**Ultraviolet Absorption Spectra of Hein's Polyphenyl-chromium Compounds.**— Hein[21] reported a number of polyphenyl chromium compounds with general composition of $Cr(C_6H_5)_n$ and $Cr(C_6H_5)_n$ X, where $n$ is equal to 3 or 4, and X denotes an anion such as iodide and anthranilate. It was only after the discovery of numerous compounds with a ferrocene-like structure that the suggestion was presented that Hein's compounds might contain chromium(I)-complexes having a sandwich structure with benzene, biphenyl, terphenyl or similar aromatic molecules[22]. Identificaion of one of Hein's compounds, $Cr(C_6H_5)_4I$, with the complex $[Cr(C_6H_5 \cdot C_6H_5)_2]I$, which was prepared from chromium(III) chloride, aluminum and biphenyl as starting materials, was made by comparison of their infrared and ultraviolet absorption spectra, X-ray absorption edges and magnetic properties[5]. Absorption spectra as well as other properties

of Hein's compounds were formerly reported, but the detailed discussion about ultraviolet spectra of the compounds has not been presented up to the present. In the following, a brief discussion will be given about the absorption spectra of these compounds on the basis of the relationships which have been obtained in the present work.

It was reported in the earlier part of the present paper that the benzene rings in combination with chromium in the compounds having linkage characteristic of the sandwich molecules show two absorption bands, which are due presumably to electronic transitions from an orbital concerned mainly with the central chromium to the two excited levels of the benzene rings. In support of this idea seems to be the fact that the frequency difference between two such transitions is nearly constant for the chromium compounds with benzene rings.

When benzene is replaced by biphenyl in a similar type of compound, a similar type of relationship may exist about the frequency difference, if the sandwich structure is kept in the biphenyl-compounds. Thus, the magnitude of the corresponding frequency difference may be constant for the compounds of chromium with biphenyl, but different from the magnitude in the case of the chromium(I)-compounds with benzene rings. Based on the concept presented here, absorption spectra of Hein's polyphenyl compounds of chromium(I) seem to be understood well if it is assumed that they contain chromium(I)-complexes with aromatic molecules, having the sandwich structure of a ferrocene-type.

In the case of $[Cr(C_6H_6)(C_6H_5\cdot C_6H_5)]^+$, for example, which has both benzene and biphenyl in combination with chromium(I), electronic transitions to the two excited levels of benzene and to a few levels of biphenyl may be possible, their superposition being observed in the absorption curve of this compound. In fact, $\nu_{III}-\nu_{II}$ obtained from the observed curve[22] of $[Cr(C_6H_6)(C_6H_5\cdot C_6H_5)]^+$ is found to be nearly equal to the value for $[Cr(C_6H_6)_2]^+$, as seen in Table I. This observation may be readily understandable on the basis of the assumption presented in this paper. Thus, if it is assumed that the maximum frequency of Band III, $\nu_{III}$, of the chromium compound is greater with biphenyl than with benzene rings, the difference $\nu_{III}-\nu_{II}$, which is obtained directly from the absorption spectrum of $[Cr(C_6H_6)(C_6H_5\cdot C_6H_5)]^+$, may correspond to the frequency difference between the two excited levels of the benzene ring in combination with the chromium. This is in agreement with the above-mentioned observation. The observation that $[Cr(C_6H_5\cdot C_6H_5)_2]^+$ shows larger $\nu_{III}-\nu_{II}$ than $[Cr(C_6H_6)_2]^+$ does may be understood in a similar way.

The fact that the absorption spectra of Hein's compounds may be explained in this way seems to indicate that *Hein's polyphenyl chromium-(I)-compounds have complex-ions with a sandwich structure similar to that of* $[Cr(C_6H_6)_2]^+$ *or* $[Cr(C_6H_5CH_3)_2]^+$.

It is to be noted that Hein's chromium(I)-complexes all show Band II at about 86 to $88\times10^{13}$ $sec^{-1}$, which is very close to the value for Band II of $[Cr(C_6H_6)_2]^+$, $[Cr(C_6H_5CH_3)_2]^+$ and $Cr(C_6H_6)(CO)_3$. This seems to indicate that *the linkage of the aromatic molecules with the central chromium is remarkably alike in these complexes.*

It was found in the preceding part of the present paper that the chromium(I)-complexes with aromatic molecules exhibit a very weak absorption band, due possibly to spin-forbidden transitions, in the long wavelength region and one of the ligand field bands in the near-infrared. The former investigators did not report a very weak absorption band in the visible or an absorption band in the infrared region for Hein's polyphenyl compounds of chromium(I). In the opinion of the present authors, however, there is good reason to expect that the "polyphenyl compounds of chromium(I)" show a spin-forbidden absorption band at about 50 to $55\times10^{13}$ $sec^{-1}$, and two of the ligand field bands, one in the infrared and the other as inflation at about $80\times10^{13}$ $sec^{-1}$, just like the bis-(benzene)- and bis-(toluene)-chromium(I) complexes.

**General Aspects of Absorption Spectra of Metal-arenes.**—In the next place, the authors will discuss the general aspects of absorption spectra of metallic complexes with aromatic molecules and related compounds on the basis of these measurements with the aid of the data by the former investigators. It may be assumed that these compounds in general display "ligand field absorption bands", due mainly to the central metal under the strong ligand field surrounding it, and absorption bands corresponding to the electronic transitions to the excited levels of the ligand groups in combination with the metal. A part of the former is often covered by more intense absorption of the latter type. The absorption bands of the latter type seem to be rather dependent upon the ligand and sensitive to the nature of its linkage with the metal. Thus, in the case of the cyclopentadienyl-radical, the latter bands are found to undergo a marked shift as the central metal is exchanged, while little change in this type of bands is given rise to when a benzene molecule combined with chromium is replaced by a biphenyl molecule

in the chromium-arenes.

Besides these two types of absorption bands, there is usually observed a very weak absorption band system in the long wavelength region, corresponding to spin-forbidden bands due mainly to the central metal. A part of this band system is also covered by the other absorption bands with much greater intensity.

With an ordinary type of metallic complex, the order of ligands is known as the "spectrochemical series"[23], which represent the decreasing order as to the magnitude of their hypsochromic effect on the ligand field bands of the metallic complexes. In the following, discussion will be undertaken concerning metallic compounds with ligands which are coordinated to a metal atom through their carbon atom. Unambiguous assignments of absorption bands to particular electronic transitions are sometimes quite difficult, but a general trend concerning the above effect may be readily derived. Thus reviewing a series of compounds, $Cr(CO)_6$, $Cr(C_6H_6)(CO)_3$ and $Cr(C_6H_6)_2$, the authors may be able to obtain the following order as to the hypsochromic effect of the ligands: $CO > C_6H_6$. In a similar way, it is easily shown that CO has a greater hypsochromic effect than a cyclopentadienyl-radical: $CO > C_5H_5^-$. It is thus seen that CO stands extremely high in the spectrochemical series, probably even higher than $CN^-$. Comparison also reveals that $C_5H_5^-$ is very close to, but only a little higher than, $C_6H_6$ in the spectrochemical series. In summary, the following order may be derived: $CO > C_5H_5^- > C_6H_6$.

It is interesting to note that the following order also is derived from the previous data[24] about mixed carbonyls of iron and wolfram: $CO > CN\cdot CH_3 > CN\cdot C_6H_5$. Comparison of the isonitriles with $C_6H_6$ and $C_5H_5^-$ as to their hypsochromic effect seems to be difficult for the present.

With the same ligands, the order of transition metal elements as to their hypsochromic effect may also be derived in a similar way. With ligands such as CO, $C_5H_5^-$ and $C_6H_6$, light absorption is found to be displaced to a shorter wavelength, as the authors go down the periodic table for elements belonging to one and the same sub-group. More or less marked hypsochromic shift is observed when a metal atom is replaced by another which stands lower in the same sub-group for a series of elements such as (Cr, Mo, W), (Fe, Ru, Os) and (Co, Rh, Ir). Absorption maxima of all these compounds are not reported, but a difference in color seems to indicate the above trend without exception. The same trend was reported with many other ligands of an ordinary type[25].

## Summary

Ultraviolet absorption spectra of $Cr(CO)_6$, $Cr(C_6H_6)(CO)_3$, $[Cr(C_6H_6)_2]I$ and $[Cr(C_6H_5CH_3)_2]I$ have been determined in various solvents. Dichroism in the visible and ultraviolet region of $Cr(C_6H_6)(CO)_3$ has been determined at room temperature by Tsuchida and Kobayashi's microscopic method with a single crystal of the compound.

The absorption spectrum of $Cr(C_6H_6)(CO)_3$ shows main features similar to those of the spectrum of the $[Cr(C_6H_6)_2]^+$ ion.

These compounds all show a weak absorption band to the long wavelength side of the intense absorption bands.

The results of the measurements have been discussed in relation to the bonding involved in these compounds. Discussion also has been undertaken about Hein's polyphenyl-compounds of chromium(I) on the basis of the present measurements. Absorption spectra of Hein's compounds of chromium(I) seem to be in agreement with the assumption of the sandwich structure.

# *Vinyl Polymerization. XLIII. Polymerization of Styrene with Vinylmagnesium Chloride*

By Minoru IMOTO and Masayoshi KINOSHITA

(Received September 21, 1959)

It was reported by Beaman[1] and others that Grignard reagents could polymerize some vinyl monomers. Recently, a synthetic method of Grignard reagent from vinyl chloride was published[2]. In this paper the authors prepared vinylmagnesium chloride after Ramsden[2] and carried out the kinetic study of the polymerization of some vinyl monomers.

## Experimental

**Materials.** — Commercial tetrahydrofuran (THF) was refluxed over potassium hydroxide and then over sodium. After distillation it was stored in the presence of lithium aluminum hydride. Before, use, it was redistilled in a stream of nitrogen. Commercial vinyl chloride was dried with potassium hydroxide, calcium chloride and then with phosphorus pentoxide.

**Vinylmagnesium Chloride.** — Vinyl chloride gas was passed into THF (507 g.) until 144 g. were absorbed. Ethyl bromide (2 ml.) was dropped into a mixture of 44 g. of magnesium turnings and 15 ml. of the vinyl chloride-THF solution was then added as rapidly as possible. After the reaction was completed, excess vinyl chloride was distilled out and the unreacted magnesium was filtered off. The homogeneous solution of vinylmagnesium chloride was stored in a brown bottle. The Grignard solution thus obtained had a concentration of 2.07 mol./l. by Gilman's titration[3] (81% yield). After a month, the concentration decreased to 2.01 mol./l. From these values it was considered that the concentration of the reagent might be kept constant throughout the experiment.

**Change of Vinylmagnesium Chloride into Acrylic Acid.** — A solution of vinylmagnesium chloride in THF was added into a large excess of powdered dry ice. After being acidified, the organic layer was distilled to give an acid, having a stimulus odor, and boiling at 84~88°C/82 mmHg, ($n^{20}=1.4223$). The acid could be polymerized easily. From these facts, it was confirmed that the acid was acrylic acid (in literature 4, $b.p._{88}=81°C$, $n^{20}=1.4224$) and the Grignard reagent was vinylmagnesium chloride.

**Polymerization.**—Styrene and methyl methacrylate were polymerized in a sealed glass tube, and acrylonitrile in a 3-necked flask equipped with a stirrer and a nitrogen inlet tube.

In the case of glass tube method, the tube was first substituted with dry nitrogen and fed with Grignard reagent from a burette, into which the reagent had been fed with the aid of nitrogen pressure. Then, the monomer and solvent were charged. The usual degassing procedure followed. These tubes were set in a water bath at constant temperature and shaken during polymerization. The reacted mixture was poured into methanol, containing excess hydrochloric acid. Polystyrene and polymethyl methacrylate were purified by reprecipitation from benzene solution by methanol. To obtain a sample of polymethyl methacrylate for infrared absorption spectrum, a freezing technique was used.

When acrylonitrile was contacted with the Grignard reagent, so much heat was evolved that the following procedure was used. To a cold mixture of Grignard reagent and a large volume of solvent (THF), the monomer was added through a long glass tube surrounded by dry ice. These operations were carried out under the atmosphere of dry nitrogen.

The intrinsic viscosities shown in Table I are the values at 30°C measured in benzene solution, using a Ubberohde viscometer.

## Results and Discussion

**Polymerization of Vinylmagnesium Chloride.** —As shown in Table I, vinylmagnesium chloride could not be polymerized by the usual methods.

excess of dry ice, acidified with hydrochloric acid and the polymer was reprecipitated. But the infrared absorption spectra of the polymers had no absorption characteristic of the hydroxyl group in carboxylic acid and were identical to those of each homopolymer.

**Polymerization of Vinyl Chloride Initiated by Vinylmagnesium Chloride.** — The mixture of vinylmagnesium chloride and vinyl chloride was sealed in a glass tube and irradiated by ultraviolet ray of 3600 Å but no polymer was obtained.

**Polymerization of Acrylonitrile Initiated by Vinylmagnesium Chloride.** — Acrylonitrile polymerized vigorously to yellow powder which contained a much smaller quantity of nitrogen than polyacrylonitrile.

**Polymerization of Styrene Initiated by Vinylmagnesium Chloride.**—In the presence of vinylmagnesium chloride styrene hardly polymerized at room temperature, but did so easily above 40°C. Fig. 1 shows the process of polymerization. As the concentration of vinylmagnesium chloride increased, the rate of polymerization also increased. Figs. 2—4 are the time-conversion curves at 50, 60 and 70°C, respectively. Fig. 5 shows the dependence of rate on monomer concentration. At a monomer concentration, the rate becomes maximum but the reason is not clear.

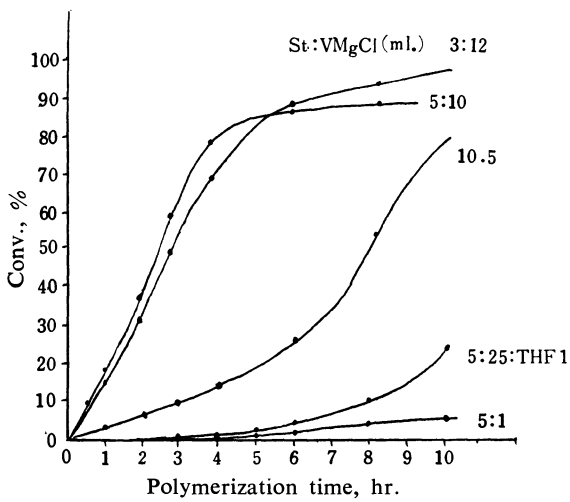

Fig. 1. Polymerization of styrene at 60°C.

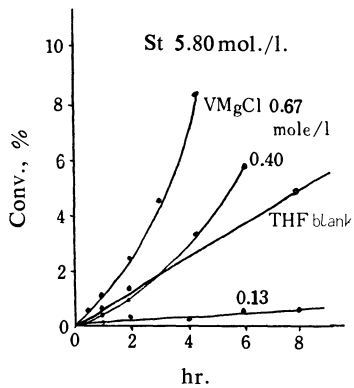

Fig. 2. Polymerization of styrene at 50°C.

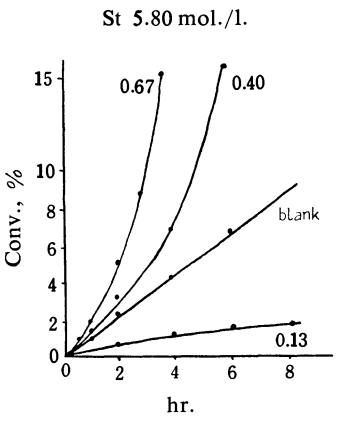

Fig. 3. Polymerization of styrene at 60°C.

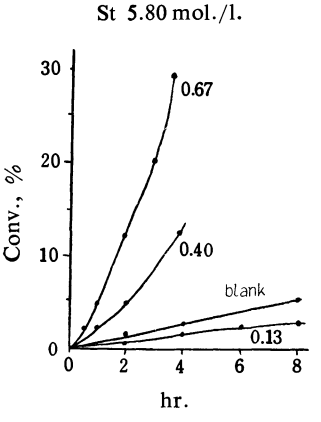

Fig. 4. Polymerization of styrene at 70°C.

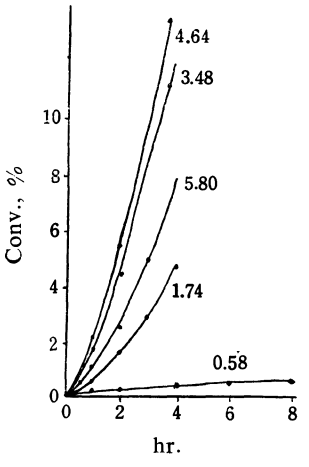

Fig. 5. Polymerization of styrene at constant initiator concentration at 50°C.

The rate of the polymerization of styrene in the absence of vinylmagnesium chloride was abnormally large, as shown in Figs. 2—4, as "blank test". The rapid rate was caused by the addition of THF instead of vinylmagnesium chloride solution. It may be considered that THF included THF-peroxide. In order to testify to this consideration, the THF above used was compared with oxygen absorbed THF. Oxygen was bubbled into THF under the irradiation of ultraviolet ray at room temperature for three days. The effects of the treatment was shown in Fig. 6. When the quantity of vinylmagnesium chloride was small, the rate decreased greatly. This was due to the consumption of the activities of Grignard reagent and peroxide by the mutual reaction.

Observation on the relation between the rate of polymerization and the concentration of vinylmagnesium chloride was carried out. As the curves for time vs. conversion were not straight, the conversions after two hours were plotted against the concentration of vinylmagnesium chloride. Straight lines were obtained as shown in Fig. 7. From the slope of these lines the following equation was derived.

$$Rp = k[C]^{1.4}$$

The overall activation energy of polymerization was about 12 kcal./mol. (Fig. 8).

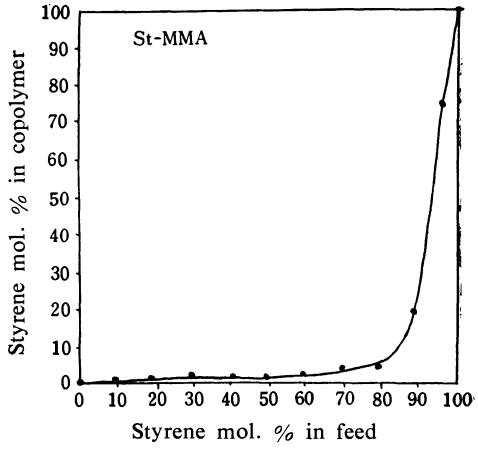

Fig. 9. The composition of styrene-methyl methacrylate copolymer.

**Copolymerization of Styrene with Methyl Methacrylate.**—In 1949, Beaman stated that the polymerization initiated by Grignard reagents proceeded through anionic mechanism. This idea has been generally accepted. To confirm the anionic mechanism in these systems, the authors carried out the copolymerization of styrene with methyl methacrylate at 10°C. From the carbon contents of copolymers their composition were calculated and plotted against the compositions in feed (Table III and Fig. 9). It was confirmed from the results in Fig. 9 that the polymerization initiated by vinyl magnesium chloride proceeded by anionic mechanism.

By the Beilstein test, it was found that no chlorine existed in the molecule of copolymer.

From the results stated above, it was possible to state that the order of the rate of polymerization was as follows:

acrylonitrile > methyl methacrylate ≫ styrene > vinyl chloride = 0

# *The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. I. The Stability of the Fission Products toward Nitric Acid Solution*

By Toshio NAKAI, Seishi YAJIMA, Koreyuki SHIBA, Jiro OSUGI and Daisaburo SHINODA

(Received September 22, 1959)

In his pioneering study McMillan[1] placed a thin film of uranium oxide powder between filters or cigarette papers and irradiated it with cyclotron neutrons. He found that most of the fission products recoiled out of the film and were captured in the paper. This separation made it possible to identify the strong activity of neptunium-239 with a half life of 2.3 days that had been left behind.

If a fission reaction is caused to proceed in particles of uranium oxide with maximum dimensions smaller than the minimum range* of the fission products, these products will probably recoil out of the uranium oxide. On the other hand, heavier nuclei formed by neutron capture and beta decay will have a much shorter range and remain within the original particles. This means that in a suitable heterogeneous system the fission products will be completely separated from the actinide elements without complicated chemical treatment. Since McMillan's work appeared in a journal, several investigators studied the separation of the fission products and the actinide by nuclear recoil using several kinds of heterogeneous systems.

The authors have been investigating the possibility of the utility of the dispersion-type nuclear fuel element which consists of a mixture of graphite and uranium dioxide. In such a fuel, the behavior of fission products is most characteristic compared with the other solid-type nuclear fuels. If the dimensions of uranium oxide powder are smaller than the minimum range of fission products and the weight ratio of graphite powder to uranium oxide powder is great enough to prevent the penetration of the fission fragments into the neighboring uranium oxide particles and if uranium oxide particles are uniformly dispersed in graphite powder, the fission products produced in uranium oxide powder will be thoroughly recoiled out of them and captured by graphite powder. In the previous paper[2], it was made obvious that when the weight ratio of graphite (particle size is about 50 microns) to uranium dioxide (particle size is about 0.1 microns) was 10, approximately 70% of the overall fission product activity remained in graphite powder and that when the ratio was 30, approximately 95% was captured. Mixtures of graphite and uranium dioxide were irradiated with JRR-1 neutrons (Japan Research Reactor-1, a water boiler type) and after the addition of saturated zinc bromide solution (hydrochloric acid was slightly added), these mixtures were centrifuged. The graphite powder of these mixtures gathered on the upper layer and the uranium oxide powder settled at the bottom. The distribution of the fission products in these fractions was determined using gamma ray spectrometry. From the results, the possibility of a brief reprocessing of the dispersion-type spent fuel was suggested.

The present study was undertaken to investigate the variation of the gross gamma ray spectra of the fission products captured in graphite powder at various cooling times after irradiation, and the stability of the fission products captured in graphite toward nitric acid of several different concentrations at varying durations of immersion at a constant temperature.

## Experimental

**The Gross Gamma Ray Spectra of the Fission Products Captured in Graphite Powder.** — *Procedure 1.*—Twenty milligrams of uranium dioxide (particle size, about 0.1 microns) was mixed with 600 mg. of natural graphite prepared by the Nippon Carbon Co., (particle size, about 50 microns), and the mixture was irradiated in the No. 16 experimental hole of JRR-1 under a thermal neutron flux of about $5\times10^{11}$ neutrons/cm$^2$ sec. for about three minutes. The irradiated mixture was transferred to a centrifuging tube with 70 ml. of a saturated zinc bromide solution which contained a small amount of hydrochloric acid. After centrifugal separation, the graphite powder fraction which was collected on the upper side was transferred into a polyethylene tube (1.5 cm. in diameter and 7 cm. in length) and was gamma-assayed by the RCL

1) E. McMillan, *Phys. Rev.*, **55**, 510 (1939).

* The minimum range of the fission products in uranium dioxide is 8 microns.

2) T. Nakai and S. Yajima, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **79**, 1267 (1958).

256-channel gamma ray scintillation spectrometer with a welll-type sodium iodide crystal (2 in. ×1.75 in. diameter) as scintillator. The separation procedure was commenced after 20 min. cooling, and finished within 30 min. after irradiation. Gamma ray spectra were measured at appropriate intervals for two days.

*Procedure 2.*—Instead of the centrifugal separation, the irradiated mixture was treated for 5 min. with 50 ml. of 4 N hot nitric acid solution in order to dissolve uranium dioxide and neptunium formed by neutron capture and beta decay. The residual graphite powder was filtered and washed twice with 20 ml. of 0.1 N nitric acid solution, and then the graphite sample was gamma-assayed by the same method as above mentioned. In this case, the separation procedure was commenced after 20 min. cooling, and finished within 15 min.

*Procedure 3.*—The abundance of the fission nuclides contained in graphite powder varied with the cooling time, and also the state of each nuclide which was captured in a graphite crystal might vary. In this experiment, the irradiated mixtures were cooled for one day after irradiation and then submitted to the centrifugal separation or the nitric acid treatment. The obtained gamma ray spectra were compared with the spectra of the samples which were treated after 20 min. cooling and then cooled for 23 hr. Comparison of gamma ray spectra of the above mentioned treatments gave a good agreement.

Several gamma ray spectra of the gross fission products obtained by procedure 2 are shown in Fig. 1.

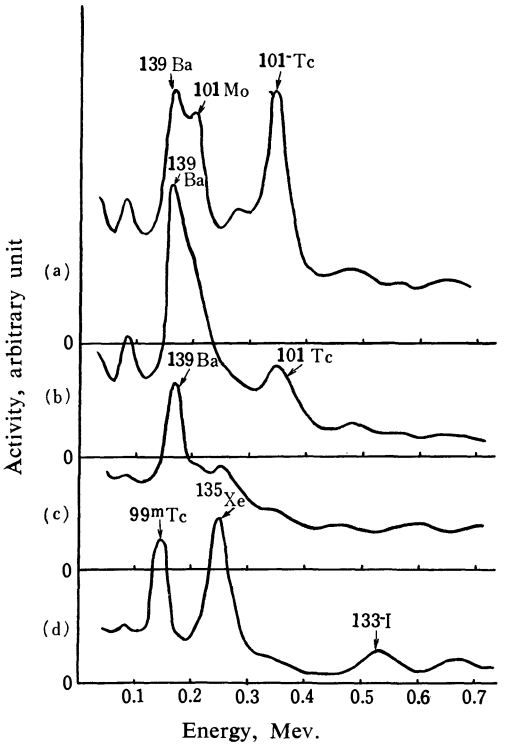

Fig. 1. Gamma ray spectrum of the fission products in graphite (a) at 26 min., (b) at 60 min., (c) at 160 min. and (d) at 20 hr. after irradiation.

The short lived nuclides in the fission products identified by these spectrodiagrams give a good agreement with those deduced from Peirson's experiment[3].

The respective abundance and the cross sections of uranium-238 and of uranium-235 are such that the irradiation of natural uranium by thermal neutrons leads to a temporary obliteration of the low energy portion of the fission products spectra by more intense X-rays and gamma rays emitted from neptunium-239 (half life 2.3 days). If a chemical treatment was used to eliminate the interfering neptunium-239, gaseous fission products such as xenon-135 would escape, and the complete spectrum of the gross fission products could not be obtained. For this reason, in Peirson's experiment[3] the gross gamma ray spectrum was measured by using a uranium, fifty times enriched in uranium-235. However, in this experiment the measurement of the gross gamma ray spectrum can be performed satisfactorily by using nautral uranium**.

The gamma ray spectrum of the fission products obtained by procedure 1 was similar to those obtained by procedures 2 and 3. From these results, it is evident that the centrifugal separation or the nitric acid treatment for such a short period can not affect the state of fission products captured in a graphite crystal. The effect of long time nitric acid treatment will be described in the next section.

**Leaching of Fission Products out of Graphite by Nitric Acid Solution.**—*Procedure.*—The graphite samples used in this experiment are artificial graphite

made from petroleum coke, and two kinds of natural graphite. Grain sizes of the samples are shown in Table I and impurities contained in the samples in Table II.

A mixture of 5 g. of graphite and 0.5 g. of uranium dioxide was irradiated for one hour under the same condition mentioned above. The irradiated mixture was transferred into a centrifuging tube with a saturated zinc bromide solution which contained a small amount of hydrochloric acid. After a centrifugal separation, the graphite was washed rapidly with a diluted hydrochloric acid solution. After being dried at 70°C or heated at 1000°C for four hours in an argon gas stream, it was divided into portions of 100 mg. each. They were immersed in 30 ml. nitric acid solution of 0~10 N concentration at 80°C for a period of 1~4 hr. After the immersion, the solution were filtered the filtrates were evaporated to 3 ml.; this volume was suitable for gamma ray spectrometry. The gamma ray spectrum of fission products in filtrates and precipitates was measured by the RCL 256 channel gamma ray spectrometer with a well-type sodium iodide crystal (2 in.×1.75 in. diameter) as scintillator. By comparing the gamma ray spectra of the filtrates with their total spectra (filtrate+precipitate), the leaching of fission products in nitric acid solution was made clear.

## Results

Experimental data are summarized in Table III. Based on these data the following results. are elucidated.

1) Fission products captured in graphite are leached with difficulty in a nitric acid solution under various conditions of immersion; however, the leaching of all the nuclides is slightly increased with the nitric acid concentration.

2) There is no difference due to varying graphite samples.

3) When the samples were heated at a high temperature, the leaching of fission products increased with acid concentration. For example, 10% of the fission products was leached by 10 N nitric acid solution.

4) However, the fraction of the fission products leached is almost constant regardless of immersion time.

From the results, it is considered that fission products in graphite are very stable toward nitric acid and such stabilities are attributed to a hindrance effect because most fission products are captured in a graphite crystal. It is not yet clearly demonstrated that the leaching is increased with acid concentration when samples are heated at a high temperature.

The authors wish to thank Dr. Kenjiro Kimura for his encouragement.

# *The Behavior of Fission Products Captured in Graphite by Nuclear Recoil. II. The Diffusion of Xenon-135 in Graphite at a High Temperature*

By Toshio NAKAI, Seishi YAJIMA, Koreyuki SHIBA, Jiro OSUGI and Daisaburo Shinoda

(Received September 22, 1959)

In the previous study[1], it was shown that, when a mixture of uranium dioxide and graphite in a weight ratio of 1 : 30 was irradiated with JRR-1 (Japan Research Reactor-1) neutrons, about 95% of the fission products recoiled out of uranium oxide powder into graphite. The orbital electrons of the recoiled fission fragments are partially stripped, and the initial velocities of fission fragments are about $10^9$ cm./sec. It has also been shown that they are highly ionized, bearing ionic charges of 20 or more. Because of this high velocity and the charge, the fission fragments interact readily with matter.

One of the practical problems connected with the operation of a reactor that employs a dispersion type fuel is the determination of the extent of diffusion of radioactive fission products from the fuel pellet when the mixture of graphite and uranium dioxide is pressed to give a density of about 1.8. Since the release of gaseous fission products from the fuel pellet will cause the destruction of the pellet and the radioactive contamination of the coolant and other establishments, it is important to study the behavior of gaseous fission products captured in graphite particles. Likewise the build-up of xenon-135 in a pellet is of some importance because of its abnormally large absorption cross section. In this case continuous elimination of xenon-135 from the pellet through some adequate process should be favorable in relation to the neutron economy of a reactor. Because of these reasons the firm retention and the continuous elimination of gaseous fission products would be of the greatest importance for the dispersion type fuel. Investigators of the North American Aviation Laboratory studied the diffusion of xenon-133 from graphite[2]. When discs of graphite, 0.84 cm. in diameter and 0.064~0.5 cm. in thickness, impregnated with uranium carbide to a concentration of about 520 mg./cc., were heated to 900~1500°C, the leakage rate of xenon varied from approximately 2% per 3 hr. of heating at 900°C to approximately 50% per 3 hr. at 1500°C.

However, an investigation of the state of

gaseous fission products diffusing from the graphite particles is thought to be worth while. Consequently, the present work has been carried out to study the diffusion, at 400, 800 and 1200°C, of xenon-135 captured in several kinds of graphite powder.

## Experimental

**Preparation of Samples.**—The mixture of 1 g. of graphite and 50 mg. of uranium dioxide was irradiated with thermal neutrons for about one hr. in an experimental hole (thermal neutron flux, about $5 \times 10^{11}$ neutrons/cm$^2$ sec.), JRR-1. After irradiation, the mixture was washed with a hot 4 N nitric acid solution in order to dissolve uranium and neptunium, and dried at 70°C. The fission products captured in graphite particles were not leached with a 4 N nitric acid solution within the short time procedure[1]. The fission products in graphite were cooled for twenty hours after irradiation and used for the diffusion experiment. During such a cooling time iodine-135, which is the precursor of xenon-135, decayed sufficiently and the xenon-135 was predominantly built up. The graphite samples used in this experiment are tabulated in Table I.

**Determination of the Diffusion of Xenon-135.**—For the escape rate of xenon-135 from graphite powder to be determined at a high temperature, graphite samples into which fission products recoiled were heated in a stream of argon. The furnace, in which the heating in argon took place, consisted of a silicon carbide heater and a silica tube. The temperature of the furnace was measured with a platinum, platinum-rhodium thermocouple and controlled with a regulator. In the range 400 to 1200°C, the temperature of the furnace was found to remain constant within 10°C throughout the experiment. Argon gas was purified through sponge titanium at about 700°C and through phosphorous pentoxide to prevent the oxidation of the graphite surface. The flow rate of argon gas was checked with a glass capillary flow meter and maintained at a constant rate. The xenon released from graphite was trapped in a charcoal trap cooled with a dry ice-benzene mixture. At appropriate intervals the trap was replaced by a new one. Xenon-135 activity in the charcoal trap was determined with a gamma ray spectrometer. In this experiment an RCL 256 channel gamma ray scintillation spectrometer with a well-type sodium iodide scintillator (2 in. × 1.75 in. diameter) was used.

The gross gamma ray spectrum of fission products in graphite after twenty hours cooling, of the trapped xenon and of the fission products which remained in graphite after the diffusion run are shown in Fig. 1. The amount of the diffused xenon was determined by comparing the heights of

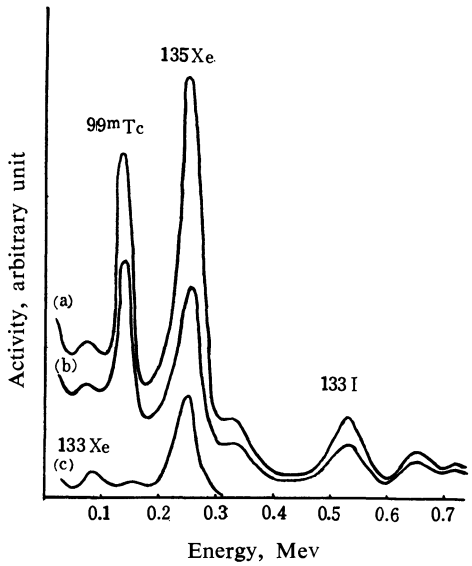

Fig. 1. Gamma-ray spectrum of the fission products in graphite.

(b) Fission products remained after diffusion.
(c) Trapped xenon.

the photoelectric peak of xenon-135 of the charcoal trap and of a standard graphite sample of a known weight which was not heat-treated.

## Results

As already mentioned, the results were obtained from gamma ray spectra at appropriate time intervals. The photoelectric peak of gamma ray spectra is proportional to the amount of xenon that escaped from graphite. On the other hand, the initial amount of xenon in graphite was obtained from the gross gamma ray spectrum of the standard graphite sample. Therefore, the fraction of xenon which escaped can be calculated as a function of time. The diffusion rates of xenon-135 from the several kinds of graphite at 400, 800 and 1200°C are shown in Figs. 2—4, respectively.

To analyze these diffusion curves the relation between the logarithmic values of the remaining amounts of xenon-135 and the time intervals at 400, 800 and 1200°C was obtained and shown in Figs. 5—7, respectively.

From these figures it is seen that the curves consist of two fractions which are a steep slope

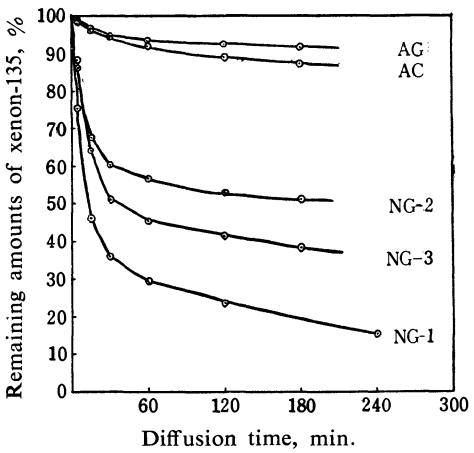

Fig. 4. Diffusion rates of xenon-135 at 1200°C.

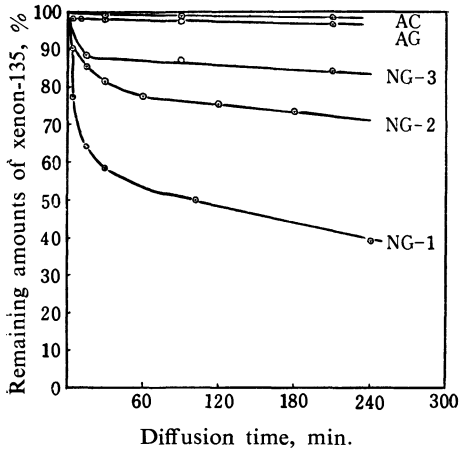

Fig. 2. Diffusion rates of xenon-135 at 400°C.

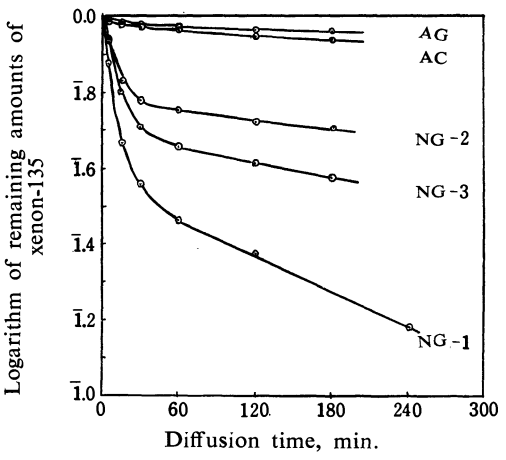

Fig. 7. Results at 1200°C.

curve for one hour and a slow inclination line after one hour. The results show that there are two mechanisms for diffusion in a graphite grain; they are a rapid and a slow diffusion.

The amounts of diffusion of xenon-135 for rapid diffusion are appreciably greater than those for slow diffusion and the amounts vary with the temperature and the kinds of sample. The amounts of diffusion from the natural graphite samples are appreciably greater than those from the artificial graphite or the amorphous carbon samples. The dependency of diffusion amounts on the kinds of sample will be discussed later.

The diffusion rate of a straight line fraction may be used to evaluate a diffusion constant of xenon-135 as shown in the following. In Figs. 5—7 the apparent inclination of a straight line fraction depends on the diffusion constant of xenon-135. Further, from the slope of the linear line for each sample, a diffusion constant is obtained, and they are summarized in Table II. Eq. 1 shows the relation between the diffusion constant and the activation energy, and from this equation the activation energy can be obtained as the inclination of the values of the logarithm of diffusion constants against the reciprocal of the absolute temperatures.

$$D = D_0 \exp\left(-\frac{\Delta H}{RT}\right) \qquad (1)$$

TABLE II. THE ACTIVATION ENERGY OF XENON-135

| Sample | Inclination | Activation energy cal./mol. |
|---|---|---|
| Natural graphite-1 | $0.50\times10^3$ | $2.3\times10^3$ |
| Natural graphite-2 | $0.50\times10^3$ | $2.3\times10^3$ |
| Natural graphite-3 | $0.58\times10^3$ | $2.7\times10^3$ |
| Artificial graphite | $0.51\times10^3$ | $2.3\times10^3$ |
| Amorphous carbon | $1.06\times10^3$ | $4.9\times10^3$ |

where $D$: diffusion constant, $D_0$: diffusion constant at 0 of absolute temperature degree, $R$: gas constant, $T$: absolute temperature degree and $H$: activation energy.

The apparent activation energy of diffusion calculation from the slow inclination of these straight lines is shown in Table II.

## Discussion

If one assumes that xenon diffuses along the interlaminar spaces in a perfect graphite crystal, the activation energy of diffusion can be calculated theoretically. An elementary process of xenon diffusion in graphite is the migration of xenon from position 1 to position 3 through position 2 in Fig. 8. As the activation energy is

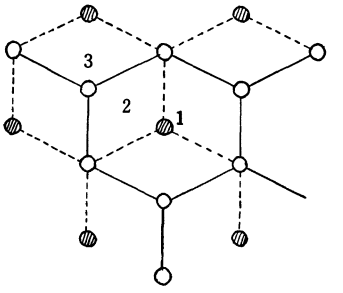

Fig. 8. A pertect graphite crystal.

represented to be the energy difference between position 1 and position 2, the activation energy can be obtained by use of the strain energy of each position. The strain energy is calculated by the interatomic force evaluated from an elastic constant as a specific heat at a low temperature. According to Suzuki[3], the activation energy calculated is about 2000 cal./mol. and is of the same order as the values obtained in this experiment. On the other hand, the calculated activation energy of diffusion across carbon layers is also about 200000 cal./mol. From this high value, the assumption that the diffusion occurs entirely along the interlaminar spaces is justified.

It is well known that graphite, in general, has a small mosaic, particularly in artificial graphite. Dislocation density in graphite is high along the boundary of mosaic structure. Xenon is trapped in trapping centers around a dislocation line rather than a interstitial site in a crystal at room temperature, because it is evident in the present experiment that the activation energy of xenon is fairly small. Therefore, the actual process of diffusion must be discussed with reference to the chemical potential of the trapping centers including the

3) H. Suzuki, private communication.

effect of a stress field as well as the concentration gradient in a sample.

The mosaic size of the graphite samples was determined by the X-ray diffraction method and the electron diffraction method. As a result, the mosaic size of the natural graphite is appreciably larger than those of the artificial graphite and of the amorphous carbon. It is evident that the dislocation density in the region of the mosaic boundary of the natural graphite is appreciably smaller than those of artificial graphite and of amorphous carbon. Therefore, in the case of the natural graphite, xenon-135 which was not captured by the trapping center, diffuses with a high concentration gradient. After that, xenon-135, which was captured by the center is successively released and slowly diffuses along the interlaminar space of a crystal. In this case, because the concentration gradient of xenon-135 in the sample is very small, it is very likely that the gradient is constant, and this warrants the calculation of activation energy.

Since the number of the trapping center of artificial graphite and of amorphous carbon and the amount of xenon-135 which was trapped in the trapping center are greater than those in the case of the natural graphite, the diffusion amounts of a rapid diffusion fraction of the amorphous carbon and the artificial graphite are relatively small.

The diffusion of gaseous fission products of dispersion type fuel will be related to the mosaic size of graphite material. It may be pointed out that, on the basis of the above discussion, the problem of xenon poisoning will be solved.

The authors wish to thank Dr. Kenjiro Kimura for his encouragement.

# *Conformation of Biaryls. Dipole Moment Measurements of o-Methylbiphenyls*

By Takeo SATO

(Received September 22, 1959)

Since the structure of biphenyl in crystals had been determined by X-ray crystal analysis[1], it was a subject of interest for many workers to elucidate the conformation of substituted biphenyls by using various physical methods. As the result of extensive works on biphenyl derivatives especially halogenobiphenyls, their conformations have been determined under various conditions. By X-ray method planar structure was advanced for 3, 3′-dichlorobenzidine[2] in accordance with the conclusion of Dhar on biphenyl itself, of which the result can be compared with a skew conformation found for 2, 2′-dichlorobenzidine[3]. For the knowledge of the free molecules, electron diffraction investigation was undertaken, and it was reported that the biphenyls without any substituent at position 2 were also non-planar[4,5] as well as 2, 2′-dihalogenobiphenyls[6]. Dipole moment measurements of 2-halogeno-[7,8], 2, 2′-dihalogeno-[7,9] and 3, 3′-dihalogenobiphenyls[9] were also reported and rotated molecular conformations were advanced for each case and the mean angles were calculated. It seemed, however, that the information on the structure of 2, 2′-dialkylbiphenyls were very limited, only two examples were reported, at present. Namely, Hargreaves et al.[10] have reported the X-ray

crystal analysis of 2,2'-dimethylbenzidine dihydrochloride and found that the compound has a rotated angle of 70.6°. Suzuki[11] has also computed the interplanar angle of biphenyls with methyl groups at position 2 (and 2') based on the ultraviolet absorption spectra and found an angle of 70.5° for 2,2'-dimethylbiphenyl.

While, in the course of synthetic studies of estrogenic biphenyl derivatives, it has been reported that 2,2'-dimethylbiphenyls[12,13] failed to show a conjugation band of biphenyl system in the near ultraviolet region[14-16]. This result was explained by the steric interference of the two methyl groups which forced the benzene nuclei into non-planar arrangement, and the mean angle between the rings was assumed to be nearly perpendicular to each other.

In an effort to verify the above postulation, this communication records the results of the dipole moment measurement and the calculation of the interplanar angle of 2-methyl- and 2,2'-dimethylbiphenyls. Dipole moment of 2,2'-dimethylbiphenyl was reported to be 0.66 D[17]. The value, however, would not be large enough for the safer calculation of the angle, when one considered the small dipole moment found for toluene (0.34 D[18]) and the experimental error of this measurement. Thus for favorable compounds, 5,5'-disubstituted 2,2'-dimethylbiphenyls (II) were prepared from the corresponding iodo-compound (I) by the Ullmann reaction. Suitable substituents at the meta positions will increase the moment of the system and alter it markedly according to the rotation around the axis of the biaryl without affecting the steric environment. The method of preparations were described in the *Experimental Part.*

The measurement was carried out for a benzene solution at 25°C. The values found for the dimethylbiphenyls are given in Table I. The moments of benzene component used for the calculations were 1.94 D for *p*-chlorotoluene[19] and 4.52 D for *p*-nitrotoluene[20]. The calculated values for *cis*-planar and perpendicular conformations are given in Table I. As can be seen, the observed values for compound II (X=Cl and $NO_2$) were essentially the same for the calculated ones for the perpendicular arrangement as long as the rings are coaxial. The present results is in good agreement with the assumption derived from the ultraviolet absorption spectra of 2,2'-dimethylbiphenyls[12,13].

It should, however, be pointed out that the calculated values would be modified in a minor degree by considering the induction effects[8,9,21-23], which comprised the effects already present in the component benzene, the effect of each dipole on the second ring and the moment induced at each dipolar substituent by the presence of the other. These inductive effects will be rather large when the polar groups are located at ortho positions as in the case of 2,2'-disubstituted biphenyls. Thus, the values of the angle for 2,2'-dichlorobiphenyl were 88° when all induction effects were ignored but 69~84° when they were considered[9]. However, as can be easily assumed, both values

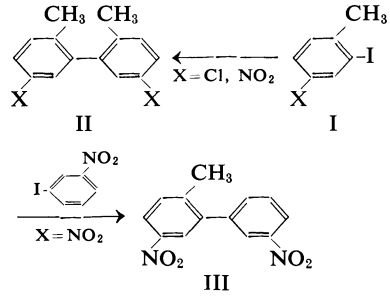

TABLE I. COMPARISON OF OBSERVED[a] WITH CALCULATED DIPOLE MOMENTS FOR 5,5'-DISUBSTITUTED 2,2'-DIMETHYLBIPHENYLS (II) AND 2-METHYL-3',5-DINITROBIPHENYL (III)

were essentially the same for 3, 3′-disubstituted biphenyls[9], to which the present series are structurally related.

It is quite natural to consider that the conformation of 2-methylbiphenyl is located somewhat between 2,2′-dimethylbiphenyls (II) and biphenyl without ortho substituent owing to the decrease in steric hindrance given by the ortho substituent compared with compound II. The same measurement was applied to 2-methyl-3′, 5-dinitrobiphenyl (III) of which preparation was illustrated in the diagram and described in the *Experimental Part.* For the calculation of the theoretical moment of the system, dipoles moments of nitrobenzene and *p*-nitrotoluene were taken as 3.96[24] and 4.52D[20], respectively.

The observed value, 4.55 D, is smaller than the calculated ones for the conformations in which both rings are in *cis*-planar and perpendicular arrangement. These facts suggest that the molecule takes conformation in which two benzene rings are twisted further from the perpendicular position to *trans*-relationship in respect to two nitro groups. The observed value agreed with the calculated one for the conformation with the rings inclined at an angle of 104°. Therefore, the molecule can be regarded to have a slightly *trans*-arrangement with inclined benzene rings at an angle of 76°. The present result might be compared with the value found for 3, 3′-dinitrobiphenyl, which was reported to have a non-planar structure with an interplanar angle of 106°[9]. The reduction in the rotation angle found in compound III compared with the dimethyl compounds (II) was quite reasonable, but it remained unexplained whether the preferred *trans*-conformation of compound III was given by the steric effect of ortho groups or by the presence of meta substituents.

## Experimental[25]

**2, 2′-Dimethyl-5, 5′-dinitrobiphenyl (II, X=$NO_2$).**—It was obtained by the Ullmann reaction of 2-iodo-4-nitrotoluene, b. p. 138~140°C/3 mmHg, m. p. 58°C (reported melting point is 58°C[26]) according to the modified method given in the literature[27]. One hundred grams (0.38 mol.) of 2-iodo-4-nitrotoluene and 150 g. of dry clean sand were preheated to 215°C and to this mixture was added with good stirring 100 g. (1.6 atoms) of activated copper bronze during one hour while the temperature was maintained at 215~220°C. It was then heated to 250°C and kept at that temperature for one and a half hour. After the reaction was over the mixture was poured onto dry sand and extracted with ethanol. The extract was recrystallized from acetic acid or acetone for several times with the aid of active charcoal. Pale yellow needles, m. p. 177~178°C, were obtained in a low yield.

**5, 5′-Dichloro-2, 2′-dimethylbiphenyl (II, X=Cl).**—Sixteen grams (0.063 mol.) of 4-chloro-2-iodotoluene, b. p. 108~109°C/10 mmHg, $n^{19}$ 1.6231 obtained from 4-chloro-2-toluidine[28] according to Wroblewski[29] or from 2-iodo-4-toluidine[30] by Sandmeyer reaction was heated at 240~250°C with stirring and 20 g. (0.32 atom) of activated copper bronze was added over a period of one hour. The reaction mixture was then heated and kept at 280~290°C for forty minutes. It was extracted with acetone and the extract was distilled to give an oil which boiled first at 140~155°C/4 mmHg, and then at 142~144°C/3 mmHg., $n^{20}$ 1.5961 on redistillation. Yield was 4 g. or 50% of the theory.

Found: C, 66.75; H, 4.74. Calcd. for $C_{14}H_{12}Cl_2$: C, 66.95; H, 4.82%.

**2-Methyl-3′, 5-dinitrobiphenyl (III).**—Under good stirring 15 g. (0.24 atom) of activated copper bronze was added to a mixture of 21 g. (0.080 mol.) of 2-iodo-4-nitrotoluene and 7.5 g. (0.030 mol.) of *m*-nitroiodobenzene in the course of thirty minutes, while the temperature was kept at 220~230°C. It was then heated to 240~250°C and kept for additional thirty minutes at that temperature. After the reaction was over, the mixture was extracted with acetone and the solution was treated with active charcoal. The solvent was evaporated and the remainder was recrystallized from ethanol for several times. Compound III was obtained as pale yellow plates, m. p. 145~146°C.

Found: N, 10.70. Calcd. for $C_{13}H_{10}O_4N_2$: N, 10.85%.

When the above reaction was conducted with an equimolar amount of iodo compounds the main product was found to be 3, 3′-dinitrobiphenyl.

The author wishes to express his hearty thanks to Drs. T. Chiba and T. Shimozawa, the University of Tokyo, for carrying out the measurements. The author's thanks are also due to Professors K. Hata, Tokyo Metropolitan University, and M. Ōki, the University of Tokyo, for their continued interest throughout this study.

# *Expansion of Nakano's Results on High Frequency Titration Using the Resistance-type Instrument*

By Sadaharu TOYODA

(Received March 25, 1959)

There have been many papers[1-7] on high frequency titration. Many interesting results have been shown by Nakano's paper[8] on this subject. It was based on an experiment using the resistance-type instrument[9]. According to the experimental results of Figs. 2 and 4, which have been obtained by Nakano, the relation between the value of variable resistance, consisting of platinum wire and mercury column, and the concentration of solution shows a minimum point in a case of the condenser-type instrument, and minimum and maximum points in a case of the coil-type instrument. Nakano proved that there exists a relation $\omega C_0 R = 1$, at the minimum point for both cases of condenser-type and coil-type instruments. These results and others have been obtained by using the equivalent circuit without the variable resistance which makes a component of the resistance-type instrument. It is, therefore, significant to see if much more accurate results are obtained by using the equivalent circuit with the variable resistance. The present paper is concerned with the results of the calculation of the equivalent circuit containing the variable resistance.

## Calculation for Condenser-type Instrument

Fig. 1 shows the equivalent circuit for the components of the portion containing the sample solution (refer to Fig. 7a). This equivalent circuit is the same as the one in Nakano's paper[8] except $R_1$ referring to the variable resistance of the platinum wire. Therefore, the physical meaning of $C$, $C_0$, $R$ and $L$ are omitted. If $Z$ denotes the impedance for the condenser

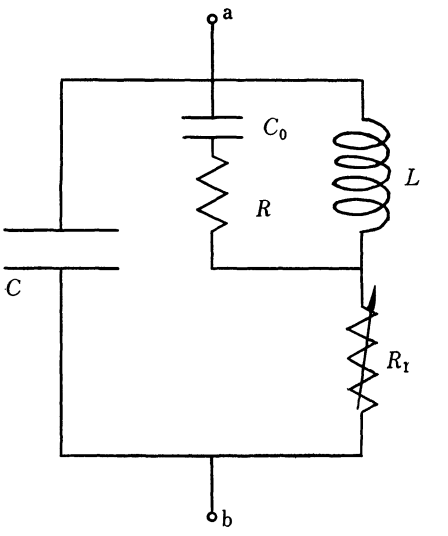

Fig. 1. Equivalent circuit for condenser-type.

element ($C_0$, $R$) and the coil ($L$), the following relation is obtained.

$$\frac{1}{Z}=\frac{(\omega C_0)^2 R}{1+(\omega C_0 R)^2}+\boldsymbol{j}\left\{\frac{\omega C_0}{1+(\omega C_0 R)^2}-\frac{1}{\omega L}\right\} \tag{1}$$

The total admittance between point a and point b in Fig. 1 is written as

$$Y=\boldsymbol{j}\omega C+\frac{1}{Z+R_1} \tag{2}$$

Putting the following expressions for the real and the imaginary parts of $1/Z$

$$A\equiv\frac{(\omega C_0)^2 R}{1+(\omega C_0 R)^2} \qquad B\equiv\frac{\omega C_0}{1+(\omega C_0 R)^2}-\frac{1}{\omega L} \tag{3}$$

and for those of $Z$

$$Z=\frac{A}{A^2+B^2}-\boldsymbol{j}\frac{B}{A^2+B^2}\equiv U-\boldsymbol{j}V \tag{4}$$

the real and imaginary parts of $Y$ can be separated as follows:

$$Y_{\text{real}}=\frac{U+R_1}{(U+R_1)^2+V^2} \tag{5}$$

$$Y_{\text{imag}}=\frac{V}{(U+R_1)^2+V^2}+\omega C \tag{6}$$

The frequency of oscillation is determined by the assumption that the imaginary part of $Y$ is equal to zero as in the previous paper[8]. Substituting this condition into Fq. 5, one finds

$$(A^2+B^2)R_1=-\frac{Y_{\text{real}}}{\omega C}B-A \tag{7}$$

On the other hand, the change of plate current takes place by putting the beaker containing the aqueous solution into the condenser-type electrode or the coil. In the previous experiment the change of plate current is compensated by adjusting $R_1$. This manipulation suggests that the value of $Y_{\text{real}}$ is kept constant. In the special case when the beaker is empty ($R=\infty$) the values of $A$ and $B$ are 0 and $-1/\omega_\infty L$, respectively. Applying these values to Eq. 7, $Y_{\text{real}}$ is obtained as follows:

$$Y_{\text{real}}=R_{1\infty}\frac{C}{L} \tag{8}$$

where $R_{1\infty}$ and $\omega_\infty$ denote the variable resistance and the angular frequency in the special case, respectively. Thus Eq. 7 becomes

$$(A^2+B^2)R_1=-\frac{R_{1\infty}}{\omega L}B-A \tag{9}$$

Substituting the above equation into $Y_{\text{imag}}=0$, the following relation between $\omega$ and $R$ will be easily obtained:

$$\omega C=-B\frac{1+(A/B)^2}{1+(R_{1\infty}/\omega L)^2} \tag{10}$$

Of course, both Eqs. 9 and 10 should be used simultaneously in order to find how $R_1$ and $\omega$ change with the concentration of solution.

The distributed capacity between the electrode and the solution, $C_0$, is determined by using the boundary conditions when the beaker is empty or full of the mercury as in the case of Nakano's experiment. From Eq. 10, one obtains

$$\begin{cases} \dfrac{1}{\omega_\infty^2 L}=C\left\{1+\left(\dfrac{R_{1\infty}}{\omega_\infty L}\right)^2\right\} \\ \dfrac{1}{\omega_0^2 L}=C\left\{1+\left(\dfrac{R_{1\infty}}{\omega_0 L}\right)^2\right\}+C_0 \end{cases} \tag{11}$$

where $\omega_\infty$ and $\omega_0$ are the angular frequency when $R=\infty$ and $R=0$, respectively, and $R_{1\infty}\approx 10\,\Omega$. Hence, the distributed capacity, $C_0$, is calculated by the following expression:

$$C_0\fallingdotseq\frac{1}{\omega_0^2 L}-\frac{1}{\omega_\infty^2 L} \tag{12}$$

which means the same as the method shown in the previous paper[8]. Referring to Table I, of course, it is clear that the following term can be neglected, if $R_{1\infty}$ is $100\,\Omega$ and $C$ is 60 $\mu\mu$F:

$$C\left|\left(\frac{R_{1\infty}}{\omega_0 L}\right)^2-\left(\frac{R_{1\infty}}{\omega_\infty L}\right)^2\right|<0.012\ \mu\mu\text{F} \tag{13}$$

Thus the average value of $C_0$ is 2.3 $\mu\mu$F.

Eq. 9 can be rearranged as follows:

$$\left\{1-\frac{2\omega^2LC_0}{1+(\omega C_0R)^2}+\frac{(\omega^2LC_0)^2}{1+(\omega C_0R)^2}\right\}R_1$$
$$=R_{1\infty}\left\{1-\frac{\omega^2LC_0}{1+(\omega C_0R)^2}-\frac{\omega C_0R}{1+(\omega C_0R)^2}\frac{\omega C_0\omega^2L^2}{R_{1\infty}}\right\} \tag{14}$$

Since the variation of frequency is fairly small as shown by the experiment[10], the frequency can be taken as constant. With this assumption, one differentiates Eq. 14 with respect to $R$, then puts it equal to zero, and finally obtains the condition which gives the minimum point of $R_1$

$$R\fallingdotseq\left(1-\alpha+\frac{\alpha}{\beta}\right)\frac{1}{\omega C_0} \tag{15}$$

where $\alpha\equiv\omega^2LC_0$ and $\beta\equiv\omega C_0\omega^2L^2/R_{1\infty}$.

Neglecting $\alpha$ and $\alpha/\beta$ which are much smaller than unity according to Table II, one obtains the condition, $\omega C_0R=1$, which is the conclusion of the previous paper[8]. The depth of $R_1$ at minimum point predominantly depends upon the third term in the right-hand side of Eq. 14. Substituting the condition, $\omega C_0R=1$, into the third term, it becomes $\beta/2$. Then, the following results can be easily found. (a) Using the same coil, the depth of $R_1$ at minimum point increases with the increase of frequency. (b) Using the same frequency, which is approximately determined by the expression, $\omega^2LC=1$, the depth increases with the increase of $L/C$. (c) Even though the same frequency is used, the concentration of aqueous solution at the minimum point varies with the salts in solution.

Investigating the results of Fig. 2 in detail, it is noticed that $R_1$ of curve 9 or 10 is a little larger than $R_{1\infty}$ when the concentration increases.

TABLE II

| No. of curve | Salt | Nos. of turn of coil | $L$ henry | Freq. cycle | $\omega$ | $\alpha$ | $\alpha/\beta$ | $\frac{\omega C_0\omega^2L^2}{2\times10}$ |
|---|---|---|---|---|---|---|---|---|
| 9 | $NH_4NO_3$ | 100 | $4.3\times10^{-4}$ | $1.12\times10^6$ | $7.037\times10^6$ | $4.90\times10^{-2}$ | $3.30\times10^{-3}$ | 7.40 |
| 10 | 〃 | 40 | $1.3\times10^{-4}$ | 1.27 〃 | 7.979 〃 | 1.90 〃 | 9.64 〃 | 0.986 |
| 11 | 〃 | 40 | 〃 | 1.88 〃 | 1.181 〃 | 4.17 〃 | 6.51 〃 | 3.20 |
| 12 | NaCl | 70 | $2.9\times10^{-4}$ | 1.26 〃 | 7.916 〃 | 4.18 〃 | 4.35 〃 | 4.79 |

This fact is attributed to the second term in the left-hand side of Eq. 14, though the right-hand side of Eq. 14 contains half the value of the same term. It is very desirable to calculate the value of $R_1$ at the minimum point, which is nearly equal to $R_{1\infty}(1-\beta/2)$. According to Table II, however, they should have a negative value except in the case of curve 10 and this is hard to be explained. Therefore, it is necessary to examine the equivalent circuit again more in detail and the results will be discussed later.

### Calculation for Coil-type Instrument

Fig. 3 is considered as the equivalent circuit for the coil-type instrument (refer to Fig. 7b). This equivalent circuit except when including $R_1$ is the same as the one in the previous paper[8] which contains the element $KLR$ showing the effect of eddy current. According to the same consideration of the equivalent circuit, the following results may be obtained:

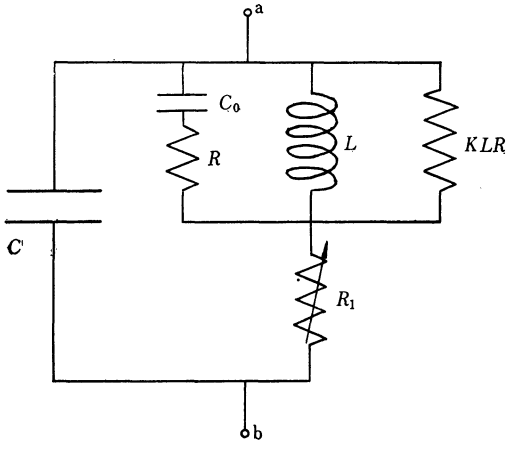

Fig. 3. Equivalent circuit for coil-type.

$$\frac{1}{Z}=\left\{\frac{(\omega C_0)^2R}{1+(\omega C_0R)^2}+\frac{1}{KLR}\right\}+j\left\{\frac{\omega C_0}{1+(\omega C_0R)^2}-\frac{1}{\omega L}\right\}\equiv A+jB \tag{16}$$

$$(A^2+B^2)R_1=-\frac{R_{1\infty}}{\omega L}B-A \tag{17}$$

$$\omega C=-B\frac{1+(A/B)^2}{1+(R_{1\infty}/\omega L)^2} \tag{18}$$

As it is rather difficult to determine the distributed capacity of coil, $C_0$, by these relations, the value shown in the previous paper[8] will be used in the following discussions.

As mentioned above, the change of frequency is expected to be caused by the change of $R$. But it is neglected, as the change of frequency was experimentally[10] found to be not so large. After the rearrangement of Eq. 17, it is written as

$$\left\{1-\frac{2\omega^2LC_0}{1+(\omega C_0R)^2}+\left(\frac{\omega L}{KLR}\right)^2+\frac{(\omega^2LC_0)^2(1+2/KL)}{1+(\omega C_0R)^2}\right\}R_1=R_{1\infty}\left\{1-\frac{\omega^2LC_0}{1+(\omega C_0R)^2}-\frac{\omega C_0R}{1+(\omega C_0R)^2}\frac{\omega C_0\omega^2L^2}{R_{1\infty}}-\frac{1}{KLR}\frac{\omega^2L^2}{R_{1\infty}}\right\} \tag{19}$$

As the first order approximation, the following expression to show the behaviors of all curves for the coil-type instrument is obtained:

$$R_1=R_{1\infty}\left\{1-\frac{\omega C_0R}{1+(\omega C_0R)^2}\frac{\omega C_0\omega^2L^2}{R_{1\infty}}-\frac{1}{KLR}\frac{\omega^2L^2}{R_{1\infty}}\right\} \tag{20}$$

The conditions which give the minimum and the maximum points are the same as the one

TABLE III

| No. of curve | Nos. of turn of coil | Freq. cycle | $\omega$ | $C_0$ / $p$ | $\alpha$ | $\frac{\omega C_0 \omega^2 L^2}{2\times 10}$ |
|---|---|---|---|---|---|---|

in the previous paper[8]

$$R=\frac{1}{\omega C_0}\sqrt{\frac{KL-2\pm\sqrt{(KL-2)^2-4(KL+1)}}{2(KL+1)}} \tag{21}$$

where positive and negative signs show minimum and maximum, respectively.

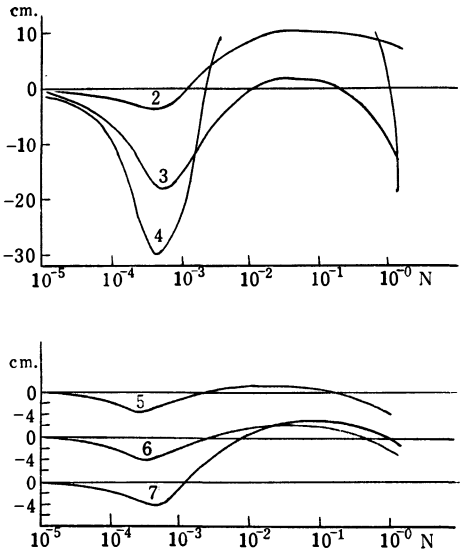

Fig. 4. Relation (Ref. 8) between change of length (resistance) of platinum wire and concentration of sodium chloride in aqueous solution for coil-type.

Investigating the curve in Fig. 4, it is noticed that the maximum value of $R_1$ is larger than the initial value $R_{1\infty}$. This fact should be ascribed to the second terms of the two sides in Eq. 19. But the value of $\alpha(\equiv\omega^2LC_0)$ in Table III is too small for this conclusion. In Table III the values of $\beta/2$ $(\equiv\omega C_0\omega^2L^2/2R_{1\infty})$ which cause the minimum points are smaller than unity except in the case of curve 4.

### Re-examination of Equivalent Circuit

It is difficult to understand, for the condenser-type and the coil-type instruments, why the value of $\beta/2$ is greater than unity. The question arises, thus, whether the resistance value of platinum wire at high frequency would be much greater than the value at direct current or not. Even if only the coil-type is taken up, it is difficult to consider that the value at about one megacycle becomes greater than four times the value at direct current. Now, let us consider the loss of coil itself. Assuming that the low resistance, $R_l$, is connected in series with the inductance of the coil, $L$, the equivalent circuit for the coil-type instrument becomes Fig. 5, in

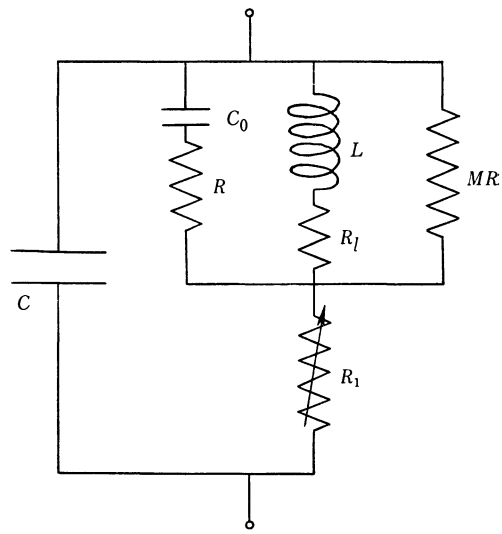

Fig. 5. Equivalent circuit with low resistance showing loss of coil.

which notation, $M$, means $KL$. The equivalent circuit for the condenser-type instrument is easily obtained by setting $M=\infty$. Repeating the calculation as before, one obtains

$$\frac{1}{Z}=\left\{\frac{(\omega C_0)^2R}{1+(\omega C_0R)^2}+\frac{R_l}{(\omega L)^2+R_l^2}+\frac{1}{MR}\right\}+j\left\{\frac{\omega C_0}{1+(\omega C_0R)^2}-\frac{\omega L}{(\omega L)^2+R_l^2}\right\}\equiv A+jB \tag{22}$$

$$(A^2+B^2)R_1=-\frac{Y_{\text{real}}}{\omega C}B-A \tag{23}$$

$$\omega C=-B\frac{1+(A/B)^2}{1+(Y_{\text{real}}/\omega C)^2} \tag{24}$$

where

$$Y_{\text{real}}=\frac{C}{L}(R_{1\infty}+R_l)$$

After the rearrangement, Eq. 23 is written as follows:

$$\left\{1-\frac{2\alpha}{1+x^2}+\frac{2\alpha x Q^{-1}}{1+x^2}+\frac{2\alpha Q^{-1}}{Mx}+\frac{\alpha^2(1+Q^{-2})}{(Mx)^2}+\frac{\alpha^2(1+Q^{-2})(1+2/M)}{1+x^2}\right\}R_1$$
$$=R_{1\infty}\left\{1-\frac{\alpha(1+Q^{-2})(R_{1\infty}+R_l)}{(1+x^2)R_{1\infty}}-\frac{x}{1+x^2}\frac{\omega C_0(\omega L)^2(1+Q^{-2})}{R_{1\infty}}-\frac{\omega C_0(\omega L)^2(1+Q^{-2})}{MxR_{1\infty}}\right\} \quad (25)$$

where $x\equiv\omega C_0R$, $\alpha\equiv\omega^2LC_0$ and $Q^{-1}\equiv R_l/\omega L$.

In Eq. 25, the term which gives the minimum value for the resistance $R_1$ is the same as the one in Eq. 19 except for the factor, $1+Q^{-2}$, being greater than unity. Therefore, it seems impossible in this procedure to find that the term in question has a value smaller than unity.

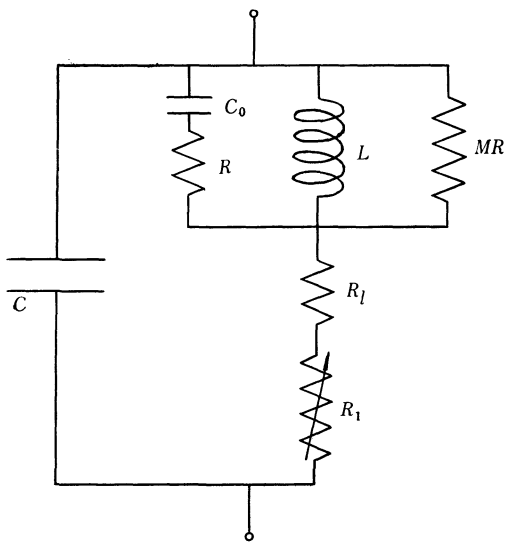

Fig. 6. Another equivalent circuit with low resistance showing loss of coil.

Now, Fig. 6 is considered instead of Fig. 5. In Eq. 19, substituting as follows $R_1\rightarrow R_1+R_l$, $R_{1\infty}\rightarrow R_{1\infty}+R_l$, the following equation is obtained:

$$\left\{1-\frac{2\omega^2LC_0}{1+(\omega C_0R)^2}+\left(\frac{\omega L}{MR}\right)^2+\frac{(\omega^2LC_0)^2(1+2/M)}{1+(\omega C_0R)^2}\right\}(R_1+R_l)$$
$$=(R_{1\infty}+R_l)\left\{1-\frac{\omega^2LC_0}{1+(\omega C_0R)^2}-\frac{\omega C_0R}{1+(\omega C_0R)^2}\frac{\omega C_0\omega^2L^2}{(R_{1\infty}+R_l)}-\frac{\omega^2L^2}{MR(R_{1\infty}+R_l)}\right\} \quad (26)$$

The $Q$ of the coil shows $\omega L/R_l$ and then $R_l$ is calculated from $Q$ at the corresponding frequency. Two cases[10] are considered for the $Q$ of the coil. One of them is to measure only the coil, and the other case is to measure the coil containing distilled water. The former should be considered for the condenser-type instrument, whereas the latter for the coil-type instrument with the assumption that the loss by distilled water is contained in $Q(=\omega L/R_l)$. In Table IV the values of the terms in question for the coil-type instrument are less than unity. The resistance value of platinum wire is 0.2 Ω/cm. and $M\approx10^3$ as shown in the previous paper[8]. The calculated values of the depth at minimum point agree with the experimental values in the case of curves 3 and 6 in Table IV. But the values of curves 4 and 5 are too great in comparison with the experimental ones, though the values of curves 2 and 7 are not discussed.

The calculated values for the condenser-type instrument are shown in Table V. In this case, the values of the terms in question become smaller than the previous value, but some of them are still greater than unity. Therefore, this equivalent circuit seems not to be useful

* According to K. Nakano[10]

The calculation on high frequency titration has been extended on the basis of Nakano's paper[8]. As a result of calculation, the relation between the variable resistance, $R_1$, and the high frequency resistance, $R$, having some connection with the concentration of solution becomes clear in some degree, including the condition, $\omega C_0 R = 1$. The term $\omega^2 LC_0/1+(\omega C_0 R)^2$, seems to cause the fact that $R_1$ becomes greater than $R_{1\infty}$ in the case of concentrated solution. Some of the calculated values of depth at minimum point are considerably great in comparison with the experimental one in the case of the coil-type instrument and can not be obtained in the case of the condenser-type instrument. Hence, it seems necessary to take into account another factor in the calculation of the equivalent circuit in order to obtain better agreement with the experimental results.

The sample solution in the condenser-type electrode or the coil has the capacitance together with the resistance as shown in Nakano's paper[8]. The former was omitted in Nakano's paper, under the assumption that the effect of the former is negligible when the value of the latter is not so great. Now, let us consider the equivalent circuit (Fig. 8) on the basis of Figs. 7a and 7b. This equivalent circuit is of the same physical meaning as in the case of Fig. 5 except in the

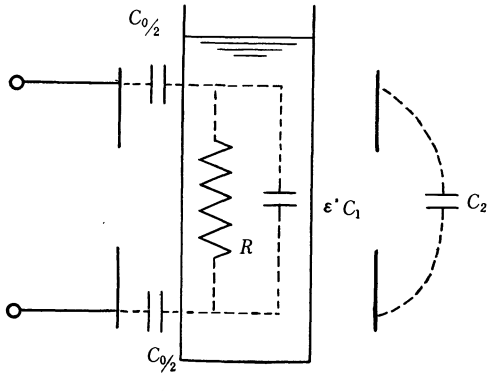

Fig. 7 (a). Relation between sample solution in condenser-type electrode and equivalent circuit.

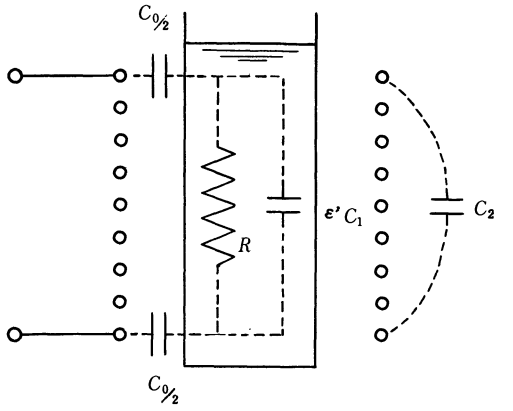

Fig. 7 (b). Relation between sample solution in coil and equivalent circuit.

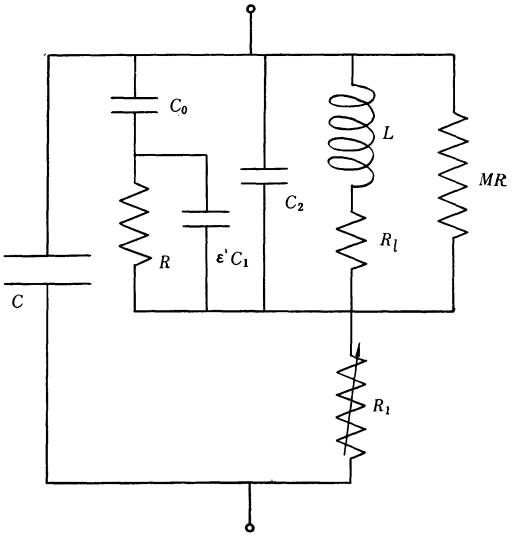

Fig. 8. Equivalent circuit taking into account another factor.

case of the capacitance, $\varepsilon' C_1$, $C_2$, which are visualized by Figs. 7a and 7b, where the notation $\varepsilon'$ means the dielectric constant (real part) of the sample solution. As mentioned above, the sample solution in the condenser-type electrode or the coil has the capacitance, which is shown by the notation $\varepsilon' C_1$ in Figs. 7a or 7b (and Fig. 8) instead of $C_1$ in Nakano's paper. The notation $C_2$ shows the rest of the capacitance of the condenser-type electrode in Fig. 7a and the rest of the self capacitance of the coil in Fig. 7b, which has also been shown by $C_3$ in the recent paper[11].

Again one repeats the similar calculation of this equivalent circuit containing another factor $\varepsilon' C_1$ and $C_2$. As a result of calculation, the following equation is easily obtained:

11) P. F. Knewstubb and T. M. Sugden, *Trans. Faraday Soc.*, **54**, 372 (1958).

$$\frac{1}{Z}=\left\{\frac{(\omega C_0)^2R}{1+\omega^2(\varepsilon'C_1+C_0)^2R^2}+\frac{R_l}{R_l^2+(\omega L)^2}+\frac{1}{MR}\right\}$$
$$+j\left[\frac{\omega C_0\{1+\omega^2\varepsilon'C_1(\varepsilon'C_1+C_0)R^2\}}{1+\omega^2(\varepsilon'C_1+C_0)^2R^2}\right.$$
$$\left.+\omega C_2-\frac{\omega L}{R_l^2+(\omega L)^2}\right]\equiv A+jB \qquad (27)$$

$$(A^2+B^2)R_1=-\frac{Y_{\text{real}}}{\omega C}B-A \qquad (28)$$

$$\omega C=-B\frac{1+(A/B)^2}{1+(Y_{\text{real}}/\omega C)^2} \qquad (29)$$

$$Y_{\text{real}}=\frac{C}{L}\frac{\{1-2\alpha_\infty+\alpha^2{}_\infty(1+Q_{\infty 1}^{-2})\}R_{1\infty}+R_l}{1-\alpha_\infty(1+Q_{\infty 1}^{-2})} \qquad (30)$$

where $Q_{\infty 1}\equiv\omega_{\infty 1}L/R_l$, $\alpha_\infty\equiv\omega^2{}_{\infty 1}L\left(C_2+\frac{C_0C_1}{C_1+C_0}\right)$, $\omega_{\infty 1}$ and $R_{1\infty}$ are the angular frequency $\omega$ and the variable resistance $R_1$, when $R=\infty$ and $\varepsilon'=1$, respectively. After the rearrangement of Eq. 28, it is written as the following expression corresponding to Eq. 25:

$$\left[1-2\alpha_2+\alpha_2^2(1+Q^{-2})-\frac{2\alpha(1+qx^2)}{1+x^2}\right.$$
$$+\frac{2\alpha pxQ^{-1}}{1+x^2}$$
$$+\frac{2\alpha\{\alpha_2(1+qx^2)+p\omega L/M_0\}(1+Q^{-2})}{1+x^2}$$
$$+\frac{\alpha^2(1+Q^{-2})\{(px)^2+(1+qx^2)^2\}}{(1+x^2)^2}$$
$$\left.+\frac{2Q^{-1}\omega L}{M_0x}+\left(\frac{\omega L}{M_0x}\right)^2(1+Q^{-2})\right]R_1$$
$$=\frac{\xi R_{1\infty}+\eta R_l}{1-\eta}\left[1-\frac{\xi R_{1\infty}+R_l}{\xi R_{1\infty}+\eta R_l}\left\{\alpha_2+\frac{\alpha(1+qx^2)}{1+x^2}\right\}\right.$$
$$\left.\times(1+Q^{-2})-\left(\frac{\alpha px\omega L}{1+x^2}+\frac{\omega^2L^2}{M_0x}\right)\frac{(1+Q^{-2})(1-\eta)}{\xi R_{1\infty}+\eta R_l}\right] \qquad (31)$$

where

$$x\equiv\omega(\varepsilon'C_1+C_0)R,\ Q\equiv\omega L/R_l,$$
$$M_0\equiv M/\omega(\varepsilon'C_1+C_0)$$
$$p\equiv\frac{C_0}{\varepsilon'C_1+C_0},\quad q\equiv\frac{\varepsilon'C_1}{\varepsilon'C_1+C_0}$$
$$\alpha\equiv\omega^2LC_0\qquad\alpha_2\equiv\omega^2LC_2$$
$$\xi\equiv 1-2\alpha_\infty+\alpha^2{}_\infty(1+Q_{\infty 1}^{-2}),\ \eta\equiv\alpha_\infty(1+Q_{\infty 1}^{-2})$$

Thus, the term in question becomes

$$\frac{\alpha px\omega L}{1+x^2}\frac{1+Q^{-2}}{R_{1\infty}} \qquad (32)$$

assuming that $\xi$ and $\eta$ are approximately equal to unity and zero, respectively. It seems that the condition giving the minimum point is almost entirely determined by this term taking the rest into account. This term contains the significant factor $p$, which contains $\varepsilon'C_1$ and $C_0$, as compared to the corresponding term in Eq. 25. The capacitance of the sample solution, $\varepsilon'C_1$, will be comparable to or larger than $C_0$, when the sample solution is an aqueous solution which has a large value of dielectric constant, though $C_1$ is considerably smaller than $C_0$. Thus, it is possible to find the possibility that the factor $p$ has a value somewhat smaller than unity, since the capacitance of the sample solution, $\varepsilon'C_1$, can not be neglected in comparison with the capacitance $C_0$. It seems likely that the consideration of the factor, $\varepsilon'C_1$, is helpful for the solution of the problem being discussed in this paper.

The author desires to thank Dr. K. Nakano for his support and advice. His numerous suggestions and interest have contributed much to this investigation. The author also desires to thank Dr. H. Honda for his kind encouragement throughout the investigation.

# *Vapor Phase Oxidation of Methyl Naphthalenes*[1]

By Shigeru MORITA

(Received September 23, 1959)

In 1916, Wohl[2] and Gibbs & Conover[3] discovered that, in the presence of vanadium pentoxide, naphthalene is oxidized to phthalic anhydride at 350 to 550°C. The ever-increasing demand for phthalic anhydride has in recent years stimulated the search for alternative raw materials. A patent claim was made that phthalic anhydride appears in the products of the catalytic air oxidation of methyl naphthalenes and phenanthrene. Methyl naphthalene oil[4] (a mixture of methyl naphthalene isomers, naphthalene and others) gave phthalic anhydride in the yield of 50~60%, but both pure 1- and 2-methyl naphthalenes[5] produced it in 30~40%. This yield is very low, in comparison with that from naphthalene (60~80%)[6]. The cause has not been studied. Reaction heat from methyl naphthalenes to phthalic anhydride is 605 kcal./mol. and is larger than that from naphthalene (450 kcal./mol.). Some investigators[7] accordingly proposed that the catalyst zone was superheated and phthalic anhydride once produced was decomposed, and the yield was lowered as a consequence.

The author studied the reaction mechanism of the vapor phase oxidation of methyl naphthalenes and related compounds and clarified the cause of the low yield.

## Experimental

**Apparatus.**—It is the same as that reported before[8].

**Experimental Conditions.**—The air rate was 150 l. per hour, the feed rate 1.5 g. per hour; the range of reaction temperatures was 350~500°C, and the catalyst volume was 50 ml.

The method of preparing the catalyst[8] was also reported before ($V_2O_5$-$MoO_3$-pumice stone).

The physical constants of reactants are listed in Table I.

## Results and Discussion

**Vapor Phase Oxidation of Methyl Benzenes.**—Methyl naphthalenes have two benzene rings condensed, whereas phthalic anhydride has one. Therefore, in order for methyl naphthalenes to produce phthalic anhydride by vapor phase oxidation, one of the two benzene rings of methyl

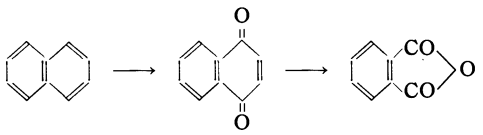
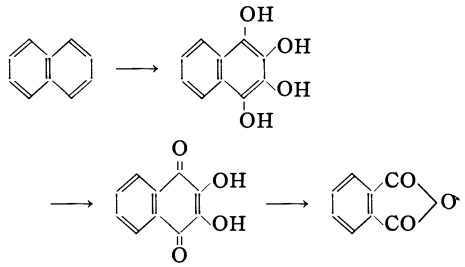
naphthalenes has to be cleaved to form benzene containing two side chains, followed by oxidation to the acid. The author studied the behavior of the side chains of the benzene ring during the vapor phase oxidation.

Toluene, *o*-xylene, 1, 2, 3- and 1, 2, 4-trimethyl benzenes were oxidized in vapor phase under the same conditions mentioned earlier. The results are listed in Table II.



As shown in Table II, phthalic anhydride was produced from *o*-xylene, and benzoic acid from toluene. Therefore, it is apparent that the methyl group is oxidized to carboxylic acid before the benzene ring is cleaved. Sasayama[9] reported that oxidation of trimethyl benzene proceeded stepwise as follows:

trimethyl benzene → benzene-tricarboxylic acid → phthalic anhydride → benzoic acid → benzene → maleic anhydride.



The results obtained by the author showed that both 1, 2, 3- and 1, 2, 4-trimethyl benzenes, on vapor phase oxidation, gave maleic anhydride (in 3% yield) and carbon dioxide, accompanied by very small amounts of 1, 2, 3- and 1, 2, 4-benzene-tricarboxylic acids, respectively, but gave neither phthalic anhydride nor benzoic acid. Furthermore, 1, 2, 4-benzene-tricarboxylic acid gave no phthalic anhydride, but only maleic, anhydride (in 5% yield) and carbon dioxide and no unreacted material was found. The yield of maleic anhydride in this case was comparable with that from 1, 2, 4-trimethyl benzene; therefore, benzene-tricarboxylic acid was presumably formed as an intermediate in the oxidative degradation of trimethyl benzene. However, decarboxylation of the extra carbonyl group did not ensue and the benzene ring was cleaved by the oxidation to form maleic anhydride and carbon dioxide.

**Vapor Phase Oxidation of Methyl Naphthalenes and their Related Compounds.**—The mechanism[10] of the vapor phase oxidation of naphthalene is described as follows:

Meanwhile, Pongratz[11] proposed the following route:

In either case, a carbon-hydrogen bond in one of two benzene rings is broken and a new carbon-oxygen bond is formed in its place, and then the benzene ring containing oxygen is cleaved.

Two benzene rings of naphthalene are equivalent reaction-wise but those of methyl naphthalenes are not, due to the presence of the methyl group in one ring.

Pongratz[11] studied the vapor phase oxidation of chloro-, nitro-, and hydroxy-naphthalenes and found that both 1- and 2-chloronaphthalenes produced phthalic anhydride and monochlorophthalic anhydride. These results show that chlorinated as well as unsubstituted benzene rings were cleaved, but he also obtained phthalic anhydride from 1, 5-dichloronaphthalene and concluded that dechlorination took place during the oxidation.

So far, no report has been made on the mechanism of vapor phase oxidation of methyl naphthalenes. The author examined four conceivable mechanisms (**a**, **b**, **c** and **d**) of vapor phase oxidation of methyl naphthalenes.

*Mechanism* ***a***.—Kato[12] and coworkers obtained naphthalene-carboxylic acids in 86% yield

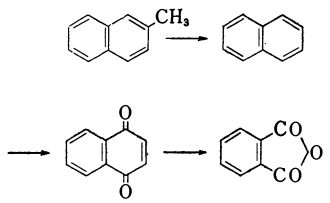
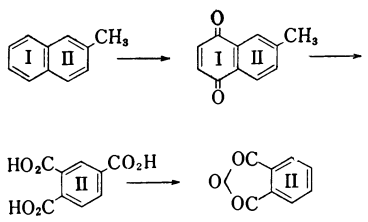
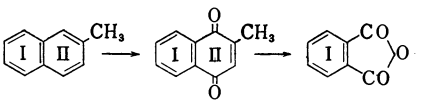
12) S. Kato et al., "Abstracts of the 11th Annual Meeting of Chem. Soc. Japan", Tokyo (1958), p. 18.



by heating methyl naphthalenes to 250°C with an aqueous solution of sodium dichromate in an autoclave. Pickering[13] et al. obtained the acid by oxidation of alkyl naphthalene with barium permanganate. In the same manner, in the vapor phase methyl naphthalene would first be oxidized to naphthalene-carboxylic acid, and then phthalic anhydride is produced as follows:



or



*Mechanism* ***b***.—Madison[14] obtained naphthalene by one-hour pyrolysis of 1- or 2-methyl naphthalene at 475°C, whereas Kynaston[15] obtained the same compound by passing acenaphthene with steam over a catalyst such as zinc oxide, chromium oxide or alumina. In the same way, methyl naphthalene would produce naphthalene by demethylation as an initial step and naphthalene would then be oxidized to phthalic anhydride:

*Mechanism* ***c***.—Unsubstituted benzene ring (I) of methyl naphthalene would be oxidized and produce phthalic anhydride with the concomitant decarboxylation of one of the three carboxyl groups.

*Mechanism* ***d***.—Benzene ring bearing the methyl group would be cleaved by oxidation and produce phthalic anhydride:

The author will discuss these four mechanisms.

*On mechanism* ***a***.—2-Methyl naphthalene was catalytically oxidized in the vapor phase under the same conditions at 350°C and the product contained 2-methyl-1, 4-naphthoquinone (identified as 2, 4-dinitrophenyl-hydrazone; m.p. 274°C uncor., no depression in mixed m.p.) but no naphthalene carboxylic acid. This result agrees with that obtained by Fieser[16].

Since decarboxylation is assumed in this mechanism, the possible occurrence of decarboxylation was examined. Naphthalene-1- or 2-carboxylic acid was passed through a reaction tube filled with pumice stone containing no vanadium pentoxide under the same conditions as in vapor phase oxidation (temperature, feed rate and air rate). The product did not contain naphthalene at all. In the same way, the acids were passed through the oxidation catalyst zone with a stream of carbon dioxide instead of air under the same conditions, but naphthalene was not obtained. Therefore, decarboxylation does not occur in the oxidation of naphthalene-carboxylic acid. This result is similar to the one obtained in the case of benzene-tricarboxylic acid.

From these results, it is supposed that mechanism **a** is incorrect.

*On mechanism* ***b***.—In order to check the assumption of demethylation, the following reaction was performed: methyl naphthalene was passed through a pumice stone zone with air or through an oxidation catalyst zone with carbon dioxide instead of air under the same conditions as in the vapor phase oxidation (temperature, feed rate and gas rate).

The products were carefully distilled, but naphthalene was not found. The density and refractive index of the product were identical with those of the starting material.

Madison's experiment[14] showed the formation of naphthalene from methyl naphthalenes but the heating period in his case was more than one hour. In vapor phase oxidation, the contact time was less than one second, and it is assumed that naphthalene was not formed in such a short time.

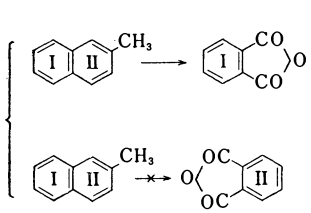
TABLE III. VAPOR PHASE OXIDATION OF METHYL NAPHTHALENES AND THEIR RELATED COMPOUNDS

| Materials | Reaction temp. °C | Products | | | | Material unreacted |
|---|---|---|---|---|---|---|
| | | Phthalic anhydride mol. % | Maleic anhydride mol. % | Benzene tricarboxylic acid | Others | |
| Naphthalene | 450 | 68 | 7 | 0 | — | 0 |
| 1-Methyl naphthalene | 400 | 26 | 4 | trace | a) | 0 |
| 2-Methyl naphthalene | 450 | 42 | 6 | trace | b) | 0 |
| Naphthalene-1-carboxylic acid | 400 | 27 | 21 | — | — | 4 |
| Naphthalene-2-carboxylic acid | 400 | 36 | 16 | — | — | 2 |
| Tetralone | 400 | 62 | 8 | 0 | — | 0 |
| 2-Methyl-1, 4-naphthoquinone | 400 | 65 | 8 | 0 | — | 0 |
| 7-Methyl tetralone | 400 | 0 | 3 | trace | — | 0 |

a) Trace of quinones
b) Trace of 2-methyl-1, 4-naphthoquinone

*On mechanism* **c**.—If the oxidation proceeds according to mechanism **c**, 1, 2, 4-benzene-tricarboxylic acid must produce phthalic anhydride. Consequently mechanism **c** is unlikely. To ascertain this conclusion, 7-methyl tetralone and tetralone were catalytically oxidized in the vapor phase under the same conditions. Tetralone produced phthalic anhydride in the same yield as that from naphthalene, but 7-methyl tetralone did not (Table III). The hydrogenated benzene ring of tetralone has an oxygen atom, and, on oxidation, this ring must have been cleaved in order to form phathalic anhydride. If the reaction proceeds similarly in the case of 7-methyl tetralone, the hydrogenated ring containing oxygen would be cleaved. This is the same course which 2-methyl naphthalene follows when it is oxidized through mechanism **c**.



The oxidation products of 2-methyl naphthalene and 7-methyl tetralone caught in the hot part of an air condenser (collector of product) contained a trace of 1, 2, 4-benzene-tricarboxylic acid, which was identified by its melting point and neutralization equivalent. Thus, it is obvious that the benzene ring of methyl naphthalenes having no methyl group was cleaved, but no phthalic anhydride was produced.

*On mechanism* **d**.—If the benzene ring (II) of methyl naphthalenes having the methyl group is cleaved first and the resulting benzene ring (I) containing two side chains is oxidized, phthalic anhydride would be produced in the same way as from *o*-xylene. The benzene ring (II) of 2-methyl-1, 4-naphthoquinone which has a methyl group, contains two oxygen atoms. Therefore, by catalytic vapor phase oxidation, the benzene ring (II) is cleaved and the reaction follows only mechanism **d**.

The experiment showed that 2-methyl-1, 4-naphthoquinone produced phthalic anhydride in the yield of 65% which is the same as that obtained in the case of naphthalene and *o*-xylene. Accordingly, it is obvious that methyl naphthalenes produce phthalic anhydride only when it is oxidized through mechanism **d**.

From these experimental results it is seen that methyl naphthalenes do not produce phthalic anhydride by mechanism **c** but produce it in 60～70% yield by mechanism **d**.

The yield of phthalic anhydride obtained from methyl naphthalenes is about 30～40% by the catalyst used in these experiments ($V_2O_5$–$MoO_3$–pumice), German catalyst ($V_2O_5$–$K_2SO_4$–silica gel) or American catalyst ($V_2O_5$–alumina) and is about one half of that from naphthalene. It is conceivable that both reactions through mechanism **c** and **d** occur simultaneously to the same extent, as the presence of a trace of benzene-tricarboxylic acid was confirmed in the products.

| Materials | Reaction temp. °C | Products | | | |
|---|---|---|---|---|---|
| | | Phthalic anhydride mol. % | Maleic anhydride mol. % | Naphthalic anhydride mol. % | Benzene tricarboxylic acid |
| 2, 6-Dimethyl naphthalene | 450 | 0 | 18 | 0 | trace |
| 2, 7-Dimethyl naphthalene | 450 | 0 | 20 | 0 | trace |
| Acenaphthene | 450 | 0 | 14 | 39 | 0 |
| Dimethyl naphthalene oil | 400 | 15 | 8 | 0 | trace |
| 2, 3-Dimethyl naphthalene[a)] | 375 | 43 | 7 | 0 | — |

a) This result was obtained by Kinney et al. ($V_2O_5$–$K_2SO_4$–silica gel).

If it is desired to produce phthalic anhydride in high yield from methyl naphthalenes, it is necessary to find the catalyst that is capable of cleaving only the benzene ring of methyl naphthalenes which have a methyl group.

**Vapor Phase Oxidation of Dimethyl Naphthalenes and Others.**—Kinney[5)] and coworkers obtained phthalic anhydride from 2, 3-dimethyl naphthalene in yields of 43% and 28% by the American and the German catalysts, respectively. Furthermore they obtained the anhydride in a 30% yield from a fraction (boiling in the 235~270°C range) of coal tar.

The author oxidized 2, 6- and 2, 7-dimethyl naphthalenes and obtained no phthalic anhydride but maleic anhydride in yields of 18 and 20%, respectively, and very small amounts of benzenetricarboxylic acid. He also obtained phthalic anhydride in a 15% yield by vapor phase oxidation of dimethyl naphthalene oil (boiling range, 260~268°C) of coal tar (Table IV).

Each of the two benzene rings of 2, 6-dimethyl naphthalene has one methyl group. Therefore, when either of them is cleaved by the oxidation, the resulting benzene ring has three side chains, and no phthalic anhydride would result according to the above-mentioned mechanism **c**. This conclusion agrees with the experimental results.

In the case of 2, 3-dimethyl naphthalene, one (II) of the two benzene rings has two methyl groups, and the other (I) has none. Therefore, when the benzene ring (II) which has two methyl groups is cleaved by vapor phase oxidation, phthalic anhydride would be produced by mechanism **d**, but when a benzene ring having no methyl group is cleaved, no phthalic anhydride would be produced by mechanism **c**. This conclusion agrees with the experimental results obtained by Kinney et al.

Acenaphthene is the compound that has an ethylidene group connecting positions 1 and 8 of naphthalene. Therefore, it is not conceivable that phthalic anhydride is formed. The author obtained naphthalic and maleic anhydrides but no phthalic anhydride.

From all the experiments mentioned above, it is concluded that the stability of rings and substituents against vapor phase oxidation in the decreasing order is as follows:

benzene ring > methyl group
> naphthalene ring > ethylidene group

# *The Nitrogen Isotopic Equilibrium between Ammonia and Ammonium Ion**

By Tatsujiro ISHIMORI

(Received September 21, 1959)

A number of studies have been reported on the enrichment of $^{15}N$ with the isotopic exchange reaction between ammonia gas and aqueous ammonium ion. The fractionation factor for this exchange reaction has been reported[1-3]. A separation of nitrogen isotopes has been made by the use of cation exchange resins[4]. One of the equilibria involved in the separation process is the equilibrium of nitrogen isotopes between ammonia and ammonium ion in aqueous solution. This paper is a report on the investigation of the equilibrium by the use of cation exchanger. The equilibrium constants and enthalpy of the reaction have been measured. It is found that the use of ion exchanger will be useful to study such an equilibrium existing in aqueous solution. Further, the measurement of the equilibrium of nitrogen isotopes between ammonia gas and ammonium ion of its solid chloride has been carried out and is described in this paper.

In an aqueous solution of ammonia and ammonium ion at isotopic equilibrium with the ammonium ion adsorbed on a cation exchange resin, the equilibria involved are described by the equations:

$$^{15}NH_{3(aq)} + {}^{14}NH_{4(aq)}^{+} = {}^{14}NH_{3(aq)} + {}^{15}NH_{4(aq)}^{+} \qquad K_1 \quad (1)$$

$$^{14}NH_4R + {}^{15}NH_{4(aq)}^{+} = {}^{15}NH_4R + {}^{14}NH_{4(aq)}^{+} \qquad K_2 \quad (2)$$

$$^{14}NH_4R + {}^{15}NH_{3(R)} = {}^{15}NH_4R + {}^{14}NH_{3(R)} \quad (3)$$

$$^{15}NH_{3(aq)} + {}^{14}NH_{3(R)} = {}^{14}NH_{3(aq)} + {}^{15}NH_{3(R)} \quad (4)$$

where $NH_4R$ represents ammonium ion taken up into the cation exchanger phase by ion-exchange mechanism and $NH_{3(R)}$ ammonia adsorbed on an ion exchange resin. Equilibria 3 and 4 can be neglected in a solution of low pH, while they exist with the solution of high pH. However, the concentration of $NH_{3(R)}$ is small compared to that of $NH_4R$ when the concentration of $NH_{3(aq)}$ is low. The amount of $NH_{3(R)}$ is also smaller than that of $NH_{3(aq)}$ if the volume of the exchanger is smaller than that of the solution. Thus, the fractionation factor between the exchanger and solution phase may not greatly involve the contribution by $NH_{3(R)}$. Further, the equation

$$^{14}NH_4R + {}^{15}NH_{3(aq)} = {}^{15}NH_4R + {}^{14}NH_{3(aq)} \quad (5)$$

which is the sum of Eqs. 3 and 4, results also from Eqs. 1 and 2. Hence, Eqs. 1 and 2 are enough to represent the equilibria involved in the system of an aqueous solution of ammonia and ammonium ion, and an exchanger of ammonium ion form.

The following quantity can be measured conveniently:

$$\frac{(^{15}N/^{14}N)_{solution} - (^{15}N/^{14}N)_{exchanger}}{(^{15}N/^{14}N)_{exchanger}} = \delta \quad (6)$$

where $(^{15}N/^{14}N)_{exchanger}$ and $(^{15}N/^{14}N)_{solution}$ are the nitrogen isotope ratios in the exchanger and solution phase, respectively. The fractionation factor between the exchanger and solution phase is defined as follows:

$$K = \frac{(^{15}N/^{14}N)_{exchanger}}{(^{15}N/^{14}N)_{solution}} = \frac{1}{1+\delta} \quad (7)$$

This value can be obtained experimentally. Let the following concentrations be represented by the associated symbols:

$$(^{15}NH_{3(aq)}) = a', \quad (^{15}NH_{4(aq)}^{+}) = b', \quad (^{15}NH_4R) = c'$$

$$(^{14}NH_{3(aq)}) = a, \quad (^{14}NH_{4(aq)}^{+}) = b, \quad (^{14}NH_4R) = c$$

Then, the following relationship between $K_1$, $K_2$ and K can be readily derived:

$$\frac{1}{K} = \frac{a}{a+b}\left[\frac{1}{K_1K_2} + \frac{b}{aK_2}\right] \quad (8)$$

The value of $a/(a+b)$ and $b/a$ can be calculated from the dissociation constants of ammonia and water: $K_{dis}$ and $K_w$; if the pH value of the solution is known:

$$\frac{b}{a} \simeq \frac{b+b'}{a+a'} = \frac{K_{dis}}{K_w}(H^+) \quad (9)$$

$$\frac{a}{a+b} \simeq \frac{1}{1+\frac{K_{dis}}{K_w}(H^+)} \quad (10)$$

* This study has been done in the Chemistry Department of the University of Arkansas, Arkansas, U. S. A.

1) H. G. Thode, R. L. Graham and J. A. Ziegler, *Can. J. Research*, **B23**, 40 (1945).

2) E. W. Becker and H. Baumgartel, *Z. Naturforsch.*, **1**, 514 (1946).

3) I. Kirshenbaum, J. S. Smith, T. Crowell, J. Graff and R. McKee, *J. Chem. Phys.*, **15**, 440 (1947).

4) F. H. Spedding, J. E. Powell and H. J. Svec, *J. Am. Chem. Soc.*, 77, 6125 (1955).

It is assumed that $a \simeq a+a'$ and $b \simeq b+b'$ are held since nitrogen with natural isotopic abundance is used and the $^{15}N$ content is about 0.36%[5]. The numerical value of $K_{dis}/K_w$ is $1.04 \times 10^9$ at 30°C[6].

If the pH of the solution phase is less than 5, the concentration of $NH_{3(aq)}$ is negligibly small. Hence,

$$K = K_2 \qquad (11)$$

for the low pH. The value of $K_1$ can be calculated from Eq. 8, using the values of $K_2$, $K$ and pH value.

If the value of $K$ is measured at high pH, the concentration of ammonium ion is very low: $b \ll a$. Hence, Eq. 8 can be written as

$$K_1 = K/K_2 \qquad (12)$$

for the value of $K$ at high pH of the solution. This relation gives approximately the value of $K_1$. Spedding, Powell and Svec[4] have evaluated the fractionation factor, $K$, in the above-mentioned condition.

## Experimental

The ammonia solution was purified by distillation. The other chemicals were of analytical grade. The cation exchange resin used was Dowex 50, X-8.

The conventional water bath for a constant temperature was used. The temperature was controlled within ±0.2°C at the vicinity of the room temperature. The air bath was used to keep the elevated temperatures constant at 200°C to 275°C within ±2°C.

The mass spectrometer used was a Nier type, 60° sector, double collecter instrument designed to measure small differences in isotopic ratio as described by McKinney et al.[7] and Dole[8]. Measurements were made on the ions of mass 28 and 29 ($^{14}N^{14}N^+$ and $^{15}N^{14}N^+$). The result of each isotopic analysis is estimated to have a precision of ±0.0003 in the quantity of $\delta$.

A solution of ammonium chloride and ammonia was added to the cation exchange resin of the ammonium ion form. This mixture was allowed to stand for ten to twelve hours in the constant temperature bath with shaking and brought to isotopic equilibrium. Then, the solution phase was pipetted and acidified with sulfuric acid solution. The resin was separated from the solution by suction filtration. In each experiment, the solution or resin phase contained one to two milligram equivalents of nitrogen. Ammonium ion was converted to nitrogen gas by the oxidation with sodium hypobromite[9]. The resulting nitrogen gas was purified by repeatedly passing the gas over copper oxide at 800°C and through the liquid air[10]. A set of nitrogen gases from the solution and resin phase was analyzed with a mass spectrometer.

The isotopic equilibrium between gaseous ammonia and solid ammonium chloride was measured. The containing vessel was made of Pyrex glass and had two 200 ml. bulbs (Bulbs A and B). A vacuum stopcock (Stopcock 1) connected Bulbs A and B. On the opposite side of Stopcock 1, Bulb A had a well to insert a thermometer and Bulb B had another vacuum stopcock (Stopcock 2). The silicon grease used in the stopcocks was satisfactory at 200 to 275°C. Water vapor and gaseous ammonia were added, at 20 to 25 mmHg and 200 to 275 mmHg, respectively, to 50 to 100 mg. ammonium chloride in Bulb A and allowed to stand for 13 to 62 hr.

It was difficult to know whether or not isotopic equilibrium had been established. The equilibrium was considered to be established if the equilibrium constant did not increase with a longer period of standing at the same temperature. The vapor pressure of ammonium chloride is 117 mmHg at 275°C and 6 mmHg at 200°C[10]. Extra gaseous ammonia was added to get a large enough sample of gas phase for analysis. Water vapor was added to help isotopic equilibrium to be established[11].

After the establishment of isotopic equilibrium, the gas phase was collected in the evacuated Bulb B through Stopcock 1. The stopcock was turned through the window of the air bath. The vessel was taken out of the air bath and cooled with water. A sufficient amount of sulfuric acid was introduced into Bulb B through Stopcock 2 and gaseous ammonia was collected as ammonium ion in aqueous solution. Bulb A was disconnected and the ammonia gas in it was evacuated and replaced with air. Then, the solid ammonium chloride was dissolved with water.

## Experimental Results

The experimental fractionation factors between resin and the solution phase are listed in Table I with the pH values of the solution phases. The value of $K_1$ is calculated by Eq. 8 using the values of the experimental fractionation

2: Pressure of ammonia added at room temperature.

also plotted against the reciprocal of the absolute temperature in Fig. 2. The equilibrium constant between ammonia and ammonium ion, both in the gaseous state, has been calculated by Urey[12]. The calculated values are also plotted in Fig. 2.

## Discussion

The equilibrium constant for the equation

$$^{15}NH_{3(gas)} + {}^{14}NH_{4(aq)}^{+} = {}^{14}NH_{3(gas)} + {}^{15}NH_{4(aq)}^{+} \quad (14)$$

has been measured and found to be 1.034 at 25°C by Kirshenbaum et al.[3] The equilibrium constant for the equation

$$^{14}NH_{3(aq)} + {}^{15}NH_{3(gas)} = {}^{15}NH_{3(aq)} + {}^{14}NH_{3(gas)} \quad (15)$$

has been obtained and found to be 1.005 at 25°C[3]. From the data by Kirshenbaum et al. the equilibrium constant for Eq. 1 is calculated to be 1.029 at 25°C. The value of $K_1$ obtained by the author compares well with the values reported in literature. Further, Fig. 1 shows that Eq. 8 is well satisfied by the experimental fractionation factors and Eqs. 1 and 2 are enough to represent the equilibria involved in the aqueous ammonia-ammonium ion solution and the exchanger of ammonium ion form.

In the equations which involved ammonia in aqueous solution the unionized ammonium hydroxide, $NH_4OH$, is assumed not to exist in the aqueous solution. Instead, $NH_{3(aq)}$ is assumed to represent ammonia in the aqueous solution. There is some uncertainity in regard to the interpretation of "ammonium hydroxide". However, the relatively weakly basic character of "ammonium hydroxide" solution is interpreted recently as resulting simply from the fact that the ammonia molecule is a weaker than the hydroxide ion. There must be a hydrogen bond between the nitrogen of ammonia in aqueous solution and hydrogen of solvent water.

The value of the equilibrium constant $K_1$ is smaller than that of the calculated equilibrium constant with the gaseous partition functions of the isotopic ammonia and ammonium ion as shown in Fig. 2. This difference may be chiefly contributed by the difference of ammonia in the aqueous state from the gaseous state. The equilibrium constant for Eq. 14 by Kirshenbaum et al.[3]: 1.005; is considered to be large enough to explain the difference of the isotopic equilibrium constant $K_1$ from the calculated values. There may not be a large isotope effect on the difference between the gaseous and aqueous ammonium ions, since the nitrogen atom is surrounded by the hydrogen atoms and the nitrogen isotope effect on the solvation in the aqueous ammonium ion may be very small.

The effect of the concentration of the solution phase on the fractionation factor between resin and solution phase (Table II) shows that there is no effect upon acidic solution or ammonium ion and that the concentration of ammonia in the aqueous solution has the tendency to increase the value of the fractionation factor.

The slope of $\log K_1$ versus $1/T$ gives $\Delta H = -13.8$ cal. per mole for the exchange reaction 1. The measurements of the equilibrium constants $K_1'$ for the gas-solid exchange reaction have some difficulty in separating phases at elevated temperatures. The data are not sufficient to determine the accurate value of the heat of the exchange reaction.

In Fig. 2, it is seen that the equilibrium constants measured are located below the line of the calculated equilibrium constants. However, the differences between the measured and the calculated values at the same temperature are smaller with the measured values of the gas-solid exchange reaction than with those of the exchange reaction in aqueous solution. This fact may be partly understood by the presence of the hydrogen bond of ammonia molecules in aqueous solution.

This work was made possible by the support of the U. S. Atomic Energy Commission. The invaluable advice and encouragement from Dr. T. C. Hoering are acknowledged with thanks.

# *Nitrogen Isotopic Equilibria between Ammonia and Metal-ammine Complex Ions in Aqueous Solution**

By Tatsujiro ISHIMORI

(Received September 21, 1959)

The isotopic exchange of ions or molecules dissolved in solution with those coordinated in complex ions have been studied on the carbon isotopes between carbonate or bicarbonate ion and the carbonate coordinated in the cobalt complex ions[1,2], the oxygen isotopes between water as solvent and that in cobalt complex ion[3], and the nitrogen isotopes between ammonia as solvent and metal-ammine complex ions in liquid ammonia[4]. These studies have given data on the nature of the bond in complex ions. This paper reports on the nitrogen isotope effect in the formation of a series of metal-ammine complex ions with ammonia in aqueous solution. Copper-, zinc-, cadmium-, silver- and nickel-ammine complex ions were studied. The experimental method using ion exchangers[5] has been employed. A theoretical relation has been derived between the isotopic equilibrium constant and the first dissociation constant of the complex ion of the stable form.

## Experimental

Using the nitrogen compound with natural isotopic abundance, the equilibrium to be measured is written as

$$\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)^{+p}} + \mathrm{^{15}NH_{3(aq)}} = \mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)^{+p}} + \mathrm{^{14}NH_{3(aq)}} \qquad K_1 \quad (1)$$

where $\mathrm{M(NH_3)_n^{+p}}$ represents a metal-ammine complex ion, $K_1$ the equilibrium constant. The cation exchanger of the metal-ammine complex ion form can be brought to isotope equilibrium with the metal-ammine complex ion or ammonia in solution The equilibria are written by the equations:

$$\mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)^{+p}} + \mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)R} = \mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)^{+p}} + \mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)R}, \qquad K_2 \quad (2)$$

$$\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH)R} + \mathrm{^{15}NH_{3(aq)}} = \mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)R} + \mathrm{^{14}NH_{3(aq)}} \qquad K_3 \quad (3)$$

where $\mathrm{M(NH_3)_nR}$'s represent the metal-ammine complex ions adsorbed on the cation exchanger, $K_2$ and $K_3$ the equilibrium constant for Eqs. 2 and 3, respectively.

The following quantity can be measured conveniently:

$$\delta = \frac{(^{15}N/^{14}N)_{solution} - (^{15}N/^{14}N)_{resin}}{(^{15}N/^{14}N)_{resin}} \qquad (4)$$

where $(^{15}N/^{14}N)_{resin}$ and $(^{15}N/^{14}N)_{solution}$ are the ratio of the nitrogen isotopes in resin and solution, respectively. The value of $\delta$ for Eq. 2 can be measured directly for the system of the complex ion adsorbed on the resin and the solution of the complex ion, if the complex ion is stable without free ammonia or with a negligible amount of the excess ammonia. The equilibrium constant for Eq. 2 can be written

$$K_2 = \frac{\mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)R}}{\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)R}} \Big/ \frac{\mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)^{+p}}}{\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)^{+p}}} \simeq (^{15}N/^{14}N)_{resin}/(^{15}N/^{14}N)_{solution} = 1/(1+\delta_2) \qquad (5)$$

Eq. 3 describes the equilibrium of the complex ion adsorbed on the resin with excess ammonia in aqueous solution. Using the symbols $\delta_3$ for this case, the equilibrium constant of Eq. 3, $K_3$, is given by the following equation:

$$K_3 = \frac{\mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)R}}{\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)R}} \Big/ \frac{\mathrm{^{15}NH_{3(aq)}}}{\mathrm{^{14}NH_{3(aq)}}} \simeq n(^{15}N/^{14}N)_{resin}/(^{15}N/^{14}N)_{solution} = n/(1+\delta_3) \qquad (6)$$

In this equation, $(^{15}N/^{14}N)_{resin}$ is assumed to represent the isotope ratio in only the exchanged complex ions, since the amount of the free ammonia in the resin is negligibly small compared with that of ammonia coordinated in the exchanged compelx ions. It is not necessary to consider ammonium ion in this equilibrium if the pH of the aqueous solution is high.

Now, $K_1$ is given with $\delta_2$ and $\delta_3$;

$$K_1 = \frac{\mathrm{M(^{14}NH_3)_{n-1}(^{15}NH_3)^{+p}}}{\mathrm{M(^{14}NH_3)_{n-1}(^{14}NH_3)^{+p}}} \Big/ \frac{\mathrm{^{15}NH_{3(aq)}}}{\mathrm{^{14}NH_{3(aq)}}} = K_3/K_2 = n(1+\delta_2)/(1+\delta_3)$$

The value of the fractionation factor, $(1+\delta_2)/(1+\delta_3)$, can be experimentally obtained.

The metal-ammine complex ion may undergo successive dissociations. However, many of the complex ions, in general, have one stable form

which exists predominantly in aqueous solution. In such a case, the isotopic equilibrium constant measured will present the equilibrium constant of the stable form of the complex ion.

Copper quadrammine sulfate was prepared[6] and its solution was made by dissolving the prepared crystal in a very dilute ammonia solution. The other complex solutions: zinc, cadmium and silver complex solution were made by dissolving the slight excess of metal sulfate in an ammonia solution and filtering the insoluble residue out. The cation exchanger used was Dowex 50, X-8. The exchanger of a complex ion form was made by passing the metal-ammine complex- ammonia solution through the exchanger column. The exchangers were washed with ammonia solution on the glass filter with a suction of water jet pump.

The general procedures were the same as described in the previous report[5]. The exchanger of the complex ion form was added to the solution of the complex ion or ammonia and allowed to stand in the constant temperature bath at 30°C over one or two nights. The periods may be long enough for the attainment of the equilibria of the exchange reactions in this experiment, which are supposed to be rapid by the rapid exchanges of ammonia between solvent liquid ammonia and copper-, silver- or nickel-ammine complex ion[4]. After the attainment of the equilibria, the exchangers were separated from the solution with suction filtration, and washed with a limited amount of water to avoid the hydrolysis of the exchanged complex ions. The washed exchanger was put into the sulfuric acid solution to convert to the metal ion and ammonium ion. Then, the exchanger and the solution were poured on the exchanger column in the hydrogen form. The ammonium ion was recovered by eluting with 0.5 N potassium sulfate-0.5 M sulfuric acid solution. Through this process, the greater part of the metal ion was removed. The ammonia solution separated from the exchanger at equilibrium was acidified with sulfuric acid solution and used for the isotopic analysis. The complex ion solution was acidified with sulfuric acid solution and treated by the same procedure as described for the complex ion exchanged.

For copper and nickel complex ions, the complex ions were separated from the complex-ammonia mixed solutions by salting out the complex salts with the addition of the large amount of alcohol and centrifuging the complex salts. The isotopic measurements were carried out for the supernatant solution and complex salts centrifuged.

The isotope ratio measurements were made in the same way as described in the previous report[5].

## Results

The experimental results are shown in Table I with the experimental conditions. In the experiments of cadmium and zinc complex ion, the value of $\delta_2$ could not be measured since these complex ions were not stable in aqueous solution without a large excess of ammonia. Their equilibrium constants were calculated by assuming the value of $\delta_2$ to be zero. This assumption seems to be reasonable since the equilibrium constant of isotopic ions between the exchanger and solution phase is nearly unity.

The experiments were carried out by the technique of salting out the complex ion from the complex ion-ammonia mixture solution with the addition of alcohol for copper and nickel complex ions. In this technique, the equilibrium constant can be readily obtained from the measured value of $\delta$:

$$\delta = [(^{15}N/^{14}N)_{solution} - (^{15}N/^{14}N)_{salt}] / (^{15}N/^{14}N)_{salt}$$

The results are also shown in Table I. Both the techniques of using cation exchanger and

6) G. Brauer, "Handbuch der Praeparativen Anorganischen Chemie", Ferdinand Bnke Verlag, Stuttgart (1954), p. 757.

salting out the complex ion gave a good agreement on the value of $K_1$. The agreement shows that the technique with cation exchanger can be efficiently used in measurements of this kind.

## Theoretical and Discussion

A theoretical relationship can be derived between the isotopic equilibrium constant of Eq. 1, $K_1$, and the first dissociation constants of the stable ammine complex ions, $k$ and $k'$ for the dissociations:

$$M(^{14}NH_3)_{n-1}(^{15}NH_3)^{+p} = M(^{14}NH_3)_{n-1}^{+p} + {}^{15}NH_{3(aq)} \quad k \quad (8)$$

$$M(^{14}NH_3)_{n-1}(^{14}NH_3)^{+p} = M(^{14}NH_3)_{n-1}^{+p} + {}^{14}NH_{3(aq)} \quad k' \quad (9)$$

The value which is defined as a ratio of the partition functions of isotopic molecules by Biegeleisen and Mayer[7], is written as,

$$\frac{s}{s'} f = 1 + \Sigma_1 G_1 \Delta u_1 \quad (10)$$

where $s$ and $s'$ are the symmetry number of isotopic molecules. The primed notation refers to the light molecule. The $G$ function relates to the difference in free energy of the formation of isotopic molecules from the isolated gaseous atoms[7]:

$$\frac{\Delta F^0 - \Delta F^{0\prime}}{RT} = -\Sigma_1 G_1 \Delta u_1 + \ln \frac{s}{s'} \quad (11)$$

The following equation can be obtained from Eqs. 10 and 11:

$$f = \frac{s'}{s}\left(1 - \frac{\Delta F^0 - \Delta F^{0\prime}}{RT} + \ln \frac{s}{s'}\right) \quad (12)$$

Then Eq. 12 is applied to the isotopic complex ions in aqueous solution, the ratio of their symmetry numbers, $s'/s$, can be replaced by the number of the ammonia molecules coordinated in the stable complex ions. Further, if Eqs. 8 and 9 are compared the difference of the free energies of formation of the complex ions becomes

$$\Delta F^0{}_c - \Delta F^{0\prime}{}_c = \Delta F^0{}_a - \Delta F^{0\prime}{}_a - RT \ln (k'/k) \quad (13)$$

where the subscripts $c$ and $a$ refer to the complex ion and ammonia, respectively. The $f$ function of the complex ion is written as

$$f_c = n\left(1 + \ln k'/k - \frac{\Delta F^0{}_a - \Delta F^{0\prime}{}_a}{RT} - \ln n\right) \quad (14)$$

For the isotopic ammonia molecules, the ratio of the symmetry numbers is one and its $f$ function is given by

$$f_a = 1 - \frac{\Delta F^0{}_a - \Delta F^{0\prime}{}_a}{RT} \quad (15)$$

With Eq. 15, the $f$ function of the complex ion is rewritten as

$$f_c = n(\ln k'/k + f_a - \ln n) \quad (16)$$

Now the equilibrium constant, $K_1$, which is the ratio of the $f$ function of the complex ion to that of ammonia, can be expressed with the dissociation constants of the stable complex ions, $k$ and $k'$:

$$K_1 = n\left[1 + \ln\left(\frac{k'}{n} \Big/ k\right) \Big/ f_a\right] \quad (17)$$

The quantity of $k'/n$ in this equation is equivalent to $k$ if the probabilities of the dissociations of the isotopic complex ions are taken into account. Both $k'/n$ and $k$ are a measure of the strength of the bond between metal and nitrogen in the complex ions which appeared at the first dissociation.

The measured fractionation factors can be compared with the relationship of Eq. 17, provided a form of the complex ion among the successively dissociated ions is predominantly stable. The successive dissociation constants have been measured[8]. The values of the dissociation constants are listed with the measured fractionation factors in Table II. Copper, zinc, cadmium and silver complex ions have one stable form. However, in the case of nickel complex ion, the successively dissociated ion may exist with comparable concentrations and they effect the value of the measured fractionation factor as an average.

TABLE II. FRACTIONATION FACTORS AND THE FIRST DISSOCIATION CONSTANTS OF COMPLEX IONS

| Complex ion | $\frac{K_1}{n}$ | $\log k'$ | $\log \frac{k'}{n}$ |
|---|---|---|---|
| $Cu(NH_3)_4^{2+}$ | 1.0117 | −2.13 | −2.73 |
| $Zn(NH_3)_4^{2+}$ | 1.0116 | −2.15 | −2.75 |
| $Cd(NH_3)_4^{2+}$ | 1.0103 | −0.93 | −1.53 |
| $Ag(NH_3)_2^{2+}$ | 1.0093 | −3.83 | −4.13 |
| $Ni(NH_3)_n^{2+}$ | 1.0076 | −0.03 for $n=6$ | −0.81 |
| | | −0.75 for $n=5$ | −1.45 |
| | | −1.19 for $n=4$ | −1.79 |

In Table II, the tendency is noted that the smaller value of $k'$ causes the greater fractionation factor or the greater value of the ratio of $k'/n$ to $k$. An exception is in the case of the silver complex ion although the reason is not clear. The greater isotope effect is found in the more tightly bound complex ion which agrees with the general rule of the isotope effects.

# *Studies on Thixotropy. II.**[1] *On the Thixotropic Gel Structure of Bentonite*

By Takehiko WATANABE

(Received August 10, 1959)

There are two kinds of structure which are currently taken as a model for thixotropic gel of bentonite. One of them is the structure in which dispersed plate-like particles are linked together at a short distance to build up a network. The other[2,3] is the structure in which particles are regularly oriented to each other at a considerable distance. According to the latter structure, however, it was difficult to explain the process of thixotropic gel formation which proceeds in two steps as described in the previous paper[1]. By making light-scattering, birefringence and viscoelastic studies on mono-disperse sol of Wyoming Bentonite, M'Ewen et al.[4] have suggested that particles are oriented edge-to-edge in the form of flat ribbons. Olphen[5] has also concluded from the results obtained by the study of the surface conductance of bentonite suspension that particles are linked with each other at a short distance. These results show that the former structure, e. g. "house of cards" structure[6] in which the particles are linked at

a short distance, is favored. Therefore, in this report, discussions will be carried out on this structure on the basis of the rheological data.

### Discussion and Proposal of Gel Structure

In Table I are collected the relations between the rheological properties and the concentration of thixotropic gel of bentonite presented by different investigators, and those derived by the present author using the data obtained by other authors. Furthermore, from the experimental data provided by Peter et al.[8] the relations between shearing stress ($\tau$) and concentration ($C$) at a fixed rate of shear ($q$) are derived and given in Table II. The relation between $\tau$ and $C$ is also dependent on C. Referring to the study of Enneking[11], in which he discussed experimental conditions similar to Peter's, in the range where the values of $\tau$ in Table II are proportional to $C^6$, the flow may be induced not in the whole but in a localized part of the gel. Therefore, it may be said that in the flowing part, the actual value of $q$ is higher than those listed. Consequently, this high $q$ is to be suddenly induced to the set gel. It may further be reasonable to assume that the experimental conditions, under which some of the measurements for Table I were carried out, must be essentially similar to those above stated. Therefore, $\mu$ and $S_\infty$ can be proportional to $C^6$.

11) H. Enneking, *Rheologica Acta*, 1, 234 (1958).

Tables I and II show that the relations between rheological properties (in the following, represented by "strength") and concentration are dependent on the condition of measurement, so that it may be expected that the particles constituting the gel do not orientate so regularly as ions in crystal lattice but link with each other at random to build up the gel structure. This leads to the conclusion that, in the gel, several kinds of agglomerated particle groups can coexist. It may also be expected that under a certain experimental condition, the gel strength is determined by a particular particle group in the gel. Namely, if the observed gel strength is proportional to $C^p$ where $p$ is a positive integer, there exists a particular particle group which performs the role of structural unit. And in this case, provided that the contribution to the gel strength is equal in each particle group of the same kind, it may be concluded that the number of the particle group per unit volume of the gel varies as $C^p$. In other words, the probability of the existence of this particle group is proportional to $C^p$. In the following discussion, a particle group such as stated above will be named structural unit-$C^p$ (abbr. S. U.-$C^p$). If many kinds of particle groups which act as S. U.-$C^p$, exist in the system, the gel strength may be determined by one of them, or by a set of particle groups which make equal contribution to the gel strength in cooperation with each other.

Since the form of bentonite particle is platelike, the association between particles may be classified into three types based on the steric condition of the junction point as described in the previous paper[1]. In the first type, two particles are linked with each other at one point (P-1 association); while, in the second, particles are linked at two or more points belonging to one straight line (P-2 association) and, in the third, particles are linked at three or more points belonging to one plane (P-3 association). Also the number of junction points in unit volume in which two adjacent particles are linked with P-1, P-2 or P-3 association is proportional to $C$, $C^2$ or $C^3$, respectively.

In the first place, it is assumed that, in the gel structure, all particles are linked to each other with P-1 association. In this case, consideration is made based on the experimental results with Yamagata Bentonite reported in the previous paper[1]. This sample shows the maximum yield value proportional to $C^2$, or $C$ according to the first or the second gelation process, respectively. Therefore, it is concluded that S. U.-$C^2$ contributes to the gel strength in the first step and S. U.-$C$ in the second. Furthermore, from the results discussed in the

previous paper[1], it has been ascertained that the particle group which acts as a structural unit in the first step does not disappear, but its contribution to the yield value diminishes in the second step under the experimental method employed. Considering the process of gel formation, the structure developed in the second step is doubtless more rigid than that of the first. S. U.-$C^2$ in the first step, is the cross-linkage in which two linear ribbons are linked to the hypothetical fixed particle which behaves as if it were restricted at a fixed position when the cross-linkage acts as structural unit. Therefore, in the second step, the existence of cross-linkage may be expected, of which more than two linear ribbons are linked to the fixed particle. Namely, there exists the S. U.-$C^p$ where $p>2$ in the second step. Consequently, the structure which satisfies all the relations listed in Tables I and II, may be as follows. The structure is formed by cross-linking of the linear ribbons which are formed of the aligned particles linked by P-1 association. For the cross-linkage, there must coexist at least five kinds of cross-linkage in which two to six linear ribbons, respectively, are linked to the fixed particle.

Based on the above consideration on the structure, in the case of Yamagata Bentonite, the structural unit is S. U.-$C$, namely, the linear ribbons; since the maximum yield value developed in the second step ($A_{2\infty}$) varies as $C$. The result obtained with Volclay[1] where $A_{2\infty} \propto C^2$ and also with Braune's results, $A_\infty \propto C^2$, may be explained as follows. The structural unit is S. U.-$C^2$, that is, the cross-linkage formed by two linear ribbons linking to the fixed particle.

Next, it is assumed that all particles in structure are linked by P-2 association. In this case, the consideration must be made based on the results obtained with Volclay in the previous paper[1]. By treatment similar to that described above in completely set gel, there must exist S. U.-$C^6$ besides S. U.-$C^2$ and S. U.-$C^4$. S. U.-$C^2$ is the linear ribbons which are formed by the aligned particles linked by P-2 association. S. U.-$C^4$ or S. U.-$C^6$ is the cross-linkage in which two or three linear ribbons, respectively, link to the fixed particle. Using this model of structure, it is possible to explain all the experimental results listed in Tables I and II except that of Yamagata Bentonite. However, as to the S. U.-$C^6$ it is not enough to consider such a simple model as that mentioned above, it must satisfy the following requirements.

(1) Among the strengths of bentonite gel measured by various methods, the one proportional to $C^6$ has the largest value of $p$. Therefore, the particle group which acts as S.U.-$C^6$ must be the one which plays the part of constituting a rigid gel structure.

(2) Packter[10] has suggested that the rate of gel formation varies as $C^6$ in the case where the maximum gel strength $S_\infty$ is proportional to $C^6$ as shown in Table I. To satisfy this fact, S. U.-$C^6$ must be the cross-linkage formed in the process where six adjacent particles which participate in the formation of separate linear ribbons, orientate to the fixed particle.

Considering the above requirements, the cross-linkage which acts as S. U.-$C^6$ will be as follows.

The fixed particle is linked to three linear ribbons composed of a certain number of particles, of which each one nearest to the fixed particle must be further linked to another different linear ribbon. The particle group formed in such a way as stated above is an overlapping assembly of the four particle groups, each of which is expected to act as S. U.-$C^6$.

Considering such a particle group, it is safely assumed that such a cross-linkage plays an important role in the rigid gel structure which satisfies requirement 1, and the rate of formation of the cross-linkage varies as $C^6$ and requirement 2 is also fulfiled.

In the above consideration, only the case of P-2 association is treated. However, provided that similar structural conditions exist in the case of P-1 association, it may be expected that a rigid gel structure is built up from the three kinds of particle groups which will be able to act as S. U.-$C$, S. U.-$C^2$ and S. U.-$C^3$, respectively.

Now, it is assumed that four states of particle agglomerate will appear in the course of thixotropic gel-sol-gel transformation. Possible

TABLE III. STRUCTURAL UNITS WHICH EXIST IN FOUR RHEOLOGICAL STATES OF THIXOTROPIC GEL-SOL-GEL TRANSFORMATION

| Type of structure | Type of association | Rheological state | | | |
|---|---|---|---|---|---|
| | | Rigid gel | Loose gel | Sol I | Sol II |
| I | P-1 | S. U.-$C$<br>S. U.-$C^2$<br>S. U.-$C^3$ | S. U.-$C$<br>S. U.-$C^2$ | S. U.-$C$ | Dispersed particles |
| II | P-2 | S. U.-$C^2$<br>S. U.-$C^4$<br>S. U.-$C^6$ | S. U.-$C^2$<br>S. U.-$C^4$ | S. U.-$C^2$ | Dispersed particles |

S. U.-$C^p$ which may contribute to the strength at each state is collected in Table III. In the state where two or more structural units exist, the strength is determined by one of them, depending on the experimental condition. S. U.-$C$ in type I structure and S. U.-$C^2$ in type II are listed on both gel and sol states. These are the linear ribbons which participate in the structure in the gel state and are free in the sol state.

As described in the previous paper[1], during the first step of the thixotropic gel formation, the increase of the yield value of the gel in the loose gel state with setting time was measured and during the second step that of the gel in the rigid gel state was measured. In the case of the second step, experiments have been made to measure the yield value corresponding to the stress necessary to induce a fixed elastic deformation to the gel in which linear ribbons act as the structural unit. This deformation may be classified as a complete, recoverable, non-ideal one[12]. Therefore, the gel at this step shows retarded elasticity. Accordingly, if the deformation within the elastic limit has been induced gradually to the gel in rigid gel state of type II, its strength varies as $C^2$ since the linear ribbons act as the structural unit. On the contrary, when the deformation has been induced to the gel under the condition where the stress is suddenly applied to the system accompanying a fairly high rate of shear, the linear ribbons may not respond to this deformation, and as a result they come to play no role as the structural unit. The cross-linkage then comes to act as the structural unit so that the strength of the gel varies as $C^6$.

When experiments are carried out to obtain a flow curve, the rate of shear induced to the system is gradually increased and the stress corresponding to a given rate of shear is estimated. In this case, the observations are made on the variation of the state, starting from the rigid gel state and ending at the sol state II, listed in Table III. In the course of this experiment, a breakdown of the cross-linkage will occur at the initial stage and will be followed by the disintegration of the linear ribbons into individual particles at a later stage. Therefore, the results derived from the curve reported by Peter et al. or Olphen as shown in Tables I and II are explained as follows.

In these experiments, it may be expected that these systems take a structure of type II shown in Table III. From the results given in Table II, the relations between the stress and the concentration at a fixed rate of shear are dependent on the concentration of the system. Similar dependence on the above is also observed with the relation between the Bingham yield stress and the concentration as shown in Table I. It was observed in the previous experiment[1] that both the ratio of $A_{2\infty}$ to $A_{1\infty}$ and the difference between the values of $A_{2\infty}$ and $A_{1\infty}$ are larger in the case of the lower concentration. Therefore, it may be expected that in the gel which is in the rigid gel state, the ratio of the number of S. U.-$C^2$ to that of S. U.-$C^4$ or S. U.-$C^6$ of low concentration is larger than that of high concentration. Hence, at low concentrations, even the gel standing for a long period has a structure of either a loose gel state or a state not strictly distinguishable from sol state I. According to the above consideration, the relations listed in Table II may be elucidated with the concept given in Table III. The Bingham yield stress ($\tau_B$) is obtained from the intersection of the extraporated straight line with the stress axis so that the relation between $\tau_B$ and concentration is determined by the kind of structural unit in the range in which a linear relationship between the rates of shear and stress is obtained.

There has been no information regarding the condition under which the particles take either the structure of type I or II. However, it may be assumed that if the dispersed bentonite particles are in the form of unit layer, they will constitute a structure of type I, and if the dispersed particles are composed of stacking of several unit layers, a structure of type II will be formed.

P-1 association may be represented typically by the edge-to-edge linkage and P-2 association by the edge-to-surface linkage.

Packter[10] has reported that the maximum gel strength is proportional to $C^3$ in non-hetero-coagulated system where polyanion is added to the bentonite suspension. The results can be clearly explained by the assumption that the particles in the structure are linked by P-3 association. However, the gel structure which is formed by the particles linked by P-3 association is a very compact one compared with those listed in Table III and it is inadequate to accept this structure as that of thixotropic gel.

## Summary

(1) Discussions are carried out on the structure of the thixotropic gel of bentonite on the basis of the relation between the gel strength and the concentration, and the steric conditions of the junction point between two particles participating in structure.

(2) The gel strength is determined by the

12) J. M. Burgers and G. W. Scott Blair, "Report on the Principles of Rheological Nomenclature", North-Holland Publishing Co., Amsterdam (1949), p. 49.

particular group of particles in the structure which acts as the structural unit.

(3) The particle group which plays the part of the structural unit is not limited to one kind but more than one may coexist in a system. The gel strength is determined by one kind of the particle groups according to the experimental method used.

(4) The structure of the thixotropic gel of bentonite is classified into two types according to the mode of association between particles. One of them is the structure in which linear ribbons, which act as structural units, are formed by the aligned particles linking each other at one point. The other is the structure in which linear ribbons are formed by the particles linking at two or more points on one straight line.

The author would like to express his gratitude to Professor Sôzaburo Ono for his kind guidance and discussion throughout this work.

# *Hydrolysis of 7-Anilinobenzyl-8-quinolinol*

By Motoko Ito

(Received August 21, 1959)

On heating with 4 N hydrochloric, acid 7-anilinobenzyl-8-quinolinol (I) gave 7-hydroxybenzyl-8-quinolinol (II) and aniline as major products. The formation of benzaldehyde was found to be very scanty at this reaction though a distinct odor of benzaldehyde was noticed, suggesting that dissociation into three components of the Mannich base proceeded only to a negligible extent. On further heating with hydrochloric acid, II produced neither 8-quinolinol nor benzaldehyde but gave undefined matter (m.p. 118~119°C, foaming at 125°C). The bromination of II produced 5, 7-dibromo-8-quinolinol and benzaldehyde.

The dissociation of I by 4 N hydrochloric acid was first studied by Phillips et al.[1], however, it was considered at that time that I dissociated into three components in one step.

## Experimental

**7-Hydroxybenzyl-8-quinolinol (II).**—A hot solution of I (0.5 g.) in 4 N hydrochloric acid (10 ml.) was kept at around 85°C for 16 min. (when an odor of benzaldehyde was noticed). After being cooled, the solution was diluted with water (50 ml.) and then sodium acetate (6 g.) was added to it. The resulting precipitate was filtered after standing overnight (when no odor of benzaldehyde was noticeable). The filtrate gave a deep violet color with bleaching powder. The crude product was heated with ligroin (20 ml.) and filtered. From the filtrate on working up a colorless solid (0.15 g.), m.p. 88~100°C, foaming at 120~130°C, was isolated. This may be an impure bakelite-type condensation product.

The undissolved II was crystallized from five hundred times its weight of hot ligroin as colorless prismatic needles, m.p. 128°C.

Found: C, 76.52; H, 5.30; N, 5.20. Calcd. for $C_{16}H_{13}NO_2$: C, 76.49; H, 5.18; N, 5.58%.

When crystallized from benzene (20 ml.), it contained a mole of the solvent, m.p. 126~127°C; yield, 0.25 g. (66%) and when crystallized from carbon tetrachloride and dried in vacuo at room temperature, it also contained the solvent.

Found: C, 80.09; H, 5.65; N, 3.85. Calcd. for $C_{16}H_{13}NO_2 \cdot C_6H_6$: C, 80.24; H, 5.78; N, 4.26%.

Found: C, 53.84; H, 4.01. Calcd. for $C_{16}H_{13}NO_2 \cdot 0.8CCl_4$: C, 53.87; H, 3.47%.

*The hydrochloride* was obtained as colorless needles by the reaction of the base and hydrogen chloride, both in ethereal solution in the cold. It gave no definite m.p., began to sinter at 265°C and became a tar at 302°C.

Found: N, 4.73. Calcd. for $C_{16}H_{13}NO_2 \cdot HCl$: N, 4.87%.

*The picrate* was crystallized from benzene as prisms, m.p. 169°C.

Found: N, 11.50. Calcd. for $C_{16}H_{13}NO_2 \cdot C_6H_3N_3O_7$: N, 11.67%

**Acetyl Derivatives.**—A mixture of II (0.2 g.), freshly fused sodium acetate (0.2 g.), acetic anhydride (0.4 ml.) and ether (20 ml.) was allowed to stand at room temperature for 3 days, ether was evaporated and then water was added to the reaction mixture. The resulting precipitate was filtered; yield, 0.26 g.

The crude product was treated with ether (50 ml.) and the undissolved solid was crystallized from benzene as thick plates, m.p. 135°C. Analysis proved it to be a monoacetyl compound. It gave no color reaction with ferric chloride. This suggests that phenolic hydroxyl was acetylated.

Found: C, 73.89; H, 4.89; N, 4.71. Calcd. for $C_{18}H_{15}NO_3$: C, 73.72; H, 5.12; N, 4.78%.

1) J. P. Phillips and A. L. Duckwall, *J. Am. Chem. Soc.*, 77, 5505 (1955).

The crude product obtained from the ether extract by evaporating the solvent, was carefully recrystallized from ether as colorless prisms, m.p. 109～110°C. The analytical figures corresponded to those of the diacetyl derivatives.

Found: C, 71.49; H, 5.00; N, 4.06. Calcd. for $C_{20}H_{17}NO_4$: C, 71.64; H, 5.07; N, 4.18%.

II (m.p. 126～127°C) on heating with 4 N hydrochloric acid for 10 min. when no odor of benzaldehyde was noticed and further working gave a product m.p. 118～119°C foaming at 125°C.

**5, 7-Dibromo-8-quinolinol.**—*Method A.*—A mixture of the Mannich base (I) (0.33 g., 0.001 mol.) and 4 N hydrochloric acid (7 ml.) was treated in the same manner as that of Phillips[1]. The reaction mixture was neutralized with sodium acetate and the separated solid was filtered; yield, 0.65 g., m.p. 105～170°C. When it was crystallized from ethanol, it gave needles (0.17 g.) melting at 194～15°C alone or on admixture with a sample of 5, 7-dibromo-8-quinolinol which was prepared by bromination of 8-quinolinol.

*Method B.*—To a mixture of II (0.33 g. 0.001 mol.) and 4 N hydrochloric acid (7 ml.) after it was diluted with water (50 ml.), one half normal bromate-bromide solution (8 ml.) was added dropwise.

After standing for 2 hr., the resulting solid (80 mg.) was filtered and crystallized from ethanol to give colorless needles, m.p. with a sample of 5, 7-dibromo-8-quinolinol 194～195°C. A mixture of the filtrate of the crude product and an ethanolic solution of dinitro-phenylhydrazine (0.1 g.), on mild warming and long standing gave a solid, which crystallized from ethanol as orange elongated plates, m.p. 235～236.5°C and identified as benzaldehyde dinitrophenylhydrazone by mixed m.p. method.

The author wishes to thank Mr. Konomu Matsumura for help and advice throughout this work.

# *The Photochemical Addition Reaction. VI. The Mechanism of the Addition Reaction of n-Butyl Mercaptan to Vinyl Acetate*

By Kazuo YAMAGISHI, Kunio ARAKI, Tadao SUZUKI and Toshio HOSHINO

(Received September 15, 1959)

Many synthetic investigations have been made on the addition reaction of mercaptans to olefins, yielding the products of $\beta$-alkylthioethyl derivatives with anti-Markownikov configuration under the influence of oxygen, peroxides and light[1]. It has been reported that, by the action of ultraviolet light, the addition of mercaptans to olefins such as vinyl acetate, vinyl chloride and allyl alcohol, proceeds according to the following overall reaction[2];

$$RSH + CH_2:CHR' \xrightarrow{h\nu} RSCH_2CH_2R' \quad (1)$$

Recently Sivertz et al.[3] studied the kinetics of the photosensitized addition reaction of a mercaptan to various olefins in order to explain the reaction mechanism kinetically, although the identification of the reaction products was not involved in their study.

The purpose of the present study is to elucidate the mechanism of the addition reaction of mercaptans to vinyl compounds. Attention has been paid to identifying the termination product as follows: In the presence of a large excess of mercaptan, butyldisulfide has been assumed as the termination product by Sivertz et al.[3] This compound, however, has been found to decompose under ultraviolet light, which was employed for the initiation of the reaction studied. It is impossible to assume that the disulfide is the final product. Hence, the formation of the cross termination product, $\alpha$, $\beta$-dibutylthioethyl derivative could not be ignored. In this connection, the analysis of all the products in the reaction has been carried out. Vinyl acetate and *n*-butyl mercaptan were chosen as the reactants, because they form 1 : 1 adduct quantitatively with no teromer formation during the reaction.

The molar ratio of vinyl acetate to mercaptan in this experiment was 1 : 20. Samples were purified by vacuum distillation for the purpose of excluding water, oxygen and oxides. The reaction mixture was irradiated with ultraviolet light of 3660 Å for forty hours. The mixture

2) T. Hoshino, K. Yamagishi and Y. Ichikawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **74**, 510 (1953); K. Yamagishi and N. Nakajima, ibid., **75**, 1086, (1954).

3) R. H. Pallen and C. Sivertz, *Can. J. Chem.*, **35**, 723 (1957).

irradiated was first divided into gas (fraction I) and liquid at room temperature. By the distillation of the liquid fraction at 20°C (20 mmHg) it was futher divided into two parts (named fractions II and III). One was the distillate (fraction II) consisting of excessively used mercaptan and unreacted vinyl acetate, which were collected in a cold trap (−78°C), and the other was the residue (fraction III) consisting mostly of the main product, β-butylthioethyl acetate, and the termination product, α, β-dibutylthioethyl acetate.

The mass-spectroscopic analysis of fraction I showed the mass number 2 and 88, which correspond to hydrogen and ethyl acetate, respectively. By the rectification of fraction II ethyl acetate was isolated from the mixture of unreacted vinyl acetate and excessively used mercaptan. This ethyl acetate was identified by Dragendorff's xanthate color test.[4] It is, therefore, certain that the mercaptan decomposed directly under the influence of ultraviolet light, yielding hydrogen atom and thyl radical by the primary initiation reaction of Eq. 2.

Prim. init.

$$RSH \xrightarrow{h\nu} RS\cdot + H\cdot \qquad (2)$$

The hydrogen atom may subsequently react with vinyl acetate and mercaptan by the secondary initiation mechanisms a) and b).

a) When a hydrogen atom is added at the double bond of a vinyl acetate molecule, the acetoxyethyl radical is produced (Eq. 3) and the acetoxyethyl radical thus formed reacts with the mercaptan giving the thyl radical and the ethyl acetate (Eq. 4).

Sec. init. a)

$$H\cdot + CH_2:CHOAc \rightarrow CH_3\dot{C}HOAc \qquad (3)$$

$$CH_3\dot{C}HOAc + RSH \rightarrow RS\cdot + CH_3CH_2OAc \qquad (4)$$

b) When a hydrogen atom abstracts the hydrogen atom from a mercaptan molecule, a thyl radical and a hydrogen molecule are produced (Eq. 5).

Sec. init. b)

$$H\cdot + RSH \rightarrow RS\cdot + H_2 \qquad (5)$$

In either secondary initiation a) or b), the thyl radical is produced ultimately, and the radical initiates the propagation reaction of Eqs. 6 and 7.

Prop.

$$RS\cdot + CH_2:CHOAc \rightarrow RSCH_2\dot{C}HOAc \qquad (6)$$

$$RSCH_2\dot{C}HOAc + RSH \rightarrow RS\cdot + RSCH_2CH_2OAc \qquad (7)$$

By the rectification of fraction III, the main product, β-butylthioethyl acetate was obtained in a good yield with a small amount of heavy colorless liquid (b. p. 110°C at 2 mmHg), which was identical with the authentic sample of α, β-dibutylthioethyl acetate. The identification of α, β-dibutylthioethyl acetate was performed as follows: (a) The physical properties of the sample were compared with those of the authentic sample, which was prepared by the reaction of vinyl acetate with butyldisulfide under the irradiation of ultraviolet light of 3660 Å at room temperature for forty hours (Table I). (b) α, β-Dibutylthioethyl acetate was hydrolyzed to butylthioacetaldehyde. This gave the hydrazone (m. p. 63~64°C) with 2, 4-dinitrophenyl hydrazine and no depression of the melting point when mixed with the hydrazone of the authentic sample. The authentic sample of the aldehyde was prepared from bromacetaldehyde dimethyl acetal[8] and sodium mercaptid.

These facts indicate that β-butylthioethyl acetate is produced by the chain propagation reaction of Eqs. 6 and 7. The isolation of α, β-dibutylthioethyl acetate from the reaction mixture supports the view that termination reaction occurred by the mechanism shown in Eq. 8.

Term.

$$RS\cdot + RSCH_2\dot{C}HOAc \rightarrow RSCH_2CH(SR)OAc \qquad (8)$$

Further support of the initiation reaction was obtained by means of the experiment with oxygen as the quencher of atomic hydrogen. By the mass-spectroscopic analysis of fraction I, no ethyl acetate was identified, although traces of water and hydrogen were detected. This result suggests that the hydrogen atom combined with oxygen and the hydrogenperoxyl radical ($HO_2\cdot$) thus formed produced the thyl radical and hydrogen peroxide. More thyl radicals may be produced by $H_2O_2$ (Eq. 11).

$$H\cdot + O_2 \rightarrow HO_2\cdot \qquad (9)$$

$$HO_2\cdot + RSH \rightarrow RS\cdot + H_2O_2 \qquad (10)$$

$$H_2O_2 + RSH \rightarrow RS\cdot + H_2O \qquad (11)$$

fractionated and the fraction of b. p. 72.6°C was collected and the sample was stored in vacuo.

The purification of these two samples was effected at first by fractional distillation under nitrogen through a Steadmann type of glass column with 100 plates and the distillate was further purified of a high vacuum system. The out gassing of the liquid sample in the vacuum distillation was achieved by repeated freezing and pumping until no more non-condensible gas was evolved. The liquid sample in the system was then distilled into a vacuum reactor.

The purity of the vinyl acetate was checked by measuring the absorption spectrum. The original crude sample showed two bands at 2680 and 2590 Å, in which the band at 2590 Å was decided to be due to the acetaldehyde present in the sample. These impurity bands were completely removed by the purification described above and no band appeared between 2500 and 3000 Å in the spectrum of the purified sample. The purified sample showed no induction period in the polymerization initiated by 2,2'-azo-bis-*iso*-butyronitrile in the concentration of $10^{-4}$ mol. per liter. This is also an indication of the high purity of the sample.

**Apparatus.** — The parallel light from a Gleiter high pressure mercury lamp (SHL-200 W.) with a condenser was filtered with a Matsuda-UVD2 filter to obtain monochromatic light of 3660 Å. The intensity of the light was measured by a photoelectric tube and was kept constant by controlling the current through the lamp. The mass spectra were observed by a modified Hitachi RMA mass spectrometer. For the study of absorption spectra, a Beckman DU Spectrophotometer was used with 1 cm. cells.

**Procedure.**—The purified vinyl acetate (5.83 g.) and *n*-butyl mercaptan (122 g.) were measured in calibrated tubes and were mixed in a reaction cell in the molecular ratio of olefin to mercaptan 1 : 20.

The reaction cell with a reaction mixture was sealed off from the vacuum line and was irradiated with ultraviolet light of 3660 Å for forty hours. The irradiated mixture which was collected from three reaction cells, was first divided into gas (fraction I) and liquid at room temperature. By the distillation of the liquid fraction at 20°C (20 mmHg), it was further divided into two parts (named fractions II and III). One was the distillate (fraction II) consisting of excessively used mercaptan and unreacted vinyl acetate, which were collected in a cold trap (−78°C), and the other was residue (fraction III), consisting mostly of the main product, β-butylthioethyl acetate, and the termination product, α,β-dibutylthioethyl acetate.

The mass-spectroscopic analysis of fraction I showed the mass numbers 2 and 88, which correspond to hydrogen and ethyl acetate, respectively.

Fraction II was distilled fractionally with a Steadmann type glass column at an atmospheric pressure under nitrogen. One gram of crude ethyl acetate (b. p. 78.1~83.0°C) and 0.5 g. of unreacted vinyl acetate (b. p. 72.1~73.0°C) were obtained together with mercaptan. In order to confirm the existence of ethyl acetate, Dragendorff's xanthate color test[6] was carried out on the crude fraction (b. p. 78.1~83.0°C). The test showed violet color, the indication of ethoxyl residue. The same color test gave us no color with vinyl acetate and blue color with mercaptan.

Fraction III was fractionated under reduced pressure. Thirty-two grams of β-butylthioethyl acetate (b. p. 62°C at 0.7 mmHg $n_D^{25}$ 1.4954) was obtained as the main product. Another product of α,β-dibutylthioethyl acetate (0.3 g.) was identified as follows.

(a) The physical properties of the sample were compared with those of the authentic sample (Table I). The authentic sample was prepared in 30% yield by the reaction of vinyl acetate (0.1 mol.) with butyldisulfide[7] (0.5 mol.) under the irradiation of ultraviolet light of 3660 Å at room temperature for forty hours.

(b) α,β-Dibutylthioethyl acetate was hydrolyzed to butylthioacetaldehyde by steam distillation with a drop of sulfuric acid. The aldehyde gave a hydrazone (m.p. 63~64°C) with 2,4-dinitrophenyl hydrazine and no depression of the melting point when mixed with the hydrazone of the authentic sample. The authentic sample was prepared as follows: The solution of sodium mercaptid (0.5 mol.) in ethanol (200 ml.) was added to the solution of bromoacetaldehyde dimethyl acetal[8] (0.5 mol.) in ethanol (30 ml.) at room temperature. After refluxing for half an hour, sodium bromide and ethanol were removed and *n*-butylthioacetaldehyde diethyl acetal (b. p. 75°C at 0.1 mmHg, $n_D^{25}$ 1.4532) was obtained in the yield of 60.0%.

Found: C, 54.02; H, 10.43. Calcd. for $C_8H_{18}O_2S$: C, 53.91; H, 10.18%.

*n*-Butylthioacetaldehyde dimethylacetal was hydrolyzed by refluxing with dilute sulfuric acid. *n*-Butylthioacetaldehyde (b. p. 88°C at 24 mmHg) was obtained from the reaction mixture by steam distillation in the yield of 77.6%. The 2,4-dinitrophenyl hydrazone of this substance had m. p. 62.0~63.0°C.

Found: N, 17.53. Calcd. for $C_{12}H_{16}O_4N_4S$: N, 17.94%.

When oxygen was used as the quencher of atomic hydrogen the reaction mixture was exposed to dry air in the reaction cell before the irradiation and

the cell was sealed off from the vacuum line at −78°C. By the analysis of fraction I no ethyl acetate was identified, although traces of water and hydrogen were detected.

The authors are indebted to Mr. Asaji Kondo for the elementary analyses and to Mr. Haruyoshi Sakurai for the mass spectroscopic analyses. The authors' thanks are also due to Dr. Shoji Shida and Dr. Saburo Fujii for their helpful discussions in carrying out this study.

# *Synthesis and Physical Properties of Normal Higher Alcohols. II. Synthesis of Normal Higher Primary Alcohols of Odd Carbon Numbers from Heptacosanol to Heptatriacontanol*

By Akira WATANABE*

(Received August 17, 1959)

In continuation of the work described in the preceding paper[1], synthesis of the normal higher primary alcohols of odd carbon numbers containing from twenty-seven to thirty-seven carbon atoms were undertaken and gave the desired products as pure as practicable.

Heptacosanol was prepared by Bowman's method[2], which was outlined in the first paper[1], from arachidic acid and ethyl ε-bromocaproate. The reaction is shown in the following equations.

$$C_2H_5O_2C(CH_2)_nBr \xrightarrow{\text{Ethyl malonate}}$$
(I)

$$C_2H_5O_2C(CH_2)_nCH(CO_2C_2H_5)_2 \xrightarrow{C_6H_5CH_2OH}$$
(II)

$$C_6H_5CH_2O_2C(CH_2)_nCNa(CO_2CH_2C_6H_5)_2 \xrightarrow{RCOCl}$$
(III)

$$C_6H_5CH_2O_2C(CH_2)_nC(CO_2CH_2C_6H_5)COR \xrightarrow{H_2}$$
(IV)

$$HO_2C(CH_2)_nC(CO_2H)COR \xrightarrow{-CO_2}$$
(V)

$$RCO(CH_2)_{n+1}CO_2H \xrightarrow{\text{Huang-Minlon}}$$
(VI)

$$R(CH_2)_{n+2}CO_2H \xrightarrow{C_2H_5OH}$$
(VII)

$$R(CH_2)_{n+2}CO_2C_2H_5 \xrightarrow{LiAlH_4} R(CH_2)_{n+3}OH$$
(VIII) (IX)

By means of the same series of reactions but starting with higher fatty acids and ω-bromoacids, higher alcohols than heptacosanol were synthesized. Since the use of ω-bromoacids is restricted by the difficulty of their preparation in pure state when the carbon chain is considerably long, the author has used a series of long chain fatty acids along with the ω-bromoacids I where $n$ is 5, 7 and 10.

The three bromoacid ethyl esters required for condensation with ethyl malonate were prepared by the following methods. Ethyl ω-bromocaproate was obtained by the method described in the first paper. Ethyl ω-bromooctanoate was prepared, with some modification, according to Hunsdiecker's method[3]. Silver salt of ethyl hydrogen azelaate was added to the carbon tetrachloride solution of bromine in reverse of the customary procedure. The yield was 80% which was better as compared with those of the analogous synthesis of Hunsdiecker (69.7%).

Ethyl ω-bromoundecanoate was obtained from undecylenic acid by addition of dry hydrogen bromide in the presence of benzoyl peroxide followed by exhaustive esterification, according to Jones' method[4].

Besides commercially available fatty acids, the long chain fatty acids such as arachidic ($C_{20}$), tricosanoic ($C_{23}$), tetracosanoic ($C_{24}$) and pentacosanoic ($C_{25}$) acids were synthesized from octadecyl bromide, heneicosyl bromide, and docosyl bromide by repetition of the modified malonic ester synthesis[5].

The condensation products of benzyl alkanetricarboxylates with acid chlorides were semisolid brown materials which were subjected to

hydrogenation without purification, since it is known[2] that the compounds of this type can not be purified. Therefore, for the successful hydrogenation of the compounds, it is essential to purify the acid chlorides by distillation. However, since arachidyl and higher acid chlorides were found to decompose even under vacuum distillation at 2 mmHg, these acid chlorides were subjected to further reaction without distillation. In this case, oxalyl chloride proved to be superior for the preparation of acid chlorides to thionyl chloride because it furnished cleaner products. On hydrogenation considerable poisoning of the catalyst was found even when distilled acid chloride was used. After debenzylation and decarboxylation, the desired ketonic acids were obtained in low yield of about 35%, considerable amount of the starting fatty acids being recovered. Huang-Minlon reduction[6] of the ketonic acids took place readily to give the corresponding fatty acids which, after conversion to their ethyl esters, were led to the final products by reduction with lithium aluminum hydride.

6) Huang-Minlon, *J. Am. Chem. Soc.*, 68, 2487 (1946).

Repeated recrystallizations of the alcohols from benzene or toluene gave products having sharp melting points and excellent analytical values. For hentriacontanol $C_{31}H_{63}OH$ and higher alcohols high vacuum distillation as well as recrystallization was employed. In order to prevent thermal degradation during distillation, the pressure was reduced to $2\times10^{-3}$ mmHg so as to maintain the bath temperature below 210°C.

Melting points, transition points and analytical data of these alcohols are given in Table I. Heptatriacontanol $C_{37}H_{75}OH$ has not been reported previously. All the transition points have been unknown. Combination of the starting materials and the melting points of the intermediate ketonic acids and fatty acids are given in Table II. The physical properties of these alcohols are being investigated and the results will be reported in a separated communication.

## Experimental

**Preparation of ω-Bromo Acids and their Condensation with Ethyl Malonate.** — *Ethyl ε-bromocaproate.*—It was prepared from caprolactone by the method described in Part I[1]. The physical constants are as follows: b. p. 118°C/14 mmHg or 98°C/4.5 mmHg, $n_D^{32}$ 1.4561.

*Ethyl ω-bromooctanoate.*—The procedure of Hunsdiecker[3] was followed with some modification to give increased yield. Pure azelaic acid (m. p. 104~106°C) obtained by repeated recrystallizations of commercial specimen from aqueous ethanol was converted to its ethyl ester by exhaustive esterification. Boiling point of the ester was 135~137°C at 6.5 mmHg (reported: 130~132°C at 5 mmHg)[7]. Above acid (130 g.) and its ethyl ester (98 g.) were treated in the same manner as described in Organic Syntheses[8] for the preparation of ethyl hydrogen sebacate and yielded 62 g. of the monoester; b. p. 161 ~ 163°C/1 mmHg (reported: 169 ~ 170°C/2 mmHg)[9]. Silver salt of the monoester was prepared by an analogous manner described in Part I[1] for the preparation of silver heneicosanoate. The thoroughly dried silver salt (85 g.) was added portionwise to a solution of 60 g. of bromine in 100 ml. of carbon tetrachloride under strict exclusion of moisture. A vigorous reaction ensued with evolution of carbon dioxide. When no more gas evolved, the solution was filtered, washed with water, aqueous solution of sodium hydroxide, again water, and dried over sodium sulfate. Following evaporation of the solvent the residue was distilled through a short Widmer column to give a liquid having a boiling point of 125°C at 3.5 mmHg. $n_D^{27}$, 1.4572: Yield, 53 g. (80%), (reported: 69.7% for methyl compound)[3].

*Ethyl ω-bromoundecanoate.* — The preparation of the corresponding acid was essentially the same as the method described by Jones[4]. The melting point of the acid was 48~49.5°C (reported: 49~50°C).

Ethylester of the acid was obtained in an almost quantitative yield by exhaustive esterification. b. p. 148~150°C/5 mmHg, m. p. 11.5~13.5°C, $n_D^{20}$ 1.4651.

The three ethyl esters of ω-bromo acids mentioned above were condensed with sodiomalonic ester by an usual method to give ethyl alkanetricarboxylates in good yields. The constants are: *Ethyl n-hexane-1, 1, 6-tricarboxylate* (II where $n$ is 5): b. p. 150~151°C/1 mmHg, $n_D^{28}$ 1.4360. *Ethyl n-octane-1, 1, 8-tricarboxylate* (II where $n$ is 7): b. p. 170~172°C/1.5 mmHg, $n_D^{28}$ 1.4380. *Ethyl n-undecane-1, 1, 11-tricarboxylate* (II where $n$ is 10): b. p. 187°C/1 mmHg, $n_D^{28}$ 1.4435.

**Preparation of Long Chain Fatty Acids.**—Except heneicosyl bromide which was prepared from behenic acid by degradative bromination[1], a long chain alkyl bromides were made by the reduction of the corresponding acid esters to the alcohols by high pressure hydrogenation or using lithium aluminum hydride followed by treatment with hydrogen bromide. Further treatment of the alkyl bromides with sodiomalonic ester in butanol[5] in place of ethanol led to the acids of two additional carbon atoms. Since these reactions are relatively well known, detailed descriptions of the experiments were omitted and the results are summarized in Table III.

**Preparation of Higher Alcohols.** — General procedures of the synthesis are very similar throughout the series, so only an example for the preparation of heptatriacontanol $C_{37}H_{75}OH$ is described in detail.

*Benzyl n-undecane-1, 1, 11-tricarboxylate.* — To a suspension of sodium ethoxide (prepared from 0.38 g. of freshly cut sodium and 10 ml. of absolute ethanol) in benzene was added 6.15 g. of ethyl undecane-1, 1, 11-tricarboxylate. After the sodium ethoxide dissolved 5.35 g. of purified benzyl alcohol was added, the mixture was distilled through a Fenske column until the boiling point reached to 80°C. During this time an almost theoretical quantity of ethanol was removed.

*13-Keto-heptatriacontanoic acid* $C_{24}H_{49}CO(CH_2)_{11}\cdot CO_2H$.—To the benzene solution of the above tribenzyl esters was added gradually 6 g. of pentacosanoyl chloride in benzene (prepared from 5.8 g. of pentacosanoic acid and 7.5 g. of oxalyl chloride, and excess of the oxalyl chloride was removed under reduced pressure at 100°C). The reaction mixture was refluxed for 1 hr. After cooling, the solution was washed with ice water to neutral reaction and then dried over sodium sulfate. The solvent was removed under reduced pressure at 50°C of bath temperature to give a brown colored oil which solidified on standing at room temperature. Yield, 20 g. Hydrogenation of the above compounds in 60 ml. of ethyl acetate over Pd-C (5 g.) and Pd-$SrCO_3$ (5 g.) took place at a slightly positive hydrogen pressure, accompanying a considerable poisoning of the catalysts. A nearly theoretical amount of hydrogen was absorbed within 3 hr. The catalyst was filtered off, then the ethyl acetate solution was refluxed for 1 hr. to decarboxylate compound V. Upon cooling to room temperature, small crystals were separated. They were recrystallized twice from ethyl acetate to give the product

having a melting point of 105 to 107°C. Further recrystallizations from benzene gave a pure acid. m. p. 108~109°C. Yield, 3.2 g. (37%). From the mother liquor, 2.5 g. of the pentacosanoic acid was recovered.

*Heptatriacontanoic acid* $C_{36}H_{73}CO_2H$.—The Hung-Minlon reduction of long chain ketonic acid was found to be superior to the Clemmensen reduction[4], because of its effectiveness and simplicity. The experimental conditions were essentially the same as those described in the first paper. A mixture of 3 g. of the ketonic acid, 3 g. of potassium hydroxide, 3 ml. of 85% hydrazine hydrate and 25 ml. of diethylene glycol (b. p. 250°C) was refluxed for 1 hr. After removing the water formed, the temperature of the mixture was gradually raised to 200°C and the refluxing was continued at this temperature for 6 hr. When the mixture was cooled to about 80°C. it was poured into a 100 ml. of water containing 15 ml. of hydrochloric acid with stirring. A white solid separated was collected and washed with water, and then dried. Yield of the crude acid was nearly quantitative. Repeated recrystallizations from benzene and then toluene gave a pure product with little loss of the material, m. p. 97.5~98.5°C.

Found: C, 78.42; H, 13.10. Calcd. for $C_{37}H_{72}O_3$: C, 78.66; H, 12.85%.

*Heptatriacontanol* $C_{37}H_{75}OH$.—Ethyl heptatriacontanoate (2.5 g.) was readily reduced to the alcohol with lithium aluminum hydride in absolute ether[1]. The reaction mixture was hydrolyzed to remove the small amount of unchanged ester, but traces of alkali or soap could not be removed from the product by crystallization. Pure alcohol could be obtained by high vacuum distillation at $2\times10^{-3}$ mmHg followed by repeated crystallizations from toluene, m. p. 92~92.7°C. Yield, 1.8 g.

# *Benzylideneaniline. I. Structure and Ultraviolet Absorption Spectrum of Benzylideneaniline*

By Nozomu EBARA

(Received July 31, 1959)

Benzylideneaniline has been believed to assume a planar structure without any experimental proof, as it has a similar molecular constitution as stilbene or azobenzene, of which the geometries are proved to be planar by the aid of X-ray diffraction method[1]. Benzylideneaniline, however, has many unusual properties which can not be accounted for by the planar structure.

1) Imoto[2] measured the p$K$ values of the several carboxyl derivatives of substituted benzylideneanilines and found that the conduction of the effects of the substituents across the central C=N double bond is extraordinarily small. His data show that *N*-(substituted benzylidene)-*p*-aminobenzoic acid has the p$K$ value almost equal to that of *p*-aminobenzoic acid.

2) Hertel and Schinzel[3] investigated the reaction of methyl iodide with the lone pair electron of N atom in benzylideneaniline and found that the substituents on the aniline ring exert remarkable effects on reaction velocity, while the effects of the substituents on the other ring are negligibly small.

3) The dipole moment of *p,p'*-dinitrobenzylideneaniline was reported to have the intermediate value between those expected for *trans* and *cis* forms[4].

4) Benzylideneaniline seems to show no geometrical isomerism, in contrast to stilbene, azobenzene and azoxybenzene, of which the two isomers can be detected and easily separated. Wyman[5], by means of the rotating-shutter technique, found that the solution of this substance does not show any spectral change when exposed to light. Gaouck and LeFèvre[6] investigated the polymorphic crystals of the derivatives of benzylideneaniline by means of

6) V. De Gaouk and R. J. W. LeFèvre, *J. Chem. Soc.*, **1938**, 741.

the measurements of dipole moments and of absorption spectra, and concluded that these molecules exist exclusively in *trans* forms.

5) It has been shown[7] that the phase diagrams of the admixtures of benzylideneaniline with *trans*-stilbene, *trans*-azobenzene, phenanthridine or bibenzyl[8] involve discontinuous curves, while those of the admixtures between *trans*-stilbene, *trans*-azobenzene and bibenzyl speak for the perfect miscibility. This fact is likely to show that the structure of benzylideneaniline corresponds to neither *trans* nor *cis* form.

6) The shape of the ultraviolet absorption spectrum of benzylideneaniline is quite different from those of stilbene, azobenzene and azoxybenzene, which resemble each other very closely. Wiegand and Merkel[7] found that the spectrum of 2-phenylbenzimidazole (I) exhibits a similarity to stilbene and not to benzylideneaniline, while that of 2-phenylindene (II) is very much similar to that of stilbene, where I and II must have planar *trans* structures. They proposed a linear planar structure for benzylideneaniline, but it seems inadequate, as it has no theoretical basis and is energetically less favorable.

I II

7) Benzylideneaniline shows no $n-\pi^*$ transition at the longer wavelength region. Jaffé[9] has assumed that this transition is hidden under the long tapering end of the absorption curve of 315 m$\mu$ band, but it appears that the strong experimental support is lacking for this assumption.

These experimental facts are not consistent with the generally accepted stilbene-type structure, and yet very few works have been carried out with regard to the very nature of the benzylideneanilinemolecule. Therefore, series of experiments are now undertaken to explain some fundamental problems of benzylideneaniline.

## Results and Discussion

Measurements were carried out on the ultraviolet absorption spectra of benzylideneaniline, stilbene, azobenzene and azoxybenzene in *n*-heptane, ethanol and 50% mixture of ethanol and concentrated hydrochloric acid, together with their variations caused by the substituent groups, and for comparison, spectra of some aromatic compounds were also measured. The results are shown in Tables I and II and in Fig. 1.

If benzylideneaniline assumes the stilbene-type planar structure, there must be some substantial similarity in behavior between the spectra of benzylideneaniline and of stilbene, azobenzene or azoxybenzene.

Stilbene, as well as azobenzene and azoxybenzene, shows an intense absorption maximum near 300~320 mμ, which has been interpreted to be the $\pi-\pi^*$ transition[9-12]. This band shifts toward longer wavelength when *p*-position is substituted. The spectrum of azobenzene in concentrated sulfuric acid was measured by several authors, and it was suggested that the band at 320 mμ in neutral solvent shifts to 420 mμ in acidic medium, whereby its intensity also increases considerably. This shift has been explained by Jaffé[9] in terms of the LCAO

method by taking into account the increase of Coulombic integral of the nitrogen atom when proton attaches to it.

In the present experiment the activity of proton seems to be insufficient to convert the substance completely into its conjugate acid, and it can be inferred from Fig. 3 that there is

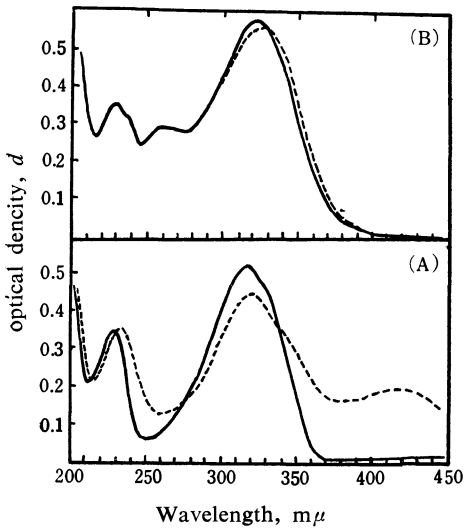

Fig. 3. Spectra of (A) azobenzene and (B) azoxybenzene in —— $C_2H_5OH$ and in ------ $C_2H_5OH$+conc. HCl

an equilibrium between azobenzene and its conjugate acid. In the same condition, azoxybenzene does not undergo any remarkable change in spectrum. This fact may be explained by the consideration that owing to the inductive effect of N→O coordination, basicity of this molecule is greatly reduced compared with that of azobenzene. But the inspection of the shape of the spectrum is likely to tell that also in this case a red shift occurs when conjugate acid is formed.

Benzylideneaniline shows an intense band at 263 mμ and a weak band at about 315 mμ, the latter has been assigned as the $\pi-\pi^*$ transition which corresponds to that of stilbene near 300 mμ[9]. But it can hardly be accepted when one compares it with those of azobenzene or azoxybenzene, as the reduction of symmetry in benzylideneaniline would not reduce the intensity more than that of azoxybenzene. Also it is difficult to assume the 263 mμ band as this transition, as its wavelength is too short and the substituents on the ring exert too little effects upon this band as compared with stilbene or azobenzene. In addition to this, these interpretation can not account for the aforementioned spectrum of 2-phenylbenzimidazole (I), for which the planar *trans* structure is to be assumed. Moreover, acidic medium causes large

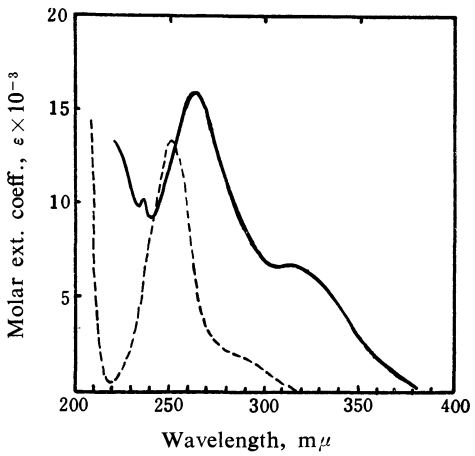

Fig. 4. Spectra of benzylideneaniline —— and its conjugate acid ---- (in $C_2H_5OH$)

unexpected change on these bands (Fig. 4): these bands become weak and shift toward shorter wavelengths, and the spectrum of free base diminishes completely. Measurements were made with various acid concentrations, but no change occurs unless acid concentration was reduced below $\cdot 10^{-3}$ mol./l. (the base concentration remaining about $10^{-4}$ mol./l.). In addition to this, these shifted bands are at the same position even when the aniline ring is substituted. As there is no time-dependence in spectrum during the measurements, and the decomposition rate of this molecule is found to be not so large, this spectrum must be attributed to the conjugate acid.

To explain these experimental results, together with the peculiarities cited above, an alternative geometrical structure must be proposed for this molecule. One possible structure may be such that the benzene ring at the N side is nearly perpendicular to the rest of the molecule (which accounts for problem 5 cited above).

When this structure is assumed, there may be a strong aniline-type resonance interaction, and, as a result, the $n-\pi^*$ transition is necessarily missing (problem 7). In addition, the interaction of benzene rings across the C=N double bond would be reduced to a large extent (problem 1), and the ultraviolet absorption spectrum would become close to the superposition of those of its components, aniline-type and styrene-type (problem 6). Then the substituent on the aniline ring would exert a large influence upon the lone-pair electron, whereas that on the other ring would not (problem 2).

The absence of geometrical isomerism can also be explained with this model. The C–N–C bond angle may be 120° with $sp^2$ hybridization, 180° with $sp$ hybridization or intermediate with higher order hybridization. If it is 180°, there can be no geometrical isomerism at all; if it is

120° or intermediate, there may be bending isomerization through intermediate *sp* structure, where the benzene ring would become absolutely perpendicular so as to reduce the energy of this state by the increase of resonance interaction between nitrogen non-bonding orbital and benzene $\pi$ orbital, and this would permit the undetectably fast reaction (problem 4). Probably the hybridization and the angle of the twist of the benzene ring would be such as to minimize the energy of the molecule, and when the ring is almost perpendicular, the hybridization will be close to *sp*.

Whether this is the case or not may be inferred also from the examination of the absorption spectra.

The spectra of the conjugate acids must be similar to the superposition of those of substituted anilinium ions and the conjugate acid of *N*-benzylidene-alkylamine, with a slight modification caused by the small interaction between these two. In benzylideneaniline, the former should have the absorption maximum at 254 m$\mu$, of which the intensity is so weak that it should be hidden under the intense band of the latter. The latter is isoelectronic with benzaldehyde and the bands of conjugate acids at 250 and 290 m$\mu$ can be compared with 249.5 and 285 m$\mu$ bands of benzaldehyde, respectively (247 m$\mu$ of benzylidene-methylamine). In the case of the conjugate acids of benzylidene-*m*- and -*p*-nitroaniline, 252 m$\mu$ band is very intense, perhaps owing to the overlap of the intense 268.5 m$\mu$ band of nitrobenzene component, as its extinction coefficient is just in the same magnitude as the sum of those of two components. For the conjugate acid of benzylidene-*o*- and -*p*-anisidine, there is an additional band at 220 m$\mu$ which coincides with 217 m$\mu$ band of anisole, intensified by the substituent ($-N^+=$). Also the 220 m$\mu$ band of chlorine-substituted conjugate acids can be compared with the 210 m$\mu$ band of chlorobenzene (216 m$\mu$ of *p*-chloranilinium ion).

The assignment of the bands near 360~370 m$\mu$ are not certain, but one tentative explanation is that they may be the transitions between orbitals of the two components, as their intensities are of the order of $n-\pi^*$ transition**.

The assignment of the spectra of free bases is more obscure, but the bands near 315 m$\mu$ experience considerable perturbation due to the introduction of substituents and can presumably be compared with the 285 m$\mu$ band of aniline (296 m$\mu$ of dimethylaniline). The latter is found to correspond with $A_{1g}$–$B_{2u}$ transition of benzene at 260 m$\mu$, allowed by the perturbation of the amino-substituent group, and becomes more intense and shifts toward red by successive substitution, because perturbation becomes larger. In the case of benzylideneanilines, the orbitals will mix to some extent with those of the other benzaldehyde-type part; therefore, one can probably expect that their positions and intensities may be such as these.

The band at 264 m$\mu$ is more difficult to interprete, but the absence of the effects of the substituents on this band is likely to show that this band comes from the styrene-type part; i.e. corresponds to the 250 m$\mu$ band. It seems at first unlikely that in the conjugate acid the band shifts toward shorter wavelength. However, this can probably be accepted when one assumes that the nitrogen valence orbital is nearly *sp* in free base but becomes $sp^2$ when conjugate acid is formed, and that the C=N bond length is longer in *sp* than in $sp^2$. Calculation was carried out for the transition energy of R–N=CH–$C_6H_5$ (R=alkyl) by the simple LCAO method, assuming that for the conjugate acid the Coulombic integral of N atom is $\alpha+\beta$, the exchange integral of C=N bond, which must have strong double bond character, $1.2\beta$, and that of C–$C_{ring}$, which is predominantly single, $0.6\beta$ and for the free base, these integrals are $\alpha+\beta/2$, $\beta$ and $0.6\beta$, respectively; where $\alpha$ and $\beta$ represent their usual meanings (Fig. 5). The

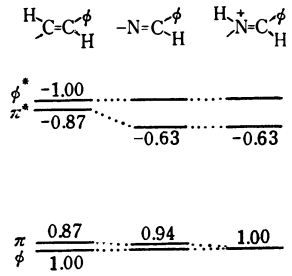

Fig. 5. Energy diagram (in $\beta$ unit).

result shows that the effect of the change in C=N bond length offsets the reverse effect of the change in Coulombic integral of the nitrogen atom, and the hypsochromic shift will occur when conjugate acid is formed.

Other bands near 230~240 m$\mu$ may be attributed to the aniline-type part, as their positions coincide and their intensities are of comparable magnitude.

The spectrum of benzylidene-*p*-nitroaniline exhibits the striking feature that it changes greatly with the solvent, whereas those of chloro-, methoxy- or unsubstituted benzylideneaniline does not. The 380 m$\mu$ band in ethanol shifts to 320 m$\mu$ in *n*-heptane, and its intensity decreases. This is not the case in *p*-nitrostilbene or -azobenzene, and it is highly likely that this band corresponds to 370 m$\mu$ *p*-nitroaniline charge-transfer band, and that the band at 243

** Or it may be that they come from the decomposition products.

mμ is the superposition of 230 mμ of *p*-nitroaniline and 250 mμ of styrene-type part. Their intensities are also consistent with this assumption. In this case, owing to the large charge-transfer resonance interaction between nitro group and nitrogen non-bonding electron, the molecule would assume almost perpendicular conformation with the result that the spectrum of this molecule is much more similar to the superposition of those of components as compared with those of any other benzylideneanilines.

There are some experimental evidences which seem to contradict this assumption. For example, Raman spectra show that the frequencies of C=N stretching vibrations of R–C=N–R′ type compounds decrease in the order R–C=N–R′> R–C=N–Ar> Ar–C=N–Ar, where R and R′ denote alkyl groups—the fact which is parallel to that of the corresponding C=C compounds[13]. This fact is at first likely to show that benzylideneaniline has the planar conformation and the increase of the number of benzene rings causes the increase of resonance interaction, and therefore decreases the force constant of vibration. But in the present model, the resonance interaction will increase though to a smaller extent, and in addition to this, hybridization-change will occur when R′ is replaced by $C_6H_5$, which would also tend to reduce the force constant.

Another strong objection to this assumption is the evidence of photoisomerism of this substance at low temperature[14]. It is not certain whether this is *cis-trans* isomerism, but if it is so, one explanation is that the bending isomerization is frozen at low temperature.

Some question may arise why benzylideneaniline can assume this structure, while azobenzene can not, and why it does not return to the planar structure when proton attaches to it. In this respect, the author has the impression, though merely speculative at this stage, that azobenzene also behaves in somewhat like manner in solution, and its thermal *cis-trans* isomerization is the mixture of ordinary and bending ones, because it belongs to neither of the two types classified by Eyring[15]. This point will be investigated in future.

## Experimental

Benzylideneanilines were prepared by direct condensation of benzaldehyde with corresponding anilines. Stilbene and azobenzene were prepared by recrystallization of commercial substances. *p*-Methoxy-stilbene was kindly supplied by Mr. H. Suzuki. Azoxybenzene was prepared by treating nitrosobenzene with ethanol and sodium hydroxide.

Absorption spectra were measured by Cary self-recording spectrophotometer model 14 M using 1 cm. quartz cell.

## Summary

The ultraviolet absorption spectra of benzylideneanilines, as well as of their conjugate acids, have been measured.

These spectra can not be explained with the ever believed stilbene-type planar structures of these molecules.

An alternative structure is proposed for benzylideneaniline with the benzene ring of aniline part nearly perpendicular to the rest of the molecule.

This structure also adequately explains many experimental evidences, which have been investigated previously but are not accounted for by the planar structure.

The author wishes to express his sincere thanks to Professor S. Nagakura for his kind instruction throughout this study. Thanks are also due to Professor K. Shiomi and to the members of his laboratory for their fruitful discussions.

# *Benzylideneaniline. II. Iodine Complexes of Benzylideneaniline and its Derivatives*

By Nozomu EBARA

(Received July 31, 1959)

In the preceding paper the author proposed for benzylideneaniline a structure with the benzene ring of N side nearly perpendicular to the rest of the molecule. Then the non-bonding electron will migrate into the benzene ring to a large extent, and the ionization potential of the lone-pair electron will increase and its donor ability will decrease compared with the case where there is no interaction. To examine the validity of this assumption, the nature of the lone-pair electron is now investigated by means of the measurement of the equilibrium constant of iodine complex.

**Iodine Complex.**—The interaction between iodine molecule and aromatic compounds was firstly suggested by Benesi and Hildebrand[1] to be the acid-base type interaction, where the iodine molecule behaves as an acid and the aromatic molecule as a base. It has been shown by Mulliken[2] that this type of interaction is based upon charge-transfer resonance stablilization, and the new absorption band in the ultraviolet region, which was absent in both component molecules but now comes into appearence in the complex, can be interpreted as the charge-transfar band, for which this resonance interaction is responsible. This band was also explained by Kuboyama and Nagakura[3] from the LCMO treatment to be due to the electron transition from the perturbed higest filled orbital of the donor component to the lowest vacant $\sigma_u$ MO of iodine component. Also the absorption band of $I_2$ shifts toward shorter wavelengths when a complex is formed, which again can be interpreted from the consideration that the $\sigma_u$ MO of $I_2$ is raised while the $\pi_g$ MO is not so much affected[4]. This phenomenon has been investigated extensively by many authors[2-7] for a large variety of compounds including as bases those with lone pair electrons or $\pi$-electrons, and the equilibrium constants, as well as heats and entropies of formation of these complexes have been measured[8-10].

Hastings, Franklin, Schiller and Matsen[11] and McConnell, Ham and Platt[12] correlated the positions of charge-transfer absorption maxima with the ionization potentials of the donor molecules and found an excellent agreement between theory and experiments.

When benzylideneaniline is used as the base, the donor orbital may be non-bonding orbital, $\pi$-orbital or both, and the position of the charge-transfer band will be the fingerpost for assuming the ionization potential of the donor orbital, and the equilibrium constant will serve as a criterion of the geometry of this molecule.

## Results and Discussion

carbon tetrachloride in the visible region is shown in Fig. 1, the concentration of the former being constant. It shows an apparent isosbestic point, which proves the formation of 1 : 1 complex. Regrettably enough, as benzylideneaniline absorbs light considerably in the region below 400 mμ, and the equilibrium constant of the complex at the room temperature is found to be very small, no charge-transfer band could be observed on account of experimental difficulty. But the shift of $I_2$ band is considerable, from which the equilibrium constant could be calculated.

The equilibrium constant can be calculated by means of the equation

$$d=C_1\varepsilon_c+(C_1\varepsilon_i-d)/C_2K$$

where $d$ is the optical density of the mixture solution at the measured wavelength, $C_1$ and $C_2$ are the concentrations of iodine and benzylideneaniline, respectively, $\varepsilon_i$ and $\varepsilon_c$ are the molar extinction coefficients of iodine and complex, respectively, at the wavelength, and $K$ is the equilibrium constant. This equation can easily be derived from the law of mass action of 1 : 1 complex, with the consideration that the concentration of benzylideneaniline is actually not altered, as it is so high compared with that of iodine, and that the observed optical density is the sum of those of iodine and a complex. As the absorption due to benzylideneaniline can not be ignored, measurements were carried out with the benzylideneaniline solutions as references.

The values of $d$ are plotted against $(C_1\varepsilon_i-d)/C_2$ (Fig. 2). They fall on straight lines which are parallel to each other, of which the slope indicates $1/K$.

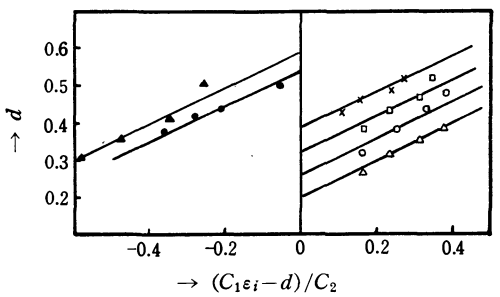

Fig. 2. Plots of $d$ values against $(C_1\varepsilon_i-d)/C_2$.

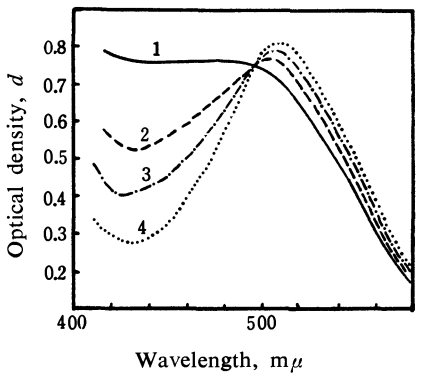

Fig. 3. Spectra of benzylidene-*p*-anisidine+$I_2$ in $CCl_4$; Base concentration: 1, —— 0.83; 2, ---- 0.42; 3, -·-· 0.21; 4, ····· 0.10 mol./l. $I_2$ concentration $2.68\times10^{-4}$ mol./l.

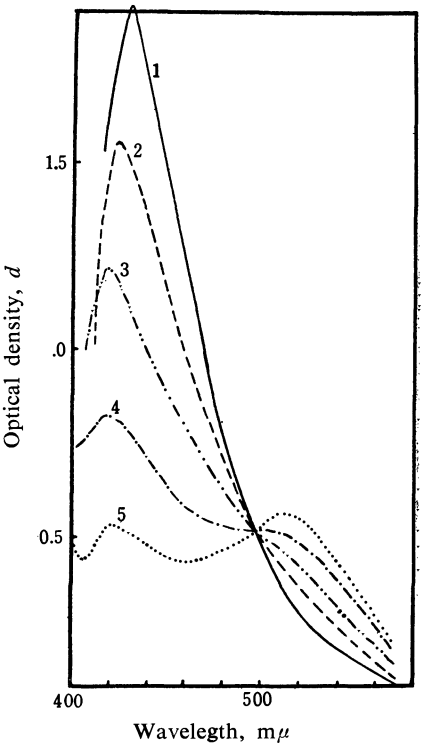

Fig. 4. Spectra of benzylidene-*o*-anisidine+$I_2$ in $CCl_4$; Base concentration: 1, —— 0.83; 2, ---- 0.42; 3, ·····-0.21; 4, ·-·- 0.10; 5, ····· 0.05 mol./l. $I_2$ concentration $1.93\times10^{-4}$ mol./l.

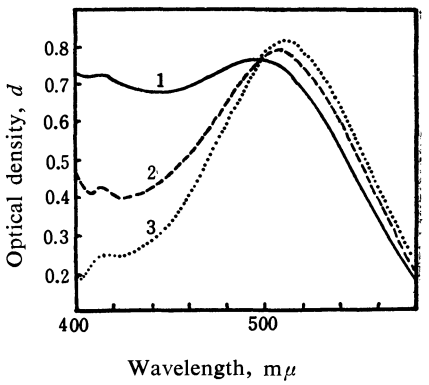

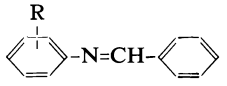

Fig. 5. Spectra of benzylidene-*o*-chloroaniline +$I_2$ in $CCl_4$; Base concentration: 1, —— 0.83; 2, ---- 0.42; 3, ····· 0.21 mol./l. $I_2$ concentration $2.68\times10^{-4}$ mol./l.

The spectra of iodine complexes of benzylidene-*p*- and *o*-anisidine are shown in Figs. 3 and 4. There is a maximum near 420~430 mμ for the latter, which is too intense to be a perturbed iodine transition, and probably it is the charge-transfer band. For the former compound, this band seems to appear at shorter wavelength. The spectra of the chlorine derivatives also show the same peculiarity for the ortho-compound (Fig. 5).

The appropriate values are listed in Table I.

TABLE I. EQUILIBRIUM CONSTANTS OF IODINE COMPLEXES OF BENZYLIDENEANILINES IN $CCl_4$ AT 11.0°C

| R | $K$ |
|---|---|
| H | 2.0 |
| *o*-$OCH_3$ | 10.6 |
| *p*-$OCH_3$ | 9.2 |
| *o*-Cl | 2.4 |
| *m*-Cl | 2.0 |
| *p*-Cl | 2.7 |

The positions of $I_2$ absorption maxima could not strictly be defined, as, at the shorter wavelengths, the absorption due to the free base and presumably due to the charge-transfer band becomes large and the exact calculations are not feasible. But the color of the solutions is bright golden yellow and the calculation shows that their positions should not be above 460 mμ. As the shifts of $I_2$ band in aromatic hydrocarbons are usually not more than 10~20 mμ, it can probably be safe to say that the iodine molecule attaches predominantly to the lone-pair orbital, which is to be more favored, if the steric requirement is fulfilled.

The influence of the methoxyl group in the aniline ring is remarkable. One explanation is that the iodine molecule attaches to the oxygen atom of the substituent, but this is not likely to be the case, because the increment of $K$ is too large to be interpreted under this assumption. Moreover, it can not account for the larger values of $K$ and longer wavelengths of the charge-transfer bands of ortho-derivatives.

If the proposed structure is assumed, it may be said that the methoxyl group will reduce the ionization potential of the lone-pair electron of the nitrogen atom and facilitate complex formation, and for *o*-methoxy-derivative, in addition to this, the two parallel and closely standing non-bonding orbitals with almost the same size will interact strongly with the iodine molecule and stabilize the complex. For the chlorine derivatives, the effects of the substituent would be small and the $K$ values not much different from that of the unsubstituted molecule as expected, and for the *o*-chloro-compound, owing to the large size of chlorine atom, the steric hindrance will predominate over other factors affecting the equilibrium.

The equilibrium constant of benzylideneaniline is unexpectedly small and can be compared with those of the hydrocarbons. But for dimethylaniline, $K$ is also small[13], and this is probably partly due to the increase of the ionization potential of the lone-pair electron caused by its migration into the benzene ring and partly due to the steric inhibition rather than to the complex formation with π-orbital as the donor, as other evidences tend to support the former model.

When the almost perpendicular structure is assumed, the hybridization of nitrogen-valence-orbitals will approach largely to the *sp*-type, then the non-bonding orbital will be almost of the *p*-type. Furthermore, as the interaction of the latter with the benzene ring is of the order of perturbation, it must retain largely its original *p* structure. This orbital is less concentrated along one direction than $sp^2$ orbital, and can not overlap well with $I_2$ orbital unless this comes nearer. This would cause the increase of steric hindrance and decrease the equilibrium constants.

## Experimental

Preparations of benzylideneanilines were described in the previous paper. Iodine was sublimed two times from the G. R. grade commercial substance.

Absorption spectra were measured by a Cary self-recording spectro photometer model 14 M and a Hitachi EPU 2 type spectrophotometer using 1 cm. quartz cell. Measurements were made as soon as the solutions were prepared, so as to avoid the change due to the reaction. Reaction occurs in considerable extent when the mixture is left standing for a long time, but in the course of measurement no remarkable change was observed.

## Summary

Absorption spectra of the mixtures of iodine with benzylideneanilines in various concentrations have been measured, and from the optical densities of the solutions the equilibrium constants have been calculated.

The equilibrium constants are unexpectedly small. But for methoxy-derivatives and especially for ortho-compound, the equilibrium constants are considerably large.

For *o*-methoxy- and *o*-chloro-derivatives, the charge-transfer bands appear at the longer wavelengths.

# *Biochemical Studies on Pearl. IX. Amino Acid Composition of Conchiolin in Pearl and Shell*

By Shozo TANAKA, Hiroyuki HATANO and Osamu ITASAKA*

(Received August 4, 1959)

An organic constituent of shells of molluscs was first named conchiolin by Frémy, and then it was recognized as a kind of protein by Schlossberger and Voit[1]. The amino acid constituents of this protein were studied by Krukenberg & Engel[1], Wetzel[2], Stary & Andratschke[3] and Friza[4]; and the presence of glycine, leucine, tyrosine, tryptophane and arginine was found in hydrolysates of conchiolin. Amino acid components of conchiolin prepared from different species of molluscs were also studied by Roche, Ranson & Eysseric-Lafon[5] and by Grégoire, Duchâteau & Florkin[6]. The composition of various kinds of conchiolin was reported to differ with the kinds of molluscs from which they were prepared. The authors have reported that about fifteen kinds of amino acids were found in hydrolysates of conchiolin prepared from the pearls and the shells of pearl oysters[7]. Halogen-containing amino acids, iodotyrosine and bromotyrosine, which are known as the peculiar components of screloproteins obtained from calciferous skeletons of marine invertebrata such as sponge and gorgonia, were not found in conchiolin of pearls and shells[7].

Electron-microscopic studies on conchiolin by Grégoire, Duchâteau & Florkin[6] and also by Grégoire[8] alone showed that the physical structure of conchiolin in the shells was reticulated unlike that of keratin or collagen which has fibrous structure. Conchiolin has been reported to be successfully fractionated into several preparations by suitable chemical reagents[6,9]. From chemical and crystallographical studies on the pearls and the shells of pearl oysters, the nacre of pearls was found to be identical with the nacreous layer of shells but quite different from the prismatic layer of shells[10]. These results may be of interest in studying the correlation between physical observations and chemical structures. This paper deals with the results of quantitative analyses of amino acids in the hydrolysates of conchiolin prepared from the pearl and the two layers of the shell of an oyster.

## Experimental

**Materials.**—*The pearl and the shell of the pearl oyster.*—The pearls were harvested from the pearl oysters, *Pinctada martensii* (Dünker)**, which had been cultured in the pearl farm at Matoya Bay near Kashikojima during two winters after culture operations. The shells were obtained from the same pearl oysters. Both were rinsed thoroughly with tap water and with distilled water, and then dried at room temperature.

*The nacreous substance of pearls.*—This substance was obtained from crushed pearls, from which nuclei had been mechanically taken away.

*The nacreous substance of shells.*—This substance was obtained from shell valves by grinding off prismatic substances after removing the sea-weed

and other adhering materials from the surface.

*The prismatic substance of shells.*—This substance was obtained from the thin posterior shell margins. All materials were crushed and pulverized into powder of about ten mesh, washed with tap water, and dried at room temperature.

**Conchiolin.** — Conchiolin was prepared from the above materials by the method described in the previous paper[7]. The materials were immersed in 1 N hydrochloric acid solutions, which were frequently renewed, until no more evolution of carbon dioxide was observed in vacuo. Insoluble matter was washed several times with distilled water and was dialyzed against running water until the chloride ion in the dialyzate became undetectable. The conchiolin prepared from the nacre of pearls and from the nacreous substance of shells had a faint yellowish color, but that from the prismatic layer of shells, had a reddish-brown tint.

**Methods.**—*Preparation of the conchiolin hydrolysates.*—About 50 mg. of pulverized conchiolin was hydrolyzed with 5 ml. of 6 N hydrochloric acid at 100°C in a sealed tube for 30 hr. After small amounts of humin formed were filtered off, the hydrochloric acid was evaporated in vacuo repeatedly. The hydrolysate was dissolved into a mixture of *n*-butanol, *n*-propanol, and 0.1 N hydrochloric acid (1 : 2 : 1, v/v).

**Amino Acid Analysis.**—The analyses were carried out chromatographically by Stein and Moore's method on starch columns[11-13]. The preparatory procedure of the columns of potato starch (150 mesh), the selection of solvents and also the procedure for chromatography followed the description by Stein and Moore[11-13]. Columns of 0.9 cm. × 40 cm. of starch containing 30% of water were prepared and were washed under pressure of 150 mmHg until the washings became negative to a ninhydrin test. The hydrolysate was poured on the columns under pressure of 150 mmHg. Two kinds of solvent were used for elution. Solvent I was a mixture of *n*-butanol, *n*-propanol, and 0.1 N hydrochloric acid (1 : 2 : 1, v/v) and Solvent II was composed of *n*-propanol and 0.5 N hydrochloric acid (2 : 1, v/v). The eluting rate had been controlled as 1.5 ml. of the effluent per hour at the optimum velocity.

Each 0.5 ml. of the effluent fractions was collected by an automatic fraction collector. The amount of amino acids in each effluent fraction was estimated by the colorimetric ninhydrin method[14]. A solution of 250 ml. of ethylcellosolve containing 5 ml. of 0.01 M potassium cyanate, a solution of 2.5 g. ninhydrin in 50 ml. of ethylcellosolve and a 0.2 M citrate buffer solution adjusted to pH 5.4 with 1 N sodium hydroxide, were mixed. After each 0.5 ml. of the effluent aliquot was adjusted to pH 5.4 with 1 N sodium hydroxide in the case of Solvent II, though the pH was not controlled in the case of Solvent I, 0.5 ml. of the citrate buffer solution and 0.5 ml. of the ninhydrin reagent were added to the effluent. The mixed solution was allowed to stand for 20 min. in a boiling water bath. By heating the definite volume of the reaction mixture (5 ml.) with 60% ethanol, violet color was developed. Colorimetric determination was carried out by measuring the optical density of the coloring solution at 570 mμ by using a Beckman model DU spectrophotometer. Only for proline, the measurement was done at 440 mμ. The color yield of each amino acid was determined by comparing it with that of pure amino acid, respectively.

## Results and Discussion

The mensuration curves obtained with the hydrolysates of conchiolin from the nacre of pearls, the nacreous substance and the prismatic substance of shells, are shown in Fig. 1.

It was noticed that relatively large amounts of leucines, alanine, glycine, and cystine are contained in both conchiolin from the pearls and the shells. Proline was not recognized in conchiolin from the nacre of the pearl and the nacreous layer of the shell, while its existence was proved in conchiolin from the prismatic substance of the shell.

It is of interest that a relatively large amount of cystine is found in conchiolin. The fact may suggest a fibrous structure of conchiolin, like keratin in the hair and the skin which

causes the elasticity of the tissues. As shown in Table I, conchiolin in the nacreous layer of the shell and that in the pearl contain less phenylalanine and proline, and more alanine than that in the prismatic layer.

## Summary

Conchiolin, a kind of screloprotein, was isolated from the pearl and the shell of the pearl oysters. The amino acid composition of conchiolin was determined by the chromatographic method with the starch column. Relatively large amounts of leucines, alanine, glycine and cystine were found in conchiolin.

Remarkable differences were found in the contents of phenylalanine, alanine and proline between conchiolin from the nacreous substance and that from the prismatic substance.

# *Chemisorption of Hydrogen on Zinc Oxide. I. Rate of Desorption and Adsorption Isotherm*

By Yutaka KUBOKAWA

(Received September 9, 1959)

The rate of adsorption and adsorption equilibrium have been measured for various chemisorption systems by many workers. As regards the rate of desorption, however, few quantitative measurements have been carried out with powdered catalysts[1]. For these catalysts the activation energy of desorption is usually taken as the sum of the activation energy of adsorption and the heat of adsorption obtained from the rate of adsorption and adsorption equilibrium, respectively. It is however frequently encountered in chemisorption that the slow attainment of equilibrium and the occurrence of bulk or surface diffusion process introduce considerable uncertainty in the values of the activation energy of adsorption and the heat of adsorption. If the activation energy of desorption is determined by direct measurements of the rate of desorption and compared with the activation energy of adsorption and the heat of adsorption, the information concerning the energy relation for a given chemisorption will be much improved. The present study was undertaken to present such an attempt for the chemisorption of hydrogen on zinc oxide. This paper reports the activation energies for desorption obtained from the rate of desorption at various temperatures, together with adsorption equilibrium data. The rate of adsorption and its relation to the results here reported, will be dealt with in a forthcoming paper.

## Experimental

**Materials.**—For zinc oxide two samples, ZnO I and ZnO II were used. ZnO I was prepared as follows: Zinc oxalate was precipitated from the solutions of ammonium oxalate and zinc nitrate. The precipitate was washed, filtered, dried at 110°C and finally converted to the oxide by heating in air at 400°C. ZnO II was prepared from zinc nitrate and sodium carbonate by the method similar to ZnO I. The reagents were of Extra Pure grade. Hydrogen was obtained by the electrolysis of 30% solution of potassium hydroxide, purified by passing through heated palladium asbestos, phosphorus pentoxide, and finally, through a trap immersed in liquid nitrogen. Nitrogen was prepared by the thermal decomposition of sodium azide, and purified by passing through phosphorus pentoxide. Helium was obtained from commercial sources, and was used without further purification.

**Apparatus and Procedure.**—The adsorbed amount was determined by using a conventional constant volume apparatus, as shown in Fig. 1. The volume of the dead space was measured by the expansion of a known volume of helium over the whole range of temperatures and pressures employed. The mercury manometer $M_1$ and the Mcleod gauge $M_2$ covered a wide range of pressure from $10^{-5}$ to 70 mmHg.

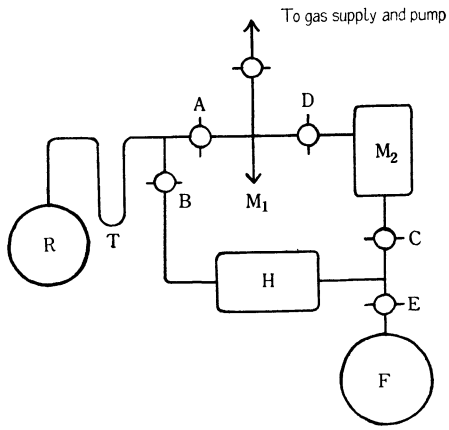

Fig. 1.

The rate of desorption was measured as follows: Before starting a measurement of desorption rate, the pressure in the adsorption vessel R was adjusted to a range of several mmHg by pumping out a known amount of gas through the Mcleod gauge $M_2$ and mercury manometer $M_1$. Then, stop-cocks A and D were closed, B and C opened, and the gas desorbed by mercury diffusion pump H was collected into $M_2$, whose pressure was followed at definite intervals. During a desorption experiment trap T was cooled to −78°C. By using the volume of H at its working state which was determined by an independent measurement, the rate of desorption was calculated from the pressure increase in $M_2$. When gas was accumulated in $M_2$ to such an extent that the rate of desorption might be affected by readsorption, the stopcock D was opened and C closed for a short time to pump out the gas in $M_2$, after which the measurement of desorption was continued. The pressure in the adsorption vessel R during the desorption experiment was measured

1) J. Weber and K. J. Laidler, *J. Chem. Phys.*, **19**, 1089 (1951); J. J. F. Scholten and P. Zwietering, *Trans. Faraday Soc.*, **53**, 1363 (1957); K. Tamaru and M. Boudart, "Advances in Catalysis", Vol. 9, Academic Press, Inc., New York (1957), p. 699.

by closing stopcock C, opening E, A and D, and leading the desorbed gas to flask F, instead of Mcleod gauge $M_2$.

The adsorption vessel was maintained at various required temperatures in the following manner; for the range above room temperature an electric furnace was used, with the constancy of $\pm 1°C$; for the range below room temperature, solid carbon dioxide in ethanol and melting chlorobenzene and bromobenzene were used; a bath for $-60°C$ was obtained by cooling acetone by the addition of a small amount of dry ice from time to time.

Preceding to the chemisorption experiment, the adsorbent was subjected to alternating evacuation and exposure to hydrogen at 400°C several times, and then evacuated for five hours at 420°C. The surface area of the adsorbents was determined by the B. E. T. method using nitrogen as an adsorbate with the following results; ZnO I, 6.6 $m^2/g$.; ZnO II, 5.2 $m^2/g$. The weight of the adsorbent was 14.64 g. (ZnO I) or 11.60 g. (ZnO II).

## Results and Discussion

**Rates and Activation Energies of Desorption at Various Coverages.**—Since the observed rate of desorption is that substracted by the rate of the reverse process, i. e. readsorption, the activation energy of desorption can not be determined from the observed rates unless the rate of readsorption is negligible. As a test to decide whether this condition is satisfied, the following experiment was carried out. After measuring the pressure in adsorption vessel during desorption rate measurements, the pressure increase caused by isolating the adsorption vessel from the mercury diffusion pump was observed. Fig. 2 represents a typical experiment carried out at room temperature. Although adsorption equilibrium was not easily attained, the rapid pressure increase observed suggests that the pressure in the adsorption vessel at the moment when the diffusion pump was cut off would have been negligible compared with the equilibrium pressure corresponding to the adsorbed amount at that moment, and hence that the rate of readsorption was negligible compared with that of desorption. The same was also found to be the case for desorption under other experimental conditions.

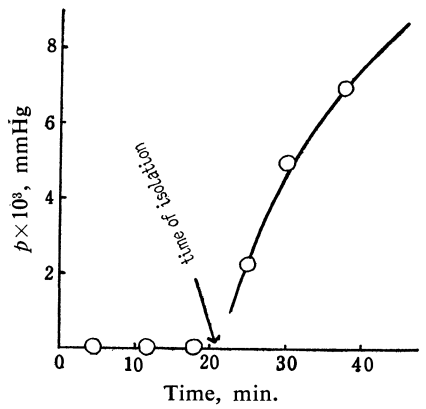

Fig. 2. Pressure increase on isolating the adsorption vessel from the mercury diffusion pump. Pressure in the adsorption vessel before the isolation was $1.3\times10^{-4}$ mmHg.

After hydrogen was allowed to be adsorbed at about 300°C and 20~25 mmHg, the system was cooled down to 209 or 22°C, at which temperature the rate of desorption was measured with the results shown in Fig. 3. Fig. 4 represents the same results as the plots of the logarithm of desorption rate $\log R_{dep}$ against desorbed amount $q$. As to the data given in Fig. 3 a simple unimolecular or bimolecular rate law was found to be inapplicable. This results, together with the fact that the plot of $\log R_{dep}$ against $q$ in Fig. 4 is nearly linear, will be explained by the increase of activation energy for desorption with decreasing amount

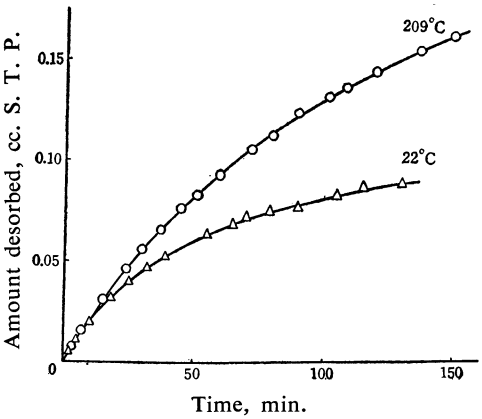

Fig. 3. Rates of desorption of hydrogen chemisorbed on ZnO II. The amount adsorbed at $t=0$ was 0.51 cc. at 209°C and 1.12 cc. at 22°C.

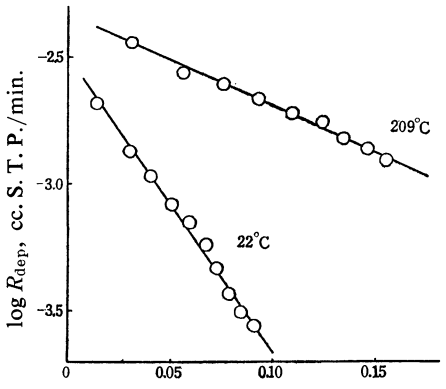

Fig. 4. Plots of $\log R_{dep}$ against the amount desorbed $q$ for the data in Fig. 3.

adsorbed, and its quantitative relationship will also be shown later.

The activation energy of desorption was determined as a function of adsorbed amount by the following procedure: The temperature of desorption was lowered abruptly during the rate measurement, as shown in Fig. 5 (hydrogen chemisorption before the desorption experiment was carried out in a similar manner to that in Fig. 3); the plot of $\log R_{dep}$ against $q$ for the curve before the temperature drop, such as shown in the figure, was extrapolated to a smaller amount adsorbed where the rate measurements after the temperature drop were carried out. Thus, the rates at the two different temperatures corresponding to the same amount adsorbed and, consequently, the activation energy of desorption were obtained.

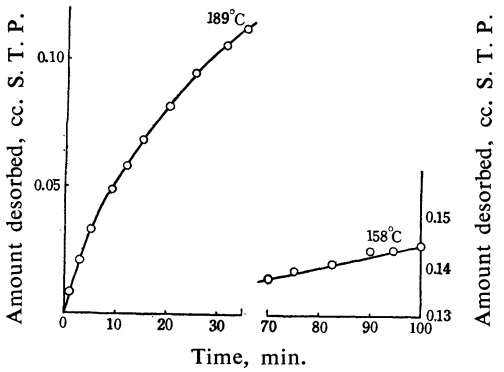

Fig. 5. Determination of the activation energy of desorption. The amount adsorbed at $t=0$ was 0.72 cc. The activation energy was estimated as 23.5 kcal./mol.

The initial admission of hydrogen was usually made at about 300°C and 30~40 mmHg, after which the temperature of the system was lowered to room temperature, and after about 10 hr. it was raised up to 400°C in stages, at each of which the activation energy of desorption was determined in the above mentioned manner. The results obtained with ZnO II are shown in Fig. 6. Fig. 7 shows similar results obtained with ZnO I[2] for a range of higher coverage where desorption was measurable at lower temperatures. It follows from the two figures that the activation energy of desorption increases with decreasing amount adsorbed, up to 31 kcal./mol., and thereafter remains nearly constant[3].

It may be noted that such behavior of the activation energy toward coverage is responsible

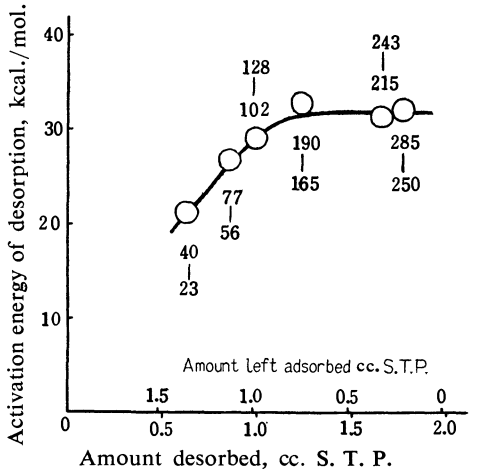

Fig. 6. Activation energies of desorption of hydrogen chemisorbed on ZnO II. The amount adsorbed before desorption at room temperature was 1.98 cc. Figures indicate the temperature interval where the activation energy was determined.

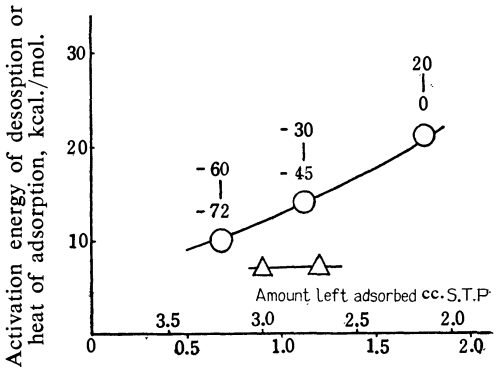

Fig. 7. Activation energies of desorption and heats of adsorption of hydrogen on ZnO I at high coverage. Figures indicate the temperature interval where the activation energy was determined. The amount adsorbed and the equilibrium pressure at room temperature before desorption were 3.90 cc. and 29.5 mmHg respectively. -○-, activation energy of desorption; -△-, heat of adsorption.

for the fact that the slope of the plot $\log R_{dep}-q$ is smaller in the higher temperature range, as seen in Fig. 4.

**Adsorption Isotherms at Various Temperatures.** —An adsorption isotherm obtained in the usual manner, i. e. by admitting a small amount of gas to an evacuated sample successively, was found to be different from that obtained in the reverse way, i. e. by successive withdrawals of the gas. These may be called the adsorption and the desorption branches of the isotherm, respectively. An example at 370°C is given in Fig. 8. This result was obtained with ZnO II

2) Results with ZnO II were similar.

3) The fact that a simple unimolecular or bimolecular rate law was not applicable to the data above 200°C, where the approximately constant activation energy was observed, appears to have resulted from a slight change of the activation energy with the amount desorbed, within the experimental error, ±2 kcal./mol.

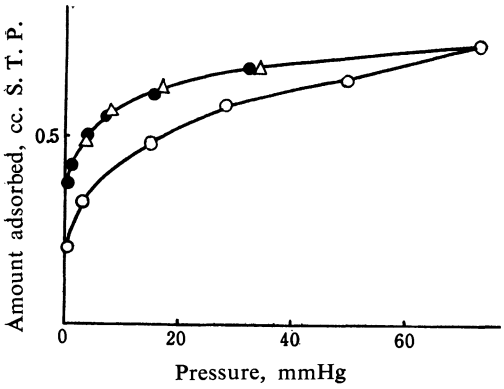

Fig. 8. Adsorption isotherms on the adsorption and desorption branch for the hydrogen chemisorption on ZnO II at 370°C. -○-, initial adsorption; -●-, desorption; -△-, readsorption.

which had been evacuated for five hours at 420°C. On the desorption branch the adsorption equilibrium was rapidly established and reproduced on decreasing or increasing pressure in the pressure range lower than the maximum pressure employed on the adsorption branch. It may therefore be concluded that the isotherm obtained on the desorption branch represents a true equilibrium. The isotherm at varied temperatures was obtained in the following way. After recording the equilibrium pressure at a particular temperature, the temperature was lowered and the new equilibrium pressure at a lower temperature was obtained; a certain amount of hydrogen was then pumped out and the measurements were repeated. The results obtained with ZnO II are shown in Fig. 9. It follows from this figure that the heat of adsorption is nearly constant and equal to 18 kcal./

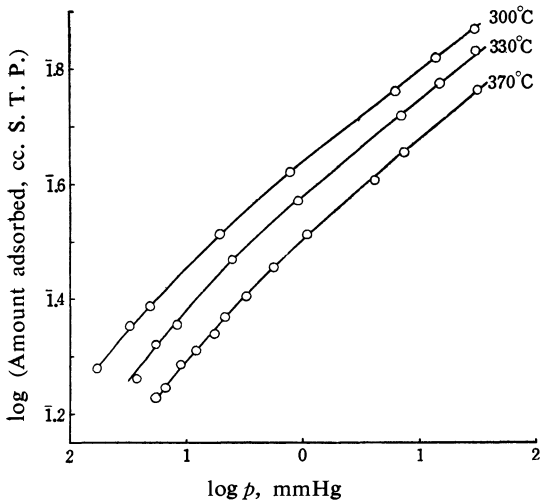

Fig. 9. Adsorption isotherms for hydrogen on ZnO II.

mol. The same value of the heat of adsorption was obtained with ZnO I.

The adsorption isobar for this system was obtained in the following way: After hydrogen was allowed to be adsorbed at about 350°C, the temperature was lowered in stages down to room temperature and then raised again to 350°C. The results obtained with ZnO I are shown in Fig. 10. It is seen in the figure that the isobars obtained by lowering and raising the temperature nearly coincide, indicating that, once hydrogen is adsorbed at a high temperature, adsorption equilibrium is nearly attained even at considerably lower temperatures, and hence that approximate adsorption isotherms can also be obtained at such low temperatures. Fig. 11 represents such isotherms at 102 and 130°C obtained with ZnO I after hydrogen adsorption at about 300°C, determined in the manner already described for the higher temperature range. Though these low temperature isotherms may be less accurate, the heat of adsorption is

estimated from these as 6~8 kcal./mol.

The activation energy of adsorption may be estimated by combining the activation energy of desorption and the heat of adsorption. As described above, the maximum value of activation energy for desorption and the heat of adsorption are 31 and 18 kcal./mol., respectively. The maximum activation energy of adsorption is, therefore, estimated as 13 kcal./mol.

For the range where the activation energy of adsorption or desorption varies with the amount adsorbed, it seems necessary to take into account the fact that on a heterogeneous surface equal amounts adsorbed do not necessarily mean identical states of adsorption. As described in Figs. 7 and 11, however, adsorbed amount and equilibrium pressure at room temperature differs a little between these two runs, suggesting that in this case the states of hydrogen adsorbed to an equal amount may be compared. Thus, in Fig. 7, the values of the heat of adsorption in the low temperature range described above were shown as a function of the adsorbed amount, together with the activation energy of desorption. It follows from this figure that the activation energy of adsorption in this range is about 5~7 kcal./mol. This figure also suggests that most part of hydrogen chemisorption on zinc oxide is an activated adsorption, although it is doubtful whether the same argument is valid for the fraction which desorbs rapidly below −72°C.

**Summary**

The rate of desorption of hydrogen chemisorbed on zinc oxide was measured over a wide range of temperatures. The rate at a constant temperature was found to obey approximately the kinetics of the Elovich type. The activation energy of desorption was determined at various coverages, with the result that it increased with decreasing amount from at least about 10~31 kcal./mol. and then remained constant. The heat of adsorption obtained from adsorption isotherms in the temperature range 300~370°C was found to be 18 kcal./mol., being roughly constant. Meanwhile, from the isotherms at about 100°C, a heat of adsorption of 6~8 kcal./mol. was obtained. Comparison between the activation energy of desorption and the heat of adsorption suggests that most part of hydrogen chemisorption on zinc oxide involves an activation energy, its highest value being estimated as 13 kcal./mol.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

# *Chemisorption of Hydrogen on Zinc Oxide. II. Rate of Chemisorption and Heterogeneity of the Surface of Zinc Oxide*

By Yutaka KUBOKAWA

(Received September 9, 1959)

Taylor and coworkers[1], in a study of hydrogen chemisorption on zinc oxide and other catalysts, found a rapid desorption followed by a slow adsorption and explained these phenomena in terms of a heterogeneity of the surface. As pointed out by various workers[2], however, there are other possibilities leading to such phenomena, which, therefore, may not be regarded as a proof of the existence of any surface heterogeneity. As a proof in relation to this problem, it seems to be promising to investigate the behavior of desorption of the chemisorbed hydrogen in the manner described in a previous report[3], since surface heterogeneity may affect seriously its behavior. The purpose of the present work is to clarify the nature of slow chemisorption by measuring not only the rate of adsorption, but also that of desorption under various experimental conditions, and to obtain, on the basis of these results combined with those described in the previous paper[3], definite conclusions as to the heterogeneity of zinc oxide surface in hydrogen chemisorption.

## Experimental

The details of materials, apparatus and procedure were described in the previous paper[3].

## Results and Discussion

**Dependence of Chemisorption Rate on Pressure and Temperature.**—In early experiments, the rate of chemisorption was measured in the usual manner, i.e. by admitting a known amount of hydrogen to an evacuated sample and measuring the pressure change in the system at a constant volume. Some examples of the results obtained at a constant temperature and various pressures are shown in Fig. 1[4]. It might be expected that comparison of the times required for the adsorption of a certain amount, determind from such plots, would give the pressure dependence of the rate at the given temperature. However,

Fig, 1. Rate of adsorption of hydrogen on zinc oxide at 140°C. Figures indicate the initial pressures in mmHg. Different samples were used in these runs.

when the rate thus obtained is represented as proportional to $p^n$, it is found that not only the exponent $n$ increases with the adsorbed amount, but is also greater than unity. The explanation for such unexpected behavior will be given below, according to which experiments such as shown in Fig. 1 do not reflect the true pressure dependence of the adsorption rate. From a similar argument, it will be shown that a series of rate measurements at a constant pressure and various temperatures does not give the true temperature dependence of the rate. Consequently, in the following experiments, the dependence of the rate on pressure or temperature was determined by observing the change in rate caused by an abrupt change of pressure or temperature during adsorption.

4) The pressure decrease due to adsorption was no more than 10~20% of the initial pressure.

The results concerning the pressure dependence are shown in Figs. 2 and 3. As seen in these figures, on increasing pressure an instantaneous adsorption followed by a slow process takes place. Hence, by extrapolation of the rates to the time when a sudden pressure change occurs, the rates at different pressures corresponding

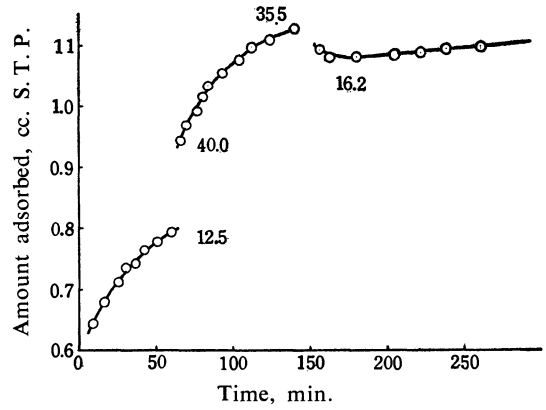

Fig. 2. Effect of the pressure change during adsorption on the rate of adsorption of hydrogen on ZnO II at 18°C. Pressure range, 10~40 mmHg. Figures indicate the pressure before and after the pressure change in mmHg.

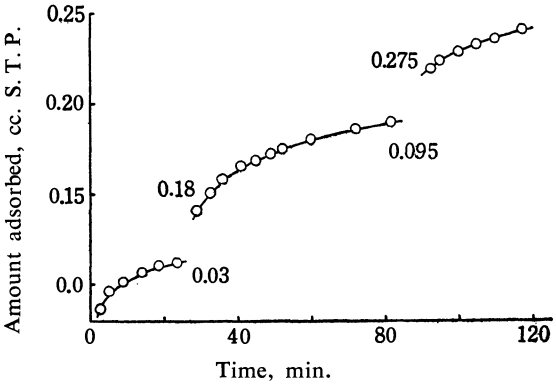

Fig. 3. Effect of the pressure change during adsorption on the rate of adsorption of hydrogen on ZnO I at 18°C. Pressure range, 0.03~0.30 mmHg. Figures indicate the pressure before and after the pressure change in mmHg.

Table I. Values of $n$ in the expression, rate $\propto p^n$ for the data shown in Figs. 2 and 3

| | Pressure before and after the pressure change | $n$ |
|---|---|---|
| Fig. 2 | 12.5 → 40.0 | 1.0±0.1 |
| | 35.5 → 16.2 | 2.0±0.3 |
| Fig. 3 | 0.03 → 0.18 | 1.1±0.1 |
| | 0.095→ 0.275 | 0.9±0.1 |

to equal amounts of slow chemisorption were evaluated. The results are shown in Table I, which shows that the rate is proportional to $p^{0.9\sim1.1}$ on increasing pressure. This relationship was found to be applicable in the whole temperature range studied. As seen in Table I, on decreasing pressure the rate decreases more markedly than is expected from the results obtained on increasing pressure.

The results concerning the temperature dependence obtained with ZnO I in the pressure range 50～70 mm Hg are represented in Fig. 4. It is seen in this figure that on an abrupt temperature change[5], as suggested by Taylor and Liang[1], a rapid desorption followed by a slow adsorption takes place. The activation energy for the slow process was determined in the same manner as for the pressure dependence, with the results shown in Table II. The activation energy

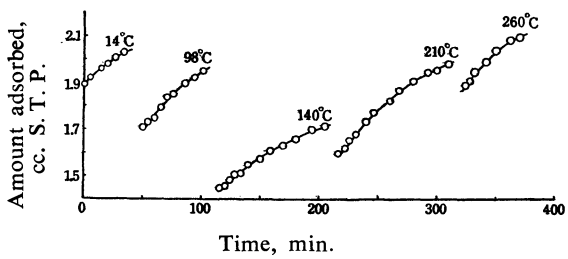

Fig. 4. Effect of the temperature elevation during adsorption on the rate of adsorption of hydrogen on ZnO I. Pressure range, 50～70 mmHg.

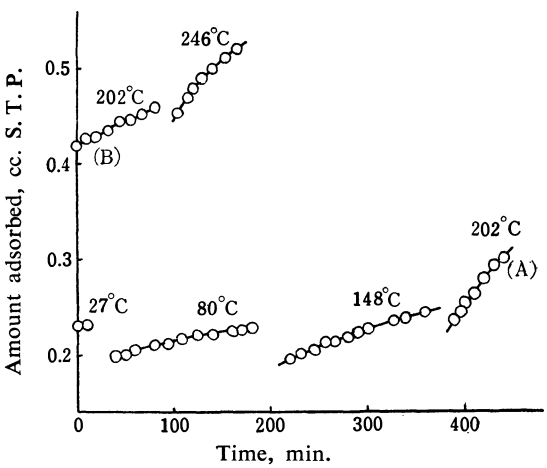

Fig. 5. Effect of the temperature elevation during adsorption on the rate of adsorption of hydrogen on ZnO I. Pressure range, 0.1～0.2 mmHg. Between the runs A and B, the sample was kept at room temperature for 10 hours.

5) A blank experiment carried out with helium in place of hydrogen showed that on such an abrupt temperature change the temperature equilibrium was attained in less than three minutes.

TABLE II. ACTIVATION ENERGIES OF ADSORPTION FOR THE DATA SHOWN IN FIGS. 4 AND 5

| Pressure | Temp. | Activation energy |
|---|---|---|
| 50～70 (Fig. 4) | 14～ 98 | 5.5±1.5 |
| | 98～140 | 7.5±1.0 |
| | 140～210 | 11.0±1.5 |
| | 210～260 | 14.5±1.5 |
| 0.1～0.2 (Fig. 5) | 80～148 | 6.3±1.0 |
| | 148～202 | 13.0±1.0 |
| | 202～246 | 15.0±1.0 |

increases steadily as the temperature becomes higher. As shown in Fig. 5 and Table II, the results obtained in the pressure range 0.1～0.2 mmHg are similar except for the smaller amount of rapid desorption on raising temperature.

In view of the occurrence of hydrogen-deuterium exchange reaction on zinc oxide and, in addition, from a comparison of the energy values for the system of hydrogen on zinc oxide described previously[3] with the information concerning the hydrogen chemisorption on metals given by Gomer and other workers[6], hydrogen chemisorption on zinc oxide at room temperature or above may be assumed to be a dissociative adsorption. Hence, if the rate-determining step of the slow process were a surface migration of the adsorbate, the exponent $n$ in the rate expression Rate $\propto p^n$ would be lower than 0.5. Such expectation is evidently inconsistent with what was observed. It may therefore be concluded that the rate-determining step is not a sort of surface migration, but an adsorption.

As described above, the pressure dependence obtained by increasing pressure differs markedly from that by decreasing pressure. This suggests that desorption can not be neglected during adsorption[7]. Because of this effect, the pressure dependence obtained by increasing pressure, may be somewhat larger than the true value, although the difference may be small compared with that in the case of decreasing pressure.

**Heterogeneity of the Surface of Zinc Oxide in Hydrogen Chemisorption.**—The considerations given above indicate that the slow process is a chemisorption with an appreciable activation energy which increases with adsorbed amount, judged from the considerable change of the activation energy of desorption as described in

6) R. Gomer et al., *J. Chem. Phys.*, 26, 1147 (1957); 27, 1099 (1957); O. Beeck, loc. cit., etc.

7) Taking into account of desorption, the rate of dissociative adsoption on a homogeneous surface will be

$$kp(1-\theta)^2[1-(p_e/p)]$$

where $p_e$ is the equilibrium pressure corresponding to a coverage $\theta$. The term $1-(p_e/p)$ is a correction for desorption. This equation predicts such behavior as observed on an abrupt pressure change during the adsorption rate measurements: In the case where desorption takes place considerably during adsorption, the decrease in the value of $1-(p_e/p)$ on decreasing pressure will be markedly larger than its increase on increasing pressure.

the previous paper[3]. With respect to the behavior observed on raising temperature during adsorption, there are apparently two possible explanations, as the rate-determining step of the slow process is confined to adsorption; one is a heterogeneity of the surface emphasized by Taylor et al. and the other is the coexistence of two types of bonding on a homogeneous surface as frequently proposed by various workers[8]

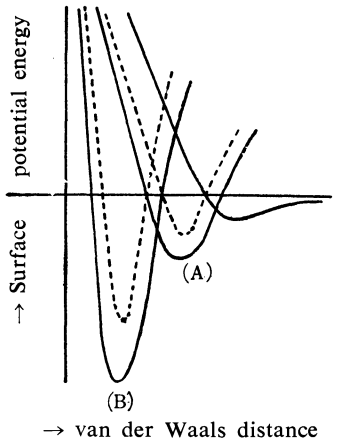

Fig. 6. Energy relation for the two types of chemisorption. Full line, for bared surface; broken line, for covered surface.

(Fig. 6). In the latter case the increase of activation energy of adsorption is attributed to the decrease of heat of adsorption with coverage. According to this model the chemisorption of type A has a low heat of adsorption and negligible activation energy, and hence the adsorption equilibrium is nearly realized throughout the course of slow adsorption, while that of type B involves an appreciable activation energy increasing with coverage and is responsible for the slow process. The behavior observed in this work on raising temperature might be explained by this model in terms of the rapid desorption of the A-type adsorbate followed by the slow adsorption of type B. On the other hand, as regards the rate of desorption, the observed slow process would solely be the desorption of the B-type adsorbate, since that of type A would be probably rapid; the rate of slow desorption would thus be determined only by the adsorbed amount at a given time, irrespective of other experimental conditions.

In order to examine if such a prediction is realized, the following experiments were carried out: At room temperature hydrogen was allowed to be left in contact with the adsorbent for 15 min. in one experiment and 16 hr. in the other one; after which, pumping out a known amount

8) E. Wicke, *Z. Elektrochem.*, 53, 279 (1949); J. H. de Boer, loc. cit.; P. M. Gundry and F. C. Tompkins., *Trans. Faraday Soc.*, 52, 1609 (1956); etc.

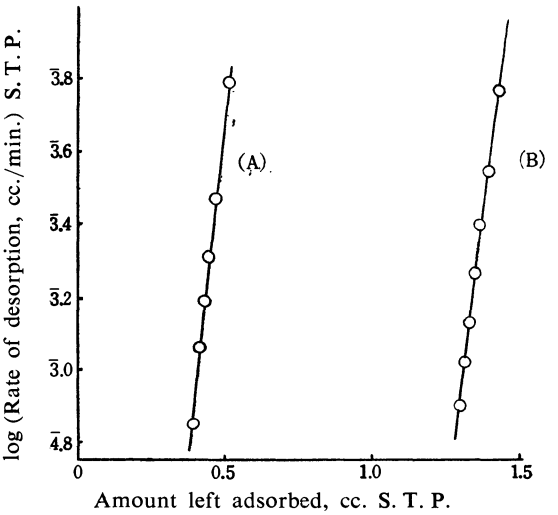

Fig. 7. Rate of desorption as a function of the amount left adorbed. Temp., 16°C.

| | Time of contact | Amount adsorbed before desorption in cc. |
|---|---|---|
| Run A | 15 min. | 1.67 |

of hydrogen from the system, the rate of desorption was measured in the manner described in the previous paper[3]. The results are shown in Fig. 7, where, contrary to what has been predicted above, the desorption rates corresponding to equal amounts adsorbed differ markedly from each other, indicating that the postulate of two types of chemisorption can not be applied to this system. Similar results were obtained by the experiments at higher temperatures, an example at 188°C being given in Fig. 8.

Of the two alternatives given above, there remains now the postulate of heterogeneity of the surface to be accepted[9,10]. In view of the continuous variation of the activation energy of desorption with adsorbed amount, the pattern of this heterogeneity seems to be characterized by a continuous distribution function of sites with the heats of adsorption and the activation energies of adsorption varying in the same direction as proposed by Halsey[11]. According to this model, on the sites with a low activation energy, the heat of adsorption is also low and adsorption equilibrium will immediately be established after admission of hydrogen. Whilst, those with a high activation energy are covered by a slow process and the activation energy becomes higher as the adsorption proceeds. On raising the temperature during adsorption, a rapid desorption takes place on the sites with a low activation energy, but on the sites with a high activation energy the slow adsorption continues. In this way this model can explain the phenomena found by Taylor and Liang[1]. Furthermore, the observation such as the marked difference in the rates of desorption corresponding to equal amounts adsorbed in the two experiments with different times of contact with hydrogen and the unexpected pressure dependence of the rate of adsorption obtained in the usual manner may be explained as follows: under different experimental conditions, e.g. different times for adsorption or different initial pressures, different sets of sites may be covered to different extents. Hence, the states of equal amounts adsorbed are not necessarily comparable.

**Activation Energy of Adsorption.**—The temperature dependence of slow chemisorption given in Table II will give the true activation energy of adsorption, if desorption is negligible. As described above, this condition is not satisfied in this system. However, in view of the nature of surface heterogeneity given above, the situation before and after a temperature raise may be supposed as follows. Before the temperature raise adsorption proceeds mainly on the sites with a particular value of activation energy, since on those with a lower activation energy the adsorption equilibrium must be almost established, while those with a higher activation energy must be nearly bare. On raising temperature, coverage on these sites may become close to the equilibrium value. Hence, adsorption now proceeds mainly on those with a higher activation energy. Since the heat of adsorption changes in parallel with the activation energy, it seems unlikely that the effect of desorption is markedly altered on raising temperature. Thus, the temperature dependence obtained by extrapolating these rates to the time of a rapid temperature change will give the activation energy not greatly in error. In fact, as described in the previous report[3], the maximum value of the activation energy of adsorption estimated from the activation energy of desorption and the heat of adsorption is 13 kcal./mol., in agreement with 15 kcal./mol. obtained directly from the adsorption rate measurements.

9) An assumption of the coexistence of three or more types of bonding on a homogeneous surface in a limited temperature range might explain the observed behavior. It is, however, difficult to work out plausible physical models for such various types of bonding.

10) The experiments described above, of course, can not decide between the two possibilities, one-type and two-type chemisorption on a heterogeneous surface. As will be shown in a later paper, there is no convincing evidence to support the latter at present.

11) G. D. Halsey, *J. Phys. Chem.*, 55, 21 (1951).

## Summary

With respect to hydrogen chemisorption on zinc oxide, the dependence of adsorption rate on pressure and temperature was determined by an abrupt change of pressure or temperature during adsorption. The pressure dependence obtained on increasing pressure differed markedly from that on decreasing pressure, indicating that desorption can not be neglected. The apparent activation energy of slow chemisorption increased from 6 to 15 kcal./mol. as the temperature range becomes higher. Marked differences were found between the rates corresponding to equal amounts adsorbed in the two experiments where the times of contact with hydrogen were different. On the basis of these results, combined with the variation of activation energy of desorption with the amount adsorbed previously, it was shown that for this system the concept of the two types of chemisorption on a uniform surface can not be applied. Instead a postulate of a heterogeneous surface where the activation energy of adsorption and the heat of adsorption varies in the same direction was found to be able to explain all the results obtained.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

(Received September 9, 1959)

Carbon monoxide chemisorption on zinc oxide at room temperature has been investigated by Garner and coworker[1] who reported that the heat of adsorption obtained from the adsorption isotherms is 10~14 kcal./mol., and that the chemisorption is instantaneous and completely reversible at room temperature. Few studies[2] have hitherto been reported on the carbon monoxide chemisorption at high temperatures, which appears to play an important role in the reaction of carbon monoxide, e. g. the oxidation of carbon monoxide. The present work has therefore been undertaken to obtain quantitative information concerning this chemisorption over a wide temperature range by measuring the rate of adsorption and adsorption equilibrium as well as the rate of desorption in the manner described in previous papers[3,4]. Moreover, in this paper, the nature of surface heterogeneity in this system is discussed on the basis of the results obtained, and especially those of the desorption under various experimental conditions which proved to be useful in clarifying the nature of the heterogeneneity of zinc oxide surface in the hydrogen chemisorption[4].

## Experimental

**Materials.**—Zinc oxide was prepared from zinc oxalate in a manner similar to that described in the previous paper[3]. The weight of adsorbent was 16.72 g. and the surface area determined by the B. E. T. method was 6.1 $m^2/g$. Carbon monoxide was prepared by the reaction of air-free formic acid and concentrated sulfuric acid, purified by passing through soda lime and phosphorus pentoxide, and finally through a trap immersed in liquid nitrogen.

**Apparatus and Procedure.** — Details of the apparatus and procedure were described in the previous paper[3]. Before a series of experiments, the pretreatment of the sample with carbon monoxide at 400°C followed by evacuation at this temperature were repeated several times.

## Results and Discussion

**Adsorption Isotherms at About Room Temperature.**—According to the investigations by Garner et al.[1], carbon monoxide chemisorption at room temperature is instantaneous and involves no appreciable activation energy. The results obtained in the present study were similar to their results except for the occurrence of a slow uptake even at room temperature, though its amount was very small. The adsorption isotherm obtained by successive

additions of the gas in the usual manner was found to be different from that obtained in the reverse way, i.e., by successive withdrawals of the gas, as shown in Fig. 1. However, the isotherms determined by the latter method were reproducible on increasing or decreasing pressure as found for the hydrogen chemisorption described in the previous paper[3]. Fig. 2 shows the results obtained, which give the heat of adsorption as 10~12 kcal./mol.

**Dependence of the Rate of Adsorption on Pressure and Temperature.**—Carbon monoxide was introduced at room temperature and its adsorption followed, the temperature being raised in stages up to about 300°C. The results obtained are shown in Fig. 3, which shows that the rate of slow uptake increases markedly with temperature, and that above 100°C only a slight rapid desorption takes place on raising the temperature, in contrast with the case of hydrogen chemisorption previously reported[4]. The pressure dependence of the slow process was obtained in a manner similar to that for hydrogen chemisorption, i.e. by comparison of the rates at equal amounts of slow chemisorption between before and after a rapid pressure change during the adsorption rate measurements. A typical result is shown in Fig. 4 and Table I. The rate is proportional to $p^{0.8\sim0.9}$ on both increasing and decreasing pressures, indicating that desorption is negligible during adsorption.

The temperature dependence of the slow process was obtained by a comparison of the rates corresponding to the equal amounts of slow chemisorption at different temperatures. The results evaluated from Fig. 3 are shown

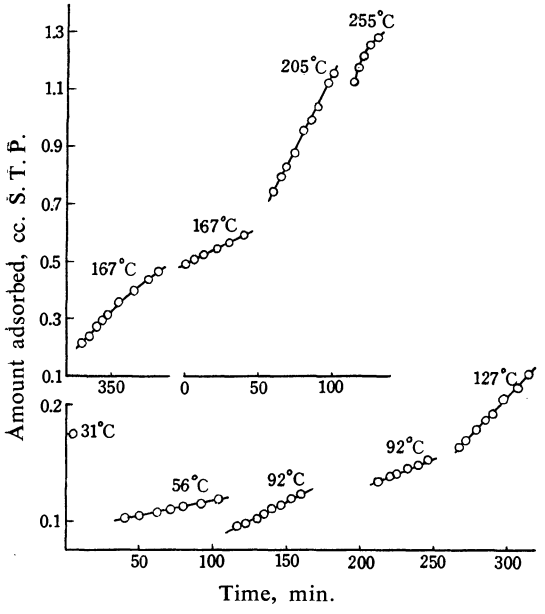

Fig. 3. Effect of the temperature change during adsorption on the rate of chemisorption of CO on ZnO. Pressure, 0.2~0.4 mmHg. Runs at 92 and 167°C were interrupted by reducing pressure or temperature.

| 127~167 | 11.5±0.7 |
| 167~205 | 16.5±0.7 |

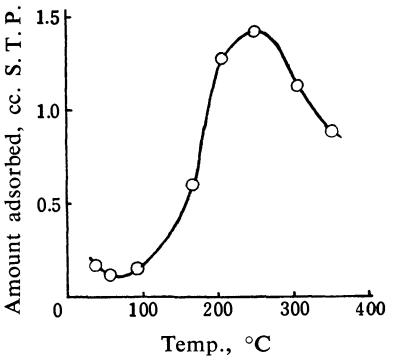

Fig. 5. Adsorption isobar of CO on ZnO at 0.2~0.4 mmHg.

in Table II, which indicates that the activation energy of the slow process increases as the temperature range becomes higher.

The adsorption isobar at approximately constant pressure 0.2~0.4 mmHg was obtained from the amount adsorbed after 1 hour at each temperature. Fig. 5 illustrates this isobar which shows a minimum at about 70°C and a maximum at about 250°C.

**Activation Energies of Desorption at Various Coverages.**—The temperature of the adsorbent which had already adsorbed carbon monoxide at about 300°C was raised from −72 to about 400°C in stages, at each of which the activation energy of desorption was determined in the manner described in the previous paper[3]. The variation of the activation energy for desorption with the amount desorbed is shown in Fig. 6. As seen in this figure, the curve of activation energy of desorption against the desorbed amount is composed of two parts, one corresponding to the desorption below room temperature with the activation energy of 2.5 kcal./mol., and the other to that above 200°C with the activation energy of approximately 40 kcal./mol. The former value is essentially the same as the heat of adsorption derived from the isotherms around room temperature, indicating that the chemisorption at room temperature involves no activation energy, as may be expected. In the latter case, the activation energy of desorption increases somewhat with decreasing coverage.

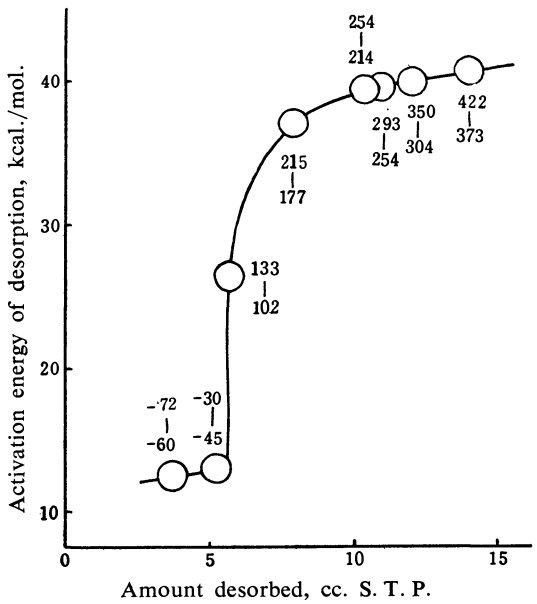

Fig. 6. Activation energies of desorption of CO chemisorbed on ZnO. Figures indicate the temperature interval where the activation energy was determined. The amount adsorbed at room temperature before desorption was 15.81 cc.

This conclusion is based on the assumption that the measured rate of desorption is not affected by the reverse reaction. This was confirmed in the manner previously described[3], i. e., by observing the pressure increase caused by isolating the adsorption vessel from the mercury diffusion pump. In the temperature range above room temperature the observed behavior was almost the some as that of the hydrogen chemisorption previously[3] described, indicating that adsorption is negligible during the desorption rate measurement. Whilst in the temperature range below room temperature, somewhat different behavior was observed as represented in Fig. 7. This shows that an equilibrium pressure $P_e$ is here easily attained, and moreover that the pressure in the adsorption vessel during the desorption experiment $P$, is now comparable to $P_e$. However, the ratio $P_e/P$ was found not to vary seriously by an abrupt change of temperature. From the data given in Fig. 7 this ratio was estimated to be 3.5 at −30°C, while the similar measurements at −45°C following these experiments gave the value of 2.6. The error introduced in the activation energy of desorption by this difference in $P_e/P$ was estimated to be at most 1 kcal./mol. It may therefore be concluded that the activation energy of desorption obtained below room temperature is also nearly equal to the true value.

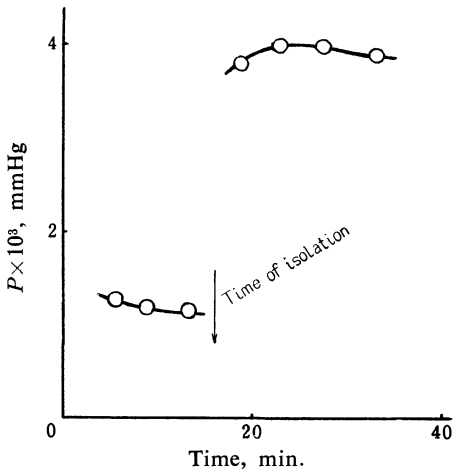

Fig. 7. Results obtained by isolating the adsorption vessel from the mercury diffusion pump. Temp., −30°C.

In order to confirm the reversibility of chemisorption the content of carbon dioxide in the desorbed gas was examined by immersing the trap attached to the MacLeod gauge in liquid nitrogen. The absence of carbon dioxide was confirmed below 350°C, while above this temperature its content amounted to the fraction 1/3~1/2 of the desorbed gas.

**Adsorption Isotherms at Higher Temperature**[5]. —The adsorption isotherms in temperature 300~370°C were determined by successive withdrawals of the gas as described for low temperature isotherms. These isotherms are strictly reproduced on increasing or decreasing pressure, as shown in Fig. 8. Fig. 9 represents the fact that the heat of adsorption derived from these isotherms decreases with the increasing amount adsorbed from 38 to 25 kcal./mol.

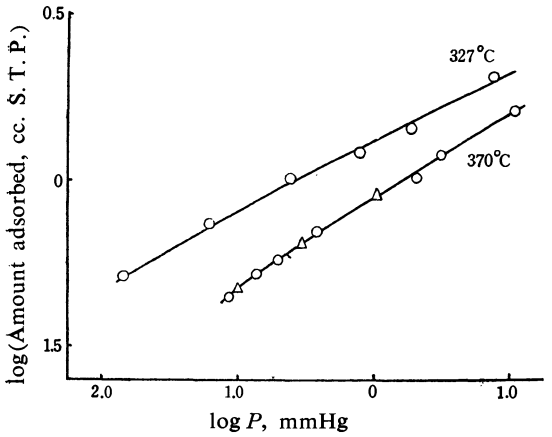

Fig. 8. Adsorption isotherms of CO on ZnO at 327 and 370°C. -○-, on decreasing pressure; -△-, on increasing pressure.

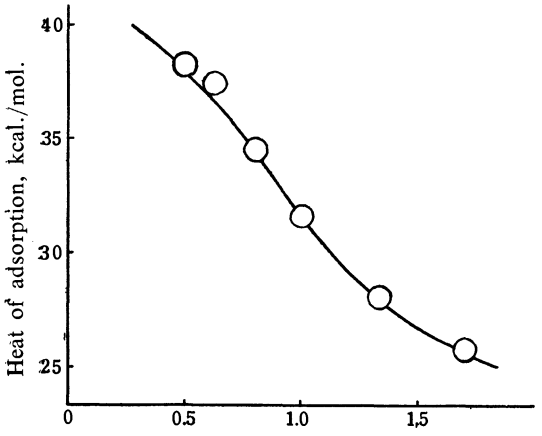

Fig. 9. Heats of adsorption of CO on ZnO.

**Two Types of Carbon Monoxide Chemisorption on Zinc Oxide.**—The plots of the activation energy for desorption against the amount adsorbed shown in Fig. 6, together with the adsorption isobar shown in Fig. 5, suggest that the two types of chemisorption are operating, one being a non-activated type predominating at a lower temperature, and the other an activated type occurring at a higher temperature. Moreover, not only the former, but also a considerable fraction of the latter is reversible, i.e. desorbed as such. Such behavior of the high temperature chemisorption appears to be inconsistent with the investigations by Garner and coworkers[6], who report that on a number of oxide catalysts the high temperature chemisorption takes place on the oxygen ion and the desorbed gas consists of carbon dioxide. However, the exchange reaction of the oxygen atom between carbon monoxide and the oxide surfaces have recently been investigated by Winter[2], who shows that the high temperature chemisorption does not necessarily lead to the desorption of carbon dioxide, in agreement with the results in the present work.

On the other hand, as described above, there is a slow uptake at room temperature which seems to imply that the chemisorption with the lower activation energy occurs even at room temperature. The phenomena of hysteresis observed at room temperature may then be accounted for, since the high temperature type is considered to be irreversible at this temperature.

**Nature of Heterogeneity of the Surface.**—The problem was dealt with in the same manner as previously reported for the hydrogen chemisorption[4]: At 192°C a known amount of carbon monoxide was left in contact with the adsorbent for fifteen minutes in one case and for fifteen hours in the other case; then, by pumping out a known amount of the gas from the system, the desorption rates in the two cases were compared with the results shown in Fig. 10, where curves A and B represent desorption rates after fifteen minute and fifteen hour contacts, respectively. After desorption B a certain amount of carbon monoxide was further pumped out at a higher temperature until the remaining amount adsorbed became comparable to that left after desorption A; thereupon, the temperature was lowered down to 192°C, and desorption rate measurements were carried out. Their results, denoted by C, are also shown in Fig. 10. It follows from this figure that the rate of desorption is greater on the surface where the larger amount is adsorbed, and is determined by the remaining amount adsorbed alone, independent of the conditions employed for the adsorption, in contrast with the behavior of hydrogen described in the previous paper[4].

These results might be explained in terms of the concept that the increase of the activation

5) During the adsorption isotherm measurements, the formation of carbon dioxide was negligibly small and darkening of zinc oxide was not observed, suggesting that the reaction $2CO \rightarrow C+CO_2$ scarcely takes place at all, in disagreement with the results obtained by Taylor and Burwell[2]. Such discrepancy appears to be explained by the severe carbon monoxide treatment in the present work, since the authors cited above reported a marked decrease in the activity toward this reaction after the carbon monoxide treatment.

6) W. E. Garner, *J. Chem. Soc.*, **1947**, 1239.

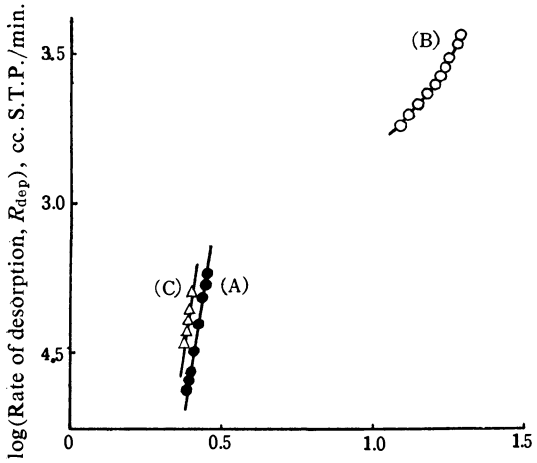

Fig. 10. Rate of desorption as a function of the amount left adsorbed. Temp, 192°C.

energy of adsorption with the adsorbed amount is due to the decrease of the heat of adsorption with coverage, without the concept of an *a priori* heterogeneity. However, the fact that the value of $d \log R_{dep}/dq$ differs markedly between the two runs, A and B, as shown in Fig. 10, can not be explained in terms of the induced heterogeneity[7] above mentioned, because there is no marked difference in the coverage $\theta$ between these two runs, considering that the adsorbed amount at $\theta=1$ estimated from Fig. 8 is about 10 cc. With respect to this problem, the following experimental results may be mentioned. From the plots of $\log R_{dep}-q$ at varied temperatures which were determined for the purpose of determining the activation energy of desorption at various coverages, the values of $d \log R_{dep}/dq$ at different adsorbed amount were estimated as shown in Fig. 11. This considerable change[8] can not be expected from the concept of induced heterogeneity. It may therefore be concluded that in this system again the variation of the heat of adsorption

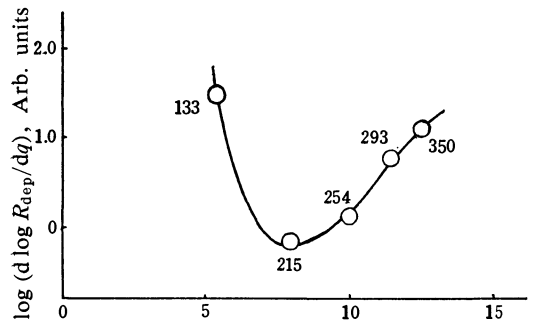

Fig. 11. Values of $d(\log R_{dep})/dq$ at various amounts adsorbed. Figures indicate the temperature in °C where the rate of desorption was measured.

with the adsorbed amount will arise mainly from *a priori* heterogeneity, the nature of which is such that the activation energy of adsorption and the heat of adsorption varies conversely to each other, in contrast with hydrogen chemisorption. Such a correlation between the activation energy of adsorption and the heat of adsorption requires that the maximum activation energy of adsorption 16 kcal./mol. should correspond to the minimum activation energy of desorption 37 kcal./mol. and the minimum of the former 5 kcal./mol. to the maximum of the latter 41 kcal./mol. This gives as the heats of adsorption 36 and 21 kcal./mol. in fair agreement with the values directly obtained from the adsorption isotherms[9].

## Summary

The rates of adsorption and desorption, and the adsorption equilibrium for carbon monoxide chemisorption on zinc oxide were measured over a wide range of temperatures as in the previous study of hydrogen chemisorption on zinc oxide. The behavior of desorption indicated the existence of two types of chemisorption; the non-activated type and the activated type. For the former type the heat of adsorption was estimated as 10~12 kcal./mol. from the adsorption isotherms, in agreement with the activation energy of desorption. The considerable fraction of the latter type was reversible, i.e. desorbed as such. For this type, the activation energy of adsorption increased with the adsorbed amount from 5 to 16 kcal./mol., and the rate was proportional to $P^{0.8\sim0.9}$. Moreover, the heat of adsorption obtained from the adsorption isotherms ranged from 25 to 38 kcal./mol., in fair agreement with those estimated from the activation energy of adsorption and desorption. The behavior of desorption suggested the predominance of surface heterogeneity, the nature of which was such that the activation energy of adsorption and the heat of adsorption varied conversely to each other.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

7) M. Boudart, *J. Am. Chem. Soc.*, 74, 3556 (1952).

8) It will be shown in a forthcoming paper that this considerable change inevitably arises on a surface where *a priori* heterogeneity is predominating.

9) In Figs. 3, 6 and 9, the states of the carbon monoxide adsorbed to an equal amount can not be be compared, since the surface has a heterogeneous character, and moreover the observed amount of adsorption includes the irreversible one, the extent of which varies with the experimental conditions.

## *Formation of Mullite from Kaolin Minerals at Low Temperature*

By Hiroshi OKUDA

(Received February 27, 1960)

Mechanism of the mullite formation has not been explained completely, and there is a widespread disagreement concerning the formation temperature in the literatures[1-4]. It was reported that the formation of mullite from well-crystallized kaolinite occurs above 950°C and the formation of mullite from poorly crystallized kaolinite and halloysite occurs at a higher temperature[5,6]. Colegrave and Rigby[7] showed that traces of mullite were formed, when kaolinite was mixed with 2% of boric oxide and heated at 900°C. for 200 hr. No literature reported that the formation of mullite from kaolin minerals occured below 900°C.

During the course of an investigation of the effects of additive on the mullite formation of kaolin minerals[8], it was found that fluoride of alkali and alkaline earth elements promoted the formation and lithium fluoride was most effective. The present experiment has been carried out to find the effect of additive lithium fluoride on the temperature of mullite formation.

A well-crystallized kaolinite from Kampaku, Tochigi Prefecture, Japan and halloysite from Korea were used. The dried minerals were mixed with 2.5, 5 and 10% of lithium fluoride. The mixtures were heated for 5 hr. at 500, 550, 600, 700, 800 and 900°C. The heated samples were examined by an X-ray diffractometer, and the results are shown in Fig. 1 and Table I.

When 2.5% of lithium fluoride was added to kaolin, mullite and β-spodumene started to be formed at 800°C. The kaolin mixed with 5% of lithium fluoride was converted into β-spodumene above 600°C and into mullite above 700°C. It was found that β-spodumene was formed at 500°C and a small amount of mullite was formed at 550°C, when kaolin was mixed with 10% of lithium fluoride.

It is concluded that by the addition of lithium fluoride the kaolin minerals form mullite at a extremely lower temperature than that reported in the literature. Further experiment, however,

# *A New Application of Neutron Activation Analysis to the Polarography of Holmium*

By Hiroshi HAMAGUCHI, Jinzo HASHIMOTO, Kyoichi HOSOHARA and Yoshio NARUSAWA

(Received February 16, 1960)

In general, two stepped reduction waves are observed in the polarograms of lanthanide elements. Conflicting explanations for the mechanism of electrode reaction have been reported as summarized in Table 1.

The present authors introduced a new method for the study of the electrode reduction process of holmium by utilizing a neutron activation technique. Assuming the electrode reaction of holmium to be $Ho^{3+}_{aq}+3e+Hg \rightarrow Ho(Hg)$, the amount of holmium $m(\mu g.)$ amalgamated in one drop of mercury is calculated by

$$m = i_1 \cdot \tau \cdot 164.94/3F$$

where $i_1$ is the limiting current (microamp.), $\tau$ the drop time (sec.), 164.94 the atomic weight of holmium and $F$ the Faraday constant. In the case of the experimental condition shown in Fig. 1, the amount of holmium that would be deposited is calculated as 0.022 $\mu$g. ($\tau$=3.08 sec.) for the first wave and 0.023 $\mu$g. ($\tau$=2.67 sec.) for the second wave. These amounts are well above the sensitivity limit of the activation analysis of the element[9].

One drop of mercury taken up immediately after electrode reaction* was sealed in a vinyl bag, and irradiated for two days with a neutron flux of $\sim 10^{11}$ $n/cm^2/sec.$ in the JRR-1 reactor. After irradiation, the induced radionuclide $^{166}Ho$ was purified by going through decontamination chemistry, and the amount of holmium was then determined by comparing the $\beta$ activity of holmium from the sample with that of the monitor.

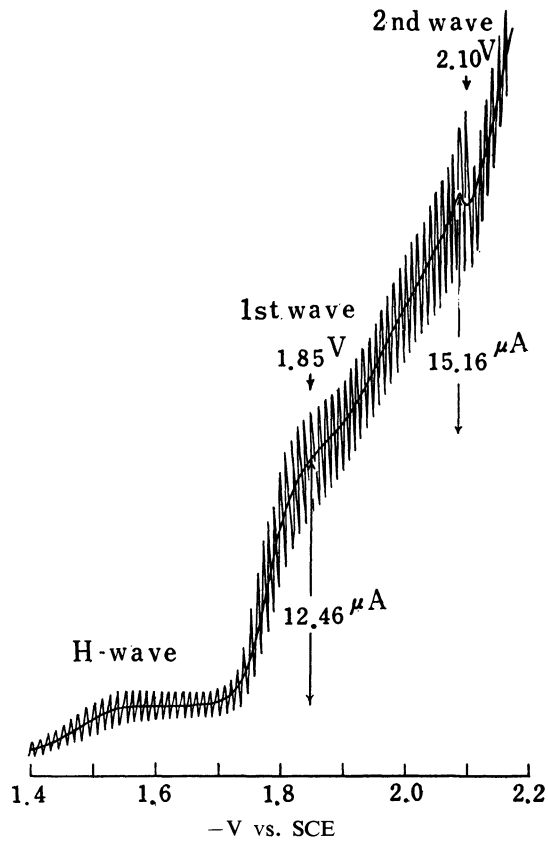

Fig. 1. Polarogram of $2.32\times10^{-3}$ mol./l. $Ho^{3+}$. aq. in 0.1 N LiCl soln. containing 0.01% gelatine. Temp. 25.0±0.01 °C.
The 1st wave: Number of electron 3(pH< 3.1), temp. coeff. 3.0%, linear relationship between wave height and concentration is obtained. Reversible at pH<3.10, quasi-reversible at 3.10<pH<3.90, irreversible at pH>3.90 are explained by Matsuda-Ayabe's theory. $E_{1/2}$ shifts toward more negative with decreasing of pH.
The 2nd wave: Followed by a maximum wave, no linear relation between wave height and concentration is obtained, although the correlation between them is held. The ratio of wave height of the 2nd to that of the 1st is not 2 : 1.

Contrary to the earlier reports that had suggested a reduction of lanthanides to the metallic state, extremely smaller amount of holmium than was expected was found at both reduction steps as shown in Table II.

In the light of the above data and of the polarographic behavior shown in Fig. 1, it should reasonably be considered that the polarographic reduction of holmium is not the reduction of the holmium aquo-complex ion to a metallic state but the discharge of hydrogen ions

## *Transport Behavior of Ferric, Aluminum and Cupric Ions across the Alginate and the Other Membranes*

By Manabu Senō, Tazuko Saitō and Takeo Yamabe

(Received January 26, 1960)

Recently many attempts have been undertaken to separate various species of ions by the electrodialyses using the ion-selective membranes, but there is no report as to the selective permeability of heavy metal ions. One of the objects of this study is to describe the transport behavior of ferric, aluminum and cupric ions across the ion-selective membranes. Another is to examine the permeability of ferric ion across the alginate membrane which is prepared from alginic acid. It is known that alginic acid adsorbs preferentially the ferric ion[1].

The electrodialyses were carried out at the constant current densities, $(0.33\sim2.50)\times10^{-2}$ amp./cm$^2$, for one hour, using a five-compartment cell which was schematically Shown in Fig. 1.

$AM_1$, SAM ; $CM_2$, SCM

Fig. 1. A five-compartment cell for the electrodialyses.

Into the central compartment, the solution containing 5~10 meq./l. of ferric and aluminum chloride or ferric and cupric chloride and being adjusted to be about pH 1.3 (ca. 0.05N HCl) were fed at the flow-rate of about 1 l./hr. The amounts of ions transferred to the adjacent compartments, which were filled with the same solution beforehand, across the ion-selective membranes were measured. The analyses were done by the simultaneous colorimetric methods[2]. The ion-selective membranes were heterogeneous and were prepared from Amberlite resins in the authors' laboratory*. The alginate membrane

TABLE II. PERMSELLCTIVITY COEFFICIENTS ACROSS THE VARIOUS ION-SELECTIVE MEMBRANES AT 0.0083 amp./cm$^2$

| Ion-selective membrane system (CM1-AM2) | Permselectivity coefficients* | | | |
|---|---|---|---|---|
| | $T^{Al}_{Fe}$ | $T^{Cu}_{Fe}$ | $T^{H}_{Fe}$ | |
| SCM-SAM | 1.23 | 1.57 | 2.55 | 2.13 |
| WCM-SAM | 1.27 | 1.32 | 2.49 | 2.00 |
| WCM-WAM | 1.07 | 1.30 | 2.06 | 2.35 |
| ACM-SAM | 1.03 | 1.70 | 1.72 | 2.50 |
| ACM-WAM | 1.01 | 1.51 | 1.75 | 2.06 |

* $T^{B}_{A}=\dfrac{[B]_f[A]_i}{[B]_i[A]_f}$

where $[A]_i$, $[B]_i$; concentration of A or B ion in the initial solution filling the compartment II, respectively; $[A]_f$, $[B]_f$; concentration of ion A or B in the final (concentrated) solution in the compartment II, respectively.

** In the first column, the values obtained for Fe-Al system were shown and in the second column, those for Fe-Cu system were presented.

(1) The order of permeabilities of these cations across the cation-selective membranes is as follows; $Fe^{3+}<Al^{3+}<Cu^{2+}<H^{+}$, excepting the case at the lowest current density**.

(2) This order remains invariable, independently of the various combinations of the ion-selective membranes. The permeability of the ferric ion across the alginate membrane is nearly the same as that in the other membrane systems. There is no parallel relationship between the selectivity in the ion exchange equilibria[1] and the permselectivity in this experiment, of the various ion-selective membranes.

(3) Some amount of the ferric ion transports across the anion-exchange membranes and this behavior seems to be due to the formation of a complex anion. A further investigation is carried out now, for the experimental error of this research prevents from giving a final conclusion to this problem.

The full data will be presented in the near future.

The authors wish to express their thanks to Professor T. Takahashi for his continuous advice, and to the Ministry of Education for grand-in-aid.

3) T. Yamabe, Y. Tanka and M. Senō, *Industrial Science (Seisan Kenkyu)*, **9**, 476 (1959).

** This order does not depend on the current density higher than 0.0083 amp./cm$^2$. The diffusion of ions through membrane and the migration of water due to the electro-osmosis make a contribution to the transport behavior to some extent. On this account, the concentration ratio of the metal ions shown in Table I is smaller than unity at the current density, 0.0033 amp./cm$^2$. When the current density is high enough and the same membrane used as AM1, the permselectivity coefficient $T^{B}_{A}$ defined in Table II is considered to be a relative measure of the permeabilities of the cations across the cation-exchange membrane CM1.

## *Two Types of Antifoamers and their Cooperating Action*

By Satiko OKAZAKI and Tsunetaka SASAKI

(Received February 18, 1960)

The present authors pointed out[1] that attention should he drawn to two factors, foam stability and foam producing power, to explain the phenomena of foam formation, and also that two factors should be taken into account, i. e., foam breaking action and foam inhibiting action, to elucidate the phenomena of antifoaming. In this relation we have already shown[2] that when an aqueous solution of saponin which is marked for its foam stabilizing action is mixed with an aqueous solution of alcohol which is marked for its foam producing power, a pronounced foam formation, presumably due to their cooperative or syergistic action, can be observed even in such a dilute solution as they can exhibit only

TABLE I. ACTION OF ANTIFOAMERS TOWARDS AQUEOUS SAPONIN AND SODIUM DODECYL SULFATE FOAMS

Saponin Foam (0.5% aqueous solution)

| Antifoamers | Foam height in cm. Before addition | 10 sec. after addition | 3 sec. after shaken again |
|---|---|---|---|
| Silicone | 10 | 9.4 | 0 |
| *i*-Amyl alcohol | 10 | 1.7 | 10 |
| *i*-Amyl alcohol +silicone* | 10 | 2.2 | 0 |
| Ethyl acetate | 10 | 5.5 | 10.6 |
| Ethyl acetate +silicone* | 10 | 5.6 | 0 |
| Ethanol | 10 | 7.3 | 11 |
| Ethanol +silicone* | 10 | 6.8 | 0 |

Sodium dodecyl sulfate foam ($10^{-2}$ mol./l. aqueous solution)

| Antifoamers | Foam height in cm. Before addition | 10 sec. after addition | 3 sec. after shaken again |
|---|---|---|---|
| Silicone | 12 | 7.0 | 0 |
| *i*-Amyl alcohol | 12 | 0.7 | 12 |
| *i*-Amyl alcohol +silicone* | 12 | 2.0 | 0.6 |
| Ethyl acetate | 12 | 4.3 | 12 |
| Ethyl acetate +silicone* | 12 | 3.3 | 0.3 |
| Ethanol | 12 | 8.7 | 12 |
| Ethanol +silicone* | 12 | 6.7 | 0.8 |

* Composition of mixtures being 1 : 1 in weight. Room temperature : 16°C

a poor foam formation when each of them exists separately.

Now we can demonstrate a similar experiment also in the case of antifoaming. As we have shown,[1] silicone oil antifoamer is a well-known excellent foam inhibitor but is not always a good foam breaker, while *i*-amyl alcohol is a strong foam breaker but is not a good foam inhibitor* when added in a small amount. Now, when these two antifoamers of rather mutually opposite in the types of their actions are mixed together and a drop of the mixture is appleid onto the aqueous saponin and sodium dodecyl sulfate foams, a remarkable foam breaking action and foam inhibiting action are observed simultaneously. The results of these experiments are shown in Table 1. Similar instances may be shown for other pairs of antifoamers of the same relation. In this table we can also confirm a slight difference in antifoaming action of a given antifoamer towards different types of foams, i. e., saponin and sodium dodecyl sulfate foams. Anyhow, we can confirm distinctly the existence of two different types of antifoaming actions, i. e., foam breaking and foam inhibiting ones which have been reported merely qualitatively in many literatures,[3] and also confirm their cooperating action, though actually we can only make a rough distinction between two types of antifoamers according to these actions.

The authors thank the Ministry of Education for the Scientific Research Expenditure given to T. Sasaki.

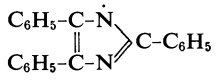
## *Preparation of a New Phototropic Substance*

By Taro HAYASHI and Koko MAEDA

(Received March 1, 1960)



Under the investigation of the mechanism of chemiluminescence which occurred when lophine (2, 4, 5-triphenyl-imidazole) was oxidized in an ethanol solution of potassium hydroxide with an oxidizing agent, there was isolated a new phototropic substance which was considerd to be an imidazole derivative. To the solution of lophine (1 g.) in a solution of potassium hydroxide (12 g.) in ethanol (100 cc.), 450 cc. of 1% potassium ferricyanide aqueous solution was added during a period of 1.5 hr. with stirring by a stream of oxygen at room temperature. The violet color of the solution, which initially appeared, gradually disappeared and white precipitates, having a tinge of pale violet, separated out. When the oxidation was carried out in a dark place, a weak greenish blue chemiluminescence was observed. The precipitates were filtered and then washed with water repeatedly until the washing showed no reaction of ferricyanide ion. The precipitates, dried in vacuo (0.9g.) were dissolved in benzene to yield a deep red violet solution. When the solution was concentrated under reduced pressure, a lemon yellow crystalline substance separated out. It was recrystallized from ethanol as lemon yellow prisms, m. p. 199~201°C.

Found: C, 85.20; H, 5.50; N, 9.41. Calcd. for $C_{21}H_{15}N_2$: C, 85.38; H, 5.11; N, 9.49%.

The molecular weight in benzene solution was determined to be about 290 by a cryoscopic method. Although this compound had the composition nearly equal to that of lophine, properties of these compounds were different from each other, showing that this compound was different from lophine. This compound was soluble in ordinary solvents, giving a pale yellow or almost colorless solution. Its ultraviolet absorption spectrum showed an absorption maximum at ca 267 m$\mu$ in ethanol. This compound was also obtained by the oxidation of lophine with an ethanol solution of bromine. In this case, the bromine solution was mixed in benzene with a solution of lophine in ethanolic potassium hydroxide. A mixture of ethanol solution of this compound with 4% aqueous solution of potassium ferrocyanide, which yielded white precipitates, was warmed in a water bath for 1 hr. and then water was added until white precipitates dissolved in a solution. The solution was evaporated to give white precipitates which were recrystallized from ethanol and identified to be lophine.

This compound showed a marked phototropy; when it was irradiated with sun light or light of mercury lamp in a solution of organic solvent as well as in solid at room temperature, it rapidly turned red violet, both in air and in vacuo. The absorption spectrum of the red violet solution showed absorption maxima at 350 and 550 m$\mu$ in benzene. In solid the red violet color faded slowly at room temperature but rapidly when the colored substance was warmed in a water bath. In solution the color faded rather rapidly even at room temperature. When the benzene solution of this phototropic substance was irradiated, no change of the molecular weight was observed. When nitrogen oxide gas was passed through the red violet benzene solution, the color immediately disappeared. This fact shows that the red violet coloration is due to the formation of a free radical. Electron spin resonance absorption was detected with this red violet substance in benzene solution as well as in solid[1]. The solution of this compound exhibited thermochromism.

From the results mentioned above, it is considered that the red violet form is an oxidation product of lophine which is a free radical $C_{21}H_{15}N_2$ (I), while the lemon yellow form may be a rather labile meso ionic form.

# *Hydrogenation and Hydrogenolysis. III*[1]. *Rhodium-Platinum Oxide as a Catalyst for the Hydrogenation of the Aromatic Nucleus*

By Shigeo NISHIMURA

(Received March 10, 1960)

It has been shown in these two decades that rhodium is useful as a catalyst for the hydrogenation of various organic compounds[2], and recently that it is specially effective for the hydrogenation of the aromatic nucleus[3-5]. However, most of the works on rhodium catalysts are concerned with the use of colloidal or supported rhodium, and none with the use of rhodium oxide of Adams' type. It seem that this is because of the difficulty of reducing rhodium oxide to the metal form under mild conditions[6].

The present author prepared a useful catalyst consisting of rhodium oxide and platinum oxide in a ratio of 3 : 1 by the weights of the metals, by fusion of the mixture of rhodium chloride and chloroplatinic acid or ammonium chloroplatinate with sodium nitrate exactly in the same way as in the preparation of Adams platinum oxide[7]. This rhodium-platinum oxide[8] can be reduced with hydrogen to rhodium-platinum

8) The mixed oxide thus prepared is not identical with the mere mixture of rhodium oxide and platinum oxide, the former being reduced with hydrogen much more rapidly and uniformly than the latter.

TABLE I. HYDROGENATION OF AROMATIC COMPOUNDS WITH RHODIUM-PLATINUM OXIDE AND PLATINUM OXIDE AS CATALYSTS AT THE ORDINARY TEMPERATURE AND PRESSURE[a]

| Compound | Amount, g. | Catalyst, g. | Hydrogen uptake, mol./mol. | Time for complete hydrogenation, min. |
|---|---|---|---|---|
| Methylphenylcarbinol | 0.611 | Rh-Pt, 0.05 | 3.04 | 36 |
| 〃 | 〃 | Pt, 0.20 | 3.87 | 80 |
| Benzhydrol | 0.553 | Rh-Pt, 0.05 | 6.03 | 105 |
| 〃 | 〃 | Pt, 0.20 | 6.73 | 120 |
| Phenol | 0.471 | Rh-Pt, 0.05 | 3.04 | 14 |
| 〃 | 〃 | Pt, 〃 | 3.35 | 40 |
| Anisole[b] | 0.541 | Rh-Pt, 〃 | 3.04 | 18 |
| 〃 | 〃 | Pt, 〃 | 3.45 | 85 |
| Cinnamyl alcohol[c] | 1.342 | Rh-Pt, 〃 | 1.04 | 11 |
| 〃 | 〃 | Pt, 〃 | 1.31 | 26 |
| Benzene[d] | 0.781 | Rh-Pt, 〃 | 2.99 | 20 |
| 〃 | 〃 | Pt, 〃 | 2.99 | 80 |
| Ethyl benzoate | 0.751 | Rh-Pt, 〃 | 3.02 | 21 |
| 〃 | 〃 | Pt, 〃 | 3.00 | 120 |

a) 20 cc. of glacial acetic acid was used as solvent.
b) Smith and Thompson (Ref. 4) reported that anisole absorbed 3.06 mol. of hydrogen with 5% rhodium on alumina and 3.40 mol. with Adams platinum oxide in acetic acid at 30°C under initial hydrogen pressures of 40–60 p. s. i.
c) Reduction to 3-phenyl-1-propanol and propylbenzene.
d) Gilman and Cohn (Ref. 5) reported that 5 ml. of benzene was hydrogenated four times as rapidly with 1 g. of 5% rhodium on alumina as with 1 g. of 5% platinum on alumina in acetic acid under ordinary conditions.

black in neutral ethanolic or acetic acid suspension at the ordinary temperature and pressure. The reduction begins in about twenty minutes and completes in about forty minutes in acetic acid at 25°C. The rhodium-platinum black thus prepared is an excellent catalyst in the hydrogenation of various aromatic compounds in acetic acid under ordinary conditions as shown in Table I. With this catalyst, methylphenylcarbinol, benzhydrol, phenol, anisole and cinnamyl alcohol are reduced rapidly and quantitatively to the corresponding saturated compounds with far less portions of hydrogenolysis than with Adams platinum oxide as indicated by the moles of hydrogen absorbed. The catalyst is four and six times as active as Adams platinum oxide in the hydrogenation of benzene and ethyl benzoate, respectively, where the hydrogen uptake is equally 3 mol. with both catalysts. Thus the results show that the rhodium-platinum catalyst retains to a large extent the nature of pure rhodium catalysts and is substantially superior to Adams platinum oxide both in activity and in selectivity in the hydrogenation of the aromatic nucleus. Details will follow.

The author wishes to express his hearty thanks to Professor Y. Urushibara for his continued encouragement.

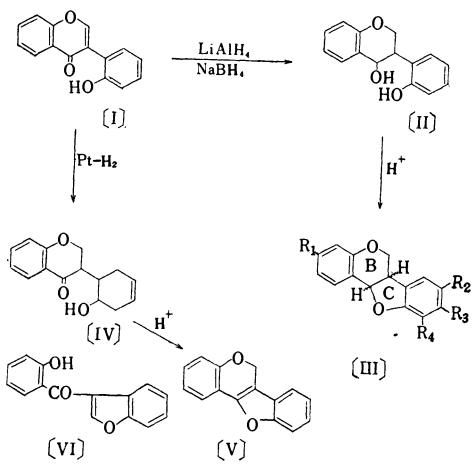
## *The Synthesis of the Pterocarpin Ring System*[1]

By Hiroshi SUGINOME and Tsukasa IWADARE

(Received March 1, 1960)

The structures of pterocarpin and homopterocarpin, the minor principles of *pterocarpus santalinus*, were elucidated in 1940 by Robertson and Whalley and by Späth and Schläger[2] as III, $R_1$=$R_4$=OMe, $R_2$, $R_3$=–O–$CH_2$–O–, and III, $R_1$=$R_3$=OMe, $R_2$=$R_4$=H, respectively. However, the syntheses of pterocarpin and homopterocarpin have not been hitherto completed.



This paper presents the syntheses of the

1) Oxygen heterocycles. (II). Previous paper in this series, Hiroshi Suginome, *J. Org. Chem.*, **24**, 1655 (1959).

2) A. Robertson and W. B. Whalley, *J. Chem. Soc.*, **1940**, 787; **1954**, 1440; E. Späth and J. Schläger, *Chem. Ber.*, **73**, 1 (1940).

simple core of pterocarpin, III, $R_1=R_2=R_3=R_4=H$, and compound V, as shown in the annexed chart, which establish a synthetic route to DL-pterocarpin and DL-homopterocarpin or their isomers.

In view of a possible biogenetic link[1,3,4] of pterocarpin and homopterocarpin to naturally occurring 2'-hydroxyisoflavonoids, the synthetic sequence, I→II→III, is of particular interest.

Mild acid hydrolysis of 2,2'-bis(methoxymethoxy) benzoin, m. p. 104~104.5°[5]. (Found: C, 64.79; H, 5.59. Calcd. for $C_{18}H_{20}O_6$: C, 65.09; H, 6.02%) afforded 2,2'-dihydroxybenzoin, m. p. 161~163°C[6] (Found: C, 68.48; H, 5.02. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%), accompanied by a small amount of an unidentified substance, m. p. 156~157°C, I. R. bands at 1627 $cm^{-1}$ (conjugated carbonyl) and 3200 $cm^{-1}$ (broad hydroxyl band).

2,2'-Dihydroxydesoxybenzoin, m. p. 102~103°C, readily prepared from above 2,2'-dihydroxybenzoin and from the unidentified substance, m. p. 156~157°C, by zinc-alkali reduction, was converted into 2'-hydroxyisoflavone (I), m. p. 153°C (Found: C, 75.67; H, 4.45. Calcd. for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%), I. R. bands at 1621 $cm^{-1}$ ($\gamma$-pyrone carbonyl) and 3187 $cm^{-1}$ (phenolic hydroxyl), with ethyl formate and sodium. No isomeric 3-benzoylcoumarone (VI) could be isolated from the reaction mixture. The isoflavone (I) was reduced to an amorphous stereoisomeric mixture of 2'-hydroxyisoflavan-4-ol (U. V. spectrum: $\lambda_{max}$(ethanol) 275 m$\mu$) by $NaBH_4$[7] or $LiAlH_4$.

The successful intramolecular dehydrocyclization of this amorphous diol by mild treatment in acidic medium, led to compound III, $R_1=R_2=R_3=R_4=H$, m. p. 125~126.5° (Found: C, 79.83; H, 5.49. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%) (U. V. spectrum; $\lambda_{max}$(ethanol) 278 m$\mu$($\varepsilon$; 3260). I. R. No band in the region 3000~3500 $cm^{-1}$), without any proof of stereochemical assignment of B/C ring junction.

On the other hand, catalytic hydrogenation of 2'-hydroxyisoflavone (I) in glacial acetic acid with Adams's platinum oxide as a catalyst, gave the corresponding 2'-hydroxyisoflavanone, m. p. 118~122°C. I. R. bands at 1660 $cm^{-1}$ (conjugated carbonyl) and 3297 $cm^{-1}$ (associated phenolic hydroxyl), which was converted into anhydro-compound V,[1] m. p. 80~83°, U. V. spectrum; $\lambda_{max}$(ethanol) 331, 299, 286, and 239 m$\mu$ ($\varepsilon$; 11190, 7350, 7240, and 11740), in a good yield by treatment in acidic medium.

The synthesis of homopterocarpin along the above synthetic line is now in progress.

Full details of this work will appear shortly.

The authors are grateful to Professors Toshi Irie, Takeshi Matsumoto and Tadashi Masamune for their interest and encouragement in this work.

# *Separation of Uranium and Protactinium from Thorium by Amine Extraction*

By Fujio ICHIKAWA and Shinobu URUNO

(Received September 18, 1959)

Preuss and Saunders[1] reported the extraction of uranium from sulfuric acid solution with amines. The use of primary amine as an extractant for thorium from sulfuric acid was reported by Crous and Denis[2]. Moore and his coworkers studied the liquid-liquid extraction of protactinium, niobium, tantalum, cobalt and zinc by amine[3-5].

In this paper, the extraction of thorium, protactinium and uranium from hydrochloric, nitric and sulfuric acid of various concentrations with secondary amine is studied. Amberlite LA-1 in kerosene diluent is used as an extractant.

The free-base form of Amberlite LA-1 removes acids from aqueous solutions by neutralization as illustrated by reaction 1,

$$(RR'NH)_{org}+H^{+}+A^{-}\rightleftarrows(RR'NH_2A)_{org} \quad (1)$$

where the ions, $H^+$ and $A^-$, refer to the aqueous phase and "org" refers to the amine salt dissolved in the organic solvent. When the amine salt formed through neutralization is brought into contact with an aqueous solution which contains another anion, the exchange of anions associated with the amine salt takes place as shown by reaction 2,

$$(RR'NH_2A)_{org}+B^{-}\rightleftarrows(RR'NH_2B)_{org}+A^{-} \quad (2)$$

where $A^-$ and $B^-$ represent two different anions.

When an element exists as a complex anion in an aqueous medium, it will be extracted by the amine according to this exchange process. Then it is of interest to compare the acid dependency of the extraction coefficient of an element by the amine with that of the distribution coefficient of the same element by the anion exchange resin. From the result of the extraction study, it is found that under the optimum conditions uranium, protactinium and thorium can be separated from each other. This separation procedure will be suitable for the recovery of uranium-233 from irradiated thorium blanket fuel. Consequently, the radiation damage of Amberlite LA-1 and LA-2 is studied by two methods.

## The Extraction Coefficient of Thorium, Protactinium and Uranium from Hydrochloric, Nitric and Sulfuric Acid of Various Concentrations by Amberlite LA-1

**Experimental.**—Two milliliters each of 5% Amberlite LA-1 in a kerosene diluent is shaken in a small glass-stopped tube for 1 min. with the same volume of an acid solution of the sample. After centrifuging, 1 ml. each of the aqueous and the organic phases are pipetted out and the concentration of the element is measured as follows. Thorium-234 ($UX_1$) and protactinium-233 are used as tracers for thorium and protactinium, and the $\gamma$-ray activity is measured with a well-type scintillation counter. Uranium nitrate is used as the starting material

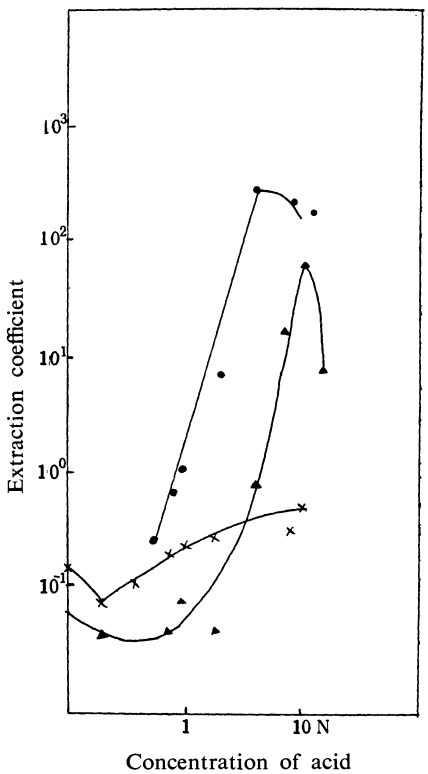

Fig. 1. Extraction coefficient of Th, Pa and U from HCl with Amberlite LA-1.
U —●—, Pa —▲—, Th —×—

5) F. L. Moore, ibid., **27**, 70 (1955).

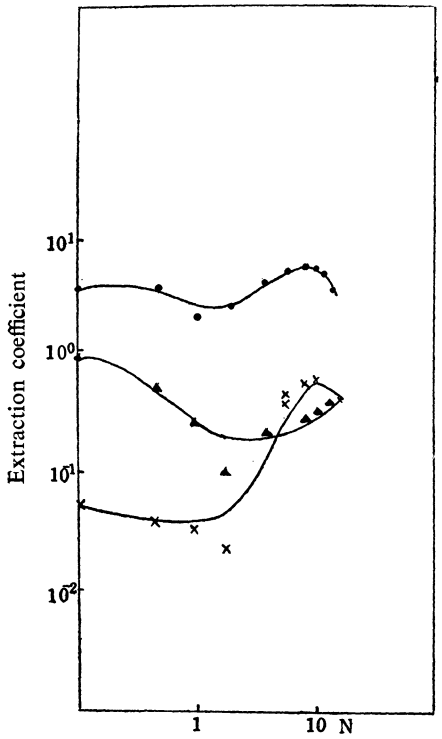

Fig. 2. Extraction coefficient of Th, Pa and U from $HNO_3$ with Amberlite LA-1.
U —●—, Pa —▲—, Th —×—

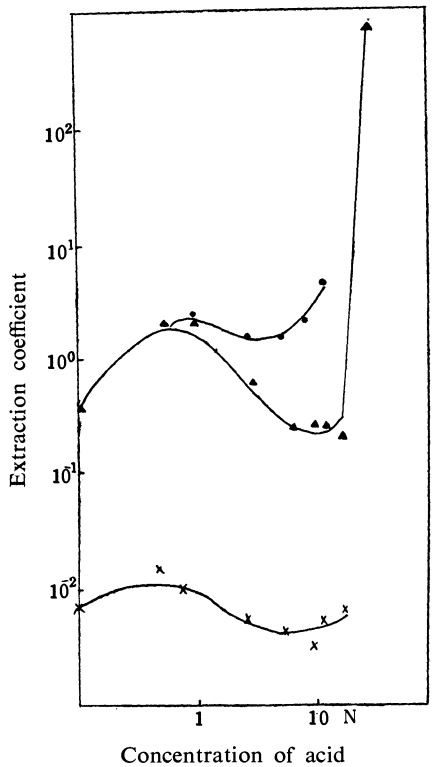

Fig. 3. Extraction coefficient of Th, Pa and U from $H_2SO_4$ with Amberlite LA-1.
U —●—, Pa —▲—, Th —×—

for extraction and its concentration is determined colorimetrically with hydrogen peroxide. The extraction coefficient is calculated by the following equation,

$$E = \frac{\text{Concentration of U, Th or Pa in organic phase/ml.}}{\text{Concentration of U, Th or Pa in aqueous phase/ml.}}$$

where $E$ is the extraction coefficient. The results are shown in Figs. 1—3.

**Results.**—The maximum extraction coefficient of uranium is about 200 at 6～12 N hydrochloric acid and below this concentration the extraction coefficient decreases with a slope of 3. From nitric acid solution, uranium is extractable in all the concentration ranges examined, giving an extraction coefficient of 2～5. The extraction coefficient of 1～3 is also found from 1～12 N sulfuric acid solution. Thorium is not extracted from these acids except 6～15 N nitric acid, but the extraction coefficient is only 0.5 even under this condition. Protactinium is favorably extracted from hydrochloric acid of higher concentration with a maximum extraction coefficient of 60. From nitric or sulfuric acid the extraction coefficient of protactinium is very low.

## Comparison of Extraction Coefficient with Distribution Coefficient

If the amine extraction is based on the anion exchange mechanism, it is valuable to compare the amine extraction curve with the acid dependency of the distribution coefficient of these elements by anion exchange resin. From this view-point, the distribution coefficient ($K$d) of thorium, protactinium and uranium between hydrochloric, nitric and sulfuric acids of various concentrations and anion exchange resin are measured by the following method.

**Experimental.**—Dowex 1 ×8 (100～200 mesh) is used as an anion exchange resin. It is treated with 10% sodium hydroxide solution, washed with water and then converted into the desired form with hydrochloric, nitric or sulfuric acid. Half a gram of dried resin is placed for 24 hr. in 5 ml. of the acid solution of thorium, protactinium or uranium. The solution is filtered and the concentration of 1 ml. of filtrate is compared with that of the reference solution which contains no resin. $K$d is calculated by the following equation,

$$K\text{d} = \frac{\text{C(1 g. of resin)}}{\text{C(1 ml. of solution)}} = \frac{\text{C(reference)} - \text{C(filtrate)}}{\text{C(filtrate)}} \times 10$$

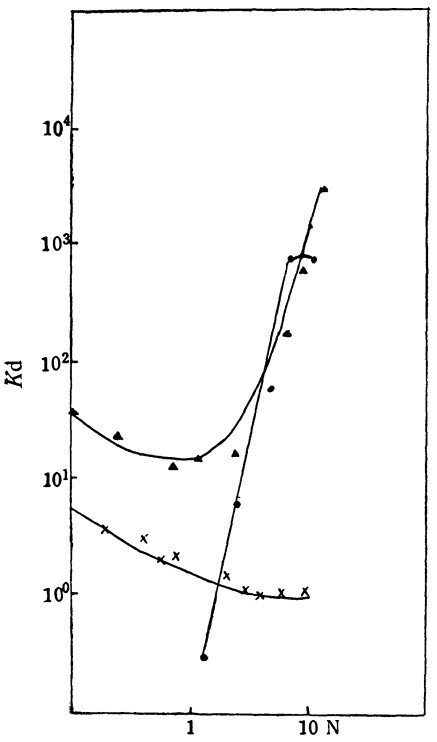

Fig. 4. Distribution coefficient of Th, Pa and U between Dowex 1 and HCl.
U —●—, Pa —▲—, Th —×—

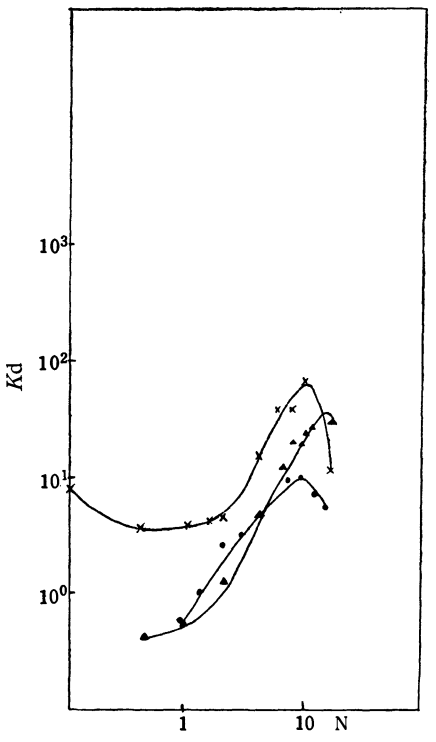

Fig. 5. Distribution coefficient of Th, Pa and U between Dowex 1 and $HNO_3$.
U —●—, Pa —▲—, Th —×—

where C means the concentration.

$UX_1$ and Pa-233 are used as tracers for thorium and protactinium, respectively. Their $\gamma$-ray activities are measured to determine the concentration. The concentration of uranium is determined by the colorimetric method.

**Results.**—The results are shown in Figs. 4—6. Concerning the anion exchange of these elements, some studies have already been reported by Kraus, Nelson and Danon[6,7]. In hydrochloric acid solution, the shapes of *K*d curves resemble those of extraction curves by LA-1, but the extraction coefficient of uranium is relatively very high. In a more concentrated nitric acid, Fig. 5 shows the order of adsorption as Th> Pa>U, but Fig. 2 shows the order of extraction as U>Th>Pa. In sulfuric acid, uranium is most favorably extractable with the amine, but Fig. 6 shows nearly the same *K*d value of uranium and protactinium.

These facts show that Amberlite LA-1 is selective in the extraction of uranium. It is not clear from these data whether or not this selectivity is due to the difference in the mechanism of amine extraction and anion exchange.

## The Separation of Uranium, Protactinium and Thorium by Amberlite LA-1

According to the study of the extraction coefficient, uranium and protactinium are sufficiently extracted from 8 N hydrochloric acid, but thorium is not extracted from hydrochloric acid of any concentration. At 3 N hydrochloric acid, the extraction coefficients are about 35, 0.1 and 0.05 for uranium, protactinium and thorium, respectively. From these facts, the separation of these elements is studied as follows.

**Experimental.**—*a) The separation of thorium and protactinium from 8N hydrochloric acid.*—Fifty milligrams of thorium nitrate is irradiated in the JRR-1 Reactor for 2 hr. at a flux of $10^{11}$ neutrons/$cm^2$/sec. The irradiated sample is dissolved in 2 ml. of 8 N hydrochloric acid and extracted with 5% Amberlite LA-1 (HCl form) in kerosene. The organic phase is scrubbed three times with 3 ml. each of 8 N hydrochloric acid, then stripped three times with 2 ml. each of 0.1 N hydrochloric acid. $\gamma$-Ray activity of about $3.8\times10^6$ c. p. m. of protactinium is collected in the stripping solution and thorium is not detected by thorin in this solution. The recovery of protactinium is about 80%.

*b) The effect of kerosene diluent on the extraction coefficient.*—The effect of kerosene diluent is tested

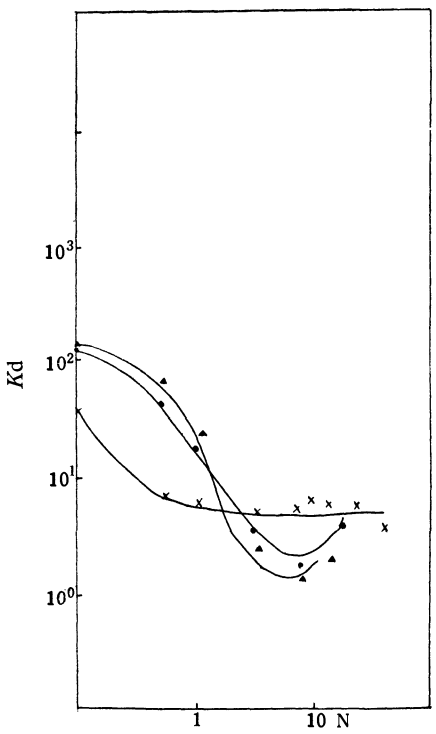

Fig. 6. Distribution coefficient of Th, Pa and U between Dowex 1 and $H_2SO_4$.
U —●—, Pa —▲—, Th —×—

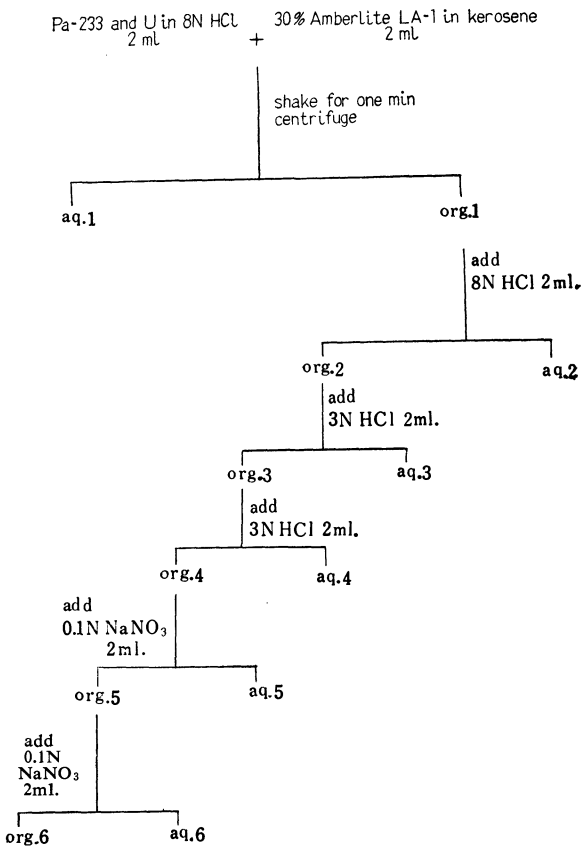

Fig. 7. Procedure of separating uranium and protactinium.

by calculating the extraction coefficient of protactinium from 8 N hydrochloric acid. From zero to 37.5% LA-1 in kerosene is used as an extractant. Two milliliters each of aqueous and organic phases are shaken for 1 min. and centrifuged. The extraction coefficient is determined as explained above. The results are shown in Table I. The effect of the diluent is negligible within the concentration of 2.5 to 37.5% LA-1 in kerosene.

TABLE I. THE EFFECT OF DILUENT TO THE EXTRACTION COEFFICIENT OF PROTACTINIUM FROM 8 N HCl

| The concentration of Amberlite LA-1 in kerosene | Extraction coefficient of Pa from 8 N HCl |
|---|---|
| 0 % | 0.05 |
| 0.5 | 27 |
| 2.5 | 194 |
| 5.0 | 150 |
| 7.5 | 158 |
| 12.5 | 256 |
| 17.0 | 143 |
| 37.5 | 197 |

*c) Stripping of uranium.*—About 10 mg. of uranium is extracted from 2 ml. of 8 N hydrochloric acid with 2 ml. of 30% Amberlite LA-1 in kerosene. Then, uranium is stripped from the organic phase with sodium nitrate, ammonium sulfate and sodium carbonate of various concentrations. The concentration of uranium in aqueous phase is measured colorimetrically with hydrogen peroxide. The results are shown in Table II.

Table II shows that uranium is completely stripped from the organic phase with 0.1 N sodium nitrate.

TABLE II. RECOVERY OF URANIUM FROM 30% AMBERLITE LA-1 IN KEROSENE

| Concentration of stripping agent | Distilled water | $NaNO_3$ | $(NH_4)_2SO_4$ | $Na_2CO_3$ |
|---|---|---|---|---|
| 0 N | 106% | — | — | — |
| 〃 | 119 | — | — | — |
| 〃 | 120 | — | — | — |
| 0.1 | — | 100 % | 88.4% | 82.0% |
| 〃 | — | 102 | — | — |
| 〃 | — | 105 | — | — |
| 0.5 | — | 94.0 | 89.4 | 75.0 |
| 1.0 | — | 89.8 | 54.3 | 94.0 |
| 2.0 | — | 80.5 | 60.5 | — |
| 4.0 | — | 54.6 | — | — |
| 5.0 | — | 30.5 | 54.3 | 87.6 |

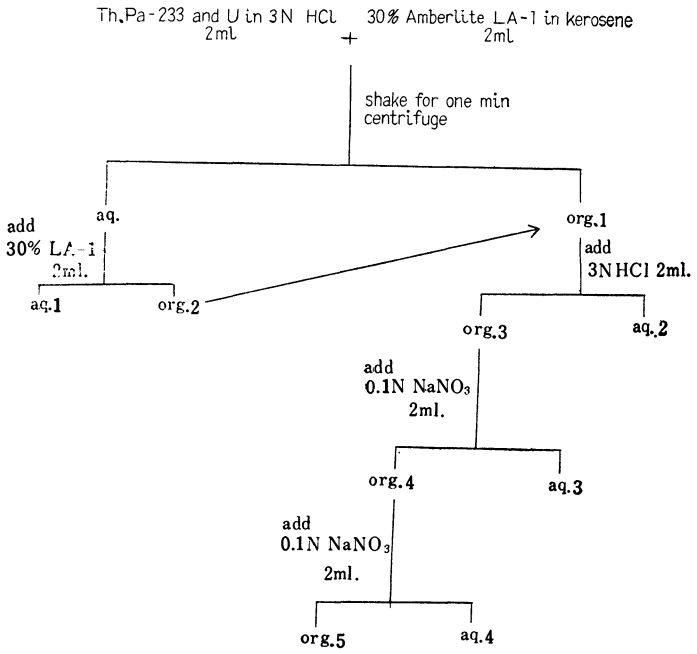

Fig. 8. Procedure of separating uranium from irradiated thorium.

Recovery with 0.1 N ammonium sulfate is 88.4%. The recovery of uranium decreases with the increase of the concentration of sodium nitrate or ammonium sulfate. Recovery with sodium carbonate is 75~94 %. When distilled water is used as a stripping agent, two phases do not separate even after centrifugation and colorimetric data show a higher value. Consequently, the best stripping agent is 0.1 N sodium nitrate.

*d) The separation of protactinium and uranium by 3N hydrochloric acid scrubbing.*—The separation scheme is shown in Fig. 7. Two milliliters of 8 N hydrochloric acid solution of protactinium-233 and uranium is shaken with 2 ml. of 30% Amberlite LA-1 in kerosene for 1 min. Most of the protactinium and uranium are extracted in this procedure. The organic phase is scrubbed with 2 ml. of 8 N hydrochloric acid, then protactinium is stripped twice with 3 N hydrochloric acid. Finally uranium is stripped twice with 0.1 N sodium nitrate. The results are shown in Table III. It is seen from these results that protactinium-233 is sufficiently extracted from 8 N hydrochloric acid and easily stripped with 3 N hydrochloric acid and that uranium is also sufficiently extracted from 8 N hydrochloric acid and about 40% of uranium is stripped with 3 N hydrochloric acid. Sixty per cent of the uranium is recovered with a slight contamination of protactinium-233 in this procedure. Thorium is not extracted under the condition explained above.

*e) The extraction of uranium from thorium and protactinium in 3N hydrochloric acid solution.*— About 50 mg. of thorium nitrate is irradiated in the J. R. R.-1 Reactor. After irradiation, 20 mg. of uranium is added to this sample and the mixture is dissolved in 2 ml. of 3 N hydrochloric acid. Two milliliters of Amberlite LA-1 in kerosene is added to this solution and the solution is shaken for 1 min. After centrifuging, the aqueous phase is re-extracted with 2 ml. of 30% LA-1 solution. Two organic phases are scrubbed with 2 ml. of 3 N hydrochloric acid. Uranium is stripped twice with 2 ml. each of 0.1 N sodium nitrate. The activity of protactinium-233 is measured by $\gamma$-ray counting. The Recovery of uranium is determined by the colorimetric method. Fig. 8 shows the separation scheme. Results are shown in Table IV.

TABLE III. RECOVERY* OF PROTACTINIUM AND URANIUM

| Sample No. | Medium | Recovery of Pa-233 | Recovery of U |
|---|---|---|---|
| aq. 1+aq. 2 | 8 N HCl | 1.3% | 8.4% |

Uranium is completely recovered from the first solution by this procedure.

### Radiation Damage of Amberlite LA-1 and LA-2

If these amines are used in reactor fuel reprocessing, radiation damage may occur on the action of high level $\gamma$-rays. Amberlite LA-1 and LA-2 are irradiated by $\gamma$-rays from Co-60 under various conditions (Table V). The degree of radiation damage is measured by extraction of protactinium-233 from 8 N hydrochloric acid and by potentiometric titration in dioxane. Two milliliters of irradiated sample is dissolved in 50 ml. of dioxane and is titrated with 0.2 N perchloric acid in dioxane. The end point is determined by drawing the potentiometric titration curve. A pH meter is used as a potentiometer. A calomel electrode, of which the aqueous solution of potassium chloride is displaced by saturated methanol solution of potassium chloride[8], is used as a reference electrode. A platinum electrode is used as an indicating electrode. The typical titration curve is shown in Fig. 9. The results are shown in Table V. Another method is to measure the extraction coefficient of protactinium-233 from 8 N hydrochloric acid by 30% irradiated amine in kerosene. The extraction coefficient is determined as mentioned above. Results are also shown in Table V. The radiation damage of Amberlite LA-1 and LA-2 is negligible under these conditions (dose rate is $8.1\times10^5$ $r$/h, maximum total dose is $5\times10^7$ $r$).

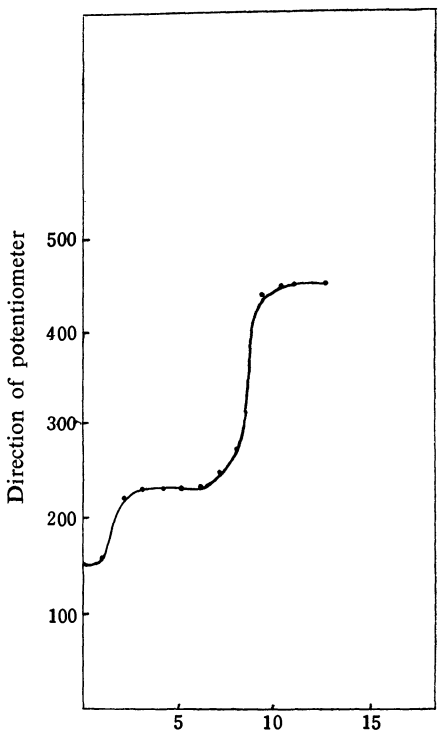

Fig. 9. Typical titration curve of Amberlite LA-1.

### Summary

Uranium, protactinium and thorium are satisfactorily separated from each other by secondary amine extraction. Amberlite LA-1 in kerosene diluent is used as the extractant. Separation from hydrochloric acid solution is superior to that from systems using other acids. The acid

8) J. S. Fritz, A. U. Moye and M. J. Richard, *Anal. Chem.*, **29**, 1685 (1957).

dependency of the extraction coefficient by amine fairly resembles that of the distribution coefficient by anion exchange resin, but the former has a selectivity for uranium. Under the total dose of $5\times10^7$ *r*., the radiation damage of Amberlite LA-1 is negligibly small. From these results, it is evident that there is a possibility of applying the amine extraction to the recovery of uranium-233 from reactor blanket fuel.

The authors wish to express sincere thanks to Dr. Toshio Nakai for his guidance.

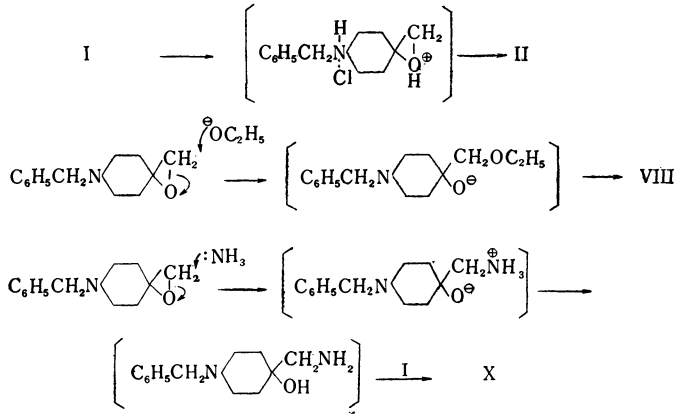
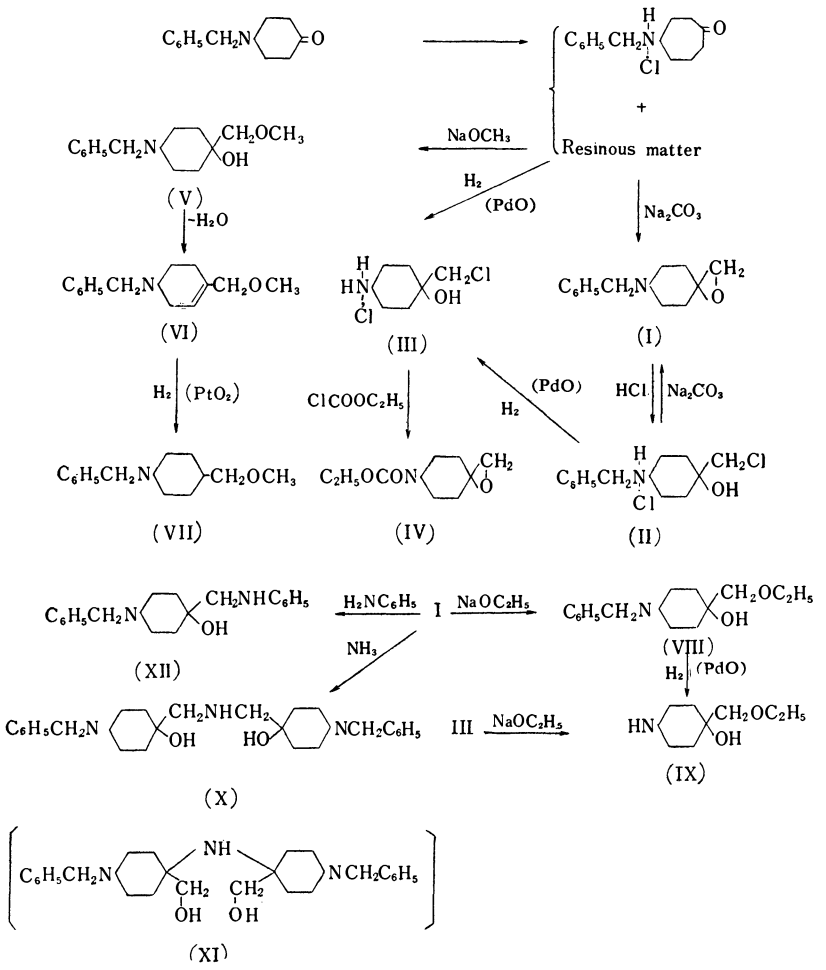
# *Studies on Seven-Membered Heterocyclic Compounds Containing Nitrogen. III. Reactions of 5-Benzyl-1-oxa-5-azaspiro(5, 2)octane*



By Shiro MOROSAWA

(Received October 29, 1959)



Previously[1] the author reported that 1-benzyl-1-azacycloheptan-4-one was obtained from 1-benzyl-1-azacyclohexan-4-one by ring enlargement and recrystallization as a hydrochloride, followed by the addition of alkali. The present study was undertaken in order to investigate an acidic resinous matter left in a considerable amount on evaporation of mother liquor of the recrystallization, and an epoxy compound was found out. Behaviors of the epoxy group to acid and base were examined.

After treatment of the resinous matter with alkaline water while hot, extraction with benzene yielded an oil, boiling at 119~121°C/0.45 mmHg (I). Infrared absorption spectrum showed that the oil was contaminated with a little ketonic substance even after several recrystallizations as a hydrochloride (II) and liberation by alkali. The oil afforded a sulfonic acid derivative[2] with sodium bisulfite, while 1-benzyl-1-azacycloheptan-4-one a normal addition product. The oil, if necessary, was further treated with 2, 4-dinitrophenylhydrazine and chromatographed on alumina, decolorizing carbon and magnesium sulfate[3]. The infrared absorption spectrum of the purified oil indicated characteristic two bands at 790 $cm^{-1}$ and 895 $cm^{-1}$, which is presumably ascribed to the epoxy group. These two bands disappeared in the infrared absorption spectrum of such compounds derived by opening the epoxy group of I as VIII, X and XII. Judging from the nitrogen analysis and the infrared absorption spectrum, the purified oil, b. p. 114°C/0.43 mmHg, was considered as an epoxy compound, 5-benzyl-1-oxa-5-azaspiro(5, 2)octane, being isomeric with 1-benzyl-1-azacycloheptan-4-one[1].

Reduction of both the resinous matter and

2) W. M. Lauer and A. Hill, *J. Am. Chem. Soc.*, **58**, 1873 (1936).
3) R. P. Linstead, J. A. Elvidge and M. Whalley, "A Course in Modern Techniques of Organic Chemistry", Butterworths Scientific Publications, London, (1955), p. 6.

II in the presence of palladous oxide produced an identical substance, m. p. 183~184°C, which was assumed to be III. III afforded a picrolonate, m. p. 228~229°C (decomp.). III and ethyl chlorocarbonate in alkali medium gave an *N*-carbethoxy epoxy compound, b. p. 94~95°C/1 mmHg (IV). The resinous matter and sodium methoxide in absolute methanol gave an oil, b. p. 146~147°C/1 mmHg (V), which was readily dehydrated to an ethylenic compound, b. p. 126°C/0.5 mmHg (VI). VI was then reduced in the presence of platinum oxide to a saturated compound, b. p. 118~120°C/4.5 mmHg (VII). In the formations of II, III and V isomeric abnormal products[4] were not detected.

In view of these facts, it was clear that II was not a primary hydroxy type but a tertiary one, and that the epoxy group of I was opened, when made acidic, and thus I might exist in the resinous matter in the form of II. Ring opening of the epoxide group by the addition of hydrogen chloride was probably due to the normal way.

I and sodium ethoxide in absolute ethanol gave an oil, b. p. 143~144°C/5 mmHg (VIII), which on reduction in the presence of palladous oxide yielded an oil, b. p. 92~93°C/7.5 mmHg (IX). On the one hand, III also gave an oil, b. p. 94°C/7.5 mmHg by the action of sodium ethoxide, which was assumed to accord with IX. This was confirmed by mixed fusion of their picrolonates. It seemed reasonable, therefore, to assume that the addition of ethanol to the epoxy group would proceed as shown below. That the ethoxide anion attacked the methylene carbon and not the spiro carbon is probably due to the steric effect.

I and ammonia in ethanolic solution yielded a crystal, m. p. 142.5°C. Among possible structures corresponding to the crystal, formula X was most probable and the other, for instance XI, could not be constructed in practice into the molecular model owing to the steric interference. The reaction might proceed in the manner like above.

4) R. E. Parker and N. S. Isaacs, *Chem. Revs.*, **59**, 737 (1959).

I and aniline gave a yellow oil, b. p. 202~203°C/0.2 mmHg (m. p. 79.5°C) (XII). This additional reaction also appeared to be the same as in the case of ammonia.

The infrared absorption spectra of VIII, X and XII exhibited characteristic peaks of the tertiary νOH at 1115 $cm^{-1}$ [5].

## Experimental

**5-Benzyl-1-oxa-5-azaspiro(5, 2)octane (I).**—A mixture of 52 g. of the resinous matter, 100 g. of sodium carbonate and 100 cc. of water was stirred for 5 hr. under heating at 70°C. An oily liberated substance was taken up in benzene and dried over potassium carbonate. Evaporation of benzene and rapid vacuum distillation in three batches gave 23 g. of crude epoxide, a colorless oil, b.p. 119~121°C/0.45 mmHg, and when not, much of the substance remained undistilled. (Found: N, 6.99%).

A mixture of 3 g. of the crude epoxide and an excessive saturated solution of sodium bisulfite was shaken vigorously for a short time. Crystals formed were filtered and recrystallized from dilute ethanol to yield 2.3 g. of colorless hexagonal prisms, m. p. 251.5°C (decomp.). It was very soluble in water and did not liberate any oil with acid or alkali.

Found: N, 4.36. Calcd. for $C_{13}H_{17}ON \cdot NaHSO_3$: N, 4.56%.

On the contrary, 1-benzyl-1-azacycloheptan-4-one gave a normal addition product, m.p. 155°C (decomp.). (Found: N, 4.40%).

A mixture of 2.7 g. of the crude epoxide, 0.8 g. of 2, 4-dinitrophenylhydrazine, 0.5 cc. of concentrated hydrochloric acid and 30 cc. of ethanol was boiled on a water bath for two minutes and let stand overnight. Crystals formed were filtered and washed with a little amount of ethanol. The ethanolic solution was passed through Amberlite IRA-400 to remove the hydrochloric acid and evaporated to dryness under reduced pressure. The residual oil was chromatographed on a column packed (from top) with alumina, decolorizing carbon and magnesium sulfate[3] and eluted with dry benzene. The eluate was evaporated and vacuum distillation of the residue yielded 1.7 g. of a colorless oil, b. p. 114°C/0.43 mmHg. Infrared absorption spectrum of the oil showed no carbonyl band.

Found: N, 7.02. Calcd. for $C_{13}H_{17}ON$: N, 6.89%.

**1-Benzyl-4-chloromethyl-4-hydroxy-1-azacyclohexane Hydrochloride (II).**—Through a solution of the crude epoxide in absolute ether was passed dry hydrogen chloride to precipitate a white amorphous hydrochloride. Ether was decanted and the hydrochloride was recrystallized from methanol and ether to give a white crystalline powder. Because of its highly hygroscopic property, it could not be analyzed, but was assumed to be 1-benzyl-4-chloromethyl-4-hydroxy-1-azacyclohexane hydrochloride from the experiment described later. Treatment of the powder with alkaline water as above reformed the epoxide, but not pure.

5) 1-Methylcyclohexane-1-ol gives the peak of the tertiary νOH at 1117 $cm^{-1}$. H. H. Zeiss and M. Tsutsui, *J. Am. Chem. Soc.*, 75, 897 (1953).

**4-Chloromethyl-4-hydroxy-1-azacyclohexane Hydrochloride (III).**—(a) A solution of 5 g. of the acidic resinous matter in 70 cc. of water was reduced under normal temperature and pressure with 0.2 g. of palladous oxide as a catalyst until the theoretical amount of hydrogen had been absorbed. The catalyst was filtered off, and evaporation of water under reduced pressure left light yellow crystals, which were recrystallized from methanol and ether to yield 2 g. of colorless prisms, m. p. 183~184°C.

Found: C, 38.97; H, 7.13; N, 7.52. Calcd. for $C_6H_{13}ONCl_2$: C, 38.73; H, 7.04; N, 7.53%.

III formed a *picrolonate* by heating with a saturated ethanolic solution of picrolonic acid, which was recrystallized from ethanol to give yellow micro prisms, m. p. 228~229°C (decomp.).

Found: N, 15.61. Calcd. for $C_{16}H_{21}O_6N_5Cl_2$: N, 15.55%.

(b) A solution of 10 g. of II in 200 cc. of water was shaken in the hydrogen atmosphere with heating in the presence of 0.2 g. of palladous oxide as a catalyst until the theoretical amount of hydrogen had been absorbed. Light yellow needles were obtained after separation of the catalyst by filtration, followed by evaporation of water. The needles were recrystallized five times from methanol to give 2 g. of colorless prisms, m. p. 183.5~184°C in 30.7% yield, and this did not depress the melting point on admixture with the colorless prisms described above. (Found: N, 7.16%).

A *picrolonate* which derived from the prisms was also not depressed by mixing with the picrolonate mentioned above, m. p. and mixed m. p. 229°C (decomp.). (Found: N, 15.73%).

**5-Carbethoxy-1-oxa-5-azaspiro(5, 2)octane (IV).**—To a solution of 2 g. of III in 10 cc. of water, under stirring and cooling at below 5°C, a solution of 1.3 g. of ethyl chlorocarbonate in 10 cc. of ether and 5 cc. of 30% sodium hydroxide solution were gradually added during 1.5 hr., at such a rate that the two solutions were added simultaneously. After stirring for 15 min. the water layer was separated and extracted three times with a portion of 30 cc. ether each. Combined ethereal solution was dried over potassium carbonate. After evaporation of ether, the vacuum distillation gave 1.4 g. of a colorless oil, b. p. 94~95°C/1 mmHg in 58% yield.

Found: N, 7.29. Calcd. for $C_9H_{15}O_3N$: N, 7.56%.

**1-Benzyl-4-methoxymethyl-4-hydroxy-1-azacyclohexane (V).**—A solution of 14 g. of the resinous matter in 40 cc. of absolute methanol was mixed with a solution of 7 g. of sodium dissolved in 100 cc. of absolute methanol. The resultant mixture was boiled under reflux for 8 hr. After that, 5 cc. of water was added and filtered from the sodium chloride present. The sodium chloride was washed with methanol. Combined methanolic solution was evaporated to leave an oily substance, which was taken up in ether, washed twice with a 10% solution of potassium carbonate and dried over potassium carbonate. Ether was removed and the residual oil was distilled in vacuo to give 7.8 g. of a colorless oil, b. p. 146~147°C/1 mmHg.

Found: N, 5.94. Calcd. for $C_{14}H_{21}O_2N$: N, 5.95%.

**1-Benzyl-4-methoxymethyl-1-azacyclohex-3-ene (VI).**—A mixture of 4.3 g. of V and 6.1 g. of β-naphthalenesulfonic acid was heated for 15 min. on a water bath under reduced pressure (water pump), and then for 1 hr. at 170°C. After cooling, 100 cc. of 10% sodium hydroxide solution was added, extracted in ether and dried over potassium carbonate. Ether was expelled and the vacuum distillation yielded 2.2 g. of a colorless oil, b. p. 126°C/0.5 mmHg. in 56.7% yield, which on standing turned pink immediately.

Found: C, 76.75; H, 8.62; N, 6.55. Calcd. for $C_{14}H_{19}ON$: C, 77.38; H, 8.81; N, 6.45%.

**1-Benzyl-4-methoxymethyl-1-azacyclohexane (VII).**—A solution of 1.1 g. of freshly distilled VI in 50 cc. of methanol containing 0.6 cc. of concentrated hydrochloric acid was reduced in the presence of platinum oxide as a catalyst and the theoretical amount of hydrogen was consumed. After removal of the catalyst by filtration, methanol was distilled off and the residue was made alkaline. Oil thereby liberated was taken up in ether and dried over potassium carbonate. The ether was removed to leave an oil, which on vacuum distillation gave 0.25 g. of a colorless, fluid oil, b. p. 118~120°C/4.5 mmHg.

Found: C, 76.23; H, 9.94; N, 6.31. Calcd. for $C_{14}H_{21}ON$: C, 76.67; H, 9.65; N, 6.39%.

**1-Benzyl-4-ethoxymethyl-4-hydroxy-1-azacyclohexane (VIII).**—A solution of 4 g. of I in 10 cc. of absolute ethanol was mixed with a separately prepared solution of 1.5 g. of sodium in 30 cc. of absolute ethanol and the whole was boiled under reflux for 8 hr. After cooling, 2 cc. of water was added and evaporated under reduced pressure to leave an oil, which was taken up in ether, washed twice with a dilute potassium carbonate solution and dried over potassium carbonate. Oil left on evaporation of ether was distilled in vacuo to yield a colorless oil boiling at 128~136°C/0.5 mmHg, which was redistilled to give 2.5 g. of the oil, b. p. 143~144°C/5 mmHg, in 50.3% yield.

Found: N, 5.77. Calcd. for $C_{15}H_{23}O_2N$: N, 5.62%.

**4-Ethoxymethyl-4-hydroxy-1-azacyclohexane (IX).**—(a) A solution of 2.5 g. of VIII in 50 cc. of water containing 1 cc. of concentrated hydrochloric acid was reduced with heating and in the presence of 0.1 g. of palladous oxide as a catalyst until the theoretical amount of hydrogen had been absorbed. After separation of the catalyst by filtration, a residue left on evaporation of water was dissolved in 10 cc. of water and neutralized with potassium carbonate. A further addition of 2 g. of sodium hydroxide liberated an oil, which was extracted in ether and dried over potassium carbonate. Evaporation of ether and distillation in vacuo gave 0.5 g. of an oil, b. p. 92~93°C/7.5 mmHg in 31% yield.

Found: N, 8.77. Calcd. for $C_8H_{17}O_2N$: N, 8.82%.

IX formed a *picrolonate*, m. p. 209°C (decomp.), which was recrystallized twice from ethanol to yield yellow micro prisms, m. p. 216~217°C (decomp.).

Found: N, 16.31. Calcd. for $C_{18}H_{25}O_7N_5$: N, 16.54%.

(b) A solution of 1 g. of III in 5 cc. of absolute ethanol was mixed with a separately prepared solution of 1 g. of sodium dissolved in 15 cc. of absolute ethanol and the whole was boiled under reflux for 8 hr. After cooling, 2 cc. of water was added and filtered from any solid, which was washed with ethanol. A tan oily substance left on evaporation of ethanol was treated as before to give 0.5 g. of an oil, b. p. 94°C/7.5 mmHg (Found: N, 8.73%).

A *picrolonate* of the oil, m. p. 216~217°C (decomp.) was not depressed on admixture with that described before. (Found: N, 16.37%).

**4-Anilinomethyl-1-benzyl-4-hydroxy-1-azacyclohexane (XII).**—A mixture of 4.2 g. of I and 3.3 g. of freshly distilled aniline was boiled under reflux for 1.5 hr. Excessive aniline was removed under reduced pressure to leave a colored residue. Vacuum distillation of the residue gave 3.7 g. of a light yellow viscous oil boiling at 202~203°C/0.2 mmHg in a 60.5% yield. The oil gradually crystallized on standing and was recrystallized from cyclohexane and benzene in light creamy plates, m. p. 79.5°C.

Found: C, 76.70; H, 8.29; N, 9.44. Calcd. for $C_{19}H_{24}ON_2$: C, 76.99; H, 8.16; N, 9.45%.

XII afforded a *picrate*, m. p. 177.5°C (from ethanol).

Found: N, 14.55. Calcd. for $C_{19}H_{24}ON_2 \cdot (C_6H_3O_7N_3)_2$: N, 14.85%.

**Bis-(4-benzyl-1-hydroxy-4-azacyclohexylmethyl)-amine (X).**—A solution of 2 g. of I in 10 cc. of 99% ethanol was saturated with ammonia at 0°C and let stand for a week at room temperature. An ether insoluble substance left on evaporation of ethanol was recrystallized from dilute ethanol after treating with decolorizing carbon to give 0.6 g. of colorless scales, m. p. 142.5°C in a 30% yield.

Found: C, 73.50; H, 8.96; N, 9.99. Calcd. for $C_{26}H_{37}O_2N_3$: C, 73.72; H, 8.80; N, 9.92%.

Both *picrate*, m. p. 225°C (decomp.) and *picrolonate*, m. p. 247°C (decomp.) were insoluble and difficult to recrystallize from any common solvent.

The author wishes to thank Professor A. Yokoo (this laboratory) for his helpful advice. Thanks are also due to Mr. A. Kondo (The Department of Organic Chemistry of Tokyo Institute of Technology) for carrying out the carbon and hydrogen micro analyses.

# *Kinetic Study on Isomerization of Anthranol to Anthrone*

By Yoshié BANSHO and Kenkichi NUKADA

(Received October 13, 1959)

Only a few studies concerning the physical and chemical properties of anthranol have been reported in literature. K. H. Meyer[1] found in 1911 that in organic solvents anthranol turns to anthrone and after a long time a chemical equilibrium between these substances is established. Bäckström et al.[2] pointed out an iodine titration method for the analysis of anthranol. Le Fèvre et al.[3] investigated the dielectrical properties of the same substance, but its purity was not satisfactory enough to determine the dielectric constant of the solutions.

Anthranol Anthrone

The authors have established the best condition for the preparation of anthranol and measured the dipole moments in several organic solvents[4].

In this paper, the authors present the methods of measuring the velocity constants of the isomerization of anthranol to anthrone by the analytical and dielectrical techniques and the calculated values of the activation energies of the reaction.

## Experimental

**Preparation of Anthranol.** — Improving the original procedures of Meyer[1] and Bäckström et al.[2], the authors have established the best method of preparation of pure anthranol and reported the findings in this Bulletin[4].

**Measurements of Velocity Constants of the Isomerization by Iodometry.**—Bäckström et al. determined the purity of anthranol by iodometric analysis. This suggests that the method may also be used for the measurement of isomerization velocity, because one mole of anthranol reacts exactly with one mole of iodine in some solvents, while anthrone does not react with iodine at all. It has been found that methanol and ethanol were suitable solvents for the measurement of isomerization velocity.

In a stream of nitrogen, 1.0 g. of freshly prepared anthranol was dissolved into 200 cc. of solvent keeping the temperature constant. After appropriate time, 10 cc. of the solution was poured into 5 cc. of 0.1 N iodine-potassium iodide aqueous solution. After a few minutes the remaining iodine was titrated with 0.1 N sodium thiosulfate solution, and thus the content of anthranol in the solution was obtained directly. These operations were repeated until an equilibrium of the reaction was attained.

**Dielectrical Measurement.**—The authors have already measured the apparent dipole moments of anthranol in several organic solvents at 6 and 15°C[4]. At these temperatures, isomerization velocities are so small that anthranol in solvents safely remains unchanged during the measurements.

When the temperature is raised, the reaction velocity of isomerization becomes greater and it becomes impossible to get the real value of dipole moment of anthranol. A kinetic study of isomerization, on the other hand, becomes possible even at elevated temperatures.

Dielectric constants of solutions (in benzene and toluene) at several temperatures were measured several times until they reached maximum values. Although it is necessary also to measure the densities of solutions at every time of measurements of dielectric constants, this procedure is very troublesome. Hence, in this paper, it was assumed that the density of solutions remained constant during the reaction.

## Results and Discussion

**Iodometry.**—First of all, it was assumed that the reaction is reversible and of the first order, so that

$$\frac{dx}{dt}=k_+(a_0-x)-k_-(a_0'+x) \qquad (1)$$

where $x$ is the amount of changed anthranol at the time $t$, $a_0$ and $a_0'$ are the initial amounts of anthranol and anthrone expressed in molar fraction, and $k_+$ and $k_-$ are the velocity constants of normal and reverse reactions, respectively. As the purity of the anthranol was about 98%,

$$a_0 \fallingdotseq 1 \quad \text{and} \quad a_0' \fallingdotseq 0$$

and then

$$K=\frac{k_+}{k_-} \fallingdotseq \frac{a_\infty}{1-a_\infty} \qquad (2)$$

where $K$ is the equilibrium constant and $a_\infty$ is the value of $x$ at the equilibrium ($dx/dt=0$).

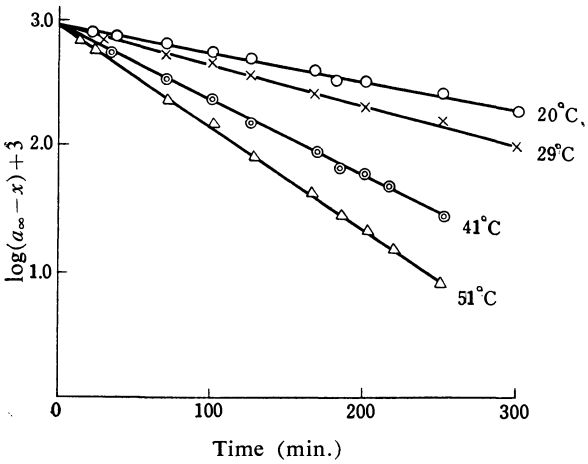

Fig. 1. Kinetics in methanol by iodometry.

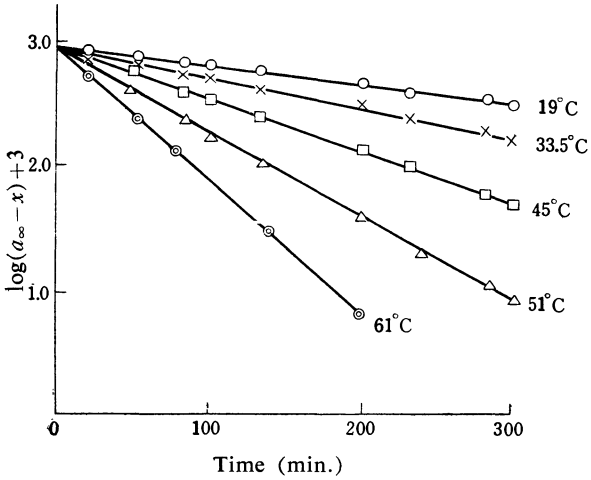

Fig. 2. Kinetics in ethanol by iodometry.

Table I. The velocity constants of isomerization

| Temp., °C | In methanol $k_+$ | In ethanol $k_+$ |
|---|---|---|
| 20 | 0.0050 | 0.0032 |
| 29 | 0.0063 | |
| 36 | | 0.0050 |
| 41 | 0.0125 | 0.0059 |
| 45 | 0.0137 | 0.0079 |
| 51 | 0.0165 | 0.0149 |
| 61 | 0.0256 | 0.0211 |

From Eqs. 1 and 2, the next equation is obtained.

$$k_+ + k_- = 1/t \ln [a_\infty/(a_\infty - x)] \quad (3)$$

From Eqs. 2 and 3, the value of $k_+$ can be obtained. In Figs. 1 and 2, $\log(a_\infty - x)$ are plotted against $t$ at between 20~60°C in methanol and ethanol solutions, respectively. Since rectilinear relationships between $\log(a_\infty - x)$ and $t$ were observed, it is reasonable to assume that the reaction of isomerization is of the first order. The calculated values of $k_+$ are shown in Table I.

According to Arrhenius' equation, the authors plotted the values of $\log k_+$ against the reciprocal of absolute temperature $(1/T)$ as shown in Fig. 3 and calculated the activation energies of the isomerizations of anthranol in methanol and ethanol. Anthranol isomerizes faster in methanol than in ethanol and the obtained values of activation energies are 5.8 and 12.4 kcal./mol. in methanol and ethanol, respectively. This might be due to the fact that ethanol is stronger in basisity than methanol.

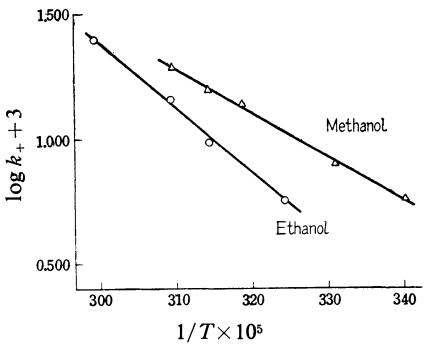

Fig. 3. Measurements of activation energies by iodometry.

The times required for the complete disappearance of fluorescence in diluted anthranol solutions were ca. 50 and 6.5 hr. in ethanol and methanol, respectively[4]. These times are supposed to depend upon the velocities of isomerization.

**Dielectrical Measurement.**—The only measurable quantity with dielectrical measurement is the time dependency of the dielectric constant of solutions at various temperatures. In order to obtain the velocity constants from these measurable quantities, some assumptions are made.

First of all, it was assumed that

$$p_{12}(t) = (1-y)p_1 + yp_2(t) \quad (4)$$

where $p_{12}(t)$, $p_1$ and $p_2(t)$ are the specific molecular polarizations of solution, solvent and solute, respectively, and $y$ is the weight fraction, of solute. The molecular polarization of solute $P_2(t)$ is obtained by substituting the following Eqs. 5—7 into Eq. 4.

$$p_{12}(t) = 1/d_{12} \times (\varepsilon_{12}(t) - 1)/(\varepsilon_{12}(t) + 2) \quad (5)$$

$$p_1 = 1/d_1 \times (\varepsilon_1 - 1)/(\varepsilon_1 + 2) \quad (6)$$

$$p_2 = P_2(t)/M \quad (7)$$

where $\varepsilon_{12}(t)$, $\varepsilon_1$ and $d_{12}$, $d_1$ are dielectric constants and densities of solution and solvent, respectively, and $M$ is a molecular weight of

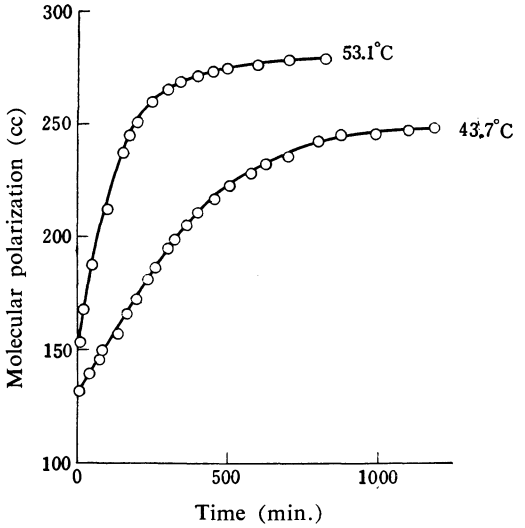

Fig. 4. The change of molecular polarization in benzene.

solute. $p_{12}(t)$, $p_2(t)$, $P_2(t)$ and $\varepsilon_{12}(t)$ mean that these quantities are functions of time. In Fig. 4, $P_2(t) \sim t$ curves are shown.

If the reaction is of the first order, Eq. 3 leads

$$\exp(-kt_i) = 1 - x(t_i)/a_\infty \qquad (8)$$

where $k = k_+ + k_-$ and $i = 1, 2, 3, \ldots\ldots, N$ ($N$ is the number of measurement). If it is possible to measure $x(t)$, the two unknown parameters $k$ and $a_\infty$ in Eq. 8 can be determind by the statistical method of least square, and then with Eq. 2 the normal velocity constant $k_+$ can be calculated. In the dielectrical measurement, however, $x(t_i)$ can not be obtained directly but only $P_2(t)$ can be measured. So it is necessary to combine the above quantities using a further assumption as follows:

$$P_2(t) = P_L[1 - x(t)] + P_N x(t) \qquad (9)$$

where $P_L$ and $P_N$ are the molecular polarizations of pure anthranol and pure anthrone, respectively, and both are unknown parameters. From Eq. 9, it is obtained the following equations.

$$x(t) = (P_2(t) - P_L)/(P_N - P_L) \qquad (10)$$

With $t = \infty$ the authors have $x = a_\infty$, so that

$$a_\infty = (P_2(\infty) - P_L)/(P_N - P_L) \qquad (11)$$

where $P_2(\infty)$ means the saturated $P_2(t)$ value. Substituting Eqs. 10 and 11 to Eq. 8, it is obtained

$$\exp(-kt_i) = (P_2(\infty) - P_2(t_i))/(P_2(\infty) - P_L) \qquad (12)$$

Eq. 12 includes two unknown parameters ($k$ and $P_L$) but they can be obtained by the statistical method of least square. In the present case the velocity constant of the reverse reaction is found to be very small compared with that of the normal reaction*. Therefor, $k_+$ is almost equal to $k$ and the final equation is obtained.

$$k_+ \fallingdotseq k = \frac{\sum_i \ln(P_2(\infty) - P_2(t_i)) \sum_i t_i/N - \sum_i t_i \ln(P_2(\infty) - P_2(t_i))}{\sum_i t_i^2 - (\sum_i t_i)^2/N} \qquad (13)$$

If Arrhenius' equation is also valid in this cace, the curve $\ln k_+ \sim 1/T$ should be linear and the results agree quite well with this requirement (Fig. 5). Activation energies, obtained from Fig. 5 are listed in Table II. These values are of the same order as those obtained in methanol and ethanol solutions by the iodine titration method. It is important to notice that the potential barrier between two isomers is rather small so that the isomerization can occur very easily.

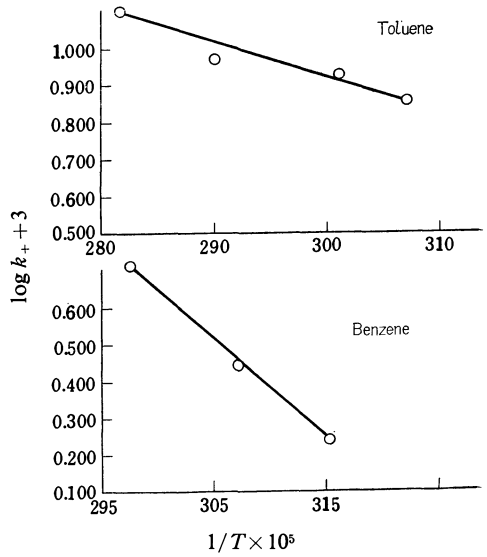

Fig. 5. Measurements of activation energies by dielectrical method.

TABLE II. THE ACTIVATION ENERGIES OF ISOMERIZATION MEASURED IN SEVERAL ORGANIC SOLVENTS

| Solvent | Method of measurement | Activation energies kcal./mol. |
|---|---|---|
| Methanol | Iodometry | 5.8 |
| Ethanol | Iodometry | 12.4 |
| Benzene | Dielectrical method | 12.2 |
| Toluene | Dielectrical method | 4.8 |

The authors could not find common solvents suitable to measure the velocity constant for

* The authors measured the molecular polarization of anthrone in benzene and toluene and ascertained that $P_2(t)$, in this case, maintained its initial value even after a long time, i. e. $k_-$ was almost equal to zero.

both the analytical and dielectrical methods for the following reasons: methanol and ethanol are polar substances and not suitable for the dielectrical measurement, while benzene and toluene are immiscible with water making iodometry titration impossible.

## Conclusion

Pure anthranol was prepared and its isomerization to anthrone was studied by analytical and dielectrical methods. The reaction was found to be of the first order and the observed heat of activations were 5.8, 12.4, 12.2 and 4.8 kcal./mol. in methanol, ethanol, benzene and toluene, respectively. These small values mean that anthranol isomerizes easily in these solvents.

Sincere thanks are tendered to Dr. Y. Mashiko of this Institute for his valuable discussion. The authors also appreciate the help rendered by Mr. Kuang Lieh Huang in performing a part of these experiments.

# β-Hydroxyleucine. I. Synthesis by Means of Copper Complex and Separation of the Diastereomeric Racemates

By Yoshikazu IKUTANI, Tôru OKUDA and Shiro AKABORI

(Received October 19, 1959)

β-Hydroxyleucine has recently been found by Kenner and Sheppard[1] to be a constituent of an antibiotic (I. C. I. No. 13959), which is unusually active against infection of *Trypanosoma congolense*, and they assigned the structure D- or L-threo isomer to the natural product. This is, as they stated, the first time that β-hydroxyleucine has been obtained from natural sources.

A survey of the literature indicates that the procedures reported hitherto for the synthetic preparation of this amino acid are rather complicated and that yields are poor.

It was synthesized by Abderhalden for the first time from isocaproic acid through isopropyl-acrylic acid in an overall yield of 7%[2], by Wieland and coworkers by adding isobutyraldehyde into a melting mixture of glycine and potassium hydroxide in a 20% yield[3], and by Buston and Bishop by hydroxybromination of isopropylacrylic acid in a 12% yield[4]. The authors have succeeded in preparing β-hydroxyleucine as a diastereomeric mixture in a high yield by the copper complex method[5] by which already threonine[5], serine[6] and β-hydroxy-β-methylaspartic acid[7] were successfully synthesized.

Glycine copper complex was allowed to react in the presence of potassium or sodium hydroxide with isobutyraldehyde. The reaction mixture was treated with aqueous ammonia and the copper was removed by means of an ion exchange resin (Dowex 50). The product thus freed from copper was found to contain no by-product but a trace of unreacted glycine by paperchromatographic analysis. Having two asymmetric carbons in α- and β-positions, β-hydroxyleucine has two diastereomeric racemates. The separation of these diastereomers was effected by utilizing the different solubility of their sodium salts in absolute ethanol. The amino acid (A) derived from the insoluble salt showed a decomposition point of 240~241°C and that of (B) from the soluble salt 255~256°C. Although Buston and Bishop[4] reported that β-hydroxyleucine is separable into two isomers with m. p. 240 and 209°C, the authors could never obtain the latter. Paperchromatography in a solvent system of methyl ethyl ketone—*n*-butanol — concentrated ammonia — water (3 : 5 : 1 : 1) permits the definite separation of these

isomers. (A-form, $R_f=0.49$; B-form, $R_f=0.32$). The ratio of A- to B-form obtained was 1.8～2.8 as measured by the ninhydrin method[8]. These results are shown in Table I. In comparison with threonine it may be assumed that A- and B-forms correspond to the threo and erythro-forms, respectively. The definite assignment of structure is under way and will be reported later.

## Experimental

**Isobutyraldehyde.**—The aldehyde was prepared according to Whitmore's method[9] with slight modification.

**β-Hydroxyleucine.**—In a 500 cc. flask, 30 g. of freshly distilled isobutyraldehyde was added to a suspension of 23 g. of copper complex of glycine in a solution of 8 g. of potassium hydroxide (or 6 g. of sodium hydroxide) in 40 cc. of water. The suspension was swirled for a few minutes, and then placed in a refrigerator overnight. The reaction mixture was transferred to a mechanical shaker and shaken at room temperature for 5 hr. Two hundred cubic centimeters of water and 170 cc. of concentrated aqueous solution of ammonia were added and the resulted solution was filtered. The filtrate was passed through a column of Dowex 50 which had previously been converted into the ammonium form. Then the column was eluted with 5 N aqueous solution of ammonia, and the eluate was collected until no further positive ninhydrin reaction.

The effluent was concentrated under reduced pressure until the crystallization of β-hydroxyleucine began, and then about three volumes of ethanol were added. After being kept in a refrigerator overnight, the crystals of β-hydroxyleucine were collected, washed with ethanol, and dried in vacuo. When potassium hydroxide was used as catalyst, the yield was 22 g. (76%); and in the case of sodium hydroxide the yield was 20 g. (69%).

The reaction product was contaminated with a small amount of unreacted glycine and it was a mixture of two racemic diastereoisomers.

Synthetic β-hydroxyleucine, when recrystallized from water by the addition of ethanol after decolorization with charcoal, showed an m. p. of 240～241°C (decomp.).

Found: C, 48.55; H, 9.07; N, 9.50. Calcd. for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%.

Determination of the ratio of A- to B-form was carried out by separating them on paperchromatogram in the solvent system mentioned above and by measuring the optical density of 50% ethanol of each spot treated with ninhydrin.

**Separation of the Diastereomeric Racemates.**—Fourteen and seventenths grams of β-hydroxyleucine was added to a hot solution of sodium ethylate prepared from 2.3 g. of sodium and 50 cc. of absolute ethanol. The suspended mixture was refluxed with agitation for an hour, and placed at room temperature overnight. The mixture was filtered to remove the sodium salt of Form A, and the separeted sodium salt of Form A was added to 50 cc. of ethanol. The mixture was refluxed for an hour and the precipitate was collected and washed with ethanol.

The collected sodium salt of Form A was dissolved in 200 cc. of water and the solution was passed through a column of Amberlite-IRC 50 which had been converted into the H-form. Water was passed through the column until the effluent became ninhydrin negative. The aqueous effluent containing free β-hydroxyleucine (Form A) was concentrated under reduced pressure to a low bulk. Excess ethanol was added, and the resulting precipitate was collected by filtration after storage in a refrigerator overnight and washed with ethanol. The yield was 10 g.

Recrystallization of the product was effected from water by the addition of ethanol after decolorization with a small amount of charcoal. The product, when chromatographed on paper, revealed only a single ninhydrin-positive spot which was identical with Form A, and it showed an m.p. of 240～241°C (decomp.).

Found: C, 48.91; H, 8.72; N, 9.60. Calcd. for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%.

On the other hand the filtrate, namely, the ethanol solution of sodium salt of Form B was treated in the same manner as described above and its free amino acid was obtained. The yield was 2.3 g. and m. p. 255～256°C (decomp.).

Found: C, 48.95; H, 8.75; N, 9.60. Calcd. for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%.

**Reduction of β-Hydroxyleucine with Hydriodic Acid.** — In a sealed tube a mixture containing 0.05 g. of β-hydroxyleucine, 0.02 g. of red phosphorous and 3 cc. of hydriodic acid ($d=1.60$) was heated for 10 hr. at 150°C. By paperchromatographic analysis of the reaction product it was confirmed that most of the starting material had been reduced to leucine, but a part of β-hydroxyleucine remained unchanged in the reaction mixture. The paperchromatograms also showed three ninhydrin-positive spots of glycine, and unidentified substances with $R_f$-values 0.22 and 0.00.

# *The Kinetic Study of Surface-chemical Reactions at Extremely Low Pressures. V. The Thermal Reaction between Water Vapor and a Tungsten Filament. Part V*

By Takuya HAMAMURA

(Received October 20, 1959)

In previous papers[1-4] of this series the reaction of water vapor with tungsten in the 1270 to 1950° K temperature range was presented. Here the data for this reaction from 1950 to 2460° K are given and discussed. The division into two temperature ranges is done for convenience in discussing the result. Below 1950° K a blue deposit having a mean apparent composition of $WO_{2.8}$ is produced on the wall of the vessel. Above 1950° K the ratio O/W of the deposit increases with the rise of the temperature and a colorless deposit is formed at higher temperatures.

## Experimental

The apparatus was the same as that used in previous experiments. Tungsten filaments, 0.114mm. in diameter and 56mm. long, were used for determining the reaction rate and the composition of the reaction product. Procedures of measuring the reaction rate and determining the composition of the reaction products have been described previously. The two-filament method was not used to obtain the reaction probability owing to the too severe influence of hydrogen pressure on the reaction rate. The temperature of the reaction vessel remained at room temperature throughout the experiments.

Uptake of oxygen by the deposit was studied as follows. After the deposit had been produced, water vapor was removed from the vessel by cooling water reservior 1 in Fig. 1* with dry ice and a definite amount of oxygen was introduced into the vessel through cock 12 after the boiler of diffusion pump 7 was cooled. Then the vessel was heated in an electric furnace and the pressure decrease was measured by a McLeod manometer.

Desorption of a permanent gas from the deposit was studied as follows. After the deposit had been produced, water vapor was removed from the vessel in the manner mentioned above. The vessel was then heated in an electric furnace and the permanent gas given off was transferred into the glass balloon by diffusion pump 7. The pressure was measured by a McLeod manometer.

## Results and Discussion

**Reaction Rate.**—Reaction rates were determined from $30\times10^{-5}$ to $103\times10^{-5}$ mmHg initial pressures of water vapor under various pressures of hydrogen in the vessel. It was found that the reaction rate decreased with the increase of hydrogen pressure more steeply as the temperature rose or the pressure of the water vapor decreased in a manner similar to that observed below 1950° K. The cause of decrease of the rate was studied by the following experiment. Two filaments of the same length** and diameter were heated in water vapor of the same initial pressure separately for the same interval of time with the same current under different pressures of hydrogen. The amount of hydrogen produced and the increment of resistance of the respective filaments were determined. Results for 1.5 amp. heating current (about 2350°K) are given in Table VI***. Increments of the resistance are almost the same for two filaments even though the amounts of hydrogen are considerably different. Therefore, it is apparent that the decrease is not caused by the retardation of the reaction of water vapor with tungsten by hydrogen.

The reaction probability at a definite temperature was evaluated from the reaction rate at zero pressure of hydrogen obtained by extrapolating back the rate vs. hydrogen pressure curve to zero pressure of hydrogen. Values of reaction probabilities at $60\times10^{-5}$ mmHg of water vapor are given in Table VII. A probability at 1890°K is also given for comparison. These values are not free from the end effect of the filament.

**Composition of Deposit.**—Results obtained are given in Table VIII. It is obvious that the ratio O/W of the deposit increases with the rise of the temperature, whereas it decreases with the increase of the hydrogen pressure. Properties of deposits are as follows.

1) Deposits having ratio values O/W smaller than 3 appeared blue in transmitted light,

whereas those having ratio values greater than 3 appeared colorless.

2) The deposition of a colorless product revealed a bleaching action upon the blue deposit, that is, when the colorless product was deposited on the blue deposit the blue color faded gradually with the accumulation of the colorless deposit.

3) When $100\times10^{-5}$ mmHg of oxygen was admitted to the blue deposit, oxygen was hardly taken up at all at room temperature, but it was taken up swiftly at 200°C with fading of the blue color.

4) When the blue and the colorless deposits were heated separately in high vacuum at 300°C for two hours, the desorption of a permanent gas and the change of the color were not observed in either case.

The bleaching action of the colorless product upon the blue deposit may be explained by making an assumption that besides the reaction between water vapor and tungsten, the thermal decomposition of water vapor takes place with an increasing rate with the rise of the temperature and oxygen thus produced reacts with the blue deposit to make it colorless. Although the reduction of the deposit by hydrogen must take place at the same time, so long as the oxidation rate predominates over the reduction rate the colorless product is produced. It is shown experimentally that the blue deposit takes up oxygen to become colorless.

It has been stated[4] that the deposit produced below 1950°K has the ratio value O/W of 2.8. On the other hand, at temperatures above 1950 °K the ratio value was found to increase with the rise of the temperature to become greater than 4. The ratio value may increase owing to the formation of a higher oxide or may appear to increase by the production of hydrogen, not being accompanied by the weight loss of the filament, because the ratio value is determined by the amount of hydrogen produced and the weight loss of the filament. The presence of a higher oxide than tungsten trioxide has not been reported in literature. If the deposit was composed of a peroxide, oxygen or hydrogen peroxide would be generated when the deposit was dissolved in sulfuric acid or in aqueous solution of sodium hydroxide. However, the oxygen

evolution was not observed at all and the hydrogen peroxide formation was not detected by luminol[5]. Peroxytungstic acids[6] have been reported by some investigators, but these acids are described as being unstable and as decomposing with the evolution of oxygen by heating. Therefore, it is obvious that the colorless deposit is not composed of these acids. The colorless deposit is composed of tungsten trioxide.

Thermal decomposition of water vapor has been assumed to explain the bleaching action of the colorless product, but if all the oxygen produced reacts with the filament to form tungsten trioxide, the ratio value can not become greater than 3. It is necessary for the ratio value to become greater than 3 that oxygen be consumed by another process than the reaction with the filament. The following processes may be considered for such consumption.

1) Oxygen leaves the reaction vessel to be introduced into the glass balloon. 2) Oxygen produces hydrogen peroxide to be caught by the trap cooled with liquid nitrogen. 3) Oxygen is taken up by the wall of the apparatus or by the deposit on the wall of the vessel.

Results of the analysis by the mass spectrometer are given in Table VIII. It is evident that the amount of oxygen introduced into the balloon is too little to explain the observed ratio value. Hydrogen peroxide[7,8] has been reported to be produced when the water vapor contacts with a Nernst tube at a high temperature or when atomic hydrogen combines with oxygen on a wall cooled with liquid oxygen. Therefore, hydrogen peroxide may be produced in the reaction of water vapor with the tungsten now being studied. The formation of hydrogen peroxide was studied by the following experiment; after a filament was heated at 2310°K in $60\times10^{-5}$ mmHg of water vapor for two hours, the filament and the boiler of diffusion pump 7 were cooled and air was introduced into the apparatus to an atmospheric pressure. Trap 6 was then detached from the apparatus, warmed to room temperature and a luminol reagent was dropped in it within a dark room to detect hydrogen peroxide by its luminescence. As a result, hydrogen peroxide was not detected by this experiment although about $2\times10^{-6}$ mol. of hydrogen peroxide must be produced if the observed ratio value is ascribed to the formation of hydrogen peroxide. A blank test revealed that about $2\times10^{-7}$ mol. of hydrogen peroxide could be detected.

The fact that a permanent gas was not given off from the deposit at 300°C suggested that oxygen had not been physically adsorbed at all or that it had been chemisorbed by the wall of vessel and/or by the deposit. The uptake of oxygen by the wall of the apparatus was studied by carrying out an electrodeless discharge in oxygen within the vessel. The discharge vessel was 30 mm. in diameter and 130 mm. long. The vessel was connected with a trap cooled with liquid nitrogen and the pressure was measured with a McLeod manometer. The electrodeless discharge was carried out by placing the vessel in a coil through which a high frequency current flowed. After evacuating and degassing the apparatus, about 0.2 mmHg of oxygen was introduced into the apparatus. Then the discharge was carried out for two minutes, and the pressure was measured again. Thus, the oxygen pressure was measured every time after the two-minute discharge. The uptake of oxygen by the tungsten trioxide deposit was studied similarly by using a vessel whose wall had been covered with tungsten trioxide deposit formed by heating a tungsten filament mounted along the axis of a vessel in oxygen. As a result, it was found that the tungsten trioxide deposit hardly took up oxygen at all, whereas the wall of the apparatus took up some amount of oxygen. It is evident that excited molecules and atoms of oxygen were produced by the discharge and a part of them were taken up by the wall. In the reaction of water vapor with tungsten, too, excited molecules and atoms of oxygen would be produced and a part of them be taken up by the wall by chemisorption. Langmuir[9] has found that oxygen adsorbed on tungsten evaporates from the surface as atoms when the surface is nearly bare. Therefore, it is most reasonable to consider that the ratio value greater than 3 is caused by the fact that some amount of hydrogen is liberated, not being accompanied by the weight loss of filament, since oxygen is produced by the decomposition of water vapor and is taken up by the wall of the apparatus, and to consider that the reaction rate and the ratio value O/W of deposit decrease with the increase of hydrogen pressure, since oxygen thus taken up reacts with hydrogen to form water vapor.

## Summary

1) Reaction probabilities above 1950°K are determined.

2) The ratio value O/W of the deposit increases with the rise of temperature.

3) The deposit having ratio value O/W greater than 3 appears colorless in transmitted light.

5) W. Langenbeck and U. Ruge, *Ber.* **70**, 367 (1937).

6) J. W. Mellor, "Comprehensive Treatise on Inorganic and Theoretical Chemistry", Vol. XI, Longmans, Green Ltd., London (1954), p. 833.

7) W. Nernst, *Z. Elektrochem.*, **11**, 710 (1905).

8) K. H. Geib and P. Harteck, *Ber.*, **65**, 1551 (1932).

9) I. Langmuir and D. S. Villars, *J. Am. Chem. Soc.*, **53**, 486 (1931).

4) The colorless deposit is composed of tungsten trioxide and the ratio value O/W greater than 3 is ascribed to the production of hydrogen, not being accompanied by the weight loss of filament, since the ratio value is determined from the amount of hydrogen produced and the amount of weight loss of filament.

5) Water vapor decomposes and a part of the oxygen thus produced is taken up by the wall of the apparatus, and hence hydrogen is produced, not being accompanied by the weight loss of filament.

6) The reaction rate and the ratio value O/W of the deposit decrease with the increase of hydrogen pressure, since the oxygen taken up by the wall recombines with hydrogen to form water vapor.

# *Investigation on Mixed Complexes. III*[1]*. Spectrophotometric Studies on Platinum(II) Complexes*

By Shigeo KIDA

(Received August 17, 1959)

In general, mixed complexes are easily formed, but it appears that mixed cyano complexes are not easily formed. For instance, many species of mixed ammine complexes of cobalt(III) and platinum(II) are known, but mixed cyano complexes of cobalt(III) and platinum(II) known hitherto are few[2], and they have a strong tendency to become cyano complexes[3].

In the preceeding paper[1] of this series, it was demonstrated that no mixed cyano complexes are formed in the case of nickel(II) and copper(I). However, these are the cases where the parent complexes (for instance, $[Ni\,en_3]^{2+}$ and $[Ni(CN)_4]^{2-}$) have different configuration from each other. In this article an experiment has been carried out on platinum(II) complexes, which have the same configuration, in order to verify whether the mixed cyano complex is formed or not.

## Results and Discussion

It has been known that chloride ions in tetrachloro platinate(II) ion are replaced by cyanide ions in solution at room temperature. Though no mixed cyano complex of platinum(II) has ever been known, a possibility of its formation in solution is still in question. The experiment was undertaken to solve this problem.

A potassium cyanide solution was added to a solution of potassium tetrachloro platinate(II) in the ratios as indicated in Table I, and extinction measurements were carried out on each of the mixed solutions. The results are shown in Fig. 1.

The extinction curves in Fig. 1 show that only the tetracyano platinate(II) and tetrachloro platinate(II) ions are present, no mixed complex ions such as $[Pt\,Cl_3CN]^{2-}$, $[Pt\,Cl_2(CN)_2]^{2-}$ and $[Pt(CN)_3Cl]^{2-}$ being present; if any of the mixed complexes were formed, the absorption curve would be subject to deformation to some degree, or a new absorption maximum would appear correspondingly, in the region where tetracyano platinate(II) ion has no absorption.

TABLE I. THE COMPOSITION OF THE SOLUTIONS (cf. Fig. 1)

| Solution number | (1) | (2) | (3) | (4) | (5) |
|---|---|---|---|---|---|
| 0.03 F $K_2[Pt\,Cl_4]$ and 3 F KCl* | 8 ml. | 8 | 8 | 8 | 8 |
| 0.1220 F KCN | 0 ml. | 2 | 4 | 6 | 8 |
| Water | 8 ml. | 6 | 4 | 2 | 0 |

* KCl is added to supress hydrolysis of $[Pt.Cl_4]^{2-}$.

2) J. C. Bailar, "The Chemistry of the Coordination Compounds", Reinhold Publ. Co., New York (1956), p. 87, "General Survey".

3) This tendency can be seen when one compares the methods of preparation of the two complxes, $[Co(NH_3)_5Cl]^{2+}$ and $[Co(CN)_5Cl]^{3+}$; the pentammine complex is readily prepared from cobaltous salt, ammonia and ammonium chloride in an aqueous solution, while the pentacyano complex is obtained only by substitution of the cyanide ion for ammonia of petammine complex under a very delicate condition.

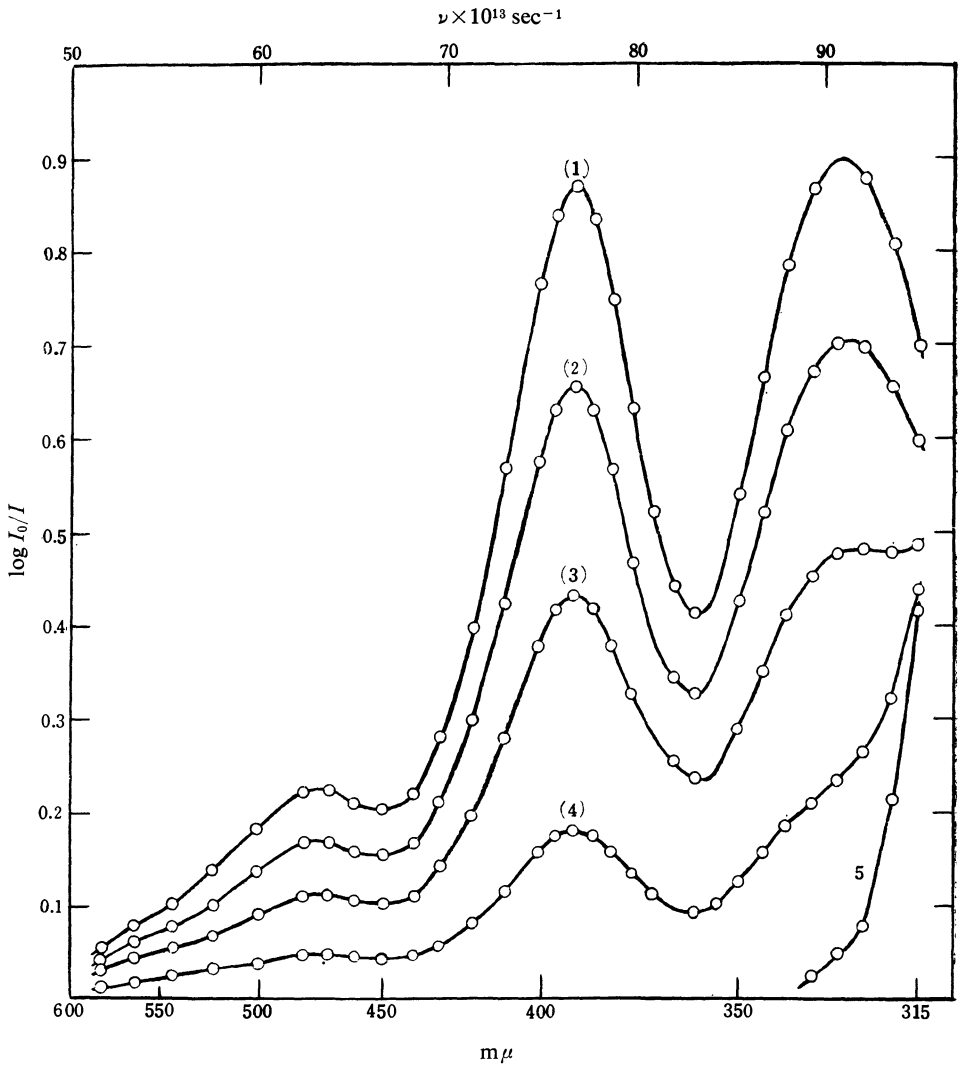

Fig. 1. (cf. Table I).

If it is assumed that all of the added cyanide ions are consumed to form the tetracyano platinate(II) ion, the calculated value of ([Pt] $-1/4$[CN])/[Pt] must accord with the experimentally obtainable value, $D/D_1$[4], where [Pt] and [CN] denote the total concentration of all platinum species and of the added cyanide ion in each solution shown in Table I and Fig. 1. Actually, a satisfactory agreement between the calculated and the experimental value can be found in Table II.

A potassium cyanide solution was added to a solution of potassium tetrabromo platinate(II), in order to examine the substitution of the cyanide ion for the coordinated bromide. The result was the same in the case of the potassium tetrachloro platinate(II); i.e. the absorption curves are not deformed in the region where the tetracyano platinate(II) ion has no absorption, and the calculated value, ([Pt] $-1/4$[CN])/[Pt] accords with the experimental value, $D/D_6$, as is shown in Fig. 2 and Table IV.

TABLE II

| | (1) | (2) | (3) | (4) | (5) |
|---|---|---|---|---|---|
| ([Pt]$-1/4$[CN])/[Pt] | 1.00 | 0.746 | 0.492 | 0.237 | 0 |
| $D/D_1$ for 470 mμ | 1.00 | 0.748 | 0.496 | 0.207 | 0 |
| for 400 mμ | 1.00 | 0.751 | 0.492 | 0.208 | 0 |
| for 390 mμ | 1.00 | 0.753 | 0.499 | 0.209 | 0 |
| for 380 mμ | 1.00 | 0.759 | 0.505 | 0.212 | 0 |

Numbers in the first row denote solution numbers in Table I.

4) If the reaction, $[PtCl_4]^{2-}+4CN^- \rightarrow [Pt(CN)_4]^{2-}+4Cl^-$, takes place quantitatively, optical densities of the solutions are expressed as in the following:
$D=\varepsilon_1([Pt]-1/4[CN])+\varepsilon_2(1/4[CN])$, and for solution 1, $D_1=\varepsilon_1[Pt]$, where $\varepsilon_1$ and $\varepsilon_2$ are extinction coefficients of $[PtCl_4]^{2-}$ and $[Pt(CN)_4]^{2-}$, respectively. However, in the region of 330~600 mμ the ratio $D/D_1$ can be reduced to ([Pt]$-1/4$[CN])/[Pt], since in this region $\varepsilon_2=0$.

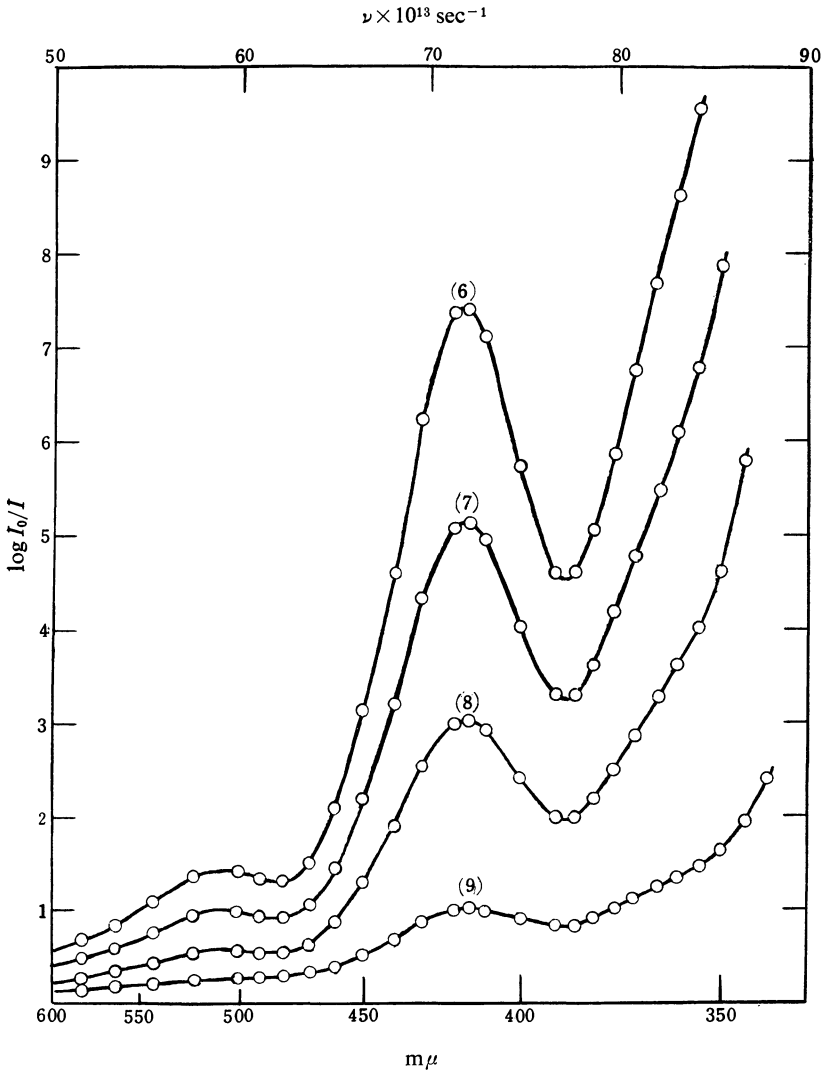

Fig. 2. (cf. Table III).

TABLE III. THE COMPOSITION OF THE SOLUTIONS (cf. Fig. 2)

| Solution number | (6) | (7) | (8) | (9) | (10) |
|---|---|---|---|---|---|
| 0.015 F $K_2[PtBr_4]$ and 1 F KBr** | 8 ml. | 8 | 8 | 8 | 8 |
| 0.0703 F KCN | 0 ml. | 2 | 4 | 6 | 8 |
| Water | 8 ml. | 6 | 4 | 2 | 0 |

** KBr is added to supress hydrolysis of $[PtBr_4]^{2-}$.

TABLE IV

| | (6) | (7) | (8) | (9) | (10) |
|---|---|---|---|---|---|
| ([Pt]−1/4[CN])/[Pt] | 1.00 | 0.707 | 0.414 | 0.121 | 0 |
| $D/D_6$ for 520 mμ | 1.00 | 0.691 | 0.403 | 0.187 | 0 |
| for 420 mμ | 1.00 | 0.690 | 0.407 | 0.137 | 0 |
| for 410 mμ | 1.00 | 0.697 | 0.411 | 0.140 | 0 |

Numbers in the first row denote solution numbers in Table III.

These results are the first example which evidently shows that no mixed complex is formed between the complexes of the same configuration. The cause of this phenomenon will be discussed in the last paper of this series[5].

Further experiments on the other compounds, especially on cobaltic complexes, to find further similar examples, are desirable. Unfortunately, however, it has been found difficult to find appropriate compounds to be examined for the present purpose.

When a potassium cyanide solution is added to a solution of hexammine cobalt(III) chloride, the coordinated ammonia is replaced by the cyanide ion, and the only product obtained is not easily soluble crystals, $[Co(NH_3)_6]\cdot[Co(CN)_6]$. From the above fact alone, one

5) S. Kida, to be published.

can not deduce a conclusion, because there are two probable cases; i.e. 1) the mixed complex is not formed because of its comparatively less stability, 2) although the mixed complexes are easily formed in solution, the least soluble compound, $[Co(NH_3)_6] \cdot [Co(CN)_6]$, separates out, and the equilibrium shifts to produce the crystals, $[Co(NH_3)_6] \cdot [Co(CN)_6]$.

## Experimental

Extinction measurements were made by the Beckman DU Spectrophotometer using 1 cm. qualtz cells at room temperature.

Potassium tetrachloro platinate(II), $K_2[PtCl_4]$, and potassium tetrabromo platinate(II), $K_2[PtBr_4] \cdot 2H_2O$, were prepared according to the literatures[6,7], and their purity was checked by analyzing their quantity of halogen. The concentration of potassium cyanide was determined by a titration with a standard solution of silver nitrate.

7) E. Billmann and A. C. Anderson, *Ber.*, **36**, 1566 (1903).

## Summary

The spectrophotometric investigation has shown that in the substitution reactions of cyanide ion for halogens($X^-$) of the complexes, $[PtX_4]^{2-}$, (X=Cl and Br) in solution, no mixed complex is formed.

The author wishes to thank Professor R. Tsuchida of Osaka University for his kind guidance throughout this work. He is also indebted to Dr. H. Yoneda and Dr. J. Fujita for their helpful discussions.

# *Adsorption of the Ferric Ion by Weakly Acidic Resins. Preferential Uptake of the Ferric Ion by Alginic Acid*

By Manabu SENŌ and Takeo YAMABE

(Received October 6, 1959)

Weakly acidic ion-exchange resins have strong affinity to the hydrogen ion and it is scarcely exchanged at all for other cations including heavy metal ions. Recently, it has been revealed[1,2] in the course of separation experiments of heavy metal ions that alginic acid adsorbs the ferric ion to a great extent, although it is a weakly dissociated acid.

In this paper, adsorptive properties for ferric ions of weakly acidic ion-exchange resins, Amberlite IRC-50 and alginate resin, are examined and discussed.

## Experimental

The exchange resins used are Amberlite IRC-50 (Rohm and Haas Co., Ltd., U. S. A.) and alginic acid*. They were washed thoroughly with pure water and air-dried, after conditioning with acid and alkali.

All the equilibrium experiments were carried out by the batch-method. Resins of acidic form were used unless otherwise stated. About 0.2 g. of the resin and 50 ml. of the external salt solution were taken in a beaker and allowed to stand for a week or more with stirring occasionally, since the rate of exchange is rather low for weakly dissociated resins as shown by the preliminary test (Fig. 1). To prevent the vaporization of the solution, the beaker was covered with polyvinylchloride sheet. The concentrations of metal ions in the added solutions were about 0.03 meq./ml. except these described otherwise. After equilibrating, the metal and hydrogen ions remaining in solution were assayed and the amount of the metal ions adsorbed on the resin was estimated as usual. The iron, aluminum and copper were analyzed colorimetrically.

All reagents are of commercial special-grade and were used without further purification.

Absorption spectra were measured using a Hitachi EPU-2A spectrophotometer.

## Results and Discussion

hydrochloric acid were given in Table I. Alginate resin adsorbs the ferric ion more strongly than Amberlite IRC-50. Amounts of ferric ions adsorbed were markedly dependent on pH of the external solution. For comparison, the data on exchange by a strongly acidic ion-exchange resin, Amberlite IR-120, were also shown in the table.

It is interesting to note that the adsorption capacity for the ferric ion is larger than the total exchange capacity**, which is obtained

** The total exchange cepacities are 10 for Amberlite IRC-50, 5.6 for alginate and 4.5 (meq./g. resin) for Amberlite IR-120, respectively.

from a titration curve by alkali, in the case of alginic acid and Amberlite IR-120.

In Fig. 2, the equilibrium diagram of the ferric ion against the hydrogen ion was shown. It is noteworthy that the ferric ion is adsorbed by alginate resin to almost the same extent as the hydrogen ion.

In Table II, the amounts of all ions remaining in external solution before and after equilibrium of the exchange reaction were described. As seen in the table, the adsorption of the ferric ion is intrinsically an exchange reaction of counter-ions of the resins.

**Preferential Adsorption of the Ferric Ion.**—In Table III and Fig. 3, the results of exchange equilibria of other heavy metal ions, $Fe^{2+}$, $Al^{3+}$ and $Cu^{2+}$, for the hydrogen ion were given. As shown already by other investigators[1], who tried successfully to separate the ferric ion from other metal ions by columns of alginic acid powder, alginate resin combines very strongly with the ferric ion compared with other heavy metal ions. This behavior is a remarkable character of alginate resin, in contrast with Amberlite IR-120 and IR C-50; the former adsorbs well all metal ions and the latter has a very strong affinity to the hydrogen ion and, therefore, metal cations replace the hydrogen ion with difficulty.

This result is valid, independently of the acidity of the external solution as seen in Table IV. Of course, as the acidity of a solution becomes very high, these resins can not combine with other cations except in the case of the hydrogen ion.

To confirm this selective uptake of the ferric ion by alginic acid, the exchange equilibria between $Fe^{3+}$ and $Al^{3+}$ or $Cu^{2+}$ were examined under the condition that the concentration of hydrochloric acid in salt solution was kept constant. Also the total concentration of the metal ions in the system was almost kept constant, 0.15 meq./ml. The results were given in Fig. 4. Preferential adsorption of the ferric

ion against the aluminum or copper ion is very remarkable and, therefore, it is clear that the ferric ion can easily be separated from these ions by using alginic acid as an ion-exchange resin.

**Desorption of Metal Ions from Resins with Acid.**—Although in all the experiments mentioned above the acidic form resins were equilibrated with salt solution, here salt form resins were treated with acid to examine the reversibility of these exchange reactions. Resin of $Fe^{3+}$-, $Al^{3+}$- or $Cu^{2+}$- salt form was prepared by treating sodium salt form resin with ferric, aluminum or cupric chloride solution respectively, and washing it several times with pure water.

A definite quantity of each salt resin was immersed in an acid solution of known concentration, and the amount of metal ion desorbed from resin was measured. The results were given in Table V.

The reversibility of the exchange equilibrium does not always hold. It must be pointed out that, in the case of Amberlite IRC-50, the amounts of metal ions retained in this elution experiment are larger than those adsorbed in the adsorption experiment, independently of the variety of ion species. Alginate resin adsorbs ferric ion remarkably and the retained quantity is nearly equal to the adsorbed one shown in Table I.

Metal ions are eluted from resins almost with 0.1 N and completely with 1 N hydrochloric acid.

**Effect of Anion.**—The effect of anion on adsorption of the ferric ion by resin was examined and the result was given in Table VI.

In both resins the effect of anion is not remarkable.

**Mechanism of Ferric Ion Adsorption on Resins.**—As mentioned above, alginic acid resin adsorbs the ferric ion more extensively than Amberlite IRC-50 and the ferric ion is more preferentially adsorbed than other heavy metal ions, aluminum and copper ions, by these weakly dissociated resins. Taking into account these facts and the structural character of resins, the mechanism of adsorption of the ferric ion on these resins is examined as follows:

**Adsorption of Chloride Complex Ions, $FeCl_n^{+(3-n)}$.**—It is well-known[3,4] that the ferric ion combines with the chloride ion to form complex ions, $FeCl_n^{+(3-n)}$, where $n$ becomes four at higher chloride concentration. If these complex ions take a part in the exchange reaction, adsorption of the chloride ion must be observed. However, this is not the case as shown in Table II, probably because the chloride concentration is rather low, less than 0.1 N, and the formation of chloride complexes is not predominant.

**Adsorption of Hydroxy Complex Ions, $Fe(OH)_n^{+(3-n)}$.**—Since in this experimental condition the hydrogen ion concentration is low in external medium, the ferric ion is hydrolyzed partially and the hydroxy complex ions, $Fe(OH)^{+2}$, $Fe(OH)_2^{+}$ and $Fe(OH)_3$, may be formed to a large extent[3,5]. Moreover, the fact that the exchanged quantity of the ferric ion is greater than the total exchange capacity leads to the conclusion that the ferric ion is exchanged not as a trivalent cation but as an ion with less valency on the average.

3) E. Rabinowitch and W. H. Stockmayer, *J. Am. Chem. Soc.*, **64**, 335 (1942).
4) G. A. Gamlen and D. O. Jordan, *J. Chem. Soc.*, **1953**, 1435.
5) A. B. Lamb and A. G. Jacques, *J. Am. Chem., Soc.*, **60**, 967, 1215 (1938).

For these reasons, it seems to be a fact that these hydroxy complexes have a part in the exchange reaction. None of the present experiments oppose the above deduction. It supports the probability of this adsorption mechanism that, when alginic acid combines with the ferric ion, it colors to reddish-brown and has a very similar absorption spectrum to that of the ferric hydroxide sol and of $Fe(OH)^{2+}$ given by Rabinowitch et al. (Fig. 5)[3].

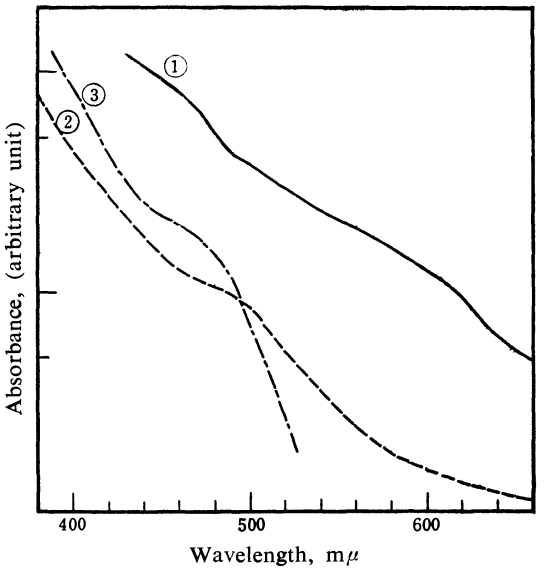

Fig. 5. Absorption spectra of
1. alginate resin membrane adsorbing ferric ion against original alginate membrane,
2. ferric hydroxide sol and
3. $Fe(OH)^{2+}$ given by Rabinowitch et al.[3]

In a case when partially hydrolyzed ions, e. g. $Fe(OH)^{2+}$, play a part in the adsorption reaction, reactions of various types may proceed at the same time. For instance, besides the normal exchange reaction 1

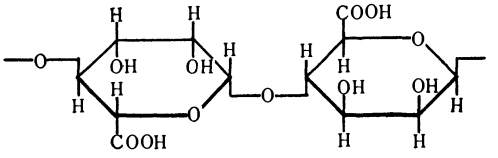
$$2HAlg + Fe(OH)^{2+} \rightleftarrows Fe(OH)Alg_2 + 2H^+ \quad (1)$$

the following reactions including neutralization may occur

$$HAlg + Fe(OH)^{2+} \rightleftarrows Fe(Alg)^{2+} + H_2O$$

$$Fe(Alg)^{2+} + 2HAlg \rightleftarrows Fe(Alg)_3 + 2H^+$$

that is,



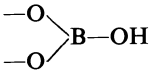
$$3HAlg + Fe(OH)^{2+} \rightleftarrows Fe(Alg)_3 + 2H^+ + H_2O \quad (2)$$

where Alg denotes a structural unit of alginate resin. Taking the hydrolysis of ferric alginate into account, reactions 1 and 2 cause the same result.

Although the present study can not give any confirmative evidence for the occurrence of these reactions, it is probably true that this mechanism may play an important part in the adsorption of the ferric ion by weakly acidic resin, for neutralization reaction can proceed to a large extent in these weakly dissociated resins.

The detailed discussion of such an exchange reaction including reactions of various types must be made clear in future.

**Complex Adsorption.**—As alginic acid has the following structure containing two hydroxyl groups and an oxygen linkage, it may be expected to combine with the ferric ion, forming an inner salt complex. To examine the effect



of the hydroxyl groups on the adsorption of the ferric ion by alginic acid, the ferric ion adsorbed on alginate resin was estimated when boric acid was added to the equilibrating system. The result was given in Table VII. The addition

TABLE VII. ADSORPTION OF THE FERRIC ION BY ALGINATE RESIN IN THE PRESENCE OF BORIC ACID

of boric acid diminishes the adsorbed quantity of ferric ions. Since it is known[6] that alginic acid having a *cis*-diol group combines with boric acid to form a chelate compound,

it is confirmed that the presence of the hydroxyl groups influences the adsorption of the ferric ion.

Moreover, to obtain further knowledge concerning the formation of a chelate compound between alginic acid and the ferric ion, absorption spectra of the ferric ion were measured in the presence of glucuronic acid, which is similar structurally to the unit of alginic acid***. As

6) H. Deuel and M. Neukom, *Makromol. Chem.*, 3, 13 (1949).

*** The structural unit of alginic acid is mannuronic acid and glucuronic acid may be structurally named galacturonic acid. However, it is safely considered that qualitative behaviors toward the ferric ion are similar for both acids.

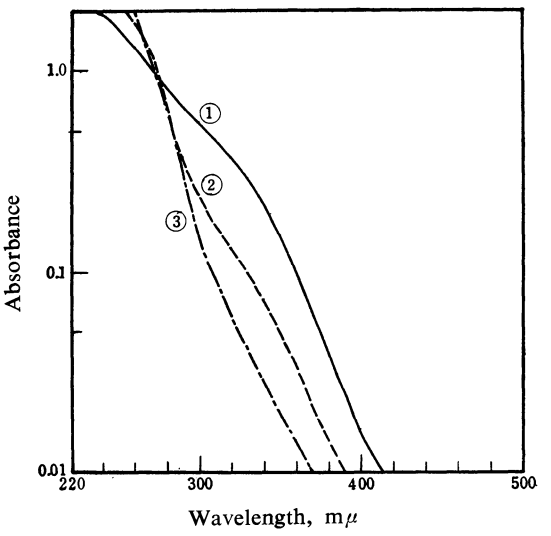

Fig. 6. Absorption spectra of ferric perchlorate $Fe(ClO_4)_3$, 0.0022 meq./ml.; $HClO_4$, 1, 0.007 N; 2, 0.031 N; 3, 0.091 N. Reference, $H_2O$.

reference, $H_2O$.

shown in Figs. 6 and 7, it is apparent that there is a shoulder at 320~340 mμ region of the absorption spectrum of the ferric ion in the presence of the glucuronate ion. That is to say, an absorption band appears at about 330 mμ and becomes weaker as the acidity of the solution increases and disappears at 0.1 N of perchloric acid.

When the concentration of the glucuronate ion is high, a weak absorption is observed over the visible wavelength region and the solution becomes weakly reddish-yellow. The absorption at 330 mμ does not become remarkable and a new weak band appears at 470 mμ.

The visible absorption spectrum**** of alginate membrane adsorbing the ferric ion also has a shoulder at 460~470 mμ, as shown in Fig. 5.

The component ions, ferric (aquo), glucuronate and alginate ions, exhibit no absorption peak in these regions[7]. Therefore, although these spectroscopic characters can not be explained completely in the present stage, it may be concluded that there are some interactions between the ferric ion and the glucuronate or alginate ion besides the simple coulombic one. Thus, it is, partly at least, due to the complex formation that alginate resin adsorbes the ferric ion intensively and preferentially.

It must be noticed that a hydroxy complex of the ferric ion has an absorption spectrum over the visible wavelength region and this spectrum has a shoulder at 460~480 mμ, as revealed from the spectrum of the ferric hydroxide sol and the spectrum of $Fe(OH)^{2+}$ obtained by Rabinowitch et al.[3] Since the concentration of the hydrogen ion is higher in the resin phase than in the external solution, it can not be expected that these hydroxy complexes exist in a free state, but it may be probable that hydroxy complexes are formed between the ferric ion and the glucuronate or alginate ion.

The absorption spectra of the ferric ion in the presence of acetate and *p*-toluene sulfonate ions were shown in Figs. 8 and 9. These ions are structurally similar to a unit of Amberlite IRC-50 and Amberlite IR-120, respectively. The spectrum of the ferric ion is not affected by the addition of the former[8] and the addition of the latter does not change in shape, but shifts the spectrum of the ferric ion to a longer wavelength. From these observations it may be concluded that these ions do not combine with the ferric ion to form chelate compounds.

**** It was measured against the original alginate membrane using opal-glass. Measurements in the region of ultraviolet wavelengths are impossible by this method.

7) Ther is a peak at 270~280 mμ in the absorption spectrum of the glucuronate ion. The chloride complexes of the ferric ion have an absorpion peak at 330~340 mμ.

8) W. Reiss et al.[9] reported that ferric acetate complex exhibits absorption peaks at 337.5 and 465 mμ when the concentration of the acetate ion is high. These peaks were not detected under the present experimental condition.

## Summary

The exchange adsorptions of the ferric ion by the cation-exchange resins of carboxylic acid type, Amberlite IRC-50 and alginate resin, were examined. Equilibration experiments revealed that alginate resin adsorbs metal ions more extensively than Amberlite IRC-50 and the ferric ion is preferentially adsorbed by these resins, especially by alginate resin. The mechanism of adsorption of the ferric ion was discussed and it was concluded that the preferential uptake of the ferric ion by alginate resin was due to the partial hydrolysis of the ferric ion and the complex formation between the ferric ion and alginate resin.

In concluding this paper, the authors wish to express their thanks to Professor T. Takahashi for his continuous advice. The cost of the present research has been partly defrayed from the grant of the Ministry of Education, for which the authors' thanks are due.

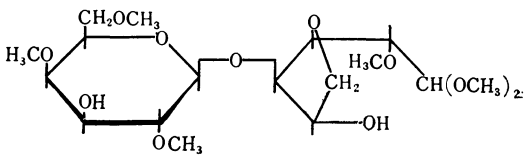
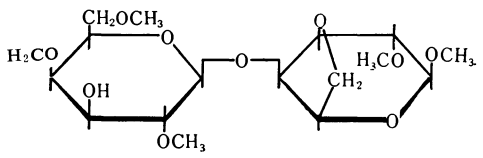
# *Studies on the Chemical Constitution of Agar-agar. XXII.*[1] *Partial Methanolysis of Methylated Agarose of Gelidium Amansii*



By Choji ARAKI and Susumu HIRASE

(Received October 8, 1959)



Agarose, a chief polysaccharide of agar, has been suggested by Araki[2], one of the present authors, to be a chain composed of alternating β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose residues. The preceding paper[1] concerned with the complete methanolysis of methylated agarose of *Gelidium amansii* provided a strong evidence to verify the above mentioned structure of agarose. A further support has now been obtained herein by partial methanolysis of the methylated polysaccharide.

The partial methanolysis was conducted with 0.5% methanolic hydrogen chloride for four hours, during which time 74% of the methylated polysaccharide was concerned in reaction. After treatment with barium hydroxide, the products were separated into neutral and acid components by fractionation with ether. The acidic component in the barium salt was obtained in too small a yield to be of structual significance. Further separation of the neutral components on a charcoal-Celite column led to the isolation of *O*-2, 4, 6-tri-*O*-methyl-β-D-galactopyranosyl-(1→4)-2-*O*-methyl-3, 6-anhydro-L-galactose dimethylacetal (I) and methyl *O*-2, 4, 6-tri-*O*-methyl-β-D-galactopyranosyl-(1→4)-2-*O*-methyl-3, 6-anhydro-β-L-galactopyranoside (II), both being derivatives of agarobiose (4-*O*-β-D-galactopyranosyl-3, 6-anhydro-L-galactose), which constitutes the repeating units of the agarose molecule. The total yield of compounds I and II amounted to 82% of the neutral products by weight.

The dimethylacetal (I) was eluted from the chromatographic column with 10~20% ethanol in water at 26~27°C and isolated in a crystalline form with the empirical formula $C_{12}H_{16}O_5 \cdot (OCH_3)_6$. Further, methylation with methyl iodide and silver oxide afforded hexa-*O*-methylagarobiose dimethylacetal, which on methanolysis yielded methyl 2, 3, 4, 6-tetra-*O*-methyl-α, β-D-galactoside and 2, 5-di-*O*-methyl-3, 6-anhydro-L-galactose dimethylacetal, identifying thereby compound I as a derivative of agarobiose. Hydrolysis with 0.02 N oxalic acid solution removed two methoxyl groups from the molecule to yield tetra-*O*-methylagarobiose, indicating that the compound I was a dimethylacetal. On methanolysis the compound I produced a mixture of methyl 2, 4, 6-tri-*O*-methyl-α, β-D-galactosides, methyl 2-*O*-methyl-3, 6-anhydro-β-L-galactopyranoside and 2-*O*-methyl-3, 6-anhydro-L-galactose dimethylacetal, the separation of the mixture being effected by selective hydrolysis of the anhydrosugar derivatives followed by fractionation with *n*-hexane. This established the positions of the four methoxyl groups connected in ether linkages with the rest of the molecule of compound I.

(I)

(II)

The methyl glycoside (II) was eluted from the charcoal column with 50% ethanol in water at 26~27°C and isolated in a crystalline form with the empirical formula $C_{12}H_{15}O_5(OCH_3)_5$. When treated with boiling methanol containing 3% of hydrogen chloride, it was converted with ease into the fore-going dimethylacetal (I). Hydrolysis of compound II with 0.02 N oxalic acid solution resulted in the formation of the reducing sugar identical with that obtainable from the dimethylacetal (I). These facts have enabled to be assigned structure II to the compound under problem, the β-configuration of the glycosidic methoxyl group being suggested on the basis of the positive value of optical rotation. Moreover, further methylation of compound II with methyl iodide and silver oxide afforded crystalline methyl penta-*O*-methyl-β-agarobioside, which agreed in all respects

with the methylated disaccharide derivative previously isolated by Araki[3], one of the present authors, by re-methylation of the methanolysis products of methylated agarose of *G. amansii*.

The isolation of compounds I and II in a good total yield emphasizes that agarobiose units are repeated through their 1 and 3′ positions in the molecule of agarose of *G. amansii* as previously suggested by Araki.

## Experimental

Evaporation and concentration of solutions were carried out under reduced pressure below 40°C. Melting points are uncorrected.

**Methanolysis of Methylated Agarose.**—Methylated agarose (10 g.) was suspended in methanol (150 ml.) containing 0.5% of hydrogen chloride and the suspension was heated under reflux for four hours, at which time undissolved material was removed by filtration. The filtrate was neutralized with silver carbonate, refiltered and evaporated to afford a sirup, which was then treated with 0.2 N barium hydroxide solution (100 ml.) at 60°C for two hours to saponify the methyl ester of the acidic component. The excess of the barium hydroxide was removed by neutralization with carbon dioxide and subsequent filtration, and the filtrate was evaporated to a sirup (7.4 g.).

**Separation of Neutral and Acidic Components.**—When the sirup obtained above was dissolved in ether (150 ml.), the acidic component was precipitated as a barium salt form. It was filtered off, washed with ether and dried in vacuo; yield, 0.18 g., $[\alpha]_D^{27}$ −26.4° in water (*c* 0.72). Evaporation of the filtrate afforded a mixture of neutral components as a colorless sirup; yield, 7.2 g., $[\alpha]_D^{27}$ −1.21° in water (*c* 0.83).

**Chromatographic Separation of Mixture of Neutral Components.**—The mixture of the neutral components (7.2 g.) obtained above was chromatographed at 25~27°C on a column (5.2×20 cm.) packed with charcoal (60 g.)and Celite (40 g.), successively higher concentrations of ethanol in water being used as developing solvents. The effluents were collected in separate receivers and evaporated to dryness to recover the contents, which were then weighed and the specific optical rotation, the methoxyl content and the molecular weight were measured. The results are shown in Table I.

TABLE I. CHROMATOGRAPHIC SEPARATION OF THE MIXTURE OF NEUTRAL COMPONENTS

| Fraction | Developer %* | Developer l. | Yield g. | $[\alpha]_D^{27}$ (°) $H_2O$ | $OCH_3$ % | M.W.** |
|---|---|---|---|---|---|---|
| I | 5 | 5 | 0.3 | − 0.6 | 42.1 | 211 |
| II | 7.5 | 5 | 0.5 | +97.8 | 48.3 | 225 |
| III | 10 | 5 | 1.6 | −29.3 | 43.3 | 423 |

* Concentration of ethanol in water.
** Molecular weight was determined by Rast's method.

Fractions I and II were obtained as colorless sirups, but on standing the latter fraction crystallized partly. Papar chromatographic examination, using cyclohexanol saturated with water as a mobile phase[1] and *O*-aminophenol in aqueous ethanol acidified with phosphoric acid as a spraying reagent[4], indicated the presence of 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal ($R_f$ 0.67) and methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside ($R_f$ 0.77) in fraction I and of the latter compound in fraction II. When these were hydrolyzed with 1 N sulfuric acid for five hours in a boiling water bath and subsequently examined on paper chromatograms with *n*-butanol-ethanol-water (4 : 1 : 2) as a mobile phase and aniline hydrogen phthalate in moist *n*-butanol as a spraying reagent, 2,4,6-tri-*O*-methyl-D-galactose was detected in the hydrolyzates of both fractions I and II, the anhydrosugar derivatives being decomposed during the hydrolysis. It was therefore considered that fraction I was a mixture of 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal, methyl 2-*O*-methyl-3,6-anhydro-L-galactopyranoside and methyl 2,4,6-tri-*O*-methyl-D-galactoside and that fraction II was a mixture of the latter two.

On the other hand, fractions III—V were proved to be entirely the dimethylacetal (I), and fractions VII and VIII were also proved to be entirely the methyl glycoside (II) as described below. Fraction VI seemed to be a mixture of compounds I and II.

**Tetra-*O*-methylagarobiose Dimethylacetal (I).**—All fractions III—V in Table I crystallized completely on standing and melted at 84~86°C. These were combined and recrystallized twice from ether containing a small amount of petroleum ether, affording the dimethylacetal (I) in prisms; m. p. 88~89°C, $[\alpha]_D^{19}$ −25.2° in water (*c* 1.19), $[\alpha]_D^{10}$ −41.9° in methanol (*c* 1.05) and $[\alpha]_D^{10}$ −46.7° in chloroform (*c* 1.07). The crude yields of the dimethylacetal thus amounted to 58% of the sample applied.

Found: C, 50.65; H, 8.06; $OCH_3$, 43.45; mol. wt., 425. Calcd. for $C_{12}H_{16}O_5(OCH_3)_6$: C, 50.69; H, 8.04; $OCH_3$, 43.67%; mol. wt., 426.5.

**Methanolysis of Dimethylacetal (I).**—The dimethylacetal (I) (1.5 g.) obtained above was dissolved in 3% methanolic hydrogen chloride (30 ml.) and heated under reflux for two hours, at which time the optical rotation of the solution reached a constant value ($[\alpha]_D$ −29° → +42°). The solution was neutralized with silver carbonate, filtered and evaporated to dryness, when a mixture of methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside, 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal and methyl 2,4,6-tri-*O*-methyl-D-galactoside was obtained as a sirup (1.3 g.); $[\alpha]_D^{25}$ +51.0° in water (*c* 1.0).

*a) Identification of methyl 2,4,6-tri-O-methyl-α,β-D-galactosides.*—The sirup obtained above was

3) C. Araki, *J. Chem. Soc. Japan*, (*Nippon Kwagaku Kwaishi*), **26**, 733 (1941).

4) S. Hirase, C. Araki and S. Nakanishi, This Bulletin **26**, 183 (1953).

5) S. M. Partridge, *Nature*, **164**, 443 (1949).

heated with 0.02 N oxalic acid solution for two hours in a boiling water bath to hydrolyze selectively the derivatives of 2-*O*-methyl-3,6-anhydro-L-galactose. The resulting product was isolated as a sirup in the usual manner and then extracted seven times each with 15 ml. of *n*-hexane at 50°C. The extracts were combined and evaporated to dryness, an anomeric mixture of methyl 2,4,6-tri-*O*-methyl-D-galactosides being obtained as crystals; yield, 0.50 g., m. p. 44~60°C, $[\alpha]_D^{27}$ +81.6° in water (*c*. 0.38), $OCH_3$ found: 51.67% (calcd. for $C_6H_8O_2(OCH_3)_4$: 52.52%). The methyl glycoside was identified by conversion in the usual manner into the corresponding reducing sugar[6], m. p. and mixed m. p. 109~110°C, $[\alpha]_D^{26}$ +116° → +90.1° in water (*c* 0.81), and its aniline derivative, m. p. and mixed m. p. 174°C, $[\alpha]_D^{26}$ −103° (initial) in acetone (*c* 0.40).

*b) Identification of 2-O-methyl-3,6-anhydro-L-galactose.* — The residual sirup, which had been separated from the methyl tri-*O*-methyl-D-galactoside by extraction with *n*-hexane as mentioned above was dissolved in acetone (5 ml.) and filtered. Evaporation of the filtrate afforded 2-*O*-methyl-3,6-anhydro-L-galactose[1] (0.65 g.), which seemed to be still contaminated with appreciable quantities of the methyl tri-*O*- methyl-D-galactoside as indicated by its positive value of the optical rotation $[\alpha]_D^{27}$ +24.1° in water (*c* 0.83) and its high methoxyl value 28.43% (calcd. for $C_6H_9O_4(OCH_3)$: 17.59%). But, without further purification, the sugar was oxidized with bromine water in the usual manner, and the resulting 2-*O*-methyl-3,6-anhydro-L-galactonic acid was crystallized from ethyl acetate; yield, 0.41 g., m. p. and mixed m. p. 141~142°, $[\alpha]_D^{25}$ −70.8° in water (*c* 0.72). One of the present authors has reported m. p. 142°C and $[\alpha]_D^{12}$ −70.0° in water for 2-*O*-methyl-3,6-anhydro-L-galactonic acid[7].

**Hexa-*O*-methylagarobiose Dimethylacetal from I.**—The dimethylacetal (I) (1.0 g.) was methylated twice with methyl iodide (15 g.) and silver oxide (10 g.) in the usual manner, giving hexa-*O*-methylagarobiose dimethylacetal as a colorless sirup; yield, 1.0 g., $[\alpha]_D^{10}$ −21.6° in water (*c* 1.11), $[\alpha]_D^{10}$ −37.3° in methanol (*c* 1.10), $[\alpha]_D^{10}$ −40.5° in chloroform (*c* 1.11), $n_D^{25}$ 1.4611, $OCH_3$ found: 54.18% (calcd. for $C_{12}H_{16}O_5(OCH_3)_6$: 54.61%). One of the present authors has reported $[\alpha]_D^{23}$ −11.09° in water, $[\alpha]_D^{23}$ −29.46° in chloroform and $n_D^{25}$ 1.4632 for hexa-*O*-methylagarobiose dimethylacetal[8].

**Methanolysis of Hexa-*O*-methylagarobiose Dimethylacetal.**—Hexa-*O*-methylagarobiose dimethylacetal (0.80 g.) obtained above was subjected to methanolysis with 3% methanolic hydrogen chloride (20 ml.) for twenty five hours. The hydrogen chloride was removed by neutralization with silver carbonate and filtration, and the filtrate on evaporation afforded a mixture of methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-galactosides and 2,5-di-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal; yield, 0.85 g., $[\alpha]_D^{10}$ +48.0° in water (*c* 1.00).

The mixture was separated at 10~13°C on a column (3.7×11 cm.) packed with charcoal and Celite into four fractions shown in Table II. Fraction I was identified as 2,5-di-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal and fractions III and IV were done as methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-galactosides as described below; while, fraction II seemed to be a mixture of the two components.

TABLE II. SEPARATION OF THE PRODUCTS OF METHANOLYSIS OF HEXA-*O*-METHYLAGAROBIOSE DIMETHYLACETAL

* Concentration of ethanol in water.

*a) Identification of 2,5-O-methyl-3,6-anhydro-L-galactose Dimethylacetal.*—The properties of fraction I in Table II agree with those of 2,5-di-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal, which have been recorded by the present authors as: $[\alpha]_D^{17}$ −6.90°[8] or $[\alpha]_D^{19}$ −6.67°[9] in water and $n_D^{25}$ 1.4533[8] or $n_D^{20}$ 1.4563[9].

For confirmative identification, the dimethylacetal (0.15 g.) was converted into 2,5-di-*O*-methyl-3,6-anhydro-L-galactonic acid by hydrolyzing with 3% hydrobromic acid for five minutes in a boiling water bath and then oxidizing with bromine in the usual manner. The resulting carboxylic acid (0.16 g.) was purified by recrystallization from ethyl acetate; m. p. and mixed m. p. 160~161°C, $[\alpha]_D^{12}$ −62.2° in water (*c* 0.90). The present authors[3,9] have reported m. p. 161°C, $[\alpha]_D^{23}$ −54.32° in water and $[\alpha]_D^{21}$ −61.9° in water for the compound.

Found: C, 46.45; H, 6.88; $OCH_3$, 30.38. Calcd. for $C_6H_8O_4(OCH_3)_2$: C, 46.60; H, 6.84; $OCH_3$, 30.12%.

*b) Identification of Methyl 2,3,4,6-tetra-O-methyl-D-galactoside.*—Fractions III and IV in Table II agree in properties with methyl 2,3,4,6-tetra-*O*-methyl-D-galactoside. The fractions were combined and hydrolyzed with 1 N sulfuric acid in the usual manner to give the corresponding reducing sugar, which was crystallized from *n*-hexane; m. p. and mixed m. p. 70~72°C, $[\alpha]_D^{12}$ +144.4° (initial) → +120° (final) in water (*c* 0.45).

Found: C, 50.41; H, 8.51; $OCH_3$, 52.45. Calcd. for $C_6H_8O_2(OCH_3)_4$: C, 50.83; H, 8.53; $OCH_3$, 52.52%.

**Methyl Tetra-*O*-methyl-β-agarobioside (II).**—Fractions VII and VIII in Table I crystallized completely and melted at 143~144°C. These were combined and recrystallized twice from ethyl acetate, affording the pure sample of compound II in prisms; m. p. 143~144°C, $[\alpha]_D^{10}$ +41.7° in water (*c* 1.15), $[\alpha]_D^{15}$ +23.6° in methanol (*c* 1.10) and $[\alpha]_D^{10}$ +35.4° in chloroform (*c* 1.13).

Found: C, 51.67; H, 7.53; $OCH_3$, 39.51; mol.

6) C. Araki, *J. Chem. Soc. Japan (Nippon Kwagaku Kwaishi)*, **58**, 1362 (1937); E. G. V. Percival and J. C. Somerville, *J. Chem. Soc.* **1937**, 1615.

7) C. Araki, *J. Chem. Soc., Japan (Nippon Kwagaku Kwaishi)*, **61**, 775 (1940).

8) C. Araki, ibid., **65**, 533, 627 (1944).

9) S. Hirase, This Bulletin, **30**, 75 (1957).

wt., 394. Calcd. for $C_{12}H_{15}O_5(OCH_3)_5$: C, 51.77; H, 7.67; $OCH_3$, 39.35%; mol. wt., 394.4.

**Conversion of the Methyl Glycoside (II) into the Dimethylacetal (I).** — When methyl tetra-*O*-methyl-β-agarobioside (0.20 g.) obtained above was heated in 3% methanolic hydrogen chloride (20 ml.), the specific rotation of the solution changed from +14° to −29° within five minutes, at the end of which time the hydrochloric acid was removed by neutralization with silver carbonate and filtration. Evaporation of the filtrate gave a sirupy mixture of the dimethylacetal (I) and the starting material; yield, 0.20 g., $[\alpha]_D^{10}$ −11.3° in water (*c* 0.53). The mixture was then resolved into the components on a column (2.7×11 cm.) of charcoal and Celite. The dimethylacetal was eluted from the column with 30% ethanol in water and crystallized from ether containing a few drops of petroleum ether; yield, 0.14 g., m. p. 88~89°C, $[\alpha]_D^{10}$ −25.0° in water (*c* 0.80). Admixture with a sample of the dimethylacetal (I) described earlier showed no depression of the melting point. Subsequent elution of the column with 50% ethanol in water led to recovery of a small amount of the starting material.

**Methyl Penta-*O*-methyl-β-agarobioside from II.** —Methyl tetra-*O*-methyl-β-agarobioside (II) (0.30 g.) was methylated twice with methyl iodide (20 g.) and silver oxide (5 g.) in the usual manner. Extraction of the product with acetone followed by evaporation afforded methyl penta-*O*-methyl-β-agarobioside (0.30 g.), which was then recrystallized by dissolving in a small volume of ether and adding petroleum ether; m. p. 98~100°C, $[\alpha]_D^{10}$ +48.1° in water (*c* 1.04). One of the present authors has reported m. p. 99~100°C and $[\alpha]_D^{27}$ +48.32° in water for the methylated disaccharide derivative[3] previously isolated from methylated agarose. Admixture of the two showed no depression of the melting point.

Found: C, 52.85; H, 7.72; $OCH_3$, 45.68. Calcd. for $C_{12}H_{14}O_4(OCH_3)_6$: C, 52.93; H, 7.90; $OCH_3$, 45.59%.

**Tetra-*O*-methylagarobiose.** — *a) From the Dimethylacetal (I).* — The dimethylacetal (I) (0.20 g.) in 0.02 N aqueous oxalic acid solution (20 ml.) was heated in a boiling water bath for one and a half hours, during which time the specific rotation of the solution changed from an initial value −25° to a constant value +12°. The solution was neutralized with calcium carbonate, filtered and evaporated to a sirup, which was then extracted with acetone. Filtration and evaporation of the extract afforded tetra-*O*-methyl-agarobiose as glass; yield, 0.17 g., $[\alpha]_D^{13}$ −15.1° (constant) in water (*c* 0.86), $OCH_3$ found: 41.65% (calcd. for $C_{12}H_{16}O_6(OCH_3)_4$: 42.07%). It was soluble in water and organic solvents except ether and petroleum ether. It slowly reduced the Fehling solution at room temperature and restored the color of Schiffs reagent. Attempt to prepare a crystalline aniline derivative was unsuccessful.

*b) From methyl glycoside (II).* — The methyl glycoside (II) (0.20 g.) was hydrolyzed with 0.02 N oxalic acid solution in a boiling water bath for one and a half hours, during which time the specific rotation of the solution changed from an initial value +41° to a constant value −12°, the final value being in exact agreement with that observed for the hydrolysis of dimethylacetal (I). The eesulting tetra-*O*-methylagarobiose was isolated as glass in exactly the same manner as described above; yield, 0.19 g., $[\alpha]_D^{13}$ −15.6° (constant) in water (*c* 0.64), $OCH_3$ found 41.69%.

The authors wish to express their hearty thanks to Mr. K. Arai for micro-combustion and to Mr. T. Itô for assistance.

# *The Kinetics of Substitution Reactions Involving Metal Complexes. III. Reaction between Copper(II) and Zinc-Ethylenediaminetetraacetate Complexes in Aqueous Solutions**

By Kiyoko KATO**

(Received October 12, 1959)

In the previous papers[1,2], the substitution reaction of copper(II) ions and lead-ethylenediaminetetraacetate (EDTA) complexes was reported. The rate of the reaction was followed by measuring the change of the polarographic diffusion current of copper(II) ions with the time. The reaction was found to proceed simultaneously through three different reaction paths.

* Requests for the reprint should be addressed to Nobuyuki Tanaka, Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai.

** Present address: The Women's Department, Tokyo College of Pharmacy, 31, Uenosakuragi-cho, Taito-ku, Tokyo.

2) N. Tanaka and K. Kato, ibid., 32, 1376 (1959).

under the experimental conditions, and the rate constants of the elementary reactions of those reaction paths were determined. The effect of acetate ions on the rate of the substitution reaction was explained quantitatively on the basis of the formation of acetato complexes of copper(II) and lead(II) and on the assumption that the substitution reaction proceeds only through the hydrated metal ions.

Since it seemed worth while to extend the study to the substitution reactions involving EDTA-complexes of other metal ions, the substitution reaction of copper(II) ions and zinc-EDTA complexes

$$Cu^{2+} + ZnY^{2-} \rightleftarrows CuY^{2-} + Zn^{2+}$$

was dealt with. The results are presented in this paper.

## Experimental

The preparation of solutions of copper(II) nitrate and disodium ethylenediaminetetraacetate was described in the previous paper[1]. A solution of zinc nitrate was prepared by dissolving a known amount of pure zinc metal in reagent-grade nitric acid.

The rate of the reaction between copper(II) ions and zinc-EDTA complexes was followed by measuring the change with the time in the polarographic diffusion current of copper(II) ions in acetate buffer solutions. Current-time curves were obtained with a Shimadzu RP-2 pen-recording polarograph. The dropping mercury electrode described in the previous paper[1] was used. This had an $m$ value of 1.27 mg./sec. and a drop time of 3.69 sec. in an air-free solution of 0.1 M potassium chloride at 25°C with open-circuit.

Measurements were made at 15 and 0°C in acetate buffers of pH 4.4 to 5.0 which contained 0.1 M of sodium acetate unless otherwise stated. The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.01% in concentration.

## Results and Discussion

In the solution containing acetate ions less than 0.2 M in concentration, copper(II) forms mono- and diacetato complexes, whereas zinc(II) forms only a monoacetato complex[3]. Therefore, the overall substitution reaction of copper(II) ions and zinc-EDTA complexes in acetate buffer solution is represented by the equations

$$Cu^{2+} + 2\,OAc^- \rightleftarrows CuOAc^+ + OAc^- \rightleftarrows Cu(OAc)_2 \quad (1)$$

$$Cu^{2+} + ZnY^{2-} \rightleftarrows CuY^{2-} + Zn^{2+} \quad (2)$$

$$Zn^{2+} + OAc^- \rightleftarrows ZnOAc^+ \quad (3)$$

where $Y^{4-}$ means a completely dissociated EDTA anion. Under the condition that both zinc ions and zinc-EDTA complexes are present in a large excess over copper(II) ions, the substitution reaction 2 can be simplified to

$$Cu^{2+} \underset{k^-}{\overset{k^+}{\rightleftarrows}} CuY^{2-} \quad (4)$$

The rate equation for reaction 4 is expressed as[2]

$$-\frac{d[Cu^{2+}]_{app}}{dt} = k^+ [Cu^{2+}]_{app} - k^- [CuY^{2-}] \quad (5)$$

where $[Cu^{2+}]_{app}$ is the concentration of copper(II) that can be determined polarographically, and given by the equation

$$[Cu^{2+}]_{app} = [Cu^{2+}] + [CuOAc^+] + [Cu(OAc)_2] \quad (6)$$

Integrating Eq. 5,

$$\ln\{[Cu^{2+}]_{app} - [Cu^{2+}]_{e,app}\} = -(k^+ + k^-)t + \ln\{[Cu^{2+}]_{0,app} - [Cu^{2+}]_{e,app}\}$$

is obtained, where subscripts 0 and e denote the initial and the equilibrium conditions, respectively. At the equilibrium of the reaction, the relation

$$\frac{k^+}{k^-} = \frac{[CuY^{2-}]_e}{[Cu^{2+}]_{e,app}} \fallingdotseq K^{Cu}_{Zn,app} \frac{[ZnY^{2-}]_0}{[Zn^{2+}]_{0,app}}$$

may be satisfied, where $K^{Cu}_{Zn,app}$ represents the apparent equilibrium constant expressed as

$$K^{Cu}_{Zn,app} = \frac{[Zn^{2+}]_{e,app}[CuY^{2-}]_e}{[Cu^{2+}]_{e,app}[ZnY^{2-}]_e}$$

The values of $K^{Cu}_{Zn,app}$ were determined polarographically to be 76 at 15°C and 92 at 0°C in acetate buffer solutions which contained 0.1 M of sodium acetate.

The apparent rate constant, $k^+/[ZnY^{2-}]_0$, was obtained at varied pH's at two different concentrations of zinc ions but at constant concentration of other species present. In Fig. 1 the values obtained at 15°C are plotted against the hydrogen ion concentration. This clearly indicates that a linear relation exists between $k^+/[ZnY^{2-}]_0$ and $[H^+]$. A similar relation was also found at 0°C.

On the basis of the dependencies of the observed apparent rate constants on the concentration of uncomplexed zinc ions, which are identical to those of the substitution reaction of copper(II) ions and lead-EDTA complexes[1,2], the following mechanisms were set down for reaction 2:

$$(i)\quad Cu^{2+} + ZnY^{2-} \underset{}{\overset{k_1^+}{\rightleftarrows}} CuY^{2-} + Zn^{2+} \quad (7)$$

$$(ii)\quad ZnY^{2-} + H^+ \rightleftarrows ZnHY^- \quad (8a)$$

3) N. Tanaka and K. Kato, ibid., 33, 417 (1960).

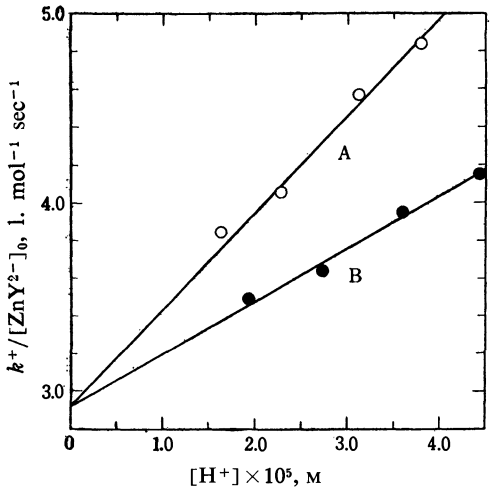

Fig. 1. $k^+/[ZnY^{2-}]_0$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app}=1.20\times10^{-4}$ M; $[ZnY^{2-}]_0=4.03\times10^{-3}$ M; $[Zn^{2+}]_{0,app}=1.12\times10^{-2}$ M (curve A) and $2.64\times10^{-2}$ M (curve B). Concentrations of free acetate are: 0.096 M (A) and 0.091 M (B).

$$Cu^{2+} + ZnHY^- \overset{k_{II}^+}{\rightleftarrows} CuHY^- + Zn^{2+} \quad (8b)$$

$$CuHY^- \rightleftarrows CuY^{2-} + H^+ \quad (8c)$$

(iii) $$ZnY^{2-} + H^+ \rightleftarrows Zn^{2+} + HY^{3-} \quad (9a)$$

$$Cu^{2+} + HY^{3-} \overset{k_{III}^+}{\rightleftarrows} CuY^{2-} + H^+ \quad (9b)$$

As has been mentioned previously[2], the concentration which was actually measured polarographically was not the concentration of hydrated copper(II) ions but the sum of the concentrations of hydrated ions and acetato complexes. If it is assumed that the substitution reaction proceeds through only the hydrated metal ions which are in equilibrium with the acetato complexes, the apparent rate of the forward reaction ($v^+=k^+[Cu^{2+}]_{app}$) determined polarographically is expressed as

$$v^+=\left\{\frac{k_1^+ + k_2^+[H^+] + k_3^+[H^+]\dfrac{1+K_{ZnAOc}[OAc^-]}{[Zn^{2+}]_{app}}}{1+\sum_{n=1}^{2}K_{Cu(OAc)_n}[OAc^-]^n}\right\}\times[Cu^{2+}]_{app}[ZnY^{2-}] \quad (10)$$

where

$$k_2^+=k_{II}^+K_{ZnHY}^H, \quad k_3^+=k_{III}^+/(K_{ZnY}K_{HY}) \quad (11)$$

$K_{ZnHY}^H$ represents the equilibrium constant of reaction 8a, $K_{ZnY}$, the formation constant of $ZnY^{2-}$ and $K_{HY}$, the fourth dissociation constant of ethylenediaminetetraacetic acid. $K_{Cu(OAc)_n}$ and $K_{ZnOAc}$ represent the overall formation constants of acetatocopper(II) and acetatozinc-(II) complexes, respectively.

From Eqs. 5 and 10, the relation

$$\frac{k^+}{[ZnY^{2-}]_0}=\frac{k_1^+ + k_2^+[H^+] + k_3^+[H^+]\dfrac{1+K_{ZnOAc}[OAc^-]}{[Zn^{2+}]_{0,app}}}{1+\sum_{n=1}^{2}K_{Cu(OAc)_n}[OAc^-]^n} \quad (12)$$

is obtained, where the initial concentrations, $[Zn^{2+}]_0$ and $[ZnY^{2-}]_0$, are substituted for $[Zn^{2+}]$ and $[ZnY^{2-}]$, respectively. Since both $Zn^{2+}$ and $ZnY^{2-}$ are present in the reaction mixture in a large excess over the concentration of copper-(II), the changes of their concentrations can be neglected.

The rate constants in Eq. 10 were calculated from the plots of $k^+/[ZnY^{2-}]_0$ against hydrogen ion concentration, which are tabulated in Table I. The values of $K_{CuOAc}$, $K_{Cu(OAc)_2}$ and $K_{ZnOAc}$ used in this calculation were 41, 190 and 5.7, respectively. These were all determined polarographically at ionic strength 0.2 at 15°C[3]. The concentration of uncomplexed acetate in the solution was calculated by successive approximation.

Table I. Rate constants in Eq. 10 obtained experimentally at ionic strength 0.2 at various temperatures

| Temp., °C | Rate constant, l. mol$^{-1}$ sec$^{-1}$ | | |
|---|---|---|---|
| | $k_1^+$ | $k_2^+$ | $k_3^+$ |
| 0 | 5.2 | $3\times10^4$ | $7.1\times10^2$ |
| 15 | 19 | $5\times10^4$ | $2.1\times10^3$ |

The rate constants of both elementary reactions 8b and 9b were calculated from the relations given in Eq. 11, using the values of $K_{ZnHY}^H$, $K_{ZnY}$ and $K_{HY}$ in Table II. The value of $K_{ZnHY}^H$ which was determined by Schwarzenbach et al.[4] at 20°C at ionic strength 0.1 was used after correction for ionic strength with the Debye-Hückel equation. The values of $K_{ZnY}$ at 15 and 0°C were obtained by dividing the value of $K_{CuY}$ by those of $K_{Zn}^{Cu}$. As for $K_{CuY}$, the values obtained by Schwarzenbach et al.[4]

4) G. Schwarzenbach, R. Gut and G. Anderegg, *Helv. Chim. Acta*, 37, 937 (1954).

were used after correction for temperature and ionic strength[2]. The equilibrium constants of reaction 2 at zero acetate concentration, $K_{Zn}^{Cu}$, used in this calculation were 320 at 15°C[3] and 310 at 0°C, the latter of which was estimated by extrapolation. The rate constants of three elementary reactions 7, 8b and 9b thus calculated are summarized in Table III.

Table II. Equilibrium constants at ionic strength 0.2 at various temperatures

| Temp., °C | $\log K_{ZnY}$ | $pK_{HY}$ | $\log K_{ZnHY}^{H}$ |
|---|---|---|---|
| 0 | 16.51 | 10.41 | — |
| 15 | 16.17 | 10.20 | — |
| 20 | — | — | 2.9 |

Table III. Rate constants for reactions 7, 8b and 9b at ionic strength 0.2 at various temperatures

| Temp., °C | Rate constant, l. mol$^{-1}$ sec$^{-1}$ | | |
|---|---|---|---|
| | $k_1^+$ | $k_{II}^+$ | $k_{III}^+$ |
| 0 | 5.2 | 40 | $8.9\times10^8$ |
| 15 | 19 | 60 | $2.0\times10^9$ |

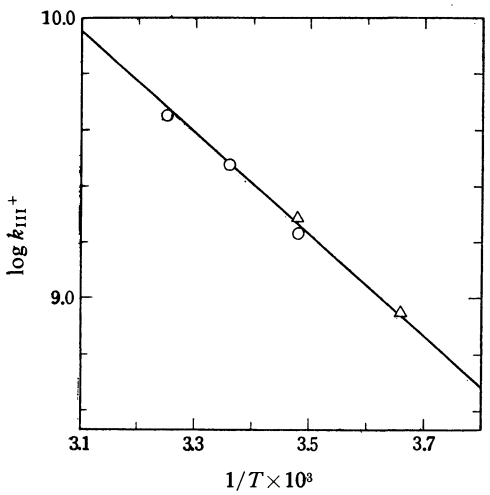

Fig. 2. The relation between the logarithm of rate constant and the reciprocal of absolute temperature for the reaction $Cu^{2+} + HY^{3-} \xrightarrow{k_{III}^+} CuY^{2-} + H^+$. ○ indicates the value obtained in the reaction of copper(II) ions and lead-EDTA complexes and △, in the reaction of copper-(II) ions and zinc-EDTA complexes.

From these results, the rate constants expressed in the form of the Arrhenius equation were derived and the heats of activation and the entropies of activation were calculated for three elementary reactions 7, 8b and 9b. The results are given in Table IV.

The rate constants of reaction 9b were obtained at 15 and 0°C in this study as given in Table III. The logarithmic values of $k_{III}^+$ are plotted against the reciprocal of absolute temperature as shown in Fig. 2. The rate constants of the same reaction were previously obtained at 15, 25 and 35° in the study of the substitution reaction of copper(II) ions and lead-EDTA complexes[2]. They are also shown in Fig. 2, which are in good agreement with the present ones. This fact supports the validity of the method for the determination of the rate constants proposed in this series of papers.

From Eq. 10, it is predicted that the reaction rate decreases with the increase of acetate concentration. Using Eq. 12, the values of $k^+/[ZnY^{2-}]_0$ were calculated at various acetate concentrations with the rate constants given in Table I and

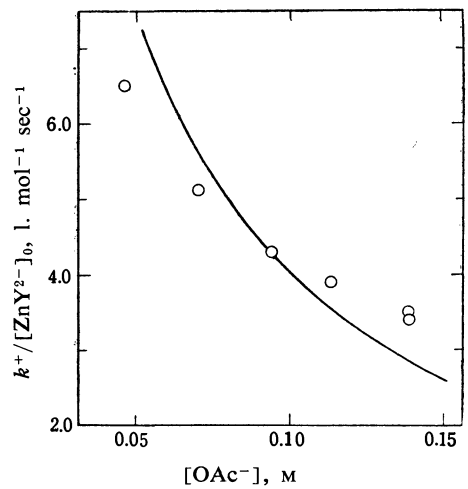

Fig. 3. $k^+/[ZnY^{2-}]_0$ as a function of the acetate concentration in acetate buffer-potassium nitrate solutions of pH 4.70 and ionic strength 0.2 at 15°C. Initial concentrations are:
$[Cu^{2+}]_{0,app} = 1.20\times10^{-4}$ M;
$[ZnY^{2-}]_0 = 4.03\times10^{-3}$ M;
$[Zn^{2+}]_{0,app} = 1.12\times10^{-2}$ M
—— indicates the theoretical curve and ○, the experimental value.

Table IV. Rate constants, heats of activation and entropies of activation for reactions 7, 8b and 9b

| Reaction | Rate constant, expressed in l. mol$^{-1}$ sec$^{-1}$ | $\Delta H^{\ddagger}$, kcal. mol$^{-1}$ | $\Delta S^{\ddagger}$, e. u. |
|---|---|---|---|
| $Cu^{2+} + ZnY^{2-} \rightarrow CuY^{2-} + Zn^{2+}$ | $k_1^+ = 1.5\times10^{11}\exp(-13{,}000/\boldsymbol{R}T)$ | 12 | − 9.3 |
| $Cu^{2+} + ZnHY^- \rightarrow CuHY^- + Zn^{2+}$ | $k_{II}^+ = 6.3\times10^5\exp(-5{,}300/\boldsymbol{R}T)$ | 4.7 | −34 |
| $Cu^{2+} + HY^{3-} \rightarrow CuY^{2-} + H^+$ | $k_{III}^+ = 3.4\times10^{15}\exp(-8{,}200/\boldsymbol{R}T)$ | 7.6 | 11 |

the formation constants of the acetato complexes. In Fig. 3, they are plotted against acetate concentration and compared with the values which were experimentally measured at various acetate concentrations, the other conditions being kept constant. The deviation of the experimental values from the calculated ones is considered as probably due to a contribution of the reactions in which acetatocopper(II) complexes participate.

## Summary

The kinetic study of the substitution reaction of copper(II) and zinc-EDTA complexes in acetate buffer solutions was carried out with the same procedure as reported previously[1,2]. The reaction was found to proceed simultaneously through three different reaction paths under the experimental conditions. The rate constants for three elementary reactions of those reaction paths were determined at 15 and 0°C, and the heats of activation and the entropies of activation for the reactions were calculated.

The author wishes to express her hearty thanks to Professor Nobuyuki Tanaka for his guidance and encouragement in the course of this work.

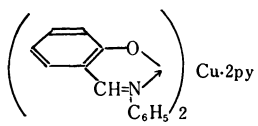
# *The Addition Compounds of Bis-salicylaldehyde Copper(II) and its Derivatives with Pyridine and α, α'-Dipyridyl. II. Some Studies on the Structures*



By Yoneichiro MUTO

(Received September 28, 1959)

There are studies by several investigators reporting that copper(II) can form a complex with coordination numbers higher than four[1]. In the first paper[2] of this series, the author has reported the isolation of the addition compounds of bis-salicylaldehyde copper(II) and a number of its derivatives with pyridine or α, α'-dipyridyl having Formula I.

I

II

(X: H, $NO_2$; Y: H, Br, $NO_2$; py: Pyridine; dip: α, α'-Dipyridyl).

Although a hexa-coordinated octahedral configuration has been considered for bis-pyridine-bis-salicylaldehyde nickel by magnetochemical study[3], it is not definitely confirmed whether or not the copper atoms of these addition compounds are coordinated with six donors as yet. This paper presents some studies undertaken in order to investigate the structures of these addition compounds.

**Spectrophotometric Studies.**—Recently, Waters and Hall[4] have suggested that bis-salicylaldehyde copper(II) is solvated in coordinating solvents such as pyridine to give a penta- or hexa-coordinated copper(II) complex from the spectral change in various solvents. On the other hand, Charles[5] has shown that the spectra of some bis-*N*-*n*-alkylsalicylaldimine copper(II) in pyridine are similar to those in dioxane or toluene, although this is not the case with the corresponding nickel complexes. Therefore, he has concluded that no specific interaction (to form hexa-coordinated complexes) is present between the complexes and pyridine. However, the present author has observed that brown

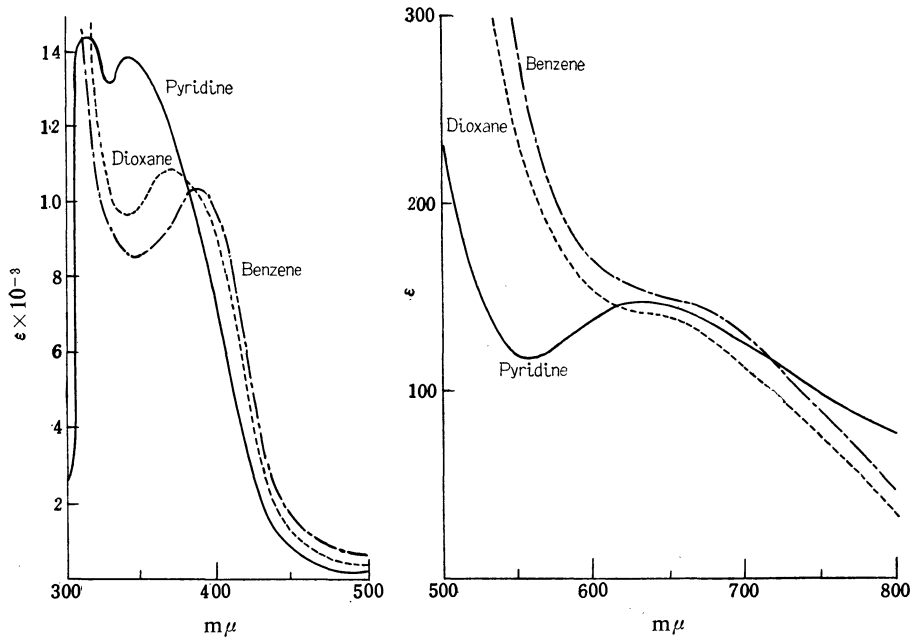
5) R. G. Charles, *J. Am. Chem. Soc.*, 81, 1793 (1959).



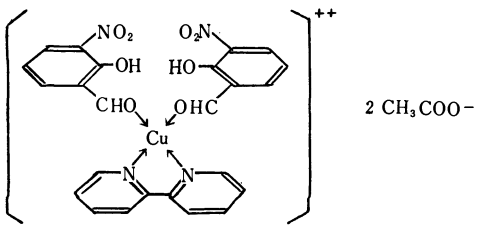


Fig. 1. Absorption spectra of bis-*N*-phenylsalicylaldimine copper(II).

bis-*N*-phenylsalicylaldimine copper(II) forms green crystals of a pyridinate having Formula II[2] and that its spectrum in pyridine is dissimilar to that in dioxane or benzene (Fig. 1). These facts confirm the formation of a hexa-coordination of the copper atom.

In addition, the author has observed that the absorption bands of bis-salicylaldehyde copper (II), a number of its derivatives, and bis-acetylacetone copper(II) in pyridine appear at longer wavelengths than those in dioxane (Figs. 2 and 3 and Table I). Probably, this indicates that the bands shift toward the longer wavelength side, owing to the formation of the hexa-coordinated copper(II) complexes in pyridine*.

**Some Behaviors of the Addition Compounds.** —Assuming that the addition compounds prepared in this study are hexa-coordinated copper-(II) complexes, the bond between the fifth or sixth donor and the copper atom should be weak relatively, as has been guessed from the fact that the usual coordination number of copper(II) is four. Actually, some of the pyridinates readily liberate pyridine. For example, bis-pyridine-bis-salicylaldehyde copper (II) lost pyridine gradually at room temperature. Also, the addition compounds with $\alpha, \alpha'$-dipyridyl were oxidized on heating in organic solvents such as ethanol to yield the derivatives of copper(II) monosalicylate[2], although $\alpha, \alpha'$-dipyridyl could be liberated from them with difficulty. This fact shows that probably the CHO → Cu bond is weak as compared with the N → Cu bond (in which N is a nitrogen atom of $\alpha, \alpha'$-dipyridyl). Namely, the CHO → Cu bond would be broken on heating in organic solvents, and then the aldehyde group would be oxidized, as benzaldehyde readily undergoes oxidation to benzoic acid in the presence of air.

**Addition Compounds of $\alpha, \alpha'$-Dipyridyl-bis-3-nitrosalicylaldehyde Copper(II).** — Among the addition compounds prepared in this study, only $\alpha, \alpha'$-dipyridyl-bis-3-nitrosalicylaldehyde copper(II) formed further addition compounds with chloroform, picric acid and acetic acid. Although no direct evidence has yet been afforded to elucidate the structures of these

III

* It has been noticed by several investigators[6-8] that the absorption bands (from the near infrared to the near ultraviolet) of copper(II) complexes generally appear at longer wavelengths for hexa-coordinated complexes than for tetra-coordinated ones.

addition compounds by physical methods such as X-ray analysis, Formula III has been presumed for the acetate for the following reasons. First, it was observed that $\alpha,\alpha'$-dipyridyl-bis-3-nitrosalicylaldehyde copper(II) could not be oxidized by heating in organic solvents and that $\alpha,\alpha'$-dipyridyl and 3-nitrosalicylaldehyde could be liberated from this complex with difficulty by the action of acetic acid, although other addition compounds with $\alpha,\alpha'$-dipyridyl were decomposed to give $\alpha,\alpha'$-dipyridyl-copper(II)-acetate. From these results, it seems that CHO → Cu and N → Cu bonds are relatively strong. Secondly, it seems that the bond between copper and phenolic oxygen in $\alpha,\alpha'$-dipyridyl-bis-3-nitrosalicylaldehyde copper(II) has an ionic character to a considerable extent owing to the presence of a nitro and an aldehyde group at the ortho positions. Also, it has been observed that relatively strong acids such as picric acid or acetic acid add to the complex, while very weak acids such as phenol or cresol do not do so**. Therefore, it is possible that the complex forms a salt as shown in III.

TABLE I. ABSORPTION MAXIMA OF BIS-SALICYLALDEHYDE COPPER(II) DERIVATIVES IN THE VISIBLE REGION

| Substituent | Solvents: Dioxane | Pyridine | (Addition compounds with $\alpha,\alpha'$-dipyridyl) Pyridine |
|---|---|---|---|
| 5-Methyl | 675 (1.71) | 750 (2.04) | |
| None | 670 (1.70) | 740 (2.02) | 700 (1.97) |
| 5-Chloro | 621 (1.62) | 759 (1.95) | |
| 5-Bromo | 655 (1.93) | 756 (2.27) | |
| 3-Nitro-5-methyl | 638 (1.65) | 760 (1.92) | 720 (1.97) |
| 3-Nitro | 670 (1.60) | 710 (1.81) | 704 (1.84) |
| 5-Nitro | 619 ( ? ) | 660 (2.45) | 636 (2.40) |
| 3,5-Dinitro | 645 ( ? ) | 675 (2.37) | |
| Salicylaldehyde-ethylenedimine | 576 (2.55) | 602 (2.53) | |
| Bis-acetylacetone | 612 (1.57) | 654 (1.88) | |

The values in parentheses are the logarithms of molar extinction coefficients ($\log \varepsilon$) at the maxima. The value marked with a question mark could not be determined accurately owing to the slight solubility of the complex in dioxane.

## Experimental

**Spectrophotometric Measurements.**—Bis-salicylaldehyde copper(II), its derivatives and bis-acetylacetone copper(II) were prepared by conventional methods. The addition compounds with $\alpha,\alpha'$-dipyridyl were prepared by the method described in the first paper[2] of this study. Although bis-*N*-phenylsalicylaldimine copper(II) was very soluble in various organic solvents, other complexes were soluble in pyridine, slightly soluble in dioxane, and soluble with difficulty in other common organic solvents.

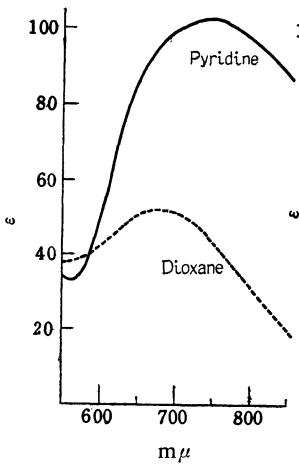

Fig. 2. Absorption spectra of bis-salicylaldehyde copper(II).

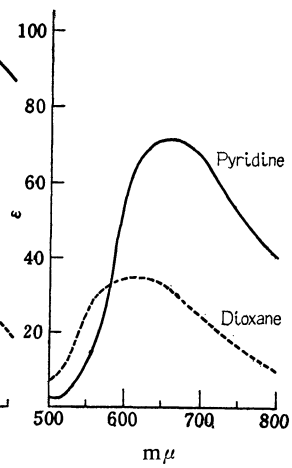

Fig. 3. Absorption spectra of bis-acetylacetone copper(II).

The absorption spectra were determined at 25 ±1°C with a Hitachi spectrophotometer (model EPU-2A) using 1 cm. quartz cells. The concentration of the complexes in solutions ranged from $5\times10^{-5}$ to $3\times10^{-3}$ mol. per liter depending upon the degree of absorption.

*Preparation of additon compounds of $\alpha,\alpha'$-dipyridyl-bis-3-nitrosalicylaldehyde copper(II) with chloroform, picric acid, and acetic acid.*—1) Cu·[O·$C_6H_3(NO_2)$·CHO]$_2$·dip·$CHCl_3$.—$\alpha,\alpha'$-Dipyridyl-bis-3-nitrosalicylaldehyde copper(II) (yellow-brown crystals) (0.6 g.) was dissolved in chloroform (30 ml.) and the resulting brown solution was filtered. The filtrate was allowed to stand overnight in air at room temperature; meanwhile the addition compound crystallized in green prismatic crystals. It was purified by repeated recrystallization from chloroform.

Found: C, 44.67; H, 2.85; N, 8.17; Cu, 8.59; $CHCl_3$, 17.82. Calcd. for $C_{14}H_8O_8N_2$·Cu·$C_{10}H_8N_2$·$CHCl_3$: C, 44.73; H, 2.55; N, 8.35; Cu, 8.56; $CHCl_3$, 17.78%.

Both $\alpha,\alpha'$-dipyridyl-bis-3-nitrosalicylaldehyde cobalt(II) and the corresponding nickel complex prepared by a method of synthesis similar to that employed for the copper(II) complex formed no addition compound with chloroform.

The cobalt complex was isolated in the form of red crystals.

Found: N, 10.16; Co, 10.82. Calcd. for $C_{14}H_8O_8N_2$·Co·$C_{10}H_8N_2$; N, 10.24; Co, 10.77%.

The nickel complex was isolated in the form of orange crystals.

Found: N, 10.29; Ni, 10.56. Calcd. for $C_{14}H_8O_8N_2$·Ni·$C_{10}H_8N_2$; N, 10.24; Ni, 10.73%.

** Although it has been observed that *p*-nitrophenol add to the complex, the addition compound can not be isolated in the pure state.

2) Cu · [O · $C_6H_3(NO_2)$ · CHO]$_2$ · dip · HO · $C_6H_2(NO_2)_3$. —$\alpha,\alpha'$-Dipyridyl-bis-3-nitrosalicylaldehyde copper(II) (0.3 g.) was added to 50 ml. of ether containing 0.2 g. of picric acid. The mixture was refluxed on a water bath for half an hour, meanwhile the addition compound crystallized in green prismatic crystals. The separated crystals were washed with ether repeatedly and then dried in a desiccator over sulfuric acid.

Found: C, 46.40; H, 2.71; N, 12.47; Cu, 8.16. Calcd. for $C_{14}H_8O_8N_2 \cdot Cu \cdot C_{10}H_8N_2 \cdot C_6H_3O_7N_3$; C, 46.13; N, 12.55; Cu, 8.15%.

3) Cu · [O · $C_6H_3(NO_2)$ · CHO]$_2$ · dip · $(CH_3COOH)_2$. —$\alpha,\alpha'$-Dipyridyl-bis-3-nitrosalicylaldehyde copper-(II) (0.6 g.) was dissolved in a mixture of ether (20 ml.) and acetic acid (3 ml.) and the resulting solution was filtered. When 30 ml. of ether was added to the filtrate, the addition compound precipitated in green prismatic crystals. The crystals were separated, washed with ether repeatedly, and then dried in a vacuum desiccator over sulfuric acid.

Found: C, 49.76; H, 3.89; N, 8.23; Cu, 9.26; $CH_3COOH$, 17.73. Calcd. for $C_{14}H_8O_8N_2 \cdot Cu \cdot C_{10}H_8N_2 \cdot C_4H_8O_4$: C, 50.04; H, 3.60; N, 8.34; Cu, 9.45; $CH_3COOH$, 17.87%.

The author is grateful to Mr. Michio Shido of Kyushu University for carrying out the elementary analysis of the compounds prepared.

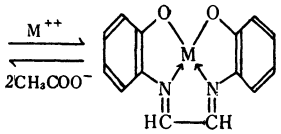
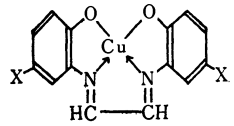
# *On the Structure of Condensation Products of o-Aminophenols with α-Dicarbonyl Compounds. III. Copper Chelates of 2, 2'-Bibenzoxazoline Derivatives*



By Ichiro MURASE

(Received October 12, 1959)

In previous papers[1,2], the condensation products of *o*-aminophenols (2 mol.) with *α*-dicarbonyl compounds (1 mol.) were determined to have the structure of 2, 2'-bibenzoxazolines (I). In addition, 2, 2'-bibenzoxazoline tautomerized to the corresponding Schiff base (II) in ethanol solution on addition of alkali, the formation of its metal chelates being explained by the scheme indicated below. The structure of metal chelates was thus in agreement with the one stated by Bayer[3] as the derivatives of glyoxal bis-(2-hydroxy anil) (III).



I II

III

Here, the reaction of copper acetate with 2, 2'-bibenzoxazoline derivatives was conducted, obtaining copper chelates of 5, 5'-dinitro (IV), 5, 5'-dimethyl (V) and 5, 5'-dichloro (VI) derivative as deep violet or blue amorphous powder.

IV, X=$NO_2$ V, X=$CH_3$ VI, X=Cl

The absorption spectra in ethanol of these compounds were taken by the method indicated in the experimental part and they are shown in Fig. 1, where $\varepsilon$ of each copper chelate was expediently calculated by means of concentrations of bibenzoxazolines dissolved.

Each spectrum did not represent the true feature of the copper chelate itself since the solution consisted of equilibrium mixture of bibenzoxazoline and copper chelate as suggested from the above scheme. However, the band at

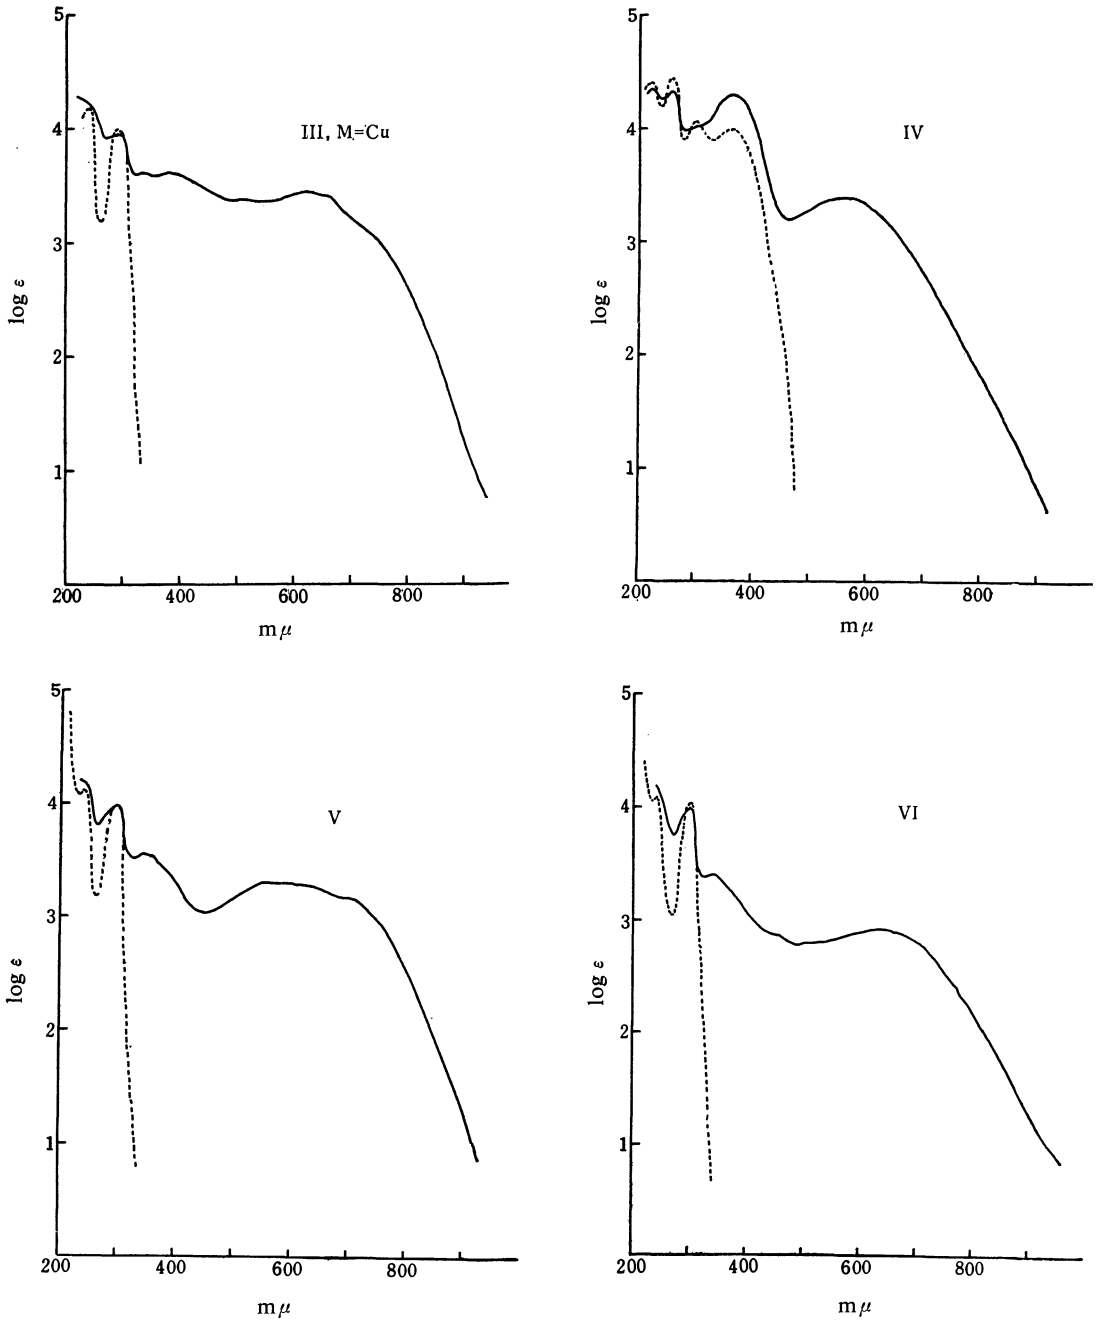

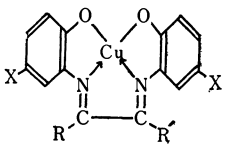

Fig. 1. Ultraviolet and visible absorption spectra of copper chelates of 2,2′-bibenzoxazoline and its derivatives in ethanol, ——; copper chelate, ------; parent bibenzoxazoline or its derivative.

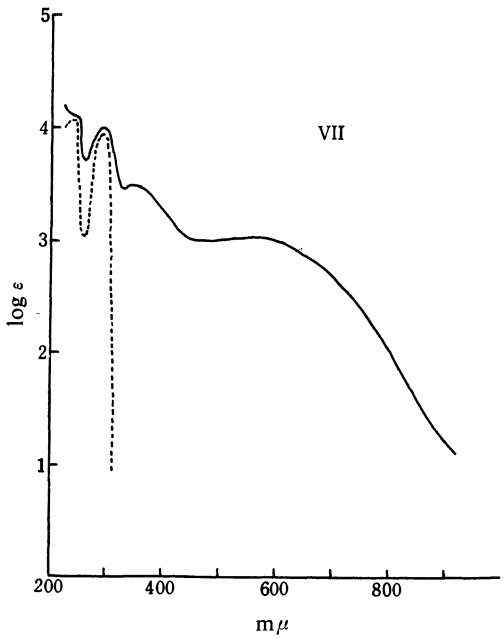
500~600 mμ in each spectrum should be due to metal-ligand linkage and it resembles the authentic one of glyoxal bis-(2-hydroxy anil)-copper (Fig. 1, III, M=Cu), the solution of which was prepared also in the same manner as other chelates. Therefore, it has been assumed from those spectra that these copper chelates have structures IV—VI.

In the case of 2-substituted and 2,2′-disubstituted derivatives of 2,2′-bibenzoxazoline such as 2-methyl-, 5,5′-dinitro-2-methyl-, 2-methyl-2′-ethyl-2,2′-diethyl- and 2-methyl-2′-phenyl-bibenzoxazoline, with the exception of 2,2′-dimethyl derivative, deep violet or blue colored solutions

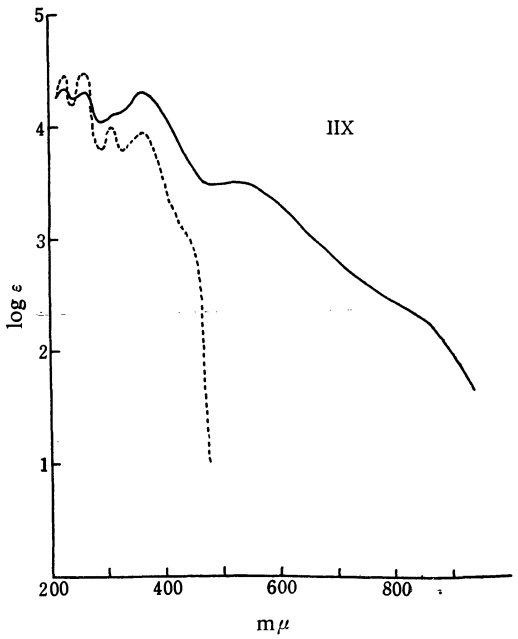
were obtained by addition of copper acetate to their ethanol solutions. On concentration of these colored solutions, no copper chelates were isolated, instead the oxazolines were recovered unchanged. However, the presence of the chelates in solution was suggested by their coloration and was revealed by their absorption spectra which are shown in Fig. 2, where $\varepsilon$ of each copper chelate was calculated in the same manner as in Fig. 1.

These spectra resemble those in Fig. 1 in having absorption bands at 500~600 m$\mu$, though their absorption intensities varied with substituents in 2, 2′-positions. Thus, the presence of copper chelates in solution of similar structures VII—XII has been recognized.

VII, R=$CH_3$, R′=X=H
IIX, R=$CH_3$ R′=H, X=$NO_2$
IX, R=R′=$CH_3$, X=H
X, R=$CH_3$, R′=$C_2H_5$, X=H
XI, R=R′=$C_2H_5$, X=H
XII, R=$CH_3$, R′=$C_6H_5$, X=H



The reason why these copper chelates could not be isolated may be that their formation constant is considerably small. Since the formation constant in each case should be introduced from overall equilibrium consisting of oxazoline, Schiff base and chelate, the proportion of the tautomeric form of oxazoline in the mixture should be considered to be very small.



With respect to the condensation product of *o*-aminophenol with diacetyl, Bayer explained its inability to form metal chelate as the result of the hindrance of methyl groups in diacetyl bis-(2-hydroxy anil), but the author previously suggested, from the spectroscopic behavior toward alkali, that 2, 2′-dimethyl-2, 2′-bibenzoxazoline does not tautomerize to diacetyl bis-(2-hydroxy anil) and forms no metal chelates[1].

Apparently no deep coloration was observed when copper acetate was added to this compound in ethanol. Nevertheless, in this case also, the presence of the chelate in solution was suggested from the careful observation of its spectrum (Fig. 2, IX); an absorption maximum was observed at 560 m$\mu$ though in very weak intensity. Thus, it was found that 2, 2′-dimethyl-2, 2′-bibenzoxazoline still possesses a tendency of tautomerism and of formation of copper chelate in solution.

Thus, it is concluded that 2, 2′-bibenzoxazolines acquire an ability of metal chelate formation through tautomerism, which is most remarkable in the case of 2, 2′-unsubstituted derivatives and is hindered by substituents at 2, 2′-position, among which the methyl group is most effective and the phenyl group is not so much.

In the case of carboxy derivatives of bibenzoxazoline, it is interesting to note that 5, 5′-dicarboxy derivative gave reddish violet precipitates on reacting with an equimolar amount

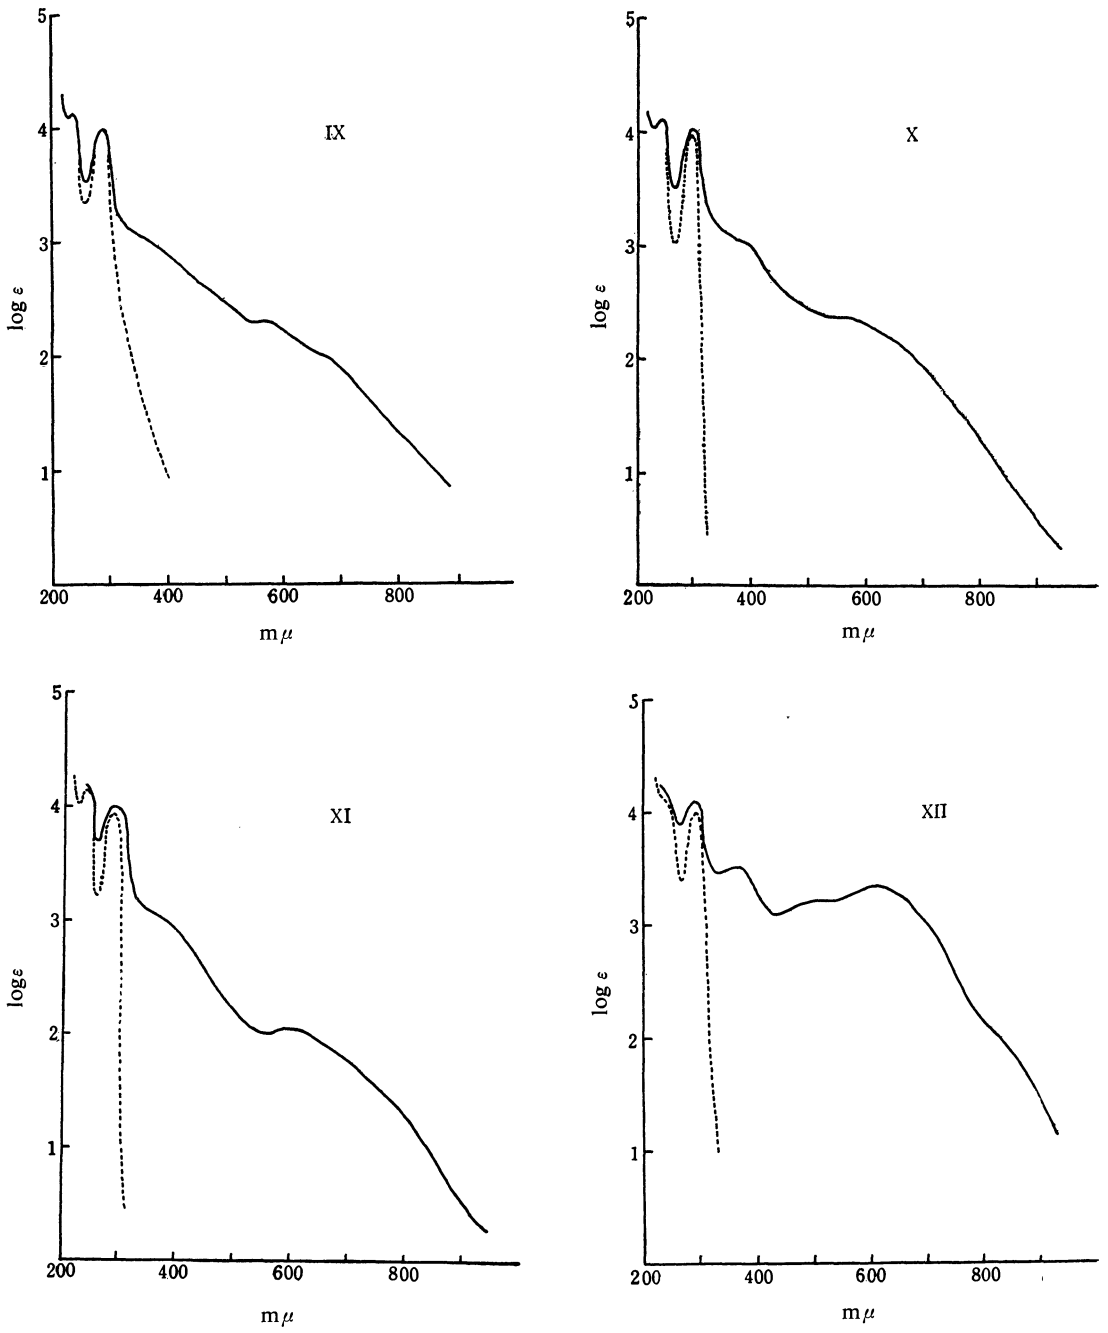


Fig. 2. Ultraviolet and visible absorption spectra of copper chelates of 2, 2'-bibenzoxazoline derivatives in ethanol, ——; copper chelate, ------; parent bibenzoxazoline derivative.

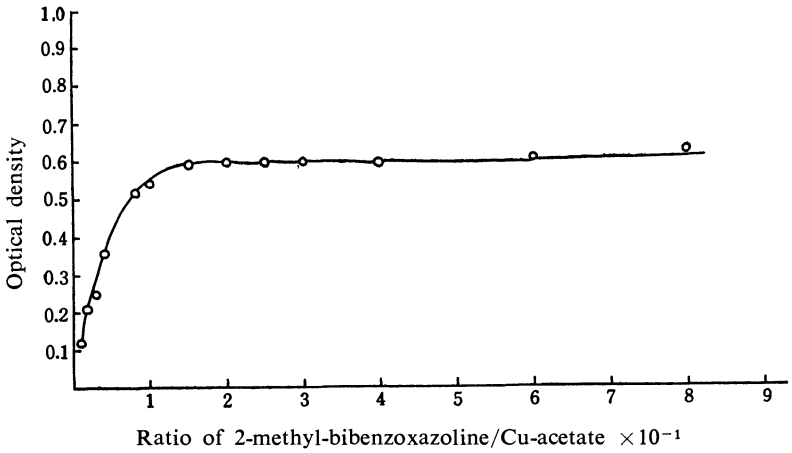

Fig. 3. Optical densities at 540 mμ of various solutions with excess 2-methyl-bibenzoxazoline present: Cu-acetate = $9.99 \times 10^{-5}$ M.

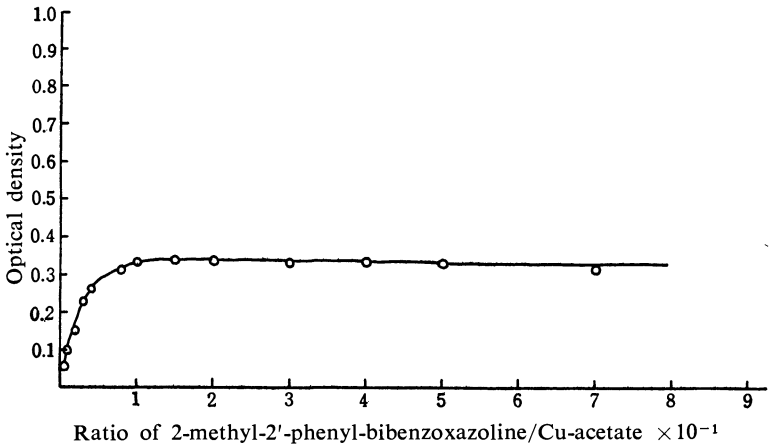

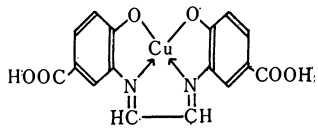

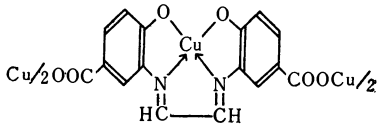

Fig. 4. Optical densities at 600 mμ of various solutions with excess 2-methyl-2'-phenyl-bibenzoxazoline present: Cu-acetate = $4.99 \times 10^{-5}$ M.

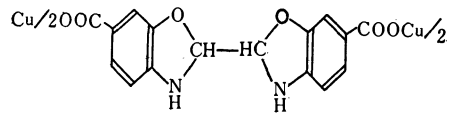
of copper acetate. Since a part of the precipitates was soluble in sodium hydrogen carbonate solution with a blue-violet coloration, the precipitates should contain copper chelate of structure XIII* in which the carboxyl groups are free and the copper atom is coordinated with the Schiff base ligand in the same manner as the other chelates. When this dicarboxy derivative reacted with bimolar amounts of copper acetate, blue-violet precipitates were obtained. This substance was insoluble in sodium hydrogen carbonate solution and consisted of two copper atoms to one molecule of ligand. The structure should be given as XIV in which one copper atom chelates and the other combines as carboxylate.

XIII



XIV

* The precipitates were treated with sodium hydrogen carbonate solution and the soluble part was reprecipitated by neutralization with acetic acid. The substance obtained did not show reasonable analytical results, possibly due to partial decomposition by this treatment.

Found: C, 44.26; H, 3.48; N, 7.04; Cu, 16.07. Calcd. for $C_{16}H_{10}N_2O_6 \cdot 2H_2O$: C, 45.13; H, 3.31; N, 6.58; Cu, 15.39%.

On the other hand, 6, 6′-dicarboxy derivative gave green precipitates with copper acetate. The substance may have the structure of simple salt of bibenzoxazoline carboxylic acid (XV), because they were insoluble in sodium hydrogen carbonate solution and consisted of one copper atom to one oxazoline molecule. The structure may further be supported by its green color which is seen in ordinary copper carboxylates. It seems that the carboxyl groups at 6, 6′-positions prevent the ring opening of oxazoline to form the Schiff base.

XV

For the determination of metal-ligand proportion in metal chelate in solution, the molar ratio method is known[4]; it consists of the measurement of optical density at a typical wavelength at which an absorption is caused by metal chelate formation, the molar ratio of the ligand being varied to a constant metal ion concentration. If a formation constant of metal chelate is appreciably large, the optical density should reach a constant value at which the metal-ligand proportion is equivalent.

In the case of the above copper chelates, in which the metal-ligand ratio is naturally 1 : 1, the optical densities should be expected to give constant values over the range of more than this ratio.

The experiment was carried out on 2-methyl-bibenzoxazoline and 2-methyl-2′-phenyl-bibenzoxazoline**. The results are shown in Figs. 3 and 4, but they fell short of expectations.

The optical density of each solution gave almost constant value for ratios greater than 20. Since such poly-coordinate chelate is considered to be impossible, these curves should mean that stability constants of these copper chelates are small. Here again, it proved that the equilibrium between bibenzoxazoline and the Schiff base exists in favor of the former.

## Experimental

**Copper Chelate of 5, 5′-Dimethyl-2, 2′-bibenzoxazoline.**—To a solution of 5, 5′-dimethyl-2, 2′-bibenzoxazoline (0.2 g.) in hot methanol (50 ml.), a solution of copper acetate (0.15 g.) in methanol (20 ml.) was added and the mixture was heated on a water bath for 30 min. The resulting deep violet-blue precipitates were centrifuged and washed with methanol and dried over phosphorus pentoxide in vacuo at 110°C.

Found: C, 55.43; H, 4.48; N, 7.98; Cu, 18.61. Calcd. for $C_{16}H_{14}N_2O_2Cu \cdot H_2O$: C, 55.24; H, 4.60; N, 8.04; Cu, 18.26%.

**Copper Chelate of 5, 5′-Dichloro-2, 2′-bibenzoxazoline.**—Prepared from 5, 5′-dichloro-bibenzoxazoline (0.2 g.) and copper acetate (0.13 g.) in the same manner as described in the case of the dimethyl derivative. Deep blue amorphous powder.

Found: C, 43.07; H, 2.71; N, 7.43; Cu, 15.96. Calcd. for $C_{14}H_8N_2O_2Cl_2Cu \cdot H_2O$: C, 43.26; H, 2.57; N, 7.20; Cu, 16.34%.

**Copper Chelate of 5, 5′-Dinitro-2, 2′-bibenzoxazoline.**—Prepared from 5, 5′-dinitro-bibenzoxazoline (0.5 g.) and copper acetate (0.4 g.) in the same manner as described in the case of the dimethyl derivative. Deep reddish violet crystalline powder.

Found: C, 41.12; H, 2.53; N, 13.55; Cu, 15.55. Calcd. for $C_{14}H_8N_4O_6Cu \cdot H_2O$: C, 40.97; H, 2.43; N, 13.65; Cu, 15.51%.

**Copper Chelate of Copper-2, 2′-bibenzoxazoline-5, 5′-dicarboxylate.**—To a solution of 5, 5′-dicarboxy-2, 2′-bibenzoxazoline (0.5 g.) in hot methanol (300 ml.), copper acetate (0.8 g.) in methanol (50 ml.) was added and the mixture was heated on a water bath for 1 hr. After cooling, resulting precipitates were filtered and washed with methanol and dried over phosphorus pentoxide in vacuo at 110°C. Deep blue-violet crystalline powder.

Found: C, 36.84; H, 3.00; N, 5.06; Cu, 24.91. Calcd. for $C_{16}H_8N_2O_6Cu_2 \cdot 4H_2O$: C, 36.71; H, 3.08; N, 5.35; Cu, 24.28%.

**Copper-2, 2′-bibenzoxazoline-6, 6′-dicarboxylate.**—To a suspension of 6, 6′-dicarboxy-2, 2′-bibenzoxazoline (0.2 g.) in ethanol (100 ml.), a solution of copper acetate (0.12 g.) in ethanol and 2 drops of acetic acid were added and the mixture was heated on a water bath for 4 hr. The crystals were gradually diminished and green precipitates were formed. After standing over-night, they were filtered and washed with ethanol and dried over phosphorus pentoxide in vacuo at 60°C.

Found: C, 45.62; H, 3.49; N, 6.21; Cu, 14.96. Calcd. for $C_{16}H_{10}N_2O_6Cu \cdot 2H_2O$: C, 45.13; H, 3.31; N, 6.58; Cu, 15.39%.

**Absorption Spectra.**—The copper chelates III~VI, when once precipitated, were very difficult to dissolve in ethanol. To obtain the ultraviolet and visible absorption spectra in ethanol of these compounds, a method was devised in the preparation of the solution. To ethanol solutions of bibenzoxazolines (ca. 1/5000~1/10000 M), equimolar amounts of copper acetate in ethanol were added and the solutions were heated at 70°C for ten minutes and cooled to room temperature. The coloration of each solution reached almost a maximum by this treatment and further heating resulted in decolorization by decomposition, thus clear colored solutions containing copper chelates being obtained.

4) S. Miyakawa and T. Uemura, This Bulletin, 24, 25 (1951); R. P. Yaffe and A. F. Voigt, *J. Am. Chem. Soc.*, 74, 2503 (1952).

** Since their own spectra have no absorption at a visible region (refer to Fig. 2, VII and XII), the optical densities could be observed without any correction. For the measurements, the solution were prepared in the same manner as the case of the measurement of their spectra and the concentration of coppr acetate was used in place of the copper ion concentration to avoid the ambiguity of the latter in ethanol.

In the case of VII—XII, the solutions were prepared also in the same manner as indicated above. The measurement of absorption spectra and optical densities in the molar ratio method were carried out using a Hitachi EPU-2A spectrophotometer with a 10 mm. quartz cell.

The author wishes to express his thanks to Professor Tokuichi Tsumaki and Professor Takeichi Nishikawa for their exceedingly kind directions of this work. The author also thanks Mr. Michio Shido and Miss Sachiko Indo for the microanalysis.

The cost of this research was defrayed by the Scientific Research Encouragement Grant from the Ministry of Education, to which the author's thanks are due.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. X. Benzaldehyde, Acetophenone and Related Compounds*

By Hiroshi SUZUKI

(Received October 30, 1959)

## Benzaldehyde and Acetophenone

In the near ultraviolet absorption spectrum of benzaldehyde as well as that of acetophenone four band systems appear. The weakest band, which appears at about 320 m$\mu$ with the molecular extinction coefficient of the order of ten, is regarded as an $n \rightarrow \pi^*$ transition in the carbonyl group (R-band). The weak band with fine structure, which appears in the range between 270 and 290 m$\mu$ with the molecular extinction coefficient of about 1000~2000, is considered to correspond to the $A_{1g} \rightarrow B_{2u}$ transition in benzene, and therefore, to the "hidden transition" at about 275 m$\mu$ in biphenyl[1] (B-band, or Benzenoid band). The band at about 200 m$\mu$ is considered to correspond to the $A_{1g} \rightarrow B_{1u}$ transition in benzene. The strongest band at near 240 m$\mu$, whose molecular extinction coefficient is about 15000, has been interpreted by Tanaka, Nagakura, and Kobayashi[2] as the "intramolecular charge-transfer absorption", which may be considered as the conjugation band (K-band). (The notation of the bands shown in parentheses is according to Gillam and Stern[3]). The present study is mainly concerned with the last "conjugation band".

O'Shaughnessy and Rodebush[4] found formerly that the introduction of two methyl groups into the ortho positions of acetophenone exerts a marked influence on the absorption spectrum, a fact which was explained in terms of the steric effect. Braude and his coworkers[5-8] have stated, on the basis of their classification of steric effects in ultraviolet absorption spectra, that *o*-methylated acetophenones and benzaldehydes show the steric effects of type 1, i. e. the steric effects which give rise to decreases in absorption intensity alone without causing any wavelength displacement of the bands. According to them, the steric effect of this type occurs when steric interaction is relatively weak, i. e. when the steric repulsion energy for the planar conformation is less than 3 kcal./mol., and is produced by "transitions between nonplanar ground states and uniplanar (or near-planar) excited states".

On the basis of the above mentioned view, they have applied their postulated relation between the intensity of the conjugation band and the angle of twist of the "single" bond to

8) E. A. Braude, "Determination of Organic Structures by Physical Methods", (edited by E. A. Braude and F. C. Nachod), Academic Press, Inc., Publishers, New York (1955), p. 172 ff.

*o*-substituted benzaldehydes and acetophenones, and found that in the aldehydes the calculated angle of twist $\theta$ (i.e. the interplanar angle between the benzene ring and the carbonyl group) is about 20° in the presence of either the one or the two *o*-methyl groups, and that in the ketones the calculated interplanar angle is about 35° in the presence of the one, and about 60° in the presence of the two, *o*-methyl groups. In the calculations, they have taken the parent compounds, benzaldehyde and acetophenone, as the planar reference compounds for the corresponding derivatives. That is, they have assumed that there is no significant steric hindrance to the coplanarity of the molecular configuration with acetophenone as well as benzaldehyde. This assumption would be considered to be supported by the fact that, according to Braude and others, both the compounds exhibit their conjugation bands at almost the same wavelength (242 m$\mu$, in hexane).

On the other hand, as will be shown in the succeeding part of this series, $\alpha$-methylstyrene exhibits the conjugation band at an appreciably shorter wavelength than its parent compound, styrene. That is, it may be said that the $\alpha$-methyl group in this system exerts the "steric effect of type 2" defined by Braude and others, i.e. the steric effect which causes not only a decrease in the intensity of the conjugation band but also a hypsochromic wavelength displacement of the band. Thus, the most probable configuration of $\alpha$-methylstyrene is inferred to be nonplanar. While the geometry of the relevant part of benzaldehyde is considered to be similar to that of styrene, that of acetophenone is considered to be similar to that of $\alpha$-methylstyrene. Accordingly, it is expected that the steric effects in acetophenone and in $\alpha$-methylstyrene are likely to be very similar. That is, it is presumed, contrary to the opinion of Braude and others, that there should be appreciable steric interaction between the methyl group and the phenyl group in the planar conformation of acetophenone, and that, consequently, the most probable configuration of the molecule is not planar. According to Auwers and Eisenlohr[9], the value of the exaltation of molecular refraction, $EM_D$, for acetophenone (+0.52) is considerably smaller than the value for benzaldehyde (+0.80). This fact may be considered to indicate that acetophenone is less conjugated than benzaldehyde, and therefore, to support the above mentioned view.

It may be somewhat doubtful whether a deviation from the coplanar configuration results in a hypsochromic displacement of the "conjugation band" also in the present conjugated system, because the system containing a hetero-atom O is not quite analogous to the hydrocarbon conjugated systems (termed "normal") treated in the preceding parts of this series. Therefore, it seems to be necessary to make some comment on this point.

According to Nagakura and Tanaka[10], in the conjugated system $C_6H_5$–C=O the interaction between the lowest vacant orbtial of the carbonyl group ($V_S$) and the highest occupied orbital of benzene ($H_B$) is predominant, and to a first approximation the intense absorption bands in the wavelength region 230~260 m$\mu$ are regarded as due to the transition between the two new orbitals $W_n$ and $W_e$ which occur by the interaction between $V_S$ and $H_B$. The new highest occupied orbital $W_n$ is lower than $H_B$, and the new lowest vacant orbital $W_e$ is higher than $V_S$. The energy separation between $W_e$ and $W_n$ will become greater when the interaction between $V_S$ and $H_B$ becomes greater. Accordingly, from this theory, it might be expected that a twist of the "single" bond between the phenyl group and the carbonyl group from the coplanar position would cause a bathochromic shift of the absorption band rather than a hypsochromic shift.

This surmise seems, however, to be denied by the fact that the absorption band maxima of 2-methylbenzaldehyde and of 2-methylacetophenone are at considerably shorter wavelengths than the corresponding 4-isomers. Especially, it is notable that the absorption maximum of 2-methylbenzaldehyde is at a shorter wavelength even than that of the 3-isomer. Thus, according to Braude and Sondheimer[6], the wavelengths (in m$\mu$) of the absorption maxima of these compounds are as follows (figures in parentheses represent the molecular extinction coefficients): 4-methylbenzaldehyde, 251(15000) and 257 (12500); 3-methylbenzaldehyde, 245(13500) and 251(12000); 2-methylbenzaldehyde, 243(12500) and 251(13000); 4-methylacetophenone, 252 (15100); 2-methylacetophenone, 242(8700) and 245(8300). Since the electronic effect of an ortho-methyl group may be said to be approximately equivalent to that of a para-methyl group, it may be quite reasonable to consider the hypsochromic displacements observed above as mainly due to the steric effect of the ortho-methyl groups. Accordingly, it may be said that a deviation of the most probable conffiguration from the coplanarity causes a hypsochromic displacement of the "conjugation band" in the case of the conjugated system $C_6H_5$–C=O, just as in the cases of the normal conjugated systems. Therefore, from the foregoing consideration it may be expected that the conjugation band of acetophenone will be at a

| | E | 278 | 1100 | 240 | 13000 | 3 |
| Benzophenone | Hp | [(286)] | 1550 | 248.5 | 19550 | *a* |
| | | [(277)] | 2540 | | | |

Solvent: Hp, *n*-heptane; Hx, hexane; E, ethanol. Wavelengths in parentheses denote inflections, and those in double parentheses denote very indistinct inflections. Ref. *a*, the present work.

shorter wavelength than that of benzaldehyde. In this connection, it may be of some interest that in the case of the conjugated system $C_6H_5$–C=N the "conjugation band" maximum of the acetophenone analogue is at a considerably shorter wavelength than the corresponding one of the benzaldehyde analogue. Thus, according to Braude and Sondheimer[6], the wavelengths of the absorption maxima of the semicarbazones of benzaldehyde and of acetophenone are 281 mμ (22000) and 270 mμ (20400), respectively.

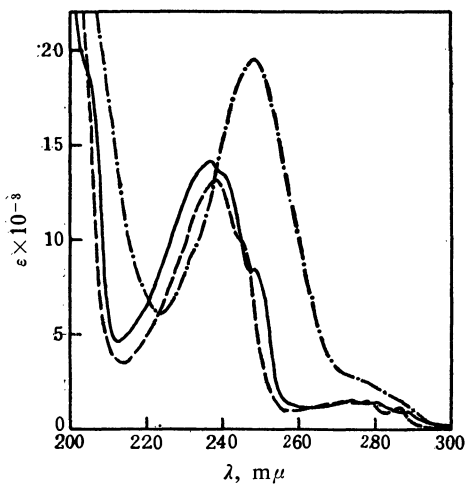

Fig. 1. Ultraviolet absorption spectra (in *n*-heptane): ——, benzaldehyde; ----, acetophenone; -·-·-, benzophenone.

From this point of view, to re-examine the steric effect in acetophenone itself, the ultraviolet absorption spectra of acetophenone and of benzaldehyde in solutions in *n*-heptane have newly been measured. The results are shown in Fig. 1. In Table I, the data of the absorption maxima are summarized together with those found in the literature.

The conjugation bands of these compounds are not structureless, but have, though considerably diffuse, fine structures. The inflection at 245.5 mμ in the spectrum of acetophenone is at a shorter wavelength than the probably corresponding maximum at 248.1 mμ in the spectrum of benzaldehyde, in accordance with the expectation. On the other hand, the maximum at 238.5 mμ in the spectrum of acetophenone appears to correspond to the two bands at 240.5 and 236.9 mμ in the spectrum of benzaldehyde. Therefore, it seems somewhat doubtful which of the two bands of benzaldehyde is to be compared with the band of acetophenone.

### *p*-Biphenylyl and 2-Fluorenyl Carbonyl Compounds

The author prepared *p*-phenylbenzaldehyde and *p*-phenylacetophenone as intermediates in the syntheses of *p*,*p*'-diphenylstilbene and its α,α'-dimethyl derivative, as described in the preceding part[11] of this series. In addition,

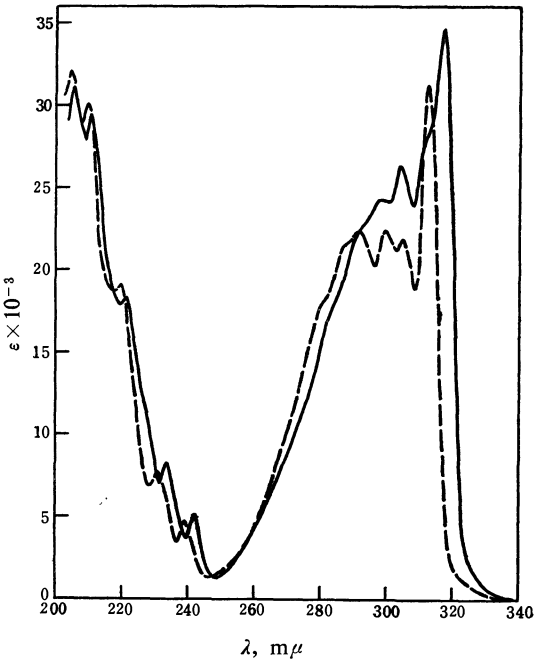

Fig. 3. Ultraviolet absorption spectra (in *n*-heptane): ——, 2-formylfluorene; ----, 2-acetylfluorene.

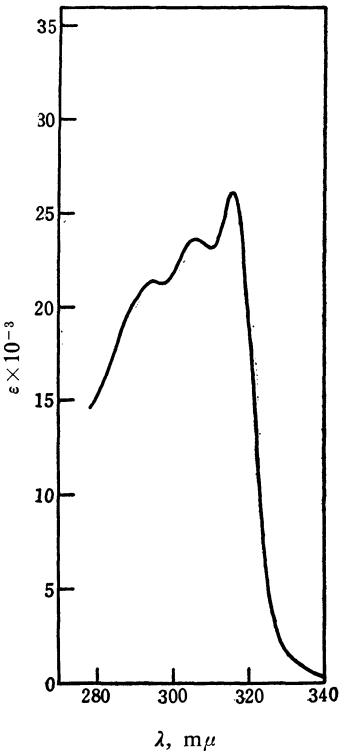

Fig. 4. Ultraviolet absorption spectrum of 2-acetylfluorene in benzene.

2-acetylfluorene and a compound which is considered to be probably 2-formylfluorene were prepared in attempts to prepare 1, 2-di-(2-fluorenyl)-ethylene and its 1, 2-dimethyl derivative. The absorption spectra of these analogues of benzaldehyde and of acetophenone seem to be of interest in connection with the above considerations. The spectra are shown in Figs. 2—4. In Table II, the data of the absorption maxima are summarized.

In the spectra of these compounds, the possible bands corresponding to the bands of benzaldehyde and of acetophenone in the range between 270 and 290 m$\mu$ are completely hidden by the intense conjugation bands. The bands appearing in the range between near 215 m$\mu$ and near 240 m$\mu$ are considered to be probably the ones due to transitions from the highest occupied orbital to the vacant orbitals localized in benzene rings whose energy is $-\beta$, or from the occupied orbitals localized in benzene rings whose energy is $+\beta$ to the lowest vacant orbital, analogously to the bands of stilbene and related compounds appearing in almost the same range[12,13]. It may be noteworthy that the bands at 200~210 m$\mu$ have about double the intensity of the corresponding band of benzaldehyde, in conformity

The notation of the bands is quite analogous to the one in the case of stilbenes in Part V of this series: A-band refers to the conjugation band. Solvent: Hp, *n*-heptane; B, benzene. Wavelengths in parentheses denote inflections, and those in double parentheses denote very indistinct inflections.

with the number of benzene rings in a molecule.

The conjugation band of *p*-phenylacetophenone is at an appreciably shorter wavelength than that of *p*-phenylbenzaldehyde, both the bands being structureless, (cf. Fig. 2). The conjugation bands of the two fluorenyl compounds have fine structures. Also with these compounds, the bands of the acetophenone analogue are at shorter wavelengths than the probably corresponding bands of the benzaldehyde analogue (cf. Fig. 3). These hypsochromic shifts of the conjugation bands observed in the comparison of the acetophenone analogues with the corresponding benzaldehyde analogues are considered to be mainly due to the steric effect of the methyl groups. This means that in these acetophenone analogues there exist steric interactions between the methyl groups and the benzene rings which cause the hypsochromic wavelength displacements of the conjugation bands relative to the conjugation bands of the corresponding benzaldehyde analogues, and that, consequently, the most probable configurations of these acetophenones are nonplanar.

By analogy with these facts, it may be inferred that the most probable configuration of acetophenone itself is nonplanar. Probably, the fact that the introduction of a methyl group at the carbonyl carbon atom of benzaldehyde to give acetophenone does not result in any appreciable hypsochromic wavelength displacement of the conjugation band is merely apparent. Further, this fact should not be considered to indicate the absence of the steric interference in acetophenone or the absence of the hypsochromic shift arising from the steric effect. It seems more reasonable to consider that the hypsochromic shift caused by the steric effect is so small that it is compensated by the electronic bathochromic effect of the methyl group. Accordingly, also the apparent absence of hypsochromic shift in *o*-methylated acetophenones, e. g. 2-methylacetophenone and 2, 4, 6-trimethylacetophenone, as compared with acetophenone should probably be interpreted similarly. From this point of view, not only the application of the hypothesis of Braude and others to the acetophenone derivatives but also their classification of steric effects in ultraviolet absorption spectra or their basic theory itself seems to be criticizable. This subject will be discussed more fully in the succeeding part of this series.

It remains to refer to the spectrum of 2-acetylfluorene in benzene shown in Fig. 4. It is of interest that this spectrum differs considerably from the spectrum in *n*-heptane. Thus, when

the solvent is changed from *n*-heptane to benzene, the first (from longer wavelengths side) maximum of fine structure of the conjugation band is reduced markedly in the intensity, and further, the second and the third maxima appear to merge into a maximum. Also with this compound, analogously to the cases of stilbene and related compounds discussed in earlier parts[11-13] of this series, considerably large red-shifts (about 3 m$\mu$) associated with the change of solvent are observed.

### Benzophenone

Lastly, the spectrum of benzophenone, which is shown in Fig. 1 and in Table I, is briefly discussed. It is evident that the two benzene rings in benzophenone can not be simultaneously coplanar with the plane of the carbonyl bond owing to the steric necessities. This situation is very similar to that in the case of 1, 1-diphenylethylene which will be treated in the succeeding part of this series. However, in contrast to the fact that 1, 1-diphenylethylene shows the conjugation band at almost the same position as the conjugation band of styrene, the conjugation band of benzophenone, which is structureless, has the maximum at an appreciably longer wavelength than that of benzaldehyde. This situation is rather similar to that observed in the comparison of the spectrum of tetraphenylethylene with that of *trans*-stilbene, the maximum of the former being at a longer wavelength than that of the latter[13]. Thus, it may be considered that the angle through which each benzene ring in benzophenone is rotated out of the plane of the carbonyl bond is not so large as the corresponding angle in 1, 1-diphenylethylene. However, it can not be asserted so, because the maximum of the conjugation band of benzophenone may be compared, alternatively, with the minor maximum of fine structure of the conjugation band of benzaldehyde at almost the same wavelength (i. e. at 248.1 m$\mu$).

### Experimental

All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

The specimens of benzaldehyde and of acetophenone were obtained by distillation of commercial products under reduced pressure.

Benzophenone was prepared by the method described in Organic Syntheses[14]; colorless prisms melting at 48~48.5°C.

*p*-Phenylbenzaldehyde was prepared by the method described in Organic Reactions[15]. From 150 g. of biphenyl, 124 g. of the purified product was obtained after treatment with activated charcoal and repeated recrystallization from petroleum ether (b. p. 80~100°C); colorless thin plates melting at 60~61°C. About 5 g. of biphenyl was recovered.

*p*-Phenylacetophenone was prepared by the method described by Long and Henze[16]. From 77.1 g. of biphenyl, 87.4 g. of the purified product was obtained (89% of the theoretical amount); colorless crystals melting at 119~121.5°C.

2-Formylfluorene was prepared almost analogously to the preparation of *p*-phenylbenzaldehyde. Thus, a stream of dry carbon monoxide and hydrogen chloride was passed for about 4.5 hr. into a well-stirred solution of 42 g. of fluorene in 200 ml. of dry benzene containing 59 g. of anhydrous aluminum chloride and 11 g. of cuprous chloride at 35~40°C. The dark-colored reaction mixture was poured into a mixture of ice and small quantities of concentrated hydrochloric acid. The violet-colored mixture was extracted with benzene. The benzene solution was concentrated to about 300 ml. by evaporation, and the solution was shaken with an excess of a saturated solution of sodium bisulfite and small quantities of ethanol. The brown bisulfite compound was collected, washed repeatedly with ethanol and then with ether, and warmed with aqueous sodium carbonate. The aldehyde was then collected, dried on a porous plate, and crystallized twice from petroleum ether. The yield of faint yellow needles melting at 85.5~86.5°C was 6.3 g. It might be somewhat doubtful whether this product is the desired compound, 2-formylfluorene, because, according to Rodd[17], treatment of fluorene with ethyl formate and potassium ethoxide gives 9-formylfluorene which sinters at about 70°C and melts at about 90°C. However, the ultraviolet absorption spectrum of this product is considered to have revealed that this product is not 9-formylfluorene, but probably 2-formylfluorene.

2-Acetylfluorene was prepared by the method described in Organic Syntheses[18]. From 40 g. of fluorene, 24.4 g. of the product was obtained after purification by treatment with activated charcoal and by twofold recrystallization from ethanol (48.9% of the theoretical amount); colorless crystals melting at 127.5~128°C.

The author desires to thank Professor Kengo Shiomi for reading the manuscript and for valuable advice.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. XI. Styrene, 1, 1-Diphenylethylene and their Methylated Derivatives*

By Hiroshi SUZUKI

(Received October 30, 1959)

An introduction of a substituent into an *o*-, the $\alpha$-, or the *cis*-$\beta$-position of styrene must cause a deviation of the phenyl group from the coplanar position with the plane of the ethylenic bond, owing to the steric interaction between the *o*-substituent and the $\alpha$- or the *cis*-$\beta$-hydrogen or between the $\alpha$- or *cis*-$\beta$-substituent and an *o*-hydrogen. On the other hand, in 1, 1-diphenylethylene, the two phenyl groups can not simultaneously be coplanar with the plane of the ethylenic bond. These steric situations must reveal themselves in the ultraviolet absorption spectra. In this part of the series, the method analogous to the one used so far in the previous parts of this series is applied to methylated styrenes, 1, 1-diphenylethylene, and its methylated derivatives, and the relations between the most probable spatial configurations of these compounds and the ultraviolet absorption spectra are discussed.

## Calculation

The method of calculation is quite analogous to the ones for biphenyls[1], terphenyls[2], and stilbenes[3,4] in the earlier parts of this series. The $\pi-\pi$ resonance integral for the ethylenic bond is denoted by $\eta\beta$, and that for the $\alpha-1$ "single" bond of styrene is denoted by $\rho\beta$, in which $\beta$ represents the $\pi-\pi$ resonance integral for a C–C bond in benzene as usual. By substituting suitable values for $\eta$ and $\rho$ according to the lengths and the angles of twist of the corresponding bonds, and by solving the secular equation for the determination of the molecular orbitals of styrene as linear combination of $2p\pi$ atomic orbitals by the usual procedure, the energy $\Delta E_A$ of the transition from the highest occupied orbital to the lowest vacant orbital, which is allowed by absorption of light polarized along the direction of the long axis of the molecule, is calculated. This value of $\Delta E_A$ is considered to correspond to the transition energy of the intense conjugation band of the molecule of the styrene-type of the configuration prescribed by the values of $\eta$ and $\rho$.

The length of the ethylenic bond is assumed to be 1.34 Å, and hence the value of $\eta$ is assumed to be 1.080 for the styrenes and 1, 1-diphenylethylenes throughout the present treatment, for the same reason as in the case of stilbenes in Part V[3] of this series. By using this value for $\eta$, the value of $\Delta E_A$ is calculated as a function of the variable $\rho$. The results are shown in Table I. It is seen in Table I that the value of $\Delta E_A$ increases with the decreasing value of $\rho$, and that the value of $\Delta E_A$ coincides with the value for benzene, $2(-\beta)$, when the value of $\rho$ is zero.

TABLE I

| $\rho$ | 1 | 0.9 | 0.8 | 0.7 | 0.6 | |
|---|---|---|---|---|---|---|
| $\Delta E_A(-\beta)$ | 1.3958 | 1.4506 | 1.5082 | 1.5684 | 1.6314 | |
| $\rho$ | 0.5 | 0.4 | 0.3 | 0.2 | 0.1 | 0 |
| $\Delta E_A(-\beta)$ | 1.6968 | 1.7646 | 1.8342 | 1.9036 | 1.9672 | 2 |

Although reliable data concerning the spatial configuration of styrene molecule are not yet available, the configuration can be presumed by analogy with the following facts. Butadiene in the vapor phase has recently been found by Almenningen and his collaborators[5] to have probably almost exclusively the planar *trans*-configuration in which the length of the 2-3 "single" bond is 1.483±0.01 Å. On the other hand, biphenyl in the crystalline state has been found to have the planar configuration in which the length of the co-annular "single" bond is 1.48Å[6]. Accordingly, it may be presumed that styrene has probably the planar or nearly planar configuration in which the length of the $\alpha-1$ "single" bond is about 1.48 Å. Even if the presumption of the bond length is not correct, a small change in the bond length for the reference compound is considered not to affect significantly the resultant calculated values for

6) (a) J. Dhar, *Indian J. Phys.*, **7**, 43 (1932); *Chem. Abstr.*, **26**, 4517 (1932). (b) Idem., *Proc. Natl. Inst. Sci. India*, **15**, 11 (1949); *Chem. Abstr.*, **43**, 4655 (1949).

the angles of twist, as suggested by the results of the similar calculations for terphenyls in Part IV[2] of this series. Therefore, the presumption is adopted in the present treatment. Then, the relation between $\rho$ and the angle of twist $\theta$ (i. e. the interplanar angle between the benzene ring and the ethylenic bond) as well as the length of the "single" bond $R$ is assumed to be quite analogous to the relation between $\mu$ (the variable analogous to $\rho$) and $\theta$ as well as $R$ postulated in the case of biphenyl in Part I[1] of this series. Thus, $\rho$ is expressed as follows:

$$\rho = \cos\theta \times S(R, 0°)/S(1.39, 0°)$$
$$= \cos\theta \times 0.77108 + \cos^2\theta \times (1.54 - 1.48) \times 1.4458$$

where $S(R, 0°)$ represents the $\pi-\pi$ overlap integral for the bond, the length and the angle of twist of which are $R$ (Å) and 0°, respectively, and $S(1.39, 0°)$ represents the overlap integral for a C–C bond in benzene, whose length is 1.39 Å and whose angle of twist is, of course, zero.

Accordingly, the value of $\rho$ when $R$ and $\theta$ are 1.48 Å and 0°, respectively, i. e. the value of $\rho$ for the planar styrene molecule, is calculated to be 0.858, and the corresponding value of $\Delta E_A$ is calculated to be 1.475 $(-\beta)$, which is referred to as $\Delta E_L$. When the wave number $\nu_A$ of the maximum of the conjugation band of a styrene derivative has been correlated with the calculated transition energy $\Delta E_A$, the value of $\rho$ for the compound can be evaluated, and then the corresponding values of $\theta$ and $R$ can be estimated.

## Styrenes

The data of the ultraviolet absorption spectra to be found in the literature for styrene and substituted styrenes are considerably variable. Especially the data of the molecular extinction coefficients are extremely variable, probably owing to the presence of polymeric materials in some of the specimens used, as pointed out already by Braude and Sondheimer[7]. Also with wavelengths of the absorption maxima, different workers using different instruments have reported values which vary by a few mμ. Further, the positions of the maxima vary more or less, depending on the solvent. With consideration for these situations, mainly the data obtained newly by the present author and those obtained recently by Schwartzman and Corson[8], both using Cary recording spectrophotometers and

using saturated hydrocarbons as the solvents, are used in the present treatment. For a few compounds, the data of the spectra of which in solutions in saturated hydrocarbon are not available, the data for ethanol solutions are used. Such data used here are summarized in Table II, and the spectra measured by the present author are shown in Fig. 1.

It is evident that the styrene derivatives with methyl substituents in the sterically hindered positions exhibit the conjugation bands at shorter wavelengths than the conjugation band of the parent compound, styrene. The bands appearing in the range between 270 and 290 m$\mu$ are considered to be the ones corresponding to the $A_{1g} \rightarrow B_{2u}$ transition in benzene, quite similarly to the corresponding bands of benzaldehyde and of acetophenone[13].

In order to infer the spatial configurations of the styrenes from the data of the spectra by applying the above-mentioned calculation method, the electronic bathochromic effect of the methyl groups (probably due to the hyperconjugation effect) should be taken into account, because the wavelength separation between the conjugation band of styrene and the center of gravity of singlets of benzene as the shorter-wavelength-side reference is so small that the magnitude of the bathochromic effect of the methyl groups may not be negligible relatively to the magnitude of the steric hypsochromic effect.

The allowance for the electronic bathochromic effect of the methyl groups is made by the method analogous to the ones used in the treatments of *o*-alkylbiphenyls in Part II[14] of this series and of the stilbene derivatives with methyl groups on the benzene nuclei in Part VIII[15] of this series, i. e. by choosing pertinently the longer-wavelength-side and the shorter-wavelength-side references in the correlation of $\nu_A$ with $\Delta E_A$.

**Longer-wavelength-side Reference.** — As the value of $\nu_A$ corresponding to $\Delta E_L$, viz. $\nu_L$, the wave number, at which the molecule concerned would exhibit the absorption maximum of the conjugation band if the molecule were planar, is taken. Thus, for example, as the value of $\nu_L$ for *o*-methylstyrene, the wave number of the absorption maximum of the conjugation band of *p*-methylstyrene, 39526 cm$^{-1}$ (253 m$\mu$), is taken, since the electronic bathochromic effect of a methyl group can be considered to be approximately equivalent in the *o*- and *p*-positions.

From the comparison of the spectrum of *p*-methylstyrene with that of styrene and the comparison of the spectrum of *o,p*-dimethylstyrene with that of *o*-methylstyrene, it may be presumed that the magnitude of the bathochromic displacement of the conjugation band per a methyl substituent at the *p*- or *o*-position of styrene is about 5 m$\mu$. Further, it may be assumed that the displacement is approximately additive, on the analogy of the case of methylated benzenes[16]. According to Schwartzman and Corson[8], *m*-methylstyrene and *m,m'*-dimethylstyrene in cyclohexane solutions exhibit the conjugation bands at 251 and 254 m$\mu$, respectively. Comparing these wavelengths with that of styrene itself (248 m$\mu$), it is seen that the magnitude of the bathochromic displacement per a methyl group at a *m*-position is 3 m$\mu$, and that the additivity holds good in this case. The magnitude of the bathochromic displacement caused by an *o*-methyl group may, strictly speaking, be not completely equal to that by a *p*-methyl group. Probably, the former is very slightly smaller than the latter, in view of the results of the calculations for *p*- and *o*-terphenyls described in Part IV[2] of this series, but must be considerably larger than the magnitude of the bathochromic displacement caused by a *m*-methyl group. Therefore, the assumption that the magnitude of the displacement per an *o*-methyl group is equal to that per a *p*-methyl group can be considered to be quite satisfactory in the present approximate treatment. When it is assumed so, *o,p*-dimethylstyrene would have the absorption maximum of the conjugation band at about 258 m$\mu$ (248+5×2 m$\mu$) if it were not for

| | 12 | α,β,β-Trimethyl- | 237.8 | 254 | 208.3 | 1.638 | 0.590 | 45 | 1.498 |
| V | 13 | α,*o*-Dimethyl- | | | | | | (90) | |

the steric hypsochromic effect. Accordingly, for the treatment of *o,p*-dimethylstyrene, the value of 38760 $cm^{-1}$ (258 mμ) is taken as the value of $\nu_L$.

Further, for example, for *cis*-β-methylstyrene, the wave number of the maximum of *trans*-β-methylstyrene is taken as $\nu_L$. The magnitude of the bathochromic wavelength displacement caused by the introduction of a methyl group into the α-position and that by the introduction into a β-position may be not equal to each other, since the two positions must be not equivalent, the α-methyl group being at the position of cross-conjugation to the conjugated system of the styrene skeleton and, on the other hand, the β-methyl group being at the position of conjugation to the conjugated system. In spite of this, the magnitude of the displacement by an α-methyl as well as a β-methyl group is provisionally assumed to be equal to the difference in wavelength between the maximum of *trans*-β-methylstyrene and that of styrene, 2 mμ, although the data of the maxima of these compounds may be not pertinent to comparison, since they are obtained in different solvents. Further, it is assumed that the additivity holds good also in this case. Then, for example, the value of $\nu_L$ for the treatment of α, β, β-trimethylstyrene becomes 39370 $cm^{-1}$ (254 mμ = 248 + 2 × 3 mμ).

**Shorter-wavelength-side Reference.**—The value of $\Delta E_A$ when $\rho$ is zero, $2(-\beta)$, is denoted by $\Delta E_S$, and the corresponding wave number is denoted by $\nu_S$, as usual. As the value of $\nu_S$ for the treatments of the styrenes which have no methyl substituent on the benzene nuclei, the center of gravity of singlets of benzene, 48000 $cm^{-1}$ (208.3 mμ), is taken, as usual.

As shown in Table II in Part II[14] of this series, the absorption bands of toluene, *m*-xylene, and mesitylene are at longer wavelengths by about 5, 9 and 11 mμ, respectively, than the corresponding bands of benzene. Accordingly, the values for these compounds corresponding to the center of gravity of singlets of benzene are considered to be approximately 46882 $cm^{-1}$ (213.3 mμ = 208.3 + 5 mμ), 46019 $cm^{-1}$ (217.3 mμ = 208.3 + 9 mμ), and 45600 $cm^{-1}$ (219.3 mμ = 208.3 + 11 mμ), respectively. Therefore, for example, as the value of $\nu_S$ for the treatment of *o, p, o'*-trimethylstyrene, the value of 45600 $cm^{-1}$ is taken.

**Application of the Calculation.** — When the references have been determined for each styrene derivative as mentioned above, the value of the calculated transition energy $\Delta E_A$ corresponding to the observed position ($\nu_A$ in wave number) of the maximum of the conjugation band of the compound can be easily obtained by the use of the usual postulated linear relation of $\Delta E_A$ to $\nu_A$ between the two reference points. Consequently, from the value of $\Delta E_A$, the corresponding value of $\rho$ can be obtained according to the relation between $\rho$ and $\Delta E_A$ shown in Table I, and then the corresponding values of $\theta$ and $R$ can be obtained. The results of the calculations are shown in Table III, in which $\lambda_A$ refers to the wavelength of the absorption maximum of the compound concerned, and $\lambda_L$ and $\lambda_S$ refer to the corresponding longer-wavelength-side and the corresponding shorter-wavelength-side references, respectively, in wavelength.

## Discussion

Although much reliance may not be placed on the individual numerical values of the calculated interplanar angles because of the approximation used, the results of the calculations shown in Table III appear to lead to the

conclusion that these styrenes can be classified into the following well-defined groups with respect to the type or the degree of the steric interaction involved in the molecule.

*Group I.* The compounds which have no methyl substituent at hindering positions, i. e. at *o*-, $\alpha$-, and *cis*-$\beta$-positions. To this group, the compounds of the entry numbers 1—3 listed in Table III belong. These compounds are probably planar.

*Group II.* The compounds which have one hindering methyl group either at an *o*-position or at the $\alpha$-position of the molecule. These compounds are considered to involve solely the steric interference either between the *o*-methyl group and the $\alpha$-hydrogen or between the $\alpha$-methyl group and an *o*-hydrogen. To this group, the compounds of the entry numbers 4–7 in Table III belong. The $\beta$-methyl group in "$\alpha$, $\beta$-dimethylstyrene" (entry 7) is probably *trans* to the phenyl group. The calculated interplanar angles for these compounds range from 31° to 33°.

*Group III.* The compounds with one hindering methyl group at the *cis*-$\beta$-position. These compounds involve solely the steric interference between the *cis*-$\beta$-methyl group and an *o*-hydrogen. To this group, the compounds of the entry numbers 8 and 9 belong. For these compounds, the calculated interplanar angles are 35° and 40°, being slightly larger than those for the compounds belonging to Group II.

*Group IV.* The compounds with two hindering methyl groups either at both *o*-positions or at the $\alpha$- and the *cis*-$\beta$-positions. These compounds involve the steric interferences between methyl groups and hydrogen atoms on both the sides of the benzene nucleus. To this group, the compounds of the entry numbers 10–12 in Table III belong. The calculated interplanar angles for these compounds range from 45° to 54°, and are considerably larger than those for the compounds belonging to Group II and those for the compounds belonging to Group III.

*Group V.* To this group, $\alpha$, *o*-dimethylstyrene (entry 13) belongs. If the most probable configuration of this compound were the configuration involving the steric interference between the $\alpha$-methyl group and the *o*-hydrogen and the interference between the *o*-methyl group and the *cis*-$\beta$-hydrogen, this compound would belong to Group IV and not to Group V. In fact, however, this compound has been reported to show no absorption maximum in the range between 210 and 300 m$\mu$, in contrast with the compounds belonging to Group IV. Accordingly, the most probable configuration of this compound is probably the one in which the two methyl groups just contact with each other, and consequently, the interplanar angle is larger than in the compounds belonging to Group IV and probably nearly 90°. This inference seems to be not unlikely, in view of the fact that *o*, *o'*-dimethylbiphenyl has probably the *cis*-like configuration in which the two methyl groups contact with each other as discussed in Part II[14] of this series.

The fact that the calculated interplanar angles for the compounds belonging to Group III are appreciably larger than those for the compounds belonging to Group II is of interest. This fact seems to lead to the conclusion that the steric interference due to the *cis*-$\beta$-methyl group is more effective than that due to the $\alpha$-methyl group.

The geometries of the relevant parts of the compounds belonging to Group IV are considered to be approximately similar to those of *trans*-$\alpha$, $\alpha'$-dimethylstilbene and of *trans*-2, 4, 6, 2', 4', 6'-hexamethylstilbene, except for the possible differences of the bond lengths and of the bond angles. The calculated interplanar angle for $\alpha$, $\beta$, $\beta$-trimethylstyrene (entry 12) is considerably smaller than that for *trans*-$\alpha$, $\alpha'$-dimethylstilbene (58°)[17]. On the other hand, the calculated interplanar angle for *o*, *o'*-dimethylstyrene (entry 10) coincides almost completely with that for *trans*-hexamethylstilbene (54.3°)[15].

At any rate, it is noteworthy that the interplanar angles for the compounds which involve the steric interferences between methyl groups and hydrogen atoms on both sides of the benzene ring (belonging to Group IV) are considerably larger than those for the compounds which involve the steric interference solely on one side of the benzene ring (belonging either to Group II or to Group III). This may mean that in the compounds with the steric interference solely on one side of the benzene ring the steric interference is relieved to some extent probably by changes in the bond angles.

Lastly in this section, it may be concluded that, by making allowance for the electronic bathochromic effect of the methyl substituents, the interplanar angles in the methylated styrenes have been almost satisfactorily inferred from the wavelength positions of the conjugation bands.

## Criticism on Braude and Forbes' Classification of Steric Effects in Ultraviolet Absorption Spectra

Braude and his coworker[18] classified the steric effects of twisting of "single" bonds in conjugated systems on the conjugation bands into

17) H, Suzuki. This Bulletin, 33, 396 (1960).
18) E. A. Braude and F. Sondheimer, *J. Chem. Soc.*, 1955, 3754.

two types: (1) Steric effect which gives rise to intensity changes only, without causing any "unusual" change in wavelength (the steric effect of type 1, or *type 1* steric effect). This effect is caused by relatively small twists. (2) Steric effect which causes changes in both wavelength and intensity (the steric effect of type 2, or *type 2* steric effect). This effect is caused by larger twists than the first effect.

To the above two types, Forbes[19] has recently added a third type; the steric effect occurring when the twist is so large that conjugation across the bond is almost completely inhibited and the molecule absorbs as two distinct entities. This effect has been termed a *type 3* steric effect.

A similar classification of steric effects into three main classes has been proposed also by Turner and Voitle[20], and such a classification appears to have been generally accepted[21].

Braude and Sondheimer have regarded *o*-methylated styrenes and related compounds[7] as well as *o*-methylated benzaldehydes and acetophenones[18] as examples of the compounds exhibiting the steric effect of type 1, and have applied their postulated equation $\cos^2\theta = \varepsilon/\varepsilon_0$ to these compounds, where $\varepsilon$ and $\varepsilon_0$ are the molecular extinction coefficient of the conjugation band of a given compound and that of the corresponding planar reference compound, respectively. According to the results, the estimated interplanar angles between the phenyl group and the CH=CX group in styrenes and related compounds are about 20~30° for one, and about 40~60° for two *o*-methyl substituted compounds.

On the other hand, Braude and Forbes[22] have stated that *o*-methylbiphenyl provides an excellent example of the steric effect of type 2, in contrast with *o*-methylated styrenes and acetophenones, notwithstanding the fact that the geometries of the relevant parts of these systems are quite similar. They have explained this rather strange difference between the biphenyl system on the one hand, and the acetophenone and styrene systems on the other, as follows: "the two possible uniplanar conformations of this compound (*o*-methylbiphenyl) are identical and involve the same extent of steric hindrance, whereas the two uniplanar conformations of 2-methylacetophenone or 2-methylstyrene are not identical and one involves much less steric hindrance than the other. Hence the steric hindrance produced by an *o*-methyl substituent will be effectively much larger in the biphenyl than in the other two systems, and the probability of any *o*-substituted biphenyl molecule's occupying a near-planar vibrational state will be extremely low. Thus, the conditions prerequisite for the display of steric effects of type 1 no longer exist".

This appears to be their main reason, although they have given two additional reasons. If this explanation were acceptable, why do *o,o'*-dimethyl substituted styrenes and acetophenones, e. g. 2, 4, 6-trimethylstyrene, 2, 6-dimethylbenzylideneacetone, and 2, 6-dimethylacetophenone, belong to the group of compounds which exhibit the steric effect of type 1 as Braude and his coworker have stated?

It will be evident, as seen in the present treatment of the styrenes and as discussed for the case of acetophenones in the preceding part[13] of this series, that the electronic bathochromic effect of the substituents is responsible for the apparent absence of an appreciable hypsochromic displacement of the conjugation band in these compounds. That is, it seems that the apparent absence of an appreciable wavelength displacement is not a proof of the absence of the hypsochromic displacement produced by the steric interaction but should be considered as a result of compensation of the hypsochromic effect by the electronic bathochromic effect of the substituents. The apparent bathochromic displacement observed sometimes with hindered compounds should, of course, be considered to be due to the electronic bathochromic effect of the substituents outweighing the steric hypsochromic effect. These considerations imply that the difference between the steric effect of type 1 and the steric effect of type 2 is not the difference in kind or in underlying mechanism as Braude and Forbes have asserted, but merely in degree.

In general, as has been discussed so far in this series, the electronic transition energy and hence the wavelength at which absorption occurs are determined by the spatial configuration or conformation of the molecule. Thus, so far as the conformation about the "single" bond is concerned, the non-planarity of the conformation must in principle produce a more or less large hypsochromic shift of the conjugation band, depending on the degree of the deviation from the coplanarity. On the other hand, the presence of steric interference in the molecule affects invariably the population ratio among conformations, and changes the most probable conformation from the planar conformation to a nonplanar one in most cases. Therefore, the wavelength displacement of the

19) W. F. Forbes, "Steric Effects in Conjugated Systems", edited by G. W. Gray, (Proceedings of a Symposium held at the University, Hull, 15-17 July, 1958 by the Chemical Society), Butterworths Scientific Publications, London (1958), p. 62.
20) R. B. Turner and D. M. Voitle, *J. Am. Chem. Soc.*, 73, 1403 (1951).
21) M. S. Newman (ed.), "Steric Effects in Organic Chemistry", John Wiley & Sons, Inc., New York (1956), p. 484.
22) E. A. Braude and W. F. Forbes, *J. Chem. Soc.*, 1955, 3776.

conjugation band caused by steric interference is not an unusual phenomenon as Braude and others have stated, but rather a usual one.

Either when the steric interference is so weak that the planar or nearly planar conformation is still the most probable one, or when the transition probability in the more probable nonplanar conformation is much smaller than the transition probability in the less probable planar conformation, it might be possible that the absorption maximum in the resultant spectrum of the sterically hindered compound is at the same wavelength as the maximum of the unhindered planar reference compound, the intensity of the former being smaller than that of the latter. However, it is doubtful whether such cases can exist in fact. The so-called steric effect of type 1 is, as mentioned above, merely superficial or spurious with respect to the steric effect, and should be considered as a special case where the steric hypsochromic shift is so small that it is almost completely compensated by the bathochromic shift due to the electronic effect of the substituents. Further, only considering that, as pointed out already in an earlier part[23] of this series, the hypsochromic shifts of the conjugation bands as compared with the bands of the corresponding planar reference compounds are observed even in the spectra cited by Braude and others as examples of the steric effect of type 1, it will be evident that the effect of this type is not clear-cut even phenomenologically.

Attention to the fact that, even when any significant wavelength displacement is apparently not observed, the presence of steric interference in the molecule or the deviation of the most probable molecular configuration from the coplanarity can manifest itself in a decrease in the intensity of the band may be of some practical significance, whatever the underlying mechanism may be. It seems, however, not to be necessary in principle to consider the so-called steric effect of type 1 separately from the so-called steric effect of type 2. Further, the steric effect of type 3 (i. e. the *type 3* steric effect) is merely the extreme case of the steric effect of type 2. Accordingly, it may be concluded that Braude and Forbes' classification of steric effects and their elucidations of the "mechanisms underlying the different types" are quite redundant, as pointed out also by Dewar[24].

### 1, 1-Diphenylethylenes

In 1, 1-diphenylethylene, the two phenyl groups can not be simultaneously coplanar with the ethylenic bond, owing to the steric necessities. Therefore, the most probable configuration of this molecule is presumed to be the configuration in which both of the phenyl groups are rotated out to the same extent as each other from the plane of the ethylenic bond, or alternatively, the configuration in which one of the phenyl groups is almost perpendicularly rotated out of the plane of the ethylenic bond, leaving the other phenyl group coplanar with the ethylenic bond.

The data of the ultraviolet absorption spectra of 1, 1-diphenylethylene and its methylated derivatives are summarized in Table IV, in which the data of the spectrum of styrene are also included for comparison. In addition, the spectra of 1, 1-diphenylethylene and its 2, 2-dimethyl derivative measured by the present author are shown in Fig. 2. These spectra are similar to each other, except for the appearance of the additional band at 235.4 m$\mu$ besides the principal band at 248.0 m$\mu$ in the spectrum of 1, 1-diphenylethylene. It is especially of interest that the absorption maxima of the principal (conjugation) bands of these four compounds appear at the almost identical wavelength.

The close similarity between the spectrum of 1, 1-diphenylethylene and that of styrene would be considered as supporting the second of the two hypotheses mentioned above concerning the

24) M. J. S. Dewar, Ref. 19, p. 71.
25) Ramart-Lucas and P. Amagat, *Bull. soc. chim. France*, [4] 51, 108 (1932).

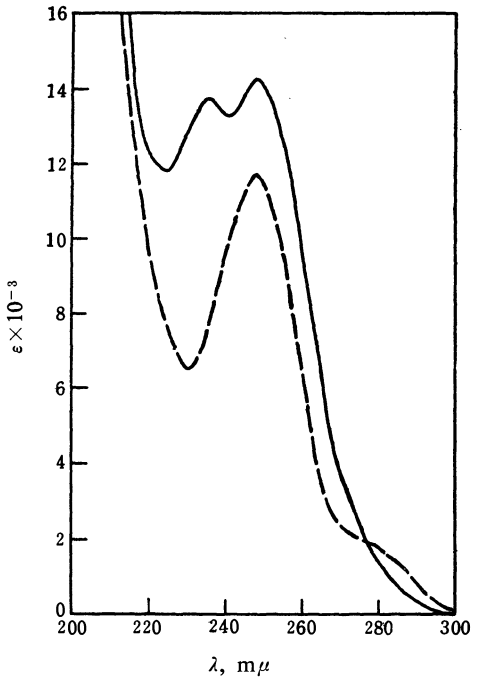

Fig. 2. Ultraviolet absorption spectra (in *n*-heptane): ——, 1,1-diphenylethylene; ----, 1,1-diphenyl-2,2-dimethylethylene.

most probable configuration of 1,1-diphenylethylene. However, the close similarity between the spectrum of 1,1-diphenylethylene and the spectra of its methylated derivatives seems to suggest that the first hypothesis is more plausible, because especially the dimethyl derivative (1,1-diphenyl-2-methylpropene) can not assume the configuration of the second hypothesis owing to the steric interferences between the phenyl groups and the methyl groups at the *cis*-$\beta$-positions relative to the phenyl groups.

Now, when it is assumed that 1,1-diphenylethylene as well as its derivatives has the configuration in which a styrene chromophore is left as the second hypothesis, these compounds can be treated by the calculation quite similar to the one in the case of styrenes.

Alternatively, when it is assumed that each compound has a configuration in which the two phenyl groups are rotated out by the identical degree from the plane of the ethylenic bond as the first hypothesis, the secular equation for the determination of the molecular orbitals as linear combinations of the $2p\pi$ atomic orbitals can be factorized into one equation identical in the form with the one for styrene and one equation for benzene, when $\rho'$ is $1/\sqrt{2} \times \rho$, $\rho'\beta$ representing the $\pi - \pi$ resonance integral for each bond connecting a phenyl group to an ethylenic carbon atom. This situation is very similar to that in the treatment of tetraphenylethylene in Part VI[26] of this series. Accordingly, also in this case, the calculation similar to the one for styrenes can be applied to these 1,1-diphenylethylenes, and from the values of $\rho$ obtained as results of the calculation, the values of $\rho'$ can be obtained. Then, from the values of $\rho'$, the values of $\theta$ and $R$ can be obtained by the use of the relation quite analogous to the one between $\rho$ and $\theta$ as well as $R$ postulated already. The results of the calculation are shown in Table V, in which the symbols have the same significance as in Table III. Allowance for the electronic bathochromic effect of methyl groups has been made by the method quite analogous to the one used in the case of the styrenes. In 1,1-diphenyl-2-methylethylene, the positions of the two phenyl groups are not completely equivalent, and therefore, their angles of twist $\theta$ must differ, though probably very slightly, from each other. In spite of this, the results for this compound obtained on the basis of the assumption that the angles of twist of the two phenyl groups are equal are shown.

It is noteworthy that the introduction ot methyl groups into the 2- or $\beta$-positions of 1,1-diphenylethylene affects only slightly the calculated interplanar angle $\theta$. The presence of the additional steric interference by the methyl groups in spite of the apparent absence of a wavelength displacement of the conjugation band is evident from the fact that the intensity of the band is decreased in the order 1,1-diphenylethylene > 1,1-diphenyl-2-methylethylene > 1,1-diphenyl-2,2-dimethylethylene, with the increasing number of methyl substituents. Thus, also in this case, the apparent absence of a wavelength displacement of the conjugation band is considered as the result of the compensation of the hypsochromic shift due to the steric interference by the bathochromic shift due to the electronic (probably hyperconjugation) effect of the methyl groups. Lastly, it may be mentioned that the calculated interplanar angles for these compounds, especially for the dimethyl compound, are very similar to those for the styrene derivatives belonging to Group IV (cf. Table III).

### Exaltation of Molecular Refraction

Mulliken[27] has indicated that the molecular refractions of positional isomeric alkylstyrenes should roughly parallel the ultraviolet absorption maxima. Following this view, Schwartzman and Corson[8] have correlated the ultraviolet absorption spectra of styrene derivatives with methyl substituents on the benzene nucleus with the molecular refractions. The present author also has frequently referred so far in this series to

$EM_\alpha$ and $EM_D$ are exaltations of molecular refraction.
$E\Sigma_\alpha$ and $E\Sigma_D$ are specific exaltations.

the exaltation of the molecular refraction as a measure of the degree of conjugation.

In Table VI, the data of the exaltations found in the literature for the styrenes and the 1,1-diphenylethylenes treated in this part of the series are summarized. The data for some compounds are considerably variable, depending on the worker. In addition, the values of the exaltations are considered to contain not only the conjugation effect but also the hyperconjugation effect of the methyl groups. Therefore, it may not be pertinent to correlate these values of the exaltations directly with the calculated interplanar angles or with the degrees of conjugation which will be inferred from the calculated interplanar angles. Notwithstanding, it will be seen that there exist roughly regular relations among these quantities.

## Experimental

All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

α-Methylstyrene (2-phenylpropene) was prepared after the procedure described by Klages[31], and purified by repeated distillation; colorless liquid, b. p. 160~162°C. The value of boiling point is in good agreement with those found in the literature (162°C[31], 160~162°C[32]).

β,β-Dimethylstyrene (1-phenyl-2-methylpropene) was prepared, after the procedure described by Tiffeneau[33], by dehydration of 1-phenyl-2-methylpropanol by heating with oxalic acid, and was purified by repeated distillation; colorless liquid, b. p. 189~193°C. The boiling point of this compound found in the literature is 179~189°C[33]. 1-Phenyl-2-methylpropanol was prepared by the Grignard reaction of benzaldehyde and the Grignard reagent prepared from isopropyl bromide and magnesium.

α,β,β-Trimethylstyrene (2-phenyl-3-methyl-2-butene) was prepared by dehydration of 2-phenyl-3-methyl-2-butanol by distillation, and purified by repeated distillation; colorless liquid, b. p. 189~

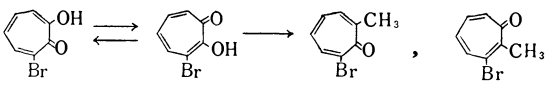
# *Reaction of Troponoids and Organometallic Compounds. V. Reaction of Bromotropolones and Alkylmagnesium Iodides*



By Katsuo KIKUCHI

(Received October 19, 1959)

It has been reported in a previous paper[1] of this series that bromo derivatives of tropolone methyl ether react with $\alpha$- and $\beta$-naphthylmagnesium bromides to yield corresponding bromo substitution products of 2-$\alpha$- and 2-$\beta$-naphthyltropones and 2-hydroxyphenyl $\alpha$- and $\beta$-naphthyl ketones.

The present paper deals with an investigation on the reaction of bromotropolones and alkyl Grignard reagents.

Reaction of methylmagnesium iodide and 3-bromotropolone (Ia) yielded colorless plates (IIa) whose ultraviolet spectrum was similar to that of tropone[2] (Fig. 1), suggesting that it is monobromo-2-methyltropone. As 3-bromotropolone is in a " high mobile tautomeric " system as represented with A and A′, two isomeric monobromo-2-methyltropone, i.e. 7-bromo-2-methyltropone (B) and 3-bromo-2-methyltropone (B′) should be obtained by this reaction. Actually, treatment of IIa with dilute alkali gave *o*-toluic acid (IIIa) indicating that IIa is 7-bromo-2-methyltropone (B).

A A′ B B′

However, the reaction of 3,7-dibromotropolone and methylmagnesium iodide under similar condition gave only minute amount of unidentified phenolic substance. Similarly, the reaction of 3, 5, 7-tribromotropolone and methylmagnesium iodide afforded only a small amount of dimethyl 3, 5-dibromo-2-hydroxyphenyl carbinol which was proved to be identical with that synthesized by the reaction of methyl 3, 5-dibromosalicylate and methylmagnesium iodide.

On the other hand, by the reaction of 3, 7-dibromotropolone methyl ether (Ib) and methylmagnesium iodide 3, 7-dibromo-2-methyltropone (IIb) was obtained. By treatment with alkali IIb was submitted to rearrangement to give 3-bromo-*o*-toluic acid (IIIb)[3], debromination of which gave IIIa. The ultraviolet absorption spectrum of IIb (Fig. 1) showed bands characteristic of tropone.

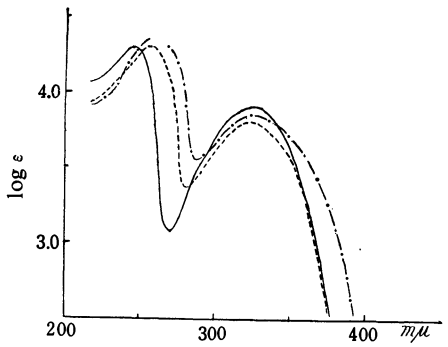

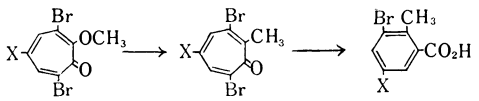

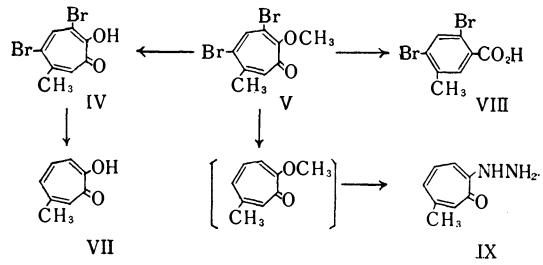

Fig. 1. Ultraviolet absorption spectra of IIa (——), IIb (------) and IIc (—·—·—) in methanol.

Reaction of 3, 5, 7-tribromotropolone methyl ether (Ic) and methylmagnesium iodide afforded four kinds of crystals as follows: pale yellow prisms (IIc), m. p. 63~64°C; colorless needles (IV), m. p. 151.5~153°C; colorless needles (V), m. p. 151~152°C and colorless needles (VI), m. p. 116~117°C. The main product was IIc.

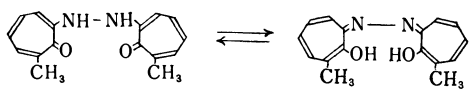
Treatment of IIc with alkali afforded an acid (IIIc) whose debromination gave *o*-toluic acid (IIIa). This fact and the analytical values of IIc and IIIc indicate that IIc and IIIc are 2-methyl-3, 5, 7-tribromotropone and 3, 5-dibromo-*o*-toluic acid, respectively. The ultraviolet spectrum of IIc is shown in Fig 1.

IV showed red coloration with ferric chloride characteristic of tropolone and gave yellow sodium salt with aqueous sodium carbonate. On catalytic debromination, IV afforded 4-methyltropolone (VII)[4,5]. Treatment of V with hydrobromic acid in aqueous acetic acid and with aqueous sodium hydroxide afforded IV and 4, 6-dibromo-*m*-toluic acid (VIII)[6], respectively. Catalytic debromination of V on palladium-charcoal gave colorless crystals which, on treatment with hydrazine hydrate, was converted to 2-hydrazino-6-methyltropone (IX)[7]. These experimental results indicate that IV is 3, 5-dibromo-6-methyltropolone and V is 3, 5-dibromo-2-methoxy-6-methyltropone as shown in the following scheme.

It was reported previously that the reaction of 7-bromo-2-methoxytropone and phenylmagnesium bromide afforded phenyltropolone[8], m. p. 96~97°C, as a by-product. Pauson[9] suggested it to be 4-phenyltropolone and later Kitahara[10] presented the mechanism of its formation. The formation of IV and V also could be explained by his mechanism.

Analysis of VI is in agreement with the formula $C_9H_8OBr_2$ and its ultraviolet absorption spectrum (Fig. 2) is quite similar to those of IIa—IIc, and it is suggested that VI has a tropone nucleus. Presumably VI will be 3, 5-dibromo-2, 7-dimethyltropone or 3, 5-dibromo-2, 6-dimethyltropone formed either by the reaction of excess of methylmagnesium iodide with IIc or V, but the determination of the structure was impossible because of limited amount of the material.

Application of ethylmagnesium iodide to Ib afforded 3, 7-dibromo-2-ethyltropone (IId), as in the case of IIb. IId was converted to 3-bromo-2-ethylbenzoic acid (IIId), and the latter was debrominated to 2-ethylbenzoic acid (IIIe). The same reaction of ethylmagnesium iodide with Ic gave no crystalline product even after chromatographic separation on an alumina column. Ethanolic solution of the oil thereby obtained, however, when treated with dilute alkali, resulted in the formation of dibromo-2-ethylbenzoic acid (IIIf) and its ethyl ester (IIIg). From this fact it seems reasonable to assume that 2-ethyl-3, 5, 7-tribromotropone (IIe) was formed in this reaction as in the case of IIc.



Some nucleophilic reactions on IIa, IIb and IIc were next examined.

Heating of IIa and IIb with *p*-toluidine respectively afforded 2-methyl-7-(*p*-toluidino)-tropone (Xa) as yellow prisms and 3-bromo-2-methyl-7-(*p*-toluidino)-tropone (Xb) as yellow plates. The ultraviolet spectrum of Xa was shown in Fig. 2. Similarly, heating of IIa and IIb with aniline respectively gave 7-anilino-2-methyltropone (Xc) as an oil and 7-anilino-3-bromo-2-methyltropone (Xd) as yellow crystals.

Application of hydrazine hydrate to IIa at

room temperature afforded yellow needles (XIa) which gave red coloration with ferric chloride. From its analytical value and the ultraviolet absorption spectrum (Fig. 2) it was assumed to be bis-(2-methyltropon-7-yl)-hydrazine (C) or its tautomer (C') but no further study was made.

C C'

Similar treatment of IIb with hydrazine hydrate yielded colorless needles (XIIa) and yellow needles (XIb). The former was assumed to be 3-bromo-*o*-toluic acid hydrazide from its analytical value and its ultraviolet absorption spectrum (Fig. 2) and the latter to have the analogous structure to XIa. On the other hand, treatment of IIc with hydrazine hydrate gave 3,5-dibromo-*o*-toluic acid hydrazide (XIIb) and the compound corresponding to XIa and XIb was not obtained.

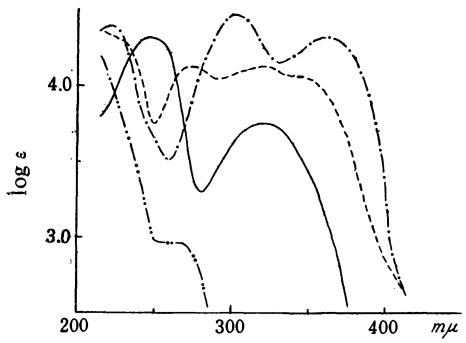

Fig. 2. Ultraviolet absorption spectra of VI (——), Xa (------), XIa (—·—·—·) and XIIa (—··—··—) in methanol.

Several methods[11-15] have already been reported by which 2-halotropones could be converted to tropolones. Application of these methods to IIb and IIc gave no satisfactory results, but by heating of IIb and IIc each with sodium acetate in acetic acid[11] 4-bromo-3-methyltropolone (XIIIa) and 4,6-dibromo-3-methyltropolone (XIIIb) were obtained respectively only with poor yields.

## Experimental

**Reaction of 3-Bromotropolone (Ia) and Methylmagnesium Iodide.**—To a solution of methylmagnesium iodide prepared from 5.0 g. of methyl iodide, 0.84 g. of magnesium and 20 cc. of absolute ether, a solution of 2.0 g. of Ia dissolved in 20 cc. of dehydrated tetrahydrofuran was added in drops under stirring, while chilling with ice. The mixture was stirred for further five hours under ice-chilling, decomposed with dilute sulfuric acid and extracted with chloroform. The chloroform solution was washed with dilute sodium hydroxide solution by which 320 mg. of Ia was recovered. The chloroform solution was then washed with water, dried and the solvent was removed to give 750 mg. of reddish brown oil. This oil was dissolved in benzene, passed through an alumina column, and 470 mg. of 7-bromo-2-methyltropone (IIa), m. p. 43~45°C, was obtained. Recrystallization from cyclohexane gave colorless plates, m. p. 46~47°C.

Found: C, 48.39; H, 3.90. Calcd. for $C_8H_7OBr$: C, 48.22; H, 3.54%.

**Reaction of 7-Bromo-2-methyltropone (IIa) and Alkali.**—A mixture of 50 mg. of IIa and 0.5 cc. of 1 N sodium hydroxide was heated on a water bath for one hour. After removal of the insoluble material, the aqueous layer was acidified with dilute hydrochloric acid and the crystals that separated out were recrystallized from dilute ethanol to give colorless crystals (IIIa), m.p. 99~101°C, undepressed at melting point on admixture with *o*-toluic acid.

**Reaction of 3,7-Dibromotropolone Methyl Ether (Ib) and Methylmagnesium Iodide.**—To a solution of methylmagnesium iodide prepared from 3.0 g. of methyl iodide, 0.5 g. of magnesium and 30 cc. of absolute ether, a solution of 3.0 g. of Ib dissolved in 30 cc. of dehydrated benzene was added in drops and stirring was continued for further two and a half hours. The reaction mixture was poured into dilute sulfuric acid, and the yellow precipitates thereby obtained were filtered off. After washing the organic solvent layer with water, the solvent was removed to give 710 mg. of 3,7-dibromo-2-methyltropone (IIb). By passing the oily portion through an alumina column 150 mg. of a second crop of IIb was obtained. Recrystallization from ethanol gave colorless needles, m. p. 121~122°C.

Found: C, 34.29; H, 2.29. Calcd. for $C_8H_6OBr_2$: C, 34.57; H, 2.18%.

**Reaction of 3,7-Dibromo-2-methyltropone (IIb) and Alkali.**—Similar treatment of IIb with 1 N sodium hydroxide as in the case of IIa gave colorless plates (IIIb), m. p. 150°C. The reported melting point of 3-bromo-*o*-toluic acid is 153°C.

Found: C, 44.88; H, 3.45. Calcd. for $C_8H_7O_2Br$: C, 44.68; H, 3.28%.

IIIb was debrominated catalytically to *o*-toluic acid (IIIa), m. p. 100~102°C, and identified by a mixture melting point determination.

**Reaction of 3,5,7-Tribromotropolone Methyl Ether (Ic) and Methylmagnesium Iodide.**—a) To an ice-chilled solution of methylmagnesium iodide prepared from 1.52 g. of methyl iodide, 0.26 g. of magnesium and 15 cc. of absolute ether, 2.0 g. of Ic dissolved in 15 cc. of benzene was added under stirring. The mixture was stirred further for one

hour and decomposed with dilute sulfuric acid. After washing the organic solvent layer successively with water, 5% sodium hydrogen carbonate solution and water, the solvent was removed and 2.1 g. of red oil was obtained. The oil was redissolved in a mixture of benzene and petroleum ether and passed through a silica column. Three kinds of crystals were thereby obtained; 670 mg. of 2-methyl-3, 5, 7-tribromotropone (IIc), m. p. 62~64°C; 80 mg. of 3, 5-dibromo-6-methyltropolone (IV), m. p. 148~150°C; 20 mg. of 3, 5-dibromo-2-methoxy-6-methyltropone (V), m. p. 147~149°C.

b) To a solution of methylmagnesium iodide prepared from 3.8 g. of methyl iodide, 4.0 g. of Ic dissolved in benzene was added. Treatment of the reaction mixture as in a) gave 920 mg. of IIc, 120 mg. of IV, 75 mg. of V and 20 mg. of dibromodimethyltropone (VI).

IIc was recrystallized from a mixture of benzene and petroleum ether to give colorless needles, m. p. 64~65°C.

Found: C, 27.26; H, 1.88. Calcd. for $C_8H_5OBr_3$: C, 26.92; H, 1.41%.

Pyridine solution of IIc gives a reddish purple coloration with dilute sodium hydroxide solution.

IV was recrystallized from a mixture of benzene and petroleum ether to give colorless needles, m. p. 151.5~153°C. Benzene solution of IV gives red coloration with ferric chloride.

Found: C, 32.95; H, 2.54. Calcd. for $C_8H_6O_2Br_2$: C, 32.68; H, 2.06%.

V was recrystallized from a mixture of benzene and petroleum ether to give colorless needles, m. p. 151~152°C. Pyridine solution of V colors reddish purple with dilute sodium hydroxide solution.

Found: C, 35.48; H, 3.00. Calcd. for $C_9H_8O_2Br_2$: C, 35.06; H, 2.60%.

VI was recrystallized from ethanol to yield colorless needles, m. p. 116~117°C. Pyridine solution gives deep reddish purple coloration with dilute sodium hydroxide solution.

Found: C, 36.96; H, 3.03. Calcd. for $C_9H_8OBr_2$: C, 36.98; H, 2.73%.

**Reaction of 2-Methyl-3, 5, 7-tribromotropone (IIc) and Alkali.**—Similar treatment of IIc with 2 N sodium hydroxide solution as in the case of IIa gave colorless crystals (IIIc), m. p. 195~197°C.

Found: C, 33.09; H, 2.36. Calcd. for $C_8H_6O_2Br_2$: C, 32.68; H, 2.06%.

IIIc was debrominated to *o*-toluic acid, m. p. 100~102°C.

**Debromination of 3,5-Dibromo-6-methyltropolone (IV).**—Catalytic reduction of 40 mg. of IV dissolved in 6 cc. of methanol, in the presence of 50 mg. of sodium acetate and 20 mg. of 5% palladium-charcoal resulted in absorption of 6 cc. of hydrogen. After removal of the catalyst by filtration, the solvent was removed and the crystalline residue was recrystallized from petroleum ether to give colorless crystals, m. p. 70~72°C. These crystals showed no depression at the melting point on admixture with 4-methyltropolone (VII).

**Acid Hydrolysis of 3, 5-Dibromo-2-methoxy-6-methyltropone (V).**—A suspension of 18 mg. of V in a mixture of 0.5 cc. of acetic acid and 0.1 cc. of hydrobromic acid (sp. g.=1.48) was heated on a water bath for one hour. Addition of water separated 14 mg. of colorless crystals, m. p. 150~151°C. These crystals showed no depression at the melting point on admixture with 3, 5-dibromo-6-methyltropolone (IV).

**Reaction of 3, 5-Dibromo-2-methoxy-6-methyltropone (V) and Alkali.**—Similar treatment of V with dilute aqueous sodium hydroxide as in the case of IIa afforded colorless plates (VIII), m. p. 181~183°C, the melting point remaining unchanged on admixture of 4, 6-dibromo-*m*-toluic acid.

**Reaction of Hydrazine and the Debromination Product of 3, 5-Dibromo-2-methoxy-6-methyltropone (V).**—A solution of 60 mg. of V dissolved in 6 cc. of methanol was catalytically debrominated with the addition of 50 mg. of sodium acetate and 5% palladium-charcoal. After removal of the catalyst by filtration, the solution was diluted with water and extracted with benzene. The benzene layer was washed with water and the solvent was removed. The crystalline residue obtained was dissolved in 0.1 cc. of methanol and two drops of 80% hydrazine hydrate was added. The mixture was warmed on a water bath, cooled and the crystals thereby formed were recrystallized from benzene to give yellow needles, m. p. 121~123°C, which showed no depression at the melting point on admixture with 2-hydrazino-6-methyltropone (IX).

**Reaction of 3, 5, 7-Tribromotropolone and Methylmagnesium Iodide.**—To a solution of Grignard reagent prepared from 1.0 g. of methyl iodide, 0.72 g. of 3, 5, 7-tribromotropolone dissolved in dehydrated tetrahydrofuran was added under chilling with ice. After being stirred for five hours, the reaction mixture was decomposed with dilute sulfuric acid and extracted with chloroform. The chloroform extract was treated with dilute sodium carbonate solution by which 250 mg. of 3, 5, 7-tribromotropolone was recovered. The chloroform solution was further treated with dilute sodium hydroxide and the aqueous layer was acidified with dilute hydrochloric acid and extracted with benzene. Benzene extract afforded, after removal of the solvent, 130 mg. of dark red oil, chromatographic separation of which through an alumina column gave 40 mg. of crystals. Recrystallization from ethanol gave colorless plates, m. p. 133~134°C.

Found: C, 35.05; H, 3.25. Calcd. for $C_9H_{10}O_2Br_2$: C, 34.87; H, 3.25%.

These crystals showed no depression at the melting point on admixture of dimethyl 3, 5-dibromo-2-hydroxyphenyl carbinol prepared from the reaction of methyl 3, 5-dibromosalicylate and methylmagnesium iodide.

**Reaction of 3, 7-Dibromotropolone Methyl Ether (Ib) and Ethylmagnesium Iodide.**—To a solution of ethylmagnesium iodide, prepared from 3.2 g. of ethyl iodide, a solution of 3.0 g. of Ib in benzene was added with stirring at 0°C, and the reaction mixture was treated as in the reaction of Ib and methylmagnesium iodide. 3, 7-Dibromo-2-ethyltropone (IId) was obtained as colorless needles, m. p. 81~82°C. Yield, 730 mg.

Found: C, 37.28; H, 3.02. Calcd. for $C_9H_8OBr_2$: C, 36.98; H, 2.73%.

IId, when heated on a water bath for three hours,

with the addition of dilute aqueous solution of sodium hydroxide, was rearranged to give colorless plates (IIId), m. p. 100~101°C.

Found: C, 47.10; H, 4.00. Calcd. for $C_9H_9O_2Br$: C, 47.18; H, 3.96%.

IIId was catalytically debrominated to 2-ethylbenzoic acid (IIIe), m. p. 64~65°C.

**Reaction of 3, 5, 7-Tribromotropolone Methyl Ether (Ic) and Ethylmagnesium Iodide.**—To a solution of ethylmagnesium iodide, prepared from 1.68 g. of ethyl iodide, 2.0 g. of Ic in benzene was added. After being stirred for one hour under ice-chilling, the reaction mixture was treated as in the case of Ic and methylmagnesium iodide. With the recovery of 350 mg. of 3, 5, 7-tribromotropolone, 1.7 g. of dark red oil was obtained. This oil was dissolved in a mixture of benzene and petroleum ether and passed through a silica column, but none of each fraction of the eluents gave crystalline products.

The red oil (800 mg.), obtained from easily eluated fraction, was then warmed with a mixture of 1 cc. of ethanol and 1.5 cc. of 2 N sodium hydroxide for several minutes and chilled with ice. From the alkali-soluble part 220 mg. of dibromo-2-ethylbenzoic acid (IIIf) was obtained. Recrystallization from ethanol raised the melting point to 145~146°C.

Found: C, 35.01; H, 2.62. Calcd. for $C_9H_8O_2Br_2$: C, 35.10; H, 2.62%.

Alkali-insoluble part gave 300 mg. of ethyl dibromo-2-ethylbenzoate (IIIg). Recrystallization from ethanol raised the melting point to 45~46°C.

Found: C, 38.85; H, 3.57. Calcd. for $C_{11}H_{12}O_2Br_2$: C, 39.32; H, 3.60%.

IIIf was debrominated to 2-ethylbenzoic acid (IIIe), m. p. 63~64°C, and was esterified to IIIg with ethanol in the presence of concentrated sulfuric acid.

**2-Methyl-7-(*p*-toluidino)-tropone (Xa).**—A mixture of 50 mg. of 7-bromo-2-methyltropone (IIa) and 50 mg. of *p*-toluidine was heated at 120~130°C for ten minutes, diluted with benzene and the benzene solution was washed successively with dilute sulfuric acid and water. The crystalline residue, obtained upon removal of benzene, was recrystallized from ethanol to give yellow prisms, m. p. 75~76°C.

Found: N, 6.40. Calcd. for $C_{15}H_{15}ON$: N, 6.22%.

**3-Bromo-2-methyl-7-(*p*-toluidino)-tropone (Xb).**—Obtained from 3, 7-dibromo-2-methyltropone (IIb) and *p*-toluidine as in the case of Xa, and recrystallized from ethanol to give orange yellow prisms, m. p. 105~106°C.

Found: N, 4.89. Calcd. for $C_{15}H_{14}ONBr$: N, 4.59%.

**7-Anilino-2-methyltropone (Xc).**—Obtained from IIa and aniline as in the case of Xa as a red oil. Picrate of Xc was obtained by the usual method and recrystallized from methanol to give yellow microneedles, m. p. 159~160°C.

Found: N, 12.98. Calcd. for $C_{20}H_{16}O_8N_4$: N, 12.72%.

**7-Anilino-3-bromo-2-methyltropone (Xd).**—Obtained from IIb and aniline by the same method as above, and recrystallized from ethanol to give yellow crystals, m. p. 109~110°C.

Found: N, 4.95. Calcd. for $C_{14}H_{12}ONBr$: N, 4.83%.

**Reaction of 7-Bromo-2-methyltropone (IIa) and Hydrazine.**—To a solution of 50 mg. of IIa dissolved in 0.1 cc. of ethanol was added 50 mg. of 80% hydrazine hydrate. After being warmed slightly on a water bath, the reaction mixture was acidified with dilute sulfuric acid. Yellow crystals that separated were collected by filtration and recrystallized from ethanol and then from *n*-butanol to give yellow needles (XIa), m. p. 200~201°C. Ethanolic solution of XIa colors red with ferric chloride.

Found: C, 71.52; H, 5.91; N, 10.57. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%.

**Reaction of 3, 7-Dibromo-2-methyltropone (IIb) and Hydrazine.**—To a solution of 100 mg. of IIb dissolved in 0.6 cc. of benzene was added 100 mg. of 80% hydrazine hydrate and the whole was allowed to stand overnight. The crystals that separated out were recrystallized from ethanol to give colorless needles (XIIa), m. p. 157~158°C.

Found: N, 12.15. Calcd. for $C_8H_9ON_2Br$: N, 12.23%.

The filtrate was acidified with dilute sulfuric acid and the crystals that separated out were recrystallized from a mixture of dioxane and *n*-butanol to give yellow needles (XIb), m. p. 283~284°C.

Found: C, 45.10; H, 3.35. Calcd. for $C_{16}H_{14}O_2N_2Br_2$: C, 45.08; H, 3.31%.

**Reaction of 2-Methyl-3, 5, 7-tribromotropone (IIc) and Hydrazine.**—A solution of IIc in benzene was treated with hydrazine hydrate as in the case of IIb. The crystals obtained were recrystallized from ethanol to give colorless needles (XIIb), m. p. 175~176°C.

Found: N, 9.50. Calcd. for $C_8H_8ON_2Br_2$: N, 9.09%.

**4-Bromo-3-methyltropolone (XIIIa).**—A mixture of 100 mg. of IIb, 80 mg. of anhydrous sodium acetate and 1 cc. of glacial acetic acid was heated at 180~200°C for one hour. The solution was then diluted with water, warmed further for a half hour, extracted with benzene and the benzene solution was treated with dilute aqueous sodium hydroxide. Yellow sodium salt that separated out was collected by filtration and acidified with hydrochloric acid. XIIIa thereby liberated was recrystallized from ethanol to give pale brownish crystals, m. p. 100~102°C; yield was very poor (about 5 mg.). XIIIa gives red coloration with ferric chloride.

Found: C, 45.30; H, 3.27. Calcd. for $C_8H_7O_2Br$: C, 44.68; H, 3.28%.

**4, 6-Dibromo-3-methyltropolone (XIIIb).**—Obtained from 40 mg. of IIc as in the case of XIIIa and recrystallized from ethanol to give pale yellow needles, m. p. 121~123°C; yield was about 5 mg.

Found: C, 33.04; H, 2.59. Calcd. for $C_8H_6O_2Br_2$: C, 32.68; H, 2.06%.

The author wishes to express his sincere thanks to Professor T. Nozoe of Tohoku University for his guidance and encouragement throughout this work, as well as to Professor S. Seto, Assistant Professor Y. Kitahara and Assistant Professor T. Mukai of Tohoku University for their kind advices and suggestions. He is also

grateful to Miss K. Kato for the measurements of ultraviolet absorption spectra and to Mr. S. Ohyama and Miss A. Iwanaga for the elemental analyses.

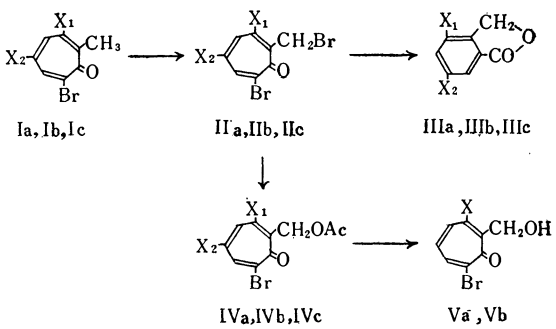
# *Syntheses and Reactions of 2-Bromomethyltropones*



By Katsuo KIKUCHI

(Received October 19, 1959)

Recently it was reported that tropone, 2-phenyltropone and several kinds of their bromine substituted compounds were comparatively easily brominated on their tropone nucleus through addition of bromine to their double bonds and subsequent dehydrobromination (and debromination in some instances), showing the unsaturated properties of the tropone nucleus[1,2].

In the present paper the bromination of 7-bromo-2-methyltropone (Ia), 3, 7-dibromo-2-methyltropone (Ib) and 2-methyl-3, 5, 7-tribromotropone (Ic)[3] was undertaken. The aim of the experiment of this paper is twofold; (1) 2-methyltropone is considered to be a vinylog of methylketone and accordingly it would be important to examine whether bromination occurs on a tropone nucleus or on a methyl group; and (2) 2-bromomethyltropones, if they were obtained, would be easily converted to 2-hydroxymethyltropones, the key intermediates for the preparation of 2-formyltropones.

Application of one molecular equivalent of bromine or *N*-bromosuccinimide on Ia afforded pale yellow needles (IIa) in a good yield. Although attempted conversion of IIa to phthalide (IIIa) directly by treating with alkali failed, the structure of IIa was proved to be 7-bromo-2-bromomethyltropone as described later. Similarly, both Ib and Ic, when treated with bromine, afforded 2-bromomethyl-3, 7-dibromotropone (IIb) and 2-bromomethyl-3, 5, 7-tribromotropone (IIc), respectively. Treatment of IIb with dilute alkali gave 4-bromophthalide (IIIb)[4], which on reduction over palladium charcoal aforded IIIa. Similar treatment of IIc with alkali afforded 4, 6-dibromophthalide (IIIc), whose debromination gave IIIa.

Bromination of IIa gave pale yellow needles (IId), the structure of which is not clear yet. On the other hand, further bromination of IIb was found to be difficult even under prolonged heating on a water bath. This fact is rather interesting from the fact that 3, 7-dibromo-2-phenyltropone was easily brominated to give 2-phenyl-3, 5, 7-tribromotropone[1]. Ultraviolet absorption spectra of IIa, IIb and IIc were shown in Fig. 1.

Although the preparations and reactions of

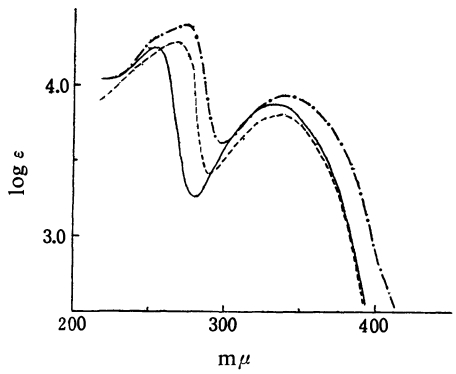


Fig. 1. Ultraviolet absorption spectra of IIa(——), IIb (----) and IIc(-·-·-) in methanol.

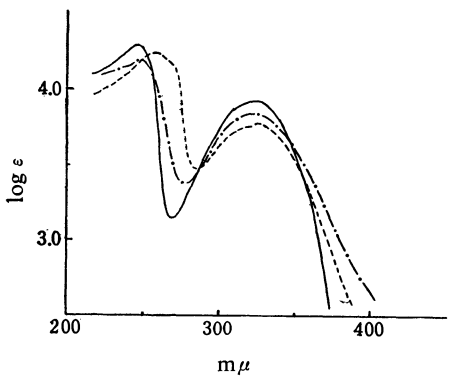
1) T. Mukai, *Sci. Repts. Tohoku Univ., Ser.* I, **38**, 280 (1954).
2) T. Nozoe, T. Mukai and K. Takase, ibid., **39**, 164 (1956).
3) K. Kikuchi, This Bulletin, **33**, 628 (1960).
4) J. Tirouflet, *Bull. soc. sci. Bretagne, Spec. No.*, **26**, 7 (1951); *Chem. Abstr.*, **47**, 8693 (1953).

hydroxymethyltropolone[5-7] and formyltropolone[7,8] derivatives have been examined in some detail, 2-hydroxymethyltropone and 2-formyltropone derivatives have remained unknown. Therefore, the synthesis of these materials were next attempted.

Application of silver acetate on IIa in acetic acid gave 2-acetoxymethyl-7-bromotropone (IVa) which, when heated with a mixture of dilute hydrochloric acid and ethanol, easily underwent hydrolysis to give 7-bromo-2-hydroxymethyltropone (Va). Va showed no coloration with ferric chloride characteristic of tropolone. The ultraviolet absorption spectrum of Va reveals that it retains tropone nucleus as shown in Fig. 2. Treatment of Va with dilute alkali gave IIIa though in a poor yield. These facts indicate that Va has the expected structure and that bromination of Ia has undoubtedly occurred on a side chain methyl group as described before.

Similar treatment of IIb with silver acetate or sodium acetate afforded 2-acetoxymthyl-3, 7-dibromotropone (IVb), which was hydrolyzed to 3, 7 - dibromo - 2 - hydroxymethyltropone (Vb). Similarly, treatment of IIc with silver acetate gave 2-acetoxymethyl-3, 5, 7-tribromotropone (IVc). Acid hydrolysis of IVc, however, resulted in the formation of IIIc. This result is curious compared with the fact that 2-halotropones usually do not rearrange to aromatic acids in acidic media.



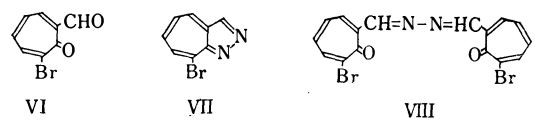


Fig. 2. Ultraviolet absorption spectra of Va(——), Vb(----) and VI(-·-·-) in methanol.

Mild oxidation of Va with activated manganese dioxide in benzene[8] or with chromium trioxide in a mixture of acetic acid and acetic anhydride afforded 7-bromo-2-formyltropone (VI). VI reduces ammoniacal silver nitrate solution and Fehling's solution and gives phenylhydrazone.

An attempted synthesis of 8-bromo-1, 2-diazaazulene (VII) by treating VI with hydrazine has not succeeded, and the only product was yellow crystals which was assumed to be symmetrical azine (VIII) of VI from its analytical value.

VI VII VIII

## Experimental

**7-Bromo-2-bromomethyltropone (IIa).**—a) To a solution of 200 mg. of 7-bromo-2-methyltropone (Ia) in 1.5 cc. of acetic acid was added 170 mg. of bromine and the mixture was heated on a water bath for 30 min. and cooled. The crystals that separated were collected by filtration. Yield, 80 mg. Mother liquor was diluted with water, extracted with benzene and the benzene layer was washed successively with water, 2 N sodium carbonate and water. Removal of the solvent afforded second crop of 60 mg. of crystals. These crystals were combined and recrystallized from ethanol to give colorless needles (IIa), m. p. 103~104°C.

Found: C, 34.50; H, 2.07. Calcd. for $C_8H_6OBr_2$: C, 34.57; H, 2.18%.

b) A mixture of 520 mg. of Ia, 520 mg. of *N*-bromosuccinimide and 6 cc. of carbon tetrachloride was heated to reflux for four and one-half hours under irradiation. The crystals were filtered, washed well with benzene and the combined solution was washed with water. Removal of the solvent provided 500 mg. of crystals, m. p. 97~101°C. These crystals showed no depression of the melting point on admixture with IIa obtained by the method of a).

**2-Bromomethyl-3, 7-dibromotropone (IIb).**—A mixture of 100 mg. of 3, 7-dibromo-2-methyltropone (Ib), 0.8 cc. of acetic acid and 60 mg. of bromine was heated on a water bath for about 30 min. From the reaction mixture 110 mg. of IIb was obtained as pale yellow needles of m. p. 141~143°C. Recrystallization from ethanol raised the melting point to 142~143°C.

Found: C, 27.26; H, 1.88. Calcd. for $C_8H_5OBr_3$: C, 26.92; H, 1.41%.

**2-Bromomethyl-3, 5, 7-tribromotropone (IIc).**—To a solution of 200 mg. of 2-methyl-3, 5, 7-tribromotropone (Ic) dissolved in 1 cc. of acetic acid was added 100 mg. of bromine, and the mixture was heated on a water bath for about 30 min. On cooling, 220 mg. of IIc was obtained as pale yellow plates of m. p. 104~106°C. Recrystallization from ethanol raised the melting point to 107~108°C.

Found: C, 22.13; H, 1.14. Calcd. for $C_8H_4OBr_4$: C, 22.05; H, 0.93%.

**Bromination of 7-Bromo-2-bromomethyltropone (IIa).**—A mixture of 50 mg. of IIa and 35 mg. of bromine in 0.3 cc. of acetic acid was heated on a water bath for about 30 min. and cooled. The crystals that separated were collected by filtration and recrystallized from ethanol to give pale yellow needles

5) T. Nozoe, T. Mukai and K. Matsui, *Proc. Japan Acad.*, 27, 561 (1951).
6) T. Nozoe, T. Mukai and K. Takase, *Sci. Repts. Tohoku Univ., Ser.* I, 36, 40 (1952).
7) S. Seto and K. Ogura, This Bulletin, 32, 493 (1959).
8) E. Sebe and S. Matsumoto, *Sci. Repts. Tohoku Univ., Ser.* I, 38, 308 (1954).

(IId), m. p. 131~133°C. Yield, 45 mg. Further recrystallization from ethanol raised the melting point to 133~134°C.

Found: C, 27.56; H, 1.76. Calcd. for $C_8H_5OBr_3$: C, 26.92; H, 1.41%.

Action of dilute aqueous sodium hydroxide on IId gave only unidentified black resinous matter. Attempted debromination of side chain bromine with zinc and acetic acid also failed.

**Attempted Bromination of 2-Bromomethyl-3, 7-dibromotropone (IIb).**—A mixture of 50 mg. of IIb and 30 mg. of bromine in 0.4 cc. of acetic acid was heated for two hours on a water bath in a closed vessel. On cooling, 20 mg. of pale yellow crystals, m. p. 136~140°C was obtained and identified as starting material by the mixture melting point method. Mother liquor, on being diluted with water, gave pale yellow crystals of m. p. 113~125°C, purification of which was difficult.

**Reaction of 2-Bromomethyl-3, 7-dibromotropone (IIb) and Alkali.**—A mixture of 100 mg. of IIb and 1 cc. of 1 N sodium hydroxide solution was heated on a water bath for one hour, treated with active carbon and filtered. Acidification of the filtrate with dilute hydrochloric acid gave 35 mg. of 4-bromophthalide (IIIb) as colorless plates of m. p. 94~97°C. Recrystallization from cyclohexane raised the melting point to 98~99°C. Reported melting point of IIIb is 103~104°C.

Found: C, 45.39; H, 2.43. Calcd. for $C_8H_5O_2Br$: C, 45.10; H, 2.37%.

Catalytic debromination of IIIb afforded phthalide (IIIa), m. p. 70~71°C, undepressed of melting point on admixture with authentic sample.

**Reaction of 2-Bromomethyl-3, 5, 7-tribromotropone (IIc) and Alkali.**—A mixture of 100 mg. of IIc, 0.6 cc. of 1 N aqueous sodium hydroxide and 0.1 cc. of ethanol was treated as in the case of IIb, and 4, 6-dibromophthalide (IIIc) thereby obtained, was recrystallized from dilute ethanol to give colorless needles, m. p. 112~113°C.

Found: C, 33.15; H, 1.51. Calcd. for $C_8H_4O_2Br_2$: C, 32.91; H, 1.38%.

Debromination of IIIc afforded IIIa, m.p. 71~72°C.

**2-Acetoxymethyl-7-bromotropone (IVa).**—To a solution of 150 mg. of 7-bromo-2-bromomethyltropone (IIa) dissolved in 1.2 cc. of acetic acid 150 mg. of silver acetate was added, and the mixture was heated on a water bath for 15 min. with occasional stirring and filtered. Acetic acid was removed from the filtrate by evaporation, and the residue was extracted with benzene. The benzene solution was washed with water and the solvent evaporated. The crystals thereby obtained were recrystallized from a mixture of benzene and petroleum ether to give colorless needles (IVa), m. p. 108~110°C. Yield, 130 mg. Further recrystallization raised the melting point to 110~111°C.

Found: C, 46.30; H, 3.16. Calcd. for $C_{10}H_9O_3Br$: C, 46.72; H, 3.53%.

**2-Acetoxymethyl-3,7-dibromotropone (IVb).** — a) To a solution of 200 mg. of 2-bromomethyl-3, 7-dibromotropone (IIb) dissolved in 2 cc. of acetic acid was added 160 mg. of sodium acetate, the mixture was heated on a water bath for one and one-half hours and filtered. The filtrate was diluted with water, extracted with benzene, and the benzene extract was washed with water and concentrated. The crystals thereby obtained were recrystallized from ethanol to give colorless crystals (IVb), m. p. 84~87°C. Yield, 160 mg. Further recrystallization from ethanol raised the melting point to 88~89°C.

Found: C, 35.90; H, 2.30. Calcd. for $C_{10}H_8O_3Br_2$: C, 35.74; H, 2.40%.

b) Similar treatment of 200 mg. of IIb with 150 mg. of silver acetate as in the case of IIa afforded 150 mg. of colorless crystals of m. p. 85~88°C, undepressed of the melting point on admixture with IVb obtained in a).

**2-Acetoxymethyl-3, 5, 7-tribromotropone (IVc).**—Similar treatment of 300 mg. of 2-bromomethyl-3, 5, 7-tribromotropone (IIc) with 180 mg. of silver acetate as in the case of IIa afforded 240 mg. of IVc, m. p. 87~90°C. Recrystallization from ethanol gave colorless needles, m. p. 88~90°C.

Found: C, 28.59; H, 1.95 Calcd. for $C_{10}H_7O_3Br_3$; C, 28.95; H, 1.70%.

**7-Bromo-2-hydroxymethyltropone (Va).**—A solution of 330 mg. of 2-acetoxymethyl-7-bromotropone (IVa) dissolved in a mixture of 3 cc. of ethanol and 1.5 cc. of 2 N hydrochloric acid was heated to reflux for 50 min. Evaporation of most of ethanol afforded 260 mg. of pale brown crystals (Va), m. p. 116~118°C (decomp.). Recrystallization from dilute ethanol gave colorless needles, m. p. 120~121°C (decomp.).

Found: C, 44.92; H, 3.74. Calcd. for $C_8H_7O_2Br$: C, 44.68; H, 3.28%.

**Reaction of 7-Bromo-2-hydroxymethyltropone (Va) and Alkali.**—A mixture of 40 mg. of Va and 0.5 cc. of 1 N sodium hydroxide solution was heated on a water bath for 30 min. The resulting clear solution was acidified with hydrochloric acid, treated with charcoal, filtered while hot and cooled. Colorless plates, m. p. 69~71°C, thereby obtained, showed no depression of melting point on admixture with phthalide.

**3, 7-Dibromo-2-hydroxymethyltropone (Vb).** — A solution of 100 mg. of 2-acetoxymethyl-3, 7-dibromotropone (IVb) dissolved in a mixture of 1 cc. of ethanol and 0.5 cc. of 2 N hydrochloric acid was heated on a water bath for one hour. Similar treatment of the reaction mixture as in the case of Va afforded 70 mg. of Vb, m. p. 100~103°C (decomp.). Recrystallization from ethanol gave colorless crystals, m. p. 109~110°C (decomp.).

Found: C, 33.08; H, 2.20. Calcd. for $C_8H_6O_2Br_2$: C, 32.68; H, 2.06%.

**Acid Hydrolysis of 2-Acetoxymethyl-3,5,7-tribromotropone (IVc).**—A solution of 300 mg. of IVc dissolved in a mixture of 2 cc. of ethanol and 1 cc. of 2 N hydrochloric acid was heated on a water bath for two hours and cooled. The crystals thereby obtained were recrystallized from ethanol to give colorless needles, m. p. 112~113°C, which showed no depression of melting point on admixture with IIIc obtained by the action of alkali on IIc.

**7-Bromo-2-formyltropone (VI).**—a) To a solution of 200 mg. of 7-bromo-2-hydroxymethyltropone (Va) dissolved in 10 cc. of benzene was added 800 mg. of active manganese dioxide, and the mixture was stirred for two hours at room temperature and filtered.

Evaporation of the solvent afforded 100 mg. of VI, m. p. 147~149°C (decomp.). Recrystallization from ethanol gave yellow needles, m. p. 148~150°C (decomp.).

Found: C, 45.05; H, 2.74. Calcd. for $C_8H_5O_2Br$: C, 45.10; H, 2.37%.

b) To a suspension of 100 mg. of Va in a mixture of 0.3 cc. each of acetic acid and acetic anhydride was added 0.3 cc. of chromium trioxide solution (prepared by dissolving 1 g. chromium trioxide in a mixture of 5 cc. each of acetic acid and acetic anhydride) at room temperature. The solution was warmed at 35~45°C for 50 min., cooled and the crystals that separated out were collected by filtraton. Yield, 40 mg. Recrystallization from ethanol gave yellow needles, m. p. 146°C (decomp.).

**Phenylhydrazone of 7-Bromo-2-formyltropone (VI).**—To a solution of 50 mg. of VI dissolved in 2 cc. of ethanol was added a solution of 40 mg. of phenylhydrazine hydrochloride in 0.3 cc. of water at room temperature. Phenylhydrazone of VI was obtained as purple needles, m. p. 142°C (decomp.). It was difficult to recrystallize from usual organic solvents.

Found: C, 55.51; H, 3.53; N, 9.15. Calcd. for $C_{14}H_{11}ON_2Br$: C, 55.46; H, 3.66; N, 9.24%.

**Azine (VIII) of 7-Bromo-2-formyltropone (VI).**—To a solution of 50 mg. of VI dissolved in 2.5 cc. of ethanol was added a solution of 20 mg. of hydrazine hydrochloride in 0.3 cc. of water at room temperature. Azine (VIII) was obtained as yellow crystals, m. p. 147~148°C (decomp.), which were difficult to recrystallize from usual organic solvents.

Found: C,45.72; H, 2.47; N, 6.49. Calcd. for $C_{16}H_{10}O_2N_2Br_2$: C, 45.55; H, 2.39; N, 6.64%.

The author wishes to express his sincere thanks to Professor T. Nozoe of Tohoku University for his guidance and encouragement throughout this work, as well as to Professor S. Seto, Assistant Professor Y. Kitahara and Assistant Professor T. Mukai of Tohoku University for their kind advice and suggestions. He is also grateful to Miss K. Kato for the measurements of ultraviolet absorption spectra and to Mr. S. Ohyama and Miss A. Iwanaga for the elemental analyses.

# *Inorganic Extraction Studies on the System between Tri-n-butyl Phosphate* and Hydrochloric Acid*

By Tomitaro ISHIMORI, Kenju WATANABE and Eiko NAKAMURA

(Received October 28, 1959)

During the course of the solvent extraction studies on fission products and actinide elements with TBP, it was felt that the behavior of other common elements ought to be clarified. In the present paper, is studied the behavior of about fifty chemical elements, ranging from sodium to curium, in the TBP-hydrochloric acid system.

## Experimental

**Sources of Materials.**—Tributyl phosphate was purified in the usual way[1-3], and used without any dilution. Hydrochloric acid solutions were prepared by diluting commercial concentrated hydrochloric acid. The acidity was determined volumetrically if necessary.

Table I[4-8] shows the sources of radioactive tracers. Most of the imported tracers were used as received, whereas Y-90, Nb-95[7] and Ra-224 were prepared from imported Sr-90, Zr-95 and Th-228, respectively. Many other tracers were prepared by irradiating suitable targets in JRR-1. In order to avoid complication as far as possible, very pure materials were used as the targets. The subsequent chemical treatments were carried out if necessary; however, in many cases targets were simply dissolved in acids and converted into chloride solutions.

The radiochemical purities were checked by $\gamma$-ray spectrometry, tracing the decay and/or $\beta$ absorption. Nickel and cadmium tracers contained some radiochemical impurities. Accordingly these tracers were measured at photopeaks using a $\gamma$-spectrometer.

Inorganic extraction,
in 100% TBP—HCl system
TBP extraction of,
Na, Mg, Al, $PO_4$, $SO_4$, Cl, K, Ca, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ga, Ge, As, Se, Br, Rb, Sr, Y, Zr, Nb, Mo, Tc, Ru, Pd, Ag, Cd, In, Sn, Sb, Te, I, Cs, Ba, La, Ce and other rare earth elements, Hf, Ta, W, Re, Os, Ir, Pt, Au, Hg, Tl, Pb, Bi, Ra, Th, Pb, Bi, Ra, Th, Pa, U, Np, Am and Cm

The specific activity of these radiochemical tracers were higher than $10^4$ cpm/100 microgram. Although in some cases the oxidation states and the chemical forms of the tracer could not be clearly defined, for the most part familiar chemical forms were chosen as far as possible.

Distribution ratios were determined radiometrically in the ordinary way[2,3,9].

## Results and Discussion

The results obtained are summarized in Fig. 1 as a series of graphs of $\log K_d$ vs. N HCl, where $K_d$ is the distribution ratio and N the molarity. Fig. 1 was compiled from some published and unpublished results. Curves for scandium[2], zirconium[2], some of the rare earth elements[10,11], thorium[2] and some other actinide elements[10,11] are taken from the work of Peppard and his coworkers. Data for zirconium[12], ruthenium[13], germanium[14], selenium[14] and tellurium[14] are taken from the observations of Umezawa et al., Kimura and Inarida. The curves for lead, bismuth, uranium, americium and curium were obtained by one of the present authors (T. Ishimori) during his stay in the Argonne National Laboratory, Lemont, Ill. U.S.A. Finally the three curves for neptunium (IV), (V) and (VI) are quoted from the previous paper[9]. The curves for iron, cobalt, nickel, copper, zinc, indium and uranyl obtained by Irving et al.[15] are added to Fig. 1 with broken lines. Morris and Bell[16] gave the acid dependence curve for cobalt which coincides with that of the present authors. It is likely that permanganate and chromate have fairly high $K_d$ values. However, their values were not plotted because of the rapid reduction of these ions in the system.

As Fig. 1 shows, the four alkali metal elements behave in a similar way, showing always very low $K_d$ values. Halogen elements keep their $K_d$ values practically constant in the higher acidity range over 4 N. There are some similarities in the shapes of the acid dependence curves for zinc, cadmium and bivalent mercury; ruthenium, palladium, osmium and platinum; and tervalent arsenic and antimony, respectively.

The $K_d$ values of scandium, yttrium and lanthanum increase with their decreasing atomic number, $Z$, at higher acidity range. A similar relationship is seen more clearly among quadrivalent zirconium, hafnium and thorium. In these cases, the element of smaller $Z$ has higher $K_d$ value. On the other hand, the extractability of alkali metal elements or the group of zinc, cadmium and bivalent mercury, does not depend on the value of $Z$. Further, $K_d$ values of chloride, bromide and iodide increase with their increasing atomic number.

Fig. 2 gives the adsorption behavior of the elements on an anion exchange resin from hydrochloric acid solutions. The curves in Fig. 2 are rewritten in a similar scale with that of Fig. 1 based on the original figure proposed by Kraus and Nelson[17]. As they did not give distribution coefficients, $D_v$, less than 1, the curves below $D_v=1$ are not drawn in Fig. 2.

The shapes of the acid dependence curve given in Figs. 1 and 2 are very similar for most elements. The high $K_d$ value of scandium is a rare exception. It is not understandable that the solvent-extraction behavior of tervalent antimony resembles the ion exchange behavior of quinquevalent antimony.

It is likely that the resemblance discussed above shows similar mechanisms of distribution between the anion exchange and the extraction with TBP.

The $K_d$ values at 12 N hydrochloric acid were plotted against the atomic number, $Z$, in Fig. 3. The figure shows that the $K_d$ values vary regularly to some extent, giving two peaks for one long period of the periodic table. The values for lanthanide and tervalent actinide elements are quoted from the work of Peppard et al.[3,10,11] who found the effect of the half-filled shell in the relationship between $K_d$ and $Z$.

The broken lines in Fig. 3 show the relationship between $D_v$ values of anion exchange and $Z$. A close similarity is seen here again between the behaviors of the solvent extraction and the ion exchange.

Fig. 4 gives $K_d$ values in the 100% TBP-hydrochloric acid system. This will be convenient for checking the possibility and efficiency

of a mutual separation of a couple of elements chosen arbitrarily. These $K_d$ values are found with tracers of fairly high specific activities. Therefore, optimum conditions of a separation found in Fig. 4 will fit farily well in a tracer scale chemical separation; however, some caution must be exercised in macro-scale separations. For example, $K_d$ for silver of more than 10 at 1 N acidity, is not applicable in a macro-scale separation because of the formation of insoluble silver chloride. Some examples are given in the following, showing how to utilize the $K_d$ values obtained.

## Applications

**a) Preparation of Y-90 (or La-140).**—The solvent extraction behavior of strontium, yttrium, barium, lanthanum and iron in the 100% TBP-hydrochloric acid system are given in Fig. 5. The curves of Fig. 5. show that the direct separation of Y-90 (or La-140) from Sr-90 (or Ba-140) is not easy. However, the difference between $K_d$ values for iron and yttrium (or lanthanum) is so great that yttrium (or lanthanum) is separated from iron very easily. Yttrium-90 (or La-140) is separated from Sr-90 (or Ba-140) by the carrying down with ferric hydroxide. The precipitate is dissolved in 3 N hydrochloric acid. The TBP extraction

The data for thorium was taken from the work of Peppard et al.

removes iron, leaving Y-90 (or La-140) carrier free in the acid solution.

**b) Radiochemical Purification of Pt-197.**— The difference of $K_d$ values between gold and platinum is shown in Fig. 6. As is seen in the figure, $K_d$ values of platinum are too high to keep platinum in the acid quantitatively. Therefore, TBP is diluted with toluene in order to make $K_d$ values for both elements lower. The TBP (1 : 2) works well for the separation of gold from platinum at 1 or 12 N hydrochloric acid.

Irradiated platinum containing Pt-197 and Au-199 is dissolved in aqua regia, and converted into 1 or 12 N hydrochloric acid solution. Extraction of Au-199 with TBP (1 : 2) brings about an aqueous solution of purified Pt-197 tracer. Gold in copper is removed similarly with diluted TBP from 1 N hydrochloric acid solution. (Fig. 6).

**c) Milking of Th-234 from U-238.** — The difference between $K_d$ values for thorium and uranyl ion is shown in Fig. 7.

In the 6 N hydrochloric acid—TBP system uranyl ion is extracted into TBP, whereas thorium remains in the aqueous solution. The TBP solution of uranyl chloride is used conveniently as a cow. In this case the addition of a small amount of bromine prevents the photoreduction of uranyl ion.

**d) Milking of Ra-244 from Th-228.**—As is shown in Fig. 7, radium is not extracted from 12 N hydrochloric acid, while thorium is extractable with a $K_d$ of about 10. Accordingly radium is left in the acid solution after several extractions of thorium with TBP. Both Pb-212 and Bi-212 remain in the acid solution with Ra-224.

# *The Aconite Alkaloids. XXXIII*. On Lucidusculine. III***

By Takashi AMIYA

(Received October 27, 1959)

In the previous reports some derivatives of lucidusculine (I), $C_{24}H_{35}O_4N$, have been reported and the extended formula of compound I has been proposed[2,3].

Lately the author has investigated the behavior of compound I toward various oxidizing agents, and the previously proposed partial formula[2] is further extended.

Oxidation of compound I with 3% hydrogen peroxide gave lucidusculine *N*-oxide-a (II), $C_{24}H_{35}O_5N \cdot H_2O$, m. p. 191°C (decomp.) in a poor yield. From the procedure for its preparation, compound II seems to contain water of crystallization[4-7].

Further, in order to obtain an epoxide derivative of compound I, perbenzoic acid oxidation has been performed. This oxidation has not given the results expected in the cases of Senecio alkaloids[8] and atisine derivatives[9]. Compound I reacted with only one mole of perbenzoic acid under different conditions and an *N*-oxide, lucidusculine *N*-oxide-b (III), $C_{24}H_{35}O_5N \cdot 1/2H_2O_2$***, m. p. 200°C (decomp.), was yielded. This reaction proceeds similar to that of strychnine[10]. Compound III lost hydrogen peroxide of crystallization on standing for several months, being converted into lucidusculine *N*-oxide-c (IV), $C_{24}H_{35}O_5N$, m. p. 209°C**** (decomp.)[5]. Infrared spectrum of compound

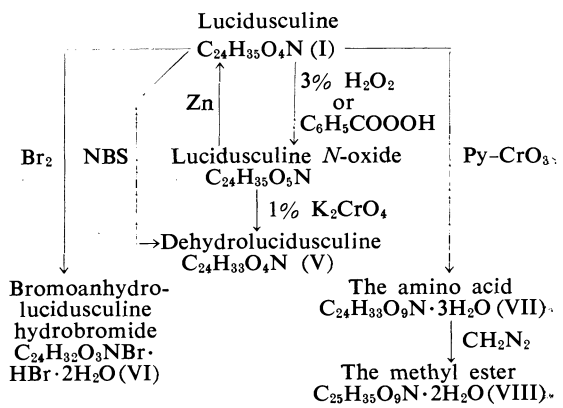
IV showed a band at 10.47$\mu$ characteristic of an *N*-oxide group[11,12]. Its ultraviolet absorption spectrum showed only end absorption.

Compound III was readily reduced with zinc dust and dilute sulfuric acid to compound I normally.

Oxidation of compound I with *N*-bromosuccinimide afforded dehydroluciduscuiline (V), $C_{24}H_{33}O_4N$, m. p. 175~180°C, with loss of two hydrogens. Its infrared spectrum showed sharp bands at 10.15 and 11.34$\mu$ which were probably indicative of a cyclic ether[13,14]. Compound I lacks the bands corresponding to these (10.15 and 11.34$\mu$) of compound V. It is, therefore, probable that the reaction proceeds as in the case of each delcosine[13] and delsoline[14] with formation of a cyclic carbinolamine internal ether between carbinolamine hydroxyl and one of the hydroxyls in compound I. This may be supported by the fact mentioned below that luciduscuiline *N*-oxide was found to change to compound V. Its ultraviolet absorptions spectrum showed end absorption.



Strychnine *N*-oxide has been rearranged to a carbinolamine, pseudostrychnine[6]. Crow[15] mentioned the transformation of sparteine *N*-oxide to three possible carbinolamines. Therefore compound III was treated under the same conditions as in the case of the isomerization of strychnine *N*-oxide. Although an expected carbinolamine was not obtained, compound V was yielded. From these facts, it is supposed that an initially formed carbinolamine is changed to compound V with loss of one mole of water and with simultaneous formation of a carbinolamine internal ether.

In contrast to isoatisine[9], on bromination of compoud I no expected dibromo derivative was obtained. In this case a hydrobromide of a monobromo derivative, bromoanhydrolucidusculine hydrobromide (VI), $C_{24}H_{32}O_3NBr \cdot HBr \cdot 2H_2O$, m. p. 210°C (decomp.) was produced. Thus, the behavior of compound I on bromination is noted. Its infrared absorption spectrum showed the disappearance of a band which was characteristic of a terminal methylene group and corresponded to that (11.07$\mu$)[16] of compound I[3]. From the observation of the molecular formula and its infrared spectrum, compound VI is perhaps yielded from an intermediate dibromo derivative, which is produced from compound I by the normal addition of one mole of bromine to a terminal methylene group, with simultaneous elimination of one mole each of water and hydrogen bromide. The ultraviolet absorption spectrum of compound VI does not correspond to that of a conjugated diene (Fig. 1). Although some interpretation of this observation might be presented, it will be left to a later occasion.

The oxidation of some of the aconite alkaloids, viz., atisine, isoatisine, kobusine and hypognavine with chromium trioxide-pyridine complex has been reported to give $\alpha,\beta$-unsaturated ketone bases[19-21]. Furthermore, delpheline and lucaconine have been shown to be oxidized to lactams[22,23] by the same reagent.

On the other hand, the action of chromium trioxide-pyridine complex on compound I yielded an amino acid, $C_{24}H_{33}O_9N \cdot 3H_2O$, (VII), which showed no definite m. p. nor d. p., and gradually

16) From the observation of infrared spectra of luciculine[2,8] and isoluciculine[17], of two bands near wavelength 11$\mu$ the one at 11.02$\mu$ corresponds to that of the terminal methylene group of luciculine, whilst the other at 11.27 $\mu$[2,3] does not correspond. Normally, each of the compounds of the type $R_1R_2C=CH_2$[18] shows a band due to a terminal methylene group near this wavelength (11.27 $\mu$). This shift from the normal wavelength is explicable by the fact that luciculine includes an allyl alcohol moiety, HO—C(H)—C=$CH_2$[17] which contains a polar group in the $\alpha$-carbon atom to the double bond[18]. Similarly, a band characteristic of a terminal methylene group of compound I is not that at 11.26 $\mu$[3] but that at 11.07 $\mu$. Furthermore, luciduscuiline diacetate, luciculine methiodide, isomesoluciculine and bromolucidusculine cyanamide[3] show the bands attributable to the terminal methylene groups at 11.07, 10.98, 11.03 and 10.95 $\mu$ in the infrared spectra, respectively.

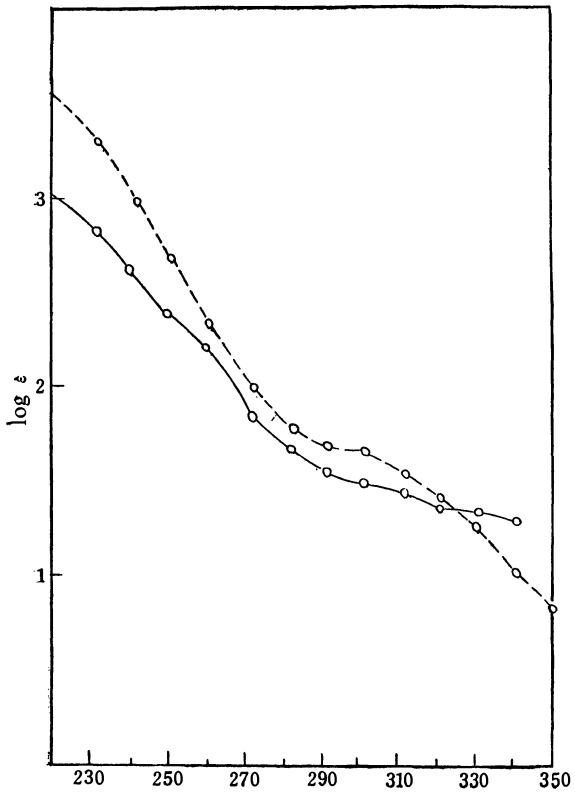

Fig. 1.

The amino acid (VII) --○--○--
Bromoanhydroluciduscuiline hydrobromide (VI) —○—○—

became black above 350°C. It is soluble in methanol and water but insoluble in ethanol and almost all other organic solvents. Although it showed no characteristic absorption maximum of a ketone carbonyl group in the ultraviolet spectrum (Fig. 1), its infrared spectrum showed a strong absorption near 5.85$\mu$, indicating the presence of a ketone carbonyl group in a six-membered ring.

Methylation of compound VII with diazomethane gave a methyl ester (VIII), $C_{25}H_{35}O_9N \cdot 2H_2O$, which gradually swelled with decomposition near 288°C. The ultraviolet spectrum of compound VIII is similar to that of compound VII.

The oxidation of compound I with this milder reagent appears to convert the primary hydroxyl group to a carboxyl group as in the case of oxidation of a dodecahydrophenanthrene derivative[24], and probably the secondary one to the above mentioned ketone carbonyl group. Furthermore, the examination of the molecular formula, $C_{24}H_{33}O_9N \cdot 3H_2O$, and the infrared absorption spectrum of compound VII suggest that this oxidation reaction may cause formation of four new hydroxyl groups. Two of them seem to be introduced into the terminal methylene group as a vicinal glycol system. This is supported by the infrared absorption specteum of compound VII. The spectrum does not indicate a band due to a terminal methylene group near 11$\mu$.

These results indicate that, of two hydroxyl groups in compound I, one is primary, and the other is secondary and is attached to a carbon atom in a six-membered ring.

Subsequently, the previously proposed partial formula[2] of I may be further summarized as[25],

$C_{16}H_{20}$ < $CH_2OH$, $OCOCH_3$, $>CH(OH)$, $>N\text{-}C_2H_5$, $>C{=}CH_2$

Lucidusculine (I)

## Experimental

**Lucidusculine *N*-Oxide-a (II).**—Powdered lucidusculine (0.5 g.) was suspended in 50 cc. of about 3% hydrogen peroxide and stirred under warming. After one hour the base was dissolved, and the resulting solution was further stirred for 1.5 hr. without warming. The excessive hydrogen peroxide was then decomposed in contact with a small quantity of freshly prepared manganese dioxide. After removal of the manganese dioxide, the solution was further decolorized with active carbon. After removal of the active carbon by filtration, the solution was evaporated to dryness in vacuo, and the residue was crystallized from aqueous methanol. It was recrystallized from methanol. It showed m. p. 191°C (decomp.).

Found: C, 65.94; H, 8.37; $H_2O$, 3.31. Calcd. for $C_{24}H_{35}O_5N \cdot H_2O$: C, 66.18; H, 8.56; $H_2O$, 4.13%.

From the above described procedure, it is probable that the substance does not contain hydrogen peroxide but water of crystallization as strychnine *N*-oxide does[6,7].

**Lucidusculine *N*-Oxide-b (III).**—Lucidusculine (0.5 g.) dissolved in chloroform (10 cc.) was added to 12 cc. of chloroform solution of perbenzoic acid (about 4 mol. equiv.). The reaction mixture was allowed to stand in a refrigerator for 6 days, and then was evaporated to dryness. To the residue, ether, about 1 cc. of 2 N hydrochloric acid and a small quantity of water were simultaneously added and the mixture was shaken. The aqueous layer separated from ether layer was passed through a column 17 cm. by 2 sq. cm. of anion-exchange resin (Amberite IRA-400) and then the column was eluted with 100, 50 and 25 cc. of water one after the other. From the first fraction (100 cc.) of elute, the residue was obtained, which gave crystals, m. p. 193°C

24) G. I. Poos, W. F. Johns and L. H. Sarett, *J. Am. Chem. Soc.*, 77, 1026 (1955).

25) The partial formula of I in a previous report[1] is revised to this.

(decomp.), on treatment with methanol. On recrystallization from methanol a material, m. p. 200°C (decomp.), $[\alpha]_D^{15}$ −101°, was obtained.

Found: C, 65.30, 65.52; H, 8.53, 8.68. Calcd. for $C_{24}H_{35}O_5N.{}^1/_2H_2O_2$: C, 66.32; H, 8.34%.

From the results described below it seems to contain hydrogen peroxide of crystallization. However, this material should be re-examined more precisely by iodometric titration.

**Lucidusculine *N*-Oxide-c (IV).**—To lucidusculine (1 g.) dissolved in 10 cc. of chloroform, were added 12 cc. of chloroform solution, containing excessive perbenzoic acid, and a few drops of water. After standing overnight, the chloroform was removed. The residue was digested with ether. To the ether-insoluble portion, 2 cc. of 2 N hydrochloric acid, water and chloroform were simultaneously added, and the mixture was shaken. The aqueous layer separated from chloroform layer was passed through the above mentioned column of anion-exchange resin and the column was eluted with water and then methanol. From the first fraction (80 cc. of aqueous elute), 0.7 g. of crystalline material, m. p. 198°C with decomposition was obtained. Subsequently, following fractions were discarded. It liberated iodine from acid solution of potassium iodide. From this fact, it seems to contain hydrogen peroxide of crystallization[4,7]. Recrystallization from methanol gave 0.2 g. of *N*-oxide-b which showed m. p. 205°C (decomp.)*. It was slightly soluble in chloroform and insoluble in ethyl acetate. The specimen several months old had lost hydrogen peroxide, and it showed no diminution of its weight by drying in vacuo at 100~110°C. It melted at 209°C with decomposition. The ultraviolet absorption spectrum of this compound in methanol showed end absorption and no maximum. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (3.15 $\mu$), an acetoxyl group (5.82 and 8.09 $\mu$), an *N*-oxide group (10.47 $\mu$) and a terminal methylene group (11.07 $\mu$).

Found: C, 69.32; H, 8.27. Calcd. for $C_{24}H_{35}O_5N$: C, 69.03; H, 8.45%.

**Reduction of Lucidusculine *N*-Oxide.** — The *N*-oxide-b (0.15 g.) freshly prepared from lucidusculine by perbenzoic acid oxidation for 2 days was dissolved in 1.5 cc. of 10% sulfuric acid**. To this solution, a drop of cupper sulfate solution was added and then 0.15 g. of zinc powder was gradually added. After standing for 2.5 hr. the reaction mixture was filtered, made alkaline with aqueous ammonia and extracted with chloroform. After removal of the chloroform, the residue was crystallized from methanol. It melted at 169~173°C and showed no depression of the melting point on admixture with lucidusculine.

**Oxidation of Lucidusculine with *N*-Bromosuccinimide [Dehydrolucidusculine (V)].**—Lucidusculine (0.5 g.) and *N*-bromosuccinimide (0.23 g.) were dissolved in 250 cc. of benzene. After boiling for 3 hr., the formed precipitate was removed by filtration. The filtrate was evaporated to dryness in vacuo. The residue dissolved in chloroform was washed three times with sodium carbonate solution and then three times with water. After removal of the chloroform, the residue was redissolved in chloroform and chromatographed on alumina. The chromatogram was eluted with chloroform and acetone and then methanol. From the chloroform portion (15 cc.), 50 mg. of residue was obtained, which on recrystallization from methanol, melted at 175~180°C. From the acetone portion (30 cc.), impure lucidusculine was obtained. Accordingly, the methanol portion (15 cc.) was discarded. The ultraviolet absorption spectrum of this compound (m. p. 175~180°C) showed end absorption and no maximum. The infrared absorption spectrum in Nujol showed the presence of a hydroxyl group (3.08 $\mu$), an acetoxyl group (5.76 and 8.09 $\mu$), a terminal methylene group (10.75 $\mu$) and a carbinolamine ether (10.15 and 11.34 $\mu$).

Found: C, 71.51; H, 8.41. Calcd. for $C_{24}H_{33}O_4N$: C, 72.15; H, 8.33%.

**Dehydrolucidusculine (V) from Lucidusculine *N*-Oxide.**—To 76 cc. of 1% $K_2CrO_4$ solution, was added lucidusculine *N*-oxide (200 mg.), which was the same sample as that used for the above described reduction. The material was heated on a water bath. The solution, which was transparent at first, became turbid in about thirty minutes. After heating for 1.5 hr., the separated material (50 mg.) was collected by filtration. It was dissolved in chloroform and the filtered solution was concentrated. On addition of methanol, a crystalline substance was obtained. On recrystallization from acetone, it melted at 173~177°C and showed no depression on admixture with sample obtained by the above described NBS oxidation.

Found: C, 72.38; H, 8.74***. Calcd. for $C_{24}H_{33}O_4N$: C, 72.15; H, 8.33%.

**Bromoanhydrolucidusculine Hydrobromide (VI).**—To a solution of lucidusculine (0.5 g.) dissolved in 10 cc. of methanol, a freshly prepared 0.25 M solution of bromine in methanol was added dropwise. Excessive bromine was detected by potassium iodide starch paper. In total 8.5 cc. of reagent were added; after one hour, excessive bromine persisted (1 mol. 5.07 cc.). When the methanol solution was concentrated, it showed acid reaction to Congo red. It was evaporated to dryness in vacuo. The residue, on recrystallization from methanol, gave crystals, m. p. 210°C (decomp.). $[\alpha]_D^{18}$ −64.63°C (methanol). The ultraviolet absorption spectrum of this compound in methanol is graphed in Fig. 1. The infrared absorption spectrum in Nujol had no band attributable to a terminal methylene group; it showed the presence of a hydroxyl group (2.99 $\mu$), an acetoxyl group (5.78 and 8.16 $\mu$) and water (6.05 $\mu$).

Found: C, 50.02; H, 6.74; Br, 29.70; $H_2O$, 5.5. Calcd. for $C_{24}H_{32}O_3NBr \cdot HBr \cdot 2H_2O$: C, 49.73; H, 6.43; Br, 27.57; $H_2O$, 6.2%.

The hydrobromide was soluble in water. The base, liberated from the hydrobromide with aqueous ammonia, could not have been obtained in a crystalline form on treatment with methanol.

**The Amino Acid (VII).**—A mixture of lucidusculine (1.8 g.) and chromium trioxide (2.4 g.) in

* This material seems to be purer than the *N*-oxide-b which showed m. p. 200°C (decomp.).

** For hydrochloric acid[1], 10% sulfuric acid is substituted.

*** The figure, 8.75[1], was misprinted.

pyridine (48 cc.) that had been allowed to stand at room temperature overnight was filtered. The filtrate was evaporated to dryness in vacuo. The residue was treated with water saturated with sulfur dioxide. After standing overnight, the acid solution was made alkaline with saturated baryta water to precipitate chromic hydroxide. The alkaline solution from which the precipitate had been removed by filtration was made slightly acid by the addition of 10% sulfuric acid, and the precipitated barium sulfate was removed. The concentrated filtrate was neutralized with baryta water and was evaporated to dryness. The residue was treated with methanol and the undissolved barium sulfate was removed by filtration. The methanol solution was evaporated to dryness. To a solution of the residue (1.8 g.) dissolved in 9.5 cc. of methanol, 34 cc. of acetone was added. Then a yellow precipitate was formed. The transparent solution separated from the precipitate was concentrated to obtain a crystalline material; it weighed 1.4 g. It was dissolved in methanol (5.5 cc.). Upon the addition of 28 cc. of ethanol, 0.3 g. of a crystalline material was obtained. The mother liquor gave a second crop (0.3 g.) on recrystallization from methanol-ethanol.

The combined crystalline material (0.6 g.) was dissolved in 30 cc. of 70% methanol. The solution was passed through a column of 10 cc. of cation-exchange resin (Dowex 50) and eluted with the same solvent. The elute (280 cc.) was evaporated to dryness and yielded 540 mg. of crystalline residue. It was recrystallized from 70% methanol and gave 200 mg. of pure material. It was soluble in water and methanol but not in ethanol and other organic solvents. It showed no definite m. p. nor d. p. and gradually became black above 350°C. $[\alpha]_D^{16}$ −26.22° (methanol). The ultraviolet absorption spectrum of this compond in methanol is graphed in Fig. 1. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (2.92 $\mu$), an acetoxyl group (5.78 and 8.11 $\mu$), a ketone carbonyl group (5.85 $\mu$), water (6.06 $\mu$) and an ionized carboxyl group (6.19 $\mu$).

Found: C, 54.22, 54.60; H, 7.88, 7.69; N, 3.05; $H_2O$, 10.11. Calcd. for $C_{24}H_{33}O_9N \cdot 3H_2O$[26]: C, 54.02; H, 7.36; N, 2.62; $H_2O$, 10.12%.

**The Methyl Ester (VIII).** — To the amino acid (0.25 g.) dissolved in methanol (12.5 cc.), a slight excess of ethereal solution of diazomethane was added. The reaction mixture was allowed to stand overnight and then was evaporated to dryness. The residue was dissolved in 1 N HCl and was precipitated by the addition of aqueous ammonia. The precipitate (0.1 g.) was crystallized from methanol-ethyl acetate and was further recrystallized from methanol. It showed no definite melting point nor definite d. p. and it swelled gradually with decomposition near 288°C. The ultraviolet absorption spectrum of this compound in methanol showed end absorption and no maximum.

Found: C, 57.01; H, 7.70; $H_2O$, 6.01. Calcd. for $C_{25}H_{35}O_9N \cdot 2H_2O$[26]: C, 56.69; H, 7.42; $H_2O$, 6.80%.

26) From the result of determination of water of crystallization the previously reported molecular formula[1] is revised to this.

## Summary

The alkaloid lucidusculine was oxidized by hydrogen peroxide and also by perbenzoic acid to lucidusculine *N*-oxide. The *N*-oxide could be converted back into the original base by reduction. Oxidation of the alkaloid with *N*-bromosuccinimide afforded dehydrolucidusculine which was also produced by transformation of lucidusculine *N*-oxide. Dehydrolucidusculine seems to be a cyclic carbinolamine internal ether. The action of bromine on the alkaloid was noticeable and gave bromoanhydrolucidusculine hydrobromide which was probably obtained from the intermediate dibromide with loss of one mole each of water and hydrogen bromide. Chromium trioxide-pyridine complex oxidized lucidusculine to an amino acid which, on methylation with diazomethane, gave a methyl ester. From these experimental results, the previously proposed partial formula of lucidusculine was further extended.

The author is grateful to Professor Harusada Suginome, President of Hokkaido University, for his unfailing kindness in encouraging this work, to Professor Shin-ichiro Fujise, Tôhoku University, for his kindness in making part of the material available and to Drs. Masao Yamaguchi and Akira Fujino, Institute of Polytechnics, Osaka City University, for their kindness in the determination of the infrared spectra.

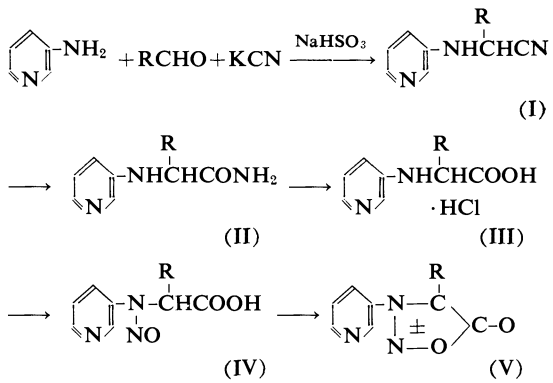
# *Untersuchungen über Meso-ionischen Verbindungen. X*[1] *Synthesen von 4-Substituierten 3-(β-Pyridyl)sydnonen*

Von Masaki OHTA und Mitsuo MASAKI

(Engegangen am 16 Oktober, 1959)

*N*-Pyridylglycin, das in der Synthese von 3-(β-Pyridyl)sydnon eine Zwischenverbindung ist, kann nicht durch die gewöhnlichen Reaktionen, z. B. durch die Reaktion von β-Aminopyridin mit Chloressigsäure, gewonnen werden, sondern nur durch Reduktivkondensation von β-Aminopyridin und Glyoxylsäureäthylester im Autoklaven, wie es schon berichtet worden ist[2]. Bisher ist kein 4-substituiertes 3-(β-Pyridyl)sydnon erhalten worden.

Nach der Umsetzungsmethode von Amin über Aminoacetonitril in Aminoessigsäure, die von Knoevenagel[3], Tiemann[4], Bristow[5], u. a. beschrieben worden sind, haben wir *N*-(β-Pyridyl)-*N*-nitrosoglycin (IV-a), *N*-(β-Pyridyl)-*N*-nitroso-α-methylglycin (IV-b), und *N*-(β-Pyridyl)-*N*-nitroso-α-phenylglycin (IV-c) gewonnen, und diese drei *N*-Nitrosoglycine setzen sich durch Erwärmen mit Acetanhydrid in die entsprechenden Meso-ionischen Verbindungen um.



Wir stellten so 3-(β-Pyridyl)sydnon (V-a), 3-(β-Pyridyl)-4-methylsydnon (V-b) und 3-(β-Pyridyl)-4-phenylsydnon (V-c) dar.

In Wasser als Lösungsmittel reagiert β-Aminopyridin mit Bisulfitverbindung des Formaldehyds und Alkalicyanids, und β-Pyridylaminoacetonitril (I-a) wird erhalten, das durch Erhitzen im Reaktiongemisch β-Pyridylaminoacetamid (II-a) liefert, aus dem durch Hydrolyse mit Alkali oder Säure *N*-(β-Pyridyl)glycin zugänglich ist.

Das Glycin wurde durch sein Salzsäuresalz (III-a) festgestellt. Man kann aber das *N*-Nitrosoglycin unmittelbar durch das Zusetzen des Natriumnitrits zu der salzsäuresaueren wässerigen Lösung von Glycin gewinnen, nachdem man das Amid in Alkalilösung erwärmt hat. Das *N*-Nitrosoglycin liefert phototropisches Sydnon, wenn man es mit Acetanhydrid erwärmt, wie J. M. Tien u. a.[2] beschrieben haben.

Ganz analog reagiert β-Aminopyridin mit Bisulfitverbindung des Acetaldehyds oder des Benzaldehyds und Alkalicyanid, wobei α-(β-Pyridylamino)propionitril (I-b) oder α-(β-Pyridylamino)-phenylacetnitril (I-c) entsteht, das sich in das entsprechende Amid durch Auflösen in konz. Schwefelsäure überführen läßt.

Durch das Erhitzen mit Salzsäure läßt sich α-(β-Pyridylamino)phenylacetamid (II-c) in das salzsauere α-(β-Pyridylamino)phenylglycin(III-c) verseifen. Nur α-(β-Pyridylamino)-propionamid (II-b) zersetzt sich bei Erwärmen mit konzentrierter oder verdünnter Salzsäure in braunrotes Öl* und Ammoniumchlorid.

(I) (II) (III) (IV) (V)

-R=-H : a)
-R=-$CH_3$ : b)
-R=-$C_6H_5$ : c)

Die beiden Amide sind aber am besten durch das mehrstündige Erwärmen mit Alkali in die entsprechende Säure unzuwandeln. Wenn man die erhaltenen Lösungen mit Salzsäure und Natriumnitrit unter Kühlen versetzt, so entstehen die entsprechenden *N*-Nitrosoglycine, aus denen durch Dehydratisierung die zwei 4-substituierten 3-(β-Pyridyl)sydnone zugänglich sind. Sie zeigen sich aber nicht phototropisch.

## Beschreibung der Versuche

**3-(β-Pyridyl)sydnon (V-a).**—*β-Pyridylaminoacetonitril (I-a).*—Man versetzt 41 g von etwa 37% Formaldehydlösung mit 13.2 g von ca. 40% Natriumbisulfitlösung und darauf mit 4.7 g β-Aminopyridin. Das Gemisch wurde auf dem Wasserbad eine Std. erwärmt, dann setzt man 4 g Natriumcyanid in konzentrierter, wässeriger Lösung zu. Nach einigem Stehen scheidet sich ein Öl ab, das 2~3 mal mit Chloroform ausgeschüttelt wird. Das nach dem

Gef. C 55.23 H 6.23 N 28.04

*Salzsaures N-(β-Pyridyl)glycin (III-a).*—Man löst 1.5 g β-Pyridylaminoacetamid in einer Mischung von 5 ccm konz. Salzsäure und 3 ccm Äthanol, und erhitzt dieses auf einem Wasserbad 3~4 Stdn. Der beim Erkalten abgeschiedene, farblose Niederschlag, Ammoniumchloride, wurde abfiltriert. Das Filtrat trocknet man durch Eindampfen unter vermindertem Druck, und die zurückgebliebene Kristallmaße kristallisiert sich aus konz. Salzsäure in farblose Prismen vom Schmp. 222~224°C. Ausb. 1.3 g (72% d. Th.).

Ber. N 14.85
Gef. N 14.80

In 14 ccm Wasser löst man 1.3 g. β-Pyridylaminoacetnitril, setzt 0.69 g. $K_2CO_3$ und 0.28 g. CaO zu, und dann wird es 4 Stdn. lang gelinde, unter Anwendung eines Asbestdrahtnetzes erhitzt. Wenn die Entwicklung von Ammoniak aufgehört hat, so kühlt man diese Lösung. Man filtriert den gebildeten farblosen Niederschlag, $CaCO_3$, ab, sättigt dann das Filtrat mit Chlorwasserstoff unter Kühlung, fügt etwa 15 ccm Äthanol hinzu und sätfigt wieder die Flüssigkeit mit Chlorwasserstoff. Der abgeschiedene Niederschlag, KCl, läßt sich abfiltrieren und das Filtrat wird durch Eindampfen im Vakuum getrocknet, wobei salzsaueres *N*-(β-Pyridyl)glycin hinterbleibt.

*N-Nitroso-N-(β-pyridyl)glycin (IV-a).* — Man löst 1.5 g NaOH in 40 ccm Wasser auf, versetzt mit 5.0 g β-Pyridylaminoacetamid, und erwärmt es 5~6 Stdn. unter mechanischem Rühren auf 40~50°C. Hierauf kühlt man die Lösung auf 0°C ab, fügt langsam 7.1 g konz. Salzsäure hinzu, und versetzt dann diese Lösung mit 2.5 g Natriumnitrit, wobei die Temperatur nicht über +1°C steigen soll. Nach einigem Stehen scheidet sich ein farbloser Niederschlag ab, der bei 158°C schmilzt. Die Mischprobe mit dem durch das Verfahren von J. M. Tien[2] erhaltenen *N*-Nitroso-*N*-(β-pyridyl)glycin, zeigt keine Schmelzpunkterniederung.

*3-(β-Pyridyl)sydnon (V-a).*—Eine Mischung von 1.5 g (IV-a) und 20 ccm Essigsäureanhydrid wird auf siedendem Wasserbad erhitzt. Nach einer halben Stunde wird die Lösung unter vermindertem Druck in $N_2$ eingeengt, wobei 3-(β-Pyridyl)sydnon sich abscheidet. Die aus dem Wasser umkristallisierten, farblosen Prismen vom Schmp. 119~121°C sind eine photropische Verbindung.

**3-(β-Pyridyl)-4-methylsydnon (V-b).**—*α-(β-Pyridyl)aminopropionitril (I-b).*—Man versetzt 26.4 g von etwa 40 proz. Natriumbisulfitlösung mit 10 g von 44 proz. Acetaldehyd und dann mit 9.4 g β-Aminopyridin. Zuerst eine halbe Stunde lang bei Raumtemperatur, darauf rührt man eine Stunde lang in einem Wagserbad von 80°C die Mischung um, und nach dam Abkühlen bis zur Raumtemperatur setzt man dazu 6.5 g Kaliumcyanid in wenigem wasser zu. Nach einigem Stehen scheidet sich ein Öl ab. 4~5 Stdn. lang rührt man das Gemisch bei Raumtemperatur um, darauf schüttelt man es 6~7 mal mit Chloroform aus, trocknet die vereinigten Chloroformextrakte mit Natriumsulfat und dampft im Vakuum ein. Es hinterbleiben 8 g α-(β-Pyridyl)-aminopropionitril (Ausb. 54% d. Th.) die zur Analyse 2 mal mit Äther gewaschen werden. Farblose Nadeln vom Schmp. 98~100°C.

# *Hydrogen Abstraction from Hydrogen Sulfide Molecules by Methyl Radicals*

By Naomi IMAI and Osamu TOYAMA

(Received November 1, 1959)

A study of the hydrogen sulfide catalyzed thermal decomposition of acetaldehyde carried out in this laboratory suggested that the catalysis is at least in part ascribed to hydrosulfide radicals produced by the reaction of methyl radicals with hydrogen sulfide molecules. It seemed then desirable to investigate this hydrogen abstraction reaction quantitatively, for only limited information was available on this reaction.

The technique used in this work is one of the competitive methods which have frequently been applied to study reactions of free radicals: acetone vapor has been photolyzed in the presence of varied amounts of hydrogen sulfide; the analysis of the products has yielded the ratio of the rate of the abstraction reaction in question to that of the recombination reaction of methyl radicals; the rate of the former reaction can then be estimated since that of the latter has already been the subject of a number of extensive investigations.

## Experimental

**Materials.**—Acetone used in this experiment was supplied commercially and purified by bulb-to-bulb distillation. Hydrogen sulfide was prepared by dropping water on aluminium sulfide in a vacuum system, dried by passing through a trap at $-78°C$ and purified by bulb-to-bulb distillation. Cupric oxide and cupric sulfate used in analyses were commercial samples.

**Apparatus.** — Photolysis was carried out in a cylindrical quarz vessel of about 110 cc. capacity placed in an electric furnace with a glass window which cuts off the light of a wave length shorter than 2800 Å. Therefore, no light was absorbed by hydrogen sulfide. The reaction vessel was connected to a mercury manometer, to an analytical system, and to a capillary tube of small volume, which had a mercury manometer and was used to measure a small quantity of hydrogen sulfide to be admitted to the vessel. The full light from a medium-pressure mercury arc was used in the present experiment. In order to increase light intensity it was placed at a focus of a half spheroidal mirror and at the other focus the center of the vessel was placed. Light intensity was kept constant by using a voltage stabilizer. The vessel, manometer, storage bulbs and the analytical system were attached to a conventional vacuum line.

**Procedure.**—A small measured quantity of hydrogen sulfide was admitted to the reaction vessel. Acetone vapor with a desired pressure was then added. After a few minutes to allow the gases to mix thoroughly and to come to a desired temperature, light was admitted into the vessel and irradiation was continued for a desired time.

**Analysis.**—After the photolysis, using a Toepler gauge, the reactants and products were passed through a trap at $-78°C$ where the unreacted acetone and low boiling point products were condensed. The uncondensable fraction at $-78°C$ was passed through a trap at $-196°C$ and the quantity of uncondensable fraction at $-196°C$ was measured by Toepler gauge. This fraction contained methane and carbon monoxide and was passed over cupric oxide at 250°C where carbon monoxide was oxidized to carbon dioxide and hydrogen, if any, to water. By the Toepler gauge these gases were passed through a trap at $-78°C$ where water, if any, was condensed, and through another one at $-196°C$ where carbon dioxide was condensed. The uncondensable fraction contained only methane, and its quantity was measured by the Toepler gauge. The condensed carbon dioxide was vaporized at room temperature and its quantity was measured by a McLeod gauge connected with the trap. The quantity of product uncondensable at $-196°C$ was always equal to the sum of quantities of methane and carbon monoxide analyzed within an error of 1%. That no water was found in all the runs showed that no hydrogen was formed in the photolysis. The fraction uncondensable at $-78°C$ and condensable at $-196°C$ contained the remaining hydrogen sulfide, ethane and other products. This fraction was vaporized and led to a trap at $-196°C$ through another one at about $-160°C$. The uncondensable fraction at $-160°C$ was vaporized and measured by the McLeod gauge. This fraction should have contained only hydrogen sulfide and ethane. Hydrogen sulfide was removed by contact with dry cupric sulfate. Thus the quantities of ethane and hydrogen sulfide were determined separately.

## Results and Discussion

A series of preliminary experiments with varied times of irradiation under otherwise constant conditions revealed that all the rates of formation of carbon monoxide, methane and ethane remain nearly constant at least during the initial stage of the photolysis up to about 0.2% conversion, which justifies the computation of initial rates of formation of these products from the analytical results at such low

conversions[1]. In Table I are listed the initial rates of formation of these products thus determined in several series of experiments. Within a series only the initial concentration of hydrogen sulfide was varied to determine the dependence of the rate on its concentration. The intensity of light was kept nearly constant throughout all the runs. As the concentration of hydrogen sulfide was increased, the rate of formation of ethane was decreased as seen in the table. On the other hand, use of too much hydrogen sulfide made its removal by dry cupric sulfate in analysis incomplete so that the rate of ethane formation was then liable to be overestimated. This situation limited the concentration range for hydrogen sulfide to those given in Table I.

It has been established[2-5] that during the photolysis of acetone, metane, ethane and carbon monoxide are produced almost entirely by the following reactions:

$$CH_3COCH_3 + h\nu = CH_3CO + CH_3 \quad (1)$$

$$CH_3CO = CH_3 + CO \quad (2)$$

$$CH_3 + CH_3 = C_2H_6 \quad (3)$$

$$CH_3 + CH_3COCH_3 = CH_4 + CH_3COCH_2 \quad (4)$$

1) It was found in the present work that the hydrogen sulfide initially added is consumed as the photolysis is continued. The ultimate fate of the hydrogen sulfide will be dealt with in a later paper.

2) K. W. Saunders and H. A. Taylor, *J. Chem. Phys.*, **9**, 616 (1941).

3) A. F. Trotman-Dickenson and E. W. R. Steasie, ibid., **18**, 1097 (1950).

4) R. Gomer and G. B. Kistiakowsky, ibid., **19**, 851 (1951).

5) M. T. Jaquiss, J. S. Roberts and M. Szwarc, *J. Am. Chem. Soc.*, **74**, 6005 (1952).

Reactions 3 and 4 lead to the following equation

$$R_{CH_4}/R_{C_2H_6}{}^{1/2} = (k_4/k_3{}^{1/2})\,[CH_3COCH_3] \quad (I)$$

which is in agreement with experimental results. In the presence of hydrogen sulfide, the reaction

$$CH_3 + H_2S = CH_4 + HS \quad (5)$$

may occur[6] and reactions 3, 4 and 5 taken together now yield

$$R_{CH_4}/R_{C_2H_6}{}^{1/2} = (k_4/k_3{}^{1/2})\,[CH_3COCH_3] + (k_5/k_3{}^{1/2})\,[H_2S] \quad (II)$$

When the concentration of acetone is kept constant, the plot of $R_{CH_4}/R_{C_2H_6}{}^{1/2}$ vs. $[H_2S]$ should give a straight line, and its intercept should be equal to the value of $R_{CH_4}/R_{C_2H_6}{}^{1/2}$ in the absence of hydrogen sulfide. Fig. 1 shows such plots of the results given in Table I and it is seen that the above requirements are in fact satisfied. That the slope of the straight line is not affected by a two-fold increase in the acetone concentration at 90°C may be taken as additional evidence for the validity of Eq. II. From the slopes of these straight lines, values of $k_5/k_3{}^{1/2}$ at various temperatures were determined and are shown in Table II together with those of $k_4/k_3{}^{1/2}$ obtained in the absence of hydrogen sulfide.

| 200 | — | 2.71 |

The Arrhenius plot of $k_4/k_3{}^{1/2}$ shows a curvature at temperatures below 100°C as is well known. According to Ausloos and Steacie[7] this falling off in the apparent activation energy at low temperatures presumably arises from a reaction between methyl radicals and adsorbed acetone molecules on the wall and a disproportionation reaction between methyl radicals and acetyl radicals. The excessive value of $k_4/k_3{}^{1/2}$ in question, however, caused no more than 3% error in the value of $k_5/k_3{}^{1/2}$ even at 50°C. The values of $k_4/k_3{}^{1/2}$ at 140° and 200°C are in satisfactory agreement with those previously reported[2-5].

In contrast, the Arrhenius plot of $k_5/k_3{}^{1/2}$ yielded a good straight line from which $E_5 - 1/2E_3 = 2.6$ kcal. mol$^{-1}$ and $A_5/A_3{}^{1/2} = 10^{4.675}$ mol$^{-1/2}$ cc$^{1/2}$ sec$^{-1/2}$ are obtained, where $E$ denotes the activation energy and $A$ the pre-exponential factor. Accepting the values $E_3 = 0$ and $A_3 = 10^{13.38}$ mol$^{-1}$ cc. sec$^{-1}$ as recommended by Shepp[8] we find

$$k_5 = 10^{11.4} \exp(-2{,}600/RT) \text{ mol}^{-1} \text{ cc. sec}^{-1}$$

The value of $A_5 = 10^{11.4}$ mol$^{-1}$ cc. sec$^{-1}$ seems to be reasonable, since most $A$ factors for hydrogen abstraction reactions by methyl radicals are of the order of $10^{11}$ mol$^{-1}$ cc. sec$^{-1}$.

On the other hand, the value of $E_5 = 2.6$ kcal. mol$^{-1}$ might be regarded unexpectedly low. Birrell, Smith, Trotman-Dickenson and Wilkie[9] have reported that the apparent order of reactivities of thiols towards methyl radical are given by

$$Bu^tSH > Pr^iSH > EtSH > MeSH > H_2S$$

6) Subsequent reactions of hydrosulfide radicals formed by reaction 5 are under investigation. There is, however, little indication that these reactions affect the importance of reaction 3 in forming ethane and that any other important source of methane besides reactions 4 and 5 must be considerd.

7) P. Ausloos and E. W. R. Steacie, *Can. J. Chem.*, 33, 47 (1955).

8) A. Shepp, *J. Chem. Phys.*, 24, 939 (1956).

9) R. N. Birrell, R. F. Smith, A. F. Trotman-Dickenson and H. Wilkie, *J. Chem. Soc.*, 1957, 2807.

According to Kerr and Trotman-Dickenson[10], the rate constants of hydrogen abstraction from thiols by methyl radical at 30°C are

MeSH 1.8, EtSH 3.5, Pr$^i$SH 4.1, Bu$^t$SH 5.9

in $10^{-7}$ mol$^{-1}$ cc. sec$^{-1}$. From these values they estimated the activation energies between 4.9 and 5.6 kcal. mol$^{-1}$, assuming $A=10^{11.3}$ mol$^{-1}$ cc. sec$^{-1}$. If the estimations given by these two studies are accepted altogether and the same value of $A$ is assumed for reaction 5, $E_5$ can not be lower than 5.6 kcal. mol$^{-1}$, while a much lower value of 2.6 kcal. mol$^{-1}$ has actually been found in this work. Presumably, there is some error in the order of reactivity estimated by Birrell et al. on the basis of qualitative considerations; although this order of reactivity for a series of thiols from methane thiol to isobutane thiol is in agreement with that of rate constrants found by Kerr and Trotman-Dickenson, and hence may be taken as established, there seems to be no convincing evidence for the least reactivity of hydrogen sulfide[11]. The expression for $k_5$ obtained in the present work gives $k_5=3.3\times10^9$ mol$^{-1}$ cc. sec$^{-1}$ at 30°C, a value far greater than Kerr and Trotman-Dickenson's rate constants for thiols cited above.

The results given in Table I show that the rate of formation of carbon monoxide, on the whole, increases with temperature in agreement with the previous observation[12-14] on the quantum yield of carbon monoxide. There is some indication in the table at low temperatures that the addition of a small quantity of hydrogen sulfide increases the rate of formation of carbon monoxide, while greater concentration of hydrogen sulfide lowers the rate though the effect is not great at high temperatures. The probable explanation for these findings seems to be given by the promotion of the primary decomposition by hydrogen sulfide and the reaction of acetyl radical with hydrogen sulfide, though anything conclusive cannot yet be drawn at present on these problems.

## Summary

Acetone has been photolyzed in the presence of the varied amounts of hydrogen sulfide in the temperature range from 50° to 140°C. From the analysis of the products at low conversions the initial rates of formation of carbon monoxide, methane and ethane have been determined, which, combined with the mechanism of acetone photolysis already established, give the values of $k_5/k_3^{1/2}$, where $k_5$ and $k_3$ are respectively the rate constants for the reactions $CH_3+H_2S=CH_4+HS$ and $CH_3+CH_3=C_2H_6$. Accepting $k_3=10^{13.38}$ mol$^{-1}$ cc. sec$^{-1}$ with zero activation energy as recommended by Shepp, the rate constant of the abstraction reaction is represented by $k_5=10^{11.4}\exp(-2.6\text{ kcal. mol}^{-1}/\boldsymbol{R}T)$ mol$^{-1}$ cc. sec$^{-1}$.

# *Temperature Dependence of the Formation of NiO-$Li_2O$ Solid Solution*

By Yoshio IIDA, Shunro OZAKI and Kenzo SHIMADA

(Received November 5, 1959)

Since Verwey[1] extensively studied the semiconductivity of a solid solution of lithium oxide in nickel oxide, many investigators[2,3,4] have studied the physical or catalytic properties of the solid solution. In the previous papers[1,2,3,4] the solid solution of NiO-$Li_2O$ was formed by heating the mixture of nickel oxide and lithium carbonate. Unfortunately, the dissolved lithium oxide was not determined chemically and was thought to be the same as the added lithium oxide. It is expected that the amount of free lithium oxide is high when the sample is heated at a low temperature and the amount of evaporated lithium oxide is high when the sample is heated at a high temperature in the process of the NiO-$Li_2O$ solid solution formation. Accordingly, it is desiarble to determine the amount of the dissolved lithium oxide.

The mixture of nickel oxide and 5 or 10 at. % of lithium was heated and studied in the previous papers[1,4]. In the present experiment about 18 at. % of lithium equivalent to 4.15 wt. % of lithium oxide was mixed. Since the dissolved lithium oxide became constant after a heating period of 3 hr. at 800°C, the mixture of nickel oxide and lithium carbonate which was equivalent to 4.15 wt. % of lithium oxide was heated for 3 hr. at various temperatures. Chemical analysis of lithium oxide was carried out by a flame photometry[5]. Nickel oxide is not soluble in cold dilute acetic acid but lithium carbonate or free lithium oxide is soluble in it. The amount of lithium oxide dissolved in nickel oxide or free oxide was determined by the extraction method and the result is shown in Table I.

Table I shows that the amount of lithium oxide dissolved in nickel oxide is very small when the sample is heated below 600°C and increases with an increase in the heating temperature up to 800°C, but decreases above 1000°C. On the other hand, the amount of free lithium decreases with an increase in the temperature. It is seen that there is a relatively large amount of free lithium oxide present when the sample is heated at high temperatures of 1400 and 1500°C. The amount of lithium oxide evaporated increases remarkably with an increase in the temperature. Table I shows that the mixture heated at 800°C loses one half of the lithium oxide added and the mixtures heated at 1400 and 1500°C have only one tenth of the lithium oxide added. High temperatures are not suitable for the formation

TABLE I. CHEMICAL ANALYSIS AND ELECTRICAL RESISTANCE OF THE MIXTURE HEATED AT VARIOUS TEMPERATURES

| Heating temp. (°C) | Free $Li_2O$ (wt. %) | Dissolved $Li_2O$ (wt. %) | Evaporated $Li_2O$ (wt. %) | Electrical resistance ($\Omega$ cm.) |
|---|---|---|---|---|

of the solid solution of lithium oxide in nickel oxide, and a temperature range of 800 to 1000°C is suitable.

Since an amount of lithium oxide less than 0.01 wt. % is not found by the flame photometry, the amount of lithium oxide dissolved in nickel oxide below 600°C could not be determined exactly. The electrical resistance of nickel oxide has been known to be sensitive to the foreign atoms incorporated with the lattice[1]. In order to find the temperature at which lithium oxide starts to dissolve in nickel oxide, the electrical resistance of the mixtures heated at various temperatures was measured at room temperature by a method similar to that described by Griffith[6]. The electrical resistance of the mixtures decreases remarkably with an increase in the temperature up to 800°C, and increases with a temperature above 1000°C. It is clearly seen from Table I that the electrical resistance of the mixture heated at 300°C is smaller than that of the pure nickel oxide. As the pure nickel oxide was prepared from ignition of nickel sulfate at 900°C in air for 10 hrs., its electrical resistance is not thought to vary when the oxide is heated below 900°C in air. It is found that NiO-$Li_2O$ solid solution starts to be formed about 300°C.

In order to confirm the fact, electrical resistance of pure nickel oxide and of the mixture were measured at a heating rate of 100°C/hr. from room temperature to 600°C. Fig. 1 clearly shows that the electrical resistance of the mixture becomes lower about 300°C than that of the pure nickel oxide. It is concluded that lithiuum oxide starts to dissolve in nickel oxide at about 300°C.

Bevan and coworkers[7] have suggested that diffusion in ionic compound only becomes appreciable above 0.5 $T_m$, where $T_m$ is the melting point absolute. Since the melting point of nickel oxide is about 2000°C, the temperature of 300°C is equivalent to 0.25 $T_m$. It is found that the diffusion of lithium oxide in nickel oxide can clearly be observed by this suitable method even at 0.25 $T_m$.

# *An Attempted Preparation of Optically Active Organometallic Compounds as Polymerization Catalysts**

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Shigeru TAKEUCHI

(Received November 13, 1959)

A number of investigations on isotactic polymerization have been carried out in recent years. As regards the mechanism of isotactic polymerization by heterogeneous catalysts, it seems to be of great interest to see if the use of optically active organoaluminum compound in combination with a titanium halide might influence the steric structure of the resulting polymer.

**Polymerization of Styrene with an Optically Active Triamylaluminum.**—From the viewpoint mentioned above, we attempted to prepare trialkylaluminum containing three optically active 2-methylbutyl groups, starting from (−)-2-methylbutanol of 96% optical purity, $[\alpha]_D^{13'}=-5.70°$.

(−)-2-Methylbutanol was purified by repeated fractional distillation of fusel oil through a Stedman column of about 70 theoretical plates. Calculation of the optical purity is based on the value −5.90° for the pure substance[1]. Treatment of the alcohol with thionyl chloride and pyridine gave (+)-2-methylbutyl chloride of 95% purity, $[\alpha]_D^{14'}=+1.62°$ (+1.70° for the pure substance[2]).

A widely used preparative method of organoaluminum compounds is that using the reaction between metallic aluminum and an alkyl halide. The method, however, was by no means feasible in the case of higher alkyl halides, such as amyl chloride, because of the occurrence of vigorous decomposition reaction[3], and hence an alternative method was adopted in the present work as shown in the following equations:

$$HgCl_2+2AmMgCl \rightarrow Hg(Am)_2+2MgCl_2 \quad (1)$$

$$2Al+3Hg(Am)_2 \rightarrow 2Al(Am)_3+3Hg \quad (2)$$

$$(Am=-CH_2-CH(CH_3)-CH_2-CH_3)$$

(+)-Bis-(2-methylbutyl)mercury was obtained in 80% yield by the reaction of Eq. 1. An ethereal solution of 2-methylbutylmagnesium chloride (from 11.0 g. of the active chloride) and mercuric chloride (12 g.) was refluxed for one hour, and then after the removal of ether by distillation the residual mass was heated in an oil bath at 120°C for one hour. The reaction mass was combined with the ether distillate, decomposed by saturated aqueous ammonium chloride, and distilled to yield the product, b. p. 135～7°C (30 mmHg), $d_4^{27.5}=1.657$, $[\alpha]_D^{27.5'}=+7.65°$.

Found: Hg, 56.6%. Calcd. for $C_{10}H_{22}Hg$: Hg, 58.5%.

As the reaction between metallic aluminum and (+)-bis-(2-methylbutyl)mercury was found to be very vigorous, leading occasionally to decomposition of the product, the exothermic reaction was suppressed by the portion-wise addition of granular aluminum into (+)-bis-2-methylbutyl)mercury, which was kept at 100～110°C in an oil bath. The yield of tris-(2-methylbutyl) aluminum was 56% based on (+)-bis-(2-methylbutyl)mercury used, b. p. 85～105°C (0.5 mmHg).

Found: Al, 11.50%. Calcd. for $C_{15}H_{33}Al$: Al, 11.24%.

The optical purity of tris-(2-methylbutyl)-aluminum thus obtained was estimated by the following procedures, i.e., oxidation with oxygen, subsequent hydrolysis to 2-methylbutanol, and checking its optical rotatory power:

$$2Al(Am)_3+3O_2 \rightarrow 2Al(OAm)_3 \quad (3)$$

$$Al(OAm)_3+aq.\,HCl \rightarrow AlCl_3aq.+AmOH \quad (4)$$

The recovered 2-methylbutanol was found to have an optical purity of 27%, $[\alpha]_D^{30'}=-1.58°$, which indicates that an extensive racemization had taken place in some stages of the synthetic process (Eqs. 1 and 2) or of recovering process (Eqs. 3 and 4). In our experiment, therefore, the optical purity of tris-(2-methylbutyl)aluminum should be estimated at 27% at the lowest.

Polymerization of styrene was carried out at 70°C in *n*-heptane using this aluminum compound (0.3 g.) in combination with titanium trichloride (3 g.) for 2 to 7.5 hr. The isotactic fractions of the polymers showed no difference

4) The content of mercury was determined by decomposition of the sample with sulfuric acid in a Kjeldahl flask and by titration of mercuric ions with ammonium rhodanate, M. Hiral and R. Hayatsu, *J. Pharm. Soc. Japan* (*Yakugakuzashi*), **70**, 76 (1950).

in the physical properties, such as melting points, X-ray diffraction pattern and optical rotation in toluene solution, in comparison with isotactic polystyrenes that were prepared with racemic tris-(2-methylbutyl) aluminum and titanium trichloride.

**Polymerization of Styrene with Optically Active Amylsodium.** — In the course of our study on the polymerization of styrene with Alfin catalysts, it was found that amylsodium alone could produce isotactic polystyrene in a suitable solvent, though in a small yield, together with a large amount of atactic polymer. Based on this observation, the amylsodium prepared from optically active amyl chloride was tested in the same way. Amylsodium was prepared from (+)-2-methylbutyl chloride and sodium dispersion in the usual manner[5] and was used as a catalyst in *n*-heptane solvent. However, the isotactic polystyrene here obtained showed again no unusual character and was quite identical with that obtained by an inactive catalyst, isoamylsodium.

# *Alkylalkoxypolysiloxanes. VIII.*[1] *Lower Members of Cyclic Methyl- and Ethyl-isopropoxypolysiloxanes*

By Rokuro OKAWARA and Masuo KATAYAMA

(Received November 11, 1959)

Cyclic trisiloxane, the first member of the cyclic polysiloxanes, has been known. While there were found stable compounds such as dialkyl cyclotrisiloxanes and $(C_2H_5Si(OC_2H_5)O)_3$[2], a group of unstable compounds was also known. Spontaneous changes of physical constants were reported with those unstable cyclotrisiloxanes; $((CH_3)HSiO)_3$[3], $((C_2H_5)HSiO)_3$[4], $(CH_3Si(OC_2H_5)O)_3$[2] and $((C_2H_5O)_2SiO)_3$[5].

In this paper, the preparation and properties of cyclic polysiloxanes as indicated by the following formula will be described.

$(RSi(OC_3H_7\text{-}i)O)_n$ $R=CH_3$ and $C_2H_5$; $n=3$ and 4

One of the objects of this paper is to assure that the rapid hydrolysis method[2,5] developed by the author is applicable for the preparation of cyclotrimers, and the other is to obtain some knowledge of their stability.

The results showed that the cyclic trimer together with the tetramer were formed by using a considerable dropping rate. Comparing the yield of cyclotrimers, the ethyl compound is formed more easily than the methyl compound in those conditions. The infrared absorption spectra of those cyclotrimers showed, as in the case of $(CH_3Si(OC_2H_5)O)_3$[2,6] and $(C_2H_5Si(OC_2H_5)O)_3$[2], a strong absorption at 1023 $cm^{-1}$ which would likely be attributed to the vibration of Si-O bond in cyclotrisiloxane ring. Though a measurable strain[7] would be expected in the cyclotrisiloxane ring of those compounds, no increase of the refractive index,

due to a spontaneous decomposition, was observed with the samples sealed in a soft glass ampule within one year.

## Experimental

**Starting Materials.** — Methyltrichlorosilane used in these experiments was supplied from the Shin-etsu Chem. Ind. Co. Ethyltrichlorosilane was obtained from the product of silicon-ethylchloride reaction. Methylisopropoxydichlorosilane (I) and ethylisopropoxydichlorosilane (II) were prepared by adding 1 mol. of isopropanol to 1 mol. of those trichlorosilanes, respectively. After the addition, the mixture was aerated with stirring to drive off the hydrogen chloride at room temperature. Then the mixture was fractionated through a Stedman column of about 20 theoretical plates. Redistilled dichlorosilanes were taken for the starting materials.

*Methylisopropoxydichlorosilane* (I) b. p. 112.5°~113°C (Reported[8]: b. p. 110°~111°C)

Found: Cl, 41.1. Calcd. for (I): Cl, 41.0%.

*Ethylisopropoxydichlorosilane* (II) b. p. 137°~8°C (Reported[9]: b. p. 67°C/60 mmHg)

Found: Cl, 37.5. Calcd. for (II): Cl, 37.9%.

**Hydrolysis and Fractionation of the Hydrolyzate.**—Hydrolysis was carried out as described in the preceding papers.[2,5] The results are summarized in Table I.

The composition of the hydrolyzate was determined by fractionation through a Stedman column of about 50 theoretical plates. In Expt. 1, gelation occurred in a still-pot after 16% of $C_4$ distilled out; accordingly the fractionation of the other runs were carried out with the distillable fraction which was obtained from the hydrolyzate through a simple distillation. Comparing the yield of $C_3$, the ethyl compound is more easy to be formed than the methyl compound.

The fractions which exhibited constant boiling points and refractive indicies were taken for the samples and their physical constants are given in Table II.

**Infrared Spectra and Stability.** — Infrared absorption spectra were obtained with a Hilger H-800 infrared spectrophotometer with a rock salt prism. In the range 700~1300 $cm^{-1}$, samples were observed as solution in carbon disulfide. The positions of the strong bands which appeared in the range 1000~1100 $cm^{-1}$ are shown in Table III.

TABLE III

| Compound | Absorption Spectra (in $cm^{-1}$) | | |
|---|---|---|---|
| $(CH_3Si(OC_3H_7\text{-}i)O)_3$ | 1023 | 1044 | — |
| ( 〃 )$_4$ | — | 1044 | 1086 |
| $(C_2H_5Si(OC_3H_7\text{-}i)O)_3$ | 1024 | 1045 | — |
| ( 〃 )$_4$ | — | 1043 | 1087 |

All the samples shown in Table II, which were sealed in a glass ampule, gave no changes of refractive index within one year.

## Summary

1) Methyl- and ethyl-isopropoxydichlorosilane were hydrolyzed with considerable dropping rate using pyridine as an acid acceptor.

2) Methyl- and ethyl-isopropoxycyclotrisiloxane have been prepared and characterized. Those compounds were found to be stable.

3) Methyl- and ethyl-isopropoxycyclotetrasiloxane have been prepared and characterized.

# *Absorption Spectra of Dyes. V*[1]. *The Composition and Intermolecular Charge Transfer Spectra of Complexes Formed in Aqueous Solution of the Mixture of Chlorazol Sky Blue FF and Chrysophenine G*

By Teruaki KOBAYASHI, Yoshié TANIZAKI and Noboru ANDO

(Received December 2, 1959)

Most of the binary mixtures of dyes in aqueous solution studied before showed more or less non-additive spectra[1-6]. Of these dyes the pair of Chlorazol Sky Blue FF and Chrysophenine G revealed the most remarkable change in spectrum. This pair was first studied by Neale and Stringfellow[2], and then in more detail by Derbyshire and Peters[4]. According to the latter workers, only a 1:1 complex is formed between Chrysophenine G and Chlorazol Sky Blue FF in equimolar solution or in the presence of an excess of Chlorazol Sky Blue FF at room temperature, while higher complexes are formed to a certain extent in the presence of an excess of Chrysophenine G. However, they made no mention of the composition of these higher complexes. In the hope of obtaining some information about the composition of the higher complexes and then interpreting the spectral change observed on the basis of quantum chemical concept, this combination has been studied in greater detail.

A series of studies of binary mixtures of Chlorazol Sky Blue FF with some other dyes have shown that the relatively small spectral change observed in mixtures of some monoazo and disazo dyes may be explained by the perturbation between molecular orbitals of two component dyes caused by the formation of loose complexes[1,5]. However, it has been impossible to apply this concept to more compact complexes: a large spectral change which appeared in a binary mixture of Chlorazol Sky Blue FF has been unable to be explained without the concept of intermolecular charge transfer[1]. As the authors pointed out before, the mixture of Chlorazol Sky Blue FF and Chrysophenine G also shows a spectral change which implies the occurrence of charge transfer[1]. Therefore, this pair, which is considered to be a typical example of these sorts of dyes having the intermolecular charge transfer phenomenon, seems to be most suitable for our purpose.

## Experimental

**Preparation of Samples.**—The purification of the dyes and the preparation of dye solutions followed the same methods as explained in the previous paper[1].

**Absorption Spectra.**—All the absorption spectra of dye solutions were measured by a Shimadzu QR-50 spectrophtometer at room temperature (27°~30°C). Cells used were 0.2, 0.5 and 1 cm. thick.

Hereafter Chlorazol Sky Blue FF and Chrysophenine G will shortly be called Blue (or B) and Yellow (or G), respectively.

## Results and Discussion

**1. The Composition of Complexes Formed in Solutions.**—As is shown in Fig. 1, absorption spectra of mixtures of Blue and Yellow at

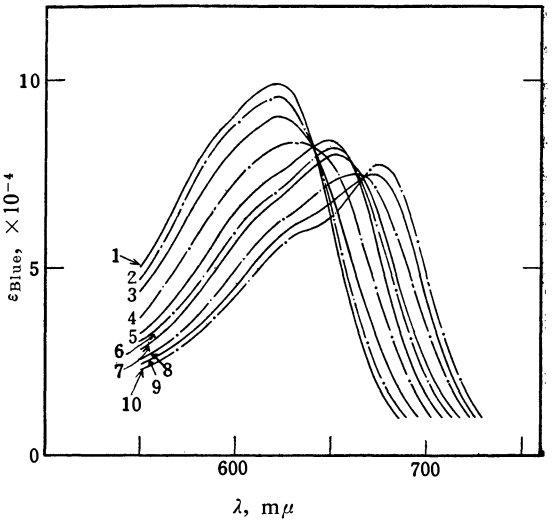

Fig. 1. Absorption spectra of mixtures of Blue and Yellow in aqueous solution at room temperature (ca. 27°C). The concentration of Blue is $1.00\times10^{-5}$ mol./l. The ratio of the concentration of Yellow to that of Blue is 1-0, 2-0.105, 3-0.313, 4-0.610, 5-1.03, 6-1.55, 7-2.07, 8-4.18, 9-8.27 and 10-51.5.

wavelengths corresponding to the first absorption band of Blue (620 m$\mu$) show a characteristic change, with an increase in the concentration of Yellow added into the solution containing a constant amount of Blue ($1.00\times10^{-5}$ mol./l.). It is already known[4] that, while the concentration of Yellow does not exceed that of Blue, spectra of mixtures of this pair have an isosbestic point at about 640 m$\mu$ accompanied with a new clear absorption band at 650 m$\mu$. Fig. 1 clearly shows that, when the concentration of Yellow has increased more than four times as high as that of Blue, the second isosbestic point appears at about 670 m$\mu$ and 650 m$\mu$ band disappears, followed by the appearance of a new band at 675 m$\mu$. Since Yellow does not absorb light in the wavelength region shown in the figure, these two isosbestic points mean that each molecule responsible for the 650 m$\mu$ band contains in itself one Blue molecule (the first isosbestic point), and that each molecule responsible for the 675 m$\mu$ band contains in itself one molecule of the complex (the second isosbestic point).

As has already been known, the 650 m$\mu$ band is due to a 1 : 1 complex[4]. Then, the molecular species of the 675 m$\mu$ band may be considered to be a complex made up of a 1 : 1 complex and Yellow in the ratio 1 : 1. Now, let us suppose that the molecular species which shows the 675 m$\mu$ band is a 1 : 2 complex richer in Yellow and that the following equilibriums exist in solutions.

$$B+G \rightleftarrows BG \qquad (K_1)$$

$$BG+G \rightleftarrows BG_2 \qquad (K_2)$$

It is possible to calculate the equilibrium constants ($K_1$ and $K_2$) corresponding to the above equilibriums, from observed obtical densities in accordance with the mass action law. They were calculated here by use of the difference $\Delta D$ between the sum of observed optical densities of the component dyes and the optical density of the corresponding mixture at 620 m$\mu$, according to the usual method[3,6]. Since the observed optical density of the mixture is, in practice, the sum of those of the single dyes and the complexes, the calculation is complicated. Therefore, an approximate one was performed. As the figure shows clearly, the amount of 1 : 2 complex is negligibly small in the concentration region [B] > [G] (where [B] and [G] mean the initial concentrations of Blue and Yellow. respectively). Consequently, the value of $K_1$ was calculated from observed optical densities in the region [B] > [G]. The optical density at 620 m$\mu$ decreases with an increrase of [G], approaching to a certain value as [G] becomes large relative to [B]. This value may be considered to be due only to the 1 : 2 complex, $BG_2$. Thus the molecular extinction coefficient of $BG_2$ may be known, and by use of it, $K(=K_1K_2)$, the overall equilibrium constant of the formation of the complexes, may be calculated. $K_2$ can easily be obtained from $K$ and $K_1$. Calculated values of $K_1$ and $K_2$ were about $6\times10^5$ and $5\times10^4$, respectively, at 27°C.

Now as the values of $K_1$ and $K_2$ were thus decided, the concentrations of BG and $BG_2$ corresponding to any amounts of Blue and Yellow will be obtained, according to mass action equations, hence the difference of optical densities $\Delta D$ will be calculated by use of them. Calculated $\Delta D\sim$ [G] curves when the initial concentration of Yellow is varied with that of Blue kept constant are shown by full lines in Fig. 2,

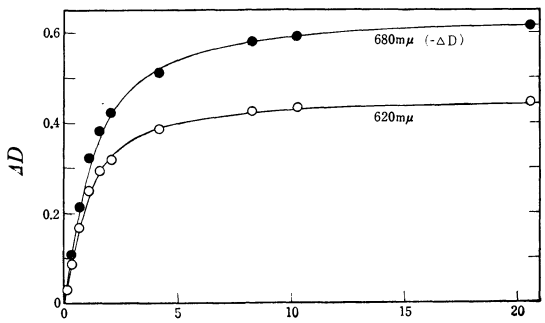

Fig. 2. The difference in optical densities when the concentration of Blue is constant ($1.00\times10^{-5}$ mol./l.) at 27°±1°C. 1 cm. thick.
Full lines: calculated differences
Black and white circles: observed differences corresponding to the respective curves

in which the lower and upper curves show the differencce at 620 m$\mu$ and at 680 m$\mu$, respectively. The latter is described as $-\Delta D$ because it has negative values. Observed values corresponding to each curve are shown by white and black circles. They are coincident well with the respective calculated curves.

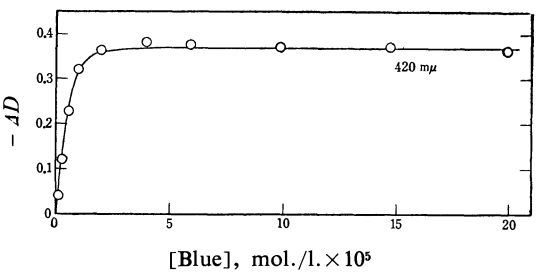

Fig. 3. The difference in optical densities when the concentration of Yellow is constant ($1.00\times10^{-5}$ mol./l.) at 28°±1°C. 1 cm. thick.
Full line: calculated difference
White circles: observed differences corresponding to the calculated curve

A corresponding calculation was then made at 420 mμ, the concentration of Yellow being kept constant. The result ($-\Delta D\sim$ [B] curve) is shown by a full line in Fig. 3, in which the white circles are corresponding observed values. The coincidence between the observed and the calculated values is also satisfactory in this case.

As seen above, each of the $\Delta D\sim$ [G] and the $\sim$ [B] curves calculated by use of $K_1$ and $K_2$, of which values were obtained from the observed optical densities at 620 mμ, explains the observed values well. This satisfactory coincidence between the observed and the calculated values of $\Delta D$ means the propriety of the assumption that a 1 : 1 complex and a 1 : 2 complex are formed in equilibrium in the mixture solution. Further it affirms that the obtained values of $K_1$ and $K_2$ are proper.

Now, it has become clear that two sorts of complexes exist in the mixture solution, in addition to the component dyes. Therefore, the behavior of the spectral change shown in Fig. 1, i. e., the shift of the first absorption band from 620 mμ to 650 mμ and to 675 mμ through the two isosbestic points with an increase in concentration of yellow, may be expressed in the quantitative relation among these components and complexes. The consentrations of Blue and the two complexes change with an increase in amount of Yellow as shown in Fig. 4, in which Curves I, II and III show the concentrations of free Blue, BG and $BG_2$, respectively. As the figure shows, the existence of $BG_2$ is negligible when it is compared with the others, in the region where the amount of Yellow is less than $0.5\times10^{-5}$ mol./l. Consequently the spectral change of the mixture will be governed only by the amounts of free Blue and BG (the first isosbestic point). When the concentration of Yellow is further increased, free Blue decreases to a nigligible amount, hence the spectral change is governed only by the amounts of BG and $BG_2$ (the second isosbestic point). Thus the change in spectra of the mixtures shown in Fig. 1 will well be understood through the relation between the concentrations of the components and the complexes shown in Fig. 4.

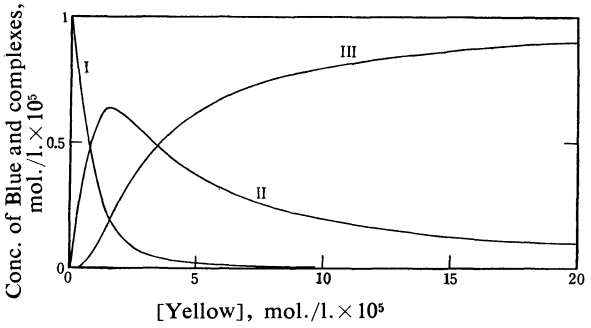

Fig. 4. The changes in concentrations of Blue and the complexes with that of Yellow when the initial concentration of Blue is $1.00\times10^{-5}$ mol./l.
I: free Blue, II: BG, III: $BG_2$

**2. The Change in Absorption Spectra.**—The discussion in the previous section has clarified that a 1 : 1 complex BG and a 1 : 2 complex $BG_2$ are formed in aqueous solution of the mixture of Blue and Yellow. The equilibrium constants ($K_1$ and $K_2$) for these complexes have also been obtained. Therefore, absorption curves of the complexes can be drawn from observed absorption spectra of mixtures. The curves shown in Fig. 5 are the absorption spectra of BG and $BG_2$ thus obtained*. Inspection of the absorption spectra of the components and the complexes

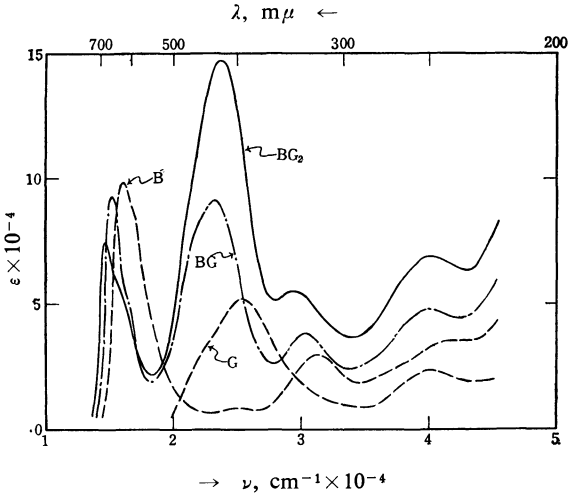

Fig. 5. Absorption spectra of the complexes and the component dyes

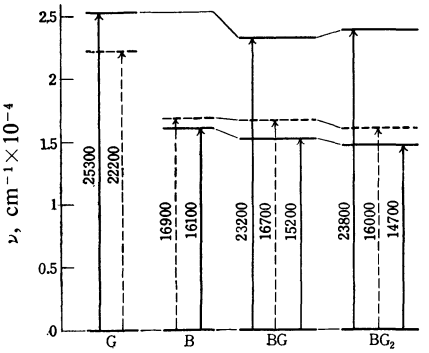

Fig. 6. Observed transition energies ($cm^{-1}$) of Yellow (G), Blue (B) and the complexes (BG and $BG_2$)

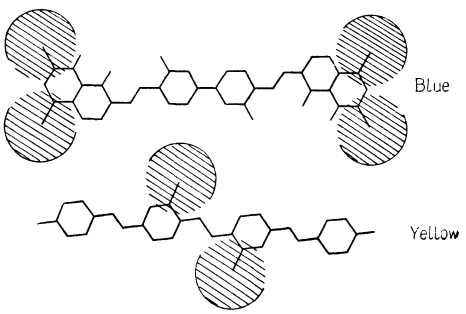
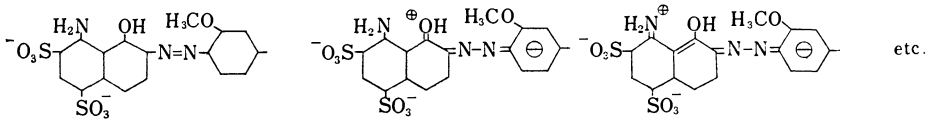
* Since these curves were made from absorption specra which were converted from those measured in various cells different in thickness so as to correspond to the unit cell, their molecular extinction coefficients and maximum wavelengths shown in the figure may have some errors.

shows that the first absorption bands shift to longer wavelengths with a change from Blue to $BG_2$; on the other hand, the absorption of BG corresponding to the first absorption band of Yellow (395 m$\mu$) is markedly shifted to longer wavelengths (430 m$\mu$) with a remarkable increase in intensity, while that of $BG_2$ to shorter wavelengths (420 m$\mu$) than that of BG is. To show these changes more clearly, the transition energies ($cm^{-1}$) of Blue, Yellow, BG and $BG_2$ are given in Fig. 6, where the dotted lines mean absorptions corresponding to shoulders. The absorptions illustrated in Fig. 6 seem to show a regular change, except those in the shorter wavelength region, in view of the fact that they shift to longer wavelengths with a change from Blue to $BG_2$. The absorptions of the complexes in the shorter wavelength rigion seem to have an unusual behavior. Perhaps they are charge transfer spectra, as the following discussion will suggest.

The first absorption bands of dyes are generally considered to be due to conjugated double bond chains connected with auxochromes. According to the VB theory, the first absorption bands of Blue and Yellow may be considered to be owing to resonances between the following extreme structures.





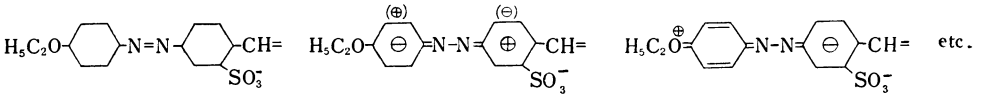


Fig. 7. Models of Blue and Yellow. The shadowed circles mean sulfonic groups.

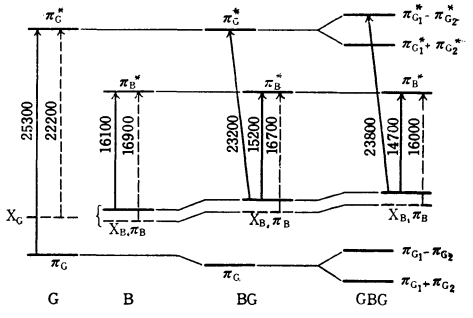
pointed out before[4] and the structures in Fig. 7 show clearly, Blue and Yellow might approach close each other without accepting the repulsion of their charged groups, if they form complexes with their molecular axes in parallel with each other. In such structures, the auxochromes of Blue may have higher possibility of being covered by the conjugated system of their partners than those of Yellow, so unshared $\pi$-electrons of the auxochromes of Blue may be more affected than those of Yellow. These conditions may make the ground state of Blue unstable, the contribution of structure I to it

I II III

I′ II′ III′

where the half of the structure of each dye is shown. Though there are a number of extreme structures, they are lumped together under the structures of which inner $\pi$-electron systems have negative charge. The first absorption band of each dye may approximately be expressed by a transition from the ground state (mainly I or I′) to an excited state (mainly II or II′)**. As



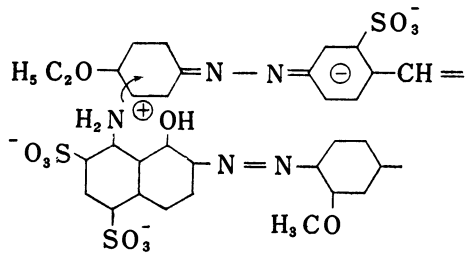


Fig. 8. Schematic representation of electronic transitions among molecular orbitals of Yellow (G), Blue (B) and the complexes (BG and GBG)

** According to empirical facts, auxochromes, which are attached to a naphthalene ring as a coupling component, show, in general, greater effects on absorption spectra, when attached to the inner ring having an azo group. Hence, the excited state of Blue seems to consist mainly of structure II. In case of Yellow, as the effect of $OC_2H_5$ as auxochrome seems to be weak because of its weak electron donating power relative to $NH_2$, ect.,[7] it may approximately be considered that the shoulder of the first absorption hand is due to the resonance I′↔III′ and the peak to I′↔II′.

7) A. E. Gillam and E. S. Stern, "An Introduction to Electronic Absorption Spectroscopy in Orgnic Chemistry", Edward Arnold, London, (1957), p. 129.

smaller, and, at the same time, charge transfer from Blue to Yellow easy. The important structure of an excited state in this case may be

in which a mobile electron of Blue in structure II or III transfers to the inner $\pi$-electron system of Yellow***.

The same discussion will be given on $BG_2$. The structure of $BG_2$ may be considered to be a sandwich type with B in its inside. The two G molecules in this complex are supposed to be close to each other in spite of holding B between them, so it is necessary to take into account an interaction between them: the mixing may occur to some extent between the excited states of G molecules, causing them to split in two different levels. The experimental results suggest that the charge transfer from B may occur to the higher level, though it can not possibly be ascertained.

According to the MO method, the spectral change will be explained as follows. A rough approximation shows that the first absorption bands of the dyes are due to electron transitions of unshared $\pi$-electrons of the auxochromes to the lowest vacant orbitals of the inner $\pi$-electron systems, i. e., the $X \rightarrow \pi^*$ transitions in Fig. 8****. In case of Yellow (G), this is $X_G \rightarrow \pi_G^*$. As the electron donating power of $OC_2H_5$ is weak relative to that of $NH_2$[7], however, this absorption may also be weak. Probably the principal absorption band of G is due to $\pi_G \rightarrow \pi_G^*$. In case of Blue, it is difficult to know which auxochrome $X_B$ corresponds to, because Blue has many auxochromes. Consequently, they are lumped together under $X_B$.

If Bule and Yellow from the complex BG with the structure mentioned above, the first probable change will arise between $\pi_G$ and $X_B$ (and $\pi_B$), because the auxochromes of B may be affected strongly by the inner $\pi$-electron system of G; a repulsion between these MO's will occur to make such a pattern as BG in Fig. 8. It was supposed here that no interaction happens between $\pi_B^*$ and $\pi_G^*$. If a geometrical arrangement of the orbitals $X_B$ and $\pi_G^*$ in the complex is taken into consideration, the $X_B \rightarrow \pi_G^*$ transition, i. e., an intermoleculer charge transfer, may be expected to occur easily.

Concerning the complex $BG_2$, as already mentioned, its structure may be as GBG, with the linear molecules standing side by side. Since the G molecules stand close to each other in spite of B existing between them and parallel with each other, the complex has at least one symmetry. Consequently, the two $\pi_G^*$ orbitals mix to separate into $\pi^*_{G_1} + \pi^*_{G_2}$ and $\pi^*_{G_1} - \pi^*_{G_2}$. As seen in the discussion based on the VB theory, it is also difficult to ascertain to which molecular orbital the charge transfer from B occurs. The experimental results, however, mean that it may be $X_B \rightarrow (\pi^*_{G_1} - \pi^*_{G_2})$. On the other hand, it is clear from the above discussion that the $X_B$ level in GBG is pushed up higher than the one in BG.

Though there is no ground for justifying the relative positions of the molecular orbitals in Fig. 8, the spectral changes shown in Fig. 6 could be explained at least qualitatively by the above discussion based on the MO method. Some parts of the above two discussions were not always perfect, but it should be noted that the spectra of the complexes could not be explained without the concept of charge transfer. Explanation of these specteal changes by a solvent effect caused by the close approach of dye molecules was attempted, without considering the charge transfer, only to fail; the first absorption band of Yellow was insensitive to the change in pH or in solvent. So, it follows that the strong absorptions at about 420 m$\mu$ of the complexes can not be explained by a mere solvent effect.

Thus the absorption spectra of the complexes formed of Blue and Yellow could be explained qualitatively on the basis of those of the components. A binary mixture of Blue, in which the formation of a 1 : 1 complex is proved, also showed a change in spectrum which might not be explained without the concept of charge transfer.[1],***** It cannot always be said, however, that its charge transfer occurs in the same mechanism as is considered in the present work. The main reason will be found in the fact that the partner of Blue has no such symmetry in its structure as Yellow has and that the obvious factors suggesting the arrangement of the component dyes in the complex are not found.

*** Since the amino groups have less effect on the spectrum of Blue than the hydroxyl groups and the electron donating power of the former is stronger than that of the latter, as mentioned in footnote 2, an electron of one of the amino groups may be considered to have high possibility of acting in the intermolecular charge transfer. However, it is impossible and unnecessary to confirm the fact.

**** X and $\pi$ mean the orbital of unshared electrons and the inner $\pi$-orbital, respectively.

***** Blue and Durazol Red 2B forms a 1 : 1 complex in aqueous solution (see Ref. 3), of which spectrum seems not to be understood without considering charge transfer.

**Summary**

1. The change in absorption spectra of mixtures of Chlorazol Sky Blue FF and Chrysophenine G in aqueous solution was stoichiometrically studied in detail and a 1 : 1 complex and a 1 : 2 complex were proved to be formed.

2. The absorption spectra of the complexes were drawn from experimental results by use of the calculated equilibrium constants, and the phenomena of these absorptions were qualitatively explained according to VB and MO methods, with the conclusion that charge transfer spectra from Chlorazol Sky Blue FF to Chrysophenine G appear in the complexes.

The authors wish to express their thanks to Professor Ikuzo Tanaka for his helpful discussion.

# *Sodium Iodide-Acetone and Zinc Bromide-Acetone Molecular Complexes*

By Haruka YAMADA

(Received November 17, 1959)

The molecular compound between sodium iodide and acetone, known as NaI·3 acetone, can be used for the purification of acetone. The nature of the bonding, however, has not been made clear. From conductivity measurements, Rosenthal[1] suggested that the molecular compound was dissociated into $Na^+$ and $(I \cdot 3 \text{ acetone})^-$ in acetone. This may indicate that the compound has an ionic structure as represented by $Na^+$ $(I \cdot 3 \text{ acetone})^-$. By infrared studies, Slovokhotova[2] reported that acetone molecules had the enol form when sodium iodide was added, but her explanation does not seem to be plausible.

On the other hand, the complex formed by the addition of iodine or lithium perchlorate to acetone is known as the charge transfer complex stabilized by the electron donor-acceptor interaction[3,4]. The sodium compounds of salicylaldehyde and methylsalicylate[5] are also known to be formed by the same interaction between the $Na^+$ ion and the C–O and C=O groups, respectively. As for the NaI-acetone complex, the charge transfer force may interpret the intermolecular bonding.

The present study has been undertaken to clarify what sort of force gives rise mainly to the intermolecular bonding of the NaI-acetone and $ZnBr_2$-acetone systems.

## Experimental

Guaranteed commercial anhydrous sodium iodide and zinc bromide were used without further purification. Sodium perchlorate was obtained by heating $NaClO_4 \cdot H_2O$ in an air bath. The anhydrous salts were stored in the dark in a desiccator. Acetone was used after drying over anhydrous sodium sulfate and fractionating. The salts were dissolved into acetone and the thin layers of the solutions were obtained by sandwiching them between polyethylene films. The solid sample was made by cooling with the dry ice-ethanol mixture. The infrared spectra were taken with a Perkin-Elmer Model 112 infrared spectrophotometer in the region $400\,cm^{-1} \sim 4000 cm^{-1}$, using KBr, NaCl, $CaF_2$ and LiF prisms.

The composition of the complex was determined as follows. The salt was dissolved into acetone at room temperature and its concentration was determined by weighing. When the solution was cooled and the complex was crystallized, an excess of acetone was eliminated by suction and the complex was weighed.

## Results and Discussion

The wave numbers of the spectra of the NaI- and $ZnBr_2$-acetone systems are shown in Table I and the curves in Figs. 1—5.

The skeletal vibrations of acetone were influenced noticeably by the addition of the salts, while the other bands were not so affected. Concerning the bands splitting into the two components, one of the components can be attributed to the complex and the other to original acetone. Although the separation of the C=O stretching band in NaI-acetone system

TABLE I. WAVE NUMBERS OF SPECTRA FOR ACETONE, NaI-ACETONE AND $ZnBr_2$-ACETONE

| Acetone (liquid) | NaI-acetone (liquid) | NaI-acetone (solid) | $ZnBr_2$-acetone (liquid) | Assignment* |
|---|---|---|---|---|
| 1717 | 1709 | 1708 | 1697(s) | $A_1$ C=O stretching |

(s) indicates the band having two components and the wave number is the value for the complex component.

* T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **74**, 915 (1953).

could not be observed, the observed band with the shifted maximum is interpreted as the complexed band closely overlapped with the non-complexed one. The fact that the band shifts observed on complex formation are small suggests that the acetone molecules in the complex are slightly perturbed. The directions and amounts of the shifts are similar to those observed for the iodine-acetone[3] and lithium perchlorate-acetone complexes[4]. These shifts may be interpreted as being due to the changes of the force constants of C=O stretching and C-C=O bending vibrations caused by the formation of the complex, similarly as the case of the iodine-acetone or lithium perchlorate-acetone complex[6].

Since the spectrum of the NaI-acetone complex exhibited a similarity to that of the $NaClO_4$-acetone complex except the absorption caused by the $ClO_4^-$ ion, the formation of the salt-acetone complex may be due to the bonding between acetone and the $Na^+$ or $Zn^{2+}$ ion.

When the NaI-acetone solution was cooled, the needle crystal was obtained. Its composition was 1 : 5 mole ratio. The spectrum of this crystal contained the original acetone bands and was similar to that of the solution. The C-C antisymmetric stretching band is shown in Fig. 2(b). This curve can be divided into the two Lorentz curves with the maxima at 1236 $cm^{-1}$ and at 1215 $cm^{-1}$. Intensities were calculated from Ramsay's method[7]. It has been shown[3] that, for the iodine-acetone system, this band does not change in intensity on complex formation. The same may be true for this complex. From this property of the band and the fact that the area intensity ratio between the two bands is about 3 : 2, it follows that three acetone molecules are regarded as those of complexed acetone and the other two as those of non-complexed acetone. Probably the $Na^+$ ion forms the tetra-coordinate compound having $I^-$ and three acetone molecules as ligands and the other two acetone molecules will be contained in the crystal without coordinating.

The overtone band of the C=O stretching vibration showed a remarkable change. As shown in Fig. 5, this band became broad and was enhanced very much. By subtracting the two bands at 3520 $cm^{-1}$ and at 3620 $cm^{-1}$ from the observed curve for the NaI-acetone system, the dotted curve was obtained. This may be attributed to the overtone band of C=O stretching vibration and not the OH band, because the similar phenomenon was observed for the overtone band of the C=O stretching vibration of the iodine-acetone complex.

Relatively large shifts were observed for the skeletal vibrations belonging to the $B_1$ type. This differs from the phenomenon observed for the iodine-acetone complex and is probably due to the fact that the mole ratio of the NaI-acetone complex is 1 : 3 even in solution, while that of the iodine-acetone is 1 :1.

2. NaI-acetone solution (0.1 mm. cell)

From the fact that the frequencies of the acetone band maxima do not vary continuously with salt concentration but the bands show the contour of two components and from the fact that observed shifts are similar to those for the iodine-acetone charge transfer complex, it may be concluded that the formation of the complex is due to the coordination of the lone pair electrons of oxygen atom to the $Na^+$ or $Zn^{2+}$ ion. No evidence for the enolization of acetone was found. As for the intermolecular bonding of these complexes, the charge transfer force, besides ion-dipole interaction etc., should be taken into account. The wave function of the normal state for the complex may be written by

$$\Psi_N = a\phi_A + b(\phi_{BI} + \phi_{BII} + \phi_{BIII}).$$

Here $\phi_A$ expresses the no-bond structure and $\phi_{BI}$, $\phi_{BII}$ and $\phi_{BIII}$ following dative structures.

The author wishes to express her sincere thanks to Professor K. Kozima for his kind guidance during this work.

# *Synthesis of 1,4,7-Cyclononatrione**

By Sin'iti KAWAI, Sanae TANAKA, Kenji TERAI, Masami TEZUKA and Tarozaemon NISHIWAKI

(Received May 26, 1959)

The hydrocarbon $C_{20}H_{20}$ (III) with the complete skeleton of a regular pentagonal dodecahedron has not yet been known. Since the hydrocarbon, which shall be tentatively called "dodecahedrane", will be a very stable, strainless compound, an attemp of its synthesis has been started with the present work.

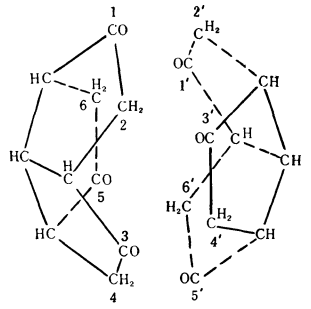
For the synthesis of dodecahedrane it is necessary to obtain the hypothetical *d*, *l*-tricyclic compound, I+I′, which shall be temporarily called "tricyclone". Although there are four asymmetric carbon atoms in the molecule of tricyclone, only one pair of optical isomers, I and I′, are possible and synthesis will lead to a racemate. The tricyclone, having three pairs each of carbonyl and active methylene groups, must be a very reactive compound. Condensation will begin with the collision of two molecules of triyclone in the following combination:

(1) I+I′; (2) I+I and (3) I′+I′.

Case 1 may be divided into three divisions, a, b and c.

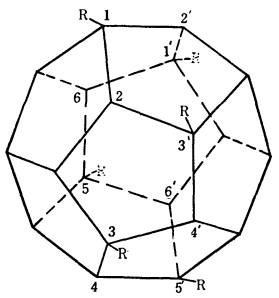
(a) Addition starts with cyclobutane ring formation, for instance, with addition of 2′ to 1 and of 2 to 1′.

(b) Addition starts with cyclohexane ring formation, for instance, with addition of 2 to 1′ and of 6′ to 3.



(c) Addition starsts with cyclopentane ring formation, for instance, with addtion of 2 to 3′ and of 4′ to 3.

Both divisions a and b will lead to undefinable polymerization products, while division c may proceed to a dodecahedrane derivative under consecutive additions of 2′ to 1, of 6 to 1′, of 6′ to 5 and of 4 to 5′.



In the presence of an appropriate agent (for instance sodium ethoxide, etc.), I and I′ will be able to add to each other to give a hexahydroxydodecahedrane (II, R=OH) through the narrow reaction route, cace 1, division c, the yield being consequently expected to be small. As soon as the hexahydroxydodecahedrane is formed, it may probably suffer spontaneous dehydration, thus affording dodecahedrahexaene (IV). It is to be noted, that formula IV denotes only a limiting structure, because the conjugated hexaene ring V contained in formula IV will resonate with another limiting structure VA and that the double linkings in the molecule will not be restricted within the one hexaene ring, V↔VA, but will be distributed equally all over the whole system of the twenty carbon atoms. Consequently the dodecahedrahexaene is expected to be a rather stable compound, but its catalytic hydrogenation may afford the desired dodecahedrane (III).

On the other hand, one possibility from case

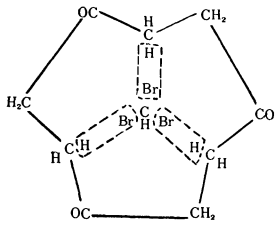
IV $C_{20}H_8$



V VA

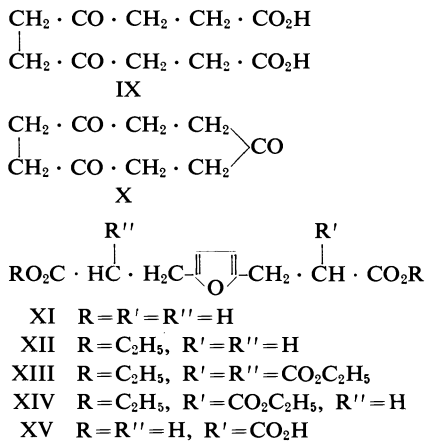
VI R=OH ; $C_{20}H_{14}(OH)_6$

VII $C_{20}H_8$

VIII

2 will similarly lead to an optically active dimerization product VI (it shall be tentatively named "hexahydroxyisododecahedrane"). The corresponding product from case 3 will be the optical isomer of VI. In both compound VI and its optical isomer not only the cyclobutane rings but also the cyclohexane rings are strongly strained, because the latter may be forced to take an almost coplanar form. Dehydration at the instant of their formation may afford the same optically inactive isododecahedrahexaene $C_{20}H_8$, as shown by formula VII with arbitrary positions of the six double bonds.

Thus *d, l*-tricyclone, I+I′, may produce dodecahedrahexaene and isododecahedrahexaene along with a large amount of undefinable polymerization products from improper collisions among the tricyclone molecules.



Success depends on our ingenuity in the synthesis of *d, l*-tricyclone because we even expect that the tricyclone, if once formed, may condense spontaneously to give hexaene IV, although it may have to be separated from isohexaene VII. When condensed with bromoform, the compound given in the title of this paper, or 1, 4, 7-cyclononatrione (X), may give *d, l*-tricyclone accompanied by other condensation products (see VIII). This paper communicates the synthetical efforts paid by us for obtaining cyclononatrione (X). The syntheses of the so-called "medium ring"[1] compounds which are composed of 9, 10 or 11 methylenes are known to be difficult[2]. Some simple compounds among them, however, were synthesized recently by Prelog and Stoll's method[2], and it is especially noteworthy, that these medium ring compounds possess particular

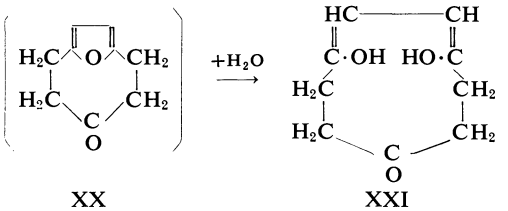
2) V. Prelog, *J. Chem. Soc.*, **1950**, 420.

internal strain (transannular effect)[3] when compared with other smaller or larger ring compounds. Apart from the question of transannular effect, there are fears lest cyclononatrione should suffer intramolecular condensation, and yet the first attempt adopted by us lay in the dry distillation of the barium salts of 4, 7-dioxodecanedioic acid (IX) according to Ruzicka's ring ketone syntheses[4]. The acid IX was obtained early by Kehrer et al.,[5] later by Asahina and Fujita[6], and then by Hachihama et al.[7], through hydrolytic furan-ring fission of δ-furfurylidenelevulinic acid.

The acid IX was mixed with barium carbonate and pyrolysis was carried out by heating under reduced pressure. Indeed, a ketone was separated as its semicarbazone (m. p. 184° (decomp.)) from the neutral part of the distillate thus obtained, but the analytical value of its nitrogen content was too small to conclude that the trissemicarbazone of the triketone X was really obtained.

The yield of this undefinable semicarbazone in the above attempt was poor, but the synthesis turned out to be successful by boiling tetraethyl 2, 5 - diethylfuran - β, β, β', β' - tetracarboxylate (XIII) or triethyl 2, 5-diethylfuran-β, β, β'-tricarboxylate (XIV) with hydrobromic acid[8]. The compounds XIII and XIV were synthesized by the following scheme.



IX

XIX R=H

4, 7-Dioxodecanediocic acid (IX), when heated over its melting point, afforded 2, 5-diethylfuran-β, β'-dicarboxylic acid (XI)[6a),7b)], which was converted into its ethyl ester XII. Introduction of an ethoxycarbonyl group into the β-position of the latter was carried out according to Jone's procedure[9]. From the reaction product, XIV was distilled at 132~155°C/0.15~0.27 mmHg in a poor yield. Without further purification the tarry residue was hydrolyzed with alcoholic potash to give 2, 5-diethylfuran-β, β, β'-tricarboxylic acid (XV) which, was identical with the hydrolysis product of XIV. 5-(Chloromethyl)-furfural (XVI)[10], on the other hand, gave tetraethyl 2-ethyl-5-vinylfuran-β, β, β', β'-tetracarboxylate, (XVII) when treated with diethyl malonate. Catalytic reduction of XVII with platinum black afforded XIII. Neither did the latter distill out even in vacuo nor showed any sign of crystallization. It was immediately hydrolyzed with alcoholic potash, and then acidified with dilute sulfuric acid whereupon XV was obtained. These facts revealed that XIII was produced accompanied by XIV. Since it seemed noteworthy that, in the above-mentioned hydrolysis of XIII, only one ethoxycarbonyl group underwent decarboxylation simultaneously with hydrolysis, two more examples of the hydrolysis of related malonic ester derivatives were carried out. When XVII was shaken with aqueous potassium hydroxide at room temperature for a long time, and the reaction mixture was acidified, one ester group remained unchanged and one of the three hydrolyzed carboxyl groups underwent decarboxylation, thus a mono ester of a tricarboxylic

acid (relative positions of its carboxyl and ester groups are ambiguous) was obtained. On the other hand, when tetraethyl 2,5-divinylfuran-$\beta, \beta, \beta', \beta'$-tetracarboxylate (XVIII)[11,12] was hydrolyzed by heating with sodium hydroxide and acidifying with sulfuric acid, 2,5-divinylfuran-$\beta, \beta, \beta', \beta'$-tetracarboxylic acid (XIX) was procured without suffering decarboxylation. Thus the malonic ester derivative (XVIII), in which the $\alpha$-carbon atoms of the malonic ester groups are connected with $\alpha$ double linkings, undergoes only hydrolysis but not decarboxylation.

Now the tricarboxylic acid ester XIV was heated with 48% hydrobromic acid for 30 min. according to Linstead's method[8]. If ring closure occurred XX should be yielded. Although the compound XX is bicyclic with two double bonds at the bridged heads it may be capable of existence, because one of the two rings is eight-membered, hence belonging to an exceptional case of Bredt's rule[2]. As a matter of fact we could isolate the triketone X (or the keto form of XXI) as its trissemicarbazone (m. p. 176~177°C (decomp.)) from the neutral part of the reaction product, thus indicating the intermediate formation of the hypothetical bicyclic compound XX. In this case, only a little amount of XI was recovered from the acidic part, but the major amount became a black polymer which was rather soluble in water. The yield of the trissemicarbazone of X based on XIV ranged from 2 to 4%. Compounds, corresponding to mono- and bis-semicarbazones, were not detected. When the crude material of XIII was used as the starting material, X was obtained with poorer yields (0.5~1%). When XIV or XII were subjected to Dieckmann's ring closure with sodium and sodium methoxide, no ring formation was observed but XI besides the starting material were yielded.

The attempt to obtain the compound X from its semicarbazone was fruitless. When the trissemicarbazone was treated with alcoholic sulfuric acid, only a tarry matter was obtained as a neutral substance, which neither distilled in high vacuum nor gave any simicarbazone when treated with semicarbazide.

## Experimental[13]

**Dry distillation of 4,7-dioxodecanedioic acid.**—A small saber flask, which was wrapped with a copper wire gauze, was attached to a well chilled trap. 4,7-Dioxodecanedioic acid (5 g., 1 mol.) and barium carbonate (4.3 g., 1 mol.) were powdered and intimately mixed and the whole was put into the flask. The flask was heated in vacuo gently at the beginning but later stronger with a free flame under constant moving. The oily distillate has an allyl-alcohol-like disagreeable smell. This pyrolysis was repeated five times and 25 g. in total of 4,7-dioxodecanedioic acid gave 4.3 g. of the distillate. The distillate was dissolved in ether, washed successively with aqeous sodium bicarbonate, 10% sodium carbonate, and 5% sodium hydroxide, and finally with water, dried and evaporated. The yield of the neutral oily substance was 220 mg. Vacuum distillation gave a colorless oil, b. p. 205~248°C/0.1~0.14 mmHg; yield, 110 mg. Its semicarbazone was obtained in an usually way. Recrystallization from chloroform gave grayish white platelets, m. p. 184°C (partly decomp.).

Found: C, 42.68; H, 7.67; N, 34.70. Calcd. for $C_{12}H_{21}N_9O_3$: C, 42.47; H, 6.24; N, 37.15%.

Acidification of the aqueous sodium bicarbonate solution with sulfuric acid gave 50 mg. of an acidic material, m. p. 141~146°. The latter (28 mg.), without further purification, was titrated with 0.098 N sodium hydroxide, 2.8 cc. being consumed. When calculated for a dibasic acid its molecular weight is 230. This value roughly corresponds to that for 2,5-diethylfuran-$\beta, \beta'$-dicarboxylic acid (XI) (m. p. 155°C with partial decomp., molecular weight 212). The sodium carbonate washing was acidified with dil. sulfuric acid and then shaken with ether. The ethereal solution, when evaporated, left an oily substance with strong phenolic smell. The sodium hydroxide washing behaved quite similarly. The phenolic oils of the two origins were therefore combined (250 mg. in total) and treated with *p*-nitrobenzoyl chloride. A small amount of crystals with m. p. 86~91°C was obtained but both its purity and quantity were insufficient for micro analysis.

**Diethyl 2,5-diethylfuran-$\beta, \beta'$-dicarboxylate (XII) and Diethyl 4,7-dioxodecanedioate**—A mixture of 2,5-diethylfuran-$\beta, \beta'$-dicarboxylic acid (XI, 45 g.), absolute alcohol (300 cc.), benzene (150 cc.) and 2 drops of conc. sulfuric acid was subjected to azeotropic distillation. When the main bulk of alcohol distilled out further azeotropic distillation was repeated twice, with the addition of alcohol (100 cc.) and benzene (30 cc.) each time. Then the solvent was removed as much as possible. The residue was dissolved in ether, and the solution was washed successively with aqueous sodium bicarbonate and water, dried and evaporated. Vacuum distillation gave 36 g. (63%) of a colorless liquid, b. p. 155~161°C/4 mmHg. Redistillation gave XII in analytical purity as a liquid of b. p. 147~148°C/3 mmHg.

Found: C, 62.62; H, 7.58. Calcd. for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

During the above written manipulation of vacuum distillation the distillate over 180°C/4 mmHg. solidified in the condenser, and the residue in the distilling flask also solidified. Combined yield, 8 g. (13%). Recrystallization from petroleum ether (b. p. 40~55°C) gave diethyl 4,7-dioxodecanedioate[5b] as colorless scales, m. p. 46~46.5°C. No melting point depression was observed, when mixed with an authentic specimen.

11) W. F. Cooper and W. H. Nuttall, *J. Chem. Soc.*, **101**, 1074 (1912).
12) W. F. Cooper and W. H. Nuttall, ibid., **105**, 2218 (1914).
13) All melting points are uncorrected.

Found: C, 58.77; H, 7.75. Calcd. for $C_{14}H_{22}O_6$: C, 58.73; H, 7.75%.

**Triethyl 2,5-diethylfuran-$\beta,\beta,\beta'$-tricarboxylate (XIV).**—The above compound XII (13 g., 1 mol.) and diethyl carbonate (75 g., 6 mol.) were mixed well in a 500 cc. distilling flask, and to the mixture was slowly added a sodium ethoxide solution [2.3 g. metallic sodium in absolute alcohol (70 cc.)] with stirring. The solution gradually changed to pinkish yellow in color and yielded gray precipitates. Alcohol was removed slowly and carefully in a water bath. Dry benzene (30 cc.) was then added, and the solvent was removed by distillation as much as possible first on a steam bath, finally in an oil-bath (160~170°C) in vacuo. After cooling water was added, the residue was acidified with sulfuric acid, and extracted with ether. The ethereal solution was washed with water, dried and evaporated. High vacuum distillation gave 3.3 g. (20%) of an oil which solidified on standing. B. p. 132~135°C/0.15~0.27 mmHg. Recrystallization from petroleum ether (b. p. 35~45°C) with exterior cooling in dry ice gave XIV as colorless platelets, m. p. 28~29°C.

Found: C, 60.29, H, 6.85. Calcd. for $C_{17}H_{24}O_7$: C, 56.99; H, 7.10%.

**Tetraethyl 2,5-diethylfuran-$\beta,\beta,\beta',\beta'$-tetracarboxylate (XIII).**—5-(Chloromethyl)-furfural (XVI, b. p. 137~138°C/5 mmHg, 16 g., 1 mol.) was added with cooling, to an alcoholic solution of magenesium salt of diethyl malonate [magnesium (2.5 g., 1 atom) dissolved in diethyl malonate (17 g., 1 mol.)]. The whole was kept standing at room temperature, and then refluxed for 1 hr. To this solution were added diethyl malonate (17 g., 1 mol.) and piperidine (0.5 cc.), and the whole was refluxed for 7.5 hr. The solvents were evaporated as thoroughly as possible, and then water was added to the risidue. After acidification with sulfuric acid, the reaction mixture was extracted with ether, washed with water and dried. Removal of the ether gave XVII as a dark red viscous oily substance which did not crystallize nor distil out on high vacuum distillation. The identification was carried out by way of its hydrolysis product (described later). An alcoholic solution (100 cc.) of the crude material of XVII (4.2 g., 0.1 mol.) was subjected to catalytic hydrogenation with platinum black (0.2 g.) as the catalyst, thereby 186 cc. (0°C, 760 mmHg; 0.085 mol.) of hydrogen gas being consumed during 60 min. Filtering off the catalyst and subsequent evaporation of alcohol gave a very viscous oily substance (XIII), its purification being fruitless.

**2,5-Diethylfurane-$\beta,\beta,\beta'$-tricarboxylic acid (XV).**—a) From XIV: A solution of XIV (3 g.) in 20% aqueous sodium hydroxide (50 cc.) was heated on a steam bath for 1 hr. The whole was acidified with sulfuric acid under cooling, salted out with table-salt, and extracted with ether. The ethereal layer was washed with water, dried and evaporated. The residue, after digestion with hot water (1 cc.), was allowed to stand for 2 or 3 days, thus yielding a little amount (0.3 g.) of crystals. Recrystallization from aqueous methanol afforded XV as colorless platelets, m. p. 102~105°C (decomp.).

Found: C, 48.66; H, 5.32. Calcd. for $C_{11}H_{12}O_7 \cdot H_2O$: C, 48.18; H, 5.15%.

An aqueous solution of the above-obtained substance (0.265 g.) was titrated with 0.102 N aqueous sodium hydroxide, phenolphthalein being used as an indicator.

Found: 30.2 cc. Calcd.: 28.4 cc.

b) From XIII: Hydrolysis of the crude material XIII, already described above, gave the same XV.

**Hydrolysis of Tetraethyl 2-ethyl-5-vinylfuran-$\beta,\beta,\beta',\beta'$-tetracarboxylate (XVII).**—The benzene (5 cc.) solution of the crude material of XVII (15 g.) was shaken with 20% aqueous potassium hydroxide (100 cc.) for 17 hr. at room temperature, then the whole was acidified with sulfuric acid under ice-cooling, and was extracted with ether. The ethereal layer was washed with water, dried and evaporated, thus a colorless solid matter (1 g.) was obtained. Recrystallization from wet benzene gave colorless plates, which melt at 148.5~149°C with decomposition. Elementary analysis as well as titration revealed, that this compound ($C_{13}H_{14}O_7 \cdot \frac{1}{2}H_2O$) may be derived from XVII through hydrolysis. Simultaneous decarboxylation occurred in any one of the four ethoxycarbonyl groups contained in the molecule of XVII.

Found: C, 53.40; H, 5.67. Calcd. for $C_{13}H_{14}O_7 \cdot \frac{1}{2}H_2O$: C, 53.61; H, 5.91%.

The above-mentioned substance (0.301 g.) was titrated with 0.102 N aqueons sodium hydroxide, giving the following results.

Found: 22.1 cc. Calcd.: 19.6 cc.

**2,5-Divinylfuran-$\beta,\beta,\beta',\beta'$-tetracarboxylic Acid (XIX).**—Tetraethyl 2,5-divinylfuran-$\beta,\beta,\beta',\beta'$-tetracarboxylate (XVIII) (2 g.), which had been obtained by Cooper's method[12], was dissolved in 27% aqueous sodium hydroxide (50 cc.) and the whole was heated on a steam bath for 1 hr. The solution was then acidified with sulfuric acid, salted out with table-salt, and then extracted with ether. The ethereal layer was washed with water, dried and evaporated. The residue was dissolved in hot water (1 cc.) and then kept in a vacuum desiccator. Crystals which appeared during 10 days were collected, and recrystallized from ethyl acetate and then from hot water. Orange red plates, m. p. 218°C (decomp.); yield, 0.5 g. (39%).

Found: C, 46.01; H, 3.39. Calcd. for $C_{12}H_8O_9 \cdot H_2O$: C, 45.87; H, 3.21%.

The above-mentioned substance (0.317 g.) was titrated with 0.102 N aqueous sodium hydroxide, giving the following result.

Found: 40.5 cc. Calcd.: 39.0 cc.

**Trissemicarbazone of 1,4,7-cyclononatrione (X).**—The tricarboxylic acid triester XIV (5 g.) was mixed with 48% hydrobromic acid (30 cc.) and the whole was refluxed gently for 30 min. After cooling, the dark solution which occasionally contained a black solid matter was treated with water (100 cc.) and ethyl acetate. The ethyl acetate layer was washed successively with water, aqueous sodium bicarbonate, and finally with water, and dried. Removal of the solvent gave a dark orange liquid. Semicarbazone was obtained by the usual method as a gray solid (0.1~0.2 g.), which, when recrystallized from methanol or alcohol, underwent decomposition. Recrystallization from benzene—although the solubility in it was small—gave grayish

white plates, m. p. 176~176.5°C (partly decomp.); yield, 30 mg.

Found: C, 42.08; H, 7.00; N, 36.79. Calcd. for $C_{12}H_{21}O_3N_9$: C, 42.47; H, 6.24; N 37.15%.

The aforesaid washings with aqueous sodium bicarbonate were acidified with sulfuric acid, yielding a grayish white solid. Recrystallization from water gave IX, m. p. 155~156° (partly decomp.). The black polymer, obtained in this reaction, was rather soluble in water, very soluble in alcohol or acetone, but insoluble in ether and ethyl acetate. Further investigation was given up, since the attempts of purification failed.

Since one of us (Kawai) must now give up his laboratory life, in consequence of his personal circumstance, we hope that anyone who feels interested in this field will persue the synthetical attack on the "dodecahedrane", the existence of which is theoretically possible.

We are indebted to the Ajinomoto Co. for the gifts of valuable compounds for the present research. Thanks are also due to the Science Research Institute and the Takamine Kenkyusho in the Sankyo Co. for microanlyses.

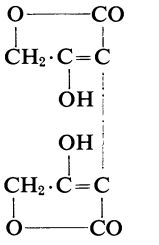
# *Bromination of Ethyl Diacetosuccinate*

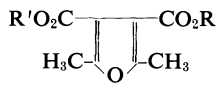
By Sin'iti KAWAI and Sanae TANAKA

(Received May 26, 1959)



Although the synthesis of 1, 4, 7-cyclononatrione has been realized by us[1], it was isolated only as its trissemicarbazone in a poor yield. We have now chosen another course to attain this cyclic triketone, thus intending at first to obtain ethyl 1, 4, 7-cyclononatrione-2, 3, 6, 8-tetracarboxylate through the condensation of $\gamma,\gamma'$-dibromodiacetosuccinate (II) and ethyl disodioacetonedicarboxylate. This attempt, however, failed presumably owing to the false constitution (II) of the so-called $\gamma,\gamma'$-dibromodiacetosuccinate. Consequently, the bromination of ethyl diaceto succinate (I) had to be reinvestigated and the present paper presents some new aspects as an exceptional example of the bromination of $\beta$-ketoesters.

Informations concerning II can be summarized as follows: Wolff et al.[2] treated ethyl diacetosuccinate (I) with two moles of bromine and ascribed formula II to the pale yellow reaction product because of the fact that the substance in question, when heated at 150~160°C, gave bistetronic acid (V) by giving up two moles of ethyl bromide. On the other hand, Hirst et al. treated the same bromination product with hydrazine and concluded from the estimation of the nitrogen gas evolved that the bromide was a mixture of 21% of $\alpha,\alpha'$-dibromo compound III and 79% of $\gamma,\gamma'$-dibromo compound II[3], in other words, an equilibrium mixture due to an $\alpha,\gamma$-shift of bromine atoms[3-5].



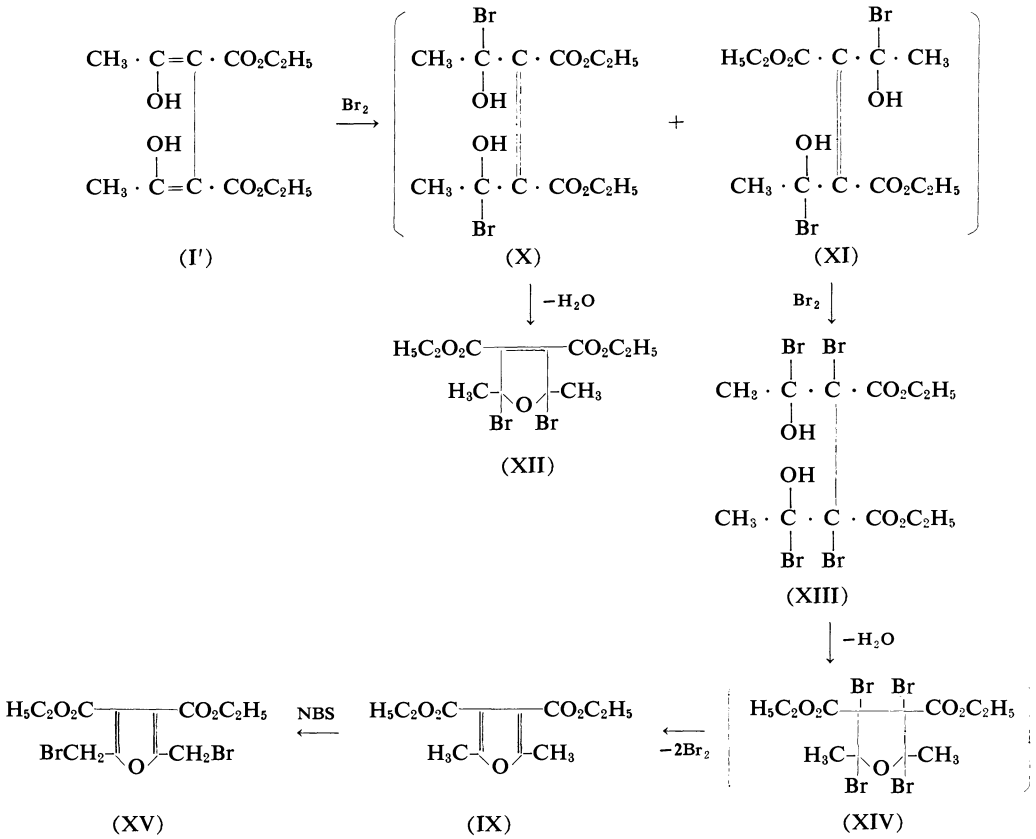
$RCH_2 \cdot CO \cdot CR' \cdot CO_2C_2H_5$

$RCH_2 \cdot CO \cdot CR' \cdot COC_2H_5$

(I) R=R'=H
(II) R=Br, R'=H
(III) R=H, R'=Br
(IV) R=R'=Br

(V)

(VI) R=H, R'=$C_2H_5$
(VII) R=R'=H
(VIII) R=R'=$CH_3$
(IX) R=R'=$C_2H_5$



In fact, we could obtain a pale orange yellow viscous oil without hydrogen bromide evolution when we brominated compound I after Wolff's method[2], but the vacuum distillation of this

oil gave only a little amount of a distillate at 150~170°C (bath temperature) and then met with a sudden rise of the pressure obviously due to decomposition. The distillate contained monoethyl 2, 5-dimethylfuran-3, 4-dicarboxylate (VI), and the residue included 2, 5-dimethylfuran-3, 4-dicarboxylic acid (VII) as one of its constituents.

Then, we gave up vacuum distillation, and kept the viscous oily bromination product of compound I (it shall be called "I-bromide" hereafter) in a cool place during one month. Crystals which gradually appeared in the meanwhile were collected at appropriate intervals and at least four new compounds, i.e. I-tetrabromide (XIII), monoester VI, dicarboxylic acid VII and the dibromide of diester IX, were isolated.

The I-bromide gave neither any indole derivative when heated with a mixture of aniline and aniline hydrobromide[6], nor a *p*-nitrophenylpyridazine derivative when treated with *p*-nitrophenylhydrazine[5]. These results show the absence of a $\gamma,\gamma'$-dibromide such as II or IV. Since the I-bromide, when heated with resorcinol or with $\alpha$-naphthol, did not give any bromophenol or bromonaphthol, the bromine atom is not so "positive"[7]. Thus the presence of $\alpha,\alpha'$-dibromide derivatives such as III or IV is excluded. The I-bromide, when heated with absolute methanol, gave dimethyl 2, 5-dimethylfuran-3, 4-dicarboxylate (VIII), and a desmotropic form[8] of diacetosuccinic acid (I, H instead of $C_2H_5$) when heated with sodium methoxide. When treated with concentrated sulfuric acid[5,9] the I-bromide did not show any sign of a ketonic hydrolysis but gave the free acid VII. The I-bromide gave no definite product when heated with aqueous potassium carbonate[10]. On the other hand, compound I gave diethyl 2, 5-dimethylfurandicarboxylate (IX) on treatment with concentrated sulfuric acid and acetonylacetone on heating with aqueous potassium carbonate, both in good yields. When hydrogen bromide gas was passed through a benzene solution of compound I, only a very little

amount of VII was obtained and the major part of compound I remained unchanged. Therefore, the two compounds, VI and VII, which were isolated from the I-bromide, should never have been derived from the starting material (I) through the catalytic action of the little amount of hydrogen bromide generated during the bromination of compound I.

As has already been mentioned, there is no positive proof for the existence cf $\alpha,\alpha'$-dibromide III and $\gamma,\gamma'$-dibromide II. Hence, the elucidation of the constitution of the I-tetrabromide, found as one constituent of I-bromide, appeared difficult. We are now forced to assume that the dienediol form I′ of compound I gave a mixture of *cis*-dibromide X and *trans*-dibromide XI as the result of 1,4-addition of bromine, and the former (X) passed over to a dihydrofuran XII while the latter (XI) took up another mole of bromine to produce tetrabromide XIII. Then, tetrabromide XIII underwent dehydration catalyzed by hydrogen bromide, thus yielding a tetrabromide XIV, which, as the result of spontaneous debromination, gave furan derivative IX. Compound IX suffered partial and total hydrolysis catalyzed by hydrogen bromide, yielding compounds VI and VII. The precise structure of dibromide XII is further shown by the fact that it is quite different from dibromide XV obtained from the dimethylfuran derivative IX through *N*-bromosuccinimide. Thus, the I-tetrabromide in question may perhaps be represented by formula XIII, because this compound is so unstable that it decomposes (dehydration?) when merely heated or treated with water-miscible solvents.

The proof that the main course involved in this reaction belongs to bromine addition but not bromine substitution can be found in the following facts: (i) during the bromination of compound I evolution of hydrogen bromide was scarcely recognized: (ii) on the other hand, hydrogen bromide evolution was observed during the manipulation of recrystallization of crystals gathered from the I-bromide.

Both Wolff[1] and Hirst[2] observed that bromine substitution took place when ethyl diacetosuccinate was treated with bromine, which does not agree with our experiments. Our observation seems more reasonable, because the more stable conjugated dienediol-form I′ may predominate over the unconjugated diketo-form I in ethyl diacetosuccinate, and the reaction may start with the 1,4- and further 2,3-addition of bromine to the conjugated system but not with bromine substitution.

## Experimental[11]

**Bromination of Ethyl Diacetosuccinate.**—To a solution of ethyl diacetosuccinate[12] (I) (140 g., 1 mol.) in chloroform (300 cc.) bromine (170 g., 1.95 mol.) was added dropwise in 2 hr. with ice-cooling and stirring, and the mixture was stirred for 2 hr. at room temperature. Hydrogen bromide was scarcely evolved, or estimated as only 0.53% of the value calculated for bromine substitution. The chloroform layer was washed successively with water, with 5% sodium thiosulfate and finally with water, dried and evaporated in vacuo on a water bath (below 38°C), giving "I-bromide" as a pale reddish orange substance containing a small amount of colorless crystals. Yield, 290 g.

**I-Tetrabromide (XIII) of Ethyl Diacetosuccinate.**—The small amount of colorless crystals, obtained above, were separated from the oily substance, washed with a small amount of petroleum ether (b. p. 40~50°C), dried and recrystallized from anhydrous benzene to yield the I-tetrabromide as colorless plates, m. p. 189°C (decomp.). Yield, 1.2g.

Found: C, 25.15; H, 2.59; Br, 55.83. Calcd. for $C_{12}H_{18}O_6Br_4$: C, 24.94; H, 3.14; Br, 55.31%.

When the above oily substance was left to stand, further crops of XIII were obtained during 2 or 3 days. The total yield was 2.7 g. On long heating in an attempt to recrystallize from aqueous benzene or anhydrous benzene, XIII changed to an indefinite substance with evolution of hydrogen bromide. On the other hand, when a water-miscible solvent such as methanol, alcohol and acetone, were used, XIII changed to VII.

**Separation of VI, VII and XII from "I-Bromide".**—When XIII was separated from the "I-bromide", and the oily substance was left to stand, crystals gradually separated out during 5~30 days. Addition of a small amount of ether promoted crystallization. Since the colection of the crystals by filtration was quite difficult because of the viscousness of the liquid, the whole was placed on a porcelain plate in spite of the loss of the yield or diluted with ether and then filtered. The solid thus obtained showed various melting points such as m. p. 60~90°C, m. p. 110~115°C (decomp.) and m. p. 130~140°C (partly decomp.), and was a mixture of VI, VII, XII, XIII and I as described below. When the oily substance was kept on standing for more than 3 months, hydrogen bromide and bromine were evolved gradually, yielding a solid which was mainly VII.

The solid obtained above was dissolved in anhydrous benzene, and then an insoluble substance was filtered off. The most soluble part was left to stand, a small amount of crystals being formed in the meanwhile. Filtration and recrystallization from petroleum ether (b. p. 40~50°C) gave VI[13] as colorless long plates, m. p. 83~84°C.

Found: C, 56.60; H, 5.83. Calcd. for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%.

The filtrate from VI was evaporated, yielding another crystalline substance. Recrystallization from petroleum ether (with active carbon) gave

11) All melting points are uncorrected.

13) (a) G. H. U. Harrow, *Ann.*, 201, 152 (1880). (b) L. Knorr, *Ber.*, 17, 2864 (1884); ibid., 22, 153 (1889).

unchanged I as colorless scales, m. p. 92~93°C, which was identified by mixed melting point determination.

Found: C, 55.86; H, 6.98. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03%.

When the crystals, separated from the part soluble in benzene, were recrystallized from anhydrous benzene, XII was obtained as colorless long pillars, m. p. 92~96°C (decomp.). It melted at 92~96°C with decomposition to a substance which melted at 128~130°C and gave the positive Beilstein halogen test.

Found: C, 36.20; H, 3.59. Calcd. for $C_{12}H_{16}O_5Br_2$: C, 36.03; H, 4.03%.

From the part more soluble in benzene than XII, a small amount of XIII, previously mentioned, was obtained.

From the part less soluble than XII and from the first insoluble part, a crude material of VII was obtained. During recrystallization XII partly changed to VII, and use of recovered benzene promoted the change. The latter was collected and recrystallized from aqueous methanol or water, yielding VII as colorless pillars of m. p. 234~236°C (partly decomp.).

Found: C, 49.70; H, 4.77. Calcd. for $C_8H_8O_5 \cdot \frac{1}{2}H_2O$: C, 49.74; H, 4.70%.

The yields of VI, I, XII and VII were 2.2 g., 0.8 g., 1.7 g. and 28.5 g., respectively.

**Vacuum Distillation of "I-Bromide".** — After removal of XIII, "I-bromide" (50 cc.) was heated under the reduced pressure of 5~6 mmHg. The pressure dropped to 30~40 mmHg at 150~170°C (bath-temperature) and again rose to 6~7 mmHg after 10 min. A pale orangish oily substance distilled out at ca. 200°C (bath-temperature). When the distillate was triturated with a small amount of ether, it solidified. Recrystallization from aqueous methanol gave VI as colorless long pillars of m. p. 83~84°C, b. p. 100~105°C/0.25~0.3 mmHg. Yield, 2.1 g. It was identified by a mixed melting pont with an authentic sample.

The residue was a very viscous reddish black syrup containing a small amount of a solid and had a distinct smell of hydrogen bromide and bromine. To the residue a small amount of ether was added, and the whole was kept standing in a stoppered flask for 2 or 3 days, yielding crystals gradually. These were collected on a filter and recrystallized from aqueous methanol (1 : 1) to give VII as colorless pillars, m. p. 234~236°C (partly decomp.). Yield, 3.8 g.

**Hydrolysis of VI.**—VI (1.2 g.) was dissolved in alcohol (60 cc.), and 50% sulfuric acid (5 cc.) was added, and the whole was refluxed for 4 hr. After removal of the alcohol, water was added. The precipitate, which formed in the meanwhile, was recrystallized from water, giving VII, m. p. 234~235°C (partly decomp.).

**Reaction of "I-Bromide" with Methanol.**—1) The oily "I-bromide" (2 g.), freed from all the crystals VI, VII, XII and XIII, was mixed with absolute methanol, and the whole was refluxed on a steam bath for 5 hr. After cooling a small amount of crystals were yielded. Recrystallization from water gave VII. The methanolic filtrate from VII was concentrated, giving first a small amount of a colorless substance of m. p. 100~110°C. Recrystallization from petroleum benzine (b. p. 60~75°C) gave colorless long pillars of m. p. 118~119°C, the amount being too little to be analyzed. From the last portion of the methanolic filtrate, colorless long plates of m. p. 45~46°C were obtained. Recrystallization from petroleum ether (b. p. 40~50°C) gave VIII[14] as colorless tetragonal plates, m. p. 58~61°C.

Found: C, 56.53; H, 5.70. Calcd. for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%.

2) The mixture of the oily "I-bromide" (2 g.), freed from all the crystals, with sodium methoxide (sodium 0.2 g., absolute methanol 50 cc.), was refluxed on a steam bath for 2 hr., and after the methanol was removed as much as possible and water was added, it was acidified with sulfuric acid to yield a white residue. Recrystallization from benzene (with active charcoal) gave a compound of m. p. 120~121°C (partly decomp.) as pale yellow plates, which were analyzed as diacetosuccinic acid.

Found: C, 47.59; H, 4.94. Calcd. for $C_8H_{10}O_6$: C, 47.53; H, 4.99%.

**Hydrolysis of "I-Bromide".**—1) The oily "I-bromide" (1 g.) freed from all the crystals was treated with concentrated sulfuric acid (5 cc.) and the whole was heated on a steam bath for 1 hr. Addition of water yielded grayish white precipitates, which, on recrystallization from benzene and then water, gave VII.

2) The oily "I-bromide" (6 g.) freed from all the crystals was dissolved in aqueous potassium carbonate (protassium carbonate 7 g., water 25 cc.) and the whole was boiled for 2 hr. After addition of water, the whole was acidified with sulfuric acid, and extracted with ether. The ethereal solution was washed with water, dried and evaporated, leaving a grayish white solid (0.2 g.). Recrystallization from ethylene chloride gave a material of m. p. 176~180°C (decomp.), which was not analyzed because of the impurity.

**Cyclization of I by Hydrogen Bromide.**—Through a cooled solution of I (12 g.) in anhydrous benzene (150 cc.) dried hydrogen bromide was passed for 30 min. The whole was placed in a stoppered flask, and kept standing overnight, yielding crystals. These were recrystallized from aqueous methanol to give 0.7g. of VII. When the benzene filtrate was concentrated, 8.5 g. of I was recovered and a small amount of colorless needles of m. p. 105~112°C were obtained, which could not be further investigated because of the scarcity of the sample.

**Ethyl 1-*p*-Nitrophenyl-3, 6-dimethyl-1, 4-dihydropyridazine-4, 5-dicarboxylate (Anhydro-*p*-nitrophenylhydrazone of I).**—A solution of I (2 g.) and *p*-nitrophenylhydrazine (1 g.) in 70% acetic acid, was kept standing for 1 hr. at room temperature. The crystals which were yielded were recrystallized from ethyl acetate, giving pale yellow long pillars, m. p. 122~123°C.

Found: N, 11.57. Calcd. for $C_{18}H_{21}O_6N_3$: N, 11.20%.

14) I. M. Heilbron, E. R. H. Jones, P. Smith and B. C. L. Weedon, *J. Chem. Soc.*, **1946**, 57.

**Ethyl 2, 5-Di(bromomethyl)furan-3, 4-dicarboxylate (XV).**—To a mixture of IX (9.6 g., 1 mol.), *N*-bromosuccinimide (14.3 g., 2 mol.) and carbon tetrachloride (100 cc.), benzoyl peroxide (ca. 0.1 g.) was added. The whole was refluxed gently on a steam bath for 5 hr and allowed to cool. Succinimide which separated was filtered off. The filtrate was concentrated, and the residue was distilled in vacuo, giving XV as a pale yellow, very viscous syrup of b. p. 170~180°C/3 mmHg. Yield, 14.5 g. (91%). When kept standing in an icebox, it solidified, but melted partly at room temperature. The solidified substance was recrystallized from petroleum ether (b. p. 40~50°C) (the solution was kept standing in an icebox to crystallize), giving XV as colorless long plates, m. p. 52~52.5°C.

Found : C, 36.13; H, 3.62. Calcd. for $C_{12}H_{14}O_5Br_2$: C, 36.19 ; H, 3.52%.

# *Near Ultraviolet Absorption Spectra of Acrolein and Crotonaldehyde*

By Kōzō Inuzuka

(Received August 24, 1959)

Near ultraviolet absorption spectra of a number of aldehydes and ketones have been studied by many workers[1]. It is well known that these compounds have a weak absorption in 33300~25000 $cm^{-1}$ region, and that this absorption arises from the transition of an electron from a non-bonding orbital to an excited orbital. We have also studied recently the effects of solvents on the near ultraviolet absorption spectra of some conjugated aldehydes and ketones[2]. In order to study the electronic properties of the carbonyl group in these molecules, we treated in this paper acrolein and crotonaldehyde which have conjugated systems. E. Eastwood and C. P. Snow[3] carried out a vibrational analysis for the n-$\pi^*$ absorption spectrum of acrolein. The purpose of the present paper is to analyze the n-$\pi^*$ absorption bands of acrorlein and crotonaldehyde, and also to estimate the amount of elongation of the C=O bond of these molecules during the n-$\pi^*$ transition from the relative intensities of the C=O progression bands using the method of J. A. Howe and J. H. Goldstein[4].

## Experimental

Acrolein and crotonaldehyde (Tokyo Kasei G. R. grade) were distilled before the experiment.

Carbon tetrachloride used as a solvent was boiled with dilute alkali several times. The carbon disulfide free solvent thus obtained was then washed several times with water, dried over phosphorus pentoxide, and distilled. Absorption spectra were measured by a Hitachi E. P. S. double beam automatic recording spectrometer. The absorption cell of 10 or of 40 cm. was used, depending upon the vapor pressure of the sample. All the absorption measurements were made at room temperature. Solution spectra were obtained with 1 cm. cell. For the purpose of checking that the transition in this region is of the n-$\pi^*$ type, the effects of solvent on the absorption spectra were also studied by changing the solvent from carbon tetrachloride to ethanol.

## Result and Discussion

Both of the compounds have weak absorption in 33300~25000 $cm^{-1}$ region in solution and vapor states. In carbon tetrachloride solution each of the absorption spectra exhibits four distinct shoulders. On addition of ethanol

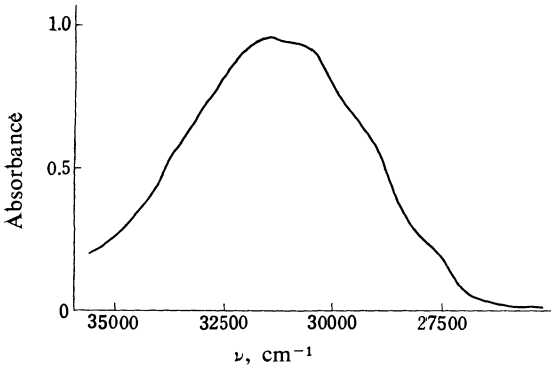

Fig. 2. Spectrum of crotonaldehyde in carbon tetrachloride solution.

to carbon tetrachloride solution the absorption shifts towards shorter wavelengths, and in pure ethanol solution the acrolein maximum shifts to the shorter wavelengths, by 400 $cm^{-1}$ compared with the pure carbon tetrachloride solution. In the case of crotonaldehyde also the blue-shift of 900 $cm^{-1}$ was observed. These blue-shifts indicate the n-$\pi^*$ nature of the electronic transition.

In the vibrational analysis of the vapor spectrum of acrolein we have taken the strong band at 25873 $cm^{-1}$ as the 0—0 band, which is accompanied on its lower frequency side by three very weak bands at 24647, 24912 and 25555 $cm^{-1}$. From the higher frequency region of the 0—0 band, we may pick out three vibrational frequencies of 1427, 1271 and 498 $cm^{-1}$ all of which forming long progressions. The progression formed by 1271 $cm^{-1}$ frequency is the most prominent feature in the spectrum. For crotonaldehyde, the 0—0 band taken at 26518 $cm^{-1}$ which is accompained by no prominent band on its lower frequency side. On the high freguency side there are three progressions with the separations of 1360, 1237 and 450 $cm^{-1}$, respectively, the one with the 1237 $cm^{-1}$ separation being the strongest. For acrolein, E. Eastwood and C. P. Snow[3] found two fundamental vibrational frequencies 1260 and 500 $cm^{-1}$ of the excited state. They assigned the former to the C=O stretching vibration and the latter to an oscillation of the methylene group about the C=C double bond. As it is well known that in ketone and aldehyde n-$\pi^*$ spectra the C=O stretching vibration generally gives rise to the main progression, the frequencies 1271 $cm^{-1}$ in acrolein and 1237 $cm^{-1}$ in crotonaldehyde may be assigned to the C=O stretching vibration in their excited states. Futhermore, since vibrational modes involving the motion of hydrogen generally do not appear prominently in the electronic spectra it seems to be more reasonable that the 498 $cm^{-1}$ in acrolein and the 450 $cm^{-1}$ in crotonaldehyde should be assigned to the skeletal bending modes instead of the assignment otherwise made by E. Eastwood and C. P. Snow. The frequencies 1427 $cm^{-1}$ of acrolein and 1360 $cm^{-1}$ of crotonaldehyde may be assigned to the C=C stretching vibration in the excited state, corresponding to the ground state vibration frequencies 1618[5] $cm^{-1}$ and 1642[6] $cm^{-1}$, respectively, observed in Raman spectra. The blue-shift by 645 $cm^{-1}$ of the 0–0 band of crotonaldehyde relative to that of acrolein is in accordance with the fact that the methyl substitution generally leads to the blue-shift of the n-$\pi^*$ absorption[7,8].

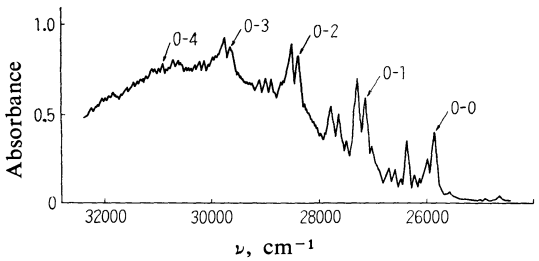

Fig. 3. Absorption spectrum of acrolein vapor.

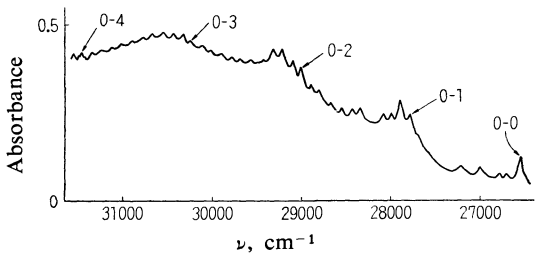

Fig. 4. Absorption spectrum of crotonaldehyde vapor.

In order to check the above assignments, the relative intensities of the member bands in the main C=O progression were calculated with the method used by Hose and Goldstein[4] and were compared with the observed intensities*. Figs. 3 and 4 show the vapor spectra of acrolein and crotonanldehyde. The procedure of this calculation was detailed by D. P. Craig[9]. The C=O group in the molecle was assumed to be a simple diatomic moleclue harmonically bound. The intensity of the 0-$n$ band is given by

$$I_n = (\omega_n/\omega_0)\left[\int \psi_0(\xi_1)\psi_n(\xi_2)\,d\tau\right]^2$$

where $\psi_i(\xi_j)$ is the $i$-th simple harmonic oscillator wave function of the $j$-th electronic state, and $\omega_n$ is a frequency of the $n$-th band in the progression. Craig has given a formula for evaluating the overlap integral as a function of the separation of the origins of coordinate $q$ of the two reduced oscillators in the electronic states 1 and 2, and also as a function of the ratio of frequencies $\rho = \nu_1/\nu_2$ where $\nu_1$ and $\nu_2$ are the C=O stretching frequencies in the ground and excited states.

The results of calculation for acrolein and crotonaldehyde are shown in Tables I and II. As seen in these tables, calculated intensities for acrolein with $q = 0.11$ Å are in fairly good

Table I. Relative intensities of the C=O progression band in acrolein

| Band | $q=$ 0.10 Å | $q=$ 0.11 Å | $q=$ 0.12 Å | Obsd. intensity |
|---|---|---|---|---|
| 0—0 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0—1 | 1.81 | 1.99 | 2.60 | 1.48 |
| 0—2 | 1.90 | 2.27 | 3.76 | 2.07 |
| 0—3 | 1.50 | 1.93 | 3.94 | 2.20 |
| 0—4 | 0.99 | 1.36 | 3.40 | 1.95 |

Table II. Relative intensities of the C=O progression bands in crotonaldehyde

| Band | $q=$ 0.11 Å | $q=$ 0.115 Å | $q=$ 0.12 Å | Obsd. intensity |
|---|---|---|---|---|
| 0—0 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0—1 | 2.17 | 2.37 | 2.62 | 2.00 |
| 0—2 | 2.74 | 3.23 | 3.83 | 3.04 |
| 0—3 | 2.59 | 3.28 | 4.10 | 3.63 |
| 0—4 | 2.04 | 2.74 | 3.65 | 3.35 |

agreement with the observed values listed in the last column of the tables. Similarly, for crotonaldehyde the calculated values with $q = 0.115$ Å are in reasonably good agreement with the observation.

On the other hand, an empirical relation between the C=O bond length and its vibrational frequency has been given by Layton et al.[10]. From using this empirical relation the $q$ values were estimated, and were compared with our calculated $q$ values given in Table III. The agreement is quite satisfactory. From the above results we may conclude that the C=O bond distances of acrolein and crotonaldehyde increase by about 0.1 Å during n-$\pi^*$ transition. In this calculation $q$ values may be correct within 0.01 Å.

Table III.

| | Acrolein | Crotonaldehyde |
|---|---|---|
| $q$(Layton) | 0.11 Å | 0.11 Å |
| $q$(calc.) | 0.11 Å | 0.115 Å |

## Summary

The positions vibrational structures and blue-shifts of absorption spectra of acrolein and crotonaldehyde in 33300~25000 $cm^{-1}$ region suggest that the transition is of the n-$\pi^*$ type. They are similar in vibrational structure except that the crotonaldehyde absorption is shifted towards higher frequencies with respect to that of acrolein. The vapor frequency of the 0-0 band is 25873 $cm^{-1}$ for acrolein, smaller by 654 $cm^{-1}$ than that of crotonaldehyde. The acrolein absorption has 1427, 1271 and 498 $cm^{-1}$ progressions, which are assigned to the C=C stretching frequency, the C=O stretching frequency and skeletal bending frequency in the excited state, respectively. For the crotonaldehyde there are 1360, 1237 and 450 $cm^{-1}$ progressions, which are assigned to the C=C stretching frequency, the C=O stretching and the skeletal bending vibration in the excited state, respectively According to our calculation, the elongation $q$ in the carbonyl bond length during the n-$\pi^*$ transition, is estimated to be approximately 0.1 Å.

The auther wishes to express his sincere thanks to Professor S. Imanishi and Dr. Y. Kanda for their encouragement throughout this work. He is also indebted to Dr. M. Ito and Mr. A. Sadō for their helpful advice and discussions.

# *Intramolecular Interaction between Hydroxyl Group and π-Electrons. VII*[1]. *Limitation of the Interaction by Chain Length in 2-(ω-Alkenyl)-phenols and 2-(ω-Phenylalkyl)-phenols*

By Michinori Ōki and Hiizu Iwamura

(Received November 16, 1959)

In the previous papers of this series[1,2,3], the authors treated the limitation of the intramolecular interaction between the alcoholic hydroxyl group and π-electrons by the chain length in ω-hydroxy-1-alkenes and ω-phenylalkanols and it has been found that, in the former series, the interaction is observed up to 3-buten-1-ol and in the latter up to 2-phenylethanol[4]. The shift of wave numbers of the O–H stretching vibration ($\nu_{O-H}$) from the free $\nu_{O-H}$ to the interacting one, and the absolute intensities of these bands in the infrared absorption were discussed with respect to the configuration, the energy and the entropy of the interaction.

As the phenolic hydroxyl group has a stronger proton donating power in the hydrogen bonding than the alcoholic one, it is naturally expected that the replacement of the alcoholic hydroxyl group in the compounds already studied by the phenolic one will release the limitation of the interaction to compounds with chains longer by one or more carbon atoms and thus some elucidation of the nature of the interaction may be obtained. In this regard, the present authors have extended the study to the two series of 2-(ω-alkenyl)-phenols (I) and 2-(ω-phenylalkyl)-phenols (II), thus completing all the types of the interaction between the alcoholic and phenolic hydroxyl groups and olefinic and benzenoid π-electrons.

I II

It has been reported that 2-allylphenol, a compound of series I, shows two $\nu_{O-H}$ maxima in the 3 μ region of the infrared absorption spectra[5]. The data for 2-hydroxybiphenyl, the lowest member of the second series II, are also available[6]. These two compounds were re-examined together with others, a high precision grating infrared spectrometer[2] being used.

## Experimental

**Measurement and Calculation.**—They were performed similarly as described previously[2]. For the decision of the disappearance of the weaker bands, the measurements were carried out with a quartz cell of 5 cm. optical length without alteration in concentration, which enables to detect a very weak absorption, even if the extinction coefficients were as small as one.

**Materials.**—The phenols used for the measurement are all known, except 2-(3-butenyl)-phenol, and were prepared in the following ways. The physical constants, after fractional distillation under diminished pressure, well agreed with those in the literature.

*2-Vinylphenol (I, n=0).*—*o*-Coumaric acid was decarboxylated by heating under diminished pressure (ca. 20 mmHg)[7]. B. p. 112°C/17 mmHg, $n_D^{27}$ 1.5775 (lit.[7], b. p. 93~94°C/12 mmHg, $n_D^{25.7}$ 1.577).

*2-Allylphenol (I, n=1).*—Allyl phenyl ether was submitted to Claisen rearrangement[8]. B. p. 109°C/23 mmHg, $n_D^{21}$ 1.5451 (lit[8]., 99°C/12 mmHg, $n_D^{20}$ 1.5453).

*2-(3-Butenyl)-phenol (I. n=2).*—A Grignard reagent was prepared from 31.3 g. (0.2 mol.) of *o*-methoxybenzyl chloride[9], 6 g. (0.25 atom) of magnesium and 150 ml. of ether and the supernatant solution was decanted into a dry flask. To the Grignard solution 24.2 g. (0.2 mol.) of allyl bromide in 50 ml. of ether was added and the mixture was refluxed for two hours to complete the reaction. The mixture was decomposed with aqueous ammonium chloride and the ether layer was dried over potassium carbonate. Fractional distillation gave 19 g. (59% of the theoretical) of 4-(2-methoxyphenyl)-1-butene, b. p. 120~123°C/18 mmHg. To a solution of methylmagnesium iodide prepared from 71 g. (0.5 mol.) of methyl iodide, 12.2 g. (0.5 atom) of magnesium and 200 ml. of ether was added 19 g. of 4-(2-methoxyphenyl)-1-butene. Ether was evaporated and the temperature was gradually raised up to 160° on an oil bath. During this time the mixture became pasty and evolution of ethane was observed. Heating was continued for two hours,

until the evolution of the gas practically ended. The mixture was dissolved in dilute acetic acid and extracted with ether. The ether extracts were extracted with aqueous sodium hydroxide. The aqueous layer was shaken with ether, treated with Norite, and then acidified with dilute hydrochloric acid. Ether extraction followed by fractional distillation gave 12.5 g. of the desired phenol (72% of the theoretical), b.p., 78°C/2.5 mmHg, $n_D^{24}$ 1.5347. *Anal.* Found: C, 80.67; H, 8.31%. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

*2-Hydroxybiphenyl (II, n=0).* — A commercial product was recrystallized from petroleum ether (b. p. 50~70°C). M. p., 59.0°C (lit[10]., 59°C).

*2-Benzylphenol (II, n=1).* — Sodium phenolate was C-benzylated with benzyl chloride in toluene according to the method described by L. Claisen and his co-workers[11]. They obtained dimorph, melting at 21°C and 52°C respectively, while the species used in the present work melted at 21C°.

*2-Phenethylphenol (II, n=2).* — 2-Hydroxystilbene[12] was quantitatively hydrogenated over Raney Ni catalyst. The substance, after recrystallization from benzene, melts at 81°C (lit.,[13] 81°C).

*2-(3-Phenylpropyl)-phenol (II, n=3).* — To a Grignard reagent prepared from 37 g. (0.2 mol.) of phenethyl bromide, 4.8 g. (0.2 atom) of magnesium and 100 ml. of ether, was added 9.2 g. (0.075 mol.) of salicylaldehyde in 50 ml. of ether, and the mixture was refluxed for two hours under stirring and then was decomposed with dilute acetic acid. The ether layer was separated, washed with aqueous sodium carbonate and dried over potassium carbonate. After evaporating the solvent, the residue was recrystallized from ligroin, giving 13.5 g. of 2-(1-hydroxy-3-phenylpropyl)-phenol (80% of the theoretical), m. p., 60~61°C. *Anal.* Found; C, 78.85, H, 7.05%. Calcd. for $C_{15}H_{16}O_2$: C, 78.92, H, 7.06%. 2-(1-Hydroxy-3-phenylpropyl)-phenol (12.15 g., 0.053 mol.) and 4 g. of a palladium-on-carbon catalyst (5% Pd) in 50 ml. of ethanol were shaken with hydrogen under atmospheric pressure. In one and half hours 1.34 l. of hydrogen was absorbed and the absorption practically stopped. After removing the catalyst and evaporating the solvent, the residue was distilled under diminished pressure, b. p., 148 ~150°C/2.5 mmHg. The distillate set to needles and melted at 21°C. The reported melting point is 21°C[14].

## Results and Discussion

The apparent O–H stretching absorption curves of the phenols examined are shown in Figs. 1 and 2, and the data of the two bands in each compounds are recorded in Tables I and II.

It should first be noted that in these phenols the free O–H stretching absorption bands at ca.

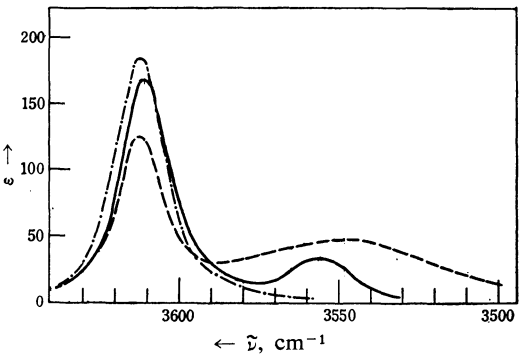

Fig. 1. $\nu_{O-H}$ absorptions of 2-($\omega$-alkenyl)-phenols $o$-$HOC_6H_4(CH_2)_nCH{=}CH_2$.
$n=0$ ——, $n=1$ – – –, $n=2$ —·—·—.

$n=0$ ——, $n=1$ – – –, $n=2$ —·—·—, $n=3$ ——.

3610 $cm^{-1}$ are always absolutely symmetric in contrast to the unsymetric ones in the free O–H stretching absorption bands in alcohols. This fact gives a support to the idea of the existence of the rotational isomers in alcohols, tentatively developed in a previous paper[15] on the unsymmetry of the free $\nu_{O-H}$ bands of almost all alcohols.

In series I, the interaction is effective up to 2-allylphenol (I, $n=1$); the number of the carbon atoms between the hydroxyl group and the nearest carbon atom which carries the $\pi$-electron participating in the interaction is three. It is one more than that in 3-buten-1-ol. In series II, the interaction is discernible up to 2-phenethylphenol (II, $n=2$), the number of the intervening carbon atom being two more than that in 2-phenylethanol. It can, therefore, be said that the limitation by the chain length is released by one or two carbon atoms, when an alcoholic hydroxyl group is replaced by a phenolic one, and the results can be

attributed to the higher acidity and the favorable structure of the phenols. In alcohols, intervening carbon atoms are all those of methylenes and there are many internal rotational degrees of freedom, of which carbon skeletons must take an *eclipsed* or at least a *gauche* form for the interaction. This is disadvantageous not only to the energy but also to the entropy of the interaction. In phenols, however, at least O-C=C-C bonds are fixed in a *cis* conformation which is favorable for the interaction. These two factors can not be evaluated quantitatively so far as the present data are concerned.

Although it has been established[16] that the shifts in wave numbers in similar classes of compounds correspond to the lengthening of the X-H bond and to the energy of the interaction, it is not yet known whether this pinciple is applicable to the phenomenon the present authors are dealing with. The energy difference in the free and the interacting forms will be dealt with in the following paper. Although the relationship between the energy and the wave number shift is ambiguous, the following will be still valid in this interaction as is empirically known; 1) The intensities represent the number of the molecules with the hydroxyl group related to the appropriate bands and are dependent not only on the energy but also on the entropy factor. 2) The half band-widths correspond to the rotational degree of freedom.

The most appreciable difference between 2-(ω-alkenyl)-phenols and 2-(ω-phenylalkyl)-phenols is found in the lowest members of the series. 2-Hydroxybiphenyl has 6.4 times as many molecules of the interacting form as those of the free, while 2-vinylphenol has the ratio of only 0.2, the free form being predominant provided that the light absorption per molecule is equal in both free and interacting forms. This phenomenon could be explained in the following way. It is generally accepted that the hydroxyl hydrogen in phenol is situated in the plane of the benzene ring so that 2pπ electrons on the oxygen atom can conjugate with π-electrons in the benzene ring, and this gives rise to the so-called "*cis*" and "*trans*" isomerism in ortho-substituted phenols[6,17]. In the biphenyl molecule, the "*trans*" form gives normal free O-H stretching vibration, while "*cis*" can not help taking the interacting form. Differing from this situation, 2-vinylphenol can be regarded as the composite of the following four conformations (I~IV) and the hydroxyl group in the

conformation I only can interact with the π-electrons of the vinyl group. Moreover, a full development of conjugation between the benzene ring and the vinyl group will be favored in the conformations II, III and IV which involve less steric interference. Thus the resonance stabilization favors the predominant contribution of II, III and IV in the equilibrium mixture and this is clearly disadvantageous to the interaction. On the other hand, the biphenyl molecule, except in the solid state, has been known not

to exist in the co-planar structure, but in the crossed structure, the angle between the two benzene rings being regarded as large as ca. 50°[18]. This enables the hydrogen atom of the "*cis*" O–H group to come to the very head of the $\pi$-electron clouds. In the interacting conformation of the 2-vinylphenol, the plane of the vinyl group is closely co-planar with that of the benzene ring and the hydrogen atom of the hydroxyl group must approach the $\pi$-electron clouds from the side. This difference in the angle of hydrogen approach in the interaction must have a significance to the amount of the interaction, and this kind of mechanism will be dealt with in future issues.

The half band-widths of the interacting $\nu_{O-H}$ become greater when a methylene chain is introduced between the hydroxyl group and the group carrying the $\pi$-electrons. This is without doubt caused by the participation of many rotational sub-levels to the fundamental transition of the O-H stretching vibration. The interacting forms of these molecules are therefore fairly complicated and have an appreciable degree of freedom.

Inspection of the data obtained with 2-benzylphenol and with 2-allylphenol indicates that these compounds give similar absorption for the interacting form. If this is taken as a significant indication, then it would possibly be the $\pi$-electron nearest[19] to the hydroxyl group that accepts the proton. However, it is not proved which $\pi$-electron interacts with the hydroxyl group. Hence the above mention is only of a reserved significance.

The measurement was extended to 2-hydroxystilbene, which had been proved to be a *trans*-form from the ultraviolet spectrum[12]. The proton acceptor must be the $\pi$-electrons on the central ethylene linkage from the structural requirement. The band properties for O–H stretching vibrations are shown in Table III.

The weaker interaction than that in 2-vinylphenol can be explained on the basis of the electronic effect of the phenyl group attached to the vinyl group, that is, the phenyl group diminishes the electron density on the proton acceptor. This presents a striking contrast to the increased interaction in *o*-propenylphenol, in which the methyl group attached to the vinyl group enriches the $\pi$-electron densities at the latter[20].

The authors are indebted to Professor Y. Urushibara and Professor T. Shimanouchi for their encouragement and discussion throughout this work. The authors' thanks are also due to the Ministry of Education for the Grant in Aid for Fundamental Scientific Research.

# *Constitution and Solubility of Vitreous Phosphates and Slags*

By Jumpei ANDO

(Received September 4, 1959)

Recently various sorts of fused phosphates and slags are being used as fertilizers to supply lime, magnesia, phosphorus pentoxide, silica and other components necessary for plants. Most of these fused phosphates and slags are produced by quenching the melts with water and thus are almost vitreous containing little crystalline minerals. The constitution of such vitreous substances have not yet been clarified, though many studies have been made on crystalline minerals.

In the present work, the constitution of such vitreous substances was investigated by X-ray diffraction, and thus citrate solubility or acid solubility of those were clarified.

## Experimental

**Samples.**—More than seventy samples including fused phosphates, slags and glasses produced in large scale or pilot plants or in the laboratory were tested by means of X-ray diffraction and microscope. Samples which were almost completely vitreous containing less than 2~3% crystalline minerals were classified according to their chemical composition (Table I).

Samples marked as CMSP or CMASP are calcium magensium phosphate fused by electric furnaces using phosphate rock and serpentine, or by blast furnaces using phosphate rock, garnierite (nickel magnesium silicate ore) and gypsum to produce nickel matte at the same time[1,2]. Samples marked as CSP are slags of phosphorus production by electric furnaces. Samples marked as CMAFS are slags of nickel production from garnierite, limestone and gypsum. A sample CMAS-6 is a blast furnace slag of iron production.

Samples marked as CP, MP, CMP and NP were prepared by fusion of mixtures of pure chemicals in platinum crucibles. Other samples were fused in graphite crucibles in the laboratory. Each sample was fused at the temperature 100~200°C higher than the softening point (Table I). Most of these were quenched by water and others were quenched by air.

Among these samples CMAFS-1,2 contain 2~3% crystalline minerals such as forstelite etc. CMAS-6 contains 2~3% melilite (Fig. 1). Blast furnace slags containing more lime include more amount of melilite. Other samples are nearly completely vitreous, containing less than 1% crystalline materials.

2) J. Ando, *Ind. Eng. Chem.*, **51**, 1267 (1959).

**Measurement of Halos by X-ray Diffractometer.**—X-ray diffraction patterns of all samples were recorded by X-ray diffractometer under conditions described in Fig. 1. Every sample gave single diffraction maximum (halo) between the diffraction angle of 20~40°. At first when recorded by the voltage of 30kV., each sample gave another maximum around 8~15°, which diminished when the voltage was reduced to 15kV. explaining that this maximum

Chart speed 0.25 cm./min.

was caused by white X-ray which was not cut satisfactorily by nickel filter.

As an interesting relationship of halos to the composition of glasses was found, the halos were recorded more precisely as is illustrated in Fig. 2 in order to measure the angle of the center of halos. The diffraction angles of the center and of maximum of each halo coincide approximately but not exactly.

**Measurement of Solubility.**—All samples were crushed so as to have the following grain sizes: 60～100 mesh 10%, 100～200 mesh 40%, and under 200 mesh 50%. To 1 g. sample 150 ml. of 2% citric acid or N/2 (about 1.8%) hydrochloric acid was added, shaken for 5, 15, 30 or 60 min. at 20 or 30 °C, then filtered quickly using suction. The insoluble residue was dried and weighed. In this case, "Solubility" means the weight loss % measured by such method. "Solubility" when dissolved in a definite time concerns mainly the velocity of dissolution in the case of most vitreous phosphates and slags of basic composition which are dissolved completely by acids ultimately. In such case the solubility of all components of samples, lime, magnesia, alumina, silica, ferrous oxide and phosphorus pentoxide ect., are nearly the same as each other, coinciding with the solubility measured by weight loss of samples.

Some of vitreous samples containing much silica or phosphorus pentoxide are not dissolved by acids completely even when shaken for a long time but leave insoluble residue consisting mainly of a silicic or phosphoric acid component. In such cases solubility of each component was measured by chemical and X-ray analysis of the residue. Citrate solubility (at 65°C) of samples was measured similarly.

**Measurement of Softening Point.**—Samples were shaped into segel cones of 3 cm. height, fixed on chromite holders, and were heated at a rate of 5°C/min. Temperatures at which the cones fell were measured by platinum-platinum · rhodium thermocouple (Table I).

## Results

**Relationship of X-ray Diffraction Halos to Chemical Composition, Construction and Properties of Glasses.**—*Outline.*—It was found that acidic samples such as silica glass, Pyrex glasses, MP-1 or MP-2 revealed a steep maximum of X-ray diffraction pattern at smaller diffraction angle of 22～24° (Fig. 1). The diffraction maximum (halo) shifts to larger angle according to the increase of the basicity of samples. Each of the samples of moderate basicity, CP-1, 2, CMP-1, soda lime glass, etc., reveals a gentle maximum around 25～29°. These samples of moderate basity have a lower softening point and are renderd to glass state most easily.

Every basic sample such as CMSP-5～8, CS-5～7, CA-4, CMAS-4～6, or CNS-3 reveals at larger angle of 30～32° a halo smaller than that of acidic samples but steeper than that of samples of intermediate basicity. The melts of these samples crystallize very quickly, and therefore can not be rendered to complete glass state without quenching. Samples which were more

basic could not be rendered to complete glass even by rapid quenching with water.

The author thinks that halos of these glasses and vitreous substances are chiefly determined by the ratio of the number of cations coordinated by six (or eight) oxygen ions to that coordinated by four oxygen ions. This ratio is shown as "coordination ratio" (CR) in Table II and Fig. 3. X-ray is chiefly diffracted to smaller angle by oxide glasses containing much $SiO_4$, $PO_4$, $MgO_4$ etc. because these tetrahedra are apt to form hexagonal rings or chains having larger spacing. On the contrary, $CaO_6$, $MgO_6$, $NaO_6$ etc. are apt to form tetragonal rings having smaller spacing, and thus diffract X ray to larger angle. When nearly equal amount of $RO_4$ and $RO_6$ is mixed the gentle halo appears in intermediate angle.

The strongest diffraction peaks of the more basic crystalline minerals of each $CaO$-$P_2O_5$, $CaO$-$SiO_2$, $CaO$-$Al_2O_3$, $CaO$-$Al_2O_3$-$SiO_2$ or other systems appear usually at larger angle: e. g. $CP \rightarrow C_2P \rightarrow C_3P$, $S \rightarrow CS \rightarrow C_2S$, $C_3A_5 \rightarrow CA \rightarrow C_3A$, $CAS_2 \rightarrow C_2AS$, etc. Moreover, the diffraction angle of the strongest peak of CP (calcium metaphosphate) coincides with that of the center of the halo of the glass of the same chemical composition similarly as in the case of cristobalite and silica glass. These facts show that there is some relation between the structure of glass and that of crystalline mineral. However, the diffraction peaks of crystalline minerals and halos of glasses of the same composition do not always agree with each other.

*Empirical formula indicating the relation of X-ray halo to chemical composition and constitution of glasses.*—It was found that for every glasses consisting of silica, alumina, lime, phosphorus pentoxide, magnesia, sodium oxide and ferrous oxide there was simple relation between the diffraction angle (or $\lambda/\sin\theta$) of the center of each halo and the value of the above-mentioned coordination ratio (Table II, Fig. 3).

In the ratio Ca, Mg, Al, Si, etc. are the number of each ion (or atom) in a unit volume of glasses. Coefficients a, b and c are given by

Fig. 4 which illustrates the relationship of the coefficients to apparent basicity number A. B. N. (= CaO + MgO + 0.7FeO + 0.25$Al_2O_3$). Here, CaO, MgO, FeO and $Al_2O_3$ of A. B. N. are weight % of each component of glasses. Fig. 4 was plotted empirically by trial-and-error method in consideration of both X-ray halo and solubility of glasses which will be described below. The coefficients a, b or c indicates principally a ratio of numbers of aluminum, magnesium and iron ions which are coordinated by four oxygen ions [these are described as Al(4), Mg(4) and Fe(4) below] to that of total aluminum, magnesium or iron ions respectively.

The apparent basicity number (A. B. N.) of calcium magnesium phosphate, slags of iron, nickel or phosphorus production which are being used as fertilizers is usually 47~52, and therefore, a=0.6~0.7, b=0.10~0.12, and c=0.06~0.07. In the case of aluminous glass containing much alumina the change of the coefficient a is smaller than in the case of glasses containing less alumina (Fig. 4).

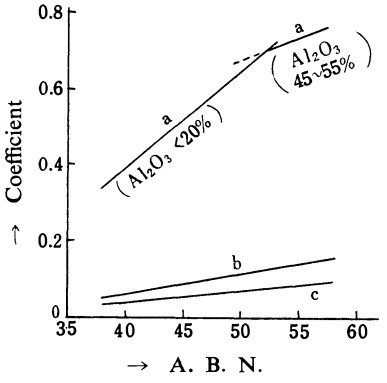

Fig. 4. Relationship of A. B. N. to the coefficients.

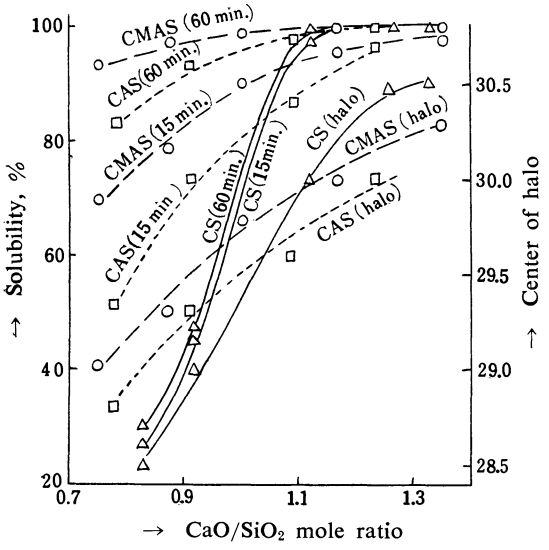

Fig. 5. Relationship of $CaO/SiO_2$ mole ratio to the solubility in N/2 hydrochloric acid (60 min. at 30°C) and to the angle of the center of halo.

As is illustrated by Fig. 5 both the diffraction angle of the center of each halo and hydrochloric acid solubility of samples of CS(CaO-$SiO_2$) system are reduced remarkably according to the decrease of $CaO/SiO_2$ mole ratio. However, the reduction of both the angle and the solubility is far smaller for the samples containing a considerable amount of alumina or magnesia and alumina (samples of CAS or CMAS systems). This is attributable to the change of oxygen coordination number of aluminum and magnesium ions—much Al(4), Mg(4) and less Al(6), Mg(6) occur in basic glasses, less Al(4), Mg(4) and much Al(6), Mg(6) occur in acidic glasses as is illustrated by Fig. 4.

It was found by both X-ray and solubility tests that in glasses which contain phosphorus pentoxide more Mg(4), Al(4) and Fe(4) occurred than in silicate glasses. The amount of such four coordinated ions increases according to the amount of phosphorus pentoxide. It seems that even a part of calcium or sodium is coordinated by four oxygen ions in phosphate glasses. From this standpoint of view, coefficients of phosphorus 1.1 for denominator and −0.1 for numerator were introduced into coordination ratio (Table II) for convenience of calculation of the value of the ratio. In this way X-ray, patterns and solubilities of phosphate glasses are indicated well (Figs. 3 and 9—11).

Especilly in the case of glasses containing magnesia and much phosphorus pentoxide, an extensive amount of magnesium ions seems to be coordinated by four oxygen ions. The X-ray diffraction halos of silica glass and that of MP-1 which consists of nearly equal mole of magnesia and phosphorus pentoxide resemble each other explaining that $MgP_2$ plays a role of $Si_3$. Coefficient b to be used for calculation of coordination ratio of glasses containing more than 40% phosphorus pentoxide is given by Fig.

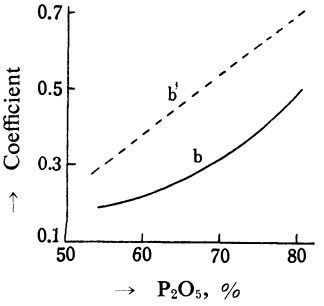

Fig. 6. Relationship of $P_2O_5$ content to coefficients.

6. In the case of phosphate glass the coefficient a, b or c does not indicate the ratio of the number of Al(4), Mg(4) or Fe(4) to that of total Al, Mg or Fe respectively because coefficients of phosphorus 1.1 and −0.1 are used for conveniene. The approximate ratio of the number of Mg(4) to total Mg of samples of CMP and MP systems is shown by dotted curve (b′) in Fig. 6.

*Relationship of glass formation to oxygen ratio.*—Oxygen ratio, a ratio of the number of total oxygen ions to that of network-forming ions, is known to relate deeply to glass formation. It was clarified by the present study that approximate oxygen ratio was calculated by ORo (Table II). Samples with the ratio less than 3.0 could easily be rendered to glass without quenching, because these are composed of long chains or networks of oxygen and network-forming ions and the melts of these are viscous. Samples with the ratio 3.0～3.3 could be rendered to glass state completely by water quenching (CMSP-6～8, CS-6, 7, CMS-4, 5, CA-2, 3, CMAS-5, 6, etc.). As an exception high temperature modification of calcium metasilicate (pseude wollastonite) was crystallized very quickly from the melt of the composition $CaO \cdot SiO_2$, oxygen ratio of which is 3.0. This mineral is composed of small $Si_3O_9$ rings[3] and therefore, is completely soluble in N/2 (about 1.8%) hydrochloric acid, though silicic acid component of the glass of the same composition is not dissolved by the acid.[4] Samples with the ratio larger than 3.3 could not be rendered to complete glass state even by rapid water quenching from high temperature forming crystalline minerals partly. The glass formation is affected by bond strength, too (Table IV).

**Solubility of Glasses.**—*Relationship of bond strength to citric and hydrochloric solubility.*—In Table IV single bond strength between oxygen and various cations[5] is illustrated. Mg(4), Ca(4) and Ca(6) were inserted by the present author into the table. Iron is thought to be intermediate between calcium and magnesium.

It was clarified in the present study that linkage Si-O, P-O or Al(4)-O, the bond strength of which is more than 80 kcal., could scarcely be broken by 2% citric acid or N/2 hydrochloric acid. The linkage Ca(6)-O, Ca(8)-O, Mg(6)-O, or Na-O, the bond strength of which is less than 50 kcal., is broken by the acids quickly. The linkage of intermediate bond strength such as Al(6)-O, Mg(4)-O, or Ca(4)-O is slowly broken by the acids.

Basic glasses containing less intermediate components are dissolved in acids very quickly

(CS-6, CMSP-6 in Fig. 7, CS-5 in Fig. 8., etc.). Basic glasses containing much intermediate components dissolve slowly but completely (CMASP-2, CMS-3, CP-3, CMAS-6, CMAFS-1, CA-4, CAS-3, 4, etc.).

Acidic glasses (CP-1, CS-2, 3, 4, CMS-2, etc.) are not dissolved completely by acids but leave mainly hydrated silica or phosphoric acid component undissolved, because such glasses contain large linkage of P-O-P-O or Si-O-Si-O which forms long chains, large rings or networks. Such large linkages, the bond strength in which is larger than 80 kcal., must not be dissolved into liquid but remain as insoluble residue or as colloidal state. On the contrary, small chains or rings must enter into solution by hydration. The magnitude of the linkage is related to oxygen ratio as will be described below.

Fig. 9 illustrates the relationship of $OR_1$ (Table II) to the solubility of glasses when shaken in N/2 HCl for an hour at 30°C. Samples with $OR_1$ larger than 3.2 are dissolved completely. Samples with $OR_1$ smaller than 3.15 leave insoluble residue. $OR_1$ 3.2~3.15 corresponds to $M_5O_{16}$~$M_6O_{19}$ which is the linkage of five ~six $MO_4$ groups and is 10~15 Å in length. It was clarified that the linkages (the bond strength in which is larger than 80 kcal.) smaller than 10 Å entered into solution and that linkages larger than 20 Å did not enter into solution usually but remained undissolved or as colloidal residue.

In citric acid the samples dissolve more slowly than in N/2 HCl. Especially the samples containing much Ca(4), Mg(4) or Al(6) are dissolved slowly and therefore not completely in an hour in 2% citric acid. It was clarified that

citric solubility of samples in 60 or 15 min. at 20°C can be indicated by $OR_2$ or $OR_3$ (Table II) as is illustrated by Fig. 10 or 11.

Citric solubility of −200 mesh/inch samples is nearly equal to hydrochloric solubility of −60 mesh/inch samples treated in the same time. Hydrochloric solubility in 15 min. is nearly equal to citric solubility in 60 min. By raising the temperature from 20 to 30°C velocity of dissolution increases somewhat. Thus acid solubility of various vitreous phosphates and slags can be known from chemical composition using above relations.

*Citrate solubility.* — Citrate solubility by American official method and citric or hydrochloric solubility is quite different. For examble, CP-1 is dissolved very quickly in neutral citrate

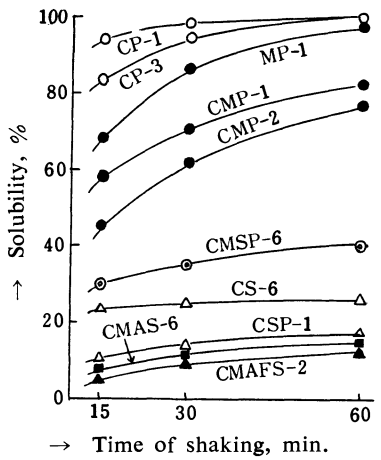

Fig. 12. Citrate solubility of samples in various times at 65°C.

though largely insoluble in acids. Phosphate glasses (CP-1—3, CMP-1—3) are dissolved more quickly in citrate but more slowly in acids when the samples are more acidic containing more phosphorus pentoxide component (Fig. 12). $NH_4^+$ and $OH^-$ of the citrate must break linkages of P-O-P-O.

Silicate or aluminate glasses is dissolved slightly. Calcium magnesium phosphate, a silicophosphate glass, is dissolved intermediately in citrate (Fig. 12).

## Discussion

The relation illustrated in Fig. 3 applies nearly exactly to glasses composed mainly of oxides of sodium, magnesium, aluminum, silicon, phosphorus, potassium and calcium atomic number of which is between 11 and 20. For glasses containing much boron, lithium, lead, barium etc., the atomic number of which is far smaller or far larger than that of the above elements, the relation between X-ray halo and composition of glasses is not so simple. In such cases the X-ray halo must be affected not only by coordination number of cations but also fairly intensely by ionic radius, the number of electron etc.

The above explanations of X-ray halos which was based only on coordination number and especially relations illustrated by Figs. 4 and 6 are not quite exact. However, many facts shown in the present study must be useful to clarify the construction and properties of various glasses and vitreous substances. Moreover, it is possible to determine the chemical composition of glasses by the measurement of X-ray halo.

Quenched phosphates and slags often contain small amount of crystalline minerals which affect the solubility considerably. Usually crystalline minerals dissolve far more slowly than glasses of the same composition. Crystallized forstelite, enstatite, diopside, apatite, anorthite and calcium pyrophosphate scarcely dissolve in citric acid or citrate. Gehlenite dissolves slowly, åkermanite and $\beta$-tricalcium phosphate dissolve fairly quickly in acids.[6,7] $\alpha$-Calcium metasilicate[4] and $\alpha$-tricalcium phosphate dissolve quickly in acids. In citrate $\alpha$ modification of tricalcium phosphate is highly soluble but $\beta$ modification is less soluble because of the difference of velocity of dissolution which is due to the difference of structure.

## Summary

The diffraction angle of center of X-ray halo of glasses composed of silica, phosphorus pentoxide, alumina, lime, magnesia, sodium oxide and ferrous oxide is principally determined by a ratio of the number of cations coordinated by six (or eight) oxygen ions to that coordinated by for oxygen ions.

Approximate ratio of the number of aluminum or magnesium ions which is coordinated by four oxygen ions to that of total aluminum or magnesium ions can be determined by measurement of X-ray halo using above relations.

Glass formation is closely related to oxygen ratio $OR_0$. Solubility of vitreous phosphates and slags in N/2 hydrochloric acid or 2% citric acid is indicated by the ratios $OR_1$, $OR_2$ and $OR_3$ all of which are calculated from chemical composition and above relations.

# *Ternary Liquid Equilibria in System n-Heptane-Thiophene-Liquid Ammonia. New Tie Line Correlation*

By Kiyoharu ISHIDA

(Received October 19, 1959)

The removal of organic sulfur compounds from petroleum products has been one of the most important problems in the petroleum refinery field for many years, although the success of the hydro-refining process has reduced the difficulties of the desulfurization. It has been reported that there is a possibility of the use of liquid ammonia and its mixed solvents as desulfurizing agents on the extraction process[1], but no fundamental data in connection with this matter have been given. This paper presents the equilibrium data at temperatures of 20 and 0°C for the system *n*-heptane-thiophene-liquid ammonia, and a new method correlating tie line data for ternary liquid equilibria has been described.

The method used to obtain data for the construction of phase equilibria was the same analytical method as described in the previous paper[2]. The heterogeneous liquid layers were separated and analyzed after the saturation equilibrium was attained in a constant temperature bath regulated within the range of ±0.05°C throughout the experiment. An aliquot of each layer, which was determined from the difference of weight of the bottle containing the system, was released to the receiver and the ammonia was absorbed by the definite quantity of the 2 N sulfuric acid solution after it was removed from the receiver by volatilization, and then backtitrated with 0.5 N standard hydroxide solution. The compositions of ammonia-free organic liquid were determined by measuring their densities and refractive indices to the nearest 0.0001 unit. The results were adjusted for the slight loss of organic liquid by volatilization by means of the lever rule[3] from the composition of the total mixture and the concentrations of ammonia in both layers. It was observed that when the vaporization loss of binary mixtures of heptane and thiophene was less than about 15%, the compositions of organic binary mixtures were practically unaffected with the vaporization of organic liquid accompanied by the determination of ammonia, though the vapor pressure of thiophene has about twice that of *n*-heptane in the neighborhood of 0°C.

*n*-Heptane used in this investigation was the reference fuel for octane number determination, having the following physical constants, b.p., 98.3°C; $d_4^{20}$, 0.6838; $n_D^{20}$, 1.3878. Commercially available thiophene was dissolved in liquid ammonia, allowed to stand overnight, and then redistilled after the yellowish precipitates were removed; the middle fractions having the constants b. p. 84.1°C, $d_4^{20}$ 1.0638, $n_D^{20}$ 1.5288 were used.

## Results and Discussion

The data of densities and refractive indices for the binary system of *n*-heptane and thiophene from which the compositions of the raffinate and the extract were determined are given in Table I, and the equilibrium data for the ternary system are given in Table II and shown in Figs. 1 and 2. As will be clear from the figures, tie lines are almost parallel to the base of the triangle and in the case of equilibrium at 0°C the distribution ratio changes from more than unity to less than unity as shown in Fig. 2. The maximum selectivity[5] for this system regarding liquid ammonia as a solvent for the separation of thiophene from paraffin are given to be 72.9 and 62.0 wt. % at 0 and 20°C., respectively. The respective maximum concentrations of thiophene in the extract are 89.3 and 78.8 wt.% at 0 and 20°C., then the maximum

separation factors[5] become the respective values of 0.650 and 0.488, these values being considerably greater when compared with those in cases of the separation of hydrocarbon mixtures.

### Tie Line Correlation

This system as in the other solutropic systems fails to give a straight line having a definite slope from the appropriate plot of conjugate values at equilibrium according to any method which has been proposed by any one of the many investigators as tie line correlations. The author has found that a straight line results from a plot of logarithm of $E''S'/E'S''$ against logarithm of $R''S'/R'S''$ where $S$, $E$ and $R$ are the respective fractions of the solvent, the solute and the diluent at equilibrium and one prime and two primes denote the diluent-rich layer and the solvent-rich layer, respectively. Plots by this method for the present data are shown in Fig. 3. In Fig. 3, plots for the several systems using liquid ammonia as a solvent are also included. It is observed that these data are correlated by this method satisfactorily.

Several ordinary systems investigated by various workers are plotted in Fig. 4, and plots for systems containing two pairs of partially miscible liquids are given in Fig. 5. Plots by this method for several solutropic systems are shown in Fig. 6. Except for some systems where it seems to be plausible that the data are correlated by two straight lines changing their slopes, the plotted data for most systems fall on straight lines having definite slopes almost within their probable experimental accuracy. When the solvent and the diluent are practically insoluble as in the case of benzene-water binary, values of $S'R''/S''R'$ and $S'E''/S''E'$ become more inaccurate at the lower concentrations of the solute, because the concentrations of the solute are very small and their accurate determinations by ordinary methods are difficult. For this reason, it may be said roughly that plots by this method would give a straight line for most ternary systems.

Since the values of $S'R''/S''R'$ for the binary systems of the diluent and the solvent are located as the abscissa on the left ends of straight lines in these figures, the initial distribution ratio at zero concentration of the solute can be estimated from the ordinate on these points. The ordinate on the right ends of straight lines in Fig. 5 represent the values of $S'E''/S''E'$ for the binary systems of the solute and the solvent, and the abscissa the product of the distribution coefficient at zero concentration of the diluent and the ratio of the concentration of the solvent in the solute rich phase to that in the solvent rich phase.

The straight lines can be represented by equations of the form

$$\log \frac{E''S'}{E'S''} = n \log \frac{R''S'}{R'S''} + k \qquad (1)$$

For the ordinary systems which comprise two miscible pairs of liquids and one partially miscible pair, the value of $k$ should be extremely near zero, since the values of $S'E''/S''E'$ and $S'R''/S''R'$ at the plait point are equal to unity. If the relative distribution ratio is designated by $\beta$,

$$\beta = \frac{E''}{E'} \cdot \frac{R'}{R''} \qquad (2)$$

Then,

$$\log \beta = (n-1) \log \frac{R''S'}{R'S''} + k \qquad (3)$$

Therefore, if a plot is made of the relative distribution ratio against the quotient of the ratio of the concentration of the solvent in the diluent rich phase to that in the solvent rich phase and that of the solute or the diluent on the double logarithmic coordinates, a straight line will be given as well not only for ordinary systems, but also for solutropic systems and those containing two partially miscible pairs.

### Summary

Phase equilibria for the system *n*-heptane-thiophene-liquid ammonia has been determined at temperatures of 0 and 20°C. A new method has been proposed which correlates tie line data in such a manner that a straight line is obtained for most systems including solutropic systems.

# *Polymerization of Methyl Methacrylate Initiated by a Combined Action of p-Tolylsulfonylacetic Acid and Dimethylaniline*

By Ryoichi UEHARA

(Received July 20, 1959)

It has been first reported by Lal et al.[1], that the polymerization of methyl methacrylate is initiated by mixtures of dimethylaniline and various carboxylic acids. In a previous paper by the present author[2], results of studies on the kinetics of the polymerization of methyl methacrylate initiated by a combined action of trichloroacetic acid and dimethylaniline have been reported, and a bimolecular reaction between these two compounds has been suggested as the initial reaction of the polymerization. In the report of Lal, per-cent-conversions after 1 hr. in the bulk polymerization of methyl methacrylate at 58.6°C by using nine carboxylic acids have been given briefly, and six acids, i. e., mono-, di- and trichloroacetic, mercaptoacetic, phenoxyacetic and 1, 4-dichlorobenzoic acids, were found to be effective.

The present author has found that *p*-tolylsulfonylacetic acid, which has been prepared by Gabriel[3] from sodium *p*-toluenesulfinate and monochloroacetic acid, is also effective as a component of the polymerization-initiating system.

$$CH_3C_6H_4SO_2Na + ClCH_2COOH = CH_3C_6H_4SO_2CH_2COOH + NaCl$$

In the present paper, per-cent-conversion of the bulk polymerization of methyl methacrylate initiated by the system of *p*-tolylsulfonylacetic acid and dimethylaniline is given, and the effects of *p*-substituted groups in dimethylaniline upon the polymerization-initiating efficiencies of the two systems, trichloroacetic acid-dimethylaniline and *p*-tolylsulfonylacetic acid-dimethylaniline, are compared.

The polymerization was carried out in the atmosphere of nitrogen. In Table I, per-cent-conversion of the bulk polymerization at 60°C is given. Each of *p*-tolylsulfonylacetic acid, and dimethylaniline alone was not responsible for the initiation of the polymerization. In Fig. 1, per-cent-conversion after 1 hr., in the bulk polymerization, by means of equimolar amounts of *p*-tolylsulfonylacetic acid and dimethylaniline at temperatures of 51, 60 and 70°C are plotted against the concentration of the acid. It is observed that the per-cent-conversion after 1 hr. is linearly dependent upon the concentration of the acid. This fact indicates that, in this polymerization, the linear dependence of the rate of polymerization upon the initial concentration of *p*-tolylsulfonylacetic acid or dimethylaniline holds, as in the case of the

polymerization initiated by equimolar amounts of trichloroacetic acid and dimethylaniline[2], because per-cent-conversion after 1 hr., can be considered to be proportional to the initial rate of polymerization.

*p*-Substituted groups in dimethylaniline significantly affect the polymerization-initiating efficiencies of the two systems, *p*-tolylsulfonylacetic acid-dimethylaniline and trichloroacetic acid-dimethylaniline. Table II shows per-cent-conversions after 1 hr. by using various dimethylanilines in bulk polymerizations of methyl methacrylate, in which *p*-tolylsulfonylacetic and trichloroacetic acids were used respectively. Electron-donating groups such as methyl and methoxyl promote, and electron-withdrawing groups such as chloro, bromo and nitroso reduce the efficiencies of the polymerization-initiating systems. In Table II, $C/C_0$ are also shown, where $C_0$ and $C$ are per-cent-conversions in the polymerizations by using dimethylaniline and *p*-substituted dimethylaniline, respectively.

Table II. Relative efficiency of *p*-substituted dimethylaniline in the polymerizations initiated respectively by systems, *p*-tolylsulfonylacetic acid-dimethylaniline and trichloroacetic acid-dimethylaniline

| Substituent | % Conversion* (TSAA and DMA) | $C/C_0$ | % Conversion** (TCA and DMA) | $C/C_0$ |
|---|---|---|---|---|
| $OCH_3$ | 11.3 | 2.35 | 11.4 | 1.752 |
| $CH_3$ | 8.7 | 1.81 | 8.9 | 1.37 |
| H | 4.8 | 1.0 | 6.5 | 1.0 |
| Cl | 2.9 | 0.604 | 4.2 | 0.646 |
| Br | 2.4 | 0.500 | 4.1 | 0.630 |
| NO | 0 | 0 | 0 | 0 |

* 0.15 mol./l. of each of TSAA and DMA were used at 60°C.

** 0.20 mol./l. of each of TCA and DMA were used at 25°C.

For each of the substituted groups, the value of $C/C_0$ in the polymerization by using *p*-tolylsulfonylacetic acid is substantially similar to that in the polymerization, in which trichloroacetic acid was employed, i.e., the relative efficiency of *p*-substituted dimethylaniline is substantially the same in the initiating systems. When the logarithms of $C/C_0$ are plotted against $\sigma$ (substitutent constant of Hammett) of each substituted groups, good straight lines are obtained as are shown in Fig. 2. It is evident that Hammett's rule holds in the two cases.

As has been mentioned above, the dependence of the initial rate of polymerization upon the concentration of *p*-tolylsulfonylacetic acid (or dimethylaniline) and the relative efficiency of the substituted dimethylaniline in the polymerization of methyl methacrylate initiated by the system of *p*-tolylsulfonylacetic acid and dimethylaniline are quite similar to those in the polymerization initiated by a combined action of trichloroacetic acid and dimethylaniline. Therefore, it is conceivable, that the polymerization initiated by *p*-tolylsulfonylacetic acid and dimethylaniline proceeds through the same mechanism as that which has been postulated previously for the polymerization initiated by trichloroacetic acid and dimethylaniline[2].

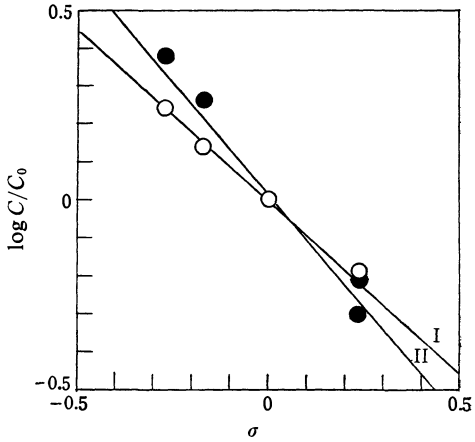

Fig. 2. Correlations of $\log C/C_0$ with $\sigma$.
I for TCA and DMA (○)
II for TSAA and DMA (●)

## Experimental

The polymerization and the purification of methyl methacrylate were carried out as mentioned previously[2]. *p*-Tolylsulfonylacetic acid was prepared by the following procedures; sodium *p*-toluenesulfinate (43 g.) and monochloroacetic acid (19 g.) were mixed with methanol (100 cc.), and sodium hydroxide (8 g.) which was dissolved in water (100 cc.) was added. The mixture was refluxed for 4 hr., and then methanol was distilled off. By treating the residue of the distillation with 30% aqueous hydrochloric acid (50 cc.), an oily material separated. The oil was cooled in an ice salt-bath until it changed into crystalline solids. They were washed with aqueous methanol (1 : 1 by volume) and recrystallized from pure methanol, giving pure *p*-tolylsulfonylacetic acid (17.5 g.), m. p. 86°C. Dimethylaniline and *p*-substituted dimethylaniline were distilled under reduced pressure in the atmosphere of nitrogen or recrystallized from methanol: dimethylaniline b. p. 56°C/5 mmHg, $-CH_3$ b. p. 73.5°C/5 mmHg, $-Cl$ b. p. 86°C/5 mmHg, $-Br$ b. p. 101°C/5 mmHg, $-OCH_3$ m. p. 48.5°C, and $-NO$ m. p. 85°C.

## Summary

It has been found that the polymerization of methyl methacrylate is initiated by the system of *p*-tolylsulfonylacetic acid and dimethylaniline.

In the polymerization initiated by equimolar amounts of *p*-tolylsulfonylacetic acid and dimethylaniline, the initial rate of polymerization is linearly dependent upon the initial concentration of the acid (or dimethylaniline). Hammett's rule holds for the relative efficiency of *p*-substituted dimethylaniline as the component of the polymerization-initiating system. These relationships are quite similar to those which are observed in the polymerization of methyl methacrylate, initiated by trichloroacetic acid and dimethylaniline. It is conceivable that the two polymerization reactions proceed through the same mechanism.

The author wishes to express his thanks to Professor Osamu Simamura of the University of Tokyo, for his interests in this work and Mr. Tsurahide Cho, the President of Tama Kagaku Kogyo Co., for permission to undertake this work.

# *Kolbe's Reaction of Higher Fatty Acids. I. Electrolysis of Lauric Acid**

By Tikami MIZUTA**, Takeo HISANO and Ryoichi MATSUDA

(Received August 21, 1959)

Kolbe's reaction of fatty acids in general has been studied by many investigators but that of lauric acid[1] in particular not in detail. In the previous paper[2], one of the present authors, R. Matsuda, studied electrolysis of acetic and propionic acids for the purpose of clarifying the mechanism of the reaction. The present study was undertaken to find a clue to approach its true aspect, dealing with higher members of fatty acid.

Four electrolytes were employed which consisted of an ethanolic solution of lauric acid and potassium hydroxide. These were different from each other with respect to the alkali content. In Experiment 1 the effect of changing anodic current density 0.08~1.20 amp./cm$^2$ upon the current efficiency of docosane production which is due to Kolbe's reaction was examined with one of the electrolytes. The increase of current efficiency with that of the anodic current density was observed with nickel anode as well as platinum anode. The former anode resulted in current efficiency which was close, but a little inferior, to that by means of the latter.

In Experiment 2 the effect of the alkalinity of the electrolyte upon the current efficiency was examined with the four solutions, and it was found that the less alkaline the electrolyte, the greater was the current efficiency. Nickel and platinum anodes behaved as in Experiment 1. In the case of lower members of fatty acid, nickel anode is known not to give rise to Kolbe's reaction.

## Experimental

An anode of platinum plate was coupled with a cathode of the same material, and so was an anode of nickel plate with a cathode of the same. The cathode in each case was in the shape of a square box without top or bottom, the horizontal section being 10×20 mm., and the height 20 mm. The anode which was rectangular 5×10 mm. was placed at the center of the cathode in each case. The upper part of the electrlytic cell was cylindrical 100 mm. long and 30 mm. in diameter, and its lower part was 50 mm. long, being flattened so as to have the two faces 25 mm. apart. The vessel was inclined by some 30° when in operation. Such a cell together with the electrodes helped not only to lessen the volume of the electrolyte and the voltage required, but also to ease the agitation of the solution without mechanical device. This sort of agitation might have the disadvantage of not always being uniform, because of the varied amount of evolving gas. It was, however, sufficiently useful for the present purpose. The lauric was 99.9% pure, the neutralization value being 279.5 against the theoretical value of 280.23 and the m. p. 44.1°C. Four solutions were prepared for electrolysis, each of which contained 1 mol. lauric acid and a different portion of potassium hydroxide in a mixture of 800 cc. ethanol and 533 cc. water: Solutions A, B, C and D contained 0.14, 0.34, 0.68 and 1.02 mol. potassium hydroxide respectively.

Each electrolysis was conducted with 40 cc. of the solution at 40°C. An oily mass floated, consisting mainly of docosane, as it was produced by

electrolysis. The content of the vessel was cooled after electrolysis, and the coagulated crude docosane was taken out, melted in 70~80°C water, and cooled again. This product was purified by extracting with benzene four to five times, and then by recrystallizing with ethanol three to four times. It was subsequently identified as docosane by the melting point, the elementary analysis and the molecular weight determination. M. p. 44.0~44.5°C (the reported m. p. 44.4°C)[3].

**Experiment 1.** Solution C was electrolyzed with the nickel as well as the platinum electrodes. The anodic current density was varied 0.08~1.20 amp./cm² in order to see the influence of anodic current density on Kolbe's reaction, 2200 coulombs were supplied for each electrolysis. This quantity was nearly 90% of that necessary to electrolyze lauric acid in the solution. The docosane production is shown in Table I and Fig. 1.

Table I. Influence of anodic current density upon docosane production

| Anodic current density amp./cm² | Pt-electrodes docosane current efficiency | | Ni-electrodes docosane current efficiency | |
|---|---|---|---|---|
| | g. | % | g. | % |
| 0.08 | 1.20 | 34.0 | 1.12 | 31.8 |
| 0.20 | 1.23 | 34.8 | 1.21 | 34.3 |

## Discussion

According to Experiment I the increase of anodic current density favored Kolbe's reaction, the influence being more noticeable when the current density was smaller. This tendency was also observed with acetic acid, in which case it was mentioned that proper regions of concentration and pH should be maintained[4]. Larger current density means a larger number of anions discharged per unit surface area of the anode. The result of Ex-periment I will be understood if it is assumed that the discharge of lauric acid anions which is responsible for Kolbe's reaction occurs dominantly under the favored condition. When the current density was larger than 1.2 amp./cm², the gas evolution made it impossible to keep the current uniform and to obtain a reliable result. It is presumed that docosane production decreases for the following two reasons: first that with current density above 1.2 amp./cm² the discharge of more easily movable hydroxyl ions might dominate, and second that the migration velocity of lauric acid ions reaches the maximum. Docosane production consequently decreased.

4) R. Matsuda, *J. Chem. Soc. Japan (Nippon Kwagaku Kwaishi)*, **51**, 662 (1930).

Platinum and nickel were compared as anode material. The latter was found as good for Kolbe's reaction of lauric acid as the former, which had been regarded practically as the superlative material for Kolbe's reaction of fatty acid in general.

It was shown by Experiment 2 that docosane production quickly dropped off with the increase of potassium hydroxide, and there was no maximum point in the curves of Fig. 2 as was expected. It seems that the discharge of lauric acid ions steadily gave place to that of hydroxyl ions as potassium hydroxide increased, and docosane production decreased. Platinum and nickel were compared again as anode material and found close to each other with respect to the current efficiency of docosane production, although the former was superior to the latter as in Experiment 1. Fichter[5] considered that oxidation of fatty acid by means of anodic atomic oxygen resulted in Kolbe's reaction. There is, however, a great difference between the oxygen overvoltages of platinum and nickel. If the overvoltage should have anything to do with anodic atomic oxygen, hence with Kolbe's reaction, these two metals would behave differently as anode material, platinum with its high over-voltage being favorable to the reaction. Besides, Kameyama[6] describes that when acetate is electrolyzed with nickel, iron or gold as an anode no Kolbe's reaction takes place, oxygen being the dominant product of the anodic reaction.

In addition to the fact that nickel was available as an good anode for Kolbe's reaction in the present case, dimethlyglyoxime failed to detect nickel ions in the electrolyzed solution, and the nickel anode showed no apparent change after electrolysis. It is likely that the nickel anode assumed the passive state during electrolysis.

The authors wish to express their thanks to Nippon Oils and Fats Co., Ltd. which kindly provided them with lauric acid.

# *Coprecipitation of Neptunium with Lanthanum Trifluoride*

By Eiko NAKAMURA

(Received November 21, 1959)

It is well known that oxidized neptunium does not coprecipitate with lanthanum trifluoride whereas reduced neptunium is carried down almost quantitatively. Although this process is studied and often utilized for the practical separation of neptunium[1-3], its oxidation state is not clearly defined. Some believe that both neptunium(IV) and -(V) are carried down by lanthanum trifluoride[4], whereas others believe that neptunium(V) is not[5]. Sometimes the expression the "lanthanum fluoride carriable state" is used in place of the "oxidation state"[6]. Thus, the coprecipitation behavior of neptunium (V) is open to question.

In the present study, the different modes of coprecipitation behavior of neptunium(IV), -(V) and -(Vl), are studied with the aids of the tracers for neptunium(IV), -(V) and -(Vl). The oxidation state of the neptunium tracer used is determined according to the solvent extraction behavior as well as to the coprecipitation behavior with zirconium phosphate.

## Experimental

**Materials.**—Neptunium-239 separated from neutron irradiated uranyl nitrate[7] is used as the tracer for neptunium. Prior to use, the tracer is treated chemically in order to confirm the fact that neptunium(IV), -(V) and -(VI) tracer is radiochemically pure.

7) T. Ishimori and E. Nakamura, This Bulletin, 32, 713 (1959).

These chemical treatments are as follows.

*Tetravalent neptunium.*—(A) *In nitirc acid system.* The tracer reduced by granulated zinc in 1 N nitric acid is extracted by TTA*-benzene, stripped by 3 N nitric acid washed with benzene and diluted with distilled water to 2 N. (B) *In hydrochloric acid system.* The tracer is reduced by granulated zinc in 1 N HCl, extracted by TTA-benzene solution, stripped by 1 N HCl in a large volume and washed with benzene.

*Pentavalent neptunium.*—In the nitric acid system, neptunium(V) tracer is prepared in the following four ways. (C) The tracer is prepared as perchloric acid solution and pipetted into 2 N nitric acid. Neptunium is almost all pentavalent in perchloric acid[7], and the neptunium(VI) which might be present is removed by 100% TBP**. (D) The tracer is oxidized with ceric ammoium nitrate[5] in 7 N nitric acid, extracted with 100% TBP, stripped by distilled water after the organic layer is diluted with a large volume of benzene, and reduced by hydrazine[5]. The acid concentration is about 2 N. Neptunium distribution ratios in the TBP nitric acid system are measured when neptunium is treated with oxidizing or reducing agent. (E) The tracer is reduced with sulfur dioxide in perchloric acid solution in order to change all of neptunium into neptunium(V), and pipetted in volume of a few lambda (0.001ml.). The distribution ratio is measured between 100% TBP and 1.7 N perchloric acid tracer solution saturated with sulfur dioxide. (F) The tracer is treated as (D), but reduced with sulfur dioxide instead of with hydrazine[5]. The distribution ratio of this tracer solution is checked between 1.7 N perchloric acid and TBP.

(G, H) In the hydrochloric acid system, the tracer is obtained in perchloric acid solution and a few lambda of it are pipetted into the acid. The acid concentration is 1 N(G) or 4 N(H) of hydrochloric acid.

(I, J) In the perchloric acid system, a perchloric acid tracer solution is used. The perchloric acid concentration is 4.6 N(I) or 1.2 N(J).

*Hexavalent neptunium.*—(K) In nitric acid system. The tracer solution is warmed and oxidized with ceric ammonium netrate in 7 N $HNO_3$[5]. Oxidized neptunium is extracted with 100% TBP. The organic phase obtained is shaken with 7 N nitric acid in order to remove Np(IV) and -(V). Neptunium is backextracted with distilled water and washed with benzene. The acid concentration is about 2 N. The distribution ratio of neptunium between 7 N nitric acid and TBP is measured. (L) In hydrochloric acid system. The tracer is oxidized by potassium chlorate[5] in 8 N hydrochloric acid during the heating of the solution, extracted with 100% TBP, backextracted with a large volume of distilled water, and washed with benzene. The distribution ratio of tracer between 8 N hdyrochloric acid and 100% TBP is checked. (M) In perchloric acid system. Tracer is oxidized with silver peroxide in 1.2 N perchloric acid[5]. Experiments are carried out in the presence of silver peroxide powder. Without silver peroxide, the tracer is carried down with lanthanum fluoride.

The lanthanum carrier solution contains 2 mg. of the lanthanum ion per ml. in acid solution. In order to avoid complexities, lanthanum carrier is dissolved in the same acid as that used for nuptunium tracer solution in every case.

The zirconium carrier solution contains 10 mg. zirconium per ml.

Hydrofluoric acid (47.1%) is used without dilution as precipitant for lanthanum fluoride. It will be seen in Table I that high hydrofluoric acid concentration in the precipitant causes marked coprecipitation of neptunium(V) in nitric acid medium. Thus, the coprecipitation behavior is supposed to be dependent on the concentration of hydrofluoric acid. However, not considering this effect, hydrofluoric acid is used without any dilution or purification in the present study.

1 M diammonium hydrogen phosphate solution is used as precipitant for zirconium phosphate.

**Procedure.**—The coprecipitation experiments are carried out as follows. Two milliliters of acid solution containing neptunium-239 in a desired oxidation state, 1 ml. of carrier solution and 1 ml. of precipitant solution are mixed thoroughly in a centrifuge tube. The hydrofluoric acid corrosion of glass is avoided by using an polyacrylic acid tube. After the white precipitate is removed by centrifugation, 2 ml. of the supernatant solution is taken in a glass tube for the measurement of the gamma activity. This is measured by Philips' scintillation counter.

## Results

The reproducibility is checked by repeating experiments under the same conditions. As is seen in Table I, most values coincide well with

* $\frac{\text{Activity remaining in solution}}{\text{Activity taken}}$

one another. However, experiments are repeated four times under the same conditions and the mean value of the ratio between the neptunium remaining and the neptunium taken, is calculated.

On the other hand, it is likely that the acidity of the tracer solution would not cause a strong effect on the coprecipitation. Table II shows that the tracer solution of 0.5~5.0 N nitric acid gives reproducible results. All results obtained are summarized in Table III.

The tracers were prepared by solvent extraction with TBP and/or TTA, as described in the experimental part and the oxidation state of the neptunium was determined according to the solvent extraction behavior and also the coprecipitation behavior with zirconium phosphate.

The oxidation state of neptunium(IV) was ascertained by TTA-extraction and zirconium phosphate coprecipitation. It is well known that only neptunium(IV) is extracted by TTA[4-6], and is carried down by zirconium phosphate[3,5,6]. Results show that neptunium(IV) coprecipitates with lanthanum fluoride in nitric and hydrochloric acid solutions. No experiment was carried out in perchloric acid solution, because neptunium(IV) is unstable in perchloric acid solution.

In the series of experiments for neptunium(V) and -(VI), the distribution ratios of the neptuium tracer were measured between mineral acid and 100% TBP. The distribution of neptunium(IV), -(V) and -(VI) between tributyl phosphate and some kinds of mineral acid had been betermined in the previous study[7]. The distribution ratio being measured, the oxidation state is assigned by comparing the distribution ratio measured and that reported. On the other hand, zirconium phosphate can not carry down neptunium(V) and -(VI) quantitatively. These results show that neptunium(V) is carried down with lanthanum fluoride whereas neptunium(VI) is not. An uncertainty may be found in the preparation of $ZrH_2(PO_4)_2$ precipitate, because it is not aged in order to prevent any change in the oxidation state of neptunium.

It will be noted in Table III that both neptuium(IV) and -(V) are carried down by lanthanum fluoride almost completely, while a remarkable amount of neptunium(VI) remains in the supernatant solution. As far as lanthanum fluoride precipitation is concerned, the difference between the behavior of neptunium(IV) and that of neptunium(V) can not be identified separately, but these two oxidation states behave quite differently in TBP-acid solution systems. It is also seen in Table III that they behave differently in coprecipitation with zirconium phosphate.

Results show that neptunium(IV) and -(V) can not be separately identified according to their behavior in being carried down with lanthanum trifluoride, whereas they are identified by the behavior in the solvent extractions or in the coprecipitation with zirconium phosphate. Thus it is presumed that both neptunium(IV) and -(V) are carried down almost completely with lanthanum trifluoride while neptunium(VI) remains in the supernatant solution.

The author wishes to thank Dr. Tomitaro Ishimori for criticism and suggestions which made a major contribution to this work.

# *On the Molecular Structure of Malononitrile*

By Eizi HIROTA and Yonezo MORINO

(Received March 28, 1960)

The structure of malononitrile molecule has been investigated by microwave spectroscopy[1], three kinds of isotopic species, $CHD(CN)_2$, $CD_2(CN)_2$, and $CH_2CNC^{15}N$, being used in addition to the normal one, $CH_2(CN)_2$. The CCN group was found to be bent slightly. However, as Dr. N. Muller pointed out in his private communication, the procedure of the analysis applied gave a mixed $r_s$ and $r_o$ structure, that is, the positions of hydrogen and nitrogen atoms were determined by isotopic substitution, on the other hand those of carbon atoms were obtained from the first moment equation and the observed moments of inertia, because the isotopic atom $^{13}C$ was not available[2]. It would be therefore worthwhile to see whether the bent structure of the CCN group is established or not, in the $r_o$ structure including inertia defect. The reanalysis is made by fitting the calculated $x$-, $y$-, and $z$-moments with the observed by the least-squares method. The result is shown in Table I and the molecular structure obtained is listed in Table II. It is found within the mean deviation that the CCN group is bent by $3°40' \pm 2°54'$[3]. The bond lengths C–C and C≡N are nearer to those found in a number of other related molecules than those obtained in the previous paper, though the mean deviations attached are large enough to include the structural parameters determined by the previous analysis.

It is very difficult to estimate the errors in the molecular structure obtained. The effect of zero-point vibration is a serious factor in the determination of molecular structure by the spectroscopic method. The mean deviations given here are considered mostly due to the effect of zero-point vibration. The error in the observed moment of inertia is of minor importance, and was taken into consideration in the previous paper where the effect of zero-point vibration was ignored. The more detailed analysis will be made possible by using the $^{13}C$ species.

# *The Equilibrium between the Sn-Pb Liquid Solution and the $H_2$-$H_2O$ Gaseous Mixture*

By Koji ATARASHIYA*, Masahiro UTA**, Mitsuo SHIMOJI and Kichizo NIWA

(Received September 28, 1959)

The thermodynamic investigation of metallic solutions is very important in order to have a deep understanding of their structure[1]. In the tin-lead system the primary solid solutions have very limited solid solubilities in the respective solvents. The immiscibility of these primary solid solutions is found over a wide range of the concentration[2]. This fact may reflect the fact that the excess heat of the tin-lead liquid solution shows a positive value according to the simple model of solutions, for example, that of the regular solution[3]. Thermodynamic data on this binary system, all of which have been based on calorimetric measurements, enable one to confirm the above expectation. The excess heat of this system has been measured by Magnus and Mannheimer[4], by Kawakami[5], by von Samson-Himmelstjerva[6], and by Kleppa[7].

However, no direct measurement of the excess free energy of this system has so far been carried out. This may presumably be due to some experimental difficulties which accompany the direct methods of measuring the activity of this system such as those of electromotive force and of vapor pressure. The activities of the tin-lead system have been calculated by Elliott and Chipman[8] from the experimental results on the tin-lead-cadmium system.

In this paper the activity of tin in the tin-lead liquid solution is obtained by measuring the equilibrium of the tin-lead system with the hydrogen-water vapor mixture.

The principle of this method is as follows:—

If the hydrogen-water vapor mixture is in equilibrium with liquid tin and its dioxide in accordance with Eq. I,

$$Sn(l) + 2H_2O(g) = SnO_2(s) + 2H_2(g) \qquad (I)$$

one can write, as the equilibrium constant $K$ for reaction I,

$$K = (P_{H_2}/P_{H_2O})^2 \qquad (1)$$

where $P_{H_2}$ and $P_{H_2O}$ are the partial pressures of $H_2$ and $H_2O$ respectively. On the other hand, a similar equation (II) can be given for the tin-lead liquid solution, if the oxide of tin is stable as compared with that of lead.

$$Sn(\text{liq. soln.}) + 2H_2O(g) = SnO_2(s) + 2H_2(g) \qquad (II)$$

Corresponding to Eq. 1, one has

$$K = (P_{H_2}'/P_{H_2O}')^2/a_{Sn} \qquad (2)$$

where $a_{Sn}$ is the activity of tin relative to pure liquid tin, and the prime labeled for the pressures means the equilibrium partial pressure in the tin-lead system. From Eqs. 1 and 2 one obtains

$$a_{Sn} = (P_{H_2}'/P_{H_2O}')^2/(P_{H_2}/P_{H_2O})^2 \qquad (3)$$

Thus, in principle, the activity of tin in this system can be determined by measuring the partial pressures of hydrogen and water vapor in equilibrium with both pure tin and tin-lead.

## Stability of Oxides

It is the fundamental condition for Eq. 3 that the oxide, $SnO_2$, is most stable among all oxides conceivable in the present system. In thermodynamic terms, an oxide should be stable in case the partial pressure of oxygen in equilibrium with the oxide is low. In other words the formation of a stable oxide is associated with a small amount of oxygen. In Table I the partial pressures of oxygen in equilibrium with several oxides are shown, which are calculated from the free energies of formation of respective oxides[9] at 1000°K.

It is readily found that tin oxides are stable

TABLE I. PRESSURES OF OXYGEN IN EQUILIBRIUM WITH TIN- AND LEAD-OXIDES AT 1000°K

| Oxides | | Pressures of oxygen $\log P_{O_2}$ (atm.) |
|---|---|---|
| $SnO_2$ | (s) | −19.6 |
| SnO | (s) | −19.0 |
| SnO | (g) | − 7.1 |
| PbO | (s) | −12.6 |
| $Pb_3O_4$ | (s) | − 8.9 |
| $PbO_2$ | (s) | − 4.5 |

compared with lead oxides. Although the value of SnO(s) is close to that for $SnO_2$(s), the solid SnO is found unstable as compared with $SnO_2$ in other studies[10]. Further, according to the electron diffraction study by Shimaoka and Yamai[11], the oxide film formed on the surface of the tin-lead solution under the condition of temperatures higher than 470°C and of pressures below 1 atmosphere of air, shows complete patterns of the stannic oxide. After the present experiment has been finished, the samples should be examined by means of the X-ray or by the electron diffraction, but the amount of oxides formed by reaction II is too small to be determined in such a way. However, the fact of the stannic oxide being most stable may be assured by the other reasons already described above.

## Experimental

The same apparatus, used in the measurement of equilibrium in $GeO_2$-$H_2$-Ge-$H_2O$ system[12], is employed with a modification of the sizes of both the furnace and the reaction tube.

Metallic solutions are prepared by fusing each mixture of pure metals (Kanto Kagaku, 1st grade) in a closed vessel under vacuum; their concentrations are confirmed by chemical analysis.

The boat of high alumina filled with 3∼4 g. of the powdered sample, which has been dispersed in alumina powder, is set in the reaction tube. After the tube has been evacuated to the pressure of $10^{-5}$ mmHg, water vapor saturated at 18±0.01°C (15.45 mmHg), is introduced for oxidation, while hydrogen, generated by electrolysis of a potassium hydroxide solution, is introduced for reduction. The oxidation method is used for liquid metallic solutions, since there is no assurance of obtaining the required metallic solution from the reduced tin metal. The rate of gas flow is about 200 cc./min. The measurements have been carried out over the range of 700∼800°C.

The whole error in $a_{Sn}$ may be about 3% which is due to the inaccuracies of the furnace temperature (±2°C) and of the temperature of water (±0.01°C), as well as of the reading of the cathetometer (pressure: ±0.01 mmHg), etc. As one of the other sources of error, the change of concentration in liquid solutions should be taken into account, since tin in the solution is oxidized during the reaction. However, the amount of this change estimated from the volume of the reaction system (about 850 ml.) is at most $10^{-5}$ mol., and small compared with the initial amount of tin in solutions (at least $10^{-3}$ mol.). Though the vapor pressure of lead is about $10^{-2}$ mmHg at 700∼800°C, the rate of vaporization is then at most $10^{-5}$ mol./hr. Thus, this effect may be negligible because of the short time taken for the present reaction (1∼5 hr.).

## Results

II. If the common logarithms of the equilibrium constant, $K$, thus obtained, are plotted against the reciprocal temperature, as shown in Fig. 1, they lie close about a straight line, which is expressed by Eq. 4. (This equation is established by means of the least square).

$$\log K = 4150/T - 4.965\ (\pm 0.05) \qquad (4)$$

This result is in good agreement with the data of other investigators[13-16]. For example, the following values are obtained by means of Eq. 4.

| $t$, °C | $K$ |
|---|---|
| 750 | 0.1235 |
| 775 | 0.0988 |
| 800 | 0.0799 |

**Equilibrium in Sn (in Soln.)—$H_2O$-$SnO_2$-$H_2$ System**:—The equilibrium constant and the activity of tin, measured in this system, are indicated in Table III. The activity of tin, shows a positive deviation from Raoult's law, as is seen in Fig. 2. The partial excess free energy of tin, $\bar{G}^e_{Sn}$, is related to its activity by

$$\bar{G}^e_{Sn} = \boldsymbol{R}T \ln a_{Sn}/x_{Sn} = \boldsymbol{R}T \ln f_{Sn} \qquad (5)$$

where $\boldsymbol{R}$ is the gas constant, $x_{Sn}$ is the atomic fraction of tin, and $f_{Sn}$ is the actitvity coefficient. If the values of $\bar{G}^e_{Sn}/(1-x_{Sn})^2$ are plotted against $x_{Sn}$, they lie close about a straight line, shown in Fig. 3, which is expressed by Eq. 6 at 775°C.

$$\bar{G}^e_{Sn}/(1-x_{Sn})^2 = 2330 - 600(1-x_{Sn}) \quad (\pm 50\ \text{cal./mol.}) \qquad (6)$$

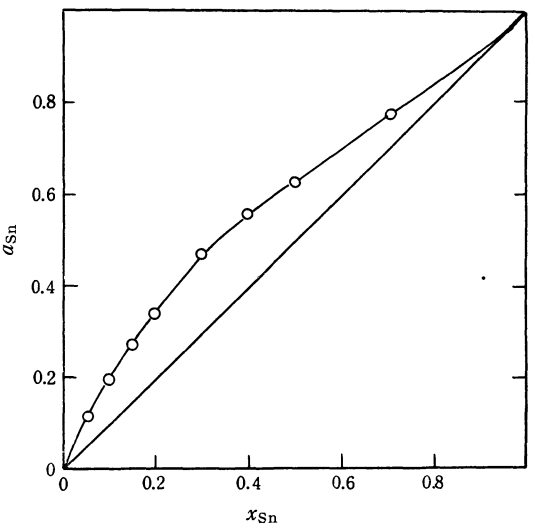

Fig. 2. Observed activity of tin in the tin-lead liquid solution at 800°C.

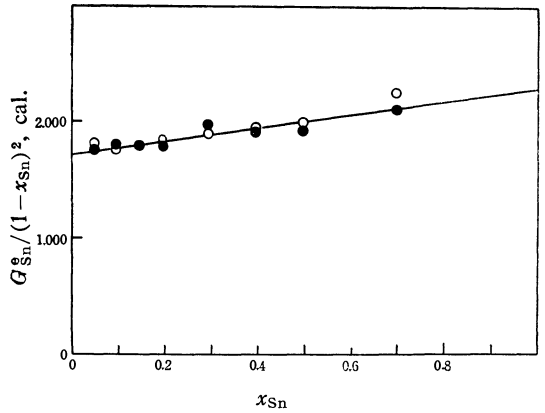

Fig. 3. Concentration dependence of partial molar excess free energy of tin in the tin-lead liquid solution. ○ Observed values at 750°C. ● Observed values at 800°C.

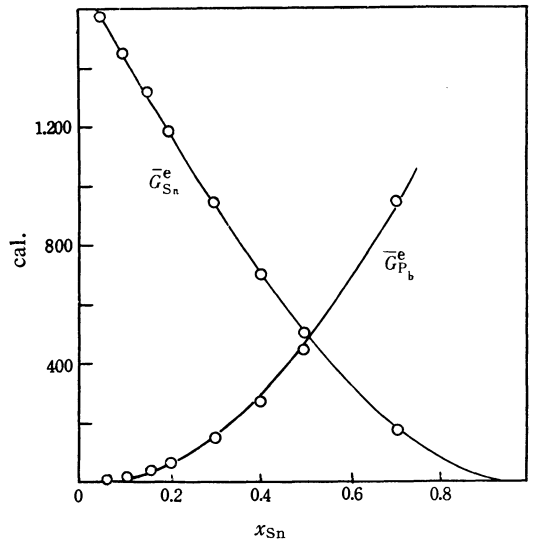

Fig. 4. Partial excess free energies in the tin-lead solution at 775°C.

Applying Gibbs-Duhem's relation to the above results, one obtains not only the partial molar excess free energy of lead, but also the (integral) excess free energy of the solutions, $G^e_m$, as are shown in Figs. 4 and 5 which are expressed respectively by Eqs. 7 and 8 at 775°C

$$\bar{G}^e_{Pb} = 1430\, x_{Sn}{}^2 + 600\, x_{Sn}{}^3 \quad (7)$$

$$G^e_m = x_{Sn} x_{Pb} (1730 + 300 x_{Sn}) \quad (8)$$

Unfortunately, the temperature dependence of $a_{Sn}$ could not be accurately obtained in this experiment owing to the limited range of temperatures (750~800°C). This limitation is due to the fact that the vapor pressure of lead is very high at temperatures above 800°C, while the reaction rate for oxidation is very slow if the temperature is lower than 700°C.

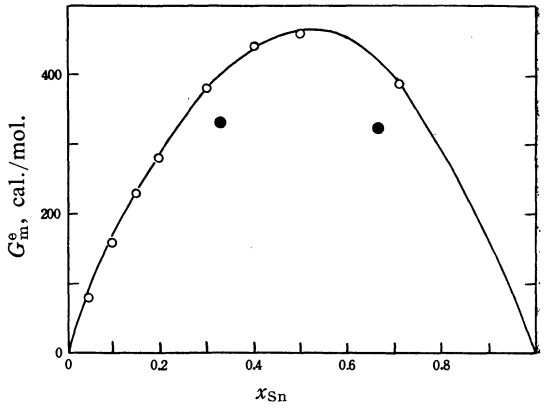

Fig. 5. Excess free energy in the tin-lead liquid solution at 775°C. ○ Observed values. ● Calculated from the data of Elliott and Chipman for the ternary system.

## Discussion

So far as the excess free energy of the tin-lead system is concerned, there are no experimental data available except an indirect result calculated from those of the cadmium-tin-lead system obtained by Elliott and Chipman[8]. They have given only two values of the excess entropy at about 500°C, which can be extrapolated to 775°C. The excess free energy, $G^e_m$, thus obtained is as follows.

| $x_{Sn}$ | 0.333 | 0.667 |
|---|---|---|
| $G^e_m$(cal.) | 333 | 320 |

By a combination of these values with the present results, a comparison is made in Fig. 5. It is found that the results, obtained by Elliott and Chipman for only two concentrations, have a tendency to represent slightly small values compared with the present ones. However, the values of the heat of mixing calculated from those for the cadmium-tin-led system are 15~20% smaller than those directly measured by Kleppa[7]. Hence, if the excess free energy is calculated by combining Kleppa's values for the excess heat with those of Elliott and Chipman for the excess entropy, the agreement between the values thus obtained and those of the present study is quite reasonable. It should be noted that the excess entropy shows a slightly negative deviation from ideal mixing.

It is of interest to examine the excess function on liquid tin-lead solutions from simplified models of metallic solutions. According to Haissinsky[17], the electronegativity of tin is almost in agreement with that of lead. ($Sn^{II}$, 1.65; $Pb^{II}$, 1.6; $Sn^{IV}$, 1.8; $Pb^{IV}$, 1.8.) So the electrochemical effect due to transfer of electrons may be very small in the tin-lead system. For

17) M. Haissinsky, *J. phys.* 7, 7 (1946).

these cases, the theoretical calculation of excess functions can be simplified, as pointed out by Hildebrand and Scott[18].

$$H_m^e = [(L_A/V_A)^{\frac{1}{2}} - (L_B/V_B)^{\frac{1}{2}}]^2 \varphi_A \varphi_B V_S \quad (9)$$

and $$S_m^e = 0 \quad (10)$$

$L_A$ and $L_B$ are the energies of vaporization of pure A and B respectively. $V_A$ and $V_B$ denote their volumes in pure states. $V_S$ represents the volume of the solution. $\varphi_A$ and $\varphi_B$ are the volume fractions respectively.

As the interatomic potential in liquid metals cannot always be expressed by the well known 6-12 potentials or 6-$\infty$ potentials, Shimoji[19] has proposed the following theoretical expression for the excess energy after taking into account the generalized potential.

$$H_m^e = [(L_A/V_A)^{\frac{1}{2}} - (L_B/V_B)^{\frac{1}{2}}]^2 \varphi_A \varphi_B V_S + \frac{nl}{8}\rho^2\left(1+\frac{\delta_v}{2}\right)\frac{L_{AA}}{V_A}\varphi_A\varphi_B V_S \quad (11)$$

Here,

$$\rho = 2(r_B - r_A)/(r_B + r_A)$$

and $$\delta_v = (L_B/V_B - L_A/V_A)/L_A/V_A) \quad (12)$$

$r_i$ means the interatomic distance in the pure state of i. It is found that the parameter $nl$ in Eq. 11 is about 10 or 20 in most liquid metals. If $nl=72$, Eq. 12 corresponds to the one derived by Prigogine[20]. Of course Hildebrand's Eq. 9 can be obtained if the term due to the difference of atomic radii (size factor) is neglected in Eq. 11. Furthermore, the assumption of the geometric mean of energies between unlike atoms used in deriving Eq. 9 might be open to doubt because of metallic forces. If the arithmetic mean is used for the energies, $H_m^e$ should be zero for Eq. 9, (or the first term of Eq. 11 should be zero.) It is noteworthy that Eq. 11 gives a positive excess energy even if the assumption of the arithmetic mean is used.

Table IV. Comparison of calculated values of the excess functions in tin-lead liquid solutions (cal./mol.)

| | Hildebrand | Shimoji ($nl=10$) | 6-12 potential | Expl. |
|---|---|---|---|---|
| $H_m^e$ | 860(0*) | 1050(200*) | 2150(1300*) | 330[7] |
| $G_m^e$ | 860 | 1000 | | 460 |

$H_m^e$: The excess heat at $x_{Sn}=0.5$
$G_m^e$: The excess free energy at $x_{Sn}=0.5$ (at 800°C)
*: Values based upon the arithmetic mean rule.

In Table IV the calculated values of the excess energy and the exsess entropy at $x_{Sn}=0.5$ are compared with the observed ones. The most reasonable approach to the excess energy of an alloy is based on the collective electron theory of metals, such as the cellular approximation etc.[21,22] Unfortunately, no reliable values of the parameters adaptable for these theories have yet been determined either experimentally or theoretically in either the liquid tin or lead systems. However, according to Varley's calculation[21] based on the free electron approximation, the electrochemical factor is nearly zero in the lead-tin system. Then, the size factor indicating the positive excess energy plays an important role in liquid metals as well as in solid alloys. Rigorous estimation in the liquid state can not be achieved because of lack of knowledge concerning the parameters of pure metals, but the same conclusion may thus be obtained either from the theories of the pair bond interaction[18,19] or from those of the free electron approximation based upon the band model of metals.

## Summary

Equilibrium in Sn (in liquid alloy)-$H_2O$-$SnO_2$-$H_2$ system has been determined from 750 to 800°C by measuring the ratio of pressures between $H_2O$ and $H_2$ gas mixtures. From this the activity of tin liquid tin-lead solutions has been calculated, and the following equation has been derived at 775°C.

$$\overline{G}_{Sn}^e = 2330(1-x_{Sn})^2 - 600(1-x_{Sn})^3 \text{ cal./mol.}$$

The temperature dependence of $\overline{G}_{Sn}^e$ could not be determined. However, if this value is calculated by combining Kleppa's value for the excess heat, calorimetrically determined, with that of Elliott and Chipman for the excess entropy, the agreement between the value thus obtained and that of the present investigation is quite reasoable, taking into consideration the accuracies of these experiments. Theoretical considerations have been given for the excess functions of this system. It shonld be emphasized that the electrochemical effect of charge transfer is very small or may be regarded as zero in the lead-tin system and that the size factor is important.

# SHORT COMMUNICATIONS

## *Three Geometrical Isomers of p-Distyrylbenzene*

By Soichi MISUMI and Motoyuki KUWANA

(Received February 24, 1960)

Three geometrical isomers are possible in *p*-distyrylbenzene (I) with regard to the ethylenic double bonds of the molecule. We have studied the synthesis and the photoisomerization of these three isomers with the purpose to compare the physical and chemical properties with those of the recently extensively studied pure polyolefinic systems such as diphenylpolyenes[1] and carotenoids[2].

The *cis, cis*- and *cis, trans*-isomers ($I_c$ and $I_b$) were prepared by the partial hydrogenation of the corresponding acetylenic compounds using Lindlar's catalyst. The *trans, trans*-isomer ($I_a$) was obtained by the dehydration of *p*-bis(β-phenyl-α-hydroxyethyl)benzene. The isomers were purified by repeated recrystallization or chromatography on alumina.

Unexpectedly the sequence of qualitative photostability of these isomers under diffused light was found to be *trans, cis* ($I_b$) ≪ *cis, cis* ($I_c$) ≤ *trans, trans* ($I_a$). Both of the sterically hindered *cis, cis*- and *cis, trans*-isomers ($I_c$ and $I_b$) showed no fine structure in their ultraviolet spectra as illustrated in Fig. 1. The *cis, trans*-isomer ($I_b$) showed the most intense

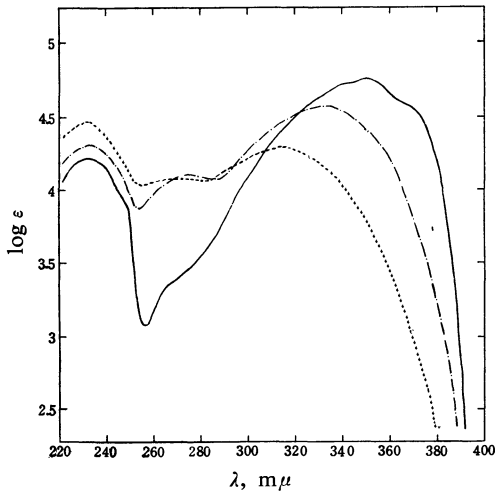

Fig. 1. Ultraviolet absorption spectra of *p*-distyrylbenzene (I) in *n*-hexane: ——, *trans, trans*; —·—, *cis, trans*; ----, *cis, cis*.

*cis*-peak[2b] (ca. 270mμ) in accord with the theory proposed by Zechmeister.

The solutions of the isomers were exposed to light of a fluorescent tube under controlled conditions and the course of the photoisomerization was followed by the change of the intensities of absorption at 270 and 350 mμ. The results are illustrated in Figs. 2 and 3. It is to be noted that the rate of spatial rearrangement of the most hindered *cis, cis*-isomer ($I_c$) is much slower than that of *cis, trans*-isomer ($I_b$). Theoretically, the same equilibrium mixture

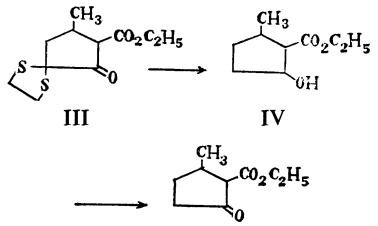
## *The Absolute Structure of Actinidine*

By Takeo SAKAN, Akira FUJINO, Fujio MURAI, Akio SUZUI, Yasuo BUTSUGAN and Yutaka TERASHIMA*

(Received March 26, 1960)

(+)-Actinidine, the enantiomeric from of the levorotatory natural product, has been synthesized from (+)-pulegone through methyl pulegenate (Ib).



The synthesis was preceded by the scrupulous confirmation of the plane structure of pulegenic acid (Ia), presented by H. Rupe and K. Schäfer[1] to be 2-isopropyliden-5-methyl-cyclopentanecarboxylic acid. The ethyl ester (Ic) of Ia was ozonolyzed to ethyl 2-methyl-5-oxo-cyclopentanecarboxylate (IIc), b. p. 95~96°C/10 mmHg (Found: C, 63.31; H, 8.35. Calcd. for $C_9H_{14}O_3$: C, 63.51; H, 8.29 %), and the racemic form of the latter was synthesized.

I II

a: R=H; b: R=$CH_3$; c: R=$C_2H_5$

The half ethylene dithio-ketal (III), m. p. 63°C (Found: C, 50.53: H, 6.23; S, 24.59. Calcd. for $C_{11}H_{16}O_3S_2$; C, 50.77; H, 6.20; S, 24.62 %) of ethyl 2-methyl-4, 5-dioxocyclopentanecarboxylate[2] was reduced on treatment with Raney nickel to the hydroxy ester (IV) ($\nu_{OH}$ 2.89 $\mu$ in infrared absorption spectrum), which was converted into the corresponding keto ester (IIc′) by the successive oxidation with the complex of chromic oxide-pyridine. IIc and IIc′ were proved to be identical through the mixed fusion test and the comparison of the infrared absorption spectra of their semicarbazones.

2) H. Staudinger and L. Ruzicka, ibid., 7, 381 (1924).

The attempts to hydroxylate the isopropyliden group in Ib with selenium dioxide under the various conditions were so all in failure that the authors were impelled to take a rather circuitous route for the purpose. The satisfactory result was achieved when the methyl ester (IIb), b. p. 90~92°C/12 mmHg (Found: C, 61.29; H, 7.91. Calcd. for $C_8H_{12}O_3$: 61.52; H, 7.75 %), was chosen as a key compound and the necessary $C_3$-moiety was re-introduced into IIb as shown below.

The condensation product (V) of IIb with ethyl cyanoacetate was treated with methyl iodide in the ethoxide solution and the methylated diester (VI) was hydrolyzed with acid or alkali to the dihydroxypyridine derivative (VII), m. p. 172~173°C (Found: C, 67.15; H, 7.51; N, 7.98. Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%). The chlorination of VII and the successive catalytic hydrogenation of the dichloro-compound, similar to those reported in the synthesis of DL-actinidine[3], yielded the base (VIII), the purified picrate (Found: C, 50.95; H, 4.36; N, 14.91. Calcd. for $C_{16}H_{16}O_7N_4$; C, 51.06; H, 4.29; N, 14.89 %) of which melted at 146~147°C. The regenerated base, b. p. 88~90°C/5 mmHg, from the latter gave the value of $[\alpha]_D^{15}+16.1°$ (c 5.52 chloroform) and the identical infrared absortion chart with the natural alkaloid. Although the absolute values of rotatory power were not equal between these two actinidines obtained, the synthesized one was likely to be in a more purified state.

As the asymmetric center of (+)-pulegone had already been correlated in the stereochemical analysis to D-series[4], the absolute configuration of $C_{(7)}$-carbon atom in natural actinidine (6, 7-dihydro-4, 7-dimethyl-5(*H*)-2-pyrindine) has now been established.

# *Effect of Metal Ions on the Radiation-Induced Decarboxylation of Aqueous Benzoic and Salicylic Acid Solutions*

By Akira SUGIMORI and Gen-ichi TSUCHIHASHI

(Received March 9, 1960)

Remarkable effect of heavy metal ions was observed in the radiolysis of benzene in aqueous solution[1] and other organic compounds[2]. In the systems hitherto studied, the interaction between metal ions and organic molecules is expected to be different from that in the compounds containing metal ions. The effect of metal ions bound to organic molecules on the radiolysis has not yet been studied.

The present authors studied the effects of added ions on the decarboxylation of benzoic and salicylic acids, in order to clarify the difference in the effect between bound and non-bound metal ions. Benzoic acid does not form any chelate compounds with metal ions, whereas salicylic acid gives stable complexes with $Fe^{3+}$, $Cu^{2+}$ and $Al^{3+}$.

(1)

The difference in the effect of heavy metal ions on $G(CO_2)$ was found between benzoic and salicylic acid, and this can be attributed to the difference in the states of ions.

The oxygen free solution containing 0.2 % of either acid and metal salts were irradiated by $^{60}Co$ $\gamma$-rays in the test tube with side cell in which 0.1 N barium hydroxide solution was

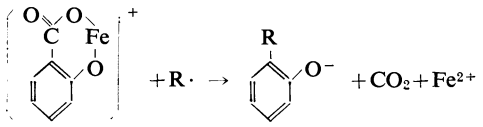
placed in order to absorb carbon dioxide formed. Dose rate and total dose were $9.5\times10^4$ r./hr. and $1.57\times10^6$ r., respectively. Carbon dioxide formed was absorbed by barium hydroxide solution and $G(CO_2)$ was measured volumetrically.

The effects of various metal ions are summarized in Table I. In the case of benzoic acid, $Fe^{3+}$ added does not bring about the increase in $G(CO_2)$, while in the case of salicylic acid, it makes $G(CO_2)$ remarkably high. This suggests that $Fe^{3+}$, chelating organic molecules and attacking redicals cooperate in the decarboxylation of the complex. This is also supported by the following experiments.



a) Fig. 1 shows the plot of $G(CO_2)$ in the radiolysis of salicylic acid against the amount of $Fe^{3+}$ added. As is shown in the figure, a remarkable break is observed at $[Fe^{3+}]/[\text{Salicylic acid}]=1$, where all of $Fe^{3+}$ ions and salicylic acid mulecules exist as complexes and neither of $Fe^{3+}$ nor salicylic acid remains in excess.

b) The addition of some masking reagents such as $F^-$ and $H^+$ to the complex makes $G(CO_2)$ low.

Based on the above results, the mechanism of the decarboxylation of the complexes is conceivably different from that of free acids.

Therefore the following sequence of reactions can be given for the decarboxylation of the complex.

$$H_2O \xrightarrow{\gamma\text{-rays}} H\cdot + HO\cdot + H_2O_2 \quad \text{etc.} \tag{2}$$

(3)

(where R· represents free radical)

The attacking radical (R·) is not yet identified but this mechanism is supported by the following observations.

a) In this case $Fe^{3+}$ is easily reduced to $Fe^{2+}$, although it is reduced only to small extent in the absence of organic compounds.

b) $Fe^{3+}$ and $Cu^{2+}$ added bring about the increase in $G(CO_2)$ of salicylic acid, whereas added $Al^{3+}$ has only a slight effect. All of them are known as metal ions which give complexes with salicylic acid.

These indicate that both the complex formation and easy reduction of metal ions are essential for this kind of metal catalyzed radiation-induced decarboxylation.

The present authors are very grateful to Dr. K. Kimura and Dr. A. Danno for their helpful discussion.

# *Separation of Lanthanons by Paper Precipitation Chromatography with 8-Quinolinol. I. Separation and Detection of Lanthanum, Cerium and Praseodymium (Part 1)*

By Hideo NAGAI

(Received September 30, 1959)

The separation of lanthanons by paper chromatography and its analogous column method was studied by Lederer[1-4] and Pollard et al.[5,6], and the separation was effective to some extent. However, the separation of adjacent elements was very difficult, although a few elements have been separated. The difficulties were principally caused by considerable tailing and the close $R_f$ values of the elements. On the other hand, precipitation chromatography with 8-quinolinol (oxine), which the author has studied[7-12], involved fundamentalf actors to reduce these difficulties. The procedure of precipitation chromatography is as follows. One drop of the test solution is applied at the center of a circular filter paper, previously impregnated with oxine, and developed with an adequate developing solvent. As the developing solvent penetrates into the filter paper, the oxine contained in the filter paper dissolves and reacts with the cations in the test solutions; the phenomenon can be compared with the dropwise addition of the precipitating agent to the test solution in the precipitation titration. Accordingly, from the analogous deduction of the precipitation titration, the cation which forms the most stable metal complex with oxine precipitates at the central part of the filter paper. By the precipitation the reaction product is removed from the reaction system. Therefore the reaction proceeds in such a way as to cause the predominant precipitation of the same kind of complex salt to continue, until the greater part of this cation was consumed. Then the deposition of the next stable complex salt in the test solution follows. Such a course of precipitation prevents the overlapping of the bands corresponding to each cation in the test solution.

In addition to the advantage described above, this chromatographic procedure scarcely ever causes any tailing. This phenomenon is probably due to the following reason: when the test solution is applied on the filter paper, nuclei of the precipitate of the cations are formed and grow smoothly during the entire development. On the other hand, the difficulties caused by the coprecipitation are encountered in this procedure, especially, when the lanthanons are treated. Accordingly, an improved procedure was devised so as to utilize the advantages of precipitation chromatography and to avoid as much as possible the coprecipitation of the elements.

## Experimental

**Apparatus.**—The apparatus used for developing the chromatogram is illustrated in Fig. 1.

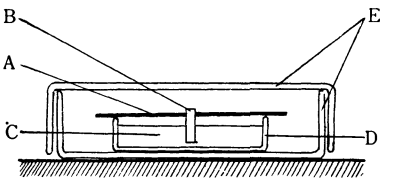

Fig. 1

A is a sheet of filter paper impregnated with oxine, which was prepared as follows. One hundred sheets of circular filter paper 9 cm. in diameter (Toyo filter paper No. 5B) were dipped in an ethanolic solution of oxine containing ca. lg. oxine in 80 ml. of ethanol (95%). After about 10 min. the paper was taken out, and dried in the open air. When the paper was almost dry, it was placed in an electric drier and completely dried. After storage for a few days in a closed vessel, the paper was used for the experiment. B is a narrow strip of untreated filter paper, 1~1.5 mm. in width, inserted in a slit cut at the center of the oxine-treated filter paper where one drop of the test solution, saturated with isobutanol, had been spotted. C is the developing solvent. D is a small Petri dish (the container for the developing solvent). E is a large Petri dish (12~13 cm. in diameter).

12) H. Nagai, ibid., **78**, 1334 (1957).

lanthanon material consisted of lanthanum oxide, praseodymium oxide, and cerous nitrate. Aqueous nitrate solutions were prepared by evaporating to dryness ca. 10 mg. of the required oxide or nitrate with a few drops of 2 N nitric acid, and dissolving the residue in water to produce the test solution containing ca. 10 mg. cation in 1 ml. solution. The following binary mixtures were prepared similarly: La-Ce, La-Pr and Ce-Pr.

**Development.** — Acetic acid-butanol system has been successfully used in a number of cases as the developing solvent for precipitation chromatography in the separation of many metallic cations, but it seemed to show insufficient separability in the case of lanthanons, though identification of each element in binary systems was possible with some difficulty. The lanthanum-cerium system developed with 0.5% acetic acid (by volume) saturated with isobutanol, and the cerium-praseodymium system developed with ca. 0.01% acetic acid and isobutanol (saturation) gave bare identification of the cations. In the separation of lanthanum and praseodymium, 0.01% acetic acid (saturated with isobutanol) was the most suitable solvent for the identification of praseodymium, while ca. 0.5% acetic acid (saturated with isobutanol) was the most suitable for the identification of lanthanum. The use of a solution more concentrated than 2% acetic acid (saturated with isobutanol) as the developing solvent caused irregular deformation of the chromatogram early in the development and then the bands of the chromatogram completely dissolved; thus the identification of the components of the test solution was scarcely ever possible.

Solution of *n*-butyric acid saturated with isobutanol showed far better results in the separation of lanthanons. Solutions of 0.005, 0.01, 0.05, 0.1, 0.5, 1, 2, 3, 5 and 10% *n*-butyric acid (by volume) saturated with isobutanol were used as developing solvent. The results were as follows. When the test solution was developed with 0.005 or 0.01% solution the innermost band was formed without leaving any blank space at the center of the chromatogram, and the bands showed practically no migration during the development. By the use of the solutions of 0.05 and 0.1% *n*-butyric acid, a blank area appeared at the central portion of the chromatogram, and, although the bands migrated a little on development, the results resembled the foregoing two cases. In the development with more than 1% *n*-butyric acid, the appearance of the bands resembled rather the chromatograms of the perfectly dissolved type than the precipitation chromatogram. When solutions of 1, 2 and 3% were used, the patterns of the chromatograms resembed one another, and the most desirable results were obtained generally in these cases (Fig. 2).

When 5% *n*-butyric acid (saturated with isobutanol) was used, the bands mixed together appreciably. And when 10% *n*-butyric acid (saturated with isobutanol) was used, the confusion of the bands became more marked, but the deformation of the chromatogram, which was observed at a higher concentration of acetic acid, was not observed in the *n*-butyric acid system.

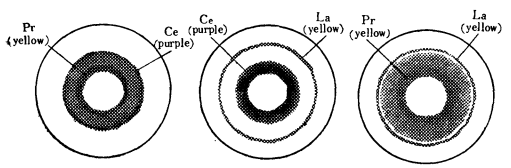

Fig. 2.

The temperature of the developing solvents was 20±1°C. After the development was finished, the chromatogram was subjected to reaction with ammonia vapor so as to stabilize the metal oxinates, and investigated under both visible and ultraviolet light.

## Discussion

When the acetic acid system (saturated with isobutanol) was used as the developing solvent, cerium and praseodymium were identified most readily by the use of 0.01% acid. Since the $R_f$ values of cerium and praseodymium hitherto reported have been the same, this can be regarded as an improvement, though their complete separation has met with little success. On the other hand, lanthanum-praseodymium and lanthanum-cerium whose $R_f$ values were reported to be somewhat different from each other (but the real separation was very difficult owing to their considerable tailing), showed rather better separation at a higher concentration of acetic acid (ca. 0.5% acetic acid).

When the *n*-butyric acid system (saturated with isobutanol) was used as the developing solvent, the separation of cations was achieved at a higher concentration than in the case of the acetic acid system. Accordingly, the chromatogram appeared to be somewhat soluble rather than of complete precipitation but a distinct difference was observed from the perfectly dissolved chromatogram. It was far superior to that of the acetic acid system described above.

These phenomena might be explained as follows. Precipitation chromatography inherently possesses the characteristic of exaggerating the separation factor among the cations, but the coprecipitation is apt to compensate for the advantage of the precipitation chromatography, as the author pointed out at the beginning of this paper. One way to minimize the influence of coprecipitation was to increase the acidity of the developing solvent. When the acidity reached a concentration adequate to prevent coprecipitation and to maintain the ability to form complex salts, the best separability could be expected. Even if the complex salts thus formed do not precipitate completely, their diffusion (migration) velocities in the filter paper decrease so markedly by complex formation that they can not migrate together with the developing front where the reaction between the complexing agent and the cation is predominantly taking place. Accordingly, it would

be reasonable to say that the reaction product (the complex salt formed) was taken out of the reaction system as in the case of precipitation. Thus, the advantages of precipitation chromatography are still retained while its minor disadvantage, coprecipitation, is avoided.

The author wishes to thank Professor T. Sasaki, Tokyo Metropolitan University, Professor N. Saito, the University of Tokyo, Professor J. Yoshimura, Kyushu University, Professor R. Matuura, Kyushu University, Professor K. Ochiai, Kumamoto University, and Assistant Professor H. Kimizuka, Fukuoka Gakugei University, for their encouragement and numerous suggestions throughout the investigation. Also the author expresses hearty thanks to Professor S. Misumi for the gift of lanthanons. The cost of this research was defrayed from the Scientific Research Fund of the Ministry of Education.

# *Intramolecular Interaction between Hydroxyl Group and π-Electrons. VIII*[1]. *Energetics of the Interaction*

By Michinori Ōki and Hiizu Iwamura

(Received December 11, 1959)

Little is known of the energy of the intramolecular interation between the hydroxyl group and π-electrons in spite of many studies on this phenomenon in a number of compounds. In the first paper[2] of the present series, the authors reported briefly that the energies of the intramolecular interaction in 2-hydroxy-4- and -4′-nitrobiphenyls are 2.5 and 0.93 kcal./mol., respectively. Goldman and Crisler[3] suggested that the strengths of this kind of interaction in 2-phenylethanol and 2-(*p*-methoxyphenyl)-ethanol are 0.88 and 0.98 kcal./mol., respectively, assuming that Badger's postulation, that 70 $cm^{-1}$ shift of the wave number of the hydroxyl stretching bands caused by the hydrogen bond formation corresponds to one kcal./mol. in the energy[4], is operative in this interaction. Necessity of elucidating the true nature of the interaction prompted the authors to examine the energy difference between the free and the interacting forms, since the results would be very useful for the discussion of the relation between band properties and the energy difference and consequently for the discussion of the nature. The present paper deals with some detailed procedures used in the measurement of the energies, which were omitted in the former short communication[2], and reports some data added recently in this laboratory. The materials include 2-allylphenol[1], 2-benzylphenol[1], 2-isopropenylphenol[5] and 2-hydroxybiphenyl[1]. The variation with the temperature of the infrared absorption spectra due to free and interacting hydroxyl groups was measured. These phenols were chosen out of many which possess the internal interaction by considering not only the fundamental structure representing each series, but also some technical advantages. The relative intensities of the free and the interacting O–H stretching absorption bands ($\nu_{O-H}$) at various temperatures can be measured most accurately when the intensities of the two bands are nearly equal. Otherwise, when the most favorable absorbance of one band is secured, the other will be either so weak that it may be affected by the noise of the recording system or so strong that it may exceed saturation. 2-Hydroxybiphenyl does not necessarily fulfill this requirement but the duplicate measurement under the best condition of the spectrometer gave reasonable data, although the probable error was fairly large in this case. To cover all the types of the intramolecular interaction, further combinations of the alcoholic hydroxyl group and the π-electrons of olefins and aromatic rings must be considered. The alcohol, however, as pointed out previously[6], shows rather complicated $\nu_{O-H}$ consisting

of two free $\nu_{O-H}$'s of rotational isomers and one interacting $\nu_{O-H}$ and thus obliges some discretion in dividing the apparent curve into absorptions due to free and interacting forms. This phenomenon caused the authors to give up the study of energy in the alcoholic series in the present work.

## Experimental

**Measurement.**—A Perkin Elmer Model 112 G Double Pass High Precision Grating Infrared Spectrometer was used as previous[6], the spectral slit width being 1.0 $cm^{-1}$ in this region. In a quartz absorption cell of 2 cm. length, having a window of 2.5 cm. diameter and protected with a heating coil covered with asbestos, about 20 ml. of the solution of the sample ($c\sim0.001$ mol./l.) in carbon tetrachloride was placed, and the temperature was controlled by varying the current through the heating coil, kept at each equilibrated temperature within $\pm0.2$°C and read by a thermometer dipped in the solution. The spectrometer being of a single beam type, a background trace was recorded every time immediately before the spectral measurement of the solution and the latter was always referred to the former, which also changed a little with the varying temperature.

**Calculation.**—Separation of the apparent curve and calculation of the integrated intensities of the two bands were made according to Ramsay's first method[6,7] for each of the absorption curves at different temperatures.

$$\text{Free form} \rightleftarrows \text{Interacting form}$$

Then the integrated form of the well-known van't Hoff equation (1) can be applied to obtain the energy difference between the two forms.

$$\ln K = -\frac{\Delta H}{RT} + \frac{\Delta S}{R} \qquad (1)$$

$K$ can be given by

$$K = \frac{C_i}{C_f} = \frac{A_i/a_i}{A_f/a_f} = a\frac{A_i}{A_f} \qquad (2)$$

where $a_i$ and $a_f$ represent intensities per molecule with a free hydroxyl group and an interacting one, respectively, and $A$'s integrated intensities. Combination of Eq. 1 with Eq. 2 gives

$$\ln\frac{A_i}{A_f} = \frac{-\Delta H}{RT} + \left(\frac{\Delta S}{R} - \ln a\right) \qquad (3)$$

The slope of the line obtained by taking $\ln(A_i/A_f)$ on the ordinate and $1/T$ on the abscissa gives the energy of the interaction ($-\Delta H$). Here it is assumed, that $a_i$ and $a_f$, or at least their ratio $a$, should be independent of the temperature, since the temperature range is rather narrow (25~70°C).

**Materials.**—Phenols used in the measurements are all known compounds and their physical constants were already reported previously[1,5].

## Results and Discussion

Apparent absorption curves of 2-isopropenylphenol at various temperatures are shown in Fig. 1 and $\ln(A_i/A_f)$ and temperature relation in Fig. 2.

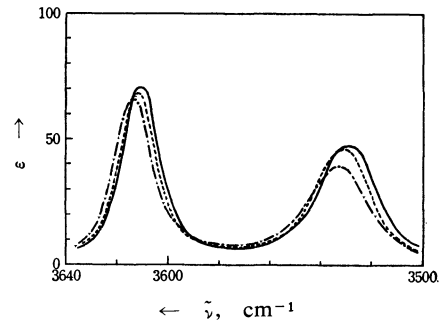

Fig. 1. $\nu_{O-H}$ absorptions of 2-isopropenylphenol at various temperatures.
28.1°C —— 45.3°C ------ 70.5°C -·-·

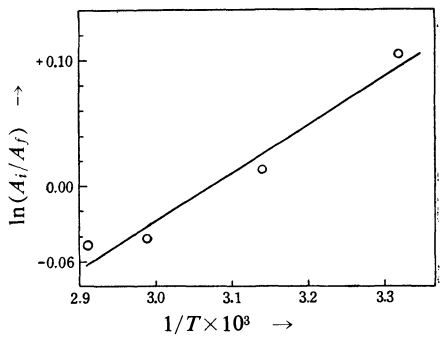

Fig. 2. Relation between $\ln(A_i/A_f)$ and temperature for 2-isopropenylphenol.

The effects of the temperature on the hydroxyl stretching frequencies and on the intensities are summarized in Tables I to IV.

There is always a slight but definite increase in absorption frequencies of both free and interacting $\nu_{O-H}$, accompanied by a decrease in the total integrated intensities ($A_i+A_f$). These effects might be attributed to the rupture of the remaining hydrogen bonding, but, in concentration employed here ($c\sim0.001$ mol./l.), the possibility of the bonding of two phenol molecules can be neglected with certainty. Liddel and Becker[8] already observed an appreciable decrease in the peak intensity and a slight increase in frequency (ca. 6 $cm^{-1}$) of the free $\nu_{O-H}$ of methanol in carbon tetrachloride in the temperature range between $-10$ and 50°C, and suggested that these variations might be considered to be owing to a weak hydrogen bonding to the solvent. This possibility is apparently reasonable because this type of interaction may be very weak and the observed shift of the frequencies is only small, besides it can be ruptured easily with the rising temperature. Tables I to IV show, however, that

TABLE V

| Phenols | $-\Delta H$ (kcal./mol.) | $\Delta S/R-\ln a$ | $\Delta\nu_{max}$(cm$^{-1}$) |
|---|---|---|---|
| 2-Allylphenol | 0.46±0.14 | −0.49±0.22 | 65.5 |
| 2-Benzylphenol | 0.33±0.05 | −0.53±0.10 | 50.8 |
| 2-Isopropenylphenol | 0.76±0.11 | −1.17±0.20 | 82.0 |
| 2-Hydroxybiphenyl | 1.45±0.27 | −0.17±0.42 | 42.0 |

the frequencies of the internally interacting $\nu_{O-H}$ which has no available proton any longer also rise in the same way with the temperature and this fact may be explained from lessening of the dipole-dipole interaction between phenols and solvent molecules by their thermal motion, to which Cole and Macritchie[9] have recently alluded. About a half of the decrease in the total intensity can be attributed to the thermal expansion of the solvent, the volume expansion coefficient of carbon tetrachloride being $1.236 \times 10^{-3}$.

In Table V are listed the energies of the interaction ($-\Delta H$), together with constant $\Delta S/R - \ln a$, obtained by applying Eq. 3 to the above data in Tables I to IV. The shifts (for the room temperature) of the $\nu_{O-H}$ absorption maxima of the interacting form from that of the free one are listed in the last column for comparison of the shifts with the energy.

$-\Delta H$'s are all smaller than the weakest one of the ordinary hydrogen bonding which ranges from 2.3 (NH···N) to 7 (FH···F) kcal./mol.[10] Even the strongest interaction of this kind ever measured, 2.5 kcal./mol. for 2-hydroxy-4-nitrobiphenyl[2], lies at the lowest limit of the energy for the hydrogen bonding. This difference in energy may be the best criterion which differentiates this interaction from the ordinary hydrogen bonding. It seems that at least no simple relation exists between $\Delta\nu_{max}$ and $-\Delta H$. The rotational degree of freedom must be taken into account. In 2-allylphenol, 2-benzylphenol and 2-isopropenylphenol, a loss of energy may be caused by the formation of the internal interaction, because the molecule must take a structure, which is otherwise the sterically unfavored one. The apparent $-\Delta H$, therefore, does not necessarily mean the true energy difference of the interaction. These considerations lead to the reasonable explanation of the arbitrary relation between $\Delta\nu_{max}$ and the energy difference. Some relation may be expected between $\Delta\nu_{max}$ and $-\Delta H$ if the compounds are limited to a certain series, but, it is still clear that the relation is not so simple as a linear one, as is understood from the three compounds in the biphenyl series. Hence, it is dangerous to evaluate the energy of the interaction from the mere comparison of the two frequencies.

Although, for strict understanding of the entropy changes of the interaction ($\Delta S$), another standard band common in frequency and in molecular absorption coefficient to both molecular types must be further used together with these two $\nu_{O-H}$'s, as shown by Mizushima and his collaborators[11], constant $\Delta S/R - \ln a$ obtained by extrapolating $T$ to infinity in the Eq. 3 can be assumed to be a measure of the entropy change, since roughly speaking it can be assumed that constant $a$ in Eq. 2 is equal to unity, when $\ln a$ becomes zero. This assumption is partly supported by the speculation that the changes of the dipole moment accompanying the vibrational motion are much smaller, than in the case of the ordinary hydrogen bonding, and partly by the observation, that the total integrated intensities ($A_i + A_f$) in these phenols possessing different degrees of interaction are about equal to $1.5 \times 10^4$ except that of 2-isopropenylphenol which is rather sterically hindered. Entropy changes accompanying the intramolecular interaction consist of those of the vibrational motion and of the internal rotation, each being estimated to be a few entropy units, when they are perfectly restricted[11,12]. With weak intramolecular interaction between the hydroxyl group and $\pi$-electrons this effect is expected to be less and it is the case in three of the phenols presented above. On the contrary, 2-isopropenylphenol shows an extraordinary great entropy term which can not be explained from the above factors only. It can be well explained by assuming that this phenol exists in four rather stable conformations near coplanarity, and only one of them can be the molecular form favorable for the interaction. Then the ratio of the number of the conformation, 1/3, must be introduced into the entropy term in the form of ln 3 and subtraction of the latter from the former gives a reasonable value ($-0.07$) comparable to the other phenols. Almost equal $\Delta S/R - \ln a$ values in 2-allylphenol and 2-benzylphenol can be understood by considering that the interaction in both cases will occur with the $\pi$-electron at the "$\beta$" carbon atom in respect of the phenol nucleus as already suggested in the previous paper[1]. The small $\Delta S/R - \ln a$ value in 2-hydroxybiphenyl is rather unexpected. One of the most interesting internal motions in this molecule is that of rotation and/or vibration around the pivot bond. This will give rise to an appreciable entropy decrease if perfectly restricted. The observed small amount of the entropy term shows that the contribution of this effect is very small, and the moderate changes in the O-H force constants between free and interacting forms can be accomodated with almost no entropy changes.

# *Electrophotoluminescence of Zinc Sulfide Phosphors*

By Yoshihide KOTERA and Kiyotaka NARAOKA

(Received October 13, 1959)

Various effects of electric fields on the light emission of zinc sulfide phosphors during or after excitation by ultraviolet or X-rays have been investigated by a number of authors[1-4]. The effects include a quenching or an enhancement of the luminescence under the electric field, a momentary stimulation of luminescence at application or removal of the electric field, and other miscellaneous effects.

If the observations on various phosphors, each having different kinds of activators or different chemical compositions of matrix, for example, hex.-ZnS : Cu, cub.-ZnS : Mn, (Zn, Cd)S : Ag and ZnS : Cu, Pb are carried out under the same conditions, then each phosphor has different influences. The purpose of this paper is to find how the influence of an alternating electric field on luminescence varies with the kinds of activator or chemical composition of the matrix.

Destriau[2] made extensive investigations of these effects, and he reported that it seems that the sulfides with a persistent phosphorescence are very sensitive to momentary stimulation and insensitive to the quenching effect, while the sulfides with brief phosphorescence show an appreciable quenching effect and a slight or even insignificant momentary stimulation. However, he[5] noted that although thermoluminescence and infrared stimulation can occur after the action of the field, application of the field after thermoluminescence or infrared stimulation, on the other hand, does not produce any emission. From this observation, it might be concluded that the electric field acts only on shallow traps but not on deep traps, but he thought that this conclusion is uncertain, because the field obviously has a directional character, whereas temperature or infrared radiation has not.

Matossi[4] has studied the electrophotoluminescence of various zinc sulfide phosphors, but he could not find any systematic dependence of the characteristics of stimulation or quenching on the method of preparation (kind of activator or flux) or on other luminescence properties, such as the time of afterglow.

It is explained by several authors that the momentary field stimulation might be caused by electron traps, from which the electron is released by electric field and returns to luminescent centers to cause emission. Further, phosphorescence, infrared stimulation and thermoluminescence are explained by the action of electron traps. Therefore it is expected that there might be a close relation between momentary stimulation and those characteristics. From this standpoint, we are going to discuss the relations between momentary field stimulation and phosphorescence, infrared stimulation, or thermoluminescence, respectively.

## Experimental

The phosphors were synthesized from the pure zinc sulfide by adding appropriate aqueous solution of activator and two weight percent sodium chloride. The mixtures were stirred well, dried, transferred to a silica crucible and fired for crystallization from 750 to 1200°C in a temperature-controlled furnace in air for half an hour. After crystallization, the preparations were washed free of water-soluble chloride and were dried. The composition of phosphors and the condition of firing are shown in columns 2 and 3 of Table I.

All phosphors were embedded in Acrylite (Polymethylmethacrylate, produced by Mitsubishi Rayon Co.) and investigated in cells of the common construction of the electroluminescent cell with about 10 $cm^2$ area and about 0.5 mm. thickness of the layer. The phosphor-dielectrics layer was held between two electrodes, one of which was conductive glass coated with tin oxide layer, and the other was aluminum

plate. A d-c operated black light lamp with a Corning glass filter 5840 transmitting from 3100 to 4200 Å served as the exciting ultraviolet source. The light emitted by phosphor was allowed to fall upon the cathode of the 1P21 photomultiplier, the anode current from the photomultiplier being measured by means of d-c amplifier and cathode ray oscillograph, and the oscillogram of transient phenomenon for emission at electric field application or removal was observed.

The applied electric field was obtained from 50 c. p. s a-c line, and field intensity was estimated to be about 10000 volts per centimeter. With this field intensity electroluminescence was not detected with the exception of zinc sulfide phosphors which contain $10^{-3}$ mol. or more of copper per 1 mol. ZnS.

## Experimental Results and Discussion

On application of the alternating electric field during continuous ultraviolet excitation, the average brightness of luminescence increases for a moment. After these transitory phenomena the average brightness reaches a new equilibrium level, lower than the luminescent level before application of the filed. Some phosphors show no steady state quenching. The transient variation of emission is shown schematically as a function of time in Fig. 1. The field quenching lasts as long as the field is applied, and recovers gradually, then reaches a steady level.

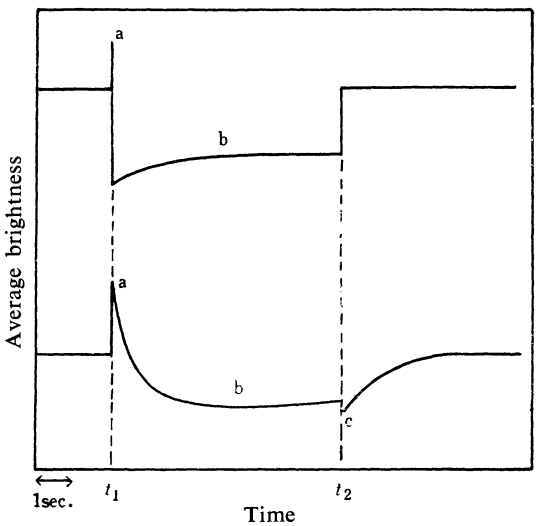

Fig. 1. Average brightness of luminescence when electric field is applied or removed.
$t_1$···field application, $t_2$···field removal,
a···momentary stimulation,
b···field quenching, c···cut-off dip.

The stimulated and quenched brightness were modulated by applied alternating electric field. A frequency of brightness wave was that of applied alternating field or twice this frequency. The modulated frequency for pure zinc sulfide phosphors was 100 c.p.s., while that of zinc-cadmium sulfide phosphors which contained 20 mol. percent cadmium sulfide or more was 50 c.p.s.. Fig. 2 shows the oscillogram of modulated wave for ZnS and (Zn, Cd)S phosphors. The (Zn, Cd)S phosphors which contain below 20 mol. percent cadmium sulfide was not studied.

When the electric field was removed, then the phosphors such as ZnS : Cu, Fe, (Zn, Cd)S : Ag (No. 11), and Zn(S, Se) : Cu (No. 32) had a short flash, while the phosphors such as ZnS : Cu and (Zn, Cd)S : Cu had a dip of brightness. On the other hand, the phosphors such as the many ZnS : Ag and (Zn, Cd)S : Ag phosphors recovered directly without flash or dip. The cut-off stimulation was found by Matossi for almost all phosphors to consist of two components, a very sharp peak and a tail of long duration. We found this cut-off

Fig. 3. Oscillogram of brightness at field application and removal. The luminescence of ultraviolet excited phosphors are affected by alternating electric field in following order, 1; steady luminescence, 2; field stimulation during excitation (the Gudden-Pohl effect), 3; field quenching during excitation, 4; cut-off stimulation or dip, 5; recovery.

stimulation only for ZnS : Cu, Fe, while (Zn, Cd)S : Ag (No. 11) and Zn(S, Se) : Cu (No. 32) showed a different kind of cut-off stimulation from Matossi's, and had no sharp peak, but the emission increased gradually with time, reaching a maximum at about one second after removal of the electric field, then decreased slowly to initial brightness. The increased emission at field removal was observed by the naked eye for the (Zn, Cd)S : Ag (No. 11). Their characteristics are shown in Fig. 3b. In Fig. 3 various typical brightness curves of luminescence which are influenced by the electric field are shown. In these figures the coordinate is brightness and the abscissa is time. Steady emission before the application of the electric field, momentary stimulation, field quenching, cut-off stimulation, and recovery are shown from left to right. During this period the phosphor was illuminated continuously by ultraviolet light.

The intensity of first stimulation depends on exciting ultraviolet intensity, the time interval between repeated field applications after first application and so on. The stimulated emission increased with the intensity of excitation and the time interval, and showed saturation. Fig. 4 shows stimulated emission as a function of the time interval at various exciting intensities.

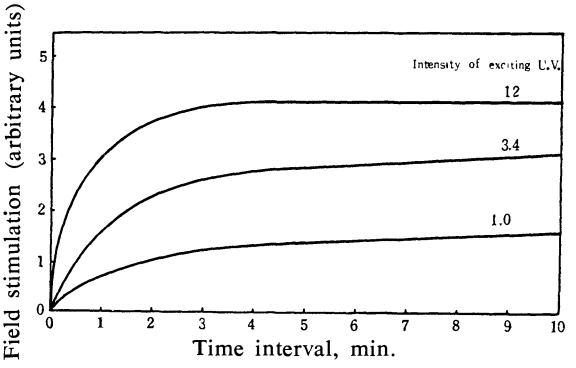

Fig. 4. Momentary field stimulation during excitation as a function of excited time interval at various intensity of ultraviolet. Phosphor ZnS : Cu (No. 17).

The time of application was about 10 sec. and in that time the momentary stimulation was over.

For the Gudden-Pohl effect after removal of the ultraviolet radiation the form of brightness pulse and dependence on kinds of activator and chemical composition of phosphors are similar to the first momentary stimulation during excitation.

The behavior under electric field, phosphorescence and infrared stimulation are shown in Table I. From this table, it is possible to compare the influence of electric field on the different phosphors. This is summarized as follows:

1. Many of the ZnS : Ag and (Zn, Cd)S : Ag phosphors with short persistent afterglow show appreciable field quenching during excitation, estimated to be 40% at a field intensity

of 10000 volts per cm., and have slight momentary stimulation. (Zn, Cd)S : Ag phosphors with longer afterglow show large momentary stimulation, but the quenching ratio does not decrease.

2. ZnS : Mn and (Zn, Cd)S : Mn which show considerable infrared stimulation have no field quenching, while ZnS : Mn which incorporates ZnO and also shows short afterglow and no infrared stimulation has a momentary stimulation whose duration is very short.

3. Cub.-ZnS : Pb with a short persistent phosphorescence and some infrared stimulation shows a strong field stimulation and a small field quenching, while hex.-ZnS : Pb with a long persistence and a strong infrared stimulation shows feeble field stimulation and no field quenching. ZnS : Cu, Pb (Fonda's phosphor) has a most remarkable infrared stimulation but shows feeble field stimulation and no field quenching.

4. The field sensitivity of ZnS : Cu and ZnS : Ag phosphors decreases by substitution of a large amount of cadmium for zinc, for example, $(Zn_{0.20}, Cd_{0.80})S : Ag$ (red) and $(Zn_{0.50}, Cd_{0.50})S : Cu$ (red) have no field stimulation and also no field quenching. But zinc-cadmium sulfide phosphors with medium substitution of cadmium for zinc still have considerable field sensitivity.

5. The influence on ZnS : Cu phosphors is very complicated. The zinc sulfide fired at 1020°C or higher is expected to have hexagonal structure, while sulfide fired below 1020°C is expected to have cubic structure. In this observation, the sulfide was fired at 1200°C for the hexagonal phosphor, and at 900°C for the cubic.

Their phosphorescence, infrared stimulation, and momentary stimulation during decay at field application are shown in Fig. 5 as a function of copper concentration. In this figure, the phosphorescence is plotted as an afterglow intensity after a lapse of one minute from removal of ultraviolet excitation, and the infrared stimulation as an initial flash-up intensity under infrared illumination also after one minute's decay, and the integral of light flash at field application (the area under the curve obtained in Fig. 6, in which the abscissa is time and the ordinate is the photocurrent from the photomultiplier) was taken as the measure of the Gudden-Pohl effect.

In hex.-ZnS : Cu, the phosphorescence is found to be increased by increasing the copper content and to reach a maximum at copper content of $3\times10^{-5}$ mol. per one mol. of ZnS, and Gudden-Pohl stimulation is also increased by increasing the copper content and reaches a maximum at a copper content of $10^{-5}$ mol.

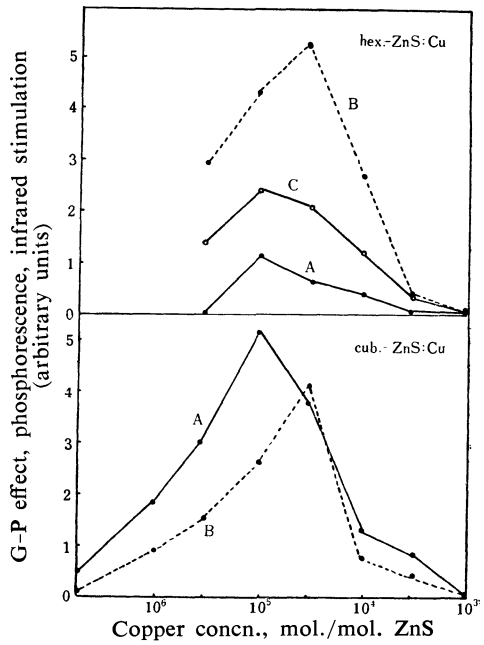

Fig. 5. The Gudden-Pohl effect during decay, phosphorescence and infrared stimulation as a function of copper concentration in hex. and cub. zinc sulfide phosphors.
A. The Gudden-Pohl effect,
B. phosphorescence, C. infrared stimulation.

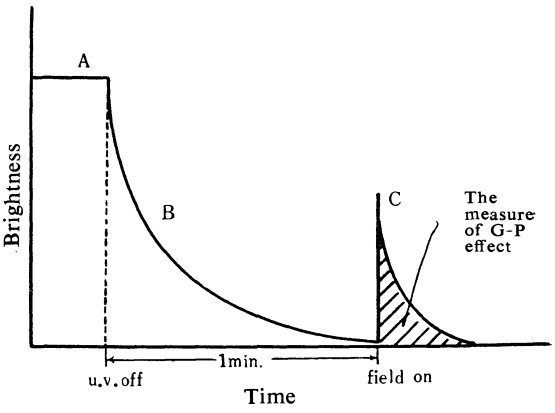

Fig. 6. The Gudden-Pohl effect (C) after removal of ultraviolet excitation.
A : steady state luminescence, B : decay.

The zinc sulfide with $3\times10^{-5}$ mol. copper has a very long persistent phosphorescence and the strongest infrared stimulation among the zinc sulfide phosphors activated with copper, but it shows weak field stimulation. Independent of the copper content the momentary field stimulation of hex.-ZnS : Cu is weaker than that of cub.-ZnS : Cu. The field stimulation of cub.-ZnS : Cu phosphors as a function of copper concentration is similar to that of hexagonal phosphors, but infrared stimulation is so feeble

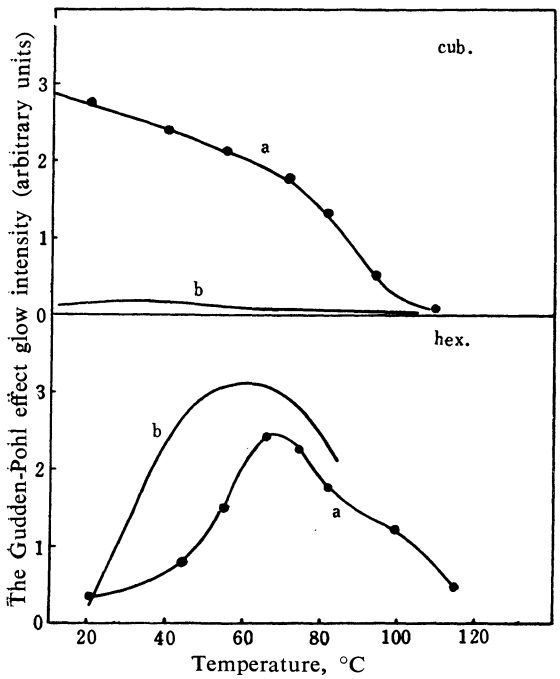

Fig. 7. The Gudden-Pohl stimulation as a function of temperature and glow curve. a: the Gudden-Pohl effect, b: glow intensity. Sample, cub.···ZnS: Cu(No. 16), hex.···ZnS: Cu (No. 24).

that it can not be detected. The Gudden-Pohl effect of cub.-ZnS: Cu with a suitable amount of copper is strong and shows relatively long duration, and it takes about one second to fall from flash-up to quenching level, and also several seconds to recover to initial brightness.

The intensity and decay of the flash by the electric field depend on temperature, that is, at higher temperature momentary stimulation at field application is sharper and its decay is more rapid. In Fig. 7 field stimulation is plotted as a function of temperature, and glow curves of phosphors which were excited and caused to decay at room temperature are shown in the same figure. The heating rate of glow curves was 0.2°C per second. In cub.-ZnS: Cu, the higher the temperature is, the smaller is the field stimulation between 20° and 120°C, and there is no peak in this temperature range. The momentary stimulation of hex.-ZnS: Cu increases with temperature reaching a maximum at 70°C, while the glow curve has a peak at 55°C.

Some knowledge of traps has been obtained from glow curve measurements by Bube[6]. He proposed that a large number of traps are present in self-activated ZnS phosphors with no added copper impurity. The incorporation of copper up to $1.7\times10^{-4}$ mol. (0.01%) causes the appearance of traps which are deeper than those present before the addition of copper. Incorporation of copper in amounts of more than $1.7\times10^{-4}$ mol. causes disappearance of the deep traps due to copper.

Comparing our experimental results with the knowledge about traps, it could be considered that there is a maximum of momentary stimulation as a function of copper concentration at $10^{-5}$ mol. copper content and the number of deeper traps has a maximum value at $1.7\times10^{-4}$ mol. copper content, that is, two maxima are uncoincident. So the deeper traps might not be contributing to the momentary stimulation.

Two glow curves of hex.-ZnS: Cu (24) depending upon whether or not the electric field has been previously are shown in Fig. 8. The application of the field was done after removal of excitation, and the time of application was ten seconds. A similar experiment was carried out by Destriau[5]. In our observation, it can be seen that the maxima of two glow curves have about the same height. From this observation, we might assume that the deeper trap which corresponds to the glow peak at 55°C does not contribute to momentary stimulation at room temperature. Rather the increase of momentary stimulation at higher temperature may be ascribed to the effect of emptying the deeper

6) R. H. Bube, *Phys. Rev.*, **80**, 655 (1950).

traps which can release their electron thermally at higher temperature.

**Summary**

The effects of the electric field on the luminescence of ultra-violet excited zinc sulfide phosphors are shown as a function of kinds of activator and chemical composition of matrix. All phosphors were measured in an electroluminescent cell of common construction. The electric field was obtained from 50 c.p.s. alternating line. The Gudden-Pohl effect of both hexagonal and cubic ZnS : Cu increased with increasing copper content and reached a maximum at a content of $10^{-5}$ mol. The effect of cubic ZnS : Cu ($10^{-5}$) is the strongest in the zinc sulfide phosphors at room temperature. Cubic sulfide phosphors activated by copper are sensitive to both momentary stimulation and field quenching.

Further, a relation between electron traps and the Gudden-Pohl effect was studied. From the temperature dependence of the Gudden-Pohl effect and glow curves, it might be assumed that the deeper trap which corresponds to a glow peak at 55°C does not produce the Gudden-Pohl effect at room temperature, rather the increase of the effect at higher temperature may be ascribed to the emptying of the deeper traps which can release their electrons thermally at higher temperature.

# *Polyethers. I. Stereospecific Polymerization of Epihalohydrins*†

By Shin'ichi ISHIDA*

(Received October 3, 1959)

Recenctly a number of publications have appeared which describe the polymerization of propylene oxide with different catalysts to give a product which contains crystalline polypropyleneoxide[1-5]. On the contrary, there has been no publication on stereospecific polymerization of epihalohydrins. In the earlier work[6] or epihalohydrin, using Friedel-Crafts catalysts such as stannic chloride, it was reported to produce only viscous liquid or pasty resins of low molecular weight.

In the present paper, the author wishes to report on the synthesis of crystalline polymers of epichlorohydrin and epifluorohydrin.

The attempted stereospecific polymerization of epiiodohydrin was unsuccessful.

## Experimentals

**Epichlorohydrin and Propylene Oxide.** — Commercial materials were dried over a molecular sieve and fractionally distilled before use.

**Epifluorohydrin.**—It was prepared from epichlorohydrin and anhydrous potassium fluoride by Gryszkiewicz-Trochimowsky's method[7]. The yield was lower than that reported; only 7 g. of the product boiling at 85~86°C was obtained from 100 g. of epichlorohydrin and 100 g. of anhydrous potassium fluoride.

**Epiiodohydrin.**—It was prepared according to the direction given by E. Wedekind.[8] Epichlorohydrin (48.5 g.) was mixed with a solution of dry sodium iodide (78.5 g.) in acetone (530 ml.) and this mixture was refluxed for 30 hr. The yield of the product boiling at 62°C (24 mmHg) was 40% (37 g.). $n_D^{20}$ 1.5418.

**Ferric Chloride Complex Catalyst.**—A complex of ferric chloride with propyleneoxide was prepared immediately before use according to the procedure of Price[1]. Analogous complexes of ferric chloride with epichlorohydrin and with epifluorohydrin were prepared in a similar manner. A pasty complex catalyst was weighed and dissolved into anhydrous acetone. (about 10% by weight.)

**Polymerization by Ferric Chloride Complex**

* No case of the complex with epichlorohydrin has been obtained fraction II.

† In the case of propylene oxide, there was found no fraction II.

**Catalyst.**—The general procedures were as follows: A catalyst solution of known concentration was injected into a glass tube and then the solvent was evaporated in vacuo at room temperature. In cooling, monomer was poured into tubes. The tubes were flushed with nitrogen and sealed and then placed in a constant temperature bath at 80±0.5°C.

**Polymer Purification.**—At the end of the reaction time the tube was cooled and opened. The polymer produced was fractionated into three parts by the following procedure.

*Fraction I.*—To the reaction mixture was added acidified (HCl) acetone. The insoluble material was collected, washed with dilute HCl-acetone and methanol successively, and then reprecipitated from tetrahydrofuran solution by adding methanol as precipitant.

*Fraction II.*—Acetone solution separated from fraction I was added dropwise with stirring to a large volume of methanol. A white powder, in some cases a pasty mass, separated out of the solution. The precipitate was further fractionated by washing with methanol in which it was partly soluble. The insoluble residue (Fraction II) was reprecipitated from acetone solution with metanol.

*Fraction III.*—The acetone-methanol solution separated from fraction II and methanol washing of fraction II, were combined, concentrated to a small volume and poured into a large excess of water, then centrifuged to give the third fraction III which was a viscous liquid or in some cases a paste.

**Polymerization by Organometallic Compounds.**—In all cases, the catalyst was added to the monomer or the solution of monomer in *n*-hexane or benzene, which was placed in the glass tube cooling in Dry-Ice acetone under nitrogen atmosphere, and then the tube was sealed and placed in a constant temperature bath. The polymers were isolated by an appropriate reprecipitation procedure.

## Results and Discussion

Epichlorohydrin was polymerized using a complex catalyst of ferric chloride and propylene oxide ($FeCl_3$–PO) or an analogous complex catalyst of ferric chloride and epichlorohydrin ($FeCl_3$–EpCl) without solvent at 80±0.5°C. Some results were shown in Table I, in which the results of polymerization of propylene oxide by the same catalysts were compared.

The product was fractionated to three fractions, an acetone-insoluble (at room temperature) fraction (I), an acetone-soluble and methanol-insoluble fraction (II) and a methanol-soluble fraction (III).

Fraction I, a white and non-tacky solid, was insoluble in boiling methanol, ethanol, and diethyl ether and cold acetone, but soluble in boiling acetone, tetrahydrofuran and benzene. This fraction was shown by X-ray diagram to be crystalline. The melting point of the fraction I obtained from the different conditions varied from 109 to 115°C, but a purified sample showed the melting point of 119°C by capillary method. The molten polymer could be formed into a strong fiber and a tough film which showed a high degree of orientation after drawing. The drawn fiber had an identity period of 7.05±0.1 Å.

This value is nearly equal to the period of 7.16 Å on polypropyleneoxide[9].

Fraction II was a white solid, melting at

about 75°C, or in some case, a tacky semi-solid from which a strong film or fiber could not be obtained. Usually, it was possible to obtain an additional crystalline polymer from this fraction by redissolving it in acetone and chilling the solution to −30°C. The amorphous polymer was recovered by evaporation of the filtrate to dryness.

Fraction III was a viscous liquid or a paste and was not found to be crystalline.

All these fractions mentioned above were confirmed to be polyepichlorohydrin by the elemental analysis (Table II).

The infrared spectra of fraction I differ from those of fractions II and III and also from an amorphous liquid polymer which was obtained by a polymerization using $BF_3$-etherate as a catalyst, and the differences might well be attributed to the presence of crystalline-sensitive bands. As may be seen in Fig. 1, the spectral difference between the amorphous and crystalline polymers is striking, several bands at 1472(w), 1336(sh.w), 1277(s), 1232(s), 1173(s), 1036(m), 972(s) and 900(s) $cm^{-1}$ were observed only in spectra of the crystalline fraction. A similar feature was found in the case of polypropylene-oxide: bands at 1480(s),1330(m),1240(s),1140(s), 1039(m) and 931(m) $cm^{-1}$ were observed only

in the crystalline fraction (Fig. 2).

Among organometallic compounds, some, such as aluminum triethyl, zinc diethyl and aluminum isopropoxide in conjunction with zinc chloride were found to be effective catalysts in converting epichlorohydrin to its polymer. The details were given in Table III. The polymerization proceeded rapidly at room temperature with the first two catalysts and went on fairly below room temperature, while with the last catalyst it was necessary to operate at higher temperatures. But in all cases, it was found that the amount of the crystalline fraction (fraction I) of the polymer obtained by these three catalysts was less than that of the $FeCl_3$-PO catalyst.

In the case of epifluorohydrin, ferric chloride complex catalyst was used. The polymer obtained was a solid powder which was soluble in acetone, and was insoluble in methanol, carbon tetrachloride and carbon disulfide. The polymer melted at about 68°C and was highly crystalline, a feature confirmed by X-ray examination. The molten polymer could be formed into a fiber and a film.

Table IV records the data from the X-ray

# *Polyethers. II. Copolymerizations of Propylene Oxide with Epihalohydrins**

By Shin'ichi ISHIDA†

(Received October 22, 1959)

Although copolymerization of vinyl monomers has been extensively studied, none of the detailed information on the copolymerization of olefine oxide or polymerizable epoxy compounds has been published. The work to be reported here was undertaken for the purpose of investigating the copolymerization of epoxides using a catalyst which commonly stereospecifically catalyzes to individual monomers.

It has been reported that propylene oxide[1-3] epichlorohydrin[4] and epifluorohydrin[4] can be polymerized by ferric chloride complex catalyst to give products which are of crystalline nature.

The present paper deals with the copolymerization of propylene oxide with epichlorohydrin using the ferric chloride complex catalyst ($FeCl_3$–PO)[1] which has been shown to be the common stereospecific catalyst. An attempted copolymerization of epifluorohydrin with propylene oxide is also contained.

## Experimental

**Monomers and Catalyst.**—Commercial epichlorohydrin and propylene oxide were dried over a molecular sieve, fractionally distilled before use. Epifluorohydrin was prepared from epichlorohydrin and anhydrous potassium fluoride by Cryszkiewicz-Trochmowski's method[5], b. p. 85~86°C. The catalyst was prepared as previously reported by Price's procedure[1,4].

**Copolymerization.** — All copolymerizations were carried out, as in our previous report on the stereospecific polymerization of epihalohydrins, in sealed glass tubes containing 10 g. of the varied monomer compositions and 5% by weight of catalyst. The tubes were thoroughly flushed with nitrogen before sealing and they were maintained at 85°C in an oil bath.

**Purification of Polymer.** — At the end of the reaction time, tubes were cooled and opened. The products were fractionated into three parts by the following procedure.

*Fraction I.*—To the reaction mixture was added acidified (HCl) acetone, and the insoluble material was filtered and washed with dilute HCl-acetone and methanol successively, and then reprecipitated from a hot acetone solution with methanol.

*Fraction II.*—The acetone solution separated from fraction I was added dropwise under stirring to a large volume of methanol. A tacky mass, or in some cases a paste, separated out from the solution.

*Fraction III.*—The acetone-methanol solution separated from fraction II and the methanol washing of fraction II were combined, concentrated to a small volume and poured into a large excess of water, then centrifuged to give fraction III which was a viscous liquid.

## Results and Discussion

The copolymerization of epichlorohydrin with propylene oxide was studied over a wide range of monomer compositions in the presence of $FeCl_3$–PO catalyst. Results were given in Table I. The products usually were able to be fractionally separated into three fractions; an acetone-insoluble (at room temperature) fraction (I), an acetone-soluble but methanol-insoluble fraction (II), and a methanol-soluble fraction (III).

TABLE I. COPOLYMERIZATION OF EPICHLOROHYDRIN (EpCl) WITH PROPYLENE OXIDE BY $FeCl_3$-PO CATALYST

exact fractionation and its evaluation appeared to be difficult. Accordingly in this paper only fraction I was investigated in some details, and the other fractions left untouched because of the difficulties of handling.

The relationships between mole per cent of epichlorohydrin in comonomer and the yield of total product as well as the percentage relationships of each fraction were shown in Fig. 1.

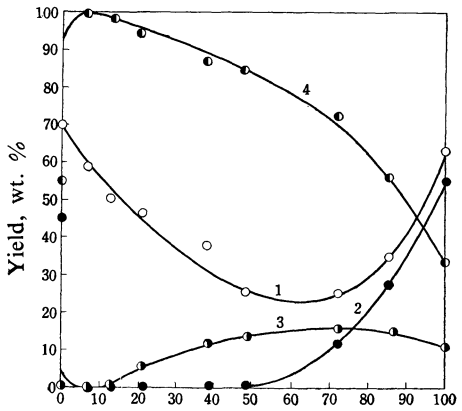

Fig. 1. The plots of yield of each fraction versus the mole % of epichlorohydrin in the comonomer.
Curve 1: total conversion, curve 2: fraction I, curve 3: fraction II, curve 4: fraction III.

Since an amorphous polypropyleneoxide is soluble in acetone and methanol, it can hardly be suspected to be contained in fraction I. Fraction I was therefore further purified by extraction with boiling ether so as to remove the crystalline homopolymer of propylene oxide. The products thus treated were white, crystalline solids. As they were believed to be true copolymers from the following evidences, they were referred as "copolymer" and were discriminated from Fraction I. Artificial mixtures of each homopolymer (crystalline polypropylene oxide : Crystalline polyepichlorohydrin =1:1 and 1:3 by weight) could be separated completely to the original components by an extraction with boiling ether.

The further evidence that the "copolymer" was not a mixture of homopolymer of epichlorohydrin and a copolymer but a genuine copolymer, was proved by the analysis of the fractions from the "copolymer"; a successive, careful fractionation of the "copolymer" from a tetrahydrofuran solution using methanol and water as precipitants gave fractions having almost the same chlorine contents. (Table II)

All "copolymers" exhibited the X-ray patterns contributed solely by the polyepichlorohydrin part, while an artificial co-precipitated mixture

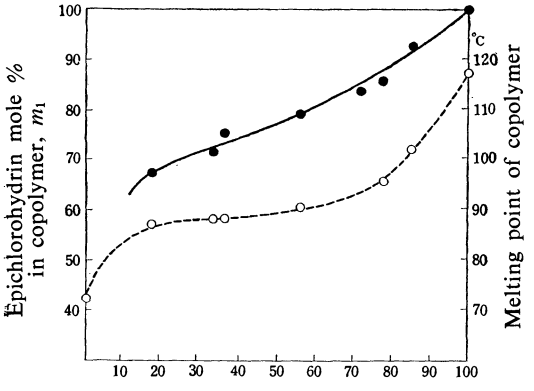

Fig. 4. Copolymer composition curve (● full line) for a system of epichlorohydrin and propylene oxide together with melting points of "copolymers" (○ dotted line).

From these data, the monomer reactivity ratios of epichlorohydrin and propylene oxide in copolymerization to crystalline "copolymer" were estimated by Mayo's method[6].

$$r_1(\text{epichlorohydrin}) = 1.8 \pm 0.3$$

$$r_2(\text{propylene oxide}) = 0.6 \pm 0.5$$

A soild non-tacky product which had been obtained by polymerization of equimolar mixture of propylene oxide and epifluorohydrin using $FeCl_3$–PO catalyst was purified by reprecipitation from an acetone solution with methanol-water. Then a fraction which was insoluble in methanol was separated from the acetone solution of the above product by adding a large excess of methanol. This fraction was a white non-tacky powder, and could not be further fractionated by reprecipitation using the same solvents and precipitants. It seemed to be possible that a crystalline polypropyleneoxide and a crystalline polyepifluorohydrin were contained in this fraction, as may be seen from the solubility data of both homopolymers in the preceding paper[4].

In fact, it was found by X-ray examination, that this fraction showed a superposed pattern of each specimen and so it might be a mixture of both the crystalline homopolymers. The attempted separation was unsuccessful because the author could not find a suitable solvent for the separation.

Attempts to copolymerize epichlorohydrin with 1, 1-dimethylethylene oxide by aluminum triethyl as catalyst did not give a copolymer but a mixture of each homopolymer.

The author wishes to express his sincere thanks to Professor S. Murahashi for his guidance and encouragement throughout this work. He is also indebted to Dr. S. Nozakura for his helpful discussions and suggestions and to Mr. K. Katayama (Textile Research Laboratory, Asahi Chem. Ind. Co., Ltd.) for X-ray examinations.

# *An Interpretation of the Elovich Equation for the Rate of Chemisorption on the Basis of Surface Heterogeneity*

By Yutaka KUBOKAWA

(Received September 9, 1959)

Taylor and Thon[1] showed that a number of chemisorption rate data are represented by the Elovich equation

$$dq/dt = ae^{-bq}$$

where $q$ is the amount of gas adsorbed and $a$ and $b$ are constants. In order to explain this equation, they postulated the annihilation of adsorption sites in the course of adsorption. Being stimulated by this work, various workers[2] discussed the applicability of this equation for chemisorption processes and presented various models leading to this equation. Although there is, of course, no reason to believe that only one and the same mechanism is operative in all systems to which the Elovich equation is applicable, the most probable interpretation of the equation seems to be the one based on surface heterogeneity at least for the adsorbents for which the existence and the effect of surface heterogeneity have been established.

Such an interpretation has been proposed by Porter and Tompkins[2] for a simple case where the distribution function of adsorption site is constant and the rate of desorption is negligibly small. The purpose of the present paper is to elaborate a similar interpretation for more complex cases where the distribution is variable and/or the rate of desorption can not be neglected and to discuss some available data with respect to the variation of constant $b$ in the Elovich equation with pressure and temperature.

**Adsorption Rate on a Heterogeneous Surface.** —For a heterogeneous surface the adsorption sites over the whole surface may be divided into a number of sets, each of which consists of sites of the same kind; the number of sites in each set is given by a distribution function which may, in the present case, be assumed to be a function of the activation energy $E$ for a given chemisorption. Taking account of desorption, the net rate of adsorption on any set of sites may be given by

$$v = d\theta/dt = kp(1-\theta) - k'\theta$$

where $\theta$ is the fraction of the sites covered and $p$ the pressure in the gas phase. Since $\theta = 0$ when $t = 0$, this rate gives on integration at a constant pressure

$$\theta = \theta_e[1 - e^{-(kp+k')t}]$$

where $\theta_e$ is the equilibrium coverage. Differentiating with respect to time

$$v = (kp + k')\theta_e e^{-(kp+k')t} = kpe^{-(kp/\theta_e)t} \quad (1)$$

The rate for the whole surface may be obtained by integration, by assuming a continuous distribution function of sites. First, let us consider the simplest case where desorption is negligible and the distribution function $N$ is constant. Since $\theta_e = 1$ in this case, Eq. 1 becomes

$$v = Ke^{-Kt} \quad (2)$$

where $K = kp$. The rate for the whole surface under such conditions will be

$$N\int_0^\infty v(E)\,dE = N\int_\infty^0 [v(E)\,dE/dK]\,dK \quad (3)$$

From the expression $k = \text{const.}\, e^{-E/RT}$, it follows that

$$dE/dK = -RT/K \quad (4)$$

Introduction of Eqs. 2 and 4 into Eq. 3 gives

$$N\int_0^\infty v(E)\,dE = -NRT\int_\infty^0 e^{-Kt}dK = NRT/t \quad (5)$$

On the sites with a high value of $E$ the rate will naturally be small, while on those with a low value of $E$ it will again be small because the coverage is here close to the equilibrium value. For a particular set of sites with an intermediate magnitude of $E$, therefore, the rate will pass through a maximum. This condition may be written as

$$\frac{dv}{dE} = \frac{dv}{dK}\frac{dK}{dE} = e^{-Kt}(1-Kt)\left(-\frac{K}{RT}\right) = 0$$

Consequently, $v$ shows a maximum at $Kt = 1$. The maximum rate, being equal to $NKe^{-1}$ or $N/te$, is proportional to the rate over the whole surface represented by Eq. 5.

When the distribution function is not constant and the rate of desorption can not be ignored, the over-all rate can not easily be integrated. However, it may be assumed as a first approximation that in this case the over-all rate is also

1) H. A. Taylor and N. Thon, *J. Am. Chem. Soc.*, 74, 4169 (1952).

2) A. S. Porter and F. C. Tompkins, *Proc. Roy. Soc.* A217, 529 (1953); H. J. Engell and K. Hauffe, *Z. Elektrochem.*, 57, 762 (1953); R. T. Landsberg, *J. Chem. Phys.*, 23, 1079 (1955); D. D. Eley, *Trans. Faraday Soc.*, 49, 643 (1953) etc.

proportional to the maximum rate.

As described above, the rate for any set of sites can be represented by

$$v = NK\mathrm{e}^{-Kt/\theta}$$

where $\theta$ is written for $\theta_e$ for brevity. The condition for the maximum rate is

$$\frac{dv}{dE} = \frac{dv}{dK}\frac{dK}{dE} = \left(-\frac{K}{\boldsymbol{RT}}\right)N\mathrm{e}^{-Kt/\theta}\left[1 + \frac{dN}{N}\frac{K}{dK} - Kt\frac{d(K/\theta)}{dK}\right] = 0$$

The dependence of $K$ on $\theta$ is determined by the relation between the activation energy of adsorption $E$ and the heat of adsorption $Q$, which is assumed to be given by

$$E - E_0 = (1/\alpha)(Q - Q_0)$$

where $\alpha$ is a constant and $Q_0$ is the heat of adsorption on the sites with the lowest activation energy $E_0$. Assuming the Langmuir isotherm to be applicable,

$$1/\theta = 1 + (A/P)\mathrm{e}^{-Q/RT}$$

so that

$$\frac{d(1/\theta)}{d(-Q/\boldsymbol{RT})} = \frac{A}{p}\mathrm{e}^{-Q/RT} = \frac{1}{\theta} - 1$$

It follows then

$$\frac{d\theta}{dK} = \frac{d\theta}{d(1/\theta)}\frac{d(1/\theta)}{d(-Q/\boldsymbol{RT})}\frac{d(-Q/\boldsymbol{RT})}{d(-E/\boldsymbol{RT})}\frac{d(-E/\boldsymbol{RT})}{dK} = \alpha\left(\frac{1}{\theta} - 1\right)\left(-\frac{\theta^2}{K}\right) \quad (6)$$

Hence

$$\frac{d(K/\theta)}{dK} = \frac{1}{\theta} - \frac{K}{\theta^2}\frac{d\theta}{dK} = \frac{1 + \alpha - \alpha\theta}{\theta}$$

By defining $\beta = (dN/N)(K/dK)$, we find that the rate $v$ shows a maximum at

$$Kt = [(1+\beta)\theta]/(1 + \alpha - \alpha\theta) = F\theta \quad (7)$$

where $F = (1+\beta)/(1+\alpha-\alpha\theta)$. So that the maximum rate $v_m$ is

$$v_m = NK\mathrm{e}^{-F} \quad (8)$$

Taking the logarithm of Eq. 8 and differentiating it with respect to $\ln K$

$$\frac{d\ln v_m}{d\ln K} = 1 + \beta - \frac{dF}{d\ln K}$$

Hence, we may write,

$$\frac{d\ln v_m}{dq} = \frac{d\ln v_m}{d\ln K}\frac{d\ln K}{dE}\frac{dE}{dq} = \left(1 + \beta - \frac{dF}{d\ln K}\right)\left(-\frac{1}{\boldsymbol{RT}}\right)\frac{dE}{dq} \quad (9)$$

where $q$ is the amount adsorbed at a given time. Taking the logarithm of Eq. 7, differentiating it with respect to time,

$$\frac{d\ln K}{dE}\frac{dE}{dt} + \frac{1}{t} = \frac{1}{F}\frac{dF}{d\ln K}\frac{d\ln K}{dE}\frac{dE}{dt} + \frac{1}{\theta}\frac{d\theta}{dK}\frac{dK}{dE}\frac{dE}{dt} \quad (10)$$

Inserting Eqs. 6 and 4 in Eq. 10, and rearranging

$$\frac{dE}{dt} = \left(\frac{\boldsymbol{RT}}{t}\right)\left(1 + \alpha - \alpha\theta - \frac{1}{F}\frac{dF}{d\ln K}\right)^{-1} \quad (11)$$

Using the definition of $F$, we can write Eq. 11 as

$$\frac{dE}{dt} = \left(\frac{\boldsymbol{RT}}{t}\right)F\left(1 + \beta - \frac{dF}{d\ln K}\right)^{-1} \quad (12)$$

Eqs. 7 and 8 give

$$v_m = (N/t)F\theta\mathrm{e}^{-F}$$

As was described above, a relationship $v_t = cv_m$ holds where $v_t$ is the over-all rate and $C$ a constant. Hence,

$$v_t = \frac{dq}{dt} = C(N/t)F\theta\mathrm{e}^{-F} \quad (13)$$

comparing Eq. 12 with Eq. 13, we obtain

$$\frac{dE}{dq} = \frac{\boldsymbol{RT}}{CN\theta}\left[\frac{\mathrm{e}^F}{1 + \beta - (dF/d\ln K)}\right]$$

Inserting this expression into Eq. (9)

$$\frac{d\ln v_m}{dq} = \frac{d\ln v_t}{dq} = -\frac{1}{CN\theta}\mathrm{e}^F \quad (14)$$

When desorption is negligible and $N$ is constant, Eq. 13 becomes

$$dq/dt = CN/t\mathrm{e}$$

Comparing this expression with Eq. 5, we obtain $C = \boldsymbol{RT}\mathrm{e}$. Hence, Eq. 14 becomes

$$\frac{d\ln v}{dq} = -\left(\frac{1}{N\theta\boldsymbol{RT}\mathrm{e}}\right)\mathrm{e}^F = -\left(\frac{1}{N\theta\boldsymbol{RT}\mathrm{e}}\right)\mathrm{e}^{\frac{1+\beta}{1+\alpha-\alpha\theta}} \quad (15)$$

where $v$ is written for $v_t$ for the sake of simplicity of representation. Eq. 15 gives the physical meaning of constant $b$ of the Elovich equation on the basis of surface heterogeneity.

**Variation of the Constant $b$ of the Elovich Equation with Temperature and Pressure.**—For the sake of simplicity, let us assume the values of $\alpha$ and $\beta$ to remain constant on changing pressure or temperature in the rate measurements, and discuss the dependence of $b$ on temperature and pressure for the following four different cases.

Case 1: Desorption is negligible and $N$ is constant. In this case Eq. 15 becomes

$$\frac{d\ln v}{dq} = -\frac{1}{N\boldsymbol{RT}} = \text{const}$$

Accordingly, strict applicability of the Elovich equation is expected. As described by various

workers[2], the value of $b$ should be independent of pressure and vary in proportion to $1/T$.

Case 2: Desorption is negligible but $N$ is not constant. In this case Eq. 15 becomes

$$\frac{\mathrm{d}\ln v}{\mathrm{d}q}=-\left(\frac{1}{NRT}\right)\mathrm{e}^{\beta}$$

The right hand side of this equation varies as adsorption proceeds. However, if the range of coverage is limited, and the change of $N$ during adsorption is not marked, we may expect that the Elovich equation will still, though approximately, be obeyed. Variation in the value of $b$ expected in this case may be as follows: If $N$ increases with $E$, the value of $N$ for the sites mainly responsible for adsorption may increase with pressure or temperature, since the set of sites with a higher value of $E$ may be covered at a higher pressure or temperature. This increase of $N$ will result in the decrease of $b$ with increasing pressure or temperature.

Case 3: Desorption can not be neglected but $N$ is constant. In this case, Eq. 15 becomes

$$\frac{\mathrm{d}\ln v}{\mathrm{d}q}=-\left(\frac{1}{N\theta RT\mathrm{e}}\right)\mathrm{e}^{\frac{1}{1+\alpha-\alpha\theta}}$$

As described in Case 2, the Elovich equation will approximately be obeyed in a limited range of coverage. Let us consider the pressure dependence of $b$ for the case $1<\alpha<2$, which seems to be the most probable case for $\alpha$ positive. Plotting $\theta\mathrm{e}^{\frac{-1}{1+\alpha-\alpha\theta}}$ against $\theta$ for the two different values of $\alpha$, $\alpha=1$ and $\alpha=2$, we obtain Fig. 1, which shows that, except in the range $\theta\simeq1$, $\theta\mathrm{e}^{\frac{-1}{1+\alpha-\alpha\theta}}$ increases with $\theta$. This result together with the fact that the sites with a higher value of $E$, i. e., with a larger value of $\theta$ come to operate at a higher pressure leads to the conclusion that the value of $b$ decreases with increasing pressure.

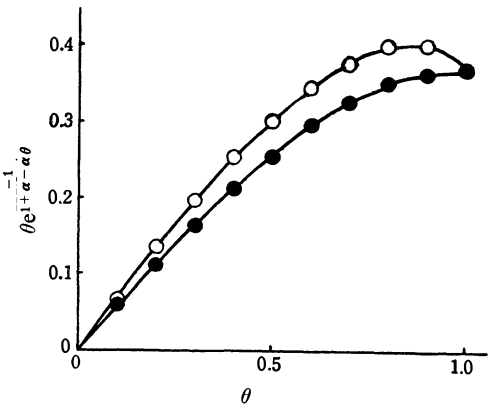

Fig. 1. Plot of $\theta\mathrm{e}^{\frac{-1}{1+\alpha-\alpha\theta}}$ against $\theta$.
—●—, $\alpha=1$; —○—, $\alpha=2$

Case 4: Desorption can not be neglected and, in addition, $N$ is not constant. Let us consider only the special case when both conditions, $\mathrm{d}N/\mathrm{d}E>0$ and $1<\alpha<2$, are satisfied. Remembering that $\beta<0$ in this case, the following conclusion in the pressure dependence of $b$ may be drawn. The extent of decrease of $b$ with increasing pressure may be greater than that in the case where either $N$ or $\theta$ alone varies, i. e., in Case 2 or 3 described above.

So far we have tacitly assumed an undissociative adsorption. For a dissociative adsorption, the adsorption rate corrected for desorption may be given by $k\sqrt{p}\,(1-\theta)-k'\theta$, or $kp(1-\theta)^2-k'\theta^2$. It is clear that the former equation leads to the same expression for the maximum rate as in the undissociative adsorption, except for the term $\sqrt{p}$. As regards the latter equation, it may also easily be shown that, in case desorption is negligible, this gives a similar expression for the maximum rate to that for the undissociative adsorption. It may therefore be expected that qualitative conclusions concerning the pressure dependence of $b$ described in Cases 3 and 4 will not be altered for the dissociative adsorption.

**A Criterion for the Negligible Desorption.**—It follows from Eq. 15 that

$$\frac{-\mathrm{d}(\ln v-\ln v_0)}{\mathrm{d}q}=\frac{\mathrm{e}^{\frac{1+\beta}{1+\alpha-\alpha\theta}}}{N\theta RT\mathrm{e}}=\frac{\mathrm{e}^{\gamma}}{N\theta RT}$$

where $\gamma=(1+\beta)/(1+\alpha-\alpha\theta)-1$ and $v_0$ represents the initial rate when $t=0$ or $q=0$, that is, the adsorption rate on the set of sites with the lowest value of $E$. Integration of this equation gives

$$q=RT\int N\theta\mathrm{e}^{-\gamma}\mathrm{d}(\ln v_0-\ln v)$$

Substituting the expression, $\ln v_0=\ln p+\ln v_0'$, where $v_0'$ represents the pressure independent terms in $v_0$, we obtain

$$q=RT\int N\theta\mathrm{e}^{-\gamma}\mathrm{d}\left[\ln v_0'-(\ln v-\ln p)\right]$$

This equation leads to the conclusion that if desorption can be neglected, i. e., the conditions $\theta=1$ and $\gamma=\beta$ are satisfied, the plots of $q$ against $\ln v-\ln p$ at different pressures should lie on the same curve, provided that the temperature is constant. On the contrary, if desorption is not negligible, such plots will give separate curves.

**Discussion of Some Available Data with Respect to Variation of $b$ with Pressure.**—*1) Hydrogen on Zinc Oxide.*—Values of constant $b$ for this system were obtained from the following integrated form of the Elovich equation

$$q=(2.3/b)\log(t+t_0)-(2.3/b)\log t_0,\quad t_0=1/ab$$

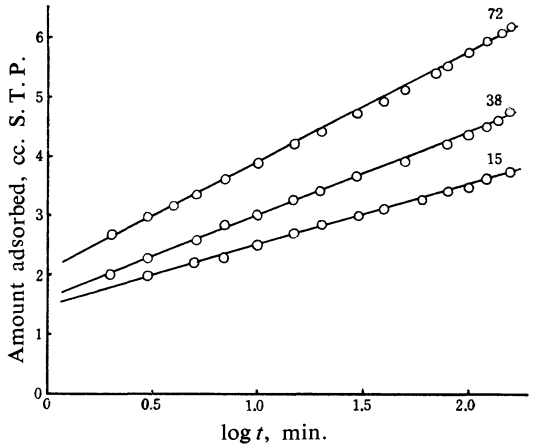

Fig. 2. Elovich plots for the hydrogen chemisorption on zinc oxide at 140°C. Figures indicate the initial pressure in mmHg.

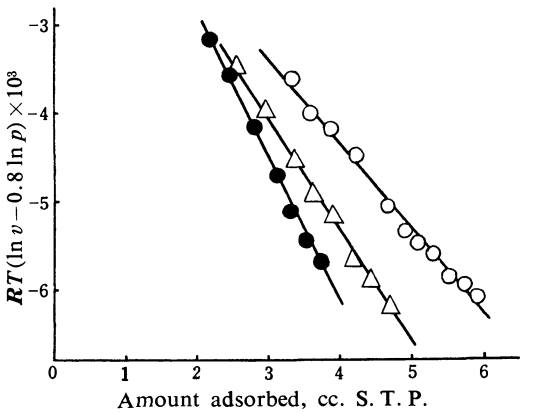

Fig. 3. Plots for the hydrogen chemisorption on zinc oxide at 140°C. —○—, 72 mmHg; —△—, 38 mmHg; —●—, 15 mmHg.

Plotting $\log(t+t_0)$ against $q$ with $t_0$ adjusted to give a linear plot, the value of $b$ was determined from the slope. The results shown in Fig. 2 indicate that the slope $2.3/b$ increases with initial pressure[3].

The same data are shown in Fig. 3 as the plots of $q$ against $\ln v - 0.8 \ln p$. The term $\ln p$ is here multiplied by a factor of 0.8, for the rate was found to be proportional to $p^{0.8}$ as reported previously[4]. As seen in this figure, the plots at different pressures give distinctly separate curves, indicating that appreciable desorption takes place during adsorption rate measurements, which is also expected from the results described in the previous paper[4].

3) The adsorption rate was measured by pressure change, using an adsorption apparatus of constant volume. The pressure decrease due to adsorption was no more than 10~20% of the initial pressure. The latter quantity was measured one minute later than the time of admission of hydrogen into the vessel.

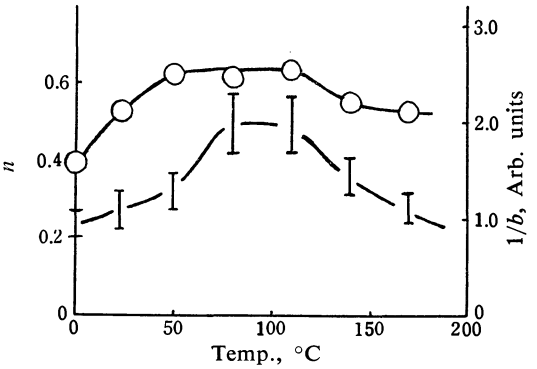

Fig. 4. Variation with temperature of the exponent $n$ and $1/b$ at the pressure 65 mmHg. —I—, $n$; —○—, $1/b$

The pressure dependence of $1/b$ for this chemisorption was found to be approximately represented by $1/b \propto p^n$. As shown in Fig. 4, the exponent $n$ varies with temperature and passes through a maximum, indicating that the pressure dependence of $1/b$ is considerably influenced by temperature. As given together in the figure, $1/b$ itself obtained at a particular pressure shows a similar dependence on temperature. It seems impossible to explain such behavior in terms of the concept that only the value of $\theta$ varies with pressure but the distribution function $N$ is constant[5]. It may therefore be concluded that hydrogen chemisorption on zinc oxide belongs to the case where both $N$ and $\theta$ change, i.e., to Case 4.

*2) Hydrogen on Chromic Oxide Gel.*—As an example for the case where the rate of desorption is negligibly small, we may mention the chemisorption of hydrogen on chromic oxide gel investigated by Burwell and Taylor[6]. Taking into account that the rate of adsorption for this system was found to be proportional to $p^{0.8}$ by these investigators, their data have been reexamined by plotting $q$ against $\ln v - 0.8 \ln p$ with the results shown in Fig. 5. As seen in the figure, all of the plots at different pressures lie on a single curve. In addition, $-\mathrm{d} \ln v/\mathrm{d}q$ increases with decreasing value of $E$[7]. We

4) Y. Kubokawa, This Bulletin, 33, 550 (1960).

5) If the value of $\theta$ alone were variable, such a marked increase in $n$ with increasing temperature from 20 to 80°C as seen in Fig. 4 would be accompanied by decrease in $1/b$ at a particular pressure, in contradiction to what was observed.

6) R. L. Burwell and H. S. Taylor, *J. Am. Chem. Soc.*, 58, 697 (1936).

7) Strictly speaking, this conclusion is valid provided that $\beta$ is unaltered with decreasing value of $N$. Even if $\beta$ is altered, however, it seems unlikely that the decrease in $e^{\beta}$ offsets the effect of the decrease in $N$, since in most cases $|\beta|$, i.e., $|\mathrm{d}\ln N/\mathrm{d}\ln K|$ may be less than 1, and the change of $\beta$ may be small compared with that of $N$. It will be shown in a later paper that the inference given here is reasonable for this adsorption.

may therefore regard this chemisorption as an example for Case 2 with $N$ increasing with $E$. In fact, the value of $b$ obtained by applying the integrated form of the Elovich equation decreases with increasing pressure as shown in Table I, in accordance with the above statement.

| Pressure, atm. | $b$, 1/cc. |
|---|---|
| 1 | 0.061 |
| 0.5 | 0.065 |
| 0.25 | 0.091 |

**On the Constant $t_0$ in the Integrated Form of the Elovich Equation.**—As described in a previous section, if desorption is negligible and $N$ is constant, we may write

$$dq/dt = RTN/t$$

Hence,

$$d \ln t/dq = (d \ln t/dt)(dt/dq) = 1/RTN$$

It is clear from this equation that, in this case, the plot $q - \log t$ is linear. Consequently, the constant $t_0$ in the integrated form of the Elovich equation should be very small in this case. Furthermore, as described above, Case 1 is the only case to which the Elovich equation is expected to apply strictly. We may therefore conclude as follows: So far as the present interpretation of the Elovich equation is applicable, the constant $t_0$ of an appreciable magnitude such as is frequently employed to make the plot $q - \log(t+t_0)$ linear implies that in such cases, the equation holds only approximately, and the constant $b$ thus determined can not be given any physical meaning such as stated above, although the equation may be useful for evaluating initial rates.

## Summary

For the heterogeneous surface where the distribution function was variable and/or desorption could not be neglected, the rate of adsorption was derived and the physical meaning of constant $b$ in the Elovich equation was given. It was shown that in complicated case the Elovich equation is expected to apply only approximately in a limited range of coverage. The variation in constant $b$ with pressure or temperature was qualitatively explained in terms of the concept that on changing pressure or temperature, different sets of sites are covered and/or the contribution of desorption in adsorption rate measurements, is altered. The chemisorption of hydrogen on zinc oxide and on chromic oxide gel was discussed on the basis of the present interpretation of the Elovich equation. Finally, it was shown that, on the basis of surface heterogeneity, the constant $b$ obtained from the integrated form of the Elovich equation can not be given any physical meaning when the constant $t_0$ of an appreciable magnitude is required.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

# *Effect of Hydrogen and Carbon Monoxide on the Electrical Conductivity of Zinc Oxide*

By Yutaka KUBOKAWA

(Received September 9, 1959)

The increase in electrical conductivity of zinc oxide caused by hydrogen was investigated in previous works[1,2] in order to get a clue to the nature of the chemisorption of hydrogen, with the results summarized as follows: On admission of hydrogen no significant change in the conductivity is observed below 100°C, while at higher temperatures a marked increase takes place; moreover, the rate and the amount of chemisorption decrease with increasing temperature up to 110°C but increase at higher temperatures. On the basis of these results, it was suggested that two types of hydrogen chemisorption exist on zinc oxide; one is predominating at higher temperatures and responsible for the increase in conductivity, and the other is observed at lower temperatures, with little effect on conductivity. Making use of the rate of increase in conductivity, the activation energy for the chemisorption of the high temperature type was estimated as 25 kcal./mol.

However, the existence of two such types of chemisorption can not yet be regarded as established, since later studies[3,4] on the rate of desorption and the adsorption isotherm in addition to those on the rate of adsorption, covering wide ranges of pressure and temperature, showed that the heterogeneity of zinc oxide surface should be taken into account. The aim in the present work has been to reinvestigate the relation between the hydrogen chemisorption and the conductivity change by more extensive experiments.

## Experimental

**Materials.**—Zinc oxide was prepared as described previously[3]. The experiments with hydrogen were carried out with zinc oxide sintered at 800°C for 5 hr., while non-sintered zinc oxide was used for the study with carbon monoxide. Hydrogen and carbon monoxide were obtained as given in previous papers[3,5].

**Apparatus and Procedure.**—Conductivity measurements were made with a powdered specimen held between two electrodes, by means of a Wheatstone bridge. Details of the apparatus and procedure were described in the previous paper[2]. In the measurements of the rate of conductivity decrease, an auxiliary heater of nickel wire was mounted in the reaction vessel for the purpose of changing the temperature rapidly, taking into account the slow attainment of thermal equilibrium at low pressures.

## Results and Discussion

**Relationship between the Rate of Conductivity Increase and that of the Formation of Donors.**—There seems to be little doubt that the observed increase in conductivity of zinc oxide brought in contact with hydrogen is related to the formation of donors of a certain type. In view of the well-known difficulties, especially in the case of a powdered sample such as used in the present work, it seems questionable to discuss the kinetics of the formation of donors, from the conductivity-time curves at a constant temperature, on the assumption of a relationship between conductivity and the number of donors. However, as shown in the previous paper[2], the activation energy of the formation of donors may be obtained in the following way. The rate of formation of donors at the time when the number of donors present is $c$ may be written as

$$(dn/dt)_c = (dn/d\kappa)_c (d\kappa/dt)_c$$

where $\kappa$ is the conductivity and $n$ the number of donors. The activation energy for the formation of donors, $E$ is therefore given by $E=E_2-E_1$, where $E_1$ and $E_2$ are the activation energies of conductivity itself and of conductivity increase, respectively, both referring to the number of donors $c$. Using this equation, we can obtain the value of $E$ provided that $E_1$ and $E_2$ are known.

**Temperature Coefficient of Conductivity.**—$E_1$ decreases with increasing number of donors as described by various workers. The value for the state with a negligible number of donors was estimated from the temperature coefficient of conductivity with the specimen evacuated at about 400°C. Fig. 1 shows a typical result, which gives a value of 1.2 kcal./mol. Values

TABLE I. VALUES OF $E_1$ AND THE ACTIVATION ENERGY OF CONDUCTIVITY DECREASE FOR THE DATA IN FIG. 2

| Temp. range (°C) | 220～269 | 269～312 |
|---|---|---|
| $E_1$ (kcal./mol.) | 0.4±0.1 | 0.7±0.2 |
| Activation energy of cond. decrease (kcal./mol.) | 31±2 | 31±2 |

of $E_1$ at an appreciable number of donors can not easily be obtained because the temperature coefficient in hydrogen such as shown in Fig. 1 does not give the true value of $E_1$, since in this case the change of conductivity with temperature may arise from two factors, i. e., from the temperature coefficient of conductivity itself and from the variation of the number of donors with temperature. However, approximate values of $E_1$ may be obtained as follows.

After hydrogen was introduced at about 400°C, the whole vessel was cooled down to a lower temperature, where the conductivity decrease by evacuation was followed for some time. Then the vessel was abruptly heated to a higher temperature, where the conductivity measurement was continued. The results are shown in Fig. 2. As described in a previous paper[4], by extrapolation of the $\kappa \sim t$ curves to the time of the abrupt change in temperature, the conductivities at different temperatures corresponding to equal numbers of donors were obtained. Values of $E_1$ thus determined are given in Table I. They are appreciably less than the value determined at the evacuated state.

**Dependence of the Rate of Conductivity Increase on Temperature.**—This was determined in two ways, i. e., by measuring the initial rates of conductivity increase at varied temperatures as described previously[2] and by observing the rate increase caused by an abrupt temperature elevation during the conductivity increase measurements. The latter method is similar in principle to that used in the adsorption rate measurements[4]. By extrapolation of the rates

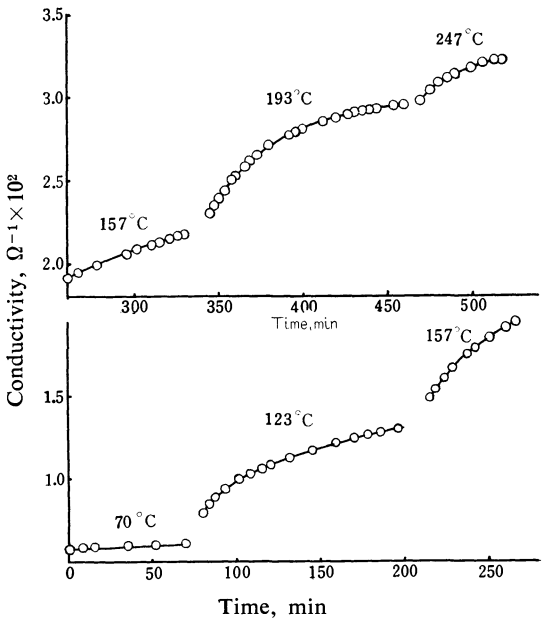

Fig. 3. Conductivity increase by hydrogen and the effect of a sudden temperature change. Pressure, 56 mmHg.

TABLE II. VALUES OF $E_2$ FOR THE DATA IN FIG. 3

| Temp. range (°C) | 70～123 | 123～157 | 157～193 |
|---|---|---|---|
| $E_2$ (kcal./mol.) | 18±1.5 | 21.7±1.5 | 20.5±1.5 |

to the time of the abrupt change, the rate at the two different temperatures corresponding to equal numbers of donors and consequently $E_2$ for that number of donors were obtained. In a typical example shown in Fig. 3, the temperature was raised in stages up to about 300°C after hydrogen was admitted at room temperature. The value of $E_2$ found here was about 21 kcal./mol., being roughly constant in the temperature range 120~200°C (Table II). $E_2$ is therefore of much greater magnitude compared with $E_1$ described above, indicating that the activation energy of the formation of donors is almost equal to that of conductivity increase.

The initial rate measurements, i. e., the other one of the two methods mentioned above, gave a value of 20 kcal./mol. for $E_2$, in agreement with that obtained by a rapid temperature elevation. The conductivity-time curves obtained were similar to those described in the previous paper[2].

**Dependence of the Rate of Conductivity Increase on Pressure.**—This was determined in two ways similar to those used for the temperature dependence. Fig. 4 shows the results obtained by a rapid pressure change during the measurements of conductivity increase. The pressure dependence was supposed to take the form $p^n$ and the values of the exponent $n$ were determined from this figure, as given in Table III. It is seen that the rate of conductivity increase is proportional to $p^{0.85}$ at increasing as well as decreasing pressure. The measurements of the initial rates of conductivity increase gave a similar pressure dependence.

An upper limit of the experimental error was ±10%.

**Dependence of the Rate of Conductivity Decrease by Reducing Pressure on Temperature.**—This may be estimated by the comparison of the rates at different temperatures corresponding to equal numbers of donors. For this purpose we may utilize the results described in Fig. 2, which were used for the determination of $E_1$. In the same manner as described above, the activation energy of conductivity decrease was estimated as 31 kcal./mol. (Table I).

**Variation of the Conductivity with Hydrogen Pressure.**—Above 300°C, the rate of conductivity increase on admitting hydrogen was found to be very great, suggesting that in this temperature range the conductivity increased to an equilibrium value may be obtained as a function of pressure in a manner similar to the adsorption equilibrium measurements. Thus hydrogen was introduced at 350°C, and the conductivity was measured at various pressures and a constant temperature by decreasing pressure successively. The results were reproducible when pressure was inversely increased as shown in Fig. 5.

**Conductivity Increase by Carbon Monoxide.**—Using carbon monoxide, in place of hydrogen, similar measurements were performed. Fig. 6 shows the $\kappa \sim t$ curves at varied temperatures and an approximately constant initial pressure, which gives a value of 25 kcal./mol. for the activation energy of conductivity increase. This

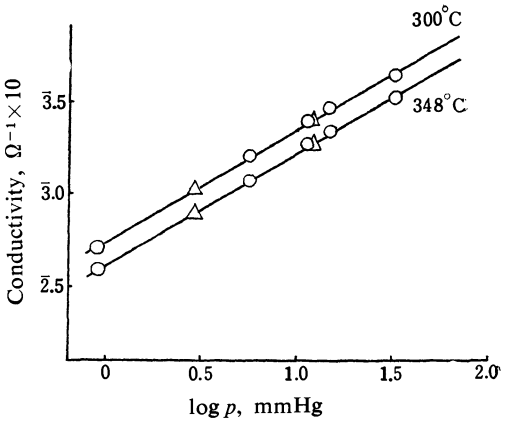

Fig. 5. Conductivity as a function of hydrogen pressure. —○—, on decreasing pressure; —△—, on increasing pressure.

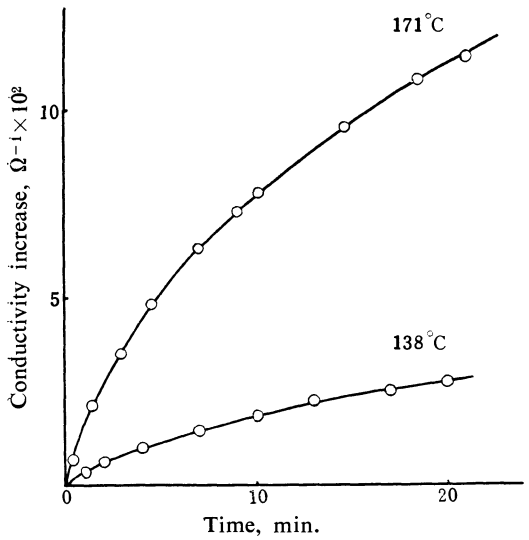

Fig. 6. Conductivity increase by carbon monoxide. Pressure, 1.4 mmHg. The activation energy was estimated as 25 kcal./mol.

may be regarded approximately as that of the formation of donors because of the negligible value of $E_1$. Almost the same value of activation energy was obtained in the method of a rapid temperature elevation. The conductivity increase was reversible as with hydrogen: by evacuation at 400°C the original conductivity was restored.

**Relation between the Hydrogen Chemisorption and the Conductivity Increase.**—As described in the previous paper[2], the conductivity enhanced by hydrogen was restored nearly to the original value by pumping out at 400°C. In addition, the conductivity increased to an equilibrium value varies reproducibly on increasing as well as decreasing pressure. These results, together with the fact that the amount of hydrogen adsorbed is almost completely desorbed as such, appear to indicate that this conductivity increase may not arise from the reduction of zinc oxide, but from the hydrogen adsorption of a certain type.

However, from the results obtained in this work, the assumption that the conductivity increase is due to a sort of chemisorption leads to the heat of chemisorption of 10 kcal./mol. and the activation energy of 21 kcal./mol. Relative magnitudes of these values are quite unusual for a chemisorption. Moreover, the activation energy of hydrogen chemisorption obtained from adsorption measurements[4] is 7～10 kcal./mol. in the comparable temperature range 100～140°C, and hence markedly less than the above value of 21 kcal./mol. These considerations suggest that the conductivity increase is not directly related to the hydrogen chemisorption of any type, and that the hydrogen uptake associated with the conductivity increase, if any, is only a negligible portion of the total uptake. It seems therefore necessary to modify the conclusion drawn from the earlier conductivity measurements[2] that two types of chemisorption exist, one of them being responsible for the conductivity increase while the other is not.

As described in the previous paper[2], the rate of adsorption and the adsorbed amount decrease with any increase in temperature up to 110°C, but increase at higher temperatures. Although such behavior, apparently, is adequately explainable in terms of the two types of chemisorption, this can not be the only explanation. Now that the heterogeneity of zinc oxide surface is undeniable through desorption measurements, the concept of single type chemisorption on a heterogeneous surface seems to present a more probable explanation. In addition, as previously described[3], the change in the activation energy of desorption is continuous, in contrast with that of carbon monoxide for which the presence of the two types of chemisorption was confirmed[5]. This again appears to favor the concept of single type chemisorption on a heterogeneous surface.

**Nature of the Conductivity Increase by Hydrogen.**—As regards the nature of the conductivity increase, an interpretation is that hydrogen atoms diffuse as protons into the lattice close to the surface, as suggested by various workers[6]. However, such an interpretation may not easily be reconciled with the following results obtained: The rate of conductivity increase is proportional to $p^{0.85}$; essentially the same behavior is observed with carbon monoxide on zinc oxide where there is no possibility of dissolution into crystals; in addition, this conductivity increase is an exothermic phenomenon, in contrast with hydrogen dissolution into a crystal of zinc oxide which is an endothermic phenomenon, as reported by Mollwo and others[7].

At present, the most plausible interpretation of the conductivity increase seems to be that proposed by Thomas et al.[8], who attributed it to the surface reduction of zinc oxide. This possibility was excluded previously on the basis of the fact that no water vapor was detected on desorption and that the conductivity increase was reversible. However, the amount of hydrogen uptake is a negligible portion of the total uptake as shown above. Hence such a

8) D. G. Thomas and J. J. Lander, *J. Phys. Chem. Solids*, **2**, 318 (1957).

small amount of water vapor will not be detectable. Moreover, the recovery of the original conductivity by pumping out at high temperature and the reproduction of the conductivity on increasing and decreasing pressure may be explained on the assumption that zinc atoms produced by reduction evaporate rapidly at high temperature. This seems to be a plausible assumption, since the reduction is probably confined to the surface layer[9,10].

This interpretation may be applied in the temperature range above 100°C, but a slight conductivity change observed below this temperature described in the previous paper[2] probably arises from the chemisorption of hydrogen, although this behavior has not been studied in detail.

## Summary

The rate of increase in conductivity of zinc oxide caused by hydrogen was found to be proportional to $p^{0.85}$ and to have an activation energy of 21 kcal./mol. For this system the activation energy of the increase of donors was shown to be almost the same as that of the conductivity increase. The activation energy of the decrease of donors by evacuation was 31 kcal./mol. A similar conductivity increase was observed with carbon monoxide. On the basis of these results together with those of adsorption measurements reported previously, it was concluded that the conductivity increase was scarcely related at all to the hydrogen chemisorption, indicating that it is untenable to postulate two such types of hydrogen chemisorption as was believed in the previous work, i. e., one responsible for the conductivity increase and the other without such effect. As for the cause of the conductivity increase, the surface reduction of zinc oxide was suggested.

The author wishes to express his sincere thanks to Prefessor O. Toyama for his guidance and encouragement throughout the course of this study.

9) The conductivity increase observed on the oxidized state described in a previous paper[1] may also be attributed to the surface reduction of zinc oxide.

10) According to the previous work[2], the activation energy of the conductivity increase is 25 kcal./mol., being somewhat different from the value of 21 kcal./mol. found in the present work. Considering that this activation energy is a composite quantity including the activation energy of adsorption and that of the surface reduction, this difference may be explained by different proportions of the contributions of the two processes.

# *Effect of Oxygen Pretreatment on Hydrogen and Carbon Monoxide Chemisorption on Zinc Oxide*

By Yutaka KUBOKAWA

(Received September 9, 1959)

Since the treatment of an electron barrier layer was suggested for the chemisorption on semiconductors by Hauffe, Weisz, and others[1], the chemisorption and catalysis on oxide catalysts have been discussed on the basis of this model, and the relation between the catalytic activities of oxides and their properties as semiconductors have been emphasized by a number of workers[2,3]. As for the catalysis by zinc oxide, Parravano and others[4] found that the activity towards hydrogen-deuterium exchange reaction increases with its electrical conductivity. On the basis of these results, Hauffe[2] emphasized the fact that the properties of oxides as semiconductors play a large part in determining the activity towards this reaction.

However, for hydrogen or carbon monoxide chemisorption on zinc oxide which belongs to a "cumulative chemisorption", the barrier is so thin that it is doubtful whether this model

will be applicable to such systems. It appears more likely that covalent-bonding, similar to that in the chemisorption on metals determines the behavior of these systems, as pointed out by several workers[5].

It was aimed in the present work to obtain unambiguous information on the relation between the electronic state of zinc oxide and the chemisorption of hydrogen as well as carbon monoxide. For this purpose, the effect of high temperature oxygen treatment of zinc oxide was investigated, inasmuch as it is well established that such treatment markedly reduces the electrical conductivity of zinc oxide.

The present work was designed with another object in addition to that stated above. As regards hydrogen chemisorption on zinc oxide, Morrison[6] proposed a model, according to which the chemisorption means nothing but an interaction of hydrogen with adsorbed oxygen remaining after high temperature evacuation in the form of $O^-_{ads}$ or $O^{2-}_{ads}$. This mechanism may be written as

$$O^-_{ads} + 1/2\,H_2 \rightarrow OH^-_{ads}$$

$$O^{2-}_{ads} + 1/2\,H_2 \rightarrow OH^-_{ads} + \text{electron}$$

He is of the opinion that the two types of chemisorption for this system as described by Taylor et al.[7], may be explained in terms of these two processes. According to Garner[8], however, $OH_{ads}$ produced by the interaction of hydrogen with adsorbed oxygen is irreversible, in contradiction to Morrison's view. It may then be expected that the present study of the effect of oxygen treatment on hydrogen chemisorption would also serve to solve this problem.

## Experimental

**Materials.**—For zinc oxide, ZnO I described in a previous paper[9] was used. Hydrogen and carbon monoxide were prepared and purified as in the previous work[9,10]. Oxygen was obtained by the electrolysis of 30% potassium hydroxide solution, and purified in the same manner as hydrogen.

**Apparatus and Procedure.**—The apparatus used in the present work was the same as that used in the previous work[9] except that a Pirani gauge was attached to the flask in which the gas desorbed was collected. By measuring the voltage required to balance the bridge, the composition of the desorbed gas could be calculated from the calibration curves for hydrogen and oxygen.

## Results

**Effect of Oxygen Pretreatment on the Amount of Hydrogen Adsorbed.**—After oxygen adsorption was allowed to proceed for 3 hr. at 450°C and at a pressure of 30 mmHg, the temperature was lowered to 260°C. The system was evacuated for 30 min. at this temperature, and then the chemisorption rate measurements were carried out at room temperature (Run A). After this run, the system was evacuated for 1 hr. at 500°C and similar measurements were taken (Run B). Run B was further followed by evacuation for 15 hr. at 500°C and thereafter the chemisorption rate measurements were repeated (Run C). The results are shown in

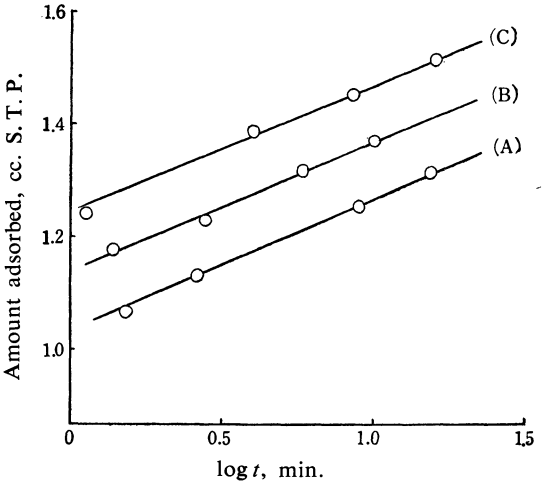

Fig. 1. Effect of oxygen pretreatment on the amount of hydrogen adsorbed at 14°C. Pressure, 20~25 mmHg.

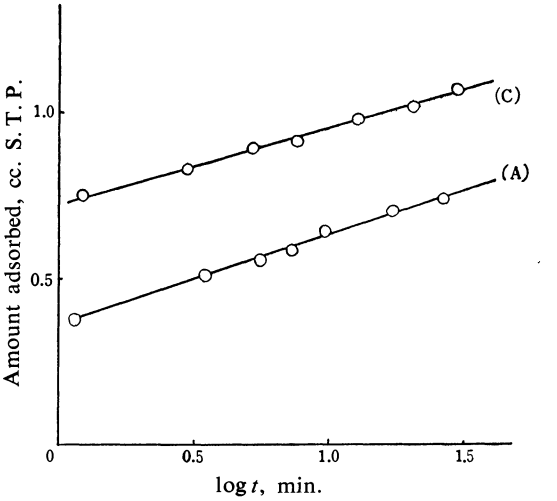

Fig. 2. Effect of oxygen pretreatment on the amount of hydrogen adsorbed at 189°C. Pressure, 20~25 mmHg.

Fig. 1. In these runs the order of the amounts of oxygen adsorbed is expected to be A>B>C. As seen in this figure, the amount adsorbed at a particular time also increases in this order. The amount adsorbed after 16 hr. was 1.95 cc. in run A and 2.21 cc. in run C, showing a slight difference. Fig. 2 represents the results obtained at a higher temperature. It follows from the figure that, in this case too, the decrease in the amount adsorbed after oxygen treatment will become unmarked in a later stage of adsorption.

**Effect of Oxygen Pretreatment on the Rate of Desorption of Hydrogen.**—After hydrogen was allowed to be chemisorbed at room temperature on the specimen pretreated with oxygen at 450°C followed by evacuation at 260°C, the activation energies of desorption at various coverages were determined in the manner described previously[9]. For comparison, similar measurements were carried out with the specimen before such pretreatment. Allowing for the different amounts initially adsorbed on these specimens, the activation energy of desorption was plotted in each case against the ratio of the amount desorbed to that initially adsorbed. As seen in Fig. 3, the results obtained with the two specimens were essentially indentical. Moreover, the comparison at various temperatures between the amount desorbed from the two specimens before the rates of desorption fell to a particular value shows, as seen in Table I, that there is no marked difference between the rates of desorption from these

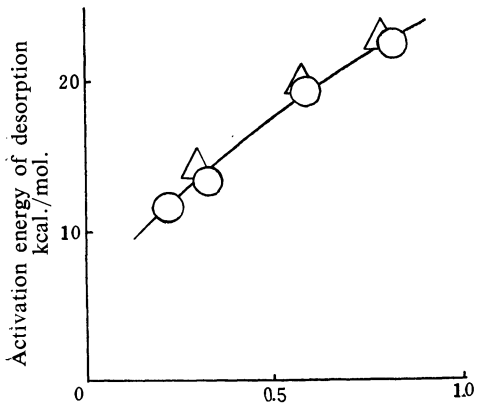

Fig. 3. Effect of oxygen pretreatment on the activation energy of desorption of hydrogen.
-○-, before oxygen pretreatment; -△-, after oxygen pretreatment. The amount of hydrogen adsorbed before desorption was 2.15 cc. before pretreatment and 1.82 cc. after pretreatment.

Table I. Ratio of the amount desorbed before the rate of desorption fell to $3.73\times10^{-3}$ cc. S. T. P./min. to the amount adsorbed before desorption

| Temp. of desorption (°C) | −30 | 20 | 71 |
|---|---|---|---|
| Before oxygen pretreatment | 0.323 | 0.572 | 0.759 |
| After oxygen pretreatment | 0.295 | 0.582 | 0.741 |

specimens. It may therefore be concluded that the rate of desorption as well as its activation energy is scarcely affected at all by oxygen treatment of the adsorbent at a temperature as high as 450°C.

**Interaction of Hydrogen with Adsorbed Oxygen.**—After hydrogen was allowed to be chemisorbed at room temperature, the temperature of the system was raised up to 400°C, and after several hours it was again lowered to room temperature. Then the amount of gas desorbed during the temperature elevation up to 400°C was measured and its composition was analyzed by means of the Pirani gauge. These measurements were carried out with a specimen which had been subjected to the same oxygen treatment as that used in the experiment shown in Fig. 1. The results are shown in Table II. In the Runs A and B the gas desorbed below 400°C consisted solely of hydrogen, while above 400°C a considerable amount of water was detected in the gas desorbed and its uncondensable fraction was found to be almost entirely oxygen. This indicates the occurrence of an irreversible chemisorption of hydrogen, the extent of which may be estimated from the amounts not removed by pumping out at 400°C. As seen in Table II, the amount of irreversible

Table II

| | Amount absorbed at room temp. before desorption (1) | Amount desorbed below 400°C (2) | Residual amount adsorbed (1)—(2) |
|---|---|---|---|
| Run A | 3.94 | 3.48 | 0.46 |
| Run B | 3.85 | 3.54 | 0.31 |
| Run C | 4.10 | 3.96 | 0.14 |

Amount adsorbed is in cc. S. T. P. The order of the amounts of oxygen adsorbed is A>B>C.

chemisorption increases with that of the oxygen adsorbed. On the other hand, in Run C where little or no oxygen remained adsorbed, no water vapor was detected even above 400°C, suggesting that hydrogen chemisorption was completely reversible in this case.

**Effect of Oxygen Pretreatment on Carbon Monoxide Chemisorption.**—As described in the

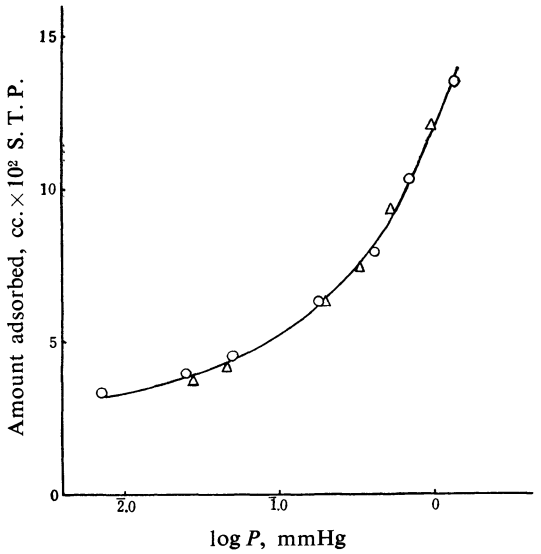

Fig. 4. Effect of oxygen pretreatment on carbon monoxide chemisorption at 15°C. -○-, before oxygen pretreatment; -△-, after oxygen pretreatment.

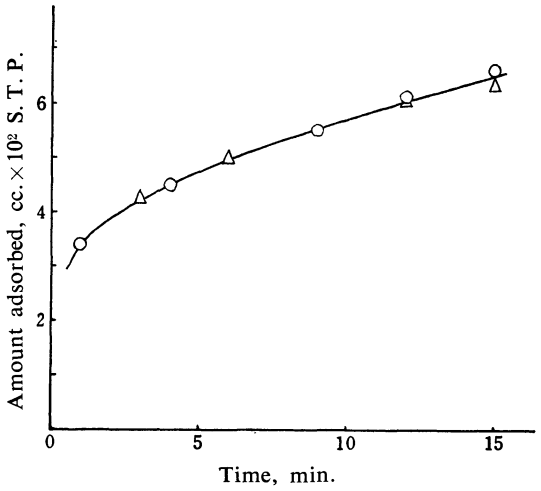

Fig. 5. Effect of oxygen pretreatment on carbon monoxide chemisorption at 90°C. -○-, before oxygen pretreatment; -△-, after oxygen pretreatment. Pressure, 0.1 ~0.2 mmHg.

previous paper[10], there are two types of chemisorption for carbon monoxide, one of them being a non-activated adsorption at low temperature, and the other an activated absorption at high temperature. The effect of oxygen treatment was therefore investigated in the following two ways. Fig. 4 shows the effect on the adsorption isotherm at room temperature obtained on a desorption branch, such as was described previously. It follows from this figure that the oxygen treatment has no effect on the chemisorption of low temperature type, in agreement with the results obtained by Garner et al.[11] For the chemisorption of high temperature type, similar results were obtained, as shown in Fig. 5. Oxygen treatment in this case was conducted at 450°C, followed by evacuation at 260°C.

## Discussion

If the electronic state of zinc oxide had played a large part in determining the behavior of hydrogen chemisorption, the amount adsorbed as well as the rate of desorption of hydrogen would have been seriously affected by oxygen treatment at high temperature, in contradiction to what was found actually in this work. It may therefore be concluded that the change of the electronic state of zinc oxide has little or no effect on hydrogen chemisorption.

This conclusion in turn suggests that a slight decrease in the amount adsorbed caused by the oxygen treatment is not due to the change of the concentrations of electrons. In view of the existence of surface heterogeneity in this system as revealed in a previous work[9], this decrease may probably be ascribed to the variation of the distribution function of sites, although details of the variation are unknown at present.

According to Parravano et al.[4], the activity of zinc oxide towards hydrogen-deuterium exchange reaction decreases markedly after oxygen treatment. On the basis of the considerations given above, it seems unlikely that this decrease in the catalytic activity is attributed to the change of the concentrations of free electrons. In addition, the extent of decrease in the activity after oxygen treatment as reported by these authors appears to be markedly greater than that in the amount of hydrogen adsorbed in the present work, although there may be more or less uncertainty in such comparisons, as no measurements with the same specimen of zinc oxide were carried out. Such a marked difference, if it is real, suggests that only a negligible portion of the total amount of hydrogen adsorbed is responsible for the exchange reaction, in agreement with what may be expected from the surface heterogeneity established for this system.

Various workers[12] have emphasized the fact that hydrogen chemisorption on zinc oxide is confined to interstitial zinc atoms or F-centers which probably exist after evacuation at high temperature. The observation in this work

11) W. E. Garner and J. Maggs, *Trans. Faraday Soc.*, **32**, 1744 (1936).
12) J. H. de Boer, "Advances in Catalysis", Vol. 8 (1956), p. 18; W. E. Garner, "Advances in Catalyss", Vol. 9 (1957), p. 169.

that the amount adsorbed is not seriously affected by the oxygen treatment indicates that such interpretation is unjustifiable.

The decrease in the amount of hydrogen adsorbed after oxygen treatment and the increase of the extent of irreversible adsorption with the increasing amount of oxygen adsorbed suggest that Morrison's mechanism is unjustifiable and that $OH_{ads}$, produced by the interaction of hydrogen with adsorbed oxygen, is irreversible and desorbed as water above 400°C, in accordance with Garner's view.

As for carbon monoxide chemisorption, the results obtained in the present work indicate again and still more clearly that this chemisorption is not affected by the electronic state of zinc oxide. Moreover, these results together with the fact that the amount adsorbed at $\theta=1$, estimated from the isotherms, amount to about a half of the amount of nitrogen adsorbed in a monolayer determined by the B. E. T. method as previously described[10] suggest that carbon monoxide chemisorption is not confined to special active sites, e. g., interstitial zinc atoms or F-centers, but the entire surface of zinc oxide participates in the chemisorption.

Finally, with respect to the change of the catalytic activity of zinc oxide caused by the addition of small amounts of $Li_2O$ or $Al_2O_3$ as shown by a number of workers, the results presented here, seem to indicate that it is doubtful in some cases that this effect can be attributed to the change of the electronic state of zinc oxide caused by the addition.

## Summary

The effect of oxygen treatment at about 500°C of zinc oxide upon the chemisorption of hydrogen as well as of carbon monoxide was investigated in order to clarify the relation between the electronic state of the adsorbent and the chemisorption. In the case of hydrogen chemisorption, the amount adsorbed was reduced only slightly and the rate of desorption remained practically unaltered after oxygen treatment. On carbon monoxide chemisorption the oxygen treatment gave no effect. It was concluded from these results that both the chemisorption of hydrogen and that of carbon monoxide are essentially independent of the electronic state of zinc oxide. On the basis of such a conclusion combined with other results, the inapplicability of the model of hydrogen chemisorption proposed by Morrison was pointed out.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

# *Hydrogen Chemisorption on $ZnO \cdot Cr_2O_3$, $ZnO \cdot MoO_3$ and $Cr_2O_3$*

By Yutaka KUBOKAWA

(Received September 9, 1959)

In previous papers[1] hydrogen chemisorption on zinc oxide was studied by measuring the rate of adsorption, adsorption equilibrium and the rate of desorption, which made it possible to obtain quantitative information on the energy relation for this system. The behavior of desorption under various experimental conditions suggested the existence of a heterogeneity of the surface, the nature of which was such that the activation energy of adsorption and the heat of adrorption varied in the same direction, in contrast with carbon monoxide chemisorption on zinc oxide where these quantities varied in the reverse direction to each other.

It seemed then desirable to ascertain whether the conclusion obtained with zinc oxide is generally applicable to hydrogen chemisorption on oxides or not. As a first step in such an investigation, the hydrogen chemisorption was measured with $ZnO \cdot Cr_2O_3$, $ZnO \cdot MoO_3$ and $Cr_2O_3$, in the same manner as with zinc oxide and the results obtained are reported in this paper.

## Experimental

**Materials.** — $ZnO \cdot Cr_2O_3$ and $ZnO \cdot MoO_3$ were prepared in the same way as described in the previous work[2]. $Cr_2O_3$ was prepared by controlled

1) Y. Kubokawa, This Bulletin, 33, 546, 550 (1960).

2) Y. Kubokawa and O. Toyama, *J. Phys. Chem.*, **60**, 833 (1956).

ignition of $CrO_3$ of extra pure grade in a stream of dry air at 450°C as described by Bevan et al.[3] The gases were obtained as described in the previous papers[1]. The weight of the adsorbent and surface area determined by the B. E. T. method using nitrogen adsorption were as follows: $ZnO \cdot Cr_2O_3$, 6.71 g., 28 $m^2$/g.; $ZnO \cdot MoO_3$, 8.83 g., 13 $m^2$/g.; $Cr_2O_3$, 14.13 g., 17 $m^2$/g.

**Apparatus and Procedure.**—Details of the apparatus and procedure were described in the previous papers[1]. Before a series of experiments, all the adsorbents were subjected to repeated pretreatments with hydrogen at 450°C followed by evacuation at this temperature.

## Results and Discussion

**Dependence of Chemisorption Rate on Temperature.**—The problem was investigated in two ways, one comparing, as usual, the rate at varied temperatures after admission of a known amount of hydrogen to a degassed sample and the other observing the rate increase caused by an abrupt temperature elevation during an adsorption rate measurement as previously applied to hydrogen chemisorption on zinc oxide. Measurements making use of the former method were already carried out in the previous work[2] with the following results: With $ZnO \cdot Cr_2O_3$ an instantaneous chemisorption followed by a slow process occurred and apparent activation energies of adsorption in the low and high temperature ranges were 7 and 13~16 kcal./mol., respectively, while with $ZnO \cdot MoO_3$, only a slow chemisorption with an activation energy of 28 kcal./mol. was observed.

Figs. 1 and 2 represent the results obtained by the latter method: After hydrogen was allowed to be adsorbed at room temperature, the temperature was raised up in stages. As seen in Fig. 1, in the case of $ZnO \cdot MoO_3$ the amount of rapid desorption due to the abrupt temperature raise is negligibly small, and the rate of slow uptake increases steadily with temperature as in the carbon monoxide chemisorption on zinc oxide described previously[4]. Similar behavior was observed on $Cr_2O_3$. On the other hand, the result obtained with $ZnO \cdot Cr_2O_3$ is similar to that for hydrogen chemisorption on zinc oxide, as seen in Fig. 2. Here on increasing the temperature a rapid desorption was followed by the occurrence of a slow

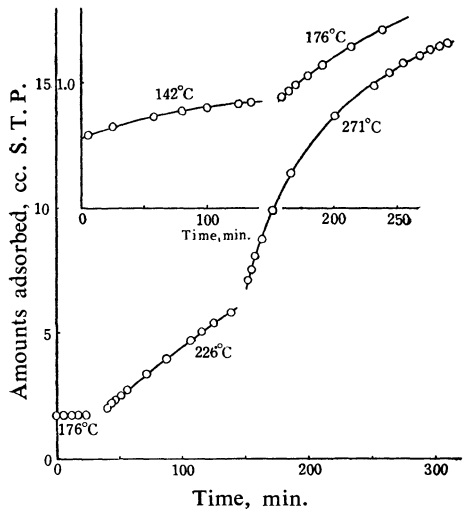

Fig. 1. Effect of temperature change during adsorption on the rate of hydrogen chemisorption on $ZnO \cdot MoO_3$. Pressure, 60~80 mmHg. Run at 176°C was interrupted by cooling the adsorbent to room temperature.

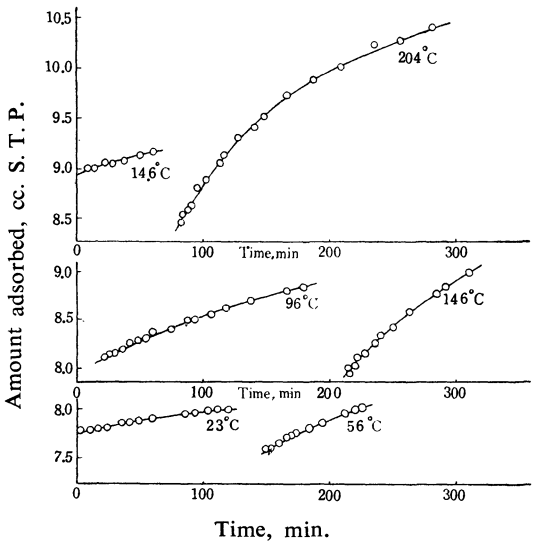

Fig. 2. Effect of temperature change during adsorption on the rate of hydrogen chemisorption on $ZnO \cdot Cr_2O_3$. Pressure, 60~80 mmHg. Both after the run at 56°C and during that at 146°C, the rate measurement was interrupted by cooling the adsorbent to room temperature.

| $ZnO \cdot Cr_2O_3$ (Fig. 2) | 23~ 56 | 8.0±1.0 |
| | 96~146 | 9.5±1.0 |
| | 146~204 | 12 ±1.0 |

3) J. M. Bevan, J. P. Shelton and J. S. Anderson, *J. Chem. Soc.*, **1948**, 1729.

4) Y. Kubokawa, This Bulletin, 33, 555 (1960).

uptake. Apparent activation energies were determined by a method similar to that described in the previous papers[1], i. e., by comparison of the rates at different temperatures, corresponding to equal amounts of the slow chemisorption. The results obtained are shown in Table I.

Although a rapid desorption on an abrupt temperature raise is observed with $ZnO \cdot Cr_2O_3$, which shows, on the whole, a normal pattern of an activated adsorption according to the previous work[2], i. e., except in the temperature range 80~110°C, the rate of adsorption increases steadily with temperature. In addition, both methods of obtaining the dependence of rate on temperature give similar values of activation energy, contrary to the results for zinc oxide. This may be attributed to a much smaller proportion of the amount desorbed rapidly on raising the temperature to the amount adsorbed before the temperature rise.

**Dependence of Chemisorption Rate on Pressure.**—As described in previous papers[1,4], the pressure dependence was determined by observing the rate change caused by an abrupt pressure change during adsorption. As an example, the results obtained with $ZnO \cdot MoO_3$ are shown in Fig. 3. The comparison of the rates at different pressures corresponding to equal amounts of slow uptake gives the pressure dependence, with the results listed in Table II.

With $ZnO \cdot MoO_3$, the rate was found to be proportional to $P^{0.8}$ on both increasing and decreasing pressure, indicating that desorption is negligible during adsorption. The results obtained with $Cr_2O_3$ were similar. In the case of $ZnO \cdot Cr_2O_3$, it is clear that desorption can not be neglected, since on decreasing pressure the exponent $n$ in the expression Rate $\propto P^n$ is, markedly larger than the value when desorption is negligible, namely 0.8, and on increasing pressure too, a value somewhat greater than 0.8 was obtained, as seen in Table II.

**Activation Energies of Desorption at Various Coverages.**—The temperature of the adsorbent which had already adsorbed hydrogen at about

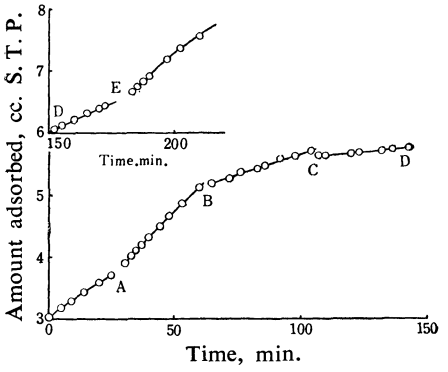

Fig. 3. Effect of pressure change during adsorption on the rate of hydrogen chemisorption on $ZnO \cdot MoO_3$. Temp., 228°C. Pressures before and after the pressure change are shown in Table II.

Figures indicate the temperature interval where the activation energy was determined.

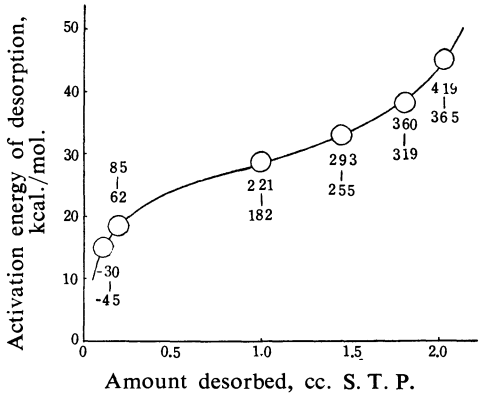

Fig. 6. Activation energies of desorption of hydrogen chemisorbed on $Cr_2O_3$. The amount adsorbed and equilibrium pressure at room temperature before desorption were 2.18 cc. and 36.4 mmHg respectively. Figures indicate the temperature interval where the activation energy was determined.

400°C was raised up from −72 to about 400°C in stages at each of which the activation energy of desorption was determined in the same manner as described previously[1]. The results obtained are shown in Figs. 4, 5 and 6. For all the systems studied in the present work, it was confirmed that adsorption could be neglected during desorption rate measurement as in the case of hydrogen chemisorption on zinc oxide. In the case of $ZnO \cdot MoO_3$, the amount desorbed with an activation energy less than 30 kcal./mol. is a negligible fraction of the total amount desorbed. In addition, the greater part of the chemisorbed hydrogen desorbs with an approximately constant activation energy of 41 kcal./mol. On the other hand, for the other systems, the activation energy of desorption varies considerably with the amount desorbed, i. e., for $ZnO \cdot Cr_2O_3$ from 10 to 35 kcal./mol. and for $Cr_2O_3$ from 15 to 45 kcal./mol. Moreover, in the former case a considerable fraction of chemisorbed hydrogen desorbs with a low activation energy of desorption (<20 kcal./mol.), while in the latter, this fraction is negligibly small.

**Adsorption Isotherms.** — After hydrogen was allowed to be adsorbed at a high temperature, the adsorption isotherm was determined by successive withdrawals of the gas. The isotherm thus determined on the desorption branch was, as in the case of hydrogen chemisorption on zinc oxide, reproducible at increasing as well as decreasing pressure. The results obtained with $ZnO \cdot Cr_2O_3$ and $ZnO \cdot MoO_3$ are shown in Figs. 7 and 8[5]. The

5) The isotherm for $Cr_2O_3$ was not determined.

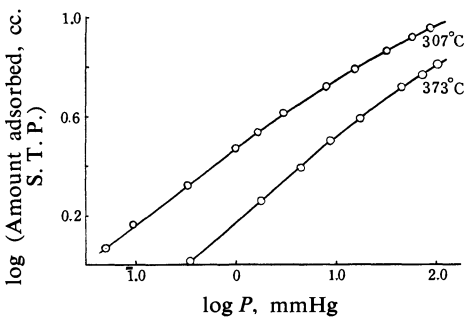

Fig. 7. Adsorption isotherms of hydrogen on $ZnO \cdot Cr_2O_3$ at 307 and 373°C.

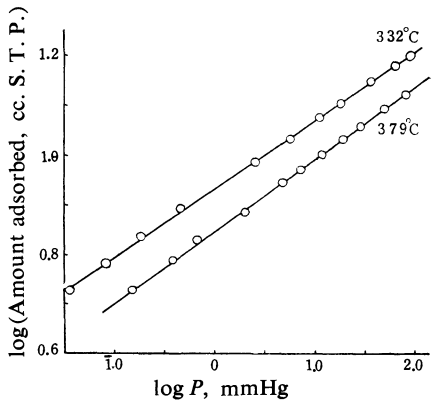

Fig. 8. Adsorption isotherms of hydrogen on $ZnO \cdot MoO_3$.

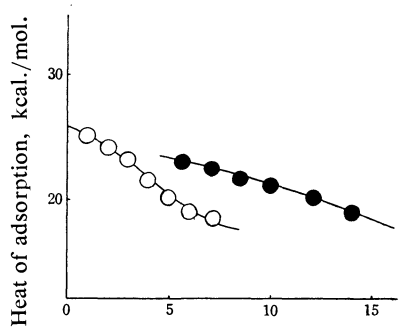

Fig. 9. Heats of adsorption of hydrogen on $ZnO \cdot Cr_2O_3$ and $ZnO \cdot MoO_3$. -○-, $ZnO \cdot Cr_2O_3$; -●-, $ZnO \cdot MoO_3$.

variations of the heat of adsorption determined from these isotherms with the amount adsorbed are represented in Fig. 9.

As seen in Fig. 5, with $ZnO \cdot Cr_2O_3$, the chemisorption with a low activation energy of desorption occurs to a considerable extent. The heat of adsorption for such chemisorption was estimated from the adsorption isotherms at 115 and 85°C, determined in desorption branch with the specimen which had chemisorbed hydrogen at about 300°C. The result

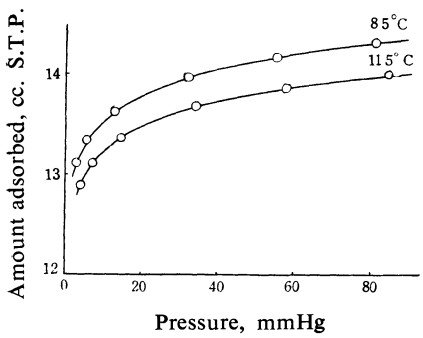

Fig. 10. Adsorption isotherms of hydrogen on $ZnO \cdot Cr_2O_3$ at 85 and 115°C.

obtained is shown in Fig. 10, from which the heat of adsorption is estimated as 7~8 kcal./mol.

**Nature of Heterogeneity of the Surface.**— The problem was dealt with as described in the previous papers[1,4]: At a particular temperature, hydrogen was left in contact with the adsorbent for some time; then, by pumping a known amount of gas from the system, the desorption rate was measured. The measurement was conducted with various times for each adsorbent. The results obtained with $ZnO \cdot MoO_3$, as shown in Fig. 11, are similar to those for carbon monoxide chemisorption on zinc oxide: The rate of desorption is greater on the surface with a larger amount adsorbed and there is a marked difference between the value of $d \log R_{dep}/dq$ for the runs of different times of contact with hydrogen. This suggests the existence of a heterogeneity of the surface where the heat of adsorption and the activation energy of adsorption vary inversely to each other as described in the previous paper[4].

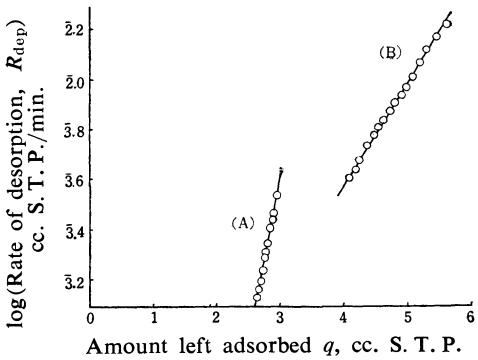

Fig. 11. Rate of desorption of hydrogen chemisorbed on $ZnO \cdot MoO_3$ as a function of the amount left adsorbed. Temp., 266°C. The weight of adsorbent used in these runs was 3.81 g. The amount adsorbed at room temperature before desorption was 3.54 cc. in Run A and 6.41 cc. in Run B. (A) After 30 min.; (B) After 3 hr.

In contrast to the case with $ZnO \cdot MoO_3$, the behavior observed on $ZnO \cdot Cr_2O_3$ was almost identical with that of hydrogen chemisorption on zinc oxide, i. e., a marked difference between the rates of desorption at equal amounts adsorbed after different contact times. Such behavior together with a rapid desorption observed on raising temperature suggests that the existence of an a priori heterogeneity of the surface where the activation energy of adsorption and the heat of adsorption vary in the same direction as was concluded in the previous work[1].

In the case of $Cr_2O_3$, although the result obtained at 162°C was similar to that with $ZnO \cdot MoO_3$ mentioned above (Fig. 11), at 206°C, somewhat different behavior was observed, as seen in Fig. 12 and Table III. Here in an early stage of adsorption, the proportion of the amount desorbed rapidly to the total amount adsorbed increases as adsorption proceeds, while after one hour since the admission of hydrogen, the situation is reversed, i. e., this proportion is now smaller on the surface with a larger amount adsorbed, indicating that the sites with a higher heat of adsorption are covered in a later stage. This behavior may be explained by assuming that the sites

* This amount was estimated by the amount desorbed before $\log R_{dep}$ fell to $\bar{3}.64$. (cc. S. T. P./min.)

with the highest heat of adsorption are not accessible to the gas phase, but can be reached by a surface or bulk diffusion process from the sites with a lower heat of adsorption. Such an explanation may be more plausible than one assuming that the relationship between the heat of adsorption and the activation energy of adsorption changes abruptly in the final stage of adsorption. Irrespective of the explanation for this phenomenon, it may be concluded that the nature of surface heterogeneity in this system is, in principle, such that the heat of adsorption varies inversely to the activation energy of adsorption, since the desorbed amount in question is only a small fraction of the total amount desorbed.

On the basis of the relationship between the heat of adsorption and the activation energy of adsorption described above, we can estimate the activation energy of adsorption indirectly from the heat of adsorption and the activation energy of desorption. In the case of $ZnO \cdot MoO_3$, from the maximum value of heat of adsorption, 26 kcal./mol., and that of the activation energy of desorption, 41 kcal./mol., the minimum value of the activation energy of adsorption can be estimated as 15 kcal./mol., in agreement with that obtained directly from adsorption measurements. Similar estimation with $ZnO \cdot Cr_2O_3$ yields 10 kcal./mol. as the maximum activation energy of adsorption, in approximate agreement with that directly determined. Considering that for the latter system the minimum activation energy of desorption is 10 kcal./mol. and the minimum heat of adsorption will be below 7 kcal./mol., it may be concluded, as in the case of hydrogen chemisorption on zinc oxide, that almost the whole process of chemisorption involves activation energy.

It may be noted that the following correlation is obtained from the results described above and in previous papers[1,4]: When desorption can not be neglected during adsorption, a rapid desorption on an abrupt temperature raise always takes place. Moreover, the presence of the fraction with a low activation energy of desorption is always associated with a rapid desorption on raising the temperature. Such correlation can be expected for the surface heterogeneity, the pattern of which is characterized by a continuous distribution function of sites with the heats of adsorption varying in the same direction with the activation energy of adsorption.

**Hydrogen Chemisorption on Oxides.** — From the results presented here, combined with those described in previous papers[1], the following common features for hydrogen chemisorption on oxides may be mentioned:

1) On oxides of reduced state, hydrogen chemisorption is reversible, in the sense that hydrogen is desorbed as such. For zinc oxide, this was already described in the previous work[6]. For $ZnO \cdot Cr_2O_3$, $ZnO \cdot MoO_3$ and $CrO_3$, essentially the same conclusion was obtained although the complete desorption requires a very long time.

2) When desorption is negligible, the rate of chemisorption is proportional to $P^{0.8}$ over a wide range of temperatures, indicating that the rate-determining step is not a sort of surface migration but an adsorption.

3) Almost the whole process of hydrogen chemisorption on oxides involves activation energy which becomes higher as the adsorption proceeds, although its magnitude varies from one oxide to another.

4) There is no evidence to support the existence of two types of hydrogen chemisorption which was believed to exist previously[2]. Although extensive conductivity measurements were not made with $ZnO \cdot Cr_2O_3$ and $ZnO \cdot MoO_3$ as in the case of zinc oxide, the concept of two types chemisorption is not required for these systems either, since all the results can be explained by the concept of single type chemisorption on a heterogeneous surface. The fact that the variation of activation energy of desorption is continuous over the whole range of the amount adsorbed appears to favour this concept.

5) The change of activation energy of adsorption with the amount adsorbed mainly arises from an a priori heterogeneity of the surface and not from the induced heterogeneity or the formation of electrical double layer owing to charge transfer between the gas adsorbed and the surface. At present the reason for the fact that the relation between the heat of adsorption and the activation energy of adsorption varies from one oxide to another is unknown. As regards the chemisorption of hydrogen on oxides other than those studied by the present author, the results obtained in this work may serve to make some prediction. In the cases of MnO and $MnO \cdot Cr_2O_3$ investigated by Taylor et al.[7], the activation energy of adsorption and the heat of adsorption will vary inversely to each other, since a rapid desorption on raising temperature is not observed. The situation with $V_2O_3$ studied by Tarama and Teranishi[8], may be similar, since the general features of the chemisorption are similar to those with $ZnO \cdot MoO_3$, i. e., the chemisorption measurement is possible

only above 200°C, and the rate increases steadily with increasing temperature. It may be concluded that the variation of the activation energy and the heat of adsorption in the reverse direction is more frequently encountered in hydrogen chemisorption on oxides.

## Summary

For hydrogen chemisorption on $ZnO \cdot Cr_2O_3$, $ZnO \cdot MoO_3$ and $Cr_2O_3$, the rates of adsorption and desorption, and adsorption equilibrium were investigated. The activation energy of adsorption ranged from 8 to 12 kcal./mol. for $ZnO \cdot Cr_2O_3$, and from 15 to 25 kcal./mol. for $ZnO \cdot MoO_3$. The value for $Cr_2O_3$ was about 13 kcal./mol. In the cases of $ZnO \cdot MoO_3$ and $Cr_2O_3$, where desorption is negligible during adsorption, the rate of adsorption was proportional to $P^{0.8}$, while with $ZnO \cdot Cr_2O_3$ desorption was found to occur appreciably. The activation energy of desorption increased with a decreasing amount adsorbed from 10 to 35 kcal./mol. for $ZnO \cdot Cr_2O_3$, and from 15 to 45 kcal./mol. for $Cr_2O_3$, while an approximately constant value of 41 kcal./mol. was obtained with $ZnO \cdot MoO_3$ except in the initial stage of desorption. The maximum heat of adsorption estimated from adsorption isotherms was about 25 kcal./mol. for both $ZnO \cdot Cr_2O_3$ and $ZnO \cdot MoO_3$. For all the systems studied, desorption experiments suggested the existence of surface heterogeneity with the activation energy of adsorption and heat of adsorption varying inversely in the cases of $ZnO \cdot MoO_3$ and $Cr_2O_3$, while with $ZnO \cdot Cr_2O_3$ the variation in the same direction was observed. On the basis of the results hitherto obtained, the general characteristics of hydrogen chemisorption on oxides were discussed.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

# *Monolayers of Some Cyclic Peptides. Fungisporin and Gramicidin $J_1$*

By Shoichi IKEDA and Toshizo ISEMURA

(Received September 19, 1959)

Chemical structures of many naturally occurring cyclic peptides and their modes of biological action have been investigated and elucidated in recent years. While many informations concerning the chain configuration and other properties of linear polypeptides in spread monolayer are obtained, the studies on cyclic peptides on surface are relatively deficient and stimulate our interest in several respects. Spread linear polypeptides are generally accepted to take the $\beta$-configuration[1,2] but spread cyclic peptides, unless the size of their rings is large enough, can not accomodate with this configuration. Thus it is desired to examine the configuration of cyclic peptides in the monolayer. Further, it is noticed that while ordinary linear polypeptides form monolayers of a condensed type owing to the intramolecular hydrogen bonding, the presence of prolyl residue[3] or ionized amino acid residue[4] in amino acid sequence, causes their monolayers to expand more. It is of importance to investigate whether or not this effect is exhibited in the monolayers of cyclic peptides.

Some investigations on the monolayers of cyclic peptides have been performed mainly by Few[5], but their configurations on the surface have so far been discussed only in the cases of tyrocidine A and B and gramicidin SA and SB[6].

From these points of view, the monolayers of two cyclic peptides, i. e., fungisporin and gramicidin $J_1$, have been studied by measuring surface pressure, potential and viscosity. Fungisporin[7],

isolated from spores of some species of *Penicillium* and *Aspergillus*, is an octapeptide, cyclo-(D-Phe-L-Phe-D-Val-L-Val)$_2$[8]. Gramicidin $J_1$[9] is a heptapeptide, cyclo-(D-Orn-L-Val-L-Orn-D-Phe-D-Leu-L-Phe-L-Pro)[10]. Fungisporin has given a monolayer of condensed type, whereas gramicidin $J_1$ that of an expanded type. The behavior of these monolayers has been discussed in the light of the configurations of these cyclic peptides.

## Experimental

Fungisporin was prepared by Dr. Miyao and was offered to our disposal. It is soluble only in dichloroacetic acid. As its spreading solvent was used a dichloroacetic acid-benzene (1 : 1 v/v) mixture which was found to be the most suitable for the surface potential measurement. Gramicidin $J_1$ dihydrochloride was a gift of Professor Otani. It was spread from a methanol solution.

Surface pressure, $\Pi$, was measured by a balance of a hanging plate type in higher pressure region, but it was measured by a balance of a float type of a better sensitivity in lower pressure or dilute region. The surface potential, $\Delta V$, was measured by the vibrating electrode method and surface viscosity, $\eta$, by the damped rotatory oscillation of a disk. From surface potential, the apparent surface moment, $\mu$, was calculated by the Helmholtz equation

$$\Delta V = \frac{4\pi\mu}{A}$$

where $A$ was the area per amino acid residue.

## Results

**Fungisporin.**—The $\Pi-A$, $\Delta V-A$, $\mu-A$ and $\eta-A$ curves of fungisporin on 0.01 M potassium chloride are shown in Fig. 1. The monolayer was found to be of a condensed type. The condensation of the film may be ascribed mainly to the hydrogen bonding and partly to the cohesion between hydrocarbon side chains. At the region of rise of the $\Pi-A$ curve the surface pressure declined gradually with time after each compression. In Fig. 1 the values at 1 min. per interval are plotted. The delay for attaining a steady surface pressure after each compression has been noticed in some condensed films of long chain substances and of high polymers with long side chain and is, therefore, closely related to the structure of fungisporin. The surface potential was reproducible only at the areas smaller than about 40 Å$^2$. This is also commonly observed for condensed films of low molecular weight substances, and consequently, consistent with the fact that fungisporin is a small molecule, an octapeptide. The surface viscosity was manifest at the areas below

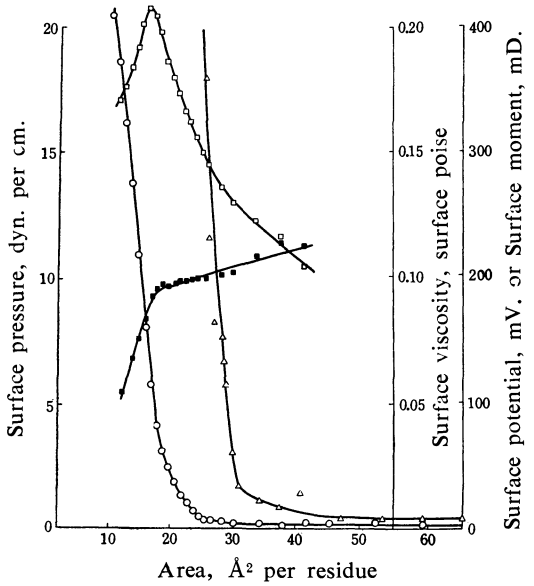

Fig. 1. Monolayer of fungisporin on 0.01 M potassium chloride (14°C). ○ surface pressure; □ surface potential; ■ surface moment; △ surface viscosity.

40 Å$^2$, where a surface potential was found to be reproducible.

The area, $A_\mu$, where the slope of $\mu-A$ curve suddenly changed was found to be 17.5 Å$^2$ and the area, $A_\Pi$, of the minimum surface compressibility was 16.0 Å$^2$. These areas are nearly identical with each other and will represent the area occupied by an amino acid residue. The surface moment, $\mu_c$, at the area, $A_\mu$, was 200 mD. Both the area and surface moment are larger than those found for linear polypeptide monolayers.

**Gramicidin $J_1$.**—Since gramicidin $J_1$ contains two ornithyl residues in a molecule, it forms an ionized monolayer on distilled water and an unionized monolayer on aqueous solution at pH higher than 10.5.

The unionized monolayer of gramicidin $J_1$ on 0.01 M potassium carbonate at pH 11.2 showed a characteristic feature, when a neutral salt such as potassium chloride was added into the aqueous subphase. The effect of the concentration of potassium chloride on the $\Pi-A$ curve is illustrated in Fig. 2. The $\Pi-A$ curve in the absence of neutral salt was smooth, but a break point appeared when potassium chloride was present. The break point was found to be independent of salt concentration and was 27 Å$^2$ and 5.6 dyn. per cm. In the absence of salt or on 0.001 M potassium chloride, slight time effects were observed in the region of surface pressure higher than the break point. The $\Pi-A$ curves were not altered by salt concentration between 0.01 M and 1 M. In Fig. 3 are

shown the $\Pi-A$, $\Delta V-A$, $\mu-A$ and $\eta-A$ curves on 0.01 M potassium carbonate when 0.01 M potassium chloride are added. Surface potential was scarcely affected by salt concentration and the corresponding break point such as observed in the $\Pi-A$ curve was not found in both $\Delta V-A$ and $\mu-A$ curves.

It was noticed that the $\Pi-A$ curves of gramicidin SA and SB likewise exhibited the same kind of break points on 1 M potassium chloride at pH 12.5, and the break was attributed to the reorientation of side chains of ornithyl residues[6]. However, no break on the $\Delta V-A$ and $\mu-A$ curves for gramicidin $J_1$ suggests that the break on the $\Pi-A$ curve would not come from the reorientation of ornithyl residues but presumably from the micelle formation as proposed for fatty acid monolayers[11].

At pH 11.2 where they were unionized, the monolayers of gramicidin $J_1$ were of an expanded type, as shown in Fig. 2. Correspondingly, the surface viscosity was manifest first in the region of high surface pressures[4,12] as shown in Fig. 3. A constant value of the surface moment was observed over a wide area. The smallest area, $A_\mu$, of constant surface moment was found to be 19.0 Å², the area, $A_\Pi$, of minimum surface compressibility to be 20.5 Å² and the gelling area, $A_\eta$, to be 20.0 Å². All these areas were scarcely dependent on salt concentrations not less than 0.01 M and nearly identical

with one another. Consequently, they represent the area occupied by an amino acid residue. The constant surface moment, $\mu_c$, was about 340 mD.

On distilled water at pH 5.6 gramicidin $J_1$ forms an ionized monolayer. In this case, the monolayer behaves unlike the unionized monolayer but in a quite specific manner, as the salt concentration is varied. The variation of the $\Pi-A$ curves with the concentration of patassium chloride is shown in Fig. 4. In the absence of salt or on 0.001 M potassium chloride, the monolayers were somewhat unstable and had a tendency to dissolve into aqueous subphases on compression. On potassium chloride of the concentrations of 0.01 M to 1 M, however, the monolayers exhibited a typical behavior of ionized monolayer. Monolayers were more condensed at higher salt concentrations and more expanded at lower concentations. The $\Pi-A$ curves pass a reversal point[13], 30.5 Å$^2$ and 4.3 dyn. per cm.

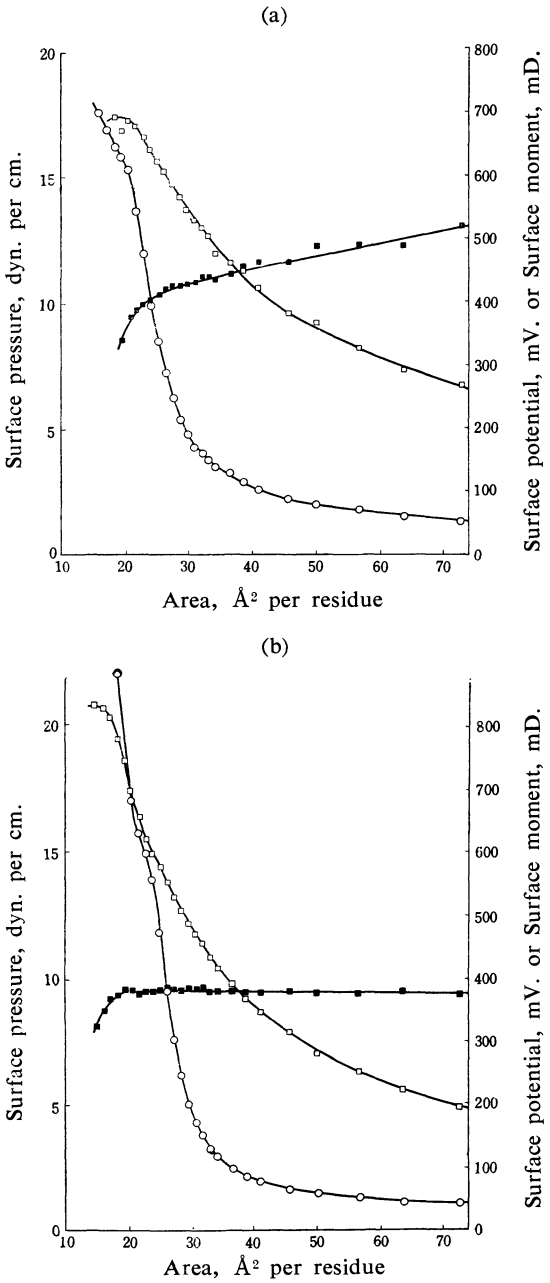

Fig. 5. Monolayers of gramicidin $J_1$ on distilled water in the presence of potassium chloride (15°C). a, 0.01 M; b, 1 M. ○ surface pressure; □ surface potential; ■ surface moment.

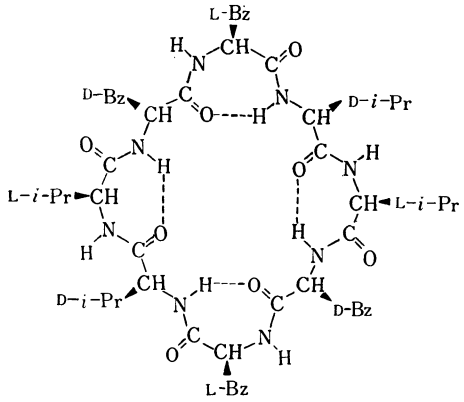
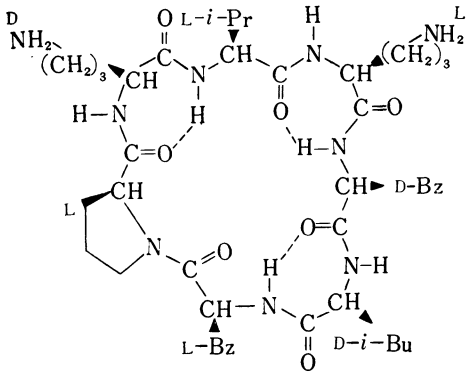
In Fig. 5 are illustrated some of the $\Delta V-A$ and $\mu-A$ curves together with the $\Pi-A$ curves. The surface moment gave no constant value on 0.01 M potassium chloride but a constant value, 380 mD, on 1 M potassium chloride. On the $\Delta V-A$ and $\mu-A$ curves no significant change was observed at the area corresponding to the reversal point on the $\Pi-A$ curve. The surface viscosity was very low and not detected even at an area as small as 10 Å$^2$ on 0.01 M potassium chloride.



In the presence of 0.01 M potassium chloride, the ionized monolayer of gramicidin $J_1$ on neutral subphase was more expanded than the unionized monolayer on 0.01 M potassium carbonate and the surface potential of the former was higher than that of the latter.

## Discussion

**Configurations of Cyclic Peptides in Monolayer.**—The molecular configuration of cyclic peptide has so far been investigated by a polarized infrared spectra[14] and an X-ray diffraction[15] on gramicidin S crystal. The infrared study suggested, that a gramicidin S molecule consists of ten seven-membered rings, each with a hydrogen bond between the imino and carbonyl groups. Few[6] has proposed the configurations of tyrocidines and gramicidin SA in a monolayer in such a way, as the maximum number seven-membered of rings can be formed in a plane and the other peptide bonds can take the $\beta$-configuration. We can deduce the configurations of fungisporin and gramicidin $J_1$ in monolayer in the same way.



In accordance with the above conditions, the configurations of fungisporin in a monolayer are confined to be square-like ones. One of them is illustrated as follows:

13) J. N. Philips and E. Rideal, *Proc. Roy. Soc.*, **A232**, 159 (1955).
14) N. B. Abbott and E. J. Ambrose, ibid., **A219**, 17 (1953).
15) D. Crowfoot-Hodgkin, *Cold Spring Harbor Symp. Quant. Biol.*, **14**, 65 (1950).

An alternative configuration is obtained by shifting each side chain one by one, in either sence, along the perimeter of this configuration, the orientation of side chains being altered. The other possibilities can be obtained by turning each of these two configurations over. It can not be distinguished which side of the molecular plane is exposed to the air or to the aqueous phase, when the molecule is put on surfaces, and consequently all of these four configurations are equally probable.

The unionized gramicidin $J_1$ molecule can take only one confiugration in the monolayer, subject to the foregoing requirements:

An alternative is obtained by turning of this configuration. In considering the difference of D-leucyl and L-valyl residues in hydrophilic nature, it is a little more favorable to choose the latter configuration (if the air is above the plane).

In all these cases of fungisporin and gramicidin, the areas occupied by a residue are consistent with those obtained experimentally. It is remarkable to note that the side chains of all the D-amino acid residues orientate oppositely to these of all the L-residues with respect to the plane of a molecule. Thus, if the side chain of the L-ornithyl residue in gramicidin $J_1$ tends towards the aqueous phase, that of the D-ornithyl residue is directed to the air.

Since the formation of a seven-membered ring will force the carbonyl groups to direct towards the aqueous phase, the surface moment is expected to be higher than that of the $\beta$-configuration. The surface moment of fungisporin is mainly composed of two different orientations of the carbonyl groups, one hydrogen bonded intramolecularly and the other not participating in hydrogen bonding. It was found to be about 200 mD, which is actually higher than that of the $\beta$-configuration, 160 mD[3]. On the other hand, the surface moment of gramicidin $J_1$ is a mean value of three orientations of carbonyl groups, hydrogen bonded, not hydrogen bonded and belonging to L-phenylalanyl residue, and two amino groups of D- and L-ornithyl residues. The experimental value was very high and 340 mD. It is much higher than 273 mD and 274 mD for gramicidin SA and SB[6]. If the contribution of each carbonyl group is assumed to be equally 200 mD, as in fungisporin, the two amino groups must contribute about 980 mD or, in the average, an amino group about 490 mD. This value would be compared with the surface moments of long chain amines, 300 to 400 mD[16]. However, this value is too high if the opposite directions of two ornithyl residues are taken into account. The reason for this and, accordingly, for the large values of the surface moment, as compared with those of gramicidin SA is not clear.

**Condensation and Expansion of the Monolayers.** — Fungisporin gave a monolayer of

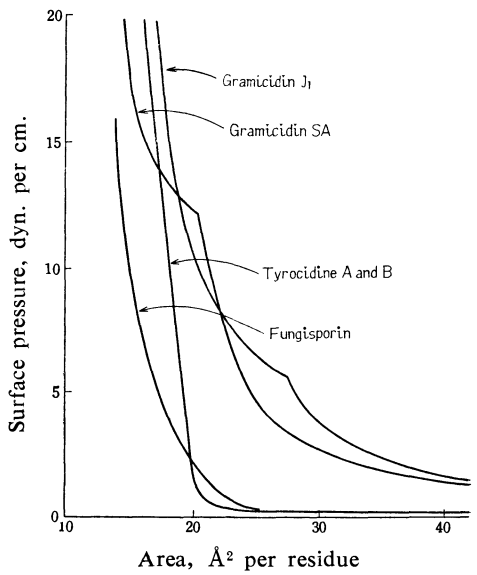


Fig. 6. Surface pressure-area curves of some cyclic peptides. Gramicidin SB gives a nearly identical curve with gramicidin SA.

16) E. F. Porter, *J. Am. Chem. Soc.*, **59**, 1883 (1937); J. Glazer and M. Z. Dogan, *Trans. Faraday Soc.*, **49**, 448 (1953).

condensed type but gramicidin $J_1$ gave an unionized monolayer of expanded type. It was noticed[6] that tyrocidine A and B formed condensed films on aqueous subphases at the ionic strength 1.0, irrespective of pH, but gramicidin SA and SB formed expanded films under the same condition. These results are summarized in Fig. 6. It was concluded by Few[6] that the expansion of films of cyclic peptides is closely related to the content of ornithyl residues. It is, however, known in the case of unionized linear polypeptides[4] that the L-lysyl residue, which has a longer side chain than the ornithyl residue only by one methylene group, does not influence the type of monolayers but remains to be of a condensed type. We, therefore, no longer regard his proposed explanation as adequate. We have previously observed that the monolayers of synthetic linear polypeptides are transformed gradually from a condensed type to an expanded type as the content of prolyl residue is increased[3,12] and further, this effect is virtually demonstrated in the case of protein films such as gelatin[17]. It can be seen that even for the monolayers of cyclic peptide the prolyl residue plays the same role as for linear polypeptides. In comparing the amino acid composition, fungisporin contains no prolyl residue in a heptapeptide[8], gramicidin $J_1$ one in an octapeptide[10], both tyrocidine A and B one in a decapeptide[18,19] and gramicidin SA two in a decapeptide[20]. The proportion of prolyl residues in gramicidins are higher than in fungisporin and tyrocidines. Thus the former peptides give more expanded monolayers than the latter. On the contrary, gramicidin SB, whose complete structure is still unknown, but whose monolayer expands to the same extent as gramicidin SA, will have two prolyl residues if it is a decapeptide.

**Ionization of Dilute Gramicidin $J_1$ Monolayer.**—Because of the expanded nature of gramicidin $J_1$ monolayers, it was possible to measure accurately the surface pressure and potential at the region of very large areas. Then the behavior of dilute ionized monolayers of gramicidin $J_1$ when spread on neutral salt solution can be treated in terms of the theory of the ionized monolayer so far presented.

In general, the surface pressure of an ionized monolayer can be divided into two parts:

$$\Pi = \Pi_0 + \Pi_i$$

where $\Pi_0$ is the surface pressure of an unionized monolayer, which is independent of salt concentration, when the other effect is ignored. In this equation the contribution of deformation due to the electric repulsion is not included. The surface pressure due to ionization, $\Pi_i$, is, according to the theory of the electric double layer[21,22], given by

$$\Pi_i = 2kT\left\{-\frac{2n}{\kappa}+\sqrt{\left(\frac{2n}{\kappa}\right)^2+\frac{1}{A_i^2}}\right\}$$

where $k$ is the Boltzmann constant, $T$ the absolute temperature, $n$ the salt concentration (molecules per $cm^3$) and $\kappa$ the Debye-Hückel parameter. Here $A_i$ is the area per ionized group. Evidently, the surface pressure is lower, as neutral salt is more concentrated in an aqueous phase. However, values of the surface

pressure, $\Pi_0$, at a constant area, which are obtained by subtracting the calculated values of $\Pi_i$ from the experimental values of $\Pi$, should be independent of salt concentration, even if the salt concentration is varied.

The $\Pi-A$ curves of dilute ionized gramicidin $J_1$ monolayers on potassium chloride solutions of various concentrations are shown in Fig. 7. The surface pressure is virtually lower at higher salt concentrations. In the monolayer of gramicidin $J_1$ in an unionized state the two amino groups of ornithyl residues, which are responsible for the ionization of the molecule, are assumed to be oppositely directed to each other. If this configration is still retained in the state of ionization, the electric double layer will be concerned with only one amino group, probably of the L-ornithyl residue. Taking account of this, we have estimated the values of $\Pi_0$ at an area, $A=200$ Å², by the foregoing procedure for both cases, that only one ionized amino group ($A_i=7A$) and two ionized groups ($A_i=(7/2)A$) are assumed to concern the electric double layer. The results are given in Table I. In the former case the obtained values of $\Pi_0$ are nearly constant and positive, unlike in the latter case. Thus it is likely, that the electric double layer is formed by the ionization of only one amino group and not related to that of the other. This might support the proposed configuration of gramicidin $J_1$ in monolayer.

According to Schulman and Hughes[23], the surface potential of an ionized monolayer can be expressed by

$$\Delta V=\frac{4\pi\mu_M}{A_i}+\psi_M$$

where $\mu_M$ is the surface moment of an ionized group (one or two seventh of the moment per amino acid residue according as one or two ionized ornithyl residues) and $\psi_M$ is the potential of the monolayer. In this equation the first term assumes the ordinary Helmholtz equation and the second term is, according to the theory of electric double layer[21,22], expressed by

$$\psi_M=\frac{2kT}{e}\sinh^{-1}\frac{\kappa}{4nA_i}$$

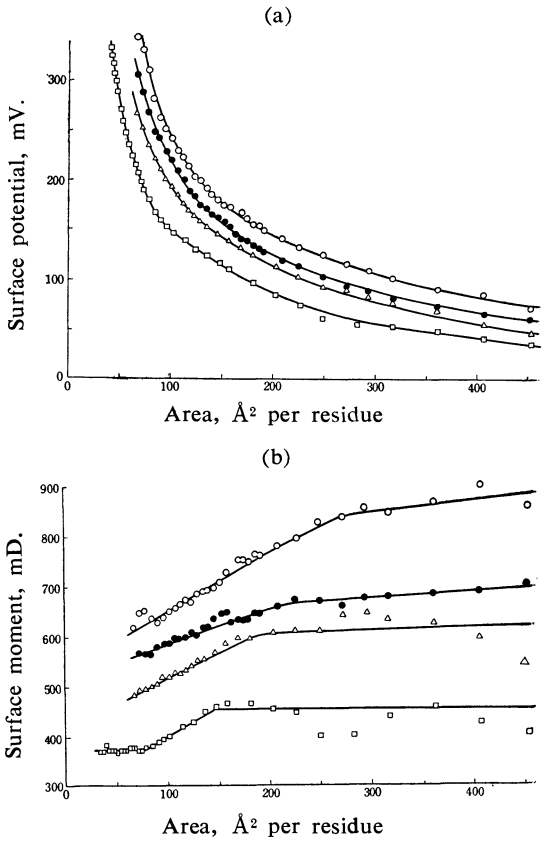

Fig. 8. Effect of potassium chloride on dilute monolayer of gramicidin $J_1$ (15°C). a, surface potential; b, apparent surface moment. ○ 0.01 M; ● 0.025 M; △ 0.1 M; □ 1 M.

where $e$ is the elementary charge. These equations indicate that the surface potential is lower, as neutral salt is more concentrated in the aqueous phase. In Fig. 8a is shown the variation of the $\Delta V-A$ curves with concentration of potassium chloride in the aqueous phase, which is in accord with the above indication. We have found, however, that the same procedure as done for the surface pressure is not suitable to distinguish whether one or two ornithyl residues concern the electric double layer, since the surface potential can not be measured with sufficient accuracy so as to allow it. Instead of doing so, we have tested the above equations by another method. These

23) J. H. Schulman and A. H. Hughes, *Proc. Roy. Soc.*, A138, 430 (1932).

equations show that the apparent surface moment, $\mu$, calculated from $A \cdot \Delta V/4\pi$, generally falls on compression and its value is lower at higher salt concentrations. On highly concentrated salt solutions the apparent surface moment should be constant over a wide region of areas, In Fig. 8b is shown the $\mu-A$ curves for gramicidin $J_1$ on potassium chloride solutions. Although a minor error in surface potential measurement causes a marked scatter of the surface moment at large areas, it can be seen that the general trend of the $\mu-A$ curves is consistent with the prediction. On such a concentrated salt solution as 1 M, however, the Helmholtz equation appears to be obeyed by the ionized monolayer at areas smaller than 90 Å$^2$ but fails to hold at larger areas.

In addition, it was found that only at moderate areas the ionized monolayer obeys the electrochemical equation[24]

$$\left(\frac{\partial \Delta V}{\partial \ln n}\right)_A = -\frac{kT}{e}$$

as illustrated in Fig. 9.

## Summary

Monolayers of two naturally occurring cyclic peptides, fungisporin and gramicidin $J_1$, were investigated by the measurements of surface pressure, potential, and viscosity. Fungisporin, an octapeptide composed of phenylalanyl and valyl residues, gave a monolayer of a condensed type. Gramicidin $J_1$, an electrolytic heptapeptide containing a prolyl and two ornithyl residues, gave an unionized monolayer of an expanded type on an alkaline subphase. It behaved in a somewhat specific manner when neutral salt such as potassium chloride was present.

The configurations of these cyclic peptides in monolayer were suggested in such a way as intramolecular hydrogen bonding could cause a maximum number of seven-membered rings. Then fungisporin can take four possible square-like configurations, which are equally probable, and gramicidin $J_1$ can take two possible configurations. When these configurations of both peptides are put on surfaces, side chains of all the D-residues always orientate oppositely to those of all the L-residues with respect to the surfaces.

In taking account of the condensation and expansion of these monolayers, together with those of tyrocidine A and B and gramicidin SA, it was concluded that cyclic peptides give more condensed monolayers as the contents of prolyl residue are higher. Thus a prolyl residue plays the same role in cyclic peptides as in linear polypeptides.

Gramicidin $J_1$ gave a monolayer of more expanded type on a neutral subphase, and exhibited a characteristic behavior common with ionized monolayers when neutral salt such as potassium chloride was added. At very large areas the the behavior was adequately explained by the theory of the electric double layer, when only one ionized residue was assumed to concern the double layer.

The authors are indebted to Professor S. Otani of the Medical School, Osaka City University, and to Dr. K. Miyao of the Faculty of Agriculture, the University of Tokyo, for the gifts of valuable peptides. This work was partly supported by a grant from the Ministry of Education, to which the authors' thanks are also due.

# *Spectrophotometric Determination of Tellurium(IV) by Extraction with Tributylphosphate*

By Seiichiro HIKIME

(Received October 21, 1959)

Several spectrophotometric methods for tellurium determination have been reported[1-7]. However these methods have still some disadvantages, e. g. troubles in separation by precipitation.

In the study of separation of tellurium from iron[8], the authors have found that tellurium-(IV) complex with thiourea is extracted by tributylphosphate (TBP) from a dilute hydrochloric acid solution in the presence of potassium thiocyanate and the yellow color develops more deeply in the TBP phase than in the aqueous phase. When thiourea or potassium thiocyanate exists alone in the solution, tellurium complex is not extracted by TBP, whereas in case where a large excess of thiocyanate ions exists in the solution whose hydrochloric acid concentration is more than 0.1 N, even a small amount of tellurium is extracted by TBP. The coloration thus developed in TBP was applied to the spectrophotometric determination of tellurium.

## Experimental

**Reagents, Materials and Apparatus.**—*Hydrochloric acid and nitric acid.*—A guaranteed reagent is diluted with pure water to the required concentrations.

*Potassium thiocyanate solution.*—The guaranteed reagent 500 g. is dissolved in pure water and diluted to 1000 ml.

*Thiourea solution.*—The guaranteed reagent 80 g. is dissolved in water at 70°C and diluted to 1000 ml.

*Standard solutions of tellurium(IV).*—Metallic tellurium (2 g.) supplied by Nippon Kogyo Co. Ltd., is dissolved in 30 ml. of aqua regia and the solution is evaporated on a water bath. Concentrated hydrochlorlc acid (10 ml.) is added to the residue and the liquid is evaporated to dryness; this procedure is repeated twice in order to expel any traces of nitric acid from the solution. The residue is again dissolved in hydrochloric acid and diluted with pure water. By this procedure two solutions of tellurium are prepared as a stock solution, i. e., 6 N hydrochloric acid solution containing tellurium in a concentration of 10 g./l. and 3 N hydrochloric acid solution containing 2 g. Te/l. Several standard series of tellurium are prepared by diluting one of these stock solutions with dilute hydrochloric acid.

*n-Tributyl phosphate (TBP).*—TBP is purified by the method reported by Alock et al.[9], and used without dilution after saturation with the reagent solutions under experimental conditions.

A Beckman DU spectrophotometer with 10 mm. cell was used for the measurements of absorbances. pH values were determined by Horiba H-type pH-meter with a glass electrode.

*Procedure.*—The same volume of TBP with that of the sample solution was used for a single extraction without any organic diluent. Although under the experimental conditions tellurium complex is extracted completely with TBP by shaking in a separatory funnel for 30 sec. The shaking was continued for 2 min. to ensure the extraction. The extraction was carried out only at room temperature.

After extraction, both TBP- and aqueous-phase became turbid to some extent, the extent depending on the initial acidity of the aqueous solution. A clean solution, however, was obtained by centrifuge; this treatment gave no remarkable volume change of the two phases.

Potassium thiocyanate solution is added to a sample solution whose pH was controlled to about 1, to which thiourea solution is added. The solution is finally fitted to a constant volume (10 or 20 ml.) and the pH value adjusted to 1 with hydrochloric acid. After 20 min., the same volume of TBP as that of the aqueous solution is added and the mixture shaken for 2 min. with a shaker. When the TBP phase is separated from the aqueous phase, the former is taken out with a centrifugal separator and the absorbance of tellurium(IV) complex in TBP is measured at 400 m$\mu$.

## Results and Discussion

**Absorption Spectrum of Tellurium(IV) Complex in TBP.**—Hydrochloric acid solutions containing 20, 50 and 100 $\gamma$ of tellurium per ml. were prepared, and to its 10 ml. portion were added 5 ml. of potassium thiocyanate solution and 4 ml. of thiourea solution. The

solution was made pH 1.0 with hydrochloric acid and made up to 20 ml. with 0.1 N hydrochloric acid. After 20 min., 20 ml. of TBP was added to the solution, and this mixture was shaken for 2 min. so that the tellurium complex could be extracted to the TBP phase thoroughly. The TBP phase was colored more deeply yellow than that obtained by the use of thiourea solution alone. This coloration was stable at least for 2.5 hr. The absorbance of the solution was measured spectrophotometrically over the range of wavelength, 330 m$\mu$ to 560 m$\mu$. The results are shown in Fig. 1.

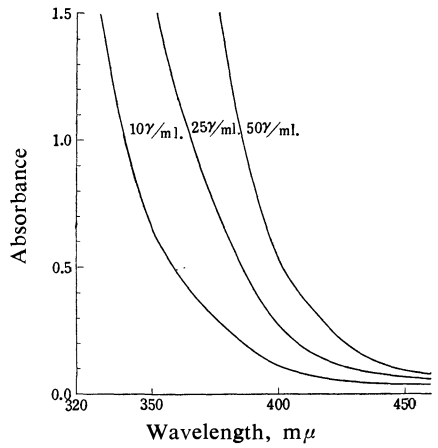

Fig. 1. Absorption curves of tellurium(IV) complex in TBP. KSCN 5 ml., $(NH_2)_2CS$ 4 ml., pH 1, total volume 20 ml., TBP 20 ml.

As shown in Fig. 1, tellurium complex in TBP has strong absorption in ultraviolet region. Although these absorption spectra are similar to those of tellurium-thiourea complex in dilute hydrochloric acid solution, absorbances of the former are several times greater than those of the latter.

**Effect of Potassium Thiocyanate.**—Varying amounts of potassium thiocyanate solution were added to solutions each containing 500 $\gamma$ of tellurium and 4 ml. of thiourea solution. The pH of the solutions was kept about 1. The final volume of each solution was then made up to 20 ml.

Table I shows the absorbance of these solutions as a function of the amount of the reagent added. Constant absorbances were obtained adding more than 2 ml. of the reagent solution; one gram of the reagent, therefore, is sufficient for extracting thoroughly 500 $\gamma$ of tellurium. To refer the effect of potassium thiocyanate on the extraction of tellurium, the amounts of tellurium remaining in the aqueous phase were determined also by thiourea method and the percentages of tellurium extracted were calculated from those values. The results agree with those obtained by the absorbance measurements.

In the absence of potassium thiocyanate, tellurium complex is not extracted with TBP under the experimental condition. However when potassium thiocyanate exists together with thiourea in the tellurium solution, percentage of the extracted tellurium increases with increasing amount of the reagent added, and the tellurium complex is extracted almost completely with TBP, when more than 1 ml. of the reagent is added.

TABLE I. EFFECT OF POTASSIUM THIOCYANATE

| KSCN solution ml. | Absorbance of TBP-phase at 400 m$\mu$ | Te | | |
|---|---|---|---|---|
| | | Taken $\gamma$ | Found, aq. phase $\gamma$ | Extracted % |
| — | 0.000 | 500 | 497 | 0.6 |
| 0.01* | 0.004 | 500 | 479 | 4.8 |
| 0.02* | 0.013 | 500 | 450 | 10.0 |

| 1.0 | 0.262 | 500 | 7.5 | 98.5 |
| 2.0 | 0.278 | 500 | 0.5 | 99.9 |
| 4.0 | 0.279 | 500 | 0.5 | 99.9 |
| 8.0 | 0.284 | 500 | 0.0 | 100 |

Thiourea solution 4 ml., pH 1, total volume 20 ml., TBP 20 ml.
* Added after dilution of the stock solution.

**Effect of Thiourea.**—Since the amount of thiourea also affects the color development of tellurium complex in dilute hydrochloric acid solution, several experiments were carried out to determine its effect. Measurements of the absorbance of the TBP phase showed that 80 mg. of thiourea is sufficient for complexing thoroughly 500 $\gamma$ of tellurium and absorbances are constant beyond this concentration of thiourea.

In order to ensure the results, the amounts of tellurium remaining in the aqueous phase were determined and the percentage of tellurium extracted into TBP phase was calculated. (Table II) The results agree with those obtained by the absorbance measurements.

TABLE II. EFFECT OF THIOUREA

| Thiourea solution ml. | Absorbance of TBP-phase at 400 m$\mu$ | Te | | |
|---|---|---|---|---|
| | | Taken $\gamma$ | Found, aq. phase $\gamma$ | Extracted % |
| — | 0.002 | 500 | 420 | 16 |
| 0.5 | 0.071 | 500 | 289 | 42 |
| 1 | 0.277 | 500 | 2 | 99.6 |
| 2 | 0.278 | 500 | 0 | 100 |
| 3 | 0.276 | 500 | 4 | 99.2 |
| 5 | 0.277 | 500 | 0 | 100 |
| 8 | 0.276 | 500 | 2 | 99.6 |

Potassium thiocyanate solution 2 ml., pH 1, total volume 20 ml., TBP 20 ml.

**Effect of pH.**—In view of possible decomposion of either potassium thiocyanate or thiourea in an acid solution, experiments were carried out in low acidity solutions. A series of solutions were prepared, containing 500 $\gamma$ of tellurium, 2 ml. of potassium thiocyanate solution and 2 ml. of thiourea sulution. The pH values of these solutions were controlled around 1 with hydrochloric acid and similarly extracted with TBP. Results are shown in Table III. The absorbance at 400 m$\mu$ remains constant in the range from pH 0.6 to 1.7, indicating that tellurium complex is extracted with TBP so that it is possibe to extract and determine tellurium over this pH range.

TABLE III. EFFECT OF pH

| pH values before extraction | Absorbance of TBP-phase at 400 m$\mu$ | Te | |
|---|---|---|---|
| | | Found, aq. phase $\gamma$ | Extracted % |
| 0.34 | 0.262 | 2 | 99.6 |
| 0.6 | 0.275 | 0 | 100 |
| 1.0 | 0.278 | 0 | 100 |
| 1.3 | 0.277 | 1 | 99.8 |
| 1.7 | 0.275 | 2 | 99.6 |

Te 500 $\gamma$, KSCN soln. 2 ml., thiourea soln. 2 ml., total volume. 2 ml., TBP 20 ml.

**Stability of Color.**—The yellow color of tellurium complex extracted into TBP phase is very stable and is several times as deep as that of the complex formed with thiourea in dilute hydrochloric acid solution. Four solutions containing 5, 12.5, 25 and 50 $\gamma$ of tellurium per milliliter respectively were prepared and, after extraction, the stability of the color of each solution was tested. No changes were found in the absorbance after exposure in diffused light for 150 min.

**Recommended Procedure.**—To 15 ml. of a sample solution (ca. 0.1 N hydrochloric acid solution containing up to 500 $\gamma$ of tellurium), add 2 ml. of potassium thiocyanate solutions (500 g./l.) and 2 ml. of thiourea solution (80 g./l.). Adjust pH to 1, and make the final volume of the solution to 20 ml. with 0.1 N hydrochloric acid. After 20 min. add 20 ml. of TBP to the solution, and shake for 2 min.

When the TBP phase separates from the aqueous phase, centrifuge the former for 2 min. The absorbance of TBP phase is measured at 400 m$\mu$ with a spectrophotometer with 10 mm. cells.

**Calibration Curves.**—Prior to the determination of tellurium in the sample solution, calibration curves were prepared with a series of solutions containing 1 to 75 $\gamma$ of tellurium per milliliter. The curves are shown in Fig. 2.

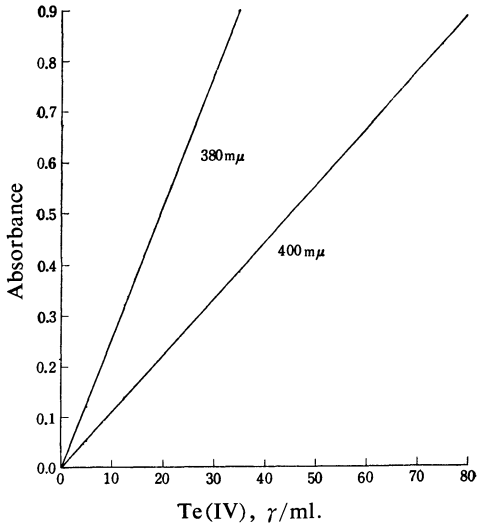

Fig. 2. Calibration curve for tellurium.

| $Al^{3+}$ | $AlCl_3$ | 500 | 0 | 〃 |
| $Mg^{2+}$ | $MgCl_2$ | 50 | 0 | 〃 |
| | | 500 | − 2 | |
| $PO_4^{3-}$ | $H_3PO_4$ | 1400 | 0 | 〃 |
| $SO_4^{2-}$ | $H_2SO_4$ | 1250 | − 2 | 〃 |
| $NO_3^-$ | $HNO_3$ | 500 | 0 | 〃 |
| $WO_4^{2-}$ | $Na_2WO_4$ | 50 | − 1 | 50 |
| | | 500 | −45 | |
| $VO_3^-$ | $NH_4VO_3$ | 10 | 3 | 10 |
| | | 50 | 17 | |
| $CrO_4^{2-}$ | $K_2CrO_4$ | 50 | −54 | 0 |

A linear relationship exists between the absorbance and the tellurium concentration over the range investigated. In many respect, however, measurement at 400 mμ is preferable to that at 380 mμ.

**Reproducibility.**—Several samples were prepared separately in the same way as unknown samples and analysed by the recommended procedure. As shown in Table IV, the reproducibility of this procedure is satisfactory.

**Effect of Diverse Ions.**—Separate tests were made to elucidate the interference of various cations as well as anions on the tellurium determination. The results are shown in Table V. In this table, by "tolerance" is meant the value that gives no significant interference. Under these values the difference between the absorbance of tellurium of the test solution and that of the standard containing no other ions is less than 3%.

A pre-extraction test was also made in which a previous attempt to remove $Bi^{3+}$, $Cu^{2+}$, $Ni^{2+}$ and $Fe^{3+}$ was made, since these ions were considered to have relatively larger interfering behavior. In this experiment, only potassium thiocyanate and no thiourea was added first to the solution of tellurium containing these ions. After a single extraction with the same volume of TBP at pH 1, the organic layer was separated off and the remaining aqueous solution was used to determine the amount of tellurium. Some more potassium thiocyanate and also a necessary amount of thiourea were added to this aqueous solution; tellurium was shaken out to the TBP layer according to the recommended procedure, and then determined spectrophotometrically. As shown in Table VI, a single pre-extraction treatment is not sufficient to give a satisfactory value for tellurium, since about 6% positive error results in the absorbance of tellurium. This means that even after the pre-extraction, there remain some fractions of these ions which are transferred to the TBP layer when the recommended procedure is applied. In the single pre-extraction, $Cu^{2+}$ and $Ni^{2+}$ seems to be extracted only partly although $Fe^{3+}$ and $Bi^{3+}$ may be extracted fairly well. It would be possible, however, to eliminate them to such an extent that they give little effect on the determination

of tellurium, if a better experimental condition were further sought.

## Summary

Spectrophotometric determination of tellurium-(IV) by means of extraction with 100% TBP was studied. Tellurium forms yellow complex, as seen in the literature, with thiourea in a dilute hydrochloric acid solution, and the complex is extracted into TBP whenever potassium thiocyanate is present in excess in the solution.

Conditions on the extraction and the determination of tellurium were examined. It was found that addition of 2 ml. of thiourea solution (80 g./l.) and 2 ml. of potassium thiocyanate solution (500 g./l.) to the sample solution is enough to extract 1 to 500 γ of tellurium per 20 ml. from the dilute hydrochloric acid solution with 20 ml. TBP. Tellurium complex was extracted thoroughly with TBP at pH 1. For the determination of tellurium, the absorbance of the TBP phase was measured spectrophotometrically at 400 mμ.

The effect of the diverse ions on the absorbance of tellurium complex was examined and also pre-extraction test on the removal of interference ions was carried out.

The author wishes to express his grateful thanks to Professor Y. Uzumasa for his kind encouragement and discussion and to Mr. H. Yoshida for technical assistance in this study.

# *A Rapid Method for Determining Fission Products Contained in Waters Using an Ion Exchanger**

By Hiroyuki TSUBOTA and Yasushi KITANO

(Received November 9, 1959)

It is essential to select a proper elutriant in order to separate many constituents in solutions by ion exchange resins. Many elutriants have been used by various researchers[1-7]; among them citrate buffer is used most extensively. However, most of these methods are time-consuming, and the preparation and preservation of elutriants are sometimes rather difficult. Moreover, it is often troublesome to treat the effluent for further chemical or radiochemical examinations. This paper deals with a procedure for rapid and easy separation of alkali, alkaline earth and rare earth elements contained in mixed fission products, by using the formate buffer solution.

A good elutriant should have the following characteristics: 1) There must be complete separation of elements; degree of separation can be expected from the complexity constants between cations in a sample and the anion of the complexing agent used as an elutriant[2,8,9]. When the complexity constants of various cations in the sample differ considerably from each other, these cations can be eluted separately

as the elutriant passes through a column of ion exchanger. 2) Buffer solutions having various pH values should be prepared easily and should be stable. 3) The reagent must be vaporized easily and completely because it is essential that all coexisting materials, other than a compound of the element in question, be removed before radioactive assay. 4) Besides these conditions, the reagents of high quality can be obtained at low cost. From the result of this experiment a formate buffer solution was proved to satisfy these conditions* and to be the best elutriant.

## Experimental

**Elutriants.**—The following elutriants were used for the present experiment:

(A) Hydrochloric acid: 0.2 N.

(B) Oxalic acid: 0.5%.

(C) A buffer solution of 1 M formic acid and 1 M ammonium formate (a formate buffer solution): As shown in Fig. 1, the buffer solutions having various pH values can be prepared by mixing 1 M formic acid solution with varying quantities of 1 M ammonium formate solution.

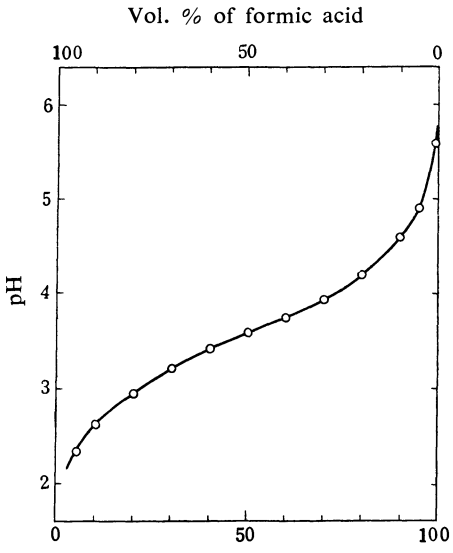

Fig. 1. pH of the buffer solution prepared by mixing 1 M formic acid and 1 M ammonium formate solution.

**Columns.**—Two columns were used:

No. 1, Dowex 50, X8, 100~150 mesh, 1.0×8.0 cm., $H^+$-saturated resin, (exchange capasity, ca. 14 meq.).

No. 2, Dowex 50, X8, 200~250mesh, 1.0×20 cm., $H^+$-saturated resin, (exchange capacity, ca. 35 meq.).

**Flow Rate.**—0.3~0.4 ml./min.

**Sample Solution of Mixed Fission Products.**—The fission products mixture used in this experiment had been supplied from ORNL, U. S. A., and was three years old. Nitric acid was added to the fission product solution, and was evaporated on a water bath. More nitric acid was added to the residue. And 0.1~1 ml. of the nitric acid solution (concentration, approx. 10 μc/ml.) were diluted with 5~10 ml. of 0.2 N hydrochloric acid. This hydrochloric acid solution was used as a sample solution.

**Procedure.**—(A) The sample solution is passed through the column No. 1.

(B) Ruthenium is eluted with about 20 ml. of 0.2 N hydrochloric acid*,[4]. The column is washed by passing 10~20 ml. of distilled water.

(C) Next, zirconium, niobium and uranium are eluted together by passing 50~70 ml. of 0.5% oxalic acid[3,4]. The column is washed with 10~20 ml. of distilled water.

(D) When the formate buffer solution of pH 3.2 (1 M formic acid: 1 M ammonium formate=7:3, in volume) has passed through the column, cesium is eluted in the effluent of a quantity between 50 and 110 ml. Thymol blue is used as indicator because cesium begins to be eluted after the thymol blue indicator in the effluent changes to yellow.

(E) When the formate buffer solution of pH

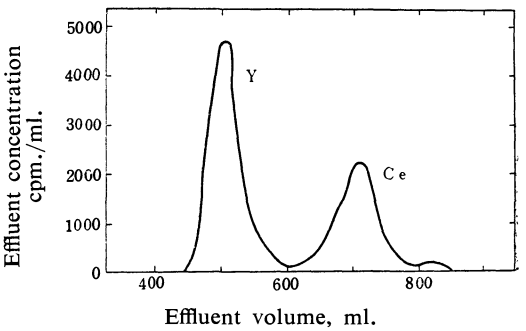

Fig. 2. Separation of rare earth elements.

Flow rate: 0.2~0.3 ml./min.

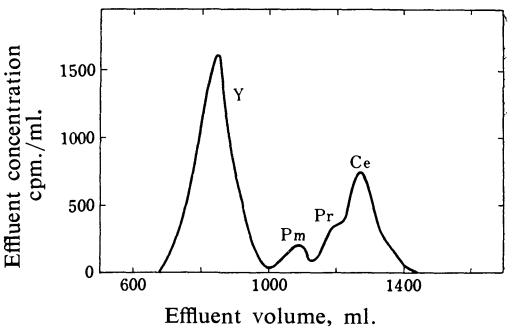

Fig. 3. Separation of rare earth elements.
Column: No. 2.
Elutriant: the buffer solution, pH 3.6.
Flow rate: 0.2~0.3 ml./min.

* They will be discussed in detail elsewhere.

* If I and Te are present, they are eluted together with Ru.

3.8 (1 M formic acid : 1 M ammonium formate=4 : 6, in volume) has passed through the column, all rare earth elements are simultaneously eluted in a fraction between 50 and 170 ml. of the effluent. After this fraction of the effluent has been vaporized, the residue containing rare earth elements is dissolved in a small amount of dilute hydrochloric acid. The resultant solution is passed through the column No. 2, and rare earth elements are adsorbed on it. When the formate buffer solution having pH 3.8 has passed, rare earth elements are separated into yttrium and cerium groups, as shown in Fig. 2. When the formate buffer solution having pH 3.6 (1 M formic acid : 1 M ammonium formate=1 : 1) is used, cerium group elements are further separated into promethium, praseodymium and cerium fractions, as shown in Fig. 3.

(F) After ruthenium, zirconium, niobium and cesium and rare earth elements have been removed, strontium is eluted by passing about 120 ml. of the formate buffer solution of pH 4.2 (1 M formic acid : 1 M ammonium formate=2 : 8) through the column No. 1.

The method is summarized in Table I, and the results are shown in Fig. 4.

**Radioactibity Measurement.** — The effluent is divided into 5 ml.-fractions by means of a fraction collector, and 1~2 ml. of each fraction is transferred into a counting dish. Evaporation and sublimation of the effluent is done by heating the counting dish with an infrared lamp and an electric heater. After the formate is removed completely, the radioactivity is measured by using a G. M. counter. The nuclides can be identified from the decay curves and the absorption curves.

## Discussion

**Elution of Cesium.**—Up to the present time, the elution of cesium has been conducted with hydrochloric acid or citrate buffer solution[10], but neither of these elutriants is satisfactory for the following reasons. When cesium is completely eluted with hydrochloric acid from the column, the adsorption band of strontium moves downward, and consequently, when a further separation of rare earth and alkaline earth elements is to be carried out, a part of

10) M. Honda, Y. Sasaki and H. Natsume, *Japan Analyst (Bunseki Kagaku)*, **4**, 240 (1955).

strontium is eluted together with the rare earth elements and the separation is incomplete. When a citrate buffer solution is used as the elutriant, the process is complicated because, to avoid the uncertainty of separating rare earth and alkaline earth elements, cesium and rare earth elements must be eluted together, and afterwards cesium and rare earth elements must be separated by resorption and chromatographic elution. Finally, it is very difficut to remove citrate from the effluent. When the formate buffer solution having a pH less than 3.4 is used, the adsorption bands of both rare earth and alkaline earth elements never move downward. Therefore cesium alone can be eluted completely by using the formate buffer solution having pH 3.2, as shown in Fig. 5. Ammonium formate and formic acid sublime easily and completely. Therefore, when the effluent containing cesium is evaporated, and an adequate acid is added to the residue and re-evaporated, pure and carrier-free cesium salts can be obtained.

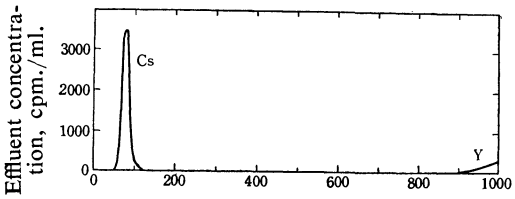

Fig. 5. Elution curve of Cs.
Column: No. 1.
Elutriant: the buffer solution, pH 3.3.
Flow rate: 0.40 ml./min.

**Separation of Rare Earth and Alkaline Earth Elements.**—As shown in Fig. 4, a fairly high radioactivity is found in the effluent intermediate between yttrium and strontium fraction. It is, however, possible to conclude that the radioactivity of this fraction is not due to the incomplete separation of rare earth from alkaline earth elements, but to the elution of $^{90}Y$ coming from $^{90}Sr$ adsorped on the column from the decay of this fraction.

When the formate buffer solution is used, lanthanum is to be eluted last among all rare earth elements to be eluted in the effluent. In other words, amoung rare earth elements lanthanum is the most difficult element to be separated from alkaline earth elements. The solution of fission products used in this experiment is not fresh; hence, it does not contain $^{140}La$ having a half-life of 40 hr. Complete separation of lanthanum from strontium is essential if the sample contains fresh fission products. For this purpose, separation of the two elements was examined by using nonradioactive strontium and lanthanum. One meq. of strontium and 1 meq. of lanthanum are passed through the column No. 1 and are adsorbed, and they are eluted by the formate buffer solution as described above. The effluent is divided into 5 ml.-fractions, and lanthanum and strontium in each fraction are determined by a semi-quantitative method, and the result is obtained as shown in Fig. 6. Fig. 6 also shows the result of 1 meq. of strontium and 1 meq. of mixed rare earth elements, viz., lanthanum, neodymium, praseodymium and cerium. From the figure, it can be seen that strontium is easily and completely separated from lanthanum and also from other rare earth elements by using column No. 1 with the buffer solution having pH 3.8. It can be concluded from this experiment that by using the formate buffer solution, rare earth elements and alkaline earth elements can be separately eluted even when fairly large amounts of carriers are present in the sample to be analysed.

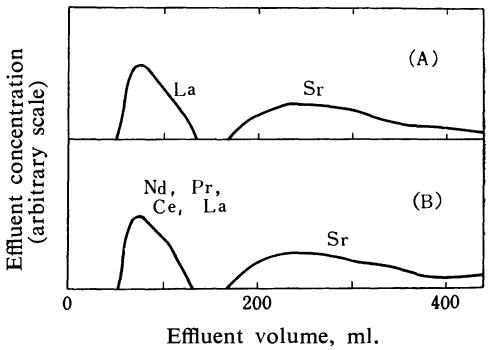

Fig. 6. (A) Separation of La-Sr, (B) Separation of rare earth elements-Sr.
Column: No. 1.
Elutriant: the buffer solution, pH 3.8.
Flow rate: (A) 0.24 ml./min., (B) 0.30 ml./min.

**Separation of Rare Earth Elements.** — Since fresh fission products contain various kinds of the rare earth element, the authors conducted separation of rare earth elements as follows:

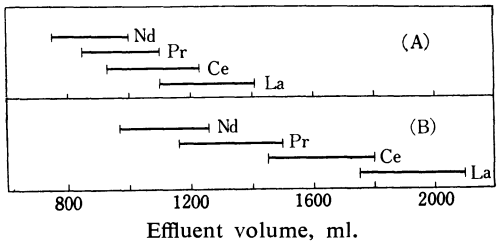

Fig. 7. Separation of rare earth elements.
Column: No. 2.
Elutriant: the buffer solution, (A) pH 3.6, (B) pH 3.4.
Flow rate: 0.25 ml./min.

a mixture of 1 meq. each of neodymium, praseodymium, cerium and lanthanum is adsorbed on column No. 2; the rare earth elements are eluted with the formate buffer solution. The effluent is divided into 10 ml.-fractions, and the elements in each fraction are determined. As shown in Fig. 7, the separation is incomplete when the formate buffer solution having pH 3.6 is used, but when the buffer solution of pH 3.4 is used the separation becomes rather complete. This procedure will be applied for the purification of rare earth elements.

**Separation of Strontium and Barium.**—With the same purpose as described in the preceding section, the authors carried out separation of strontium and barium by adsorbing 1 meq. of strontium and of barium on the column No. 1. As shown in Fig. 8, barium can be separated from strontium very easily and completely.

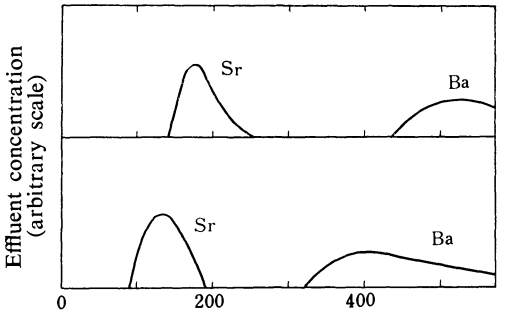

Fig. 8. Separation of Sr-Ba.

Elutriant: the buffer solution, (A) pH 4.0, (B) pH 4.2.
Flow rate: (A) 0.40 ml./min., (B) 0.42 ml./min.

**Separation of Fission Products from Iron.**—To determine exactly fission products in natural waters by ion exchange resin, it is essential that the coexisting elements or carriers must be separated from fission products. Sodium, potassium, magnesium, calcium, ferric and aluminum ions are often found in natural waters, and barium and ferric ions are used as carriers. By using the formate buffer solution fission products can be separated easily from the other metals such as alkali, alkaline earth elements and iron. The separation of alkali and alkaline earth elements will be reported eleswhere[11], and the separation of

Flow rate: 2.0 ml./min.
Arrow indicates the point at which thymol blue indicator changes to yellow from red.

iron and fission products is reported here; this is particularly important for the determination of fission products in natural waters. As shown in Fig. 9, the ferric ion is completely eluted before thymol blue indicator in the effluent changes from red to yellow. By using the buffer solution of pH 3.2, the ferric ion can be eluted long before cesium is eluted.

## Summary

The essential point of this method is the use of the formate buffer solution. This method would be used for the analysis of fission products in natural waters and for the preparation of pure and carrier-free radioactive elements from mixed fission products.

The authors express their sincere appreciation to Professor Yasuo Miyake of Tokyo University of Education and Mr. Masami Izawa of National Institute of Radiological Sciences for their helpful advice and encouragement throughout this work.

# *A Rapid Method for Determining Alkali and Alkaline Earth Elements Using an Ion Exchanger**

By Hiroyuki TSUBOTA and Yasushi KITANO

(Received November 9, 1959)

The present authors previously reported[1] that fission products can be separately eluted more easily and rapidly by using a buffer solution of formic acid and ammonium formate as the elutriant than by using any other elutriants. As reported in that paper, even when fission products in a sample coexist with large amounts of other elements or carriers, they can be completely separated.

Many researchers have separated alkali metals[2-7] and alkaline earth elements[8-10] by using an ion exchanger. They have tried to analyse a mixture of alkali and alkaline earth elements containing other metal ions by using an ion exchange resin; moreover, separation of sodium, potassium, magnesium and calcium ions, which are abundant in nature, has been successful[6,11,12]. They did not, however, include in their experiments such rare elements as cesium or barium. Without including the cesium ion in their experiments, some researchers have stated that univalent ions and divalent ions can easily be separated with an ion exchanger[13,14]. However, the separation between cesium and magnesium ions would be difficult because the cesium ion is eluted last among alkali metals and the magnesium ion is eluted first among alkaline earth elements. The authors conducted systematic experiments on these elements with an ion exchanger and finally succeeded by using the buffer solution of 1 M formic acid and 1 M ammonium formate (the formate buffer solution).

## Experimental and Discussion

**Selection of an Elutriant.**—Separation of alkali metals from alkaline earth metals has been conducted by using hydrochloric acid as an elutriant, when cesium was not included. To find out whether efficient separation can be realized when cesium is present, the following experiment was carried out. 0.1~1 meq. of potassium, cesium and magnesium ions, respectively, were mixed and passed into the column, Dowex 50, X12, 200~250 mesh, 1.1×15 cm., $H^+$-saturated resin, (exchange capacity, ca. 37 meq.), and eluted chromatographically with 1 N hydrochloric acid or 0.5 N hydrochloric acid at the flow rate of 1 ml./min. The effluent was divided into 10 ml. fractions. After evaporation of the fractions potassium and cesium in each fraction were determined from chloride content using silver nitrate standard solution and fluorescent indicator, and magnesium was determined by EDTA standard solution and Eriochrom Black T(EBT) indicator after the pH of the fractions had been adjusted to 10 with ammonium hydroxide.

When 1 N hydrochloric acid is used, potassium and cesium can be partially separated from each other, but magnesium and cesium can not be separated at all although magnesium begins to be eluted shortly before the elution of cesium (Fig. 1). When 0.5 N hydrochloric acid is used, potassium and cesium can be separated completely, but cesium and magnesium can not be separated although cesium begins to be eluted shortly before the elution of magnesium (Fig. 2). Based on these results, it can be concluded that, when cesium and magnesium are to be separated completely, a much longer column and a larger amount of a very dilute hydrochloric acid must be used. In other words, hydrochloric acid is not a practical elutriant for separating cesium from magnesium. The effect of the concentration of hydrochloric acid on the elution of magnesium, as seen in Figs. 1 and 2, can be understood by the fact that the magnesium ion forms $MgCl^+$ complex ion with the chloride ion. Therefore, in order to separate magnesium from cesium, it is essential to use an acid or salts other than chloride. As previously reported[1], when a formate buffer solution was used as the elutriant, cesium and magnesium were completely separated. This elutriant could be prepared and preserved easily and after-treatment of the effluent was done easily because ammonium formate could be sublimed easily and completely. Thus, it was decided to use the formate buffer solution as the elutriant, and separation of elements by using the buffer solution was examined.

**Examination of Methods for Analyzing Alkali and Alkaline Earth Elements.** — (A) *Alkali metals.*—The following two methods were used for determination of alkali metal ions in an effluent.

i) When an effluent containing alkali metals is evaporated and the residue is heated with infrared lamp or electric heater to remove ammonium formate completely, only alkali formate remains. A small amount of hydrochloric acid is added to the alkali formate and evaporation is repeated. The chloride content of the residue is determined by silver nitrate standard solution and fluorescent indicator;

E. B. T.: Eriochrom Black T
P. C.: Phthalein Complexone
*: End point of titration can not be detected.
**: End point is not clear.

then, alkali content can be determined from the chloride content. The results are shown in Table. I.

ii) Alkali content in an effluent is determined directly by flame photometric method. The effect of a large amount of ammonium and formate ions upon the determination of alkali metals must be carefully examined. As given in Table II, however, interference of ammonium formate is not found in 0.5 M ammonium formate solution, and is found slightly in 1.0 M.

(B) *Alkaline earth elements.*—Alkaline earth elements are titrated by EDTA solution containing the magnesium ion using EBT indicator. The formate ion does not interfere, as shown in Table III. It is necessary to adjust pH over 9.5 for the titration with EDTA. As the effluent has a buffer action, the use of an indicator will be preferable, since it does not obscure the end point of the titration by EDTA and changes its color at pH 9.5. Thymol blue indicator satisfies the conditions. One drop of 0.1% water solution of thymol blue is added to an effluent to be titrated, and ammonium hydroxide is added until the color of the solution changes from yellow to blue and then the solution is titrated by EDTA with EBT indicator. As shown in Table IV, the values obtained by EDTA titration are about 1% lower than the added values, and therefore the observed value must be corrected. In some cases strontium and barium are determined by EDTA standard solution and phthalein-complexone indicator.

TABLE IV. THE EFFECT OF pH-INDICATOR ON THE DETERMINATION OF ALKALINE EARTH IONS WITH EDTA

in each fraction were determined by the same method as shown above. The results are as follows:

*(A) Separation of alkali metals.*—It is known that separation factors of sodium, potassium and ammonium in cationic resin of sulphonic type are increased according to the series: sodium < ammonium < potassium. It is, therefore, expected that sodium and potassium can be easily separated when ammonium salt is used as an elutriant. Fig. 3 shows the elution curves of sodium and potassium when ammonium formate solution and the formate buffer solution are used. The separation of potassium and cesium, however, can not be conducted with this buffer solution, as shown in Fig. 4.

*(B) Separation of cesium and magnesium.*—As shown in Fig. 5, cesium and magnesium can be separated completely from each other by using the formate buffer solution having pH 3.2.

*(C) Separation of alkaline earth elements.*—The elution curves of magnesium and calcium, as shown in Fig. 6, are obtained when the formate buffer solutions of various pH are used as an elutriant. From Fig. 6, it can be seen

that magnesium and calcium can be easily separated by the buffer solutions. As shown in Fig. 7, calcium and strontium can be separately eluted by the buffer solution having pH 4.1. Finally, to separate strontium and barium, strontium is first eluted by the buffer solution of pH 4.5, and then barium is eluted by 2 M ammonium formate solution, as shown in Fig. 8.

*(D) Separation of alkali and alkaline earth elements.*—To separate completely alkali and alkaline earth elements, a column of 10 cm. in length may be used. This column length was determined by the plate theory[6] for two ions, sodium and potassium ions which are most difficult to separate in the above experiments.

Sodium and potassium can be separately eluted by using 0.1 M ammonium formate solution. For an early start of elution of sodium, 0.2 M ammonium formate solution may be passed through a column before 0.1 M ammonium formate solution is passed.

To separate potassium and cesium with the formate buffer solution, it is necessary to use a very long column and a large amount of the elutriant. Therefore first it was better to elute

The values in parenthesis are obtained by resorping the $K^+$ and $Cs^+$ fraction in longer column (1.1×15 cm.) and eluting with 0.5 N HCl separately (as shown in Fig. 2).

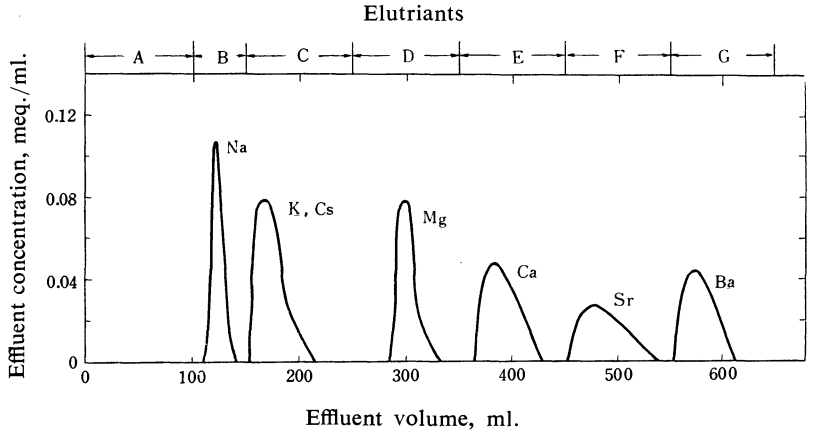

Fig. 9. Elution of alkali and alkaline earth elements.
Column: Dowex 50, X8, 1.1×10 cm., 100~150 mesh, $H^+$-saturated resin.
Flow rate: 2 ml./min.
Elutriants: A 0.2 M ammonium formate solution, B 0.1 M ammonium formate solution, C the buffer solution, pH 3.2, D the buffer solution, pH 4.0, E the buffer solution, pH 4.1, F the buffer solution, pH 4.4, G 2 M ammonium formate solution.

both simultaneously with the formate buffer solution of pH 3.2, and then to separate potassium and cesium by resorption and chromatographic elution with 0.5 N hydrochloric acid.

Cesium and magnesium can be separated by the formate buffer solution having pH 3.2. And the separation of magnesium, calcium, strontium and barium can be conducted by using the same buffer solution with different pH.

Using the column of Dowex 50, X8, or Amberlite IR-120, 100~150 mesh, 1.1×10 cm., and $H^+$-saturated resin, (exchange capacity, ca. 21 meq.), 0.5~1 meq. of sodium, potassium, cesium, magnesium, calcium, strontium and barium ions, respectively, are separated at a flow rate of 2~3 ml./min. The results are shown in Fig. 9 and Table V. Alkali and alkaline earth elements can be successfully separated from each other by the procedure shown in Fig. 9.

**Summary**

Alkali and alkaline earth elements, including their rare elements, can be separately eluted easily, rapidly and completely by the elutriants here described. This procedure and its modified procedures* can be applied to routine analysis of natural waters.

The authors express their sincere appreciation to Professor Yasuo Miyake of Tokyo University of Education and Mr. Masami Izawa of National Institute of Radiological Sciences for their helpful advice and encouragement throughout their work.

# *Studies on Organic Peroxides. V. Decomposition of Benzoyl Peroxide by Iron(II)**

By Shigeo HASEGAWA and Norio NISHIMURA

(Received October 28, 1959)

It has been found that the rate of the decomposition of peroxides was greatly accelerated by ferrous ion[1]. In the presence of the latter, the decomposition is supposed to take place according to the Haber-Weiss one-electron transfer mechanism as follows[2]:

$$P + Fe^{2+} \xrightarrow{k_1} RCOO\cdot + RCOO^- + Fe^{3+} \quad (1)$$

where P and R denote benzoyl peroxide and phenyl group respectively. It is noted that this decomposition is not homolytic but semi-ionic. Therefore, it would be expected that the physical properties of solvents play an important role apart from the discussions about the induced decomposition of benzoyl peroxide. In the previous paper[3], this mechanism was postulated in order to explain the dependence of the initial rate of polymerization of vinyl acetate in the benzoyl peroxide-Fe(II)-benzoin redox system on the initial concentration of ferrous ion. In this paper, the analytical method was applied to the ferrous ion catalysed decomposition of peroxide in order to verify this mechanism.

## Experimental

Reagents used were of reagent grade or prepared by the method reported previously[3]. A definite amount of ferrous chloride crystals ($FeCl_2 \cdot 4H_2O$) was dissolved in ethanol (50 ml.) in a three-necked flask provided by a condenser. The reaction was initiated by the addition of ethanolic solution (50 ml.) of benzoyl peroxide. Oxygen-free carbon dioxide gas was bubbled through the reaction mixture for the purpose of stirring the solution and preventing the ferrous ions from being oxidized by air. Reactions were carried out at temperatures between 15 and 32°C. The analytical procedures of benzoyl peroxide was a modification of the method recommended by Nozaki[4]. At specified times after

the beginning of the reaction, aliquots of the reaction mixture were pipetted out from the flask into an Erlenmeyer flask containing 1 ml. of saturated sodium hydrogen phosphate to eliminate ferric ions, which would, otherwise, disturb the correct analysis of benzoyl peroxide. Five milliliters of acetic anhydride in which 0.3 g. of sodium iodide had been dissolved was added and then allowed to stand about half an hour at room temperature. Iodine liberated was titrated with 0.01 N sodium thiosulfate solution adding 1% starch solution towards the last. This method of analysis is favored by the fact that the atmosphere above the solution to be analysed need not be replaced by inert gas.

Ferrous ion is known to react with $\alpha\alpha'$-bipyridyl forming a very stable red complex which has the maximum absorbance at 510 m$\mu$. Colorimetric measurement was, therefore, applied to determine the concentration of the ferrous ion in the reaction mixture. One milliliter of an aqueous solution of 1% $\alpha\alpha'$-bipyridyl was buffered at pH of 4.75 by acetic acid~sodium acetate solution. Ten milliliters of the reaction mixture was added to the solution followed by dilution with water. When it was allowed to stand at room temperature, colloidal particles of benzoyl peroxide appeared which grew up to precipitate after standing for 2~3 hr. This precipitate was filtered off and the absorbance of the solution at 470 m$\mu$ was measured by a photoelectric colorimeter. A plot of the absorbance against the ferrous ion concentration in a series of blank experiments showed a straight line relationship up to about $1.5\times10^{-4}$ mol./l. of ferrous ion, in accordance with Beer's law.

The initial concentration of benzoyl peroxide was $5\times10^{-3}$ mol./l. in each run.

## Results and Discussion

The extent of the decomposition of benzoyl peroxide induced by ferrous ions was plotted against time as shown in Fig. 1. As is seen from the figure, this reaction takes place with considerable rate even at room temperature.

According to the reaction 1, the rate of the ferrous ion induced decomposition of benzoyl peroxide should be expressed as follows:

$$-\mathrm{d}[P]/\mathrm{d}t = k_1[P][\mathrm{Fe}^{2+}] \qquad (2)$$

or rearranging Eq. 2,

$$-\mathrm{d}\ln[P]/\mathrm{d}t = k_1[\mathrm{Fe}^{2+}] \qquad (3)$$

Instead of the extent of the decomposition, the logarithm of the corresponding volume $v$ of sodium thiosulfate consumed in titration, was plotted against time $t$; this is shown in Fig. 2 for various initial ferrous ion concentrations at 25°C. Extrapolated values of each curve evidently correspond to the initial concentration of benzoyl peroxide. It is to be noted from Fig. 2 that the slope of the curves, i. e., d log $[P]/\mathrm{d}t$ has not suffered a marked change during the reaction. This means that the apparent decomposition rate of benzoyl peroxide is

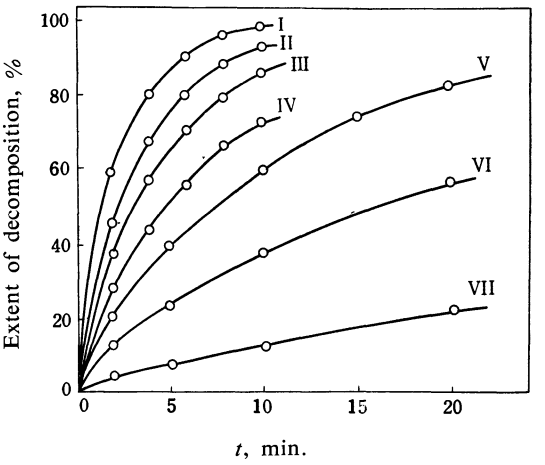

Fig. 1. Extent of decomposition of benzoyl peroxide in ethanol at 25°C. $[FeCl_2]_0\times10^4$: I, 25.1; II, 16.5; III, 13.6; IV, 10.6; 6.8; VI, 5.4; VII, 2.5 mol./l., respectively; $[BPO]_0$: $5\times10^{-3}$ mol./l.

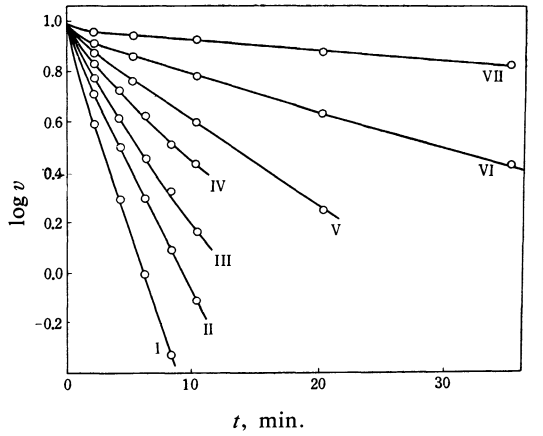

Fig. 2. Relation between log $v$ and $t$. Numbers are identical with those in Fig. 1.

nearly of the first order with respect to benzoyl peroxide. Another evidence for the first order reaction lies in the fact that the slope of the curves in Fig. 3 in which log $v$ was plotted against $t$, seems to be independent of the initial concentration of benzoxyl peroxide.

The slopes of the curves in Fig. 2 seem to be linearly proportional to the initial concentration of ferrous ion. Although care was taken to remove oxygen, the trace of oxygen in the solution might oxidize the ferrous ions. In addition, ferrous ions are oxidized by reaction 1. Therefore, it is necessary to determine the true concentration of ferrous ions in solution.

The ferrous ion concentration in the reaction mixture at any time was determined by the colorimetric method. The slope −d log

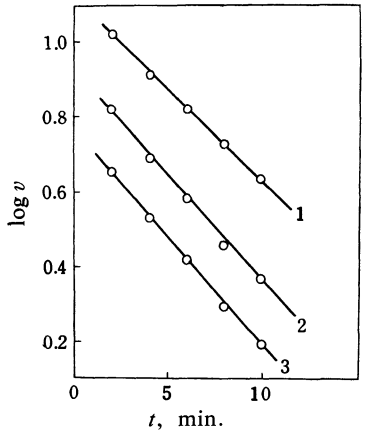

Fig. 3. Relation between $\log v$ and $t$ at 25°C; $[BPO]_0\times10^3$: 1, 7.5; 2, 5.0; 3, 3.3 mol./l., respectively; $[FeCl_2]_0$: $10.1\times10^{-4}$ mol./l.

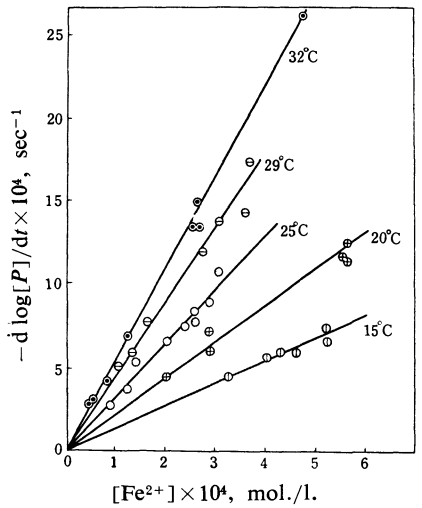

Fig. 4. Plots of $-\mathrm{d}\log[P]/\mathrm{d}t$ against actual ferrous ion concentration in ethanol at various temperatures.

$[P]/\mathrm{d}t$ was plotted against the ferrous ion concentration as shown in Fig. 4. The plots gave straight lines, all of which converged to the origin of the coordinate at each temperature.

Thus it could be said that equation 2 is the complete expression for the reaction rate in accordance with the mechanism postulated above.

Table I shows the numerical values for $[Fe^{2+}]$, $-\mathrm{d}\log[P]/\mathrm{d}t$ and $k_1$ at various temperatures. Fig. 5 shows the Arrhenius plot which gives a straight line. The Arrhenius equation for the decomposition reaction was calculated to be $k_1=2.2\times10^{11}\exp(-14.21\times10^3/\boldsymbol{RT})$ mol.$^{-1}$ l. sec.$^{-1}$ with a standard deviation of 0.40 for $\log A$ and 0.55 kcal. mol.$^{-1}$ for $E$, where $A$ and $E$ represent the frequency factor and the activation energy, respectively.

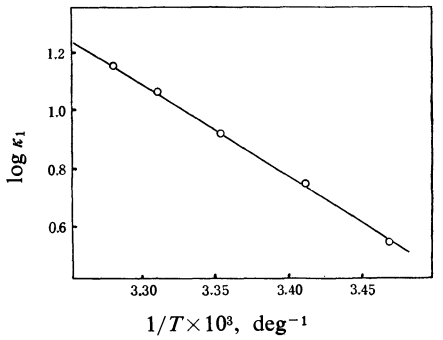

Fig. 5. Arrhenius plot of $\log k_1$ against $1/T$.

As is seen above, the reaction proceeds bimolecularly in accordance with the Haber-Weiss mechanism, and hence the reaction should be of the second order. However, as shown in Fig. 2, the apparent decomposition was approximately of the first order. In order for the reaction to be of the first order, the ferrous ion concentration in Eq. 2 must be kept constant during the reaction. Ferrous ion concentration was decreased rapidly at first, but became nearly contant within 2~3 min. It could be said therefore, that ferrous ion concentration was roughly kept constant during the stationary state.

It is well known that the thermal decomposition rate of peroxides in various solvents can be expressed as[5]

$$-\mathrm{d}[P]/\mathrm{d}t = k_d[P] + k_i[P]^x \qquad (4)$$

where $k_d$ represents the specific rate of spontaneous cleavage, $k_i$ the specific rate constant of induced decomposition and $x$ the order of the induced reaction which may vary between 0.5 and 2.0. In ethanol solution, $x$ was reported to be unity[6], and the apparent decomposition rate was of the first order. In this case, the essential reactions were considered to take place as follows:

$$\mathrm{P} \xrightarrow{k_d} 2\mathrm{RCOO}\cdot \qquad (5)$$

$$\mathrm{RCOO}\cdot + \mathrm{CH_3CH_2OH} \xrightarrow{k_2} \mathrm{RCOOH} + \mathrm{CH_3\dot{C}HOH} \qquad (6)$$

$$\mathrm{CH_3\dot{C}HOH} + \mathrm{P} \xrightarrow{k_3} \mathrm{CH_3CHO} + \mathrm{RCOO}\cdot + \mathrm{RCOOH} \qquad (7)$$

$$\mathrm{CH_3\dot{C}HOH} + \mathrm{RCOO}\cdot \xrightarrow{k_4} \mathrm{RCOOH} + \mathrm{CH_3CHO} \qquad (8)$$

and the apparent decomposition rate was given by

$$-\mathrm{d}[P]/\mathrm{d}t = k'[P] \qquad (9)$$

where $k'$ is a constant including some specific rate constants in the equations given above. The specific rate constant for the spontaneous decomposition $k_d$ may be negligible at room temperature. Hence, in the presence of ferrous ion, reaction 7 will take part in the decomposition of benzoyl peroxide together with reaction 1. The overall rate of the decomposition reaction may be expressed as

$$-\mathrm{d}[P]\,\mathrm{d}t = k_1[P][\mathrm{Fe}^{2+}] + k'[P] \qquad (10)$$

If the reaction 7 occurs predominantly, the mole ratio of benzoyl peroxide decomposed to ferrous ion consumed will be greater than unity. In fact as is seen from Fig. 2, the amount of the peroxide decomposed in each case was much greater than those expected from reaction 1. However, comparing Eq. 10 with Eq. 2 which was confirmed experimentally, the second term of the right hand side in Eq. 10 could be neglected. This indicates that radical-induced decomposition of benzoyl peroxide may be suppressed by the presence of ferrous ions, as in the case of the decomposition of benzoyl peroxide by dimethyl aniline[7].

In order to explain both the first order decomposition and the suppression of reaction 7, reduction of ferric to ferrous ion may be postulated. Since ethanol radical is considered as an electron donor, this reduction would take place through reaction 11:

$$\mathrm{CH_3\dot{C}HOH} + \mathrm{Fe}^{3+} \xrightarrow{k_5} \mathrm{CH_3CHO} + \mathrm{Fe}^{2+} + \mathrm{H}^+ \qquad (11)$$

Thus it may be assumed that the reactions 1, 6, 8 and 11 are predominant. If the stationary state conditions for radicals are applied, then for RCOO·,

$$k_1[P][\mathrm{Fe}^{2+}] = k_2[\mathrm{RCOO}\cdot][\mathrm{CH_3CH_2OH}] + k_4[\mathrm{RCOO}\cdot][\mathrm{CH_3\dot{C}HOH}] \qquad (12)$$

and for $\mathrm{CH_3\dot{C}HOH}$,

$$k_2[\mathrm{RCOO}\cdot][\mathrm{CH_3CH_2OH}] = k_4[\mathrm{RCOO}\cdot][\mathrm{CH_3\dot{C}HOH}] + k_5[\mathrm{CH_3\dot{C}HOH}][\mathrm{Fe}^{3+}] \qquad (13)$$

Therefore, from these equations, it follows

$$k_1[P][\mathrm{Fe}^{2+}] = k_5[\mathrm{CH_3\dot{C}HOH}][\mathrm{Fe}^{3+}] + 2k_4[\mathrm{RCOO}\cdot][\mathrm{CH_3\dot{C}HOH}] \qquad (14)$$

The left hand side in Eq. 14 represents the rate of the oxidation of ferrous ion and the first term of the right hand side is that of reduction of ferric ion. As mentioned earlier, the ferrous ion concentration did not suffer a marked change during the reaction after a stationary state was attained. Hence, the second term of the right hand side in Eq. 14 may be neglected. The main reactions in this study may, therefore, be reduced to reactions 1, 6 and 11. Among these reactions, iron may be considered to serve as electron transferer.

Swain et al.[8] believe that two benzoxy groups

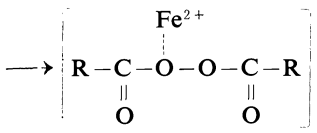
in benzoyl peroxide are dipoles attached to one another in such a way as to repel each other:



and they ascribed the driving force of the decomposition of the peroxide to the electrostatic repulsion between two benzoxy groups. Whereas, Imoto et al.[7] proposed that the driving force was due to the repulsion between oxygen atoms on carbonyl groups,

and successfully explained the effect of substituents on phenyl rings of benzoyl peroxide upon the rate of decomposition in the presence of dimethyl aniline.

In the reaction of benzoyl peroxide with ferrous ion, as is the case for the reaction between benzoyl peroxide and dimethyl aniline, the two species, when they approach, will interact with each other forming an activated complex:

$$RCOO-OOCR+Fe^{2+}$$

$$\longrightarrow RCOO^- + RCOO\cdot + Fe^{3+} \qquad (15)$$

An electron jump from ferrous ion to either of the oxygen atoms bonded to each other will easily take place. Orr and Williams[9] suggested the formation of the activated complex by coördination of the ferrous ion and hydroperoxide.

The spontaneous decomposition of benzoyl peroxide in various solvents has been widely studied by many authors[10] and they found that the activation energy was 28~30 kcal./mol., which is slightly lower than the O—O bond energy, 34 kcal./mol., calculated by Pitzer[11].

A short discussion of activation entropy may be relevant to the present problem. It is noted that the frequency factor of the thermal decomposition of benzoyl peroxide in various solvents is of the order of $10^{13}$~$10^{15}$ $mol^{-1}$ l. $sec^{-1}$, the value for which is abnormally large owing, probably, to the chain process. But, as already stated, in the present case, the factor $A$ was found to be $2.2\times10^{11}$. This will also suggest the fundamental difference in the reaction mechanisms in two cases. Rollefson[12] considers that the activation entropy is a measure of the bond strength of activated complex. The frequency factor of $2.2\times10^{11}$ corresponds to the entropy loss of about 11.2 e. u. provided the transmission coefficient is unity. The value may be compared with $\Delta S^{\neq}$ of $-10$ e. u. which is accompanied by the loss of only one degree of translational freedom[9]. Accordingly, it seems that ferrous ion forms a weakly combined complex with benzoyl peroxide molecule. From the standpoint of the entropy factor, the decomposition mechanism proposed above could again be considered to be reasonable.

## Summary

An investigation of the rate of decomposition of benzoyl peroxide by ferrous ion in ethanol has been made. The rate of the reaction was linearly proportional to the concentrations of benzoyl peroxide and ferrous ion, in accordance with Haber-Weiss one electron transfer mechanism. But the apparent decomposition rate was of the first order. The Arrhenius equation was $k_1=2.2\times10^{11}\exp(-14{,}210/\boldsymbol{RT})\,mol^{-1}$ l. $sec^{-1}$.

# *Molecular Complexes between Ketones and Alkali Salts*

By Haruka YAMADA

(Received December 14, 1959)

Sodium or lithium perchlorate and sodium iodide have high solubilities in ketones. These salts form a sort of molecular complex with ketones. From infrared studies[1,2] it has been shown that the change of the ketone band with salt concentration differs from that in general solvation case, and the non-complexed ketone band is replaced by the shifted band of the complexed ketone; namely, one absorption maximum falls gradually in intensity to be replaced by another. Further, it has been shown that the separation between the complexed and non-complexed ketone bands is independent of anion species. Based on these facts, it has been understood that the formation of the complex is due to the bonding between the C=O group and metallic cation.

These complexes are of interest, because they will give information upon the covalent bond formation, besides the other intermolecular interactions such as ion-dipole, dipole-dipole interaction, London force etc., of alkali metallic ions with some electron donor molecules. The present studies are undertaken to elucidate the electronic states of the complexes.

In ultraviolet absorption spectra, the shifts caused by the formation of the complexes are measured for the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ bands. In order to know whether or not the experimental results obtained here are interpreted based on the theory of charge transfer complex[3], the covalent characters and the stabilization energies of the complexes have been estimated by use of Pauling's " bond-length " relation[4]. By these estimated values, the $n\rightarrow\pi^*$ transition energies of the complexes have been calculated and compared with the observed data.

## Experimental

Ultraviolet absorption spectra were taken with a modified* Perkin-Elmer Model 112 Infrared Spectrophotometer equipped with LiF prism. A $H_2$-lamp and a 1P28 photomultiplier were used as light source and detector, respectively. Wavelength calibration was made by means of the spectra of Hg-lamp and benzene vapor. Cells had quartz windows and lead Spacers. The thickness of the cell was measured by interference method. Spectral slit width ranged from 10 $cm^{-1}$ to 20 $cm^{-1}$.

Infrared spectra were taken with the spectrophotometer mentioned above, by use of $CaF_2$ prism.

Organic compounds were purified by fractionating after drying. Guaranteed commercial anhydrous sodium iodide was used without further purification. Anhydrous sodium perchlorate was obtained heating $NaClO_4 \cdot H_2O$ in an air bath. Lithium perchlorate was prepared by neutralizing lithium carbonate with a slight excess of 60% perchlorate acid, and digesting the mixture on a hot plate until evolution of carbon dioxide ceased, and a clear solution remained. The solution was heated to remove excess acid and the white solid remained. The salt was dehydrated by heating in vacuo to approximately 100°C over phosphorus pentoxide. The anhydrous salts were stored in the dark in a desiccator. Measurements were made for pure ketones and the ketone solutions of the salts. No diluent was added, as no suitable solvent for the complexes was found.

## Experimental Results

**Infrared Absorption Spectra.**—The wave numbers for C=O stretching bands are tabulated in Table I. From this table, it can be seen that the wave numbers for the NaI- and the $NaClO_4$-ketone system are about the same and that the observed shifts are larger for lithium salt than for sodium salt and exhibit a similarity between the acetone- and the cyclohexanonesalt system.

TABLE I. WAVE NUMBERS FOR C=O STRETCHING BANDS

| | Pure liquid | NaI-ketone complex | $NaClO_4$-ketone complex | $LiClO_4$-ketone complex |
|---|---|---|---|---|
| Acetone | 1717 | 1709 | 1710 | 1702 |
| Cyclohexanone | 1714 | 1706 | 1706 | 1702 |
| Acetophenone | 1685 | (1684) | (1680) | (1677) |

**Ultraviolet Absorption Spectra.**—The curves obtained for the $NaClO_4$- and the $LiClO_4$-acetone systems both in 1:4 mole ratio are shown in Fig. 1. The non-complexed acetone band attributed to the $n\rightarrow\pi^*$ transition has a maximum at 36400 $cm^{-1}$. By the addition of the salt the band shifts to higher frequencies with

1. Pure acetone.
2. Acetone-$NaClO_4$ solution (in 4 : 1 mole ratio).
3. Acetone-$LiClO_4$ solution (in 4 : 1 mole ratio).

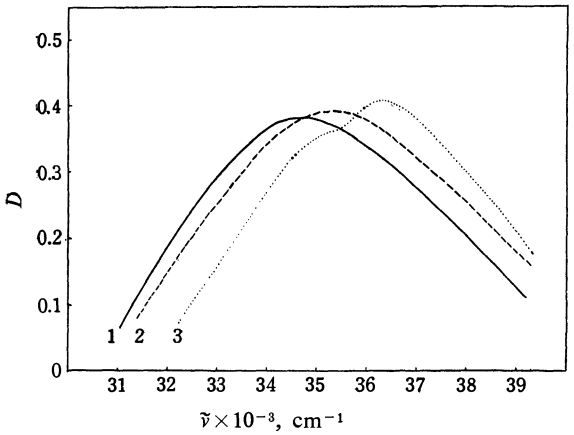

Fig. 2. $n\rightarrow\pi^*$ bands of cyclohexanone and cyclohexanone-salt solutions.
1. Pure cyclohexanone.
2. Cyclohexanone-$NaClO_4$ solution (in 4 : 1 mole ratio).
3. Cyclohexanone-$LiClO_4$ solution (in ca. 6.5 : 1 mole ratio).

the maximum at 36900 $cm^{-1}$ for the $NaClO_4$-acetone system and at 38000 $cm^{-1}$ for the $LiClO_4$-acetone system. The band for the $LiClO_4$-acetone system shows a contour with two peaks at a lower perchlorate concentration. In 1 : 4 mole ratio, almost all the acetone molecules are, therefore, regarded as forming the complex with the salt. For the $NaClO_4$-acetone system the separation between acetone and the complex bands is relatively small and the variation of band contour is not found for changing mole ratio.

The observed curves for the $NaClO_4$- and the $LiClO_4$-cyclohexanone system are shown in Fig. 2. The $n\rightarrow\pi^*$ band maximum of cyclohexanone at 34700 $cm^{-1}$ shifts to 35300 $cm^{-1}$ by the addition of $NaClO_4$ and to 36400 $cm^{-1}$ by that of $LiClO_4$. The curves for the $LiClO_4$-cyclohexanone system measured for various concentrations are shown in Fig. 3. Each band shows the contour of two components. Since all these curves intersect at about 35600 $cm^{-1}$ and the number of cyclohexanone molecules in unit volume, calculated from the specific gravity of the solution, is almost constant over this range of concentration, this point at about 35600 $cm^{-1}$ is the so-called isosbestic point for the $LiClO_4$-cyclohexanone system.

The curves for the $NaClO_4$- and the $LiClO_4$-acetophenone system are shown in Fig. 4. Acetophenone shows a $\pi\rightarrow\pi^*$ band together with the $n\rightarrow\pi^*$ band in ultraviolet region. Although the solubilities of the salts in acetophenone are relatively low, the shifts are observed distinctly. By adding the salt the $n\rightarrow\pi^*$ band, having a maximum at 31250 $cm^{-1}$, shows the blue shift similar to the $n\rightarrow\pi^*$ bands of the other ketones. The red shift of the $\pi\rightarrow\pi^*$ band was observed, although the band maximum was difficult to determine owing to the high intensity. As shown in Fig. 4, the peak of $n\rightarrow\pi^*$ band for the $LiClO_4$-acetophenone system is hardly ever found in 1 : 10 mole ratio and can not be found in 1 : 6 mole ratio, because it is covered with the $\pi\rightarrow\pi^*$ band shifted to lower frequencies.

Although it might be expected from the results of infrared studies that the ultraviolet spectrum of the sodium iodide-ketone system is similar to that of the sodium perchlorate-ketone system, it is not actually the case.

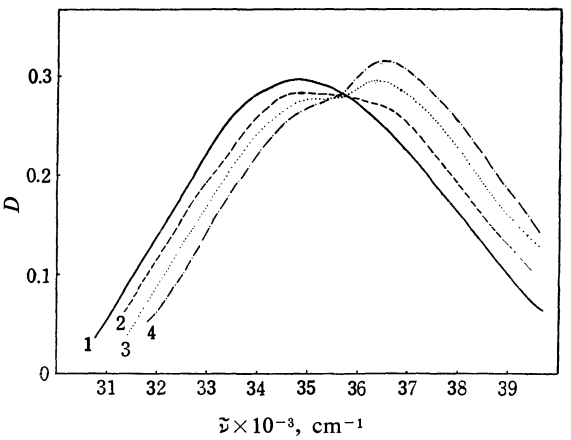

Fig. 3. Curves for cyclohexanone-$LiClO_4$ solutions in various concentrations (27.2 $\mu$ cell).
1. Pure cyclohexanone.
2. ca. 15 : 1 mole ratio.
3. 8.1 : 1 mole ratio.
4. 6.5 : 1 mole ratio (saturated).

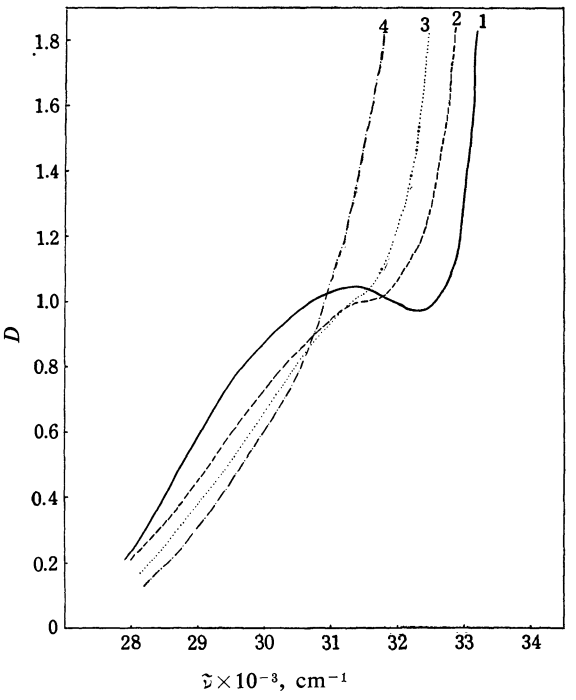

Fig. 4. Spectra of acetophenone and acetophenone-salt solutions.
1. Pure acetophenone.
2. Acetophenone-$NaClO_4$ solution (in ca. 12 : 1 mole ratio).
3. Acetophenone-$LiClO_4$ solution (in ca. 10 : 1 mole ratio).
4. Acetophenone-$LiClO_4$ solution (in ca. 6 : 1 mole ratio).

The curve measured for the sodium iodide-ketone system, however, has a strong absorption ranging from about 31000 $cm^{-1}$ to higher frequencies, which is probably caused by the iodide ion in the solution.

The $n\rightarrow\pi^*$ blue shift and $\pi\rightarrow\pi^*$ red shift phenomena observed here are similar to but generally much larger than those usually observed as general solvent effects. The band contours can be separated into two components. These phenomena are just like those observed for the hydrogen bond formation.

## Interpretations

**Infrared Spectra.**—Although only the C=O bands are shown in Table I, the slight changes for the other ketone bands were also found similar to the sodium iodide-acetone complex[2]. From the fact that the $NaClO_4$-ketone and NaI-ketone complexes show the same frequencies, it follows that the formation of the complexes is independent of anion species. The solubilities of the salts in acetophenone are low and the spectra of the saturated solutions are not those of the complexes but those of the complexed acetophenone overlapped with the non-complexed one. The observed shifts for the acetophenone-salt systems, therefore, are small.

**Covalent Contribution to the Intermolecular Bond.**—By considering a charge transfer force between C=O group and metallic ion, besides the other intermolecular interactions such as ion-dipole, dipole-dipole interaction, London force etc., the intermolecular bonding is expressed as a resonance between following two structures.

$$\text{(A)}\quad C{=}O\quad M^+$$

$$\text{(B)}\quad C{=}\overset{+}{O}{-}M$$

The structure A expresses a no-bond structure and the structure B dative one which is formed by the transfer of the lone pair electrons of oxygen atom to the cation.

To estimate the contribution of the B structure to the complex, Pauling's "bond-length" relation[4] seems to be useful for the complex[5], since this relation holds for intermetallic compounds and also for organic compounds. The relation is represented by

$$R(n)-R(1)=-C\log_{10}n$$

Here, $R$ expresses the atomic radius, $n$ is the number of shared electron pairs involved in the bond and is proportional to the bond order[5], and $C$ a constant. As for the bond length $L$ the following formula is obtained from the formula described above.

$$L(n)-L(1)=-2C\log_{10}n$$

The values of $L(n)$ are estimated to be 2.15 and 2.46 Å for O—$Li^+$ and O—$Na^+$ bonds, respectively. These values are the same as those obtained for $LiClO_4\cdot3H_2O$[6a] and $Na_3SbS_4\cdot9H_2O$[6b] or $Na\cdot Al(SO_4)_2\cdot12H_2O$[6c] crystals in which the $Li^+$ or $Na^+$ ion combines with the ligands of six water molecules by the coordination of the lone pair electrons of oxygen atoms. As $C$ is usually 0.30 for intermetallic compounds and 0.35 for organic compounds, the mean value of them, 0.325, is used for these complexes. By use of the usual covalent radii for $R(1)$[7], the relation $L(1)=R_O(1)+R_M(1)$ and the values of $L(n)$, the values of $n$ are obtained. The suffixes O and M refer to

5) Coulson and Danielson applied in to the hydrogen bonds to estimate the contribution of the B structure, and reported that the results obtained agreed satisfactorily with the results calculated by a semi-empirical method. C. A. Coulson and U. Danielson, *Arkiv För Fysik*, **24**, 239 (1954).

6) a) C. D. West, *Z. Krist.*, **88**, 198 (1934).
b) A. Grund and A. Preisnger, *Acta Cryst.*, **3**, 363 (1950).
c) H. Lipson, *Proc. Roy. Soc.* (*London*), **A151**, 347 (1935).

7) The covalent radii used are $R_O(1)=0.66$, $R_{Li}(1)=1.34$ and $R_{Na}(1)=1.54$ Å.

oxygen and metal, respectively. From the meaning of $n$, the following formula should hold for the complexes,

$$b^2 = n \times (\text{covalent character of the } L(1) \text{ bond})$$

Since the covalent character of the $L(1)$ bond can be estimated from the difference between the electronegativities of two atoms, the covalent character of $L(n)$ bond, $b^2$, is calculated. The results are contained in Table II.

Table II

| | $n$ | Difference of electronegativities | Covalent character of the $L(1)$ bond | $b^2$ |
|---|---|---|---|---|
| O—$Li^+$ | 0.59 | 2.5 | 22% | 0.13 |
| O—$Na^+$ | 0.40 | 2.6 | 20% | 0.08 |

The covalent character of O—$Li^+$ is 13% and that of O—$Na^+$ 8%. It can be seen that these complexes mainly consist of the no-bond structure and the covalent character of O—$Li^+$ is about 1.5 times that of O—$Na^+$.

**Stabilization Energy of the Complex.**—By use of the amount of contribution of the B structure obtained above, the stabilization energy of the complex per one ketone molecule was estimated. According to Mulliken[3], the ground state wave function of the complex is written by

$$\Psi_N = a\phi_A + b\phi_B$$

and the stabilization energy of the complex in ground state is given by

$$W_{AA} - W_N = (W_{BB} - W_{AA})b^2/a^2$$

where $\phi_A$ is the no-bond wave function and $\phi_B$ the dative one,

$$W_{AA} = \int \phi_A H \phi_A d\tau$$

$$W_{BB} = \int \phi_B H \phi_B d\tau = I_P - E_A + V$$

In this case, $I_P$ is the ionization potential of the oxygen atom for lone pair electrons, $E_A$ the electron affinity of the metallic ion and $V$ the energy of the covalent bond between the oxygen atom and the ion. Although the exact values of $I_P$ and $E_A$ are not available, the following ones seem to be reliable, i.e. $I_P = 10.1$ eV., $E_A = 5.39$ eV. for $Li^+$ and 5.14 eV. for $Na^+$. The energy $V$ may be expressed by Morse's function, i. e.

$$V = D_e(e^{-2a(L-L_e)} - 2e^{-a(L-L_e)}), \quad L_e = L(1)$$

where the dissociation energy, $D_e$, is given by the geometric mean of the bond energies $D$(O—O) and $D$(M—M), and $a$ is determined by Badger's rule.

$$a = (k/2D_e)^{1/2}$$

where $k$ expresses the force constant.

Table III

| | $D_e$ (kcal./mol.) | $k$ (dyne/cm.) | $a$ (Å$^{-1}$) | $V$ (eV.) |
|---|---|---|---|---|
| O—$Li^+$ | 30.8 | $0.808 \times 10^5$ | 1.37 | −1.29 |
| O—$Na^+$ | 25.3 | $0.847 \times 10^5$ | 1.55 | −0.977 |

The formation energy of the complex bond, namely the stabilization energy of the lone pair electrons is determined as follows.

$$W_{AA} - W_N = (I_P - E_A + V)b^2/a^2$$
$$= 0.51 \text{ eV. } (O—Li^+)$$
$$0.34 \text{ eV. } (O—Na^+)$$

where $W_{AA}$ is taken to be zero.

**Computation of the $n \rightarrow \pi^*$ Transition Energies of the Acetone-salt Complexes.**—By taking into account the stabilization energies, the $n \rightarrow \pi^*$ transition energies of the complexes can be calculated. As the energy level of lone pair electrons is approximately expressed by the coulomb integral of oxygen atom, the stabilization energy of the complex is due to the decrease of the coulomb integral of oxygen atom. The stabilized energy level may be expressed by

$$\alpha_O' = \alpha_O + (W_{AA} - W_N)/2$$

Here, $\alpha_O$ expresses the coulomb integral of oxygen atom. As for the other numerical values required for the computations, Nagakura's values[8] for acetone molecule are used. They are, $X_C = 2.5$, $X_O = 3.5$, $k = 4.1$, $\alpha_C = 4.35\beta$, $\alpha_O = 5.44\beta$ and $\beta_{CO} = 0.838\beta$ in his notation. The calculated results are shown in Table IV(A), in which the $n \rightarrow \pi^*$ transition energy is expressed by $E_2 - \alpha_O'$. In Table IV(B) the calculated $n \rightarrow \pi$ transition energies are shown in wave number unit, together with the observed data. Here, $\beta = 2.84$ eV. $= 23000$ cm$^{-1}$. It seems more reasonable to compare the calculated

Table IV

value for acetone with the observed value in non-polar solvent than that in liquid.

Although the formation of the complexes is mainly due to the no-bond structures, the $n \rightarrow \pi^*$ blue shift phenomenon is interpreted by use of the results calculated by considering the charge transfer interaction.

The author wishes to express her sincere thanks to Professor K. Kozima for his kind guidance.

# *Intramolecular Interaction between N–H Group and π-Electrons in N-Benzylanilines*

By Michinori Ōki and Kiyoshi Mutai

(Received December 14, 1959)

The discovery[1] of the rotational isomers and the intramolecular interaction between the hydroxyl group and π-electrons in benzyl alcohol derivatives has prompted the authors to examine the N–H stretching absorption of the benzylamine derivatives, since the situation will be much similar in these two series of compounds. The observation of two $\nu_{N-H}$ bands for *N*-benzylaniline was reported by Ōki and Iwamura[1], while Russel and Thompson[2] had reported the presence of two $\nu_{N-H}$ bands for *N*-benzylaniline and attributed them to the rotational isomerism. Moritz[3] also noticed the existence of two $\nu_{N-H}$ bands for some derivatives of *N*-benzylaniline while the present paper was in preparation and the observation of two $\nu_{N-H}$ bands for *N*-allylaniline by Schleyer et al.[4] may also fall into this category.

The present paper deals with the rotational isomers of *N*-alkylanilines in respect of the $C_{aliph}$–N axis and the intramolecular interaction between the N–H group and π-electrons in N-benzylanilines. Aniline derivatives are not the indispensable choice but are convenient for handling, since they do not absorb carbon dioxide from the air owing to the low basicity.

## Experimental

**Measurement and Calculation.**—They were performed as reported previously[5]. The concentration of the carbon tetrachloride solution ranged from 0.003 to 0.005 mol./l.

**Materials.**—The compounds used in the present study are known compounds unless otherwise stated, and were purified through the known method. Their physical constants agreed well with those reported.

*N-(m-Methoxybenzyl)-aniline.*— *m*-Methoxybenzanilide obtained by heating methyl *m*-methoxybenzoate with aniline was reduced with lithium aluminum hydride in ether and the product was purified through fractional distillation. It is a colorless oil, b. p. 200~202°C/21 mmHg, $n_D^{25.5}$ 1.6039.

Found: C, 78.97; H, 7.34. Calcd. for $C_{14}H_{15}NO$: C, 78.84; H, 7.09%.

*N-(m-Dimethylaminobenzyl)-aniline.*—It was prepared similarly as above, starting from *m*-dimethylaminobenzanilide, and recrystallized from ethanol. It forms colorless needles melting at 60–61°C.

Found: C, 79.65; H, 8.12. Calcd. for $C_{15}H_{18}N_2$: C, 79.60; H, 8.02%.

## Results and Discussion

***N*-Alkylanilines.**—The apparent absorption curves for N–H stretching of *N*-alkylanilines are shown in Fig. 1. The curves for *N*-methylaniline is symmetric, while those for N-ethylaniline and for *N*-isopropylaniline are unsymmetric. The unsymmetric curves are divided, assuming that the curve is an overlap of two symmetric curves which can be expressed by the Lorentz function. The results are summarized in Table I.

Inspection of Table I reveals that the positions of absorption curves can be classified as three categories. Namely, band I is located at about 3444 $cm^{-1}$, band II at about 3421 $cm^{-1}$ and band III, at about 3395 $cm^{-1}$. The origin of the splitting of the $\nu_{N-H}$ absorption cannot be attributed to hydrogen bonding among the solute molecules, because firstly, the low concentration such as 0.005 mol./l.

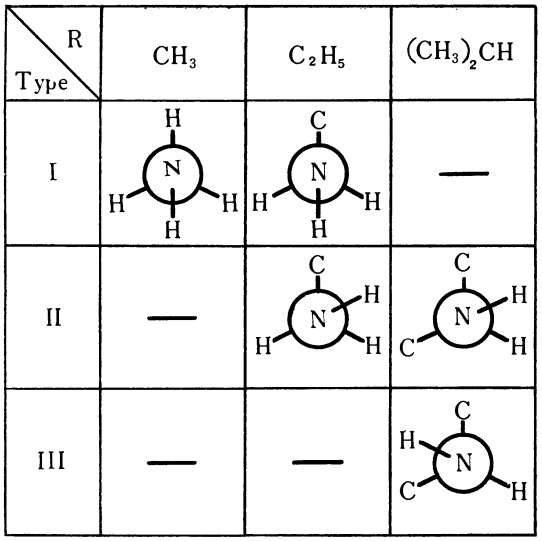

Fig. 2. Classification of rotational isomers in alkylanilines.
The phenyl group is omitted from the diagram for convenience.

TABLE I. $\nu_{N-H}$ ABSORPTION OF *N*-ALKYLANILINES ($RNHC_6H_5$)

| *R* | Band | $\nu_{max}$ cm$^{-1}$ | $\Delta\nu^a_{1/2}$ cm$^{-1}$ | $A\times10^{-3}$ mol$^{-1}$·l.·cm$^{-2}$ |
|---|---|---|---|---|
| $CH_3$ | I | 3442.6 | 29.8 | 4.13 |
| $C_2H_5$ | I | 3445.2 | 18.2 | 0.28 |
| | II | 3421.4 | 34.2 | 2.44 |
| $(CH_3)_2CH$ | II | 3420.5 | 31.2 | 2.19 |
| | III | 3394.5 | 22.0 | 0.30 |

would not permit the dimeric form to exist and secondly any kind of association of the molecules does not explain the symmetry of the absorption curve of *N*-methylaniline examined under the similar conditions as the others.

Thus the variation of the curves must be attributed to the variation of the alkyl group attached to the nitrogen atom and the concept of the rotational isomerism about the $C_{aliph}$–N axis will be valid for the explanation as for a similar phenomenon in the aliphatic alcohols[6].

In Fig. 2, the projection of the molecule through the $C_{aliph}$–N axis, the nitrogen atom being located at the upper side, is shown. A circle indicates a carbon atom as is customary in Newman projection. It is assumed that the molecule does not take an eclipsed form, thence the hydrogen atom of the N-H group in *N*-methylaniline must be in the same situation, because it always comes between the two hydrogen atoms attached to the alpha-carbon atom, no matter what rotational position is taken. On the other hand, when the alkyl group is an ethyl, there are two posibilities, that the hydrogen atom of the N-H group comes either between the two hydrogen atoms of the alpha-carbon atom or between the carbon and the hydrogen atoms combined with the alpha-carbon atom. Thus two rotational isomers are possible for *N*-ethylaniline. Similarly, *N*-isopropylaniline can take two conformations. Band I may be considered to correspond to rotational isomer I, band II to isomer II and band III to isomer III.

The probability of isomer II is 2/3 for both *N*-ethylaniline and *N*-isopropylaniline. However, the observed values widely differ from those expected and isomer II seems to be an overwhelming majority, since it is probable to assume that the light absorption of a molecule is the same irrespective of its conformation. The reason is not completely understood at the present time but it is clear that the steric effect plays an important role, because the nitrogen atom carries a large phenyl group.

**N-Arylmethylanilines.**—*N*-Benzylaniline derivatives have two distinct maxima for N-H stretching absorption and the separation of the two bands are much clearer than in *N*-alkylanilines (compare Fig. 3 with Fig. 1). The apparent absorption curves for *N*-(*p*-nitrobenzyl)-aniline, *N*-benzylaniline and *N*-(*p*-dimethylaminobenzyl)-aniline are shown in Fig. 3.

The electron-withdrawing group such as the nitro group enhances the band at the higher wave number and diminishes the band at the lower wave number. On the other hand, the electron-donating group such as the dimethylamino group shows just the contrary tendency

6) M. Ōki and H. Iwamura, ibid. 32, 950 (1959).

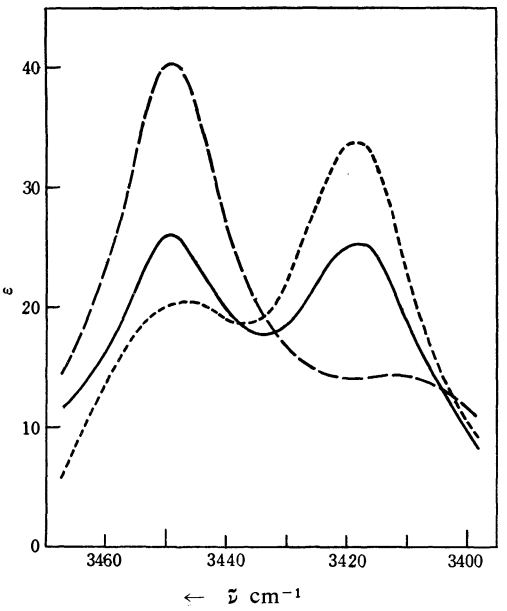

Fig. 3. $\nu_{N-H}$ absorptions of benzylaniline (——), *p*-nitrobenzylaniline (----) and *p*-dimethylaminobenzylaniline (------).

and the absorption at the lower wave number forms the main peak. It is again assumed that the curves are the overlaps of the two symmetric curves which obey the Lorentz function and the apparent curves are divided by Ramsay's first method. The results are shown in Table II.

The ratio $A_i/A_f$, where $A_i$ is the integrated intensity of the absorption due to the interacting form and $A_f$ that of the free form, varies with the electron-donating or electron-withdrawing nature of the substituent and the tendency is indicative of the interaction between the $\pi$-electron and the N-H group. The summation of the integrated intensities due to the two forms also changes when the substituent varies, but this fact may be left out, for comparison of the ratio $A_i/A_f$.

Hammett's $\sigma$ values[7] of the substituents are taken and the relation with $\log(A_i/A_f)$ is compared. $\mathrm{Log}(A_i/A_f)$ instead of $A_i/A_f$ is taken, because the equilibrium between the interacting and the free forms is the subject of the present discussion. As is seen from Fig. 4, the relation is linear when the $\sigma$ constants representing the electron density on the carbon atom[8] ($C_1$), to which the anilinomethyl group is attached, are taken. However, $\sigma$ values for the other carbon atoms or for the position between two carbon atoms are not proportional to $\log(A_i/A_f)$.

Since the benzylaniline derivatives are secondary amines, which belong to the *N*-ethylaniline type (Fig. 2), they should have two

rotational isomers. The absorption due to the free form is closely related to type I of *N*-ethylaniline, because it lies at about 3450 $cm^{-1}$, while type I of *N*-ethylaniline absorbs at 3445 $cm^{-1}$. Thus, the free form of *N*-benzylaniline corresponds to the rotational isomer IV and the interacting form to structure V in Fig. 5. The interaction takes place between the $\pi$-electron on $C_1$ atom and the N-H group, as judged from the relation between $\sigma$ constants and $\log(A_i/A_f)$. Therefore, the structural formula for the interacting form can be represented by structure V.

One problem remains in the above assignment. That is, the number of molecules of the free form of the *N*-benzylaniline derivatives seem to increase in spite of the expectation that the formation of the internal interaction will lessen the free molecules when compared with the number of molecules belonging to type I in *N*-ethylaniline. In the earlier paper[1], it was pointed out that the internal interaction between the hydroxyl group and $\pi$-electrons decreases the number of free molecules. This contradiction may be attributed to the steric effect, since the nitrogen atom carries a large phenyl group. And/or it may be attributed to the difference of the nature of the interactions with the N-H group and with the O-H group series.

The far deviation of the point for *N*(*m*-dimethylaminobenzyl)-aniline might be interpreted in the following way. Jaffé[7] gave $\sigma$ value of −0.20 for the *m*-dimethylamino group and this value is taken in Fig. 4. On the other hand, $\sigma$ value of the *p*-dimethylamino group has been given by Jaffé as −0.60, while the recent paper by McDaniel and Brown[7] gives −0.83. From an analogous consideration, $\sigma_m$ given by Jaffé may be smaller than the true and ambiguous, because of lack of examples. The authors obtain $-0.55\pm0.05$ for the $\sigma_m$ of the dimethylamino group from Fig. 4.

Fluctuation of the position for the interacting $\nu_{H-N}$ will be discussed in "the nature of the interaction".

**N-Benzylarylamines.** — The substituent is introduced into the benzene ring which carries the N-H group to understand the electronic effect. It is expected, that the substituent will vary the nature of the N-H bond. The results are given in Table III.

The effect of the substituent on $A_i/A_f$ is not found in Table III. Thus the electron density at the site of hydrogen approach seems

a) The values are taken from reference 1.

to determine the number of internally interacting molecules.

The things which vary with the varying substituent are the individual absorption peak of the free and the interacting molecules, and the difference of positions of peaks ($\Delta\nu_{max}$) corresponding to each species of the molecule. The absorption maxima of both free and interacting forms move to higher frequencies as the substituent becomes more electronegative, although the relation between the $\sigma$ constants and the frequencies of absorption is not perfectly linear. This result roughly agrees with the data obtained by others[9] who have revealed the relationship in aniline derivatives.

One thing noticeable is that $\Delta\nu_{max}$ between the free and the interacting forms relates linearly with the $\sigma$ value of the substituent (Fig. 6), although the rate of increase or decrease of the frequencies of the free and the interacting forms is not the same and the straight lines, which show the relation between $\sigma$ value and $\nu_{max}$, are not parallel to each other. The phenomenon will be discussed in "the nature of the interaction".

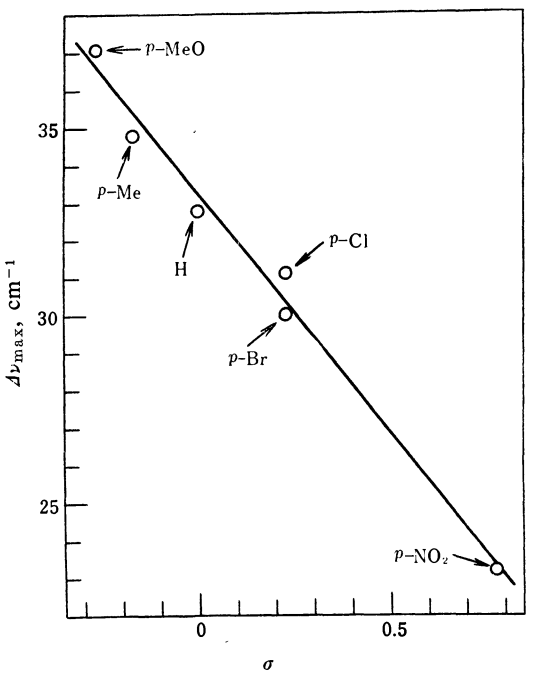

Fig. 6. Comparison of $\Delta\nu_{max}$ of *N*-arylbenzylamines with $\sigma$-values.

**Nature of the Interaction.**—It is now known from Table II that the $\nu_{N-H}$ absorption due to the interacting form does not always appear at the constant wave number, when the substituent is introduced into the benzene ring (ring A) which is included in the benzyl group. This is the striking difference when the situation of the benzyl alcohol derivatives is considered, of which interacting hydroxyl groups

absorb at a reasonably constant frequency. As was already pointed out, the free form absorbs at the constant wave number, ca. 3450 $cm^{-1}$, irrespective of the substituent, indicating the effect of the substituent through the methylene group is negligible.

The relation between $\Delta\nu_{max}$ and $\sigma$ values for the compounds carrying a substituent in ring A, is shown in Fig. 7, which reveals, that the slope of the straight line is not constant but shows a crease at some point. When the electron density on ring A is decreased, $\sigma$ constants and $\Delta\nu_{max}$ are in linear relation, the slope being positive. On the other hand, when $\sigma$ value is below 0.00~0.10, the slope of the straight line is almost zero, i. e., $\Delta\nu_{max}$ seems to have no connection with the substituent.

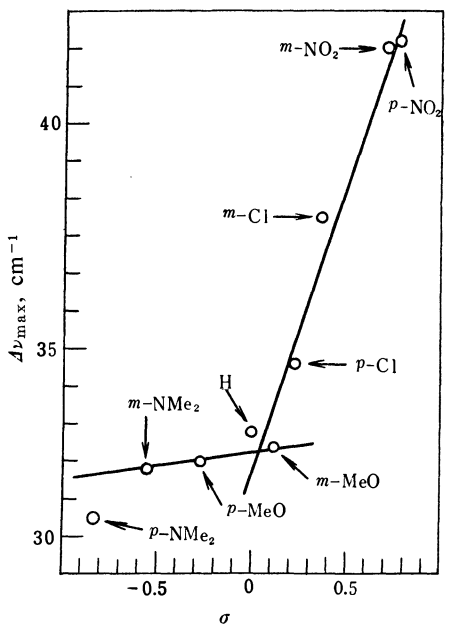

Fig. 7. Comparison of $\Delta\nu_{max}$ of *N*-(arylmethyl)-anilines with $\sigma$-values.

Yet, splitting of the $\nu_{N-H}$ band into two distinct maxima must be attributed to the intramolecular interaction between the N-H group and the $\pi$-electron, no matter which ring carries the substituent. The mechanism of the interaction must also be common in both series of compounds and will satisfy the following conditions. 1) The larger the $\sigma$ constant, the

9) M. St. C. Flett, *Trans. Faraday Soc.*, **40**, 767 (1944); S. Califano and R. Mocca, *Gazz. chim. ital.*, **86**, 1014 (1956); P. J. Krueger and H. W. Thompson, *Proc. Roy. Soc.*, **A243**, 143 (1957).

smaller is the $\Delta\nu_{max}$, when the benzene ring (ring B), which carries the N-H group, bears the substituent. In the case of the substituent involved in ring A, $\Delta\nu_{mnx}$, increases as the $\sigma$ value increases, as far as the $\sigma$ value is larger than 0.1. 2) When a substituent of which the $\sigma$-constant is less than 0.1 is introduced into ring A, $\Delta\nu_{max}$ changes to a negligible extent, regardless of the substituent.

It must be noticed that condition 1 is just the contrary to the case mentioned in $\omega$-arylalkanols[10], In the case of $\omega$-arylalkanols, the hydrogen atom of the hydroxyl group possesses at least a proton-like character and the increasing electron density in the benzene nucleus favors the interaction. The above considerations lead to an idea that is quite different from that developed for the interaction between the hydroxyl group and $\pi$-electrons.

That is, one of the possibilities which will explain the results is the idea of "flow-in" of the electron from the N-H group to ring A. If this idea were taken into consideration, above conditions 1 and 2 would be explained in the following way. The greater the electron-density gap between ring A and the N-H group, the easier the flow of the electron of the latter into the former, as far as the electron density of the N-H group is higher, Thus the force constant of the N-H group is lessened to result in appearance of the N-H band at a lower wave number and also in more $\Delta\nu_{max}$. If the difference of electron densities between ring A and the N-H group approaches zero or the electron density of ring A is higher than that of the latter, the electron of the N-H group does not "flow-out". Then, it will be the field effect that plays the most important role, and $\Delta\nu_{max}$ may appear at the constant wave number, irrespective of the substituent.

Furthermore, if the above assumption is made, it is easier to understand the phenomenon found in *N*-benzylarylamines. When an electron-withdrawing substituent is introduced into ring B, the electron of ring B is attracted to the substituent, hence the electron of the N-H group flows into ring B. The lack of the electron in the N-H group results in a smaller electron-density difference between ring A and the N-H group. This permits the flow of the electron from the N-H group to ring A to a very limited extent, the interaction between $\pi$-electron and N-H group becoming weaker. Thus the strength of the interaction or $\Delta\nu_{max}$ may be proportional to $\sigma$ constant of the substituent, when the substituent is introduced into ring B.

In the above hypothesis, it is assumed, that the interaction takes place as a mere probability. The interaction must be caused by an overlap of the orbitals belonging to the electrons of the N-H group and the $\pi$-electrons of ring A. And the overlap of orbitals will occur more easily, when the electron density of ring A is heightened by the presence of an electron-repelling group. Accordingly, the molecular species which has the internal interaction increases when the electron density of ring A is higher, although the electron flows out of the N-H group into ring A.

A support to the above hypothesis is being sought.

The authors are thankful to Professor Y. Urushibara and Professor T. Shimanouchi for their valuable advice and encouragement and to Mr. H. Iwamura for his technical assistance. The authors are also indebted to the Ministry of Education for the Grant in Aid for the Fundamental Scientific Research.

# *Hydrogen Reduction of a Single Crystal of Nickel Oxide*

By Yoshio IIDA and Kenzo SHIMADA

(Received November 24, 1959)

In an earlier paper[1] it was shown that the reduction of nickel oxide was strongly affected by a small amount of additive incorporated in the nickel oxide lattice. Little attention has been paid to the mechanism of hydrogen reduction of metal oxide, while the mechanism of oxidation of metal has been studied successfully since Wagner's theory[2]. Recently Baba[3] explained the mechanism of hydrogen reduction of germanium dioxide by assuming that the reduction is governed by an autocatalytic behavior. Murata[4] reported that a diffusion process of cation or anion is a rate-determining process in the hydrogen reduction of iron oxide. In their experiments oxide powder was used as a specimen. As powder exhibits complicate properties resulting from particle size and shape, powder is thought to be unfavorable to the study of the mechanism of the hydrogen reduction. From these points it is desirable to study the hydrogen reduction of a single crystal. In the present study the hydrogen reduction of a single crystal of nickel oxide has been carried out to explain the mechanism of the reduction.

## Experimental Procedure

A single crystal of nickel oxide was prepared by Tochigi-Kagaku Co. in a way similar to Verneuil's method[5]. Rectangle specimens of 6×4×3 mm. were cut out from the raw material. The specimens were not subjected to further treatment.

Nickel nitrate recrystallized four times was heated at 800°C for 10 hr. to obtain nickel oxide powder. The average particle size of the nickel oxide was about 0.5 $\mu$ according to an electron micrograph.

The weight loss during the reduction process was measured by the thermobalance with a sensitivity of 0.5 mg. The apparatus could be used in hydrogen or in vacuo. After the specimen was heated in vacuo at a desired temperature, it was reduced with hydrogen. Hydrogen was used from a commercially available tank after purifying it with concentrated sulfuric acid, hot platinum asbestos, potassium hydroxide and phosphorus pentoxide.

## Results and Discussion

**Time-dependent Study.**—A comparison of a reduction-temperature curve of a single crystal of nickel oxide with that of nickel oxide powder when heated at a velocity of 100°C/hr. is shown in Fig. 1. It is seen that a rate of reduction of the single crystal is much lower than that of the powder. It should be noted that there is the stage at about 500°C in the case of the single crystal where the reduction slows down. In order to elucidate the mechanism of the hydrogen reduction of nickel oxide, the isothermal reduction of the single crystal was studied in the range of 300°C to 800°C. The results are shown in Fig. 2. To see whether

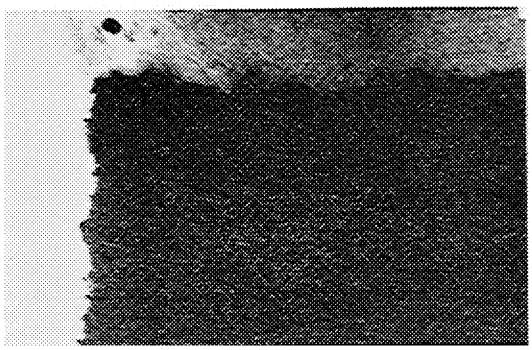
the isotherms can be expressed by the parabolic law, a square of the reduction loss per gram is plotted against the reduction time. Fig. 3 shows that the reduction of the single crystal does not obey the parabolic law. A rate of reduction of the single crystal does not always increase with an increase in the reduction temperature. In Fig. 4, the time required to obtain 50% reduction is plotted against the reduction temperature. It is seen that the time at 350°C is shorter than that at 300°C whereas the time increases with an increase in the reduction temperature in the range of 350°C to 500°C. Since the time is reversely proportional to the rate of the reduction, the rate is lowest at 500°C and then increases with an increasing temperature as do ordinary chemical reactions. The stage at which the reduction does not proceed in the reduction-temperature curve of the single crystal at 500°C is attributed to the lowest rate of the reduction at 500°C. In the reduction of nickel oxide powder or other metal oxide such as ferric oxide and tungsten oxide powder, these phenomena were not observed.

**Microscopical Examination.** — Reduction of the single crystal oxide proceeds layer by layer as shown in Fig. 5. The specific gravity of



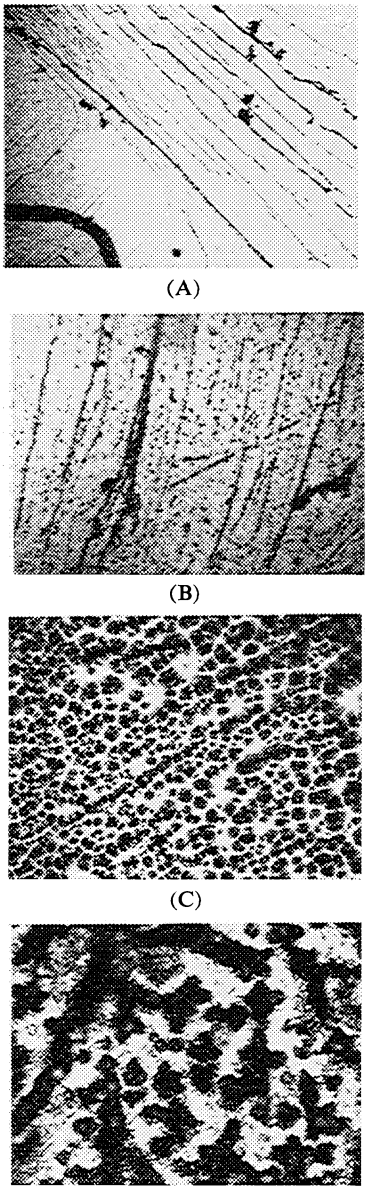


Fig. 5. A section of a single crystal of nickel oxide reduced partially. A white part is a reduced nickel phase and a brack part is an unreduced nickel oxide phase. (×20)

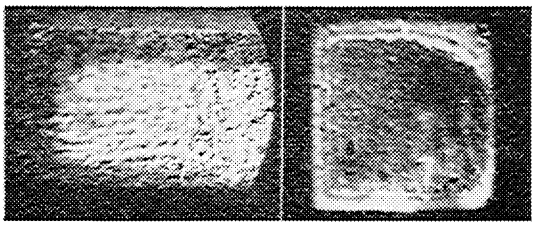
the single crystal of nickel oxide is 6.8 and that of nickel is 8.90. As a volume ratio of nickel oxide is 6.8/8.9=0.76, the specific volume of nickel is lower than that of nickel oxide. Accordingly, the nickel layer formed on the nickel oxide by the hydrogen reduction should be very porous. The reduction mechanism is considered schematically as follows. Hydrogen passes through the porous nickel layer, and reacts with nickel oxide at the boundary of nickel and nikel oxide. The water formed as a result of the reduction is released from the boundary. The penetration of hydrogen through the porous nickel layer is very easy because of its small molecular size. However, the desorption of water through the nickel layer is thought to be very difficult because of its large molecular size. By this reduction schema, the desorption of water formed is considered to be a rate-determining step in the hydrogen reduction process. Nickel formed on the surface of nickel oxide by the reduction is composed of very fine particles, and the particles start to sinter with an increase in the reduction temperature[6,7]. It is expected that the number and size of the pores decrease at higher temperatures by sintering, and the desorption of water through the pores is retarded. It may be attributed to

6) R. Ueda, *J. Japan Inst. Metals (Nippon Kinzoku Gakkai-Shi)*, **23**, 292 (1959).
7) P. H. Emmett, "Catalysis" Vol. I The Waverly Press, Inc., New York (1954), p. 371.

the change of the pores by sintering that the rate of reduction decreases in the range of 350 to 500°C.

While the sintering is enhanced above 500°C, a pressure of water vapor increases and thus the water vapor passes through the nickel layer forming large pores at higher temperatures. Water vapor can easily be released through the large pore and then the reduction process is promoted above 500°C as shown in Fig. 4.



(A) (B) (C) (D)

Fig. 6. Microphotographs of the surface of a single crystal of nickel oxide reduced at various temperatures. (A) is for the unreduced crystal; (B), for the crystal reduced at 400°C: (C), for the crystal reduced at 800°C: and (D), for the crystal reduced at 1000°C. (×400)

A microscopical examination shows that these explanations are correct. Fig. 6a is a microphotograph of the free surface of the unreduced single crystal. Fig. 6b shows that there are many small pores on the surface of the single crystal reduced at 400°C. It is seen in Figs. 6c and 6d that the pores become larger when the single crystal was reduced at 800 and 1000°C. From these facts it is concluded that the release of water from the boundary of the metal and the oxide is a rate-determining step in the hydrogen reduction of the single crystal of nickel oxide.

**Study on the Reduction of Nickel Oxide Powder.**—It is of interest to see whether the reduction of nickel oxide powder can be explained by the above mechanism. Nickel oxide powders of which praticle size was about 1 $\mu$ were compressed to a tablet of 10 $\phi \times 5$ mm. at a pressure of 1000 kg./cm$^2$. The bulk density of the tablet was 3.2 g./cc. and its porosity was 52%, which was thought to be sufficient for the penetration of hydrogen or the release of water. It is expected that each nickel oxide powder can be reduced homogeneously all over the tablet, and the reduction of each powder is governed by the above mechanism. The tablet was reduced at 180 and 250°C. Fig. 7 shows the section of the tablet reduced incompletely. It is seen that the reduction proceeds layer by lager in spite of the porous tablet. At 250°C at which there is no induction period, the reduction starts at the exterior of the tablet. At a reduction temperature of 180°C at which there is an induction period of reduction, the reduction starts at the interior of the tablet. It is generally accepted that a rate of oxidation of nickel is negligibly small below 300°C[8]. The outer oxide layer observed in the reduction of 180°C can not be attributed to the re-oxidation with oxygen contained in hydrogen or with water formed. These facts can not be explained completely by the mechanism reported in the previous literatures[2,3]. At present there is no

(A) (B)

Fig. 7. A section of a compact of nickel oxide powder reduced at 250°C (A) and 180°C (B). (×10)

8) A. E. Gulbransen and K. F. Andrew, *J. Electrochem. Soc.*, **101**, 128 (1954).

alternative but to say that the reduction of nickel oxide powder proceeds topochemically.

**Crystal Growth of Nickel Reduced.**—It is reported[9] that oxide film formed on the metal surface by oxidation has a preferential orientation related to the crystal orientation of the metal. No attention has been paid to the crystal growth of the reduced metal on the metal oxide by the hydrogen reduction from the viewpoint of the crystal orientation of the reduced metal and the metal oxide.

The plane of cleavage of the single crystal of nickel oxide is known to be (100) plane[5]. The nickel layer reduced on the (100) plane of the single crystal of nickel oxide at 1000°C was etched and examined microscopically. The result is shown in Fig. 8, where a square etch pit is seen. It is concluded that nickel formed on (100) plane of nickel oxide by the reduction has (100) plane as perferential orientation.

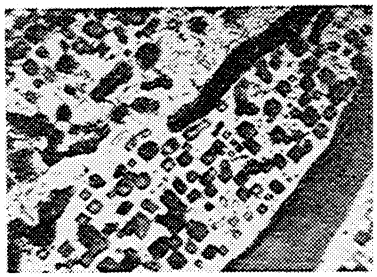


Fig. 8. Etch pit of reduced nickel. The etching reagent is concentrated nitric acid. (×400)

## Summary

In the hydrogen reduction of a single crystal of nickel oxide, the rate of reduction does not always increase with an increase in the reduction temperature. In the range of 350 to 500°C the rate decreases with the temperature, and the rate is the lowest at 500°C. These facts are explained reasonably by the microscopical examination of the surface of the reduced nickel. It is concluded that the desorption of the water formed through the pores is a rate-determining step in the reduction of the single crystal of nickel oxide. The nickel formed on (100) plane of nickel oxide by the reduction has (100) plane as a preferential orientation.

The single crystal of nickel oxide was kindly presented to us by Tochigi Kagaku Kogyo Co.

# *Partial Molal Volumes of Butyl Alcohols and of Related Compounds in Aqueous Solution*

By Koichiro NAKANISHI

(Received December 4, 1959)

The excess function of any thermodynamic quantities for liquid mixtures is symmetric in form with regards to the mole fraction of component, if the components are the "normal liquids" which consist of the spherical molecule with no specific interaction. However, this symmetry fails when the size and form of one component are different from those of another, or when a specific interaction plays an important role in intermolecular force. In the "associated solution", this specific interaction which is attributed to the formation of hydrogen bonding is predominant, and the anomaly in the behavior of the excess function is often observed for a number of such systems[1].

The same is true for the excess volume (the volume change on mixing). For binary mixtures of the normal liquids the excess volume is generally small and nearly symmetric in form, and the interrelationships with other thermodynamic properties and parameters of the intermolecular force have been also investigated, both experimentally and theoretically, by many authors[2]. On the other hand, large negative excess volume is observed generally for the liquid mixtures containing water, alcohols or other associated liquids as one or both

components. The partial volumes of both components show complicated behavior with the variation in the composition of the component. The case of water-ethanol system, which has often been cited in many text-books of chemical thermodynamics, is a well-known example. At present, we have no clear understanding of this phenomenon, although a qualitative explanation[3] accounts for it as the disintegration of structure in water by the solute molecule which is capable of forming the hydrogen bonding with water.

It seems to be natural to expect an anomaly similar to the above for the case of aqueous solutions of alcohols other than ethanol and of other compounds having the hydroxyl group. In the present study, we obtained the dependence of partial molal volumes in water upon the composition for four isomers of butyl alcohol from the density measurement and compared them with that of other alcohols. For comparison's sake, the partial molal volume of ethylene glycol was also evaluated. In each case concerned, the general feature of partial volume vs. composition curve was the same as that for the case of ethanol in water.

3) For example, A. G. Mitchell and W. F. K. Wynne-Jones, *Discussion Faraday Soc.*, No. 15, 161 (1953).

## Experimental

**Purification of Materials.**—*Normal*, *iso*-, *sec*.- and *tert*.-butyl alcohols and ethylene glycol were prepared as follows. The best grade available was dried over dehydrating agents and then fractionally distilled.

*n*-Butyl alcohol was at first treated with dilute sulphuric acid and sodium bisulphate solution for the removal of ketones and aldehydes, and then heated under reflux with a small amount of sodium hydroxide solution for the removal of esters. After the removal of alkali, the material was dried over calcium hydroxide, refluxed with calcium oxide, and then fractionally distilled a few times.

Isobutyl alcohol and *sec*.-butyl alcohol were boiled under reflux over calcium oxide for a few hours, and then fractionally distilled.

*tert*.-Butyl alcohol was dried over anhydrous potassium carbonate at 46°C for a long time, and then fractionally distilled.

Ethylene glycol was distilled under reduced pressure, and the middle fraction was dried over anhydrous sodium sulphate for a long time. The material was then redistilled.

Water was obtained by the repeated distillations of conductivity water.

All the sample liquid were stored in sealed glass containers and redistilled immediately before use. The densities of the sample liquids at 20°C were within 0.00005 g./cc. of the values given in literature.

**Pycnometers.**—The pycnometers used were of ordinary bicapillary type. Type A held slightly more than 25 cc. of liquid, while type B slightly less than 10 cc. The main body of the pycnometer was the usual flat-bottom type. The capillaries were calibrated with a travelling microscope by the conventional method of moving a small mercury column. In the middle of each capillary, a horizontal razor mark was applied and the volume of pycnometer with meniscus on this mark was obtained by the measurement with water.

**Density Measurement.**—The component liquids were mixed in a glass-stoppered weigh-bottle having a narrow mouthpiece. The mole fraction of the sample solution was determined from the weight of each component.

After being kept over night, the sample solution was transfused into the pycnometer by injection with a medical syringe until each of the two meniscus was near the horizontal mark on the capillary. The pycnometer was then placed into the thermostat at $20\pm0.005$°C, and when complete thermal equilibrium was attained, the height difference between the meniscus and the mark was determined by means of a travelling microscope reading to $\pm0.01$ mm.

Immediately after the volume determination, the apparent weights of the pycnometer and the sample solution were determined with an analytical balance. The values were converted into true weights by the cnventional procedure in which the buoyancy corrections were applied.

Thus, the densities of sample solutions were obtained with a precision of $\pm2\times10^{-5}$.

## Results and Discussion

**Densities.**—The density data of butyl alcohol-water and ethylene glycol-water systems are summarized in two tables. Table I shows the densities of aqueous solution of four isomers of butyl alcohol, and Table II shows the densities of ethylene glycol-water system at 20°C. In all cases concerned, the densities of the solution can not be expressed by the conventional power series relation.

Table II. Densities of aqueous solution of ethylene glycol at 20°C

| Wt. % | Density | Wt. % | Density |
|---|---|---|---|
| 1.5193 | 1.00013 | 30.440 | 1.03894 |

| 15.768 | 1.01879 | 80.617 | 1.09830 |
| 17.972 | 1.02182 | 87.942 | 1.10459 |
| 21.213 | 1.02621 | 94.169 | 1.10924 |
| 23.957 | 1.03001 | 100.000 | 1.11313 |
| 28.545 | 1.03628 | | |

**Volume of Mixing (Excess Volume).**—Since the specific volumes of both components are known (except for *tert.*-butyl alcohol which has the melting point above 20°C), the volume of the mixing $\Delta V$ is easily calculated from the present data. It is a common characteristic that $\Delta V$ has large negative value in the whole range of composition and that there is an inflection point below the alcohol mole fraction of 0.1. Fig. 1. shows the general feature schematically.

**Partial Volumes.**—Partial specific (molal) volumes of alcohols $V_2$ are calculated from the density data directly by Eq. 1, or from the concentration dependence of apparent specific volume $\phi_2$ by Eq. 2,

$$V_2=(1/d_{12})+(1-w_2)\frac{\partial(1/d_{12})}{\partial w_2} \quad (1)$$

$$V_2=\phi_2+w_2(1-w_2)\frac{\partial\phi_2}{\partial w_2} \quad (2)$$

where the apparent specific volume is defined as follows,

$$\phi_2=(1/d_1)-(d_{12}-d_1)/(d_{12}d_1w_2) \quad (3)$$

and $d_{12}$ is the density of solution, $d_1$ is the density of water and $w_2$ is the weight fraction of alcohols.

As in the well-known example of ethanol-water system, characteristic behaviors of partial molal volume vs. composition curves are obtained with all systems investigated. Partial molal volume of alcohol decreases with increasing its mole fraction, reaches a minimum value and then increases gradualy to the molal volume. In the whole range of composition, it is always smaller than the molal volume $V_2^0$. Partial molal volume of water, on the other hand, increases slightly with increasing the alcohol mole fraction, reaches an indistinct maximum and then decreases gradually.

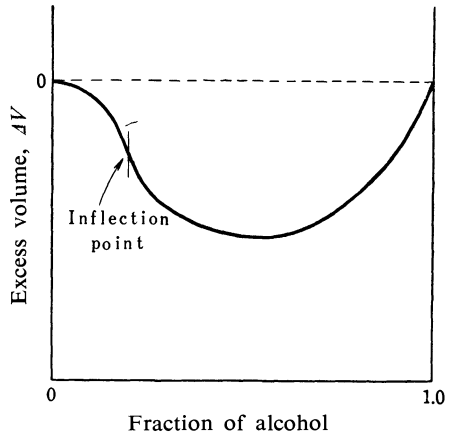

Fig. 1. Schematic diagram of excess function in alcohol-water systems.

The general feature just described above can well be understood by the case of ethylene glycol-water system given in Fig. 2.

For the partial volumes of four isomers of butyl alcohol in water, the diagram is incomplete owing to the phase separation or high melting point. Fig. 3 shows the isomeric variation in the partial volumes of butyl alcohols in their low concentration region where the characteristic behavior is clearly observed.

For comparison's sake, the partial molal volumes of methanol, ethanol, propyl alcohols and glycerol in water are calculated and plotted in Fig. 4 together with the present data. The calculation is made with the ICT data[4]. In

addition, an interesting temperature dependence, which is found in ethanol, is shown in Fig. 5.

**Summary of Experimental Observations.**— Partial volume behavior presented above may be summarized as in the following.

1) Partial volumes of alcohols take a minimum value at a definite point. The position of this minimum shifts systematically to the lower concentration of alcohol in the order of BuOH, PrOH, EtOH and MeOH, as is shown in Table III.

2) Depth of the minimum in $V_2-V_2^0$ depends on the kind of alcohol in a more

Table III. Minimum point in the value of $V_2-V_2^0$

| Compound | | Minimum point at mole % | wt. % |
|---|---|---|---|
| Monohydric alcohol | $CH_3OH$ | 10.5 | 17. |
| | $C_2H_5OH$ | 7.0 | 16. |
| | *n*-$C_3H_7OH$ | 4.5 | 14. |
| | *iso*-$C_3H_7OH$ | 5.0 | 15. |
| | *n*-$C_4H_9OH$ | 1.5 | 6. |
| | *iso*-$C_4H_9OH$ | >2.1 | >8. |
| | *sec.*-$C_4H_9OH$ | 1.8 | 7. |
| | *tert.*-$C_4H_9OH$ | 3.0 | 11. |
| Dihydric alcohol | $CH_2OH$ \| $CH_2OH$ | 6.0 | 16. |
| Trihydric alcohol | $CH_2OH$ \| $CHOH$ \| $CH_2OH$ | — | — |

complicated manner than the above. The largest volume contraction is observed with *tert.*-butyl alcohol.

3) Volume contraction of polyhydric alcohols in water is generally smaller than that of monohydric alcohols. Moreover, it is of interest that the partial volume of ethylene glycol has a minimum value near the glycol mole fraction of 0.06, while that of glycerol has no minimum (Fig. 4).

4) Partial volume $V_2$ of ethanol at high dilution (below the alcohol mole fraction of 0.04) has a small temperature coefficient nearly half the value of ethanol itself. Thus, with the raise in temperature, a) the increase in the depth of $V_2-V_2^0$ at high dilution is observed, although b) the value at the minimum point decreases gradually.

**Discussion.**—Examination of all the experimental data available leads us to the conclusion that the partial volume behavior of mono- and dihydric alcohol-water system has a common characteristic. Qualitatively, the abrupt fold in the partial volume vs. composition curve would be interpreted[3] as the disintegration of the hydrogen-bonded structure in water by the increased strain due to the invading alcohol molecule with increasing fraction of the alcohol. It may be that there are two kinds of configuration of alcohol molecule in aqueous solution, one has a specific volume of alcohol itself, while the other has a small effective volume, and the fraction of the two may change with composition in a complicated manner in an alcohol-water system.

In this connection, it is of interest to examine the other properties of aqueous solution of alcohols. For example, ultrasonic absorption in aqueous solution of alcohol has a marked maximum in some definite composition[5]. But, this maximum in absorption does not always correspond to the minimum in partial volume, and moreover the former is found in aqueous solution of acetone which has smoothed partial volume vs. composition curve[6].

Another interesting result to be noted here is the partial volume behavior in dioxane-water system[7] in which a similar anomaly is observed. In this case, however, partial volume of water has a minimum point instead of a maximum as in alcoholic solutions, and the partial volume of dioxan has a maximum. It is an interesting fact that the role of the OH- group in alcohol molecules contrasts remarkably with that of ether bond -O- in the formation of intermolecular hydrogen bonding in aqueous solution.

In conclusion, all the available data seem to comprise only indirect evidences and it is obvious that more direct information about the inner structure of solutions is desirable for the elucidation of this phenomenon.

## Summary

Partial molal volumes of four isomers of butyl alcohol and ethylene glycol in water are evaluated from the density measurement. They are compared with those of other monohydric alcohols and all the available data which have a common characteristic in the dependence upon the alcohol fraction are summarized.

# *On the Hydrolysis Products of Abietic Acid-Maleic Anhydride Adduct*

By Masahiro ABO

(Received November 26, 1959)

In 1932 Ruzicka and his coworkers[1] found that the saponification product of methyl abietate-maleic anhydride adduct could not be isolated as tricarboxylic acid but identified with the anhydride adduct directly obtained from the reaction between colophony and maleic anhydride, and they stated that the tricarboxylic acid, which was produced at the beginning of the saponification, had a tendency to convert easily into the anhydride acid in the course of acidification or recrystallization.

It was also reported that *cis*-9, 10-dihydroanthracene-9, 10-endo-$\alpha$, $\beta$-succinic acid[2] and alkyl-1, 4-dihydronaphthalene-1, 4-endo-$\alpha$, $\beta$-succinic acid[3] had similar tendencies. These dibasic acids could not be successfully purified by recrystallization, even from the low-boiling solvents, because of their partial or complete conversion to the corresponding anhydrides. It may be seen that these tendencies are common characteristics of these structural homologues.

In the present work an attempt has been made to isolate the hypothetical tricarboxylic acid which might be directly produced by means of the hydrolysis of the abietic acid-maleic anhydride adduct. Some properties of those hydrolysis products which were obtained in a few ways were compared with those of maleic anhydride- or fumaric acid- adducts with abietic acid and discussion was offered as to their chemical structures.

## Experimental

**Maleic Anhydride Adduct with Abietic Acid.**—60 g. of abietic acid (so-called Steele's acid which was produced by refluxing Chinese gum rosin with acetic acid) and 20 g. of maleic anhydride were heated at 170~180°C with stirring under a slow stream of carbon dioxide for two hours. The reaction mixture was dissolved in 100 ml. of glacial acetic acid, and this was poured into a large amount of water with stirring. The separated yellowish resinous product was refluxed with a small amount of carbon tetrachloride to remove the unreacted abietic acid, and recrystallized from glacial acetic acid. Further recrystallization was carried out from benzene-carbon tetrachloride according to the procedure of Ruzicka and his coworkers[1]. Thirty-two grams of fibrous white needles melting at 226~228°C were obtained.

Found: C, 71.63; H, 7.82. Calcd. for $C_{24}H_{32}O_5$: C, 71.96; H, 8.06%. $[\alpha]_D^{15}$ −31.0° (10% in chloroform).

Besides the above, the most refined sample could be obtained by purification with the aid of sublimation of the above crystal under reduced pressure of 1 mmHg at 190~210°C. Its analytical data are shown in Table I with other properties.

**Fumaric Acid Adduct with Abietic Acid.**—50 g. of abietic acid and 20 g. of fumaric acid were heated at 195~200°C with the same procedure as the above for two hours. The reaction mixture was dissolved in 150 ml. of glacial acetic acid, and this was poured into a large amount of hot water with stirring and filtered through a hot funnel. This procedure was repeated twice. The unreacted abietic acid was removed from the yellowish powder by refluxing in benzene, filtered and the filtrate was recrystallized from glacial acetic acid. An analytical sample was obtained by repeated recrystallization from dioxane. Its properties and analytical results are shown in Table I with others. Purification by the vacuum sublimation method was unsuccessful owing to its thermal decomposition.

**Hydrolysis of Maleic Anhydride Adduct.**—It was carried out in two ways. (1) 30 g. of purified maleic anhydride adduct was dissolved in 100 ml. of acetone and added 30 ml. of water. The flask was immersed in a water bath kept at 60~70°C, and boiled gently under a reflux condenser for two hours. On cooling at room temperature, white crystals began to precipitate. After the crystallizations from acetone-water were repeated, they were filtered and ground into fine powder and then dried at room temperature under reduced pressure (2~5 mmHg). They reached the constant weight after about two hours. The analytical data are shown in Table I with others. (2) Ten grams of purified maleic anhydride adduct was dissolved in excess of 10%, aqueous sodium hydroxide solution and precipitated by acidification with 2 N hydrochloric acid. The precipitate was collected, washed with water repeatedly and recrystallized from acetone. All the procedures after hydrolysis were carried out at room temperature, in order to prevent the reversion to the original anhydride. Drying was carried out under the same condition as above. The analytical data are shown in Table I with others.

a) Refluxed the acetone containing water solution of maleic anhydride adduct for two hours and recrystallized from its solution. b) Precipitated by acidification of the alkali solution of maleic anhydride adduct. c) Measured in a sealed capillary tube. d) Calculated for hypothetical tricarboxylic acid $C_{24}H_{34}O_6$ which may be produced on the hydrolysis process.

mixture of 1 : 3 *tert.*-butyl alcohol and acetone was dissolved, and about 10 ml. of water were added to prevent the turbidity which happened often in titration, and titrated with 0.1 N aqueous sodium hydroxide solution by means of potentiometric titration method. — *Apparent Number.* — 0.2~0.3 g. of the sample was dissolved in about 50 ml. of ethanol and titrated with 0.1 N alcoholic sodium hydroxide.

**Thermal Degradation Curves.**—An apparatus of Honda's thermal balance[5] was used. About 0.5 g. of fine powdered sample was heated at constant rate of 10°C/5 min. and loss of weight of sample was measured.

## Discussion

As was shown in Table I, the elementary analytical data of both hydrolysis products, which were obtained in two ways as mentioned above, were in good agreement with that expected for the aimed tricarboxylic acid $C_{24}H_{34}O_6$ respectively. They were insoluble in benzene or chloroform, similarly to fumaric acid adduct, at room temperature, but soluble at elevated temperature. Their specific rotation was negative like that of the maleic anhydride adduct, and the decrease of the rotation nearly corresponded with the decrease of the concentration of the asymmetric carbons attendant upon the increase of their molecular weights. The melting points which were measured by the ordinary method agreed with that of the maleic anhydride adduct. However, when they were measured in a sealed capillary tube they showed a remarkable depression and were distinct from anhydride.

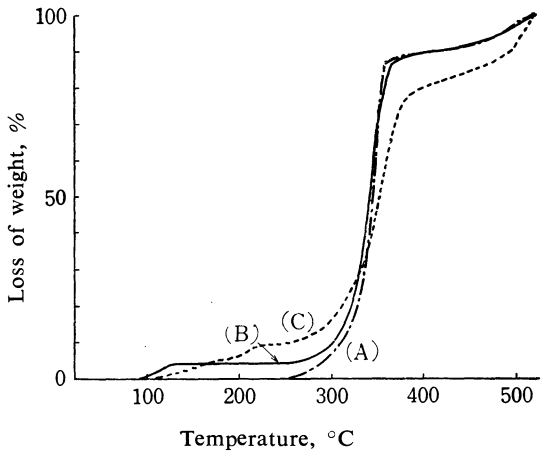

Fig. 1. Thermal degradation curves of (A) abietic acid-maleic anhydride adduct, (B) hydrolysis product of A, and (C) abietic acid-fumaric acid adduct.

Another distinguished difference was observed in the thermal degradation curves of the three kinds of adducts (Fig. 1). The hydrolysis product showed suddenly 4.1 to 4.4% weight loss at about 100 to 120°C (Curve B, Fig. 1), which corresponded approximately to the loss of

5) K. Honda, *Sci. Rep. Tohoku Univ.*, 4, 97 (1915).

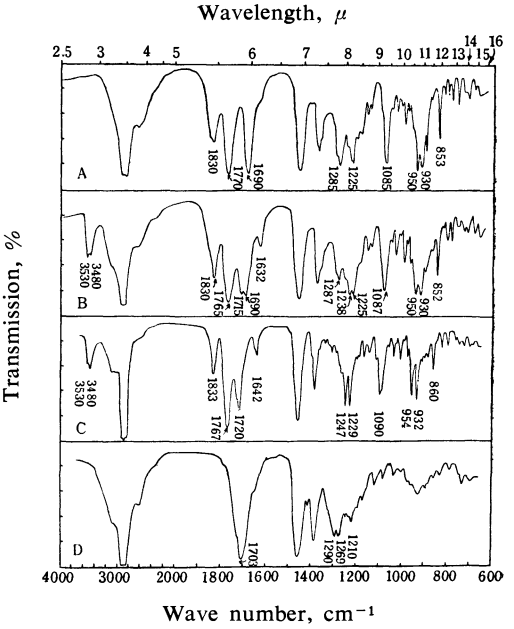
one molecule of water from one molecule of the hypothetical tricarboxylic acid. After it was heated at that temperature the weight was kept constant till it began once more to lose the weight nearly along the curve A of anhydride adduct at about 250°C. In the other run, when the heating was stopped at 150°C, it was confirmed that the remaining product was the same one as anhydride adduct by its mixed melting point and infrared spectrum.

Now, if the above mentioned hydrolysis products had the same structure as the hypothetical tricarboxylic acid (I) which corresponded with the abietic acid-maleic acid adduct, it should be expected that there would be no difference in titer between titrations in a primary alcoholic and a tertiary alcoholic medium. Contrary to our expectation, it was found that they titrated only about two thirds of the expected titration in ethanol (Table I).

Incited by this fact, we were led to find more interesting facts: (a) When the titration of above hydrolysis product was carried out in the mixed solution of acetone — *tert.*-butyl alcohol—water, with alcoholic (ethyl) alkali solution as titer, we also obtained only about the apparent acid number, two thirds of the expected one for the tricarboxylic acid I. (b) Even if it was titrated after the solution was kept at its refluxing temperature for two hours, we also found the same result. Under the same condition, ordinary anhydrides, e. g. maleic anhydride and phthalic anhydride etc., were titrated to their own total acid number respectively. (c) Furthermore, it was also confirmed that the maleic anhydride adduct itself showed only an apparent acid number under the same condition as (a) or (b).

From these facts it seems that they have not the expected tricarboxylic acid structure but an anhydride one in spite of their elementary analyses and other evidences mentioned above. And then, it seems that the anhydride adduct cannot be hydrolyzed in a hydrous medium, even at its refluxing temperature, but proceeds readily to monoesterification with primary alcohol included in titer.

On the other hand, the infrared spectra of them, compared with those of maleic anhydride- and fumaric acid- adducts (Fig. 2), supported an existence of five membered ring anhydride structure. And also, it was first revealed by these spectra that there were two forms of products according to their hydrolysis method, (1) or (2). In either case, two characteristic bands due to the carbonyls in five membered anhydride ring appeared near 1770 and 1830 $cm^{-1}$ similar to that found in the anhydride adduct. These results make it possible to explain their anomality in acid number consistently.



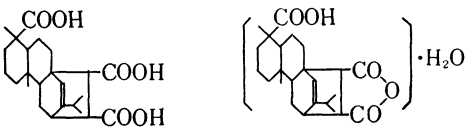


Fig. 2. Infrared spectra in Nujol of (A) abietic acid-maleic anhydride adduct, (B) hydrolysis product (α-form), recrystallized from acetone-water solution of A, (C) hydrolysis product (β-form), precipitated by acidification of the alkali solution of A, (D) abietic acid-fumaric acid adduct.

But if it is so, it becomes difficult to make compatible their elementary analytical data or their thermal degradation curves etc. with an existence of anhydride structure. The only reasonable explanation for this would be that the anhydride adduct had a tendency to form a monohydrate II without opening the anhydride ring in hydrate solution for some reason, e. g. it may be due to the stereochemically unusual approach in positions between the two carbonyl groups belonging to the succinic acid structure added to 6-, 14-carbons of abietic acid.

It was considered that the bands at 3530, 3480 and 1642 $cm^{-1}$ suggested the existence of a hydrated water. Two forms of the hydrolysis products perhaps appeared from the difference in the mode of hydrogen bonding. It is considered that the carbonyl band at 1720 $cm^{-1}$ in β-form is assigned to that of the tertiary carboxyl group under the influence of hydrogen bond caused by the hydrated water. In α-form, it divided in two bands, at 1715 and 1690 $cm^{-1}$.

It seems that one is under the influence of hydrogen bond and the other is not.

It seems to be almost sure that the hydrated water is stoichiometric component in the hydrolysis products, because those products which were dried to the constant weight at room temperature under reduced pressure always showed the reproducible stepwise loss of weight at the range of about 120 to 250°C in the thermal degradation curves, while abietic acid or its fumaric acid adduct which was recrystallized from acetone-water and dried under the same condition showed neither such a stepwise loss of weight in that curve nor the water bands in its infrared spectrum. It seems probable that the hydrated water is the same sort as the zeolitic water by reason of the fact that the collapse of crystals which should happen near their dehydrating temperature can not be observed in an open capillary. It could be also analyzed by Karl Fischer's method. The water content measured by this method was compared with the loss of weight at 150°C in the thermal degradation curve about the samples which were dried under various conditions in Table II.

Table II. Drying time and water content of hydrolysis products of maleic anhydride adduct

| Drying time, hr. (at 2 mmHg/28°C) | Loss of weight at 150°C, % | Water content by means of Karl Fischer's method % |
|---|---|---|
| 1 | 4.43 | 4.20 |
| 2 | 4.32 | — |
| 4 | 4.31 | 4.10 |
| 6 | 4.15 | 4.42 |
| 11 | 4.30 | 3.98 |

Samples: Hydrolysis products precipitated from acetone containing water solution.

## Summary

Hydrolysis of abietic acid-maleic anhydride adduct was carried out in two ways. The elementary analytical data of both resulting products were in good agreement with that calculated for the hypothetical tricarboxylic acid $C_{24}H_{34}O_6$, and at about 100 to 120°C these products lost the weight, which corresponded to the loss of one molecule of water from one molecule of the acid, to revert to the original anhydride adduct. But, they showed only an apparent acid number when the titrations were carried out in ethyl alcohol, similarly to the case of the anhydride adduct. Their infrared spectra suggested an existence of five-membered ring anhydride structure and a hydrated water. On the basis of these facts, we offered an anhydride adduct monohydrate structure II for the above hydrolysis products.

The author wishes to thank Dr. Shiro Tsuruta, Dr. Wataru Koga and Dr. Kiyoshi Sakashita for many stimulating discussions and helpful suggestions.

# *Pyrolysis of Organic Compounds. I. Kinetic Study of the Pyrolysis of Toluene*

By Makoto TAKAHASI

(Received October 16, 1959)

In 1948 Szwarc[1] measured the reaction velocities of the pyrolysis of toluene by the flow technique in the temperature range 738~864°C. He assumed that the reaction is homogeneous, and proposed the following reaction scheme:

$$C_6H_5CH_3 \longrightarrow C_6H_5CH_2\cdot + H\cdot \quad (1)$$
initiation

$$H\cdot + C_6H_5CH_3 \longrightarrow H_2 + C_6H_5CH_2\cdot \quad (2)$$
abstraction by H atom

$$H\cdot + C_6H_5CH_3 \longrightarrow C_6H_6 + CH_3\cdot \quad (3)$$
metathesis

$$CH_3\cdot + C_6H_5CH_3 \longrightarrow CH_4 + C_6H_5CH_2\cdot \quad (4)$$
abstraction by $CH_3$ radical

$$2C_6H_5CH_2\cdot \longrightarrow C_6H_5CH_2CH_2C_6H_5 \quad (5)$$
termination by recombination

He considered that the rate determining step

1) H. Szwarc, *J. Chem. Phys.*, **16**, 128 (1948).

is the unimolecular reaction 1, and assumed that the velocity constant $k$ observed by the flow method corresponds to that of the reaction 1. The activation energy and the temperature independent factor of the reaction 1 obtained by plotting $\log k$ versus $1/T$ are 77.5 kcal./mol. and $2\times10^{13}$ respectively, and he assumed that the activation energy corresponds to the bond dissociation energy, $D(C_6H_5CH_2\text{-}H)$. H. R. Anderson Jr., H. A. Scheraga, and E. R. Van Artsdalen[2] studied the thermal bromination of toluene, and they derived 89.5 kcal./mol. for the upper limit of the bond dissociation energy of toluene. H. Blades, A. T. Blades and E. W. R. Steacie[3] repeated the study of the pyrolysis of toluene in a flow system, and they carried out a more elaborate analysis of the reaction products. Styrene, dimethylbiphenyls and anthracene were obtained in addition to bibenzyl which was reported by Szwarc to be the sole nonvolatile product in the reaction. Steacie and Blades ascribed the origin of the dimethylbiphenyls to the secondary decomposition of bibenzyl. They observed that the first order rate constant increases, as the contact time is increased, and that the rate of the reaction depends upon the condition of the surface of the reaction vessel. They calculated the apparent activation energy to be 90 kcal./mol., keeping the contact time constant at 0.068 sec., although they did not assert that the value corresponds to the true bond dissociation energy of toluene $D(C_6H_5CH_2\text{-}H)$.

Most recently, S. W. Benson and J. H. Buss[4] reviewed various attempts to determine the bond dissociation energy of toluene, and they attempted a measurement of the equilibrium constant for the reaction:

$$C_6H_5CH_3(g)+Br_2(g) \rightleftarrows C_6H_5CH_2Br(g)+HBr(g)$$

at 150°C, and they estimated the bond dissociation energy of toluene to be 84 kcal./mol., together with the known thermal data.

The bond dissociation energy was also obtained by electron impact measurement by D. O. Schissler and D. P. Stevenson[5] as 77.3 kcal./mol., and J. B. Farmer, I. H. S. Henderson, C. A. McDowell and F. P. Lossing[6] criticized the value, and they presumed that the bond dissociation energy is possibly higher by about 20 kcal./mol.

From the theoretical point of view, the present author considers that Szwarc's value of the bond dissociation energy of toluene is somewhat too low, for the difference:

$$D(CH_3-H)-D(C_6H_5CH_2-H) = 103-77.5=22.5 \text{ kcal./mol.}$$

is too large compared with the extra resonance energy of the benzyl radical which was calculated as about 14 kcal./mol.[7] If such an abnormal weakening of toluene bond were assured by experiments, the fact might be an interesting theoretical problem, but at present it seems to be premature to discuss this point, for there remain many points which should be made clear in the experiments.

It is to be noted that the value obtained by Steacie and his collaborators for the activation energy of the pyrolysis of toluene is different from that by Szwarc, although the method was the same. A. F. Trotman-Dickenson[8] pointed out that Steacie and his collaborators measured the rate constant, keeping the contact time far less than in the experiments by Szwarc.

However, the present author considers that it is very unfortunate that the two groups made experiments in the different ranges of the reaction temperatures; that is, Szwarc in the range between 738~864°C, and Steacie and his collaborators between 860~940°C. Therefore, the present experiment was carried out to cover the whole temperature range 737~953°C, and efforts were made to elucidate the cause of the discrepancy of the bond dissociation energies of toluene obtained by the two groups.

## Experimental Procedure

**Materials.**—Both Szwarc's and Steacies groups used toluene prepyrolyzed to remove interfering impurities which would give extra hydrogen and light hydrocarbons by pyrolysis. The present author attempted to obtain toluene of higher purity which is usable without prepyrolysis. Toluene from two sources were examined, the one of which was obtained by the usual purification process combined with azeotropic distillation with acetonitrile to remove interfering impurities which were presumed to be cycloalkanes. This toluene was conceived to be of very high purity, but nevertheless it gave some amount of ethylene and propylene in addition to hydrogen and methane by pyrolysis, if it was subjected to prepyrolysis.

In order to obtain toluene of higher purity which contains no alkanes nor cycloalkanes, the author prepared toluene from toluidine by applying the method described in Organic Syntheses[9]. A cold diazonium solution was prepared from 105 g. of toluidine, 190 ml. of concentrated hydrochloric acid,

and 69 g. of sodium nitrite in 200 ml. of water, and it was poured into a flask containing 520 g. of sodium hypophosphorite, $NaH_2PO_2 \cdot H_2O$, 256 g. of concentrated hydrochloric acid and 40 g. of water. Evolution of nitrogen was controlled, keeping the solution at 5°C. The flask was placed in a refrigerator overnight, and the reaction product was transfered to a separating funnel, and the upper oil was separated from the aqueous phase. Ether extraction should be avoided, for it causes the contamination of toluene with ether. A fraction boiling at 110°C. was gathered by simple distillation which weighed about 55 g., and then it was distilled through a spinning band fractionating column of 150 cm. in length. This toluene did not give any appreciable amount of ethylene and higher hydrocarbons in the pyrolysis, even if prepyrolysis was not carried out, and therefore the latter toluene was used in the present kinetic study.

**Apparatus and Procedure**—The general arrangement of apparatus for pyrolysis shown in Fig. 1 is similar to that used by Szwarc but with a small modification to improve experimental accuracy. Toluene which had been refluxed with sodium for about one hour was distilled under reduced pressure into the storage vessel $T_1$. This vessel was weighed before and after each run of experiment, to measure the amount of toluene passed in each run, if it was necessary to calculate accurate contact time. In the usual runs, the amount of toluene was determined by volume in the storage flask. During runs, the vessel was kept in a Dewar vessel contaning water maintained at a temperature constant to 0.1°C. Toluene was evaporated from $T_1$ through cock $C_1$ to maintain its vapor pressure 4~10 mmHg, and led into a silica reaction vessel heated by an electric furnace. Contact time was controlled by replacing silica reaction vessels which were designated as I, II, and III. (Table V). The electrical furnace was about 70 cm. long, and the variation of temperature along the reaction vessel was ±2°C. The temperature of the reaction vessel was measured by a calibrated Pt-Rh thermocouple with a potentiometer. It was checked to discover whether temperature difference inside and outside the reaction vessel might be caused by passing toluene, but the difference did not exceed 2°C.

The reaction system was evacuated to $10^{-6}$mmHg before the experiment, and pressure increase in the reaction system in the course of about 20 min. was checked without passing toluene. The increase of pressure was caused mainly by evaporation of toluene previously dissolved in grease of cocks but not by leakage of air, being suppressed to about $10^{-3}$ mmHg in the course of about 20 minutes, a time comparable to that of one usual run of pyrolysis.

The vapor leaving the reaction vessel passed through traps $T_2$ and $T_3$ which were cooled with a mixture of ether and solid carbon dioxide. Toluene and the less volatile products such as bibenzyl and dimethylbiphenyls were almost completely condensed in trap $T_2$. The noncondensable gas passed through trap $T_4$ which was cooled by liquid nitrogen or oxygen. Trap $T_5$ was reserved for distillation, and

* Condensable gas at liquid nitrogen temperature amounted to 2% of total gas product.

kept at room temperature. Noncondensable gas in trap $T_4$ was composed of hydrogen and methane, and it was pumped out by a Toepler pump and collected in a storage vessel of about 100 ml. The quantity of hydrogen and methane produced was given by reading the pressure in the storage vessel with a McLeod gauge or a U tube manometer according to the pressure. The reaction time extended from 3 to 30 minutes, according to the quantity of gas produced. After the flow of toluene vapor was stopped, the trap $T_2$ was warmed to room temperature to distil toluene from trap $T_2$ to $T_3$. All the produced gas, remaining in the reaction system and dissolved in toluene of trap $T_2$, was pumped out by a Toepler pump to the storage vessel. Hydrogen and methane expelled from trap $T_2$ amounted to about 10% of the total gas produced. Operation of Toepler pump was continued for 15 min. after flow of toluene was stopped. After the pressure of a mixture of hydrogen and methane was read, trap $T_4$ was warmed to $-70°C$ by changing the cooling material to a mixture of ether and carbon dioxide. The amount of gas condensable in trap $T_4$ at liquid nitrogen temperature was at most a few per cent of that of condensable gas, if toluene which was synthesized from toluidine as described above was pyrolyzed.

As the experimental conditions were so chosen that the decomposition ranged from 0.001 percent to 0.6 percent of total toluene, the reaction rate constant for the unimolecular reaction was calculated by the equation,

$$k=\frac{P_s\times V_s\times T_R}{P_t\times t\times T_r\times V_R} \tag{6}$$

where $P_t$ is vapor pressure of toluene (mmHg), $T_R$ is reaction temperature (°K), $V_R$ is volume of reaction vessel (l.), $t$ is time of flow (sec.), and $P_s$ is pressure of product gas ($H_2+CH_4$) (mmHg) at $T_r$ °K in a storage vessel of $V_s$. The contact time was calculated according to Eq. 7,

$$\tau=V_R/v=\frac{V_R\times P_t\times t}{m\times 0.082\times T_R\times 760} \tag{7}$$

$$k=\text{fractional decomposition}/\tau \tag{8}$$

where $m$ is moles of toluene passed, and $v$ (l.) is volume of toluene which passed through the reaction vessel per second at $T$ °K. Contact time was calculated in several runs, but not in all runs, because it depends mainly on the value of reaction vessel and vapor pressure of toluene, the latter being varied over a small range.

## Experimental Results

The results are shown in Tables I, II and III, and the relation of $\log k$ versus $1/T$ is shown in Fig. 2. From the figure it may be apparently concluded that the relation was linear, but the more precise analysis makes clear the curve is slightly concave. Therefore, the temperature range was rather arbitrarily divided into three parts, that is, higher, medium, and lower temperature ranges, and a linear relation of $\log k$ versus $1/T$ was assumed in each range, and experimental activation energies and temperature independent factors were calculated by the least square method. The results are summarized in Table IV. Different gradients were obtained in each temperature range, corresponding to different activation energies and different frequency factors. The probable cause of deviation of the relation of

$\log K$ versus $1/T$ from linearity is discussed below.

**Identification and Analysis of Products.**—The mole ratio of hydrogen to methane was determined by a mass spectrometer of CEC 21-103A type by using peaks of $m/e$ 2 and 16, although quantitative analysis of hydrogen by the mass spectrometer did not give sufficient accuracy. Complete analysis of solid and oily matters which were obtained in trap $T_2$ was not carried out, but the ultraviolet absorption spectrum (Fig. 3) showed that the main products were composed of bibenzyl and dimethylbiphenyls, and this result agrees with that of Steacie and his collaborators.

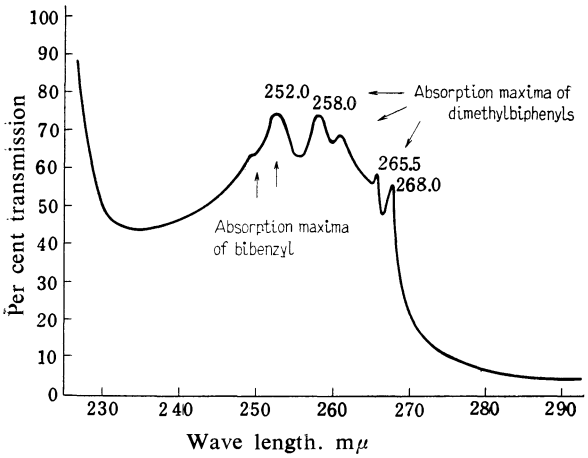

Fig. 3. Absorption spectrum of the nonvolatile reaction products of pyrolysis of toluene in ethanol.

## Discussions

As described above, the present experimental results show that the relation of $\log k$ versus $1/T$ in the temperature range 737～953°C is not strictly linear and that high activation energies and high frequency factors are obtained in the higher temperature range in the series of the experiments which were carried out at contact time of 0.1～0.3 sec. In the case of shorter contact time, 0.02～0.04 sec., (Table IV), the activation energy is obtained only in the higher temperature range 812～960°C, because the experiment in the lower temperature range should give a smaller amount of gas product and involve larger experimental error, compared with the experiments of longer contact time. It is to be noted that the lower activation energy is obtained even in the higher temperature range, compared with the experiment of longer contact time in the same temperature range.

Now the author will discuss the probable cause of systematic deviation of the relation of $\log k$ versus $1/T$ from linearity.

1) Experimental errors: It may be possible that $k$ at lower temperatures involves relatively large error, because the amount of the product gas at lower reaction temperature is very small, even if the reaction time is lengthened. As was described in the experimental part, the pressure increase in the storage vessel in the blank test amounted to about $10^{-3}$ mmHg in the course of about 15 min. Total pressure of product gas which was given by pyrolysis of toluene for ten minutes at the lowest reaction temperature, 738°C, amounted to about 0.06 mmHg (cf. Exp. No. 13). This may mean that the observed velocity constants at lower reaction temperatures should be reduced by some percentage, but such correction seems not to increase so much the activation energy obtained at the lower temperature range.

Alkanes and cycloalkanes which may supposedly exist in commercial toluene may be decomposed more rapidly than toluene, and

such toluene may increase the apparent $k$ at lower reaction temperatures, but the toluene which was synthesized from toluidine may be free from such impurities.

2) Correction by using the more elaborate Arrhenius equation: As was pointed out by many authors[10], under some conditions the frequency factor is a function of the temperature and a more accurate equation 10 than the usual Arrhenius equation 9 should be used.

$$k = A\exp(-E_a/RT) \quad (9)$$

$$k = AT^n\exp(-E/RT) \quad (10)$$

or $$\ln k = -E/RT + n\ln T + \ln A$$

and the difference of the two activation energies is

$$E = E_a - nRT. \quad (11)$$

In the present case, $n$ is not known, but if $n$ is assumed to be 1/2 as in the usual collision theory, $n(\ln T_1 - \ln T_2)$ amounts to 0.042, when $T_1$ and $T_2$ are assumed 953°C and 737°C respectively. This may reduce activation energies in the higher temperature range to some extent, but the correction seems not to contribute so much to reducing the concave nature of the relation of $\log k$ versus $1/T$.

3) Complications due to competitive reactions: H. Blades, A, T. Blades and E. W. R. Steacie[3] pointed out that the first order rate constants for the pyrolysis of toluene depends on the condition of the surface of the reactor, and the contact time, and on the pressure. A. Frost and R. G. Pearson[10] pointed out that a plot of $\log k$ versus $1/T$ shows a curvature if there are two competing reactions with different activation energies.

One case is that where the same reaction occurs both homogeneously and heterogeneously. The homogeneous reaction usually has a higher activation energy, and it is favored at high temperatures whereas the heterogeneous reaction predominates at lower temperatures. In the present experiment, it is shown that $k$ at the same temperature varies slightly as shown in Fig. 2, when the reaction vessel is replaced (I, II, and III). Contact time, volume and surface area of reaction vessel are varied as shown in Table V by replacing the reaction vessel, but it is not yet elucidated how these conditions affect the velocity constant and activation energy of pyrolysis of toluene. The present author presumed that any unfavorable secondary reaction may be suppressed, if the experiment is carried out under a smaller contact time, but such a presumption could not be confirmed in the present experiment.

10) A. A. Frost and R. G. Pearson, "Kinetics and Mechanism", John Wiley Sons, Inc., New York (1953), p. 24.

Table V

| Reaction vessel | Volume ml. | Contact time, sec. | Surface area, $cm^2$ |
|---|---|---|---|
| I | 53.7 | 0.3 | 113 |
| II | 31.0 | 0.2—0.1 | 94 |
| III | 6.4 | 0.03 | 44 |

Thus, the author's efforts to obtain a value as much smaller than $k$ as possible especially in the lower temperature range appeared not to modify the concave nature of $\log k$ versus $1/T$, and another source of complications of the present reaction is now considered in the following. At the higher temperature range between 900~950°C, it may be possible that the observed $k$ becomes rather increased, as the reaction temperature is increased, because some competitive side reaction takes place, giving hydrogen and methane. Already both Szwarc[1] and Steacie[3] considered the following reaction,

$$C_6H_5CH_3 \longrightarrow C_6H_5\cdot + CH_3\cdot$$

as one of possible side reactions, but they considered that such a reaction is less probable, because the ratio of hydrogen to methane does not vary over the whole temperature range. The present experimental results of the ratio of hydrogen to methane appear to support their conclusion. Another possible reaction is one involving the participation of ring-hydrogen in initiation and/or propagation reaction as follows:

$$C_6H_5CH_3 \longrightarrow \cdot C_6H_4CH_3 + H\cdot \quad \text{initiation}$$

$$C_6H_5CH_3 + H\cdot \longrightarrow \cdot C_6H_4CH_3 + H_2$$
abstraction by hydrogen atom

$$C_6H_5CH_3 + CH_3\cdot \longrightarrow \cdot C_6H_4CH_3 + CH_4$$
abstraction by methyl radical

Blades and Steacie[11] pointed out such a possibility in the experiment of pyrolysis of $n$-propylbenzene in the presence of toluene-$\alpha$-$d_3$ at 722°C. They found that the amount of methane in the reaction product is unexpectedly large compared with the amount of methane-$d$. Recently S. H. Wilen and E. L. Eliel[12] assumed abstraction of ring-hydrogen by methyl radicals in the reaction of acetyl peroxide with ring-deuterated toluene at 131~147°C. which gave rise to some methane-$d$. The present author's experiment of toluene-3-$d$ and toluene-4-$d$ which confirms the involvement of ring-hydrogen in the pyrolytic reaction of toluene itself will be reported in the succeeding paper, although it remains unsolved whether the involvement of ring-hydrogen modifies the overall activation energy or not.

**Summary**

Pyrolysis of toluene by the flow technique was carried out under various conditions, and the velocity was measured over the wide temperature range 737~953°C at contact time 0.02~0.3 sec. The relation of log $k$ versus $1/T$ appears to be linear, but the more precise analysis shows a slight concave nature, and therefore activation energy tends to increase, as the reaction temperature is raised. Detailed investigation on its cause was made, and it is presumed that such an increase of activation energy with rise of temperature is mainly brought about by some competitive reaction, but not by experimental conditions. The present author considers that the involvement of ring-hydrogen reaction may compete with the reaction of fission of C–H bond of the methyl group, and such competitive reaction may modify the activation energy of the fission of the methyl bond of toluene, if the experiment is carried out over the wide reaction temperature range.

The author wishes to express his hearty thanks to Professor Y. Urushibara and Professor O. Simamura for their kind guidance and encouragement of the present work. The author is grateful to Dr. M. Kobayashi for experimental help and for stimulating discussions, and to Dr. T. Tamura and Mr. H. Saito for fractional distillation of toluene.

# *Pyrolysis of Organic Compounds. II. Pyrolysis of Toluene-3-d and Toluene-4-d*

By Makoto TAKAHASI

(Received October 16, 1959)

In recent years the bond dissociation energy of toluene, $D(C_6H_5CH_2\text{–}H)$, has become a topic of considerable dispute, and various attempts to determine the bond dissociation energy were reviewed by Benson & Buss[1] and by the present author[2]. Szwarc[3] estimated the activation energy of the pyrolytic reaction of toluene by the flow method to be 77.5 kcal./mol., and the frequency factor to be $2\times10^{13}$ in the reaction temperature range 738~864°C. H. Blades, A. Blades and Steacie[4] repeated the study of the pyrolysis of toluene by the same method, and they observed that the first order rate constant increases, as the contact time is increased. They calculated the apparent activation energy of the pyrolytic reaction to be 90 kcal./mol., keeping the contact time constant at 0.068 sec. in the reaction temperature range 860~940°C, but they concluded that it is premature to assign any definite value to the bond dissociation energy of toluene. At first, in order to explain the higher activation energy and the occurrence of methane, they suggested reaction 2, which proceeds concurrently with the main reaction 1.

$$C_6H_5CH_3 \rightarrow C_6H_5CH_2\cdot + H\cdot \quad (1)$$

$$C_6H_5CH_3 \rightarrow C_6H_5\cdot + CH_3\cdot \quad (2)$$

Later, however, they[5] approved of Szwarc's view that the contribution of reaction 2 to the apparent activation energy of pyrolysis of toluene is of a minor degree, for they considered the facts that the ratio of hydrogen to methane in the reaction product of pyrolysis of toluene is constant over the reaction temperature range, and that the ratio does not vary even in the decomposition of *n*-propylbenzene in the presence of excessive toluene[6].

The present author[2] carried out the pyrolysis of toluene in both of the temperature ranges, 738~864 and 860~940°C, to elucidate the cause of the discrepancy of the bond dissociation energies of toluene obtained by the two groups, and it was found that the apparent activation energy for the first order rate expression of pyrolysis of toluene increases, as the reaction

temperature was extended to a higher range. The author discussed the possible causes of the nonlinearity of the relation of $\log k$ versus $1/T$, and suggested complication by the involvement of some competitive reaction. Blades and Steacie[5] suggested the same possibility in the reaction, and carried out the pyrolysis of *n*-propylbenzene in an excess of deuterated toluenes (mixture of toluene-$\alpha$-$d_3$: 66%, toluene-$\alpha$-$d_2$: 29%, and toluene-$\alpha$-$d$: 5%) at 722°C at contact time 0.45 sec. They found the products were composed of hydrogen, methane, ethane, ethylene, benzene and bibenzyl, and the ratios of the gaseous products were:

$$H_2 : HD : D_2 = 1 : 1 : 0$$

and

$$CD_4 : CD_3H : CD_2H_2 = 1 : 1.5 : 1$$

respectively.

The large ratio of $H_2$ to HD suggested that hydrogen atoms may be abstracted from the ring as well as from the side chain. In addition, they concluded that concerning two mechanisms 3 and 4 suggested by Szwarc,

$$H\cdot + C_6H_5CD_3 \text{ (or } C_6H_5CD_2H) \rightarrow C_6H_5\cdot + CD_3H \text{ (or } CD_2H_2) \quad (3)$$

$$C_6H_5\cdot + C_6H_5CD_3 \rightarrow C_6H_5D + C_6H_5CD_2\cdot$$

$$H\cdot + C_6H_5CD_3 \text{ (or } C_6H_5CD_2H) \rightarrow CD_3\cdot \text{ (or } CD_2H\cdot) + C_6H_6$$

$$CD_3\cdot \text{(or } CD_2H\cdot) + C_6H_5CD_3 \text{(or } C_6H_5CD_2H) \rightarrow CD_4 + C_6H_5CD_2\cdot \text{(or } CD_3H,\ CD_2H_2) \quad (4)$$

mechanism 3 would give $CD_3H$ and $CD_2H_2$, while mechanism 4 would give $CD_4$, $CD_3H$ and $CD_2H_2$. They considered that the production of $CD_4$ in their experiment is a good evidence for mechanism 4, and that mechanism 3 contributes to a minor degree. As the pyrolysis of toluene itself was not carried out in their experiment, it was not clear whether the initiations reaction of pyrolysis of toluene involves the ring-hydrogen or not. The present author attempted to study the pyrolysis of toluene-3-*d* and toluene-4-*d* in the temperature range 830~955°C, and investigated the reactivities of the meta and para positions of toluene.

## Experimental

**Materials.**—Toluene-3-*d* and -4-*d* were prepared by the reaction of *m*- and *p*-tolylmagnesium bromide with deuterium hydroxide according to Gold[7] with some modifications. The Grignard reagent was prepared from 50 g. of *m*- or *p*-bromotoluene, 7 g. of magnesium and 120 ml. of ethyl ether; and 6 ml. of deuterium hydroxide (99.78 g. $D_2O$/100 g.) was added to the reaction mixture. In adding deuterium hydroxide, care should be taken to continue vigorous stirring to secure the contact of deuterium hydroxide with the Grignard reagent. The reaction mixture was refluxed for about ten minutes, and left to stand overnight. In order to decompose the remaining Grignard reagent, dry carbon dioxide was passed through for some time, and then 7 g. of ammonium chloride solution in 25 ml. of water was added, a solid material being formed. Then 20 ml. of concentrated hydrochloric acid was added to dissolve the solid. Ether layer was separated, and the aqueous layer was extracted with 100 ml. of ether. The combined ether solution was washed with a dilute sodium hydroxide solution and with distilled water successively, and dried with calcium chloride. Ether was removed by distillation with Vigreux's columm, and toluene fraction boiling at 111~112°C was collected, weighing about 15 g. The toluene fraction was then shaken with about 15% hydrochloric acid to remove a trace of ether which interferes with pyrolysis of toluene, and distilled through a spinning band column of 150 cm. in length. Although the deuterated toluenes thus obtained contained about 22% of undeuterated toluene (see the next section), some improvements of isotopic purity may be obtained by the more elaborated method proposed by Weldon[8].

**Determination of Isotopic Purity of Deuterated Toluenes.** — For the determination of the isotopic purity of the deuterated organic compounds, mass spectrometry under reduced ionization voltage[9] is recommended, but the available mass spectrometer of CEC 103 A type operated at ionizing voltage 70 V. was unsuitable for the present purpose. So the present author was obliged to apply the infrared spectra for the determination of the isotopic purity of synthesized deuterated toluenes, in spite of less accuracy of the method. Infrared spectra of toluene, toluene-3-*d* and toluene-4-*d* were already given by Tiers[10] in the region of 693~835 $cm^{-1}$. Comparison of their spectral data of toluene with those of the present author gave good agreement in the wave numbers of the absorption maxima, but not in the intensity, their absorption coefficients at characteristic absorption maxima being larger by about twice than the present author's. While standard toluene-3-*d* and -4-*d* of isotopic purity of more than 99% were not available to us, Tier's data were not proper to be applied to the present analysis, so that the present author adopted the method to determine the content of undeuterated toluene in the synthesized mixture. The infrared spectral data obtained by a Perkin Elmer 112 infrared spectrometer are shown in Table I. The absorption band of toluene at 730 $cm^{-1}$ is too strong to determine the absorption coefficient in liquid state. Therefore, the absorption band at 695 $cm^{-1}$ was used in the analysis of the mixture of toluene and toluene-4-*d*, the latter of which has no characteristic absorption at the wave number. The extinction coefficient of standard

toluene at 695 $cm^{-1}$ being 840, the content of toluene in Sample II (mixture of toluene and toluene-4-*d*) was ascertained as 22%. In the analysis of Sample I (mixture of toluene and toluene-3-*d*) the band at 695 $cm^{-1}$ is unsuitable, for toluene-3-*d* has the absorption band of nearly the same strength as toluene at the position. However, as the extinction coefficient of Sample I at 730 $cm^{-1}$ is accidentally almost the same as that of Sample II, the content of toluene in Sample I was presumed to be nearly the same as that of Sample II, that is, 22%. Mass spectrometric data which are shown in Table II may support the above conclusion, although they are not sufficient for determining the precise isotopic purity.

**Apparatus and Procedure of Pyrolysis.** — They were previously described in Part I. Experiments in the temperature range lower than 830°C and at a contact time less than 0.1 sec. were not carried out, for a sufficient amount of gas for the mass spectrometric analysis was not produced under these conditions.

## Analysis of Gaseous Products and Experimental Results

The gas products of pyrolysis of the mixture of toluene and toluene-3-*d* or -4-*d* consisted of $H_2$, HD, a trace of $D_2$, $CH_4$ and $CH_3D$. No complete method of determination of the ratio of HD to $H_2$ appeared to be established until most recently[11], in the case where the relative abundance of HD to $H_2$ is more than 10% and the total amount of hydrogen is small. Recent development of gas chromatography has made it possible to separate HD from $H_2$, using a very small amount of a sample[12], and this method may be applied to the analysis. In the present experiment, the author was satisfied with determining the ratio approximately. As pure HD for a standard was not available, its mass spectrometric sensitivity at *m/e* 3, was assumed to be equal to that of $H_2$ at *m/e* 2. It has been pointed out that the peak at *m/e* 3 contains the component of $H_3^+$, in addition to that of $HD^+$, but its contribution was not appreciable in the present case, using ionizing current of 10.5 $\mu$A. The contribution of $D^+$ to *m/e* 2 is not known, but it may be neglected.

considering that the relative abundance of $H^+$ produced from $H_2$ is 2.1% to that of $H_2^+$ [13].

The ratio $CH_3D/CH_4$ was determined according to the following procedure. As each peak of the mixture of $CH_4$ and $CH_3D$ at $m/e$ 18~13 is composed of the following several components as shown in Table III, Eqs. 5 and 6

$$P_{17}=\frac{1}{100}\{S_{CH_4}(a_{^{13}CH_4^+}\times 0.0101)X + S_{CH_3D}(b_{CH_3D^+}\times 0.9896+b_{^{13}CH_2D^+}\times 0.0101)Y\} \quad (5)$$

$$P_{16}=\frac{1}{100}[S_{CH_4}(a_{CH_4^+}\times 0.9896+a_{^{13}CH_3^+}\times 0.0101)X + S_{CH_3D}\{b_{CH_2D^+}\times 0.9896+(b_{^{13}CHD^+}+b_{^{13}CH_3^+})\times 0.0101\}Y] \quad (6)$$

are derived, where $P_{17}$ and $P_{16}$ are observed peak heights at $m/e$ 17 and 16, $S_{CH_4}$ and $S_{CH_3D}$ are sensitivities of $CH_4$ and $CH_3D$ at their parent peaks, $a_{R^+}$ and $b_{R^+}$ are relative abundances of ions produced from $CH_4$ and $CH_3D$, and $X$ and $Y$ are pressures of $(CH_4+{}^{13}CH_4)$ and $(CH_3D+{}^{13}CH_3D)$, respectively.

TABLE VI. MASS SPECTRA OF $CH_4$ AND $CH_3D$

| $m/e$ | $CH_4$ ($a$) | $CH_3D$ ($b$) | $CH_4$ ($a'$) |
|---|---|---|---|
| 17 | | 100 | |
| 16 | 100 | 79.8 | 100 |
| 15 | 89.3 | 23.7 | 88.1 |
| 14 | 19.4 | 10.5 | 19.8 |
| | Mohler's data, | this work | |
| | $^{13}CH_4$ component has been removed. | | |

For the measurement of standard $CH_4$ by the present author gave nearly the same cracking pattern $a'$ as $a$ of Mohler[14] (Table IV), the author applied his data $a$ and $b$ to the present analysis. From Eqs. 5 and 6, Eq. 7 is derived assuming $S_{CH_4}=S_{CH_3D}$, and using Mohler's data,

$$Y/X=99.052\frac{(1.00808\,P_{17}-0.0101\,P_{16})}{(98.96\,P_{16}-79.207\,P_{17})} \quad (7)$$

The data of mole ratios $HD/H_2$ and $CH_3D/CH_4$ obtained in the pyrolysis of Samples I and II under various conditions are shown in Table V, where Eq. 7 was applied to the determination of $CH_3D/CH_4$. The determination of the mole ratio $(H_2+HD)/(CH_4+CH_3D)$ was not performed, for sufficient accuracy was not expected for the determination by the mass spectrometric analysis, and from the previous data it may be presumed that the ratio is about 2[2].

Analyses of liquid products were carried out by both infrared and mass spectrometric methods. Toluene recovered from the reaction products of Samples I and II gave nearly the same infrared spectra as the original ones. Therefore, it may be concluded that any transfer of deuterium from the initial position did not occur in the pyrolysis. Mass spectra of the recovered toluene were also nearly the same in the mass range of $C_7$ groups, but some differences were observed in the range of $C_6$ groups as shown in Table VI.

Table VI shows that the peak at $m/e$ 78 includes $C_6H_6^+$, $C_6H_4D^+$ and $C_5{}^{13}CH_5^+$, and the peak at $m/e$ 79 does $C_6H_5D^+$, $C_6H_3D_2^+$ and $C_5{}^{13}CH_6^+$, but it was not carried out to determine the ratio $C_6H_6 : C_6H_5D : C_6H_4D_2$ from these data. It is to be noted that the increase of benzene content due to the rise of the reaction temperature is rather small compared

with the increase of velocity constant in the same reaction temperature range (cf. Table V).

These experimental results are summarized as follows:

1) Toluene-3-*d* and -4-*d* (isotopic purity: 78%) gave $H_2$, HD, a trace of $D_2$, $CH_4$ and $CH_3D$ by pyrolysis, and their mole ratios were determined by mass spectrometric analysis.

2) There was not any distinct difference in the mole ratios of $HD/H_2$ and $CH_3D/CH_4$ in the reaction of either toluene-3-*d* or -4-*d*, and it may be concluded that the reactivities of *m*- and *p*-hydrogen of toluene are of the same order.

3) As the pyrolyzed toluene gave a nearly similar infrared spectra as those of unpyrolyzed one, exchange reaction of hydrogen between toluenes did not occur to an appreciable extent in the temperature range 830~900°C.

The following reaction mechanism may be presented to explain the formation of HD and $CH_3D$.

In the above schemes, statistical weight shows numbers of reacting hydrogens in each set of elementary processes. The production of HD may be explained by one or more of reactions 5'—7, and that of $CH_3D$ by 10 and/or 13. If it is assumed that eight hydrogens of toluene

(toluene-3-*d* or -4-*d* containing 22% toluene)

(The reactions of undeuterated toluene omitted.)

had the reactivities of the same order both in the initiations and propagations, (that is, here both isotope effect and structure effect are neglected), the expected ratio $H_2 : HD : D_2$ in the pyrolysis of toluene-*d* of 100% of isotopic purity might be $7/8\times7/8+7/8\times1/8 : 1/8\times7/8 : 1/8\times1/8 = 1 : 0.29 : 0.02$. On the other hand, if it is assumed that HD was produced only by the abstraction of D atom from benzene ring by hydrogen atom (reaction 5′), not by reactions 6 and 7, the ratio $H_2 : HD : D_2$ might be $7/8 : 1/8 : 0 = 1 : 0.14 : 0$ (natural abundance 0.02% of D is neglected). As the experimental results (Table V) show the ratio, $1 : 0.10\sim0.19 : 0.000\sim0.007$, it is indicated that the ratio is in the middle of the two assumed ratios, and it may be expected that $HD/H_2$ is augmented, if 22% of undeuterated toluene is removed from Samples I and II. Although these results do not suffice to establish the initiation reactions 2 and 2′, they may not be a negative evidence for such processes. A more direct evidence supporting the existence of process 2′ may be obtained by pyrolyzing $C_6D_5CH_3$, for $C_6D_5CH_3$ would give $D_2$ by the successive reactions 2′, 6 and 7 in a high yield.

The ratio $CH_3D : CH_4$ is relatively low compared with that of $HD : H_2$ in the whole reaction temperature range. The possible processes to produce $CH_3D$ may be 10 and/or 13′, and if it is assumed that processes 2 and 2′ gave H and D atoms in the ratio 7 : 1, and that processes 12—13′ proceeded with statistical weights (3 : 4 : 1), the ratio of $CH_3D$ to $CH_4$ obtained by reactions 8 and 10 might be 1/7, and the ratio of $CH_3D$ to $CH_4$ obtained by reactions 12—13′ might be also 1/7. On the other hand, if it is assumed that D atom was not produced by the initiation reaction 2′, $CH_3D$ might be produced only by reaction 13. In this case, the ratio $CH_3D : CH_4$ depends on the relative velocity rate of reactions 8 and 9. If it is assumed that the relative rate ratio is $\alpha : 1$, the ratio $CH_3D/CH_4$ should be $1/(7+8\alpha)$, and less than 1/7.

These experimental results are rather unexpected, considering the generally accepted fact that $D(C_6H_5\text{–}H)$ is larger than $D(C_6H_5CH_2\text{–}H)$. Dr. Kobayashi[15] suggested that the benzyl radical would rearrange to cycloheptatrienyl radical, considering the mass spectrometric evidence of the rearrangement of benzyl cation to cycloheptatrienium cation[16]. If such a rearrangement took place, transfer of deuterium atom in the aromatic ring would be observed. Unfortunately the amount of aromatic products produced by pyrolysis was not sufficient to be analyzed. On the other hand, it has been known that $CH_3$ radical abstracts hydrogen from the benzene ring[17,18], and this fact may explain the production of $CH_3D$. As may be described in the succeeding paper, pyrolysis of benzene proceeds in the relatively low temperature range, and its apparent activation energy is unexpectedly low. Although the reaction mechanism of pyrolysis of benzene is not yet completely established, it may be compatible with the present results.

15) M. Kobayashi, private communication.

## Summary

In order to elucidate the mechanism of the pyrolysis of toluene, pyrolysis of toluene-3-*d* and -4-*d* was carried out by the flow method in the temperature range 830∼955°C, and the mole ratios $D_2 : HD : H_2$ and $CH_3D : CH_4$ were determined by mass spectrometry. The involvement of the reaction of ring-hydrogen in the pyrolysis has been confirmed from the formation of HD and $CH_3D$. As there was not any distinct difference in the mole ratios between the reactions of toluene-3-*d* nor -4-*d*, it is concluded that the reactivities of *m*- and *p*-hydrogens of toluene are of the same order. Considering these results, the possible elementary processes involving ring-hydrogen are discussed.

The author wishes to express his hearty thanks to Professor Y. Urushibara and Professor O. Simamura for their kind guidance and encouragement for the present work. The author is grateful to Professor S. Araki for kind advice in mass spectrometry, to Dr. M. Kawano for measurements of infrared spectra, to Dr. M. Kobayashi for stimulating discussions and also to Mr. A. Suzuki for experimental help.

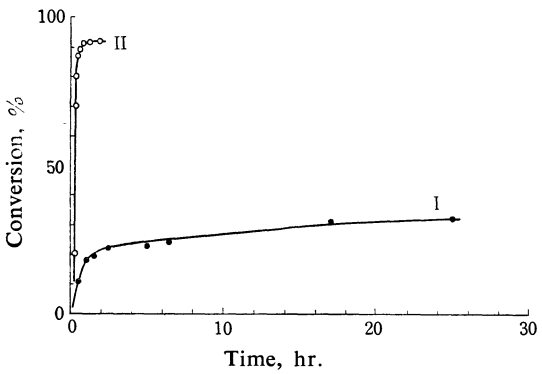
# *Studies on Dehydroalanine Derivatives. II. Synthesis of Polydehydroalanine*

By Shumpei SAKAKIBARA

(Received November 30, 1959)

In the preceding paper of this series[1] the synthesis and properties of *N*-carboxy dehydroalanine anhydride (I) were described. The present investigation was designed to synthesize polydehydroalanine using the anhydride I as starting material, and to obtain some information concerning the structure of the polypeptide.

**Synthesis of Polydehydroalanine.** — It was previously observed, that the carbamic acid II, which formed from the *N*-carboxy anhydride I, after hydrolysis or aminolysis was unusually stable as compared with those derived from ordinary amino acids[1]. Therefore, it was expected that the rate of polymerization of the *N*-carboxy anhydride I would be much slower than that of usual *N*-carboxy anhydrides at ordinary temperature. In order to ascertain this expectation, the rate of polymerization of *N*-carboxy dehydroalanine anhydride (I) was compared with that of *N*-carboxy DL-alanine anhydride at 30°C using cyclohexylamine as initiator. As can be seen from Fig. 1, the time-conversion curve of the polymerization of the *N*-carboxy anhydride I reached the 25% line only after 5 hours, and then very slowly approached the 35% line, while the *N*-carboxy DL-alanine anhydride polymerized very quickly, and the curve arrived at the 90% line within half an hour. It was concluded from these findings that the polymerization reaction of the *N*-carboxy anhydride I should be carried out at sufficiently high temperatures to permit a more rapid rate of the decarboxylation reaction, and that tertiary amines should be used as initiators. The tertiary amine used, would overcome the inclination for low conversion of the polymerization reaction which may be induced by the formation of ureide III as the termination reaction. A rapid rate of the polymerization reaction also seemed to be desirable in order to suppress a vinyl-type polymerization.



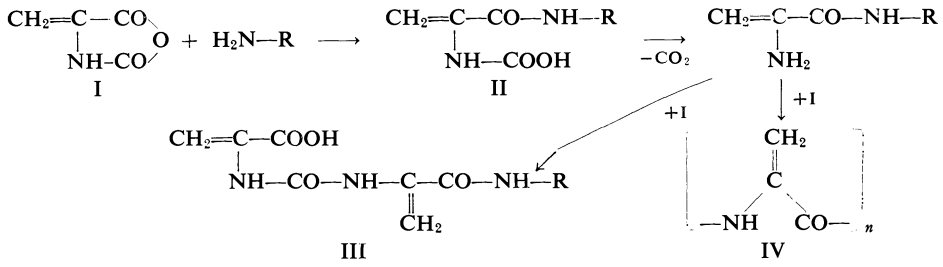


Fig. 1. Polymerization rates of *N*-carboxy anhydrides at 30±0.1°C in dioxane containing cyclohexylamine (10 mol. % against the *N*-carboxy anhydrides): I. *N*-Carboxy dehydroalanine anhydride; II. *N*-Carboxy DL-alanine anhydride.

In the present experiment, polydehydroalanine was prepared by heating a dry pyridine solution of the substance I, at 100°C, or by adding a small amount of triethylamine into a boiling dry toluene solution of the substance I. In the case of the former, the reacting solution gradually became dark-brown as the polymerization reaction proceeded and brown precipitates (IVa) formed. Evolution of carbon dioxide almost ceased after about 2 hr. In the case of the latter, the starting, slight-yellow, clear solutidn suddenly turned into brown, when a small amount of triethylamine was added into

1) S. Sakakibara, This Bulletin, 32, 13 (1959).

the solution. At the same time a vigorous evolution of carbon dioxide was observed and brown precipitates gradually formed. This precipitates were partially insoluble in water, and the water soluble part was collected as polydehydroalanine (IVb).

**Properties of the Polydehydroalanine.** — The freshly formed brown product IV (IVa or IVb) was completely soluble in water, formic acid and dichloroacetic acid, slowly dissolved in dimethylformamide and *m*-cresol, but after complete drying it became partially insoluble in these solvents. Furthermore, about 80% of the substance IV was converted into a water-insoluble form, when preserved under ordinary conditions for about six months. Such a solubility behavior of the substance IV was similar to that of poly-DL-alanine[2,3]. It was, however, found that 34% of the aged substance IV, was completely insoluble even in formic acid, in which the aged poly-DL-alanine is readily soluble[3]. This fact seems to indicate that the substance undergoes not only $\alpha$-$\beta$-configuration change of the polypeptide-bonds, but also the intermolecular cross-linkage formation due to its double bonds. After reprecipitation from water-ethanol, the polypeptide IV was still brown in color, and its ultraviolet absorption spectrum (Fig. 2) suggested the presence of some kinds of conjugated double bonds. When the polypeptide was hydrogenated as described in a later part of this paper, this absorption bands at 230~350 m$\mu$ corresponding to the conjugated double bonds vanished and the brown color extremely reduced at the same time.

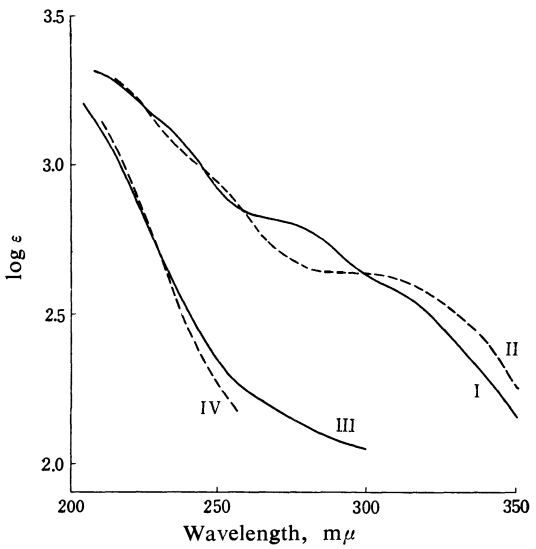

Fig. 2. Ultraviolet absorption spectra recorded on a Beckman DK-2 spectrophotometer: I. Polydehydroalanine (PDA) dissolved in distilled water; II. PDA dissolved in aq. 1 N NaOH solution; III. Hydrogenated PDA dissolved in water; IV. Poly-DL-alanine dissolved in water.

The determination of the molecular weight of the polymer was very difficult. The end-amino group of the polypeptide should not be expected to be present in this material, because of the instability of the *N*-terminal dehydroalanyl group[1]. Therefore, amino-nitrogen determination for calculating the mean molecular weight of the polymer is not significant. When this polymer was titrated with sodium methoxide for determining the end-carboxylic acid, equivalent weights of 330 and 435 were obtained, which corresponded to about 4.7 and 6.2 monomer residues, and these values were much smaller than those calculated hereafter from the expected molecular weight of the polymer. This fact suggested the following two possibilities: (1) Enolization of peptide bonds, which has been mentioned previously by Bergmann, et al. in the cases of dehydroalanyl peptides or diketopiperazines[4]. (2) Partial hydrolysis of pyrolidone rings (VI) which may be formed spontaneously from the dehydroalanyl residues as described in a later part of this paper. The delicate difference between the ultraviolet absorption spectrum of the polymer in 1 N sodium hydroxide solution and that in distilled water would also suggest the fact of enolization. Viscosities of 0.5% dichloroacetic acid solutions of these polymers, IVa and IVb, were determined at 25±0.01°C, and $\eta_{sp}/C = 1.8$ and 0.9 ($C$ expressed in base mol./l.) were obtained, respectively. If an assumption is permitted, that this polymer behaves quite similarly to poly-DL-alanine in dichloroacetic acid, the molecular weight of the polymer may be determined by comparison of the viscosity number with that of known poly-DL-alanine under the same conditions[5]. From the above consideration, about 7000~5000 and 4000~2000 were calculated for their molecular weights, respectively.

**Hydrogenation and Hydrolysis of Polydehydroalanine for Elucidation of the Actual Structure.** —Elucidation of the structure of the polymer was very difficult because double bonds involved in the molecule are expected to be reactive and they may interact with one another within the molecule. If the structure of the polymer is exactly identical with the structural formula

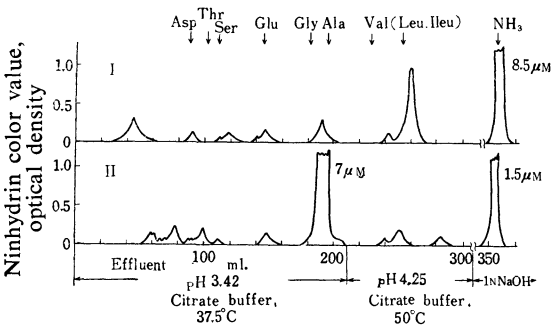
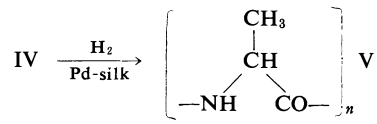
IV, poly-DL-alanine should be derived as a result of hydrogenation of the polymer. An attempt of catalytic hydrogenation of the polymer IV under the presence of palladium-charcoal was unsuccessful, since the polymer was adsorbed on the catalyst and separation of the catalyst from the product was very difficult. Recently, Izumi[6] has published an excellent catalyst, which was prepared by reduction of palladium chloride co-ordinated with silk-fibroin. When this catalyst was used, the hydrogenation reaction of the polymer IV, proceeded successfully, and the starting brown solution of the polymer IV turned into a slight-yellow one, after the reaction was finished. Since the palladium atoms have previously adsorbed between peptide layers of silk-protein, no more polypeptide was adsorbed on the catalyst during the reaction. From the hydrochloric acid hydrolyzate of the product V, alanine was detected in a yield of about 5% of the theoretical by the Dowex 50 column chromatography under the condtions of Moore and Stein[7] (Fig. 3).





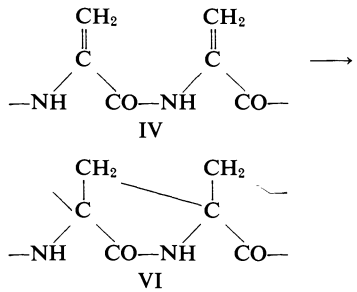


Fig. 3. Chromatographic analysis of ninhydrin-positive materials of the HCl-hydrolyzates: I. Polydehydroalanine (10 mg.); II. Catalytic hydrogenated polydehydroalanine (10 mg.). Arrows indicate the position of the peaks of standard amino acids.

The ultraviolet absorption spectrum of the hydrogenated product V (Fig. 2) was similar to that of the poly-DL-alanine and the absorption bands corresponding to the conjugated double bonds at 250~350 mμ disappeared after hydrogenation as described previously. The infrared spectrum of the hydrogenated product V (Fig. 4), however, was neither quite different from that of the starting polymer, nor similar to that of poly-DL-alanine. This infrared spectrum resembled rather that of poly-α-amino acrylic acid[8]. Since the actual structure of the poly-α-amino acrylic acid is considered to be polypyrolidone[9], a greater part of the polymer would be composed of such a polypyrolidone-type structure VI, which might form spontaneously from the polydehydroalanine by interaction of the neighboring double bonds. The infrared absorption bands at 1700~1760 $cm^{-1}$ (Fig. 4) supported also the presence of five membered cyclic amide. If the structure of the polydehydroalanine corresponds to the formula IV exactly, its hydrochloric acid hydrolyzate must all be pyruvic acid and ammonia. However,

many kinds of ninhydrin-positive materials, the total yield of which was about 10% of the ideal formula IV, were detected by ion-exchanger column chromatography from the hydrochloric acid hydrolyzate (Fig. 3). Ammonia, which formed in this case was also directly ascertained[10] and amounted to 9.5% of the theoretical. These facts all supported the formation of the non-hydrolyzable material which was considered to be such a polypyrolidone. Actually, the hydrochloric acid hydrolyzate of the polymer IV became dark brown, and this fact indicated a formation of huminic material during the course of the reaction. From the result of the experiments and the above considerations, it may be appropriate to consider that the obtained polymer IV, consists of about 90% of polypyrolidone-type polypeptide and about 10% of dehydroalanyl residues. In other words, the synthesis of polydehydroalanine, which was exactly expressed as the structural formula IV, was unsuccessful in the present experiment. If the preparation of co-polymer of dehydroalanine and another stable amino acid is possible, the interaction of the neighboring double bonds would decrease more

distinctly. A communication on the reactivity of the dehydroalanyl groups involved in the present polymer will be published in the near future.

## Experimental

**Materials.**—*N*-Carboxy dehydroalanine anhydride (I) and *N*-carboxy DL-alanine anhydride were prepared according to the description in the previous paper[1].

**Determination of the Polymerization Rate of I.**—The substance I (350 mg.) was dissolved in freshly distilled dry dioxane (15.00 ml.) containing cyclohexylamine (30.4 mg.). The solution was divided into 14 test tubes so that each tube contains 1.00 ml. of the solution, and the tubes were sealed. Then, they were allowed to react in a bath at 30± 0.1°C, simultaneously. Each of the portions was opened successively at times and dry nitrogen was introduced for about one min. into the solution, which was then titrated with a methanol-benzene solution of sodium methoxide, using thymol blue as an indicator according to the description of Berger, et al.[11] (Fig. 1). The sodium methoxide solution (ca. 0.3 N) was standardized every 5 hr. with purified benzoic acid. *N*-Carboxy DL-alanine anhydride was subjected to the reaction under the same condition described above (Fig. 1).

**Polymerization of I in Pyridine (Preparation of Polydehydroalanine IVa).**—A solution of I (5 g.) in purified dry pyridine (15 ml.) was heated in a boiling water bath for about 2 hr. After cooling to room temperature, the reddish brown reaction mixture was poured into ethyl acetate (100 ml.). The precipitated brown material was centrifuged, washed thoroughly with ethyl acetate and ether, and dried. The brown powder obtained (3.05 g.) was reprecipitated from water-ethanol and dried under reduced pressure at room temperature. The yield was 2.4 g. (64%).

Found: C, 43.8; H, 5.76; N, 15.5; volatile part at 135°C, 17.9. Calcd. for $(C_3H_3ON+14/18\cdot H_2O+1/20\cdot C_2H_6O$ (ethanol)$)_n$: C, 43.7; H, 5.71; N, 16.5; volatile part, 18.8%.

Found*: C, 49.50; H, 4.24; N, 18.86; ash, 1.2%; Na-equiv. wt.[12], 330. Calcd. for $(C_3H_3ON)_n$: C, 52.17; H, 4.35; N, 20.3%.

This material was hard to burn up for analysis.

**Polymerization of I in Toluene (IVb).**—Few drops of triethylamine were added into a boiling toluene solution of I (1 g./20 ml.). The starting clear solution, which was light-yellow, suddenly turned into brown as the reaction occurred and reddish brown precipitates formed immediately under the vigorous evolution of carbon dioxide. After about 30 min., the reaction mixture was cooled and the formed precipitates were filtered off, washed three times with ethyl acetate and dried. The yield was 0.62 g. This material was extracted with sufficient amount of water. The water extract was concentrated to about 5 ml. and brown powder (0.19 g.) (IVb) was reprecipitated with ethanol. The water insoluble part of the material was about 0.18 g. Na-equiv. wt. of the material IVb was 435.

**Hydrogenation of IVa.**—The substance IVa (300 mg.) was dissolved in water (50 ml.) and hydrogenated in an autoclave under 100 atm. of hydrogen at 50~60°C for about 8 hr. using palladium-silk catalyst (200 mg.). After the reaction was complete, the catalyst was filtered off and the filtrate was concentrated to about 10 ml. Ethanol (100 ml.) was added into the concentrate and about 160 mg. of light-yellow powder was precipitated. This material was reprecipitated from water-ethanol and dried under reduced pressure at 118°C.

Found: C, 47.67; H, 5.13; N, 16.68. Calcd. for $(9/10\cdot C_3H_3ON+1/10\cdot C_3H_5ON+2/5\cdot H_2O)_n$: C, 47.1; H, 5.36; N, 18.3%.

11) A. Berger, M. Sela and E. Katchalski, *Anal. Chem.*, 25, 1554 (1953).

12) M. Sela and A. Berger, *J. Am. Chem. Soc.*, 77, 1893 (1955).

*) This material was dried over phosphorus pentoxide under reduced pressure at 135°C, in which procedure a certain extent of decomposition might occur, such as liberation of formaldehyde or ammonia.

The hydrogenated material (10 mg.) was hydrolyzed with 6 N hydrochloric acid for about 20 hr. and the hydrolyzate was concentrated to dryness. The residue was then subjected to column chromatography under the Stein-Moore's condition (Fig. 3). The fraction corresponding to alanine was collected, treated with 2,4-dinitrofluorobenzene and purified by celite column chromatography using ether-phosphate buffer (0.25 M, pH 6.5) as a developer. Infrared spectrum of the purified main fraction was agreed with that of authentic DNP-alanine.

## Summary

The polymerization rate of *N*-carboxy dehydroalanine anhydride (I) was compared with that of *N*-carboxy DL-alanine anhydride, and it was found, that the former was much slower than the latter at 30°C. Polydehydroalanine (IV) was obtained by heating the substance I in dry pyridine at 100°C, or by adding a small amount of triethylamine into the boiling toluene solution of I. The substance IV was water-soluble brown powder, the actual structure of which was supposed to be a pyrolidone-type polypeptide VI containing about 10% of dehydroalanyl residues.

The author wishes to express his thanks to Professor Shiro Akabori and Professor Shunsuke Murahashi for their guidance and encouragement throughout the course of this study.

# *Systematic Separation of Fission Products by Solvent Extraction Method*

By Toshiyasu KIBA, Shigeru OHASHI and Toyoo MAEDA

(Received October 27, 1959)

Solvent extraction methods have often been employed for the separation of individual fission products. The purpose of the present investigation was to establish a new scheme of systematic separation of fission products having relatively long half-lives by combining and modifying the solvent extraction methods developed previously. The fission products considered in this investigation were limited to the nuclides, the radioactivities of which are higher than one per cent after all the fission products have been aged for one year. The nuclides which fall in this category are zirconium-niobium-95, cerium - praseodymium - 144, promethium - 147, strontium-yttrium-90, ruthenium-rhodium-106, cesium-137-barium-137$^{m}$, strontium-89, and yttrium-91. Since the chemical behaviors of strontium-89 and yttrium-91 are just the same as those of strontium-90 and yttrium-90, respectively, these were excluded from the scope of the present investigation. All of the other nuclides except promethium-147 are composed of the pairs of parent and daughter. Among these pairs, praseodymium-144, rhodium-106, and barium-137$^{m}$ are relatively short-lived daughters. Therefore, the nuclides considered finally for this study were zirconium-niobium-95, cerium-144, promethium-147, strontium-yttrium-90, ruthenium-106, and cesium-137.

Marinsky, Hume and Ballow[1] reported that zirconium-95 and niobium-95 can be extracted from a hydrochloric acid solution into chloroform with cupferron. Kiba and Kanetani[2] found that rare earth nuclides, cerium-144, promethium-147, and yttrium-90 can be separated from an acetate solution of pH 4 to 5 into chloroform with cupferron. Kiba and Mizukami[3] investigated the separation of strontium-90 and yttrium-90 and found that strontium-90 can be extracted from an acetate solution of pH 8 with TTA dissolved in hexone. Kiba and Hirono[4] reported that ruthenium-106 can be extracted from hydrochloric acid solution into a mixture of TBP and kerosene with diphenyl thiourea. Combining and modifying the methods mentioned above the present authors have presented a new systematic method for the separation of fission products by the liquid-liquid extraction processes.

## Experimental

All of the radioactive nuclides were purchased from the Oak Ridge National Laboratory of the

4) T. Kiba and H. Hirono, presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April 5, 1958.

United States of America. Stock solutions of these unclides were made as follows. The original solution of zirconium-niobium-95 in 0.03 M oxalic acid was diluted with 0.33 M oxalic acid. The original solution of cerium-144 as cerous nitrate in nitric acid, that of promethium-147 in hydrochloric acid, that of strontium-yttrium-90 in nitric acid, that of ruthenium-106 as nitrosyl ruthenium trinitrate in 8 M nitric acid, and that of cesium-137 in 1 M nitric acid were diluted with 3.75 M hydrochloric acid, respectively. About 0.05 to 0.1 $\mu$c of the carrier-free nuclides was used for each experiment.

TBP was purified by distillation. All other chemicals of the guaranteed or the first grade of Japan Industrial Standards were used without further purification. An electric shaker was used for shaking of separatory funnels. Whole or aliquots of both aqueous and organic phases were taken into small porcelain dishes after five to ten minute shaking for each extraction. The content of each dish was evaporated or ignited, and the beta activity was measured with an end-window type GM counter.

## Results and Discussion

The whole scheme of the systematic separation is demonstrated in Table I. The method is composed of four-step extractions. The first

a. Some of $^{95}$Zr and/or $^{95}$Nb was lost probably by the adsorption.
b. These values were calculated from the total activities and the activities in the aqueous phase.
c. This value was obtained by the stripping of $^{137}$Cs from the organic phase with 15 M nitric acid. The loss of $^{137}$Cs in the 4B step was unaccountable.

step is the extraction of zirconium-95 and niobium-95 from a 3 M hydrochloric acid solution into chloroform with cupferron. The second step is the extraction of rare earth nuclides, i. e. cerium-144, promethium-147, and yttrium-90 from an acetate buffer solution of pH 4 to 5 into chloroform with cupferron. The third step is the extraction of strontium-90 from an acetate buffer solution of pH 8 into hexone with TTA. The fourth step is the extraction of ruthenium-106 from a 5 M hydrochloric acid solution into a mixture of TBP and kerosene (1 : 2) in the presence of stannous chloride. Another method for the fourth step is the extraction of ruthenium-106 from a 5 M hydrochloric acid solution into TBP in the presence of hydroxylamine. Thus cesium-137 remains is the last aqueous solution. The detailes of the extraction procedures are tabulated in Table II. The distribution of each radioactive nuclide in the aqueous and organic phases in each extraction step was determined. The results are summarized in Table III, in which the data shown under the step-like line in each column were obtained only for reference. Recovery on the stripping of the radioactive nuclides from the organic phase is shown in Table IV. The data given in Tables III and IV are mean values obtained from three or four experiments.

TABLE IV. RECOVERY OF NUCLIDES FROM ORGANIC PHASE BY STRIPPING

| Nuclide | Stripping agent | Number of stripping | Recovery % |
|---|---|---|---|
| $^{95}$Zr—$^{95}$Nb | 10 M $HNO_3$ | 2 | 83.9 |
| $^{144}$Ce | 3 M $HNO_3$ | 1 | 98.4 |
| $^{147}$Pm | 3 M $HNO_3$ | 1 | 88.8 |
| $^{90}$Y | 3 M $HNO_3$ | 1 | 98.8 |
| $^{90}$Sr | 3 M $HNO_3$ | 1 | 98.4 |
| $^{106}$Ru | 15 M $HNO_3$ | 3 | 99.8 |

In the first step oxalic acid is added to the solution to prevent the adsorption of zirconium-95 and niobium-95 onto a glass vessel by forming complexes with these nuclides. Hydroxylamine protects cupferron from oxidation with air and a trace amount of nitric acid. The data disclose that by the first step extraction only zirconium-95 and niobium-95 are extracted as cupferrates into the organic phase and all other nuclides are left in the aqueous phase. The zirconium-95 and niobium-95 extracted in the organic phase can be stripped with 10 M nitric acid as shown in Table IV.

In the second step aqueous ammonia is added to the aqueous phase remaining after the first step extraction to neutralize hydrochloric acid, and then ammonium acetate solution is added to adjust the pH of the aqueous phase to 4~5. In order to complete the separation of rare earth nuclides the concentration of cupferron should be considerably high and the extraction should be repeated three times. Before each extraction with chloroform 3 ml. of a 5% cupferron solution is added to the aqueous phase. By this step cerium-144 and promethium-147 are extracted into the chloroform phase.

Strontium-90 and yttrium-90 in their radioactive equilibrium are separated from each other, the former being in the aqueous phase and the latter in the organic phase, as shown in the sixth column of Table III. The decay or the growth curve and the Harley plot of the activity in each phase indicates that the separation of the nuclides can be carried out completely. The rare earth and yttrium nuclides extracted in the organic phase can easily be stripped with 3 M nitric acid.

After the second step extraction, a small amount of aqueous ammonia is added to the resulting aqueous phase to raise the pH of the

solution up to 8[3]. Then the third step extraction is carried out with a 0.05 M TTA-hexone solution. Two extractions complete the separation of strontium-90. The data in the sixth column of Table III shows that yttrium-90, if it could be present, by the later decay of strontium-90 is also extracted into the organic phase. The strontium-90 extracted in the organic phase can be stripped with 3 M nitric acid.

The fourth step extraction is that of ruthenium-106. It was found in the previous investigation[4] that ruthenium-106 can be extracted from 6 M hydrochloric acid solution with diphenyl thiourea dissolved in a mixed solvent of TBP and kerosene (1 : 2) in the presence of stannous chloride. However, it is difficult to strip the ruthenium-106 extracted in the mixed solvent into an aqueous phase. The present authors reexamined the extraction condition for ruthenium-106 and found that ruthenium-106 can be almost completely extracted, in the presence of stannous chloride from 6M hydrochloric acid solution with the mixed solvent of TBP and kerosene containing no chelating agent such as diphenylthiourea. Almost all of the ruthenium-106 extracted in the organic phase can be stripped with concentrated nitric acid, but a part of stannous chloride which is extracted from into the organic phase is also stripped with concentrated nitric acid. It is difficult to remove the stannous chloride from the nitric acid solution as well as to obtain the salt-free aqueous solution of ruthenium-106. So this method would not be suitable for preparing carrier-free ruthenium-106, but the procedure might be used as an analytical method for ruthenium-106 in the fission products.

Another method for the extraction of ruthenium-106 is as follows: ruthenium-106 can be extracted from 5 M hydrochloric acid solution in the presence of hydroxylamine with TBP which is not diluted with kerosene but is saturated with a 5 M hydrochloric acid solution. By this method about 94 per cent of ruthenium-106 is extracted and almost all of it is stripped with concentrated nitric acid from the organic phase. Some amount of hydroxylamine is also extracted with TBP and then also with concentrated nitric acid. But it is possible to decompose the hydroxylamine stripped together with ruthenium-106 by heating after neutralizing the nitric acid with aqueous ammonia. Then we can get the salt-free aqueous solution of ruthenium-106. Although the yield of ruthenium-106 is less than that obtained by the former method, this method is superior to the former one from the point of view of the preparation of carrier-free ruthenium-106.

## Summary

A new scheme for separating fission products, zirconium-niobium-95, cerium-144, promethium-147, yttrium-90, strontium-90, ruthenium-106 and cesium-137, by the four-step liquid-liquid extractions was presented. First, zirconium-95 and niobium-95 were extracted from a 5 M hydrochloric acid solution into chloroform with cupferron. Second, rare-earth nuclides, cerium-144, promethium-147 and yttrium-90 were extracted from an acetate buffered solution of pH 4 to 5 into chloroform with cupferron. Third, strontium-90 was extracted from an acetate buffered solution of pH 8 into hexone (methyl isobutyl ketone) with TTA (2-thenoyltrifluoroacetone). Fourth, ruthenium-106 was extracted from 5 M hydrochloric acid solution with TBP (tri-*n*-butyl phosphate)-kerosene in the presence of stannous chloride or extracted with TBP in the presence of hydroxylamine. then cesium-137 was left in the last aqueous solution. Strippings of nuclides extracted in the organic phases could be attained by shaking each organic phase with nitric acid.

This study was done as a part of the cooperative research on fission products and fissile materials which was superintended by Prof. N. Saito, the University of Tokyo. The authors wish to express many thanks to him and the Ministry of Education for financial help of this study.

# *Dielectric Properties of Polypeptide Solutions. Measurement of the Dielectric Properties of the α-Helix by the Low Frequency Bridge Method*

By Akiyoshi WADA

(Received November 6, 1959)

The exhaustive research on the polypeptide solution by Doty, Blout and their co-workers[1] revealed the important fact that the α-helix can exist not only in the solid state but even in solution. One significant implication of their work is that the α-helix, one of the stable configurations of polypeptide molecules described by Pauling, Corey and Branson[2], can be studied in solution where each α-helix exists as a free molecule, that is, almost free from solute-interaction. These results then suggest the possibility and necessity of another type of research, the measurement of the electric dipole moment and the critical frequency of such a molecule with a highly ordered arrangement of residues.

The measurement of the electric dipole moment of the molecule has been considered a useful method of finding the charge distribution and the orientation of the polar groups in a molecule. The method has often been used to determine the molecular structure of a simple molecule in the field of physical chemistry. However, in the usual chain polymer molecule, because of the flexibility of the chain the observed electric dipole moment becomes a complicated function of the internal coordinates and the internal energy of the molecule, and this method does not appear to be as useful as in the case of the simple molecule. For the α-helix, however, if the Pauling-Corey model is given as the proper configuration and if the molecule is rigid as Doty et al. concluded[1], the resultant molecular dipole moment would be proportional to the degree of polymerization, unlike the usual chain polymer, and would have a tremendous value in a highly polymerized molecule.

As the measurement of the dipole moment, which is a vectoral value, is essentially different from investigations on non-directional values such as molecular dimension, the observation will approach the α-helix and related problems from an entirely different angle.

## Description of the Low-Frequency Bridge Circuit

Though the heterodyne beat method or the resonance method has often been used for the measurement of the dielectric constant of solution, they could yield reliable data only in the high-frequency range and would not be adequate for the purpose of the present investigation. Because the solute, the α-helix, is a rigid and highly assymmetric rod-shaped molecule and the relaxation time of over-all molecular rotation in the solvent must be fairly great, the apparatus must be designed to cover the low-frequency range where sufficient time can be allowed for very slow orientation polarization. The bridge method seems to be appropriate for the present purpose and the apparatus by which the dielectric constant and loss factor can be measured from 30 cycle to 20 kilocycle was constructed as described below.

1) **Low-Frequency Bridge.**—The bridge method has been known as the best device for the measurement of the dielectric constant in the low-frequency range.[3] For instance, Cole and Gross[4] developed a transformer bridge, and Hippel et al. employed the Schering bridge method in their comprehensive research on dielectric materials.[5]

The Cole and Gross bridge was designed to fit the guard without the use of the Wagner ground. The measurement of capacitance was obtained by balancing the bridge by changing the capacity of the precision condenser which was set in the conjugated arm of the unknown capacitance. The conductance measurement is performed by a device called the conductance shifter.

The latter, designed by Hippel and his co-workers, has a sample holder in the arm of the precision condenser, and is generally known as a substitution method. In such an apparatus the cell constant used is calibrated by the standard substance. The conductance is given, in this apparatus, by the reading of the dissipation balancing condenser.

For the present purpose the apparatus was designed to combine the substitution method and the conductance shifter. The block diagram of the bridge circuit is shown in Fig. 1.

The low frequency oscillator which continuously

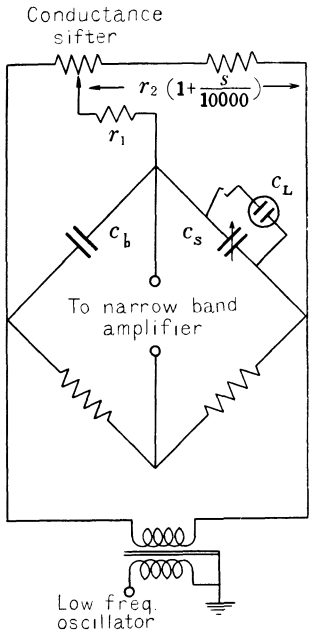

Fig. 2. Low frequency bridge circuit.

generates sine waves in the range of 30 to 20,000 cycles and output voltage from 0 to 20 volts has the same circuit as the Heathkit Model AO-1.

The circuit of the bridge section is shown in Fig. 2. $C_s$ is the liquid cell whose capacitance is compared with that of a portion of the calibrated precision condenser. The precision condenser (Yokogawa Elect. Co. CDS-500 Variable Air Condenser), in which the use of the worm drive makes possible a scale which can be read to one part in 50,000 of full scale, has a maximum capacitance of 500 $\mu\mu$F. By using low resistance for the balancing arm the undesirable effects of stray capacitance and induction from the external field can be suppressed at the sacrifice of sensitivity. In the reading of the conductance shifter, the conductance, $G$, can be given as a three-digit number, $s$, by the following equation

$$G=\frac{(s/10000)/r_1}{1+(r_2/2r_1)\{1-(s/10000)^2\}} \qquad (1)$$

when $s \ll 10000$

$$G\fallingdotseq\frac{(s/10000)/r_1}{1+r_2/2r_1} \qquad (2)$$

where $r_1$ and $r_2$ are the resistances which are shown in Fig. 2. The present apparatus was designed so that $r_1$ can be set at four different values by the use of a rotary switch, which made the measurement of the conductance from $10^{-5}$ to $10^{-9}$ mho possible. The null detector consists of a narrow-band amplifier and vacuum tube voltmeter. The narrow-band amplifier, in which the Wien bridge and the negative feedback system are combined, has a sharp frequency response, an example of which is shown in Fig. 3, and amplifies only the given frequency, cutting out the hamper noise and harmonic frequency. The wave pattern was checked by the cathode-ray oscillograph. The null point can be obtained from the minimum reading of the vacuum tube voltmeter. The relation between the reading of the precision condenser and the vacuum tube voltmeter is plotted for different

|---|---|---|---|---|
| Accuracy | ±0.5 | ±0.2 | ±0.1 | ±0.1 $\mu\mu$F |

frequencies in Fig. 4, and the accuracy of the measurement is given below.*

2) **Liquid Cell.**—The liquid cell consists of a concentric double cylinder of glass as shown in Fig. 5; the inside of the outer cylinder and the outside of the inner cylinder are silver gilt or spattered with gold. The latter was found to be more satisfactory in chemical and mechanical durability.

3) **Calibration.**—Because the substitution method was used here, the cell constant had to be determined by a pure liquid of known dielectric constant. Benzene, the dielectric constant of which has been given as 2.274 at 25°C with a probable accuracy of 0.1%, was used as a standard substance for the calibration.[6]

The dielectric constant of ethylene dichloride and dioxane measured by the calibrated liquid cell are plotted against frequency in Fig. 6. The apparent increase in the dielectric constant at low-frequency range may be due to the polarization capacitance

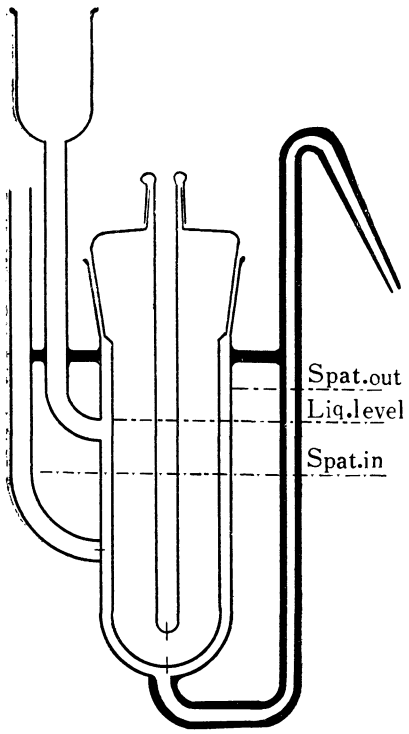

Fig. 5. Liquid cell for the measurement of dielectric constant of solution.

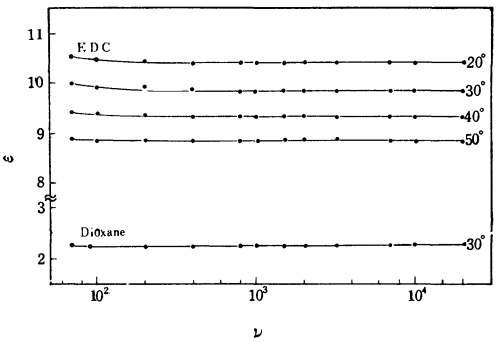

Fig. 6. Dielectric constant of ethylene dichloride and dioxane at various temperatures and frequencies.

on the electrode surface. The polarization effect increases and must be corrected for a liquid of high conductivity but it was negligible for one of small conductivity. The dielectric constants of liquids mentioned above at 1000 cycles where the polarization effect satisfactorily diminished are listed in Table II and were consistent with the values observed by other workers.

## Characterization of Poly-γ-benzyl-L-glutamate (PBLG)

1) **Polymerization.**—The sample used here was prepared by the Blout-Karlson method[7]. The procedure adopted consisted of polymerizing γ-benzyl-N-carboxy-L-glutamate anhydride, usually 3—5% in dioxane solution, by a sodium methoxide initiater at room temperature. After polymerization was completed the reaction mixture was poured into cold ethanol with vigorous stirring. The precipitate was redissolved in dioxane and precipitated by cold ethanol again. No difference in intrinsic viscosity was found between the reprecipitated

* The bridge was found to be stable enough that the reading of the vacuum-tube voltmeter did not fluctuate more than 3/100 full scale after a 20-min. warm-up of the apparatus.

7) E. R. Blout and R. H. Karlson, *J. Am. Chem. Soc.*, 78, 941 (1956).

PBLG and that liopholyzed from the first dioxane solution.

**2) Solvent.** — Dimethyl formamide (DMF) was used as the solvent for the light scattering measurement because the PBLG was found to exist as a non-associated molecule in this solvent. DMF was dried by dry sodium bicarbonate and fractionally distilled at 47°C (14 mmHg). For the dielectric constant and light scattering measurement dioxane was purified according to the method of Fieser[8] and fractionally distilled after 24 hr. refluxing with sodium. For the polymerization reaction, dioxane was purified by refluxing with sodium for 24 hr. and fractionally distilled just before use. The ethylene dichloride (EDC) for the measurement of the dielectric constant was dried by $P_2O_5$ and fractionally distilled at 84°C.

**3) Light Scattering.** — The Brice Phoenix type light scattering photometer made by the Shimadzu Co. was used to obtain the molecular weight of PBLG. The apparatus was calibrated according to the Rayleigh ratio of pure benzene ($R_{90}=48.4\times10^{-6}$ at 436 m$\mu$.[9]). The spectrophotometric calibration was independently done by Ludox solution and the result was quite consistent with the calibration by benzene. Scattering from DMF solution of PBLG was measured by the Erlenmeyer cell and the circular uniformity of which was checked with clean fluorescein by measuring the angular envelope. The cell used had good circular uniformity as the light intensity from the unit volume of the solution was constant to ±1% from $\theta=30°$ to 135°. The angle made by the side of the Erlenmeyer cell was sufficient to exclude the effects of back reflection, so that no correction for the data was necessary. Centrifuge by a Hitachi Preparative Ultracentrifuge using a polyethylene tube with a specially constructed tefron cap, at about 60,000 $g$ for 1 hr. and filtration by ultra-fine sintered glass filter were performed to make a dust-free solution and solvent respectively. Measurements were made on the solutions obtained by adding a weighed amount of 1% PBLG dust-free solution to a known volume of clean solvent in an Erlenmeyer cell, on which the scattering was already measured. The concentration after each addition was determined gravimetrically relative to the stock solution.*

The refractive index increment $dn/dc$ for the evaluation $K=2\pi^2n_0^2(dn/dc)^2/N\lambda^4$ where $n_0$ is the refractive index of the solvent, $\lambda$ is the wave length of the incident light in vacuo, $N$ is the Avogadro number, was determined by the Debye-type defferential refractometer made by Shimadzu Co. The instrument was usually calibrated before each measurement with a standard KCl solution, $c=\frac{10.8691\,\text{g.}}{H_2O\,(\text{kg.})}$, for which the increment was taken as 0.0015204 on the basis of an extrapolation of data by Kruis.[10]

According to the well known equation established by Zimm,[11]

$$Kc/R_\theta=\{M_wP(\theta)\}^{-1}+2A_2c \qquad (3)$$

the weight average molecular weight $M_w$ can

TABLE III. MOLECULAR WEIGHT, MOLECULAR LENGTH, SPECIFIC POLARIZATION, DIPOLE MOMENT AND CRITICAL FREQUENCY OF PBLG IN EDC

| PBLG | $M_w$ | $L_{z,z+1}$ | $P_2^{00}$(cc) | $\mu$(D) | $\mu_0$(D) | $\nu_0$ |
|---|---|---|---|---|---|---|
| 202 | 180,000 | 1350 | 963 | 2910 | 3.54 | 3000 |
| 105 | 154,000 | 1100 | 805 | 2450 | 3.48 | 7000 |
| 102 | 102,000 | 750 | 494 | 1570 | 3.36 | 16000 |
| 201 | 86,000 | 690 | 470 | 1404 | 3.58 | 20000 |
| 103 | 70,000 | 600 | 314 | 1040 | 3.25 | 40000 |

be obtained after extrapolating to $c=0$ and $\theta=0$, where the particle scattering factor $P(\theta)$ is known to be unity. A typical double plot, that is, the so-called Zimm plot, for one of the PBLG samples in DMF is shown in Fig. 7a. Measurements were also conducted for the dioxane solution as one of the Zimm plot and are shown in Fig. 7b. The molecular length, assuming a rigid rod-shaped molecule at present, can be calculated from the initial slope of the angular envelope in the Zimm plot;

$$L^2_{z,z+1}=\frac{9\lambda'^2}{8\pi^2}\frac{(\text{slope})_{c=0,\ \theta=0}}{(\text{intercept})_{c=0,\ \theta=0}} \tag{4}$$

where $\lambda'$ refers to the wave length in solution.

The final results of the measurement of molecular weight and molecular length are listed with the polymerization condition in Table III. The remarkable increase in molecular weight and molecular length in dioxane solution might result from molecular association which will be discussed in detail later.

## Dielectric Properties of PBLG in Ethylene Dichloride and Dioxane

For a long, rigid rod-shaped molecule, the cavity field in the direction of the rod axis can be assumed to be the same as the external field, and in the $\alpha$-helix having point dipoles parallel with the rod axis, only the field of this direction has to be taken into consideration. So the relation between the static dielectric constant of the solution $\varepsilon_{12}^0$ and the specific polarization of the solute $P_2$ is given in terms of the weight fraction of the solute $w_2$, the specific polarization of the solvent $P_1$, and the density of the solution $d_{12}$ as follows[12]

$$P_2^0=[(\varepsilon_{12}-1)/3d_{12}-P_1]/w_2+P_1 \tag{5}$$

The specific polarization extrapolated to zero concentration $P_2^{00}$ and the dipole moment of the $\alpha$-helix in the solvent are related

$$\mu^*=(9k/4\pi N)^{1/2}(P_2^{00}\bar{M}_wT)^{1/2}$$
$$=0.0128(P_2^{00}\bar{M}_wT)^{1/2} \tag{6}$$

In the dipole moment $\mu^*$, the moment induced in the polarizability $\alpha$ by the reaction field $\mu^*R(\varepsilon)$ is taken into consideration and it is given by the moment in vacuo $\mu$.[13]

$$\mu^*=\frac{\mu}{1-\alpha R(\varepsilon)} \tag{7}$$

To obtain the static dielectric constant $\varepsilon^0_{12}$ or specific polarization, those values measured by the bridge method at various frequencies must be extrapolated to zero frequency. In this procedure the following problems must be considered:

1) The relation between $\varepsilon_{12}$ and $\nu$ is not linear.

2) The dispersion curve does not agree, in general, with Debye's theoretical one in which a single relaxation time is assumed.

3) In the low-frequency range, the polarization effect on the electrode surface of the liquid cell can not be negligible. To cope with these problems, three methods for extrapolation are proposed as follows.

I) Assuming an empirical functional relation which gives a linear relation especially at the low-frequency range, we extrapolate it to zero frequency.

II) Extrapolation is made to zero frequency on the Cole-Cole's arc plot.[12] This method, however, does not seem appropriate because of the increase in experimental error of the loss factor at low-frequency.

III) Extrapolation of the flat part at the low-frequency range in $\varepsilon_{12}\sim\nu^{-1}$ plotting to $\nu^{-1}\to 0$.[14] This extrapolation will be useful to exclude electrode polarization because it becomes zero at infinite frequency. An underestimate of the dielectric constant will result when the polydispersity in the $\alpha$-helix is present.[13]

**1) Ethylene Dichloride Solution.** — The dispersion curve of each PBLG sample in EDC is shown in Fig. 8. It can be seen that the critical frequency becomes lower as the specific polarization and the molecular weight become larger.

In Figs. 9a, 9b and 9c three plottings of these samples are shown and the extrapolated values of $P_2$ are compared in Table IV. For

C $M_w$: 70,000.

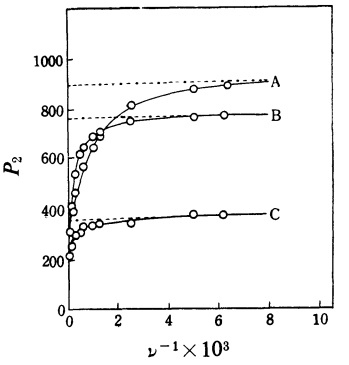

Fig. 9c. Specific polarization of PBLG as a function of $\nu^{-1}$.
A $M_w$: 180,000, B $M_w$: 154,000,
C $M_w$: 70,000.

the first extrapolation method it was incidentally given a linear relation in $P_2\nu \sim P_2$ plot. This means that the relation $P_2 = P_2^0\left(1+\frac{\nu}{\nu_0}\right)^{-1}$ can be maintained in this system and $P_2^0$ and the critical frequency $\nu_0$ are given from the intercept and the slope of this plot respectively. The deviation from the linearity at the low-frequency range may be due to electrode polarization. Though the extrapolated values by these three methods differ slightly, they do not seriously affect the result, as can be seen in Table IV.

For the calculation of the molecular dipole moment, the $P_2^0$ measured in several concentrations were extrapolated to zero concentration. A typical plot is shown in Fig. 10 and

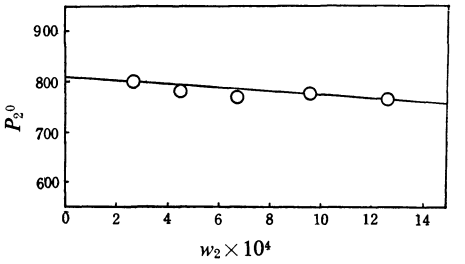

Fig. 10. Concentration dependence of specific polarization of PBLG sample No. 105 in EDC at 25°C.

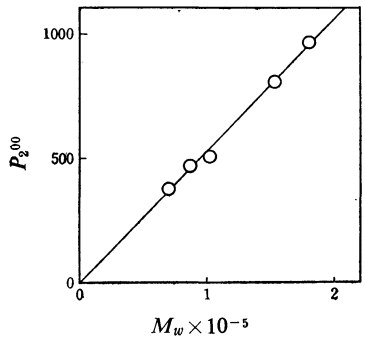

Fig. 11. Dependence of specific polarization of PBLG samples in EDC upon molecular weight.

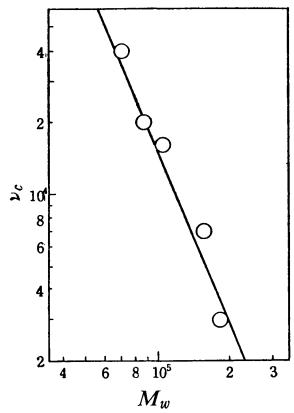

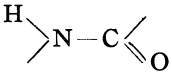

Fig. 12. Double logarithmic plot of critical frequency of PBLG samples in EDC against molecular weight.

the final results are listed with the dipole moment calculated in Table III.

The measured $P_2$ and dipole moments increase proportionately to the molecular weight as shown in Fig. 11. The dipole moment of the amino acid residue in the $\alpha$-helix then can be calculated as 3.5 D. This value is quite consistent with the parallel orientation of the dipole moment of polar groups  in the $\alpha$-helix. Further, the critical frequency, on the other hand, is known to have a linear relation in double logarithmic plot as shown Fig. 12. This behavior is well explained using Perrin's equation with the hydrodynamically equivalent ellipsoid of revolution which has the same volume and length as the $\alpha$-helix. That is

$$\tau_0 = (2\pi\tau)^{-1}$$

$$\tau = \frac{2\tau_0}{3}\,\frac{1}{2\rho^2 \ln(2/\rho) - \rho^2} \qquad (8)$$

$$\rho = b/a, \quad \tau_0 = 4\pi\eta ab^2/kT$$

The solid line in Fig. 13 is the theoretical plot corresponding to 18.3 Å of the minor axis, that is 15 Å for the diameter of the $\alpha$-helix. All of the above results are consistent with and tend to support the belief that in this solvent the PBLG exists as a rigid rod-shaped molecule, the $\alpha$-helix given by Pauling and Corey.

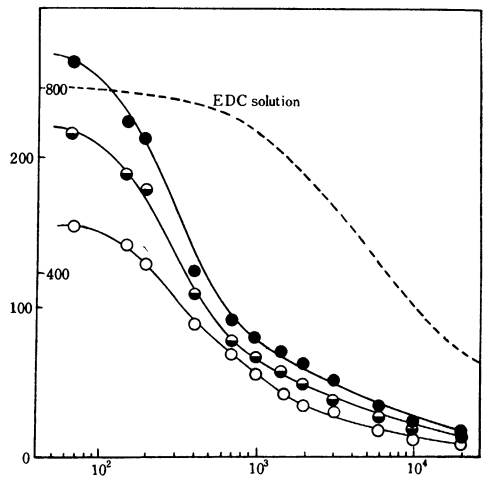

Fig. 13. Dependence of specific polarization of PBLG samples in dioxane solution upon frequency at 30°C.
Filled circle No. 105 $w_2=0.000824$. Half filled circle No. 103 $w_2=0.001282$. Open circle No. 102 $w_2=0.001112$.

**2) Dioxane Solution.** — In dioxane the $\alpha$-helix of PBLG may be in an associated state as Doty et al. concluded.[1] They emphasized that the association is of the end-to-end type but that the rod-like form is not preserved. The increase in the molecular weight and molecular length of PBLG in this solvent, which has been given by the light scattering measurement as shown in Table III, seems to endorse this idea. Moreover, the non-linear relation between the molecular weight and the molecular length suggests that the associated molecule is no longer linear and/or rigid.

For further study on the mechanism of molecular association the information from the electric dipole moment, as a vectoral quantity along the direction of the helical axis, will be useful. Leaving quantitative considerations of this interesting problem to another report[15], we may conclude, however, that the $\alpha$-helix still has a large electric dipole moment in dioxane which is the only non-polar solvent in which PBLG can dissolve.

Examining the dispersion curve of this system in Fig. 13 the critical frequency reveals

15) A. Wada, *J. Polymer Sci.*, (1960), in press.

a remarkable shift to lower frequencies compared with that of the same sample in EDC for which the dispersion curve is plotted in the same figure in a dotted line. Therefore, the third extrapolation method could not be used because the left part of the dispersion curve goes out of the range of measurement. Only the second method, the extrapolation in Cole-Cole's arc plot, is effective, as shown in Fig. 14. A linear relation in the plot which was given in the case of EDC solution no longer holds in dioxane. This discrepancy between dioxane and EDC suggests that the molecular association will change the molecular weight distribution. The molecular weight distribution seems to be more polydisperse than that of the most probable distribution as in the case of EDC solution. The broader distribution may also be suggested from the flat shape of Cole-Cole's arc in this solvent (Fig. 14). This fact means that the molecules preferably aggregate in certain ranges of molecular weight more than in others as Doty et al. mentioned.[1)]

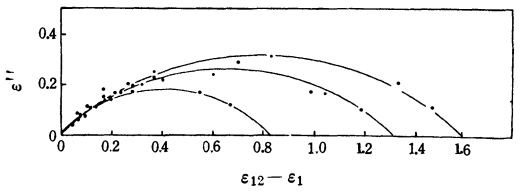

Fig. 14. Cole-Cole's arc plot for the dioxane solution of PBLG No. 105. $w_2=0.003058$, 0.001794, 0.000824.

The $P_2^0$ depends strongly upon the concentration in dioxane as shown in Fig. 15. This strong dependence may originate from the molecular association and/or dipole-dipole interaction which becomes stronger in a nonpolar solvent such as dioxane than in a polar one such as EDC. The absence of concentration dependence in light scattering measurement will support the latter possibility. It is empirically found that the $P_2^{0-1}\sim c$ plot gives a straight line as shown in Fig. 16. From these extrapolated values the electric dipole moment is computed. In Table V the electric dipole moment, calculated from the original molecular weight and from that of the associated molecule, are listed. Though the result is no longer proportional to the molecular weight, the dipole moment 1~3 D per amino acid residue still suggests that the molecule has an ordered form which has a partial $\alpha$-helical configuration.

**Summary**

The work described above has produced the following conclusions.

(1) A large electric dipole moment corrospoinding to the $\alpha$-helix described by Pauling, Corey and Branson is found in EDC and dioxane.

(2) A linear relation between the electric dipole moment and the molecular weight in EDC suggests that the molecule is linear and not flexible.

(3) The critical frequency of the orientation polarization was elucidated by using an equivalent ellipsoid model and the equation for the rotatory diffusion constant derived from Perrin's equation. This fact will support the conclusion of Doty, Bradbury and Holtzer that the $\alpha$-helix is fairly rigid in the solution.

(4) In dioxane the $\alpha$-helix can be found to be associated and to have a different distribution in molecular weight.

methods are not included in the table. Curcumin methods are generally more sensitive than carmine methods. However, the curcumin methods which have been reported up to the present consist of varied procedures according to different authors. Moreover, the reasons for using each procedure are not always evident. Consequently, in order to obtain optimum conditions, the available methods have been critically studied.

As shown in Table I, a phosphoric acid or a hydrochloric acid medium appears to be widely used for the separation of boron as methyl borate from uranium. In the case of the phosphoric acid medium, that methanol vapor must be passed through a hot sample solution[7] is considered to be disadvantageous, since connection of two distilling flasks is necessary; Otherwise phosphoric acid solutions of uranium form gels. When the hydrochloric acid medium is employed, the removal of excess of water is not easily effected[15].

In the determination of boron in uranyl sulfate, the authors found that a sulfuric acid medium was very suitable for the separation of boron as methyl borate, and that the above-mentioned disadvantage and difficulty could be avoided. Further investigation has shown that satisfactory results of analyses of $U_3O_8$ and uranium metal (after conversion into $U_3O_8$) can be obtained by using the same medium for the dissolution of the sample and distillation of methyl borate. These results are reported in the present paper.

## Experimental

**Apparatus.**—The distilling apparatus (quartz) is shown in Fig. 1. The volume of the flask is about 300 ml. Absorbance measurements were made with a Hitachi Model EPU-2A spectrophotometer, using 1-cm. cells.

**Reagents.** — In purification and preparation of reagents, as well as in analysis, redistilled water was used. For purification by distillation described below, a quartz distilling apparatus was used. All the solutions (except hydrogen peroxide) were kept in polyethylene bottles.

*Water, redistilled.*—Small amounts of mannitol (dissolved in distilled water) are added to the flask for redistillation.

*Sulfuric acid*, 1 : 3.—In a quartz beaker 5 ml. of 48% hydrofluoric acid is added to 100 ml. of concentrated sulfuric acid and heated to strong fumes. After cooling water is added.

*Hydrogen peroxide*, 30%.—Purification was effected by modification of Luke's procedure[16]. A 2.5 g. portion of Amberlite IR-120 ($H^+$ form) and 7.5 g. of Amberlite IRA-400 ($OH^-$ form) are transferred to a 100 ml. polyethylene beaker. While cooling,

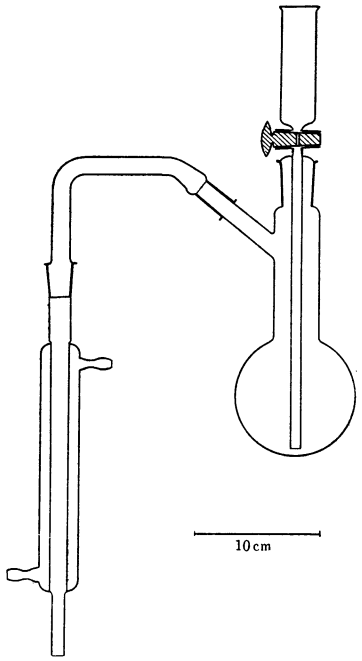

Fig. 1. Distilling apparatus.

60 ml. of cold 30% hydrogen peroxide is added and stirred for 10 min. The product is filtered through a paper (washed with water and dried) to a brown glass bottle and kept in a refrigerator.

*Methanol*, redistilled from sodium hydroxide.

*Calcium hydroxide suspension*, 0.1 N. — Distilled calcium is washed with water and the oxide scraped. One gram of calcium is dropped into a 500 ml. quartz flask and enough water is added cautiously. After cooling the contents are transferred to a bottle and diluted to 500 ml. with water.

*Curcumin-oxalic acid solution*[17,18].—A 0.40 g. portion of finely ground curcumin and 50 g. of oxalic acid are dissolved separately in ethanol. Both solutions are mixed and diluted with ethanol to 1 l.

*Ethanol*, redistilled from sodium hydroxide.

*Standard boron solution.*—A 0.5716 g. portion of boric acid is dissolved in 100 ml. of water (1.00 mg. B/ml.). From this stock solution 1 and 0.2 p.p.m. B solutions are prepared.

**Procedure.** — *Uranium metal.* — Ignite cautiously 1.00 g. of the sample in a platinum crucible at a low temperature. Then heat the crucible in an electric oven at about 800°C for one hour. Cool, and transfer the oxide formed to the distilling flask. Then continue as described below.

$U_3O_8$.—Transfer 1.00 g. of sample to the distilling flask and assemble the distilling apparatus. Place a 100 ml. platinum dish containing 10 ml. of water under the condenser. To the flask add 5 ml. of 1 : 3 sulfuric acid and 1 ml. of 30% hydrogen peroxide. Heat gently with a small flame until the sample is in solution. Replace the burner by an infrared lamp (300~500 W.) and distil excess of

water. Heat several times the side arm of the flask to remove water droplets. Stop heating when fumes begin to appear. Cool.

Immerse the fiask in a 1 l. beaker containing water (this serves as a water bath). Add 5.0 ml. of 0.1 N calcium hydroxide suspension to the platinum dish and raise the dish so that the tip of the condenser is in the solution. (The dish is protected from the heat of the burner by an appropriate shield.) From the tap funnel add 30 ml. of methanol. Raise the temperature of the bath slowly to approximately 95°C, giving a slow but steady distillation of methyl borate and methanol*. Continue heating until no more liquid comes over. Remove the burner and replace the hot water by cold water. Add 2.0 ml. of 0.1 N calcium hydroxide suspension to the solution in the dish. Add 20 ml. of methanol through the tap funnel and distil again. Lower the dish and wash down the stem of the condenser. Mix the distillate and washings with a quartz stirring rod (confirm that the solution is alkaline), and evaporate gently to dryness on a water bath.

To the residue add 2 ml. of water and 4.0 ml. of curcumin-oxalic acid solution and mix with a quartz stirring rod. Wash the rod with a small amount of water. Evaporate the solution on a water bath at 55±3°C, and allow to remain for 30 min. after the contents are dry. Cool the dish to room temperature (in a desiccator). Extract the colored products with 9 : 1 ethanol by stirring with a quartz rod. Transfer the colored solution to a 25 ml. volumetric flask and make up to volume with 9 : 1 ethanol. Mix, transfer the contents to a centrifuge tube, cover the tube with parchment paper, fasten the paper with a rubber band, and centrifuge at about 3000 r.p.m. for 10 min. Transfer the clear solution to a 1 cm. cell, and measure the absorbance at 550 mμ, using 9 : 1 ethanol as the reference.

Establish the standard curve by taking, for example, 0, 0.2, 0.5, and 1 μg. of boron, adding 7 ml. of 0.1 N calcium hydroxide suspension, and proceeding as described above. Run a blank, preferably in duplicate, throughout the entire procedure. As the recoveries of boron are low, a correction of +15% is advisable. When the standard curve is established by including the separation, this correction is naturally unnecessary.

## Results and Discussion

**Spectrophotometric Determination of Boron.** —In general, it may be summarized that the variable factors in the curcumin methods are use of alkalis (sodium hydroxide[8,12,13,19] and calcium hydroxide[7,18]), addition of hydrochloric acid, amounts of curcumin and oxalic acid, and extractants (ethanol[7,18], methanol[8], acetone[8,11]) of the colored products. Spicer and Strickland[19] used a glycerol-sodium hydroxide reagent, of composition of 1% sodium hydroxride, 0.1% sodium chloride, and 3% glycerol, to collect methyl borate. In this case hydrochloric acid must be added before adding curcumin. Muraki and Hiiro[18] used calcium hydroxide, and did not add hydrochloric acid, while other workers (e. g., Ref. 7) added the acid.

The preparation of curcumin-oxalic acid solution, described by Muraki and Hiiro[18], appears most satisfactory, because the preparation is simple, and the solution is stable. When the solution has been allowed to stand for 2 days after preparation, the absorbance becomes practically constant (Fig. 2). The workers mentioned[18] allowed the solution to stand for 7~10 days before use. The solution can be kept for one month at room temperature in the dark.

○ With Wako-Eastman curcumin and other points with Koso curcumin (cf. Table VII).
●: 97%(v./v.) EtOH, ○ and × : 87% (v./v.) EtOH, ▼ : MeOH, ■ : acetone.

Table II shows the effects of alkalis and extractants on the determination of boron. In each case 4 ml.[18] of curcumin-oxalic acid solution was used. It is seen that the presence of calcium hydroxide increases the absorbance of colored solution*, while that of sodium chloride decreases the absorbance. Addition of hydrochloric acid to calcium hydroxide is not

* This distillation requires about 15 min., and the second distillation about 10 min.

19) G. S. Spicer and J. D. H. Strickland, *Anal. Chim. Acta*, **18**, 523 (1958).

* Data obtained by Muraki and Hiiro[18] also indicate this phenomenon.

* Based on the standard absorbance obtained by omitting methanol distillation (direct color development).

recommended (cf. Table IV). When the glycerol-sodium hydroxide reagent is used, addition of 2 ml. of 1 N hydrochloric acid gives the maximum absorbance. From the data in Table II, it may be concluded that, on the basis of sensitivity and simplicity in manipulation, calcium hydroxide is superior to glycerol-sodium hydroxide (and sodium hydroxide) and that 87% ethanol (=9 : 1) gives most reproducible results. The method of Silverman and Trego[11] is not sensitive enough to be used for the present purpose.

The absorbances of the colored solutions (ethanol and acetone) remain practically constant for 2 hours after the beginning of extraction of colored products. After that there is a gradual decrease in absorbance. The absorbance of a methanolic solution tends to decrease more rapidly than that of other solutions.

For the purpose of studying the influence of curcumin of different origins, several products were examined (Table III).

The effects of some foreign substances on the determination of boron were investigated (Table IV). Five ml. of 0.1 N calcium hydroxide suspension and the foreign substance, with or without 1 μg. of boron, was evaporated to dryness and then subjected to color development. The addition of 2 milliequivalent of hydrochloric acid to 0.5 milliequivalent of calcium hydroxide resulted in about a 20% decrease in absorbance (1 μg. B). If the same quantity of the acid is added to 0.7 milliequivalent of calcium hydroxide, the absorbance is low by as much as 40%. The effect of formic acid was investigated because of the possible formation formic acid during methanol distillation[20]. During evaporation of the methanolic solution about 5% of boron is lost. A loss of 4% was reported by Spicer and Strickland[19] during evaporation of methanolic solution in the presence of glycerol-sodium hydroxide reagent.

**Separation of Boron from Uranium.** — Table V summarizes the results of methanol distillation from sulfuric acid solution. Excess of water was removed by heating and methanol distillation was carried out as described in the procedure. Larsen[21] states that the addition of chloride in catalytic amounts to a mixture of sulfuric acid and hydrogen peroxide increases the rate of solution of uranium very markedly. This is the reason that 0.1 milliequivalent of hydrochloric acid was added in some cases. The effect of this solution method will be discussed later.

On the basis of the standard absorbance obtained by omitting the methanol distillation (i. e., direct color development), the average recovery of 1 μg. of boron from sulfuric acid solution is 84% (standard deviation 4.2%). Addition of hydrogen peroxide to sulfuric acid does not affect the recovery of boron (average 87%). The weighted average of recovery from the sulfuric acid-hydrogen peroxide-hydrochloric acid mixture is 85% (standard deviation 4.9% for 1 μg. B). The loss may be due to incomplete distillation of methyl borate, volatilization of boron during the evaporation of distillate, and slight difference in the composion between the sample solution and the standard solution. Most of the previous papers (cited in Table I) lack the information

* New Brunswik Laboratory, NBL-65-3. Certified values of other constituents (in p. p. m.): 0.2 Cd, 12 Cr, 12 Cu, 28 Fe, 6 Mn, 1.0 Mo, 22 Ni, 50 P, 25 Si, 0.6 Ag, 20 V.

** New Brunswick Laboratory analyzed sample No. 16. Other certified values (in p. p. m.): 10 Al, 410 C, 2 Cu, 45 Fe, 1 Pb, 2 Mg, 6 Mn, 45 Ni, 40 N, <1 K, 50 Si, <0.1 Ag, 2 Na, 0.3 Th.

*** Three methods of standardization were studied:

1. Based on the standard curve involving MeOH distillation.
2. Seven ml. of 0.1 N $Ca(OH)_2$ solution evaporated to dryness. Color development followed. +15% correction.
3. Twenty ml. of water and 50 ml. of MeOH evaporated to dryness in the presence of $Ca(OH)_2$. Color development followed. +10% correction.

on the recoveries of boron, and the calibration curves were constructed by including the distillation step. A calculation from the data reported by Muraki and Hiiro[18] gives an apparent recovery of 80% for 0.2~2.0 μg. of boron. Also, a recovery of 75% is calculated from Luke's results[22] that were obtained by the distillation of 0.2~0.6 μg. of boron from chloride solutions.

Known amounts of boron were added to uranyl sulfate (1 g. U) solution and the boron was separated by distillation after removing excess of water (Table VI). A recovery (weighted average) of 87% is obtained with 0.2~1 μg. boron. When a correction factor of +15% (100/87=1.15) is applied, the error is not likely to exceed ±0.1 p. p. m. for this concentration range.

The results of analyses of standard samples of $U_3O_8$ and uranium metal, obtained in applying the proposed method, are shown in Table VII. The reagent blank (against the blank of direct color development) was about 0.1 μg. of boron. The $U_3O_8$ sample dissolved in the mixture of sulfuric acid and hydrogen peroxide readily. Three methods of standardization give essentially the same results.

The mixture of sulfuric acid-hydrogen peroxide-hydrochloric acid, described by Larsen[21], does not dissolve uranium readily unless the sample is very fine or thin. Anodic dissolution of uranium appears promising*. Since the solution of $U_3O_8$ in sulfuric acid and hydrogen peroxide is easily effected, uranium metal was converted in to the oxide by ignition. From the table it is seen that boron is not lost by the heat-treatment. Because the state of this element in uranium is not well known, and other standard metal samples were not available, further experiments were not made.

## Summary

Procedure is described for the spectrophotometric determination of 0.1~1 p. p. m. of boron in uranium (metal, $U_3O_8$, and uranyl sulfate). Uranium metal was first converted to $U_3O_8$, and the oxide was dissolved in sulfuric acid and hydrogen peroxide. Boron was separated by distillation as methyl borate from sulfuric acid solution, and finally determined by the curcumin method.

# *Polarographic Studies on the Rare Earths. III. Yttrium.*

By Seizo MISUMI and Yasushi IDE

(Received October 8, 1959)

Polarographic studies on the reduction of the tripositive yttrium ion had been reported and discussed by Noddack and Brukl[1], Kolthoff and Lingane[2], and Purushottam and Raghava Rao[3], but the electrode reaction in the reduction process was not completely solved, because of the special properties of the aquo yttrium complex ion and of the anomalies of the reduction wave. Noddack and Brukl obtained a double wave for 0.01 M solution of yttrium sulfate, without any supporting electrolyte, having the half-wave potentials of $-1.76$ V. and $-1.84$ V. vs. S. C. E., respectively and concluded the reduction process to be $Y^{3+} \rightarrow Y^{2+} \rightarrow Y^{0}$. However, it is very doubtful. Kolthoff and Lingane suggested that it was more probable that the first wave resulted from the reduction of hydrogen ion produced by the hydrolysis of the aquo yttrium complex ion and the second wave corresponded to the three electron reduction to metal. Purushottam and Raghava Rao also obtained the double wave with yttrium chloride using lithium chloride as supporting electrolyte. From the reciprocal slope of the logarithmic plots of both waves, they concluded that the electrode reaction of the first wave was of one-electron change, and that of the second wave, of two-electron change, that is, $Y^{3+} \rightarrow Y^{2+} \rightarrow Y^{0}$ the same as before. However, all these results were incomplete because the effects of pH and concentration of yttrium ions on the diffusion current, the half-wave potential and further on the electrode reaction in reduction process were not discussed in detail. The present authors, for the purpose of solving the electrode reaction in the reduction process, studied the reduction wave of the aquo tripositive yttrium complex ion in an unbuffered solution under various conditions and obtained a different result from other reports. By the addition of a small amount of dilute acid to prevent the hydrolysis of the aquo yttrium complex ion, the hydrogen wave was completely separated from the reduction wave of the aquo yttrium complex ion, which was generally a single wave in a perchlorate solution and often a double wave in a halide solution. The electrode reaction of the single wave was irreversible and of a three-electron reduction. This wave was due to the reduction of the hydrogen ion which was produced from the dissociation of the aquo yttrium complex ion as the yttrium acid. In the case of the double wave, the first wave was irreversible or quasi-reversible and its electrode reaction was also of a three-electron reduction. The second wave was irreversible and anomalous. The two-stepped wave in the solution of the halide ions, added as supporting electrolyte, was considered to be attributed probably to the reduction of the aquo halo complex ion.

## Experimental

All current-voltage curves were recorded by a Yanagimoto photographic polarograph PEL-Model 3. All cathode potentials were referred to a saturated calomel electrode. The capillary used had an *m* value of 0.706 mg./sec. and drop times of 3.25 sec. at $-1.8$ V. and 2.98 sec. at $-1.9$ V. vs. S. C. E., when measured in an air-free 0.1 M lithium perchlorate solution at 57.6 cm. of effective height of mercury. The measurement of pH was done with the Hitachi glass electrode pH meter Model EHM-1 for a micro amount scale. All experiments were carried out in a thermostat of $25.0 \pm 0.1$°C.

An yttrium stock solution was prepared by dissolving pure yttrium perchlorate or sulfate. (As yttrium oxide, the purity was higher than 99.99%.). The concentration of the stock solution was 0.01 M. The lithium perchlorate and tetramethyl ammonium iodide which were used as the supporting electrolytes were guaranteed grade reagents and recrystallized before use. The concentration of these stock solutions were 1 and 0.2 M., respectively. The gelatine solution used as the maximum suppressor was prepared afresh in every experiment. Perchloric acid and sulfuric acid solutions of 0.01 N in concentration were prepared from the analytical pure reagents and used for the adjustment of pH.

To the sample solution of yttrium, appropriate quantities of the supporting electrolyte and gelatine were added to give the final concentrations, 0.1 M and 0.01% respectively. Then a micro amount of 0.01 N acid was added to prevent the hydrolysis of the aquo yttrium complex ion and to adjust the pH at the same time. The total volume of the solution was made up to 5 ml. with distilled water. The concentration of the yttrium ion was in the range from 0.5 to 2.0 millimol./l. and the pH of the solution

was varied from 4.00 to 2.60. Dissolved oxygen was removed by passing purified nitrogen gas through the solution at least for 20 min. The polarograms were recorded at 25.0±0.1°C.

The diffusion coefficient of the yttrium ion was calculated from Nernst's equation, using the value of equivalent conductance at infinite dilution[4].

$D$: $5.721\times10^{-6}$ cm. sec$^{-1}$ (for $Y(ClO_4)_3$)

$D$: $5.764\times10^{-6}$ cm. sec$^{-1}$ (for $Y_2(SO_4)_3$)

## Results and Discussion

*The reduction wave of aquo tripositive yttrium complex ion.*—The reduction wave of the aquo yttrium complex ion (Fig. 1) at pH about 4.5 differed from the true reduction wave owing to the precedence of the hydrogen wave produced by the hydrolysis of the aquo yttrium complex ion. The typical reduction wave was obtained by adding a micro amount of acid to prevent the hydrolysis when the hydrogen wave was completely separated from the reduction wave of the aquo yttrium complex ion under a certain condition. The reduction wave was generally a single wave in a perchlorate medium and often a double wave in a halide (chloride or iodide) medium.

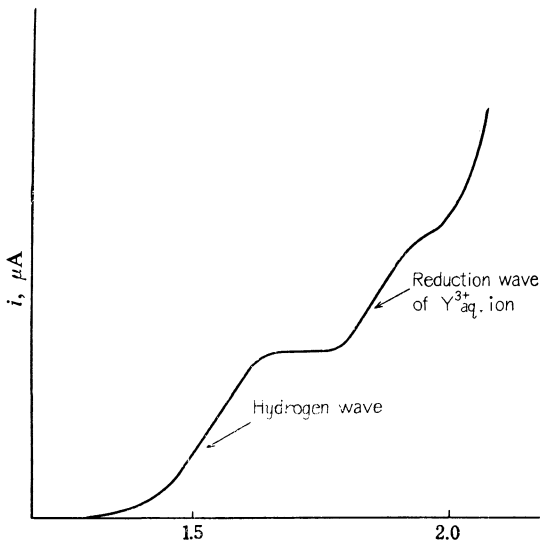

Fig. 1. Reduction wave of the aquo yttrium complex ion. (1) In perchlorate medium
$Y^{3+}$ ion: 1.25 mM in 0.1 M $LiClO_4$ and 0.01% gelatine medium
pH: 2.95 S: 1/200 25.0°±0.1°C

From the results obtained by the variation in pH and the concentration of the yttrium ion, the following common characters of the reduction wave were derived: 1) At a pH higher than 3.4, only a single wave was obtained in both perchlorate and halide medium. 2) At a pH less than 2.7, only a single wave was observed, but as the height of the hydrogen wave became large, the wave was ambiguous. 3) At a pH between 2.7 and 3.4, in a perchlorate solution, only a single wave was obtained clearly and as the pH decreased, there was a tendency for a small maximum wave to appeare ofteh after the reduction wave. In a halide solution, when the two-stepped wave was obtained, the second wave decreased gradually as the pH decreased or the concentration of yttrium ions increased until it finally disappeared.

*Dependence of the limiting current on the pressure upon the dropping mercury electrode and the influence of temperature on the limiting current and the half-wave potential.*—A relationship between the limiting current and the height of mercury column is shown in Table I. As the limiting current is proportional to the square root of the height of mercury column, the limiting current was diffusion-controlled.

The temperature coefficient of the half-wave potential and that of the diffusion current in the range from 25° to 35°C were 0.7 mV./deg. and 1.86%/deg., respectively, which were nearly in agreement with the values that would be expected in the case of the diffusion-controlled process.

*The plots of E vs. log{$i/(i_d-i)$}.*—The reduction waves of the aquo tripositive yttrium complex ion were analyzed by the logarithmic

plot. The results are shown in Table II. With decreasing pH, the value of the reciprocal slope of the reduction wave decreased. In a perchlorate solution, the electrode reaction was irreversible and at a pH less than 3.00, it indicated a tendency to approach to a three-electron reduction, provided that the reduction of the aquo yttrium complex ion is followed by amalgamation at electrode. This tendency was evidently observed in a halide midium. In a halide solution, at a pH less than 3.4, the electrode reaction of the first wave was irreversible, but it approached from irreversible to quasi-reversible and corresponded to three-electron change. The electrode reaction of the second wave was also irreversible and very anomalous.

*The effects of pH on the reduction waves.*—

The reduction waves were recorded at various pH from 4.00 to 2.60 under a certain condition. The results are shown in Table III.

Half-wave potentials of all reduction waves shifted to more negative potentials as pH decreased. It is considered that this was probably due to the increasing stability of hydroxo yttrium complex ion, which was formed by the hydrolysis of the aquo yttrium complex ion owing to the weak basicity of yttrium. This shift was always dependent only on the concentration of the free hydrogen ion. It was observed that at the same pH the half-wave potential was more negative in a perchlorate medium than in a halide medium under a given condition. The diffusion current of the reduction wave, $i_d$, was independent of pH from 3.4 to 2.6 and almost constant in a perchlorate medium. However it was observed that at a pH higher than 3.4, the diffusion current tended to decrease slightly. In the halide medium, at a pH higher than 3.6, there was the same tendency. The diffusion current of the second wave, in a halide medium, increased slightly with the decrease of the pH down to 3.1 and had a small maximum, but with the further decrease of the pH, $i_d$ decreased gradually and anomalously. The diffusion current constant of the reduction wave, $I_d$, was constant at a pH from 3.4 to 2.6 in the perchlorate medium and that of the first wave in the halide medium, $I_{d_1}$, was also constant at a pH less than 3.6. The value of the diffusion current constant of the second wave, $I_{d_2}$, was irregular, and anomalous.

*The effects of concentration of the yttrium ion on the reduction wave and the value of n, calculated from diffusion current constant.*—The reduction waves were recorded in the range of concentration of yttrium ion 0.5 to 2.0 millimol./l. at a constant pH. The results are shown in Table IV.

The half-wave potential of the reduction wave shifted to more negative potentials slightly, with the increasing concentration at a constant pH. The diffusion current, $i_d$, was apparently proportional to the concentration of $Y^{3+}$ ion in the perchlorate medium. The first diffusion current in the halide medium gave a similar result, but the second diffusion current was anomalous. The diffusion current constant of the reduction wave was constant, independent of the concentration of the yttrium ion and its average value was about 4.46 in 0.1 M $LiClO_4$ and about 3.51 in 0.1 M $(CH_3)_4NI$, while the theoretical value of the diffusion current constant is 4.34, which was calculated by assuming that the number of the electrons associated with the electrode reaction of the reduction wave, $n$, was three and the value of the diffusion coefficient of the yttrium ion $D$, $5.721\times10^{-6}$ cm. $sec^{-1}$ ($Y(ClO_4)_3$). It is considered that the average value observed in 0.1 M lithium perchlorate was almost equal to the theoretical one. The diffusion coefficient of the yttrium ion ($Y_2(SO_4)_3$) is $5.764\times10^{-6}$ cm. $sec^{-1}$ and the diffusion current constant was calculated to be 4.35. Although the average value of the diffusion current constant in the halide medium was smaller than the calculated one, it is also considered that the former was closer to the latter than the value which would be expected in the case of $n=2$. From these experimental values of the diffusion current constants, the number of the electrons involved in the electrode reaction, $n$, was calculated. The calculated value of $n$ was 3.06 in the case of 0.1 M lithium perchlorate, where the perchlorate ion has no tendency to complex with cation. Therefore, the electrode reaction was of three-electron change. The calculated value of $n$ for the first wave in the case of 0.1 M tetramethylammonium iodide, where iodide ion forms generally an aquo iodo-

Table IV. The effects of concentration of yttrium ion on the half-wave potential, the diffusion current, and the diffusion current constant

(pH=2.90, $Y_2(SO_5)_3$, in 0.1 M $(CH_3)_4NI$ and 0.01% gelatine medium.)

complex ion, was about 2.60, which seemed apparently smaller than three, owing to the probable formation of the aquo iodo complex ion. The value of the diffusion current constant of the second wave was irregular because of the anomaly of the reduction wave.

*Polarographic depolarizing action of the hydrolyzable aquo yttrium complex ion.*—The aquo tripositive yttrium complex ion, $Y(H_2O)_x^{3+}$ ion, behaves as a weak acid, "yttrium acid," in aqueous solution, owing to its weak basicity. Generally, the half-wave potential of the reduction wave which is due to the deposition of hydrogen from a weak acid, HA, has the following well known equation in excess of an indifferent electrolyte,

$$E_{1/2} = -3\boldsymbol{R}T/2\boldsymbol{F}\cdot\ln i_d/2 + k = -0.089 \log i_d/2 + k$$

where $k$ is a constant. Accordingly, it follows that the half-wave potential of a weak acid should shift to more negative potentials with the increasing acid concentration and $dE_{1/2}/d\log(HA) = -0.089$ V. In fact, as shown in Table IV, the half-wave potential of the reduction wave shifted slightly to more negative potentials with the increasing concentration at a certain pH. The value of $dE_{1/2}/d\log(Y(H_2O)_x^{3+})$ for the reduction wave calculated by extrapolation and given as follows: $dE_{1/2}/d\log(Y(H_2O)_x^{3+})$ equals $-0.090$ V. in perchlorate medium and $-0.088$ V. in an iodide medium. These values are considered to be equal to the theoretical value of $-0.089$ V. This fact indicates that the reduction wave of the aquo yttrium complex ion was the same as the reduction wave of the hydrogen ion from the yttrium acid, that is, the reduction wave was not due to the reduction of the yttrium ion, ($Y^{3+}$ ion), itself, but was attributed to the deposition of hydrogen from the yttrium acid. It is also in accordance with the results of irreversibility and of a three-electron change in electrode reaction. Of course, the hydrogen ion from "the yttrium acid" was at first combined and not free. Since the hydrogen ion was produced by hydrolysis of the aquo yttrium complex ion as the yttrium acid, the following equation would be given:

$$Y(H_2O)_x^{3+} + yH_2O = Y(H_2O)_{x-y}(OH)_y^{(3-y)+} + yH_3O^+$$

where $x$ is the coordination number of the tripositive yttrium ion (usually 6 in the case of a mononuclear yttrium ion), and $y$ is the number of the hydrogen ion produced from the yttrium acid by hydrolysis at a certain pH. The yttrium acid $Y(H_2O)_x^{3+}$ has three hydrogen ions per one molecule to be released and reduced at electrode. Therefore the quantities of electricity to be exchanged by the hydrogen ions at dropping mercury electrode are just the same as those which tervalent yttrium ions require when reduced to metal. Actually, the reduction of the hydrogen ion from the aquo yttrium complex ion at dropping mercury electrode requires a large overpotential, but still the hydrogen ion seems to take an electron more easily than the aquo yttrium complex ion or the hydroxo yttrium complex ion does. Thus the electrode reaction was irreversible (or quasi-reversible in the halide medium) and three-electron change as described above. It is considered that the reduction proceeds for example as follows:

$$Y(H_2O)_x^{3+} + 3e^- \rightarrow 3/2H_2 + Y(H_2O)_3(OH)_3$$

The second wave in the halide medium, if it existed, was supposed also to be the hydrogen wave which is due to the reduction of the hydrogen ion from dissociation of water in the aquo halo complex. This wave was also irreversible. Consequently, it was concluded that the polarographic depolarising action of the aquo yttrium complex ion was indicated by the reduction of the hydrogen ion from the yttrium acid and not by the reduction of the yttrium ion itself to metal.

## Conclusion

The logarithmic plot for the reduction wave of yttrium(III) indicated a straight line, independent of concentration of yttrium(III) at a pH less than 3.4. The value of its reciprocal slope approached the theoretical value for three-electron reduction with decreasing pH. The average value of the diffusion current constant was about 4.46 in 0.1 M lithium perchlorate and 3.60 in 0.1 M tetramethylammonium iodide from which the value of $n$ was calculated to be 3, it being assumed that in the reduction of the aquo yttrium complex ion at dropping mercury electrode, amalgamation would follow. In short, the reduction wave was irreversible and three-electron reduction. However, it was found that the aquo yttrium complex ion behaved as a weak acid, "the yttrium acid", and that the reduction wave was due to the deposition of hydrogen from the hydrolyzable aquo yttrium complex ion as the weak acid. It is also supposed that the second reduction wave, if it appeared in the halide medium, was due to the deposition of hydrogen from dissociation of water in aquo halo yttrium complex formed during the first reduction step. This second reduction wave was irreversible and anomalous.

At pH 3.00, the half-wave potential of the reduction wave was $-1.881$ V. vs. S. C. E. for the concentration of $Y^{3+}$ ion of 0.917 mM in 0.1 M lithium perchlorate and 0.01% gelatine medium.

# *Thermodynamic Studies on Cobalt Complexes. V. On the Solubility and the Thermal Dissociation of Aquopentamminecobalt(III) Nitrate and Bromide, and on the Thermodynamic Stability of Monoacidopentamminecobalt(III) Complexes**

By Motoshichi Mori and Ryokichi Tsuchiya

(Received December 2, 1959)

In the preceding paper[1] the authors determined the standard free energies of formation of aquopentamminecobalt(III) chloride in the solid state and in aqueous solution. In the present study the standard free energies of formation of aquopentamminecobalt(III) nitrate and bromide in the solid state were determind by measuring their solubilities, and those of nitratopentamminecobalt(III) nitrate and bromopentamminecobalt(III) bromide in the solid state were determined by measuring their dissociation pressures.

On the basis of these data the thermodynamic stability of aquopentamminecobalt(III) chloride, nitrate and bromide, that of monoacidopentamminecobalt(III) complexes and that of their ions in aqueous solution were compared and discussed.

## Experimental

Aquopentamminecobalt(III) nitrate was precipitated with nitric acid from an aqueous solution of its chloride. The bromide was prepared by the double decomposition of its chloride with ammoium bromide in aqueous solution.

Solubilities of these aquopentamminecobalt(III) complexes were obtained by analyzing the cobalt content in their saturated solutions by iodometry in the same manner as described in the second paper[2] of this series. The dissociation pressures of the complexes were measured with the same apparatus as described in the third paper[3].

## Results and Calculation

**Solubility of Aquopentamminecobalt(III) Nitrate.**—The results obtained for aquopentamminecobalt(III) nitrate are listed in Table I.

As the activity coefficient of the compound was not known, it was assumed that it was approximately equal to that of hexamminecobalt(III) chloride[4] in relatively lower concentrations. When aquopentamminecobalt(III) nitrate is dissolved in water, the change is expressed by

$$[Co(NH_3)_5OH_2](NO_3)_3\ (s) = [Co(NH_3)_5OH_2]^{3+}(aq.\ a) + 3NO_3^-(aq.\ a)$$

If the solubility of the salt in molality and its mean activity coefficient are expressed by $m$ and $\gamma_\pm$ respectively, the equilibrium constant

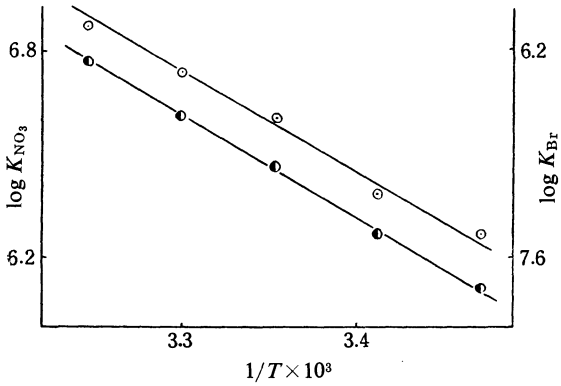

Fig. 1. The relationship between the equilibrium constant of the solution and the temperature.

| 35 | 0.1472 | 3.246 | 0.155 | 7.317 | $\bar{6}$.8643 |

of the solution, $K_{NO_3}$, is given by

$$K_{NO_3}=27m^4\gamma_\pm^4$$

The plots of its logarithm against the reciprocal of the absolute temperature are shown in Fig. 1, giving an almost straight line. Its equation computed by the method of least squares is

$$\log K_{NO_3}=3.884-2774/T$$

From this equation the heat of solution is obtained as $\Delta H=12.7$ kcal.

The standard free energy change of the solution, $\Delta G^0$, is calculated by the following formula,

$$\Delta G^0=-RT\ln K_{NO_3}=12690-17.76T \quad (1)$$

from which the values of the standard free energy change of the solution at 25°C, $\Delta G^0_{298}=7396$ cal. and its entropy change at 25°C, $\Delta S^0_{298}=17.76$ entropy unit are obtained.

On the other hand, the standard free energy of formation of the aquopentamminecobalt(III) ion in unit activity was calculated in the preceding paper[1] as

$$\Delta G_f{}^0=-192900+296.6T \quad (2)$$

and that of the nitrate ion, $NO_3^-$, was obtained in the second paper[2] of this series as

$$\Delta G_f{}^0=-49370+77.03T \quad (3)$$

From formulae 1, 2 and 3, the standard free energy of formation of aquopentamminecobalt(III) nitrate in the solid state is calculated as

$$\Delta G_f{}^0=-353700+545.4T \quad (4)$$

The value at 25°C is $\Delta G^0_{298}=-191100$ cal. and the heat of formation is $\Delta H=353.7$ kcal.

**Dissociation Pressure of Aquopentamminecobalt(III) Nitrate.**—The weight loss of aquopentamminecobalt(III) nitrate upon heating was followed by a thermobalance. The relationship between the weight loss and the temperature is plotted in Fig. 2, together with those of aquopentamminecobalt(III) bromide, chloride and perchlorate. It is found in this figure

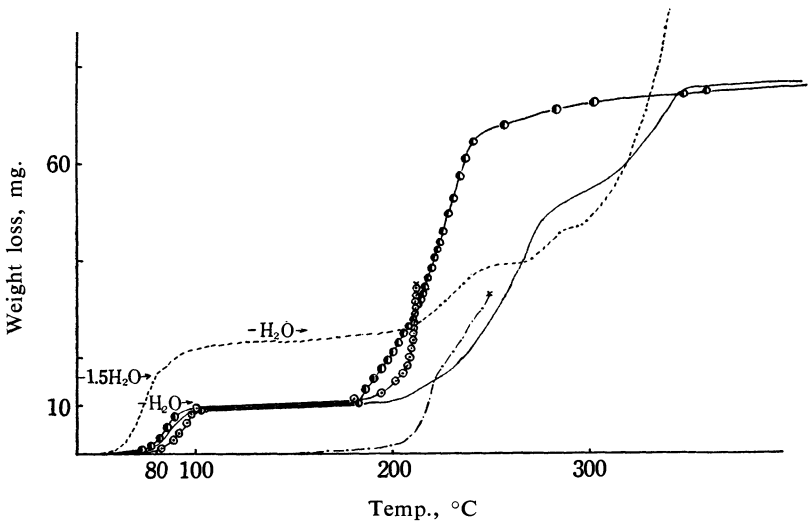

Fig. 2. The relationship between the weight loss and the temperature upon heating for several aquopentamminecobalt(III) complexes by a thermobalance.

-·-·-; aquopentamminecobalt(III) perchlorate

that the nitrate decomposes upon heating at 80~100°C to nitratopentamminecobalt(III) nitrate according to the following equation;

$$[Co(NH_3)_5OH_2](NO_3)_3(s) = [Co(NH_3)_5NO_3](NO_3)_2(s) + H_2O(g)$$

The vapor pressure of water produced by this docomposition at 30~68°C, that is, the dissociation pressure of aquopentamminecobalt(III) nitrate measured is shown in Table II.

Table II. Dissociation pressure of aquopentamminecobalt(III) nitrate

| Temp. °C | $1/T\times10^3$ | Dissociation pressure mmHg | $\log p_{mm}$ |
|---|---|---|---|
| 30 | 3.299 | 1.35 | 0.1303 |
| 33 | 3.267 | 1.70 | 0.2305 |
| 39 | 3.204 | 2.19 | 0.3404 |
| 45 | 3.144 | 3.19 | 0.5038 |
| 52 | 3.076 | 4.09 | 0.6117 |
| 56 | 3.039 | 4.59 | 0.6618 |
| 62 | 2.984 | 6.34 | 0.8021 |
| 68 | 2.932 | 8.48 | 0.9284 |

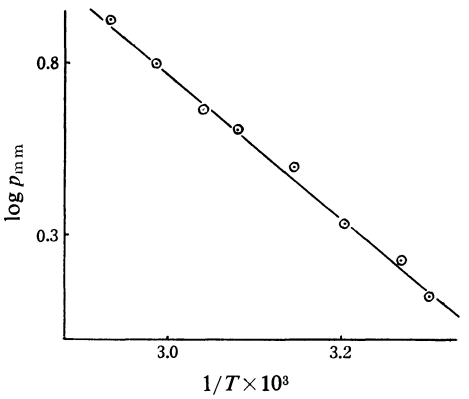

Fig. 3. The relationship between the dissociation pressure and the temperature for aquopentamminecobalt(III) nitrate.

The logarithm of the dissociation pressure, $p_{mm}$, is plotted against the reciprocal of the absolute temperature in Fig. 3, which shows an almost straight line. By the method of least squares the equation of this line is computed as follows:

$$\log p_{mm} = 7.045 - 2091/T$$

From this equation the heat of dissociation is obtained as $\Delta H = 9562$ cal. The standard free energy change of dissociation, $\Delta G^0$, is given by the following formula,

$$\Delta G^0 = -RT \ln p_{atm} = 9562 - 19.05\,T \qquad (5)$$

from which the values of the free energy change of dissociation at 25°C, $\Delta G^0_{298} = 3885$ cal. and the entropy change of the solution at 25°C, $\Delta S^0_{298} = 19.05$ entropy unit are obtained.

The standard free energy of formation of aquopentamminecobalt(III) nitrate in the solid state was already calculated above as formula 4, and that of $H_2O(g)$ was obtained in the preceding paper[1] as

$$\Delta G_f^0 = -57800 + 10.61T \qquad (6)$$

By subtracting formula 6 from the sum of formulae 4 and 5, the standard free energy of formation of nitratopentamminecobalt(III) nitrate in the solid state is calculated as

$$\Delta G_f^0 = -286400 + 515.8T$$

The value at 25°C is

$$\Delta G^0_{f298} = -132600 \text{ cal.} \qquad (7)$$

and the heat of formation is

$$\Delta H_{298} = -286.4 \text{ kcal.}$$

By using the solubility[5] and the heat of solution[6] of nitratopentamminecobalt(III) nitrate and by assuming that its activity coefficient is equal to that of bromopentamminecobalt(III) bromide[7], the free energy change of the solution of the former at 25°C is obtained as

$$G^0_{298} = 7347 \text{ cal.} \qquad (8)$$

Subtracting twice the standard free energy of formation of $NO_3^-$, $-26.41$ kcal.[8], from the sum of the formulae 7 and 8, the free energy of formation of nitratopentamminecobalt(III) ion in unit activity in aqueous solution is obtained as follows:

$$\Delta G^0_{f298} = 72440 \text{ cal.}$$

If $\Delta H = -168.8$ kcal.[9] is used as the heat of formation of its ion, the relationship between the free energy of formation and temperature is expressed by

$$\Delta G_f^0 = -168800 + 323.3T$$

**Solubility of Aquopentamminecobalt(III) Bromide.**—The results obtained for aquopentamminecobalt(III) bromide are listed in Table III.

When the aquopentamminecobalt(III) bromide is dissolved in water, the change is expressed by

$$[Co(NH_3)_5OH_2]Br_3(s) = [Co(NH_3)_5OH_2]^{3+}(aq.\ a) + 3Br^-(aq.\ a)$$

TABLE III. EQUILIBRIUM OF SOLUTION FOR AQUOPENTAMMINECOBALT(III) BROMIDE

| Temp. °C | Solubility in molality $m$ | $1/T\times10^3$ | Mean activity coefficient $\gamma\pm$ | $K_{Br}\times10^7$ | $\log K_{Br}$ |
|---|---|---|---|---|---|
| 15 | 0.03304 | 3.471 | 0.317 | 3.250 | $\bar{7}.5119$ |
| 20 | 0.03899 | 3.412 | 0.294 | 4.663 | $\bar{7}.6686$ |
| 25 | 0.04771 | 3.355 | 0.268 | 7.218 | $\bar{7}.8584$ |
| 30 | 0.05556 | 3.299 | 0.251 | 10.21 | $\bar{6}.0091$ |
| 35 | 0.06722 | 3.246 | 0.228 | 14.89 | $\bar{6}.1730$ |

The plots of the logarithm of the equilibrium constant, $K_{Br}$, against the reciprocal of the absolute temperature are shown in Fig. 1, giving a straight line. Its equation is calculated as follows

$$\log K_{Br}=3.756-2953/T$$

The heat of solution is obtained as $\Delta H=13.5$ kcal.

The free energy change of solution is given by the following formula,

$$\Delta G^0=-RT\ln K_{Br}=13510-17.18T \qquad (9)$$

and the value at 25°C is $\Delta G^0_{298}=8385$ cal. and the entropy change at 25°C is $\Delta S^0_{298}=17.18$ entropy unit.

As the standard free energy of formation of bromide ion, $Br^-$, was obtained in the second paper[2] of this series as

$$\Delta G_f{}^0=-28900+14.51T \qquad (10)$$

that of aquopentamminecobalt(III) bromide in the solid state is obtained from formulae 2, 9 and 10 as:

$$\Delta G_f{}^0=-293100+357.3T \qquad (11)$$

Its value at 25°C is $\Delta G^0_{f298}=-186600$ cal. and the heat of formation is $\Delta H=-293.1$ kcal.

**Dissociation Pressure of Aquopentamminecobalt(III) Bromide.** — Aquopentamminecobalt(III) bromide changes to bromopentamminecobalt(III) bromide upon heating at 75~95°C as

$$[Co(NH_3)_5OH_2]Br_3(s)=[Co(NH_3)_5Br]Br_2(s)+H_2O(g)$$

The vapor pressure of water produced by the above reaction at 18~32°C, that is, the dissociation pressure of aquopentamminecobalt(III) bromide is listed in Table IV.

TABLE IV. DISSOCIATION PRESSURE OF AQUOPENTAMMINECOBALT(III) BROMIDE

| Temp. °C | $1/T\times10^3$ | Dissociation pressure mmHg | $\log p_{mm}$ |
|---|---|---|---|
| 18 | 3.435 | 3.84 | 0.5843 |
| 20.5 | 3.406 | 5.23 | 0.7185 |
| 24 | 3.366 | 8.40 | 0.9243 |
| 26 | 3.343 | 9.35 | 0.9708 |
| 27 | 3.332 | 12.04 | 1.0806 |
| 29 | 3.310 | 14.75 | 1.1688 |
| 32 | 3.278 | 17.89 | 1.2526 |

The logarithm of the dissociation pressure, $p_{mm}$, is plotted against the reciprocal of the absolute temperature in Fig. 4, which shows an almost straight line. By the method of least squares the equation of this line is computed as:

$$\log p_{mm}=15.65-4382/T$$

From this equation the heat of dissociation is obtained as $\Delta H=9562$ cal.

The standard free energy change of dissociation is given by the formula,

$$\Delta G^0=-RT\ln p_{atm}=20040-58.41T \qquad (12)$$

from which the value at 25°C, $\Delta G^0_{298}=2633$ cal. and the entropy change of solution at 25°C, $\Delta S^0_{298}=58.41$ eutropy unit are obtained.

As the standard free energy of formation of aquopentamminecobalt(III) bromide in the solid state was already calculated above according to formula 11, that of bromopentamminecobalt(III) bromide in the solid state is calculated from formulae 6, 11 and 12 as

$$\Delta G_f{}^0=-215300+288.2T$$

The value at 25°C is

$$\Delta G^0_{f298}=-129300 \text{ cal.} \qquad (13)$$

and the heat of formation is $\Delta H=-215.3$ kcal.

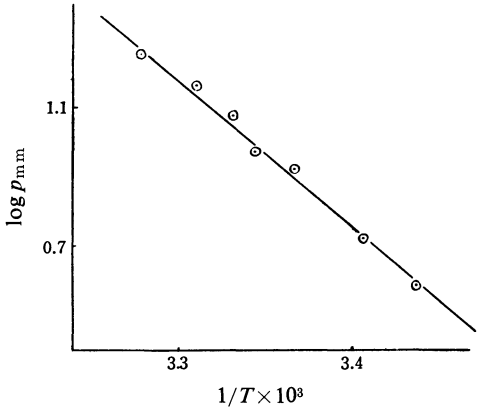

Fig. 4. The relationship between the dissociation pressure and the temperature for aquopentamminecobalt(III) bromide.

By using the solubility[5], the heat of solution[6] and the activity coefficient[7] of bromopentamminecobalt(III) bromide, the free energy change of solution of it at 25°C is obtained as

$$\Delta G^0_{293} = 8855 \text{ cal.} \quad (14)$$

Subtracting twice the free energy of formation of $Br^-$, $\Delta G^0_{293} = -24.57$ kcal.[10], from the sum of formulae 13 and 14, the free energy of formation of bromopentamminecobalt(III) ion in unit activity in aqueous solution is calculated as:

$$\Delta G_{f^0_{298}} = -71340 \text{ cal.}$$

If $\Delta H = -146.8$ kcal.[11] is used as the heat of formation of its ion, the relationship between the free energy of formation and temperature is expressed by

$$\Delta G_f{}^0 = -146800 + 253.2T$$

## Discussion

**Thermodynamic Stability of Aquopentamminecobalt(III) Complexes.** — The standard free energy of formation of aquopentamminecobalt(III) nitrate and bromide in the solid state, the free energy of the solution and the heat of solution of them calculated above together with those of its chloride obtained in the preceding paper[1] and the radii of each anions are again shown in Table V.

According to these values, it will be seen that the thermodynamic stability of these three aquopentamminecobalt(III) complexes in the solid state and aqueous solution decreases in the following order,

$$[Co(NH_3)_5OH_2]Cl_3 > [Co(NH_3)_5OH_2](NO_3)_3 > [Co(NH_3)_5OH_2]Br_3$$

This order is in good agreement with the decreasing order of the thermodynamic stability of hexamminecobalt(III) complexes,

$$[Co(NH_3)_6]Cl_3 > [Co(NH_3)_6](NO_3)_3 > [Co(NH_3)_6]Br_3$$

reported as in the second paper[2] of this series.

The heat of solution of these aquopentamminecobalt(III) complexes increases in the order, chloride < nitrate < bromide, and increases with the radius of anion as shown in Table V. It is generally known[12] that for simple salts of which the radius of the cation is 2.4 Å, the heat of solution increases with the radius of the anion. It is concluded that this relationship is also valid for these aquopentamminecobalt(III) complexes, the radius of the cation, $[Co(NH_3)_5OH_2]^{3+}$, being 2.4 Å.

The solubility of these complexes decreases in the order, chloride > nitrate > bromide. This may be due to the fact that the radius of anions becomes larger and consequently the ionic character of the bond between the complex cation and anion of the salts diminishes in the order, chloride > nitrate > bromide.

**Thermodynamic Stability of Monoacidopentamminecobalt(III) Complexes.** — The standard free energy of formation of nitratopentamminecobalt(III) nitrate and bromopentamminecobalt(III) bromide in the solid state obtained above, that of chloropentamminecobalt(III) chloride obtained in the third paper[3] of this series and that of chloropentamminecobalt(III) nitrate and bromide, nitratopentamminecobalt(III) chloride and bromopentamminecobalt(III) chloride and nitrate calculated from the solubility[5] and the heat of solution[9] in the literature are summarized in Table VI.

TABLE V. STANDARD FREE ENERGY OF FORMATION, FREE ENERGY OF SOLUTION AND HEAT OF SOLUTION OF AQUOPENTAMMINECOBALT(III) CHLORIDE, NITRATE AND BROMIDE, AND THE RADII OF EACH ANIONS

| Complexes | Free energy of formation kcal. | Free energy of solution cal. | Heat of solution kcal. | Radius of anion, Å |
|---|---|---|---|---|
| $[Co(NH_3)_5OH_2]Cl_3$ | −203.0 | 4488 | 8.75 | 1.81 |
| $[Co(NH_3)_5OH_2](NO_3)_3$ | −191.1 | 7396 | 12.7 | 1.89 |
| $[Co(NH_3)_5OH_2]Br_3$ | −186.6 | 8385 | 13.5 | 1.96 |

TABLE VI. STANDARD FREE ENERGY OF FORMATION OF MONOACIDOPENTAMMINECOBALT(III) COMPLEXES

| Complexes | $\Delta G_{f^0_{298}}$, kcal. | Complexes | $\Delta G_{f^0_{298}}$, kcal. |
|---|---|---|---|
| $[Co(NH_3)_5Cl]Cl_2$ | −144.9 | $[Co(NH_3)_5NO_3]Cl_2$ | −141.4 |
| $[Co(NH_3)_5Cl](NO_3)_2$ | −133.7 | $[Co(NH_3)_5NO_3](NO_3)_2$ | −132.6 |
| $[Co(NH_3)_5Cl]Br_2$ | −131.7 | | |
| | | $[Co(NH_3)_5Br]Cl_2$ | −142.1 |
| | | $[Co(NH_3)_5Br](NO_3)_2$ | −131.8 |
| | | $[Co(NH_3)_5Br]Br_2$ | −129.3 |

10) G. Jones and S. Bäckström, *J. Am. Chem. Soc.*, **56**, 1524 (1934).
11) K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), p. 178.
12) K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), p. 45.

On the basis of these values, it is found that the thermodynamic stability of these complexes in the solid state decreases in the following order:

$$\begin{array}{ccccc} [Co(NH_3)_5Cl]Cl_2 & > & [Co(NH_3)_5Cl](NO_3)_2 & > & [Co(NH_3)_5Cl]Br_2 \\ \vee & & \vee & & \\ [Co(NH_3)_5NO_3]Cl_2 & > & [Co(NH_3)_5NO_3](NO_3)_2 & & \vee \\ \wedge & & \vee & & \\ [Co(NH_3)_5Br]Cl_2 & > & [Co(NH_3)_5Br](NO_3)_2 & > & [Co(NH_3)_5Br]Br_2 \end{array}$$

The levels of the standard free energy of formation for these complexes are diagrammatized in Fig. 5. From these figures it is found that the decrease of the thermodynamic stability of these monoacidopentamminecobalt(III) complexes is far less for the case when $Cl^-$ in the inner sphere is replaced by $NO_3^-$ or $Br^-$ than for the case when $Cl^-$ in the outer sphere is replaced by $NO_3^-$ or $Br^-$. This fact might be partly interpreted by the increase of the radius of the anion in the outer sphere in the order, $Cl^- < NO_3^- < Br^-$.

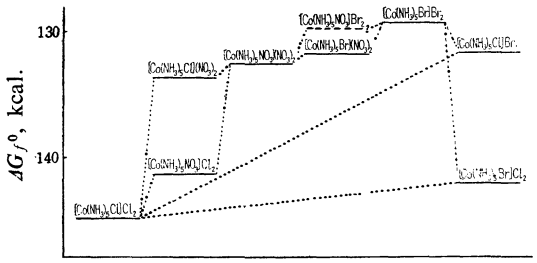

Fig. 5. The levels of the standard free energy of formation for several monoacidopentamminecobalt(III) complexes in the solid state.

**Thermodynamic Stability of Monoacidopentamminecobalt(III) Ions.** — From the standard free energies of formation of nitratopentamminecobalt(III) and bromopentamminecobalt(III) ions obtained above, and those of chloropentamminecobalt(III) ion[1], nitropentamminecobalt(III) ion[13], sulfatopentamminecobalt(III) ion[6], aquopentamminecobalt(III) ion[1] and hexamminecobalt(III) ion[13], the free energy change for the following substitution reactions are calculated:

$$[Co(NH_3)_5OH_2]^{2+} + NO_2^- = [Co(NH_3)_5NO_2]^{2+} + H_2O(l) \qquad \Delta G^0_{298} = -52590 \text{ cal.}$$

$$[Co(NH_3)_5OH_2]^{3+} + SO_4^{--} = [Co(NH_3)_5SO_4]^+ + H_2O(l) \qquad -6750$$

$$[Co(NH_3)_5OH_2]^{3+} + NH_3\ (aq.) = [Co(NH_3)_5NH_3]^{3+} + H_2O(l) \qquad -320$$

$$[Co(NH_3)_5OH_2]^{3+} + Br^- = [Co(NH_3)_5Br]^{2+} + H_2O(l) \qquad 1040$$

$$[Co(NH_3)_5OH_2]^{3+} + NO_3^- = [Co(NH_3)_5NO_3]^{2+} + H_2O(l) \qquad 1780$$

$$[Co(NH_3)_5OH_2]^{3+} + Cl^- = [Co(NH_3)_5Cl]^{2+} + H_2O(l) \qquad 3825$$

From these values it is concluded that the thermodynamic stability decreases in the order:

$$[Co(NH_3)_5NO_2]^{2+} > [Co(NH_3)_5SO_4]^+ > [Co(NH_3)_6]^{3+} > [Co(NH_3)_5OH_2]^{3+} > [Co(NH_3)_5Br]^{2+} > [Co(NO_3)_5NO_3]^{2+} > [Co(NH_3)_5Cl]^{2+}$$

This order is in good agreement with the spectrochemical series[14] with the exception of $[Co(NH_3)_5SO_4]^+$ and $[Co(NH_3)_5Br]^{2+}$.

## Summary

1. By measuring the solubility and the dissociation pressure of aquopentamminecobalt(III) nitrate, the standard free energy of formation of the salt and that of nitratopentamminecobalt(III) nitrate produced by the decomposition of the former in the solid state were determined.

2. In the same way the standard free energy of formation of aquopentamminecobalt(III) bromide and that of bromopentamminecobalt(III) bromide were determined.

3. On the basis of these results, the thermodynamic stabilities of three aquopentamminecobalt(III) complexes, several monoacidopentamminecobalt(III) complexes and their ions were determined.

# *Rotatory Dispersion of Metallic Co-ordination Compounds. II. Absorption Spectra and Rotatory Dispersion of Cobalt(III) Complexes of EDTA*

By Jinsai HIDAKA, Yoichi SHIMURA and Ryutaro TSUCHIDA

(Received November 25, 1959)

It is well known that rotatory dispersion is closely related to the absorption band, and there are many reports[1] concerning the rotatory dispersion of some metallic complex ions but very few on the relation between the partial "inversive dispersion" and the absorption band. In the former paper of this series[2], anomalous rotatory dispersion in the visible and ultraviolet region has been measured for the cobalt(III) ethylenediamine complexes, analyzed in partial "inversive dispersion" and discussed in relation to their absorption band. Furthermore, a possibility of determining the absolute configuration of the complex ion has been suggested from the viewpoint of the inversive dispersion curve in the wavelength region of the first absorption band.

In the present paper, the anomalous rotatory dispersion of D-$Na_2[Co(edta)NO_2]\cdot 3H_2O$, D-K$[Co(edta)]\cdot 3H_2O$ and D-$K_2[Co(edta)Cl]\cdot 3H_2O$, which were recently resolved by Dwyer et al.[3,4], and D-*cis*-$[Co\,en_2(NO_2)_2]$ I will be studied in the visible and ultraviolet region in the same way as was done in the former report[2].

## Experimental

**Measurements.**—The rotatory dispersion measurements were carried out with a Rudolph photoelectric spectropolarimeter, Model 200S-80. The measurements were made in the region from 700 m$\mu$ ($42.8\times10^{13}$/sec.) to 365 m$\mu$ ($82\times10^{13}$/sec.) using mainly the lines of the mercury spectrum. A xenon or a tungsten lamp was also used when necessary. The measurements of D-$[Co(edta)NO_2]^{2-}$ and D-$[Co(edta)]^-$ were made in aqueous solutions of $1/5\times10^2$ F, $1/10^3$ F, $1/2\times10^3$ F, and $1/4\times10^3$ F. The solvent employed for D-$[Co(edta)Cl]^{2-}$ was hydrochloric acid (1 : 1) because this complex ion is not so stable in an aqueous solution that it undergoes aquotization rapidly. The concentration of the solution was $1/5\times10^2$ F or $1/10^3$ F, and the measurements were made as rapidly as possible after preparation of the solution to reduce the reaction of the complex ion with weter to the minimum. The concentration of D-*cis*-$[Co\,en_2(NO_2)_2]^+$ was $1/10^3$ F, $1/3\times10^3$ F and $1/6\times10^3$ F in aqueous solutions. The absorption measurements were made by a Beckman DU spectrophotometer. All measurements were made at room temperature.

**Material.**—Potassium-(ethylenediaminetetraacetato) cobalt(III) trihydrate, $K[Co(edta)]\cdot 3H_2O$, was prepared in violet crystals and resolved by the method of Dwyer et al[3]. Optically active complex ions, D-$[Co(edta)]^-$, were precipitated as a more sparingly soluble salt with D-$[Co\,en_3]^{3+}$.[5] The preparation and resolution of disodium nitro-(ethylenediaminetetraacetato) cobalt(III) trihydrate, $Na_2[Co(edta)NO_2]\cdot 3H_2O$, and dipotassium chloro-(ethylenediaminetetraacetato) cobalt(III) trihydrate, $K_2[Co(edta)Cl]\cdot 3H_2O$, were also made by the direction of Dwyer et al.[4] The D-isomer of both the complex ions was precipitated as a more sparingly soluble salt with L-*cis*-$[Co\,en_2(NO_2)_2]^+$. *cis*-Dinitro-bis-(ethylenediamine) cobalt(III) iodide was prepared and resolved by the method of Werner[6]. The D-isomer was precipitated as a more sparingly soluble salt with *d*-camphorsulphonic acid. These optically active complex ions gave positive value of optical rotation at green lines of a mercury spectrum, and were denoted as a D-isomer.

## Results and Discussion

The rotatory dispersion and the absorption curve of D-$Na_2[Co(edta)NO_2]\cdot 3H_2O$, D-K$[Co(edta)]\cdot 3H_2O$, D-$K_2[Co(edta)Cl]\cdot 3H_2O$ are shown in Figs. 1~3. The structures of these complex ions were well established by Dwyer[4] and other workers[7]. The observed curves were analyzed on the basis of the following consideration. It is assumed that the observed curve is the superposition of the partial inversive dispersion[8] and the tail of a total dispersion which has its inversion center in the far ultraviolet

region. For the analysis, the method of successive approximation was employed.

D-$Na_2[Co(edta)NO_2]\cdot 3H_2O$. As is seen in Fig. 1, the observed curve indicates that total the dispersion curve is apparently displaced to the negative side on the whole. In the analysis of the curve, therefore it is assumed that the observed curve is the superposition of the partial dispersion in the visible region and the negative tail of a total dispersion concerned in the far ultraviolet region. The shape of the rotatory dispersion curve suggests that an overlapping of two inversive dispersions occurred in its first absorption band. As a result of tentative curve analysis, it was found that two inversive dispersions overlapped with each other in the visible region. The sign of the Cotton effect concerned in the first inversive dispersion is negative. Thus the molar rotation changes from negative (long wavelength side) to positive values (short wavelength side) at about 49 ($\times 10^{13}$/sec.). On the other hand, the second inversive dispersion appears at about 59 ($\times 10^{13}$/sec.) and shows a positive Cotton effect. The magnituds of these two partial dispersions is found to be of the same order. The two inversive dispersions may be regarded as corresponding to the absorption band in these wavelength regions. As is shown in Fig. 1, the first absorption band of $[Co(edta)NO_2]^{2-}$ distinctly splits into two components. The Ia-component is at 60.4 ($\times 10^{13}$/sec.) in the shorter wavelength as compared with the first band of $[Co(edta)]^-$, and the sub-component, Ib, is at 51.4 ($\times 10^{13}$/sec.) in the long wavelength side of the first band of $[Co(edta)]^-$ [9]. It has been reported that the center of the inversive rotatory dispersion was almost always in the longer wavelength region in comparison with the position of the absorption maximum[10]. In this respect, the result of the present measurements is in good agreement.

D-$K[Co(edta)]\cdot 3H_2O$. The rotatory dispersion curve of D-$[Co(edta)]^-$ is shown in Fig. 2. The total dispersion curve is apparently displaced to the negative side. This complex ion also shows two inversive dispersions in the region of the first absorption band. The one, with its center at about 51.5 ($\times 10^{13}$/sec.), has a negative Cotton effect and the other, with its center at 61.0 ($\times 10^{13}$/sec.), a positive Cotton effect. As is seen in Fig. 2, the first absorption band of this complex does not split. Judging from the symmetry of the complex ion, however, it is expected that its first absorption band splits into two component

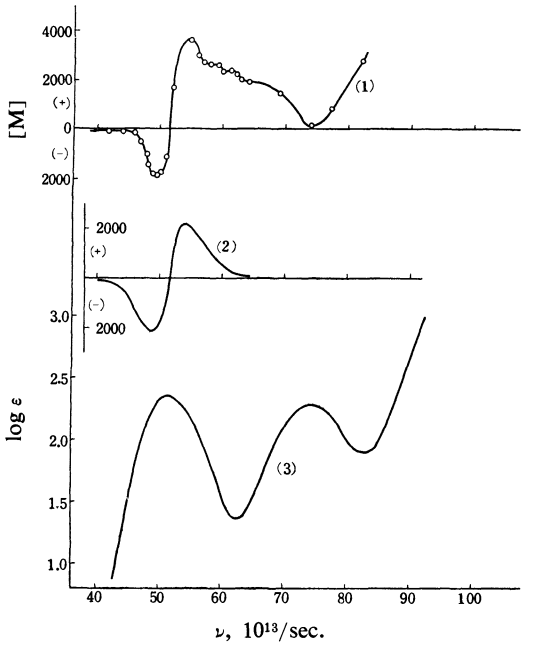

Fig. 3. Rotatory dispersion and absorption of D-$K_2$[Co(edta)Cl]·$3H_2O$: 1, rotatory dispersion curve; 2, curve analyses of the rotatory dispersion curve; 3, absorption curve; first band, $\nu_{max}$=ca. 52.0 ($\log \varepsilon_{max}$=2.35); second band, ca. 74.0 (2.28).

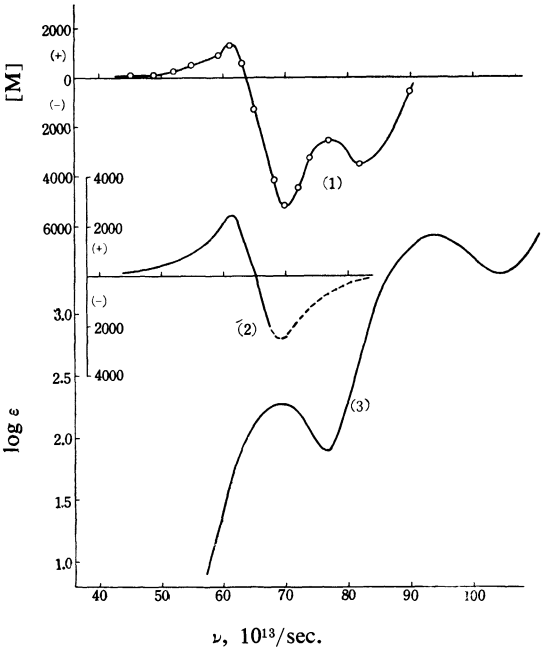

Fig. 4. Rotatory dispersion and absorption of D-*cis*-[Co $en_2(NO_2)_2$]I: 1, rotatory dispersion curve; 2, curve analyses of the rotatory dispersion curve; 3, absorption curve.

absorptions, Ia and Ib. It is considered, therefore, that the two inversive dispersions obtained above probably correspond to the two components of the first absorption band. The optical activity is due to the arrangement of the groups about the central cobalt atom, so the rotatory dispersion curve of complexes of similar configuration should have the same chracteristic. Therefore, the similarity of the rotatory dispersion curve of D-[Co(edta)-$NO_2$]$^{2-}$ and D-[Co(edta)]$^-$ complexes, in the region of the first absorption band, shows that the two complex ions have a similar configuration. There is another small inversive dispersion with its center at about 77 ($\times 10^{13}$/sec.), which probably belongs to the second absorption band.

D-$K_2$[Co(edta)Cl]·$3H_2O$. Contrary to the preceding two complexes, the observed curve is apparently displaced to the positive side by the tail of total dispersion from the far ultraviolet side. The result of the measurement and the analysis is shown in Fig. 3. According to the analysis, the inversive dispersion of the first absorption band occurred at 51.8 ($\times 10^{13}$/sec.), which has a negative Cotton effect. In the shorter wavelength side of the first absorption band at about 57~63 ($\times 10^{13}$/sec.), there is a small hump in the rotatory dispersion curve. This fact shows that the first absorption band has a sub-component in this region, although no evidence is observed in the absorption curve. Because this complex is not so stable toward aquotization in solutions, it was not possible to measure the rotation in the region of a wavelength shorter than 82.5 ($\times 10^{13}$/sec.). However, as regards the behavior of the short wavelength end of the observed curve, it may be considered that an inversive dispersion which belongs to the second absorption band also contributes to the observed rotatory dispersion curve. From the results mentioned above for the cobalt(III) complexes of EDTA, it will easily be understood that the analysis of the rotatory dispersion curve is very useful for the study of the absorption bands, especially for the study of their splitting and overlapping.

D-*cis*-[Co $en_2(NO_2)_2$]I. In the region of the first absorption band, as is shown in Fig. 4, there is an inversive dispersion with its center at about 65.5 ($\times 10^{13}$/sec.), which has a positive Cotton effect, and this result coincides with Methieu's[11]. The behavior of the dispersion curve, that is that the observed curve has apparently one inversive dispersion in the region of the first band, resembles that of D-*cis*-[Co$en_2$Cl $NO_2$]$^+$ [2].

11) J.-P. Mathieu, *Bull. soc. chim. France*, [5] 3, 487 (1936).

This fact is considered as follows. The two components of the first absorption band, which have the positive sign of the Cotton effect, are so close together that a complete overlapping of two inversive dispersions occurred. In the shorter wavelength region, the observed value of the molar rotation is smaller. Judging from the position of the absorption maximum, it may be suggested that there begins in this region an inversive dispersion which belongs to the nitro-specific absorption band too. Similarly, on the observed curve of D-$[Co(edta)NO_2]^{2-}$, the increase of molar rotation for the negative side in the shorter wavelength end may be regarded as originating from the nitro-specific absorption band.

## Summary

The rotatory dispersion measurements have been made for D-$Na_2[Co(edta)NO_2]\cdot 3H_2O$, D-$K[Co(edta)]\cdot 3H_2O$, D-$K_2[Co(edta)Cl]\cdot 3H_2O$ and D-*cis*-$[Co\,en_2(NO_2)_2]I$. On the basis of these measurements, the relation of the splitting of the first absorption band with the so-called anomalous rotatory dispersion has been discussed. In the anomalous rotatory dispersion of D-$[Co(edta)NO_2]^{2-}$, there appear two inversive dispersions due to the component absorption, Ia and Ib, of the split first absorption band. Similarly considered, it has been shown that the first absorption band of $[Co(edta)]^-$ or $[Co(edta)Cl]^{2-}$ may have two component absorptions in accordance with the behavior of its rotatory dispersion curve.

# *Ultraviolet Absorption Spectra of Aqueous Solutions and Single Crystals of Thioacetamide and Thiourea*

By Haruo HOSOYA, Jiro TANAKA and Saburo NAGAKURA

(Received December 15, 1959)

In a series of previous papers by Nagakura and Tanaka[1-4], electronic absorption spectra of various molecules, in which electron donating and accepting groups are connected with each other directly or through a bridge of conjugated double bonds, were discussed from both experimental and theoretical points of view. In these studies, special attention was paid to absorption bands which can be ascribed to neither of the component groups but to the interaction between the electron donating and accepting groups within a molecule. Since the transition corresponding to this kind of absorption band is apparently accompanied by a great amount of electron transfer from the electron donor to the acceptor, it may be called an intramolecular charge-transfer absorption by analogy with intermolecular cases developed by Mulliken[5]. From both experimental results of polarized ultraviolet absorption spectra and theoretical studies based on the LCMO treatment, it was actually shown that the intramolecular charge-transfer absorption can be found with formamide ($O=CH-NH_2$), acrolein ($H_2C=CH-CH=O$), nitramide ($H_2N-NO_2$), nitrobenzene ($C_6H_5-NO_2$), benzoic acid ($C_6H_5-COOH$), *p*-nitroaniline ($O_2N-C_6H_4-NH_2$) and other similar molecules. For example, the strong 370 m$\mu$ band of *p*-nitroaniline could reasonably be interpreted as an intramolecular charge-transfer absorption, in view of the fact that the direction of the transition moment associated with the band is parallel to the molecular axis connecting the two nitrogen atoms. A similar interpretation was applied to the 237 m$\mu$ band of aniline by Longuet-Higgins and Murrell[6].

In the present paper, electronic absorption spectra of thioacetamide ($S=C\langle^{CH_3}_{NH_2}$) and thiourea ($S=C\langle^{NH_2}_{NH_2}$) are studied as a subject of much interest from the aspect of intramolecular charge-transfer absorption. In these molecules, the thiocarbonyl (C=S) and amino ($NH_2$) groups are electron acceptor and donor, respectively, and the appearance of the intramolecular charge-transfer absorption may be expected. Especially thiourea seems to be most suitable for studying the effect of so-called cross-conjugation upon the charge-transfer absorption. This is because this molecule shows absorption bands at relatively longer wavelengths than the similar compounds, say urea ($O=C\langle^{NH_2}_{NH_2}$), do. By the way, the absorption bands of urea appear at wavelengths below 190 m$\mu$ and therefore are difficult to be measured with spectrophotometric instruments usually available at present.

Katagiri et al. measured absorption spectra of thioacetamide and thiourea in ethereal solution and pointed out that the weak band of thioacetamide at 318 m$\mu$ is conceivably ascribed to the $n\rightarrow\pi^*$ transition[7]. However, the assignment of the $\pi\rightarrow\pi^*$ transition bands of these two molecules has never been made. In the present paper, it is undertaken to obtain a definite conclusion on the assignment of the absorption bands by measuring the polarized ultraviolet absorption with their crystals and, moreover, by combining the experimental results with theoretical consideration based on the semi-empirical molecular orbital method including configuration interaction.

As is well known, thioacetone ($(H_3C)_2C=S$) can not exist as a stable monomer but usually as a trimer[8]. Therefore, it is difficult to obtain peak wavelengths of the absorption spectrum pertinent to the C=S bond, which is one of the important and basic data indispensable for the present study. In order to remove this difficulty, we have undertaken to measure the absorption spectrum of the conjugate acid of thioacetamide ($S=C\langle^{\overset{+}{N}H_3}_{CH_3}$) which is isoelectronic with thioacetone. In this connection, the equilibrium between thioacetamide and a proton is studied in detail and its equilibrium constant is obtained by means of the spectrophotometric method.

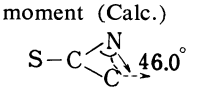
## Experimental

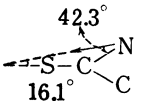
**Materials.**—Commercial thioacetamide of G. R. grade was purified by repeating recrystallization from ethyl ether, m. p. 109.5~110.5°C (uncorrected). The reported value is 107.5~108.5°C[9]. After the purification it was subjected to spectrophotometric measurements as soon as possible, because it has a tendency to decompose easily. Commercial thiourea of G. R. grade was recrystallized from ethanol, m. p. 177~178.5°C (uncorrected). The reported value is 180°C[10]. Hydrochloric acid and sulfuric acid, which are both of G. R. grade, were used as solvents without further purification.

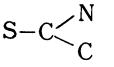
**Measurement.** — *Ultraviolet Absorption Spectra of Solutions.* — A Cary recording spectrophotometer model 14 M was used for the ultraviolet absorption measurements of solutions. Measurements were usually carried out at room temperature (20~25°C), the quartz cell with a stopper of 1 cm. light path being used. If necessary, however, the temperature of the absorption cell was kept constant by circulating water of a desired constant temperature through the cell jacket.

*Ultraviolet Absorption Spectra of Crystals.* — An ultraviolet microscope equipped with a Hitachi model EPU monochromator and a polarizer of Rochon prism type was used for the measurement of polarized ultraviolet absorption in the wavelength region of 220~650 m$\mu$[11]. Crystalline axes and planes were identified by the aid of X-ray rotation photographs and of optical examination with a polarizing microscope.

The single crystal of thioacetamide suitable for the measurement of polarized ultraviolet absorption was prepared by sublimation. The crystal showed a well developed (001) cleavage plane and was about 1×2 mm. in size and about 1~2 $\mu$ in thickness. The single crystal of thiourea was prepared directly on a quartz plate by dipping it into the ethanol solution and by evaporating the solvent slowly. Two kinds of crystals were obtained, one of which was hexagonal and the other rectangular. The latter was used for the spectroscopic measurement. Its developed plane was shown to be (110) by X-ray rotation photographs.

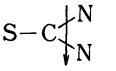


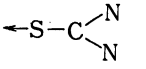


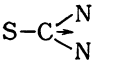


## Experimental Results

**Absorption Spectra of Thioacetamide in Aqueous and Hydrochloric Acid Solutions.** — The results obtained with the aqueous and hydrochloric acid solutions of thioacetamide are summarized in Table I and Figs. 1 and 2. The ultraviolet absorption spectrum of thioacetamide in aqueous solution apparently consists of three bands. Two of them, which appear at 261 and 210 m$\mu$, are fairly strong and may reasonably be attributed to allowed $\pi\rightarrow\pi^*$ transitions. On the other hand, the longest wavelength band at 318 m$\mu$, whose molar extinction coefficient is only 60, may be regarded as an $n\rightarrow\pi^*$ transition band.







11) For the detail of the instrument, see Ref. 4.

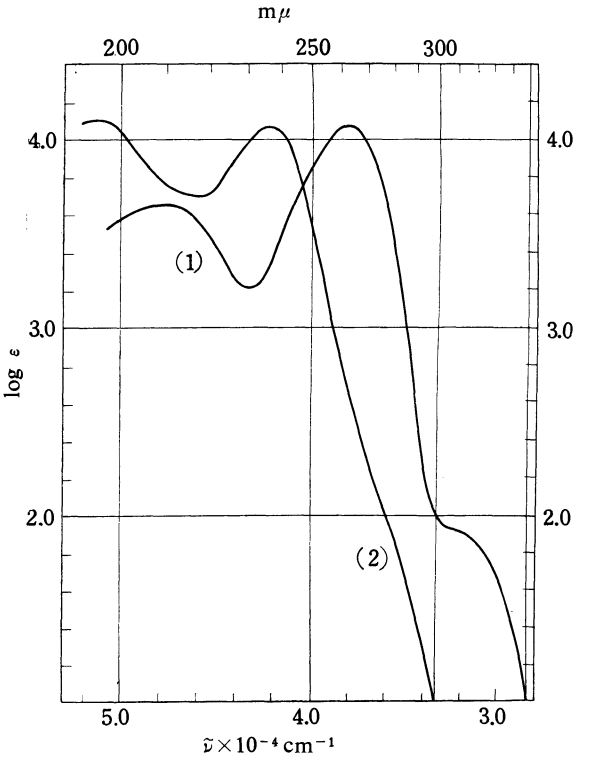

Fig. 1. Ultraviolet absorption spectra of thioacetamide (1) and thiourea (2) in aqueous solutions.

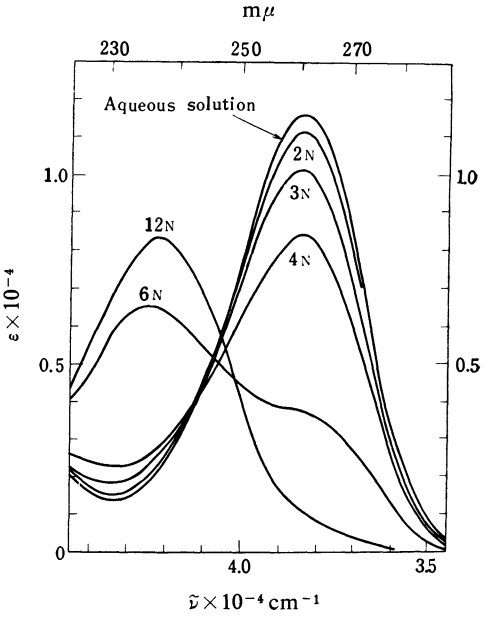

Fig. 2. Ultraviolet absorption spectra of thioacetamide in hydrochloric acid solutions with various acid concentrations.

The absorption spectrum of thioacetamide in hydrochloric acid solution changes considerably from that in aqueous solution. As is seen from Fig. 2, with the increasing concentration of hydrochloric acid, the 261 mμ band gradually decreases its intensity and a new band appears at 237 mμ[12]. Further, an isobestic point can be observed at 245 mμ, though the crossing of absorption curves is not always complete for the solutions of the higher concentrations of hydrochloric acid*. This fact conclusively indicates the existence of an equilibrium between thioacetamide and its conjugate acid. Concerning the mechanism of this equilibrium, there are two possible alternatives which are different from each other in the position where a proton is attached to the parent thioacetamide molecule. They are represented by the following equations:

$$H_2N\text{-}\overset{\overset{S}{\|}}{C}\text{-}CH_3 + H_3O^+ = H_3\overset{+}{N}\text{-}\overset{\overset{S}{\|}}{C}\text{-}CH_3 + H_2O$$

$$H_2N\text{-}\overset{\overset{S}{\|}}{C}\text{-}CH_3 + H_3O^+ = H_2N\text{-}\overset{\overset{{}^+SH}{\|}}{C}\text{-}CH_3 + H_2O$$

Here the former equilibrium is adopted as the more probable one. Some details on this point will be discussed in some later parts of the present paper.

From the experimental results regarding the absorption spectrum of thioacetamide in hydrochloric acid solutions of various concentrations, the basicity constant ($pK_B$) of thioacetamide can be obtained by the aid of the following equations:

$$K_B = (H_3\overset{+}{N}CSCH_3)/(H_2NCSCH_3)(H^+)$$
$$= (\varepsilon - \varepsilon_B)/(\varepsilon_{HB^+} - \varepsilon)(H^+)$$
$$pK_B = \log\{(\varepsilon_{HB^+} - \varepsilon)/(\varepsilon - \varepsilon_B)\} + pH$$

Quantities $(H_2NCSCH_3)$, $(H_3\overset{+}{N}CSCH_3)$ and $(H^+)$ are activities of thioacetamide, its conjugate acid and a proton, respectively. Activity coefficients of thioacetamide and its cation are assumed to be equal to unity because of their low concentrations. The activity of the proton can be evaluated by combining the concentration of the solution determined by titration with the value of activity coefficient taken from the literature[13]. Quantities $\varepsilon$, $\varepsilon_B$ and $\varepsilon_{HB^+}$ represent the apparent molar extinction coefficient of thioacetamide in dilute hydrochloric acid solution, in aqueous solution and in concentrated hydrochloric acid solution, respectively. The values of the above-mentioned quantities actually used for the evaluation of $pK_B$ are listed in Table II, together with the calculated $pK_B$ value.

The average value of $pK_B$ is obtained to be 1.2 at 24.5°C. Concerning the evaluation of this value, there are some ambiguities on the adoption of activity coefficients and on the medium effect upon the absorption spectrum of thioacetamide in concentrated hydrochloric acid. However, the $pK_B$ value of thioacetamide evaluated here seems to be reasonable compared with the value of thiourea quoted in the literature[14].

**Polarized Ultraviolet Absorption Spectra of Thioacetamide Crystal.**—According to the structural analysis data of thioacetamide crystal by Truter[15], the molecules lie on the (001) plane as is schematically shown in Fig. 3. The polarized ultraviolet absorption spectra of thioacetamide parallel to *a* and *b* axes are shown in Fig. 3. From this figure it is easily seen that the 261 mμ band has stronger intensity in the direction of *b*-axis than in the direction of *a*-axis, and that the reverse is the case for the 210 mμ band, though the dichroism is not so conspicuous for this band as for the 261 mμ band. For these two bands, unfortunately, it is

Average $pK_B$ value: 1.19.

* This may be due to the medium effect of the acid.

12) The band corresponding to the 210 mμ band of thioacetamide can not be observed in hydrochloric acid solution, because hydrochloric acid is not transparent in the wavelength region below 220 mμ. However, the spectrum in concentrated sulfuric acid solution which is transparent until 200 mμ shows only one absorption band at 240 mμ, namely the one corresponding to the 237 mμ band in hydrochloric acid solution. This seems to support the opinion that the 210 mμ band of thioacetamide disappears in strongly acidic solution.

difficult to determine exactly the direction of the transition momont from the combination of these spectral data with the crystal analysis result. This is because they overlap with each other and it is difficult to obtain the accurate value of oscillator strength for each band separately. However, it is well accepted that the transition moment of the 261 mμ band is directed very closely to the line connecting the nitrogen and the sulfur atom, thus the absorption intensity being greater in the b-axis spectrum than in the *a*-axis spectrum, while the transition momen of the 210 mμ band is approximately parallel to the line joining the nitrogen atom to the methyl carbon atom, thus the absorption intensity being a little stronger in the *a*-axis apectrum than in the *b*-axis spectrum.

A weak absorption band probably due to $n\rightarrow\pi^*$ transition appears in the 320~340 mμ region and its intensity is much stronger in the direction of *b*-axis than in the direction of *a*-axis. Concerning this weak band, however, one must be careful in determining the direction of the transition moment from the observed absorption intensity ratio, because weak forbidden bands often appear strongly in crystals by borrowing intenisty from allowed transition bands situated nearby[16]. Therefore it seems most likely that the weak band appearing at 320~340 mμ may not exhibit the dichroic property intrinsic to itself but rather the dichroic property characteristic of the 261 mμ band. In fact, the intensity ratio (about 5/1= $I_b/I_a$) measured with the weak band is completely consistent with the above-mentioned direction of transition moment of the 261 mμ band.

**Absorption Spectra of Thiourea in Aqueous Solution.**—As is seen from Table I and Fig. 1, absorption bands of thiourea have a conspicuous tendency to appear at shorter wavelengths compared with the corresponding band of thioacetamide. The same tendency seems to be found also in the case of comparing the absorption spectrum of urea with that of acetamide, though a definite conclusion can not be obtained for the case of these two molecules because of some difficulties from the experimental point of view. Another characteristic of the absorption spectrum of thiourea is the fact that the longest wavelength band of thioacetamide, which is probably associated with $n\rightarrow\pi^*$ transition, disappears.

**Polarized Absorption Spectra of Thiourea Crystal.**—According to the X-ray crystal analysis study by Wyckoff and Corey and by Kunchur and Truter[17], the molecules of thiourea lie on the (110) plane as is shown in Fig. 4. The polarized ultraviolet absorption spectra of thiourea measured by the use of the incident radiation polarized parallel and perpendicular to the *c*-axis of the crystal are shown in Fig. 4. From this figure it is easily

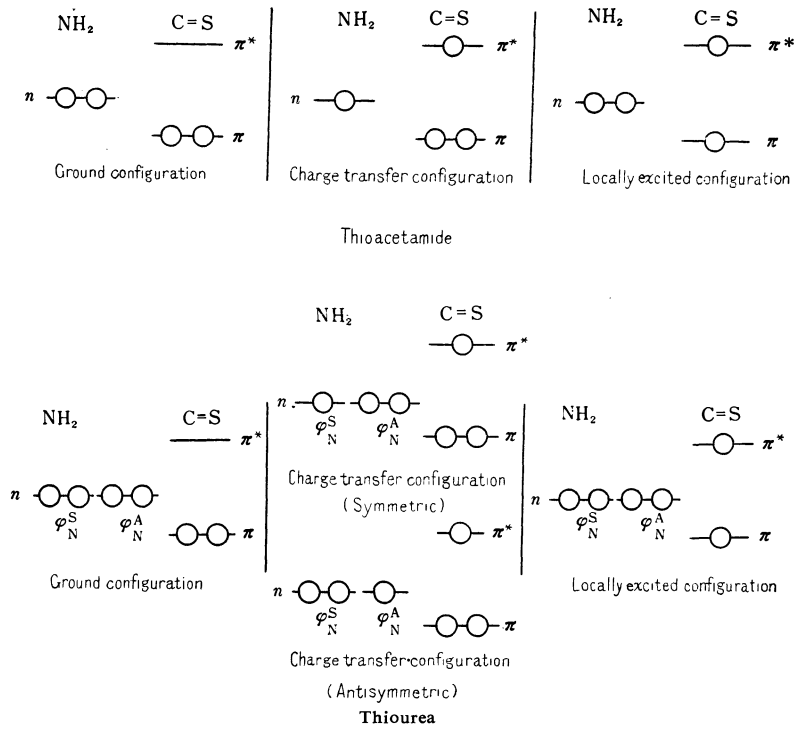

Fig. 5. Electron configurations for thioacetamide and thiourea.

seen that the observed intensity of the longer wavelength band is overwhelmingly great in the direction perpendicular to the *c*-axis compared with that in the direction parallel to the same axis, while the reverse is the case for the shorter wavelength band. This means that the transition moment of the longer wavelength band is evidently perpendicular to the *c*-axis, namely parallel to the C=S bond axis. On the other hand, the transition moment of the shorter wavelength band is determined to be perpendicular to the C=S bond axis.

## Theoretical

In the present calculation, only $\pi$-electrons are taken into account and moreover the approximation of zero-differential overlap is adopted. In actual calculations, four and six $\pi$-electrons are taken for thioacetamide and thiourea, respectively. Now let us explain the actual calculation procedure in some detail, initially taking thioacetamide as an example.

Following Longuet-Higgins and Murrell's procedure[6], three electron configurations are constructed for this molecule in terms of $\pi$-electron molecular orbitals ($\varphi_1$, $\varphi_2$) of the electron accepting groups (C=S) and the nonbonding $2p$ atomiic orbital ($\chi_N$) on the nitrogen atom of the electron donating group ($NH_2$)[18]. These configurations (a), (b) and (c) corresponding to ground, charge-transfer and locally excited configurations, respectively, are schematically shown in Fig. 5. As is well known, the wave functions for these configurations are written as follows:

$$\psi_G = 1/\sqrt{4!}\ \sum(-1)^p P\varphi_1(1)\alpha(1)\varphi_1(2)\beta(2) \times \chi_N(3)\alpha(3)\chi_N(4)\beta(4) \quad (1)$$

$$\psi_{CT} = 1/\sqrt{4!}\ \sum(-1)^p P\varphi_1(1)\alpha(1)\varphi_1(2)\beta(2) \times \chi_N(3)\alpha(3)\varphi_2(4)\beta(4) \quad (2)$$

$$\psi_{LE} = 1/\sqrt{4!}\ \sum(-1)^p P\varphi_1(1)\alpha(1)\varphi_2(2)\beta(2) \times \chi_N(3)\alpha(3)\chi_N(4)\beta(4) \quad (3)$$

Here, $\sum(-1)^p P$ is the usual antisymmetrizing summation over all permutations of the electrons. The wave functions $\varphi_1$ and $\varphi_2$ in Eqs. 1—3. can be determined following the procedure described in the Appendix.

Next one must take into account configuration interaction in terms of the three electron configurations mentioned above. According to this procedure, the energy levels of the molecule turn out to be obtained as solutions of the following secular equation:

18) According to the X-ray crystal analysis data of thioacetamide, hydrogen atoms of amino group are almost coplanar with heavy atoms.[15] This means that the nonbonding electrons of nitrogen may reasonably be assumed to belong to the pure $2p\pi$ atomic orbital.

$$\begin{vmatrix} H_G-E & H_{G\cdot LE} & H_{G\cdot CT} \\ H_{G\cdot LE} & H_{LE}-E & H_{LE\cdot CT} \\ H_{G\cdot CT} & H_{LE\cdot CT} & H_{CT}-E \end{vmatrix}=0 \qquad (4)$$

where, $H_G=\int \psi_G H \psi_G d\tau$, $H_{G\cdot LE}=\int \psi_G H \psi_{LE} d\tau$, etc.

Suppose the energy of the ground configuration is taken as a standard. The value of $H_{CT}$, the energy of the charge-transfer configuration, can be evaluated by the following equation:[2]

$$H_{CT}=I_N-A_{C=S}-\{d^2_{11}(CC \mid NN)+d^2_{12}(SS \mid NN)\} \qquad (5)$$

where $I_N$ and $A_{C=S}$ are the ionization potential of the nonbonding electron of the amino nitrogen atom and the electron affinity of the C=S group, respectively. The former is set equal to the ionization potential of ammonia which is determined as 10.15 eV by Watanabe from the photoionization experiment.[19] The quantities $d_{11}$ and $d_{12}$ are coefficients of atomic orbitals in $\varphi_1$ or $\varphi_2$ molecular orbital and are evaluated to be 0.6902 and 0.7236 (see Appendix), respectively. Two center Coulomb integrals (CC | NN) and (SS | NN) are calculated with the aid of uniformly charged sphere approximation, by taking the C–N and C=S bond distances as 1.324 and 1.713 Å, respectively, and further by taking ∠SCN as 121.6°[15]. The value of $A_{C=S}$ is assumed to be −0.32 eV which seems to be reasonable compared with that of the C=O bond, −1.20 eV.[2]

The energy value of the locally excited configuration, $H_{LE}$, is set equal to the observed excitation energy corresponding to the $\pi\rightarrow\pi^*$ transition pertinent to the C=S group. It is natural to take this value from the experimental result on the absorption spectrum of thioacetone. Unfortunately, however, this expectation can not be satisfied, because thioacetone usually exists as trimer like $Me_2C<^{S-C-Me_2}_{S-C-Me_2}>S$[8]. Then in the present calculation this value is taken to be 5.24 eV from the experimental result of the absorption spectrum of thioacetamide in hydrochloric acid solution. As mentioned above, thioacetamide in this condition exhibits the peak absorption at 237 mμ. This absorption band is conceivably ascribed to the protonated thioacetamide represented by $R>C-\overset{+}{N}H_3$. Since in this protonated cation the resonance effect of the amino group can be neglected to the first approximation, the 237 mμ band may be regarded as due to the $\pi\rightarrow\pi^*$ transition pertinent to the C=S bond. The present consideration on this point is consistent with the observation by Katagiri et al.[7] that thiocamphor shows a peak absorption at 242 mμ (5.12 eV).

Following the procedure developed by Longuet-Higgins and Murrell,[6] and also by Pople,[20] values of $H_{G\cdot CT}$, $H_{G\cdot LE}$ and $H_{CT\cdot LE}$ can easily be evaluated as follows:

$$H_{G\cdot CT}=\sqrt{2}\, d_{12}\beta_{CN}$$
$$=1.414\times 0.7236\times(-2.1)=-2.15 \text{ eV}$$
$$H_{G\cdot LE}=0$$
$$H_{CT\cdot LE}=-d_{11}\beta_{CN}=-0.6902\times(-2.1)=1.45 \text{ eV}$$

Here $\beta_{CN}$ is the core resonance integral between the π-electron orbital of carbon and the nonbonding orbital of nitrogen. In the present calculation $\beta_{CN}$ is assumed to be an appropriate value of −2.1 eV.

By inserting the energy integral values into Eq. 4 and by solving it, the three energy levels of thioacetamide can be determined. Further, wave functions corresponding to these energy levels can easily be evaluated following the usual procedure in the variation method. The results are shown in Table III. Here values in parentheses are squares of coefficients of corresponding component wave functions. In view of the fact that these values represent magnitudes of contributions of electron configurations to a certain state of the molecule, it may be said that the lowest state ($E_1$) is principally composed of the ground configuration and the contribution of the charge-transfer configuration to that state is only 17%.[21] On the other hand, in the $E_2$ state contributions of the charge-transfer and locally excited configurations are almost equal and amount to 43%.

From the energy values for the states of thioacetamide given in Table III, excitation energies corresponding to $E_1\rightarrow E_2$ and $E_1\rightarrow E_3$ transitions can be calculated to be 4.77 eV and 7.44 eV, respectively. Values of the transition moments $Q_{1i}$'s and oscillator strength $f_{1i}$'s associated with these transitions are calculated by the following equations[22]:

$$Q_{1i}=\int \Psi_1 \, er \, \Psi_i \, d\tau \qquad i=2, 3 \qquad (6)$$

$$f_{1i}=4.704\times 10^{-7}\,\tilde{\nu}_{1i}Q^2_{1i} \qquad (7)$$

where $\tilde{\nu}_{1i}$ is the wave number ($cm^{-1}$) of the absorption peak under consideration and $Q_{1i}$ is represented in Debye units. The calculated

TABLE IV. ENERGY LEVELS AND WAVE FUNCTIONS FOR THIOUREA

| Energy level | Symmetry | Wave function |
|---|---|---|
| $W_1=-1.7653$ eV | $A_1$ | $\Phi_1=0.8555\,\phi_G-0.1454\,\phi_{LE}+0.4968\,\phi^S{}_{CT}$ (0.7319 0.0211 0.2468) |
| $W_2=3.7397$ eV | $A_1$ | $\Phi_2=-0.4328\,\phi_G-0.7275\,\phi_{LE}+0.5324\,\phi^S{}_{CT}$ (0.1873 0.5293 0.2835) |
| $W_3=7.3357$ eV | $A_1$ | $\Phi_3=-0.2840\,\phi_G+0.6705\,\phi_{LE}+0.6854\,\phi^S{}_{CT}$ (0.0807 0.4496 0.4698) |
| $W_4=4.0700$ eV | $B_1$ | $\Phi_4=\phi^A{}_{CT}$ |

values of $f_{1i}$'s are listed in Table I in comparison with the observed valuse which are obtained from absorption curves with the aid of the following equation:

$$f_{1i}^{obs}=4.32\times10^{-9}\int\varepsilon d\tilde{\nu} \qquad (8)$$

where $\varepsilon$ denotes the molar extinction coefficient. Directions of transition moments can also be evaluated readily from magnitudes of their components parallel and perpendicular to the C=S bond axis in the molecular plane. Consequently it is found that directions of transition moments associated with transitions $E_1\rightarrow E_2$ and $E_1\rightarrow E_3$ are inclined by 16° to the C=S bond and by 46° to the N–C bond, respectively. These theoretical results are schematically shown in Table I.

The calculation of $\pi$-electron structure is carried out also with thiourea by the same method as described in the case of thioacetamide. Therefore, it seems tedious to describe repeatedly the details of the calculation procedure. However, it may be necessary to add some note on the fact that in the case of thiourea two group orbitals, whose wave functions are represented by $\varphi^S{}_N=(\chi_{1N}+\chi_{2N})/\sqrt{2}$ and $\varphi^A{}_N=(\chi_{1N}-\chi_{2N})/\sqrt{2}$, can be obtained from the two nonbonding orbitals belonging to the amino groups. Consequently, in this case two charge-transfer configurations must be taken into account. Suppose that the wave functions of these two charge-transfer configurations and of the ground and locally excited configurations can be designated by $\psi^S{}_{CT}$ and $\psi^A{}_{CT}$[23], $\phi_G$ and and $\phi_{LE}$, respectively (see Fig. 5). Among these wave functions, only $\psi^A{}_{CT}$ is antisymmetric with respect to the symmetry plane perpendicular to the molecular plane and including the C=S bond axis, while $\psi^S{}_{CT}$, $\phi_G$ and $\phi_{LE}$ are all symmetric with the same symmetry plane. Therefore it is readily concluded that the electron configuration represented by $\psi^A{}_{CT}$ can not mix with the other configurations. On the other hand, three configurations represented by $\phi_G$, $\psi^S{}_{CT}$ and $\phi_{LE}$ interact with one another. The configuration interaction in terms of these three configurations finally results in three new states. The energy values and wave functions of these new states are given in Table IV[24].

From the energy values given in Table IV, excitation energies corresponding to $W_1\rightarrow W_2$, $W_1\rightarrow W_4$ and $W_1\rightarrow W_3$ are evaluated to be 5.51, 5.84 and 9.11 eV., respectively. It is inferred from this that the observed two absorption bands (236 and 195 m$\mu$) in near ultraviolet region may reasonably be ascribed to the $W_1\rightarrow W_2$ and $W_1\rightarrow W_4$ transitions. The directions of transition moments for these two transitions

23) $\psi^S{}_{CT}=1/\sqrt{6!}\,\Sigma(-1)^P p\phi_1(1)\alpha(1)\phi_1(2)\beta(2)\phi^S{}_N(3)\alpha(3)\phi_2(4)\beta(4)\phi^A{}_N(5)\alpha(5)\phi^A{}_N(6)\beta(6)$
$\psi^A{}_{CT}=1/\sqrt{6!}\,\Sigma(-1)^P p\phi_1(1)\alpha(1)\phi_1(2)\beta(2)\phi^S{}_N(3)\alpha(3)\phi^S{}_N(4)\beta(4)\phi^A{}_N(5)\alpha(5)\phi_2(6)\beta(6)$

24) The values of matrix elements used for the evaluation of energy levels of thiourea are as follows:
$H_G=0$
$H^S{}_{CT}=H^A{}_{CT}=4.07$ eV.
$H_{LE}=5.24$ eV.
$H_{G\cdot CT}=2d_{12}\beta_{CN}=2\times0.7236\times(-2.1)=-3.04$ eV.
$H_{G\cdot LE}=0$
$H_{LE\cdot CT}=-\sqrt{2}\,d_{11}\beta_{CN}=-1.414\times0.6902\times(-2.1)=2.05$ eV.
The values of $I_N$ and $A_{C=S}$ necessary for the evaluation of $H^S{}_{CT}$ and $H^A{}_{CT}$ are the same as those employed in the case of thioacetamide (see Eq. 5). The values of (NN | CC) and (NN | SS), however, are newly calculated for thiourea by the method as described in the case of thioacetamide, by the use of the C-N and S-N distances determined by X-ray crystal analysis ($d_{C-N}=1.35$ Å, $d_{C=S}=1.64$ Å, $\angle NCS=126°$; see Ref. 16 for these data).

can easily be found from the symmetry properties of the upper and lower states for each transition. That is to say, the direction of transition moment for the $W_1 \rightarrow W_2$ transition is expected to be exactly parallel to the C=S bond axis, while that for the $W_1 \rightarrow W_4$ transition is perpendicular to the same axis. Combining this theoretical expectation with the experimental results regarding polarized ultraviolet absorption, it is possible to determine clearly the assignment of these two absorption bands. This point will be explained in the next chapter.

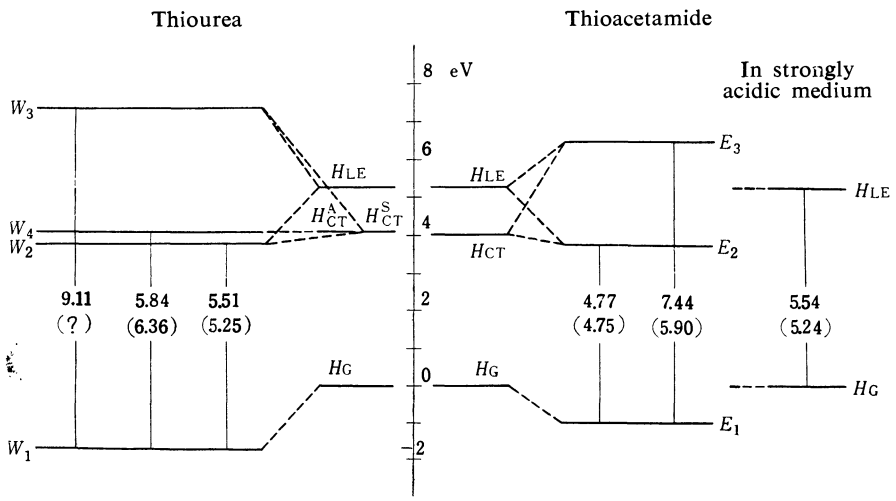
## Discussion

**Assignment of Absorption Bands of Thioacetamide.** — Experimental and theoretical results concerning the absorption spectra of thioacetamide are summarized in Table I and Figs. 1 and 3. From these results it is seen that the directions of transition moments determined theoretically for $E_1 \rightarrow E_2$ and $E_1 \rightarrow E_3$ transitions, whose excitation energies are calculated to be 4.77 eV. (260 m$\mu$) and 7.44 eV. (167 m$\mu$), respectively, are approximately equal to the directions of transition moments observed with the 261 m$\mu$ and 210 m$\mu$ bands, respectively. This fact gives a powerful support for the assignment that the 261 m$\mu$ and 210 m$\mu$ bands ought to be ascribed to the transitions $E_1 \rightarrow E_2$ and $E_1 \rightarrow E_3$, respectively. According to the above assignment, the agreement between the theoretical and experimental excitation energies is satisfactory for the 261 m$\mu$ band, but some discrepancy is seen for the 210 m$\mu$ band. A principal reason for this discrepancy is thought to be the neglect of electron configurations with higher energies, say configurations including two electron jumps. Although there is the above-mentioned difficulty from the quantitative point of view, the assignment of the two absorption bands of thioacetamide may be thought to be finally determined by the present experimental and theoretical studies.

Concerning the assignment of the weak band at 318 m$\mu$, much can not be said. As pointed out by Katagiri et al.[7], however, this band is tentatively due to an $n \rightarrow \pi^*$ transition, namely due to the excitation of a nonbonding electron of the sulfur atom to the excited $\pi$-electron orbital of the C=S bond.

**Assignment of Absorption Spectrum of Thiourea.** — The results regarding the absorption spectrum of thiourea are given in Table I and Figs. 1 and 4. This molecule shows fairly strong absorption bands at 236 and 195 m$\mu$. Calculated excitation energies for the $W_1 \rightarrow W_2$ and $W_1 \rightarrow W_4$ transitions are 5.51 (225 m$\mu$) and 5.84 eV. (212 m$\mu$), respectively. In this case, it is dangerous to determine the assignment of these two bands from the theoretical excitation energies alone, because the energy difference between $W_2$ and $W_4$ states is only 0.33 eV. and there may be some possibility that energy levels of these two states are reversed with each other by changing to only a small extent some parameters adopted in the present calculation. Fortunately, however, this difficulty is completely removed by considering the result of the polarized ultraviolet absorption measurement on the single crystal.

As is seen from Fig. 4, experimental results on the polarized ultraviolet absorption spectrum shows that the directions of transition moments of the longer and shorter wavelength bands are parallel and perpendicular to the C=S bond axis, respectively. Theoretical consideration in



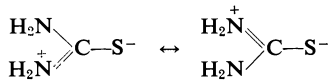


Fig. 6. Energy level diagrams for thioacetamide and thiourea, showing the relation between observed (in parentheses) and calculated transition energies.

the preceding chapter concludes that the transition moments associated with $W_1 \rightarrow W_2$ and $W_1 \rightarrow W_4$ ought to have directions exactly parallel and perpendicular to the C=S bond axis, respectively. These facts lead to the conclusion that the 236 m$\mu$ and 195 m$\mu$ bands correspond to the $W_1 \rightarrow W_2$ and $W_1 \rightarrow W_4$ transitions, respectively.

Of these two absorption bands, the shorter wavelength (195 m$\mu$) band may be called a typical intramolecular charge-transfer band, because the upper state ($W_4$) of the corresponding transition is completely constructed from the charge-transfer configuration. This charge-transfer configuration includes electron transfer from the orbital represented by an antisymmetric combination of the nonbonding electron orbitals of the two nitrogen atoms to the $\varphi_2$ orbital pertinent to the C=S bond. From the resonance viewpoint, this means that the upper state of the 195 m$\mu$ band can be represented approximately by the resonance hybrid between the following two structures:

On the other hand, the 236 m$\mu$ band exhibits strongly the character of the locally (C=S) excited band, because in the excited state corresponding to this band the contribution of the locally excited configuration is great and amounts to 53%. In this sense, the 236 m$\mu$ band of thiourea may be regarded as the shifted one of the 237 m$\mu$ band pertinent to the C=O bond.

The relation between the energy state and the ultraviolet absorption spectrum described hitherto on thioacetamide and thiourea are schematically shown in Fig. 6.

**Absorption Spectrum of Thioacetamide in Hydrochloric Acid Solution.**—The fact that the 261 m$\mu$ and 210 m$\mu$ bands ($E_1 \rightarrow E_2$ and $E_1 \rightarrow E_3$ transitions, respectively) of thioacetamide disappear and a new band appears at 237 m$\mu$ in concentrated hydrochloric acid solution (240 m$\mu$ in concentrated sulfuric acid solution) seems to give an important information regarding the position of the proton attached to the parent molecule. Concerning the position of the proton, there are conceivably two alternatives, namely the nitrogen atom of the amino group and the sulfur atom of the thiocarbonyl group. In the latter case, it may be expected that the electron affinity of the C=S group increases considerably and the energy of the charge-transfer configuration given by Eq. 5 apparently decreases. From this it may be predicted that the 261 m$\mu$ band of thioacetamide will shift toward longer wavelengths if the proton be attached to the sulfur atom. The experimental result is completely reverse to this prediction. This seems to support the other possibility, namely the fact that proton is attached to the nitrogen atom. This conclusion is in agreement with the result obtained from the absorption measurement in the infrared region[25].

## Appendix

**The Molecular Orbital Functions Pertinent to the C=S Bond.** — $\pi$-Electron orbitals of the C=S bond are represented by the linear combination of the $2p$ atomic orbital of carbon ($\chi_C$) and the $3p$ atomic orbital of sulfur ($\chi_S$):

$$\varphi_1 = d_{11}\chi_C + d_{12}\chi_S \tag{9}$$

$$\varphi_2 = d_{12}\chi_C - d_{11}\chi_S \tag{10}$$

The problem is to calculate the values of coefficients $d_{11}$ and $d_{12}$. The calculation is carried out by the aid of the combination of Roothaan's LCAO SCF method[26] with Pariser and Parr's approximation[27]. The values of energy integrals actually adopted to the calculation are as follows:

$$\alpha_C = -I_C + \int \chi_C U_S \chi_C d\tau = -11.54 - 7.76 = -19.30 \text{ eV}. \tag{12}$$

$$\alpha_S = -I_S + \int \chi_S U_C \chi_S d\tau = -12.50 - 7.65 = -20.15 \text{ eV}. \tag{11}$$

$\beta_{CS} = -2.0$ eV. (assumed value)

$$(CC|CC) = \int \chi_C(1)\chi_C(2)\frac{e^2}{r_{12}}\chi_C(1)\chi_C(2)d\tau = 11.54 - 0.46 = 11.08 \text{ eV}.$$

$$(CC \mid SS) = \int \chi_C(1)\chi_S(2)\frac{e^2}{r_{12}}\chi_C(1)\chi_S(2)d\tau = 7.37 \text{ eV}.$$

$$(SS \mid SS) = \int \chi_S(1)\chi_S(2)\frac{e^2}{r_{12}}\chi_S(1)\chi_S(2)d\tau = 12.50 - 2.70 = 9.80 \text{ eV}.$$

Here U and $\alpha$ represent core potential and core Coulomb integral concerning atoms each of which is referred to by a suffix, respectively. $\beta_{CS}$ is the core resonance integral between the $\chi_C$ and $\chi_S$ orbitals. $I_C$ and $I_S$ are the ionization potential of the $2p$ electron of carbon and of the $3p$ electron of sulfur, respectively. These values are taken from Pritchard and Skinner's table[28]. Integrals $\int \chi_C U_S \chi_C d\tau$ and $\int \chi_S U_C \chi_S d\tau$ are assumed to be equal to electrostatic attraction between two spherically charged ($-e/2$ each) tangent balls on one atom and the opposite charge ($+e$) on the other

atom. Following Pariser and Parr's procedure[27], one center Coulomb repulsion integral, (CC | CC) or (SS | SS) is set equal to the difference between the ionization potential and the electron affinity. These two quantities are taken from Pritchard and Skinner's table. The two center Coulomb repulsion integral (CC | SS) is evaluated under the uniformly charged sphere approximation[29], taking the C=S bond distance as 1.71 Å, the value obtained by Truter from the X-ray analysis data on thioacetamide[15].

In order to obtain more accurate values for the core Coulomb integrals, the polarization effect of the $\sigma$-electrons of the C=S orbital upon them is taken into account. According to Moffit's method[30], the corrected ionization potentials can be obtained by the following equation[31]:

$$I'_C = -11.54 - 0.1436(11.08 - 7.37) = -12.08 \text{ eV}.$$

$$I'_S = -12.50 + 0.1436(9.80 - 7.37) = -12.15 \text{ eV}.$$

Substituting these values for $I_C$ and $I_S$ in Eqs. 11 and 12, the corrected core Coulomb integrals become as follows:

$$\alpha'_C = -19.84 \text{ eV}. \qquad \alpha'_S = -19.80 \text{ eV}.$$

By using these integral values, the iterative procedure following Roothaan's method is continued until self-consistent results are obtained with $d_{11}$, $d_{12}$ and orbital energies ($\varepsilon_1$, $\varepsilon_2$). The final results thus obtained are as follows[32]:

$$d_{11} = 0.6902 \qquad d^2_{11} = 0.4764$$

$$d_{12} = 0.7236 \qquad d^2_{12} = 0.5236$$

$$\varepsilon_1 = -12.946 \text{ eV}. \qquad \varepsilon_2 = -1.566 \text{ eV}.$$

$$\varphi_1 = 0.6902\chi_C + 0.7236\chi_S$$

$$\varphi_2 = 0.7236\chi_C - 0.6902\chi_S$$

Further the excitation energy $\Delta E$ corresponding to the $\varepsilon_1 \rightarrow \varepsilon_2$ transition can be calculated by the following equations:

$$\Delta E = \varepsilon_2 - \varepsilon_1 - (11 \mid 12) + 2(12 \mid 12) = 5.54 \text{ eV}.$$

$$(11 \mid 22) = d^2_{11}d^2_{12}\{(CC \mid CC) + (SS \mid SS)\} + (d^4_{11} + d^4_{12})(CC \mid SS)$$

$$(12 \mid 12) = d^2_{11}d^2_{12}\{(CC \mid CC) + (SS \mid SS) + 2(CC \mid SS)\}$$

The calculated value, 5.54 eV., may be said to be in fairly good agreement with the observed one, 5.24 eV.

29) R. G. Parr, *J. Chem. Phys.*, **20**, 1499 (1952).
30) W. Moffitt, *Proc. Roy. Soc.* (*London*), **A202**, 534 (1950).
31) In this calculation the following energy values are used:

$I^\sigma_S = 20.0$ eV. $\quad A^\sigma_S = 4.0$ eV.
$I^\sigma_C = 15.42$ eV. $\quad A^\sigma_C = 3.32$ eV.
$\beta^\sigma_{CS} = -2.0$ eV.

where $I$ and $A$ represent ionization potential and electron affinity, respectively, and the superscript $\sigma$ means that the corresponding quantity is concerned with $\sigma$-electrons. The quantities on carbon are taken from Pritchard and Skinner's table[28] and those on sulfur are roughly estimated from corresponding values for oxygen which are also obtained from the table.
32) Katagiri et al. calculated independently the wave functions and orbital energies of the C=S bond and obtained the following results:

$\phi_1 = 0.6330\chi_C + 0.7741\chi_S$
$\phi_2 = 0.7741\chi_C - 0.6330\chi_S$
$\varepsilon_1 = -11.98$ eV $\quad \varepsilon_2 = -1.90$ eV

## Summary

Ultraviolet absorption spectra of thioacetamide and thiourea are measured under various conditions. In aqueous solution, three bands (210, 261 and 318 m$\mu$) for thioacetamide and two bands (195 and 236 m$\mu$) for thiourea are observed. Further, polarized ultraviolet absorption spectra are measured with their crystals. On the basis of the results regarding the polarized ultraviolet absorption spectra, the directions of transition moments can be determined as follows: 1) the directions of transition moments of the 261 and 210 m$\mu$ bands of thioacetamide are approximately parallel to the axis connecting the nitrogen and sulfur atoms and connecting the nitrogen and methyl carbon atoms, respectively, 2) the directions of transition moments of the 236 and 195 m$\mu$ bands of thiourea are parallel and perpendicular to the C=S axis, respectively. From the combination of the experimental results concerning the directions of transition moments with theoretical consideration based on semi-empirical LCAO treatment including configuration interaction, the assignment of the four absorption bands under consideration are finally determined. One of the noticeable conclusions is that the 195 m$\mu$ band of thiourea can be regarded as a typical intramolecular charge-transfer absorption.

It is shown that in the hydrochloric acid solution of thioacetamide the 261 m$\mu$ band decreases its intensity and a new band appears at 237 m$\mu$. By measuring the dependence of intensities of these two bands upon the acid strength of the solution, it is concluded that the 237 m$\mu$ band is due to the conjugate acid of thioacetamide. The p$K_B$ value of thioacetamide is determined spectrophotometrically to be 1.2 at 24.5°C. From the comparison of the wavelength of the peak absorption of thioacetamide with that of its conjugate acid, it is seen that the proton is conceivably attached to the amino group.

The authors wish to express their sincere thanks to Dr. M. R. Truter for her kindness in giving valuable information on the X-ray crystal analysis data of thioacetamide prior to publication. Their thanks are also due to Dr. T. Sakurai in our Institute for his kind cooperation in identifying the crystal axis of thiourea.

## *The Crystal Structure of Tetra-thiourea-palladium(II) Chloride*, $[Pd(SCN_2H_4)_4]Cl_2$

By Shun'ichiro Ooi, Tsuyoshi Kawase, Kazumi Nakatsu and Hisao Kuroya

(Received April 11, 1960)

It is well known that thiourea is capable of forming a number of coordination compounds with metallic ions. Recently, we reexamined the preparation methods of some of them, the chemical analyses being carried out carefully, and obtained quite well-formed crystals of the palladium(II) complex salt, $Pd(SCN_2H_4)_4Cl_2$. We have therefore, attempted to investigate the crystal structure of this compound. There are only a few structural studies[1-4] of the thiourea coordination compounds.

The crystal was prepared by the method of Kurnakow[5]. The products are monoclinic, showing the predominant (100) face. The crystallographic data are: $a=16.89$, $b=11.18$ $c=8.89$ Å, $\beta=91.5$, $Z=4$, $\rho_{obs}=1.92$ and $\rho_{calc}=1.91$ g./cm$^3$. Space group $C2/c$ or $Cc$ was given by the observation of the systematically absent reflections. However, the method of Howells

et al.[6], applied to (*hk*0) reflections, was indicative of the presence of a center of symmetry, which was, in turn, favorite to $C2/c$. The structure analysis was carried out by using (*h0l*) and (*hk*0) data obtained from Weissenberg photographs which were taken with Cu$K\alpha$ radiation. From Patterson projections on (010) and (001), the positions of palladium, chlorine and sulfur atoms could be deduced. A usual Fourier method was, then, applied to further analysis. Atomic coordinates listed in Table I gave the reliability index $R=0.18$ and 0.16 for (*h0l*) and (*hk*0), respectively.

In Fig. 1, the structure projected on (010) is shown. The crystal is essentially ionic and consisted of $[Pd(SCN_2H_4)_4]^{2+}$ and $Cl^-$. A palladium atom is surrounded by four sulfur atoms in an approximately rectangular configuration with 3.00 and 3.15 Å for the lengths of shorter sides, and 3.50 Å for the longer ones. A complex ion has a two-fold rotation axis bisecting the two shorter sides and passing through the palladium atom. All S—C bonds projected on the plane formed with 4S's and Pd, are parallel to the shorter sides. Bond distances and angles found in a complex ion are: Pd—S=2.33 and 2.35 Å, ∠S—Pd—S=82°, 85° and 97°, ∠Pd—S—C=106 and 107°, S—C=1.72 and 1.75 Å, C—N=1.32, 1.37 and 1.47 Å, ∠S—C—N=120, 121, 123 and 126° and ∠N—C—N 117°. No significant discrepancies could be found in the dimensions between the thiourea molecule reported by Kunchur and Truter[7] on the thiourea crystal and the one in the present work. The bond angles formed at S's can be compared with those in $Cu(SCN_2H_4)_3Cl$[3] and in $Pb(SCN_2H_4)_2Cl_2$[4].

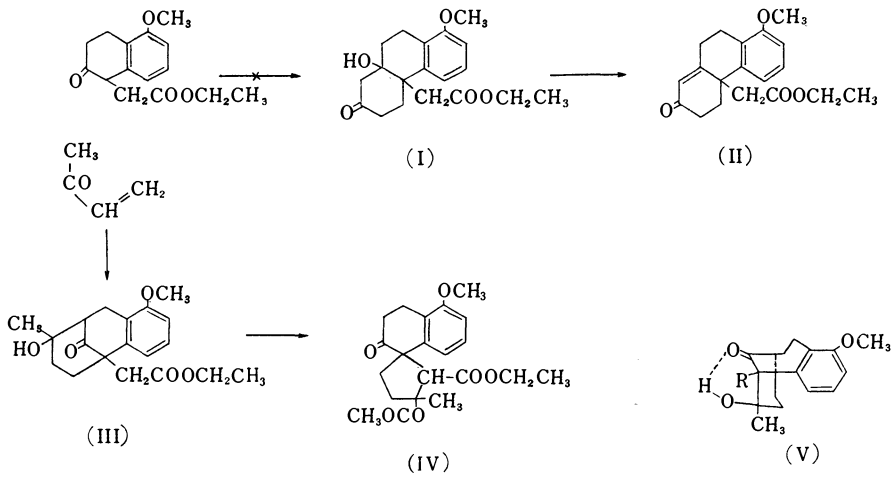
# *The Structure and a Novel Type Rearrangement of a Ketol Produced by the Robinson Annelation Reaction*



By Takeshi MATSUMOTO and Akira SUZUKI

(Received May 17, 1960)

In the course of a study directed to the synthesis of a certain diterpenoid skeleton[1], the authors condensed ethyl 1, 2, 3, 4-tetrahydro-2-oxo-5-methoxy-1-naphthyl acetate[2] with methyl vinyl ketone, expecting the formation of either ketol I or its dehydration product II. However, the obtained ketol [m. p. 134~135°C; $\nu_{max}^{Nujol}$ 3380 (OH), 1733 and 1185 (ester), and 1700 $cm^{-1}$ (ketone); $\lambda_{max}^{MeOH}$ 271 ($\varepsilon$ 1410) and 278 m$\mu$ ($\varepsilon$ 1310); Found: C, 68.44; H, 7.10. Calcd. for $C_{19}H_{24}O_5$: C, 68.65; H, 7.28%] was actually a bridged ring compound III. Moreover, attempted acetylation of III with isopropenyl acetate in the presence of *p*-toluenesulfonic acid resulted in a remarkable change in the carbon skeleton of compound III, a spirocyclic acetate IV [m. p. 97.5~98.5°C; $\nu_{max}^{Nujol}$ 1730 (ester) and 1715 $cm^{-1}$ (ketone); Found: C, 67.10; H, 6.94. Calcd. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00%] being produced. The formation of a similar bridged ring ketol system through the Robinson annelation reaction was first disclosed only quite recently by W. S. Johnson and his co-workers[3]. Conversion of the skeletons III to IV seems, so far as the authors are aware, to have never been described in the literature.

The structures of both compounds III and IV were determined by the NMR spectra[4]. The spectrum of ketol III showed one sharp maximum at high applied magnetic field characteristic of proton resonance for the $-\overset{|}{\underset{|}{C}}-CH_3$ group (203 c. p. s., standard, benzene; observed relative peak area, 3.4) and is completely accounted for in terms of structure III. Further, presence of an intramolecular hydrogen bond, as indicated by the infrared spectrum ($\nu_{max}$ 3430 $cm^{-1}$, in 0.0046 M solution in tetrachloroethylene) clearly defines the conformation of the ketol as V. In the NMR spectrum of acetate IV, presence of a $-\overset{|}{\underset{|}{C}}-CH_3$ group and

absence of the $-\overset{|}{\underset{|}{C}}-CH_2-CO_2-$ group are indicated respectively by the appearance of a sharp peak at 190 c. p. s. (relative peak area, 3.1) and by the disappearance of the singlet peak at 151 c. p. s. (relative peak area, 1.7) of III. The only one structure consistent with the observed findings is expressed by formula IV. The resonance line due to $-\overset{|}{\underset{|}{C}}-CH_3$ group of the acetate is shifted to the lower magnetic field by 13 c. p. s. as compared with that of the ketol. This shift might be an indication of the *cis* location of the methyl and ethoxycarbonyl groups.

## *The Existence of Acid Centers of a Lewis Type on Silica-Alumina Surface*

By Michio Okuda and Taro Tachibana

(Received May 10, 1960)

Recently, attention has been paid to the nature of acid centers on silica-alumina surface[1]. In order to study this problem spectroscopically, we have measured electronic spectra of some reagents adsorbed from their cyclohexane solutions on silica-alumina according to a procedure described by Robin[2].

A sample of silica-alumina was kindly supplied by Professor Shiba of Tokyo Institute of Technology and stated to contain approximately 13% alumina and no ferric ion. This sample was used as an adsorbent without further heat treatment (SA-1), or after heat treatment for 3 hr. at 110°C (SA-2), for 3 hr. at 430°C (SA-3) in dry air.

By using benzeneazodiphenylamine ($pK_a$: 1.52) as Walling's acid-base indicator, it was found that the adsorbent shows surface acidity. As is clearly seen from Fig. 1, benzeneazodiphenylamine adsorbed exhibits the two absorption bands at 440 m$\mu$ and 538 m$\mu$, which are evidently associated with the free base of the dye and its conjugated acid respectively. The latter specimen is produced by the reaction of the free base with a proton of protonic acid or aluminum atom as Lewis acid. The heat treatment of adsorbents increases the intensity of the acid band, indicating the increase of the amount of acid centers on the silica-alumina surface.

To obtain some information on whether or not these acid centers involve those of a Lewis type, *p*-phenylenediamine, which is a typical electron donor and is suitable for detecting electron accepting ability of the opponent entity, was adsorbed on silica-alumina adsorbents and its absorption spectrum was examined. The absorption spectrum of *p*-phenylenediamine adsorbed showed two characteristic bands at 324 m$\mu$ and 468 m$\mu$, as shown in Fig. 2. The former band was identified with that of *p*-phenylenediamine in alcohol ($\lambda_{max}$: 312 m$\mu$)[3] and the latter band with that of its semiquinone

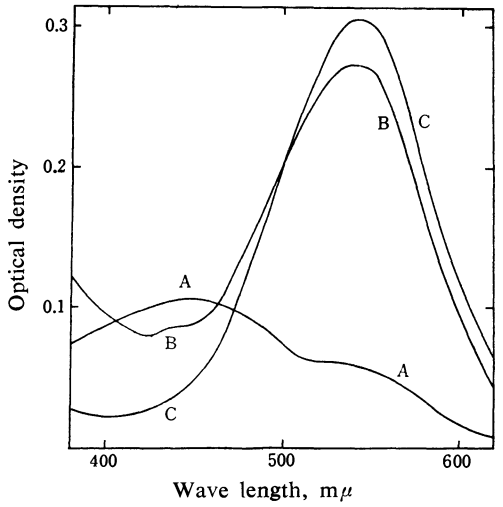

Fig. 1. Absorption spectra of benzeneazodiphenylamine adsorbed on silica-alumina (A, SA-1; B, SA-2; C, SA-3).

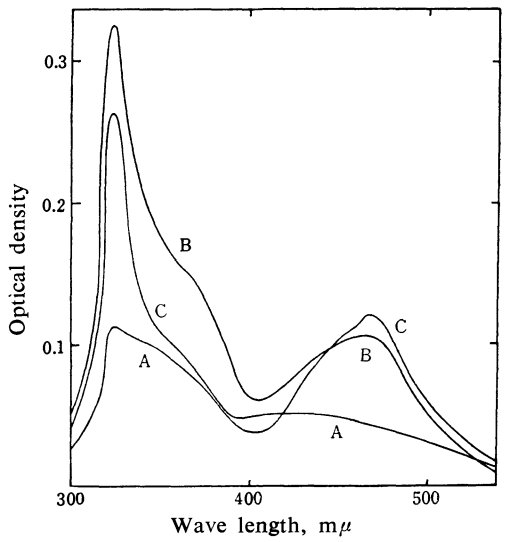

Fig. 2. Absorption spectra of *p*-phenylenediamine adsorbed on silica alumina (A, SA-1; B, SA-2; C, SA-3.)

cation radical $(NH_2C_6H_4NH_2)^+$ in water ($\lambda_{max}$: 462 mμ)[4]. Fig. 2 shows also that the intensity of absorption band of semiquinone increases with the increasing temperatures of heat treatment of adsorbent. The existence of semiquinone radicals on the adsorbent was also confirmed by the appearence of electron spin resonance spectrum. On the other hand, semiquinone radical could not be observed with the absorption spectrum of *p*-phenylenediamine adsorbed on a silica gel sample containing protonic acid.

The present results lead us to consider that the vacant $3p$ orbital of the aluminum atom on silica-alumina surface accepts one electron from the highest occupied $\pi$ orbital of the *p*-phenylenediamine molecule adsorbed and, therefore, aluminum atoms react with a base as Lewis acid centers, the structure of which has been proposed by Mills et al.[5]. It was also shown that the amount of Lewis acid centers increases with the temperature of heat treatment of the silica-alumina sample. The method of electronic spectra studied by us has given a more direct evidence for the existence of Lewis acid centers on silica-alumina sample than that obtained by other methods hitherto reported[1].

# *Ein Beitrag zur Entwicklung der Harztüpfelmethode mittels Zentrifugierens der fein zerriebenen Ionenaustauscherteilchen**,[1]

Von Masatoshi FUJIMOTO

(Eingegangen am 6. Mai, 1960)

Beim Zentrifugieren einer mit einem Farbreaktionssystem berührenden, wäßrigen Suspension der fein zerriebenen Ionenaustauscherteilchen lassen sich die an den Austauscher stark adsorbierten, stark sich färbenden Bestandteile der genannten Reaktion an die Spitze des Zentrifugenröhrchens schnell und dicht ausammeln. Durch raffinierte Anwendung dieser Erscheinung auf die Harztüpfelmethode[2] wurde es bei der vorliegenden Arbeit eine Reihe von schnellen und wesentlich empfindlichen Nachweismethoden neu festgestellt.

Die wesentlich größere Ausdehnung der Oberfläche an den fein geteilten Harzteilchen

c) M. Fujimoto und T. Iwamoto, unveröffentlichte Resultate.

** Dieser Nachteil wurde dadurch teilweise verbessert, daß man die fein zerriebenen Harzteilchen als Träger der stark sich färbenden Bestandteile an die Grenzfläche zweier flüssigen Phasen ansammeln läßt[1)].

Reagenslösung) mit einem Tropfen der Harzsuspension versetzt. Sodann wird ein Tropfen der Reagenslösung (od. der Probelösung) hinzugefügt, wobei die Harzteilchen eine Weile in der ganzen Lösung schweben und sogleich die in der Lösung vorhandenen, stark sich färbenden Ionen adsorbieren (Abb. 2a). Nach 1 bzw. 3 Min langem Stehen wird das Gemisch etwa 1 Min zentrifugiert. Es ist dabei empfehlenswert, daß man dies unter einer Anzahl der Drehung wesentlich größer als die bei der Reinigung der Harzsuspension abschleudern läßt, um die gefärbten Harzteilchen an die Spitze der Kapillare möglichst scharf, dicht und schnell ansammeln zu lassen. Das 1 Min lange Abschleudern unter höchstens 3000 Drgg. pro Min ist zur Abtrennung des Harzteilchens genügend. Die Farbe der auf solche Weise an die Spitze angesammelten Harzteilchen ist mit einer Lupe (20 mal) leicht zu erkennen.

Weil die kleineren Harzteilchen, die die sich färbenden Bestandteile schneller als die größeren Teilchen anreichern können, sich in der Kapillare langsamer als die größeren fallen, färbt sich die dabei an der Spitze gebildete Harzschicht von unten nach oben allmählich stärker (Abb. 2b'), und infolgedessen wird die Nachweisempfindlichkeit bedeutend erhöht.

Zwei sinnfällige Beispiele für die Erhöhung der Empfindlichkeit des Nachweises mittels oben vorgeschlagenen Verfahrens, sogenannter „Harz-zentrifugierenmethode", stehen in Tabelle I, in der das Erfassungsgrenze beim vorliegenden Verfahren mit dem bei der gewöhnlichen Tüpfelmethode sowie der Harztüpfelmethode verglichen wird.

Die obenerwähnte Methode ist nicht nur der gewöhnlichen Tüpfelmethode sondern auch der Harztüpfelmethode daran weit überlegen, daß man durch einfaches Zentrifugieren der gereinigten Harzsuspension eine wesentlich verbesserte Empfindlichkeit schnell und sicher gewinnen kann. Die große Austauschgeschwindigkeit beim kleinsten Harzteilchen ermöglicht den schnellen und empfindlichsten Nachweis gegen größere Menge der hoch verdünnten Probelösung. Überdies sei es möglich, durch Vergleichung der an der gleichen Menge der Harzteilchen entstehenden Farben mit den einer Reihe von Standards entschieden kleine Stoffmenge ziemlich genau zu bestimmen, worüber der Verfasser zur Zeit einige Versuche durchführt.

# *Magnetic and Spectrophotometric Studies on Decoloration of Thiocyanato Iron(III) Complexes in Solutions. I*

By Chie MIYAKE*

(Received August 20, 1959)

The reaction between iron(III) and thiocyanate ions has been studied in detail by many authors for more than 30 years. Despite the vast experimental data thus accumulated, no decisive conclusion seems to have been drawn as to the nature of the species which exist in the solutions. In 1953, reviewing all the reports ever published, S. Z. Lewin et al.[1] have shown the following series of equilibria as the basis upon which all of the experimental evidences can be correlated.

$$Fe^{3+} + SCN^- \rightleftharpoons FeSCN^{2+} \quad (1)$$

$$FeSCN^{2+} + SCN^- \rightleftharpoons Fe(SCN)_2^+ \quad (2)$$

$$Fe(SCN)_2^+ + SCN^- \rightleftharpoons Fe(SCN)_3 \text{ or } [1/2Fe_2(SCN)_6] \quad (3)$$

$$Fe(SCN)_3 + SCN^- \rightleftharpoons Fe(SCN)_4^- \quad (4)$$

and probably also:

$$Fe(SCN)_4^- + SCN^- \rightleftharpoons Fe(SCN)_5^{2-} \quad (5)$$

$$Fe(SCN)_5^{2-} + SCN^- \rightleftharpoons Fe(SCN)_6^{3-} \quad (6)$$

On the other hand, in the field of chemical analysis the color reaction between iron(III) and thiocyanate ions has long been used as a proof of the existence of iron(III) ions, as well as being used as the procedure of its quantitative determination. However, in the above-mentioned solutions there exists a gradual color change with time, which makes the quantitative measurements somewhat difficult. And indeed the explanation of this change itself is still in question. In 1952, Hiraki et al.[2] from the spectrophotometric measurements with a Dubosk spectrophotometer, reported that the fading of color is caused by the reduction of iron(III) to iron(II) by thiocyanate ions. If this reaction did exist, there should be a change of magnetic susceptibility of the solutions as the fading of color proceeds. Thus, the decoloration mechanism of the solutions is one of the most interesting subjects to be clarified in the field of magnetochemistry. In this paper were summarized the measurements of the magnetic susceptibility and the visible absorption spectra during the decoloration.

## Experimental

**Materials.**—Iron solution: A given amount of Mohr's salt was dissolved in distilled water containing several drops of conc. sulfuric acid. Adding a small amount of hydrogen peroxide (30%) in order to oxidize iron(II) to iron(III), the solution was heated on a water bath to expel the excess of hydrogen peroxide. After cooling, the solution was diluted to exactly 0.05 M with distilled water.

Potassium thiocyanate: The reagent of analytical grade was dissolved and diluted to 0.5 M with distilled water. The solution obtained was completely colorless and its test by $\alpha\cdot\alpha'$-dipyridyl was also negative. Therefore, neither iron(III) nor iron(II) ions can exist in our prepared solution.

Hydrochloric acid: The hydrochloric acid was purified by distillation until it gave a negative test for iron.

Sample solution: The solution to be measured was prepared by adding a given amount of hydrochloric acid and potassium thiocyanate to the iron stock solution and then was diluted to the desired concentrations.

**Measurements.**—The magnetic susceptibility of the solutions was measured from time to time during the decoloration by the torsion magnetometer with fused silica[3].

Absorption spectra were determined by a Beckman Model DU Spectrophotometer. Matched 10 mm. silica cells with quartz 9.5 mm. thick were used; this gave an effective optical path of 0.5 mm.

## Experimental Results

**Magnetic Data.**—The magnetic moments in Bohr magnetons for total iron in the solutions of thiocyanato iron(III) and thiocyanato iron(II) complexes are shown in Table I. The magnetic moment is calculated from the formula $\mu = 2.84\sqrt{\chi \times T}$ where $\chi$ is the susceptibility per gram atom of total iron in the solutions and $T$ the absolute temperature[4]. Here, any magnetic interaction is neglected, since all of the solutions are magnetically dilute. Fig. 1 shows

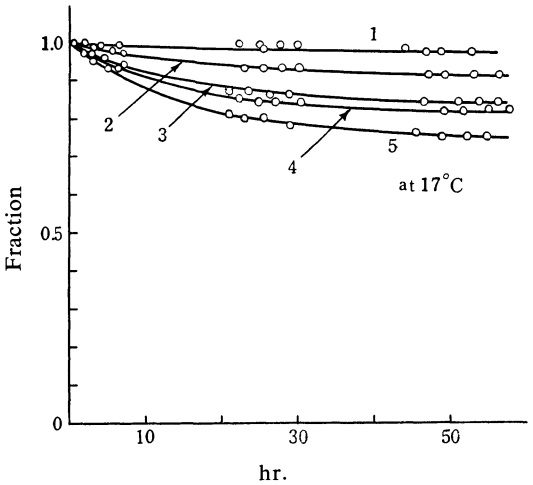
in Fig. 5.[5] In Table II, the results of spectrophotometric measurements are summarized. Here, it seems to be of importance for the following discussion to compare the time-change in magnetic moment (already shown in Figs. 1 and 2) and the similar change in absorbance at about 470 mμ (shown in Fig. 6).

## Discussion

Before going directly into the discussion, the following remarks seem to be necessary.

The magnetic measurement is quite useful and important for determining the electronic spatial configuration in the complex containing transition element. For example, if the complex be assumed to have the inner orbital type of binding, then the 3d-electrons of iron(III) ion are necessarily paired, leaving only one residual electron to be unpaired, giving 1.7 Bohr magnetons (theoretical) to the complex. But on the other hand, when the complex has a binding of the so-called outer orbital type, all of the 3d-electrons of iron(III)

5) M. Ishibashi, T. Shigematsu, Y. Yamamoto, M. Tabushi and T. Kitagawa, This Bulletin, 30, 433 (1957).



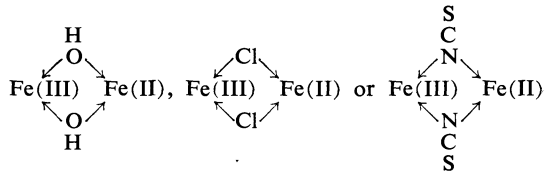


Fig. 6. Decrease of absorbances with time at about 470 mμ of ferric thiocyanate solutions.
1 : corresponds to 3 in Fig. 2
2 : 3 in Fig. 1
3 : 2 in Figs. 1 and 2
4 : 1 in Fig. 1
5 : 1 in Fig. 2

ion are left unpaired, thus giving 5.9 Bohr magnetons (theoretical). In case of iron(II), the complex with the inner orbital type has no magnetic moment and that with the outer orbital type has 4.8 Bohr magnetons (theoretical), respectively. The number of unpaired electrons $n$ of complex can generally be calculated from the magnetic measurements by the formula $\mu=\sqrt{n\times(n+2)}$.

The present magnetic observations which are shown in the preceding section and tabulated in Table I, show that thiocyanato iron(III) complex has five unpaired electrons and thiocyanato iron(II) complex four unpaired electrons, both belonging to the outer orbital type of binding. If the decoloration depends upon the simple reduction of iron(III) to iron(II) by thiocyanate ions, it is required that the magnetic moment decreases by 0.47 Bohr magneton and completely reduced solutions become colorless. This is evident from Fig. 3 in which it is shown that the iron(II) has no absorption in the region of visible light.

Although the magnetic data in Figs. 1 and 2 seem to support the idea that the above-mentioned simple reduction had actually been taking place, the spectrophotometric data are not favourable, because the absorbances at 470 mμ are still greater even after the decrease of the magnetic moment. In order to harmonize the above-mentioned discrepancy there must be another scheme by which all of the obtained data can be consistent. If we assume that the iron(II) ion already reduced in the solutions and the iron(III) ion still remaining were combined through the bridges of hydroxo ions, chloride ions or thiocyanate ions, and also that they were formed in the so-called "binuclear complex" or "dimer", whose unpaired electron is single, the reduction of the magnetic moment in solution and the amount of the remaining color may be plausible, despite the fact that a question still remains whether or not the free iron(III) ion and that combined into the dimer have the same absorbance character in the region of visible light.

The probable formula of the dimer is considered to be one of the following three types:

The study of the problem concerning the determination of the actual type existing in the present solutions must be continued. However, a series of reactions up to the above-mentioned formation of dimer, seems to be initiated in any way by the partial reduction of iron(III) to iron(II) as has already been stated. This argument is directly proved in Figs. 1, 2 and 6, which indicate that the solution with greater decrease in magnetic moment shows a greater decreases in absorbance. At the same time, we can say from the figures that both the decoloration and demagnetization with time proceed almost proportionally to the concentration of thiocyanate ions and inversely proportionally to the acidity of the solutions (hydrochloric acid). The acidity is generally considered to suppress the power of reduction of thiocyanate ions[6]. These tendencies are shown in Table II.

On the basis of the formation of the dimer which the present author has proposed, both the magnetic and spectrophotometric data are summarized in the following way. In the formation of the dimer which we supposed to have the inner orbital type of binding, five unpaired electrons of the original iron(III) ion and six electrons of iron(II) ion are paired with each other, leaving in the dimer only one unpaired electron. The number of the unpaired electrons thus reduced, hence the reduction of magnetic moment, is quite large. Therefore, we can say that the number of the originally unpaired electrons of 2×Fe(III),

6) G. Charlot, "L'analyse qualitative et les réactions en solution", Masson et Cie (1957), p. 334.

ten, are reduced and finally only one unpaired electron is left in the dimer.

Supposing that $\alpha$-fractions of iron(III) in the original solutions are reduced to iron(II) and converted into the 1 : 1 dimer with iron(III), the final number of the unpaired electrons in the dimer is given by

$$5\times(1-2\alpha)+\alpha=5-9\alpha \qquad (1)$$

and the corresponding theoretical magnetic moment by

$$\{5.92^2\times(1-2\alpha)+1.73^2\times\alpha\}^{1/2} \qquad (2)$$

In the above relation only the spin contribution to the magnetic moment is taken into consideration and at the same time for simplicity's sake, the true equilibrium conditions in the formation of the dimer is ignored.

On the other hand, the spectrophotometric fractional absorbances of the solutions can be expressed by

$$\varepsilon\times(1-\alpha) \qquad (3)$$

where $\varepsilon$ is the molar extinction coefficient. Here, the difference of the extinction coefficient between free iron(III) and iron(III) in the dimer are again neglected. The present results of measurements so far obtained seem to show a good agreement with the above relations (2) and (3).

Werbel et al.[7], in their results for the same substance using 0.06 M thiocyanato iron(III) complex in 1.9 M perchloric acid solution, have reported that the magnetic moment of 5.88 Bohr magnetons was obtained about one hour after its preparation and that about one percent of the total amount of iron(III) originally present was converted into iron(II). They have also pointed out that the magnetic moment of thiocyanato complex is too small to account for the reaction due to simple reduction from iron(III) to iron(II), because of the too small difference in magnetic moment between them. The result obtained by Werbel et al. seems, however, to be quite reasonably explained on the present consideration of the existence of dimer.

## Summary

The decoloration mechanism of thiocyanato iron(III) complex solutions was investigated by means of both the magnetic and spectrophotometric methods. The data for the magnetic measurements supported that the decoloration was caused by the simple reduction of iron(III) to iron(II) by thiocyanate ions. But such a simple model of the reduction was not favourable for the observed decoloration, because the decrease in the absorbance was too small, being only about twenty percent. In order to eliminate this discrepancy, another scheme was proposed, which ascribes the magnetic and spectral observations to the formation of a binuclear complex of iron(III) and iron(II), a so-called dimer, during the decoloring reaction. This dimer possesses only one unpaired electron and accordingly very small magnetic moment, but possesses the significant absorbance due to iron(III). On this model, the greater decrease in magnetic moment and the rather smaller decrease in absorbance which we obtained, were quite satisfactorily clarified.

The author wishes to express her sincere thanks first to Professor H. Takaki for his continuous encouragement and interest throughout the present work. She wishes to convey her sincere thanks to Dr. Y. Yamamoto whose advice and discussions were very fruitful in this experiment. The author's thanks are also tendered to professor M. Ishibashi, whose kind permission to use the Beckman spectrophotometer gave added value to her study.

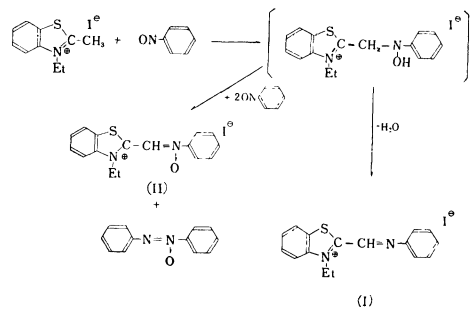
# *Synthesis of Dyes with the Neocyanine Structure Presented by Brooker, and Related Dyes. III. Condensation of 3-Ethyl-2-methylbenzothiazolium Iodide and Nitrosobenzene, and the Dyes Obtained from its Condensates*

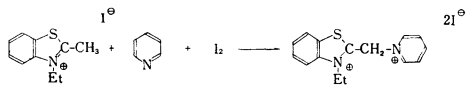
By Shiro KIMURA



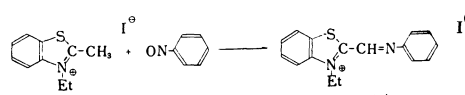
(Received November 17, 1959)

The synthetic process for the "Brooker-type dyes" described in the preceding paper[1] could possibly be improved with regard to the yield and by-product formation. The present series of experiments was carried out in order to obtain some fundamental concept of this reaction. An attempt was first made to prepare the 2-aldehyde anil derivative I of 3-ethyl-2-methyl-benzothiazolium iodide by the condensation of 3-ethyl-2-methylbenzothiazolium iodide and nitrosobenzene. In accordance with the report Katayanagi[2], the condensation of 3-ethyl--2-methylbenzothiazolium iodide and nitrosobenzene was carried out in ethanol with piperidine as a condensation agent. The product of this reaction was obtained as dark purple-needle crystals, m. p. 213–214°C (decomp.) $\lambda_{max}$ 390 m$\mu$ which became bluish purple prisms, m. p. 215°C (decomp.), when recrystallized from acetic anhydride. But this was not the expected anil I and was found to be a nitrone II.

(I)



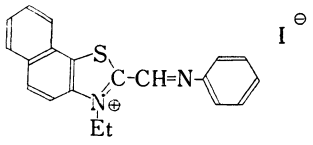
The basic condensation reactions of active methyl and nitroso compounds in general has been known from olden times as the Ehrlish-Sachs reaction[3]. It has been clarified in recent years that this reaction is accompanied by an oxidative reaction to form a nitrone as a by-product, besides the anil. It is also known that these two products are difficult to separate. The nitrone obtained in the present series of experiments was not completely pure and rather difficult to separate. When the impure nitrone was boiled with nitrosobenzene in ethanol, a dark purple substance was obtained which crystallized in reddish brown needles, m. p. 219°C (decomp.). Its analytical values were closer to those of the phenylnitrone. Then a mixture of 1 mol. of 3-ethyl-2-methyl-benzothiazolium iodide and 3 mol. of nitroso-benzene in ethanol was reacted with the addition of piperidine and reddish brown needles, m. p. 219°C (decomp.) were obtained. This was found to be pure nitrone II from its analytical values. The mechanisms of this reaction were shown by the following scheme:



(II)

(I)

Synthesis of the phenylnitrone was also attempted with reference to the general method of synthesis by Kröhnke and others[4] for the phenylnitrone of 1-methyl-2-formylpyridinium iodide, and preparation of *N*-(3-ethyl-1-thia-3-azoniainden-2-ylmethyl) pyridinium diiodide was undertaken, but the product seemed to be labile and the objective was not attained.



A purely synthetic preparation of the anil from heterocyclic ammonium salts has recently been reported by Mcgookin[5]. This process was applied to 3-ethyl-2-methylbenzothiazolium iodide and pure anil I of 3-ethyl-2-formyl-benzothiazolium iodide was obtained. In this case, equimolecular amounts of 3-ethyl-2-methylbenzothiazolium iodide and nitroso-benzene were reacted in absolute ethanol, with anhydrous potassium carbonate as the condensation agent, and red needles, m. p. 199°C (decomp.) were obtained.

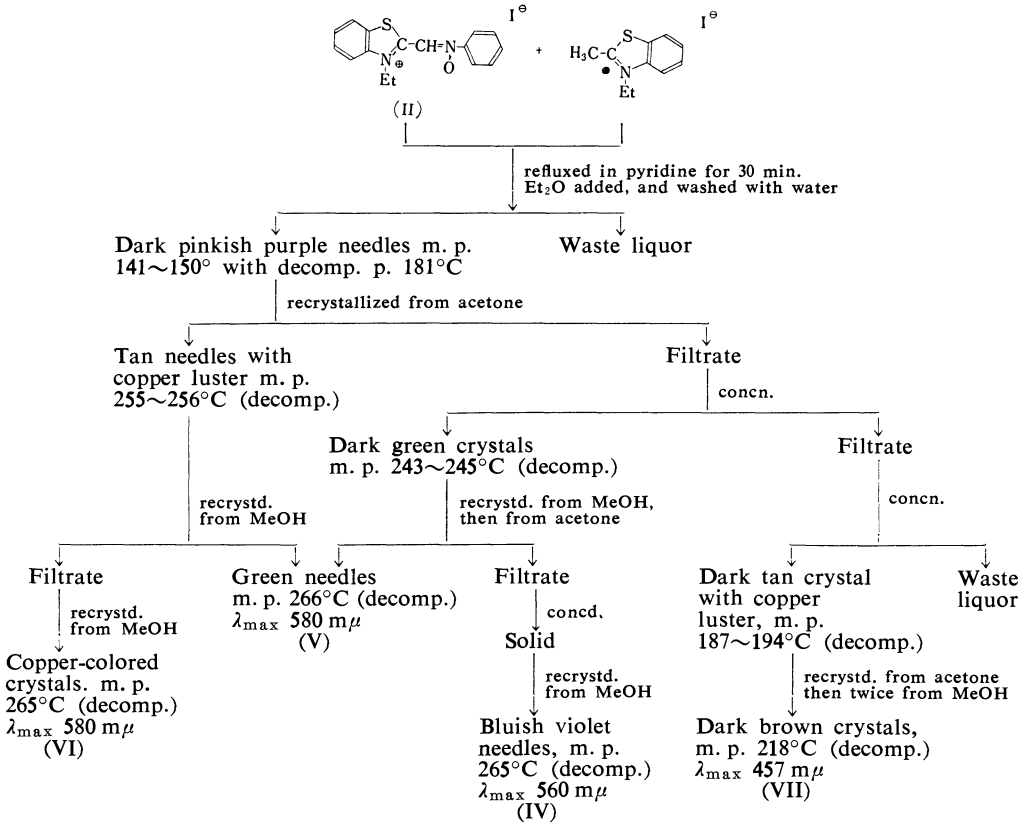
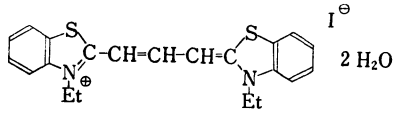
2) M. Katayanagi, *J. Pharm. Soc. Japan*, **69**, 38 (1949).
3) P. Ehrlich and F. Sachs, *Ber.*, **32**, 2341 (1899).
4) F. Kröhnke and H. Leister, ibid., 71, 2583 (1938).
5) A. Mcgookin, *J. Appl. Chem.*, **5**, 65 (1955).

Similarly, condensation, of 3-ethyl-2-methylnaphtho[2, 1-*d*]-thiazolium iodide and nitrosobenzene afforded the anil III of 3-ethyl-2-formylnaphtho[2, 1-*d*]thiazolium iodide.



(III)

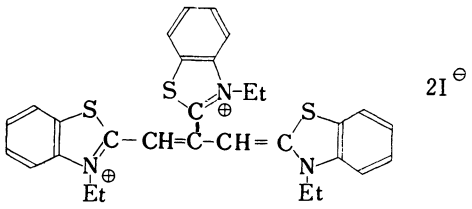
We then attempted the synthesis of 3, 3′-diethyl-2, 2′-vinylidendibenzothiazolium diiodide as a clue to the synthesis of "Brooker-type dyes", by the condensation of 3-ethyl-2-methylbenzothiazolium iodide with these nitrone derivative obtained above. Unexpectedly, however, this reaction was found to be much more complicated than was anticipated.



By refluxing an equimolar mixture of this phenylnitrone of 3-ethyl-2-formylbenzothiazolium iodide and 3-ethyl-2-methylbenzothiazolium iodide in pyridine for 30 min., a mixture of four kinds of dyes was obtained: the dyes were purified by fractional crystallization from acetone according to the scheme shown:

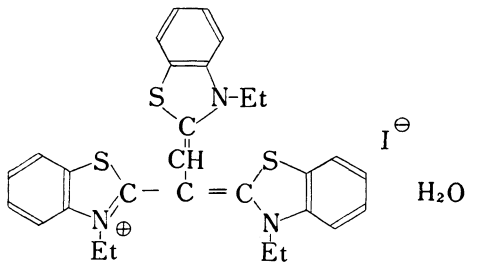
These dyes were also examined by paper chromatography and exactly the same four kinds of dyes were found to have been formed.

The structures of these four kinds of dyes



(IV)

were examined from their analytical values and absorption spectra and IV was identified with the known 3,3′-diethylthiacarbocyanine iodide dihydrate by comparison with the dyes prepared by a known route.



The analytical values of V were very close to those of the known trinuclear carbocyanine, 3, 3′-diethyl-9-(3-ethyl-2-benzothiazolinylidenemethyl)thiacarbocyanine iodide, but the absorption spectra and physical characteristics were entirely different and no presumption could be made of its structure. The analytical

values of VI suggested it to be a diiodide, and accordingly a trinuclear carbocyanine, 3, 3'-dietyl-9-(3-ethyl-1-thia-3-azoniainden-2-yl)-thiacarbocyanine diiodide, was presumed. The dye with this structure had earlier been synthesized by Tanabe[6] who recorded the melting point of 85°C and $\lambda_{max}$ 545 m$\mu$, but these data are entirely different from those of VI and definite conclusion can be drawn. Its 8-substituted isomer was synthesized by Anish[7] and shwos entirely different physical properties.

(VI)

VII was assumed to be a monomethine from its absorption spectrum and analytical values suggested the structure of a trinuclear monomethinecyanine, 3, 3'-diethyl-8-(3-ethyl-2-benzothiazolinylidenemethyl)thiacyanine iodide monohydrate.

(VII)

Chemical evidences for the structure of these four dyes will be discussed in the following paper.

## Experimental

**Preparation of the Phenylnitrone II of 3-Ethyl-2-formylbenzothiazolium Iodide.**—A solution of 50 g. of 3-ethyl-2-methylbenzothiazolium iodide and 18 g. of nitrosobenzene dissolved in 500 ml. of ethanol with warming on a water bath, added with 7 drops of piperidine, was stirred thoroughly and allowed to stand for about 2 hr. The dark purple crystals that separated out were collected by filtration, washed with water and methanol, and 21 g. (yield, 33%) of a dye, m. p. 156~164°C (decomp. at 174°C), was obtained. Recrystallization of this dye from 200 ml. of methanol afforded 7 g. (yield, 11%) of dark purple needles, m. p. 213~214°C (decomp.). Approximately the same result was obtained on repeating this experiment several times.

These dyes were boiled with about 40 volumes of acetic anhydride for 30 min. and the dark bluish purple prismatic crystals thereby formed were collected by filtration. After washing with ether the dye melted at 215°C with decomposition and its analytical value supported the nitrone structure.

Found: C, 46.56; H, 4.07; N, 6.62; I, 29.93. Calcd. for $C_{16}H_{15}ON_2IS$: C, 46.82; H, 3.66; N, 6.83; I, 30.98%.

**Condensation of the Phenylnitrone II of 3-Ethyl-2-formylbenzothiazolium Iodide and 3-Ethyl-2-methylbenzothiazolium Iodide.**—A solution of 6 g. of the phenylnitrone II of 3-ethyl-2-formylbenzothiazolium iodide and 4.8 g. of 3-ethyl-2-methylbenzothiazolium iodide in about 100 ml. of pyridine was refluxed for 30 min. and the major part of pyridine was distilled off under reduced pressure. About 100 ml. of ether was added to the residue, the dark purple crystals that precipitated out were washed with several 300 ml. portions of ether. The residue was mixed with 50 ml. of water, filtered, and the precipitate on the filter was washed with water. The dark pinkish violet crystals, m. p. 141~150°C (decomp. at 181°C) so obtained were dissolved in ca. 1 l. of acetone, concentrated to 400 ml., and 0.5 g. of dark tan crystals with copper luster, m. p. 255~256°C (decomp.) was obtained. Concentration of its mother liquor afforded 0.3 g. of dark green crystals, m. p. 243~245°C (decomp.). Further concentration of its mother liquor to about 50 ml. separated an oily substance which crystallized upon addition of ca. 50 ml. of ether. The crystals were collected by filtration and washed with ca. 30 ml. of ether, affording 0.4 g. of dark tan crystals with copper luster, m. p. 187~197°C (decomp.). These three kinds of crude dyes were purified through fractional crystallization and four kinds of pure dyes were isolated.

**Purification of the Dark Tan Crystals, M. P. 255~256°C (Decomp.).**—A solution of 0.5 g. of the crude dye dissolved in 50 ml. of methanol was concentrated to about 30 ml. and 0.35 g. of green needles, m. p. 260~262°C, separated. This substance was recrystallized twice from methanol to 0.18 g. of green needles V m. p. 266°C (decomp.) $\lambda_{max}$ 580 m$\mu$.

Found: C, 53.31; H, 4.06; N, 6.95; I, 20.53. Calcd. for $C_{28}H_{24}N_3IS_3$: C, 53.75; H, 3.84; N, 6.72; I, 20.25%.

The initial filtrate left after separation of the green crystals was concentrated and the copper-colored crystals m. p. 258°C (decomp.), so formed were recrystallized from methanol to clustered crystals VI m. p. 265°C (decomp.) $\lambda_{max}$ 580 m$\mu$.

Found: C, 45.80; H, 4.29; N, 5.22. Calcd. for $C_{30}H_{29}N_3I_2S_3$: C, 46.10; H, 3.70; N, 5.38%.

**Purification of Dark Green Crystals, M. P. 243~245°C (Decomp.).**—A solution of 0.3 g. of the crude dye dissolved in 60 ml. of methanol was concentrated to about 30 ml. and a mixture of green and bulish purple needle crystal was obtained. The green crystals were comparatively sparingly soluble in acetone and, therefore, the bluish purple crystals

6) Y. Tanabe, *J. Pharm. Soc. Japan*, 74, 814 (1954).
7) A. W. Anish, U. S. Pat. 2,427,177 (1944).

dissolved out with 100 ml. of acetone, leaving 0.1 g. of green needles, m. p. 262°C (decomp.). The acetone solution was concentrated to 80 ml. and 0.05 g. of the same green crystals, m. p. 265°C (decomp.) separated. These green crystals were found to be identical with the dye V described above. The acetone mother liquor was concentrated to 20 ml. and 0.04 g. of bluish purple needles, m. p. 260°C (decomp.), was obtained. This was recrystallized from a small amount of methanol to 0.01 g. of bluish purple needles IV m. p. 265°C (decomp.) $\lambda_{max}$ 560 m$\mu$.

Found: C, 48.03; H, 4.55; N, 5.52; I, 25.61. Calcd. for $C_{21}H_{21}N_2IS_2 \cdot 2H_2O$: C, 47.70; H, 4.73; N, 5.31; I, 24.03%.

**Purification of the Dark Tan Crystals with Copper Luster, M. P. 187~194°C (Decomp.).** —A solution of 0.4 g. of the crude dye dissolved in 300 ml. of acetone was concentrated to 50 ml. and 0.3 g. of dark brown needles, m. p. 210~211°C (decomp.) was obtained. This was mixed with a small amount of bluish purple crystals which were removed and the rest was recrystallized twice from methanol to 0.12 g. of dark brown needles, VII, m. p. 218°C (decomp.) $\lambda_{max}$ 457 m$\mu$.

Found: C, 52.25; H, 4.55; N, 6.c9; I, 19.65. Calcd. for $C_{29}H_{28}N_3IS_3 \cdot H_2O$: C, 52.80; H. 4.55; N, 6.37; I, 19.28%.

**Separation of Dye Mixture by Chromatography.** —Instead of the fractional crystallization as described above, the precipitate obtained from the pyridine reaction mixture was purified through chromatography. A solution of 2 g. of this mixture was dissolved in ca. 200 ml. of acetone concentrated to about 100 ml. and allowed to stand overnight. About 400 ml. of acetone was added to this mixture to dissolve the crystals but sparingly soluble crystals V remained undissolved. The green crystals were removed by filtration, the filtrate was concentrated about 200 ml., and the solution was passed through a column of alumina (Merck), requiring about 1.5 hr., the adsorbed layers separated into pale orange, violet, and pink bands. Each of these bands was eluted with acetone, the acetone elute was concentrated, and separated crystals were recrystallized from methanol. Dark brown needles VII m. p. 216°C(decomp.) $\lambda_{max}$ 457 m$\mu$. were obtained from the pale orange band, green needles V m. p. 260°C (decomp.), $\lambda_{max}$ 580 m$\mu$, from the violet band, and bluish purple needles IV m. p. 267~268°C (decomp.), $\lambda_{max}$ 560 m$\mu$, from the pale pink band. The dye VI obtained by fractional crystallization, was not isolated from this chromatographic separation.

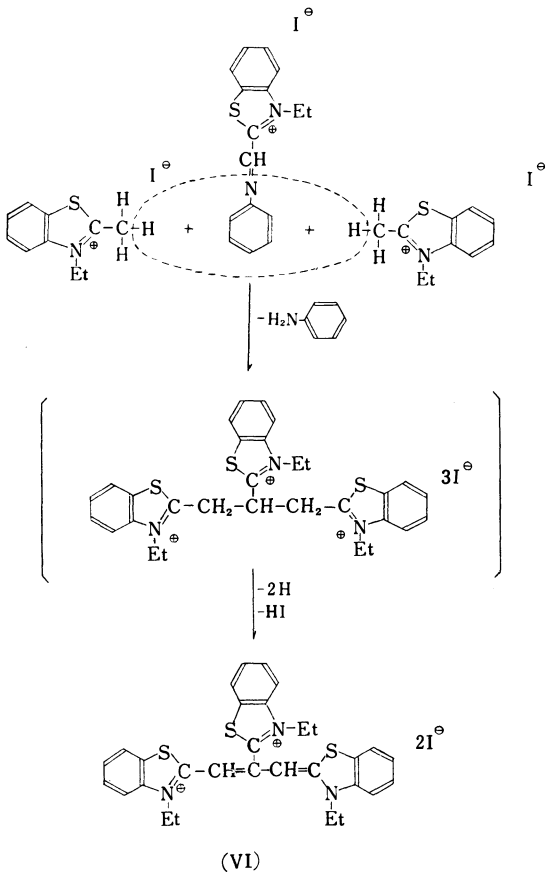
# *Synthesis of Dyes with the Neocyanine Structure Presented by Brooker, and Related Dyes. IV. Structure of the Dyes Obtained by the Condensation of 3-Ethyl-2-methylbenzothiazolium Iodide with Nitrone or Anil Derivatives*

By Shiro KIMURA



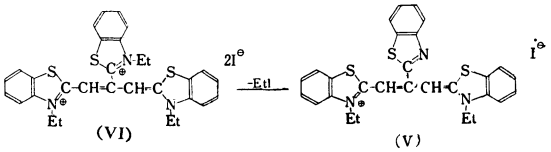
(Received November 17, 1959)

It has been shown in the preceding paper[1] that the condensation of phenylnitrone of 3-ethyl-2-formylbenzothiazolium iodide and 3-ethyl-2-methylbenzothiazolium iodide in pyridine gave four kinds of dyes and their structures were deduced from analytical values and absorption spectra.

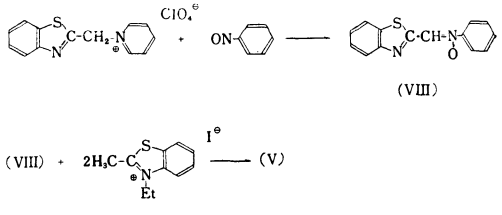
In order to examine the formation process of these dyes, the anil I and 3-ethyl-2-methylbenzothiazolium iodide were reacted by refluxing for a short time (8~15 min.) in pyridine and, in this case, 3, 3-diethyl-9-(3-ethyl-1-thia-3-azoniainden-2-yl)thiacarbocyanine diiodide (VI) alone was obtained. This result shows that

1) S. Kimura, This Bulletin, 33, 872 (1960).

this dye VI is initially formed in the early stage of this reaction and its formation mechanism is considered to be as follows:



(VI)

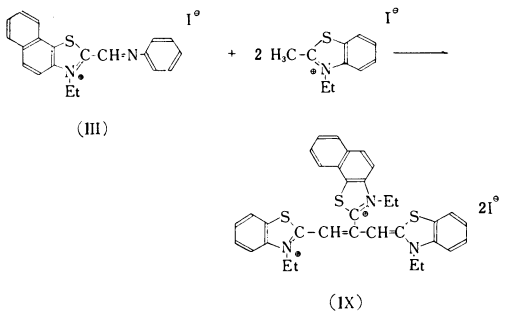


Dehydrogenation of cyanines in pyridine had been observed already by Mills[2] and the present reaction was considered to be of similar mechanism. The dye VI obtained earlier was isolated as an anhydrous salt, but the same dye obtained in the present series of experiments possessed 2 mol. of water of crystallization. The same dye VI was also obtained on replacing the anil I with the nitrone II but the yield of the dye was better when the anil was used.

Tanabe synthesized dyes of this structure and reported the formation of 3-ethyl-2-trichloromethylbenzothiazolium chloride as an intermediate during the reaction of 3-ethyl-2-methylbenzothiazolium iodide and thionyl chloride. On following this reaction, a substance of m. p. 124°C (decomp.), identical with that reported in the literature, was obtained in a good yield. The elemental analytical values, however, did not correspond to those of the objective intermediate and further, iodine was detected besides the chlorine atom. Therefore, this product was not considered to be 3-ethyl-2-trichloromethylbenzothiazolium chloride as reported in the literature. Further, an attempt was made to prepare a dye with this intermediate but a single dye of m. p. 85°C as given in the literature was not obtained and in its stead, a crude dye of m. p. 185°C (decomp.) was obtained. This dye was submitted to paper chromatography and dye spots of yellow, magenta, and purple were separated on the chromatogram, showing the dye to be a mixture. Although further examination of this crude dye mixture was not made, it is certain that the dye VI obtained in the present series of experiments is not the same as the dye obtained by Tanabe.

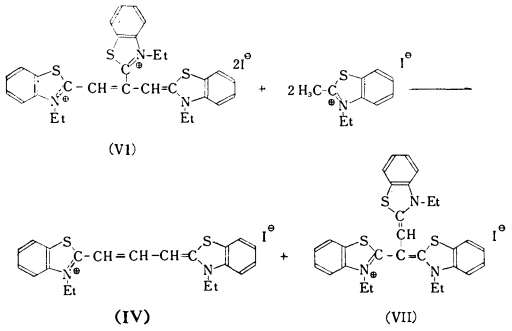
This dye VI was heated at 130°C for about 12 hr. in the Abderhalden apparatus for the purpose of determining the water of crystallization and the loss in weight was more than that calculated. Therefore, the dried sample was examined by paper chromatography and it was found that the dye VI had changed into the structurally unknown dye V described in the preceding paper. Consideration of this phenomenon showed the necessity of assuming the liberation of ethyl iodide and analytical results supported this assumption. Therefore, the structure of this dye V must be 3,3'-diethyl-9-(2-benzothiazolyl)thiacarbocyanine iodide.

In order to clarify the structure of this dye V an attempt was made to synthesize it by a different route. With reference to the report of Ried and others[3], iodine was applied to 2-methylbenzothiazole in pyridine, and the *N*-(benzothiazol-2-ylmethyl)pyridinium perchlorate obtained therefrom was reacted with nitrosobenzene to form the phenylnitrone VIII of 2-formylbenzothiazole. Condensation of VIII with 2 mol. of 3-ethyl-2-methylbenzothiazolium iodide in pyridine afforded the same dye as V. This fact proves the correctness of the structure of 3,3'-diethyl-9-(2-benzothiazolyl)thiacarbocyanine iodide for V.



2) W. H. Mills, *J. Chem. Soc.*, **121**, 455 (1922).

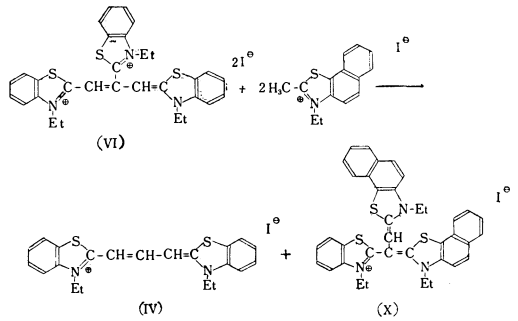
3) W. Ried and H. Bender, *Ber.*, **89**, 1893 (1956).



With the identification of the structure of the dye V, the structure of the dye VI also became certain and conversion of this dye VI into V was experimentally proved by refluxing in pyridine for about 2 hr.

Condensation of the anil III of 3-ethyl-2-formylnaphtho-[2, 1-*d*] thiazolium iodide with 2 mols. of 3-ethyl-2-methylbenzothiazolium iodide in pyridine afforded, as anticipated, 3,3'-diethyl-9-(3-ethyl-1-thia-3-azoniacyclopenta-[*a*] naphth-2-yl) thiacarbocyanine diiodide (IX). It was thereby found that this process can be recommended as a general method for the synthesis of dyes of this type.

(III) (IX)



The foregoing experiments have revealed the course of formation of the dyes V and VI in the reaction described in the preceding paper and, consequently, formation of the dyes thought to be 3, 3'-diethylthiacarbocyanine iodide (IV), and 3, 3'-diethyl-8-(3-ethyl-2-benzothiazolinylidenemethyl) thiacyanine iodide (VII) was found to occur through the reaction of 3-ethyl-2-methylbenzothiazolium iodide with 3, 3'-diethyl-9-(3-ethyl-1-thia-3-azoniainden-2-yl)-thiacarbocyanine diiodide (VI) in pyridine.

(VI) (IV) (VII)

The structure of the dye VII was merely presumed from its analytical values and absorption spectrum, and unequivocal establishement of this structure has not succeeded as yet, but it is certain that the dye VI is cleaved at the 9-position to liberate the substituent group to form the dye IV. In order to ascertain this cleavage reaction, the dye VI was refluxed with 3-ethyl-2-methylnaphtho [2, 1-*d*] thiazolium iodide in pyridine and the same dye (IV) was found to be formed. Whether the dye X formed at the same time is the anticipated 3, 3'-diethyl-8-(3-ethyl-2-naphtho [2, 1-*d*] thiazolinyl-idenemethyl)-6', 7'-benzothiacyanine iodide or not is still uncertain since, although the analytical values of the dye X are comparatively close to the theoretical values, its absorption maximum is in a longer wavelength region (650 m$\mu$), and this is unthinkable in the case of monomethine dyes.

Therefore, structural determination of these dyes VII and X must await further studies.

(VI) (IV) (X)

## Experimental

**Reexamination of Synthetic Method Tanabe's for the So-called 3, 3'-Diethyl-9-(3-ethyl-1-thia-3-azoniainden-2-yl) thiacarbocyanine Diiodide.**—The experiments followed Tanabe's report[4]. To 6.1 g. (0.02 mol.) of 3-ethyl-2-methylbenzothiazolium iodide, 24 ml. of thionyl chloride was added dropwise with cooling, by which the iodide turned black and dissolved gradually. Ether was added to this reaction mixture and the yellow precipitate thereby formed was collected to 7 g. of a solid, m. p. 100°C. This was dissolved in thionyl chloride, reprecipitated with ether, and 5 g. (yield, 79%) of yellow powder, m. p. 124°C (decomp.), was obtained. This substance agrees with the so-called 3-ethyl-2-trichloromethylbenzothiazolium chloride, m. p. 125°C (decomp.), reported by Tanabe, but he had assumed this structure from the analytical value of the chlorine alone, and elemental analyses in the present series of experiments gave results which were inconsistent with this structure.

Found: C, 30.81; H, 3.43; N, 3.70. Calcd. for $C_{10}H_9N\,Cl_4S$: C, 37.85; H, 2.84; N, 4.42%.

A solution of 1 g. (0.0032 mol.) of this intermediate product and 2 g. (0.0057 mol.) of 3-ethyl-2-methylbenzothiazolium iodide dissolved in 2.5 ml. of acetic anhydride, added with 1 g. of anhydrous potassium acetate, was heated in an oil bath at 120~130°C for 10 min., cooled, and ether was added to this reaction mixture. The crude dye that precipitated out was collected by filtration washed with water, and the powdery dye so obtained was recrystallized from acetone to 0.5 g. of pale purplish brown powder, m. p. 185°C (decomp.). This dye

4) Y. Tanabe, *J. Pharm. Soc. Japan*, 74, 814 (1954).

is different from that of m. p. 85°C reported in the literature and was found to be a mixture of three kinds of dyes, giving spots colored violet, pink, and yellow by paper chromatography. $R_f$ values were 0.54 (violet), 0.72 (pink), and 0.81 (yellow) (butanol : water=6 : 1). This dye was also different from the dye VI obtained in the present series of experiments.

Results of this reexamination indicated that there is some doubt about the structure of this intermediate and the dye produced in the present series of experiments was never identical with that reported in the literature. Therefore, this examination was not followed further.

**Formation of 3, 3'-Diethyl-9-(2-benzothiazolyl)-thiacarbocyanine Iodide (V) by Liberation of Ethyl Iodide from 3, 3'-Diethyl-9-(3-ethyl-1-thia-3-azonia-inden-2-yl) thiacarbocyanine Diiodide (VI).** — The dye VI was heated in the abdelhalden apparatus at 120~130°C in 20 mmHg for 12 hr. and the loss in weight amounted to 12.22%. The values calculated for 2 mol. of water of crystallization is 4.41%. This dried dye was developed by paper chromatography by which it separated into two kinds of dyes : one a violet zone of $R_f$ 0.44 and the other of reddish violet zone of $R_f$ 0.89 (butanol : water= 6 : 1). The violet zone was that of the starting dye VI and the reddish violet zone agrees with $R_f$ 0.89 of the dye V.

On boiling this dye VI in pyridine for 2 hr., the dye VI completely changed into V and the unity of this dye was proved by the reddish violet single zone of $R_f$ 0.90 in the paper chromatogram.

The fact that the chromatographic purification of the mixture of four kinds of dyes through alumina column only afforded three kinds of dyes, IV, V and VII, as described in the preceding paper, indicates that VI had transited into V.

**Preparation of the Phenylnitrone VIII of 2-Formylbenzothiazole.** — To a solution of 6.52 g. (0.02 mol.) of *N*-(benzothiazolyl-2-methyl)-pyridinium perchlorate and 2.14 g. (0.02 mol.) of nitrosobenzene dissolved in 40 ml. of pyridine, 20 ml. of 2 N sodium hydroxide solution was added and the mixture was stirred, by which process exothermic reaction took place. The mixture was allowed to cool and crystals separated out after 2 hr. The crystals were collected by filtration, washed with ethanol, and 3 g. of yellowish brown needles, m. p. 160~167°C, was obtained. Recrystallization from ethanol afforded 1.1g. (yield, 21.6%) of pale yellowish brown needles, m. p. 163~164°C.

Found : C, 66.28 ; H, 4.17 ; 10.82. Calcd. for $C_{14}H_{10}ON_2S$ : C, 66.15 ; H, 3.98 ; N, 11.02%.

**Preparation of 3, 3'-Diethyl-9-(2-benzothiazolyl)-thiacarbocyanine Iodide (V).**—A solution of 0.254 g. (0.001 mol.) of the phenylnitrone VIII of 2-formylbenzothiazole and 0.61 g. (0.002 mol.) of 3-ethyl-2-methylbenzothiazolium iodide in 3 ml. of pyridine was refluxed in an oil bath of 120°C for 10 min. The color of the reaction mixture changed from the initial yellow through green to purple. Ether was added to the reaction mixture to precipitate the dye formed which was collected by decantation and washed with wather to 0.4 g. of crystalline powder, m. p. 192~195°C (decomp.). Recrystallization from ethanol afforded 0.1 g. (yield, 16%) of green needles, m. p. 266°C (decomp.): $\lambda_{max}$ 580m$\mu$. Paper chromatogram : $R_f$ 0.89 (butanol : water=6 : 1) : single spot of violet, indicating the substance to be identical with dye V among the four kinds of dyes isolated from a mixture.

**Synthesis of 3, 3'-Diethyl-9-(3-ethyl-1-thia-3-azoniacyclopenta[*a*]naphth-2-yl)thiacarbocyanine Diiodide (IX).**—A mixture of 2.2 g. of the anil III of 3-ethyl-2-formylnaphtho[2, 1-*d*]thiazolium iodide and 3.0 g. of 3-ethyl-2-methyl-benzothiazolium iodide in 30 ml. of pyridine was heated in an oil bath of 130°C for 25 min., cooled, and ether was added to this mixture. The precipitate thereby formed was separated by decantation, washed with ether and water, and warmed with a small amount of ethanol. On allowing this solution to cool, navy-blue crystalline powder was obtained which melted once at 185°C, resolidified, and again melted with decomposition at 245°C. Two recrystallizations from ethanol failed to change this mode of melting. Paper chromatogram exhibited a single zone of bluish purple color at $R_f$ 0.51, $\lambda_{max}$ 585 m$\mu$. The analytical values agreed with those calculated as a monohydrate.

Found : C, 48.06 ; H, 4.07 ; N, 5.08 ; I, 29.54. Calcd. for $C_{34}H_{31}N_3I_2S_3 \cdot H_2O$ : C, 48.06 ; H, 3.89 ; N, 4.95 ; I, 29.95%.

**Formation of 3,3'-Diethylthiacarbocyanine Iodide (IV) and 3, 3'-Diethyl-8-(3-ethyl-2-benzothiazolinyl-idenemethyl)thiacyanine Iodide (VII) from the Dye VI and 3-Ethyl-2-methylbenzothiazolium Iodide.**— A mixture of 0.1 g. of VI and 0.075 g. of 3-ethyl-2-methylbenzothiazolium iodide in 30 ml. of pyridine was boiled and an aliquot of this reaction mixture was periodically examined by paper chromatography (butanol : water=6 : 1) to find the formation of dyes. After 30 min., the starting dye still appeared as a spot at $R_f$ 0.35, but this disappeared after 60 min., and the reaction solution contained three kinds of dyes, one of reddish pink zone at $R_f$ 0.75 (dye IV), one of violet zone at $R_f$ 0.86 (dye V), and one of brown zone at $R_f$ 0.93 (dye VII).

**Formation of 3,3'-Diethylthiacarbocyanine Iodide (IV) and 3, 3'-Diethyl-8-(3-ethyl-2-naphtho[2, 1-*d*]-thiazolinylidenemethyl)-6', 7'-benzothiacyanine Iodide (X) from the Dye VI and 3-Ethyl-2-methyl-naphtho[2, 1-*d*]thiazolium Iodide.** — A mixture of 1 g. of IV and 0.9 g. of 3-ethyl-2-methylnaphtho[2, 1-*d*]-thiazolium iodide in 300 ml. of pyridine was boiled at 130°C for 4 hr., pyridine was removed under a reduced pressure, and the residue was washed with 2 portions of ether. The residue was dissolved in acetone and the solution was developed through an alumina column by which the product separated into three bands of greenish black, reddish pink, and violet, from bottom to top. The reddish pink band was eluted with acetone, acetone solution was evaporated, and the residue was treated with ether, affording 0.1 g. of a crude dye, m. p. 200°C (decomp.) : $\lambda_{max}$ 580 m$\mu$ : paper chromatogram : $R_f$ 0.74 (butanol : water=6 : 1). This was identified with the dye IV.

The greenish black zone was eluted with acetone and the residue obtained on evaporation of acetone was treated with ether, affording greenish black

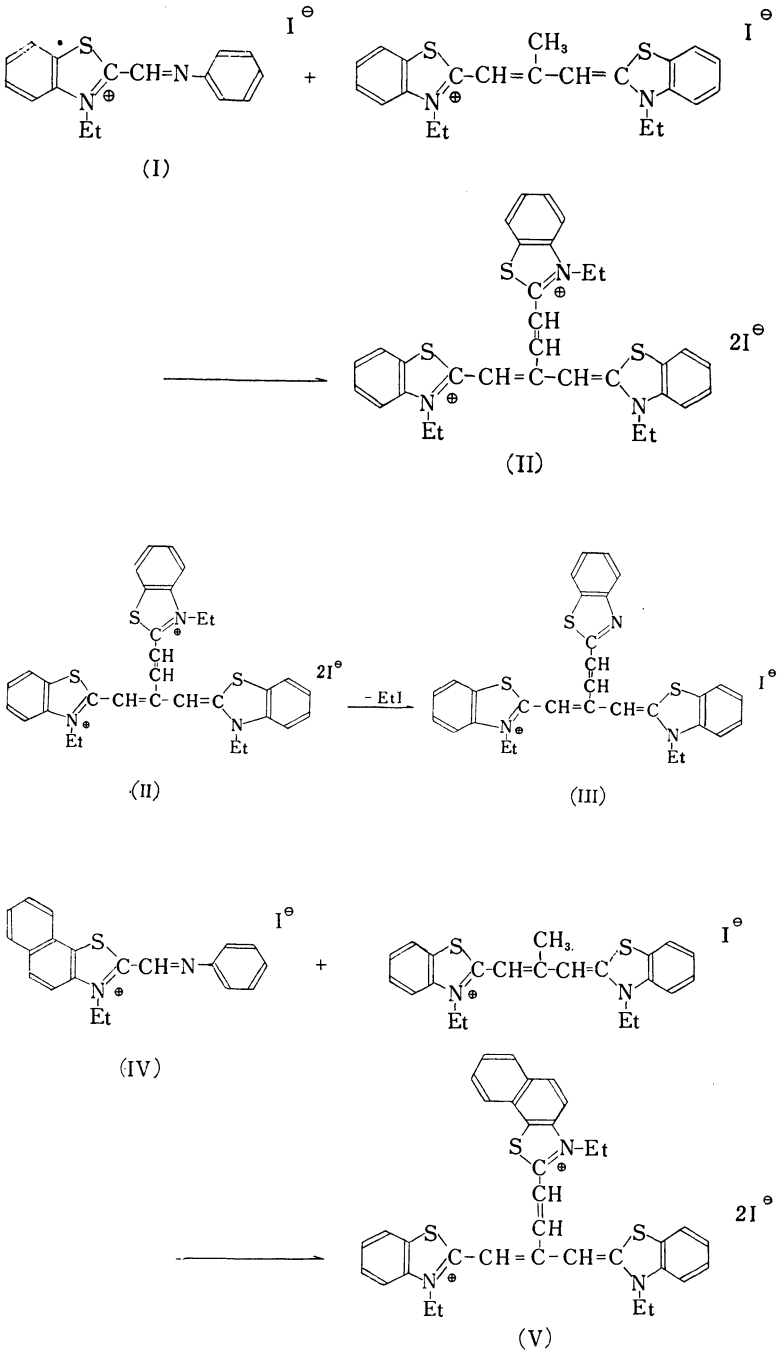
# *Synthesis of Dyes with the Neocyanine Structure Presented by Brooker, and Related Dyes. V. Synthesis of the Brooker-type Dyes from the Anil of 3-Ethyl-2-formylbenzothiazolium Iodide*

By Shiro KIMURA

(Received November 17, 1959)



Synthesis of the Brooker-type dye, 3, 3′-diethyl-9-[2-(3-ethyl-1-thia-3-azoniainden-2-yl) vinyl] thiacarbocyanine diiodide (II) in a good yield from the anil I of 3-ethyl-2-formylbenzothiazolium iodide and 3, 3′-diethyl-9-methylthiacarbocyanine iodide is discribed in this paper and this is the reverse of the reaction given in Part II of this series[1] for synthesis of the Brooker-type dyes from the nitrone of 3, 3′-diethyl-9-formylthiacarbocyanine bromide. At the same time, properties of the dye and synthetic process for similar dyes are described.

Pure synthetic process for the anil I was described in the preceding paper[2]. An equimolar mixture of this anil and 3, 3′-diethyl-9-methylthiacarbocyanine iodide was warmed in piperidine at 80～100°C for 5 min. and the dye II was obtained as brownish black leaflet crystal with copper luster, m. p. 257°C (decomp.).

It was shown in II that, during the course of the synthesis of this dye, heating of the mixture in a basic solvent for a long period of time or development of the product through alumina column afforded a dye of m. p. 219°C (decomp.). It was assumed that, similar to the case of 3, 3′-diethyl-9-(3-ethyl-1-thia-3-azonia-

1) S. Kimura, *Bull. Soc. Sci. Phot. Japan*, 9, 45 (1959).

2) S. Kimura, This Bulletin, 33, 872 (1960).

inden-2-yl) thiacarbocyanine diiodide described in the preceding paper, this dye II might also have undergone liberation of ethyl iodide to form 3, 3'-diethyl-9-[2-(2-benzothiazolyl) vinyl] thiacarbocyanine iodide (III). This dye III had already been synthesized by Hamer[3] and examination of her synthetic process showed that they are identical dyes.

Condensation of 3-ethyl-2-formylnaphtho-[2, 1-*d*] thiazolium iodide (IV) and 3, 3'-diethyl-9-methylthiacarbocyanine iodide in pyridine similarly afforded 3, 3'-diethyl-9-[2-(3-ethyl-1-thia-3-azoniacyclopenta [*a*] naphth-2-yl) vinyl] thiacarbocyanine diiodide (V) as purplish black crystalline powder of m. p. 257°C (decomp.): $\lambda_{max}$ 650 m$\mu$.

3) F. M. Hamer, *J. Chem. Soc.*, **1952**, 3197.

This synthetic process for the Brooker-type dyes from anils gives the product in comparatively good yield and can be recommended as a general method of synthesis of this type of dyes.

## Experimental

**Preparation of 3, 3'-Diethyl-9-[2-(3-ethyl-1-thia-3-azoniainden-2-yl) vinyl] thiacarbocyanine Diiodide (II).**—A solution of 0.95 g. of the anil I of 3-ethyl-2-formylbenzothiazolium iodide and 1 g. of 3, 3'-diethyl-9-methylthiacarbocyanine iodide in 80 ml. of pyridine was heated at 80~100°C for 5 min. and cooled; ether was added to the reaction mixture to precipitate the dye formed. The precipitate was collected by filtration, washed with water, and 1.2 g. of the crude dye was obtained as purplish black powder, m.p. 180~190°C (decomp.). Recrystallization from methanol afforded 0.045 g. (yield, 2.8%) of brownish black leaflets, m. p. 257°C (decomp.). Paper chromatogram showed a single zone of violet color at *Rf* 0.37 (butanol : water=6 : 1), $\lambda_{max}$ 560 m$\mu$. This was identified with the dye II whose preparation was described in Part II of this series[1].

Found: C, 47.48; H, 3.91; N, 5.48; I, 30.94. Calcd. for $C_{32}H_{31}N_3I_2S_3$: C, 47.60; H, 3.81; N, 5.21; I, 31.50%.

**Formation of 3, 3'-Diethyl-9-[2-(2-benzothiazolyl) vinyl] thiacarbocyanine Iodide (III) by Liberation of Ethyl Iodide from the Dye II.**—Examinations were made on elementary analytical values of the green needles, m. p. 219°C (decomp.), isolated during alumina chromatography of the product obtained from preparation of the dye II, described in Part II[1], and the values were found to be close to those calculated for III.

Found: C, 55.60; H, 4.82; N, 6.44. Calcd. for $C_{30}H_{26}N_3IS_3$: C, 55.29; H, 4.02; N, 6.45%.

The dye of m. p. 218°C (decomp.), obtained on following the synthetic process of Hamer, exhibited the same absorption curve as this dye III with $\lambda_{max}$ at 563 m$\mu$, proving these dyes to be identical.

**Preparation of 3' 3'-Diethyl-9-[2-(3-ethyl-1-thia-3-azoniacyclopenta [*a*] naphth-2-yl) vinyl] thiacarbocyanine Diiodide (V).**—A mixture of 1 g. of the anil IV of 3-ethyl-2-formylnaphtho[2, 1-*d*]thiazolium iodide and 1 g. of 3, 3'-diethyl-9-methylthiacarbocyanine iodide in 80 ml. of pyridine was heated in an oil bath of 115~120°C for 10 min. Insoluble matter was filtered off, ether was added to the filtrate to precipitate the dye formed, and the mixture was allowed to stand over night. The precipitate was collected by filtration, washed with ether, and 0.8 g. of crude dye, m. p. 185~195°C (decomp.), was obtained. Recrystallization from 50 ml. of methanol afforded, as the first crop, the starting dye as indigo prisms, m. p. 275°C (decomp.), and concentration of this mother liquor to one-half the original volume afforded 0.17 g. of crystals of m. p. 195°C (decomp.). Recrystallization of this second crop of crystals from 30 ml. of methanol gave 0.05 g. of purplish black crystalline powder, m. p. 257°C (decomp.): $\lambda_{max}$ 650 m$\mu$.

Found: C, 50.00; H, 3.94; N, 5.00. Calcd. for $C_{36}H_{33}N_3I_2S_3$: C, 50.40; H, 3.86; N, 4.90%.

# *Rapid Determination of Thorium by Fluoride Titration Using Some Chromotropic Azo Dyes*

By Sachindra Kumar DATTA

(Received January 8, 1960)

Thorium nitrate has been employed by many workers as a reagent for the volumetric analysis of fluoride. Willard and Winter[1] used alizarin sulfonate as indicator in the titration of fluorine with thorium nitrate. This method for the determination of fluorine in minerals and rocks has undergone many modifications in the hands of many workers[2]. Menis and co-workers[3] used alizarin red-S for the titration of fluoride by an automatic spectrophotometric device. Gurev and Ioffe[4] employed the thorium-alizarin red-S lake for the photometric determination of fluorine in zinc concentrates and electrolytes. This dye found application in the determination of this halogen by column chromatography with cellulose supported with alizarin red-S[5]. This thorium-alizarin sulfonate method has also been used by Guntz and Arene[6] for the colorimetric determination of fluorine in waters. Organic fluorine has also been determination by this method by Musgrave and Smith[7] and later the method was modified by Stross and coworkers[8] and also by Ellis and Musgrave[9]. Milton and Liddel[10] employed solochrome Brilliant Blue B. S. as indicator for the estimation of fluorine. Willard and Horton[11] made a comparative study on the use of many indicators for the titration of fluoride with thorium nitrate and showed that purpurin sulfonate and alizarin red-S gave reproducible results. Banerjee[12] used his dye SPADNS as indicator for such titration. The present author employed three dyes: SNADNS-4, di-SNADNS-4 and nitroso-SNADNS-4 for the determination of fluorine present in fluorides and rocks[13].

The reversed procedure, i. e., titration of thorium with a soluble fluoride in presence of a metal indicator is also feasible. Banerjee[14] carried out such a titration using SPADNS dye. The present paper describes a method for the titrimetric determination of thorium with sodium fluoride using three chromotropic azo dyes: nitroso-SNADNS-4, SNADNS-6[15] and CHPADNS[16], prepared from 1-naphthylamine-4-sulfonic acid, 1-naphthylamine-6-sulfonic acid and *p*-aminosalicylic acid respectively. The dyes form pink to violet complexes with thorium, which are decomposed by the addition of a standard fluoride solution resulting in the liberation of the free dyes showing a marked color change at the end point.

## Experimental

**Reagents and Chemicals.**—*Sodium Fluoride.*—A stock solution was prepared from Merck's analytical grade sodium fluoride, previously dried at 120°C to constant weight.

*Thorium Nitrate.*—A thorium nitrate solution of strength 0.0128 M was prepared from thorium nitrate tetrahydrate (E. M.) by standardising gravimetrically with oxalic acid and phenyl acetic acid.

*Dye Solution.*—The dyes were prepared by following methods previously described[15,16]. A 0.1% solution of the dyes was used.

*Buffer Solution.*—Standard acetate buffer mixtures of different pH were prepared as usual.

*Starch Solution.*—A 5% starch solution was prepared when required.

**Optimum Conditions for the Determination of Thorium.**—*Hydrogen Ion Concentration.*—Titration of thorium was carried out in solutions having different pH, adjusted by 0.01 N hydrochloric acid, sodium hydroxide or acetate buffer. It was observed that a pH range from 2.4 to 2.8 was more or less suitable for estimation with these dyes. (Table-I).

*Concentration of the Dyes.*—A. half ml. of 0.1% dye solution was sufficient to give good end points with smaller amounts thorium in 50 ml. volume.

*Concentration of Thorium Solution.*—Reproducible results were obtained when very dilute solutions of thorium were titrated. The end point becomes obscure and a considerable amount of the indicator is absorbed by the increased amount of thorium fluoride precipitate. The quantity of thorium present should not be more than 50 mg. per 50 ml.

*Starch Solution.*—A 5 ml. portion of 5% freshly prepared starch solution should be added per 50 ml. solution to reduce the precipitation of thorium fluoride, acting as a protective colloid[8].

*Volume of Titrating Solution.*—In order to find out the effect of dilution of the volume of the titrating solution on the end point, titrations were carried out by varying the final volume of the solution keeping all other things constant. It was found that titration was best done in 40~50 ml. volume.

*Temperature.*—The titration is to be carried out at room temperature. At higher temperature the end point became indistinct.

**Analytical Procedure.**—An aliquot quantity of thorium nitrate solution was taken in a 250 ml. Erlnmeyer flask to which was added 0.5 ml. of the indicator, the mixture was diluted to 40 ml. the pH was adjusted to 2.5 with 0.01 N sodium hydroxide or hydrochloric acid, 5 ml. of starch solution were added and the volume was finally made up to 50 ml. The titration was carried out rapidly with the standard sodium fluoride solution till the end point was attained. Blank titrations were also carried out side by side. Titration should be completed quickly as the efficacy of the starch solution is soon lost. At the end point the color of the solution with nitroso-SNADNS-4, changed from reddish-pink to yellow, with SNADNS-6 the change was from pinkish-blue to pink and with CHPADNS the color changed from pinkish-violet to red. The end point with nitroso-SNADNS-4 was very sharp and distinct. Some of the representative data given in Table II, show that the method is stoichiometric up to about 50 mg. of thorium, within the limits of experimental error. The results have been compared with those obtained by the use of alizarin red-S indicator at pH 2.9~3 and the results were found to agree favorably.

**Determination of Thorium in Micro Quantities.** The procedure for titrating microgram amounts of thorium was the same as before, excepting that a micro-burette, more dilute solutions of the fluoride and thorium nitrate and 0.5 ml. of 0.05% dye solution per 50 ml. final volume, were used. The end points were sharper in this titration as the bulk of thorium fluoride formed was small. The data recorded in Table III, indicate that as low as 3.8 $\mu$g. of thorium per 50 ml. may be determined using these dyes with fair accuracy.

TABLE III. MICRO-TITRATION OF THORIUM WITH FLUORIDE

| Th taken $\mu$g. | Th found in $\mu$g. (NaF=0.0013 M): Nitroso-SNADNS-4 | SNADNS-6 | CHPADNS |
|---|---|---|---|
| 22.88 | 22.90 | 22.86 | 22.89 |
| 15.26 | 15.22 | 15.19 | 15.21 |
| 11.44 | 11.41 | 11.40 | 11.38 |
| 7.63 | 7.60 | 7.60 | 7.62 |
| 3.81 | 3.78 | 3.74 | 3.76 |

**Effect of Various Ions on the Determination.**—Possible interference in this determination was investigated. The ions that complex thorium or the dyes and also those which react with fluoride, interfere strongly. The elements which caused interference are as follows: lead, mercury(I), alkaline earth metals, iron, tin, manganese, magnesium, cerium, rare earth elements, zirconium, phosphate, borate, oxalate, tartrate and citrate. Determination could be carried out in the presence of other elements like copper, cadmium, aluminum, beryllium, zinc, mercury(II), cobalt, nickel, sodium and potassium. The results have been placed in Table IV.

TABLE IV. DETERMINATION OF THORIUM IN PRESENCE OF DIVERSE IONS

Th taken = 8.91 mg. = 5.84 ml. of 0.0263 M NaF

| Elements | Amount mg. | Titre value (ml.) with | | |

**Summary**

The thorium-chromotropic azo dye complexes are found to be fast-reacting with fluorides, in which exchange of dye molecule for fluoride ion takes place. The colored thorium-dye complexes are thereby decomposed with the liberation of the free dye and formation of thorium fluoride. The color changes at the end point enable visual comparison. Three dyes: nitroso-SNADNS-4, SNADNS-6 and CHPADNS have been used here as thorium complexing agents or indicators. The color change with the nitroso-SNADNS-4 at the end point is very sharp. Titrations are best carried out at pH range 2.4~2.8 and thorium present should not be more than 50 mg. per 50 ml. solution. With the increased precipitation of thorium fluoride the dyes are adsorbed in the precipitate and the end point becomes more obscured. Microgram amounts of thorium may also be determined by this method. A large number of cations and anions interfere in the process, of which the most important are: iron, cerium, rare earth elements, alkaline earth elements, phosphates, borates, oxalates, tartrates and citrates. This method is best applicable to thorium solutions from which the interfering elements have been removed.

# *Separation of Radioactive Arsenic from Germanium Irradiated with Protons*

By Kazuo SAITO, Shigerô IKEDA and Makoto SAITO

(Received January 26, 1960)

Concerning the preparation of radioactive arsenic including $^{70}As$, $^{71}As$, $^{72}As$ and $^{74}As$, from a germanium target irradiated with protons, a little information is available. Green et al.[1] extracted germanium tetrachloride with benzene and left arsenic in the aqueous phase consisting of 11 N hydrochloric acid. Irvine[2] distilled off germanium tetrachloride in an oxidative atmosphere in the presence of carrier arsenic and hydrochloric acid. These reports, however, give only insufficient information on the preparation of radioactive arsenic of a very high specific activity (e. g. 1 mc in 0.05 ml. of aqueous solution containing less than 10 $\mu$g. of arsenic).

With the aims of measuring the accurate energy of the gamma rays of arsenic $-74$ by the internal conversion method and using the product for a tracer of a high specific activity, the present authors examined the separation of almost carrier-free arsenic by distillation with reference to the rate of distillation; they also applied the solvent extraction method[3] with diethyldithiocarbamate to the present purpose. Since commercial germanium of a high purity contains a very small amount of arsenic (e. g. less than 0.0001%), the product can not be called carrier-free. However this is regarded as practically carrier-free from either a nuclear spectroscopic or a radiochemical viewpoint; never-the-less the term "carrier-free" is not used in this paper.

It was elucidated that the distillation of arsenic trichloride in the absence of germanium, is completed within 5 min. (Table I.) and the

2) W. Irvine Jr., *J. Applied Phys.*, 13, 910 (1942).
3) N. Stanford, P. F. Wyatt and F. G. Kershaw, *Analyst*, 70, 232 (1945).

distillate contains no appreciable amount of solute other than hydrogen chloride, hydrogen bromide and radioactive arsenic in an almost carrier-free state. It is often seen that the distillation of a substance is retarded on a micro scale, but this is not the case. It remains uncertain, however, whether the rapid distillation is due to the possible presence of a very small amount of carrier or to the fact that a large amount of hydrogen chloride simultaneously distils out. The distillate can be used as a tracer for arsenic. It was found, however, more convenient to extract arsenic into an organic phase and extract it back into an aqueous layer, for the product to be submitted to conversion electron measurement in a beta-ray spectrometer.

The extraction of diethyldithiocarbamate with carbon tetrachloride provides satisfactory results on such a micro scale, provided that a sufficient amount of the reagent is present. (Fig. 1) The use of an acetate buffer, which is generally involved in the analytical use of this reagent, was not found essential for a quantitative extraction, whenever the pH is duely adjusted. It appears as if the use of a buffer causes the presence of a salt-like substance in the final product, which vitiates the specific activity and hence the conversion electron spectrum. Although the presence of germanium does not interfere with the extraction, most satisfactory results were obtained by the application of the extraction method to the distillate of almost carrier-free arsenic trichloride. Retardation of the extraction, which is often involved in the case of carrier-free separation, was not recognized. The reason is uncertain, but it must be noticed that a large excess of diethyldithio carbamate is essential for a rapid extraction and that a very small amount of the reagent is extracted into the organic phase at the given pH.

When relatively short-lived arsenic-69, 70, 71, 72 and 76 decay after one week, the redioactivity consists of arsenic-74 (half-life, 17.5 days) and arsenic-73 (76 days); the latter gives only two gamma rays of 14 and 54 keV. and does not interfere with the measurement of gamma-rays of arsenic-74 having higher energies, by the scintillation method. Hence the product is satisfactorily used for the study of the decay scheme of $^{74}$As and as a tracer of arsenic having an apparent half-life of 17.5 days. The result of the study of the decay scheme was published elsewhere[5]. A part of the spectrum is shown in Fig. 2, which clearly shows that the source is thin enough to give a resolution of $\pm 0.8\%$. The amount of miscellaneous substances in the final product, including carrier arsenic is less than 10 $\mu$g. for 0.4 mc, the specific activity for $^{74}$As being about 1 mc per 25 $\mu$g. immediately after preparation. The overall yield for $^{74}$As is about 70%.

## Experimental

**Target and Irradiation.**—Elementary germanium of a purity more than 99.99999999% (measured by the Hole effect) (possible chemical purity more than 99.999%) and germanium dioxide (purity more than 99.999%) were used as target. The germanium was placed on a water-cooled detachable stem and covered with a thin (20 $\mu$) foil of aluminum. The oxide was mixed with a dilute solution of glycerin phthalate resin (glyptal) in ethylacetate, mounted on an aluminum plate and dried at 250°C; the plate was fixed on the head of the stem.

Irradiation was made in INS cyclotron (diameter of the magnet pole piece, 163 cm.) with protons of various energies ranging from 10 to 14 MeV. for 2 to 5 hr., the intensity of the beam current being 10 to 20 $\mu$A. The irradiated target was set aside in the vacuum chamber for 1 hr., the head of the stem taken out and the target submitted to chemical separation.

The irradiated unit contained arsenic-70, 71, 72, 73, 74 and 76, germanium-69 and 71 (produced by (p, pn) reaction) and probably a small amount of gallium-67, 68, 70 and 72 (produced by (p, 2p) and (p, $\alpha$) reaction) as radioactive nuclides. The total amount of radioactive substance was of the order of several ten mc immediately after irradiation, when the beam current was 15 $\mu$A and the duration of irradiation was 5 hr.; the amount of arsenic-74 appeared to be 1 mc or a little less. Irradiation was made five times altogether. Chemical behavior of the produced nuclides was carefully checked. Essential parts are described as follows.

**Distillation.**—The elementaryger manium (10 g., in four pieces) was placed in a Clysen-type flask, dissolved in aqua regia (30 ml.) and germanium tetrachloride distilled in a current of chlorine with the addition of 6 N hydrochloric acid (50 ml.) until the volume of the residue is less than 1 ml. The addition of hydrochloric acid and the distillation were repeated three times. Germanium oxide taken off the plate was placed in the flask and similarly distilled. The remaining charred resin did not interfere with the subsequent distillation of arsenic. The removal of germanium was almost complete. The chlorine being removed in a current of nitrogen, the arsenic trichloride was distilled in the presence of 10 N hydrochloric acid (10 ml.) and 9 N hydrobromic acid (5 ml.), into an ice-cooled adapter containing water (10 ml.). The arsenic was found in the first a few milliliters' portion. This fact was clearly demonstrated by a small-scaled distillation

| 7 | 5 | 35 | 23 | |
| 8 | 7 | 42 | 16 | |

* The amount of the radioactive As is much smaller than that in the practical separation, but the volume of the aq. soln. is almost the same.

** Initial vol. of the aq. soln. 0.5 ml.; the counting rate, 12100 c.p.m.

shown in Table I. The total recovery was about 94%; most of the remaining radioactive arsenic was found on the surface of the rubber stoppers.

**Solvent Extraction.**—The experimental procedure shown in the original paper[3] was followed.

Since this method has been examined for use in micro analysis of arsenic[4], the following experiments were centered around the rate of extraction on such an ultra-micro scale. The distillate was heated to dryness with sulfuric acid (1 N, 2 ml.) and nitric acid (15 N, 5 ml.), mixed with hydrochloric acid (12 N, 1 ml.) and water (15 ml.) and again heated to 50°C. The product is treated with potassium iodide solution (10%, 3 ml.) and sodium sulfite (1 g.), made pH 5 with sodium acetate (10%, 5 ml.) and aqueous ammonia solution and shaken with carbon tetrachloride for 1 min. (equal volume to the aqueous layer) in the presence of variable amounts of sodium diethyldithiocarbamate solution (0.1%, in water). The results are shown in Fig. 1.

It is clearly seen that the extraction largely depends on the amount of the reagent. No appreciable adsorption of radioactive arsenic was observed on the surface of the glass wares, not excepting the ground parts. A similar extraction curve was obtained in the presence of germanium. A satisfactory extraction of arsenic was also effected in the absence of any buffer, provided that the pH was duely adjusted. Back-extraction of radioactive arsenic was substantiated from the carbon tetrachloride solution, by the use of 8 N nitric acid, 6 N hydrochloric acid or aqueous ammonia solution. Single extraction suffices for the recovery of more than 90% of the radioactive arsenic.

**Measurement of Radioactivity.**—For checking the procedures for separation, a G. M. counter was used, the sample being placed at a reproducible geometry. Since one series of experiments is completed within a few hours, the radiochemical composition of the sample can be regarded as identical, although the sample solution contains, especially at the early stage of separation, several radioactive nuclides. Hence the counting rate was shown in c. p. m. on an arbitrary scale in the figures and tables.

For the measurement of the conversion electron spectrum, the back-extracted arsenic in nitric acid solution was mounted on a trace of insulin on a thin polyvinylchloride foil lined with a thin layer (several $\mu$g. per cm$^2$) of vacuum-evaporated aluminum, dried up under an infrared lamp or in vacuo and attached to a beta-ray spectrometer. (INS-III, $\rho = 18$ cm.)

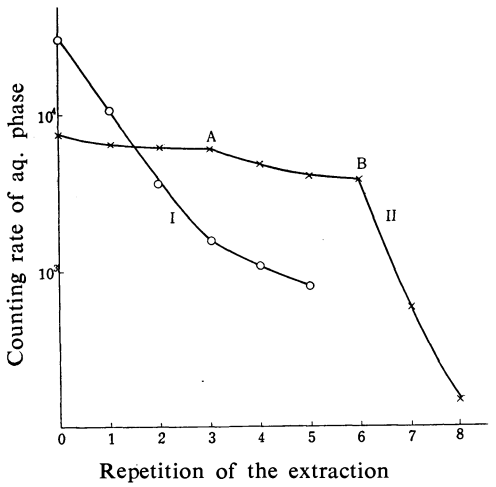

Fig. 1. Extraction of arsenic with carbontetrachloride in the presence of diethyldithiocarbamate.

Curve I. Extraction in the presence of 3 ml. of 0.1% reagent soln.; vol. of the aq. phase, 6 ml.; time of shaking 1 min. each.

Curve II. Extraction in the presence of a less amount of reagent; initial, 0.5 ml.; vol. of the aq. phase, 6 ml.; time of shaking, 1 min. At point A and B, 0.5 ml. and 1.0 ml. of 0.5% reagent soln. were respectively added.

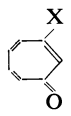
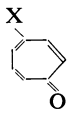
# *The Synthesis of 4-Aminotropone*



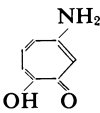
By Kozo Doi

(Received November 17, 1959)

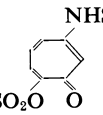


Tropolone[1] (I) and its isomers, 3-hydroxytropone[2] (II) and 4-hydroxytropone[3] (III) have been synthesized and their reactions have also been investigated. The amino homologues, of tropolones, 2-aminotropone[1] (IV) and derivatives, have already been synthesized and their reactions have been studied in detail. The isomeric 3-aminotropone (V) and 4-aminotropone (VI), on the other hand, have sofar not been prepared. The present communication deals briefly with the synthesis of the 4-isomer VI starting from 4-aminotropolone[4] (VII).

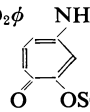
I: X=OH IV: X=$NH_2$



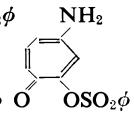
II: X=OH V: X=$NH_2$



III: X=OH VI: X=$NH_2$



Reaction of 4-aminotropolone sulfate and *p*-toluenesulfonyl chloride in pyridine afforded, with company of a di-*p*-toluenesulfonate (VIII), 4-amino-2-*p*-toluenesulfoxytropone (IX), of which hydrogenolysis[5] over 5% palladized charcoal gave easily 4-aminotropone (VI).



VII

VIIIa

VIIIb

IX

The ultraviolet absorption of the aminotropone VI shows an tropone type of spectrum[6], having maxima at 228 m$\mu$ (log $\varepsilon$ 4.35), 260 (3.89) and 365 (4.38) (Fig. 1).

The structure of the aminotropone VI is more reasonably assumed from the fact, that its infrared spectrum has two absorption bands,

5) T. Nozoe, S. Seto, T. Sato and S. Ninagawa (to be published) have found the formation of tropones from 2-*p*-toluenesulfoxytropones with a similar hydrogenolysis procedure.
6) M. Tsuboi, This Bulletin, **25**, 369 (1952).

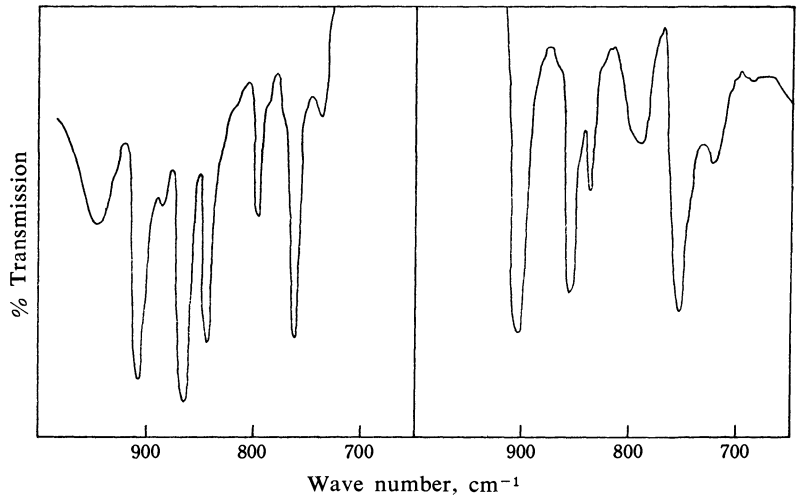

Fig. 2. Infrared absorption spectra of 4-aminotropone (VI, right) and 4-hydroxytropone (III, left).

790 and 903 $cm^{-1}$, which have been assigned[7] to the bands based on the CH out-of-plane vibrations of 4-substituted tropones. It may support the structural assignment above described, that the infrared spectrum of 4-hydroxytropone[7] (III) has two absorption bands, 797 and 865 $cm^{-1}$, and the features of the absorption in this region are closely ressembling to that of the aminotropone VI (Fig. 2).

## Experimental

**4-Amino-2-*p*-toluenesulfoxytropone (IX).**—To a stirred solution of 4-aminotropolone sulfate[4] (2 g.) and pyridine (3 cc.), was added *p*-toluenesulfonylchloride (1.9 g.) for 3 min. at room temperature. After 30 min., dilution with water (20 cc.) and subsequent filtration afforded a pale yellow solid (2.6 g.), m. p. 199~200°C (decomp.), of which fractional recrystallization from methanol gave a less soluble product, a di-*p*-toluenesulfonate (VIII, 1.8 g.), m.p. 213°C (decomp.),

Found : C, 56.37 ; H, 4.54 ; N, 3.56. Calcd. for $C_{21}H_{19}O_6NS_2$ : C, 56.61 ; H, 4.30 ; N, 3.14%.

and more soluble product IX (0.12 g.), yellow needles, m. p. 194°C (decomp.).

Found : C, 57.67 ; H, 4.41 ; N, 5.00. Calcd. for $C_{14}H_{13}O_4NS$ : C, 57.73 ; H, 4.50 ; N, 4.82%.

**4-Aminotropone (VI).**—A mixture of IX (0.3 g.), sodium acetate trihydrate (0.15 g.), 5% palladized charcoal (50 mg.) and methanol (100 cc.) was shaken in the hydrogen atmosphere until absorption of hydrogen ceased. After 8 hr., the catalyst was removed and the filtrate was concentrated in vacuo. The residual solid, after chromatographic purification (ethyl acetate-alumina) followed by crystallization from ethyl acetate, afforded 4-aminotropone (VI, 20 mg.), yellow prisms, m. p. 218°C (decomp.).

Found : C, 69.08 ; H, 5.83 ; N, 11.63. Calcd. for $C_7H_7ON$ : C, 69.40 ; H, 5.83 ; N, 11.56%.

The author thanks Professor Yoshio Kitahara very much for his unfailing guidance, also Mr. Yusaku Ikegami for the infrared spectral analysis and Messrs. Shinichi Ohyama and Yoko Endo for the microanalyses.

# *Magnetic Susceptibilities of Sulfur, Selenium and Tellurium from Room Temperature to 1100°C*

By Shōtarō Tobisawa

(Received August 18, 1959)

The temperature-dependences of magnetic susceptibilities of sulfur, selenium and tellurium have, hitherto, been investigated by many workers. Some different results can, however, be found among their data. The magnetic susceptibilities of the three elements have, therefore, been measured with the recording magnetic balance to compare the present results with those reported by other investigators and to compare the present results with experimental results observed on the physical properties such as viscosity, specific heat, electrical conductivity and so on.

## Experimental

**Materials.**—*Sulfur.*—Guaranteed sulfur, Kanto Chemical Co. Ltd., was purified by Bacon and Fanelli's procedure[1], and then was treated by Gardner and Fraenkel's method[2] to eliminate magnetic impurities.

*Selenium.*—Guaranteed selenium, Junsei Chemical Co. Ltd., was distilled several times under high vacuum to obtain selenium of spectro grade. A glassy solidified black-selenium (glassy selenium) was prepared by quenching a sample of molten selenium under vacuum of $10^{-5}$ mmHg. This sample was confirmed to have diffused rings without diffraction patterns by X-ray analysis. Hexagonal selenium was obtained by heating a sample of glassy selenium at about 130°C for 48 hr. under vacuum of $10^{-5}$ mmHg. This sample was found to have hexagonal patterns.

*Tellurium.*—Tellurium of Merck (sample A) and a specimen produced by Mitsubishi Ōsaka Refinery (sample B) were distilled three and five times, respectively, to obtain tellurium of spectro grade. Both the samples were crystallized by cooling very slowly from the molten state under vacuum of $10^{-5}$ mmHg. It was ascertained by X-ray examinations that both the samples had hexagonal patterns.

**Measurements.**—Measurements were carried out by using the recording magnetic balance described in detail in the previous report[3]. The dimension of the sample bulb was the same as the previously reported one. The apparatus, which was operated by the Faraday method, was modulated on a recording chart to be able to indicate the changes of

—— heating ---- cooling

0.1 mA, which corresponded to $-1.3\times10^{-9}$ e.m.u. in magnetic susceptibility. In each experiment, a sample of about 50 mg. was charged into a fused quartz bulb. This bulb was sealed carefully, after having been evacuated to about $10^{-5}$ mmHg. The measurements were made with heating or cooling rates of 300°C per hour, at constant field, 8250 Oersteds. The results obtained are shown in Figs. 1—4.

## Results

**Comparison with the Results Obtained by other Investigators.**—*On the Solid State.*—The magnetic susceptibilities of the three elements obtained at room temperature are given in Table I. The susceptibility of sulfur scarcely changes with temperature, while those of selenium and tellurium change slightly with temperature.

Table I. The magnetic susceptibilities of the three elements

| Sample | $\chi\times10^6$ (per g.) |
|---|---|
| Sulfur | −0.49 |
| Glassy selenium | −0.33 |
| Hexagonal selenium | −0.29 |
| Hexagonal tellurium | −0.30 (Sample A)<br>−0.32 (Sample B) |

*On the Behavior of Susceptibilities at the Melting Points and their Neighborhood.*—(1) The susceptibility of sulfur showed no particular changes at the melting point and its neighborhood. It began to decrease from 157°C, and reached $-0.43\times10^{-6}$ per g. at 171°C. Ishiwara[4] reported that the susceptibility of sulfur decreased at about 160°C, while Honda[5] showed that the susceptibility of sulfur had a minimum value at the melting point.

(2) Busch et al.[6] reported that the volume susceptibility of hexagonal selenium increased on fusion. In Figs. 2 and 3, the susceptibility of glassy selenium decreased slightly at 210°C, while that of hexagonal selenium increased slightly at 220°C. On cooling, both kinds of liquid selenium turned to glassy selenium, showing slight increases in susceptibilities at about 125°C under the present experimental condition. Busch et al. reported that the volume susceptibility of glassy selenium had no abrupt changes despite the fast cooling of molten selenium.

(3) The susceptibility of hexagonal tellurium of sample A began to decrease at 442°C and reached the value of $-0.12\times10^{-6}$ per g. at 462°C. The susceptibility of sample B began to decrease at 448°C and reached the value of $-0.03\times10^{-6}$ per g. at 470°C. The susceptibility-temperature curve for hexagonal tellurium deflected toward sides opposite to that for hexagonal selenium, as shown in Figs. 3 and 4. Under the present experimental condition, sample A was supercooled to 350°C, while sample B was supercooled to 270°C.

*In the Liquid State.*—(1) The susceptibility

4) T. Ishiwara, *Science Repts. Tōhoku Imp. Univ.*, **9**, 233 (1920).
5) K. Honda, ibid., **1**, 1 (1911).
6) G. Busch and O. Vogt, *Helv. Phys. Acta*, **30**, 224 (1957).

of liquid sulfur scarcely changed until 353°C ($-0.43\times10^{-6}$ per g.).

(2) The susceptibility of fused selenium, $-0.31\times10^{-6}$ per g. at 220°C, decreased slightly with temperature. The values reported as the susceptibility of fused selenium are as follows: $-0.31\times10^{-6}$ [7], $-0.304\times10^{-6}$ [8] and $-0.32\times10^{-6}$ per g.[9] Busch et al.[6] showed that the volume susceptibility of fused selenium was $-1.347\times10^{-6}$ per cc. at the melting point. Taking 3.987 g. per $cm^3$ [10] as the density of fused selenium at 220°C, Busch's value corresponded to $-0.338\times10^{-6}$ per g. in mass susceptibility. This value is greater than the present experimental value at 220°C.

(3) The value of liquid tellurium from sample B at 470°C, $-0.03\times10^{-6}$ per g., consistent with the values of liquid tellurium obtained by Honda[11] and Endo[12], was smaller than that of sample A. On the other hand, values reported as the volume susceptibility of liquid tellurium by the other authors were $-0.3\times10^{-6}$ [13] and $-0.767\times10^{-6}$ [6] per cc.

*In the Higher Temperature Range.*—(1) The curve in Fig. 1 deflected toward paramagnetic sides above 353°C. Néel[14] and Scott[15] reported that the diatomic sulfur molecule produced by the dissociation of sulfur at high temperature,

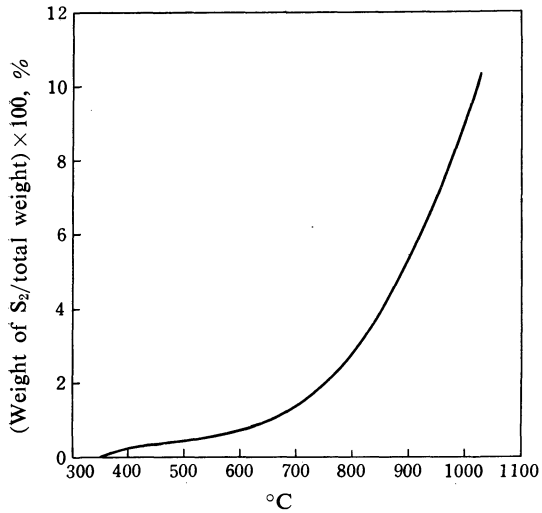

Fig. 5. (Weight of $S_2$/total weight)-temperature curve for sulfur.

was paramagnetic. On the assumption that the deflection toward paramagnetic sides above 353°C is due to the paramagnetism of the diatomic sulfur molecule, an attempt was made to estimate the weight of the diatomic sulfur molecule at every temperature by comparing the experimental value of paramagnetic susceptibility with the value calculated from Van Vleck's equation[16]. The ratios of the weight of the diatomic sulfur molecule to the total weight of sulfur at every temperature, are shown in Fig. 5.

(2) From Figs. 2 and 3, it is clear that selenium shows paramagnetism above 690°C and that the paramagnetic change occurs reversibly with temperature. Bhatnagar et al.[17] found that selenium vapor as well as sulfur vapor was paramagnetic. The ratio of the weight of the diatomic selenium molecule to the total weight of selenium was estimated in the same way as that used for sulfur. The results are given in Fig. 6.

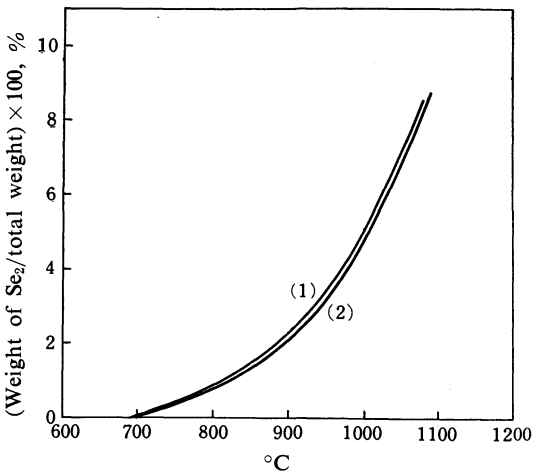

Fig. 6. (Weight of $Se_2$/total weight)-temperature curve for selenium.
(1) for glassy selenium.
(2) for hexagonal selenium.

(3) In contrast with sulfur and selenium, tellurium showed no paramagnetic changes until 1100°C under the present experimental condition. On the other hand, Busch et al. reported that tellurium was paramagnetic above 980°K.

has anomalies in regard to the physical properties such as viscosity[1,18,19], specific heat[20] and others[19,21] in the vicinity of 160°C. Gee[22] has interpreted these anomalies from the standpoint of the equilibrium between eight-membered sulfur rings and long chain polymers. Gee and his colaborators[23] measured the susceptibility of sulfur to investigate the existence and concentration of free radicals. They could not find any paramagnetic contribution from free radicals. On the other hand, Gardner et al.[2] confirmed the paramagnetism due to free radicals by the paramagnetic resonance absorption measurements over the range from 189° to 414°C, and stated that the paramagnetism increased reversibly with temperature. From the comparison of the present results with various results mentioned above, it can be concluded that the change in susceptibility of liquid sulfur at 157 ~171°C suggests the formation of free radicals due to the scission of the eight-membered sulfur rings. Therefore, it is reasonable to suppose from the curve in Fig. 1 that there occurred no scission of the eight-membered sulfur rings from the melting point to 157°C. Also no scission was acceptable in the temperature range from 171° to 353°C, because the curve in Fig. 1 showed no change in this range. The results mentioned above are supported by the fact that the maximum viscosity of liquid sulfur decreased rapidly with temperature in the corresponding range.

*Selenium.*—The change in susceptibility of hexagonal selenium at 220°C is due to phase transition on fusion, because the melting point of hexagonal selenium reported in the literature is 217.4°[24] or 220.2°C[25]. On the contrary, it is known that glassy selenium has no definite melting point. By X-ray investigations Lark-Horovitz[26] has concluded that glassy selenium consists of supercooled liquid, and that the chain structure was preserved in the liquid states. On the other hand, from X-ray analysis Krebs[27] insists that about one-third of glassy selenium is in the form of eight-membered selenium ring and the rest in poly-membered ring with about one thousand selenium atoms. From the electrical measurements on selenium, glassy selenium is an insulator and liquid selenium is a semiconductor with predominant hole conduction[28]. According to Krebs' interpretation, this difference between the electrical properties for glassy and liquid selenium can be ascribed to the difference between ring structure of glassy selenium and the chain structure of liquid selenium. It is reasonable to conclude that the decrease in susceptibility of glassy selenium at about 210°C can be attributed to the scission of selenium rings similar to the scission of sulfur at 157~171°C, and that the increases in susceptibilities of liquid selenium at about 125°C on cooling are related to the reclosing of chains into rings. No scission was acceptable in the temperature range from 220° to 690°C, because the susceptibility-temperature curves for selenium in Figs. 2 and 3 showed no abrupt changes in this temperature range. This interpretation is supported by the fact that the viscosity of liquid selenium decreases smoothly with temperature, showing no scission of rings[29].

*Tellurium.*—Umino[30] reported an anomaly in specific heat of solid tellurium. By X-ray investigations of tellurium layers in vacuo, Scanlon et al.[31] showed that no structure change of solid tellurium occurred up to fusion. In Fig. 4, the susceptibility-temperature curves for solid tellurium showed no abrupt changes.

Epstein et al.[32] showed that the electrical resistivity, the Hall coefficient and the thermoelectric power of tellurium decreased at the melting point of 445°C. Busch et al.[6] stated that the volume susceptibility of tellurium decreased abruptly together with the decreases in the electrical resistivity, the Hall coefficient and the thermoelectric power. In Fig. 4, the susceptibilities of samples A and B decreased in the ranges from 442° to 462°C and from 448° to 470°C, respectively. On the other hand, as the melting point of tellurium, diversely discordant values from 420° to 455°C have been listed by Machol et al.[33] The results of X-ray investigations[34] on tellurium

immediately after fusion have shown that the number of nearest neighbors and the distance between the nearest neighbors determined for the crystal persist in the liquid state. This indicates the existence of chain molecules bound by covalent bonds in the liquid. The results of electrical investigations[28,32,35] on tellurium have shown that liquid tellurium shows a semiconducting property in which hole conduction is predominant, and that the semiconductor-metal transition occurs gradually at higher temperatures. From the results of electrical measurements Epstein et al. stated that tellurium atoms bound by covalent bonds into chains of various lengths, tellurium ions, and free electrons will be present in liquid tellurium, and that, as the temperature increases, the chains will be ionized, giving off free electrons which leave behind holes, i. e., missing covalent bonds, which in turn are able to migrate within the chains, until very high temperatures are reached, at which the liquid will be composed of tellurium ions and free electrons. It can, therefore, be considered that the decrease of susceptibility during fusion in Fig. 4 is due to a paramagnetic contribution from unpaired spins produced by incomplete ionization of the valence shell[36]. That the susceptibilities of tellurium after fusion in Fig. 4 are independent of temperature, may be owing to the mixed effects of diamagnetic and paramagnetic contributions associated with the semiconductor-metal transition mentioned above.

## Summary

(1) The susceptibility of sulfur showed the first change at about 157°C, showing no changes at the melting point and its neighborhood. The change is attributed to the radical chains owing to the scission of eight-membered sulfur rings.

(2) On fusion the susceptibility-temperature curve for glassy selenium deflected toward sides opposite to that for hexagonal selenium. It is considered that the decrease in susceptibility of glassy selenium can be ascribed to free radicals produced by the scission of selenium rings. On cooling, liquid selenium turned to glassy selenium, showing the increase in susceptibility at about 125°C. It can be considered that this change is related to the reclosing of chains into rings.

(3) The susceptibility of hexagonal tellurium decreased abruptly on fusion. It may be considered that this change is due to a paramagnetic contribution from unpaired spins produced by incomplete ionization of the valence shell.

(4) The susceptibility-temperature curves for sulfur and selenium were deflected toward paramagnetic sides above 353° and 690°C, respectively. The paramagnetism increased reversibly with temperature, while the susceptibility of tellurium was independent of temperature to 1100°C. On sulfur and selenium, the ratios of the weight of the diatomic molecule to the total weight at every temperature were obtained from the weight of the diatomic molecule estimated by comparing the experimental value of paramagnetic susceptibility with the value calculated from Van Vleck's equation.

The author wishes to express his sincere gratitude to Professor Y. Nomura for his helpful suggestions and encouragement in the course of this work. The author is also indebted to Mr. T. Ashida for his valuable assistance in X-ray analysis and to Mr. S. Uchida for his kind assistance.

# *On the Mechanism of the Extraction of Uranyl Nitrate by Tributyl Phosphate II. Infrared Study*

By Kenkichi NUKADA, Keiji NAITO and Utako MAEDA

(Received January 26, 1960)

The uranium extraction by TBP (tri-*n*-butyl phosphate) has been studied by many workers especially from the standpoint of distribution equilibrium. For the extraction of uranyl nitrate by TBP, the following mechanism was presented by Moore[1].

$$UO_2^{2+}(aq.) + 2NO_3^-(aq.) + 2TBP(org.) \rightleftharpoons [UO_2(NO_3)_2](TBP)_2(org.) \quad (1)$$

Naito, one of the present authors, has given an analytical method for studying the extraction mechanism and applied it to a uranyl nitrate extraction system[2]. As a result of this analysis, it was shown that the extraction of nitric acid (Eq. 2) competes with that of uranyl nitrate (Eq. 1), when uranyl nitrate is extracted by TBP from a nitric acid solution,

$$H^+(aq.) + NO_3^-(aq.) + TBP(org.) \rightleftharpoons HNO_3 \cdot TBP(org.) \quad (2)$$

However, the results obtained by the partition study were not enough to demonstrate how the TBP complex was formed from the species involved in the extracted system. In this paper the authors present the results of the infrared study concerning the mechanism of extraction. At first, discussions for the systems TBP-water, TBP-nitric acid and TBP-uranyl nitrate are given individually, and secondly the extraction mechanism of the system TBP-uranyl nitrate-nitric acid is presented.

## Experimental

Perkin-Elmer Model 12C and 321 Spectrometers equipped with rock salt prisms were used in the infrared measurement. The liquid cell was constructed from spacers and frames made by polyethylene with silver chloride windows, since the usual cell made from metal spacers and frame with alkaline halide windows is attacked by nitric acid and a considerable loss of nitric acid takes place. The above-mentioned non-metallic cell, designed and constructed by the present authors, was quite useful for this experiment and the detail of the design will be reported elsewhere.

The concentration of nitric acid was determined by titration against standard alkali, and the water content in the TBP phase was determined by the Karl-Fisher titration method. The uranium concentration was determined by the alkaline peroxide method. TBP was purified by refluxing with 0.5% aqueous sodium hydroxide according to the method shown by Alcock et al.[3] In some cases, the purified TBP was further distilled in vacuo in order to remove a trace of water. Analytical-grade uranyl nitrate (after recrystallization), nitric acid and carbon tetrachloride were used.

## Results and Discussion

**Spectra of Pure TBP.**—First of all, tentative assignment of TBP itself will be explained in order to analyze the spectra of the systems described below. The spectrum of pure TBP is shown in Fig. 1. Two bands at 2911 and 2840 $cm^{-1}$ are assigned to CH stretching frequencies of *n*-butyl group. Two bands at 1459 and 1382 $cm^{-1}$ are assingned to $CH_3$ and $CH_2$ deformation frequencies of *n*-butyl group, respectively. A strong band at 1270 $cm^{-1}$ is assigned to P=O stretching frequency according to Bellamy[4]. A triplet band at 1059, 1027 and 991 $cm^{-1}$ is assigned to the P–O–C group. The assignment of the weak bands at 1237, 1168, 1149, 1119, 959 and 910 $cm^{-1}$ is not clear at present.

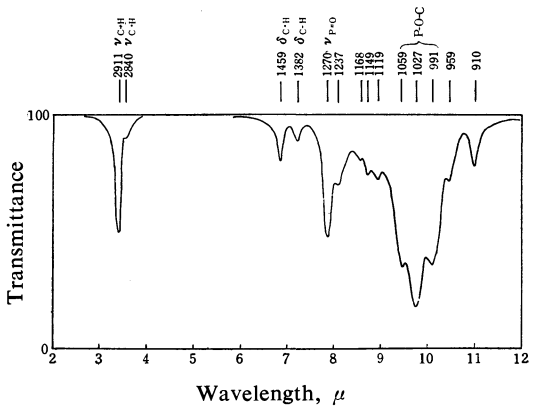

Fig. 1. Infrared spectra of pure TBP capillary.

**TBP-Water System.**—The infrared spectra of the system TBP-water, obtained by Cobb, have

1) R. L. Moore, *AECD-3196* (1951).
2) K. Naito, This Bulletin, 33, 363 (1960).
3) K. Alcock et al., *Trans. Faraday Soc.*, 52, 39 (1956).
4) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", 2nd Ed., John Wiley and Sons, Inc., New York (1958), p. 258.

been mentioned in the paper by Alcock et al.[3] He has shown that as water is added to pure TBP the band due to the P=O group at 1283 $cm^{-1}$ is shifted to 1267 $cm^{-1}$ and a shift of 16 $cm^{-1}$ suggests the formation of weak hydrogen bonding (with water) at P=O oxygen.

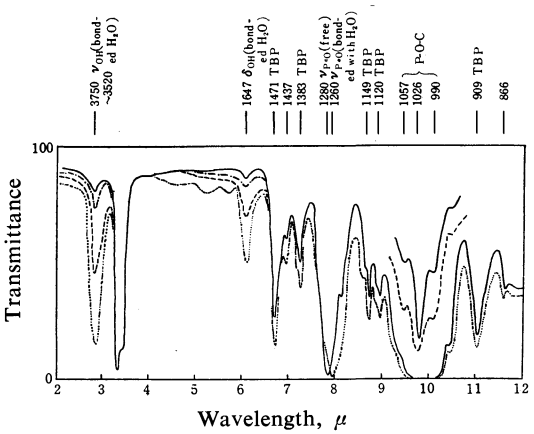

Fig. 2. Infrared spectra of TBP-$H_2O$ system. Thickness : 0.015 mm.
—— No. 1, (0.968 mg. water per ml. of solution)
·-·- No. 2, (5.98 mg. water per ml. of solution)
---- No. 3, (31.9 mg. water per ml. of solution)
····· No. 4, (64.0 mg. water per ml. of solution)

The spectra for this system obtained by the authors are shown in Fig. 2. Samples No. 1, 2, 3 and 4 contain 0.968, 5.93, 31.9 and 64.0 mg. water per ml. of solution, respectively. It is observed from Fig. 2 that as water is added to pure TBP the band due to P=O at 1280 $cm^{-1}$ is shifted to 1260 $cm^{-1}$ in agreement with Cobb's result. At the same time an increase in intensities of bands at 3750~3550 and 1647 $cm^{-1}$, is observed which are assigned to the stretching and deformation vibrations of the OH group respectively. The positions of these two bands are near to those of stretching and deformation vibrations of free water and this fact also suggests the formation of weak hydrogen bonding between P=O oxygen and water molecules.

Since the positions of the absorption bands due to P–O–C at 1057, 1026 and 990 $cm^{-1}$ have no appreciable change by the addition of water, it is concluded that in this system water does not bond with the P–O–C group.

**TBP-Nitric Acid System.**—The samples for TBP-nitric acid system were prepared as follows: 5% carbon tetrachloride solution of TBP was shaken with aqueous solution of nitric acid having various concentrations (where the volume ratio of the organic phase to the aqueous is equal to unity). After separating the organic phase from the aqueous phase, the former was used as a sample. A 5% TBP solution was used for the reason that the adequate intensities of bands can be obtained with 0.1 mm. spacer. The results of analysis for nitric acid and water contents in these samples are summarized in Table I.

Table 1. Result of analysis for the samples of TBP-nitric acid system

| Sample No. | Initial conc. (aqueous phase) of $HNO_3$, M | Equilibrium conc. $HNO_3$, M | (TBP phase) of $H_2O$, M |
|---|---|---|---|
| 1 | 0 | 0 | 0.0250 |
| 2 | 0.995 | 0.0095 | 0.0328 |
| 3 | 3.41 | 0.099 | 0.0368 |
| 4 | 5.14 | 0.151 | 0.0267 |
| 5 | 7.10 | 0.173 | 0.0211 |
| 6 | 9.23 | 0.188 | 0.0239 |
| 7 | 10.83 | 0.192 | 0.0250 |

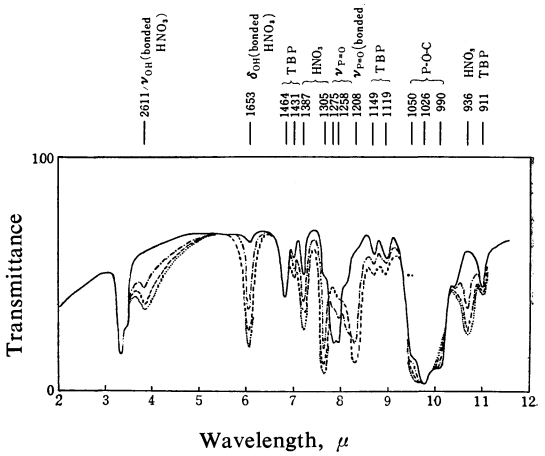

Fig. 3. Infrared spectra of TBP-$HNO_3$ system. Thickness 0.1 mm.
—— No. 2, (0.995 N $HNO_3$)
·-·- No. 3, (3.41 N $HNO_3$)
---- No. 4, (5.14 N $HNO_3$)
····· No. 5, (7.10 N $HNO_3$), No. 6, (9.23 N $HNO_3$) and No. 7, (10.83 N $HNO_3$)

The infrared spectra obtained for these samples are shown in Fig. 3. As the concentration of nitric acid in the TBP phase increases, the intensities of bands due to P=O at 1275 $cm^{-1}$ and 1258 $cm^{-1}$ decrease and one at 1208 $cm^{-1}$ rises in its place. It is not clear at present whether the branches of the doublet due to P=O are assigned to the free and bonded (with water) P=O respectively or are to be considered as a solvent effect caused by dilution with carbon tetrachloride. A new band at 1208 $cm^{-1}$ is assigned to bonded P=O with

nitric acid. The shift amounts to 50~66 $cm^{-1}$ and this fact suggests a strong bonding between P=O and nitric acid. In the case of samples No. 5—7. the bands at 1275 and 1258 $cm^{-1}$ almost disappear and the same spectra are obtained for all of these samples. Accordingly in the case of samples No. 5—7 all molecules of the TBP are entirety bonded with nitric acid at their P=O bonds. This is in agreement with the analytical data shown in Table I.

The triplet band assigned to the P–O–C group (1050, 1026 and 990 $cm^{-1}$) shows a change to some extent in samples No. 2—5 in which the increase in nitric acid content brings the increase in the intensity of the band at 1050 $cm^{-1}$ together with the decrease in that at 990 $cm^{-1}$, whereas the intensity of the band at 1026 $cm^{-1}$ remained unchanged. However, in the case of samples No. 5—7, little change is observed at the P–O–C band. Though it is not easy to interpret the above-mentioned change of spectra due to the P–O–C group, it may be attributed directly to the complex formation at P=O in view of the parallel nature between the spectra of the P–O–C group and that of the P=O group.

The bands at 2611 and 1653 $cm^{-1}$, the intensities of which are roughly proportional to the content of nitric acid in the TBP phase, are assigned to the stretching and deformation vibrations of the OH group, respectively. The band at 2611 $cm^{-1}$ is shifted obviously from the band due to free OH stretching vibration, so that the formation of strong hydrogen bonding is also confirmed.

The intensities of bands at 1387 and 1305 $cm^{-1}$ are also roughly proportional to the nitric acid content although the former band is overlapped with the band due to the deformation vibration of $CH_3$ groups of TBP at 1381 $cm^{-1}$. These two bands are then assigned to the bonds of the bonded nitric acid. It was found by Kamiyama[5] that when an alkaline halide window is used instead of a silver chloride window, a *single band* at 1387 $cm^{-1}$, which is assigned to the absorption due to the nitrate ion, appeared instead of these two bands*. It was interpreted as the result of the exchange reaction between alkaline halide and nitric acid in the TBP phase, which in turn formed nitrate ion at the surface of the window, so that the use of an alkaline halide window in this case should be strictly avoided. Tuck[6] described briefly the infrared spectra of the TBP-nitric acid system and found bands at 1400 and 810 $cm^{-1}$, which are assigned to the ionic organic nitrate. The discrepancy between his result and the authors' may have originated from the fact that he used an alkaline halide window.

The intensity of the band at 936 $cm^{-1}$ is also roughly proportional to the content of nitric acid in the TBP phase. Thus the bands at 2611, 1653, 1387, 1305 and 936 $cm^{-1}$ have the same tendency with respect to the content of nitric acid in the TBP phase, and therefore these bands are useful as the indication for bonded nitric acid in TBP phase.

**TBP-Uranyl Nitrate System.** — The samples used here consist of the following three samples: No. 1; 5% TBP solution (carbon tetrachloride is used as a diluent) saturated with uranyl nitrate monohydrate, No. 2; sample No. 1 was diluted with 5% TBP solution (the volume ratio equals 1 : 1), No. 3; sample No. 1 was diluted with 5% TBP solution (the volume ratio equals 5 : 1).

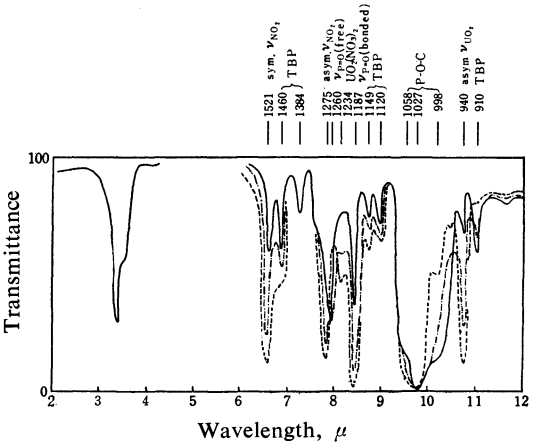

Fig. 4. Infrared spectra of TBP-$UO_2(NO_3)_2$ system. Thickness : 0.1 mm.
---- No. 1 (TBP saturated with $UO_2(NO_3)_2$)
·-·- No. 2 (1/2 diluted solution of No. 1)
—— No. 3 (1/6 diluted solution of No. 1)

The infrared spectra obtained for these samples are shown in Fig. 4. As the solution is diluted, the intensity of the band at 1187 $cm^{-1}$, which the authors assign to P=O bonded with uranyl nitrate, decreases and that at 1260 $cm^{-1}$, due to free or bonded (with water) P=O rises in its place. The shift of frequency between the two bands amounts to 70 $cm^{-1}$ and this fact suggests the strong complex formation between P=O and uranyl nitrate.

The triplet band assigned to P–O–C group at 1058, 1027 and 998 $cm^{-1}$ also shows a similar appreciable change with dilution. As uranyl nitrate content in the TBP phase increases, the intensity of the band at 1058 $cm^{-1}$ increases

5) H. Kamiyama, unpublished.
6) D. G. Tuck, *J. Chem. Soc.*, **1958**, 2783.
* Miller et al. mentioned that the ionic nitrates of alkali metals illustrates the point group $D_{3h}$, where the strong nitrate asymmetrical stretching frequency is centered in the region of 1380 $cm^{-1}$ and no splitting occurs. F. A. Miller and C. H. Wilkins, *Analyt. Chem.*, **24**, 1253 (1952).

and one at 998 $cm^{-1}$ decreases, whereas one at 1027 $cm^{-1}$ shows little change. As in the case of TBP-nitric acid system, the change of P–O–C band may be directly related to the complex formation at P=O.

The intensities of bands at 1521, 1275, 1234 and 940 $cm^{-1}$ are roughly proportional to the uranyl nitrate content. The band at 940 $cm^{-1}$ is assigned to the uranyl group[7]. According to Ferraro, the former two bands are assigned to $NO_2$ asymmetric and symmetric stretching of covalent nitrate, respectively[8]. The assignment of the band at 1234 $cm^{-1}$ is not clear at present.

**TBP-Uranyl Nitrate-Nitric Acid System.**—It is known that when uranyl nitrate is extracted from an aqueous solution of nitric acid by TBP, the extraction peak of uranyl nitrate appears at nitric acid concentration of 5~6 mol./l. in the aqueous phase. As an illustration, the result obtained by McKay is shown in Fig. 5[9]. The existence of such a peak was concluded by Naito as the result of competition to form TBP complex between uranyl nitrate

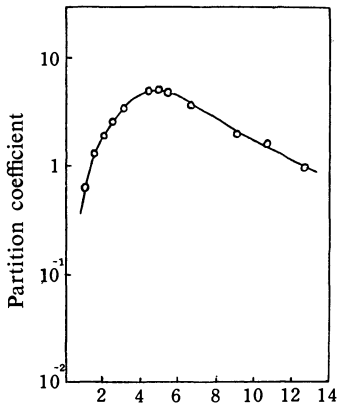

Fig. 5. Extraction of $UO_2(NO_3)_2$ by TBP. Kerosine is used as a diluent. (The original curve by H. A. C. McKay)

and nitric acid[2]. The mechanism of extraction was described as follows; in low nitric acid concentration the extraction of uranyl nitrate predominates over the extraction of nitric acid which serves merely as a salting-out agent, whereas the increase in nitric acid concentration promotes the extraction of nitric acid into the TBP phase with the progressive replacement of uranyl nitrate by nitric acid. This illustrates the existence of the peak in the extraction curve.

The mechanism obtained by the partition study was checked by the infrared spectroscopy as follows:

*Replacement of Nitric Acid by Uranyl Nitrate.*—Fig. 6 shows the infrared spectra in which the replacement of nitric acid by urany nitrate in TBP phase is demonstrated. The samples were prepared as follows: 5% carbon tetrachloride solution of TBP was shaken with aqueous solution of 5 N nitric acid containing uranyl nitrate of various concentrations (where the volume ratio of organic phase to the aqueous equals unity). After separating the organic phase from the aqueous phase, the former was used as a sample. The initial concentrations of uranyl nitrate in aqueous phase for samples No, 1, 2, 3 and 4 were 0.05, 0.1, 0.3 and 0.5 M, respectively.

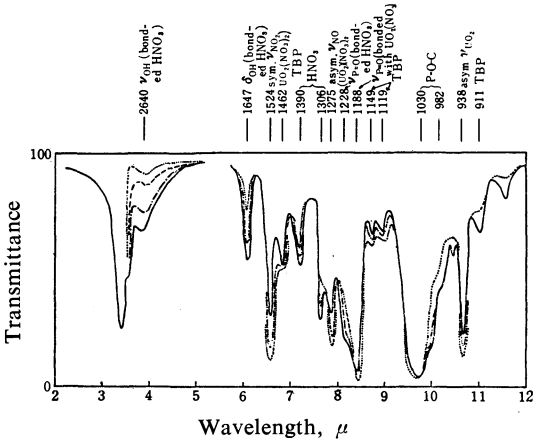

Fig. 6. Infrared spectra of TBP-$UO_2(NO_3)_2$-$HNO_3$ system. (a) Replacement of nitric acid by uranyl nitrate. Thickness: 0.1 mm.
—— No. 1 (Initial concentration of $UO_2(NO_3)_2$: 0.05 mol./l.)
·-·- No. 2 (Initial concentration of $UO_2(NO_3)_2$: 0.1 mol./l.)
---- No. 3 (Initial concentration of $UO_2(NO_3)_2$: 0.3 mol./l.)
····· No. 4 (Initial concentration of $UO_2(NO_3)_2$: 0.5 mol./l.)

In the spectra of Fig. 6, the bands at 1228 and 1188 $cm^{-1}$ are assigned to the P=O bonded with nitric acid and uranyl nitrate respectively as mentioned above. As going from sample No. 1 to No. 4, the intensity of the band at 1228 $cm^{-1}$ decreases and the one at 1188 $cm^{-1}$ rises in its place. At the same, the intensities of the bands at 1524, 1275 and 940 $cm^{-1}$, which are assigned to the vibrations of uranyl nitrate, increase and those of the bands at 2640, 1647, 1390 and 1306 $cm^{-1}$, which are assigned to the vibrations of nitric acid, decrease.

One can obviously observe from these facts that when going from sample No. 1 to No. 4, the concentration of uranyl nitrate in the TBP phase increases, while that of nitric acid decreases, and that all sites at the P=O group initially occupied by nitric acid are progressively replaced by uranyl nitrate.

*Replacement of Uranyl Nitrate by Nitric Acid.*— Fig. 7 shows the infrared spectra of samples in which nitric acid expels uranyl nitrate. The samples were prepared as follows: 5% carbon tetrachloride solution of TBP was shaken with an aqueous solution of uranyl nitrate (0.05 M) containing nitric acid of various concentrations (where the volume ratio of the organic phase to the aqueous one equals unity). The initial concentrations of nitric acid in aqueous phase of sample No. 1, 2 and 3 are 2, 6 and 12 mol./l., respectively.

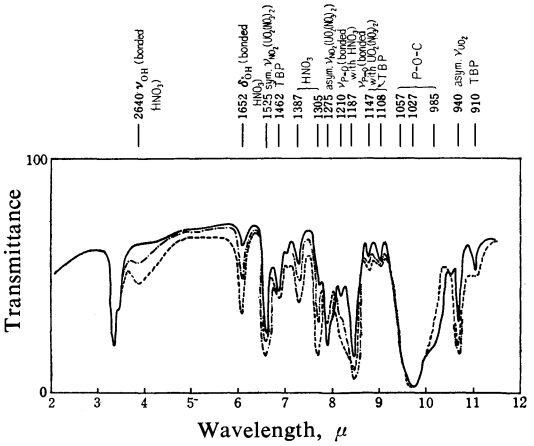

Fig. 7. Infrared spectra of TBP-$UO_2(NO_3)_2$-$HNO_3$ system. (b) Replacement of uranyl nitrate by nitric acid. Thickness: 0.1 mm.
—— No. 1 (Initial concentration of $HNO_3$: 2 mol./l.)
·–·– No. 2 (Initial concentration of $HNO_3$: 6 mol./l.)
---- No. 3 (Initial concentration of $HNO_3$: 12 mol./l.)

When going from sample No. 1 to No. 3, the intensity of the band at 1210 $cm^{-1}$ due to P=O bonded with nitric acid increases, on the other hand that at 1187 $cm^{-1}$ due to P=O bonded with uranyl nitrate shows a maximum in sample No. 2. At the same time, the intensities of the bands at 2640, 1652, 1387 and 1305 $cm^{-1}$, which are assigned to the vibrations of nitric acid, increase and those at 1525, 1275 and 940 $cm^{-1}$, which are assigned to the vibrations of uranyl nitrate, show a maximum at sample No. 2, except for one at 1275 $cm^{-1}$. The band at 1275 $cm^{-1}$ of sample No. 1 is overlapped with the band due to free or bonded (with water) P=O at 1275~1258 $cm^{-1}$, therefore this band only looks to be irregular.

Thus it is evidently seen from these facts that when going from sample No. 1 to No. 3 the concentration of nitric acid in the TBP phase increases monotonously, while that of uranyl nitrate shows a maximum in sample No. 2. Therefore the peak of extraction of uranyl nitrate from nitric acid solution appears at 5~6 M of nitric acid concentration in aqueous phase beyond which the sites of P=O occupied by uranyl nitrate are progressively replaced by nitric acid.

In conclusion, the above-mentioned infrared study confirms the competition between uranyl nitrate and nitric acid in TBP phase and is in good agreement with the result obtained by the partition study.

## Summary

The complex formation of TBP in the systems TBP-water, TBP-nitric acid, and TBP-uranyl nitrate was confirmed by means of infrared spectroscopy. The infrared spectra of uranyl nitrate in the system TBP-nitric acid-uranyl nitrate lead to the conclusion that the competition extraction of both uranyl nitrate and nitric acid takes place during the extraction process.

# *Effect of Temperature on the Viscosity and the Optical Rotation of Poly-ε-aminocaproyl-α-alanine**

By Mituo EBATA

(Received November 25, 1959)

An interesting property of the synthetic poly-ε-aminocaproyl-α-alanine, an reversible coagulation by heat in acidic or neutral aqueous solution, has been shown by Noguchi and his coworkers[1,2]. In the previous paper[3] the author reported, that the coagulated form of the polymer is much more susceptible than the dissolved form, to the action of trypsin. This fact has been explained by assuming some probable difference which might be present in the structure of both forms of the polymer, although the mechanism of the reversible heat coagulation was not yet clear. Thus, it is interesting to examine the effect of temperature on some physical property of this material, especially the rotatory dispersion for the estimation of the degree of folding of the polymer chain. The present paper deals with the results obtained from experiments on the viscosity and the optical rotation of the D, L- or L-alanine polymer under several temperatures.

## Experimental

The preparation method and some properties of poly-ε-aminocaproyl-D, L-alanine (M. W., 21,800) and poly-ε-aminocaproyl-L-alanine (M. W., 7,000) were described previously[3]. The polymer solution was prepared as follows: To 10 ml. of water 100 mg. of the polymer was added and the mixture was stood for over night. After filtration by a glass filter, polymer concentrations in the solution were determined by the method of Kjeldahl N-analysis. pH value of the solution was adjusted by adding 0.2 volume of M/15 phosphate buffer, if it was necessary, small amounts of N HCl or N NaOH were added.

The viscosity was measured by Ostwald's viscosimeter.

The optical rotation of the polymer was determined with the automatic recording polarimeter[4]. Measurements on the optical dispersion were made at a wavelength of 400, 437, 452, 471, 498, 527, 549 and 589.3 mμ; these were obtained from a tungsten lamp and filters except the last one which was the D line of sodium lamp. As sample tube of the polarimeter the capillary cells of 10 cm. in length were used. Temperature control of the polymer solution was carried out by varying the temperature on the water jacket of the sample tube.

## Results

The specific viscosity of the polymer was found in an acidic or alkaline media as shown in Fig. 1. A minimum value of the viscosity of the D, L-alanine polymer was found at 55°C in all cases, and was independent on pH and on the concentration of the polymer. The coagulation of the polymer occured at 40 and 50°C in curves I and II respectively, while no coagulation was found in the curve III owing to its high pH value of the medium. This indicates, therefore, that the result given by curves I and II at high temperatures might be meaningless. However, an analogous curve, curve III, was obtained by an

experiment in the heating process, even under no coagulable conditions. Another experiment in the cooling process agreed with that of the rising one. Curve III shows, that the polymer was transformed to a different type by heating as evidenced by the appearance of a minimum viscosity. The specific viscosity at 55°C in curve III was of a negative value. Thus negative values were often found in the specific viscosity measurement, when the concentrations of the polymer were low although the reason was obscure. Similar curves were also obtained with the viscosity of the L-polymer.

The effect of temperature on the optical rotation of poly-ε-aminocaproyl-L-alanine was studied. The specific rotation of the polymer in aqueous solution was a constant value between 15° to 50°C as shown in Fig. 2. A remarkable increase in *levo*-rotation was found by heating above 53°C. This increase in the rotation was completely reversible with heating and cooling. Addition of a large amount of salts, acids, alkalis and denaturating reagents such as urea did not induce an optical rotation change of the polymer at room temperature, and no coagulation by heat was observed.

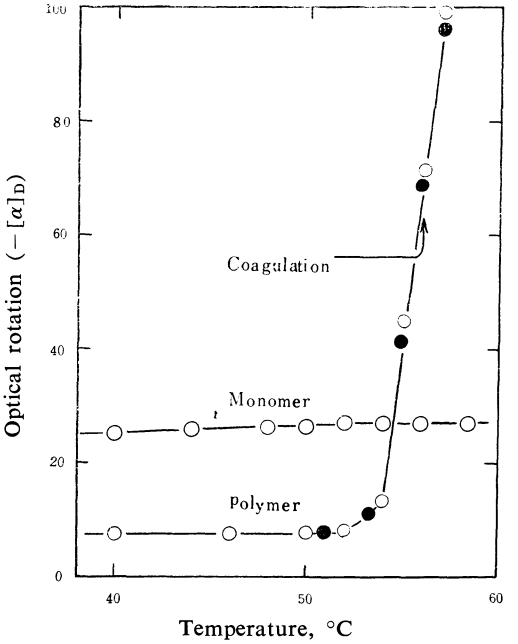

Fig. 2. Optical rotation of poly-ε-aminocaproyl-L-alanine.

●, Points obtained with temperature falling
Temperature, ±0.05°C

The rotatory dispersion of the polymer was measured in the aqueous solutions at several different temperatures. When the measurement was made on the solution, its rotatory dispersion was belived to be obeyed Drude's one-term equation, $[\alpha]_\lambda = k_c/(\lambda^2 - \lambda^2_c)$. Where $\lambda$ stands for the wavelength, $[\alpha]_\lambda$ for the specific rotation at $\lambda$, and $k_c$, $\lambda_c$ are the rotation constant and the dispersion constant, respectively. In the present experiment the constants were estimated from the data by the usual manner. The $\lambda_c$ values were 385 mμ (at 30°C), 345 mμ (at 53°C), 315 mμ (at 54°C) and 155 mμ (at 55°C) as can be seen in Fig. 3. No serious coagulation was found at 55°C under the conditions as shown in Fig. 2. Due to the appearance of coagulation, the reasonable value of $\lambda_c$ could not be estimated from the rotatory dispersion measured at 56°C.

## Discussion

The denaturation of protein is known to be accompanied by an increase in specific viscosity and *levo*-rotation and a shift of its $\lambda_c$ value to shorter wavelength[5,6]. The result on the polymer reported here clearly resembles this information. When the similarity between the protein and the polymer examined here is considered, it is suggested, that a mechanism analogous with protein denaturation might be presented in the nature of the coagulation of the present sample.

According to Doty's results[6,7], a high $\lambda_c$ value is a measure of the high helix content

of a protein molecule. It is therefore reasonable to assume that the polymer has probably a compact structure in aqueous solution at room temperature and the structure is unfolded by heating. Then, an interesting conclusion described previously[3] that, the coagulated form of the polymer is more susceptible than the dissolved form to the action of trypsin, can be explained by this assumption.

## Summary

Viscosity and optical rotation of a synthetic polymer, poly-ε-aminocaproyl-α-alanine, were studied connecting with the reversible heat coagulation. A minimum viscosity of the poly-ε-aminocaproyl-D, L-alanine solution was found at 55°C. Heating of the poly-ε-aminocaproyl-L-alanine solution produces an increase in its *levo*-rotation and a shift of its dispersion constant ($\lambda_c$ value) to shorter wavelength. The mechanism of the reversible heat coagulation of the polymer was discussed to be based on the obtained result.

# *Quantitative Spectrochemical Analysis of Minor Elements in Silicates with Double Internal Standards*

By Hiroshi HAMAGUCHI, Rokuro KURODA and Ryokichi NEGISHI

(Received December 3, 1959)

The spectrochemical procedures for determining a number of traces of elements in silicate rocks involve some difficult problems. The fact that many of the geochemical studies on the minor elements in the lithosphere have been carried out with a semiquantitative scheme, may be, in part, attributed to the troublesome problems associated with the accurate simultaneous determination of minor elements in silicate rocks. The main difficulty arises from the different rates of volatilization of the elements from the electrode cavity into the arc column.

Ahrens[1] divided the minor elements into two groups, i. e. volatile and involatile group. For the elements of the volatile group which complete their distillation before or at the same time that the alkali metals complete theirs, Ahrens suggested a general arcing procedure with or without an internal standard. In the former case indium has been chosen as the internal standard for its volatility, satisfactory excitation properties and its extremely low concentration in most silicates. For the involatile group that includes all elements which emit their maximum line intensity after the main phase of alkali metal distillation has subsided, one part of the sample was buffered with two parts of carbon powder containing palladium as the internal standard and the mixture was completely distilled with 7 amp. d. c. carbon arc. Shaw[2] employed the total energy method for determining about 19 minor elements in silicate rocks. He also divided the subject elements into two groups according to the volatility difference of the elements, as was done in the case of Ahrens.

These schemes of quantitative spectrochemical analysis are rather tedious and even without the internal standard two arcing procedures are needed. The selection of suitable internal standards, buffer and excitation conditions may eliminate the necessity of separate arcing for volatile and involatile group. An attempt was made to determine the minor elements differing much in the volatilization rates, i. e. lead, gallium, tin, chromium, vanadium, cobalt, nickel and scandium in silicates in a single arcing procedure by using double internal standards. As a result a method was established without serious loss of precision and with reasonably high sensitivities.

## Experimental and Results

**Equipment and Procedure.**—To establish the procedure the densitometric and the logarithmic sector method were used. Although the logarithmic sector method is rather obsolete, some special advantages are obtained by this method. The intensity ratio of subject to internal standard lines is generally independent of conditions of exposure, slit width, development and plate calibration. The time required for the analysis is shortened by a factor of 2 or 3, compared with the densitometric method. No expensive densitometer is necessary.

Equipment and excitation conditions are listed in Table I for both calibrating methods.

**Standard, Internal Standard and Buffer.**—As the object for analysis is naturally occurring silicates, the general chemical composition and physical

properties of the standards should approximate as closely as possible those of the unknown ones. Thus, a potash feldspar was used as a base material of the standards for nickel, chromium, cobalt and scandium. It was also possible to use a serpentinite and two specimens of granite as the base materials for lead, gallium, tin and vanadium. Since traces of gallium were apparent on the granite-base material, the granite was analyzed for gallium fluorometrically (Sandell)[3] and a correction was made for the residual impurity of gallium.

For the simultaneous determination of elements with the arc excitation, it is essential to volatilize all elements in approximately the same rate from the electrode cavity. The addition of carbon causes the elements of widely different volatilities to evaporate simultaneously. Though it would be possible to suppress considerably the selective volatilization with the addition of a large amount of carbon, some loss of sensitivities will result in general. In the present work 1 : 1 ratio of carbon to each of standard and sample was selected to maintain the highest sensitivities for most elements. In the presence of such a small amount of carbon buffer the choice of internal standard is highly critical. Consequently, two internal standards were used to assure the similarity in volatilization rates for the selected pairs of subject and internal standard elements; antimony(III) oxide for the elements of volatile group i. e., lead, tin and gallium, and palladium black for the elements of involatile group i. e., nickel, cobalt, chromium, vanadium (and scandium). The carbon powder as the buffer was previously well mixed with antimony-(III) oxide and palladium black to give the concentrations 0.80 per cent for antimony(III) oxide and 0.04 per cent for palladium Selected internal standard and analysis lines are listed in Table II with their excitation potentials and analysis ranges.

**Procedure for Constructing Working Curves.**— To one part of the final standard one part of the carbon powder prepared as described in the previous section is added and the mixtures are excited according to the analytical conditions listed in Table I. The spectrograms are recorded on Fuji Process Hard plate. The plate is developed for 3 min. in Fuji FD 31 developer, placed in a 3% acetic acid stop bath for 30 sec., and fixed in Fuji Fixer for 5 min. After washing for 20 min. with running water, the plate is air-dried.

In the case of the densitometric method, the intensity ratios of analysis pairs were obtained by a self-calibrating method. The working curves are

* Sx is the standard deviation of log concentration of a sample for its single analysis.

prepared by plotting the logarithm of the intensity ratios against the logarithm of the concentrations of the elements. Typical results are shown in Figs. 1 and 2.

In the case of the logarithmic sector method, the ratio of intensities between two lines is measured by their difference in lengths. The working curves are obtained in the same manner as by the densitometric method. A typical working curve is shown in Fig. 3.

The procedure for sample analysis is almost the same as that for the standards.

**Precision.**—The precision of the methods was evaluated from the working curve data and from the standard diabase W-1 (U. S. Geological Survey) analysis, following the treatment of the statistical method described by Shaw and Bankier[4]. The results are listed in Table III. As tin and lead were not detected in the standard diabase W-1, a gneiss and a potash feldspar were analyzed instead of the standard W-1.

## Discussion

The procedure presented could be extended to cover further species of minor elements except for extremely involatile elements, e. g., rare earth elements.

To check the accuracy of the methods, the ranges previously reported and the recommended values concerning the contents of minor elements in the standard diabase W-1 are also listed in Table III. Satisfactory agreement is observed with the recommended values by Ahrens except for cobalt, nickel and scandium.

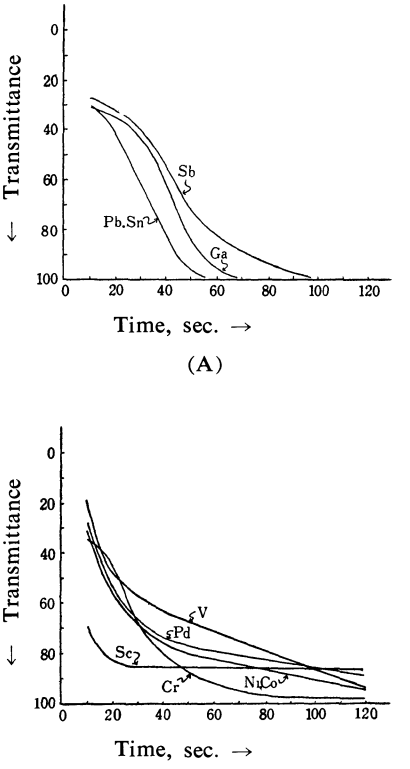

Fig. 4. Volatilization curves for the elements of valatile and involatile groups.
A: Volatile group
B: Involatile group

4) D. M. Shaw and J. D. Bankier, *Geochim. et Cosmochim. Acta*, 5, 111 (1954).

Smales[5] has found the values 54, 52, 50, 46, 46, 45 p. p. m. Co for the W-1 with the radioactivation method of analysis which may be regarded at present as the most reliable tool for the trace analysis. The present figure for cobalt agrees rather well with the values obtained by Smales. The nickel content of the W-1 was also obtained by Smales, who gave the values of 78, 78, 76, 73, 71, 63, p. p. m. Ni. The recommended value for nickel might be somewhat higher. The present figure for scandium is remarkably high and probably in error. The cause may be attributed to the matrix effect depending on the difference in chemical composition between the potash feldspar used as a base material for the standards and the analyzed diabase W-1. The analysis line Sc II 3613.836 is an ionic line having high excitation potential (10.1 eV.) and its intensity may be largely suppressed in the low temperature arc prevailing in the excitation of the alkali-rich feldspar. The low temperature arc also accelerates the selective volatilization of scandium remarkably, as illustrated in Fig. 4. For other elements the matrix effect may not be remarkable, as judged from the comparison of given data with the recommended value by Ahrens in Table III. The matrix effect on scandium can be completely eliminated by the addition of a large amount of carbon buffer, at least three times the weight of each standard and sample, as pointed out previously by Hamaguchi and coworkers[6]. The requirement for the establishment of highly sensitive methods obliges us to compromise with a 1 : 1 weight ratio of each standard or sample to the carbon buffer. Under this circumstance the volatilization trends of the subject and the selected internal standard elements are illustrated in Fig. 4. Reasonably parallel volatilization trends are found for the pairs of the subject element and its internal standard. However, the volatilization curve for scandium differs significantly from that for palladium, as described previously.

Using the medium type spectrograph, available analysis lines are limited because of the rather complex spectrum of silicate rocks. Especially, highly sensitive analysis of tin is practically impossible owing to the coincidence of its sensitive lines with interfering lines. The entire coverage of concentration range of chromium encountered in silicate rocks is also impossible even with the utilization of several spectral lines. Thus the establishment of procedure for chromium and tin with the medium type spectrograph was not attempted.

## Summary

Two internal standards have been used in the spectrographic analysis of silicates, antimony(III) oxide for volatile elements and palladium black for the involatile group. The former was used as the standard for the determination of gallium, lead and tin, and the latter for the determination of nickel, cobalt, chromium, vanadium and scandium. A medium spectrograph is not suitable for the determination of chromium or tin, and scandium did not volatilize in a manner parallel to the palladium but it was possible to obtain reasonable results for the other elements.

# *The Transition Polymerization of Acrylamide. I. On the Polymerization Condition and the Property of Polymer**

By Naoya OGATA

(Received November 27, 1959)

Generally, amino acid tends to cause an intermolecular condensation reaction between two molecules to form a ring compound and almost never makes linear polyamide by heating. It was reported by Breslow[1] that acrylamide was polymerized into poly-β-alanine (Nylon 3) of high degree of polymerization in the presence of an alkali catalyst and an inhibitor of the vinyl polymerization. The polymerization proceeds through the transition of an amide hydrogen to a double bond of acrylamide and can be designated as the transition polymerization.

$$n\mathrm{CH_2{=}CHCONH_2} \rightarrow [-\mathrm{CH_2CH_2CONH}-]_n$$

The condition of polymerization and the property of the polymer have been investigated in this study.

## Experimental

**The Effect of Solvent.**—Acrylamide was dissolved in various solvents at the concentration of 10% and the solution was heated at 115°C for 2 hr. in the presence of 1/32 mol./mol. of sodium-*tert*-butyrate and 0.02% of phenyl-β-naphthylamine. Polymer precipitated gradually from the solution after the addition of catalyst and adhered massively to the wall of a reaction vessel or a stirrer. Polymer was extracted with water for an hour and the weight of water-soluble and water-insoluble polymer was determined. The relative viscosity of the polymer was determined for 1% solution in 98% sulfuric acid. Polymer was hydrolyzed by sulfuric acid and the qualitative and quantitative analyses of β-alanine were carried out by paperchromatography, using a mixed solvent of *n*-butanol/ammonia =80/20 as a developer. These results are shown in Table I.

The yields of polymer are larger in the solvents of lower dielectric constant and in aromatic solvents than in aliphatic solvents. The polymerization hardly ever occurs in the solvents with active hydrogen, such as alcohol, amine or amide.

In the case of a *N*-substituted amide such as dimethylformamide or dimethylacetamide, the polymer was obtained in the form of suspension in spherical particles of about 100 μ diameters.

**The Concentration of Monomer and Inhibitor.**—Acrylamide was dissolved in pyridine at various concentrations and the solution was heated in the presence of sodium-*tert*-butyrate. The yield and the relative viscosity of polymer was largest at 10% monomer concentrations, as shown in Table II.

The quantity of an inhibitor of the vinyl polymerization, such as hydroquinone or phenyl-β-naphthylamine, does not necessarily affect the yield of the polymer, and poly-β-alanine is obtained without such inhibitors. These results are shown in Table III.

Contamination of water in the solvents decreases the yield of polymer and the vinyl polymerization occurs in the presence of more than 1% of water in the solvents, as shown in Table IV.

**The Effect of Catalyst.**—The catalytic effect of several alkali compounds was investigated in chlorobenzene at 10% monomer concentrations, which is shown in Table V. The yield of polymer is largest for tertiary alkoxide and the catalytic effect of alkali metals is in the order of K>Na>Li.

The yield of the polymer is approximately in proportion to the square root of the concentration of the catalyst, while the relative viscosity of the polymer does not change markedly, as shown in Table VI and Fig. 1.

**The Rate of Polymerization.**—The rates of polymerization of acrylamide were determined in various solvents at 10% monomer concentrations in the presence of 1/32 mol./mol. of sodium-*tert*-butyrate and 0.02% of phenyl-β-naphthylamine. These

results are shown in Tables VII—XII.

**The Property of Polymer.** — *i) Melting Point.*— The melting point of water-soluble and water-insoluble polymer was determined in the nitrogen atomosphere in an electric heater, which was 330°~335°C.

*ii) Infrared Spectrum.*—The infrared spectrum of water-soluble and water-insoluble polymer was determined with KBr disc. by Hitachi spectrophotometer IR II. The characteristic absorption band (Amide II band) of a monosubstituted amide appears at 6.5 $\mu$ and no absorptions due to ethylenic double bond appear in comparison with the spectrum of polyacrylamide, which is shown in Figs. 2—5.

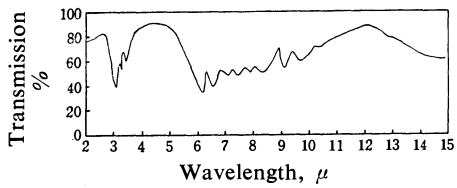

Fig. 2. The infrared spectrum of water-insoluble poly-$\beta$-alanine, which is obtained in chlorobenzene at 115°C for 30 min. (KBr disc).

*iv) Solubility of polymer.*—The solubility of the polymer in various solvents at 25°C is shown in Table XIII. Anhydrous formic acid containing 5% of calcium chloride is a good solvent for poly-β-alanine.

## Discussion

The conversion curve of acrylamide to water-soluble poly-β-alanine shows a maximum, while the yield of water-insoluble polymer increases with time after a short induction period. The total yield of water-soluble and insoluble polymer is not affected so much with time. The final yield of water-insoluble polymer increases as the reaction temperature becomes higher. Therefore, it is expected that the transition reaction of acrylamide to poly-β-alanine occurs very rapidly as soon as a catalyst is added and then the growth of polymer follows slowly.

It is assumed that the transition of an amide hydrogen may be hindered in the solvents with active hydrogen, as the yield of polymer decreases with the amount of active hydrogen of the solvents. The alkoxide ion may decompose in the solvents with active hydrogen, as follows:

$$RO\text{–}Na+H\text{–}X \rightleftarrows ROH+Na\text{–}X$$

It is expected that the transition polymerization may proceed at first through the addition of alkoxide ion to acrylamide, because no absorptions due to double bond appear in the infrared spectrum of water-soluble polymer which is obtainded at the initial stage of the reaction.

The reaction mechanism will be proposed in a later paper, and the further investigation on the property of polymer and the application to fiber or plastics is now being carried out.

## Summary

The polymerization condition for the transition polymerization of acrylamide to poly-β-alanine has been investigated in the presence of alkali catalyst. The catalytic effect of alkali catalysts is largest for tertiary alkoxide and that of alkali metals is in the order as K>Na>Li. The yield of polymer is larger in the solvents of lower dielectric constant and in aromatic solvents than in aliphatic solvents. The polymerization seldom occurs in the solvents with active hydrogen. The property of the polymer has also been investigated.

The author wishes to express his gratitude to Dr. K. Hoshino and Dr. H. Kobayashi for their instructions and permissions to publish this study, and he also thanks Mr. K. Sugii for his assistance in experiments.

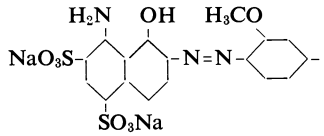
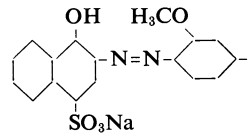
# *Absorption Spectra of Dyes. VI.*[1] *Steric Effects in Conjugated Systems of Benzidine Disazo Dyes and their Copper Derivatives*

By Teruaki KOBAYASHI, Yoshié TANIZAKI and Noboru ANDO



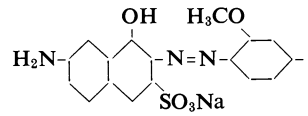
(Received December 25, 1959)

The first absorption bands of dyes are considered to be due to the longest conjugated systems connected with auxochromes, and as is well known, their intensities are the highest when these systems are coplanar. For examples, $\varepsilon_{max}$ of the first absorption band of Benzopurpurine 4B in methanol is 55,000, compared with 42,000 for that of meta-Benzopurpurine[2]. The case is the same with Congo Red. The corresponding value of it in ethanol is 54,000, while there can always be seen remarkable reductions in those of its dimethyl, dichloro and dibromo derivatives, which are prepared with the substituents introduced into the 2- and the 2'-positions of the diphenyl nucleus[3]. Such a decrease in intensity should apparently be caused by steric effects of the substituents. The same phenomena are also found for other dyes: Chlorazol Sky Blue FF has $\varepsilon_{max}$ of 100,000, compared with 74,000 for Direct Sky Blue 5B which is different from the former only in positions of sulfonic groups. Further, their copper derivatives have weaker intensities. Such difference in intensity also seems to be caused by steric effects.

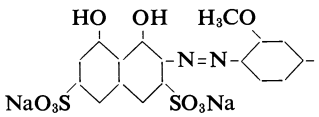


In previous works of this series, absorption spectra of dyes under various conditions have been studied mainly with respect to their first absorption bands, in order to see how they vary with aggregation or formation of complexes. In this paper, absorption spectra in aqueous solutions of both benzidine disazo dyes such as Chlorazol Sky Blue FF and their copper derivatives have been studied in connection with their stereochemical forms and steric hindrances.

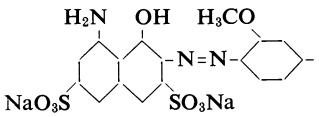
## Experimental



**Preparation of Samples.**—The following dyes were used in the present work. They will be called the abbreviations shown in the parentheses.

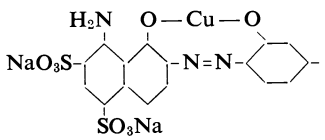


(Dye I)



(Dye II)

(Dye III)



(Dye IV)

(Dye V)

Where the halves of their structures are shown. Their copper derivatives will be called Dye I', Dye II', etc., corresponding to each of them. These copper derivatives are known to have the following structures[4]; e. g., Dye I' is

(Dye I')

Dye I—Dye V were purified by Robinson and Mills' method[5]. The copper derivatives were prepared from these dyes by a method reported elsewhere.[4],*1 The purification of them followed the above method. Found values of copper contents of Dye III' and Dye V' were 90% and 86%, respectively*2. The concentrations of dye solutions were $(1\sim130)\times10^{-6}$ mol./l., which were determined by weight.

**Absorption Spectra.**—All the absorption spectra were measured in 0.2 to 10 cm. cells by a Shimadzu QR-50 spectrophotometer at room temperature (ca. 20°C).

## Results

The absorption spectra of Dye I and Dye I' and of Dye V and Dye V' are illustrated as

examples in Figs. 1 and 2 respectively, in which the full lines mean the results of Dye I and Dye V and the dotted lines those of Dye I′ and Dye V′. Inspection of them shows that the absorption intensity of Dye I is high compared with that of Dye V, and the copper derivatives have remarkably decreased intensities. The same phenomena are observed for the other dyes. In order to investigate these changes in spectra in more detail, $\lambda_{max}$, $\varepsilon_{max}$ and oscillator strengths of the first absorption bands of the dyes are shown in Table I. Variation of the concentrations of these dyes over a wide range revealed that $\lambda_{max}$, $\varepsilon_{max}$ and the shapes of their first bands all vary with concentrations: e. g., results of Dye IV′ are shown in Fig. 3. Therefore, the values in Table I correspond only with the respective concentrations shown in the same table and

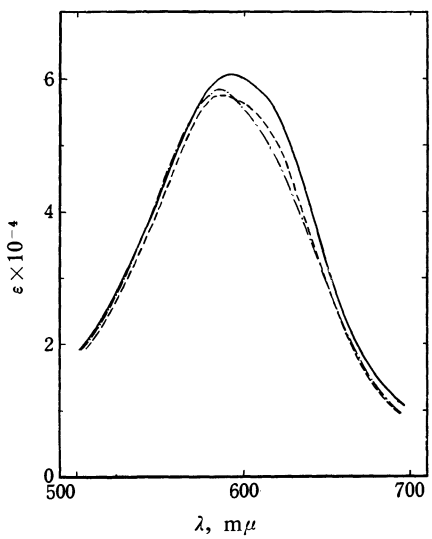

Fig. 3. Absorption spectra of Dye IV′ in aqueous solution at room temperature.
—— $1.01\times10^{-6}$ mol./l.
---- $1.01\times10^{-5}$ 〃
-·-· $0.87\times10^{-4}$ 〃

will somewhat vary with concentrations*3. Oscillator strengths $f$ were calculated by[6]

$$f=4.31\times10^{-9}\int\varepsilon_\nu d\nu$$

As the calculation was carried out for the absorptions longer than 460 m$\mu$ because their train in short wavelengths were obscure, the values are not true ones. However, they will at least satisfy the purpose of mere mutual comparisons. The molecular extinction coefficients and the oscillator strengths of the copper derivatives were distinguished by the suffix c as $\varepsilon_c$ and $f_c$ from those of the non-copper dyes. The table shows that

1. The absorption intensity of Dye I is the highest of all.
2. All the intensities of the dyes are decreased by the introduction of copper into them. The relative order of the percentage decrease in intensity is

Dye I$\approx$Dye II$>$Dye III$>$Dye IV$>$Dye V

The copper derivatives have nearly equal intensities to one another, except Dye II'

3. $\lambda_{max}$ of each dye shifts somewhat to shorter wavelengths by the introduction of copper*4.

## Discussion

As shown in the previous section, the intensities of the first absorption bands of Dye I—Dye V all decrease by the introduction of copper. Comparison of the intensities of Dye I, Dye IV and Dye V which have similar structures to one another shows that while Dye IV and Dye V have nearly equal values, Dye I has a very large one relative to them. If the first absorption bands of these dyes are due to the conjugated double bond chains connecting their auxochromes, they should be the same with one another, because they have the same conjugated chains and auxochromes. The difference in the structures of the dyes is found in positions of sulfonic groups. It should reasonably be considered that the difference in intensity was caused not by the difference in auxochromic effects of the sulfonic groups due to their positions on the naphthalene rings, but rather by their steric effects. On the other hand, the strain in a conjugated system generally causes a decrease in absorption intensity*5. Some of the present results seem to be the case: the intensity of Dye IV or Dye V, which has sulfonic groups in the positions adjacent to the azo groups is remarkably weak compared with that of Dye I which has sulfonic groups in the positions far from the azo groups. Consequently, it would be proper to discuss the experimental results with respect to the positions of sulfonic groups from the stand point of steric effects.

If the dyes are of coplanar structures, scale drawings give conformations as in Fig. 4, in which the halves of the structures of Dye I, Dye II and Dye V are shown. The figure clearly shows that a repulsion between the sulfonic group and the unshared electrons of N may be anticipated in Dye V, but not in

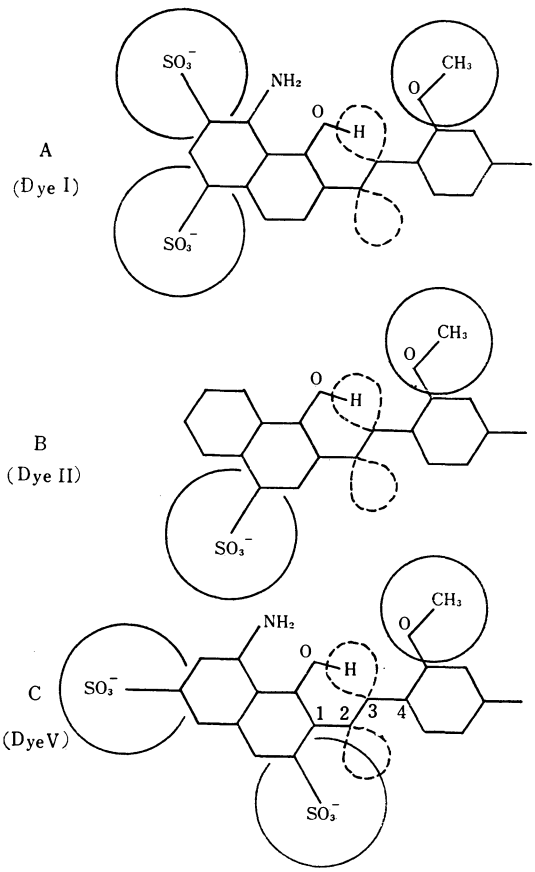

Fig. 4. Models of Dye I, Dye II and Dye V.

*3 The first absorption band of Dye III' varied remarkably with changes in outside conditions and time from preparation of its solutions till measurements. Hence, its values in Table I are less valid.

6) W. West, "Technique of Organic Chemistry", Interscience Publisher, New York (1956), Vol. IX, p. 66.

*4 The first absorption bands of these dyes are considered to be composed of two bands [Y. Tanizaki, T. Kobayashi and N. Ando, This Bulletin, 32, 119 (1959)]. In fact, their behaviors are complicated, apart from variations owing to changes in concentrations. This leads us to difficulty in our exact investigation of their behaviors.

*5 It is not always easy to predict whether absorption bands are shifted to red or blue by steric hindrances. Recently Dewar has discussed the relationship between noncoplanarity of cyanine dyes and shifts of wavelengths of their absorption (M. J. S. Dewar, "Steric Effects in Conjugated Systems", Proceedings of a Symposium held at the University, Hull, 1958, by the Chemical Society (Butterworths, London, 1958), p. 46).

Dye I and Dye II*6. Hence, Dye V (also Dye III and Dye IV) seems to be less planar relative to Dye I (or Dye II) because of the repulsion owing to the sulfonic group. Propriety of this expectation is proved by the fact that $\varepsilon_{max}$ of Dye I is 100,000, compared with 74,000 for that of Dye V which has the same structure as Dye I except the positions of the sulfonic groups.

Now, let us suppose simply that in such a dye as Dye V the repulsion by the sulfonic group only results in twist of the 1–2 bond (see Fig. 4C). Then, owing to the bond twist, the repulsion between the sulfonic group and the unshared electrons of N in position 2 (N(2)) will decrease, whereas the one by the unshared electrons of N(3) will increase. The exchange integral of the 1–2 bond also changes. Hydrogen of the auxochrome OH is generally considered to form a hydrogen bond with N(3), hence the energy of the bond will also change with the twist. On the basis of such consideration, an approximate calculation of the change in energy of the molecule with the twist will be performed.

The change of the exchange integral of a bond with twist has already been studied[7]. According to this procedure, the exchange integral of the 1–2 bond is expressed by

$$V_1(\theta)=\beta S(R)\cos\theta/S(1.39) \quad (1)$$

$$\frac{S(R)-S(1.47)}{S(1.40)-S(1.47)}=\cos\theta \quad (2)$$

where $S(1.39)$, $S(1.47)$, $S(1.40)$ and $S(R)$ are the $\pi$–$\pi$ overlap integrals of the C–C bond of benzene, the normal C–N single bond, the conjugated C–N bond of azobenzene and the 1–2 bond when its length is $R$ corresponding to the angle of twist $\theta$, respectively. These values can be obtained from Mulliken's Table[8].

The repulsion between the charges on the sulfonic group and of the unshared electrons may roughly be estimated, if the center of the charge on the sulfonic group is approximately taken at the point where the extension of the C–S bond crosses the plane decided by the three oxygen atoms, and the distance between this point and the center of the unshared electrons (1.2 Å from the nitrogen nucleus) is taken as that between the two charges, though the effective charges spread widely. Let us put $a_S e$ and $a_N e$ (where $a_S$ and $a_N$ are numerical constants) as the effective charges, with $a_S a_N = a$, and the repulsive energy is expressed by

$$V_2(\theta)=ae^2\{1/r_2(\theta)+1/r_3(\theta)\} \quad (3)$$

where $r_2(\theta)$ and $r_3(\theta)$ are the distances between the sulfonic group and the unshared electrons of N(2) and N(3) respectively.

As mentioned above, the auxochrome OH is considered to form a hydrogen bond with N(3). If the energy of the hydrogen bond O–H···N is approximately estimated to be −5 kcal. and is assumed to be electrostatic, it becomes

$$V_3(\theta)=-2.45/r(\theta) \quad (4)$$

where $r(\theta)$ means the distance between hydrogen and the unshared electrons.

On putting $V(\theta)=V_1(\theta)+V_2(\theta)+V_3(\theta)$ (5)

the change in energy of the molecule becomes

$$\Delta V(\theta)=V(\theta)-V(0)$$

Fig. 5 illustrates $\Delta V(\theta)$-$\theta$ curves, which were drawn by use of various values of $a$ appeared in Eq. 3. As $a$ relates mainly to the effective charges of the sulfonic group and the unshared electrons, it would not exceed two. Although the above calculation is quite simple, the appearance of minima in the curves in a certain range of $a$ suggests that the molecule becomes stable when the 1–2 bond was twisted by 50° to 60° on account of the repulsion. This coincides with the result that the absorption intensity of the dyes in which a sulfonic group is adjacent to the C–N bond is remarkably weak compared with that of the dye which has no such sulfonic group.

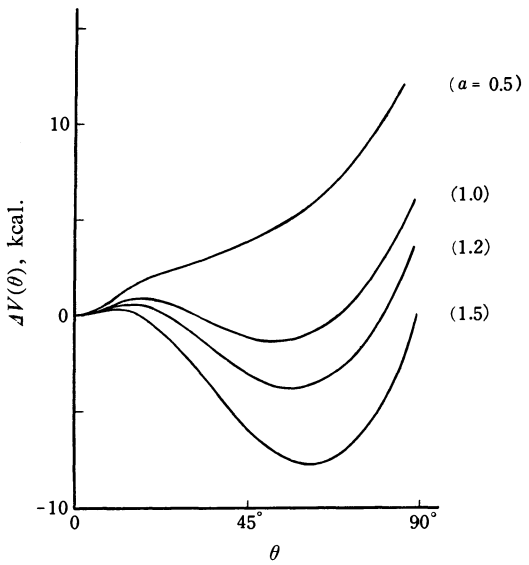

Fig. 5. The change in energy of the sterically hindered dyes with the angle of twist.

*6 The steric effect of unshared electrons of N has been discussed concerning phenyl-azo-azulene, and a reasonable result has been obtained [F. Gerson, T. Gäumann und E. Heilbronner, *Helv. Chim. Acta*, **41**, 1481 (1958)].

7) H. Suzuki, This Bulletin, **25**, 145 (1952); **27**, 597 (1954).

8) R. S. Mulliken, C. A. Lieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

Copper derivatives of *o*, *o'*-dihydroxy-azo-compounds or of similar compounds have been studied by many workers[9-11], but little is known about their stereochemical forms. In general, coplanar structures seem to be adopted[9], whereas a structure in which a copper atom is centralized on the –N=N– double bond is also considered[11]. Consequently, the stereochemical forms of the dyes studied in the present work are not yet clear.

Absorption spectra of copper derivatives of this kind have also been measured. Inspection of them reveals that intensities of their first bands are generally weak or equal as compared with those of the non-copper substances, without showing any tendency to increase. All of the present copper derivatives have decreased intensities, as mentioned in the previous section, and further a certain tendency was observed in the decrease in intensity: the decrease in intensity of the copper derivative of Dye V (or Dye IV or Dye III) which seems to have a strained conformation was slight, compared with the very remarkable one of the copper derivative of Dye I (or Dye II) which is considered to have a relatively planar conformation. Further the absorption intensities of the copper derivatives are nearly equal to one another. These results prove a great possibility that copper derivatives may have strained conformations.

## Summary

1. Absorption spectra of benzidine disazo dyes and their copper derivatives in aqueous solution were measured at room temperature, and they are compared with one another.

2. It was shown by a simple calculation that the dyes, each of which has sulfonic groups adjacent to the azo groups, have strained conformations caused by the repulsion between the sulfonic groups and the unshared electrons of nitrogen. It was also shown that the relationship between the relative positions of sulfonic groups to the azo groups and the relative absorption intensities could well be explained.

3. The absorption intensities of the copper derivatives were nearly equal, having no relation to the positions of the sulfonic groups, and in addition they were near to those of the non-copper dyes which have the sulfonic groups adjacent to the azo groups. Hence, it was pointed out that the introduction of copper caused the same extent of strain in conjugated systems as sulfonic groups did.

The authors wish to express their thanks to Mr. Yoshiji Ishii of the Gumma University for his kind present of some of the dyes.

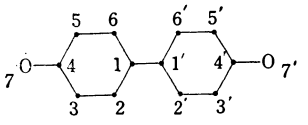
# $\pi$-Electronic Structure of Diphenoquinone

By Akira KUBOYAMA

(Received January 11, 1960)

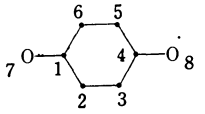
In previous papers the $\pi$-electronic structures of *p*-quinones[1] (*p*-benzoquinone, $\alpha$-naphthoquinone and anthraquinone) and *o*-quinones[2] (*o*-benzoquinone, $\beta$-naphthoquinone and phenanthrenequinone) were studied by the aid of the simple LCAO MO method, with good agreement between the calculated and experimental results concerning the near UV absorption bands of these quinones. In the present paper, it is undertaken to carry out a similar study on the $\pi$-electronic structure of diphenoquinone*, the spectroscopic feature of which has never been theoretically studied.

## Method of Calculation



As the molecular dimension of diphenoquinone(DQ) has never been known, it is

1) A. Kuboyama, This Bulletin, 31, 752 (1958).
2) A. Kuboyama, ibid., 32, 1226 (1959).



* C. A. Coulson has studied the bond orders of diphenoquinone [*Trans. Faraday Soc.*, 42, 106 (1946)].

impossible to calculate the overlap integrals necessary for the evaluation of exchange integrals ($\beta_{ij}$). Therefore, the values of exchange integrals as well as of Coulomb integrals ($\alpha_i$) were determined by referring to the corresponding values for *p*-benzoquinone(BQ)[1]. The values of these integrals eventually used for the present calculation are shown in Chart I. As it was expected that owing to the steric hindrance between hydrogen atoms at the 2, 6-positions and at the 2′, 6′-positions, two six-membered rings of DQ are somewhat twisted together around the $C_1$–$C_{1'}$ bond, the adopted value for $\beta_{11'}$ was a little smaller than that for $\beta_{23}$.

Chart I. Values of exchange and Coulomb integrals

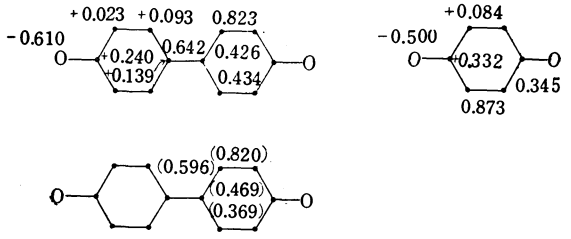
$\alpha_7=\alpha+1.3\beta$,
$\alpha_4=\alpha+0.2\beta$,
$\alpha_1=\alpha_2=\alpha_3=\alpha$,
$\beta_{47}=\beta_{23}=\beta$,
$\beta_{11'}=0.9\beta$,
$\beta_{12}=\beta_{34}=0.8\beta$

$\alpha_7=\alpha+1.3\beta$,
$\alpha_1=\alpha+0.2\beta$,
$\alpha_2=\alpha$,
$\beta_{17}=\beta$,
$\beta_{12}=0.8\beta$,
$\beta_{23}=1.1\beta$

## Results

The molecular diagrams are given in Charts II and III, together with those of BQ.

Chart II. Charge densities and bond orders



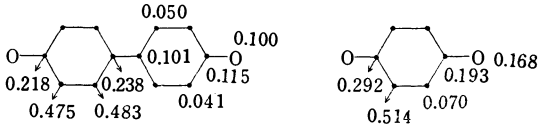


Chart III. Free valences and unpaired electron densities

In these diagrams, the unpaired electron densities are the squares of the coefficients of atomic orbitals in the lowest unfilled orbital. The bond order values of DQ in parentheses are those obtained by Coulson**. The orbital

** In the calculation*, the adopted integral values are as follows. $\alpha_7$ and $\beta_{47}$ are respectively $\alpha+2\beta$, $2\beta$ and the other Coulomb and exchange integrals are all $\alpha$ and $\beta$, respectively.

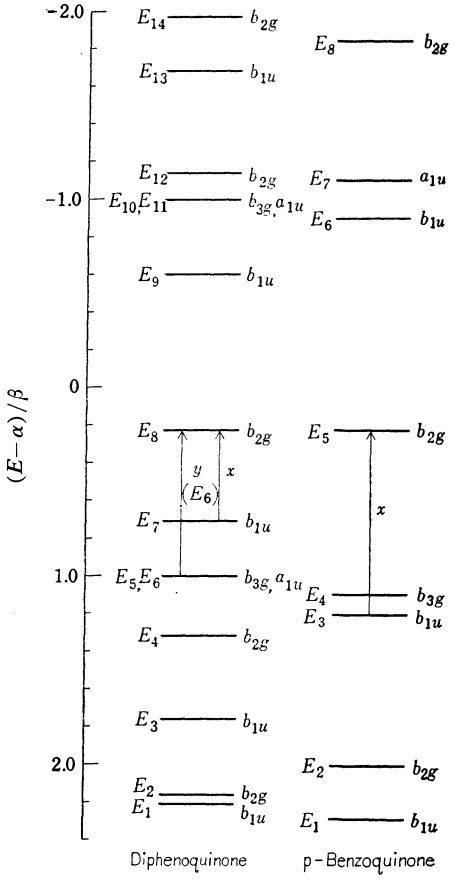

Fig. 1.

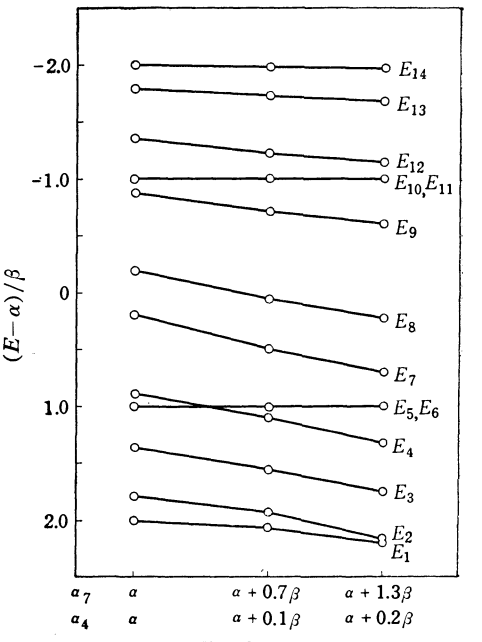

Fig. 2.

energies of DQ are given in Fig. 1, together with those of BQ. The dependence of the orbital energies upon the Coulomb integral of the oxygen atoms of DQ is shown in Fig. 2. the molecular orbitals are classified according to their symmetry properties in the symmetry group ($D_{2h}$), the O–O direction being taken as the $x$-axis and the molecular plane as the $xy$ plane. The $E_5$ and $E_6$ orbitals as well as the $E_{10}$ and $E_{11}$ orbitals are accidentally degenerate. The letter "$x$" or "$y$" attached to the arrow showing a transition denotes the direction of polarization in an allowed transition. The filled and the lowest unfilled molecular orbitals of DQ are given below with their energy values. $\chi_i$ denotes the $2p\pi$ atomic orbital of the $i$th atom.

## Discussion

**Molecular Diagram.**—As for charge distribution, the negative charge of the oxygen atom of DQ is a little larger than that of BQ and of anthraquinone (0.567 $e$). As for bond orders, the general feature of DQ is in qualitative agreement with the one obtained by Coulson. The bond order of the $C_2$–$C_3$ bond of DQ is nearly as large as that of the $C_2$–$C_3$ bond of BQ, and the bond orders of the $C_1$–$C_2$ and $C_3$–$C_4$ bonds of DQ are nearly equal. The bond order obtained by Coulson is considerably smaller in the $C_3$–$C_4$ bond than in the $C_1$–$C_2$ bond. The free valences of DQ are in general nearly equal to those of BQ. In DQ the free valency value of the $C_1$ atom is almost the same as that of the $C_4$ atom. As for the unpaired electron densities, in $o$- and $p$-quinones previously studied, the part larger than sixty percent of the total unpaired electron density exists at the two carbonyl groups, while in DQ the part smaller than fifty percent of the total unpaired electron density exists at the two carbonyl groups. The relatively large unpaired electron density value for the $C_1$ atom of DQ is noticeable. Unfortunately, in DQ the hfs of the electron paramagnetic resonance absorption of the semiquinone ion has never been measured due to the unstability of the ion, but for 3, 5, 3′, 5′-tetramethyl-DQ Matsunaga*** obtained the splitting constant (0.78 gauss) of the hfs due to ring protons. This value is considerably smaller than the one (1.39 gauss) calculated from the combination of the obtained unpaired electron density with McConnell's formula[3].

**Energy Levels.**—Concerning the energy levels given above, two points should be mentioned. First, the lowest unfilled orbital ($E_8$) is far lower than the other unfilled orbitals, as was previously obtained with $o$- and $p$-quinones, and is near the orbital ($E_5$) of BQ. Second, the highest filled orbital ($E_7$) is considerably higher than the ones of the $p$-quinones. The electronic spectrum of DQ in dioxanë obtained by Hartmann and Lorenz[4] is given in Fig. 3. As is seen in Fig. 3, DQ has three adsorption bands at about 500, 390 and 260 mμ. Now these absorption bands are reasonably attributed to the transitions from the rather higher filled

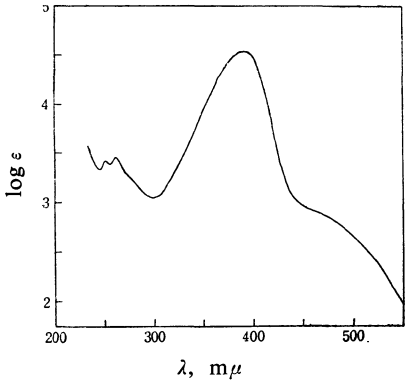

Fig. 3[4]. Electronic spectrum of diphenoquinone, solvent dioxane.

*** Unpublished data.

3) H. M. McConnell, *J. Chem. Phys.*, **24**, 632 (1956).

4) H. Hartmann and E. Lorenz, *Z. Naturforsch.*, **7a**, 360 (1952).

orbitals to the lowest unfilled orbital($E_8$) of DQ. The transitions $E_4 \rightarrow E_8$, $E_5 \rightarrow E_8$ are forbidden. The dipole strengths, calculated with Mulliken's approximation[5], are 0.0014 ($Å^2$) and 5.97 ($Å^2$) for the transitions $E_6 \rightarrow E_8$ and $E_7 \rightarrow E_8$, respectively. Thus, the strong band near 390 m$\mu$ is unambiguously assigned to the transition $E_7 \rightarrow E_8 (A_{1g} \rightarrow B_{3u})$. This transition corresponds to the transition $E_3 \rightarrow E_5 (A_{1g} \rightarrow B_{3u})$ of BQ. For the $A_{1g} \rightarrow B_{3u}$ transition bands, the calculated transition energies ($0.979\beta$ for BQ, $0.483\beta$ for DQ) are reasonable in comparison with the observed ones (ca. 5.0 e. V. for BQ, ca. 3.2 e. V. for DQ). The weak band near 500 m$\mu$ may be assigned to the transition $E_6 \rightarrow E_8 (A_{1g} \rightarrow B_{2u})$ or $E_5 \rightarrow E_8 (A_{1g} \rightarrow B_{1g})$, but the transition energy ($0.772\beta$) seems too great for this assignment. This band may tentatively be due to the $n$-$\pi^*$ transition. The intensity of this band seems considerably great compared with the $n$-$\pi^*$ transition band of other quinones but is nearly equal to that of the $n$-$\pi^*$ transition band of *trans*-azobenzene[6]. The band near 260 m$\mu$ is tentatively assigned to the transition $E_4 \rightarrow E_g (A_{1g} \rightarrow A_{1g})$.

## Summary

The electronic structure of diphenoquinone was studied with the simple MO method using the similar integral values as adopted in our previous work on *p*-quinones. The obtained result was discussed in comparison with the previously obtained one for *p*-benzoquinone. As for energy levels, the lowest unfilled orbital ($b_{2g}$) of diphenoquinone is far lower than the other unfilled orbitals as was obtained with the *p*-quinones The highest filled orbital ($b_{1u}$) of diphenoquinone is considerably higher than the ones of the *p*-quinones. From the calculated result the intense absorption band near 390 m$\mu$ was unambiguously assigned to the $A_{1g} \rightarrow B_{3u}$ transition.

The author wishes to express his sincere thanks to Professor S. Nagakura of the University of Tokyo for his kind guidance and to Dr. Y. Mashiko of this Institute for his kind offices. The author's thanks are also due to Dr. Y. Matsunaga of the University of Tokyo for his kindness in giving valuable information on the EPR data of semiquinone ions prior to publication.

# *Harmonic Oscillator Model for the Analysis of NMR Spectra of Di-substituted Benzenes*

By Hiroshi SHIMIZU* and Shizuo FUJIWARA*

(Received December 28, 1959)

Since the experiments of the high-resolution spectrum of the proton magnetic resonance in organic compounds showed very fruitful results, many efforts have been made to continue the measurements and to analyze the spectra of many compounds[1]. During these measurements, one encountered spectra so complicated that they can not be analyzed by the simple inspection of the chemical formula of the samples. These complicated spectra arise in the systems where the differences of the chemical shift values, $\Delta\sigma_{ij}$, and the spin-spin coupling constants, $J_{ij}$, are comparable to each other, where $i$ and $j$ refer to the resonating nuclei, and they can be analyzed by quantum-mechanical procedures. Two methods have so far been proposed for the analysis of these complicated spectra; one was shown by Banerjee, Das, and Saha[2] in the treatments of the two- and three-proton systems and the other, which is more general than the former, was shown by McConnell, McLean and Reilley[3].

This paper concerns the analyses of such

complicated spectra, using di-substituted benzenes of the type X-  -Y as an example. The method to be shown here is based on the classical treatment of the nuclear magnetic resonance (NMR) phenomena, and is assumed to be helpful for chemists who are not familiar with the quantum-mechanical procedures to obtain the necessary understanding of the analysis of the NMR spectrum.

## Analysis of NMR Spectrum by a Harmonic Oscillator Model

First, the nuclear magnetic resonance of a molecule which has only one hydrogen atom is considered. As there is no interest in the time-dependent phenomena, the equation of the classical or macroscopic vector $\vec{M}$ placed in a static magnetic field $\vec{H}_0$ may be written as

$$d\vec{M}/dt = \gamma\vec{M}\times\vec{H}_0 \qquad (1)$$

where, $\gamma$ is the gyromagnetic ratio of proton. Eq. 1 is the formula given by Bloch[4]. The intensity of the signal due to the nuclear magnetic resonance can be measured by the $x$-component $\vec{M}(z//H_0)$ when $\vec{M}$ is forced to flip down onto the $x$-$y$ plane by the interaction of the nucleus with the oscillating magnetic field $\vec{H}_1(t)$ which rotates in the $x$-$y$ plane with the angular frequency $\omega_0$. Thus, the resonance angular frequency is defined as that of $\vec{H}_1$ which flips $\vec{M}$ most effectively, called as the angular frequency of the Larmor precessional motion of $\vec{M}$ in the field of $\vec{H}_0$. Hence, we can calculate the resonant frequency and the relative intensity of the spectrum, even if we omit the effect of $\vec{H}_1$, and the contribution of $\vec{H}_1$ is taken into account in the considerations of the amplitude of the precession.

From (1), it is easily seen that $M_x$ behaves as a simple harmonic oscillator which obeys Eq. 2 at resonance:

$$d^2M_x/dt^2+\omega_0^2M_x=0 \qquad (2)$$

On the other hand, the equation of the motion of a simple harmonic oscillator may be written as

$$m(d^2X/dt^2)+fX=0 \qquad (3)$$

where $m$ and $f$ are the mass and the force constant of the oscillator. Eq. 3 will become equal to Fig. 2 by making the following interpretation:

$$X=M_x,\quad f=\gamma H_0=\omega_0 \text{ and } m=1/\omega \ (=1/\omega_0 \text{ at resonance}) \qquad (4)$$

4) F. Bloch, *Phys. Rev.*, **70**, 460 (1946).

These relations can be extended to any many-spin system by slight modification of the definition of the force constants. For example, the straightforward extension to a two-spin system composed of two protons, A and B, may be made by additional replacement of the force constant, $f$, by the spin-spin coupling constant $J$ as

$$f_{AB}=\pm J_{AB}/2 \qquad (4a)$$

A positive sign is used when $\vec{M}_A$ and $\vec{M}_B$ are parallel, and the negative sign antiparallel. The situation of this model of the interacting oscillators is illustrated in Fig. 1. The interaction energies of these oscillators refer the off-diagonal terms of secular equations, where the sign of eac term his taken to be positive as well as that of J. Justification of this choice of the sign will be given later.

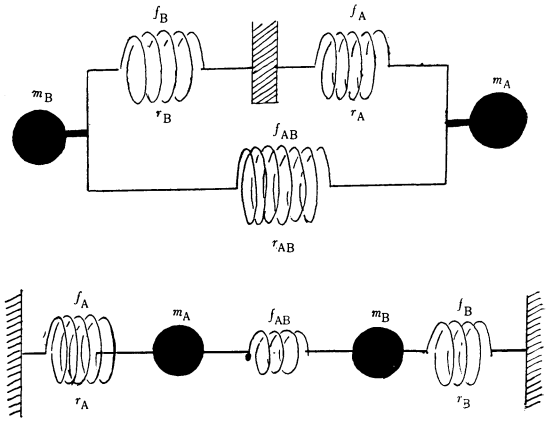

Fig. 1. Explanation of the oscillator model.
(a) $f_{AB}=J_{AB}/2$
(b) $f_{AB}=J_{AB}/2$

The potential energy of the system may be written as Eq. 5,

$$V=1/2\cdot[f_A(\Delta r_A)^2+f_{AB}(\Delta r_{AB})^2+f_B(\Delta r_B)^2] \qquad (5)$$

where $r_A$, $r_B$ and $r_{AB}$ are the elongations of the springs, A, B and C, whose force constants are $f_A$, $f_B$, and $f_{AB}$, respectively. The expression (5) may be rewritten by the Cartesian coordinate $x$ as

$$\begin{aligned} V&=1/2\cdot[(f_A+f_{AB})x^2{}_A+2f_{AB}x_Ax_B \\ &\quad+(f_B+f_{AB})x^2{}_B] \\ &=1/2\cdot[(\omega_A+J_{AB}/2)M^2{}_{Ax}+J_{AB}M_{Ax}M_{Bx} \\ &\quad+(\omega_B+J_{AB}/2)M^2{}_{Bx}] \end{aligned} \qquad (6)$$

In Eq. 6 we used the relations, $\Delta r_A=x_A$, $\Delta r_B=-x_B$ and $\Delta r_{AB}=x_A+x_B$.

The kinetic energy of the system, $T$, is as shown by

$$T=m[\dot{x}^2_A+\dot{x}^2_B]/2 \tag{7}$$

$$=[\dot{M}^2_{Ax}+\dot{M}^2_{Bx}]/2\omega \tag{7a}$$

As the $x$-$y$ components of the magnetic vectors, $\vec{M}_{Axy}$ and $\vec{M}_{Bxy}$ rotate about the $z$-axis, the $x$-components of these vectors may be written as

$$\left.\begin{aligned} M_{Ax}&=M_{Axy}\cos\omega t \\ M_{Bx}&=M_{Bxy}\cos\omega t \end{aligned}\right\} \tag{8}$$

Substituting Eq. 8 into Eqs. 6a and 7a, the motion of $M_{Ax}$ and $M_{Bx}$ are given by the classical equation of motion,

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{M}_{ix}}\right)+\frac{\partial V}{\partial M_{ix}}=0 \quad (i=A, B)$$

which leads a set of two homogeneous equations,

$$(\omega_A+J_{AB}/2-\omega)M_{Ax}+J_{AB}M_{Bx}/2=0 \tag{10}$$

$$J_{AB}M_{Ax}/2+(\omega_B+J_{AB}/2-\omega)M_{Bx}=0 \tag{10a}$$

These equations have a non-vanishing solution only when the determinant of the coefficients of $M_{Ax}$ and $M_{Bx}$ is zero, i. e.,

$$\begin{vmatrix} \omega_A+J_{AB}/2-\omega, & J_{AB}/2 \\ J_{AB}/2, & \omega_B+J_{AB}/2-\omega \end{vmatrix}=0 \tag{11}$$

and from the secular equation (11), we obtain the relation,

$$\omega_0=1/2\cdot[(\omega_A+\omega_B)+J_{AB}\pm(\sigma^2_{AB}+J^2_{AB})^{1/2}] \tag{12}$$

where $\sigma_{AB}=\delta_A-\delta_B$ is the chemical shift between the protons of A and B. Similar treatment of model 2b gives the resonant frequency,

$$\omega_0=1/2\cdot[(\omega_A+\omega_B)-J_{AB}\pm(\sigma^2_{AB}+J^2_{AB})^{1/2}] \tag{12a}$$

It is reasonable to assume that the energy absorbed by the system at resonance is proportional to the magnitude of the mean kinetic energy of the oscillator, i. e., to the square of the vector $\vec{M}_{xy}=\vec{M}_{Axy}+\vec{M}_{Bxy}$. Hence, the relative intensity of the spectrum at the frequency $\omega_0$, $I(\omega_0)$, is calculated from Eq. 10 or 10a with the normalization condition of the magnetic vector, (13),

$$M_{Axy}(\omega_0)^2+M_{Bxy}(\omega_0)^2=1 \tag{13}$$

as

$$I(\omega_0)=[M_{Axy}(\omega_0)+M_{Bxy}(\omega_0)]^2 \tag{14}$$

$$=1-2\frac{(\omega_A-\omega_0)(\omega_B-\omega_0)}{(\omega_A-\omega_0)^2+(\omega_B-\omega_0)^2} \tag{15}$$

The calculated spectrum is shown in Fig. 2.

Although the present method of analysis is based on the classical treatment of an oscillator model, it is shown that the results of this analysis are in accordance with those to be obtained quantum-mechanically.

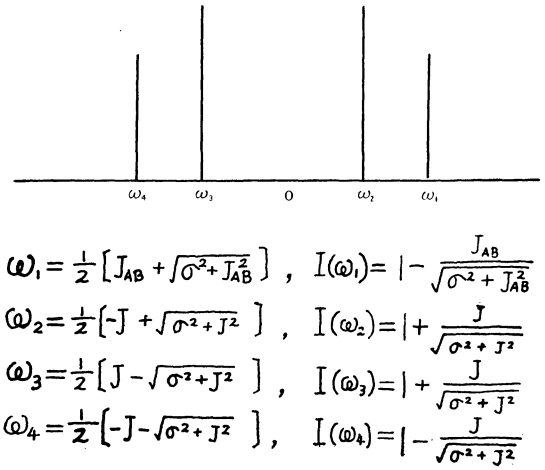

Fig. 2. Calculated spectrum.

The quantum-mechanical Hamiltonian of a two-spin system in a laboratory coordinate system may be expressed as

$$\mathcal{H}=-\gamma_A\vec{I}_A\cdot\vec{H}_A-\gamma_B\vec{I}_B\cdot\vec{H}_B+J_{AB}\vec{I}_A\cdot\vec{I}_B \tag{16}$$

The time-dependent Schroedinger equation is given by Eq. 17 in a rotating coordinate system which rotates with angular velocity, $\vec{\omega}$, as

$$i\hbar\dot{\Psi}_r=[-\gamma_A\vec{I}_A(\vec{H}_A+\omega/\gamma_A)-\gamma_B\vec{I}_B(\vec{H}_B+\omega/\gamma_B)+J\vec{I}_A\vec{I}_B]\Psi_r \tag{17}$$

The fields at $I_A$ and $I_B$ are effectively reduced to zero, provided that the angular velocities of the coordinates are given by

$$\vec{\omega}_A=-\gamma_A(\vec{H}_A-J_{AB}\vec{I}_B/\gamma_A) \tag{18}$$

and

$$\vec{\omega}_B=-\gamma_B(\vec{H}_B-J_{AB}\vec{I}_A/\gamma_B) \tag{18a}$$

If we return to the laboratory coordinate system, the effective fields at $\vec{I}_A$ and $\vec{I}_B$ are written as

$$\vec{H}_A-J_{AB}\vec{M}_B/2\gamma_A \tag{19}$$

and

$$\vec{H}_B-J_{AB}\vec{M}_A/2\gamma_B \tag{19a}$$

respectively.

By assuming the macroscopic equations which have the same form as Eq. 1, we obtain the equations,

$$d\vec{M}_A/dt=\gamma_A\vec{M}_A\times(\vec{H}_A-J_{AB}\vec{M}_B/2\gamma_A) \tag{20}$$

and

$$d\vec{M}_B/dt=\gamma_B\vec{M}_B\times(\vec{H}_B-J_{AB}\vec{M}_A/2\gamma_B) \tag{20a}$$

By taking the time-independence of the components of $M_{Az}$ and $M_{Bz}$ into consideration,

Eqs. 22 and 22a are substituted into Eqs. 21 and 21a, respectively.

The equations for the $x$-components of Eqs. 20 and 20a are

$$dM_{Ax}/dt=(\gamma_A-J_{AB}M_{Bz}/2)M_{Ay}+J_{AB}M_{By}M_{Az}/2 \quad (21)$$

and

$$dM_{Bx}/dt=(\gamma_B-J_{AB}M_{Az}/2)M_{By}+J_{AB}M_{Ay}M_{Bz}/2 \quad (21a)$$

where

$$\left.\begin{aligned}M_{Ax}&=M_{Axy}\cos\omega t\\ M_{Ay}&=-M_{Axy}\sin\omega t\end{aligned}\right\} \quad (22)$$

and

$$\left.\begin{aligned}M_{Bx}&=M_{Bxy}\cos\omega t\\ M_{By}&=-M_{Bxy}\sin\omega t\end{aligned}\right\} \quad (22a)$$

## Experimental

Calculations and measurements of the NMR spectra were performed for the di-substituted benzenes of the type of X-  -Y: $p$-aminobenzoic acid was dissolved in a concentrated aqueous solution of potassium hydroxide, and $p$-toluidine, $p$-nitrophenol, and $p$-nitrobenzaldehyde were dissolved in carbon tetrachloride, methanol and acetone, respectively. These solutions were saturated at 28°C and sealed in the glass tubes with the diameter of 3.5~3.8 mm.

The apparatus of the NMR measurements is the one constructed in this laboratory having the same structure as the one reported by Gutowsky et al. before[5], and operated at the frequency of 27.030 Mc. The samples were spinned during the measurements. The separations of each component of the spectra were measured on the recorded charts using the records of ethanol as the standard reference: the $J$ value of the coupling between the methyl and methylene groups in ethanol was taken as 6.90 cps.[5]

## Discussion

In Fig. 3, the spectrum for the anisaldehyde is shown as an example of NMR measurements. The values of the chemical shift and the spin-spin couplings were calculated from Eqs. 12 and 12a as listed in Table I. The maximum error in the results of Table I is about 10%, which is assumed to be mainly due to the fluctuations in the chart speed of the recorder. Rigorously speaking, the compounds used here are not the two-spin system, but belong to four-spin system, and the values listed in Table I contain some error due to this approximation. But, this error is assumed to be quite small.

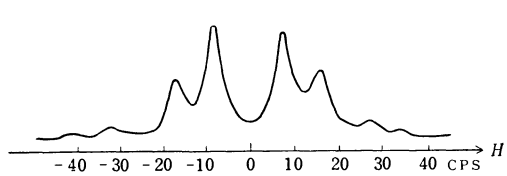

Fig. 3. The spectrum of anisaldehyde. Resonance frequency=27 Mc.

Table I. $J$ and $\sigma$ values of the ring protons of X-  -Y type molecules

Res. freq.=27 Mc.

| X | Y | $J$ cps. | $\sigma$ cps. |
|---|---|---|---|
| -CHO | $CH_3O$- | 8.62 | 24.2 |
| -COOH | $NH_2$- | 8.21 | 30.1 |
| $-CH_3$ | $NH_2$- | 8.70 | 13.54 |
| $-NO_2$ | HO- | 9.06 | 31.1 |
| $-NO_2$ | OHC- | 9.24 | 6.6 |

It is seen in Table I that the $\sigma$'s are dependent on the species of the substituents of X and Y, whereas $J$'s are not dependent with a constant value of about 8.7($\pm$0.5) cps. If we can assume that an additive law holds with the chemical shifts of the ring protons, $\delta$, of monosubstituted benzenes, the magnitudes of $\sigma$'s could be related by the relation,

$$|\sigma|=|(\delta_X{}^o-\delta_Y{}^m)-(\delta_Y{}^o+\delta_X{}^m)| \quad (23)$$

where, for example, $\delta_X{}^o$ and $\delta_Y{}^m$ refer to the chemical shifs of *ortho*-proton of X and the meta-proton of Y, respectively.

We calculated the magnitudes of $\sigma$ by using the values of $\delta$'s for the monosubstituted benzenes reported by Corio and Dailey[7], and compared the calculated results with those obtained experimentally. Agreements are not good between the $\sigma$'s of calculation and of observation whereas the observed values of $\sigma$'s showed good proportionality to $|\delta_x{}^o-\delta_y{}^o|$. This seems to suggest that the additivity does not hold with the $\delta$'s for the ring protons of di-substituted benzenes.

The authors are indebted to Professor Shōji Shibata and Professor Tyūnoshin Ukita and to Miss Motoko Nakahara of the University of Tokyo for their help in the preparation of the samples. Thanks are also due to Mr. Ichiro Yamaguchi of the Japan Atomic Energy Research Institute, who kindly sent us the preprint of his work on the substituted benzenes.

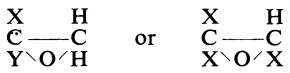
# *Polyethers. III. Polymerizations and Polymers of Some Substituted Ethylene Oxides**



By Shin'ichi ISHIDA**

(Received December 18, 1959)

A variety of polyethers has been prepared by ring-opening polymerization of cyclic ethers, for example from ethylene oxide[1], propylene oxide[2], fluorine-containing olefine oxides[3], oxacyclobutanes[4] and from tetrahydrofuran[5].

A systematic survey in this field will offer an interesting new field for studies both on stereospecific polymerization and on structure of crystalline polyethers.

In the light of this consideration, polymerizations of some substituted ethylene oxides were tried with attempts to obtain crystalline polymers by a stereospecific polymerization for some oxides of the types.

The present paper is in the nature of a survey and a tentative report on some oxides involved.

## Experimental

**Materials.**—*1-Chloro-2-methyl-2-propanol.*— It was prepared by Burgin's method[6]. After the treatment of 90 g. of methallyl chloride with molar proportion of 80% sulfuric acid at 5~10°C for 2.5 hr. with vigorous stirring, the reaction mixture was hydrated on cracked ice. The chlorohydrin was distilled as a constant boiling mixture which, after being salted out, redistilled, b. p. 126~129°C. The yield was about 40~50% (63~66% reported).

*1,1-Dimethyl Ethylene Oxide.*— The preceding chlorohydrin (50 g.) was slowly added to powdered potassium hydroxide (120 g.) with stirring at such a rate that the temperature of the distillate did not exceed 55°C. When the reaction ceased the remaining volatile matter was distilled off under water pump vacuum at room temperature to a trap cooled at −70°C. The total condensate was dried with potassium hydroxide and fractionated to yield the desired oxide; 25 g., 63% of theory, b. p. 50.2~50.5°C. $n_D^{20}$ 1.3730 (reported b. p. 53°C, $n_D^{20}$ 1.3730)[7].

*2-Methyl-3-chloro-2-butanol.*—It was prepared from 3-chlorobutanone-2 (b. p. 114°C) obtained by chlorination of methylethylketone in the presence of marbel and methyl magnesium bromide by Fourneau's method[8]. 20% yield of light yellow liquid boiled at 140°C (reported b. p. 141~142°C). This chlorohydrin was also prepared by the action of hypochlorous acid on trimethyl ethylene in some runs but the yield and the purity were rather poor.

*1,1,2-Trimethyl Ethylene Oxide.*—It was prepared by dehydrochlorination of trimethyl ethylene chlorohydrin. Dehydrochlorination was carried out in all cases by adding the chlorohydrin slowly on to solid potassium hydroxide with stirring. The yield was about 30% based on the chlorohydrin.

*Tetramethyl Ethylene Oxide.* — Anhydrous pinacol (115 g.) obtained from acetone was treated with molar proportion of anhydrous hydrogen chloride (41 g.) at 35~45°C and the resulting chlorohydrin was recrystallized (melted at 63°C) and treated as above with solid potassium hydroxide to produce the epoxide (35 g.), b. p. 90~93°C, $n_D^{20}$ 1.3985 (lit. b. p. as reported[9], $n_D^{20}$ 1.3986). The yield was 13% based on anhydrous pinacol.

*1-Methyl-1-phenyl-2-chloro Ethanol.*—It was prepared by King's procedure[10] from monochloroacetone and phenylmagnesium bromide.

The reaction mixture was stirred at −10°C during the addition of Grignard reagent under the protection of dry nitrogen and then allowed to warm slowly to room temperature after being kept standing overnight. To the cold reaction mixture was then added dropwise with stirring a solution of ammonium chloride (100 g.) in water (400 ml.). The ether layer was separated and the aqueous layer was extracted with ether. The combined ether extracts were washed once with 250 ml. of water and dried over anhydrous sodium sulfate. Removal of the ether by distillation gave a crude residue (50 g.) which was fractionated under reduced pressure. Eighty grams (72.7%) of the product distilled at 109~112°C/12 mmHg were obtained (lit. b. p. 129~132°C/21 mmHg).

*1-Methyl-1-phenyl Ethylene Oxide.*—The chlorohydrin was decomposed with sodium ethoxide to give methylphenyl ethylene oxide. A colorless liquid

b. p. 75～76°C/12 mmHg (lit.[10] b. p. 72～75°C/11 mmHg).

*1, 1-Diphenyl-2-chloroethanol.* — To a stirred solution of ethyl chloroacetate (84 g.) in dry ether (300 ml.) was added dropwise over a period of 4.5 hr. a solution of phenylmagnesium bromide previously prepared from magnesium (36.5 g.) and bromobenzene (252 g.) in dry ether (650 ml.). The reaction mixture was maintained at 0 to −5°C and then treated according to the procedure similar to the synthesis of 1-methyl-1-phenyl-2-chloroethanol. The product was isolated by distillation under reduced pressure and purified by recrystallization from ligroin. A yield 46 g. (26%), m. p. 53～56°C (lit. m. p. 52～57°C).

*1,1-Diphenyl Ethylene Oxide.*—A yield of an almost quantitative amount of crude oxide (m. p. 42～45°C) was obtained by action of the chlorohydrin on the aqueous solution of sodium hydroxide by Zaugg's method[11]. Twice recrystallization from absolute ethanol gave a pure oxide, m. p. 55～56°C (reported m. p. 56～57°C).

*1, 1-Diethyl-2-chloroethanol.* — It was prepared by the same procedure used in the synthesis of 1,1-diphenyl-2-chloroethanol. To a stirred solution of ethylchloroacetate (65 g.) in dry ether (300 ml.) was added a solution of ethylmagnesium bromide previously prepared from magnesium (24 g.) and ethyl bromide (109 g.) in dry ether (200 ml.). Resulting chlorohydrin was obtained in a yield of 44%, b. p. 66～67°C/16～18 mmHg (lit.[12] b. p. 70°C/20 mmHg).

*1, 1-Diethyl Ethylene Oxide.*—It was prepared by the conversion of the chlorohydrin by the same procedure as in the synthesis of 1,1-dimethyl ethylene oxide mentioned above. Thirty grams of the chlorohydrin gave 15 g. of the raw epoxide, which gave by the fractional distillation a distillate boiling at 105～106°C (lit. b. p. 107°C).

**General Procedure of Polymerization.**—A catalyst was added to a monomer or a monomer solution in a glass tube which was flashed by nitrogen previously and then cooled in dry ice-acetone.

The tube was sealed and placed in a constant temperature bath. At the end of the reaction time, the tube was recooled and opened. To the reaction mixture, a small quantity of methanol or some appropriate agents for stopping the reaction were added and the resulting polymer was washed thoroughly with methanol so as to remove the catalyst residue. In the case when the reaction product was an oil it was dissolved in acetone and precipitated with a large volume of methanol.

## Results and Discussion

**1, 1-Dimethyl Ethylene Oxide (D. M. E. O.).**— 1,1-Dimethyl ethylene oxide was attempted to polymerize by different catalysts and some details were given in Table I. The polymer was found to consist of two fractions; fraction I was insoluble in acetone, benzene, methanol and ether and soluble in hot tetrahydrofuran, dioxane and dimethylformamide, except in some cases, where a small quantity of the insoluble part in these solvents was contained. Fraction II was soluble in acetone but insoluble in methanol.

Fraction I, a white and nontacky powder, was shown by X-ray examination to be crystalline. The melting points of these materials obtained from the different catalysts varied from 127 to 155°C. Fraction II was usually a white solid, melting at about 90～100°C, but in the case, where diethyl zinc and $FeCl_3$–PO was used as catalyst, it was a tacky semi-solid or a pasty mass.

As may be seen in Table I, the polymerization with the catalysts borontrifluoride etherate ($BF_3$-$Et_2O$) and triethyl aluminum ($AlEt_3$) and diethyl zinc ($ZnEt_2$) respectively proceeded very rapidly at low temperatures;

the reaction mixture was solidified as soon as the catalyst was added. Aluminum isopropoxide (AIP) and the one in conjunction with zinc chloride (AIP-$ZnCl_2$)[13] as well as diethyl zinc-alumina system[14] were completely inactive for this monomer in contrast to the fact of their being active for propylene oxide.

Copolymerizations of 1,1-dimethyl ethylene oxide with epichlorohydrin (EpCl) were also studied. Epichlorohydrin was chosen for the convenience of its analysis and $AlEt_3$ was used as catalyst because of the feasibility of its purification from resulting polymer compared with those from $FeCl_3$-PO catalyst. Some runs of polymerization were carried out at a low temperature. (The catalyst was added to the monomer solution in a glass tube cooled in dry ice-acetone, the reaction started and the reaction mixture was solidified immediately, and then the glass ampoule was placed in a water bath and kept at room temperature for further promotion of polymerization.) The other runs were done in an oil bath at 80°C from the beginning. The resulting products were in both cases fractionated by the precipitation method. In the case at low temperature, the products were divided into two fractions; methanol-insoluble fraction (I) and methanol-soluble fraction (II). In the latter case at the higher temperature, the product was separated into three fractions; acetone-soluble fraction (I'), acetone-soluble but methanol-insoluble fraction (II') and methanol-soluble fraction (III). These results were shown in Tables II and III.

In both the cases, there existed a minimum of conversion versus monomer composition fed in the range of monomer composition of about 70% of 1,1-dimethyl ethylene oxide ($M_1$) in comonomer, and this corresponded also with a minimum yield of fractions I, I' and II' at about 40% of $M_1$. Of these fractions, fractions I and I' were white powders and these two were examined in some details. Melting points, chlorine contents and X-ray patterns of these fractions showed that these fractions were either homopolymer of D. M. E. O. or that of EpCl depending upon the preference of one monomer in the monomer composition.

The critical monomer composition coincided with the composition corresponding to a minimum percent of fraction I and I'.

From the results mentioned above, it may be seen, in this comonomer system, that a crystalline copolymer had not been obtained and fractions I and I' are both of the pure homopolymers.

**1,1,2-Trimethyl Ethylene Oxide (tri-M.E.O.).** —This oxide was polymerized neither with $FeCl_3$-PO nor with AIP-$ZnCl_2$ as catalyst but with $BF_3Et_2O$ it was rapidly polymerized at low temperature to a viscous liquid (Table IV). A tacky solid or an elastic mass could be obtained only with $AlEt_3$ at room temperature. The polymer was soluble in ether and acetone but insoluble in methanol.

**1,1,2,2-Tetramethyl Ethylene Oxide (tetra-M. E. O.).** — Both the catalysts $AlEt_3$ and AIP-$ZnCl_2$ were inactive for the polymerization

of this monomer but $BF_3Et_2O$ gave a crystalline polymer (Table V). The polymer neither melted and nor decomposed even at 300°C. No usual organic solvents could be found for this polymer but the polymer was swollen by decalin or tetralin at 80~90°C. An attempt to copolymerize this monomer with 1,1-dimethyl ethylene oxide by $BF_3Et_2O$ was failed and gave only polymer of tetra-M. E. O. which was proved by X-ray examination, melting point and solubility (Table VI).

**1-Methyl-1-phenyl Ethylene Oxide (M.P.E.O.)**—$BF_3Et_2O$, $AlEt_3$ and $ZnEt_2$ were active to polymerize this epoxide which was converted into viscous liquid polymers which were insoluble in methanol. $BF_3Et_2O$ gave a reddish brown oily polymer, while the others gave colorless polymers.

No polymer could be obtained with AIP-$ZnCl_2$ system even after prolonged heating at 80°C for two days. $FeCl_3$-PO catalyst gave a colored oily product accompanied by a small quantity of needle crystals whose structure has not yet been determined in this work.

**1.1-Diphenyl Ethylene Oxide (D.P.E.O.).**—$AlEt_3$ and AIP–$ZnCl_2$ were inactive for this monomer while both $BF_3Et_2O$ and $TiCl_4$ were active catalysts. To a cooled solution of the oxide in methylene dichloride, the catalyst, for instance $BF_3Et_2O$ 3% by weight was added slowly and the reaction mixture was sealed and placed in a dry ice-acetone bath for two days. The glass ampoule was then opened and an ammoniacal methanol was poured into the ampule and the product was washed thoroughly with methanol.

The product (38.5% yield) was needle crystals and did not melt at 300°C but was found to sublime slightly. This material was believed to be a ring dimer of the epoxide

and was shown from the elemental analysis and the molecular weight determination, both of which were demonstrated in good accordance with a calculated value for the ring dimer (Table VII).

dioxane and these bands were in agreement with 877 (11.40 $\mu$), 812 (12.3 $\mu$) $cm^{-1}$ of styrene oxide and 863 (11.85 $\mu$), 786 (12.72 $\mu$) $cm^{-1}$ of $\alpha$-methyl styrene oxide oberved by Patterson[16] (Fig. 1).

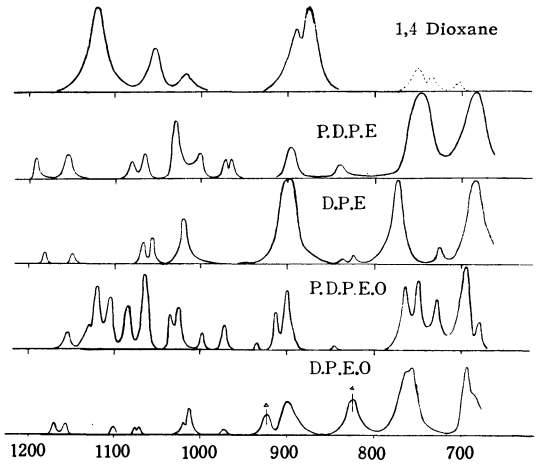

Fig. 1. Infrared spectra of diphenyl ethylene oxide and related compounds ; D.P.E.O. ; diphenyl ethylene oxide P.D.P.E.O. ; polymer of D.P.E.O., D.P.E. : diphenyl ethylene, P.D.P.E. : polymer of D.P.E. Epoxy bands were marked by triangle.

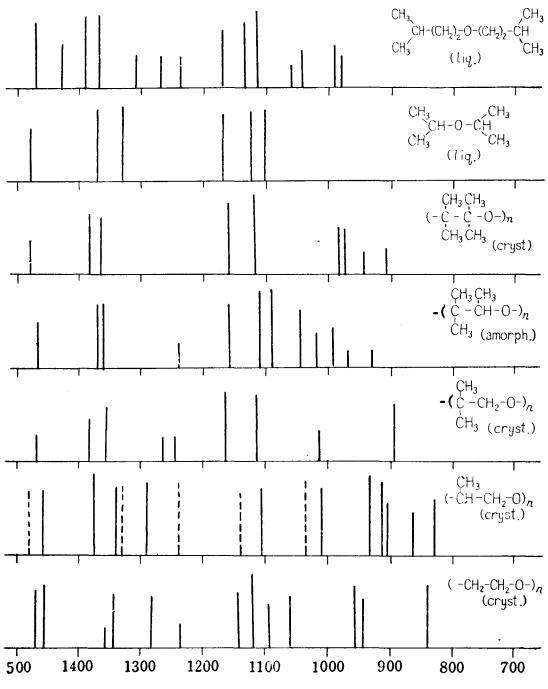

Fig. 2. Infrared spectra of polymers of methyl-substituted ethylene oxides and some related ethers (dotted line : crystalline sensitive bands).

Since absorption bands characteristic of 6-membered carbon oxygen ring had been noted to occur at near 11 $\mu$ and in the range 1124~1030 $cm^{-1}$ by Shreve[17], bands at near 1100 $cm^{-1}$ and 912 $cm^{-1}$ which appeared in the spectra of the dimer, would be bands characteristic of ring ether.

**1,1-Diethyl Ethylene Oxide.**—Using both $BF_3Et_2O$ and $TiCl_4$ as catalyst, no polymer-like substance could be obtained while a resin-like material was produced by $AlEt_3$ as catalyst. But no further experiments could proceed because of paucity of the material.

Infrared spectra of polymers from four methyl-substituted ethylene oxides together with some related ethers for comparison were shown in Fig. 2 and their characteristic bands were tabulated for comparison in Table VIII.

Some properties of polymers were summarized in Table IX and X-ray spectra of crystalline polymers were shown in Table X and Figs. 3 and 4.

The action of $AlEt_3$ as polymerization catalyst for epoxides used in this experiment might well be compared with those of cationic

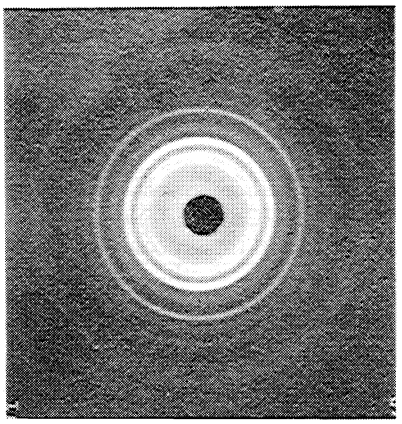

Fig. 3. X-ray pattern of the polymer of 1,1-dimethyl ethylene oxide.

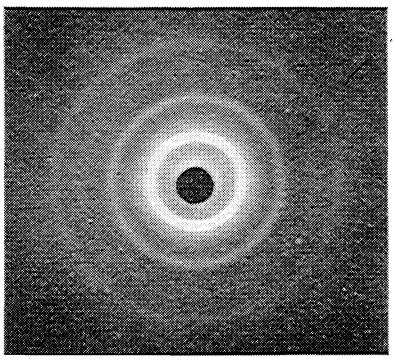

Fig. 4. X-ray pattern of the polymer of tetramethyl ethylene oxide.

catalysts. These epoxides were polymerized by $AlEt_3$ as well as $BF_3Et_2O$ and $TiCl_4$ at low temperature. The similar feature was illustrated in the case of four and five membered cyclic oxides[18], that is, ring ethers such as oxacyclobutanes, tetrahydrofuran were polymerized by $AlEt_3$ as well as $BF_3Et_2O$. While catalyst $ZnEt_2$ seemed to act in a manner unlike that of $AlEt_3$.

"Coordinated complex catalyst" such as $FeCl_3$-PO and AIP-$ZnCl_2$ could be applied to polymerization of limited kinds of epoxides and the polymerization by these catalysts proceeded much slower in the rate than that both by some cationic catalysts and some organometallic compounds such as $AlEt_3$ and $EnEt_2$.

The author offers sincere thanks to Professor Dr. S. Murahashi for his kind guidance and encouragement throughout this work and he is indebted to Dr. H. Tani, Dr. T. Takizawa and Dr. S. Nozakura for their valuable discussions and helpful suggestions in the experiments and to Mr. K. Katayama (Textile Res. Lab., Asahi Chem. Ind. Co. Ltd.) for X-ray examinations.

# *Spectrochemical Study of Microscopic Crystals. XXI*[1]. *The Structure and Absorption Spectra of the Red and the Black Form of Nitrosopentammine-cobalt Salts*[2]

By Shoichiro YAMADA, Hiroaki NISHIKAWA and Ryutaro TSUCHIDA

(Received December 16, 1959)

Two series of compounds with the same composition of $[Co(NH_3)_5NO]X_2$, have been known for a long time[3], one of them being colored black and the other red. The marked difference in the color and other properties between the two series of compounds has attracted a number of investigators[4-10], but rather conflicting conclusion have so far been drawn about the configuration and the electronic structure of the two compounds. It seems, therefore, to be of significance to examine the compounds using some new sorts of materials which have neither been much discussed nor obtained before. This paper presents ultraviolet absorption spectra of the black and the red salt in the crystalline state, and discusses their structure on the basis of the present measurement.

## Experimental

**Materials.** — Red nitrosopentammine-cobalt(III) nitrate, $[Co(NH_3)_5NO](NO_3)_2$, was prepared in rectangular, thin plates by the method of Asmussen and others[9]. The compound is comparatively stable, and may be recrystallized from water.

Black nitrosopentammine-cobalt chloride, $[Co(NH_3)_5NO]Cl_2$ was prepared according to the direction of Asmussen and others[9]. The compound is unstable, undergoing decomposition by water, acid or alkali. On exposure to the air, the compound gradually changes into a red material. The decomposition, however, seemed to be so slow that no change of the crystal surface was observed under the microscope after the dichroism measurement. The compound is often contaminated with the $[Co(NH_3)_6]^{2+}$, which is very sensitive with respect to magnetic susceptibility, but not to ultraviolet spectra of the salt.

**Measurements.** — Visible and ultraviolet spectra of both the red and the black compound in the crystalline state have been quantitatively determined

at room temperature on well-developed planes by Tsuchida and Kobayashi's microscopic method[11] using linearly polarized light. The A- and the B-absorption refer to the direction shown in the figures.

Visible and ultraviolet absorption spectrum of the red salt in an aqueous solution was measured by a Beckman DU spectrophotometer.

The symbols used in the present paper are the same as those in the former reports of this series.

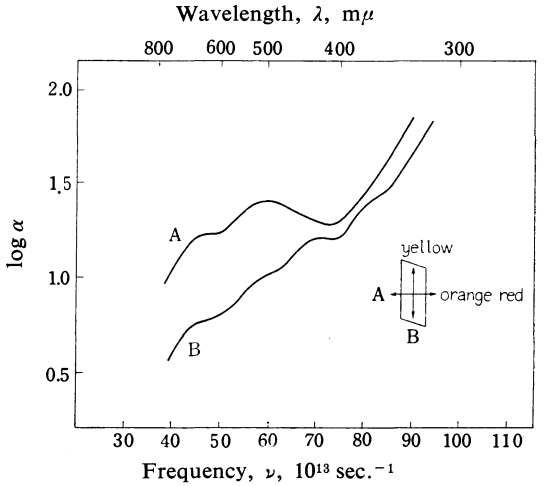
In the analysis of the absorption curve in Fig. 4, it is assumed that the second absorption band has a molar extinction coefficient almost equal to that of the first band, the distance between the maxima of the first and the second bands being almost equal for complexes of cobalt(III).

## Results and Discussion

**Structure of Black Nitrosopentammine-cobalt Salt.** — Uninuclear and binuclear structures have been given to the black nitrosopentammine-cobalt salt. Contrary to the result by former investigators that the "black salts" were paramagnetic, Asmussen and others[9] found that the "black salts", when carefully purified, actually showed diamagnetism. The structures, as suggested formerly on the erroneous magnetic data, need not be given serious consideration. The black series of the salts were regarded by Asmussen and others as a co-ordination compound of cobalt(III), the lowest energy level being very close to the level of the bivalent cobalt.

Bertin and others[10] concluded on the basis of the infrared spectra of these compounds that the isomerism of the black and the red series is dependent upon the nature of the linkages of the co-ordinated NO-group and not upon difference in the oxidation state of the central metal. However, they did not discuss the structure of the salts in detail. Griffith and others[8] discussed the same problem on the basis of the chemical reactions, and finally favored the binuclear structure for the "black salt". Most of their discussion, however, seems to be rather speculative, and reexamination from materials of different kinds might be desirable.

Dichroism in the visible and ultraviolet region of the "black salt" is shown in Fig. 1. It seems fortunate that the impurity, $[Co(NH_3)_6]^{2+}$, often appearing in the "black salt" is not important in the UV-absorption spectra of the compound, in contrast to magnetic susceptibility which is affected seriously by a small amount of the impurity. The absorption spectra, as shown in Fig. 1, seem to be so complicated that they would not be understandable on the assumption of the uninuclear



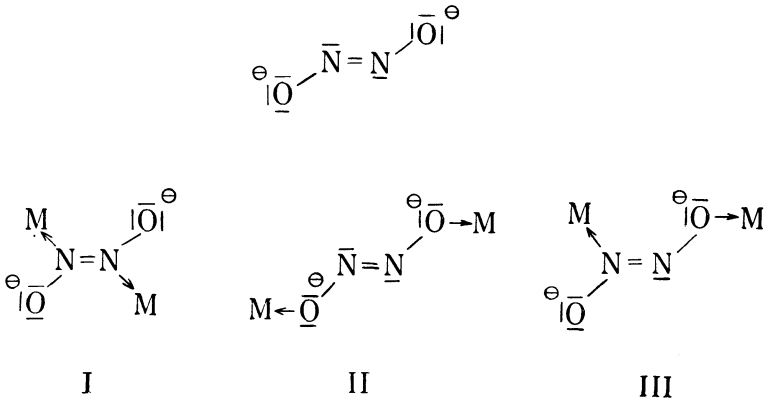


Fig. 1. Absorption spectra of black nitrosopentammine-cobalt chloride, $[Co(NH_3)_5NO]Cl_2$, in the crystalline state.

model of the "black salt". Thus the "black salt" exhibits an absorption band at about $46\times10^{13}\,sec^{-1}$, the wavelength region which is much longer than would be expected for the uninuclear nitrosopentammine-cobalt(III) complex. There might be a possibility that the band at about $46\times10^{13}\,sec^{-1}$ would originate from a nitroso-group. In fact, a number of nitroso-derivatives, such as nitroso-benzene and its derivatives, are known to show a rather special type of an absorption band characteristic of a nitroso-group in the long wavelength region. It may be difficult, however, to assume that the NO-group in the "black salt" should be isolated electronically from the cobalt ion to such an extent that the band of this sort may appear in this wavelength region. The band at about $46\times10^{13}\,sec^{-1}$ of the "black salt", therefore, may not be regarded as due to a nitroso-group which is rather isolated in the cobalt-complex. Moreover, the absorption curve of the "black salt" appears to be too complicated for a uninuclear complex of cobalt(III).

On the contrary, the absorption curve of the "black salt" may be understood much more readily as that of a binuclear complex than as that of a uninuclear complex. Possible structures for a binuclear form are shown in Fig. 2, the $\pi$-bonding between the metal and the $NO^-$ ion being neglected for the present. It is to be noted that the dichroism of the "black salt" is markedly similar to that of $\mu$-peroxo-dicobalt complexes with an $O^{2-}$ group which connects two cobalt ions together[12]. Moreover, just as the peroxo-dicobalt compound

Fig. 2.

has an absorption band in the very long wavelength region, so the "black salt" shows an absorption band at about $46\times10^{13}\,sec^{-1}$. The band of the peroxo-dicobalt compound in the longer wavelength region, with maximum at about $46\times10^{13}\,sec^{-1}$, was ascribed to a group of Co–$O_2$–Co with a special electronic structure which gives rise to a special absorption band due to the interaction between the two cobalt ions through the peroxide group[12]. The band in question of the "black salt", therefore, may be a special type of the interaction band due to a group of atoms having an electronic structure of Co–X–Co somewhat similar to that of Co–$O_2$–Co, originating from the interaction between the two cobalt ions through $N_2$ group. A-absorption in Fig. 1 may be regarded as representing the main features of the component absorption which is richer with the interaction absorption due to the Co–$N_2$–Co group than is the other component absorption.

Since it is difficult to expect the interaction band with structure II and structure III, structure I having a group of Co–N–N–Co may be favored best as a model of the "black salt" by the ultraviolet absorption spectra with the interaction band. The conclusion obtained here by the present authors about the structure of the "black salt" is found to be in agreement with the view of Griffith and others[8], who regarded it as most likely that the "black salt" has a binuclear structure with a hyponitrite-group as a bridge, on the ground that the "black salt" undergoes decomposition by acid or carbon dioxide to give nitrous oxide and that the salt can be prepared, though in a low yield, from sodium hyponitrite and a cobalt salt.

It may also be noteworthy that an infrared absorption band at 1620 to 1640 $cm^{-1}$ due to the NO part of the "black salt"[10] is very close to the frequency of the –N=N– group in ordinary azo-compounds. This to beseems consistent with structure I, having a kind of interaction between the two cobalt ions through the $N_2$ group, as has been concluded to be most probable in the present work. The order of the N–N bond may be almost equal to the bond order in ordinary azo-groups of organic azo-compounds.

In summary, it may be concluded that *the "black salt" has structure I with the Co–N=N–Co group, displaying the special band due to the interaction between the two cobalt ions through the –N=N– group.*

**Polarized Absorption Spectra of Red Nitroso-pentammine-cobalt(III) Nitrate.** — Ultraviolet absorption spectra of the "red salt" in the crystalline state are shown in Fig. 3 and Table I. The crystal structure analysis has not been

reported with the compound as yet. However, the dichroism, as has been determined in the present work, may be regarded to represent the main characteristics of the component absorptions of the complex-ion itself under slight perturbation from the surrounding ions.

A striking dichroism is observed with the first absorption band. It may be assumed that A-absorption in Fig. 3, having the stronger absorption band at about $62\times10^{13}\,sec^{-1}$ represents characteristics of the component absorption of the complex-ion with electric vector along the direction connecting the cobalt(III) ion and the nitroso-group.

The specific band due to the NO-group in co-ordination is observed as a distinct maximum at about $84\times10^{13}\,sec^{-1}$ in Fig. 3, whereas the band is obscured by neighboring stronger absorption in the absorption curve of the compound in solution. The present measurement shows that the specific band is greatly polarized along the Co–ON direction. This is readily understandable if it is assumed that the band is due to electron transfer, possibly from the ON-group to the central metal-ion.

The band at about $102\times10^{13}\,sec^{-1}$ is seen to be polarized in the direction perpendicular to the Co–ON direction. The absorption band due to nitrate ions is expected to appear at about $100\times10^{13}\,sec^{-1}$, but the band of the nitrate ion is so low that the band at about $102\times10^{13}\,sec^{-1}$, as observed with the "red salt" in the present work, may be due to another origin. This band may be a sort of charge transfer band, but its origin is not quite clear for the present.

The second ligand field band is covered under greater specific band in A-absorption, but appears as inflation at about $87\times10^{13}\,sec^{-1}$ in B-absorption. This may be consistent with the frequency difference of about $25\times10^{13}\,sec^{-1}$ between the first and the second band, which was reported with numerous cobalt(III)-complexes.

**Structure of Red Nitrosopentammine-cobalt Salts.**—Both the uni- and the bi-nuclear structure have been proposed for the "red salt". Very recently Asmussen et al.[9] regarded, mostly from magnetic measurements, that the "red salt" may be either a uninuclear or a binuclear complex of cobalt(III). Griffith et al.[8] concluded from examination of its chemical property that the "red salt" may be uninuclear. Bertin et al.[10] concluded, from its infrared spectrum, the oxidation state of the cobalt to be tervalent, but presented no detailed discussion about the structure of the "red salt". Thus the "red salt" may be a uninuclear or a binuclear complex of cobalt(III). In the following, we shall discuss about the structure of the "red salt" on the basis of the present measurements with consideration to the former results.

Possible structures of the binuclear ions for the "red salt" are shown in Fig. 2. Structure I is assigned to the "black salt", as discussed above. Structure II and structure III may be rejected on the ground of the chemical reactions of the "red salt", since the compound with structure II or structure III would be expected to give nitrous oxide in acidic solution, just like the hyponitrite ion. In fact, the "red salt" is stable in water, whereas the "black salt" is readily decomposed to give nitrous oxide. Moreover, the fact that the "red salt" in solution or in the crystalline state shows a definite maximum for the first absorption band seems to be inconsistent with structure III, which would show two "first ligand field absorption bands" originating from the two kinds of cobalt ions. Therefore, the "red salt" can not be assigned to a binuclear form. Thus the present authors are inclined to assume that the "red salt" be uninuclear.

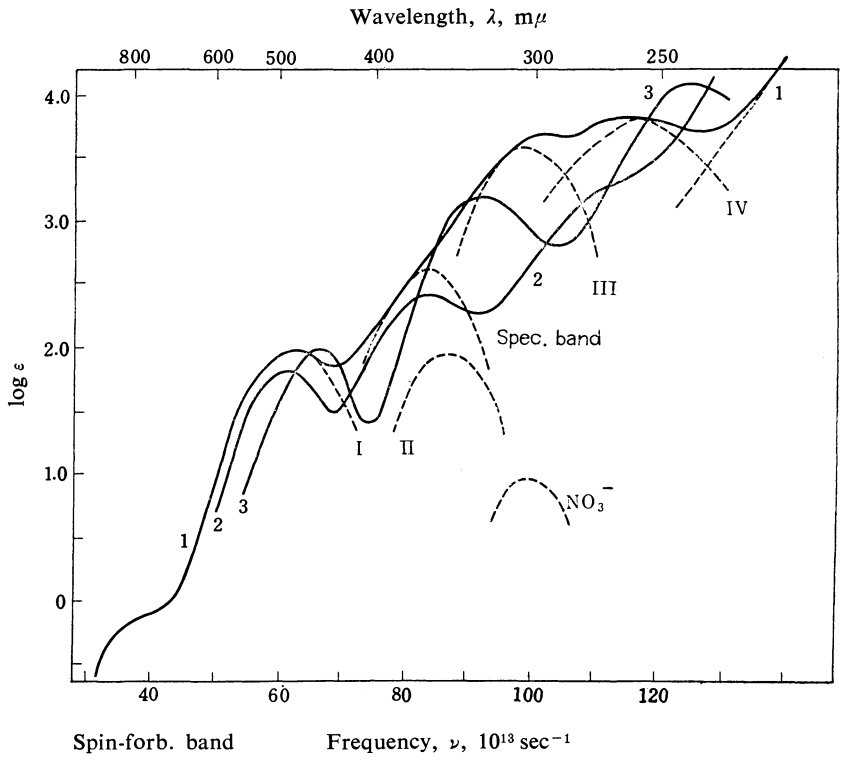

Fig. 4. Absorption spectra of $[Co(NH_3)_5X]^{2+}$ in aqueous solution: 1, $X=NO^-$; 2, $X=ONO^-$ (nitrito); 3, $X=NO_2^-$ (nitro-). Dotted curves represent absorption bands obtained by analysis of the absorption curve 1. The curves 1 and 2 are taken from Ref. 13 in the text.

In addition, the absorption spectra of the "red salt" may be consistent with the assumption of the uninuclear model of the "red salt", as shown in the succeeding paragraph of the present discussion.

Ultraviolet absorption spectra of the "red salt" in solution and in the crystalline state have been determined in the present work, and are shown in Figs. 3 and 4 and Table I. The absorption curve of the compound in solution, as determined in the present work, shows absorption maxima which generally agree with those reported by the former investigators with the compound in solution[9]. Asmussen and others[9] pointed out vague similarity of its absorption spectrum to spectra of most cobaltic compounds, but gave no further discussion about the spectrum. After all, they seemed to conclude that the "red salt" may be either uninuclear or binuclear. It is seen in Fig. 3 and Table I that the "red salt" shows a well-defined maximum for the first band at about 61 to $62\times10^{13}\,sec^{-1}$. The second band, which is characteristic of most complexes of cobalt(III), is covered under strong neighboring absorption bands in the curve of the salt in aqueous solution. Analysis of the absorption curve reveals that there appears a band at about $84\times10^{13}\,sec^{-1}$ which may be regarded as a specific band due mainly to an NO-group in combination with the cobalt(III)-ion. The intensity of the specific band is found to be much smaller than the intensity of the specific band due to a nitro-, an isothiocyanato- or an azide group in the pentammine-cobalt(III) complex. As is evident from inspection of the data in Table II, it is difficult to assume that the band at about $100\times10^{13}\,sec^{-1}$ in the curve of the "red salt"

c) Present measurement.

may correspond to the specific band due to the NO-group in the complex-ion. On the contrary, it is noteworthy that the band at about $84\times10^{13}$ sec$^{-1}$ of the "red salt" is almost as intense as the specific band of a nitrite-group in the pentammine-cobalt(III) in which a nitrite group is co-ordinated to the cobalt-(III) ion through its oxygen atom.

It also is to be noted that the absorption curve of the "red salt", $[Co(NH_3)_5ON](NO_3)_2$ in solution bears a resemblance to the curve[13] of the $[Co(NH_3)_5ONO]^{2+}$ ion in which a nitrite ion is co-ordinated to the cobalt(III) ion through its oxygen atom. This seems to indicate that the NO-group in the "red salt" is co-ordinated to the cobalt(III) ion through its oxygen atom, as will be described in more detail in the later part of the present discussion.

It is known from existing data that substitution of a nitro-group for ammonia in the hexammine-cobalt(III) ion gives rise to a hypsochromic shift of the first absorption band, whereas the substitution of a nitrite group for ammonia yields a bathochromic shift of the first band. In the case of a nitrate-group, an even greater bathochromic shift is observed. It is found in Fig. 4 and Table II that the first absorption band of the "red salt" lies at a longer wavelength than the first band of the hexammine-cobalt(III) ion. Therefore, it may be concluded, from comparison of the wavelength of the first absorption band of the "red salt" with those of the relevant complexes, that *the NO-group in the "red salt" is co-ordinated to the cobalt(III) ion throuh its oxygen atom, and not through the nitrogen atom*, as is customarily assumed for this compound.

Inspection of existing data, summarized in Table II and Fig. 4, also reveals that the specific band due to a nitrite-group lies at about 83 to $84\times10^{13}$ sec$^{-1}$ and the band due to a nitro-group lies at about $92\times10^{13}$ sec$^{-1}$ in the pentammine-cobalt(III) complex. It is seen that the nitrite-group with its oxygen co-ordinated to the cobalt(III) ion shows its specific absorption band at a longer wavelength than does the nitro-group with its nitrogen co-ordinated to the cobalt(III) ion. The present measurement shows that the "red salt" has its specific band at about $84\times10^{13}$ sec$^{-1}$ with log $\varepsilon$ of about 2.6. Thus it is concluded also from examination of the specific band that the NO-group in the "red salt" is co-ordinated to the cobalt(III) ion through its oxygen atom.

The intensity of the specific band due to the nitroso-group in the "red nitroso-pentammine complex" is found to be smaller than the intensity of the specific band due to a nitro-group in the metallic complex, but is almost equal to the intensity of the specific band due to the nitrite group in the pentammine-cobalt(III) complex. This fact also may be consistent with the conclusion that the nitroso-group is co-ordinated to the cobalt(III) ion through the oxygen atom in the "red salt".

In this connection, the close similarity of the absorption curve of the "red salt" to the curve of the nitritopentammine-cobalt(III) complex is noteworthy. In the case of the "red salt", band III and band IV are seen to be displaced to a little longer wavelength than the corresponding bands of the nitritopentammine-cobalt(III) complex, as is seen in Fig. 4, but the correspondence of the absorption bands between the "red salt" and the nitritopentammine-cobalt(III) complex may be evident. This fact also may be taken as indicating that the absorption spectrum of the "red salt" is understood on the assumption of the mononuclear model with the cobalt-to-oxygen bond.

It is interesting to find that a very weak absorption system appears at about $39\times10^{13}$ sec$^{-1}$ in the absorption curve of the "red salt" in solution, as shown in Fig. 4. This absorption band is regarded as being due to electronic transitions between levels with different multiplicities. This spin-forbidden band of the "red salt" is found to lie in the longer wavelength region than $[Co(NH_3)_6]Cl_3$ which shows the band at about $40\times10^{13}$ sec$^{-1}$. This fact is also compatible with the conclusion in the present article that the NO-group is bound to the cobalt ion through its oxygen atom, since the band of this kind would appear in the shorter wavelength region if the NO-group were bound to the cobalt(III) ion through its nitrogen atom.

Summarizing the above discussion, mainly on the basis of the absorption spectra, it is concluded that *the "red salt" is uninuclear, with the nitroso-group co-ordinated to the cobalt-(III) ion through the oxygen atom.*

## Summary

In order to examine the structure of the red and the black nitrosopentammine-cobalt salts, their dichroism in the visible and near-ultraviolet region has been quantitatively determined at room temperature by the microscopic method.

The absorption spectrum of the "black salt" is found to be understandable best on the assumption that the "black salt" has binuclear complexes of cobalt(III), showing a special kind of absorption band due to the interaction between the two cobalt(III) ions through the $N_2$ group.

13) M. Weigel, H. Siebert and M. Linhard, *Z. anorg. allgem. Chem.*, **278**, 287 (1955).

The absorption spectrum of the "red salt" is concluded to be consistent with the model of the uninuclear complex of cobalt(III) with the NO-group co-ordinated to the cobalt(III) ion through its oxygen atom.

# *Chemisorption of Hydrogen on Zinc Oxide. III. The Effect of Additions of Foreign Ions to Zinc Oxide*

By Yutaka KUBOKAWA

(Received January 20, 1960)

Since the electron barrier theory was suggested for the chemisorption on semiconductors by Hauffe, Weisz, and others[1], the importance of the electronic structure of oxides in catalysis has been emphasized by various workers. As an approach along this line, the following method has often been adopted. The electronic structure of a given oxide is modified by the addition of small amounts of foreign ions, and the resulting changes in catalytic activity are then studied. As regards the hydrogen-deuterium exchange reaction on zinc oxide, Parravano et al.[2] found that the addition of $Al^{3+}$ or $Ga^{3+}$, which should increase its electrical conductivity, increased the activity and lowered the activation energy, while the addition of $Li^+$ showed a reverse effect. On the basis of these results, Hauffe[3] suggested that the rate-determining step in this case was the electron transfer from zinc oxide to adsorbed hydrogen ions to allow it to desorb, closely correlating the catalytic activity of zinc oxide with its properties as a semiconductor.

Whatever mechanism may be operative in the hydrogen-deuterium exchange reaction, it is obvious that the hydrogen chemisorption on zinc oxide samples containing these foreign ions must be studied before any conclusive explanation of the activity changes caused by such additions can be given. Apart from the exchange reaction, such a study may be of considerable interest concerning the relation between the electronic structure of oxide and its hydrogen chemisorption. At present the only work along this line seems to be that of Cimino et al.[4] In this work, as described in previous papers,[5,6] hydrogen chemisorption has been investigated by measuring the rates of adsorption and desorption, and the adsorption equilibrium, with zinc oxide modified by the addition of foreign ions such as $Li^+$, $Al^{3+}$ and $Ga^{3+}$.

## Fxperimental

**Materials.**—Zinc oxide without foreign ions was prepared by sintering at 800°C for 5 hr. of non-sintered zinc oxide, which was obtained from zinc oxalate as described previously.[5] ZnO+1 mole % $Al_2O_3$, ZnO+1 mole% $Ga_2O_3$, and ZnO+0.5 mole% $Li_2O$: Non-sintered zinc oxide was impregnated with a solution containing a desired amount of aluminum, gallium, or lithium nitrate, dried at 110°C, and sintered at 800°C for 5 hr. Hydrogen and other gases used were prepared and purified as described in the previous work[5,7].

The weight of adsorbent and the surface area determined by the B. E. T. method using nitrogen adsorption are shown in Table I.

TABLE I.

| Adsorbent | Weight, g. | Surface area, $m^2/g.$ |
|---|---|---|
| ZnO | 19.6 | 1.0 |
| ZnO+1 mole% $Al_2O_3$ | 20.6 | 1.7 |
| ZnO+1 mole% $Ga_2O_3$ | 22.7 | 3.6 |
| ZnO+0.5 mole% $Li_2O$ | 27.5 | 0.40 |

**Apparatus and Procedure.** — Details of the apparatus and procedure were already described in the previous paper[5]. Prior to a series of experiments, all the adsorbents used in the present work

were subjected to repeated pretreatments with hydrogen at 450°C followed by evacuation at the same temperature.

## Results

**The Variation in the Adsorbed Amount on Raising Temperature During Adsorption.** — Hydrogen was allowed to be chemisorbed by the adsorbent at room temperature and the temperature of the whole system was raised up to a higher temperature in stages, at each of which, in most cases, a rapid desorption followed by a slow uptake was observed. The activation energy of adsorption was determined by comparison of the rates at different temperatures corresponding to equal amount of the slow chemisorption as described in the previous paper[6]. As an example, a run between 215 and 266°C on ZnO+1 mole% $Ga_2O_3$ is shown in Fig. 1. The activation energies thus obtained in various temperature ranges with ZnO, ZnO+1 mole% $Ga_2O_3$, and ZnO+0.5 mole% $Li_2O$ are shown in Table II. Here, the activation energies in similar temperature ranges are almost of the same order of magnitude throughout all the adsorbents, suggesting that the activation energy of adsorption is not affected seriously by the addition of foreign ions. However, the proportion of the amount rapidly desorbed on an abrupt temperature rise to the total amount adsorbed is clearly affected by the addition of foreign ions. The amount of such rapid desorption at each stage is shown in Figs. 2—4, together with the amount adsorbed in a certain constant time period at each temperature. Comparison between Figs. 2 and 3 shows that for ZnO+1 mole% $Ga_2O_3$ the rapid desorption occurs to a much less extent than for ZnO.

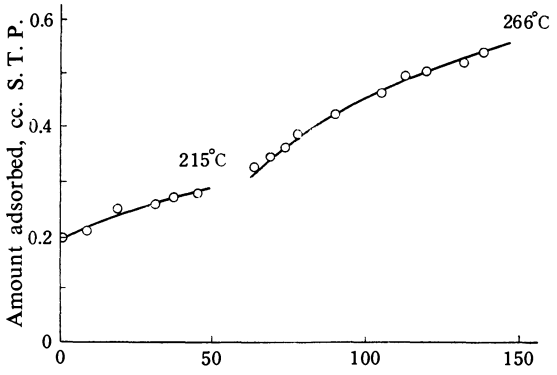

Fig. 1. Rate of hydrogen chemisorption on ZnO+1 mole% $Ga_2O_3$ in case of temp. change during adsorption ; Pressure, 50~60 mmHg.

TABLE II. ACTIVATION ENERGY OF ADSORPTION*

| Adsorbent | Temp. range, °C | Activation energy of adsorption, kcal./mole |
|---|---|---|
| ZnO | 72~143 | — |
| | 143~203 | 12 |
| | 203~254 | 15 |
| ZnO+0.5 mole% $Li_2O$ | 98~146 | 7.5 |
| | 146~196 | 11 |
| | 196~244 | 14.5 |
| ZnO+1 mole% $Ga_2O_3$ | 124~171 | 8.5 |
| | 171~215 | 11.5 |
| | 215~266 | 16 |

* The upper limit of the experimental error was ±10%.

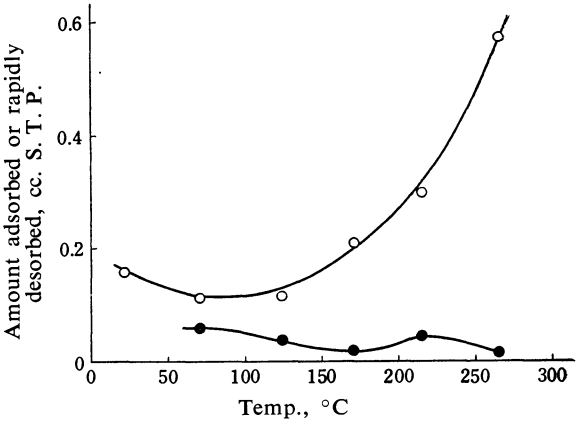

Fig. 3. Variation in the amount adsorbed on ZnO+1 mole% $Ga_2O_3$ on raising temp. ; Hydrogen pressure, 50~60 mmHg ; -○-, the amount adsorbed after 1.5 hr. -●-, the amount rapidly desorbed.

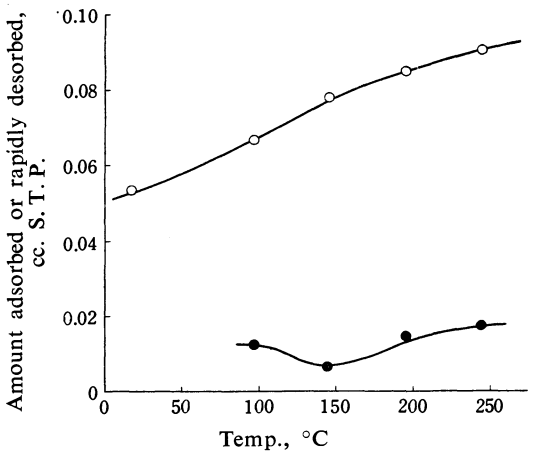

Fig. 4. Variation in the amount adsorbed on ZnO+0.5 mole% $Li_2O$; on raising temp.; Hydrogen pressure, 0.2~0.3 mmHg; -○-, the amount adsorbed after 1 hr.; -●-, the amount rapidly desorbed.

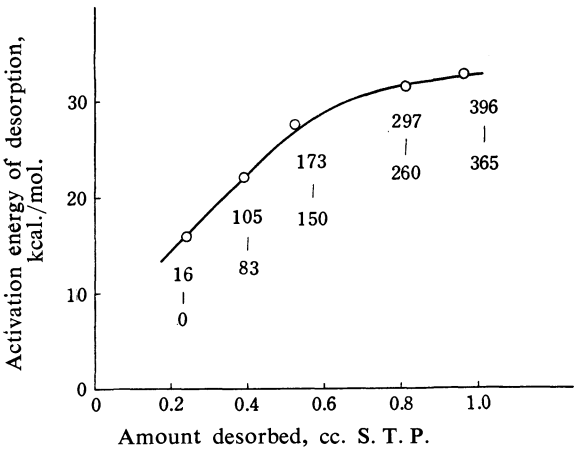

Fig. 5. Activation energies of desorption of hydrogen chemisorbed on ZnO. The amount adsorbed and equilibrium pressure at room temp. before desorption were 1.10 cc. and 42.2 mmHg, respectively. Numerical values in Figs. 5, 6, and 7 refer to the temp. interval where the activation energies were determined.

The results with ZnO+0.5 mole% $Li_2O$ can not be compared directly with the others owing to different pressure conditions.

**The Activation Energies of Desorption at Various Coverages.**—After hydrogen was allowed to be adsorbed at about 400°C, the temperature of the specimen was raised from 0 to 400°C in stages, at each of which the activation energy of desorption was determined from comparison between the rates of desorption at different temperatures corresponding to equal amounts left adsorbed as stated

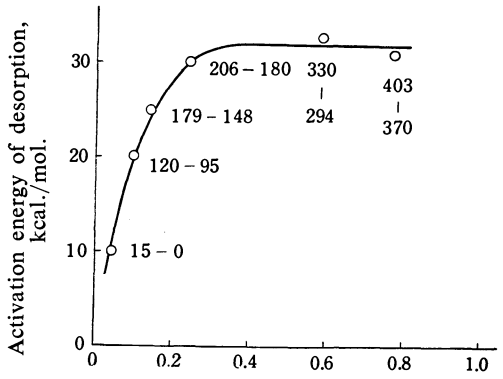

Fig. 6. Activation energies of desorption of hydrogen chemisorbed on ZnO+1 mole% $Ga_2O_3$. The amount adsorbed and equilibrium pressure at room temp. before desorption were 0.98 cc. and 52.3 mmHg, respectively.

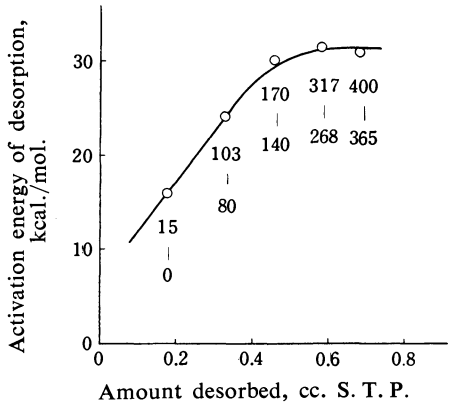

Fig. 7. Activation energies of desorption of hydrogen chemisorbed on ZnO+0.5 mole% $Li_2O$. The amount adsorbed and equilibrium pressure at room temp. before desorption were 0.78 cc. and 41.0 mmHg, respectively.

in the previous paper[5]. The results obtained with ZnO, ZnO+1 mole% $Ga_2O_3$ and ZnO+0.5 mole% $Li_2O$ are shown in Figs. 5—7. Here, it was confirmed, in the same manner as described previously, that the rate of adsorption was negligible during the desorption experiment for all the adsorbents studied. From these figures the following picture would be obtained. For all the adsorbents with and without foreign ions, the activation energy increases with decreasing amount adsorbed up to almost the same value of 30~33 kcal./mol., although the proportions of the amounts desorbed with a lower activation energy (<20 kcal./mol.) to the total amount desorbed are different from one another, the smallest value being found with ZnO+1 mole% $Ga_2O_3$ in accordance with the results of adsorption experiment above mentioned.

**Adsorption Isotherms.** — Adsorption equilibrium measurements were carried out only with ZnO and ZnO+1 mole% $Al_2O_3$ in the same manner as described previously[5]: After hydrogen was allowed to be adsorbed at about 350°C, the isotherms were determined by successive withdrawals of the gas. The isotherms thus obtained were found to be reproduced on increasing or decreasing pressure subsequently. For both systems the Langmuir plot was applicable in the pressure range

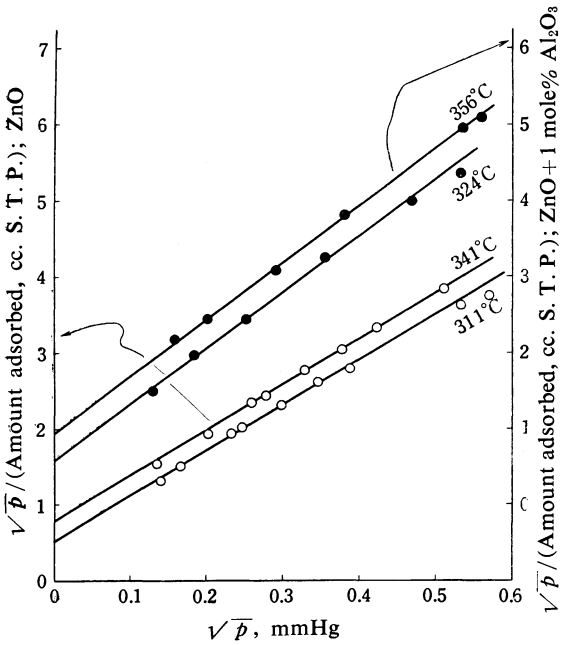

Fig. 8. Langmuir plots for ZnO and ZnO +1 mole% $Al_2O_3$; -○-, ZnO; -●-, ZnO+1 mole% $Al_2O_3$.

studied as seen in Fig. 8. It follows from this figure that the heat of adsorption is unaffected by the addition and is equal to 18 kcal./mol. Although such applicability of the Langmuir plot probably results from a limited range of coverage, the slopes of the lines in Fig. 8 may be utilized to estimate the magnitude of the surface available for the chemisorption under the given experimental conditions; (Reciprocal of the slope per unit area) is 0.0039 cc. for ZnO+1 mole% $Al_2O_3$ and 0.0085 cc. for ZnO.

**The Effect of Additions of Foreign Ions on Carbon Monoxide Chemisorption.** — According to the previous work[7] on carbon monoxide chemisorption on zinc oxide, there are two types of chemisorption, one predominating at low and the other at high temperatures. The effect of foreign ions was studied only for the adsorption of the former type. Because of a small amount adsorbed on ZnO+0.5 mole% $Li_2O$, the adsorption isotherms were determined only with ZnO and ZnO+1 mole% $Al_2O_3$ in similar way to that given previously. The heats of adsorption thus obtained for the two adsorbents proved to be almost the same, i. e., 10~12 kcal./mol.

## Discussion

In view of the low temperature used in preparing the samples, it seems unlikely that the added foreign ions are distributed uniformly throughout. As seen in Table I, however, surface area of the adsorbents is increased by the addition of $Ga_2O_3$ or $Al_2O_3$ and decreased by that of $Li_2O$. According to Hauffe[8] and Parravano[3], such variation in surface area suggests a decrease in the concentration of interstitial zinc ions, i. e., an increase in the concentration of free electrons in the former case, and the reverse change in the latter case. It may therefore be supposed that at least in a qualitative sense the electronic structure of the adsorbents in this work has been modified by such addition in the manner predicted by the theory of Hauffe and others.

As for the interpretation of the effect of the addition of foreign ions in the present work, it should be taken into consideration that such addition will change the heterogeneity of the surface as well as the electronic state of zinc oxide, both affecting the features of its hydrogen chemisorption. Although it is difficult to separate these two effects, the results obtained in this work, however, may be interpreted as follows: The identical heat of adsorption of 18 kcal./mol. for ZnO and ZnO +1 mole% $Al_2O_3$ is in agreement with the maximum heat of adsorption for non-sintered zinc oxide given in the previous work[5], suggesting that the maximum heat of adsorption is probably unaffected by the additions of foreign ions. This result together with the identical maximum activation energy of desorption throughout all the adsorbents with and without foreign ions would be unexpected, if the electronic state of zinc oxide played a large part in determining the features of hydrogen chemisorption. In addition, the activation energies of adsorption in similar temperature ranges are almost the same throughout all the adsorbents. Moreover, as described in the previous paper[9], the oxygen pretreatment at a high temperature which should change the electronic state of zinc oxide, gives little effect on its hydrogen chemisorption. Thus, taking account of the existence of surface heterogeneity in this system, the following tentative conclusion may be drawn:

8) K. Hauffe and A. L. Vierk, *Z. physik. Chem.*, **196**, 160 (1950).
9) Y. Kubokawa, This Bulletin, **33**, 743 (1960).

The heat of adsorption and the activation energy of adsorption associated with each set of sites may not be affected seriously by the addition of foreign ions; the variation in the features of the hydrogen chemisorption caused by such addition can probably be attributed to the change in the distribution function of sites rather than to that in the electronic structure of the adsorbents.

According to Cimino et al.[4], the adsorption isobars obtained with ZnO and ZnO+0.5 mole% $Li_2O$ show one or two maxima, while on ZnO+0.3 mole% $Ga_2O_3$ the amount adsorbed increases steadily with temperature, in qualitative agreement with the results mentioned above; the addition of $Ga_2O_3$ reduces the amount adsorbed over the whole range of temperature in an analogous way to that of $Al_2O_3$ (Fig. 8). This is reflected in the change of the amount adsorbed before desorption experiments (Figs. 5—7); the amount adsorbed on unit surface area is 0.056 cc. for ZnO, 0.012 cc. for ZnO+1 mol% $Ga_2O_3$, and 0.071 cc. for ZnO+0.5 mole% $Li_2O$. Although the true nature of such change in the amount adsorbed is not yet clear, there seems to be little or no doubt that such behavior can not be explained in terms of the change in the electronic structure of zinc oxide alone.

As regards the change in activity towards the hydrogen-deuterium exchange reaction caused by the addition of foreign ions, the considerations given above seem to indicate that it is doubtful that such an effect is attributed to the change in the electronic structure of zinc oxide. In fact, according to Heckelsberg et al.[10], although the activity is higher on ZnO+1 mole% $Al_2O_3$ than on ZnO, the activation energy is essentially the same for the two adsorbents, in contradiction with the results of Parravano. Such an identical activation energy is, however, what would rather be expected from the results in the present work. Further study of the hydrogen chemisorption and the exchange reaction with one and the same specimen of zinc oxide will probably lead us to a more consistent picture of all the related phenomena.

## Summary

The hydrogen chemisorption on zinc oxide samples modified by the addition of foreign ions such as $Li^+$, $Al^{3+}$, and $Ga^{3+}$ was investigated by measuring the rates of adsorption and desorption, and the adsorption equilibrium. The addition of foreign ions gave little or no effect on the maximum values of the activation energy for desorption and of the heat of adsorption, and the activation energies of adsorption in similar temperature ranges. On the basis of these results combined with the effect of oxygen treatment on this chemisorption on zinc oxide described previously, it was tentatively concluded that the variation in the features of hydrogen chemisorption caused by the addition of foreign ions is probably attributable to the change in a heterogeneity of the surface rather than that in the electronic state of zinc oxide. Finally, it was mentioned that the heat of adsorption of carbon monoxide at room temperature was also unaffected by such additions.

The author wishes to express his sincere thanks to Professor O. Toyama for his guidance and encouragement throughout the course of this study.

# *Zur Darstellung von 3-Methylpolymethoxyphthaliden*

Von Eturô MAEKAWA und Yukiko SUMIMOTO

(Eingegangen am 23. Januar, 1960)

3-Methylpolymethoxyphthalide erweckten unser Interesse, weil sie durch Grignardreaktion mit Alkylmagnesiumbromiden und durch anschließende Oxydation mit Kaliumpermanganat Polymethoxy-*o*-acyl-acetophenon ergeben, die dann durch Oxydation mit Selendioxyd in Polymethoxynaphthochinone übergehen[1]. Aus *o*-Phthalaldehydsäure wurde 3-Methylphthalid durch Grignardreaktion mit Methylmagnesiumjodid in guter Ausbeute[2] dargestellt. Auf diese Weise wurden auch 3-Methyl-6. 7-dimethoxy-[2,3], 3-Methyl-4. 5. 6-trimethoxy-[4] und 3-Methyl-4. 5. 6. 7-tetramethoxyphthalid[1] aus den entsprechenden polymethoxylierten *o*-Phthalaldehydsäuren gewonnen. Bei den polymethoxylierten Derivaten, besonders bei Opiansäure nimmt die Ausbeute der Grignardreaktion jedoch stark ab, offenbar weil die Löslichkeit der Polymethoxyphthalaldehydsäuren in Äther viel geringer ist. Obwohl die Ausbeute dadurch einigermaßen verbessert werden konnte[5], daß man die Dosis des Äthers als Lösungsmittels bei der Grignardreaktion erhöhte, oder, daß man einer ätherischen Suspension der Polymethoxyphthalaldehydsäuren des vorher hergestellten Grignardreagens zutropft, und obwohl es uns weiter gelingt, drei in der Literatur noch nicht beschriebene Produkte, nämlich 3-Methyl-5. 6-dimethoxy-, 3-Methyl-5. 6. 7-trimethoxy- und 3. 7-Dimethyl-4. 5. 6-trimethoxyphthalid, auf diese Weise darzustellen, erscheint diese Methode der Darstellung nicht sehr praktisch.

Andererseits stellten Gabriel und Michael aus *o*-Acetylbenzoesäure, die aus Phthalsäureanhydrid und Malonsäure in Pyridin leicht zugänglich ist[6], durch Reduktion mit Natriumamalgam 3-Methylphthalid in einer fast quantitativen Ausbeute dar[7]. Es wurde von uns fesgestellt[4], daß sich aus Polymethoxyphthaliden durch Behandeln mit doppeltermolekularer Menge *N*-Bromsuccinimid (abgekürzt NBS) unter Bestrahlung und durch anschließende Hydrolyse des bromierten Produktes neben den Polymethoxyphthalaldehydsäuren die entsprechenden Polymethoxy-*o*-phthalsäuren bilden. Um eine praktische Darstellungsmethode der Polymethoxyphthalsäure zu finden, wurde nun die Reaktion des NBS auf Polymethoxyphthalaldehydsäuren, die aus den entsprechenden Phthaliden durch Versetzen mit NBS leicht hergestellt werden können[1,4,8], ausführlich untersucht. Yamaguchi stellte fest, daß Piperonal beim Versetzen mit NBS 3. 4-Methylendioxybenzoesäure und daneben noch Protocatechualdehyd sowie 6-Brom-3. 4-methylendioxybenzoesäure ergab[9], während Vanilin keine Carbonsäuren sondern 5-Bromvanilin und daneben wenig Dehydrodivanilin lieferte[10], und nahm an, daß die Aldehydgruppe über Bromcarbonyl-in die Carboxylgruppe übergeht[11].

Erhitzt man *o*-Phthalaldehydsäure oder deren

polymethoxylierte Derivate in Tetrachlorkohlenstoff in Gegenwart von Dibenzoylperoxyd (abgekürzt BPO), so entwickelt sich Bromwasserstoff und aus dem Reaktionsgemisch können die entsprechenden Phthalsäureanhydride in guter Ausbeute leicht isoliert werden. Da die Reaktion unter Bromwasserstoffentwicklung zu Phthalsäureanhydriden führt, scheint sie gemäß folgendem Schema zu verlaufen:

I: $R_1=R_2=R_3=R_4=H$
II: $R_1=R_4=H$, $R_2=R_3=OCH_3$
III: $R_1=R_2=H$, $R_3=R=OCH_3$
IV: $R_1=R_2=R_3=OCH_3$, $R_4=H$
V: $R_1=H$, $R_2=R_3=R_4=OCH_3$
VI: $R_1=R_2=R_3=R_4=OCH_3$
VII: $R_1=R_2=R_3=R_4=H$
VIII: $R_1=R_4=H$, $R_2=R_3=OCH_3$
IX: $R_1=R_2=H$, $R_3=R_4=OCH_3$
X: $R_1=R_2=R_3=OCH_3$, $R_4=H$
XI: $R_1=R_2=R_3=R_4=OCH_3$

Die Ergebnisse sind zusammenfassend in der Tabelle I angegeben. Weder kernbromierte noch dimerisierte Produkte wurden in den Reaktionsgemischen gefunden; Bildung von Substanzen, die mit Eisenchlorid eine violette Farbreaktion zeigen, wurde auch nicht festgestellt.

Da die Ausbeute an den Phthalsäuren bei der Reaktion der Polymethoxyphthalide mit doppelter molekularer Menge NBS von der Feuchtigkeit der Reaktionssysteme abhängig ist, scheinen die Phthalsäuren zum Teil über die freien *o*-Phthalaldehydsäuren, die sich durch die Wirkung der Feuchtigkeit auf die 3-Bromphthalide bilden, durch deren Reaktion mit NBS über die Phthalsäuremonobromide zu entsehen. Die Entstehung von Phthalsäuren muß jedoch aus Polymethoxyphthaliden auch anders, als über die freien *o*-Phthalaldehydsäuren möglich sein, da sich Phthalsäuren auch unter Feuchtigkeitsausschluß ohne Entwicklung von Bromwasserstoff bilden, man kann sie erst nach der Hydrolyse des Produktes isolieren.

Die gebildeten Polymethoxyphthalsäuren werden durch Erhitzen zu ihren Anhydriden geführt, welche dann mit Malonsäure in Pyridin erwärmt werden. Da es im allgemeinen schwierig war, aus den Reaktionsgemischen die erwarteten Polymethoxy-*o*-acetylbenzoesäuren rein zu isolieren, werden sie in rohem Zustand mit Natriumamalgam oder Zink und Essigsäure versetzt und 3-Methylpolymethoxyphthalide aus den schwach angesäuerten Reaktionsgemischen ausgeäthert (Tabelle II). Hemipinsäure- bzw. 3. 4. 5-Trimethoxyphthalsäureanhydrid ergibt 3-Methylmekonin bzw. 3-Methyl-5. 6. 7-trimethoxyphthalid, wobei 3-Methyl-4. 5-dimethoxy- bzw. 3-Methyl-4. 5. 6-trimethoxyphthalid im Reaktionsgemisch nicht gefunden wurden, was vermutlich auf die sterische Behinderung durch die *o*-stehende Methoxygruppe zurückzuführen ist. Bei der Reduktion des rohen Reaktionsproduktes aus 4. 5-Dimethoxyphthalsäureanhydrid und Malonsäure, das noch die entsprechende freie Phthalsäure zu erheblicher Menge enthält, bildete sich auch daneben durch deren Reduktion 5. 6-Dimethoxyphthalid. Die Kondensation der Polymethoxyphthalsäureanhydride, die in Pyridin als Phthalsäureanhydrid viel weniger löslich sind, verlief mit Malonsäure nur in sehr schlechten Ausbeuten, und ihre präparative Bedeutung blieb noch zweifelhaft, obgleich wir noch nicht versucht haben, optimale Bedingungen zu suchen.

## Beschreibung der Versuche

**1. *o*-Phthalaldehydsäuren.**—Wurden aus den entsprechenden Phthaliden durch Versetzen mit NBS und durch anschließende Hydrolyse der bromierten Produkte hergestellt[1].

**2. Phthalsäureanhydrid.**—5 g (1/30 mol) *o*-Phthalaldehydsäure wurden in 200 ccm Benzol gelöst, ca. 20 ccm des Benzols abdestilliert, um die Feuchtigkeit des Systems azeotropisch zu beseitigen, dann mit 200 ccm Tetrachlorkohlenstoff und 5,9 g (1/30 mol) NBS in Gegenwart von wenig BPO und unter Bestrahlung mit einer 500 W-Wolframlampe

1 Std. am Rückfluß erhitzt. Das beim Erkalten ausgeschiedene Succinimid (ca. 3,3 g) wurde abgesaugt, das Filtrat eingeengt, der Rückstand vorsichtig mit wenig kaltem Wasser zum Beseitigen des Succinimids gewaschen und aus Benzol umkristallisiert, 4,66 g (94,5%) farblose Nadeln, Fp. 127~128°C* (Lit.[12] 130, 8°C).

**3. Polymethoxyphthalsäureanhydride.**—Die entsprechenden Polymethoxyphthalaldehydsäuren wurden wie vorstehend mit NBS versetzt: die besten Ergebnisse sind in der Tabelle I zusammenfassend angegeben.

**4. 3-Methyl-5. 6-dimethoxyphthalid (*α*-Methyl-*m*-mekonin).**—(a) Einer gut umgerührten Suspension von 3,7 g 4. 5-Dimethoxyphthalaldehydsäure (*m*-Opiansäure) in 500 ccm Äther wurde ein Grignardreagens aus 9,5 g Methyljodid und 1,7 g Magnesiumspänen unter Eiskühlung langsam zugetropft. Das Gemisch wurde 1 Std. unter Eiskühlung und noch 1 Std unter Erwärmen am Rückfluß umgerührt, dann mit 2 N Schwefelsäure angesäuert und mit Äther ausgezogen, wobei aus der wässerigen Schicht 3,1 g nicht umgesetzte *m*-Opiansäure zurückgewonnen wurden. Die ätherische Lösung wurde mit Sodalösung und anschließend mit Wasser gewaschen, mit Natriumsulfat getrocknet und eingeengt. Der Rückstand wurde aus ca. 250 ccm Wasser kristallisieren gelassen, 160 mg farblose Prismen oder Nadeln, Fp. 108~110°C.

Gef.**: C 63,20; H 5,62. Ber. für $C_{11}H_{11}O_4$ (208,2): C 63,50; H 5,81.

Es fiel unter Umständen aus den Wasser in durchsichtigen Nadeln aus, die bei 118,5~120°C schmelzen; sie scheinen kristallwasserhaltig zu sein, reichten jedoch zu einer Elementaranalyse nicht.

(b) 4 g 4. 5-Dimethoxyphthalsäureanhydrid wurden 3 Std mit 2,3 g Malonsäure und 3 ccm Pyridin in 10 ccm Xylol auf dem Wasserbad unter Feuchtigkeitsausschluß erwärmt. Beim Erkalten des Reaktionsgemisches fielen 3,3 g des Anhydrids aus. Das Gemisch wurde abfiltriert, das Filtrat mit 80 ccm Wasser gemischt, mit Salzsäure angesäuert und mit Äther ausgezogen. Der ätherische Ausznng wurde mit Wasser gewaschen und einge engt, der Rückstand mit Wasser zum Sieden erhitzt, um das Xylol azeotropisch zu entfernen, und die wässerige Lösung eingeengt. Der Rückstand (0,45 g) wurde 2 Std. mit 1 g Zinkstaub in einem Gemisch aus 1 ccm Wasser und 4 ccm Essigsäure am Rückfluß erhitzt, das Gemisch im Vakuum eingeengt, der Rückstand in Äther gelöst und die ätherische Lösung mit Sodalösung gewaschen und eingeengt. Aus Wasser umkristallisiert ergab der Rückstand wenig *m*-Mekonin (Fp. 154~155°C) und daneben 185 mg 3-Methyl-5. 6-dimethoxyphthalid (Fp. 109~110°C), der beim Mischschmelzpunkt mit dem obenerwähnten Produkt keine Depression zeigte.

**5. 2. 7 - Dimethyl - 4. 5. 6 - trimethoxyphthalid.** — Einem Geignardreagens aus 0,8 g Magnesiumspänen und 5,5 g Methyljodid wurde eine Lösung von 2 g 3. 4. 5-Trimethoxy-6-methylphthalaldehydsäure (Fp. 109~113°C) in 320 ccm Äther unter kräftigem Umrühren und Eiskühlung langsam zugetropft und das Gemisch wie üblich aufgearbeitet. Aus der ätherischen Lösung wurden durch Waschen mit Sodalösung 0,2 g Ausgangsprodukt und durch anschließendes Einengen ein fettartiger Rückstand gewonnen, der aus alkoholhaltigem Wasser in farblosen Nadeln ausfiel, 0,76 g, Fp. 80~81,5°C.

Gef.: C 62,16; H 6,33. Ber. für $C_{13}H_{16}O$ (252,2): C 61,89; H 6,39.

**6. 3 - Methyl - 5. 6. 7 - trimethoxyphthalid.** — (a) Einem Grignardreagens aus 0,5 g Magnesiumspänen und 3,0 g Methyljodid wurde eine Suspension von 1,5 g 4. 5. 6-Trimethoxyphthalaldehydsäure in 500 ccm Äther unter Eiskühlung zugetropft. Es wurde wie üblich aufgearbeitet und das Produkt aus Wasser umkristallisiert, 0,80 g farblose Nadeln, Fp. 103, 5~104,5°C.

Gef. C 60,53; H 6,00. Ber. für $C_{12}H_{14}O_5$ (238,2): C 60,50; H 5,92.

(b) 3,5 g 3. 4. 5-Trimethoxyphthalsäureanhydrid wurden 3 Std in 4,5 ccm Pyridin mit 1,8 g Malonsäure auf dem Wasserbad unter Feuchtigkeitsausschluß erwärmt. Das Reaktionsgemisch wurde in 25 ccm Wasser gelöst, die Lösung mit Salzsäure angesäuert und mit Äther ausgezogen. Die ätherische Lösung wurde nach dem Waschen mit Wasser eingeengt, der Rückstand in wenig Wasser gelöst und die wässerige Lösung bei Zimmertemperatur eindunsten gelassen, wobei 2,3 g 3. 4. 5-Trimethoxyphthalsäure zurückgewonnen wurden. Die Mutterlauge wurde eingeengt und der Rückstand (1 g) in einer Natronlauge aus 2 g Natriumhydroxyd und 150 ccm Wasser gelöst, mit einem Natriumamalgam aus 0,65 g Natrium und 30 g Quecksilber 24 Std. bei Raumtemperatur stehengelassen und anschließend 8 Std. unter Zusatz von 50 ccm Wasser auf dem Wasserbad erwärmt. Die wässerige Schicht wurde mit Salzsäure angesäuert, auf 50 ccm eingeengt und ausgeäthert. Die ätherische Lösung wurde mit Wasser, mit Natriumhydrogencarbonatlösung und mit Wasser gewaschen und eingeengt. Der Rückstand wurde aus Wasser mit Aktivkohle kristallisieren gelassen, 150 mg farblose Nadeln, Fp. 103,5~104,5°C, die beim Mischschmelzpunkt mit dem oberen Produkt keine Depression zeigte.

**7. 3-Methyl-6. 7-dimethoxyphthalid (*α*-Methyl-mekonin).**—4 g 3. 4-Dimethoxyphthalsäureanhydrid (Hemipinsäureanhydrid) wurden 3 Std mit 5 ccm Pyridin und 2,3 g Malonsäure auf dem Wasserbad in Abwesenheit von Feuchtigkeit erwärmt. Das Reaktionsgemisch wurde wie bei Darstellung der von 3-Methyl-5. 6. 7-trimethoxyphthalid nach der Methode (b) aufgearbeite, wobei 2,67 g 3. 4-Dimethoxyphthalsäure zurückgewonnen und 230 mg des Produktes erhalten wurden. Das Produkt zeigte aus Wasser umkristallisiert einen Fp. von 100~101°C (Lit.[2] 101°C).

## Zusammenfassung

Polymethoxy-*o*-phthalaldehydsäuren wurden mit *N*-Bromsuccinimid zu den entsprechenden Phthalsäureanhydriden unter Bromwasserstoffentwicklung in guter Ausbeute oxydiert, wobei kernbromierte bzw. dimerisierte Produkte oder

* Schmelzpunkte wurden mikroskopisch bestimmt, aber nicht korrigiert.

12) K. P. Monroe, *Ind. Eng. Chem.*, **11**, 1116 (1919).

** Für Mikroanalyse der Verbindungen sind wir der Zentralen Mikroanalysenstelle Univ. Kyoto sehr dankbar.

phenolische Verbindungen nicht nachgewiesen wurden. Aus den Polymethoxyphthalsäureanhydriden wurden durch Versetzen mit Malonsäure in Pyridin die *o*-Acetylpolymethoxybenzoesäuren hergestellt, die zu den 3-Methylpolymethoxyphthaliden reduziert wurden, obwohl die erste Stufe der Reaktion, nämlich die Kondensation mit Malonsäure, nur in sehr schlechter Ausbeute verlief. Bei dieser Kondensation wurde eine sterische Behinderung durch die *o*-ständige Methoxygruppe beobachtet, wie sich aus 3. 4. 5-Trimethoxyphthalsäureanhydrid nur 3-Methyl-5. 6. 7-trimethoxyphthalid bildet. 3-Methyl-5. 6-dimethoxy-, 3-Methyl-5. 6. 7-trimethoxy- und 3. 7-Dimethyl-4. 5. 6-trimethoxyphthalid wurden aus den entsprechenden *o*-Phthalaldehydsäuren durch die Grignardreaktion unter Verwendung von großer Dosis des Äthers, oder durch eine umgekehrte Grignardreaktion dargestellt.

Herrn Prof. Dr. F. Weygand, München, sind wir für seine Anregung und Anleitung zu vorstehender Arbeit zum aufrichtigsten Dank verpflichtet. Auch Doktor der Technology, Frau Seiko Nan'ya danken wir für ihre intensive Mitwirkung bestens.

# *The Ultraviolet Absorption Spectra of Stilbene and Some Related Compounds in the Solid State Measured by the Pressed KCl Disk Technique*

By Hiroshi SUZUKI

(Received December 15, 1959)

Molecular structures are, needless to say, not rigid. Even the equilibrium or most probable conformation of a compound can vary, depending on, above all, the aggregation state and the temperature. Thus, the equilibrium conformation of a compound determined by the X-ray crystal analysis, for example, is not necessarily maintained in a state other than the crystalline state. A typical example is biphenyl. This compound is planar in the crystalline state, non-planar in the gaseous state, and probably slightly non-planar in solution[1-1)].

If the most probable conformation of a compound is appreciably different in various states, the electronic absorption spectra of the compound in the various states must be correspondingly different from each other. The author has shown in a series of papers[1)] that the most probable conformations of many conjugated componds in various states, especially in solution, can be inferred with almost complete satisfaction from the electronic absorption spectra. The principle of the inference consists in comparison of the spectrum of a given compound under a given condition with that of a suitable reference compound under a suitable condition, whose conformation is already known, or else, can be presumed reasonably. Since the conformation of the reference compound is determined by the X-ray crystal analysis in most cases, it is frequently necessary to compare the concerned spectrum with the spectrum of the reference compound in the crystalline state.

The spectra of compounds in the crystalline state have been measured so far by various methods and for various purposes. Thus, they have been measured often with single crystals and with polarized light[2)]. This method is useful particularly for the assignment of absorption bands. Alternatively, they have been measured also with solid films prepared on quartz, silica, or glass plates by sublimation of crystals, by evaporation of thin layers of solutions, or by solidification of melted substances[3)]. These methods have been used sometimes for the purpose of studying the crystal spectra themselves, and sometimes simply for the reason that the spectra can not be measured in solutions because of the low solubilities of the substances.

In the crystal spectra measured by these

1) H. Suzuki This Bulletin, (I) **32**, 1340, (II) 1350, (III) 1357 (1959), (IV) **33**, 109, (V) 379, (VI) 389, (VII) 396, (VIII) 406, (IX) 410, (X) 613, (XI) 619 (1960).

2) See, for example, A. C. Albrecht and W. T. Simpson, *J. Chem. Phys.*, **23**, 1480 (1955).

3) See, for example; J. W. Weigl, ibid., **24**, 364 (1956).

methods the effect of the orientation of molecules in crystals reveals itself markedly[4]. This marked orientation effect is, of course, essential to the purpose of assignment of bands. However, this effect makes the spectra measured by these methods unsuitable for direct comparison with the spectra of solutions where molecules are oriented at random.

For this reason, in the foregoing series of papers the spectra measured by the "pressed KCl disk technique" were used as the crystal spectra of the reference compounds. The pressed KCl disk technique is quite analogous to the well-known pressed KBr disk technique developed for infrared spectroscopy, and was applied to electronic absorption spectroscopy first by Dale[4] in 1957. It may be somewhat doubtful whether or not the state of molecules in pressed KCl disks is quite the same as that in the crystals. Thus, there may be a possibility that the state is near to that of solid solutions. It seems, however, to be more probable that micro-crystals are oriented at random in disks. If it is so, it seems reasonable to consider that the spectra measured by this method are most suitable, as the spectra of the compounds in the crystalline state, to be directly compared with the solution spectra.

An additional advantage of this method over the others is that the influence of reflection at the disk surface can approximately be eliminated by using a pressed disk of pure potassium chloride as the reference in measurement of the spectra. In contrast, in spectra measured by the other methods the influence of reflection at the crystal surface, at the surface of the plate, or at the crystal-plate interface is frequently sufficiently great to cause serious distortion of the absorption spectra[5], and consequently it is necessary to correct for this influence of reflection. In addition, the pressed KCl disk technique will be very useful to measure the spectra of compounds of low solubility in usual solvents, and particularly of crystalline molecular complexes, whose spectra are difficult in general to measure by other methods.

It is to be noted here that the difference between the spectrum of a compound in the crystalline state and that in solution may be due partly at least to the effect of intermolecular interactions in crystals, besides the possible difference of the most probable conformation in both the states. In general, molecules in crystals can not be treated simply by a so-called oriented gas model. Forces between molecules in aromatic crystals are small compared with intramolecular forces, but they frequently exert appreciable effects on the electronic states of molecules and consequently affect the electronic absorption spectra. In a spectrum measured with a single crystal and with polarized light, the most important effect of a crystal field appears to reveal itself as a so-called Davydov splitting[6]. It seems to be of interest to notice how the effect of a crystal field manifests itself in the spectrum measured by the pressed KCl disk technique, if the spectrum is the one of micro-crystals oriented at random.

At any rate, in view of the possible usefulness of the pressed KCl disk technique in electronic absorption spectroscopy, it seems to be not only interesting but also desirable to study general characteristic features, if any, of the spectra measured by this technique as compared with the corresponding solution spectra.

The author has measured the spectra of stilbene and its related compounds by this technique, of which the spectra of *trans*-stilbene and tolan were already reported in previous papers (Refs. 1-V and VI), and he has found that some generalizations can be drawn from comparison of the spectra with the corresponding spectra of solutions in *n*-heptane, although their theoretical interpretation has not yet been attained. In the present paper, the results of the measurement are summarized and discussed mainly from a phenomenological standpoint.

## Experimental

**Materials.**—The compounds used in this study were prepared as reported previously[1-V-IX]. Potassium chloride was precipitated from water solution with hydrochloric acid to obtain small particle size and dried at 400~450°C for about 6 hr., according to the procedure described by Hales and Kynaston[7].

**Measurements of the Solid State Spectra.**—The general procedure of measurements of the solid state spectra by the pressed KCl disk technique is quite analogous to the procedure for *trans*-stilbene and tolan described in the previous papers. Thus, 1 to 10 mg. of the pure organic compound was thoroughly ground in an agate mortar (for about 15~20 min.) with about 200 mg. of the pure potassium chloride. About 10 mg. of the mixture was then ground with about 350 mg. of new potassium chloride. The concentration of the substance in the final mixture, from which a disk was prepared, was adjusted in order that the disk might show suitable absorbances (about 0.8~1.9 at the most intense absorption maximum). For example, in

the case of *trans-p*-phenylstilbene, the mixing was carried out as follows; 2.35 mg. of the substance was ground with about 200 mg. of KCl, and about 10 mg. of the first mixture was ground with about 350 mg. of KCl to get the final mixture. II the case of triphenylethylene, 8.35 mg. of the compound was ground with 200 mg. of KCl, 10 mg. of the first mixture was ground with 350 mg. of KCl, and finally 80 mg. of the second mixture was ground with 177 mg. of KCl. As will be described later, the apparent molecular extinction coefficients in the spectra measured by this technique were generally lower than the corresponding values in the solution spectra, and furthermore, were not reproducible. Therefore, the adjustment of the concentrations in the final mixtures was not straightforward and frequently had to be carried out by the method of trial and error.

In most cases except for the cases of *trans*-stilbene and tolan, about 150 mg. (146~148 mg.) of each final mixture was pressed under vacuum in the usual manner into a transparent disk (pressure: about 12 tons per sq. cm.). The ultraviolet absorption spectrum of the disk was measured with a Cary recording spectrophotometer Model 14 by using a disk prepared of about 150 mg. (146 and 148 mg.) of pure potassium chloride as the reference. The transmission spectrum of one of the reference disks used (weight: 146.25 mg.) is shown in Fig. 1. It is characteristic that the spectrum exhibits a feeble absorption band at near 270.5 mμ. This band was observed similarly in all the spectra of the reference disks used.

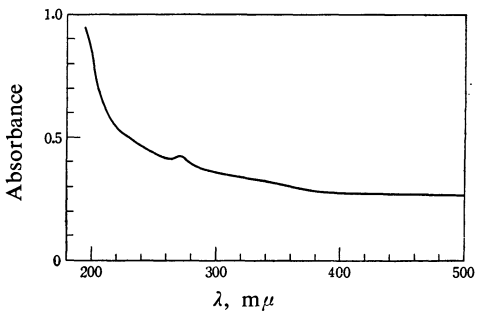

Fig. 1. The transmission spectrum of a reference KCl disk (weight: 146.25 mg.).

**Calculations of Thicknesses of Disks, Concentrations, and Molecular Extinction Coefficients.**— The radius of a disk is 0.65 cm. Since the weights of the disks used are 146~148 mg. in most cases, the thicknesses of the disks are calculated to be 0.055~0.056 cm, when it is assumed that the density of the disks is 1.988. These values of the thicknesses are in fairly good agreement with the rough values obtained by direct measurement. The concentrations of the organic substances in the disks can be calculated easily, on the basis of an assumption that micro-crystals or molecules are evenly dispersed in each mixture. Then, the molecular extinction coefficients (ε) are evaluated in the usual manner as the values of absorbance divided by the thickness of the disk and the molar concentration of the substance in the disk.

## Discussion

In the ensuing discussion, the spectra measured by the pressed KCl disk technique are referred to as the solid state spectra. The solution spectra refer to the spectra of solutions in *n*-heptane, except where indicated otherwise.

The newly measured solid state spectra are shown in Figs. 2—6, together with the corresponding solution spectra reported in previous

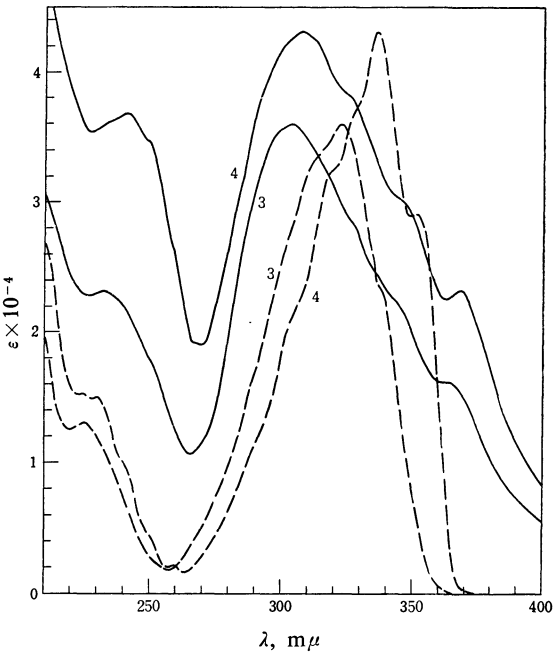

Fig. 2. Ultraviolet absorption spectra: 3, *trans-p*-phenylstilbene; 4, *trans*-1-phenyl-2-(2-fluorenyl)-ethylene.

papers (Refs. 1-VI—IX). The solid lines represent the solid state spectra and the broken lines the solution spectra. In these figures, the extinction of the most intense maximum of the conjugation band in each solid state spectrum has been arbitrarily set equal to the extinction of the most intense maximum of the conjugation band in the corresponding solution spectrum, because reliable solute extinction values for the solid state spectra could not be obtained. In addition, in Fig. 3 the extinction of the maximum of the conjugation band in the spectrum of *n*-heptane solution has been

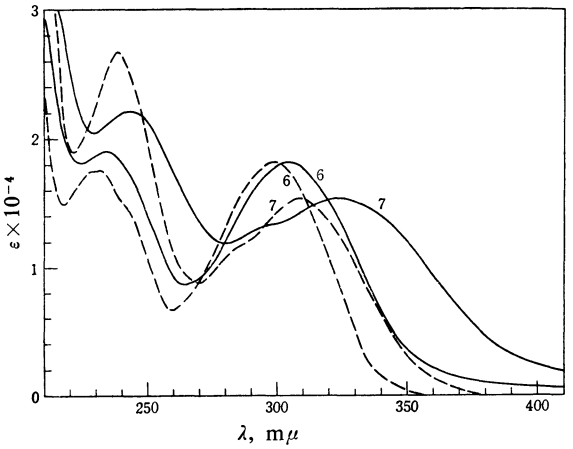

Fig. 4. Ultraviolet absorption spectra: 6, triphenylethylene; 7, tetraphenylethylene.

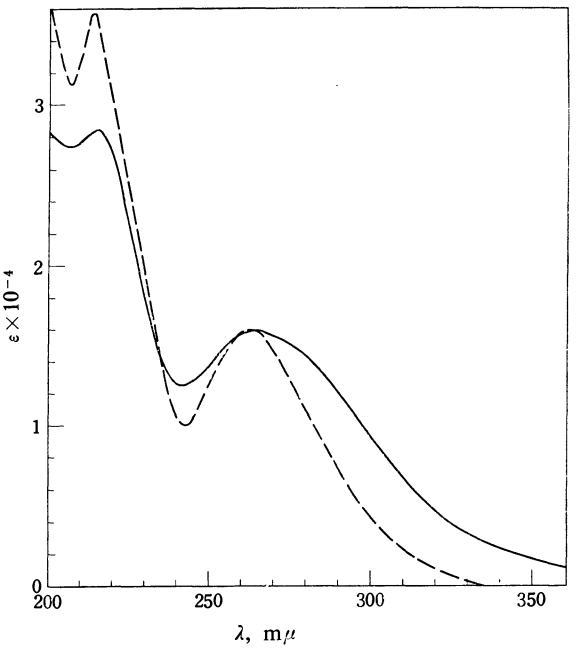

Fig. 5. Ultraviolet absorption spectra: *trans*-1, 2-dimesitylethylene.

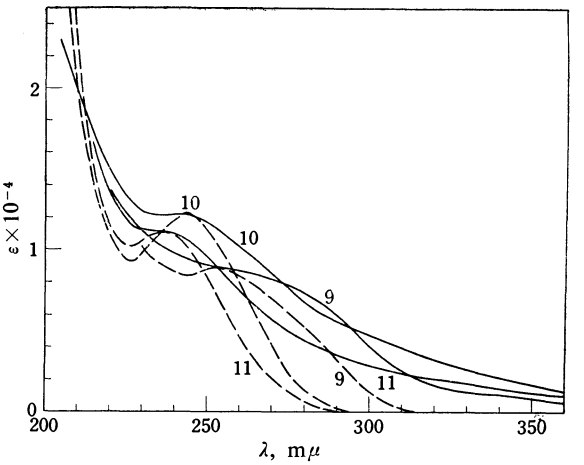

Fig. 6. Ultraviolet absorption spectra: 9, *cis*-$\alpha$, $\alpha'$-dimethylstilbene; 10, *trans*-$\alpha$, $\alpha'$-dimethylstilbene; 11, *trans*-$\alpha$, $\alpha'$-diethylstilbene.

arbitrarily set equal to that in the spectrum of benzene solution (cf. Ref. 1-IX). It is seen that the solid state spectra resemble considerably the corresponding solution spectra on the whole.

The data of the maxima and the inflections in these spectra as well as in the spectra of *trans*-stilbene and tolan are summarized in Table I. In this table, A refers to the A-band, i. e. the conjugation band due to transitions from the highest occupied orbital to the lowest vacant orbital, and B refers to the B-band, i. e. the band probably due to transitions from the highest occupied orbital to the vacant orbitals localized in the benzene nuclei or from the occupied orbitals localized in the benzene nuclei to the lowest vacant orbital (cf. Ref. 1-V). The symbol △ denotes the most intense maximum of fine structure of the conjugation band in each spectrum. Wavelengths (in m$\mu$) in parentheses denotes inflections, and those in double parentheses denote very indistinct inflections. $\Delta\lambda$ represents the wavelength difference (in m$\mu$) between the band in the solid state spectrum and the probably corresponding band in the solution spectrum. Values of $\Delta\lambda$ in parentheses are values for the cases in which either or both of the bands to be compared are inflections. $\varepsilon_K/\varepsilon_H$ represents the ratio of the apparent value of the molecular extinction coefficient of the band in the solid state spectrum to the value of the corresponding band in the solution spectrum.

**Absorption Intensities.**—The molecular extinction coefficients in the solid state spectra, calculated by the above mentioned procedure, were not reproducible. Not withstanding, it may be said that they are generally considerably

* Values estimated by taking the value for the maximum of the conjugation band in the spectrum of the *n*-heptane solution to be equal to the value in the spectrum of the benzene solution.

smaller than the values in the corresponding solution spectra. Thus, as is seen in Table I, the values of $\varepsilon_K/\varepsilon_H$ are about 1/3∼2/3 for the compounds of the numbers 3—8, and are only about 1/20∼1/5 for the compounds of the entry numbers 1, 2, 9, 10 and 11.

These depressions of intensities seem to be partly at least intrinsic ones. As is seen in Figs. 2—6, the bands, especially the A-bands, are markedly more broad in the solid state spectra than in the solution spectra. Therefore, it is believed that the intensities of especially the A-bands are actually considerably smaller in the former spectra than in the latter. This presumption is supported also by the fact that in the figures the intensities of the B-bands are apparently much larger in the solid state spectra than in the solution spectra in most cases. If it is assumed that the actual intensities of the B-bands are not markedly different in both spectra, this fact is, of course, considered to indicate the actual depressions of intensities of the A-bands in the solid state spectra.

In addition to the actual or intrinsic depressions, the intensities may be apparently depressed by contribution of other factors. As the factor contributing to the apparent depressions, the following possibilities may be considered. (1) A part of the organic substance weighed in may be lost during grinding and evacuation of the press, as pointed out already by Dale[4]. (2) Mixing may be imperfect in each process of grinding. That is, the substance may be unevenly dispersed in each mixture, and consequently, the actual concentration in the final mixture may be more or less different from the culculated value. (3) The absorption intensities in the solid state spectra may essentially depend on the condition of dispersion of the micro-crystals or the sizes of the micro-crystals, as suggested by the somewhat similar phenomenon observed by Weigl[3] in his study on the absorption spectra of some crystalline cationic dyes. Especially in the cases where the values of $\varepsilon_K/\varepsilon_H$ are extraordinarily small, the contribution of factor 1 may be predominant.

**Shapes of Absorption Curves and Wavelengths of Bands.**—Although the shape of the absorption curve of the solid state spectrum of a compound varies slightly from disk to disk in some cases, the reproducibility of the wavelength positions of the absorption maxima and the inflections was almost always fairly good.

Comparison of the solid state spectra with the solution spectra seems to suggest that it is convenient to divide the compounds into the following four groups with respect to the shapes of the absorption curves as well as the magnitudes of the wavelength displacements $\Delta\lambda$: (I) entry 1 in Table I, (II) entries 2—5, (III) entries 6 and 7, and (IV) entries 8—11.

**Group I.**—Tolan. The solid state spectrum it not significantly different from the solution spectrum, except for the bathochromic displacement of the normal magnitude (see below) of each band (cf. Fig. 2 in Ref. 1-VI). *trans*-Azobenzene also belongs to this group, whose spectra will be reported and discussed in a

later publication.

**Group II.—Redistribution of Intensity among the Vibrational Sub-bands.**—*trans*-Stilbene, *trans*-*p*-phenylstilbene, *trans*-1-phenyl-2-(2-fluorenyl)-ethylene, and *trans*-*p*,*p*'-diphenylstilbene. All these compounds are *trans*-stilbene-type compounds which have no substituent at sterically hindering positions and consequently are probably planar. It is a common distinctive feature of the spectra of these compounds that the bands, especially the conjugation bands, exhibit more or less well-resolved fine structures. With these compounds, a marked redistribution of intensity among the vibrational fine structure bands of the conjugation band occurs, that is, the relative intensities of the vibrational bands change markedly, when the state is changed from solution to solid. Thus, the band which appears as the most intense maximum in the solution spectrum, appears as the inflection at a longer wavelength than the most intense maximum in the solid state spectrum. On the other and the band which appears as the inflection at a shorter wavelength than the most intense maximum in the solution spectrum, appears as the most intense maximum in the solid state spectrum.

A typical example is *trans*-stilbene. As described in Ref. 1-V, when the vibrational sub-bands of the conjugation band of this compound are called $\alpha$, $\beta$, $\gamma$, $\delta$, ..... in the order from longer-wavelength-side, the most intense maximum is the $\gamma$-band in the solution spectrum, and is the $\delta$-band in the solid state spectrum. In this connection, it has been known that the temperature affects markedly the relative intensities of the vibrational sub-bands. Thus, in the spectrum of *trans*-stilbene in mixed alcohols at $-130°C$ measured by Beale and Roe[8], the fine structure is much more sharply resolved, the intensities of the $\alpha$- and the $\beta$-bands are much greater, and the intensity of the $\gamma$-band is much smaller than in the solution spectrum measured at room temperature. In this low temperature spectrum, the most intense maximum is the $\beta$-band. To illustrate the situation, the three spectra of *trans*-stilbene are shown in Fig. 7.

In the present case, both the solution spectra and the solid state spectra are the ones measured at room temperature. Therefore, the fact that the marked redistribution of intensity among the vibrational sub-bands occurs between them may be said to be rather surprising. Further investigation seems to be necessary to interpret satisfactorily this interesting phenomenon.

8) R. N. Beale and E. M. F. Roe, *J. Chem. Soc.*, 1953, 2755.

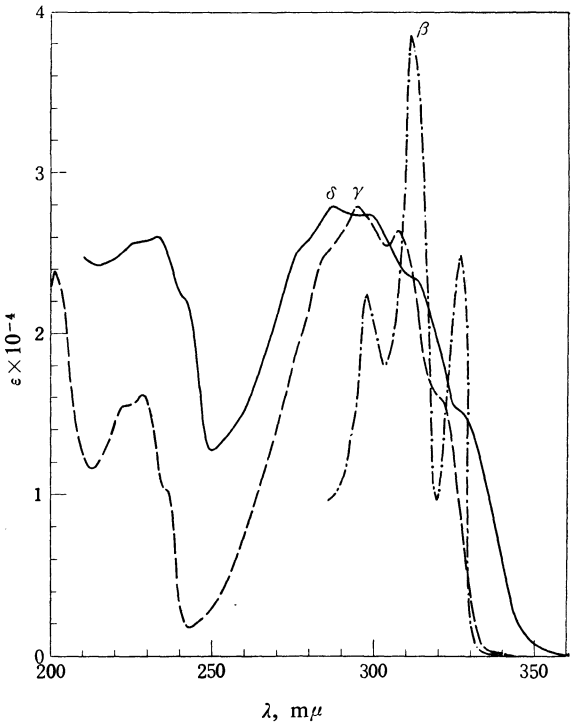

Fig. 7. Ultraviolet absorption spectra of *trans*-stilbene: ——, the solid state spectrum; ----, the solution spectrum; -·--·, the low temperature spectrum (in mixed alcohols at $-130°C$, redrawn from Beale and Roe's paper[8]).

**Wavelength Shifts of Bands.**—In Fig. 8, the values of $\Delta\lambda$ for the compounds belonging to Groups I and II are plotted against the wavelengths $\lambda$ of the corresponding maxima or inflections in the solution spectra. As mentioned already, $\Delta\lambda$ represents the magnitude of the wavelength shift of the band associated with the change of the state from *n*-heptane solution to solid.

A positive value of $\Delta\lambda$ indicates that the shift is bathochromic. As is seen in Table I, all the shifts, except for that in the case of *trans*-$\alpha$, $\alpha'$-dimethylstilbene, are bathochromic. Of course, the individual numerical values of $\Delta\lambda$ may not be decisive because of inevitable uncertainty in determination of the wavelength positions of the absorption maxima and especially of the inflections. Notwithstanding, it may be said that a rough correlation exists between $\lambda$ and $\Delta\lambda$. Thus, in Fig. 8, almost all the points for the A-bands of all the compounds as well as the B-band of tolan are nearly on a correlation line, which has been drawn as the solid line in the figure. This means that $\Delta\lambda$ for these increases fairly regularly with $\lambda$ from about 1.5 m$\mu$ at 220 m$\mu$ to about 5 m$\mu$ at 300 m$\mu$, and to about 9.5 m$\mu$

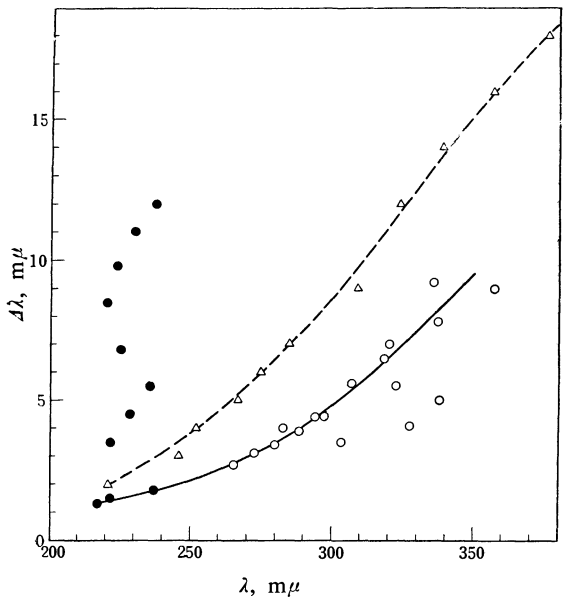

Fig. 8. Correlations between the magnitudes of wavelength shifts of bands (from solution to the solid state) and the wavelengths of the bands in the solution spectra.
○, for the A-bands of tolan and the stilbenes.
●, for the B-bands of tolan and the stilbenes.
△, for the bands of naphthalene and anthracene (according to Dale's data[4]).

at 350 mμ. On the other hand, most of the points for the B-bands, the bands which appear in the region about 220~250 mμ, are markedly deviating from the correlation line. There appears to be a very rough relation that the longer the conjugated system is, or in other words, the longer the wavelength of the A-band is, the value of $\Delta\lambda$ for the corresponding B-band is the larger.

What is the cause of such bathochromic shifts of bands? This problem is unsettled. If the solid state spectra can be considered to be the spectra of micro-crystals oriented at random directions, the shifts are probably due to the intermolecular interactions in the crystals. Alternatively, if the solid state spectra are to be considered as the spectra of solid solutions, the shifts are probably due to a sort of solvent effect. Furthermore, the shifts may be due to other unknown causes. At any rate, whatever the mechanism of the shifts may be, the fact that there is a regular relation between the magnitudes of the shifts and the wavelengths of the bands is very interesting.

A similar regular relation has been found already by Dale[4] for the spectra of naphthalene and anthracene. According to him, the magnitude of the wavelength shift of a band of these "rigid" molecules due to the change of the state from hexane solution to solid, viz. the "normal red-shift", increases regularly with the wavelength of the band, from about 2 mμ at 220 mμ to about 8 mμ at 300 mμ, and to about 19 mμ at 400 mμ. As discussed in a previous paper (Ref. 1–I), this regular relation appears to hold good regardless of kinds of compounds, of characters of bands, and of intensities of bands. In Fig. 8, the values of the "normal red-shifts" are also plotted against the wavelengths of the bands in the spectra of hexane solutions according to Dale's data. A correlation line for these points is shown as the broken line.

It may be noteworthy that the correlation line obtained in the present work for stilbenes, which is subsequently referred to as the present correlation line, is located considerably lower than Dale's correlation line. That is, it may be said that the *trans*-stilbene-type compounds show the red-shifts of the normal magnitudes in themselves, which are smaller than the magnitudes of the normal red-shifts of naphthalene and anthracene. The latter compounds are, to use Dale's words, the "rigid" compounds which obviously can not assume other conformations in solution thanin the crystal lattice. Therefore, the above mentioned fact may be considered as an evidence indicating that the most probable conformationsof these stilbenes in solution are not significantly different from those in the solid, probably crystalline state, and accordingly, are probably planar.

While the probably planar compounds show the red-shifts of normal magnitudes, some compounds, which are discussed in the succeeding paragraphs as belonging to Groups III and IV, show the shifts of more or less abnormal magnitudes. It may be significant that the latter compounds are evidently non-planar. The conjugation bands of these compounds have no distinct fine structure, in contrast with the foregoing sterically unhindered compounds, and as a matter of fact, the shapes of the solid state spectra of these compounds are apparently not markedly different from those of the solution spectra.

**Group III.**—Triphenylethylene and tetraphenylethylene. The values of $\Delta\lambda$ for triphenylethylene are very slightly greater, and the values for tetraphenylethylene are much greater than those anticipated from the present correlation line in Fig. 8. The extraordinarily large shifts especially in the case of tetraphenylethylene may be considered to indicate that the most

probable conformation of this compound in the solid state is considerably different from that in solution. That is, it may be inferred that the interplanar angles between the phenyl groups and the ethylenic bond are appreciably smaller in the most probable conformation in the solid, probably crystalline state, than in that in solution (cf. Ref. 1–VI).

**Group IV.**—*trans*-2, 4, 6, 2′, 4′, 6′-Hexamethylstilbene (*trans*-1, 2-dimesitylethylene), *cis*- and *trans*-$\alpha$, $\alpha'$-dimethylstilbenes, and *trans*-$\alpha$, $\alpha'$-diethylstilbene. The values of $\Delta\lambda$ for these compounds are smaller than anticipated from the present correlation line. Thus, the value for dimesitylethylene is slightly smaller, and the values for $\alpha$, $\alpha'$-dialkylstilbenes are much smaller than anticipated from the correlation line. The value for *trans*-$\alpha$, $\alpha'$-dimethylstilbene is apparently even negative.

The most probable conformations of these compounds are undoubtedly non-planar, owing to the steric effects of the alkyl substituents (cf. Refs. 1–VII and VIII). Therefore, it seems quite reasonable to correlate the smallness of the shifts with the non-planarity of the molecular structures. It may be presumed that with these non-planar compounds the intermolecular interactions in the crystals (or the interactions of the molecules with potassium chloride) are smaller than in the case of the foregoing planar compounds.

The author desires to thank Mr. Akira Kuboyama of Government Chemical Industrial Research Institute, Tokyo, for the use of the spectrophotometer.

# *Paramagnetic Resonance of Radicals of Some Aromatic Vinyl Compounds. I*

By Kazuo MORIGAGI, Keiji KUWATA and Kozo HIROTA

(Received January 20, 1960)

Free radicals produced by the reaction of aromatic hydrocarbons with alkali metals have been investigated by the paramagnetic resonance method for several years by Weissman[1] and others. Usually the paramagnetic resonance spectra of these radicals consist of many lines which are coming from the hyperfine interaction of the unpaired electron with protons in these radicals. We have observed the paramagnetic resonance of radicals. We have obtained from the following aromatic vinyl compounds: styrene, $\alpha$-methyl styrene, $p$-methyl styrene, 1, 1-diphenylethylene, stilbene and 1, 4-diphenylbutadiene. A part of the experimental results has been already reported briefly[2]. The paramagnetic resonance of the above radicals, except that of stilbene, shows many absorption lines, which are attributed to the hyperfine structure arising from the hyperfine interaction of the unpaired electron with protons in the radicals.

The results obtained by the analysis of these spectra contribute not only to the determination of the unpaired electron density in the radicals, but also give some information about the mechanism of polymerization of these aromatic hydrocarbons, because some of the above compounds polymerize easily by the reaction with monomer, turning into so called "living polymers".

The experimental results and discussion in the case of styrene, $\alpha$-methyl styrene and $p$-methyl styrene will de described in the present paper, and the forthcoming paper will describe the results in the case of 1, 1-diphenyl-ethylene, stilbene and 1, 4-diphenylbutadiene.

## Experimental

**1) Paramagnetic Resonance Spectrometer and Experimental arrangement.**—The measurements of paramagnetic resonance of the above radicals were performed at room temperature, except that of styrene radicals which were measured at about $-100$°C and $-40$°C besides room temperature. The spectrometer used for the paramagnetic resonance measurements was a transmission type operating at 9300 Mc. The rectangular cavity, which has a

hole at the half-point of the narrow side, was excited at the mode of $TE_{012}$. The sample, being enclosed in a glass tube, was put into the cavity through the hole. By modulating the applied magnetic field at the frequency of 315 c/s, the resonance signal was detected with a phase sensitive detector, and was recorded on a milliampere recorder. The cavity system and the Dewar arrangement for measurement at low temperatures were designed as shown in Fig. 1. The sample enclosed in a

(C) Mica

small glass-tube was attached with some cement to the end-plane of the inner glass tube of the Dewar inserted into the cavity. The temperature at the position of the sample was measured by a copper-constantan thermocouple, which indicated a temperature of $-100$°C or $-40$°C when liquid nitrogen or methanol mixed with dry-ice was filled in the Dewar, respectively, As the outer part of the Dewar was jointed on a copper-head standing out of the cavity on its narrow side, removal of the entire assembly from the cavity for cleaning or using the cavity for measurements at room temperature was done easily. The space between the inner and outer parts of the Dewar and the inside part of the cavity were pumped out to get vacuum by closing the waveguide with thin mica foils in front of and behind the cavity.

2) **Preparation of Samples.**—The samples used in our experiment were prepared by two ways. One of them may be called the method I, while the other the method II. The latter will be described in details. As shown in Fig. 2, the apparatus for preparing the samples consists of several reaction vessels, all of which can be kept at high vacuum.

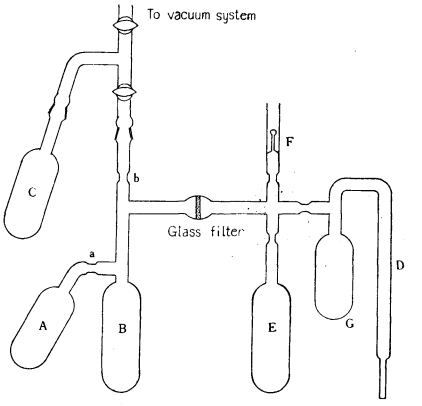

Fig. 2. Apparatus for preparation of sample.

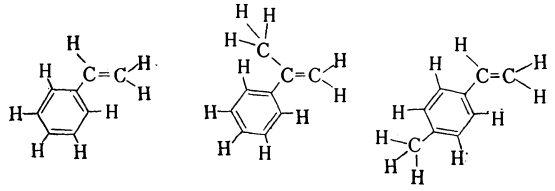
The samples were prepared using this apparatus as follows. Connecting the entire vessel to the vacuum system, water and oxygen adsorbed on the wall of the glass vessels were excluded by heating and discharging the tube with a tesla coil. The sodium metal contained inside the glass vessel A was distilled into the reaction vessel B under reduced pressure, and the vessel A was sealed off from the system at the part "a". Then the aromatice hydrocarbons and toluene contained in the vessel were distilled into the vessel B under reduced pressure, and the vessels B, D, E and G were taken off from the vacuum system at the part of "b". The reaction vessel B was kept at about 100°C for a long time, in order to change the high-polymerized adduct of the aromatic hydrocarbon, formed inside the reaction vessel B before the heat-treatment, to a low-polymerized one. After the precipitate* inside the reaction vessel B was separated from the solvent, was transfered into the vessel E and was distilled under reduced pressure through the breakable joint, the precipitate was dissolved into the tetrahydrofuran or dioxane which was stored in the vessel G through the breakable joint F. Tetrahydrofuran and dioxane were used here as the solvent in which paramagnetic free radicals were contained as a diluted state. For the measurement of paramagnetic resonance the sample thus prepared was used in the glass tube D, the end part of which was inserted into the cavity. The method II described above was applied to the production of radicals of styrene, $\alpha$-methyl styrene, $p$-methyl styrene and 1, 1-diphenylethylene.

In the method I the aromatic hydrocarbon whose radical was to be produced was reacted directly with sodium metal in tetrahydrofuran or dioxane in a way similar to that of the method II without using toluene. The radicals of styrene, $\alpha$-methylstyrene, $p$-methylstyrene, 1, 1-diphenylethylene, stilbene, 1, 4-diphenylbutadiene and isoprene** could be produced by this method.



Determining the concentration of sodium ion in

* A strong paramagnetic resonance line was observed in the precipitate of the sodium adducts of styrene. The line width and $g$-factor were about 2 gauss and 2.002 respectively, and the line shape was Lorentzian.

** Reported briefly: K. Kuwata, K. Morigaki and K. Hirota, This Bulletin, 32, 895 (1959).

sample of styrene by flame spectroscopy, the ratio of radical part to an ionic part was estimated. It was of the order of one tenth. All measurements were carried out in the concentration range of about $10^{-3}$ to $10^{-4}$ spin per liter.

In the preparation of radicals described above precautions are taken against contamination of the reaction vessel used, because a trace of water and oxygen, if left in the vessel, may react easily with the adduct of the aromatic hydrocarbon and make the concentration of radicals decrease. Purification of aromatic hydrocarbons, sodium metal and solvents was performed in the following way. The aromatic hydrocarbons purified by the usual method were put in contact with sodium metal so as to remove the remaining water and were purified by vaccum distillation. The solvent purified in the usual way was reacted with stilbene anions or naphthalene anions by utilizing the reactive properties of these anions with the water and oxygen, and then the stilbene or the naphthalene was removed from the solvent by distillation. Naphthalene was used only in the preparation of the first samples of styrene radical. In the other samples, stilbene was used in most cases including the preparation of the styrene radical, because the stilbene anion gave no more than a broad resonance line without any structure even if it remained in the solvent.

Styrene α-Methyl styrene p-Methyl styrene

Fig. 3

## Results and Discussion

**Styrene.**—We have observed three kinds of paramagnetic resonance spectra in the styrene radical*. They were i) four lines, ii) nine lines and iii) many complex lines respectively.

i) Four lines.—The four-lines spectrum has been observed in many samples of dilute solution of the styrene adduct with sodium metal, when the solvent is tetrahydrofuran or dioxane. Even if either solvent is used and potassium metal is used in place of sodium metal, almost identical spectra of four lines were given. The above samples were prepared by the methods I and II described in the section 2. The spectrum consists of almost equally spaced four lines of which the intensities of each components are 1 : 3.2 : 3.3 : 1.2 in ratio in order of the strength of the magnetic field corresponding to the resonance lines. From the above results the hyperfine splitting is considered to arise from the hyperfine interaction between the unpaired electron and three equivalent protons. The hyperfine splitting is 4.3±0.5 gauss and the $g$-factor is 2.0031±0.0006.

The line-shape of each components is almost Gaussian with the half-width of about 3.9 gauss as shown in Fig. 5 (B).

The spectra observed at low temperatures, −40°C and −100°C, were almost identical with those observed at room temperature. From these results the width of each component is attributed to the unresolved hyperfine interaction with protons.

Three equivalent protons contributing to the

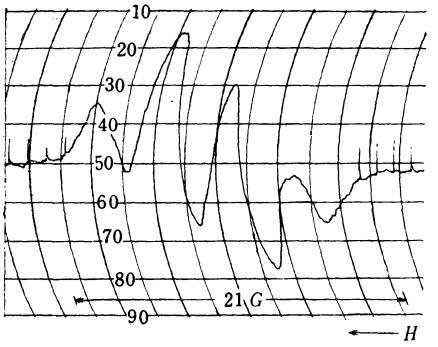


Fig. 4. Paramagnetic resonance spectrum of styrene radical.

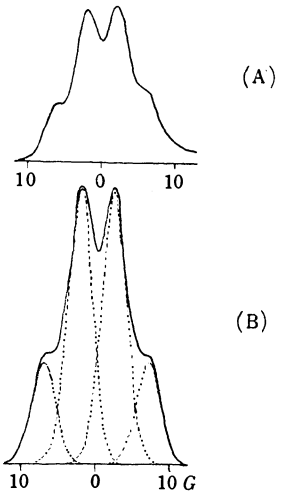

Fig. 5. Paramagnetic resonance spectra of styrene radical.

(A) The observed spectrum obtained by numerical integration.

(B) The calculated spectrum constructed from four Gaussian shaped lines with relative intensities of 1 : 3 : 3 : 1.

* Besides the three kinds of spectra, the other spectrum similar to that of the naphthalene anion was observed in the styrene radical in the tetrahydrofuran solution prepared by the methods I and II with sodium metal at the first stage of our experiment, which has been already reported briefly[2]. As it has not been reproducible, it will not be described here.

hyperfine splitting and some protons constructing the line-width of each components have not been able to be given a definite correspondence to the protons of the styrene anion.

ii) Nine lines.—The spectrum consisting of equally spaced nine lines has been observed in the styrene radical in the tetrahydrofuran solution prepared by the method I with sodium metal. The spacing between each components was 2.2±0.2 gauss.

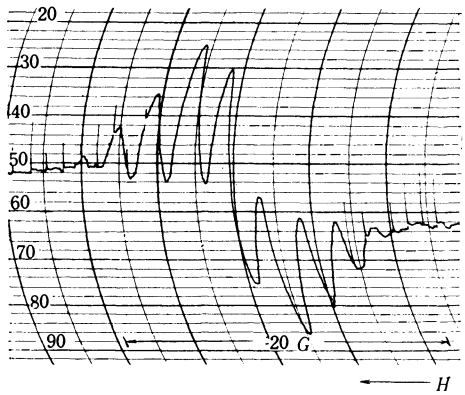

Fig. 6. Paramagnetic resonance spectrum of styrene radical

iii) Many complex lines.—The complex spectrum has been observed in the styrene radical in the tetrahydrofuran solution prepared by the method I with sodium metal. The spectrum extends to the length of 24±3 gauss on the scale of the magnetic field. The *g*-factor is 2.0028±0.0005.

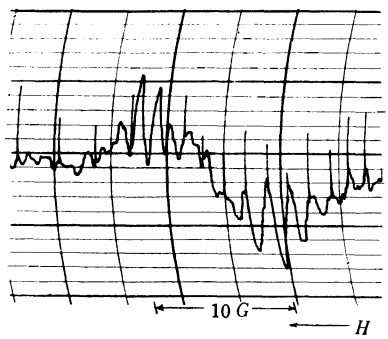

Fig. 7. Paramagnetic resonance spectrum of styrene radical.

The relation among the above three spectra on the point of the preparation of the styrene radical and the magnetic centers corresponding to the spectra have not been found in the present stage, so further experiments will be required to obtain some information about this problem.

On the other hand, we tried to observe the paramagnetic resonance of the styrene radical formed on the film of the vaporized sodium metal, but it gave a negative result*.

**α-Methylstyrene.**—We have observed the paramagnetic resonance spectrum, as shown in Fig. 8, of the α-methylstyrene radical in the tetrahydrofuran solution prepared by the method I with sodium metal. This spectrum extends to the length of about 32 gauss on the scale of the magnetic field. It may be explained by assuming that the hyperfine splitting is mainly attributed to the hyperfine interaction with three equivalent protons and another two equivalent protons with the coupling constant of 4.2 gauss and 2.5 gauss respectively and some protons contribute to construct the line shape of each components. If the magnetic center corresponding to the above spectrum is assumed to be the unpaired electron being localized on the α-methylstyrene anion, the following assignment might be reasonable on the basis of the unpaired electron density calculated by using the simple LCAO-MO theory: the three equivalent protons and two equivalent protons in the above analysis correspond to the *ortho*, *para*-protons and β-protons respectively, and the *meta*-protons

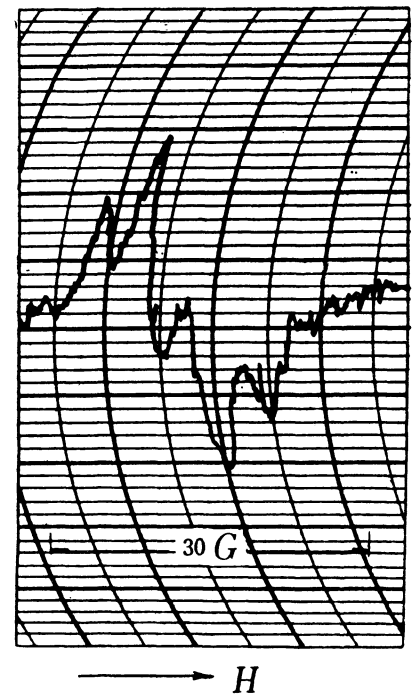

Fig. 8. Paramagnetic resonance spectrum of α-methylstyrene radical.

* It might be necessary to refer to the Weissman's answer in discussion [*J. Phys. Chem.*, 57, 507 (1953)], that "the paramagnetic resonance absorption in styrene as it is undergoing polymerization initiated by metallic sodium is not reproducible".

and the protons belonging to the methyl-group construct the line width of each components. The simple LCAO-MO calculation gives the following unpaired electron densities on the carbon atom of *ortho*, *meta*, *para*, $H_3$ and $\beta$ positions respectively.

$$\rho_o=0.091, \quad \rho_m=0.016, \quad \rho_p=0.149,$$
$$\rho_{H_3}=0.026, \quad \rho_\beta=0.355.$$

***p*-Methylstyrene.**—The observed spectrum of the *p*-methylstyrene radical is shown in Fig. 9. This sample consists of *p*-methylstyrene and *ortho*-methylstyrene with concentration of 60% and 40% respectively. This situation complicates the spectrum. Besides, the proton of the methyl group seems to contribute to the observed spectrum much more than in the case of the $\alpha$-methylstyrene radical. We have not been able to analyze the observed spectrum.

A few months later than the time of preparation of the samples during which the sample was kept at room temperature, the spectrum became simpler and weaker than that observed immediately after the preparation of the samples. This changes of the spectrum is shown in Fig. 10. No change of the color and viscosity accompained with that of the spectrum were observed. The hyperfine structure of the spectrum exists in the region of the length of about 25 ($\pm$5) gauss on the scale of the magnetic field. After this change, the samples always showed the same patterns of the spectrum as the above one, but the intensity of the resonance lines has decreased gradually with time.

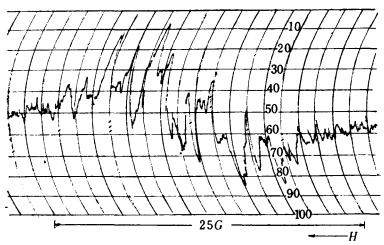

Fig. 9. Paramagnetic resonance spectrum of *p*-methylstyrene radical.

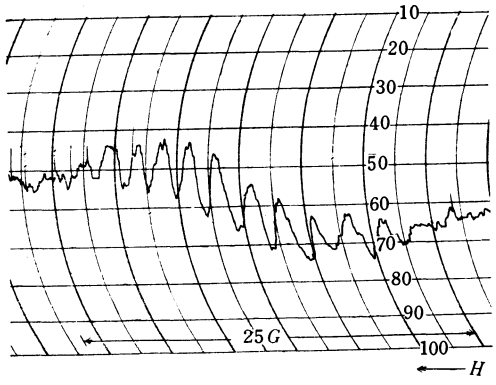

Fig. 10. Paramagnetic resonance spectrum of *p*-methylstyrene radical

### Reaction of the Aromatic Hydrocarbons with Alkali Metals

As described briefly in the section 1, the aromatic vinyl compounds, especially styrene, are initiated to polymerize with alkali metal. This property of styrene adducts with sodium metal as chain initiators was found independently by Szwarc et al.[3] and by Meshitsuka et al.[4] When the monomers of styrene exist in some suitable solvents (toluene, tetrahydrofuran, dioxane etc.), polymerization of them proceeds under existence of the adducts which produce the living polymer. The styrene adducts similar to that in the above case are produced by Scott's method in which naphthalene anions are used as a substitute of alkali metal. In this case, according to Szwarc, the living polymers consist of the dimerized styrene anions with both ends "living",

$$[:\mathrm{CH}(\phi)-\mathrm{CH_2}-\mathrm{CH_2}-\ddot{\mathrm{C}}\mathrm{H}(\phi)]^{2-} \quad (\phi=\mathrm{C_6H_5})$$

which is formed by dimerization of univalent monomer anions

$$[:\mathrm{CH}(\phi)-\dot{\mathrm{C}}\mathrm{H_2}] \quad \text{or} \quad [\dot{\mathrm{C}}\mathrm{H}(\phi)-\ddot{\mathrm{C}}\mathrm{H_2}]^-$$

being produced through the following process of electron transfer,

$$\text{naphthalene}^- + \text{styrene} \rightarrow \text{naphtharene} + \text{stylene}^-$$

The above situation in the case of polymerization of styrene initiated by the styrene adduct formed through electron transfer which takes place between naphthalene anions and the monomers of styrene will be applied to our cases in which the styrene adducts with sodium metal form the living polymers. Then, the existence of the radical anions will not be detected because dimerization of univalent monomer anions is performed in a very short time in the above process.

On the other hand, two of the present authors found that if the styrene adduct with a high degree of polymerization formed at the first stage of the reaction of styrene with sodium metal reacts with sodium metal still

3) M. Szwarc, M. Levy and R. Milkovich, *J. Am. Chem. Soc.*, **78**, 2656 (1958); M. Szwarc, *Nature*, **178**, 1168 (1956).
4) G. Meshitsuka and Y. Okada, *Chem. High Polymers (Tokyo)*, (*Kobunshi Kagaku*) 14, 33, 37, 123 (1957).

more, the dark red precipitates are formed in the solution of toluene as a result of dissociation of the styrene polymer. These precipitates showed a strong paramagnetic resonance line, of which the line width and $g$-factor were about 2 gauss and 2.002 and the line shape was Lorentzian, and when they were diluted into the tetrahydrofuran, the hyperfine splitting in the paramagnetic resonance spectra was observed as described in the former sections. These spectra were attributed to be coming from monomer anions of styrene or polymer radicals with the low degree of polymerization.

The observations of the paramagnetic resonance of radicals of the aromatic vinyl compounds may be considered to become possible for the following reasons. Under non-existence of the monomer of aromatic vinyl compounds radical anions will exist stably in the polar solvents*, as tetrahydrofuran and dioxane, because they are electrically repulsed by each other in the polar solvent to be obstructed to dimerize.

In the case of the radicals with a high degree of polymerization, it will be difficult to observe their paramagnetic resonance owing to the following two reasons; one of the reasons is that the concentration of radicals in the solution becomes small, and the other is that the motion of such radicals becomes slower than that of monomer radicals or radicals with a low degree of polymerization to extend the linewidth of each components of the hyperfine structure by contribution of the anisotropic hyperfine interaction of the unpaired electron with the protons. Indeed, no paramagnetic resonance of the radicals of a highly polymerized styrene diluted in the tetrahydrofuran was observed and the intensity of the resonance lines which were observed in most of the other samples of the aromatic vinyl compounds, described in the present paper, decreased gradually with time in accordance with the progress of polymerization. In some cases the change of patterns of the paramagnetic resonance spectrum was accompanied by decrease of intensity. As an example of such a change of spectrum we can see clearly the tendency in the case of $p$-methylstyrene as described in the section 3.

In the forthcoming paper, which will describe the results of the paramagnetic resonance of radicals of 1, 1-diphenylethylene, stilbene and 1, 4-diphenylbutadiene, a formulation which describes the process of polymerization will be presented.

* We could not observe paramagnetic resonance of the styrene radicals diluted in the solution of toluene which was a non-polar solvent.

## Summary

Paramagnetic resonance of radicals of the aromatic vinyl compounds in the tetrahydrofuran and dioxane solutions was observed: styrene, $\alpha$-methyl styrene and $p$-methyl styrene. By analyzing the observed spectra the structure of the radicals is discussed. From these results it may be concluded that the reaction of the aromtic vinyl compounds with alkali metal proceeds through two steps; formation of their radical anions, and successive addition of the monomers to this radical anion turning into "living polymers".

The authors wish to express their sincere thanks to Professor Junkichi Itoh of Osaka University for his continuous encouragement and his helpful discussions throughout this work.

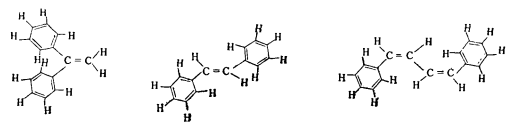
# *Paramagnetic Resonance of Radicals of Some Aromatic Vinyl Compounds. II*



By Kazuo MORIGAKI, Keiji KUWATA and Kozo HIROTA

(Received January 20, 1960)

In the preceding paper[1] the results of the paramagnetic resonance of radicals of styrene, $\alpha$-methylstyrene and *p*-methylstyrene were described. Here the results of the paramagnetic resonance of radicals of 1, 1-diphenylethylene, stilbene and 1, 4-diphenylbutadiene will be described and will be discussed in connection with the problem of the process of the polymerization of these compounds.

## Experimental

The measurements of paramagnetic resonance of the above radicals were performed at room temperature by using the same apparatus as that being described in the preceding paper and the samples were also prepared by the same method as that described in the preceding paper.

1-1 Diphenylethylene Stilbene 1-4 Diphenylbutadiene

Fig. 1.

## Results and Discussion

**1,1-Diphenylethylene (DPE).** — Two spectra have been observed in the 1, 1-diphenylethylene (DPE) radical in the tetrahydrofuran solution with its concentration of $10^{-3}\sim10^{-4}$ M under different conditions of the sample. In the DPE radical produced by method I described in section 2 of the preceding paper, many lines were observed as shown in Fig. 2.

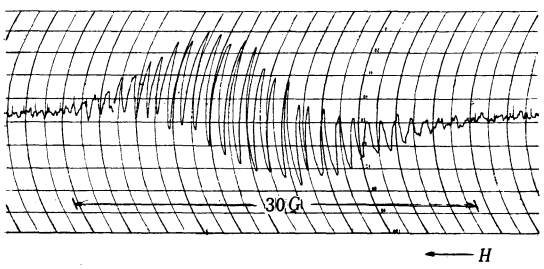


Fig. 2. Paramagnetic resonance spectrum of 1-1 diphenylethylene radical.

We tried to explain the observed spectrum through the following spin Hamiltonian,

$$\mathcal{H}=g\beta \boldsymbol{H}\boldsymbol{S}+\sum_{i=1}^{4} A_o \boldsymbol{I}_{o_i}\boldsymbol{S}+\sum_{i=1}^{4} A_m \boldsymbol{I}_{m_i}\boldsymbol{S} + \sum_{i=1}^{2} A_p \boldsymbol{I}_{p_i}\boldsymbol{S}+\sum_{i=1}^{2} A_\beta \boldsymbol{I}_{\beta_i}\boldsymbol{S} \qquad (1)$$

where the first term describes the Zeeman energy and $\boldsymbol{I}_o$, $\boldsymbol{I}_m$, $\boldsymbol{I}_p$ and $\boldsymbol{I}_\beta$ describe the spin of the proton in the *ortho*-, *meta*-, *para*- and $\beta$ position respectively, and the suffix $i$ given under the spins of the proton $\boldsymbol{I}$ shows a different position in the same site with respect to the symmetry of the molecule. Although the observed spectrum is so complicated that we can not analyze it definitely, the following values of the parameters, $g$, $A_o$, $A_m$, $A_p$ and $A_\beta$, in the above spin Hamiltonian seem to fit best with the observed spectrum: $g=2.002$ $A_p=A_p\sim6$ gauss, $A_m\sim1$ gauss, $A_\beta\sim3$ gauss. However, some ambiguities are left in these values except in the case of $g$. The calculated spectrum is shown in Fig. 3, where several lines at both sides apart from the center are assumed not to be observed owing to their weak intensities. The above analysis indicates that the magnetic center corresponding to the observed spectrum is the unpaired electron in the DPE monomer anion.

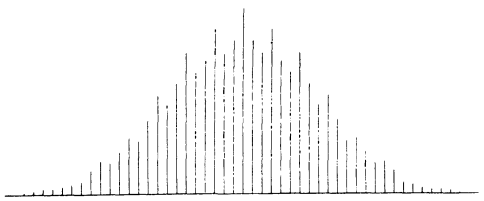

Fig. 3. The calculated spectrum of 1-1 diphenylethylene anion.

According to McConnell[2] the hyperfine splitting constant is proportional to the unpaired electron density on the carbon atom adjacent to the proton in the aromatic hydrocarbon. From the above hyperfine splitting

1) K. Morigaki, K. Kuwata and K. Hirota, This Bulletin, 33, 952 (1960).

2) H. M. McConnell, *J. Chem. Phys.*, **24**, 764 (1956); H. M. McConnell and D. B. Chesnut, ibid., **28**, 107 (1958).

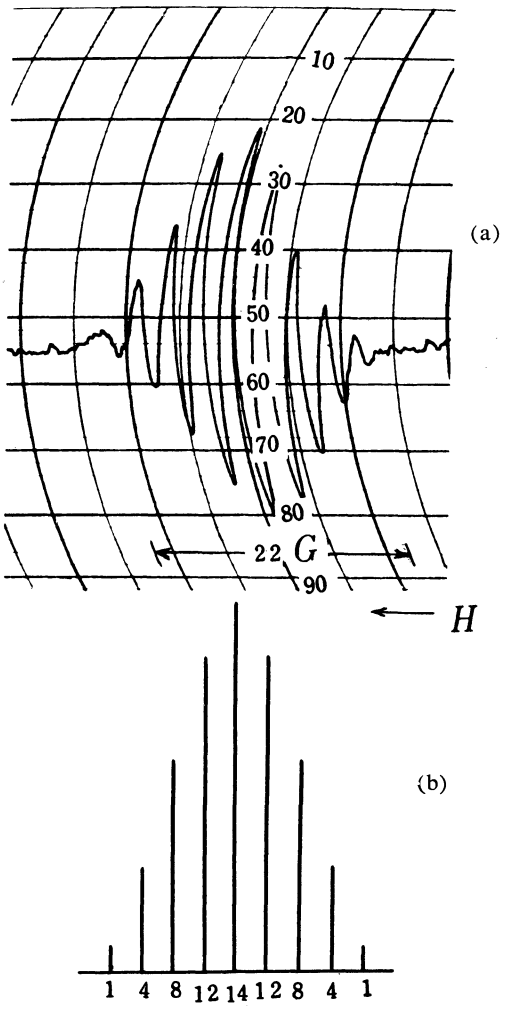

Fig. 4. (a) Paramagnetic resonance spectrum of 1-1 diphenylethylene radical.
(b) The calculated spectrum of 1-1 diphenylethylene radical.

constant in Eq. (1) the unpaired electron densities of the DPE monomer anion at each carbon atom in the aromatic ring can be derived, i. e., they are given in ratio as follows:

$$\rho_o : \rho_p : \rho_m = 6 : 6 : 1$$

where $\rho_o$, $\rho_p$ and $\rho_m$ give the unpaired electron densities on the carbon atom adjacent to the *ortho*-, *para*- and *meta*-hydrogen atom respectively.

On the other hand, the simple LCAO-MO calculation gives the normalized unpaired electron densities the following values,

$$\rho_o = 0.05521, \quad \rho_p = 0.07813, \quad \rho_m = 0.00622$$

or

$$\rho_o : \rho_p : \rho_m = 8.9 : 12 : 1$$

The observed spin densities on the *ortho*- and *para*-carbon atoms are smaller than those expected from the simple LCAO-MO calculation. The normalized unpaired electron density on the $\beta$-carbon atom given by the simple LCAO-MO calculation is given by $\rho_\beta = 0.3856$. In spite of the large value of the electron density on the $\beta$ carbon atom, the observed hyperfine splitting is half as much as that corresponding to the unpaired electron densities on the *para*- and *ortho*- carbon atoms. This means that there is a marked difference between the cases of the $\beta$-proton and the ring proton in the proportionality constants connecting the unpaired electron density to the hyperfine splitting. However, the origin of the small proportionality constant for the hyperfine splitting at the $\beta$-proton has not been found.

Another spectrum, as shown in Fig. 4 (a), was observed in the sample of DPE which has been kept at 110°C for two days after the observation of the first spectrum shown in Fig. 2. The change of the spectrum coming from the heat-treatment of the sample is drastic and is accompanied with that of its color from dark yellow to green. This indicates that the DPE radical was changed into another kind of radical through the heat-treatment. From the following analysis of the observed spectrum the magnetic center corresponding to the second spectrum seems to be identified with the unpaired electron being localized around the end of the anion of the DPE polymer as shown in Fig. 5.

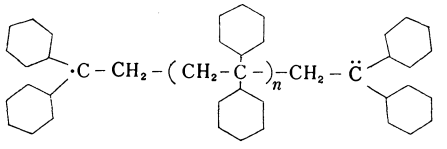

Fig. 5. Structural formula for 1-1 diphenyl polymer anion.

The observed spectrum can be explained by the following spin Hamiltonian,

$$\mathcal{H} = g\beta \boldsymbol{H}\boldsymbol{S} + \sum_{i=1}^{4} A_o \boldsymbol{I}_{oi}\boldsymbol{S} + \sum_{i=1}^{4} A_m \boldsymbol{I}_{mi}\boldsymbol{S} + \sum_{i=1}^{2} A_p \boldsymbol{I}_{pi}\boldsymbol{S} \qquad (2)$$

with $g = 2.0026 \pm 0.0005$, $A_p = 5.4 \pm 0.5$ gauss, $A_o = 2.7 \pm 0.3$ gauss and $A_m \sim 0$ gauss. Although two kinds of hyperfine interaction with four equivalent protons are indistinguishable from each other in the resonance experiment, it is assumed in the above assignment from the theoretical point of view that the hyperfine interaction with the *ortho*-protons will be stronger than that with the *meta*-protons. A pattern of the spectrum is constructed from the above spin Hamiltonian with the parameters given above

as shown in Fig. 4 (b). This spectrum consists of nine lines with relative intensities of 1 : 4 : 8 : 12 : 14 : 12 : 8 : 4 : 1. The relative intensities of each component in the calculated spectrum are in good agreement with the observed ones of 1 : 4 : 8 : 12.5 : 14 : 12.5 : 7.5 : 3.8 : 1. If the line widths of each component are attributed to the unresolved hyperfine interaction due to the four *meta*-protons, the coupling constant $A_m$ is given by the value of about 0.7 gauss.

The above model of the magnetic center is similar to the diphenylmethyl radical concerned with the part on which the unpaired electron is localized. The calculation of the spin densities of the $\pi$-electrons on the carbon atoms in the diphenylmethyl radical performed by using the Pauling-Wheland valence-bond theory shows that the spin densities of the $\pi$-electrons on the *para*-, *ortho*- and *meta*-carbon atoms are given as follows (See Appendix):

$$\rho_p = 0.2790, \quad \rho_o = 0.2732, \quad \rho_m = -0.1483.$$

The spectrum constructed on the basis of the above spin densities, as shown in the appendix, is slightly different from the observed spectrum. The relative spin densities obtained from the above analysis of the observed spectrum are not in agreement with the calculated ones. The actual situation of distribution of the $\pi$-electrons in the DPE polymer radical will not be so simple as the case of diphenylmethyl. Indeed the DPE polymer forms a bending chain, so the two benzene rings in which the unpaired electron is to be localized may not be on the co-plane. However, it has not been clear at the present stage whether the above difference between the observed spectrum and the calculated one shows that the magnetic center corresponding to the observed paramagnetic resonance may not be the unpaired electron in the DPE polymer radical.

**Stilbene.** — A resonance line without any structures was observed in the stilbene radical in tetrahydrofuran solution with its concentration of $10^{-3}\sim10^{-4}$ M (Fig. 6). It has the maximum separation of thirteen gauss in the derivatives of the absorption line and the *g*-factor of 2.002. This result indicates that the hyperfine structure can not be resolved because many protons contribute to the hyperfine splitting. This situation is consistent with the simple LCAO–MO calculation of the unpaired electron density in the stilbene anion. The stilbene radical in tetrahydrofuran with its concentration of $10^{-1}$ M showed a Lorentzian-shaped line with the line width of 1.8 gauss.

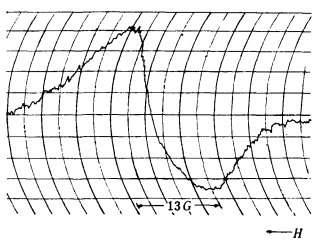

Fig. 6. Paramagnetic resonance spectrum of stylbene radical.

**1,4-Diphenylbutadiene.**—In a sample including the radical of 1,4-diphenylbutadiene prepared by method I, a resonance spectrum with unresolved h. f. s., which extends in the region of the magnetic field of about thirty-four gauss with $g=2.00$, has been observed as shown in Fig. 7. But it has not been investigated in detail.

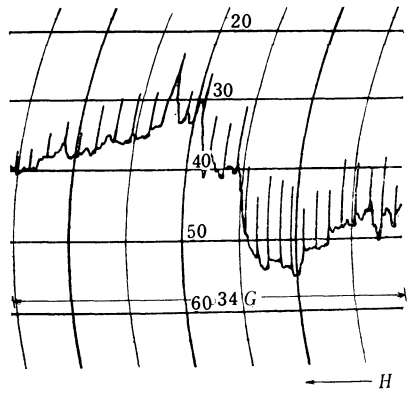

Fig. 7. Paramagnetic resonance spectrum of 1,4-diphenylbutadiene radical.

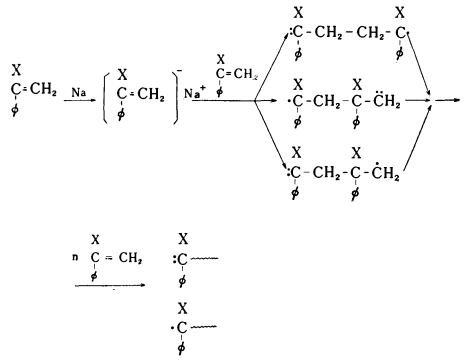

## Discussions on the Process of Polymerization

As described in the preceding paper, the pattern of the paramagnetic resonance spectra of radicals of styrene and *p*-methylstyrene depends sensitively on the degree of polymerization. In the latter substance changes of pattern and intensity of the paramagnetic resonance with time have been clearly observed. In the former samples three kinds of spectra have been observed, according to the conditions of preparation of the radicals. In the preceding paper the situations under which the polymerization of styrene and its derivatives proceeds were discussed by considering the above results.

In the case of DPE radicals, when a renewed reaction of DPE adducts, which had shown many resonance lines, with the sodium metal was performed by keeping the sample at 100°C for two days, another new spectrum was observed, which was considered to be coming from the hyperfine interaction of the unpaired electron being localized around the end molecule of DPE polymer, probably with a

low degree of polymerization, with its protons.

From these results it may be considered that polymerization is initiated through the process in which the monomer of the aromatic vinyl compound forms a bond between itself and the $\alpha$- or $\beta$-carbon atoms of the radical anion to grow into the polymer. This situation can be described in the following formula.

where X means H, $CH_3$ or $\phi(=C_6H_5)$.

The process of polymerization of the aromatic vinyl compounds has been studied through the optical absorption spectroscopy[3]. In order to confirm the above model of the process of polymerization, further experiments will be necessary.

## Summary

Paramagnetic resonance absorption of the radicals of 1, 1-diphenylethylene, stilbene and 1, 4-diphenylbutadiene in tetrahydrofuran solution was investigated at room temperature. In diphenylethylene (DPE) radicals two kinds of spectra were observed corresponding to two states of the radicals; one is the DPE monomer anion and the other the DPE polymer anion. In connection with the experimental results in the case of styrene, $\alpha$-methylstyrene and *p*-methylstyrene described in the preceding paper, the process of polymerization of some aromatic vinyl compounds was discussed.

The authors wish to express their sincere thanks to Professor Junkichi Itoh of Osaka University for his continuous encouragement and his helpful discussions throughout this work.

## Appendix

### Spin Densities in the Diphenylmethyl Radical

Spin densities of $\pi$-electrons on carbon atoms in the diphenylmethyl radical are calculated by using valence-bond theory. Valence-bond theory has been so far applied also to calculations of spin densities on carbon atoms in the triphenylmethyl radical by Brovetto and Ferroni[4] and in the perinaphthenyl radical by McConnell and Dearman[5] in good agreements with the experimental results. Therefore, valencebond theory is adequate to calculate the spin densities of $\pi$-electrons in these odd-alternant hydrocarbon radicals.

Valence-bond structures for calculation of the spin densities of $\pi$-electrons on carbon atoms in the diphenylmethyl radical can be divided into three groups shown in Fig. 8. To these three groups belong the 4, 4, 8 independent wave functions for the unpaired electron on the methylic carbon atom, and the *para*- and the *ortho*-carbon atoms of the benzene ring respectively. All functions related to Dewar structures will be neglected.

$\varphi_1$ $\varphi_2$ $\varphi_3$

Fig. 8.

With a linear combination for the $\varphi_{ik}$ the wave function $\Psi$ in the ground state can be constructed in such a way as to minimize the total energy of electrons. Then, $\Psi$ is given by the following equation,

$$\Psi = \sum_i C_i \sum_k \varphi_{ik} \qquad \text{(A1)}$$

The total Hamiltonian fo the $\pi$-electrons under the existence of the external magnetic field is:

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_1 + \mathcal{H}_2 \qquad \text{(A2)}$$
$$\mathcal{H}_1 = g\beta \boldsymbol{HS}$$
$$\mathcal{H}_2 = -(8\pi/3) g\beta g_N \beta_N \sum_k \boldsymbol{I}_k \boldsymbol{S} \delta(\boldsymbol{r}_e - \boldsymbol{r}_k)$$

where $\mathcal{H}_0$ means the kinetic energy and the Coulomb potential energy of the electrons; $\mathcal{H}_1$ is Zeeman energy in which the external magnetic field and the electronic spin are described by $\boldsymbol{H}$ and $\boldsymbol{S}$ respectively, $\mathcal{H}_2$ is the hyperfine interaction energy coming from the Fermi type contact hyperfine interaction between the electron and the $k$th-proton with

4) P. Brovetto and S. Ferroni, *Nuovo Cimento*, **5**, 142 (1957).

5) H. M. McConnell and H. H. Dearman, *J. Chem. Phys.*, **28**, 51 (1958).

the nuclear spin $I_k$, $\beta$ and $\beta_N$ are the electronic and nuclear Bohr magnetrons respectively, and $g$ and $g_N$ are the electronic and nuclear $g$-factors and $\delta(\boldsymbol{r}_e-\boldsymbol{r}_k)$ means the Dirac delta function for the distance between the electron and the $k$th-proton. In the above Hamiltonian the dipolar interaction between the electron and the proton is neglected, because it is averaged out not to contribute to the paramagnetic resonance spectrum by a tumbling motion of the molecule in the solution.

After some computations the minimum energy $W$ of the Hamiltonian $\mathcal{H}_0$ is given in the following equation,

$$W=Q+4.7046\alpha \qquad \text{(A3)}$$

where $Q$ means the Coulomb integral and $\alpha$ the single exchange integral.

Corresponding to the state with the minimum energy, the wave function in the ground state is given as follows:

$$\Psi=0.1572\varphi_1+0.1341\varphi_2+0.1312\varphi_3 \qquad \text{(A4)}$$

The matrix element of the hyperfine interaction $\mathcal{H}_2$ is calculated by using the Brovetto-Ferroni method as applied to triphenylmethyl. By using Eq. (A1) the matrix element $\langle\Psi|\mathcal{H}_2|\Psi\rangle$ is given in the following equation,

$$\langle\Psi|\mathcal{H}_2|\Psi\rangle=\sum_{ij} c_i c_j \sum_{kl}\langle\varphi_{ik}|\mathcal{H}_2|\varphi_{il}\rangle \qquad \text{(A5)}$$

The matrix elements $\langle\varphi_{ik}|\mathcal{H}_2|\varphi_{il}\rangle$ can be calculated in a similar way to the case of triphenylmethyl.

$$\langle\Psi|\mathcal{H}_2|\Psi\rangle=-(8\pi/3)g\beta g_N\beta_N A \times[0.2790I_{zp}-0.1483I_{zm}+0.2732I_{zo}]\cdot S_z \qquad \text{(A6)}$$

where $I_{zp}$, $I_{zm}$ and $I_{zo}$ mean the component along the external magnetic field of the total spin of the protons in the *para*, *ortho* and *meta* position of the benzene ring respectively, and $A$ is the factor which depends on the strength of the $\sigma-\pi$ interaction.

The magnetic field $H$ corresponding to the transition $\Delta S_z=\pm1$, $\Delta I_z=0$ in the experiment using the microwave with the frequency $\nu$ is given by the following equation

$$H=h\nu/g\beta+(8\pi/3)g_N\beta_N A \times[0.2790I_{zp}-0.1483I_{zm}+0.2732I_{zo}] \qquad \text{(A7)}$$

Then, the paramagnetic resonance spectrum can be constructed by Eq. (A7) as shown in Fig. 9, where only the upper part of the spectrum corresponding to the value of $H$ larger than $h\nu/g\beta$ is given, because the spectrum is symmetrical with respect to the value of the magnetic field $H=h\nu/g\beta$.

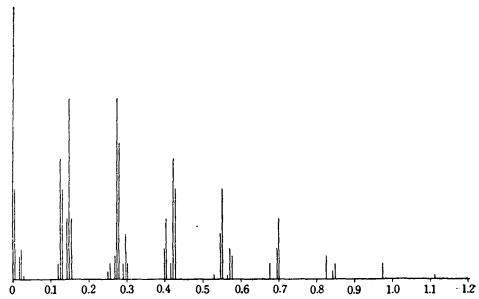

Fig. 9. The calculated spectrum of diphenylmethyl radical.

A comparison of the above calculated spectrum with the observed one in the DPE radical shows some differences as shown in Fig. 9. Though the observed spectrum consists of nine lines, more lines should be expected from the results of the calculation. Especially, the fifth line from the central one, which has about half the intensity in comparison with the fourth line in the calculated spectrum, should be observed from the experimental condition of our spectrometer. The origin of the above differences between the theoretical spectrum and experimental one is discussed in the text.

# *A Further Study of Simple LCAO MO Perturbation Treatment of Conjugated Molecules*

By Kenichi FUKUI, Keiji MOROKUMA, Teijiro YONEZAWA and Chikayoshi NAGATA

(Received December 19, 1959)

The perturbation theory in the simple LCAO MO method has been studied by many authors, for instance, by Coulson and Longuet-Higgins[1] and by Dewar[2]. Recently, by the present authors[3], a new mathematical method of perturbation theory, named the method of perturbed secular determinant, has been developed and several useful equations have been derived which give the orbital energy, the electron density and the bond order of the perturbed system.

The only system involved in these works, however, was the one which suffered only one perturbation, that is, a small change of a Coulomb integral or of a resonance integral, or a weak bonding to another system. There could be seen no systematic perturbation treatment of the system which was affected by two or more perturbations, for instance, changes of two Coulomb integrals, changes of a Coulomb integral and of a resonance integral, and a weak bonding with a change of a Coulomb integral. To deal with such a system would be of practical interest in discussing the chemical reactivity, absorption spectrum, dipole moment and other electronic properties of large conjugated molecules.

In the present paper are derived several equations or relations which give the molecular orbital, its orbital energy, the electron density and the bond order of systems affected by two perturbations, and lastly they are extended to a more general case of many perturbations.

## Non-degenerate System

**1. Summary of Results for Single Perturbation.**—In order to simplify the expression of various equations appearing in the treatment of multiple-perturbed systems, it would be convenient to summarize the results for single perturbation. The following formulae, obtained by the method of perturbed secular determinant and also by the existing method of perturbation, were given in the previous paper, though some of them not explicitly.

In this section it is assumed that the system to be treated is not degenerate in itself, nor has it any degenerate level between another system to conjugate with.

First, if the Coulomb integral, $\alpha_r$, of the $r$th atom in a conjugated system, $\Delta(\varepsilon)$,* is increased by $\alpha_r'$ (Case A of Ref. 3), then, as its consequence, the $j$th orbital energy, $\varepsilon_j$, will increase by $(\delta\varepsilon_j)_r$, the separate bond order, $p_{uv}{}^j$, by $(\delta p_{uv}{}^j)_r$, the separate electron density, $p_{uu}{}^j$, by $(\delta p_{uu}{}^j)_r$, the total $\pi$ electronic energy, $\varepsilon$, by $(\delta\varepsilon)_r$, the bond order, $p_{uv}$, by $(\delta p_{uv})_r$, the electron density, $p_{uu}$, by $(\delta p_{uu})_r$ and the $j$th molecular orbital, $\Psi_j$, by $(\delta\Psi_j)_r$, in such a way that**

$$(\delta\varepsilon_j)_r=(c_r{}^j)^2\alpha_r'+\sum_{k(\neq j)}^{\text{all}}\frac{(c_r{}^jc_r{}^k)^2}{\varepsilon_j-\varepsilon_k}(\alpha_r')^2+\cdots\cdots \tag{1}$$

$$\begin{aligned}(\delta p_{uv}{}^j)_r=&\sum_{k(\neq j)}^{\text{all}}\frac{c_r{}^jc_r{}^k(c_u{}^jc_v{}^k+c_v{}^jc_u{}^k)}{\varepsilon_j-\varepsilon_k}\alpha_r'\\&+\sum_{k(\neq j)}^{\text{all}}\frac{c_r{}^jc_r{}^k}{\varepsilon_j-\varepsilon_k}\left[\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^m\{c_r{}^jc_u{}^kc_v{}^m+c_r{}^m(c_u{}^jc_v{}^k+c_v{}^jc_u{}^k)\}}{\varepsilon_j-\varepsilon_m}\right.\\&\left.-\frac{c_r{}^j\{c_r{}^kc_u{}^jc_v{}^j+c_r{}^j(c_u{}^jc_v{}^k+c_v{}^jc_u{}^k)\}}{\varepsilon_j-\varepsilon_k}\right](\alpha_r')^2+\cdots\cdots\qquad(u=v\text{ or }u\neq v)\end{aligned} \tag{2}$$

1) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc. (London)*, **A191**, 39 (1947); **A192**, 16 (1947): **A193**, 447, 456 (1948); **A195**, 188 (1948).

3) K. Fukui, C. Nagata, T. Yonezawa, H. Kato and K. Morokuma, *J. Chem. Phys.*, **31**, 287 (1959).

* $\Delta(\varepsilon)$ is the secular determinant of the system and will be used also to characterize a conjugated system.

** As for the nomenclature, see Ref. 3. Electron density will be looked upon as a special case ($u=v$) of bond order in the further discussion.

$$(\delta\varepsilon)_r = p_{rr}\alpha_r' + 2\sum_j^{\text{occ}}\sum_k^{\text{unocc}} \frac{(c_r{}^j c_r{}^k)^2}{\varepsilon_j - \varepsilon_k}(\alpha_r')^2 + \cdots\cdots \tag{3}$$

$$(\delta p_{uv})_r = 2\sum_j^{\text{occ}}\sum_k^{\text{unocc}} \frac{c_r{}^j c^{\ k}(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k)}{\varepsilon_j - \varepsilon_k}\alpha_r' + 2\sum_j^{\text{occ}}\{\text{the second order term in}(\delta p_{uv}{}^j)_r\} + \cdots\cdots \quad (u=v \text{ or } u\neq v) \tag{4}$$

$$(\delta\Psi_j)_r = \sum_{k(\neq j)}^{\text{all}} \frac{c_r{}^j c_r{}^k}{\varepsilon_j - \varepsilon_k}\alpha_r'\Psi_k - \frac{1}{2}\left\{\sum_{k(\neq j)}^{\text{all}} \frac{(c_r{}^j c_r{}^k)^2}{(\varepsilon_j - \varepsilon_k)^2}\right\}(\alpha_r')^2\Psi_j + \sum_{k(\neq j)}^{\text{all}} \frac{c_r{}^j c_r{}^k}{\varepsilon_j - \varepsilon_m}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{(c_r{}^m)^2}{\varepsilon_j - \varepsilon_m} - \frac{(c_r{}^j)^2}{\varepsilon_j - \varepsilon_k}\right\}(\alpha_r')^2\Psi_k + \cdots\cdots \tag{5}$$

Secondly, when the resonance integral, $\beta_{st}$, of the bond $(st)$ in the system $\Delta(\varepsilon)$ is increased by $\beta_{st}'$ (Case B of Ref. 3), increases of those quantities are written as follows:

$$(\delta\varepsilon_j)_{st} = 2c_s{}^j c_t{}^j\beta_{st}' + \sum_{k(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)^2}{\varepsilon_j - \varepsilon_k}(\beta_{st}')^2 + \cdots\cdots \tag{6}$$

$$(\delta p_{uv}{}^j)_{st} = \sum_{k(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k)}{\varepsilon_j - \varepsilon_k}\beta_{st}' + \sum_{k(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)}{\varepsilon_j - \varepsilon_k}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^m + c_t{}^j c_s{}^m)c_u{}^k c_v{}^m + (c_s{}^k c_t{}^m + c_t{}^k c_s{}^m)(c_u{}^j c_v{}^m + c_v{}^j c_u{}^m)}{\varepsilon_j - \varepsilon_m} - \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)c_u{}^j c_v{}^j + 2c_s{}^j c_t{}^j(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k)}{\varepsilon_j - \varepsilon_k}\right\}(\beta_{st}')^2 + \cdots\cdots \quad (u=v \text{ or } u\neq v) \tag{7}$$

$$(\delta\varepsilon)_{st} = 2p_{st}\beta_{st}' + 2\sum_j^{\text{occ}}\sum_k^{\text{unocc}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)^2}{\varepsilon_j - \varepsilon_k}(\beta_{st}')^2 + \cdots\cdots \tag{8}$$

$$(\delta p_{uv})_{st} = 2\sum_j^{\text{occ}}\sum_k^{\text{unocc}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k)}{\varepsilon_j - \varepsilon_k}\beta_{st}' + 2\sum_j^{\text{occ}}\{\text{the second order term in}(\delta p_{uv}{}^j)_{st}\} + \cdots\cdots \quad (u=v \text{ or } u\neq v) \tag{9}$$

$$(\delta\Psi_j)_{st} = \sum_{k(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)}{\varepsilon_j - \varepsilon_k}\beta_{st}'\Psi_k - \frac{1}{2}\sum_{k(\neq j)}^{\text{all}} \frac{(c_s{}^j c_t{}^k + c_t{}^j c_s{}^k)^2}{(\varepsilon_j - \varepsilon_k)^2}(\beta_{st}')^2\Psi_j + \sum_{k(\neq j)}^{\text{all}} \frac{c_s{}^j c_t{}^k + c_t{}^j c_s{}^k}{\varepsilon_j - \varepsilon_k}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{c_s{}^k c_t{}^m + c_t{}^k c_s{}^m}{\varepsilon_j - \varepsilon_m} - \frac{2c_s{}^j c_t{}^j}{\varepsilon_j - \varepsilon_k}\right\}\Big](\beta_{st}')^2\Psi_k + \cdots\cdots \tag{10}$$

Thirdly, when a conjugated system, $\Delta(\varepsilon)$, conjugates at the $r$th atom through a weak bonding, whose resonance integral is $\gamma_r$, with another conjugated system, whose secular determinant is $\Delta_1(\varepsilon)$, (Case C of Ref. 3), then the increases of molecular quantities by this perturbation are given by the following formulae. The orbital energy of the $k$th orbital $\phi_{1k}$ of the system $\Delta_1(\varepsilon)$ is $\eta_{1k}$ and the coefficient of the $\xi$th atomic orbital in that molecular orbital is written as $d_\xi{}^{1k}$.

$$(\delta\varepsilon_j)_{r\xi} = \sum_k^{\text{all}} \frac{(c_r{}^j d_\xi{}^{1k})^2}{\varepsilon_j - \eta_{1k}}(\gamma_r)^2 + \left\{\sum_k^{\text{all}} \frac{(c_r{}^j d_\xi{}^{1k})^2}{\varepsilon_j - \eta_{1k}}\right\}\left[\sum_k^{\text{all}} \frac{(d_\xi{}^{1k})^2}{\varepsilon_j - \eta_{1k}}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{(c_r{}^m)^2}{\varepsilon_j - \varepsilon_m} - \frac{(c_r{}^j)^2}{\varepsilon_j - \eta_{1k}}\right\}\right](\gamma_r)^4 + \cdots\cdots \tag{11}$$

$$(\delta p_{uv}{}^j)_{r\xi} = \sum_k^{\text{all}} \frac{c_r{}^j d_\xi{}^{1k}}{\varepsilon_j - \eta_{1k}}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{c_r{}^m d_\xi{}^{1k}(c_u{}^j c_v{}^m + c_v{}^j c_u{}^m)}{\varepsilon_j - \varepsilon_m} - \frac{c_r{}^j d_\xi{}^{1k} c_u{}^j c_v{}^j}{\varepsilon_j - \eta_{1k}}\right\}(\gamma_r)^2 + \cdots\cdots \quad (u=v \text{ or } u\neq v) \tag{12}$$

$$(\delta p_{r\xi}{}^j)_{r\xi} = \sum_k^{\text{all}} \frac{(c_r{}^j d_\xi{}^{1k})^2}{\varepsilon_j - \eta_{1k}}\gamma_r + 2\sum_k^{\text{all}}\sum_n^{\text{all}} \frac{(c_r{}^j d_\xi{}^{1k} d_\xi{}^{1n})^2}{(\varepsilon_j - \eta_{1k})(\varepsilon_j - \eta_{1n})}\left\{\sum_{m(\neq j)}^{\text{all}} \frac{(c_r{}^m)^2}{\varepsilon_j - \varepsilon_m} - \frac{(c_r{}^j)^2}{\varepsilon_j - \eta_{1k}}\right\}(\gamma_r)^3 + \cdots \tag{12'}$$

$$(\delta p_{uv}{}^{1k})_{r\xi} = \sum_j^{\text{all}}\sum_m^{\text{all}} \frac{c_r{}^j c_r{}^m (d_\xi{}^{1k})^2 c_u{}^j c_v{}^m}{(\eta_{1k} - \varepsilon_j)(\eta_{1k} - \varepsilon_m)}(\gamma_r)^2 + \cdots\cdots \quad (u=v \text{ or } u\neq v) \tag{13}$$

$$(\delta\Psi_j)_{r\xi}=\sum_k^{\text{all}}\frac{c_r{}^j d_\xi{}^{1k}}{\varepsilon_j-\eta_{1k}}\gamma_r\psi_k-\frac{1}{2}\sum_k^{\text{all}}\frac{(c_r{}^j d_\xi{}^{1k})^2}{(\varepsilon_j-\eta_{1k})^2}(\gamma_r)^2\Psi_j+\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^j c_r{}^m}{\varepsilon_j-\varepsilon_m}\sum_k^{\text{all}}\frac{(d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}(\gamma_r)^2\Psi_m+\cdots\cdots \quad (14)$$

where the atom $u$ and the bond $(uv)$ are in the system $\Delta(\varepsilon)$, and $\xi$ is the position of weak conjugation in the system $\Delta_1(\varepsilon)$. Similar formulae would be obtained for the system $\Delta_1(\varepsilon)$. Thus the change of bond order and that of electron density and total $\pi$ electronic energy change of the combined system are obtained as follows:

$$\begin{aligned}(\delta\varepsilon)_{r\xi}&=2\sum_j^{\text{occ}}(\delta\varepsilon_j)_{r\xi}+2\sum_k^{\text{occ}}(\delta\eta_{1k})_{r\xi}\\&=2\Big(\sum_j^{\text{occ}}\sum_k^{\text{unocc}}-\sum_j^{\text{unocc}}\sum_k^{\text{occ}}\Big)\frac{(c_r{}^j d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}(\gamma_r)^2+2\sum_j^{\text{occ}}\{\text{the fourth order term in}(\delta\varepsilon_j)_{r\xi}\}\\&\quad+2\sum_k^{\text{occ}}\{\text{the fourth order term in}(\delta\eta_{1k})_{r\xi}\}+\cdots\cdots\end{aligned} \quad (15)$$

$$\begin{aligned}(\delta p_{uv})_{r\xi}&=2\sum_j^{\text{occ}}(\delta p_{uv}{}^j)_{r\xi}+2\sum_k^{\text{occ}}(\delta p_{uv}{}^{1k})_{r\xi}\\&=2\Big(\sum_k^{\text{occ}}\sum_j^{\text{unocc}}-\sum_k^{\text{unocc}}\sum_j^{\text{occ}}\Big)\Big[\frac{(d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}\Big\{\frac{(c_r{}^j)^2c_u{}^jc_v{}^j}{\varepsilon_j-\eta_{1k}}\\&\quad-\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^jc_r{}^m(c_u{}^jc_v{}^m+c_v{}^jc_u{}^m)}{\varepsilon_j-\varepsilon_m}\Big\}\Big](\gamma_r)^2+\cdots\cdots\end{aligned} \quad (u=v \text{ or } u\neq v) \quad (16)$$

$$(\delta p_{r\xi})_{r\xi}=2\Big(\sum_j^{\text{occ}}\sum_k^{\text{unocc}}-\sum_j^{\text{unocc}}\sum_k^{\text{occ}}\Big)\frac{(c_r{}^j d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}\gamma_r+2\sum_j^{\text{occ}}\{\text{the third order term in}(\delta p_{r\xi}{}^j)_{r\xi}\}$$

$$+2\sum_k^{\text{occ}}\{\text{the third order term in}(\delta p_{r\xi}{}^{1k})_{r\xi}\}+\cdots\cdots \quad (16')$$

Here it was assumed that the highest occupied orbitals of the systems $\Delta(\varepsilon)$ and $\Delta_1(\varepsilon)$ are lower than the lowest unoccupied orbitals of the systems $\Delta_1(\varepsilon)$ and $\Delta(\varepsilon)$, respectively. The total charge transfer, $\delta Q$, from the system $\Delta_1(\varepsilon)$ to the system $\Delta(\varepsilon)$ is defined by

$$\delta Q=\sum_{u=1}^{n}\delta p_{uu} \quad (17)$$

where $n$ is the number of atomic orbitals in the system $\Delta(\varepsilon)$.

For this case $\delta Q$ is given by the following equation.

$$(\delta Q)_{r\xi}=2\Big(\sum_k^{\text{occ}}\sum_j^{\text{unocc}}-\sum_k^{\text{unocc}}\sum_j^{\text{occ}}\Big)\frac{(c_r{}^j d_\xi{}^{1k})^2}{(\varepsilon_j-\eta_{1k})^2}(\gamma_r)^2+\cdots\cdots \quad (18)$$

As a special case involved in the Case C, when the system $\Delta_1(\varepsilon)$ is an atom or a mesomeric group, X, Eqs. 11 to 16 and 18 become

$$(\delta\varepsilon_j)_{rX}=\frac{(c_r{}^j)^2}{\varepsilon_j-\alpha_X}(\gamma_r)^2+\frac{(c_r{}^j)^2}{\varepsilon_j-\alpha_X}\Big\{-\frac{(c_r{}^j)^2}{(\varepsilon_j-\alpha_X)^2}+\sum_{m(\neq j)}^{\text{all}}\frac{(c_r{}^m)^2}{(\varepsilon_j-\alpha_X)(\varepsilon_j-\varepsilon_m)}\Big\}(\gamma_r)^4+\cdots\cdots \quad (11\text{-a})$$

$$(\delta\alpha_X)_{rX}=\sum_j^{\text{all}}\frac{(c_r{}^j)^2}{\alpha_X-\varepsilon_j}(\gamma_r)^2+\Big\{\sum_j^{\text{all}}\frac{(c_r{}^j)^2}{\alpha_X-\varepsilon_j}\Big\}\Big\{-\sum_j^{\text{all}}\frac{(c_r{}^j)^2}{(\alpha_X-\varepsilon_j)^2}\Big\}(\gamma_r)^4+\cdots\cdots \quad (11\text{-b})$$

$$(\delta p_{uv}{}^j)_{rX}=\Big\{\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^jc_r{}^m(c_u{}^jc_v{}^m+c_v{}^jc_u{}^m)}{(\varepsilon_j-\varepsilon_m)(\varepsilon_j-\alpha_X)}-\frac{(c_r{}^j)^2c_u{}^jc_v{}^j}{(\varepsilon_j-\alpha_X)^2}\Big\}(\gamma_r)^2+\cdots\cdots \quad (12\text{-a})$$

$$(\delta p_{rX}{}^j)_{rX}=\frac{(c_r{}^j)^2}{\varepsilon_j-\alpha_X}\gamma_r+\frac{2(c_r{}^j)^2}{(\varepsilon_j-\alpha_X)^2}\Big\{\sum_{m(\neq j)}^{\text{all}}\frac{(c_r{}^m)^2}{\varepsilon_j-\varepsilon_m}-\frac{(c_r{}^j)^2}{\varepsilon_j-\alpha_X}\Big\}(\gamma_r)^3+\cdots\cdots \quad (12'\text{-a})$$

$$(\delta p_{uv}{}^X)_{rX}=\Big\{\sum_j^{\text{all}}\sum_m^{\text{all}}\frac{c_r{}^jc_r{}^mc_u{}^jc_v{}^m}{(\varepsilon_j-\alpha_X)(\varepsilon_m-\alpha_X)}\Big\}(\gamma_r)^2+\cdots \quad (13\text{-a})$$

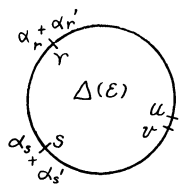
$$(\delta p_{rX}{}^X)_{rX}=\sum_j^{\text{all}}\frac{(c_r{}^j)^2}{\alpha_X-\varepsilon_j}\gamma_r-2\Big\{\sum_j^{\text{all}}\sum_m^{\text{all}}\frac{(c_r{}^jc_r{}^m)^2}{(\alpha_X-\varepsilon_j)^2(\alpha_X-\varepsilon_m)}\Big\}(\gamma_r)^3+\cdots\cdots \quad (13'\text{-a})$$

$$(\delta p_{XX}{}^{j})_{rX}=\frac{(c_r{}^{j})^2}{(\varepsilon_j-\alpha_X)^2}(\gamma_r)^2+\cdots\cdots \tag{12-b}$$

$$(\delta p_{XX}{}^{X})_{rX}=-\sum_{j}^{\text{all}}\frac{(c_r{}^{j})^2}{(\alpha_X-\varepsilon_j)^2}(\gamma_r)^2+\cdots\cdots \tag{13-b}$$

$$(\delta p_{uv})_{rX}=(\nu\sum_{j}^{\text{all}}-2\sum_{j}^{\text{occ}})\left\{\frac{(c_r{}^{j})^2c_u{}^{j}c_v{}^{j}}{(\varepsilon_j-\alpha_X)^2}+\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^{j}c_r{}^{m}(c_u{}^{j}c_v{}^{m}+c_v{}^{j}c_u{}^{m})}{(\alpha_X-\varepsilon_j)(\varepsilon_j-\varepsilon_m)}\right\}(\gamma_r)^2+\cdots\cdots \tag{16-a}$$

$$(\delta p_{XX})_{rX}=(2\sum_{j}^{\text{occ}}-\nu\sum_{j}^{\text{all}})\frac{(c_v{}^{j})^2}{(\alpha_X-\varepsilon_j)^2}(\gamma_r)^2+\cdots\cdots \tag{16-b}$$



$$(\delta p_{rX})_{rX}=(2\sum_{j}^{\text{occ}}-\nu\sum_{j}^{\text{all}})\frac{(c_r{}^{j})^2}{\varepsilon_j-\alpha_X}\gamma_r+2\sum_{j}^{\text{occ}}\{\text{the third order term in}(\delta p_{rX}{}^{j})_{rX}\}$$
$$+\nu\{\text{the third order term in}(\delta p_{rX}{}^{X})_{rX}\}+\cdots\cdots \tag{16'-a}$$

$$(\delta Q)_{rX}=(\nu\sum_{j}^{\text{all}}-2\sum_{j}^{\text{occ}})\frac{(c_r{}^{j})^2}{(\alpha_X-\varepsilon_j)^2}(\gamma_r)^2+\cdots\cdots \tag{18-a}$$

where $\nu$ is the number of electrons in the atom X. The equations corresponding to Eqs. 14 and 15 are omitted for simplicity.

In the following paragraphs some important cases of doubly perturbed systems will be treated.

**2. Case I. Changes of Two Coulomb Integrals.**—If two atoms, say the $r$th and the $s$th atoms, in a conjugated molecule, $\Delta(\varepsilon)$, are replaced by two heteroatoms, the Coulomb integrals of these atoms will become $\alpha_r+\alpha_r'$ and $\alpha_s+\alpha_s'$, respectively. Then the perturbed secular determinant of the system will be written

$$D(\varepsilon)=\Delta(\varepsilon)+\alpha_r'\Delta_{rr}(\varepsilon)+\alpha_s'\Delta_{ss}(\varepsilon)+\alpha_r'\alpha_s'\Delta_{rrss}(\varepsilon) \tag{19}$$

where $\Delta_{rr}(\varepsilon)$ and $\Delta_{rrss}(\varepsilon)$ are the $(rr)$ minor and the $(rr, ss)$ minor of $\Delta(\varepsilon)$, respectively. Regarding these changes, $\alpha_r'$ and $\alpha_s'$, as perturbations, one can easily obtain the perturbed orbital energy, of the $j$th molecular orbital, the perturbed bond order and the perturbed electron density by the use of the method of perturbed secular determinant, as will be briefly explained in the following.

First if one intermediately considers a system where $\alpha_s'$ is zero, the intermediate perturbed secular determinant is given as:

$$\square(\varepsilon)=\Delta(\varepsilon)+\alpha_r'\Delta_{rr}(\varepsilon) \tag{20}$$

According to the procedure utilized in the previous paper, the intermediate perturbed orbital energy, $\tilde{\varepsilon}_j$, and the intermediate perturbed separate bond order, $\tilde{p}_{uv}{}^{j}$, are expanded in powers of $\alpha_r'$:

$$\left.\begin{aligned}\tilde{\varepsilon}_j&=\sum_{m=0}^{\infty}a_r{}^{j(m)}(\alpha_r')^m\\ \tilde{p}_{uv}{}^{j}&=\sum_{m=0}^{\infty}a_{r,uv}{}^{j(m)}(\alpha_r')^m\end{aligned}\right\} \tag{21}$$

and the coefficients, $a_r{}^{j(m)}$ and $a_{r,uv}{}^{j(m)}$, are given by the following formulae.

$$\left.\begin{aligned}a_r{}^{j(m)}&=\frac{(-1)^m}{m!}\left[\frac{\mathrm{d}^m}{\mathrm{d}z^m}\frac{z\{\Delta_{rr}(z)\}^{m-1}\{\Delta'(z)\Delta_{rr}(z)-\Delta(z)\Delta_{rr}'(z)\}}{\{\Delta(z)/(z-\varepsilon_j)\}^{m+1}}\right]_{z=\varepsilon_j}\\ &\qquad(m=0,1,2,\cdots\cdots)\\ a_{r,uv}{}^{j(m)}&=\frac{(-1)^{m+1}}{m!}\left[\frac{\mathrm{d}^m}{\mathrm{d}z^m}\frac{\{\Delta_{rr}(z)\}^m\Delta_{ur}(z)\Delta_{rv}(z)}{\{\Delta(z)/(z-\varepsilon_j)\}^{m+1}}\right]_{z=\varepsilon_j}\\ &\qquad(m=0,1,2,\cdots\cdots)\end{aligned}\right\} \tag{22}$$

Directly from these formulae the following expressions are obtained

$$\left.\begin{aligned}\tilde{\varepsilon}_j &= \varepsilon_j + (\delta\varepsilon_j)_r \\ \tilde{p}_{uv}{}^j &= p_{uv}{}^j + (\delta p_{uv}{}^j)_r\end{aligned}\right\} \tag{23}$$

where $(\delta\varepsilon_j)_r$ and $(\delta p_{uv}{}^j)_r$ are given by Eqs. 1 and 2.

Then the second perturbation, $\alpha_s'$, is to be taken into account. The perturbed secular determinant of the system in question is expressed with the aid of the secular determinant of the intermediate system,

$$D(\varepsilon) = \square(\varepsilon) + \alpha_s' \square_{ss}(\varepsilon) \tag{24}$$

A similar procedure leads to the expansion formulae

$$\left.\begin{aligned}\varepsilon_j' &= \sum_{m=0}^{\infty} b_s{}^{j(m)} (\alpha_s')^m \\ P_{uv}{}^j &= \sum_{m=0}^{\infty} b_{s,uv}{}^{j(m)} (\alpha_s')^m\end{aligned}\right\} \tag{25}$$

where the coefficients, $b_s{}^{j(m)}$ and $b_{s,uv}{}^{j(m)}$, are the functions of $\alpha_r'$ and are given by

$$\left.\begin{aligned}b_s{}^{j(m)} &= \frac{(-1)^m}{m!}\left[\frac{\mathrm{d}^m}{\mathrm{d}z^m}\frac{z\{\square_{ss}(z)\}^{m-1}\{\square'(z)\square_{ss}(z) - \square(z)\square_{ss}'(z)\}}{\{\square(z)/(z-\tilde{\varepsilon}_j)\}^{m+1}}\right]_{z=\tilde{\varepsilon}_j} \\ &\qquad (m=0, 1, 2, \cdots\cdots) \\ b_{s,uv}{}^{j(m)} &= \frac{(-1)^{m+1}}{m!}\left[\frac{\mathrm{d}^m}{\mathrm{d}z^m}\frac{\{\square_{ss}(z)\}^m \square_{us}(z)\square_{sv}(z)}{\{\square(z)/(z-\tilde{\varepsilon}_j)\}^{m+1}}\right]_{z=\tilde{\varepsilon}_j} \\ &\qquad (m=0, 1, 2, \cdots\cdots)\end{aligned}\right\} \tag{26}$$

Thus we finally reach the following results for this perturbed system.

$$\varepsilon_j' = \varepsilon_j + (\delta\varepsilon_j)_r + (\delta\varepsilon_j)_s + 2\sum_{k(\neq j)}^{\text{all}} \frac{c_r{}^j c_r{}^k c_s{}^j c_s{}^k}{\varepsilon_j - \varepsilon_k}\alpha_r'\alpha_s' + \cdots\cdots \tag{27}$$

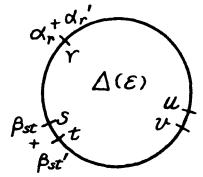
$$\begin{aligned}P_{uv}{}^j = p_{uv}{}^j &+ (\delta p_{uv}{}^j)_r + (\delta p_{uv}{}^j)_s \\ &+ \Bigg[\sum_{k(\neq j)}^{\text{all}}\sum_{m(\neq j)}^{\text{all}} \frac{c_r{}^j c_s{}^j (c_r{}^k c_s{}^m + c_s{}^k c_r{}^m) c_u{}^k c_v{}^m + c_r{}^m c_s{}^m (c_r{}^j c_s{}^k + c_s{}^j c_r{}^k)(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k)}{(\varepsilon_j - \varepsilon_k)(\varepsilon_j - \varepsilon_m)} \\ &- \sum_{k(\neq j)}^{\text{all}} \frac{c_r{}^j c_s{}^j\{(c_r{}^j c_s{}^k + c_s{}^j c_r{}^k)(c_u{}^j c_v{}^k + c_v{}^j c_u{}^k) + 2c_r{}^k c_s{}^k c_u{}^j c_v{}^j\}}{(\varepsilon_j - \varepsilon_k)^2}\Bigg]\alpha_r'\alpha_s' + \cdots\cdots\end{aligned} \tag{28}$$

where $(\delta\varepsilon_j)_r$ and $(\delta p_{uv}{}^j)_r$ are the change of the orbital energy and the separate bond order (or the separate electron density) respectively, of the $j$th molecular orbital caused by the perturbation $\alpha_r'$, as were given in Eqs, 1 and 2.

On inspection of Eqs. 27 and 28 it is clearly seen that, as concerns the first order terms, two perturbations have no effect upon each other and, therefore, the so-called "additivity rule" comes into being. That is to say, the change of the orbital energy, the bond order or the electron density caused by two perturbations is expressed by the mathematical sum of its changes caused by each perturbation. In the second order a cross term appears, which may become comparable in magnitude with the non-cross term and cannot be neglected. Also as for the total $\pi$ electronic energy, the bond order and the electron density, which are expressed by the sum of corresponding separate quantity, the circumstances are the same, as follows:

$$\varepsilon' = \varepsilon + (\delta\varepsilon)_r + (\delta\varepsilon)_s + 2\sum_{j}^{\text{occ}}\sum_{k}^{\text{unocc}} \frac{c_r{}^j c_r{}^k c_s{}^j c_s{}^k}{\varepsilon_j - \varepsilon_k}\alpha_r'\alpha_s' + \cdots\cdots \tag{29}$$

$$P_{uv} = p_{uv} + (\delta p_{uv})_r + (\delta p_{uv})_s + \sum_{j}^{\text{occ}}\{\text{cross term of the order } \alpha_r'\alpha_s' \text{ in } P_{uv}{}^j\} + \cdots\cdots \tag{30}$$



where $(\delta\varepsilon)_r$ and $(\delta p_{uv})_r$, given by Eqs. 3 and 4, are the changes of total $\pi$ electronic energy and the bond order (or the electron density) respectively, caused by the perturbation $\alpha_r'$. Eqs. 27 to 30 can also be derived by the existing method of perturbation.

The explicit expression of perturbed molecular orbital would be useful for some purposes. It is

$$\Psi_j' = \Psi_j + (\delta\Psi_j)_r + (\delta\Psi_j)_s - \sum_{k(\neq j)}^{\text{all}} \frac{c_r^j c_r^k c_s^j c_s^k}{(\varepsilon_j - \varepsilon_k)^2} \alpha_r' \alpha_s' \Psi_j$$
$$+ \sum_{k(\neq j)}^{\text{all}} \frac{(c_r^j c_s^k + c_s^j c_r^k)}{\varepsilon_j - \varepsilon_k} \left\{ \sum_{m(\neq j)}^{\text{all}} \frac{c_r^m c_s^m}{\varepsilon_j - \varepsilon_m} - \frac{c_r^j c_s^j}{\varepsilon_j - \varepsilon_k} \right\} \alpha_r' \alpha_s' \Psi_k + \cdots\cdots \quad (31)$$

where $(\delta\Psi_j)_r$ is given by Eq. 5.

**3. Case II. Changes of a Coulomb Integral and a Resonance Integral.**—When at the same time the Coulomb integral of the $r$th atom is increased by $\alpha_r'$ and the resonance integral of the bond $(st)$, $\beta_{st}$, by $\beta_{st}'$, then the perturbed secular determinant of the system is expressed* by

$$D(\varepsilon) = \Delta(\varepsilon) + \alpha_r' \Delta_{rr}(\varepsilon) + (-1)^{s+t} 2\beta_{st}' \Delta_{st}(\varepsilon) - (\beta_{st}')^2 \Delta_{sstt}(\varepsilon)$$
$$+ (-1)^{s+t} \alpha_r' \beta_{st}' \Delta_{rrst}(\varepsilon) - \alpha_r' (\beta_{st}')^2 \Delta_{rrsstt}(\varepsilon) \quad (32)$$

As well as in Case I, the following expressions of the orbital energy, the separate bond order and the separate electron density are obtained.

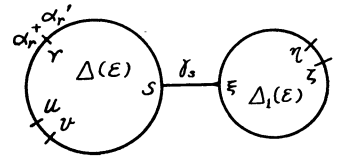
$$\varepsilon_j' = \varepsilon_j + (\delta\varepsilon_j)_r + (\delta\varepsilon_j)_{st} + 2 \sum_{k(\neq j)}^{\text{all}} \frac{c_r^j c_r^k (c_s^j c_t^k + c_t^j c_s^k)}{\varepsilon_j - \varepsilon_k} \alpha_r' \beta_{st}' + \cdots\cdots \quad (33)$$

$$P_{uv}^j = p_{uv}^j + (\delta p_{uv}^j)_r + (\delta p_{uv}^j)_{st}$$
$$+ \left[ \sum_{k(\neq j)}^{\text{all}} \sum_{m(\neq j)}^{\text{all}} \frac{c_r^j c_r^k (c_s^j c_t^m + c_t^j c_s^m)(c_u^k c_v^m + c_v^k c_u^m)}{(\varepsilon_j - \varepsilon_k)} \right.$$
$$\times \frac{\{c_r^k c_r^m (c_s^j c_t^m + c_t^j c_s^m) + c_r^m c_r^j (c_s^k c_t^m + c_t^k c_s^m)\}(c_u^j c_v^k + c_v^j c_u^k)}{(\varepsilon_j - \varepsilon_m)}$$
$$\left. - \sum_{k(\neq j)}^{\text{all}} \frac{2\{2c_r^j c_r^k c_s^j c_t^j + (c_r^j)^2 (c_s^j c_t^k + c_t^j c_s^k)\}(c_u^j c_v^k + c_v^j c_u^k) c_r^j c_r^k (c_s^j c_t^k + c_t^j c_s^k) c_u^j c_v^j}{(\varepsilon_j - \varepsilon_k)^2} \right] \alpha_r' \beta_{st}'$$
$$+ \cdots\cdots \quad (34)$$

where $(\delta\varepsilon_j)_r$, $(\delta\varepsilon_j)_{st}$, $(\delta p_{uv}^j)_r$ and $(\delta p_{uv}^j)_{st}$ are given by Eqs. 1, 6, 2 and 7, respectively. Also in this case a cross term between the two perturbations, both in the orbital energy and in the bond order (and the density), first arises in the second order, and therefore the additivity rule is correct in the first order. The circumtances are the same for the total energy, the bond order and the electron density.

$$\left.\begin{aligned} \varepsilon' &= \varepsilon + (\delta\varepsilon)_r + (\delta\varepsilon)_{st} + 2 \sum_j^{\text{occ}} \{\text{cross term of the order } \alpha_r' \beta_{st}' \text{ in } \varepsilon_j'\} + \cdots\cdots \\ P_{uv} &= p_{uv} + (\delta p_{uv})_r + (\delta p_{uv})_{st} + 2 \sum_j^{\text{occ}} \{\text{cross term of the order } \alpha_r' \beta_{st}' \text{ in } P_{uv}^j\} \\ &+ \cdots\cdots \end{aligned}\right\} \quad (35)$$

where $(\delta\varepsilon)_{st}$ and $(\delta p_{uv})_{st}$ are given by Eqs. 8 and 9. The perturbed molecular orbital is obtained as follows:



$$\Psi_j' = \Psi_j + (\delta\Psi_j)_r + (\delta\Psi_j)_{st} + \sum_{k(\neq j)}^{\text{all}} \left\{ \sum_{m(\neq j)}^{\text{all}} \frac{c_r^k c_r^m (c_s^j c_t^m + c_t^j c_s^m) + c_r^j c_r^m (c_s^k c_t^m + c_t^k c_s^m)}{(\varepsilon_j - \varepsilon_k)(\varepsilon_j - \varepsilon_m)} \right.$$
$$\left. - \frac{2c_r^j c_r^k c_s^j c_t^j + (c_r^j)^2 (c_s^j c_t^k + c_t^j c_s^k)}{(\varepsilon_j - \varepsilon_k)^2} \right\} \alpha_r' \beta_{st}' \Psi_k$$
$$- \sum_{m(\neq j)}^{\text{all}} \frac{c_r^j c_r^k (c_s^j c_t^k + c_t^j c_s^k)}{(\varepsilon_j - \varepsilon_k)^2} \alpha_r' \beta_{sr}' \Psi_k + \cdots\cdots \quad (36)$$

where $(\delta\Psi_j)_{st}$ is given by Eq. 10.

**4. Case III. A Weak Bonding with a Change of a Coulomb Integral.** — When a conjugated system, $\Delta(\varepsilon)$, conjugates at the $s$th atom through a weak bonding, whose

* When $r=t$, though the perturbed secular determinant becomes $D(\varepsilon) = \Delta(\varepsilon) + \alpha_r' \Delta_{rr}(\varepsilon) + (-1)^{s+r} 2\beta_{sr}' \Delta_{sr}(\varepsilon) - (\beta_{sr}')^2 \Delta_{ssrr}(\varepsilon)$, Eqs. 33 to 36 are valid.

resonance integral is $\gamma_s$, with another conjugated system $\Delta_1(\varepsilon)$, and at the same time the Coulomb integral of the $r$th atom is increased by $\alpha_r'$, as illustrated in the figure, then the following formulae are obtained.

$$D(\varepsilon)=\Delta(\varepsilon)\Delta_1(\varepsilon)+\alpha_r'\Delta_{rr}(\varepsilon)\Delta_1(\varepsilon)-(\gamma_s)^2\Delta_{ss}(\varepsilon)\Delta_{1\xi\xi}(\varepsilon)-\alpha_r'(\gamma_s)^2\Delta_{rrss}(\varepsilon)\Delta_{1\xi\xi}(\varepsilon) \tag{37}$$

$$\varepsilon_j'=\varepsilon_j+(\delta\varepsilon_j)_r+(\delta\varepsilon_j)_{s\xi}+\sum_k^{\text{all}}\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\varepsilon_j-\eta_{1k}}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\alpha_r'(\gamma_s)^2+\cdots\cdots \tag{38}$$

$$\eta_{1k}'=\eta_{1k}+(\delta\eta_{1k})_{s\xi}+\sum_j^{\text{all}}\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\eta_{1k}-\varepsilon_j}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\alpha_r'(\gamma_s)^2+\cdots\cdots \tag{39}$$

$$P_{uv}{}^j=p_{uv}{}^j+(\delta p_{uv}{}^j)_r+(\delta p_{uv}{}^j)_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots\cdots \tag{40}$$

$$P_{s\xi}{}^j=(\delta p_{s\xi}{}^j)_{s\xi}+\sum_k^{\text{all}}\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\varepsilon_j-\eta_{1k}}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\alpha_r'\gamma_s+\cdots\cdots \tag{40'}$$

$$P_{uv}{}^{1k}=(\delta p_{uv}{}^{1k})_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{41}$$

$$P_{\eta\zeta}{}^{1k}=p_{\eta\zeta}{}^{1k}+(\delta p_{\eta\zeta}{}^{1k})_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{42}$$

$$P_{s\xi}{}^{1k}=(\delta p_{s\xi}{}^{1k})_{s\xi}+\sum_j^{\text{all}}\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\eta_{1k}-\varepsilon_j}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\alpha_r'\gamma_s+\cdots\cdots \tag{42'}$$

$$P_{\eta\zeta}{}^j=(\delta p_{\eta\zeta}{}^j)_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{43}$$

where $\xi$ is the position of weak conjugation in the system $\Delta_1(\varepsilon)$, the bond $(\eta\zeta)$ is in the system $\Delta_1(\varepsilon)$; and $(\delta\varepsilon_j)_{s\xi}$, $(\delta p_{uv}{}^j)_{s\xi}$, $(\delta p_{s\xi}{}^j)_{s\xi}$ and $(\delta p_{uv}{}^{1k})_{s\xi}$ are given by Eqs. 11, 12, 12′ and 13, from which $(\delta\eta_{1k})_{s\xi}$, $(\delta p_{\eta\zeta}{}^j)_{s\xi}$, $(\delta p_{\eta\zeta}{}^{1k})_{s\xi}$ and $(\delta p_{s\xi}{}^{1k})_{s\xi}$ will easily be formulated. Therefore the total $\pi$ electronic energy of the combined system is

$$\varepsilon'=\varepsilon+(\delta\varepsilon)_r+(\delta\varepsilon)_{s\xi}+2\Big(\sum_j^{\text{occ}}\sum_k^{\text{unocc}}-\sum_j^{\text{unocc}}\sum_k^{\text{occ}}\Big)\times\left[\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\varepsilon_j-\eta_{1k}}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\right]\alpha_r'(\gamma_s)^2+\cdots\cdots \tag{44}$$

And

$$P_{uv}=p_{uv}+(\delta p_{uv})_r+(\delta p_{uv})_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{45}$$

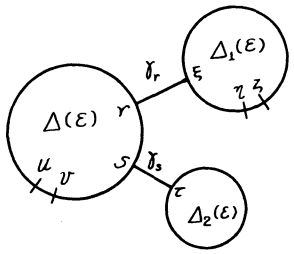
$$P_{s\xi}=(\delta p_{s\xi})_{s\xi}+2\Big(\sum_j^{\text{occ}}\sum_k^{\text{unocc}}-\sum_j^{\text{unocc}}\sum_k^{\text{occ}}\Big)\left[\frac{c_r^jc_s^j(d_\xi^{1k})^2}{\varepsilon_j-\eta_{1k}}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\right]\alpha_r'\gamma_s+\cdots\cdots \tag{45'}$$

$$P_{\eta\zeta}=p_{\eta\zeta}+(\delta p_{\eta\zeta})_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{46}$$

$$\delta Q=(\delta Q)_{s\xi}+\{\text{cross term of the order }\alpha_r'(\gamma_s)^2\}+\cdots \tag{47}$$

where $(\delta\varepsilon)_{s\xi}$, $(\delta p_{uv})_{s\xi}$, $(\delta p_{s\xi})_{s\xi}$ and $(\delta Q)_{s\xi}$ are given by Eqs. 15, 16, 16′ and 18. $(\delta p_{\eta\zeta})_{s\xi}$ is easily written on inspection of Eq. 16. As is seen in Eqs. 45 to 47, a cross term first appears in the third order, that is, the order of $\alpha_r'(\gamma_s)^2$, and the additivity rule is valid up to the second order perturbation.

The wave functions of this perturbed system are represented by



$$\Psi_j'=\Psi_j+(\delta\Psi_j)_r+(\delta\Psi_j)_{s\xi}+\sum_k^{\text{all}}\frac{c_r^jd_\xi^{1k}}{\varepsilon_j-\eta_{1k}}\left\{\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r^jc_s^j}{\varepsilon_j-\eta_{1k}}\right\}\alpha_r'\gamma_s\phi_{1k}+\cdots\cdots \tag{48}$$

$$\phi_{1k}'=\phi_{1k}+(\delta\phi_{1k})_{s\xi}+\sum_j^{\text{all}}\frac{c_r^jd_\xi^{1k}}{\eta_{1k}-\varepsilon_j}\sum_{m(\neq j)}^{\text{all}}\frac{c_r^mc_s^m}{\eta_{1k}-\varepsilon_m}\alpha_r'\gamma_s\Psi_j+\cdots \tag{49}$$

where $(\delta\Psi_j)_{s\xi}$ is given by Eq. 14, from which also $(\delta\phi_{1k})_{s\xi}$ may easily be written.

**5. Case IV. Weak Bondings to Two Conjugated Systems.**—Here we consider a case in which a conjugated system, $\Delta(\varepsilon)$, conjugates at the $r$th and the $s$th atoms with two other

conjugated systems, $\Delta_1(\varepsilon)$ and $\Delta_2(\varepsilon)$, respectively, making weak bondings whose resonance integrals are $\gamma_r$ and $\gamma_s$, respectively. The molecular orbital, its orbital energy and the coefficient of atomic orbital in the non-perturbed $\Delta_1(\varepsilon)$ system are designated by $\psi_{1k}$, $\eta_{1k}$ and $d_\mu{}^{1k}$, respectively, and in the system $\Delta_2(\varepsilon)$ by $\psi_{2k}$, $\eta_{2k}$ and $d_\nu{}^{2k}$. Then the following expressions are easily obtained for the perturbed combined system.

$$D(\varepsilon)=\Delta(\varepsilon)\Delta_1(\varepsilon)\Delta_2(\varepsilon)-(\gamma_r)^2\Delta_{rr}(\varepsilon)\Delta_{1\xi\xi}(\varepsilon)\Delta_2(\varepsilon)$$
$$-(\gamma_s)^2\Delta_{ss}(\varepsilon)\Delta_1(\varepsilon)\Delta_{2\tau\tau}(\varepsilon)+(\gamma_r\gamma_s)^2\Delta_{rrss}(\varepsilon)\Delta_{1\xi\xi}(\varepsilon)\Delta_{2\tau\tau}(\varepsilon) \tag{50}$$

$$\varepsilon_j'=\varepsilon_j+(\delta\varepsilon_j)_{r\xi}+(\delta\varepsilon_j)_{s\tau}+\sum_k^{\text{all}}\frac{c_r{}^j(d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}U_{jk}(\gamma_r\gamma_s)^2+\cdots\cdots \tag{51}$$

$$U_{jk}=\sum_l^{\text{all}}\frac{c_s{}^j(d_\tau{}^{2l})^2}{\varepsilon_j-\eta_{2l}}\left\{2\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^mc_s{}^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r{}^jc_s{}^j}{\varepsilon_j-\eta_{1k}}-\frac{c_r{}^jc_s{}^j}{\varepsilon_j-\eta_{2l}}\right\} \tag{51-a}$$

$$\eta_{1k}'=\eta_{1k}+(\delta\eta_{1k})_{r\xi}+\sum_j^{\text{all}}\frac{c_r{}^j(d_\xi{}^{1k})^2}{\eta_{1k}-\varepsilon_j}U_{jk}(\gamma_r\gamma_s)^2+\cdots\cdots \tag{52}$$

$$P_{uv}{}^j=p_{uv}{}^j+(\delta p_{uv}{}^j)_{r\xi}+(\delta p_{uv}{}^j)_{s\tau}+\{\text{cross term of the order }(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{53}$$

$$P_{r\xi}{}^j=(\delta p_{r\xi}{}^j)_{r\xi}+\sum_k^{\text{all}}\frac{c_r{}^j(d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}U_{jk}\gamma_r(\gamma_s)^2+\cdots\cdots \tag{53'}$$

$$P_{uv}{}^{1k}=(\delta p_{uv}{}^{1k})_{r\xi}+\{\text{cross term of the order }(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{54}$$

$$P_{r\xi}{}^{1k}=(\delta p_{r\xi}{}^{1k})_{r\xi}+\sum_j^{\text{all}}\frac{c_r{}^j(d_\xi{}^{1k})^2}{\eta_{1k}-\varepsilon_j}U_{jk}\gamma_r(\gamma_s)^2+\cdots\cdots \tag{54'}$$

$$P_{uv}{}^{2l}=(\delta p_{uv}{}^{2l})_{s\tau}+\{\text{cross term of the order }(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{55}$$

$$P_{r\xi}{}^{2k}=\sum_k^{\text{all}}\frac{(d_\xi{}^{1k})^2}{\eta_{2l}-\eta_{1k}}\sum_j^{\text{all}}\sum_m^{\text{all}}\frac{c_r{}^jc_r{}^mc_s{}^jc_s{}^m(d_\tau{}^{2l})^2}{(\eta_{2l}-\varepsilon_j)(\eta_{2l}-\varepsilon_m)}\gamma_r(\gamma_s)^2+\cdots\cdots \tag{55'}$$

$$P_{\eta\zeta}{}^{1k}=p_{\eta\zeta}{}^{1k}+(\delta p_{\eta\zeta}{}^{1k})_{r\xi}+\{\text{cross term of the order }(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{56}$$

$$P_{\eta\zeta}{}^j=(\delta p_{\eta\zeta}{}^j)_{r\xi}+\{\text{cross term of the order}(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{57}$$

$$P_{\eta\zeta}{}^{2l}=\{\text{cross term of the order}(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{58}$$

where $\xi$ and $\tau$ are the positions of the weak conjugation in the systems $\Delta_1(\varepsilon)$ and $\Delta_2(\varepsilon)$, respectively, and the bond $(uv)$ or the atom $u$ is assumed to be in the system $\Delta(\varepsilon)$, and the bond $(\eta\zeta)$ or the atom $\eta$ in the system $\Delta_1(\varepsilon)$. Similar expressions as above may be written for the system $\Delta_2(\varepsilon)$. Thus the total $\pi$ electronic energy and the bond order of this perturbed system are given as follows:

$$\varepsilon'=2\sum_j^{\text{occ}}\varepsilon_j'+2\sum_k^{\text{occ}}\eta_{1k}'+2\sum_l^{\text{occ}}\eta_{2l}'$$
$$=\varepsilon+(\delta\varepsilon)_{r\xi}+(\delta\varepsilon)_{st}$$
$$+\left\{\sum_j^{\text{occ}}\left(\sum_k^{\text{unocc}}\sum_l^{\text{unocc}}-\sum_k^{\text{occ}}\sum_l^{\text{occ}}\right)-\sum_j^{\text{unocc}}\left(\sum_k^{\text{occ}}\sum_l^{\text{all}}+\sum_k^{\text{all}}\sum_l^{\text{occ}}\right)\right\}\frac{c_r{}^jc_s{}^j(d_\xi{}^{1k})^2(d_\tau{}^{2l})^2}{(\varepsilon_j-\eta_{1k})(\varepsilon_j-\eta_{2l})}$$
$$\times\left(2\sum_{m(\neq j)}^{\text{all}}\frac{c_r{}^mc_s{}^m}{\varepsilon_j-\varepsilon_m}-\frac{c_r{}^jc_s{}^j}{\varepsilon_j-\eta_{1k}}-\frac{c_r{}^jc_s{}^j}{\varepsilon_j-\eta_{2l}}\right)(\gamma_r\gamma_s)^2+\cdots\cdots \tag{59}$$

$$P_{uv}=p_{uv}+(\delta p_{uv})_{r\xi}+(\delta p_{uv})_{s\tau}+\{\text{cross term of the order }(\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{60}$$

$$P_{r\xi}=(\delta p_{r\xi})_{r\xi}+\left[2\left(\sum_j^{\text{occ}}\sum_k^{\text{unocc}}-\sum_j^{\text{unocc}}\sum_k^{\text{occ}}\right)\frac{c_r{}^j(d_\xi{}^{1k})^2}{\varepsilon_j-\eta_{1k}}U_{jk}\right.$$
$$\left.+2\sum_l^{\text{occ}}\sum_k^{\text{all}}\frac{(d_\xi{}^{1k})^2}{\eta_{2l}-\eta_{1k}}\sum_j^{\text{all}}\sum_m^{\text{all}}\frac{c_r{}^jc_r{}^mc_s{}^jc_s{}^m(d_\tau{}^{2l})^2}{(\eta_{2l}-\varepsilon_j)(\eta_{2l}-\varepsilon_m)}\right]\gamma_r(\gamma_s)^2+\cdots \tag{60'}$$

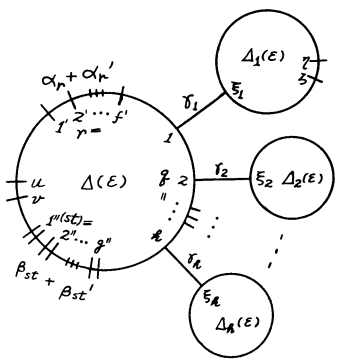
$$P_{\eta\zeta}=p_{\eta\zeta}+(\delta p_{\eta\zeta})_{r\xi}+\{\text{cross term of the order } (\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{61}$$

The changes of total charge involved in the systems $\Delta(\varepsilon)$ and $\Delta_1(\varepsilon)$ are designated as $\delta Q$ and $\delta Q_1$, respectively, which are written as follows:

$$\delta Q=(\delta Q)_{r\xi}+(\delta Q)_{s\tau}+\{\text{cross term of the order } (\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{62}$$

$$\delta Q_1=(\delta Q)_{r\xi}+\{\text{cross term of the order } (\gamma_r\gamma_s)^2\}+\cdots\cdots \tag{63}$$

A similar equation may be written also for the system $\Delta_2(\varepsilon)$.



The molecular orbitals of this perturbed system are

$$\Psi_j'=\Psi_j+(\delta\Psi_j)_{r\xi}+(\delta\Psi_j)_{s\tau}+\{\text{cross term of the orders } \gamma_r(\gamma_s)^2 \text{ and } (\gamma_r)^2\gamma_s\}+\cdots\cdots \tag{64}$$

$$\psi_{1k}'=\psi_{1k}+(\delta\Psi_{1k})_{r\xi}+\sum_{j}^{\text{all}}\sum_{l}^{\text{all}}\frac{c_r{}^j c_s{}^j d_\xi{}^{1k} d_\eta{}^{2l}}{(\eta_{1k}-\eta_{2l})(\eta_{1k}-\varepsilon_j)}\gamma_r\gamma_s\psi_{2k}+\cdots\cdots \tag{65}$$

As to special cases in which either or both of the systems $\Delta_1(\varepsilon)$ and $\Delta_2(\varepsilon)$ are single atoms, one may simplify the results of Cases III and IV by using Eqs. 11-a to 18-a instead of Eqs. 11 to 18 for non-cross terms and by abridging cross terms.

**6. More General Case of Many Perturbations.** — Perturbation treatment of systems affected by two perturbations stated above may be extended to a more general case of many perturbations. As illustrated in the figure, we consider a conjugated system, $\Delta(\varepsilon)$, and increase the Coulomb integrals of the $r$th atoms in it ($r=1', 2', \cdots\cdots, f'$) by $\alpha_r'$ and the resonance integrals of the bonds $(st)$ ($st=1'', 2'', \cdots\cdots, g''$) by $\beta_{st}'$, and make weak bondings, whose resonance integral is $\gamma_q$, between the $q$th atoms ($q=1, 2, \cdots\cdots, h$) in the system and the $\xi_q$th atoms in other conjugated systems $\Delta_q(\varepsilon)$. Here some of the $r$'s, $s$'s and $q$'s may be the identical atoms.

Then the perturbed $j$th orbital energy of the system $\Delta(\varepsilon)$ is

$$\begin{aligned}\varepsilon_j'=\varepsilon_j&+\sum_{r=1'}^{f'}(\delta\varepsilon_j)_r+\sum_{(st)=1''}^{g''}(\delta\varepsilon_j)_{st}+\sum_{q=1}^{h}(\delta\varepsilon_j)_{q\xi}\\&+C(\alpha^2,\alpha\beta,\beta^2)+C(\alpha^3,\alpha^2\beta,\alpha\beta^2,\beta^3,\alpha\gamma^2,\beta\gamma^2)\\&+C(\alpha^4,\alpha^3\beta,\alpha^2\beta^2,\alpha\beta^3,\beta^4,\alpha^2\gamma^2,\alpha\beta\gamma^2,\beta^2\gamma^2,\gamma^4)+\cdots\cdots\end{aligned} \tag{66}$$

where $(\delta\varepsilon_j)_r$, $(\delta\varepsilon_j)_{st}$ and $(\delta\varepsilon_j)_{q\xi}$ are energy changes caused by perturbations $\alpha_r'$, $\beta_{st}'$ and $\gamma_q$, respectively, and are given by Eqs. 1, 6 and 11. and $C$ means the cross term among perturbations. For instance $C(\alpha^2,\alpha\beta,\beta^2)$ consists of cross terms of orders $\alpha_1'\alpha_2'$, $\alpha_1'\alpha_3'$, $\cdots\cdots$, $\alpha_2'\alpha_3'$, $\cdots\cdots$, $\alpha_1'\beta_1'$, $\alpha_1'\beta_2'$, $\cdots\cdots$, $\alpha_2'\beta_1'$, $\cdots\cdots$, $\beta_1'\beta_2'$, $\beta_1'\beta_3'$, $\cdots\cdots$, $\beta_2'\beta_3'$, $\cdots\cdots$; and $C(\alpha^3,\alpha^2\beta,\alpha\beta^2,\beta^3,\alpha\gamma^2,\beta\gamma^2)$ of orders $(\alpha_1')^2\alpha_2'$, $\cdots\cdots$, $\alpha_1'\alpha_2'\alpha_3'$, $\cdots\cdots$, $(\alpha_1')^2\beta_1'$, $\cdots\cdots$, $\alpha_1'\alpha_2'\beta_1'$, $\cdots\cdots$, $\alpha_1'(\beta_1')^2$, $\cdots\cdots$, $\alpha_1'\beta_1'\beta_2'$, $\cdots\cdots$, $(\beta_1')^2\beta_2'$, $\cdots\cdots$, $\beta_1'\beta_2'\beta_3'$, $\cdots\cdots$, $\alpha_1'(\gamma_1)^2$, $\cdots\cdots$, $\beta_1'(\gamma_1)^2$, $\cdots\cdots$. The perturbed separate bond order by this orbital of the bond $(uv)$ in the system $\Delta(\varepsilon)$ is

$$\begin{aligned}P_{uv}{}^j=p_{uv}{}^j&+\sum_{r=1'}^{f'}(\delta p_{uv}{}^j)_r+\sum_{(st)=1''}^{g''}(\delta p_{uv}{}^j)_{st}+\sum_{q=1}^{h}(\delta p_{uv}{}^j)_{q\xi}\\&+C(\alpha^2,\alpha\beta,\beta^2)+C(\alpha^3,\alpha^2\beta,\alpha\beta^2,\beta^3,\alpha\gamma^2,\beta\gamma^2)\\&+C(\alpha^4,\alpha^3\beta,\alpha^2\beta^2,\alpha\beta^3,\beta^4,\alpha^2\gamma^2,\alpha\beta\gamma^2,\beta^2\gamma^2,\gamma^4)+\cdots\cdots\end{aligned} \tag{67}$$

where $(\delta p_{uv}{}^j)_r$, $(\delta p_{uv}{}^j)_{st}$ and $(\delta p_{uv}{}^j)_{q\xi}$ are the changes caused by $\alpha_r'$, $\beta_{st}'$ and $\gamma_q$, respectively, and are given by Eqs. 2, 7 and 12. The perturbed separate bond order by this orbital of the bond $(\eta\zeta)$ in another system, say, the system $\Delta_1(\varepsilon)$, is

$$\begin{aligned}P_{\eta\zeta}{}^j=&(\delta p_{\eta\zeta}{}^j)_{1\xi}+C\{\alpha(\gamma_1)^2,\beta(\gamma_1)^2\}\\&+C\{\alpha^2(\gamma_1)^2,\alpha\beta(\gamma_1)^2,\beta^2(\gamma_1)^2,\gamma^2(\gamma_1)^2\}+\cdots\cdots\end{aligned} \tag{68}$$

The perturbed $k$th orbital energy of a system, say, the system $\Delta_1(\varepsilon)$, is

$$\eta_{1k}'=\eta_{1k}+(\delta\eta_{1k})_{1\xi}+C\{\alpha(\gamma_1)^2,\beta(\gamma)_1)^2\}$$
$$+C\{\alpha^2(\gamma_1)^2,\alpha\beta(\gamma_1)^2,\beta^2(\gamma_1)^2,\gamma^2(\gamma_1)^2\}+\cdots\cdots \quad (69)$$

The perturbed separate bond orders by this orbital of bonds $(\eta\zeta)$ and $(\mu\nu)$ are

$$P_{\eta\zeta}{}^{1k}=p_{\eta\zeta}{}^{1k}+(\delta p_{\eta\zeta}{}^{1k})_{1\xi}+C\{\alpha(\gamma_1)^2,\beta(\gamma_1)^2\}$$
$$+C\{\alpha^2(\gamma_1)^2,\alpha\beta(\gamma_1)^2,\beta^2(\gamma_1)^2,\gamma^2(\gamma_1)^2\}+\cdots\cdots \quad (70)$$
$$P_{\mu\nu}{}^{1k}=(\delta p_{\mu\nu}{}^{1k})_{1\xi}+C\{\alpha(\gamma_1)^2,\beta(\gamma_1)^2\}$$
$$+C\{\alpha^2(\gamma_1)^2,\alpha\beta(\gamma_1)^2,\beta^2(\gamma_1)^2,\gamma^2(\gamma_1)^2\}+\cdots\cdots \quad (71)$$

Also this bond order by this orbital of the bond $(\mu\nu)$, which is located in another system, say, the system $\Delta_h(\varepsilon)$, is given by

$$P_{\mu\nu}{}^{1k}=C\{(\gamma_1)^2(\gamma_h)^2\}+\cdots\cdots \quad (72)$$

The perturbed separate bond order of the bond which is made anew by perturbation between conjugated systems, say, the bond $(1\xi_1)$ between the systems $\Delta(\varepsilon)$ and $\Delta_1(\varepsilon)$, may be written as

$$P_{1\xi}{}^{j}=(\delta p_{1\xi}{}^{j})_{1\xi}+C\{\alpha\gamma_1,\beta\gamma_1\}+C\{\alpha^2\gamma_1,\alpha\beta\gamma_1,\beta^2\gamma_1,\gamma^2\gamma_1\}$$
$$+C\{\alpha^3\gamma_1,\alpha^2\beta\gamma_1,\alpha\beta^2\gamma_1,\beta^3\gamma_1,\alpha\gamma^2\gamma_1,\beta\gamma^2\gamma_1,\alpha(\gamma_1)^3,\beta(\gamma_1)^3\}+\cdots\cdots \quad (73)$$
$$P_{1\xi}{}^{1k}=(\delta p_{1\xi}{}^{1k})_{1\xi}+C\{\alpha\gamma_1,\beta\gamma_1\}+C\{\alpha^2\gamma_1,a\beta\gamma_1,\beta^2\gamma_1,\gamma^2\gamma_1\}$$
$$+C\{\alpha^3\gamma_1,\alpha^2\beta\gamma_1,\alpha\beta^2\gamma_1,\beta^3\gamma_1,\alpha\gamma^2\gamma_1,\beta\gamma^2\gamma_1,\alpha(\gamma_1)^3,\beta(\gamma_1)^3\}+\cdots\cdots \quad (74)$$
$$P_{1\xi}{}^{ql}=C\{(\gamma_q)^2\gamma_1\}+C\{\alpha(\gamma_q)^2\gamma_1,\beta(\gamma_q)^2\gamma_1\}+\cdots\cdots \qquad (q=2,3,\cdots\cdots,h) \quad (75)$$

As for the total $\pi$ electronic energy an equation similar to Eq. 66, as for the total bond order (and the electron density) one similar to Eq. 67, and as for the total bond order of a newly formed bond one similar to Eq. 75 may be obtained.

Thus it has become clear to what order of perturbation terms the additivity rule applies, and what kinds of terms appear in several molecular quantities. If it is necessary, one could formulate cross terms in reference to the results of two perturbations.

## Degenerate System

In the previous section it was assumed that no molecular orbital is degenerate with any other molecular orbital in the same molecule, not with molecular orbitals in any other system to be subjected to conjugation.

Even if some levels in the non-perturbed systems are degenerate, so far as they are chosen mutually orthogonal, the perturbed orbital energy and the perturbed separate bond order (and electron density) corresponding to non-degenerate orbitals are not affected at all, that is, equations derived in the preceding section, giving separate quantities, are valid also in this case.

As for degenerate levels, on the other hand, the sum of the perturbed orbital energies or of the perturbed bond orders over all the degenerate levels is easily obtained by taking a limit of the corresponding sum which is derived as if they were not degenerate. For instance, in Case I, when the $l$th and the $(l+1)$th levels are degenerate,

$$\varepsilon_l'+\varepsilon_{l+1}'=\lim_{\varepsilon_{l+1}\to\varepsilon_l}[\varepsilon_l',_{\text{nondeg}}+\varepsilon_{l+1}',_{\text{nondeg}}]$$
$$=2\varepsilon_l+[\delta(\varepsilon_l+\varepsilon_{l+1})]_r+[\delta(\varepsilon_l+\varepsilon_{l+1})]_s$$
$$+2\sum_{(\neq l,l+1)}^{k,\text{all}}\frac{c_r{}^k c_s{}^k(c_r{}^l c_s{}^l+c_r{}^{l+1}c_s{}^{l+1})}{\varepsilon_l-\varepsilon_k}(\alpha_r'\alpha_s')+\cdots\cdots \quad (76)$$

where

$$[\delta(\varepsilon_l+\varepsilon_{l+1})]_r=[(c_r{}^l)^2+(c_r{}^{l+1})^2]\alpha_r'$$
$$+\sum_{(\neq l,l+1)}^{k,\text{all}}\frac{(c_r{}^k)^2[(c_r{}^l)^2+(c_r{}^{l+1})^2]}{\varepsilon_l-\varepsilon_k}(\alpha_r')^2+\cdots\cdots \quad (77)$$

and $\varepsilon_l',_{\text{nondeg}}$ is given by Eq. 27, which is derived for non-degenerate system. Explicit formulae for other various degenerate cases are omitted here for the sake of brevity, but one

might write them down without difficulty according to the above principle. The total $\pi$ electronic energy and the bond order (or the electron density) being represented as the sums of orbital energies and separate orders (or densities) over the occupied orbitals, it is concluded that, even in the degenerate cases, if all the degenerate levels are occupied, the degeneracy does not affect the additivity rule, though concrete formulae involved may differ from the case of no degeneracy.

## Discussion

By the results obtained in the preceding sections the additivity rule concerning multiple perturbations and its limits of use have been clarified.

When a hetero-substitution of an atom in a conjugated system causes changes of the Coulomb integral of the atom and of the resonance integrals between neighboring atoms, their effects as a whole may be additively estimated in the first order perturbation treatment. When introduction of a conjugable group into a conjugated system at its certain atom gives rise simultaneously to a change of the Coulomb integral of the atom, the additivity rule applies to the first order terms.

Further, for the introduction of many substituents and hetero-substitutions, the additivity of these effects are materialized, and various examples are seen in experiments. The additivity of shift of absorption sprctra would be explained by the additivity in the orbital energy. The vector additivity of dipole moment would be understood as the additivity in the electron density or in the amount of charge transfer. Aono and Higuchi[4] interpreted the additivity of hyperfine splitting in the electron spin resonance spectrum of substituted semiquinones in terms of the additivity in the unpaired electron density.

Speaking of reactivity indices, i. g. the frontier electron density, $P_{uu}{}^{f}$, localization energy, $\varepsilon'$(localized state)$-\varepsilon'$(non-localized state), total $\pi$ electron density, $P_{uu}$, free valence, $\sqrt{3}-\sum_{v}{}'P_{uv}$, and most other indices, the additivity rule is applicable to a certain order of perturbation terms. Superdelocalizability is also proved to fulfil the additivity rule.

If one practically evaluates the cross terms appearing in the formulae, one would be able to discuss the deviation from the additivity rule, which is also often realized in experiments.

The authors are much indebted to Mr. Shigeyuki Aono for his helpful suggestions.

# *The Adsorption of Dye Mixtures by Cellophane Sheet. II*[1]. *A Quantitative Discussion of the Adsorption of Dyes*

By Yukio HORIKI

(Received November 27, 1959)

In the previous work[1], a method of quantitative discussion of the interaction between dyes in a binary mixture dyebath has been discussed on the assumption that the decrease in adsorption of dyes from mixture dyeing is due to interaction. Further, the behavior of dyes in mixture dyeing has been qualitatively explained from those of single dyeings, taking account of the interaction obtained by the above method.

In this paper, the single dyeings of Chlorazol Sky Blue FF and Chrysophenine G and their mixture dyeing have been carried out in detail, to discuss quantitatively their behavior in mixture dyeing. In the single dyeing, the surface layer volume in Vickerstaff's theoretical equation for adsorption[2] has been discussed to obtain constant values of the standard affinity. In the mixture dyeing, the observed amounts of adsorption of the dyes have been compared with those calculated on the basis of the information both about the single dyeing particularly discussed and about the interaction obtained from the single and the mixture dyeings by the method reported before[1].

## Experimental and Results

The single dyeings of Chlorazol Sky Blue FF (shortly called Blue dye) and Chrysophenine G (Yellow dye) and the mixture dyeing of them follow a method quite similar to that in the previous work[1].

In the single dyeings, the initial concentration ranged from $1\times10^{-6}$ to $1.5\times10^{-5}$ mol./l. for Blue dye and $1.25\times10^{-6}$ to $1\times10^{-4}$ mol./l. for Yellow dye, and in the mixture dyeing, that of Blue dye was fixed at about $1\times10^{-5}$ mol./l. and that of Yellow dye varied from $2.5\times10^{-6}$ to $1\times10^{-4}$ mol./l.

Each dyeing was carried out for three, two and one day* at 50°, 70° and 90°C, respectively. The concentration of sodium chloride (2 g./l.) was the same as that in the previous work.

Results for single dyeings are shown in Figs. 1 (Blue dye) and 2 (Yellow dye) in terms of the relation between logarithms of the final dyebath concentration (Blue dye, $F_\sigma$ mol./l.; Yellow dye, $G_\sigma$ mol./l.) and those of the amount of adsorption (Blue dye, $F_\phi$ mol./kg.; Yellow dye, $G_\phi$ mol./kg.) of the dyes. The affinities of Blue dye and Yellow dye ($-\Delta\mu^0_F$ cal./mol.; $-\Delta\mu^0_G$ cal./mol.) were calculated by Vickerstaff's equation with $V=0.45$ l./kg. These results are shown in Figs. 3 (Blue dye) and 4 (Yellow dye) in terms of the relation between

the affinity and the logarithm of the final dyebath concentration. The relations of ($\log F_\phi\ Na^4_\phi - \log F_\sigma\ Na^4_\sigma$) and of ($\log G_\phi\ Na^2_\phi - \log G_\sigma\ Na^2_\sigma$) are shown in Figs. 5 and 6, respectively. It is recognized that they are nearly linear. Results of mixture dyeing, that is, the adsorptions of Blue dye ($F_\phi$ mol./kg.) and Yellow dye ($G_\phi$ mol./kg.), their effective dyebath concentrations obtained by the method reported before[1] ($F_\sigma'$ mol./l.; $G_\sigma'$ mol./l.), their dyebath concentrations which contributed to the interaction ($F_c$ mol./l.; $G_c$ mol./l.), and the ratios $G_\sigma/F_\sigma$ and $G_c/F_c$ are shown in Table I, together with the instability constant $K$ (mol./l.) calculated in the region where $G_\sigma/F_\sigma = 0.8 \sim 1.1$, according to

$$K = \frac{\frac{F_\sigma' \cdot G_\sigma'}{F_c + G_c}}{2} = \frac{2F_\sigma' \cdot G_\sigma'}{F_c + G_c} = \frac{2(F_\sigma - F_c)(G_\sigma - G_c)}{F_c + G_c} \quad (1)$$

## Discussion

The standard affinity of dye anions for the fiber in the single dyeing can be calculated theoretically by[2]

$$\log \frac{D_\phi \mathrm{Na}^z{}_\phi}{V^{z+1}} = \log D_\sigma \mathrm{Na}^z{}_\sigma + \left(\frac{-\Delta\mu^0}{RT}\right) \quad (2)$$

$$\mathrm{Na}_\phi = D_\phi \left\{\frac{z}{2} + \left(\frac{z^2}{4} + \frac{V^2 \mathrm{Na}_\sigma \cdot \mathrm{Cl}_\sigma}{D^2_\phi}\right)^{1/2}\right\} \quad (2')$$

where $D_\phi$ is the amount of adsorbed dye anions on the fiber at equilibrium (mol./kg.), $D_\sigma$, the dyebath concentration of dye anions at equilibrium (mol./l.), $\mathrm{Na}_\phi$, the concentration of the sodium ion in the fibre phase at equilibrium (mol./kg.), $\mathrm{Na}_\sigma$, $\mathrm{Cl}_\sigma$, the concentrations of the sodium and the chloride ions in the dyebath at equilibrium (mol./l.), $-\Delta\mu^0$, the standard affinity of dye anions for the fiber (cal./mol.), $z$, the valency of dye anions, $R$, $T$, the gas constant and the absolute temperature, and $V$, the surface layer volume of the fiber (l./kg.). However, the relation of Eq. 2 does not always come into being, depending on values employed as the surface layer volume, and it forms the following relations usually:

$$\log \frac{D_\phi \mathrm{Na}^z{}_\phi}{V^{z+1}} = \alpha \log D_\sigma \mathrm{Na}^z{}_\sigma + \left(\frac{-\Delta\mu^{0\prime}}{RT}\right) \quad (3)$$

Hence, $-\Delta\mu^{0\prime}$ corresponding to the affinity in this equation does not show a constant value. This was also seen in the present results; the value of $\alpha$ obtained from the results of the single dyeing of Blue dye or Yellow dye by using $V=0.45$ l./kg. does not become unity, as is shown clearly by the relations of $\log F_\phi \mathrm{Na}^4_\phi - \log F_\sigma \mathrm{Na}^4_\sigma$ and of $\log G_\phi \mathrm{Na}^2_\phi - \log G_\sigma \mathrm{Na}^2_\sigma$ in Figs. 5 and 6. Consequently, $-\Delta\mu^{0\prime}$ does not show constant values as shown in Figs. 3 and 4. Theoretically the affinity should remain constant. In order to discuss quantitatively the behavior of dyes in the mixture dyeing, it is desirable that $-\Delta\mu^{0\prime}$ obtained from the single dyeing should be constant. Now, let us assume simply that the reason why $\alpha$ is not unity is due to the improper value of $V$. If

$V'$ is put as the surface layer volume corresponding to $\alpha=1$, $V$ should be replaced by $V'$ in Eq. 2, and then $Na_\phi$ by $Na_\phi'$ (mol./kg.) corresponding to $V'$. Thus we obtain

$$\frac{1}{\alpha}\log\frac{D_\phi Na^z{}_\phi}{V^{z+1}}=\log\frac{D_\phi Na_\phi{}'^z}{V'^{z+1}} \tag{4}$$

Then, Eq. 3 becomes

$$\log\frac{D_\phi Na_\phi{}'^z}{V'^{z+1}}=\log D_\sigma Na_\sigma{}^z+\frac{1}{\alpha}\left(\frac{-\Delta\mu^0}{RT}\right) \tag{5}$$

Thus we shall obtain constant affinities by putting

$$\frac{1}{\alpha}\left(\frac{-\Delta\mu^{0\prime}}{RT}\right)=\frac{-\Delta\mu^0}{RT} \tag{6}$$

Such a surface layer volume $V'$ can be calculated as follows: from a graph of $\log D_\phi Na^z{}_\phi-\log D_\sigma Na^z{}_\sigma$ drawn by using any seemingly adequate value of $V$ (e. g. 0.45 l./kg.), we obtain a value of $\alpha$, and then putting it into Eq. 4 together with any two pairs of the results of single dyeing $(D_{\phi_1}, Na_{\phi_1})$ $(D_{\phi_2}, Na_{\phi_2})$, we have

$$\frac{1}{\alpha}\log\frac{D_{\phi_1}Na^z{}_{\phi_1}}{V^{z+1}}=\log\frac{D_{\phi_1}Na'^z{}_{\phi_1}}{V'^{z+1}} \tag{7}$$

$$\frac{1}{\alpha}\log\frac{D_{\phi_2}Na^z{}_{\phi_2}}{V^{z+1}}=\log\frac{D_{\phi_2}Na'^z{}_{\phi_2}}{V'^{z+1}} \tag{7'}$$

Thus the following equation is obtained,

$$\frac{Na'_{\phi_1}}{Na'_{\phi_2}}=\left(\frac{D_{\phi_1}}{D_{\phi_2}}\right)^{\left(\frac{1}{\alpha}-1\right)/z}\cdot\left(\frac{Na_{\phi_1}}{Na_{\phi_2}}\right)^{\frac{1}{\alpha}} \tag{8}$$

On the other hand, if each of $(D_{\phi_1}, Na'_{\phi_1})$ and $(D_{\phi_2}, Na'_{\phi_2})$ satisfies Eq. 2', we obtain from Eqs. 8 and 2'

$$\frac{Na'_{\phi_1}}{Na'_{\phi_2}}=\frac{D_{\phi_1}\left\{\frac{z}{2}+\left(\frac{z^2}{4}+\frac{V'^2Na_{\sigma_1}\cdot Cl_{\sigma_1}}{D^2{}_{\phi_1}}\right)^{1/2}\right\}}{D_{\phi_2}\left\{\frac{z}{2}+\left(\frac{z^2}{4}+\frac{V'^2Na_{\sigma_2}\cdot Cl_{\sigma_2}}{D^2{}_{\phi_2}}\right)^{1/2}\right\}} \tag{9}$$

where $Na_{\sigma_1}$, $Cl_{\sigma_1}$, etc. denote the concentrations of the sodium and the chloride ion in the dyebath at equilibrium (mol./l.) respectively. When we solve Eq. 9 with respect to $V'$ and put it into Eq. 5, we may be able to obtain constant values of the standard affinity.

Now in practice, values of the surface layer volume $V'$ for the single dyeings of Blue dye and Yellow dye are obtained by use of $\alpha$ resulting from $V=0.45$ l./kg. and the affinities

are calculated from Eqs. 5 and 6 by use of this $V'$. These results are shown in Table II, Figs. 3 and 4. "$-\Delta\mu^0_{mean}$" in the table denotes the mean values of adjusted affinities of Blue dye and Yellow dye. They give rather constant values**. Such adjustment of the surface layer volume so as to obtain a constant affinity means to treat $V$ as a parameter.

The observed amounts of adsorption of the dyes from the mixture dyeing are compared with those calculated by using the adjusted $-\Delta\mu^0_{mean}$ (Table II) and the instability constant $K$ (Table I), which was obtained from the results of the single and the mixture dyeings as mentioned before[1], on the assumption

TABLE II

| Dye | $T$°C | $\alpha$ | $V'$ l./kg. | $-\Delta\mu^0_{mean}$ cal./mol. |
|---|---|---|---|---|
| Blue dye | 50 | 1.32 | 0.81 | 6500 |
| | 70 | 1.20 | 0.66 | 6000 |
| | 90 | 1.05 | 0.45 | 5300 |
| Yellow dye | 50 | 0.85 | 0.26 | 4970 |
| | 70 | 0.84 | 0.22 | 4640 |
| | 90 | 0.82 | 0.13 | 4550 |

that the reduction in amounts of adsorption from mixture dyeing is mainly due to an interaction between both dyes in the dyebath. These results are shown in Figs 7, 8 and 9. However, on the supposition that only a one to one complex is formed over the whole concentration region of the dyes and that dye molecules which contribute to the complex formation have no relation to adsorption, the effective dyebath concentration of Blue dye $F'_{\sigma cal}$ (hereafter "cal" is suffixed to calculated values) is obtained from Eq. 10

$$F'_{\sigma cal}=1/2\{(G_\sigma-a)^2+(b^2-a^2)\}^{1/2}+1/2(a-G_\sigma) \quad (10)$$

where $a=F_\sigma-K$ and $b=F_\sigma+K$, and the mean value of the instability constant shown in Table I is used as $K$, i. e. $2\times10^{-7}$, $8\times10^{-7}$ and $4\times10^{-6}$ (mol./l.) at 50°, 70° and 90°C, respectively. The final dyebath concentration of Blue dye and Yellow dye in Table I are used as $F_\sigma$ and $G_\sigma$ in Eq. 10.

The effective dyebath concentration of Yellow dye $G'_{\sigma cal}$ is obtained from

$$G'_{\sigma cal}=G_\sigma-G_{c cal}=G_\sigma-(F_\sigma-F'_{\sigma cal})=G_\sigma-F_{c cal} \quad (11)$$

** Standing has discussed the value of $V$ for Chrysophenine G ($z=2$) using the so-called $p$-$q$ equation (*J. Text. Inst.*, **45**, T 21 (1954)). With his method, however, the calculation for Chlorazol Sky Blue FF ($z=4$) becomes complicated. Hence in this work, $V$ was adjusted as above. The results for Chrysophenine G are considerably approximated to his result.

The amount of adsorption of both dyes are calculated by the following equations, on the assumption that the affinity of each dye does not change in the mixture dyeing.

$$F_{\phi cal}=F'_{\sigma cal}Na^{-4}_{F\phi cal}Na^4{}_\sigma V_F{}'^5\times\exp\left(\frac{-\Delta\mu^0_{F mean}}{RT}\right) \quad (12)$$

$$G_{\phi cal}=G'_{\sigma cal}Na^{-2}{}_{G\phi cal}Na^2{}_\sigma V_G{}'^3\times\exp\left(\frac{-\Delta\mu^0_{G mean}}{RT}\right) \quad (12')$$

where the values for $Na_{F\phi cal}$ and $Na_{G\phi cal}$ are approximately obtained from the equations derived by eliminating $D_\phi$ in Eqs. 2 and 2′,

$$Na^3_{F\phi cal}(Na^2_{F\phi cal}-V_F{}'^2Na_\sigma\cdot Cl_\sigma)=4Na_\sigma{}^{-4}F'_{\sigma cal}V_F{}'^5\exp\left(\frac{-\Delta\mu^0_{F mean}}{RT}\right) \quad (13)$$

$$Na_{G\phi cal}(Na^2_{G\phi cal}-V_G{}'^2Na_\sigma\cdot Cl_\sigma)=2Na_\sigma{}^{-2}G'_{\sigma cal}V_G{}'^3\exp\left(\frac{-\Delta\mu^0_{G mean}}{RT}\right) \quad (13')$$

where the values of $V_F'$, $V_G'$, $-\Delta\mu^0_{F mean}$ and $-\Delta\mu^0_{G mean}$ are obtained from the respective values at the various temperatures shown in Table II.

It is brought out from these results that the observed amounts of adsorption of the dyes agree well with those calculated over the whole range of concentration at 90°C (Fig. 9); this means that the behavior of the dyes in mixture may be explained quantitatively by the formation of a 1 : 1 complex in the dyebath. Though both values calculated and observed show considerably good agreement at 70 and 50°C, too, some deviation is recognized at these temperatures in the range where $2\lesssim G_\sigma/F_\sigma\lesssim 8$. It may be due to the fact that where $G_\sigma/F_\sigma\geqq 2$, the dyes form not only one to one complex, but higher complexes richer in Yellow dye (may be one to two), which promote the reduction of adsorption***. In the region $G_\sigma/F_\sigma\approx 10$, the observed adsorption of Yellow dye tends to approach that in the single dyeing. This will be explained by the thought that even if the composition of complexes becomes completely one to two, Yellow dye may behave as in the single dyeing, because of its comparatively higher concentration than

*** It has been recognized by spectral measurements that a 1:2 complex richer in Yellow dye is also formed in the mixture of Blue and Yellow dye at room temperature (T. Kobayashi, Y. Tanizaki and N. Ando., This Bulletin, **33**, 661 (1960)). On the other hand, it has been concluded that only a one to one complex is formed at 60°C (A. N. Derbyshire and R. H. Peters, *J. Soc. Dyers Col.*, **72**, 268 (1956)).

However, the spectral measurements for the mixture solution in the presence of sodium chloride at high temperature has not yet been carried out, so the composition of complexes may be open to discussion.

that of Blue dye. On the other hand, since $F_a$ is almost constant, the formation of complexes and their compositions may have considerable influence on the adsorption of Blue dye with an increase of Yellow dye. In fact, the observed values of adsorption of Blue dye shown in Figs. 7 and 8 are small compared with those calculated on the basis of the formation of only a one to one complex.

Thus the behavior of dyes in the mixture dyeing may be well explained quantitatively by the method mentioned above if both dyes interact with each other (complex formation) in the dyebath. If further information on these matters, i. e. on the single dyeing and the interaction, is obtained hereafter, this problem will be treated more clearly.

## Summary

1. The single dyeings of Chlorazol Sky Blue FF and Chrysophenine G and the mixture dyeing of them were carried out at 50, 70 and 90°C.

2. In the single dyeing, the surface layer volume in Vickerstaff's equation was adjusted so as to obtain constant values of the standard affinity.

3. In the mixture dyeing, the behavior of dyes was explained quantitatively on the basis of the information of the single dyeing and the interaction between both dyes in the dyebath.

The author is greatly indebted to Professor Noboru Ando and Mr. Yoshié Tanizaki for their valuable advice and encouragement throughout this work.

# *Dichroism of Dyes in the Stretched PVA Sheet. III*[1]. *Direction of Absorption of Pinacyanol Iodide*[*1]

By Yoshié TANIZAKI

(Received December 18, 1959)

In the previous paper[1], a theoretical expression was derived concerning the relation between the optical density ratio $R_d(=D_{\parallel}/D_{\perp})$ and the stretch ratio $R_s$ of the sample sheet, for the analysis of the relative absorption direction of dye molecules in the stretched PVA (polyvinyl alcohol) sheet. It was also proved experimentally that the adopted assumption in the derivation of the distribution function and accordingly the above $R_d$ expression are adequate[2]. A parameter $r$ in the $R_d$ expression, which determines the $R_d-R_s$ curve practically, is a particular one to each absorption band. Also this $r$-value determines the angle between the transition direction and the orientation axis of the molecule. Therefore, the greater the number of the absorption band in the observable region, the easier would be the discussion on the correspondence between the relative transition direction and the molecular structure.

In this paper, turning our attention to the fact that the pinacyanol cation reveals a number of absorption bands from the visible to the near ultraviolet region, we determined the relative transition direction of some absorptions from the quantitative analysis. We also deduced the directions of other absorptions.

## Experimental

The pinacyanol iodide used was synthesised and purified in the Laboratory of Fuji Photo Film Co., Ltd.

The experiment was carried out in the same way as before[1,3]. When a quantitative test is required, the correction of absorption and reflection by the substrate of the sheet becomes important, especially in the ultraviolet region.

Resultant optical density $D$ from the absorption and/or the reflection of the PVA sheet itself in the visible region is as small as less than 0.05, almost

independent of the stretch ratio $R_s$, and the difference of $D_{\parallel}$ and $D_{\perp}$ is negligible because it is of the order of 0.001. In the near ultraviolet region, however, with decrease in wavelength, not only $D_{\parallel}$ and $D_{\perp}$ but their differences increases gradually, and these are all dependent on $R_s$. Accordingly, in the dichroic measurement the error arising from the incongruity in the stretch directions of the sample sheet and the correction sheet with each other (in ihe same $R_s$-value) becomes considerably large in general in the ultraviolet region. For this reason, the correction in the ultraviolet region, especially for the comparatively small density absorption, is of importance. So it was taken into consideration that the specific directions—the stretch directions—of the stained and the unstained sheet must be kept parallel with each other. An example of the observed relation between angle $\theta$ and optical density $D_\theta$ is illustrated in Fig. 1, in which $\theta$
