to 5.0 ml. of the standard boron solution in quartz evaporating dishes, 1 ml. of hydrochloric acid (1 : 1) and 2 ml. of curcumin oxalic acid solution were added, then they were diluted with distilled water to make the total volume 8 ml. These evaporating dishes were floated on a water bath which was kept at 55±2°C until the contents were dried up. The evaporation could be accelerated by the aid of a gentle air flow on the liquid surface. Ten ml. of ethanol was added to each dish to dissolve the residue, and the solution was transferred to an absorption measurement cell of 10 mm. length. The absorbancy at 540 mμ was measured using a spectrophotometer.

As shown in Fig. 5, curcumin solution itself has absorption maximum at 430 mμ, while boron complex has its maximum at 540 mμ. The curcumin-boron complex is rather stable and no detectable change was observed after several hours as shown in this figure. Beer's law plot is shown in Fig. 6. It was necessary to make

blank tests on each sample in order to minimanize the fluctuation of the results.

Determination of Born Distribution in Zonerefined Silicontetraiodide. — Generally, elementary silicon used for iodination experiment contains enough boron in itself, so that a detectable amount of boron should be present in iodide without adding any on purpose. So the hydrolyzed product used for activity measurement of ^{32}P could be used for the determination of boron. About 10 ml. of distilled water was added to the sample and it was heated gently in a quartz evaporating dish to extract the boron into solution as boric acid. Then it was filtered and the precipitate of silicon dioxide on filter paper was washed several times with warm water to remove the boron compound completely. The filtrate was evaporated by heating in a quartz evaporating dish to about 5 ml. Using this solution, boron was determined as described above.

Curve 1 in Fig. 7 shows the distribution of

boron after six passes of single zone with a moving speed of 2.4 mm. per min., and curve 2 shows that of three passes with a speed of 0.83 mm./min. In both cases the width of the molten zone was about 20 mm.

Consideration of the Results

Several studies have been reported on the segregation effect of the binary solution of metals. The zone purification method was developed from this principle by Pfann, and the behavior of impurity elements in semiconducting materials has been made clear by many workers. It is well known that the distribution of impurity concentration throughout the ingot after normal segregation is expressed by the equation[5]

$$C = kC_0(1-g)^{k-1} \qquad (1)$$

In this equation, g represents the solidified fraction, C_0 the initial concentration, C the impurity concentration at a point g, and k the distribution constant defined by the ratio of impurity concentration in solid to that in liquid. In the case of segregation of phosphorus in silicontetraiodide this equation may be also applicable. Let k be equal to 0.1 and 0.8, the distributions of phosphorus throughout the iodide bar are represented by curve 2 and 3 respectively in Fig. 3. Comparing these curves with experimental results, it can be said that the results can not be represented by the above equation, but it consists of two different k values. As colloidal silicon dioxide produced by the hydrolysis of tetraiodide has a tendency to adsorb phosphorus as well as some other trace impurities, it is reasonable to consider that a part of phosphorus will be adsorbed by the colloidal silicon dioxide and segregated together. For the reason given above, the beginning portion of the curve shows a large k value corresponding to the distribution constant of phosphorus itself, and the end portion of the curve shows a small k value which corresponds to that of the hydrolyzed product. In this case, the segregation equation can be written as

$$C = C_0\{k_1(1-g)^{k_1-1} + k_2(1-g)^{k_2-1}\} \qquad (2)$$

Curve 1 and 2 in Fig. 8 show the distribution of solute assuming $k=0.1$ and $k=0.8$ respectively. Curve 3 shows the result of calculation from Eq. 2 using $k_1=0.1$ and $k_2=0.8$. C_0 is unity in each case. The resultant curve 3 shows good correspondence with experimental results.

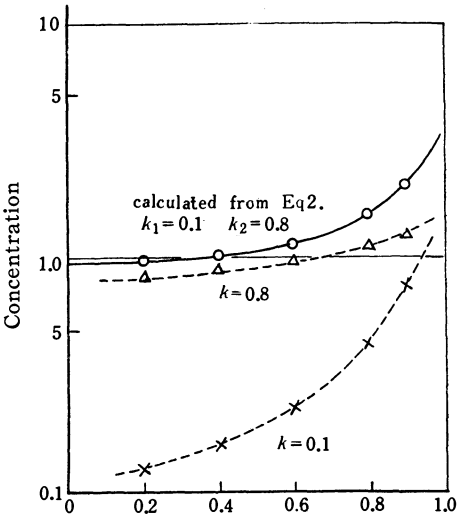

Fig. 8. Resultant distribution calculated from Eq. 2. $k_1=0.1$ $k_2=0.8$

The results of the zone refining process showed a promising effect to remove phosphorus after three passes of single zone, for instance, the concentration could be decreased one tenth of the initial amount at the top portion and the ratio of concentration of phosphorus at the end and the top parts of the bar reached three powers of ten.

As for boron, the results were not so distinct as in the cace of phosphorus, but better refining efficiency could be expected by this process than in the case of its elementary state.

Summary

The behavior of phosphorus and boron as impurity elements in silicon tetraiodide was studied during the normal segregation and zone melting processes. Both of them can be removed efficiently by this process, and it is considered that the colloidal hydrolyzed product suspended in silicon tetraiodide plays a predominant role for segregation because of its high adsorptivity to these elements. The distribution curve of radioactive phosphorus seems to show the influence of this material.

The authors are pleased to express their gratitude to the Director Dr. T. Niimi, and Dr. S. Yanagisawa, Professor of Chemistry at Keio University, for helpful guidance and encouragement during the course of this study.

Formation of Tetraazaporphin from Phthalic Anhydride and its Reduced Products

By Masahiro SHIGEMITSU

(Received September 25, 1958)

Phthalic anhydride easily reacts with urea and metallic salts to produce metal phthalocyanine, a kind of tetraazaporphin. Particularly, copper phthalocyanine which is obtained almost quantitatively by the above reaction is one of the most widely used blue organic pigments. But in the case of 3, 4, 5, 6-tetrahydrophthalic anhydride which is the reduced product of phthalic anhydride, the yield of tetraazaporphin is rather small[1].

In the present experiment, the effect of structure of the starting materials on the tetra-azaporphin formation was examined. Phthalic anhydride (I), 3,4,5,6-tetrahydrophthalic anhydride (II), 1,2,3,6-tetrahydro-*cis*-phthalic anhydride (III), hexahydro-*cis*-phthalic anhydride (IV) and 3,6-endomethylene-1,2,3,6-tetrahydro-*cis*-phthalic anhydride (V) were chosen as the examples for the starting materials.

Experimental

Materials.—Phthalic anhydride (I), m. p. 130～131°C. 3,4,5,6-Tetrahydrophthalic anhydride (II) was prepared by reducing phthalic anhydride with sodium-amalgam, m. p. 68～69°C (reported m.p. 68～69°C)[2] (*Anal.* Found: C, 63.09; H, 5.20. Calcd. for $C_8H_8O_3$: C, 63.15; H, 5.26%). 1,2,3,6-Tetrahydro-*cis*-phthalic anhydride (III) was prepared with the aid of Diels-Alder reaction from butadiene and maleic anhydride, m.p. 99～101°C (reported m. p. 99～101°C)[3] (*Anal.* Found: C, 63.08; H, 5.22. Calcd. for $C_8H_8O_3$: C, 63.15; H, 5.26%). Hexahydro-*cis*-phthalic anhydride (IV) was prepared by reducing III with sodium-amalgam, m. p. 33～34°C (reported m. p. 32～33°C)[4] (*Anal.* Found: C, 62.29; H, 6.45. Calcd. for $C_8H_{10}O_3$: C, 62.34; H, 6.49%). 3,6-Endomethylene-1,2,3,6-tetrahydro-*cis*-phthalic anhydride (V) was prepared with the aid of Diels-Alder reaction from cyclopentadiene and maleic anhydride, m. p. 164～165°C (reported m. p. 164～165°C)[5,6] (*Anal.* Found: C, 65.77; H, 4.91. Calcd. for $C_9H_8O_3$; C, 65.84; H, 4.87%).

Methods.—A mixture of 15 g. of phthalic anhydride or its reduced products, cuprous chloride (1/4 mol. of starting materials as shown in Table I), 60 g. of urea, 0.5 g. of ammonium molybdate and 175 g. of nitrobenzene was heated with stirring. Tow model cases will be shown in relation to the experimental conditions. First, the mixture was stirred at room temperature for 30 min., and then heated up to 150°C during ca. 1 hr. at a definite rate, and finally at 150～155°C for 4 hr. In the second example, the mixture was stirred at room temperature for 30 min., and then heated up to 190°C during ca. 2 hr. at a definite rate, and finally at 190～195°C for 3 hr. After the reaction was completed, nitrobenzene was removed by steam distillation

and the resulting mixture was heated with 5% hydrochloric acid and then 2% caustic soda, filtered, washed with water and dried at 60~70°C.

When I was used as the starting material, the coloring matter (copper phthalocyanine) was treated with ethanol to remove impurities. In the case of II, the coloring matter (copper tetracyclohexenotetraazaporphin) was extracted from the dark brown product with *o*-dichlorobenzene[7]. In the case of III, IV and V, the coloring matters (tetraazaporphins) could not be obtained by the extraction from the dark brown products with α-chloronaphthalene (good solvent of tetraazaporphins) and *o*-dichlorobenzene.

Coloring matters were formed only in the cases of I and II, both of which were of similar blue shades. Reflectance curves concerning these shades of colors were measured with a recording spectrophotometer (General Electric Co.). Samples were prepared in the following way. One part of copper phthalocyanine obtained from I was dissolved in 3 parts of 98% sulfuric acid at room temperature, and was poured into water. Fine crystals deposited were washed with water free from acid and dried at 60~70°C. One part of β-form copper phthalocyanine here obtained[8] and copper tetracyclohexenotetraazaporphin obtained from II were mixed respectively with 1.5 parts of polymerized linseed oil and were made into paste by grinding 400 rounds in Hoover automatic muller. To 1 part of this paste was added 70 parts of zinc white paste (obtained by grinding 2 parts of zinc oxide in 1.5 parts of polymerized linseed oil), which was applied in 0.5 mm. thickness on a coated paper with a bladeoapplicator (Gardner Laboratory). These were dried at room temperature and used as samples for measuring reflectance curves.

Results and Discussion

Table I shows the relation between the reaction conditions and the reaction products.

As is seen from Experiments 1 and 2 (Table I), the reaction proceeded easily at a reaction temperature of either 150~155°C or 190~195°C when the reaction was conducted with I as the starting material, copper phthalocyanine being obtained in good yield (*Anal.* Found: C, 66.78; H, 2.90; N, 19.38; Cu, 11.00. Calcd. for $C_{32}H_{16}N_8Cu$: C, 66.72; H, 2.78; N, 19.46; Cu, 11.04%). As is shown by Experiments 3 and 4, the use of II as starting material remarkably reduced the yield of the coloring matter (4.1 and 1.4%, respectively). The coloring matter obtained was copper tetracyclohexenotetraazaporphin (*Anal.* Found: C, 65.02; H, 5.54; N, 18.76; Cu,

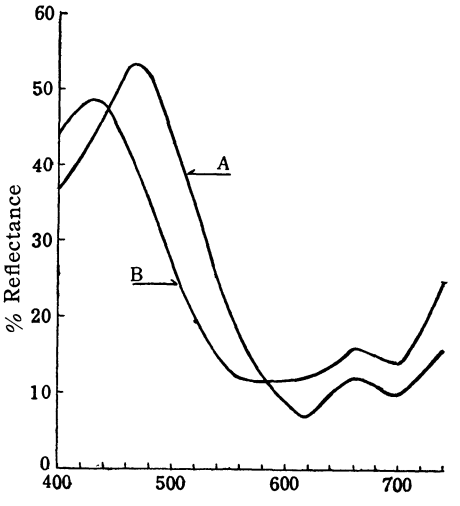

Fig. 1. Reflectance curves of β-form copper phthalocyanine (A) and copper tetracyclohexenotetraazaporphin (B).

7) British Pat., 686,395 (1953).
8) G. von Susich, *Anal. Chem.*, **22**, 425 (1950).

10.67. Calcd. for $C_{32}H_{32}N_8Cu$; C, 64.91; H, 5.41; N, 18.93; Cu, 10.76%).

While copper phthalocyanine slightly dissolves only in α-chloronaphthalene, copper tetracyclohexenotetraazaporphin easily dissolves in *o*-dichlorobenzene and has a color somewhat more reddish than copper phthalocyanine. Their reflectance curves are shown in Fig. 1 and their C. I. E. Notations are given in Table II. In this table, Y denotes luminosity, P_e purity and λ_D dominant wavelength.

TABLE II. C. I. E. NOTATIONS

Sample	Y%	P_e%	λ_D mμ
A	19.10	55.8	475.8
B	17.00	47.0	470.2

A; Copper phthalocyanine (β-form).
B; Copper tetracyclohexenotetraazaporphin.

The dominant wavelength of copper tetracyclohexenotetraazaporphin is shorter by 5.6 mμ than that of β-form copper phthalocyanine with blue color tinged with red.

In the Experiments 5 and 6 where III, which carries the bond in a different position from that in II, was used as starting material; only alkali-soluble dark brown products were obtained, but coloring matters could not be isolated either by α-chloronaphthalene or *o*-dichlorobenzene.

When IV (Experiments 7 and 8) which has no double bond, and V (Experiments 9 and 10) were used as starting materials, only alkali-soluble dark brown products were obtained without formation of tetraazaporphin. Thus, it was confirmed that, when I is reduced and aromaticity is weakened, or when aromaticity is very small as in the case of V, tetraazaporphin can not be produced. However, when the double bond between carbonyl groups is not reduced, tetraazaporphin is produced, though the yield is small.
