It is already known that hinokitiol (β-thujaplicin) and α-thujaplicin are present as tropolonic constituents in the essential oil of *Thujoposis dolabrata Sieb. et Zucc*[1]. Recently, the presence of β-dolabrin (4-isopropenyltropolone) in this oil was revealed in this laboratory[2], and more recently, it was also found in other species[3,4]. β-Dolabrin is the first of natural tropolones to possess a double bond in the side chain conjugated to the tropolone ring and it is interesting not only from the point of biogenesis of natural tropolones but also in the study of the chemical nature of such troponoids. For example, oxidation of β-dolabrin easily affords 4-acetyltropolone** in a high yield[2] which is an important starting material for synthesizing colchicine and its allied compounds[5].

Since there are a number of conifers containing α-, β- and γ-thujaplicines, though on different combinations according to species and habitat, there is still a possibility that α- and γ-isomers (3- and 5-isopropenyltropolones) of β-dolabrin might exist in nature[6]. In the present paper will be described the syntheses of isomeric (α-, β- and γ-) dolabrins.

According to Sato[7] in this laboratory, it is possible to convert 4-substituted tropolones to 5-substituted tropolones by utilization of the abnormal substitution of *p*-toluenesufonate of tropolones. Its reverse conversion is also possible. This reaction was applied to β-dolabrin (I). I forms two kinds of tosylates, one of m. p. 128°C and the other of m. p. 82°C, in a good yield. It is certain from the following series of experiments that the tosylate of m. p. 128°C has the structure of II and that of m. p. 82°C, the structure III. Reaction of II with methanol saturated with ammonia gives two kinds of products (IV and V), both corresponding to $C_{10}H_{10}ON$. IV turns green with ferric chloride and forms a picrate. Together with evidence of its ultraviolet spectrum (Fig. 1), IV is known to be an aminotropone derivative, while the ultraviolet spectrum of V (Fig. 1) shows it to be a benzenoid compound formed by rearrangement. Reduction of V affords *m*-cumic acid amide and, therefore, V is 3-isopropenylbenzamide. When II reacts with liquid ammonia, IV is obtained in a good yield but the rearrangement product is not

obtained. Hydrolysis of IV with alcoholic alkali gives a tropolone derivative (VI), $C_{10}H_{10}O_2$ as colorless scaly crystals, m. p. 101°C, and its reduction affords γ-thujaplicin, indicating that VI is the objective 5-isopropenyltropolone, which may be called γ-dolabrin. $pK_a$ value of VI is 7.17 at 25°C***.

γ-Dolabrin (VI) so obtained can be led back to β-dolabrin by the same process. VI affords only one kind of tosylate (VII) whose reaction with liquid ammonia gives 2-amino-4-isopropenyltropone (VIII) and 4-isopropenylbenzamide (IX). VIII turns green with ferric chloride and is hydrolyzed in alcoholic alkali to β-dolabrin. The structure of IX was also confirmed by its reduction to *p*-cumic acid amide. Reaction of VII with methanolic ammonia gives a small amount of methyl 4-isopropenylbenzoate (X), besides VIII and IX. The ultraviolet spectra of VIII and IX are shown in Fig. 1.

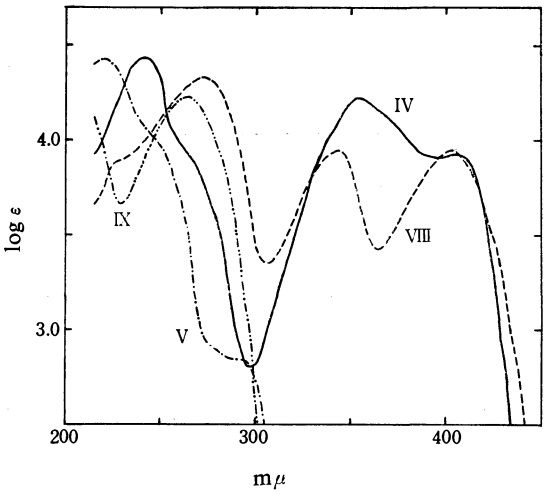

Fig. 1. Ultraviolet absorption spectra of IV, V, VIII and IX in methanol.

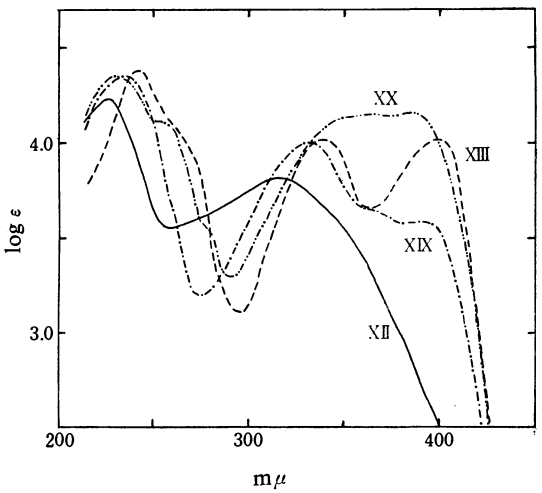

Fig. 2. Ultraviolet absorption spectra of XII, XIII, XIX and XX in methanol.

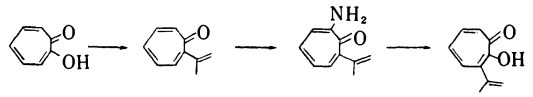
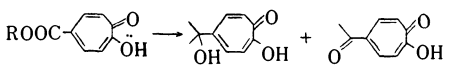
Reaction of III with liquid ammonia produces an oily substance containing aminotropone and a rearrangement product, 3-isopropenylbenzamide (V). The oily substance was not induced to crystallize or led to form a crystalline derivative such as a picrate but its hydrolysis with alcoholic alkali afforded a small amount of a tropolone derivative (XI) whose copper complex was found by mixed fusion to be identical with the copper complex of α-dolabrin which will be described below. Reaction of III with methanolic ammonia afforded V but the aminotropone derivative was not isolated. The results of the amination of III show that the large steric hindrance of the 7-position to undergo abnormal substitution in III makes it difficult to be attacked by ammonia and rearrangement product V should be formed in a larger amount.

Alkaline hydrolysis of tosylate II gives β-dolabrin and rearrangement product 3-isopropenylbenzoic acid, however acidic hydrolysis of II and III gives β-dolabrin.



Tropolone is known to form the corresponding 2-alkyltropones by the action of alkyllithium or Grignard reagents[8,9] and this process was attempted for the introduction of isopropenyl group into the tropone ring. Reaction of excess of isopropenyllithium to tropolone afforded an oily substance (XII), $C_{10}H_{10}O$, whose ultraviolet spectrum (Fig. 2) indicated two absorption maxima corresponding to those of tropone[9]. Moreover, the maximum absorption of XII showed a bathochromic shift of 3 and 16 mμ respectively, from those of tropone and it seems appropriate to consider that this shift originates in the conjugation of the side chain double bond with the tropone ring. The infrared spectrum of XII supports the structure as 2-isopropenyltropone. XII is the first tropone derivative with a double bond in the side chain conjugated to the tropone ring and examination of its chemical properties appeared of interest. XII is fairly labile and increased its viscosity when left in the air. Attempted distillation at a reduced pressure resulted in resinification. XII forms an oily hydrochloride but does not produce distinct picrate or 2,4-dinitrophenylhydrazone.

Attempted amination of XII with hydrazine[10]



*** $pK_a$ value was measured by Dr. N. Yui of the Institute of Applied Science, Faculty of Technology, Tohoku University, to whom the authors are deeply indebted.

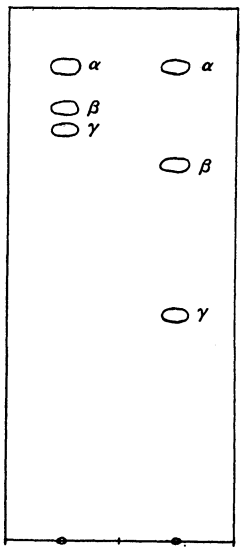
turned it black and the 2-aminotropone derivative was not isolated. Reaction of XII with hydroxylamine hydrochloride in pyridine[10] afforded the product as a brown viscous substance in the main with a trace of yellow oily substance (XIII), whose ultraviolet absorption spectrum (Fig. 2) indicated a typical curve for 2-aminotropone derivative. Hydrolysis of XIII with alcoholic alkali gave a very minute amount of a tropolone derivative (XIV), m. p. 36°C, which showed coloration with ferric chloride characteristic of tropolones and easily formed a copper complex, $C_{20}H_{18}O_4Cu$. This copper complex showed no depression of the melting point when fused with the copper complex of XI mentioned above. Paper chromatography of XI and XIV also gave spots with identical $R_f$ value.



(XII) (XIII) (XIV)

(XVI~XVIII) (XIX) (XX)

Synthesis of γ-dolabrin was attempted by the Grignard reaction of tropolone-5-carboxylic acid alkylester. Methylmagnesium iodide was applied to tropolone-5-carboxylic acid (XV)[11], its methyl ester, and iron complex, but all these compounds were sparingly soluble in ether and the starting compound was recovered in all cases. In order to increase solubility in ether, amyl (XVI), octyl (XVII), and cyclohexyl (XVIII) esters of tropolone-5-carboxylic acid were prepared. Application of about six molar equivalents of methylmagnesium iodide against these esters afforded 5-α-hydroxyisopropyltropolone (XIX) and 5-acetyltropolon (XX). The ultraviolet absorption spectra of XIX and XX are indicated in Fig. 2. The structure of XIX was confirmed from the fact that dehydration of XIX by heating with potassium hydrogensulfate easily afforded γ-dolabrin (VI). XIX turns green in aqueous layer to ferric chloride but the color does not transfer to benzene or chloroform layer. This is the general behavior of hydroxyl or carboxyl derivatives of tropolone. XIX is easily dehydrated and changes partly into VI on heating with acid or by sublimation. 5-Acetyltropolone (XX) is also obtained by oxidation of VI. XX easily forms an oxime, the same as 4-acetyltropolone as already reported[5], and also undergoes condensation with benzaldehyde derivatives to

Dolabrin Thujaplicin

Fig. 3. Paper chromatogram of α-, β- and γ-dolabrin and α-, β- and γ-thujaplicin.

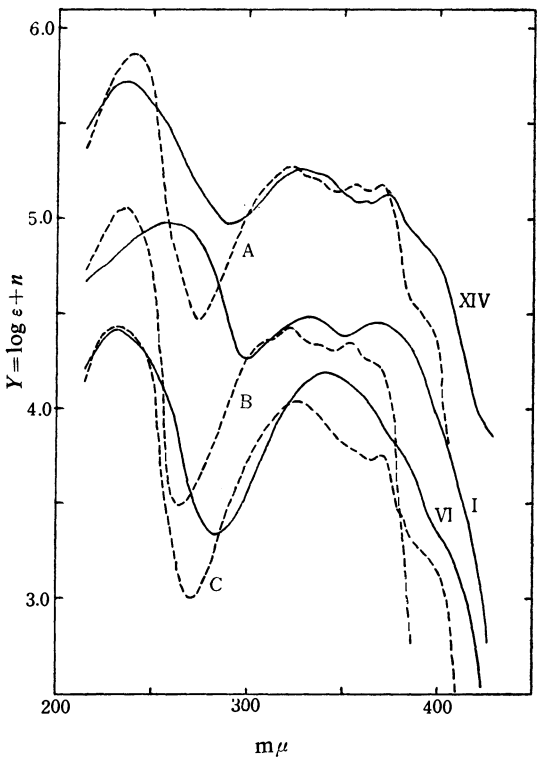

Fig. 4. Ultraviolet absorption spectra of α-, β- and γ-dolabrin (XIV, I and VI), and α-, β- and γ-thujaplicin (A, B and C).

$Y = \log + 1.5$ (for α-series)
$Y = \log + 0.7$ (for β-series)
$Y = \log + 0$ (for γ-series)

form 5-cinnamoyltropolone derivatives.

The work described in this paper has completed the total syntheses of α-, β- and γ-dolabrins, and 4-, and 5-acetyltropolones.

The paper chromatogram**** of α-, β- and γ-dolabrins so obtained is shown in Fig. 3, and their ultraviolet absorption spectra, together with those of corresponding thujaplicins are given in Fig. 4. The spectra of dolabrins show a bathochromic shift from those of corresponding thujaplicins, due to conjugation of the isopropenyl group with the tropolone ring. The absorption of γ-dolabrin in the longer wavelength region differs from that of α- and β-isomers.

## Experimental[12]

**p-Toluenesulfonate (II and III) of β-Dolabrin (I).**—To a solution of 1 g. of β-dolabrin dissolved in 1.5 ml. of pyridine, 1.4 g. of p-toluenesulfonyl chloride was added and the mixture was allowed to stand for about 1 hr. The colorless needles that precipitated out by addition of 4 ml. of ethanol were collected by filtration. Recrystallization of crude crystals, m. p. 124~126°C, from ethanol afforded 820 mg. of II as colorless plates, m. p. 127~128°C. Ethanol was evaporated from the filtrate left after removal of II, water was added to the residue, and the solution was extracted with benzene. The benzene extract was dried, passed through a chromatographic column of alumina, and eluted with benzene. 850 mg. of crystals, m.p. 72~74°C, thereby obtained were recrystallized from ethanol to III as pale yellow scales, m. p. 81~82°C.

Found (for II): C, 64.67; H. 4.66. Found (for III): C, 64.64; H, 4.96. Calcd. for $C_{17}H_{16}O_4S$: C, 64.55; H, 5.10%.

**Reaction of 2-Tosyloxy-4-isopropenyltropone (II) and Ammonia** a) A solution of 300 mg. of II dissolved in 30 ml. of methanol saturated with ammonia was allowed to stand at room temperature for 4 days. Methanol was evaporated under reduced pressure and the residue was treated with benzene, from which 165 mg. of ammonium p-toluenesulfonate was obtained as the insoluble portion. The benzene soluble portion was chromatographed over alumina and eluted with benzene, affording 70 mg. of yellow crystals m. p. 99~102°C. Subsequent elution with ethyl acetate gave 30 mg. of crystals, m. p. 119~123°C. Recrystallization of the former from benzene-cyclohexane mixture afforded IV as yellow needles, m. p. 110~112°C, while that of the latter from benzene-cyclohexane gave V as colorless scales, m. p. 126~126.5°C.

Found (for IV): C, 74.34; H, 6.90; N, 8.09. Found (for V): C, 74.29; H, 6.93; N, 8.75. Calcd. for $C_{10}H_{11}ON$: C, 74.51; H, 6.88; N, 8.69%.

IV forms a picrate of yellow prisms, m. p. 174~175°C (decomp.).

Found: C, 48.80; H, 3.26; N, 14.42. Calcd. for $C_{16}H_{14}O_8N_4$: C, 49.23; H, 3.62; N, 14.36%.

b) A mixture of 200 mg. of II and 13 ml. of liquid ammonia was allowed to stand at room temperature for 2 days and ammonia was evaporated. The residue was extracted with benzene and 60 mg. of IV was obtained. Purification of its filtrate by chromatography afforded 30 mg. of IV but none of V.

**γ-Dolabrin (VI) from 2-Amino-5-isopropenyltropone (IV).**—A mixture of 200 mg. of IV and 500 mg. of sodium hydroxide in 3 ml. of 30% ethanol was refluxed. The yellow crystals that precipitated out were collected, dissolved in water, and the solution was neutralized with 2 N hydrochloric acid, from which 150 mg. of colorless crystals, m. p. 94~96°C, was obtained. Recrystallization from benzene-cyclohexane mixture afforded VI as colorless scales, m. p. 100~101°C.

Found: C, 73.72; H, 5.86. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%.

I. R. Spectrum: $\tilde{\nu}$ (O-H, C=O, C=C) 3215, 1606, 1595, $\delta$ ($=CH_2$) 907 $cm^{-1}$. (in KBr disk).

Copper complex: Green needles, m. p. over 290°C.

Found: C, 62.02; H, 4.49. Calcd. for $C_{20}H_{18}O_4Cu$: C, 62.24; H, 4.70%.

**Reduction of γ-Dolabrin (VI) and 3-Isopropenylbenzamide (V).**—a) A solution of 20 mg. of VI dissolved in 4 ml. of ethanol, added with 5 mg. of palladium-carbon, was submitted to hydrogenation and 3 ml. of hydrogen was absorbed. Ethanol was evaporated and the crystalline residue was sublimed under reduced pressure. Recrystallization of the sublimate from cyclohexane afforded colorless needles, m. p. 77~78°C, which showed no depression on admixture with γ-thujaplicin, m. p. 80°C.

b) Fifteen mg. of V was hydrogenated by the same way as above to afford 7 mg. of colorless scales, m. p. 94~95°C after recrystallization from benzene-cyclohexane, which showed no depression on admixture with m-cumic acid amide m. p. 95~95.5°C.

**p-Toluenesulfonate (VII) of γ-Dolabrin (VI),**—To a solution of 260 mg. of γ-dolabrin dissolved in 0.5 ml. of pyridine, 360 mg. of p-toluenesulfonyl chloride was added and the mixture was allowed to stand. After about 1.5 hr. 2 ml. of ethanol was added to it and 410 mg. of crystals m. p. 121~124°C was obtained. The filtrate was evaported and the residue was poured into water, separating 70 mg. of crystals m. p. 119~124°C. The combined crystals were recrystallized from ethanol to VII as pale yellow prisms, m. p. 125~126°C.

Found: C, 64.74; H, 5.04. Calcd. for $C_{17}H_{16}O_4S$: C, 64.55; H, 5.10%.

**Reaction of 2-Tosyloxy-5-isopropenyltropone (VII) and Ammonia.**—a) A mixture of 320 mg. of VII dissolved in 15 ml. of liquid ammonia was allowed to stand for 5 days at room temperature,

**** Chromatography is carried out on the paper treated with 17% aqueous solution of phosphoric acid, and benzene used as developing solvent.

12) M. p. are uncorrected. The microanalyses were carried out by Messrs Shin-ichi Ohyama, Kazuyoshi Azumi and Miss Ayako Iwanaga, and infrared spectra were measured with Perkin-Elmer Model 21 double beam spectrophotometer by the member of Prof. Kinumaki's laboratory of the Chemical Research Institute of Non-aqueous solutions, to whom the authors' acknowledgements are hereby extended.

then ammonia was evaporated, and the residue was extracted with benzene. The benzene solution was passed through an alumina layer. The first elution with benzene-ethyl acetate afforded 100 mg. of yellow crystals, m. p. 90~97°C, and subsequent elution with ethyl acetate afforded 30 mg. of colorless crystals, m. p. 181°C. Recrystallization of the former from benzene-petroleum ether afforded VIII as yellow needles, m. p. 100~101°C. The latter was recrystallized from a mixture of ethyl acetate and petroleum ether, affording IX as colorless plates, m. p. 180.5~182°C. Catalytic reduction of IX with polladium-carbon afforded colorless crystals, m. p. 152°C, which showed no depression on admixture with *p*-cumic acid amide, m. p. 153°C.

Found (for VIII): C, 74.17; H, 6.41; N, 8.92. Found (for IX): C, 74.33; H, 6.62; N, 8.62. Calcd. for $C_{10}H_{11}ON$: C, 74.51; H, 6.88; N, 8.69%.

Picrate of VIII: m. p. 130~131°C.

Found: C, 49.72; H, 3.48; N, 14.41. Calcd. for $C_{16}H_{14}O_8N_4$: C, 49.23; H, 3.62; N, 14.36%.

b) A solution of 400 mg. of VII dissolved in 50 ml. of methanol saturated with ammonia was allowed to stand for 4 days at room tepmerature and then the methanol was evaporated. The residue was extracted with benzene, and the benzene-insoluble portion was extracted with water. The insoluble residue was 100 mg. of crystals melting at 180°C. The sparingly soluble portion of benzene extract afforded 30 mg. of the same crystals. Both lots of crystals corresponded to IX. The benzene-soluble portion was chromatographed over alumina and elution with benzene gave 5 mg. of crystals X, m. p. 50~53°C, which showed no depresseon on admixture with methyl *p*-isopropenylbenzoate. The portion eluted with ethyl acetate affored 15 mg. of β-dolabrin, m.p. 51°C, by the same hydrolysis as below.

**Hydrolysis of 2-Amino-4-isopropenyltropone (VIII).**—A solution of 30 mg. of VIII dissolved in a mixture of 150 mg. of potassium hydroxide, and 1 ml. of 50% methanol was refluxed for 3.5 hr. The methanol was then evaporated, 2 ml. of water was added to the residue, and this was extracted with benzene to remove an unreacted substance, the mother liquor was acidified, extracted with benzene, and benzene was evaporated after drying. Recrystallization of its residue from cyclohexane afforded 23 mg. of pale yellow needles, m. p. 54~56°C, which showed no depression on admixture with β-dolabrin

**Reaction of 2-Tosyloxy-6-isopropenyltropone (III) and Ammonia.**—a) A mixture of 2 g. of III and about 20 ml. of liquid ammonia was allowed to stand for 2 days at room temperature. The ammonia was evaporated and the residue was extracted with benzene. The benzene solution was washed with water, dried, and chromatographed over alumina. Elution with benzene afforded 490 mg. of yellow oil (A), and subsequent elution with ethyl acetate afforded 220 mg. of (V), m. p. 124°C. A was refluxed with a mixture of 1 g. of potassium hydroxide, and 5 ml. of 50% ethanol for 8 hr. Ethanol was then evaporated, 5 ml. of water was added to the residue, and this was extracted with benzene. Mother liquor was acidified and extracted with benzene, affording a minute quantity of oil (XI), and this was derived to a copper complex by reaction with copper sulfate solution and 50 mg. of green crystals was obtained. Recrystallization from chloroform-petroleum ether afforded greenish yellow needles, m. p. 250°C (decomp.).

b) A solution of 2 g. of III dissolved in 200 ml. of methanol saturated with ammonia was allowed to stand for 3 days at room temperature and the solvent was evaporated. The residue was dissolved in benzene and 220 mg. of V m. p. 124°C was obtained. The filtrate was evaporated and the residue was refluxed for 2 hr. with a solution of 1 g. of sodium hydroxide in 5 ml. of 50% ethanol. The colorless needles, $C_{10}H_{13}O_2N$, m. p. 179.5~180.5°C (after recrystallization from benzene) were obtained by neutralization of the solution. However, the structure of this acidic substance was not defined.

Found (for m. p. 179.5°C): C, 66.97; H, 7.11; N, 7.73. Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%.

**Synthesis of 2-Isopropenyltropone (XII) from Tropolone.** — A solution of 6.4 g. (0.053 mol. eq.) of 2-bromopropene dissolved in 10 ml. of ether was added dropwise into 0.65 g. (0.093 mol. eq.) of lithium in 12 ml. of ether with stirring in nitrogen atmosphere and the mixture was refluxed for 2 hr. After removal of residual lithium pieces, a solution of 1.15 g. (0.0093 mol. eq.) of tropolone dissolved in 50 ml. of ether was added dropwise with stirring and the mixture was stirred for 1 hr. The solution was cooled with ice and 20 ml. of 2 N sulfuric acid was added, the ether layer was separated, and the aqueous layer was extracted with ether. The combined ether solution was washed with sodium chloride solution, passed through an alumina layer to remove unreacted tropolone, and the ether was evaporated from the effluent, leaving 1.5 g. of pale reddish brown oil. Bromination of this oil in glacial acetic acid failed to produce any crystalline derivative. The oil was dissolved in benzene and dry hydrogen chloride gas was passed through this solution. The oily hydrochloride that separated out was collected, decomposed with water, and extracted with ether. The ether extract was washed with water, dried, and passed through a column of alumina. Evaporation of ether from the effluent afforded a reddish brown oil, $n_D^{25}$ 1.6978, which was submitted to elemental analyses and spectral measurement.

Found: C, 81.33; H, 7.01. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.90%.

I. R. spectrum: $\tilde{\nu}$ (C=O, C=C) 1627, 1570~1600, $\delta$ (=$CH_2$) 897 $cm^{-1}$ (in KBr disk).

**Reaction of 2-Isopropenyltropone and Hydroxylamine: (Synthesis of α-Dolabrin (XIV)).** — A solution of 0.2 g. of 2-isopropenyltropone and 0.3 g. of hydroxylamine hydrochloride dissolved in a mixture of 1.5 ml. of dehydrated ethanol and 1.5 ml. of pyridine was refluxed for 2 hr. Ethanol was then evaporated, water was added to the residue, and the solution was extracted with benzene. The benzene extract was washed with water and passed through an alumina layer. First elution with benzene

afforded 20 mg. of red oil (A) and subsequent elution with chloroform and ethanol respectively afforded 10 mg. of yellowish oil (B) and 50 mg. of yellowish brown oil (C). A part of A underwent crystallization but was not purified and it was assumed to be an oxime from its ultraviolet spectrum. $\lambda_{max}^{MeOH}$ mμ (log ε): 223 (4.17), 299 (3.71), 390～400 (3.11).

B also afforded no crystalline picrate but it was assumed from its ultraviolet spectrum to be 2-aminotropone derivative.

It was considered possible that C contains a 2-aminotropone derivative. Therefore, it was refluxed for 2 hr. with 0.2 g. of sodium hydroxide and 2 ml. of 50% ethanol, the ethanol was evaporated, water was added to the residue, and the solution was extracted with chloroform to remove the neutral portion. The aqueous layer was acidified and extracted with chloroform, affording 20 mg. of a brown oil. Distillation of this oil under a reduced pressure gave pale yellow crystals, m. p. 35～36°C, which was dissolved in petroleum ether and derived to a copper complex. The copper comprex came as greenish yellow crystals, m. p. 250°C (decomp.).

Found: C, 61.56; H, 5.15; Cu, 16.29. Calcd. for $C_{20}H_{18}O_4Cu$: C, 62.24; H, 4.70; Cu, 16.46%.

**Synthesis of Esters of Tropolone-5-carboxylic Acid (XV).**—*a) Amyl Ester (XVI).*—To a solution of 600 mg. XV dissolved in 10 ml. of amyl alcohol, 0.15 ml. of conc. sulfuric acid was added and the mixture was refluxed for 2 hr. The solution was filtered to remove carbonized material, the filtrate was concentrated, and the residue was allowed to stand with the addition of ethanol. The residue afforded 450 mg. of crystals melting at 60°C which was recrystallized from petroleum ether to XVI as colorless, scales m. p. 61～62°C. This substance turns red with ferric chloride and the color transfers to the chloroform layer.

Found: C, 66.30; H, 6.74. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Hydrolysis of this mother liquor with alkali resulted in recovery of 150 mg. of XV, m. p. over 250°C.

*b) Octyl Ester (XVII).* — Obtained by the same method as a) as colorless scales, m. p. 55°C.

Found: C, 69.53; H, 8.12. Calcd. for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

*c) Cyclohexyl Ester (XVIII).*—To a solution of 600 mg. of XV dissolved in 12 ml. of cyclohexanol, 0.6 ml. of conc. hydrochloric acid was added and the mixture was refluxed for 8 hr. The reaction mixture was filtered while hot, the filtrate was concentrated, and allowed to stand. Evaporation was repeated twice and 800 mg. of crystals of m. p. 85°C was obtained as the first crop, and 140 mg. of crystals of m. p. 90°C as the second crop. The combined crystals were recrystallized from ethanol and 60 mg. of tropolone-5-carboxylic acid, m. p. over 250°C, was obtained from the sparingly soluble portion, and 600 mg. of pale brown plates XVIII, m. p. 94～95°C, from the easily soluble portion. Further recrystallization of the latter raised its melting point to 97～98°C.

Found: C, 67.07; H, 6.23. Calcd. for $C_{14}H_{16}O_4$; C, 67.73; H, 6.50%.

**Synthesis of γ-Dolabrin (VI) from the Esters of Tropolone-5-caboxylic Acid.**—a) A solution of 0.5 g. (0.0017 mol. eq.) of XVII dissolved in 10 ml. of ether was added with stirring under ice-cooling to the Grignard reagent from 1.6 g. (0.0113 mol. eq.) of methyl iodide, 0.26 g. (0.0104 mol. eq.) of magnesium, and ether, and the mixture was stirred for 3 hr. Ten ml. of 15% ammonium chloride solution was added to this mixture and the whole mixture was extracted thoroughly with ether. The ether was evaporated, the residue was heated with 10 ml. of 6 N sulfuric acid for 10 min. and the mixture, was extracted with three 5-ml. portions of chloroform, affording 250 mg. of dark brown oil **A**. The mother liquor left after chloroform extraction was extracted with eight 5-ml. portions of ethyl acetate, affording 40 mg. of pale yellow oil (B). A part of B crystallized on being allowed to stand, but its melting point could not be measured. B was submitted to paper chromatography with benzene as a solvent but it did not move with this solvent. A mixture of B and finely divided fused hydrogensulfate was heated for a few minutes at 140°C and the mixture was sublimed under reduced pressure, from which 20 mg. of colorless crystals, m. p. 90～95°C, was obtained. Recrystallization from cyclohexane afforded colorless plates, m. p. 99～100°C, undepressed on admixture with γ-dolabrin. This has indicated that B chiefly contains the objective 5-α-hydroxy-isopropyltropolone (XIX). Some crystals separated out on standing A and 25 mg. of pale yellow crystals, m. p. 178°C, was obtained. It showed no depression of the melting point on admixture with 5-acetyltropolone (XX). The mother liquor left after separation of these crystals was found to contain the octyl ester, XIX, and XX.

b) Reaction of 0.42 g. of the amyl ester (XVI) with 6 molar equivalents of methylmagnesium iodide, as in the case of the above a), was carried out. After completion of the reaction, the product was decomposed with 15 ml. of 6 N sulfuric acid. After separation of the ether layer, the mother liquor was extracted with 20 ml. and 10 ml. of chloloform, and the combined ether and chloroform extracts were washed with eight 10-ml. portions of 8 N sulfuric acid. Evaporation of the solvent from this combined extract left 250 mg. of oil **A**. Sulfuric acid layer and washings were combined, neutralized to pH 4 with dil. potassium hydroxide solution, and the solution continuously extracted with chloroform for 10 hr. Evaporation of chloroform from this extract afforded 80 mg. of oil which underwent crystallization. The crystals were washed out repeatedly with cyclohexane, the cyclohexane was evaporated, and the residue was sublimed under reduced pressure, affording 40 mg. of pale yellow crystals, m. p. 98～99°C, undepressed on admixture with γ-dolabrin (VI). Paper chromatographic examination showed A to be a mixture of the recovered ester, XIX, and XX.

c) A solution of 0.42 g. of the cyclohexyl ester (XVIII) dissolved in 12 ml. of ether was reacted with 6 molar equivalents of methylmagnesium iodide as in the case of (a), stirring for 1 hr. and

refluxed for 30 min. After it was cooled, 15 ml. of 4 N sulfuric acid was added to effect decomposition, extracted with ether, and the ether was evaporated after washing with water and drying over sodium sulfate, affording 250 mg. of yellow oil (A). The sulfuric acid layer was extracted 5 times with 5 ml. of chloroform each time, and the extract was washed with water, dried, and evaporated, to leave 50 mg. of oil. This crystallized immediately and was found to contain chiefly XIX and a small amount of XX. This substance actually gave green coloration in the aqueous layer and pale reddish brown coloration in the chloroform layer with ferric chloride. There was no suitable solvent for recrystallization of the above crystals but on leaving its ethalolic solution, comparatively large plate crystals, m. p. 101~104°C, separated out on the wall of the vessel. A chromatographic test indicated that A contained the recovered ester, XIX, and XX. Crystals separated out on standing A and 15 mg. of XX, m. p. 178~180°C, was obtained. The benzene solution of filtrate was chromatographed over silica gel but it was not successfully separated into its components.

**5-Acetyltropolone (XX) from γ-Dolabrin (VI).**—A solution of 770 mg. of VI dissolved in 27 ml. of formic acid, to which was added 6 ml. of 35% hydrogen peroxide, was stirred at 40°C for 3 hr. and formic acid was distilled off under reduced pressure. Further 7 ml. of 1.2 N sodium hydroxide was added and the mixture was stirred at 40°C for 3 hr. This was acidified with 2 N hydrochloric acid and extracted with chloroform. The aqueous layer was cooled with ice, an aqueous solution of 900 mg. of periodic acid dihydrate was added, mixture was stirred, and 590 mg. of crystals was obtained. The same amount of crystals, 70 mg., was obtained from the chloroform layer. The combined crystals were recrystallized from ethanol to XX as yellow plates, m. p. 182~183°C.

Found: C, 65.69; H, 4.49. Calcd. for $C_9H_8O_3$: C, 65.85; H, 4.91%.

Oxime: Pale yellow plates, m. p. 201~202°C (decomp.).

Found: C, 60.55; H, 4.75; N, 7.81. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.00; N, 7.82%.

**Condensation of XX with Benzaldehyde and 3, 4, 5-Trimethoxybenzaldehyde.**—a) A mixture of 650 mg. of XX suspended in 10 ml. of methanol to which was added 700 mg. of benzaldehyde, 1.3 ml. of 5% potassium hydroxide solution, and 15 ml. of water was stirred thoroughly and the orange crystals that separated out were collected by filtration. This substance was dissolved in 100 ml. of water, acidified with 2 N hydrochloric acid, and 900 mg. of yellow needles was recrystallized from ethanol to yellow needles, m. p. 158~159°C.

Found: C, 76.04; H, 4.32. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

b) A mixture of 100 mg. of XX and 150 mg. of trimethoxybenzaldehyde afforded 150 mg. of a condensate of m. p. 207.5~208.5°C after recrystallization from acetic acid.

Found: C, 66.16; H, 5.12. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

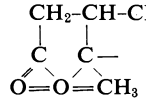
# *Infrared Spectra of p-Bromophenacyl Esters*

By Hisao NAKATA, Shuzo MATSUO* and Yoshimasa HIRATA

(Received January 6, 1960)

In previous papers[1,2] it has been demonstrated that aureothinic acid and *N*-benzoyl aminotetrahydroaureothinic acid have structures (I) and (II), respectively. The location of an etheric oxygen at an $\alpha$-position of the carboxyl group in these acids was suggested by the comparison of infrared spectra of several model compounds[1] and was established rigorously by oxidative studies[2].



During the course of the structural elucidation of these acids, however, attention was called to the fact that the infrared spectra of their *p*-bromophenacyl esters in chloroform solution show ester carbonyl absorption at

a) All melting points are uncorrected.
b) The value is taken from Taft (Refs. 3 and 4), unless otherwise indicated.
c) Approximated with the value for *n*-$C_4H_9$- substituent.
d) The ester carbonyl group appeared at 1738 $cm^{-1}$.
e) Calculated from the value for $CH_3OCO$- substituent using the inductive parameter of 2.8 (Refs. 3 and 4).
f) Calculated using the additive nature of $\sigma^*$ values (Refs. 3 and 4).
g) T. Kubota and T. Matsuura, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **72**, 482 (1951).
h) The amide carbonyl group appeared at 1663 $cm^{-1}$.
i) Estimated from the relations $\sigma^*=\sigma_I/0.45$ and $\sigma_I=(\alpha\cdot\sigma_p-\sigma_m)/(\alpha-1)$ (Refs. 3 and 4, and R. W. Taft, Jr. and I. C. Lewis, *J. Am. Chem. Soc.*, **80**, 2436 (1958).), using $\sigma_p$ of +0.078 and $\sigma_m$ of +0.217 (H. H. Jaffe, *Chem. Revs.*, **53**, 191 (1953).) and $\alpha=+0.443$ (J. L. Roberts and H. H. Jaffe, *J. Am. Chem. Soc.*, **81**, 1635 (1959).).
j) The amide carbonyl group appeared at 1660 $cm^{-1}$.
k) R. B. Bradbury and S. Masamune, *J. Am. Chem. Soc.*, **81**, 5201 (1959).
l) The lactone carbonyl group appeared at 1779 $cm^{-1}$.
m) The $\sigma^*$ value for $CH_3COOCH_2$- group was estimated as +1.010 from the same relations cited in foot-note i) of this Table using $\sigma_p$ of +0.31 and $\sigma_m$ of +0.39 (D. H. McDaniel and H. C. Brown, *J. Org. Chem.*, **23**, 420 (1958).), and $\alpha=+0.448$ (J. L. Roberts and H. H. Jaffe, *J. Am. Chem. Soc.*, **81**, 1635 (1959).). The additive nature of $\sigma^*$ values then leads to the value of +0.720 for this $\gamma$-lactone grouping.

(I) R=H, aureothinic acid
(Ia) R=$CH_2COC_6H_4Br$-*p*

(II) R=H, *N*-benzoyl aminotetrahydro-aureothinic acid
(IIa) R=$CH_2COC_6H_4Br$-*p*

1758 $cm^{-1}$, which is considered to be an abnormally high frequency, and it became desirable to examine the infrared spectra of several *p*-bromophenacyl esters. Consequently, twenty *p*-bromophenacyl esters were prepared and their spectra were measured in chloroform solution. The results are summarized in Table I.

The absorption bands of keto carbonyl groups appear in the same frequency range of 1705~1710 $cm^{-1}$. On the other hand, in the spectra of the ester carbonyl groups an etheric function located at an $\alpha$-position of the carboxyl group causes a considerable shift of frequency, as is evident from Table I (compounds No. 11, 12, 16, 21 and 22). While the inductive effect of electronegative $\alpha$-oxygen substituents has usually been cited as the probable cause for the frequency shifts, it has not been possible to differentiate this from direct field effects. A more quantitative understanding of these may be discussed in terms of inductive parameters of the substituents. When the polar substituent constant $\sigma^*$ reported by Taft[3,4] is taken as a measure of inductive effects, the ester carbonyl frequencies presented in Table I define a straight line when plotted against the appropriate $\sigma^*$-values (Fig. 1). The linear correlation obtained is reasonably good and it was found possible to write the following approximate relation:

$$\nu_{C=O}\ cm^{-1} = 1745\ cm^{-1} + 9.1(\Sigma\sigma^*)cm^{-1} \quad (1)$$

It is apparent from Fig. 1 that the absorption bands of both aureothinic (No. 21) and *N*-benzoyl aminotetrahydroaureothinic (No. 22) esters deviate from the correlation line by an amount of 10 $cm^{-1}$. The deviations are more serious with the ethoxy- (No. 11) and *n*-butoxy-acetic (No. 12) esters and even more so with phenoxy-acetic (No. 16). Therefore,

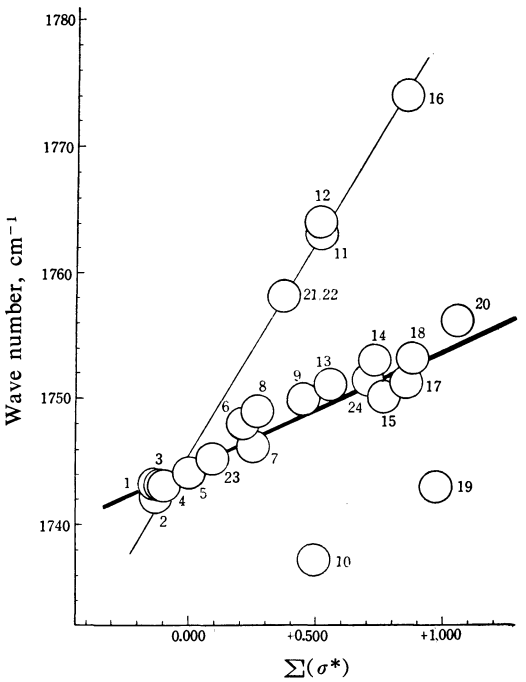

Fig. 1. The linear correlation between polar substituent constants and ester carbonyl frequencies of *p*-bromophenacyl esters. (The numbers refer to the compounds listed in Table II.)

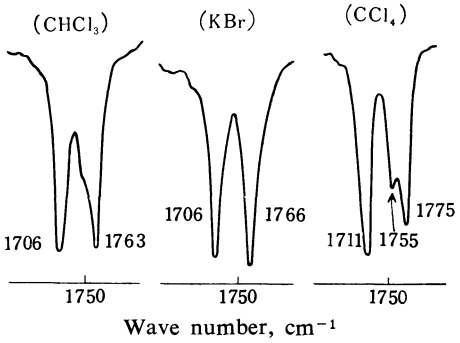

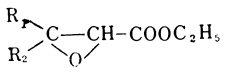

Fig. 2. Infrared spectra of *p*-bromophenacyl ethoxy acetate.

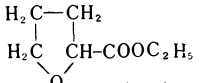
it may be concluded that these deviations are characteristic with esters having an etheric oxygen at their $\alpha$-positions.



As is shown in Fig. 2, the band of these esters in chloroform solution had a shoulder at a low frequency region, while only a sharp band appeared when the spectrum was measured in the solid state (potassium bromide disks). Recently, House and Blaker[5] have reported that in the carbonyl region glycidic esters such as III and ethyl tetrahydrofuroate (IV) both

3) R. W. Taft, Jr., *J. Am. Chem. Soc.*, **75**, 4231 (1953).

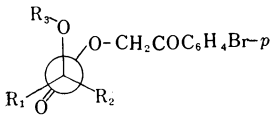
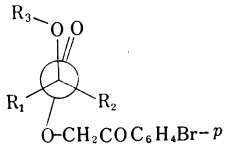
5) H. O. House and J. W. Blaker, *J. Am. Chem. Soc.*, **80**, 6389 (1958).

exhibited two bands attributable to the presence of two conformations of esters in the solution[6]. The same explanation can be applied to *p*-bromophenacyl esters having an $\alpha$-oxygen substituent.



(III)



(IV)

These esters would exist in two conformations V and VI in solution. Since the C=O and C-O dipoles are oriented in opposite directions in the conformation V, the spectrum of this structure would be expected to have a normal carbonyl absorption band of *p*-bromophenacyl esters in the range of 1740~1755 $cm^{-1}$, while in the conformation VI, where these dipoles are oriented in the same direction, the direct field effects between these dipoles would be expected, which would result in the carbonyl vibration shifting towards higher frequencies.

(V)

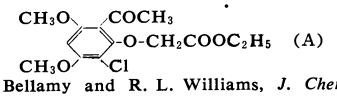
(VI)

These considerations are exactly parallel with those employed in interpret the infrared spectra of $\alpha$-haloketones and $\alpha$-haloesters[7].

The molecular extinctions of the two conformations are not known and the actual concentrations of the two conformations could not be calculated. However, it may be concluded that these esters exist largely as the conformation VI in chloroform solution, since the lower frequency band of the conformation V is a shoulder and since a study of $\alpha$-bromoketo steroids suggests that the molecular extinction of the conformation VI should have a lower value than that of V[8]. Recently, Brown[9] has reported the value 3.36 : 2.77 for the ratio of apparent intensities of the corresponding conformations for ethyl $\alpha$-ethoxy acetate.

To explore the validity of the above presumption, infrared spectra of these esters were examined in carbon tetrachloride solution. As was evident from studies[10] of $\alpha$-bromocyclohexanone in various solvents, the less polar conformation V is stabilized by the less polar solvent so that the spectra of conformations V and VI would be separated from each other. This is actually the case; thus, as is shown in Fig. 2, the spectrum of *p*-bromophenacyl ethoxyacetate in carbon tetrachloride solution exhibits two bands at 1755 and 1775 $cm^{-1}$ in ester carbonyl region corresponding to the conformations V and VI, respectively. The same is true for *n*-butoxyacetic and monochloroacetic esters. The band frequencies of some esters in carbon tetrachloride solution are shown in Table II. Monoiodoacetic ester and $\alpha$-bromobutyric ester did not exhibit two bands even in this non-polar solvent. This observation agrees with the conclusion of Brown[9] that the distribution of two conformations of these esters is controlled largely by the size of the group rather than by the dipole-dipole repulsion.

Table II. Infrared spectra of *p*-bromophenacyl esters ($RCOOCH_2COC_6H_4Br$-*p*) in carbon tetrachloride solution



| Compound[a] No.[b] | R- | Ester C=O $cm^{-1}$ | Keto C=O $cm^{-1}$ |
|---|---|---|---|
| 3 | *n*-$C_3H_7$- | 1753 | 1712 |
| 4 | $C_2H_5$- | 1755 | 1712 |
| 5 | $CH_3$- | 1759 | 1712 |
| 6 | $C_6H_5CH_2$- | 1751 | 1711 |
| 8 | $CH_3CHClCH_2$- | 1753 | 1711 |

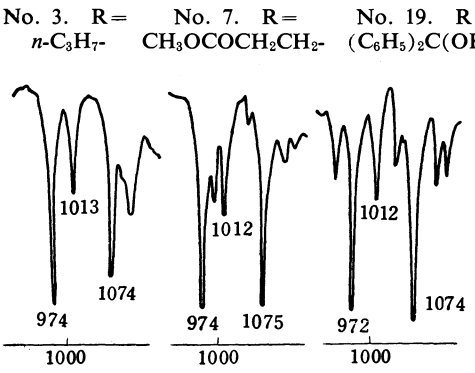

Fig. 3. Characteristic bands of *p*-bromophenacyl ester ($RCOOCH_2COC_6H_4Br$-*p*) around 1000 $cm^{-1}$ ($CHCl_3$).

group. Thus, these bands appear at 1076±2 $cm^{-1}$ (strong), 1014±2 $cm^{-1}$ (medium), and 972±4 $cm^{-1}$ (strong), and are almost independent of the structure of respective acids. These bands are therefore useful for the recognition of *p*-bromophenacyl esters. The characteristic shapes of these bands are shown in Fig. 3.

Provided that direct comparisons of spectra of *p*-bromophenacyl esters with the linear correlation of Eq. 1 are possible, the ester carbonyl absorption band would enable one to evaluate the appropriate $\sum\sigma^*$ value, which, in turn, would predict the nature of substituents around the carboxyl group of the respective acid, since only a few anomalies have been observed in the correlation except for those described above. While the abnormal frequency lowering in formic ester (No. 10) is not unexpected, the cause for the considerable deviation from the correlation in benzilic ester (No. 19) is not known.

Finally it is of interest to note that the frequencies of esters having an etheric function at their $\alpha$-position define another straight line in Fig. 1. Since the abnormally high frequency of these esters is ascribable to the direct field effect of alkoxyl groups, this linear correlation would probably suggest the linearity between the field effect and the inductive effect, at least, for these alkoxyl groups. However, more accurate and sufficient data may be required in order to test such a quantitative correlation.

## Experimental

**General Procedure for Preparation of *p*-Bromophenacyl Esters.** — About 500 mg. of the acid are added to a mixture of 1 ml. of water and 2 ml. of alcohol in a small flask and are neutralized carefully with crystalline sodium bicarbonate. The mixture is warmed very gently on a water bath until evolution of carbon dioxide ceases. The remaining sodium bicarbonate is filtered and the filtrate is added with one or two drops of the acid. Five ml. of alcohol and 500 mg. of *p*-bromophenacyl bromide are added and the mixture is then heated under reflux for 1 hr. Occasionally the addition of a few more milliliters of alcohol may be necessary if a solid separates during the refluxing. The solution is allowed to cool, and the precipitated ester is purified by recrystallization from alcohol or from aqueous alcohol. The melting point of the ester is listed in Table I.

**Infrared Absorption Measurements.**—The spectra were recorded on a Hilger H 800 double beam instrument equipped with sodium chloride optics. Spectra of the solution were measured using 0.16 mm. sodium chloride cells.

The authors wish to express their gratitude to Dr. Isao Satoda, Nippon Shin-yaku Co. for his interest in this research. They are indebted to the Parke Davis Co. for fellowships to H. N. during the course of the research, and are also grateful for a grant from the Ministry of Education.

## *Proton Magnetic Resonance Absorption of Aluminum Hydroxides and of their Thermal Dehydration-Products*

By Tokutaro HAGIWARA and Tatsuo SAITO*

(Received February 29, 1960)

The phase transformations occurring in the thermal decomposition of the alumina trihydrate belong, as of old, to the subject of extensive researches. The present authors have now tried to study the thermal dehydration of alumina trihydrate by means of a method of proton magnetic resonance absorption**.

The starting material here employed was a bayerite prepared by a chemical reaction of an aluminum chloride solution with an aqueous ammonia. Each specimen was subjected to the corresponding heating of this starting material during 3 hr. in the air at 100°, 200°, 220°, 250°, 300°, 450° and 600°C, respectively. They were sealed in the evacuated glass tubes which were pumped out to a high vacuum, either at room temperature during 12 hr. or at 110°C during 6 hr., the latter having the purpose of an after-treatment. We call the former group as "a-series" and the latter one as "b-series".

For the NMR measurements, we have used the a.c. modulation technique of the magnetic field at the d.c. magnetic field of about 3100 gauss. The detecting apparatus has the ordinary constitution, which is composed of an autodyne oscillator, an audio-frequency amplifier, a lockin-amplifier and a recording milliammeter.

The measurements of the proton magnetic resonance were also made in the well-known definite hydrargillite, bayerite, böhmite and natural diaspore, respectively. Some reproductions of the experimental line shapes of the proton resonances are shown in Figs. 1 and 2.

As is seen in Fig. 1, the line shapes of the hydrargillite and of the bayerite or the starting material may be presumably understood as being composed of two parts: one is situated at the center with the narrower width and another is of very broad at both sides of it. The line shape of the böhmite shows the signal of the three spin type, while that of the

* Present address; Government Chemical Industrial Research Institute, Tokyo, Honmachi 1-chōme, Shibuya-ku, Tokyo.

** Presented partly at the Symposium on Structural Chemistry, Osaka, Oct. 31, 1954.

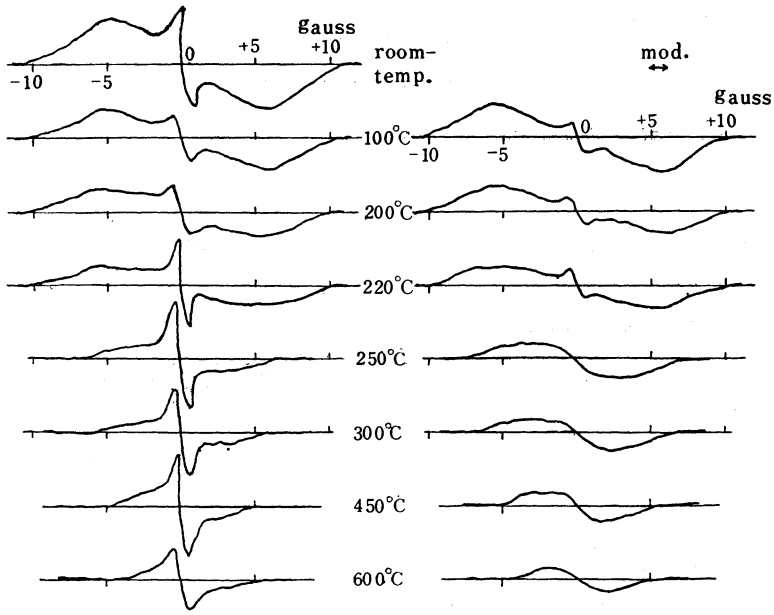

Fig. 2. Recorded derivatives of proton resonance in the a- and b-series—(without and with the after-treatments, in vacuo, 110°C).

diaspore shows the single and narrow line. The values of the second moments calculated from the experimental derivative curves are shown in Table I.

The line shapes of each specimen dehydrated at 100° and 200°C are both similar to that of the starting material. The amplitudes of the central components observed for these line shapes are somewhat reduced by the thermal after-treatment, as in a high vacuum pumping at 110°C, but they yet never disappear by such a treatment. Nevertheless, the line shapes of the specimens dehydrated at about 220°C and higher make quite a difference from above two specimens and the height of the central peaks in these line shapes considerably increases. It is noteworthy that these central peaks, however, disappear by the such after-treatment, as in a high vacuum pumping at 110°C. These interesting behaviors can be seen in Fig. 2. Therefore, we are to suppose that these central peaks in the latter case originate from the water-molecules which are adsorbed by the decomposed products and are in the thermal motion.

Based upon the above experimental fact, the following conclusions can be drawn:

1) The decomposition of this starting material does not occur till the thermal dehydration temperature of about 200°C. This is ascertained in our NMR experiments.

2) The sudden and considerable variation of the central part observed in the line shapes at an about 220°C and higher, seems to show that the first dehydration process of this starting material brings forth an active lower hydroxide, exhibiting very high activity for an adsorption.

3) The gradual decrease of the line width occurring in the range from about 250 to 600°C might be regarded as a result due to the changing of the mixed ratio of the lower hydroxide and alumina phases.

These conclusions will be ascertained by the additional experiment by means of X-ray diffraction method which is in progress in our laboratory.

The authors wish to express their sincere thanks to Professor Tunahiko Shidei and Assistant Professor Syukuro Yano in Kyoto University, under whose continual advice and encouragement the present experiments has been carried out, and also for their so kindness as to allow us the loan of their equipments and the technique throughout this study. This study also has been partly supported under the Scientific Research Expenditure from the Ministry of Education.

## *Thermal Isomerization of 2-Thenylthiocyanate*

By Kensuke TAKAHASHI, Tyo SONE, Yasuo MATSUKI and Genjiro HAZATO

(Received March 12, 1960)

During the studies of the structural investigation and the identification of thenyl derivatives by means of the NMR technique, we happened upon the occurrence of the thermal isomerization of 2-thenylthiocyanate at about 150°C.

Resonance was observed at 40 mc, the apparatus and the procedure were similar to those previously described[1], and in every sample, cyclohexane was used as an internal reference. The spectrum of the raw product synthesized from thiophene by the procedure of thiocyanomethylation, is shown in Fig. 1a. The lines coming from the aromatic hydrogens in thiophene ring spread over the range of about 20 cps at the low-field side of the spectrum. At the high-field side two lines at 107.5 and 125 cps, referred to cyclohexane signal, are assumed to be the lines coming from the hydrogens of the methylene group. We had expected formerly to be observed only one line coming from this group; whereas, the experimental result showed that the methylene peak was divided into two lines, corresponding to two isomers respectively. After this measurement, the sample was heated at about 150°C for two hours by immersing in a constant temperature bath. In the spectrum of the heated sample, the two lines coming from the methylene hydrogens were found at the same positions but there was a marked difference in their intensities as compared with the non-heated sample, as shown in Fig. 1b. This result indicates the occurrence of a thermal isomerization between two compounds of which our synthesized product consists. The thermal isomerization in allylthiocyanate was firstly shown by Gerlich[2]. Here we have studied the benzyl thiocyanate which shows the thrmal isomerization at about 250°C, reported already by Hennicke[3]. Its spectrum shows two lines coming from methylene and aromatic hydrogens at 96 and 229 cps, referred to cyclohexane signal, respectively. By heating of this compound at about 150°C for two hours, no change of its NMR spectrum was observed in comparison with 2-thenyl derivative, but after heating at about 250°C for two hours, the line coming from the methylene group was found at 111 cps with the other small neighboring peaks, and the lines of the aromatic hydrogens were found at 224 and 228 cps. This phenomenon is assumed as the isomerization from thiocyanate to isothiocyanate which is promoted by heating, the same is the case with that observed in 2-thenyl derivative. The isomerization in question here observed in the NMR spectrum is represented by the shift of the line coming from the methylene group to the lower field, which is attributed to the change of the electronegativity and of the second-order high frequency paramagnetism of the adjacent group. The detailed result on the thiocyanomethylation of thiophene will be published in the Journal of the Chemical Society of Japan, Ind. Chem. Sec.

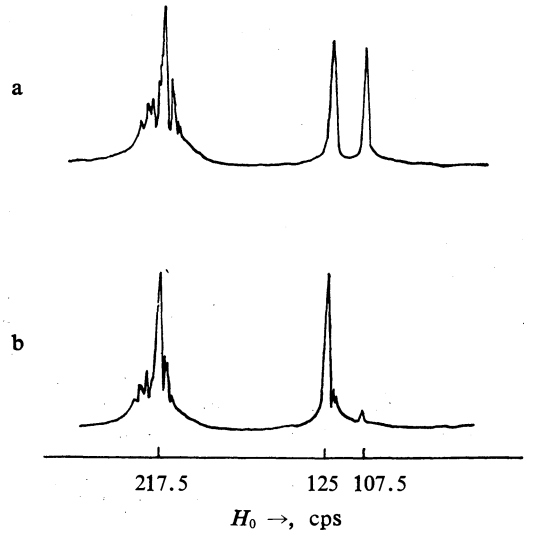

Fig. 1. The proton magnetic resonance spectra of the raw product synthesized from thiophene by thiocyanomethylation, (a) before heating; (b) after heating at about 150°C for two hours. Applied magnetic field increasing from left to right.

## *On the Electronic Structure of Thiothiophten*

By Kôgorô MAEDA

(Received June 10, 1960)

Recently the structure of a thiothiophten molecule was clarified through the X-ray analysis by Bezzi, Mammi and Garbuglio[1], who proposed a condensed ring system characterized by no-bond resonance structure. On the basis of this peculiar structure, Giacometti and Rigatti[2] have made simple LCAO treatment on the superimposed $\sigma$ and $\pi$ systems of nonlocalized electrons in thiothiophten, by using only $p$ type orbitals for valence states of sulfur atoms. However, since the system involving no-bond resonance structure is somewhat unlikely to occur, an alternative interpretation on the electronic structure of thiothiophten will be given in the present report.

It is possible that a $3p$ electron of the sulfur atom is promoted to a $3d$ orbital and interacts with other $3p$ electrons through $pd$ hybridization[3]. Then it may be reasonable to consider that the central sulfur atom in the straight bond S–S–S of thiothiophten is in a valency state capable of forming the $\sigma$ skeleton of bonds through the $pd$ hybridization. The expected valency state of the central sulfur atom would be in the electron configuration $3s^2 3p^3 3d$; one of $3p$'s, $3p_x$, hybridizes with a $3d$ orbital, going to make up the $\sigma$ bonds of S–S–S in the linear arrangement, and $3p_y$ is adopted to form a C–S $\sigma$ bond with one of $sp^2$ orbitals of the neighboring central carbon atom. These configurations can account for both the so-called abnormal length of the bond between two sulfur atoms[3-5] and the right angle of S–S–C with respect to the central sulfur atom. Thus it might be said that the full $\sigma$ skeleton of the condensed ring system of thiothiophten is composed of the bonds obtained above through the hybridization and other C–S and C–C bonds without introducing the no-bond resonance structure. Over this $\sigma$ ring system covers the $\pi$ electron conjugation system, in which the remaining $3p$ orbital, namely the $3p_z$ orbital participates. The electronic structure of thiothiophten can now be treated according to the usual LCAO approximation without considering the $\sigma$ skeleton.

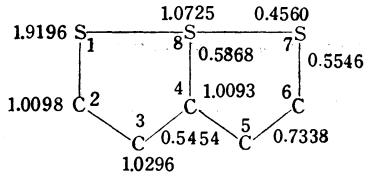

Fig. 1. Molecular diagram of thiothiophten.

In Fig. 1 are given the results obtained by the simple LCAO $\pi$ approximation on thiothiophten. In calculating the molecular diagram, the following assumptions were adopted: All the Coulomb intengrals were taken to be equal to the common value (so-called $\alpha_c$) except for two sulfur atoms $S_1$ and $S_7$ (see Fig. 1), for which a value less by $0.2\beta$ was applied, because the equivalent conjugation systems of thiothiophten in terms of valence bond method are liable to make the atoms positively charged[6]. Furthermore Longuet-Higgins' idea was employed for the two atoms[7]. With respect to the exchange integrals, the standard of the value, $\beta$ was used for all C–C bonds. For S–S and central C–S bonds were given the values $0.3\beta$ and $0.6\beta$, respectively, which are both found in the report of Giacometti and Rigatti[2]. The results given in Fig. 1 are those obtained when the exchange integral of C–S involving $S_1$ or $S_7$ bears the same value as that of C–C. The employment of the value is due to non-symmetrical character between the two bonds on the sulfur atom.

The results obtained in this paper are almost the same as those of Giacometti and Rigatti[2], but they are not necessarily the best. It must be noticed, however, that the results obtained without the help of no-bond resonance idea are appropriate at any rate, although many approximations were necessary in the calculation. The insufficient character of the results may be due to the inadequate values of parameters, which should be determined to predict correctly the values of the dipole moment and resonance energy[6]. Details will be further discussed in subsequent publications.

## *Hydration of Thujopsene to Widdrol*

By Shizuo NAGAHAMA

(Received August 18, 1960)

Hydration of thujopsene was first reported by Tanaka and Yamashita[1], who obtained an alcohol $C_{15}H_{26}O$, m. p. 120~122°C, $[\alpha]_D$+115.3° (yield 6%) under mild Bertram-Wahlbaum condition.

In the course of studies on the acid catalyzed isomerization of thujopsene, it was found that thujopsene gave another alcohol which was identified as widdrol by direct comparison with the sample obtained by Erdtman and Thomas[2].

A mixture of oxalic acid (50 g.), water (50 cc.), ethanol (600 cc.) and thujopsene (100 g.) was refluxed for 10 hr. The highest boiling fraction of the reaction products (b. p. 124~129°/5mmHg, 25 g.) solidified on standing and repeated recrystallization of this material from petroleum ether and sublimation under reduced pressure gave widdrol, m. p. 98°C, $[\alpha]_D$+105° (c=0.87), $C_{15}H_{26}O$ (Found: C, 81.02, H, 11.79%). The hydrocarbon fraction (b. p. 105~114°C/5 mmHg, 65 g.) was treated under the same condition as mentioned above and further 4 g. of crude widdrol was obtained. The hydrocarbon fraction (b. p. 104~111°C/5 mmHg, 41 g.) recovered from this reaction mixture underwent the same treatment further to give the product; b. p. 113~114°C/5mmHg, $n_D^{30}$ 1.5022, $d_4^{30}$ 0.9251, $[\alpha]_D$+22.2° (neat), I. R. bands 1638, 888 $cm^{-1}$ (17 g.).

The author wishes to express his gratitude to Professor H. Erdtman and Dr. C. Enzell for kind offer of the precious natural widdrol. He also appreciates the kind guidance of Professor S. Akiyoshi.

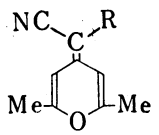
# *Non-benzenoid Aromatic Heterocycles. III*[1]. *Conversion of 4-Pyrone Derivatives into 4-Pyridone Derivatives*

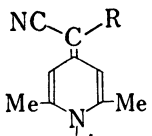
By Hiroshi KATO, Takatoshi OGAWA and Masaki OHTA

(Received August 20, 1960)



In the first paper of this series[2], the condensation of active methylene compounds with 2, 6-dimethyl-4-pyrone has been reported. In the present communication, the action of amines on these condensation products is described. These compounds are similar to pyrone in their electronic structure, and it is of interest to examine if these compounds are converted into the corresponding pyridone derivatives like pyrones. If the reaction takes place, it will be a valuable route to many pyridone derivatives. As model compounds, 4-(dicyanomethylene)-2, 6-dimethyl-4*H*-pyrane (Ia) and 4-(ethoxycarbonylcyanomethylene)-2, 6-dimethyl-4*H*-pyrane (Ib) were selected. With Ia, the reaction with amines (aniline, benzylamine, hydrazine hydrate) took place and gave the corresponding *N*-substituted 4-(dicyanomethylene)-2, 6-dimethyl-1, 4-dihydropyridines (IIa-c). As to the structure of the reaction product with hydrazine hydrate, two structures, IIc and III, are possible, but the *N*-aminopyridone structure (IIc) was established by condensing it with benzaldehyde to form the benzal derivative (IIg). Although Ia did not react with ammonium chloride, it was converted into pyridone derivative (IId) by heating it in formamide. Of special interest is IId, since it may be isomerized to pyridine derivative IV and would afford a valuable route to many pyridine derivatives*.

Starting from Ib, the corresponding pyridone derivatives (IIe, f) were prepared with benzylamine and hydrazine hydrate, but with aniline or formamide, the starting material was recovered unchanged. It may be worth while to note that the ester group of Ib did not suffer amminolysis.



An attempt to prepare 1-thiapyrone derivatives by treatment of Ia and Ib with potassium hydrosulfide was not successful.

## Experimental

**Reaction of Ia or Ib with Amines.**—**IIa,** A mixture of Ia (3.5 g.) and an excess of aniline (4 g.) was gently refluxed for an hour. The reaction mixture was washed with dil. hydrochloric acid and the residue (1.0 g., m. p. 310~313°C) was recrystallized from acetic acid giving white needles, m. p. 314~315°C. Yield 20%.

Found: N, 17.11. Calcd. for $C_{16}H_{13}N_3$: N, 16.99%.

Similarly, the following compounds were obtained:

**IIb,** (from Ia and benzylamine; heated at 150°C.) yellow needles (recrystallized from ethanol) m. p. 242~245°C. Yield 34%.

Found: N, 16.28. Calcd. for $C_{17}H_{15}N_3$: N, 16.08%.

**IIc** (from Ia and hydrazine hydrate; heated at 100°C) white needles (recrystallized from acetic acid) m. p. 291~292°C (decomp.) Yield 40%.

Found: N, 30.36. Calcd. for $C_{10}H_{10}N_4$: N, 30.09%.

**IIe,** (from Ib and benzylamine) white needles (recrystallized from ethanol) m. p. 183~184°C. Yield 80%.

Found: N, 9.15. Calcd. for $C_{19}H_{20}O_2N_2$: N, 9.09%.

**IIf,** (from Ib and hydrazine hydrate) pale yellow needles (recrystallized from ethanol) m. p. 217~218°C. Yield 71%.

Found: N, 17.70. Calcd. for $C_{12}H_{15}O_2N_3$: N, 18.02%.

**N-Benzalamino-4-(dicyanomethylene)-2,6-dimethyl-1,4-dihydropyridine (IIg),**—A solution of IIc (0.6 g.) and benzaldehyde (0.4 g.) in acetic acid was refluxed for an hour, and then diluted with water and the precipitate that separated out was collected (0.6 g., m. p, 254~255°C). Recrystallization from acetic acid afforded yellow needles, m. p. 294~295C°.

Found: C, 74.21; H, 5.25; N, 20.00. Calcd. for $C_{17}H_{14}N_4$: C, 74.43; H, 5.14; N, 20.43%.

**4-(Dicyanomethylene)-2,6-dimethyl-1,4-dihydropyridine (IId).**—A solution of Ia (5 g.) in formamide (5 g.) was heated at 150°C for an hour. The crystals which separated out on cooling were collected (1.7 g., m. p. 280~300°C) and recrystallized from formic acid giving yellow needles, m. p. 330~331°C.

Found: C, 70.37; H, 5.36; N, 24.44. Calcd. for $C_{10}H_9N_3$: C, 70.15; H, 5.30; N, 24.55%.

**Reaction of Potassium Hydrosulfide with Ia or Ib,**—When Ia or Ib was refluxed in methanol solution of potassium hydrosulfide, the starting material was recovred unchanged.

The authors are indebted to Mr. Asaji Kondo for performing the microanalyses.

# *Studies on Metal Complex Species Using an Anion Exchange Resin. I. Derivation of Equations and Application to Mercury(II)-Nitrate Complex*

By Hirohiko WAKI

(Received July 16, 1960)

A generalized equation for determining the composition of metal complex species was derived by introducing the complex formation equilibrium in the resin phase, which has not been considered formerly.

When most part of a metallic element exists in the form of $MX_m^{a-bm}$ in the solution phase and $MX_n^{a-bn}$ in the resin phase as a result of complex formation between the metal ion $M^{a+}$ and the anion $X^{b-}$, the following equation may be derived:

$$\log D = (n-a/b)\log[X^{b-}] - (m-a/b)\log(X^{b-}) + K + G \qquad (1)$$

where $D$ represents the distribution coefficient of the metallic element, ( ) and [ ] indicate the concentrations in the solution phase and the resin phase, respectively, and $K$ and $G$ the terms containing the complex formation constant and the activity coefficient in both phases. Under the condition in which $K$ and $G$ are constant,

$$\frac{d\{\log D+(m-a/b)\log(X^{b-})\}}{d\log[X^{b-}]}=n-a/b \quad (2)$$

$$\frac{d\{\log D-(n-a/b)\log[X^{b-}]\}}{d\log(X^{b-})}=-(m-a/b) \quad (3)$$

Accordingly, when $m$ is known and $D$, $(X^{b-})$ and $[X^{b-}]$ are measurable, $n$ can be determined graphically, and $m$ is also obtained when $n$ is known. Even if both are unknown, one of them can be determined when either $(X^{b-})$ or $[X^{b-}]$ is kept constant. Although it is practically impossible to set a condition in which the activity coefficient term is strictly constant, that may be roughly realized when a small quantity of the metallic element is used and the ionic strengths in the two phases are each kept constant by the addition of an indifferent anion, and therefore the complex form may be determined through measurements in the range where the predominant anionic species is $X^{b-}$.

As an application of these equations, adsorption of mercury(II) from a sodium nitrate solution was studied by means of $NaNO_3+NaClO_4$ mixed medium, where $Hg^{2+}$ was employed as $M^{a+}$, $NO_3^-$ as $X^{b-}$ and $ClO_4^-$ as an additional anion. Assuming that mercury is present as $Hg^{2+}$ in a sodium nitrate solution acidified by nitric acid, Eq. 1 is obtained simplified as follows:

$$\log D-2\log(NO_3^-)=(n-2)\log[NO_3^-]+K+G \quad (4)$$

The experiment was carried out by equilibrating 2 g. of an anion exchanger "Dowex 1-X8" (100~200 mesh) of nitrate form with a mixed solution containing 0.1 millimole of mercury(II) nitrate, 0.5 millimole of nitric acid, and a series of mixtures $NaNO_3+NaClO_4$ of various mixing ratios (total concentration is 3 M or 5M), followed by determination of mercury in the solution and nitrate in the resin. Mercury in the resin and nitrate in the solution were determined by subtraction since their total amounts are known. The distribution coefficient of mercury was calculated as

$$D=\frac{\left(\begin{matrix}\text{millimole of Hg adsorbed per}\\ \text{milliequivalent of resin}\end{matrix}\right)}{\left(\begin{matrix}\text{millimole of Hg per}\\ \text{milliliter of solution}\end{matrix}\right)}$$

The ion concentrations in the resin phase were always represented as millimole of the ion per milliequivalent of the resin.

$\log D-2\log(NO_3^-)$ was plotted against logarithm of the nitrate ion concentration in the resin, as shown in Fig. 1. The curves show linearity and their slopes correspond to $n=3.8$ for both cases of 3 M and 5 M of the external total concentration. Accordingly, it may be recognized that most mercury(II) is adsorbed in the form of $Hg(NO_3)_4^{2-}$ from the acidified 3~5 M sodium nitrate solution.

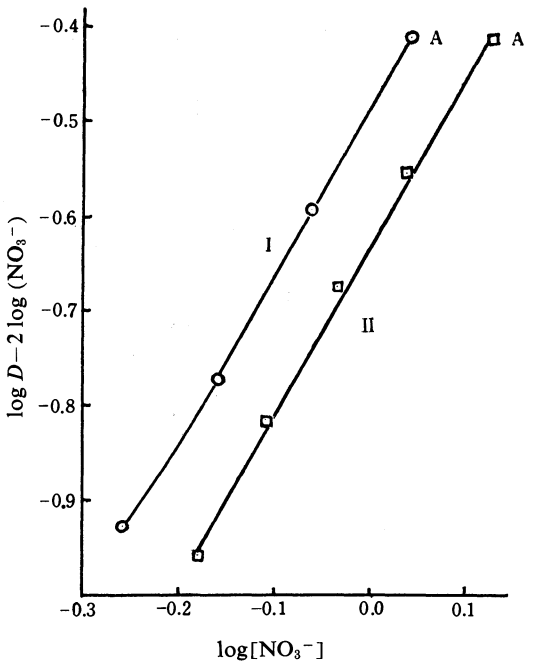

Fig. 1. Distribution coeficient of Hg(II) as a function of the nitrate concentration in the resin phase.
The measurements were carried out at the nitrate-rich range. A is the point in the absence of perchlorate.
I. Total concentration of the external solution is 3 M
II. 〃 5 M

It may also be possible that the lower complex species, such as $Hg(NO_3)^+$ or $Hg(NO_3)_2^0$, exist in the solution. However, since the degree of change in nitrate concentration in the solution phase was much smaller than that in distribution coefficient, the change of the second term on the right side in Eq. 1 may slightly affect the conclusion. Details of this investigation will be reported later.

The author wishes to express his sincere thanks to Professor J. Yoshimura of Kyushu University for his suggestion and encouragement.

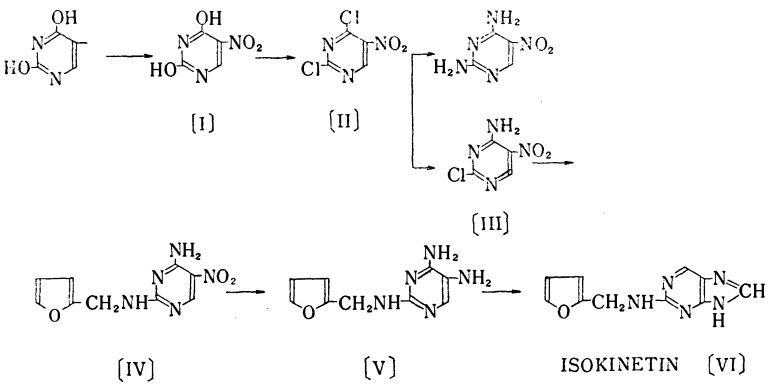
## *Synthesis of Isokinetin, 2-N-furfurylaminopurine and its Leaf-growth Activity (Studies of Isokinetin and its Analogs. Part I)*

By F. Shigeo OKUMURA, Hiroshi KUSAKA and Tetsuji TAKEMATSU

(Received July 11, 1960)

More than fifty kinetin-analogs which belong to 6-(*N*-substituted)-aminopurine, have been prepared and it was found[1] that some of them have a leaf-growth stimulating activity. During the course of this study, our interest was directed to investigate whether the leaf-growth activity is still retained after the furfurylamino group at 6-position of the purine ring migrates to the 2-position.

After making many unsuccessful attempts to synthesize 2-(*N*-furfuryl)-aminopurine, we succeeded in preparing this new compound by the process outlined in Fig. 1.



Nitration of uracil with fuming nitric acid gave 2, 6-dihydroxy-5-nitropyrimidine (I) in 90.7% yield, m. p. 294~295°C (Found: N, 26.70. Calcd. for $C_4H_3N_3O_4$: N, 26.75%). This was chlorinated with phosphoroxychloride in the presence of dimethylaniline to give 2, 6-dichloro-5-nitro-pyrimidine (II) in 64% yield.

Amination of II by ammonia in methanol-ether solution gives the mixture of 2, 6-diamino-5-nitro-pyrimidine and 2-chloro-6-amino-5-nitro-pyrimidine (III). However, III can be obtained in 60% yield when amination takes place at low temperature (below 0°C), m. p. of III, 220~221°C, Found: N, 31.95. Calcd. for $C_4H_3N_4O_2Cl$: N, 32.10%. III was then converted into 2-furfurylamino-6-amino-5-nitropyrimidine (IV) in 69.7% yield by refluxing with furfurylamine for 3~4 hr. (m. p, 159~160°C, Found: N, 29.50. Calcd. for $C_9H_9N_5O_3$: N, 29.76%).

IV was finally reduced catalytically with Raney nickel in methanol to give 2-furfuryl-amino-4, 5-diaminopyrimidine (V) which was refluxed with formamide yielding 2-(*N*-furfuryl)-aminopurine (VI) in 24% yield. Tan-colored needle from absolute alcohol, m. p. 195~196°C, (Found: C, 55.88; H, 4.01; N, 32.55. Calcd. for $C_{10}H_9N_5O$: C, 55.55; H, 4.67; N, 32.37%). The ultraviolet spectrum of isokinetin showed almost the same absorption as that of kinetin.

The leaf-growth activity of isokinetin was compared with that of kinetin by using *Rhaphanus cotyledon* by the Takematsu method[2]. The 200 mg./1. solution of kinetin or isokinetin was sprayed by using 0.4 ml. microsprayer on both sides of *Rhaphanus cotyledon*, which was cultured on the sand for 4 days at 15~18°C after coming out the *cotyledon* of *Rhaphanus sativa*. The increase of the leaf-area was measured 5 days after spraying. Isokinetin stimulates leaf-growth, but activity was observed to be about 80% of that of kinetin.

Okumura and Kuraishi[3] observed that kinetin inhibits the growth of the root of *Brassica chinensis L var. amplexicaulis Makino* at the concentration of $10^{-3}$mg./l. In the present communication we have observed the same inhibiting action of both kinetin and isokinetin against the growth of roots of *Rhaphanus sativa* and *Brassica juncea*. Kinetin inhibited the growth of roots remarkably, even in the concentration of 5mg./1. but the inhibiting action of isokinetin was observed only at the concentration of 50 mg./1. or higher. As gibberelline and indol acetic acid has no inhibitory

3) Unpublished work.

effect against the growth of plant roots, this inhibiting action is specific for the kinetin and isokinetin groups.

From the above observation it is clear that there are some interesting relationships between the leaf-growth and root-inhibition among the kinetin and isokinetin groups. Concerning this aspect, further studies are now in progress.

# *Studies on the Mucilage of the Root of "Tororo-aoi" (Abelmoschus manihot, MEDIC). I. On the Characteristic Colloidal Nature of the Mucilage*

By Saburo INOKAWA

(Received January 22, 1960)

Japanese hand-made paper, as is well known, is very elegant and refined, strong and tenacious, and is considered as a piece of work of Japanese characteristic arts. It is said that its elegance and strength mainly depend upon the properties of "*Neri*" which is indispensable for making Japanese hand-made paper.

"*Neri*" is a plant mucilage, and the mucilage obtained from the root of "*Tororo-aoi*" (*Abelmoschus manihot*, MEDIC) is most widely used. The chemical constituent of this plant mucilage was first investigated by Ozawa[1], and later Oguri[2] studied its distribution in cellular tissue. Oguri et al.[3,4], Machida et al.[5], and Oshibuchi et al.[6] reported that this plant mucilage was mainly made of polyrhamnogalacturonide, which contained rhamnose and galacturonic acid in the ratio of 1 : 1 or 1 : 2, and was accompanied by small quantities of araban, xylan, galactosan, and glucosan. However, concerning the colloidal behavior of this plant mucilage, little work has been done[7,8]. Taking an interest in this mucilage, we have been studying it for several years[9-13]. In this paper, such a purification method in which colloidal characteristics are kept well, was studied and then some colloidal characteristics of the purified mucilage were observed.

## Experimental

**Material.** — Roots of "*Tororo-aoi*" were stored in 0.5% formalin.

**Crude Mucilage.**—The roots were washed with water, ground with a hammer, extracted with distillated water at 0°C for 24 hrs. and the extracted mucilage was filtered through a piece of cotton cloth.

**Viscosity.**—Viscosity determinations were carried out at 20°C by an Ostwald viscometer.

**Intrinsic Viscosity.** — Intrinsic viscosity determinations were carried out at 20°C in 1% sodium chloride solution.

**Spinnability.**—Spinnability was expressed by the maximum length (cm.) of the mucilage threads spun by a rod (7 mm. diameter) raised out of the mucilage. The determinations were carried out at 20°C and the velocity of the ascending of a testing rod was controlled at 4 cm./sec.

**Filterability.** — Filterability means the rate of clogging up a filter paper. The determinations were carried out at 20°C as follows. A filter paper was fitted at the end of a glass cylinder (500 cc.) as in Fig. 1. a) Five hundred cc. of distilled water were poured into the cylinder and the times to filter 100 cc., 200 cc., 300 cc. and 400 cc. of water were measured (respectively, $t_1$, $t_2$, $t_3$ and $t_4$ sec.). b) Five hundred cc. of mucilage were poured into the cylinder, 400 cc. of the mucilage were filtered, and the residual mucilage (100 cc.) was discarded. c) Again, 500 cc. of distillated water were poured into the cylinder, and the times to filter 100 cc., 200 cc., 300 cc. and 400 cc. of water were measured (respectively, $T_1$, $T_2$, $T_3$ and $T_4$ sec.). Mean values of $T_1/t_1$, $T_2/t_2$, $T_3/t_3$ and $T_4/t_4$ are indicated as values for filterability.

**Elasticity.**—Elasticity determinations were carried out at 30°C by Schwedoff's method[14].

## Results and Discussion

**Effect of Heat Treatment on Spinnability, Filterability, Elasticity, and Viscosity, of the Mucilage.**—Although spinnability, filterability, elasticity, and viscosity, of the crude mucilage were considerably large, spinnability, filterability, and elasticity decrease very rapidly by heating at 80°C, as shown in Fig. 2. These are the characteristic properties of the mucilage.

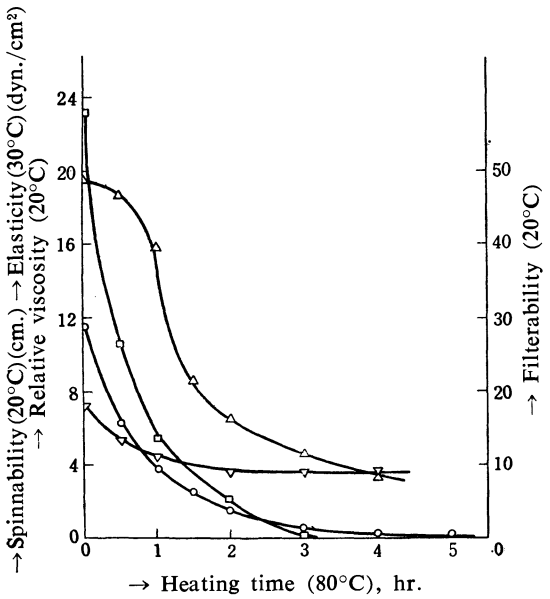

Fig. 2. Effect of heat treatment on the crude mucilage. Concentration of mucilage: 0.20%; $3.2\times10^{-5}$% (filterability).
○, Spinnability △, Filterability
□, Elasticity ▽, Relative viscosity

**Effect of Mixer Treatment on Spinnability, Filterability, Elasticity, and Viscosity, of the Mucilage.**—The crude mucilage in the original state was difficult to filter through a filter paper, but by homogenizing with a mixer, it was made easily filterable. Starch and other impurities contained in the crude mucilage could be removed by the filtration. The change of colloidal properties by mixer treatment is shown in Fig. 3. The spinnability and filterability almost disappeared by mixer treatment but the high elasticity remained. However, the high elasticity decreased considerably by heating or by longer standing in the similar way to that of the crude mucilage. The viscosity decreased rapidly also in the first 1 hr. of heating, the initial rapid fall being followed by a further slow reduction. The white precipitates obtained by the addition of alcohol-ether (8:2) mixture to the mucilage, were composed mainly of rhamnose and galacturonic acid and the mucilage prepared by redissolving the precipitates in water, had nearly equal elasticity to the original mucilage treated by a mixer. The mucilage thus obtained was used in subsequent studies as purified mucilage.

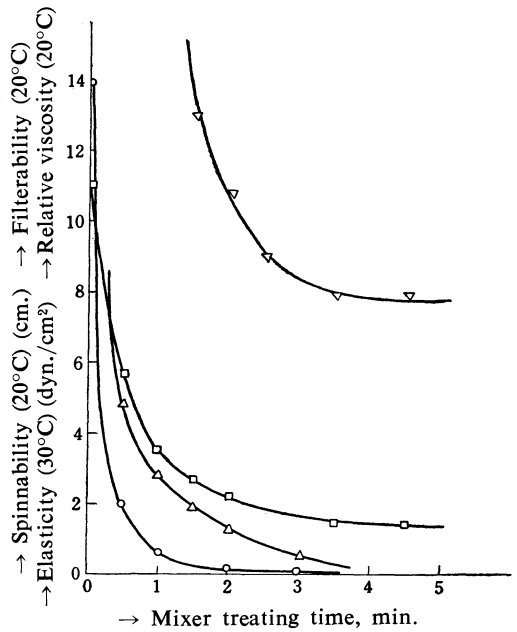

Fig. 3. Effect of mixer treatment on the crude mucilage. Concentration of mucilage: 0.16%; $1.1\times10^{-5}$% (filterability).
○, Spinnability △, Filterability
□, Elasticity ▽, Relative viscosity

**Effect of Heat Treatment on Elasticity and Intrinsic Viscosity of the Purified Mucilage.**—By heating at 80°C for varying periods of time, the elasticity of the purified mucilage fell down very rapidly to nearly zero. The intrinsic viscosity decreased rapidly in the first 30 min. of heating, the initial rapid fall being followed

14) Th. Schwedoff, *J. de Phys.*, [2] 8, 341 (1889).

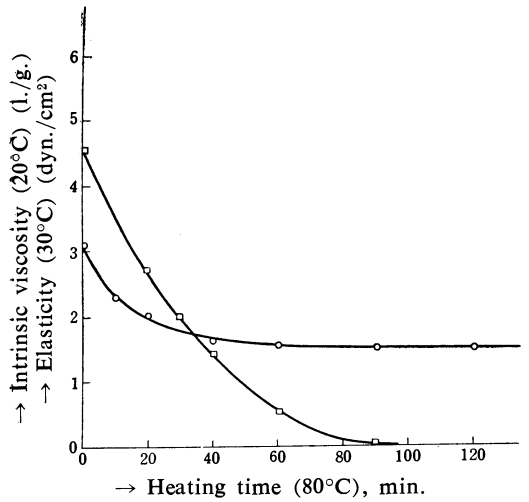

Fig. 4. Effect of heat treatment on the purified mucilage. Concentration of mucilage: 0.37%.
○, Intrinsic viscosity (in 1% NaCl solution)
□, Elasticity

by a slow reduction over a period of some hours as shown in Fig. 4. It seems that the fall of the elasticity does not always depend upon degradation of molecules of the mucin.

**Effect of Electrolytic Groups in the Mucin on Elasticity of the Purified Mucilage.** — 1) Effect of sodium chloride, calcium chloride, disodium ethylenediaminetetraacetate, and sodium oxalate on the elasticity of the purified mucilage was observed (Fig. 5). The elasticity

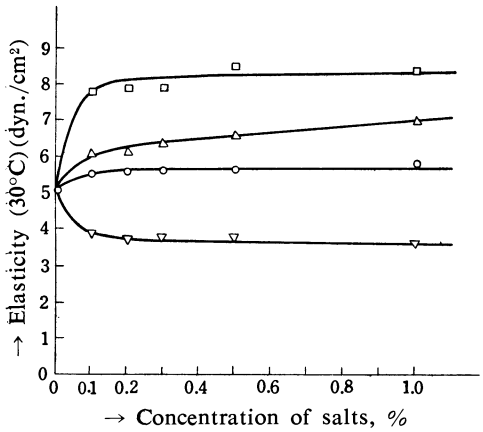

Fig. 5. Effect of addition of salts on the elasticity of the purified mucilage. Concentration of mucilage: 0.37%
○, Sodium chloride
△, Disodium ethylenediaminetetraacetate
□, Sodium oxalate ▽, Calcium chloride

was hardly influenced at all by the addition of sodium chloride, but increased by the addition of disodium ethylenediaminetetraacetate and sodium oxalate which are able to interchange calcium (about 40%) contained in ash of the mucilage, with sodium, and decreased by the addition of calcium chloride. 2) Electrodialysis experiments were carried out. By electrodialysis of the purified mucilage, pH of the mucilage changed from 6.1 to 2.9 and the value for the elasticity of 0.35% mucilage changed from 4.3 (dyn./cm²) to 10 (dyn./cm²). The change of the elasticity of the electrodialyzed mucilage is plotted against the change of pH with the addition of sodium carbonate in Fig. 6. The addition of calcium oxide to

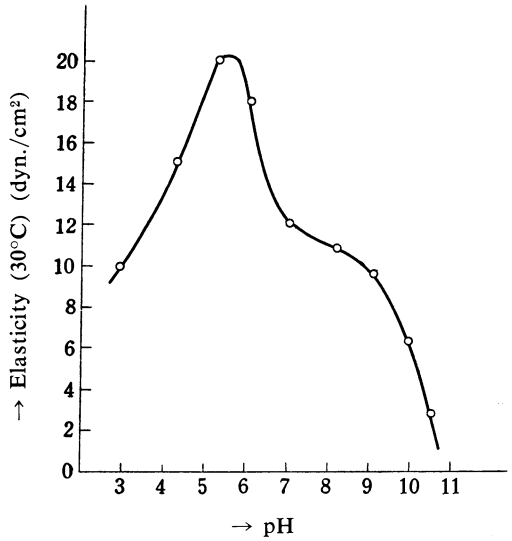

Fig. 6. Effect of pH on the elasticity of the electrodialyzed mucilage. Concentration of mucilage: 0.35%

the electrodialyzed mucilage always decreased the elasticity and at pH 4.2, the value for the elasticity fell to 4.2 (dyn./cm²). From results of above two experiments, it is considered that electrolytic groups in the mucin have effect on the elasticity but are not a major cause for the elasticity.

## Summary

1) The crude mucilage could be filtered after homogenizing by a mixer. By the addition of alcohol-ether mixture to the filtrate, the precipitates were obtained, which gave purified mucilage on redissolving in water.

2) The purified mucilage had noticeable elasticity and could be used for the research work instead of crude mucilage.

3) Some colloidal behavior of the purified mucilage was observed.

The author wishes to express his hearty thanks to Professor R. Goto, Kyoto University,

# *Studies on the Mucilage of the Root of "Tororo-aoi" (Abelmoschus manihot, MEDIC). II. Effect of Heating on the Colloidal Characteristics of the Mucilage*

By Saburo INOKAWA

(Received February 16, 1960)

In the previous paper[1] it has been shown that the elasticity, spinnability, and filterability of the crude mucilage and the elasticity of the purified mucilage decreased remarkably by heating at 80°C for 1~3 hr. Taking an interest in this characteristic of the mucilage, the present investigation was undertaken in order to observe the effect of heating on the mucilage by electron micrography, sedimentation in an ultracentrifuge, and electrophoresis.

## Experimental

**Material.**—Roots of "*Tororo-aoi*" were stored in 0.5% formalin.

**Crude Mucilage and Purified Mucilage.**—These preparations were similar to those described in the previous paper[1].

**Electron Microscope.**—The sample mucilage was mounted on a specimen holder for electron microscopy with a formvar supporting-fiim and dried. After chromium-shadowing the specimen was observed by an electron microscope of the type Shimadzu SM-T4.

**Ultracentrifuge.**—Sedimentation diagrams of an approximately 0.4% solution of mucilage in the presence of a 0.7% sodium chloride were taken by an ultracentrifuge of the type Spinco E under the centrifugal force of 259700 ***g*** at speed of 59780 r. p. m..

**Electrophoresis.**—Electrophoresis patterns of an approximately 0.3% solution of mucilage in a phosphate and sodium chloride buffer of ionic strength 0.02 and 0.18 respectively, were taken by a Tiselius electrophoresis apparatus of the type Hitachi HT-B.

**Elasticity and Intrinsic Viscosity.**—These determinations were the same as those described in the previous paper[1].

## Results and Discussion

**Observations from Electron Micrographs.**—The microscopic observation of network structure, which appears by the addition of methylene blue solution to the crude mucilage, is reported[2]; but the structure has been presumed[3] not to exist originally in the mucilage

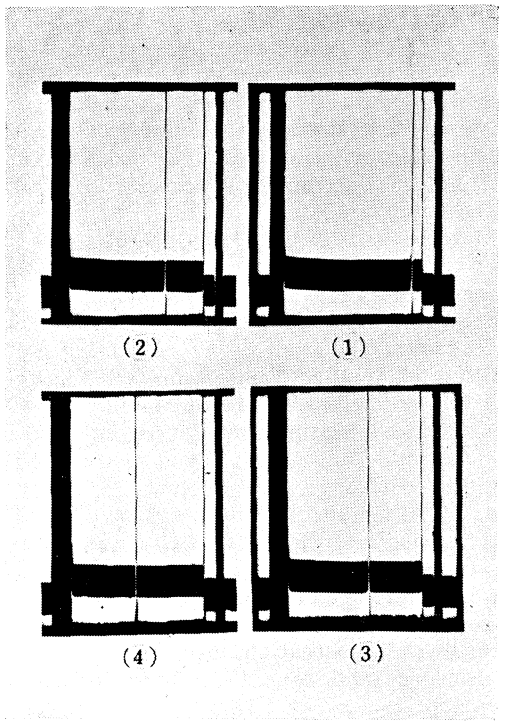

Fig. 3. Sedimentation diagram of the purified fresh mucilage in 0.7% NaCl solution. Speed 59700 r. p. m.; approximate concentration 0.4%; times for each measurement, 16 (1), 90 (2), 112 (3) and 144 (4) min. after reaching full speed.

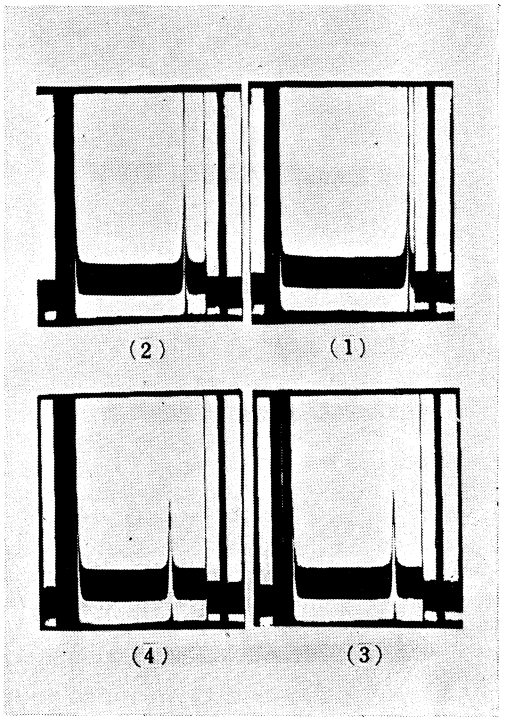

Fig. 4. Sedimentation diagram of the mucilage heated at 80°C for 2 hr. in 0.7% NaCl solution. Speed 59700 r.p.m.; Approximate concentration 0.4%; times for each measurement, 16 (1), 56 (2), 80 (3) and 104 (4) min. after reaching full speed.

but to be formed by an aggregation of composing substances by the addition of the reagent. The present writer has observed that the electron micrograph of the crude mucilage showed a typical network structure as shown in Fig. 1, which by heating at 80°C for 2 hr., was broken to a granular structure as shown in Fig. 2.

**Observation from Sedimentation Diagrams in an Ultracentrifuge.**—Sedimentation diagrams of the purified fresh mucilage and the mucilage heated at 80°C for 2 hr. are shown in Fig. 3 and in Fig. 4 respectively. The shape of the initial strikingly sharp boundary, as a line, of the fresh mucilage, remained perfectly unchanged through sedimentation. The sedimentation boundary of the heated mucilage was also very sharp, but a little spreading of the boundary occurred with the elapse of time. From Figs. 3 and 4 it may be considered that in the fresh mucilage, a network built by a very strong interaction between the mucin molecular chains moves as a whole under the influence of the centrifugal field, and the considerable weakening of the intermolecular force between chains occurs by heat treatment[4].

**Observation from Electrophoresis Patterns.**—Electrophoresis patterns of the purified fresh mucilage and the mucilage heated at 80°C for 2 hr. are shown in Fig. 5 and in Fig. 6, respectively. The initial strikingly sharp ascending pattern[5] of the fresh mucilage remained unchanged through electrophoresis similar to the

TABLE I. RELATIONS BETWEEN pH AND MOBILITY AT 0°C IN PHOSPHATE AND NaCl BUFFER OF IONIC STRENGTH 0.02 AND 0.18

| | pH | 2.1 | 5.3 | 6.9 | 9.6 |
|---|---|---|---|---|---|
| Mobility | Purified fresh mucilage | $1.1\times10^{-5}$ | $1.2\times10^{-4}$ | $1.3\times10^{-4}$ | $2.2\times10^{-5}$ |
| ($cm^2$/sec. V.) | Heated mucilage | $3.0\times10^{-5}$ | $2.6\times10^{-4}$ | $2.4\times10^{-4}$ | $5.0\times10^{-5}$ |

4) In the heated mucilage it was observed that there was something which sedimented rapidly in the initial few minits.

5) The pronounced boundary disturbance in the descending boundary was caused by the adhering of the mucilage on the electrophoresis cell-wall.

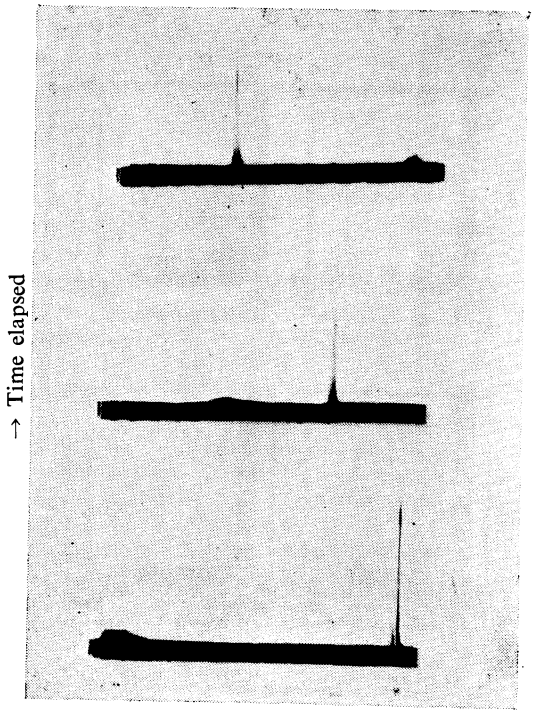

Fig. 5. Electrophoresis pattern of the purified mucilage. Approximate concentration 0.3%; phosphate-NaCl buffer; pH 6.5.

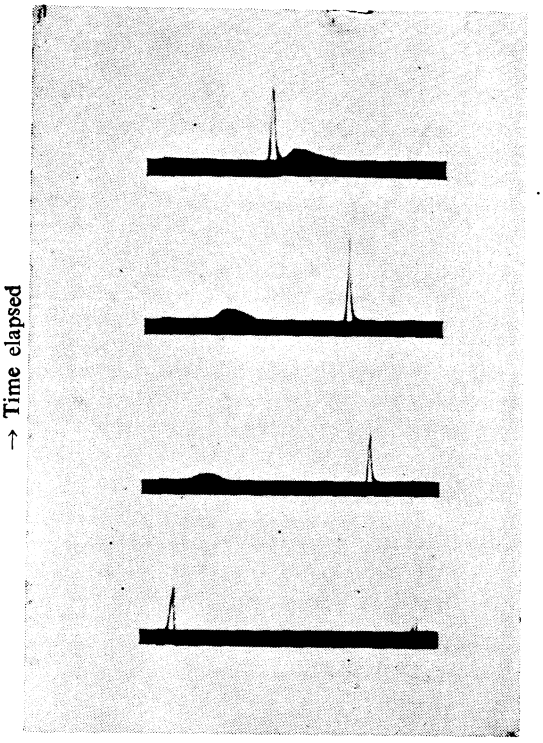

Fig. 6. Electrophoresis pattern of the mucilage heated at 80°C for 2 hr. Approximate concentration 0.3%; phosphate-NaCl buffer; pH 6.5.

centrifugal boundary (Fig. 4). The ascending pattern of the heated mucilage became somewhat broader as time went by. From Figs. 5 and 6 it may also be considered that there exists a very strong interaction between the mucin molecular chains in the fresh mucilage, and that the interaction decreases considerably by heating.

Measurements of the electrophoresis patterns over pH 2.1~9.6 were carried out without observing any change of the shape, and the relations between pH and mobility are tabulated in Table I.

**Effect of Heating Temperature on Elasticity and Intrinsic Viscosity of the Mucilage.**—Relations between heating temperature and decrease of elasticity and intrinsic viscosity of the purified mucilage were observed at heating time of 30, 60 and 90 min. as shown in Fig. 7. The decrease of the elasticity was gradual up to approximately 50°C and then sharp at the higher temperature, but that of intrinsic viscosity was nearly constant. The results seem to indicate that the decrease of elasticity by heating is not caused simply by degradation of mucin molecules. This is also supported by the previous experimental results[6] that

6) S. Inokawa, R. Goto and I. Morimoto, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 783 (1960).

there was no considerable difference in molecular weight between the fresh and the heated mucilage.

**Summary**

1) From electron micrographs it was observed that in the crude mucilage there exists a network structure, but its structure is broken by heating.

2) From sedimentation diagrams and electrophoresis patterns it seems reasonable to assume that in the purified fresh mucilage there exist very strong intermolecular forces like those in gel and these forces decrease markedly by heating.

3) It is conceivable that the degradation of the mucin macromolecule does not play an important role in the marked decrease of the elasticity of the purified fresh mucilage by heating.

Finally the writer wishes to express his hearty thanks to Professor R. Goto, Kyoto University, for his invaluable advice and encouragement throughout this work. He is also indebted to Professor E. Suito and Dr. K. Takiyama of Kyoto University for their help in taking the electron micrographs, to Dr. K. Fukai of Osaka University for taking the sedimentation photographs, to Professor S. Tanaka of Kyoto University for his help in taking electrophoresis photographs. It is also a pleasure to thank Koshin Kogyo Co. for their generous supply of the root of "*Tororo-aoi*".

# *Glass Transition of Coal*

By Yuzō SANADA, Naoyuki MOCHIDA and Hidemasa HONDA

(Received September 29, 1959)

The study of mechanical or thermal properties of coal on heating is of great importance in structural investigation and industrial problems. It is well known that coals, especially caking or coking coals, have a polymeric character, and show plastic deformation at room temperature[1] and softening or flow phenomena on heating.[2] It appears, however, that very few detailed investigations on the change of mechanical or thermal properties of coals heated over the range from room temperature to the softening point have yet been made. D. H. Bangham and R. E. Franklin[3] measured the thermal expansion coefficient of three bright coals. They showed that coals have a gradual increase in the thermal expansion coefficient over the range from room temperature to about 300°C. The present authors have measured the change of hardness and volume for several vitrains of every rank over the range from room temperature to about 160°C by using two distinct hardness methods and one dilatometric method, and have found that coals have a few characteristic points over this temperature range.

2) D. W. van Krevelen and J. Schuyer, loc. cit. p. 286.
3) D. H. Bangham and R. E. Franklin, *Trans. Faraday Soc.*, **42B**, 289 (1946).

## Experimental Procedure

**Indentation Hardness Method.**—Coal specimens about 1 cm. wide and 5 cm. long, and about of 2 cm. thick parallel plane were cut perpendicular to the bedding planes, using a motor-driven diamond cutter. One plane of surface perpendicular to the bedding planes of the specimen was highly polished by using glass plates with carborundum and alumina, and woollen cloth with alumina. The specimens were air-dried at room temperature and ordinary humidity.

Fig. 1 shows the experimental apparatus which modified the Akashi micro-hardness tester having a diamond Knoop indenter.[4] The coal specimen, of which the base and two long sides are covered with three electric heating plates settled in a vise, is placed on a steel table with a copper block cooled by water. The position of the vitrain layer can be adjusted by means of screws. The temperature of the vitrain layer is measured by a thermistor surface thermometer located very closely to the indenter and controlled by a suitable variable resistor. The coal specimen is heated at the heating rate of 1°C/min. over the range from room temperature to 160°C. The load of indenter is 100 g. and

4) H. Honda and Y. Sanada, *Fuel*, **36**, 403 (1957).

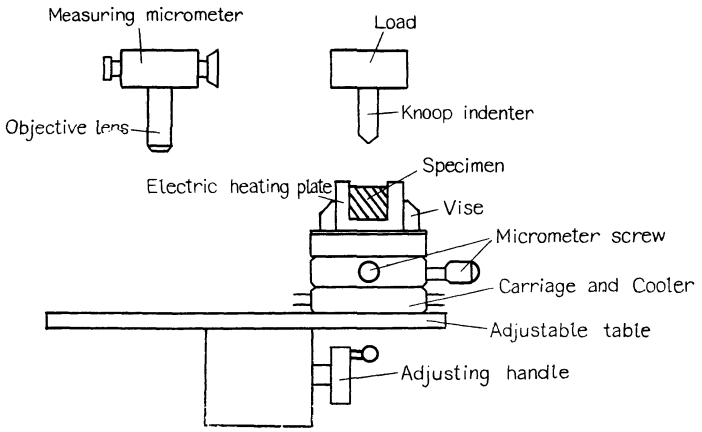

Fig. 1. Apparatus for the determination of the indentation hardness.

the time taken in the duration of the load is 30 sec. The hot impression under the elevated temperature is made every five minutes, i. e. every 5°C. After an impression has been made, the specimen is moved to a new position along the vitrain layer by means of the screw for the distance of 15/100 mm. After all impression have been completed, the furnace is cooled to room temperature and then Knoop hardness numbers are determined from the length of the long diagonal of indentation.

**Pendulum Hardness Method.** — The preparation of coal specimens, the heating method, the heating rate, and the measurements of temperature are the same as those in the case of indentation hardness test.

The apparatus of the pendulum hardness tester of Walker Steele type is given in Fig. 2. It consists of the wedge-type agate fulcrum, two brass arms with weights and a small mirror. The length between the weights at the ends of the arms of the pendulum is 20 cm. The weight of the pendulum is 78 g. The damping of the pendulum hardness tester on the vitrain layer of the specimens is determined by the lamp-and-scale method. The apparatus is held in an air-thermostat. The logarithmic decrement $\lambda$ of the pendulum is given by the following equation, provided that the periodic time is a constant :[5]

$$\lambda = (2.303 \log \theta/\theta')/2n$$

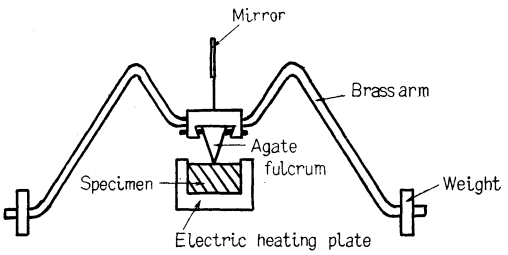

Fig. 2. Apparatus for the determination of the logarithmic decrement.

where $\theta$ and $\theta'$ are the angle from the position of rest, $n$ is the frequency of the pendulum between $\theta$ and $\theta'$. In this experiment, the chosen values of $\theta$ and $\theta'$ were 4° and 3°26′ respectively.

**Dilatometric Method.**—The coal specimen was pulverized to pass through a 30 and stand on a 60 Tyler mesh sieve. The vitrain, of specific gravity less than 1.30, was isolated by the float-or-sink method using mixtures of benzene and carbon tetrachloride. The volume change of vitrain with temperature was measured using a Pyrex glass

dilatometer following the modified Bekkedahl's method[6]. The dilatometer employed in the test is shown in Fig. 3. The dilatometer consists of the capillary tube, the sample holder and the mercury holder. The inner diameter and the length of the capillary tube are 1.5 mm. and about 70 cm. respectively. The inner diameter and the length of the sample holder are 15 mm. and about 13 cm. respectively. One end of the sample holder is left open at first. About 15 g. of the air-dried sample is weighed into the sample holder. A hollow glass bulb, of which the outer diameter is a little smaller than 15 mm. and of which the height is about 3 cm., is settled in the sample holder, and then the end of the sample holder is sealed up. This method makes it possible to avoid any heating of the sample during the sealing operation. Mercury is put in the mercury holder. The coal sample in the dilatometer is evacuated to $10^{-3}$ mmHg for 6 to 8 hr. at room temperature in order to remove gas and then the desired volume of mercury is filled through the capillary. The dilatometer is settled in a stirring liquid paraffin bath, whose temperature is controlled under the heating rate of 1°C/min. The measurements of the height of mercury in the capillary tube were made visually, usually once every minute, from room temperature to 160°C.

The accuracy of determination of the Knoop hardness number itself has already been described in detail.[4] The scatter of the results in this indentation hardness method depends upon the inhomogeneity of the vitrain layer and the temperature control. Though the pendulum hardness is used as a conventional method in the measurements of the glass transition point of high polymers, the scatter of the results in this method may also depend upon the inhomogeneity of vitrain, the temperature control, and the error in the reading of $n$. The dilatometric method is the most conventional and its experimental accuracy is most high in the measurements of the glass transition point of high polymers. The surface temperature of vitrain is easily measured and precisely detected within 1°C by the thermistor having a very small thermo-sensitive element.[7] When the load is applied to the indenter, the surface temperature of vitrain decreases instantaneously. The maximum instantaneous decrease of temperature was about 2°C over the range of 50 to 100°C and about 5°C over the range of 100 to 160°C. In general, the glass transition temperature obtained by the pendulum method is considerably higher than that obtained by the dilatometric method. But this discrepancy becomes smaller by using a wedge instead of two balls as the fulcrum of the pendulum.[8]

The characteristics of various vitrains used are listed in Table I.

## Results and Discussion

The relation between the Knoop hardness number, $H_K$, of air-dried coals and temperature is shown in Fig. 4. For brown coal, $H_K$

7) B. M. Zeffert and S. Hormas, *Anal. Chem.*, 21, 1420 (1949).
8) K. Sato and Y. Inoue, *Chem. High Polymers, Japan (Kobunshi Kagaku)*, 15, 421 (1958).

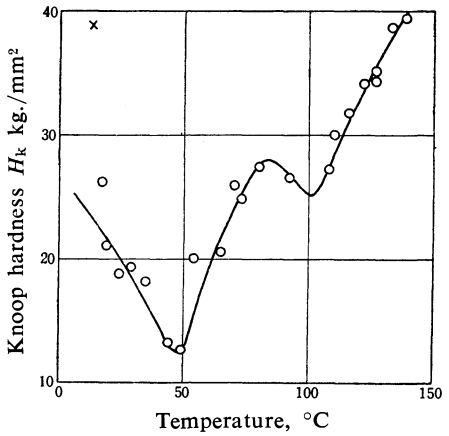

Fig. 4a. Variation of Knoop hardness with temperature for Nakagō brown coal (d. a. f. C=74.33%).

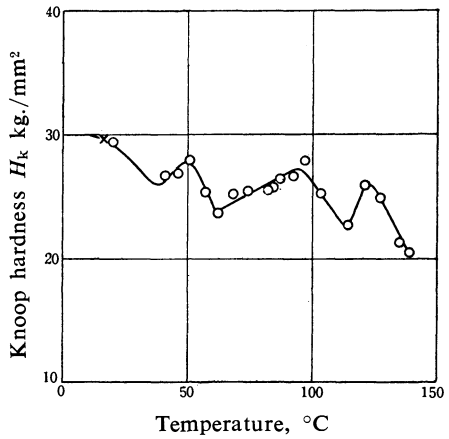

Fig. 4b. Variation of Knoop hardness with temperature for Yūbari coking coal (d. a. f. C=84.85%).

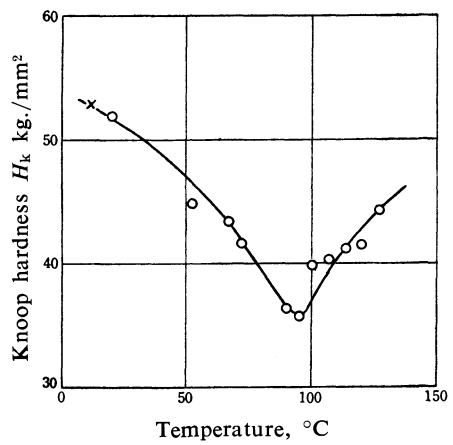

Fig. 4c. Variation of Knoop hardness with temperature for Hongei anthracite (d. a. f. C=93.02%).

decreases with temperature increase to a minimum at about 50°C, increases with temperature to a maximum, decreases again with temperature increase to a second minimum at about 100°C, and then increases with temperature. For bituminous coal $H_k$ shows three minimum values over the range from room temperature to 160°C. For anthracite $H_k$ decreases with temperature increase to a minimum at about 100°C, and then increases with temperature. The temperatures showing the minimum values of $H_k$ of various air-dried vitrains are listed in the first column of Table II. Namely, over this temperature range, air-dried brown coal, bituminous coal and anthracite have two, three and one characteristic points respectively.

After the specimens heated to about 160°C were allowed to cool in an ordinary atmosphere, the Knoop hardness of the specimens was again measured at room temperature. These values of $H_k$ at room temperature are shown by cross marks in Fig. 4. The values of $H_k$ of the cooled bituminous coal and anthracite coincide almost exactly with those of the non-heated original coals respectively. This shows that these coals do not change their chemical constitutions if heated over the range from room temperature to about 160°C. However the value of $H_k$ of the cooled brown coal is much higher than that of the non-heated original brown coal and the cooled brown coal has many tiny cracks on the surface. These phenomena may be attributed to the fact that some chemical reactions such as dehydration occur in the specimen of brown coal by heating over the range from room temperature to about 160°C, as if in the curing of thermosetting plastics, e. g. phenol-formaldehyde resin.

The relations between the logarithmic

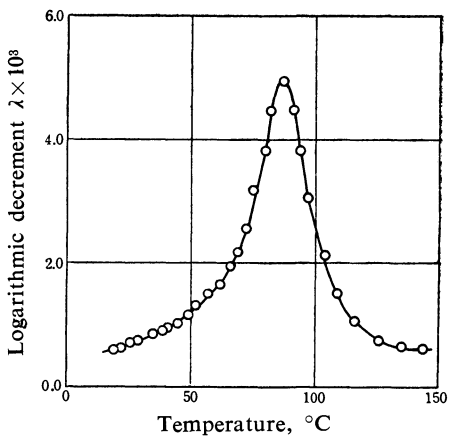

Fig. 5. Variation of logarithmic decrement with temperature for maleic acid-glycol-styrene resin.

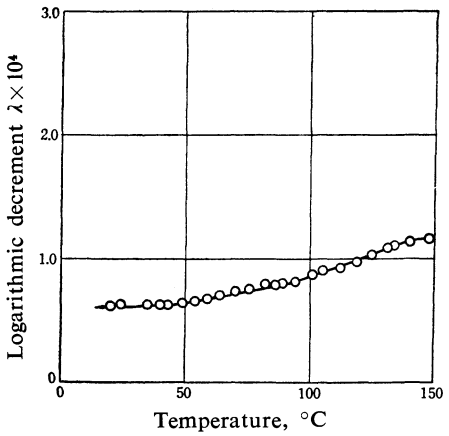

Fig. 6. Variation of logarithmic decrement with temperature for phenol-formaldehyde resin.

decrement, $\lambda$, of the pendulum on maleic acid-glycol-styrene resin, loosely cross-linked linear polymer, and phenol-formaldehyde resin (moulded C state), three-dimensional network polymer, and temperature are shown in Fig. 5 and Fig. 6 respectively. The value of $\lambda$ of maleic acid-glycol-styrene resin increases suddenly with temperature to a maximum at 87°C. Thereafter the value of $\lambda$ decreases suddenly with temperature increase and becomes almost the same at about 150°C as that of room temperature. This change of $\lambda$ with temperature shows a typical glass transition phenomenon of loosely cross-linked linear polymer. Further, the glass transition point of maleic acid-glycol-styrene resin is 87°C. On the other hand, the value of $\lambda$ of phenol-formaldehyde resin increases slowly with the temperature over the range from room temperature to 150°C and does not show a maximum. This change of $\lambda$ with temperature shows a character of three-dimensional network polymer.

The relation between the logarithmic decrement, $\lambda$, of the pendulum on air-dried coals and temperature is shown in Fig. 7. For brown coal $\lambda$ increases with temperature to a maximum at about 50°C, decreases with temperature increase to a minimum, increases again with temperature to a second maximum at about

100°C, and then decreases with temperature increase. For bituminous coal $\lambda$ shows three maximum values over the range from room temperature to 160°C. For anthracite $\lambda$ increases with temperature to a maximum at about 130°C and then decreases with temperature increase. The temperature showing the maximum values of $\lambda$ of various air-dried vitrains are listed in the second column of Table II. Over this temperature range, air-dried brown coal, bituminous coal and anthracite have two, three and one characteristic points respectively.

The relation between the reading of mercury height, $V$, in the glass capillary tube of dilatometer containing powdered maleic acid-glycol-styrene resin and temperature is shown in Fig. 8. The value of $V$ increases with temperature and shows a break at 77°C. This change of $V$ with temperature shows a typical glass transition phenomena of loosely cross-linked linear polymer. That is to say, the glass transition point of maleic acid-glycol-styrene resin obtained by the dilatometric method is 77°C and this value is slightly lower than that obtained by the pendulum method.

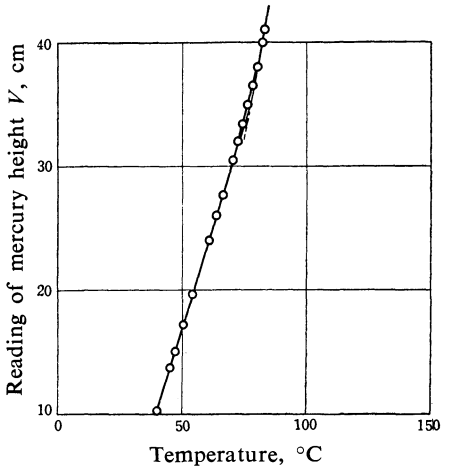

Fig. 8. Variation of reading of mercury height with temperature for maleic acid-glycol-styrene resin.

The relation between the reading of the mercury height, $V$, in the glass capillary tube of dilatometer containing air-dried powdered coals and heating temperature is shown in Fig. 9. As to brown coal $V$ increases suddenly at about 50°C and again at about 100°C. For bituminous coal the sudden increase of $V$ appears three times over the range from room temperature to 160°C, As for anthracite $V$ increases suddenly at about 120°C. The temperatures showing the breaks of $V$-temperature curve of various air-dried vitrains are listed in the third column in Table II. In this case too, the characteristic points of air-dried brown coal, bituminous coal and anthracite are two, three and one respectively.

In order to ensure whether the characteristic points, especially the one at about 100°C, are affected by moisture or combined water of coals or not, the $V$-temperature relations of the samples dried strongly at 130 to 140°C

in vacuo of $10^{-3}$ mmHg for 6 to 8 hr. have been measured using the dilatometer over the range from room temperature to 160°C. The characteristic points in this case are shown in the last column of Table II. For brown coal the break of $V$-temperature curve at about 50°C does not vanish but the one at about 100°C disappears. For bituminous coal the three breaks coincide almost exactly with those of the air-dried sample, though the third break of the strongly dried sample somewhat diminishes. For anthracite the break at about 100°C disappears. Therefore, the $V$-temperature

○ heating, ● cooling

curve of bituminous coal dried at room temperature in vacuo does not show the thermal hysterisis, though those of brown coal and anthracite dried at room temperature in vacuo have the thermal hysteresis as shown in Fig. 9, if heated coals are cooled under the cooling rate of 1°C/min.

The influence of moisture on the characteristic points is great in brown coal and anthracite, though it is almost negligible in bituminous coal. This may be attributed to the relation between internal surface area and the rank of coal.[9] On the other hand, the glass transition point of completely dried poly(vinylalcohol), one of the hydrophilic polymers, is 73°C. When the moisture content of the sample increases, this glass transition point shifts to a lower temperature and another transition point appears at a higher temperature.[10] Consequently it may be supposed that the effects of moisture on the characteristic points of brown coal are similar to those on the transition points of poly(vinylalcohol). The disappearance of the characteristic point at about 100°C in strongly dried anthracite may be attributed to the cross-linkages among the base units which anthracite has by nature.[11]

When amorphous polymers are heated, in general, they show a minimum of indentation hardness,[12] a maximum of logarithmic decrement of the pendulum[5], and a change of slope of volume-temperature curve[13] at the glass transition point or zone. Table II shows that

the temperatures showing minimum values of Knoop hardness, the temperatures showing maximum values of logarithmic decrement and the temperatures showing breaks of $V$-temperature curve of the air-dried vitrain roughly coincide with one another, though the hardness methods and the dilatometric method are independent respectively. Moreover, in the dilatometric method, the temperatures showing breaks of $V$-temperature curve of the strongly dried bituminous coal coincide almost exactly with those of the same air-dried sample and the temperature showing a break of $V$-temperature curve of the strongly dried brown coal also coincides with that of lower temperature of the same air-dried sample. Therefore it seems that these characteristic points, which are not constant but change with experimental time scale etc., are the glass transition points of coals (although D. H. Bangham and R. E. Franklin[3] did not detect them) over the range from room temperature to 160°C, though the influence of adsorbed water films can not be neglected at all.

In an investigation of microplasticity, D. H. Bangham and N. Berkowitz[14] measured the critical deformation force, $F_c$, at which the coal particles flowed to form a translucent film. They found that $F_c$ does not vary uniformly with temperature, but $F_c$ shows its maxima at 120, 200 and 300°C. Also they concluded that the undulating character of the curves representing the variation of $F_c$ with increasing temperature is associated with monolayer films adsorbed on the internal surface of the coal which are evaporated at specific temperatures; the maximum at 120°C, they relate to the loss of water vapor from the coal structure. Results similar to those of D. H. Bangham et al. were reported by C. Ellis[15] following an investigation by a similar method.

On the other hand, J. C. Macrae and A. R. Mitchell[16] studied the shapes of the curves relating failure stress to temperature for two bituminous coals and found that the maxima at 120 and 200°C are closely similar to those reported by both D. H. Bangham et al. and C. Ellis for the $F_c$, at which microplasticity is observable in particles of less than 30 $\mu$ in size. They, however, emphasized that it seems probable that heating to 120°C results in an increase of the failure stress by a mechanism in the nature of a strain relief in which an increased thermal vibration modifies the effect of weakness in the coal structure upon the failure stress and influence of adsorbed water films can not be considered to be wholly acceptable.

The authors' experimental results of bituminous coals may rather give support to the opinion of J. C. Macrae et al. than those of D. H. Bangham et al. and C. Ellis.

# *Self-consistent Field Molecular Orbital Treatment of Benzenium Ion for a Simplified Model of Hyperconjugation*

By Toshifumi MORITA

(Received December 16, 1959)

Electronic spectra of a number of aromatic carbonium ions were studied theoretically by several investigators[1]. In their explorating work which was greatly suggestive, Muller, Pickett and Mulliken[2] treated the benzenium ion by the simple LCAO MO method including self-consistent technique taking into account the variations of resonance integrals with interatomic distances and of Coulomb integrals with charge distributions. These authors as well as Morita[3,4], who tried to explain spectral shifts of the protonated methyl benzenes by

the methyl substituents, ignored the inter-electronic interaction. In explaining electronic spectra, the self-consistent field molecular orbital (SCF MO) treatment seems to be most satisfactory. Works going along this are those of Mackor et al.[5,6] However, hyperconjugation of the $H_2$–C bond of protonated aromatics was shut out of their computations. When hyperconjugation of the $H_2$ quasi-atom is taken into account, aromatic carbonium ions have odd numbered centers and belong to the so-called "strongly hyperconjugated" system, or system of "isovalent hyperconjugation"[2,7,8]. Morita[9] also indicated that basic properties of isomeric xylenes were interpreted considerably well in terms of hyperconjugation of the $H_2$–C bond in their protonated compounds. Owing to reasons mentioned above, it seems to be of great significance to carry out the SCF MO calculations, taking the hyperconjugative effect into consideration. However, even in the benzenium ion, the simplest of the aromatic carbonium ions, the SCF MO calculation is rather cumbersome and simplification of the model for computation of hyperconjugation may be desired. This paper contains simplification of the model for hyperconjugation in the semiempirical SCF LCAO MO method and discussion of importance of hyperconjugation deduced from the calculated results for the hyperconjugation model compared with those for the bond localization model of the benzenium ion, a prototype of the aromatic carbonium ions.

## A Model for Hyperconjugation in the Semi-empirical SCF MO Method

From the proton magnetic resonance absorption measurement of aromatic carbonium ions, MacLean, van der Waals and Mackor[10] showed that, when a bond was formed between a proton and a carbon atom in an aromatic hydrocarbon ring, valence state of the carbon atom attacked by a proton was altered from $sp^2$- to $sp^3$-hybridization. Accordingly, the configuration of the methylene group constructed at the position of proton attack should be tetrahedral. In a technique for the theory of hyperconjugation, however, it is customary, subject to Mulliken's original idea[11], to assume the $sp^2$-hybridized carbon atom and group orbitals of $H_2$, $\phi_1=2^{-1/2}(1+S)^{-1/2}(h_a+h_b)$ and $\phi_2=2^{-1/2}(1-S)^{-1/2}\times(h_a-h_b)$: ($h_a$, $h_b$: $1s$ orbital of hydrogen atoms a and b; $S$: overlap integral between H atoms). Of the two group orbitals $\phi_1$ and $\phi_2$, $\phi_1$ forms $\sigma$-bond and $\phi_2$ $\pi$-bond, the latter being in conjugation with the benzene ring. Aono[12], in his non-empirical SCF MO treatment of hyperconjugation in methylacetylene, replaced one of the $H_3$ group orbitals by the $2p\pi$ carbon orbital itself and assumed the distance between this orbital and the next carbon to be the same as the length of the C-H bond of the methyl group. We intend, however, in the following way, to treat the orbital $\phi_2$ in question as the quasi-$2p\pi$ orbital and to give a reasonable value of the distance between this quasi-$2p\pi$ and the next lying carbon $2p\pi$ orbitals.

In the SCF MO calculations, the quantities associated with the $\phi_2$ orbital, which embody its characteristics well, are its energy and the effective nuclear charge of $H_2^+$ core. The former determines the valence state ionization potential of the $H_2$ group and the latter contributes to the estimation of interelectronic Coulomb repulsion integrals. In consequence, the matter reduces to the estimation of these quantities. The energy of the $\phi_2$ orbital is calculated from

$$W(\phi_2)=\int \phi_2^* H \phi_2 d\tau \qquad (1)$$

using the Hartree-Fock type Hamiltonian,

$$H=T+U,\ U=-\frac{1}{r_a}-\frac{1}{r_b}+(\phi_1\phi_1 \mid -\frac{1}{2}(\phi_1 \mid \phi_1 \qquad (2)$$

where, $1/r_i$ is the operator showing the potential energy from the $i$'th hydrogen nucleus; $(\phi_1\phi_1 \mid$ and $(\phi_1 \mid \phi_1$ are respectively electronic Coulomb and exchange potential energy operators. $I(H_2)=-W(\phi_2)$ indicates the valence state ionization potential of the $H_2$ group. For the isoelectronic series of C, $N^+$ and $O^{++}$, the empirical relation between valence state ionization potentials ($I_\mu$) and effective nuclear charges ($Z_\mu$) determined using the Slater rule for $2p\pi$ orbitals is formulated by the use of energy values of appropriate valence state[13] and of the atomic spectroscopic data[14]. Knowledge of $I(H_2)$, hence, enables us to obtain the effective nuclear charge $Z(\phi_2)$ associated with the $\phi_2$ orbital. The $Z(\phi_2)$ value is also determined by the alternative method. Subject to Paoloni[15] an empirical relation exists between the nuclear effective charges obtained by the use of Slater rule and one center electronic Coulomb repulsion integrals, for the first row atoms, as follows:

$$(\mu\mu \mid \mu\mu)=3.29_4 Z_\mu \qquad (3)$$

The calculated value of one center Coulomb repulsion integral on the $\phi_2$ orbital, $(\phi_2\phi_2 \mid \phi_2\phi_2)$, allows us to estimate the value of the effective nuclear charge associated with the $\phi_2$ orbital by the use of Eq. 3.

15) L. Paoloni, *Nuovo Cimento*, **4**, 410 (1956).

The distance between the quasi-$2p\pi$ and the next lying carbon $2p\pi$ orbitals may be estimated in the following way. The interelectronic Coulomb integral between $\phi_2$ and the next lying carbon $2p\pi$ orbitals is evaluated legitimately by the equation[16] (cf. Fig. 1),

$$(\phi_2\phi_2 \mid 2p\pi C\, 2p\pi C) = [(aa \mid CC) - (ab \mid CC)]/(1-S) \quad (4)$$

The empirical formula indicating the same quantity may be formulated by the Pariser-Parr's method[17] using the value of the effective nuclear charge $Z(\phi_2)$ obtained by either $I_\mu \sim Z_\mu$ relation or Eq. 3, this being a functional relation of the distance $r(H_2\text{-}C)$ between $\phi_2$ and carbon $2p\pi$ orbitals. By putting the value obtained by Eq. 4 into this empirical formula, the distance $r(H_2\text{-}C)$ in question may be evaluated.

Core integral $\beta_{H_2-C}$ between $H_2$ and C can be obtained by the assumption of the proportionality relation,

$$\beta_{H_2-C}/\beta = S_{H_2-C}/S \quad (5)$$

where, $\beta$ is the core integral in benzene molecule; $S$ the overlap integral between two carbon $2p\pi$ orbitals separated by 1.39Å; $S_{H_2-C}$ the overlap integral between carbon $2p\pi$ and next lying $H_2$ quasi-$2p\pi$ orbitals.

As above mentioned, the role of the methylene in the SCF MO method may be understood in the simplified manner.

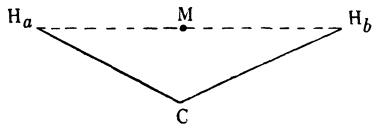

Fig. 1. Assumed geometrical structure of $CH_2$. $C\text{-}H_a = C\text{-}H_b = 1.071$ Å, $\angle H_aCH_b = 120°$.

In the actual calculation, geometrical structure of $C\text{-}H_2$ assumed is the same as that of ethylene by Gallaway and Barker[18] and is indicated in Fig. 1; $C\text{-}H_a = C\text{-}H_b = 1.071$Å, $H_aCH_b = 120°$. (Assumption of $\angle H_aCH_b = 109°28'$ does not seriously affect the calculated results). Semi-empirically calculated values of the quantities determining the model for hyperconjugation are shown in Table I. Although the procedure of this paper goes along the approximation including zero differential overlap by Pariser-Parr[19], or Pople[20], it is desirable to obtain $W(\phi_2)$ with moderate exactness. Indeed, the value calculated with neglect of differential overlap is $-11.834$ eV., and unsuitable for our purpose, if we remember the valence state ionization potential of the $2p\pi$ carbon is 11.54 eV. The value calculated with inclusion of differential overlap is $-11.176$ eV. and this value also may not be said to be appropriate. The moderate value, $-10.256$ eV., is obtained omitting the interelectronic Coulomb integral, $(ab \mid ab)$[21].

Using the value, 2.83, of the effective nuclear charge $Z(\phi_2)$, estimated from Eq. 3, the empirical formula of the interelectronic Coulomb integral $(H_2H_2 \mid CC)$ is obtained as follows,

$$(H_2H_2 \mid CC) = 10.203 - 2.4607r + 0.1933r^2 \quad (r \leqq 2.8A) \quad (6)$$

Substituting the value of $(\phi_2\phi_2 \mid 2p\pi C\, 2p\pi C)$ in the $C\text{-}H_2$ group calculated from Eq. 4 into Eq. 6, the distance $r(C\text{-}H_2)$ between quasi-$2p\pi$ and carbon $2p\pi$ orbitals in the $C\text{-}H_2$ group is estimated as 1.383 and 1.031 Å for the cases with and without differential overlap. (For the case with differential overlap, $r(H_2\text{-}C)$ is estimated to be 1.031 Å from somewhat different equation from Eq. 6 based on somewhat different value of $Z(\phi_2)$). It will be noticed here that when differential overlap is neglected Eq. 4 reduces to

$$(\phi_2\phi_2 \mid 2p\pi C\, 2p\pi C) = (aa \mid CC) \quad (7)$$

It is clear that this approximation 7 is too crude. It is desirable, therefore, to adopt for $r(H_2\text{-}C)$ the middle value between 1.031 and 1.383 Å.

We have performed calculations by the use of some assumed values of $r(H_2\text{-}C)$ between 1.031 and 1.383 Å, and, for $r(H_2\text{-}C) = 1.10$ Å, obtained satisfactory results in agreement with experimental observations. Hence, we describe below on the assumption of $r(H_2\text{-}C) = 1.10$Å. Table I indicates the semi-empirically fixed values of quantities determining the model of hyperconjugation for $C\text{-}H_2$ group (values on the last row of Table I are referred to in the next paragraph).

Somewhat larger value of the C-H distance than that usually accepted in aliphatic hydrocarbons is seen in some papers[22] published after our calculations have finished. Reasonable assumption of $r(H\text{-}C) = 1.11$Å based on these papers leads to $r(H_2\text{-}C) = 1.10$Å by the similar calculations with

| −10.256 | 9.326 | 2.83 | 7.73 | 1.10 |
| −10.373 | 9.214 | 2.80 | 7.73 | 1.10 |

zero differential overlap to those mentioned above. Values of quantities relating to hyperconjugation of C-$H_2$ group are listed on the last row of Table I, and these are almost identical with those mentioned in the preceding paragraph, hence leading to seriously unaffected results.

At any rate we assume for the orbital of $H_2$ group, which take part in hyperconjugation with the residual part of the molecule, the $2p\pi$ orbital, associated with the effective nuclear charge, 2.83, and standing at a distance, 1.10 Å, from the carbon $2p\pi$ orbital in the methylene group.

The SCF LCAO MO CI calculation for benzenium ion whose co-ordinate system and numbering are as indicated in Fig. 2, is carried out by means of Poples scheme[23] which is based on the theory of Roothaan[24] and combined with Pariser-Parr's approximation[17,19]. The technical procedure for computation is described elsewhere[23,25,26]. What should be stated here is that the core integral $H_{\mu\mu}$ is assumed as follows,

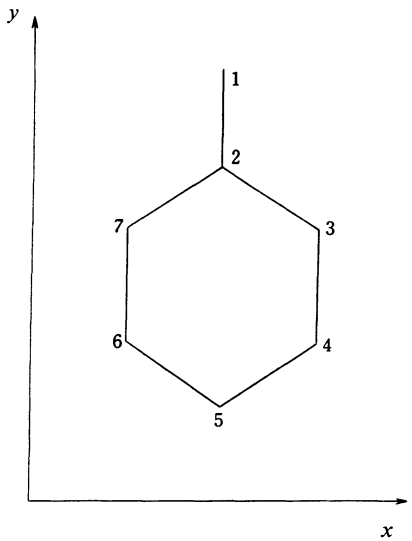

Fig. 2. Co-ordinate system and numbering of benzenium ion for computation.
$\overline{12}=1.10$ Å, $\overline{23}=\overline{34}=\cdots\cdots=\overline{72}=1.39$ Å

$$H_{\mu\mu}=U_{\mu\mu}-\sum_{\alpha(\neq\mu)}{}'(\mu \mid V_\alpha \mid \mu)$$
$$=U_{\mu\mu}-\sum_{\alpha(\neq\mu)}{}' Z_\alpha(\mu\mu \mid \alpha\alpha) \qquad (8)$$

where, $Z_\alpha$ is assumed to be unity.

The approximation of Eq. 8, which Sidman[27] also assumed, leads to that of Pariser and Parr[17,19].

The value of the core integral $\beta$ is taken to be −2.39 eV. except for $\beta_{H_2-C}$ which is estimated to be −4.111 eV. from Eq. 5. Values of valence state ionization potentials are taken from the tables of Skinner and Pritchard[13]. Values of electronic Coulomb repulsion integrals are evaluated using Pariser-Parr's approximations[17].

## Results and Discussion

**(a) Self-consistent Field Molecular Orbitals.** —SCF MO's calculated and expressed by the linear combination of atomic orbitals, $\chi_\mu$, for the models of hyperconjugation and bond localization are shown in Tables II (A) (hyperconjugation) and II (B) (bond localization), which include also the energies, $\varepsilon$, of MO's. The highest occupied molecular orbital is $\phi_3$ in each case and $-\varepsilon_3$ correspond to the ionization potential.

Table II. Calculated self-consistent field molecular orbitals and energies

(A) For the hyperconjugation model

$\varepsilon_1=-21.379$ eV. $\phi_1(1b_2)=0.500\chi_1+0.715\chi_2$
$+0.294(\chi_3+\chi_7)+0.151(\chi_4+\chi_6)+0.143\chi_5$
$\varepsilon_2=-18.381$ eV. $\phi_2(2b_2)=0.248\chi_1+0.239\chi_2$
$-0.103(\chi_3+\chi_7)-0.462(\chi_4+\chi_6)-0.658\chi_5$
$\varepsilon_3=-16.592$ eV. $\phi_3(1a_2)=0.464(\chi_4-\chi_6)$
$+0.534(\chi_3-\chi_7)$
$\varepsilon_4=-8.249$ eV. $\phi_4(3b_2)=0.561\chi_1-0.043\chi_2$
$-0.503(\chi_3+\chi_7)-0.045(\chi_4+\chi_6)+0.416\chi_5$
$\varepsilon_5=-5.607$ eV. $\phi_5(2a_2)=0.534(\chi_4-\chi_6)$
$-0.464(\chi_3-\chi_7)$
$\varepsilon_6=-4.083$ eV. $\phi_6(4b_2)=0.461\chi_1-0.396\chi_2$
$+0.012(\chi_3+\chi_7)+0.408(\chi_4+\chi_6)-0.545\chi_5$
$\varepsilon_7=-2.122$ eV. $\phi_7(5b_2)=0.400\chi_1-0.523\chi_2$
$+0.548(\chi_3+\chi_7)-0.437(\chi_4+\chi_6)-0.274\chi_5$

(B) For the bond localization model

$\varepsilon_1=-19.757$ eV. $\phi_1(1b_2)=0.644\chi_1+0.765\chi_2$
$\varepsilon_2=-19.198$ eV. $\phi_2(2b_2)=0.214(\chi_3+\chi_7)$
$+0.484(\chi_4+\chi_6)+0.664\chi_5$
$\varepsilon_3=-17.056$ eV. $\phi_3(1a_2)=0.457(\chi_4-\chi_6)$
$+0.540(\chi_3-\chi_7)$
$\varepsilon_4=-8.277$ eV. $\phi_4(3b_2)=0.602(\chi_3+\chi_7)$
$+0.085(\chi_4+\chi_6)-0.512\chi_5$
$\varepsilon_5=-6.023$ eV. $\phi_5(2a_2)=0.540(\chi_4-\chi_6)$
$-0.457(\chi_3-\chi_7)$
$\varepsilon_6=-3.684$ eV. $\phi_6(4b_2)=0.765\chi_1-0.644\chi_2$
$\varepsilon_7=-3.678$ eV. $\phi_7(5b_2)=0.304(\chi_3+\chi_7)$
$-0.509(\chi_4+\chi_6)+0.545\chi_5$

27) J. W. Sidman, ibid., **27**, 429 (1957).

**(b) Electronic Spectra.**—In the calculations with configurational interactions (CI), the singlet configurations considered of excited states for $^1B_1$ symmetry are $V_{3\to4}$, $V_{3\to6}$ and $V_{2\to5}$; those for $^1A_1$ symmetry are $V_{2\to4}$, $V_{3\to5}$ and $V_{1\to4}$. Table III shows, for the hyperconjugation model, the wave functions of excited states with the values of matrix elements.

Electronic spectra theoretically calculated are denoted in Tables IV, V and Fig. 3. The calculated energy of the first transition is, for example, in the case with no configuration interactions, considerably larger for the bond localization model than for the hyperconjugation (Table IV). This suggests that the hyperconjugative effect would possibly be much larger in such a system of isovalent hyperconjugation as benzenium ion than is in the ordinary hyperconjugated molecules.

It is seen in Fig. 3, that the order of excited configurations differs considerably between bond localization and hyperconjugation models.

As the experimental absorption data for protonated compounds of benzene and methylbenzenes are referred those of Reid[28], of Kilpatrick and Hyman[29], as well as of Dallinga, Mackor and Stuart[6]. Among these, the data of Kilpatrick-Hyman and Dallinga-Mackor-Stuart coincide with each other for methylbenzenes. Methyl shifts of the spectra by these investigators are reasonably bathochromic, while are hypsochromic by Reid's measurements. We take up, therefore, the data by Dallinga, Mackor and Stuart, 3700, 2600 and 2000 Å absorptions for benzenium ion, although the experimental extinction curve has not been given explicitly. Theoretical data agree satisfactorily with those experimentally observed (Table V). The oscillator strengths calculated also coincide, in the tendency, with the experimental extinction coefficients by Dallinga, Mackor and Stuart[6] for the protonated compounds of some methylbenzenes. Among these, for example, the mesitylene carbonium ion has the following values of the molar extinction coefficients, 11100, 8800, >13000, respectively, for the first, second and third bands. Further the calculated oscillator strengths by Dallinga, Mackor and Stuart are cited in Table V. These also agree well with our values.

It is striking that the hyperconjugation shift of the first absorption band is, as is seen in Table IV, toward red, while it is, in the Hückel MO calculations, toward blue. Indeed, our Hückel MO calculations using $\alpha_1=\alpha-0.4\beta$ show for the first transition energy the values 1.0709 $(-\beta)$ and 1.0000 $(-\beta)$, of which the former refers to the hyperconjugation and the latter to the bond localization model[30]. By means of the semi-empirical ASMO method also the similar tendency is seen. In performing the semi-empirical ASMO calculations our

TABLE VI. ENERGIES OF THE FIRST TRANSITION CALCULATED BY THE HÜCKEL AND PARISER-PARR METHODS

| | Hückel method | Pariser-Parr's method | Modified Hückel method | Modified Pariser-Parr's method |
|---|---|---|---|---|
| Hyperconjugation | 1.0709 $(-\beta)$ | 3.798 eV. | 1.0709 $(-\beta)$ | 3.798 eV. |
| Bond localization | 1.0000 $(-\beta)$ | 3.575 eV. | 1.0833 $(-\beta)$ | 3.864 eV. |

procedure is almost the same as that for toluene by Morita[16]. The value of the core integral $\beta_{H_2-C}$ used is $-4.435$ eV., which is somewhat different from that in the semi-empirical SCF MO method extended in the early part of this paper. Values of the atomic integrals also differ from those used in the SCF MO method. This does not prevent us, however, from judging the calculated results. The calculated energies for the first transition are 3.798 eV. for the hyperconjugation model and 3.575 eV. for the bond localization.

This discrepancy between the results of the SCF MO and ASMO methods might be taken off by introducing the laborious technique of configurational interaction. This seems to be in vain, however, if we take into account the same extent of configurations as in the SCF MO calculations. If any simple modification is tried, however, for the naive and the anti-symmetrized molecular orbital calculations, the identical tendency in all cases will be accomplished.

The modification is done as follows. In the bond localization model, as is seen in Fig. 4, the $\pi$-electron system is cut off into two parts, one being the system 1-2 (A), the other the system 3-4-5-6-7 (B). In the part B, terminal carbons (3 and 7) seem to be electropositive compared to the inner carbons[31]. Consequently, we should give negative value of $\delta$ for the Coulomb integral $\alpha_3$ or $\alpha_7=\alpha+\delta\beta$. We have no thorough materials which suggest the exact way determining the value of $\delta$ in this case. It may not be said, however, that the

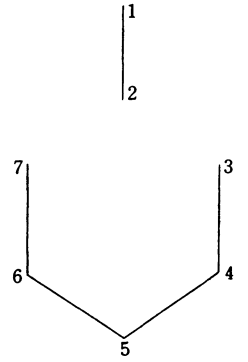

Fig. 4. The effective $\pi$-electron system of the benzenium ion for its bond localization model.

leectropositiveness of the carbon atom 3 or 7 is not satisfactory when it is equated to that of the $H_2$ group. Hence, we assume, for a moment, $\alpha_3=\alpha_7=\alpha-0.4\beta$. The corresponding modification in the ASMO method is to equalize $I_3$ (the valence state ionization potential of the carbon atom 3 or 7) to $I(H_2)$ (the valence state ionization potential of the $H_2$ group, namely $I(H_2)=-W(\phi_2)=-\int\phi_2^*H\phi_2 d\tau$) in the formula expressing the core integral $\alpha_3$ or $\alpha_7$ (Pariser-Parr's notation)

$$\alpha_3=\alpha_7=-I_3-\sum_{\nu\neq 3}{}' (33\mid\nu\nu) \qquad (9)$$

(Although the electronic Coulomb repulsion integrals, $(33\mid\nu\nu)$, have to take different values corresponding to the change in $I_3$, this correction may be omitted for the present purpose.) These modifications in the naive and antisymmetrized molecular orbital methods lead to the

31) R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).

same tendency as in the SCF MO method with regard to the absorption spectra. Calculated results are indicated in Table VI.

**(c) Charge Densities and Bond Orders.**—Fig. 5 shows $\pi$-electron densities and $\pi$-bond orders calculated for the hyperconjugation and bond localization models.

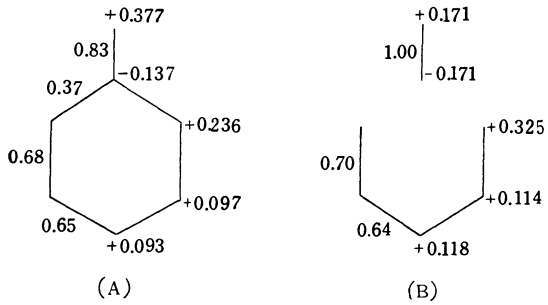

Fig. 5. Calculated formal charges (unit of $+e$) and $\pi$-bond orders of benzenium ion.
A : hyperconjugation, B : bond localization

The proton magnetic resonance spectra of pentamethylbenzene in $CF_3COOH+H_2O\cdot BF_3$ and in $HF+BF_3$ show for the methyl groups the following shifts compared to the benzene proton signal; 196, 199, 204 and 180, 187, 198 (in c/sec.) in each case[10]. The manner in which the assignment of the signals is undertaken is different, according as which model, hyperconjugation or bond localization, is adopted. Namely, the hyperconjugation model predict the signals 196, 199, 204 or 180, 187, 198 (in c/sec.) attributing, in order, to the methyl groups at the positions 3, 4, 5; in contrast, for the bond localization model, these signals should be assigned to the methyl groups at the positions 3, 5, 4 in order. This discrepancy will probably be due to the crudeness of approximations. It will be probably necessary, in the configurational interaction calculations, to take into account further more configurations including the ground state configuration, $V_0$, which is shut out of our computations.

**(d) Hyperconjugation Energy.**—The hyperconjugation energy is obtained by subtracting the energy of hyperconjugation model from that of bond localization one, taking further the compressional energy correction into consideration. The compression energy is evaluated on the assumption of harmonical distortion of a bond. Calculated energy of hyperconjugation is 19.7 kcal./mol., which is much larger than in the case of the ordinary hyperconjugation.

## Summary

Semi-empirical SCF LCAO MO calculations of benzenium ion was undertaken for the model of localization as well as hyperconjugation of the $H_2$–C bond constructed at the position of proton attack. A simplified model of hyperconjugation in the semi-empirical SCF MO method was extended. Calculated results for the hyperconjugation model agreed satisfactorily with the experimental electronic spectra.

Superiority of the SCF MO method to the Hückel MO or ASMO method was indicated in connection with the ordinarily accepted spectral shift through hyperconjugation. Further, some modifications were tried, for the bond localization model, which would have to be taken in the Hückel MO as well as ASMO calculations.

The proton magnetic resonance signals due to methyl substituents in the carbonium ions of methylbenzenes were discussed from charge densities of benzenium ion.

The author wishes to thank Professor T. Titani, Tokyo Metropolitan University, for his interest and to Professors A. Kotera, Tokyo University of Education, and S. Nagakura, the University of Tokyo, and Mr. Y. Mori, Tokyo Institute of Technology, for their kind advices and helpful discussions. # *Studies on Constituents of Coal Carbonization Light Oil. I. On Saturated Hydrocarbons Contained in High-temperature Coal Carbonization Light Oil*

By Hiroshi YASUI

(Received December 23, 1959)

Constituents and their contents of coal carbonization light oil, are influenced by their carbonization temperature. It has been reported, that components contained in high-temperature coal carbonization light oil differ from those in low-temperature coal carbonization light oil, qualitatively and quantitatively[1,2]. Apparently, such constituents of low-temperature coal carbonization light oil are mainly saturated hydrocarbons and less aromatic and unsaturated hydrocarbons. By contrast, those of high temperature coal carbonization light oil are mainly aromatic and less saturated and unsaturated hydrocarbons. In the studies on the constituents of high-temperature coal carbonization, nearly all the aromatic hydrocarbons contained in the light oil have been determined[3-5]. But the saturated hydrocarbons in the light oil are not present in any large quantity, but separation of these saturated hydrocarbons is difficult, resulting data of such separation being scanty. Saturated hydrocarbons contained in the light oil, previously reported, are *n*-heptane[6-8], octane[9], *n*-decane[10,11] as *n*-paraffin, and 2, 2, 4-trimethylpentane[6,7] and 3-ethyl-3-metylpentane[12] as isoparaffin, and cyclopentane[10], methylcyclopentane[8,10] cyclohexane[7,8,10], methylcyclohexane[10], 1, 2-, 1, 3- and 1, 4-dimethylcyclohexane[10], 1, 3, 5-[13] and 1, 2, 4-trimethylcyclohexane[14] and 1, 2, 4, 5-tetramethylcyclohexane[13] as cycloparaffin. While, the presence of *n*-decane, *n*-undecane and 1, 2, 3, 4-tetramethylcyclohexane in solvent naphtha produced from Yawata Iron & Steel Co., Ltd. in 1949, has been already ascertained by S. Kimura and the author[15]. In this research, the author has ascertained and identified the saturated hydrocarbons contained in benzene[16,17], toluene[17,18] and solvent naphtha fractions[19,20] separated from high-temperature coal carbonization light oil (carbonization temperature, 1250°C) of Yawata Iron & Steel Co., Ltd. in 1952.

## Experimental

**Materials. — Crude Saturated Hydrocarbon Oil Obtained from Benzene Fraction.**—A residual oil after chlorination of benzene fractiton (b. p. 79.5~81°C) at Nihon Kayaku Co., Ltd., which is colorless oil and has $d_4^{20}=0.7755$ and $n_D^{20}=1.444$, was used as material.

**Toluene Fraction.**—Toluene fraction purified by treatment with conc. sulfuric acid, manufactured by Yawata Iron & Steel Co., Ltd. in January, 1952, a colorless oil of b. p. 110.3~111.2°C, $d_4^{20}=0.8633$ and $n_D^{20}=1.493$, was used as material.

**Solvent naphtha.**—Solvent naphtha prepared at Yawata Iron & Steel Co., Ltd. in January, 1952, consisting of 17.8% of 10°-xylene (136~142°C fraction), 40.5% of solvent naphtha I (125~172°C fraction) and 41.7% of solvent naphtha II (149~203°C fraction) in proportion to each rate of production, a pale yellow oil of $d_4^{20}=0.8698$ and $n_D^{20}=1.496$, was used as material.

**Separation of Saturated Hydrocarbon Oil in the Materials.—Saturated Hydrocarbons Contained in Benzene Fraction.**—As benzene was expected to be contained in the material from its physical constants, 500 ml. of it was shaken vigorously with the mixture of 50 ml. of conc. nitric acid ($d_4^{20}=1.42$) and 100 ml. of conc. sulfuric acid ($d_4^{20}=1.84$); and aromatic hydrocarbons were removed. The residual oil was washed by water, neutralized with 10% sodium hydroxide solution, rewashed similarly and dried with calcium chloride to obtain 433 ml. of

crude saturated hydrocarbon, which has b. p. 85~105°C, $d_4^{20}=0.7711$ and $n_D^{20}=1.430$. Now 300 ml. of this oil was submitted to fractional distillation with metallic sodium and 120 ml. of 78~90°C fraction ($d_4^{20}=0.8059$, $n_D^{20}=1.458$), and 150 ml. of 90~103°C fraction ($d_4^{20}=0.7290$, $n_D^{20}=1.406$) were obtained. But, in the 78~90°C fraction, residual benzene was still expected from its physical constants and ultraviolet spectrum[17]. The residual benzene in this fraction, therefore, was again removed with a mixture of conc. sulfuric acid and conc. nitric acid, and the residual oil and 90~103°C fraction were fractionated by Podbielniak distillation equipment, and 4 per cent by weight of 78~90°C fraction ($d_4^{20}=0.7067$, $n_D^{20}=1.398$) and 96 per cent by weight of 96~100°C fraction ($d_4^{20}=0.7170$, $n_D^{20}=1.405$), were obtained.

**Saturated Hydrocarbons Contained in Toluene Fraction.**—In an iron-pot provided with a stirrer, toluene contained in 169 kg. of toluene fraction, was extracted with 361.7 kg. of conc. sulfuric acid and 2.1 kg. of crude saturated hydrocarbon oil, and about 1.2% by weight of toluene fraction was obtained. Residual toluene in 756 g. of this oil was again removed completely with conc. sulfuric acid. 709 g. of saturated hydrocarbon oil, amounting to about 1.1% of toluene fraction, was obtained. This oil was distilled with metallic sodium and 120~126°C fraction, which has $d_4^{20}=0.7234$ and $n_D^{20}=1.406$, was obtained.

**Saturated Hydrocarbons Contained in Solvent Naphtha.**—In an iron-pot provided with a stirrer, aromatic hydrocarbons contained in 200 kg. of the material, were extracted four times with conc. sulfuric acid (total of 197.34 kg.), and 6.44 kg. of crude saturated hydrocarbon oil, was obtained. Moreover, the residual aromatic hydrocarbon in 760 g. of this oil was removed with conc. sulfuric acid repeatedly and 708 g. of saturated hydrocarbon oil, amounting to about 3% by weight of the material, was obtained. This oil has b. p. 132~198°C, $d_4^{20}=0.7632$ and $n_D^{20}=1.425$. 616 g. of this oil was submitted to the fractional distillation with metallic sodium and six fractions shown in Table I, were obtained.

Total of 118~147°C and 147~161°C fractions were fractionated by Podbielniak distillation equipment, and five fractions shown in Table II were obtained.

Moreover, total of 155~162°C fraction in Table II and 161~172°C, 172~177°C fractions in Table I, were fractionated and three fractions shown in Table III were obtained.

Analyses were carried out on the main fractions of 143.5~155°C in Table II and of 165~174°C in Table III.

TABLE I. FRACTIONS OBTAINED BY FRACTIONAL DISTILLATION OF 616 g. OF 132~198°C FRACTION

| Frac. °C | g. | $d_4^{20}$ | $n_D^{20}$ |
|---|---|---|---|
| 118~147 | 126 | 0.7492 | 1.419 |

TABLE III. FRACTIONS OBTAINED BY FRACTIONAL DISTILLATION OF A TOTAL OF 155~162°C IN TABLE II AND 161~172°C, 172~177°C FRACTIONS IN TABLE I

| Frac. °C | g. | $d_4^{20}$ | $n_D^{20}$ |
|---|---|---|---|
| 145~147 | 7.5 | 0.7571 | 1.420 |
| 147~165 | 36 | 0.7596 | 1.422 |
| 165~174 | 83 | 0.7643 | 1.425 |

**Identification of *n*-Paraffin.**—*n*-Paraffin was isolated by means of urea adduct[21]. According to an estimation *n*-paraffin contained was about 30% in each fraction. It was added to urea (about 4 mol.) moistened with methanol (about 1 mol.). The suspension was stirred for 30 min. at 25°C and filtered, removing unreacted oil. The mixture of urea adduct and residual urea, were washed with anhydrous ether, which was removed under reduced pressure, and decomposed with water, and oil (*n*-paraffin) was obtained. And, unreacted oil was added to urea moistened with methanol, and treated as mentioned above, repeatedly until oil (*n*-paraffin) was no longer obtained by decomposition with water of urea adduct.

**78~90°C and 96~100°C Fractions.**—These fractions were treated as mentioned above, but oil was not obtained by decomposition with water of the urea adduct[17], suggesting difficulty by means of urea adduct, to separate *n*-paraffin expected to be contained in these fractions as stated by Kuwata and co-workers previously[22].

TABLE IV. ISOLATION OF *n*-PARAFFINS BY MEANS OF UREA ADDUCTS IN 120°~126C, 143.5~155°C AND 165~174°C FRACTIONS

| Frac. | | Oil isolated by means of urea adduct | | | | Residual oil | |
|---|---|---|---|---|---|---|---|
| °C | g. | g. | % for frac. | b. p. °C | $d_4^{20}$ | g. | % for frac. |

**120～126°C[18], 143.5～155°C[19] and 165～174°C[20] Fractions.**—*n*-Paraffin contained in the three fractions were isolated by means of urea adduct and the result was shown in Table IV.

**Oil Isolated by Means of Urea Adduct in 120～126°C Fraction.** — Physical constants (Table IV) of this oil are identical with those of *n*-octane[23] (b. p. 125.6°C, $d_4^{20}=0.703$, $n_D^{20}=1.397$). IR spectrum bands[18] (wavelengths; 7.68, 7.87, 8.16, 8.33, 8.8, 9.27, 9.65, 9.95, 10.34, 10.92, 11.4, 11.84, 12.6, 13.08, 13.32, 13.85 $\mu$) of this oil are analogous to those of *n*-octane.

**Oil Isolated by Means of Urea Adduct in 149～151°C Fraction.**—Physical constants (Table IV) of this oil are identical with those of *n*-nonane[23] (b. p. 150.7°C, $d_4^{20}=0.718$, $n_D^{20}=1.406$) and IR spectrum bands[19] (wavelengths; 7.67, 7.94, 8.22, 8.41, 8.81, 9.2, 9.41, 9.58, 10.14, 10.29, 10.79, 11.22, 11.84, 12.05, 12.89, 13.29, 13.86 $\mu$) of this oil are analogous to those of *n*-nonane.

**Oil Isolated by Means of Urea Adduct in 165～174°C Fraction.**—Physical constants (Table IV) of this oil are identical with those of *n*-decane[23] (b. p. 174°C, $d_4^{20}=0.7298$, $n_D^{20}=1.412$). IR spectrum bands[20] (wavelengths; 7.67, 8.01, 8.25, 8.42, 8.81, 9.16, 9.29, 9.92, 10.05, 10.86, 11.15, 11.83, 12.28, 13.0, 13.85 $\mu$) of this oil are analogous to those of *n*-decane.

**Identification of Cycloparaffin.**—Dehydrogenation of the residual oil free from *n*-paraffin, was carried out with Pt-C catalyst at 300～310°C.

**Dehydrogenation[24,25] Catalyst.** — Pt-C catalyst was prepared by Berl's method[24]. About 10 g. of granulated active carbon was mixed with 1 g. of platinum chloride ($PtCl_2 \cdot 2HCl + 6HCl$) dissolved in 25 ml. of water acidified with hydrochloric acid, and the mixture was dried at 110°C with frequent stirring. These were put in a quartz reaction tube (dia., 2 cm., length, 80 cm.) and kept in position by a stopper of glass wool. They were heated to 200°C by electric furnace and the platinum compound was decomposed. Hydrogen was sent to the tube from the entrance until no more hydrochloric acid was formed and a treatment with hydrogen at 300°C was carried out for 30 min.

**Apparatus.**—The sample was dropped into one end of a reaction tube from the sample flask, the dropping velocity regulated by the opening of the cock provided at the lower part of the sample flask, and the oil produced was received from the other end by a receiving flask with an ice-cooled condenser and the gas produced was collected in a gas collector, its pressure being controlled by a pressure

TABLE V. DEHYDROGENATION

Reac. temp. 300～310°C; Dropping velocity 5～6 g./hr.

| Sample | g. | Dehydrogenated oil g. | Gas produced ml. (N. T. P.) | $H_2$* ml. (N. T. P.) |
|---|---|---|---|---|
| (a) | 7 | 4.5 | 828.8 | 812.2 |

control device. 78~90°C (a) and 96~100°C fractions (b) and each residual oils (c), (d), (e) free from *n*-paraffin in 120~126°C, 143.5~155°C and 165~174°C fractions were dehydrogenated as mentioned above, and the oil condensed in the receiver were subjected to dehydrogenation repeatedly, and the results, shown in Table V, were obtained.

**Identification of Aromatic Hydrocarbons Produced by Dehydrogenation — UV Spectrum of Dehydrogenated Oil**[15-20]. — UV spectra of dehydrogenated oils dissolved in purified cyclohexane, was measured with a Beckman spectrophotometer, model DU and the aromatic hydrocarbons produced by dehydrogenation were estimated from their UV spectra.

**Nitration of Dehydrogenated Oil**[15-20].—Dehydrogenated oil was added to a mixture of 1 vol. of conc. nitric acid and 2 vol. of conc. sulfuric acid and the mixture was heated to boil for five minutes and poured into cold water, and crude nitro-compounds were obtained. These compounds were purified or separated by recrystallization from ethyl alcohol solution, obtaining pure nitro-compounds. The results were shown in Table VI.

The aromatic hydrocarbons contained in each dehydrogenated oil, were determined from UV spectra and Table VI, and the original cycloparaffins contained in (a), (b), (c), (d) and (e) were estimated. The result was shown in Table VII.

TABLE VII. CYCLOPARAFFINS CONTAINED IN (a), (b), (c), (d) AND (e)

| | Cycloparaffin | Ratio* |
|---|---|---|
| (a) | Cyclohexane | 1 |
| | Methylcyclohexane | 4 |
| (b) | Methylcyclohexane | |
| (c) | 1,3-Dimethylcyclohexane | 15 |
| | 1,4-Dimethylcyclohexane | 1 |
| (d) | 1,2,4-Trimethylcyclohexane | 9 |
| | 1,2,3-Trimethylcyclohexane | 1 |
| (e) | 1,3,5-Trimethylcyclohexane | 1 |
| | 1,2,3,5-Tetramethylcyclohexane | 3 |

* The ratio of cycloparaffins contained in each fraction was calculated from weights of nitro-compounds obtained.

TABLE VIII. PHYSICAL CONSTANTS OF OILS, REMOVED AROMATIC HYDROCARBONS CONTAINED IN DEHYDROGENATED OILS

| | Dehydrogenated oil | Oil (saturated hydrocarbon) | | | |
|---|---|---|---|---|---|
| | g. | g. | b. p., °C | $d_4^{20}$ | $n_D^{20}$ |
| (a) | 2.1 | 1.7 | 93 ~ 96 | 0.6865 | 1.389 |
| (b) | 2.2 | 1.5 | 98.5~ 99.5 | 0.6942 | 1.393 |
| (c) | 1.6 | 1.35 | 114 ~116 | 0.7221 | 1.405 |
| (d) | 2.0 | 1.5 | 140 ~145 | 0.7265 | 1.407 |
| (e) | 1.6 | 1.3 | 164 ~166 | 0.7340 | 1.413 |

**Identification of Isoparaffin.**—Aromatic hydrocarbons produced by dehydrogenation were removed from dehydrogenated oils by mixture of 2 vol. of conc. sulfuric acid and 1 vol. of conc. nitric acid or by conc. sulfuric acid[15-20]. The residual oils were washed by water and neutralized with alkaline solution. Similarly rewashed and dried with calcium chloride and distilled with metallic sodium, and the oils, having the physical constants shown in Table VIII were obtained.

IR spectra of these oils were measured with a Baird infrared spectrophotometer and isoparaffins contained in each oil were determined. IR spectrum bands of oil of (a) (wavelengths; 7.45, 7.68, 8.78, 9.30, 9.79, 10.4, 10.74, 11.1, 11.42, 11.57, 12.01, 12.91, 13.54, 13.83 $\mu$) are analogous to those of *n*-heptane. In IR spectrum bands of oil of (b), those of *n*-heptane and 2,2,4-trimethylpentane (wavelengths; 7.7, 8.01, 8.30, 8.56, 9.84, 10.2, 10.82, 11.58, 13.4 $\mu$) were observed. It was observed that IR spectrum bands of oil of (c) contain the bands of the spectrum for 2-methylheptane (wavelengths; 7.45, 7.68, 7.9, 8.55, 9.28, 10.42, 10.56, 10.74, 12.3, 13.06, 13.82 $\mu$) and those of the spectrum for 3-methylheptane (wavelengths; 7.68, 7.9, 9.28, 10.42, 10.95, 11.43, 12.3 $\mu$). In IR spectrum bands of oil of (d), those of 3-methyloctane (wavelengths; 8.7, 9.97, 10.3, 10.48, 10.72, 10.94, 11.22, 11.43, 12.3 $\mu$) and 4-methyloctane (wavelengths; 8.7, 9.26, 10.48, 10.72, 10.94, 11.22, 12.94, 13.5, 13.8 $\mu$) were observed. In IR spectrum of bands of oil of (e), those of 3-methylnonane (wavelengths; 8.6, 9.43, 9.77, 9.96, 10.34, 10.95, 11.2, 13.0, 13.8 $\mu$) and 4-methylnonane (wavelengths; 8.6, 9.24, 10.47, 11.2, 11.86, 12.3, 13.0, 13.6, 13.8 $\mu$) were observed.

## Results and Discussion

The saturated hydrocarbons identified from each fraction and the proportion of *n*-paraffin, isoparaffin and cycloparaffin to each fraction, are shown in Table IX.

It is obvious that saturated hydrocarbons contained in benzene fraction consist of *n*-heptane (about 74.5%), cyclohexane (about 0.1%), methylcyclohexane (about 25.4%) and 2, 2, 4-trimethylpentane (trace). In the saturated hydrocarbons contained in toluene fraction, *n*-octane (30%), mixture of 2-methylheptane and 3-methylheptane (42%) and 1, 3-dimethylcyclohexane (9%) and 1, 4-dimethylcyclohexane (0.5%) were determined. Saturated hydrocarbons contained in solvent naphtha fraction were determined to contain *n*-nonane (about 5.4%), *n*-decane (about 4.7%), mixture of 3-methyloctane and 4-methyloctane (about 10.8%), mixture of 3-methylnonane and 4-methylnonane (about 4.3%), 1,2,4-trimethylcyclohexane (about 0.2%), 1, 2, 4-trimethylcyclohexane (about 2%), 1, 3, 5-trimethylcyclohexane (about 0.1%) and 1, 2, 3, 5-tetramethylcyclohexane (about 0.4%).

The following observations are based on a study of the data presented in this research.

TABLE IX. SATURATED HYDROCARBONS IDENTIFIED AND THE PROPORTION OF *n*-PARAFFIN, ISOPARAFFIN AND CYCLOPARAFFIN TO EACH FRACTION

* Aromatic hydrocarbons in high-temperature coal carbonization light oil prepared at Yawata Iron & Steel Co., Ltd. as identified previously by S. Kimura, H. Suzumura and the author[3].

1) The saturated hydrocarbons contained in benzene, toluene and solvent naphtha fractions are all composed of saturated aliphatic hydrocarbon, about 85%, and cycloparaffinic hydrocarbon, about 15%.

2) The saturated aliphatic hydrocarbons contained in benzene fraction are nearly all *n*-paraffins and the corresponding isoparaffins are expected to be contained in the forerunnings. In the saturated aliphatic hydrocarbons contained in toluene and solvent naphtha fractions, the proportion of contents of *n*-paraffins and isoparaffins are about 1 : 1.5.

3) The isoparaffins, contained in the three fractions mentioned above, are all monomethylparaffins.

4) Comparing cycloparaffins with aromatics, cyclohexane corresponding to benzene, methylcyclohexane to toluene, dimethylcyclohexane to dimethylbenzene and trimethylcyclohexane to trimethylbenzene, are present respectively. In dimethylbenzene isomer, *m*-xylene is the highest in contents, *p*-xylene, half as much as *m*-xylene and *o*-xylene is of trace[3]. Similar tendency is observed in the contents of dimethylcyclohexane isomers, but 1, 2-dimethylcyclohexane can not be identified in this investigation. It is recognized that in trimethylbenzene isomers, much of 1, 2, 4- and 1, 3, 5-isomers are contained, and almost equally[3]. But it has become clear that in trimethylcyclohexane, the content of 1, 2, 4-isomer is more than that of 1, 3, 5-isomer and 1, 2, 3-isomer is of trace. Thereafter a presence of 1, 2, 3, 5- and 1, 2, 3, 4-isomers[15] in tetramethylcyclohexane isomer is observed. They cannot be compared, however, with the corresponding tetramethylbenzene since it is not analyzed yet by the author. It was reported[27] that 1, 2, 4, 5-tetramethylcyclohexane is contained in high-temperature carbonization tar, but the result obtained in this research presents a different result. Moreover, *p*- and *m*-methylethylcyclohexane[3], which correspond to ethyltoluene isomers, are not found.

The author wishes to express his hearty thanks to Professor Sakujirô Kimura of Kyoto University, Professor Tamon Matsu'ura and Professor the late Bunkichi Masumoto of Hiroshima University and Professor Shôzô Tanaka of Kyoto University for their kind guidance and valuable advice throughout this study.

Thanks are also due to Yawata Iron & Steel Co., Ltd. for donation of the materials used

# *Studies on Constituents of Coal Carbonization Light Oil. II. On Saturated Hydrocarbons Contained in Low-temperature Coal Carbonization Light Oil*

By Hiroshi YASUI

(Received January 6, 1960)

Apparently, constituents of high-temperature coal carbonization light oil are mainly aromatic hydrocarbons and those of low-temperature coal carbonization light oil, are mainly saturated hydrocarbons[1]. But, resulting data of identification of saturated hydrocarbons in low-temperature coal carbonization light oil, are scanty. In 1955, some of them have been reported by A. Jäger and G. Kattwinkel[2] and the following results have been found. 1) The saturated hydrocarbons, contained in low-temperature coal carbonization light oil, consist mainly of straight-chain paraffins. 2) The branched-chain paraffins contained in this oil are all monomethylparaffins. 3) Contents of cycloparaffins are scanty.

Ohyama[3] reported that the neutral oil contained in low-temperature coal carbonization light oil, Ube Kôsan Co., Ltd. production, amounted to about 90 per cent and also the contents of the saturated hydrocarbon in the neutral oil to about 40 per cent. However, the constituents of the individual saturated hydrocarbons in this light oil and their contents have never been ascertained. Therefore, the author has studied on the constituents of the saturated hydrocarbons contained in this oil and found five straight-chain hydrocarbons (*n*-hexane, *n*-heptane, *n*-octane, *n*-nonane and *n*-decane) and five branched-chain hydrocarbons (2-methylhexane, 2-methylheptane, 2-methyloctane, 2-methylnonane and 3-methylnonane) and four cycloparaffins (cyclohexane, methylcyclohexane, 1, 3-dimethylcyclohexane and 1, 3, 5-trimethylcyclohexane) and determined their contents approximately and compared them with the result obtained in a previous paper[4].

## Experimental

**Materials.**—Residual oil after extraction of acidic and basic oils in low-temperature coal carbonization light oil (carbonization temperature, 780°C) manufactured by Ube Kôsan Co., Ltd. in August, 1954, with dilute sulfuric acid and alkaline solution, brown colored, was used. This oil kept in a glass reagent bottle for some years and precipitation, amounting to about 1.5 per cent of this oil, was produced. The oil, removing the precipitation by filtration, had a boiling range of 92~265°C, $d_4^{25}=0.8062$ and $n_D^{25}=1.456$. The contents of olefinic, aromatic and saturated hydrocarbons in this oil, were determined to be olefins 9.5 per cent (volume absorbed by 80% $H_2SO_4$), aromatics 49 per cent (volume absorbed by 98% $H_2SO_4$) and saturated hydrocarbons 41.5 per cent (residue) by sulfuric acid absorption method.

**Separation of the Saturated Hydrocarbon Oil.**—Olefinic and aromatic hydrocarbons contained in 320 g. of the material, were removed by extracting with concentrated sulfuric acid. The residual oil was washed by water, neutralized with 10 per cent sodium hydroxide solution, rewashed similarly and dried with calcium chloride to obtain 148 g. of crude saturated hydrocarbon oil (46.2 per cent by weight of the material). This oil was fractionated and 100 g. of 98~220°C fraction, which had $d_4^5=0.7403$ and $n_D^{25}=1.417$, and 45 g. of residual oil, were obtained. Residual aromatic hydrocarbons in 100 g. of 98~220°C fraction, were again removed completely with concentrated sulfuric acid and washed with water and neutralized with alkaline solution and rewashed similarly and dried with calcium chloride and 89 g. (27.8 per cent by weight of the material) of saturated hydrocarbon oil

| Residue | — | 34.4 | 39.5 | 0.7924 | 1.442 |

Analyses were carried out on 48～98°C, 98～126°C, 126～148°C and 148～165°C fractions in Table I.

**Gas Chromatographic Analysis.**—Gas chromatographic analysis of 48～98°C, 98～126°C, 126～148°C and 148°～165°C fractions was performed with a Perkin-Elmer vapor fractometer. Hydrogen was used as carrier gas and di-*n*-decylphthalate was used as liquid substrate. The identification of the peak in the chromatograms was based on synthetic hydrocarbon data. The retention time of hydrocarbons contained in these fractions was obtained from each synthetic hydrocarbon and comparing the retention times of the peak chromatogram of each synthetic hydrocarbon under identical conditions. Contents of the hydrocarbons in these fractions were calculated from the area of each measurable peak.

**Identification of *n*-Paraffn.**—*n*-Paraffins in these fractions were isolated by means of urea adducts[5]. According to the estimation *n*-paraffin was contained about 50 per cent in each fraction. It was added to urea (about three times in weight of the *n*-paraffin) moistened with methanol (about a fifth of the weight of the urea used). The suspension was stirred for 30 min. at 0°C in 98～126°C, or 20°C in 126～148°C and 148～165°C fractions, and filtered, and unreacted oils were removed. The mixture of urea adduct obtained and the residual urea was washed with anhydrous ether, removed under reduced pressure, decomposed with water, and oil (*n*-paraffin) was obtained. Unreacted oil was once more added to urea moistened with methanol and treated as mentioned above until no more oil (*n*-paraffin) was obtained by decomposition with water of urea adduct. The result was shown in Table II. As stated by the author[4] and Kuwata and co-workers[6] previously, it is difficult to isolate *n*-hexane and *n*-heptane expected to be contained mainly in 48～98°C fraction. Therefore this method was not employed.

**IR Spectra of Oils Obtained by Decomposition with Water of Urea Adducts.**—IR spectra of 48～98°C fraction and oils isolated by decomposition

TABLE II. ISOLATION OF *n*-PARAFFIN BY UREA ADDUCTS IN 98～126°, 126～148° AND 148～165°C FRACTION

| Fraction | | Oil isolated by urea adduct (*n*-paraffin) | | | | | Residual oil | |
|---|---|---|---|---|---|---|---|---|
| °C | g. | g. | % | b. p., °C | $d_4^{25}$ | $n_D^{25}$ | g. | % |
| 98～126 | 12 | 5.5 | 46 | 120～124 | 0.6983 | 1.396 | 5 | 42 |
| 126～148 | 14 | 6.5 | 54 | 142～151 | 0.7111 | 1.405 | 6.5 | 32 |
| 148～165 | 6.5 | 3.0 | 46 | 152～170 | 0.7248 | 1.410 | 2.2 | 34 |

with water of urea adducts of 98～126°C, 126～148°C and 148～165°C fractions, were measured with an Oh'yô Kôken infrared spectrophotometer.

**48～98°C Fraction.** — In IR spectrum bands of this fraction, those of *n*-hexane (wavelengths; 7.45, 7.73, 8.02, 8.20, 8.6, 8.79, 9.38, 9.46, 9.86, 9.95, 10.29, 11.04, 11.24, 11.31, 11.51, 12.13, 12.6, 12.94, 13.18, 13.78 $\mu$), *n*-heptane (wavelengths; 7.45, 7.68, 7.81, 8.09, 8.27, 8.78, 9.3, 9.79, 10.4, 10.74, 11.1, 11.42, 11.57, 12.01, 12.91, 13.54 13.83 $\mu$), 2-methylhexane (wavelengths; 7.3, 7.41, 7.71, 7.97, 8.18, 8.53, 8.73, 9.3, 9.53, 9.7, 9.85, 10.46, 10.63, 11.0, 11.17, 12.16, 12.81, 13.74 $\mu$), 2-methylheptane (wavelengths; 7.32, 7.46, 7.67, 8.05, 8.28, 8.54, 8.74, 9.22, 9.56, 9.98, 10.41, 10.53, 10.71, 10.88, 11.2, 11.94, 12.31, 13.04, 13.26, 13.81 $\mu$), cyclohexane (wavelengths; 7.4, 7.95, 8.7, 9.1, 9.6, 9.9, 11.1, 11.68 $\mu$) and methylcyclohexane (wavelengths; (7.28, 7.44, 7.69, 8.02, 8.62, 9.06, 9.7, 10.38, 11.02, 11.49, 11.87 $\mu$) were observed.

**Oil Isolated by Decomposition with Water of the Urea Adduct of 98～126°C Fraction.**—Physical constants (Table II) of this oil were analogous to those of *n*-octane[7] (b. p. 125.6°C, $d_4^{20}=0.703$, $n_D^{20}=1.397$). In IR spectrum bands of this oil, those of *n*-heptane, *n*-octane (wavelengths; 7.46, 7.68, 7.87, 8.16, 8.33, 8.8, 9.27, 9.65, 9.95, 10.34, 10.92, 11.1, 11.21, 11.4, 11.84, 12.6, 13.08, 13.52, 13.85 $\mu$) and *n*-nonane (wavelengths; 7.46, 7.67, 7.94, 8.22, 8.81, 9.2, 9.41, 9.58, 10.29, 10.79, 11.22, 11.4, 11.84, 12.05, 12.89, 13.29, 13.86 $\mu$) were observed.

**Oil Isolated by Decomposition with Water of the Urea Adduct of 126～148°C Fraction.**—Physical constants (Table II) of this oil were analogous to those of *n*-nonane[7] (b. p. 150.7°C, $d_4^{20}=0.7111$, $n_D^{20}=1.405$), and in IR spectrum bands of this oil, those of *n*-nonane and *n*-octane were observed.

**Oil Isolated by Decomposition with Water of the Urea Adduct of 148～165°C Fraction.**—Physical constants (Table II) of this oil denoted the values between those of *n*-nonane and *n*-decane[7] (b. p. 174°C, $d_4^{20}=0.7298$, $n_D^{20}=1.412$), and therefore the fraction was expected to be a mixture of *n*-nonane and *n*-decane. In IR spectrum bands of this oil, those of *n*-nonane and *n*-decane (wavelengths; 7.26, 7.45, 7.67, 7.82, 8.01, 8.25, 8.81, 9.16, 9.29, 9.92, 10.05, 10.86, 11.15, 11.83, 12.28, 13.0, 13.85 $\mu$) were observed.

**Gas Chromatographic Analysis.** — The gas chromatographic analysis of oils, obtained by decomposition with water of urea adducts of 98～126°C, 126～148°C and 148～165°C fraction, was performed and chromatograms of these oils were shown in Fig. 2.

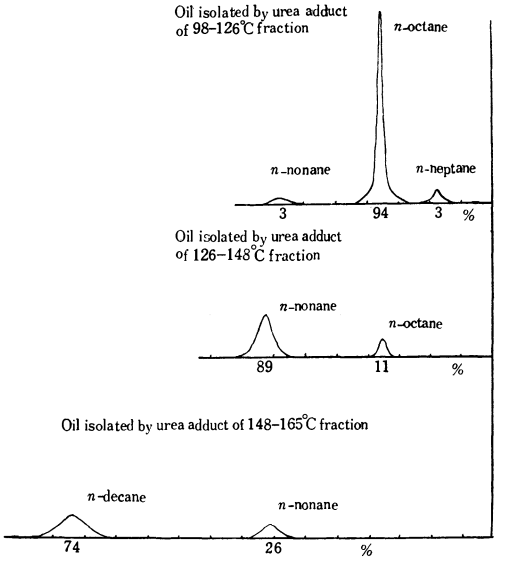

Fig. 2. Gas chromatograms of oils obtained by decomposition with water of urea adducts of each fraction.
Column temp., 100°C; $H_2$ flow rate, 98.6 ml./min.

**Identification of Cycloparaffin and Isoparaffin—IR Spectra.**—IR spectra of residual oils, in 98～126°C, 126～148°C and 148～165°C fractions, are measured with an Oh'yô Kôken spectrophotometer.

**Residual Oil in 98～126°C Fraction Shown in Table II.**—Physical constants of this oil are b. p. 110～125°C, $d_4^{25}=0.7218$, $n_D^{25}=1.404$. In IR spectrum bands of this oil, those of 2-methylheptane, 2-methyloctane (wavelengths; 7.6, 7.67, 7.86, 8.15, 8.33, 8.54, 9.14, 9.3, 9.4, 9.77, 10.18, 10.55, 10.9, 11.25, 11.42, 12.15, 12.7, 13.5, 13.8 $\mu$), 1,3-dimethylcyclohexane (wavelengths; 7.25, 7.66, 7.88, 8.36, 8.6, 8.96, 9.28, 9.45, 10.0, 10.2, 10.53, 10.71, 11.43, 11.72, 12.13 $\mu$) and 1,3,5-trimethylcyclohexane (wavelengths; 7.52, 7.92, 8.53, 8.87, 8.96, 9.35, 9.56, 9.66, 10.0, 10.63, 10.74, 11.84, 11.91, 12.78 $\mu$) were observed.

**Residual Oil in 126～148°C Fraction Shown in Table II.**—Physical constants of this oil are b. p. 139～151°C, $d_4^{25}=0.7406$ and $n_D^{25}=1.414$. In IR spectrum bands of this oil, those of 2-methyloctane, 1,3-dimethylcyclohexane, 2-methylnonane (wavelengths; 7.67, 7.93, 8.21, 8.40, 8.54, 8.76, 9.12, 9.4, 10.07, 10.4, 10.65, 10.9, 11.1, 11.48, 12.0,

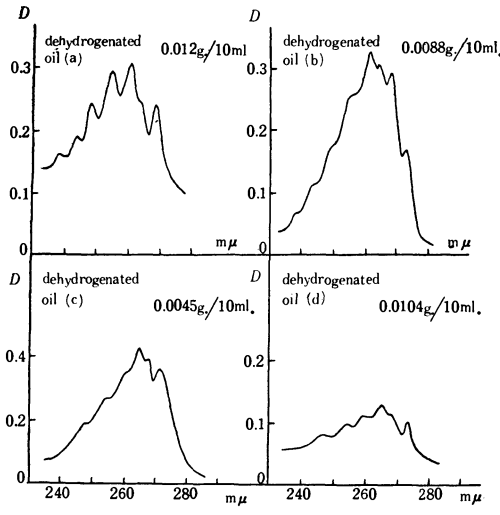

Fig. 4. Ultraviolet spectra of dehydrogenated oils.

**Residual Oil in 148~165°C Fraction Shown in Table II.**—Physical constants of this oil are b. p. 148~164°C, $d_4^{25}=0.7673$ and $n_D^{25}=1.425$. In IR spectrum bands of this oil, those of 2-methylnonane, 3-methylnonane and 1,3,5-trimethylcyclohexane were observed.

**Gas Chromatographic Analysis.**—Gas chromatographic analysis of residual oils, in 98~126°C, 126~148°C and 148~165°C fractions was performed and the chromatograms were shown in Fig. 3.

**Dehydrogenation[4,8].** — Dehydrogenation of 48~98°C fraction (a) and residual oils (b), (c) and (d) in 98~126°C, 126~148°C and 148~165°C fractions shown in Table II, was carried out with Pt-C catalyst prepared by the method described previously[4], at 290~300°C repeatedly, until no hydrogen was producible and by this method, cycloparaffins contained in these fractions were changed to corresponding aromatic hydrocarbons. The result was shown in Table III.

TABLE III. DEHYDROGENATION
REAC. TEMP. 290~300°C; DROPPING VELOCITY 5~6 g./hr.

| Sample | g. | Dehydrogenated oil g. | Gas produced ml. (N. T. P.) | $H_2$* ml. (N. T. P.) |
|---|---|---|---|---|
| (a) | 4 | 2.8 | 284.8 | 263.5 |
| (b) | 4 | 3.0 | 632.9 | 623.8 |
| (c) | 2 | 1.3 | 144.1 | 136.5 |
| (d) | 2 | 1.5 | 48.1 | 40.6 |

* The gas produced by dehydrogenation was analyzed by the Hempel method, and the volume of hydrogen produced was the volume of the gas removed of that of air.

**Identification of Aromatic Hydrocarbons Produced by Dehydrogenation. — Ultraviolet Spectra of the Dehydrogenated Oils.** — Ultraviolet spectra of dehydrogenated oils, dissolved in purified ethanol, were measured with a Beckman spectrophotometer model DU, and were shown in Fig. 4.

**Nitration of Dehydrogenated Oil[9].** — Dehydrogenated oil was added to a mixture of 1 vol. of concentrated nitric acid and 2 vol. of concentrated sulfuric acid and shaken, then boiled for five minutes and poured into cold water, and crude nitro-compounds were obtained. These compounds were separated by fractional recrystallization from ethanol solution, obtaining pure nitro-compounds. The result was shown in Table IV.

From Fig. 3 and Table IV, aromatic hydrocarcons produced by dehydrogenation were confirmed, and their original cycloparaffins and the ratio of their contents were estimated as shown in Table V.

## Results and Discussion

Saturated hydrocarbons identified from the low-temperature coal carbonization light oil produced at Ube Kôsan Co. Ltd. in this research are given below.

It has become clear, that the constituents of the saturated hydrocarbons, contained in this oil, consist of five straight-chain hydrocarbon (*n*-hexane, *n*-heptane, *n*-octane, *n*-nonane and *n*-decane) and five branched-chain hydrocarbon (2-methylhexane, 2-methylheptane, 2-methyloctane, 2-methylnonane and 3-methylnonane) and four cycloparaffins (cyclohexane, methylcyclohexane, 1,3-dimethylcyclohexane and 1,3,5-trimethylcyclohexane). Moreover, percentage of their contents in the saturated hydrocarbon oil (Sample A) separated from the material, is given in the gas chromatograms shown in Fig. 1, and Table VI.

The following observation is based on a study of the data presented in Table VI.

1) Saturated hydrocarbons, contained in the low-temperature coal carbonization light oil, are composed of about 91 per cent of saturated aliphatic hydrocarbon and about 9 per cent of cycloparaffinic hydrocarbon.

2) Saturated aliphatic hydrocarbons contained in this oil, are composed of two parts of *n*-paraffins and one part of isoparaffins.

3) The isoparaffins are all monomethylparaffins and these monomethylparaffins are nearly all 2-methylparaffins.

Comparing the saturated hydrocarbons, contained in high-temperature coal carbonization

light oil produced at Yawata Iron & Steel Co. Ltd., and identified by the author[4], with those identified in this investigation, the following observations are made.

1) Saturated hydrocarbons identified from both low-temperature and high-temperature coal carbonization light oils, consist mainly of saturated aliphatic hydrocarbons of 90 per cent saturated hydrocarbons in low-temperature coal carbonization light oil, and about 85 per cent in high-temperature coal carbonization light oil.

2) In low-temperature coal carbonization light oil, the ratio of contents of *n*-paraffins and isoparaffins is about 2 : 1. In high-temperature coal carbonization light oil, about 1 : 1.5.

3) Isoparaffins, contained in low- and high-temperature coal carbonization light oils, are all monomethylparaffins, and those contained in low-temperature coal carbonization light oil are all 2-methylparaffins, except 3-methylnonane, and the monomethylparaffins contained in high-temperature coal carbonization light oil, consist of 3-methylparaffins and 4-methylparaffins except 2-methylheptane.

F. D. Rossini and B. J. Mair[10] studying the saturated hydrocarbons contained mainly in U. S. A. Mid-Continent, Ponca petroleum concluded that the saturated hydrocarbons consisted mainly of saturated aliphatic hydrocarbons, which contains a large quantity of *n*-paraffin and monomethylparaffin and a trace of branched paraffin which has many branchings. This conclusion is analogous to that of the present studies on saturated hydrocarbons contained in coal carbonization light oil.

The author wishes to express his hearty thanks to Professor Sakujirô Kimura of Kyoto University, Professor Tamon Matsu'ura and the late Professor Bunkichi Masumoto of Hiroshima University and Professor Shôzô Tanaka of Kyoto University for their kind guidance and valuable advice throughout this study.

Thanks are also due to Ube Kôsan Co. Ltd. for donation of the materials used for this investigation. The author is indebted to Yawata Chemical Industries Co. Ltd. for the measurement of gas chromatograms.

# *Thermodynamic Studies on Cobalt Complexes. VI. Solubility of Nitropentamminecobalt(III), cis- and trans-Dinitrotetramminecobalt(III) and Trinitrotriamminecobalt(III) Complexes**

By Motoshichi MORI, Ryokichi TSUCHIYA and Hiroshi FUKUDA

(Received May 11, 1960)

Thermodynamic discussion of the monoacidopentamminecobalt(III) complexes which have $Cl^-$, $NO_3^-$ or $Br^-$ as the anionic ligand was carried out in the preceding paper[1]. In the present study the discussion is extended to the cobalt(III) complexes which have one, two or three nitro groups in the coordination sphere. Solubilities of nitropentamminecobalt(III) chloride, nitrate, bromide and perchlorate, *cis*- and *trans*-dinitrotetramminecobalt(III) chlorides and trinitrotriamminecobalt(III) complex were measured, and the standard free energies of their formation were calculated. The thermodynamic stability of the complexes formed by the substitution of ammonia by one, two or three nitro groups was also discussed.

## Experimental

Nitropentamminecobalt(III) chloride was prepared by the method of Jörgensen[2]. The nitrate, bromide and perchlorate were precipitated by nitric acid ammonium bromide and perchloric acid respectively from the aqueous solution of the

* Read at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo April, 1960.

1) M. Mori and R. Tsuchiya, This Bulletin, 33, 841 (1960).

2) S. M. Jörgensen, *Z. anorg. Chem.*, 17, 463 (1898).

chloride. *cis*- and *trans*-Dinitrotetramminecobalt (III) chlorides and trinitrotriamminecobalt(III) were also prepared by the method of Jörgensen[2-4].

The solubility in the saturated aqueous solution was measured colorimetrically by means of a Hitachi EPU-2 spectrophotometer. Since these nitro-complexes are unstable towards light, equilibrium of the solution was attained in a brown flask immersed in the thermostat to prevent the photo-decomposition.

## Results and Calculation

**Solubility of Nitropentamminecobalt(III) Complexes.** — The results obtained for nitropentamminecobalt(III) chloride, nitrate, bromide and perchlorate are listed in Tables I—IV.

The equilibrium of nitropentamminecobalt-(III) complex in water is expressed by,

$$[Co(NH_3)_5NO_2]X_2(s) = [Co(NH_3)_5NO_2]^{2+}(aq.) + 2X^-(aq.)$$

where X is an anion. If the activities of the cation, the anion and their activity coefficients are expressed by $a_{[Co(NH_3)_5NO_2]^{2+}}$, $a_{X^-}$, $\gamma_{[(Co(NH_3)_5NO_2]^{2+}}$ and $\gamma_{X^-}$ respectively, the equilibrium constant, $K$, is given by

$$K = a_{[Co(NH_3)_5NO_2]^{2+}} \cdot a^2_{X^-} = (m\gamma_{[Co(NH_3)_5NO_2]^{2+}})(2m\gamma_{X^-})^2 = 4m^3\gamma_{[Co(NH_3)_5NO_2]^{2+}} \cdot \gamma^2_{X^-}$$

where $m$ is the solubility in molality. When the mean activity coefficient is expressed by $\gamma_\pm$, the equilibrium constant is given by

$$K = 4m^3\gamma^3_\pm \quad (1)$$

The mean activity coefficient is calculated by the following formula[5] which gives the activity

Table I. Equilibrium of solution for nitropentamminecobalt(III) chloride

coefficient of an ion,

$$\log \gamma_{\text{ion}} = \frac{-0.358z^2\sqrt{2\omega}}{1+0.2325\times10^8 a\sqrt{2\omega}} - \log(1+0.018\,\nu m)$$

where $z$ is the charge of the ion, $\omega$, the ionic strength of the solution, $a$, the closest distance between an ion and another one and $\nu$, the number of ions dissociated from one molecule of the salt.

The logarithm of the equilibrium constant of the solution calculated by Eq. 1 is plotted in Fig. 1 against the reciprocal of the absolute temperature. A straight line is obtained. By the method of least squares the equations of these lines are calculated as follows:

$\log K = 6.243 - 2734/T$ for the chloride

$\log K = 7.636 - 3473/T$ for the nitrate

$\log K = 6.732 - 3156/T$ for the bromide

$\log K = 13.080 - 4715/T$ for the perchlorate

The free energy changes of solution are given as

$$\begin{aligned} \Delta G^\circ &= -RT\ln K = 12510 - 28.56\,T \\ \Delta G^\circ_{298} &= 3991 \text{ cal. for the chloride} \\ \Delta G^\circ &= 15890 - 34.93\,T \\ \Delta G^\circ_{298} &= 5477 \text{ cal. for the nitrate} \\ \Delta G^\circ &= 14440 - 30.79\,T \\ \Delta G^\circ_{298} &= 5262 \text{ cal. for the bromide} \end{aligned} \quad (2)$$

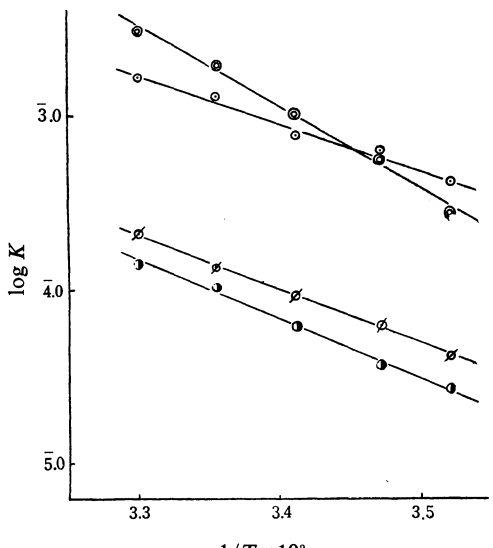

Fig. 1. The relationship between the equilibrium constant of solution and the temperature for nitropentamminecobalt-(III) chloride (⊙), nitrate (◑), bromide (Ø) and perchlorate(◎).

$$\begin{aligned} \Delta G^\circ &= 21570 - 59.84\,T \\ \Delta G^\circ_{298} &= 3728 \text{ cal. for the perchlorate} \end{aligned}$$

From these equations the heats of solution of the chloride, nitrate, bromide and perchlorate are obtained as $\Delta H = 12.51$, 15.89, 14.44 and 21.57 kcal. respectively. The entropy changes for each salt are calculated as $\Delta S^\circ =$ 28.6, 34.9, 30.8 and 59.8 e. u., respectively.

Since the standard free energy of formation of nitropentamminecobalt(III) ion in unit activity is known as $\Delta G^\circ_{f298} = -108.9$ kcal[6]. and the heat of formation as $\Delta H_f = -153.1$ kcal.[7], the relationship between the former and the absolute temperature is calculated as

$$\Delta G^\circ_f = -153100 + 148.3\,T \quad (3)$$

The free energies of formation $Cl^-$, $NO_3^-$, $Br^-$ and $ClO_4^-$ in unit activity were already obtained in the second paper[8] of this series as follows:

$$\begin{aligned} \Delta G^\circ_f &= -40020 + 29.1\,T \text{ for } Cl^- \\ \Delta G^\circ_f &= -49370 + 77.03\,T \text{ for } NO_3^- \\ \Delta G^\circ_f &= -28900 + 14.51\,T \text{ for } Br^- \\ \Delta G^\circ_f &= -31410 + 96.75\,T \text{ for } ClO_4^- \end{aligned} \quad (4)$$

Therefore the standard free energy of formation of nitropentamminecobalt(III) chloride in the solid state is calculated by Eqs. 3, 6 and 4 as

$$\begin{aligned} \Delta G^\circ_f &= -245700 + 235.1\,T \\ \Delta G^\circ_{f\,298} &= -175.6 \text{ kcal.} \end{aligned}$$

The values for the nitrate, bromide and perchlorate of the same complex were calculated by combining respective equations:

$\Delta G^\circ_f = -267700 + 337.3\,T$,

$\Delta G^\circ_{f\,298} = -167.2$ kcal., for the the nitrate

$\Delta G^\circ_f = -225300 + 208.1\,T$,

$\Delta G^\circ_{f\,298} = -163.3$ kcal., for the bromide

$\Delta G^\circ_f = -237500 + 401.6\,T$,

$\Delta G^\circ_{f\,298} = -117.8$ kcal., for the perchlorate

**Solubility of Dinitrotetramminecobalt(III) Complexes.**—The results obtained for *cis*- and *trans*-dinitrotetramminecobalt(III) chlorides are listed in Tables V and VI.

The process of solution of dinitrotetramminecobalt(III) chloride is represented by the following equation,

| 30 | 0.0627 | 3.299 | 0.805 | 25.48 | $\bar{3}$.407 |

$$[Co(NH_3)_4(NO_2)_2]Cl(s) = [Co(NH_3)_4(NO_2)_2]^+(aq.) + Cl^-(aq.)$$

When the activities of the cation, the anion and their activity coefficients are expressed by $a_{[Co(NH_3)_4(NO_2)_2]^+}$, $a_{Cl^-}$, $\gamma_{[Co(NH_3)_4(NO_2)_2]^+}$ and $\gamma_{Cl^-}$ respectively, the equilibrium constant of solution, $K$, is given as

$$K = a_{[Co(NH_3)_4(NO_2)_2]^+}\cdot a_{Cl^-} = (m\gamma_{[Co(NH_3)_4(NO_2)_2]^+})(m\gamma_{Cl^-}) = m^2\gamma_{[Co(NH_3)_4(NO_2)_2]^+}\cdot\gamma_{Cl^-} = m^2\gamma^2_\pm,$$

$m$ and $\gamma_\pm$ being the solubility in molality and the mean activity coefficient.

The plots of the logarithm of the above equilibrium constant against the reciprocal of the absolute temperature are given in Fig. 2 as straight lines for both salts. The straight lines are expressed by the following equations:

$$\log K = 5.970 - 2215/T$$

*cis*-$[Co(NH_3)_4(NO_2)_2]Cl$

$$\log K = 5.234 - 2376/T$$

*trans*-$[Co(NH_3)_4(NO_2)_2]Cl$

The free energy changes of solution are given as for the cis salt,

$$\Delta G^\circ = 9111 - 23.87\,T, \quad \Delta G^\circ_{298} = 1995 \text{ cal.} \quad (5)$$

and for the trans salt,

$$\Delta G^\circ = 9556 - 19.42\,T, \quad \Delta G^\circ_{298} = 3767 \text{ cal.} \quad (6)$$

From these equations $\Delta H = 10.13$ kcal. and $\Delta H = 10.87$ kcal. are obtained as the heats of solution of the cis and trans salts respectively and $\Delta S^\circ = 27.3$ e. u. and $\Delta S^\circ = 23.9$ e. u. are obtained as the entropy changes of the cis and trans salts respectively.

Since the energies of formation of *cis*- and *trans*-dinitrotetramminecobalt(III) ions in unit activity are known as $\Delta G^\circ_{f298} = -164.7$ kcal. and $\Delta G^\circ_{f298} = -161.4$ kcal[6]. and their heat of formation as $\Delta H_f = -159.9$ kcal. and $\Delta H_f = -159.1$ kcal[9]. respectively, the relationships between the free energies of formation and the absolute temperature are calculated for the cis salt as,

$$\Delta G^\circ_f = -159900 - 16.10\,T \quad (7)$$

and for the trans salt as,

$$\Delta G^\circ_f = -159100 - 7.72\,T \quad (8)$$

Then the free energy of formation of *cis*-dinitrotetramminecobalt(III) chloride in the solid state is calculated by Eqs. 4, 5 and 7 as

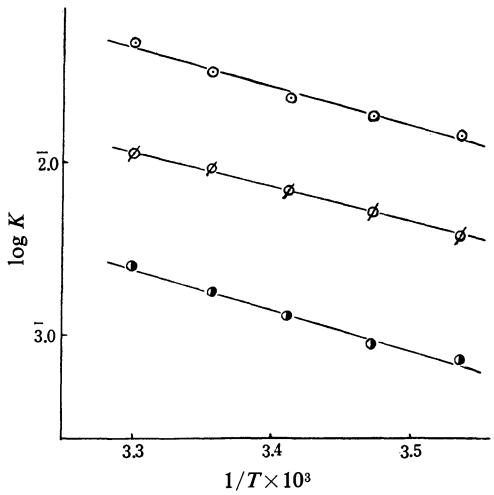

Fig. 2. The relationship between the equilibrium constant of solution and the temperature for *cis*-dinitrotetramminecobalt(III) chloride (⊙), corresponding *trans*-chloride (◑) and trinitrotriamminecobalt(III) complex (∅).

9) K. B. Yatsimirskii and L. L. Pankowa, *Zhur. Obshchei Khim.*, **19**, 623 (1949); K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), pp. 179, 180.

TABLE VII. EQUILIBRIUM OF SOLUTION FOR TRINITROTRIAMMINECOBALT(III) COMPLEX

| Temp. (°C) | Solubility (Molality $m\times10^3$) | $1/T\times10^3$ | $K\times10^3$ | log $K$ |
|---|---|---|---|---|
| 10 | 3.88 | 3.533 | 3.88 | $\bar{3}.588$ |
| 15 | 5.18 | 3.471 | 5.18 | $\bar{3}.714$ |
| 20 | 6.96 | 3.412 | 6.96 | $\bar{3}.843$ |
| 25 | 9.15 | 3.355 | 9.15 | $\bar{3}.961$ |
| 30 | 11.19 | 3.299 | 11.19 | $\bar{2}.049$ |

$$\Delta G_f^\circ = -210100+40.3\ T,$$
$$\Delta G_{f\,298}^\circ = -198.0 \text{ kcal.}$$

and that of *trans*-dinitrotetramminecobalt(III) chloride by Eqs. 4, 6 and 8 as

$$\Delta G_f^\circ = -210000+45.3\ T,$$
$$\Delta G_{f\,298}^\circ = -196.5 \text{ kcal.}$$

**Solubility of Trinitrotriamminecobalt(III) Complex.** — The results obtained for trinitrotriamminecobalt(III) complex is listed in Table VII.

When the solubility in molality of this complex is expressed by $m$, the equilibrium constant of the solution, $K$, is given by $K=m$. The relationship between the logarithm of $K$ and temperature is shown in Fig. 2 and it is expressed by the equation as below:

$$\log K = 4.696 - 2008/T.$$

The heat of solution is $\Delta H=9.19$ kcal. The free energy change of solution is given as,

$$\Delta G^\circ = 9186 - 21.44\ T,$$
$$\Delta G_{293}^\circ = 2795 \text{ cal.} \qquad (9)$$

The entropy change at 25°C is $\Delta S^\circ_{298}=21.44$ e. u.

The entropy of formation of hexamminecobalt(III) ion, nitropentamminecobalt(III) ion, *trans*- and *cis*-dinitrotetramminecobalt(III) ions were obtained as $-306.9$[8], $-148.3$[10], $7.72$[10] and $16.10$ e. u.[10], respectively. From these values it is found that the entropy of formation increases by 160 e. u., when every one gram equivalent of ammonia is replaced by one gram equivalent of nitro group. Therefore, if it is assumed that the entropy of formation of trinitrotriamminecobalt(III) complex in unit activity in aqueous solution is larger by three times 160 e. u. than that of hexamminecobalt(III) ion in unit activity, the entropy of the former is obtained as $\Delta S^\circ=172$ e. u. As the heat of formation of trinitrotriamminecobalt(III) complex in unit activity in aqueous solution is known as $\Delta H=-160$ kcal.[9], the free energy of formation is obtained as

$$\Delta G_f^\circ = -160000-172\ T,$$
$$\Delta G_{f\,298}^\circ = -211300 \text{ cal.} \qquad (10)$$

By Eqs. 9 and 10 the free energy of formation of trinitrotriamminecobalt(III) complex in the solid state is obtained as

$$\Delta G_f^\circ = -169200-150.6\ T,$$
$$\Delta G_{f\,298}^\circ = -214.1 \text{ kcal.}$$

10) See Eqs. 6, 11 and 10, in this paper.

## Discussion

**Thermodynamic Stability of Nitropentamminecobalt(III) Complexes.** — The solubility, the free energy of solution, the heat of solution and the free energy of formation of nitropentamminecobalt(III) complexes 25°C obtained above are summarized in Table VIII together with the radius of anions[11] forming these complexes. The lattice energy, $U_k$, required for the dissociation of solid complexes into gaseous ions is calculated by using the heat of solution and the heat of hydration of ions[11] which constitute complexes, and the values are shown in Table VIII.

From this table, the order of decrease of the solubility, the free energy of solution, the heat of solution, the lattice energy, the free energy of formation and the thermochemical and thermodynamic stability are found and shown in Table IX.

The same order was found for the solubility, the free energy of solution and the heat of solution of hexamminecobalt(III) complexes[8]. The order of the thermochemical and thermodynamic stability for the above nitropentamminecobalt(III) chloride, nitrate, bromide and perchlorate is in agreement with the order for the corresponding hexamminecobalt(III)[8], aquopentamminecobalt(III)[1] or acidopentamminecobalt(III) complexes[1]. The above order of the thermodynamic quantities may suggest that the ionic bond character between the complex cation and the anions generally diminishes as the ionic radius of the latter decreases, although several cases of reversal between the nitrate and the bromide are found as shown in Table VIII.

**Entropy of Solution of *cis*- and *trans*-Dinitrotetramminecobalt(III) Chlorides.** — The solubility, the free energy of solution, the heat of solution and the entropy of solution

11) K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), pp. 38—40.

Table IX. Order of decrease of the thermodynamic quantities

| | |
|---|---|
| Solubility | Chloride>Bromide>Nitrate |
| Free energy of solution | Nitrate>Bromide>Chloride |
| Heat of solution | Nitrate>Bromide>Chloride |
| Lattice energy | Chloride>Nitrate>Bromide>Perchlorate |
| Free energy of formation | Perchlorate>Bromide>Nitrate>Chloride |
| Thermochemical and thermodynamic stability | Chloride>Nitrate>Bromide>Perchlorate |

Table X. Thermodynamic functions of *cis*- and *trans*-dinitrotetramminecobalt(III) chlorides

| Complex | Solubility $m$ | Free energy of solution $\Delta G°$ cal. | Heat of solution $\Delta H$ kcal. | Entropy of solution $\Delta S°$ e. u. |
|---|---|---|---|---|
| *cis*-$[Co(NH_3)_4(NO_2)_2]Cl$ | 0.263 | 1990 | 10.13 | 27.3 |
| *trans*-$[Co(NH_3)_4(NO_2)_2]Cl$ | 0.0521 | 3731 | 10.87 | 23.9 |

of these two isomers at 25°C are summarized in Table X.

As shown in Table X, the cis chloride is more soluble than the trans chloride and the free energy of solution of the former is much lower than that of the latter. The large difference between the free energies of solution is attributed to the fact that the entropy of solution of the cis salt is considerably larger than that of the trans salt, since the heat of solution is approximately the same. In other words, the free energy changes of solution of these two isomers are affected much more by the entropy effect rather than the enthalpy effect.

**Relationship between the Free Energy of Formation and the Number of Coordinated Nitro-groups.** — The free energies of formation of nitropentamminecobalt(III), dinitrotetramminecobalt(III) and hexamminecobalt(III) complexes are plotted against the number of coordinated nitro-groups in Fig. 3. Straight lines were obtained for the chlorides, nitrates, bromides and perchlorates. These four lines all converge at a point which corresponds to the free energy of formation of trinitrotriamminecobalt(III) complexes. It shows that an additivity rule holds between the free energy of formation and the number of nitrogroups.

When the free energy of formation of these complexes and the number of nitrogroups are expressed by $\Delta G_f°$ and $n$ respectively, these straight lines are expressed by

$$\Delta G_f° = an + c, \qquad (11)$$

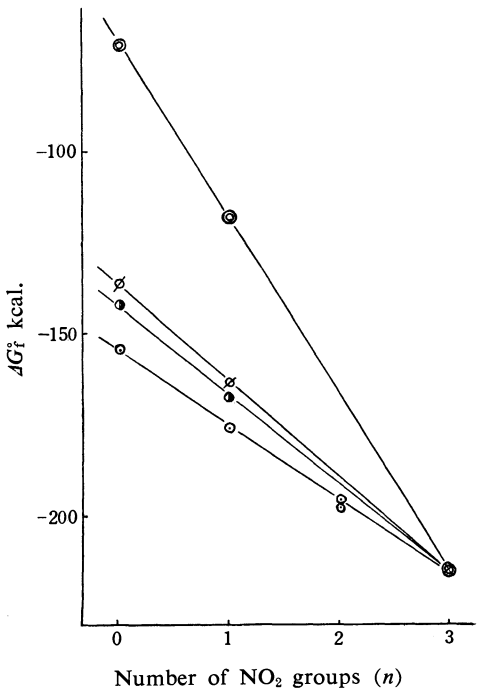

Fig. 3. The relationship between the free energy of formation and the number of nitro-groups coordinated in the series of cobalt(III) nitroammine complexes, that is
$[Co(NH_3)_{6-n}(NO_2)_n]Cl_{3-n}$ (⊙),
$[Co(NH_3)_{6-n}(NO_2)_n](NO_3)_{3-n}$ (◑),
$[Co(NH_3)_{6-n}(NO_2)_n]Br_{3-n}$ (Ø)
and $[Co(NH_3)_{6-n}(NO_2)_n](ClO_4)_{3-n}$ (◎).
(⊗) is trinitrotriamminecobalt(III) complex.

where $c$ is the free energy of formation of a hexamminecobalt(III) complex[8] and $a$ a constant. The constant $a$ gives the difference between the free energy of formation of $[Co(NH_3)_{6-n}(NO_2)_n]X_{3-n}$ and that of $[Co(NH_3)_{6-n-1}(NO_2)_{n+1}]X_{3-n-1}$, which is obtained from Fig. 3 as:

$a=-19.9$ kcal. for chloride

$a=-24.1$ kcal. for nitrate

$a=-26.0$ kcal. for bromide

$a=-47.6$ kcal. for perchlorate

**Free Energy Required for the Dissociation of the Anion from Nitroamminecobalt(III) Complexes.** — The value of $a$ in Eq. 11 for the chlorides is assumed as the sum of the changes of the free energy of formation in two processes such as:

(a) $[Co(NH_3)_6]Cl_3(s) \rightarrow [Co(NH_3)_6]Cl_2(s) \quad \Delta(\Delta G_f^\circ)_a$

(b) $[Co(NH_3)_6]Cl_2(s) \rightarrow [Co(NH_3)_5NO_2]Cl_2(s) \quad \Delta(\Delta G_f^\circ)_b$

that is,

$$a=\Delta(\Delta G_f^\circ)_a+\Delta(\Delta G_f^\circ)_b$$

If it is assumed that the change of the free energy of formation in process (b) is approximately equal to that in the following process,

$[Co(NH_3)_6]^{3+}(aq.) \rightarrow [Co(NH_3)_5NO_2]^{2+}(aq.) \quad \Delta(\Delta G_f^\circ) = -54.4$ kcal.[6]

that is,

$$\Delta(G_f^\circ)_b \fallingdotseq \Delta(G_f^\circ) = -54.4 \text{ kcal.}$$

then the value in the above process (a) is calculated as $\Delta(\Delta G_f^\circ)_a=34.5$ kcal. by using the value $a=-19.9$ kcal. for the chloride. The value $\Delta(\Delta G_f^\circ)_a$ is the free energy required for the elimination of one gram equivalent of chloride ion in the outer coordination sphere frome nitroammin cobalt(III) chloride.

In the same way, the free energies required for eliminating one gram equivalent of $NO_3^-$, $Br^-$ or $ClO_4^-$ in the outer sphere from the respective complexes are calculated as below:

$\Delta(\Delta G_f^\circ)_a=30.3$ kcal. for nitrate

$\Delta(\Delta G_f^\circ)_a=28.4$ kcal. for bromide

$\Delta(\Delta G_f^\circ)_a=6.8$ kcal. for perchlorate

These values show that the dissociation of the anion from cobalt(III) nitroammine complexes becomes more difficult in the order: perchlorate <bromide<nitrate<chloride. This also indicates that the thermodynamic stability of these complexes increases in the same order.

## Summary

1. From the solubility of cobalt(III) nitroammine complexes the thermodynamic stability was found to decrease in the order, chloride> nitrate>bromide>perchlorate.

2. The free energy of solution of *cis*-dinitrotetramminecobalt(III) chloride is lower than that of the trans chloride. This fact is attributed to the abnormally large value of the entropy of solution of the former compared with the latter.

3. Between the free energy of formation of cobalt(III) nitroammine complexes and the number of coordinated nitro-groups there exists a linear relationship.

# *Thermodynamic Studies on Cobalt Complexes. VII. Solubility of Erdmann's Salt and Related Complexes**

By Motoshichi MORI, Ryokichi TSUCHIYA, Eishin KYUNO and Takashi NISHIDE

(Received May 11, 1960)

Although there have been several investigations[1] on the structure of Erdmann's salt, ammonium tetranitrodiamminecobaltate(III), no thermodynamic study has ever been made on it. In the preceding paper[2] we determined the solubility of nitropentamminecobalt(III), *cis*- and *trans*-dinitrotetramminecobalt(III) and trinitrotriamminecobalt(III) complexes and calculated the standard free energy of formation of solid cobalt(III) ammine complexes containing one, two or three nitrogroups. In the present paper the solubility of the cobalt-(III) ammine complexes containing four nitrogroups, i. e., tetranitrodiamminecobaltate(III) complexes was measured. The solubilities of some of these salts have already been reported[3,4]. In the present study the measurement was extended to several other salts and to different temperatures.

## Experimental

The complexes studied were the following: [I] the so called Erdmann's salt, namely ammonium tetranitrodiamminecobaltate(III) $NH_4[Co(NH_3)_2(NO_2)_4]$, [II] the corresponding potassium salt $K[Co(NH_3)_2(NO_2)_4]$, [III] *cis*-dinitrotetramminecobalt(III) - tetranitrodiamminecobaltate(III) *cis*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$, and [IV] the corresponding trans isomer among 1-1 valency type salts, [V] nitropentammincobalt(III)-tetranitrodiamminecobaltate(III) $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$ and [VI] chloropentamminecobalt(III)-tetranitrodiamminecobaltate(III) $[Co(NH_3)_5Cl][Co(NH_3)_2(NO_2)_4]_2$ among 1-2 valency type salts and [VII] hexamminecobalt(III) - tetranitrodiamminecobaltate(III) $[Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3$ among 1-3 valency type salts.

Erdmann's salt [I] was prepared by the method of Jörgensen[5] and the potassium salt [II] was precipitated from the aqueous solution of I with potassium nitrate. III and IV were prepared by the double decomposition of I and *cis*-dinitrotetramminecobalt(III) nitrate[6] and the trans form chloride[7] respectively. V, VI and VII were prepared by the double decomposition of I and nitropentamminecobalt(III) chloride[8], chloropentamminecobalt(III) chloride[9] and hexamminecobalt(III) chloride[10], respectively.

The measurement of the solubility was made by measuring the cobalt content or the absorbancy of the saturated aqueous solution. The former was carried out by iodometry and the latter with a Hitachi EPU-2 spectrophotometer.

## Results and Calculation

The results of measurement are listed in Tables I—VII. The solubilities are expressed in molality, $m$. The mean activity coefficients $\gamma_\pm$ given for I and II are the values obtained in the first paper of this series[11] and those for the other salts are the values calculated by Debye-Hückel's limiting formula,

$$\log \gamma_\pm = -0.505\, z_+ z_- \sqrt{\mu}$$

where $z_+$ and $z_-$ are the charges of each cation and anion and $\mu$ is the ionic strength of each solution.

**Equilibrium Constant of Solution and Standard Free Energy of Formation of Erdmann's Salt.**— When Erdmann's salt is dissolved in water, the change is expressed by

$$NH_4[Co(NH_3)_2(NO_2)_4]\,(s) = NH_4^+\,(aq.) + [Co(NH_3)_2(NO_2)_4]^-\,(aq.)$$

The equilibrium constant of the solution, $K$, is given as in the preceding paper[2] by $K = m^2\gamma^2_\pm$.

A plot of the logarithm of $K$ against the reciprocal of the absolute temperature is given in Fig. 1 as a straight line, the equation being calculated by the method of least squares as

$$\log K = 0.8981 - 771.8/T$$

The free energy change of solution is given by

$$\Delta G^\circ = 3530 - 4.108\,T, \quad \Delta G^\circ_{298} = 2305 \text{ cal.} \qquad (1)$$

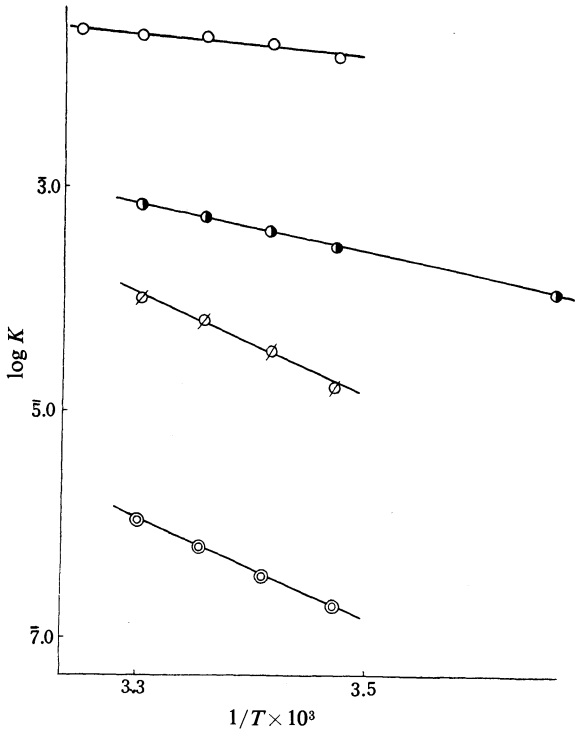

Fig. 1. The relationship between the equilibrium constant of solution and the temperature for Erdmann's salt, $NH_4[(Co\cdot(NH_3)_2(NO_2)_4]$ (○), $K[Co(NH_3)_2(NO_2)_4]$ (◑), *cis*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2\cdot(NO_2)_4]$ (∅), and *trans*-$[Co(NH_3)_4(NO_2)_2]\cdot[Co(NH_3)_2(NO_2)_4]$ (◎).

The heat of solution and the entropy change of solution at 25°C are obtained as $\Delta H=3530$ cal. and $\Delta S^\circ=4.108$ e. u., respectively.

As described in the preceding paper[2], it is found that the entropy of formation of cobalt (III) nitroammine complexes increases by 160 e. u. for each replacement of one gram equivalent of ammonia by one gram equivalent of nitrogroup. Therefore the sum of this value and the entropy of formation of trinitrotriamminecobalt(III) complex in unit activity in aqueous solution, $\Delta S^\circ=172$ e. u., may be regarded as that of tetranitrodiamminecobaltate (III) anion in unit activity in aqueous solution, i. e. $\Delta S^\circ=332$ e. u. Since the heat of formation of the latter is $\Delta H=-164.9$ kcal.[12], the free energy of formation is given by the equation:

$$\Delta G_f^\circ=-164900-332\,T,\quad \Delta G_{f\,298}^\circ=-263.9\text{ kcal.} \tag{2}$$

The free energy of formation of $NH_4^+$ in unit activity is given as[13]

$$\Delta G_f^\circ=-31740-42.74\,T \tag{3}$$

From Eqs. 1, 2 and 3, the free energy of formation of Erdmann's salt in the solid state is calculated as

$$\Delta G_f^\circ=-200200-288.9\,T,$$

$$\Delta G_{f\,298}^\circ=-286.3\text{ kcal.}$$

**Free Energy of Formation of Potassium Tetranitrodiamminecobaltate(III).**—The equilibrium constant of the solution of potassium tetranitrodiamminecobaltate(III) is given by $K=m^2\gamma^2_\pm$ in the same way as that of Erdmann's salt described above. The relationship between $\log K$ and $1/T$ is given by a straight line in Fig. 1, which is expressed by the equation,

$$\log K=3.917-2138/T$$

The free energy change of solution is given as

$$\Delta G^\circ=9777-17.92\,T,\quad \Delta G_{298}^\circ=4436\text{ cal.} \tag{4}$$

and the heat of the solution is $\Delta H=9777$ cal., and the entropy change of the solution at 25°C is $\Delta S^\circ=17.92$ e. u. The free energy of formation of $K^+$ in unit activity in aqueous solution is given as

$$\Delta G_f^\circ=-60040-24.91\,T \tag{5}$$

From Eqs. 2, 4 and 5, the free energy of formation of potassium tetranitrodiamminecobaltate(III) in the solid state is calculated as below:

$$\Delta G_f^\circ=-234700-339\,T,\quad \Delta G_{f\,298}^\circ=-335.8\text{ kcal.}$$

**Free Energy of Formation of *cis*- and *trans*-Dinitrotetramminecobalt(III)-Tetranitrodiamminecobaltates(III).**—The equilibrium constants of solution of these salts are given by $K=m^2\gamma_\pm{}^2$ as above and the relationships between $\log K$ and $1/T$ are given by two straight lines for both salts in Fig. 1, which are expressed for the cis salt by

$$\log K=10.71-4450/T$$

and for the trans salt by

$$\log K=9.014-4532/T$$

The free energy change of solution of the cis salt is obtained as

$$\Delta G^\circ=20350-48.98\,T,\quad \Delta G_{298}^\circ=5751\text{ cal.} \tag{6}$$

and that of the trans salt is obtained as

$$\Delta G^\circ=20730-41.23\,T,\quad \Delta G_{298}^\circ=8438\text{ cal.} \tag{7}$$

The heat of solution and the entropy change of solution of the above cis salt are $\Delta H=20350$ cal. and $\Delta S^\circ=48.98$ e. u. and those of the above trans salt are $\Delta H=20730$ cal. and $\Delta S^\circ=41.23$ e. u., respectively.

13) C. C. Stephenson, *J. Am. Chem. Soc.*, **66**, 1436 (1944).

14) A. E. Hill and J. E. Ricci, *J. Am. Chem. Soc.*, **53**, 4305 (1931).

In the preceding paper[2] the free energy of formation of *cis*- and *trans*-dinitrotetramminecobaltate(III) ions was obtained respectively as

$$\Delta G_f^\circ = -159900 - 16.10\,T \quad (8)$$

$$\Delta G_f^\circ = -159100 - 7.72\,T \quad (9)$$

From Eqs. 2, 6 and 8, the free energy of formation of the cis salt in the solid sate is obtained as

$$\Delta G_f^\circ = -345200 - 299.1\,T,$$

$$\Delta G_{f\,298}^\circ = -434.4 \text{ kcal.}$$

and from Eqs. 2, 7 and 9, that of the trans salt in the solid state is obtained as

$$\Delta G_f^\circ = -344700 - 298.5\,T,$$

$$\Delta G_{f\,298}^\circ = -433.7 \text{ kcal.}$$

**Free Energy of Formation of Nitropentamminecobalt(III)-Tetranitrodiamminecobaltate(III).** —The equilibrium constant of solution of this complex is given by $K = 4\,m^3\gamma^3_\pm$ and a plot of $\log K$ against $1/T$ gives a straight line in Fig. 2, which is expressed by the equation:

$$\log K = 7.530 - 4667/T$$

The free energy change of solution is given by

$$\Delta G^\circ = 21390 - 34.44\,T,$$

$$\Delta G_{298}^\circ = 11130 \text{ cal.} \quad (10)$$

The heat of solution and the entropy change of solution are obtained as $\Delta H = 21.39$ kcal. and $\Delta S^\circ = 34.44$ e. u.. respectively.

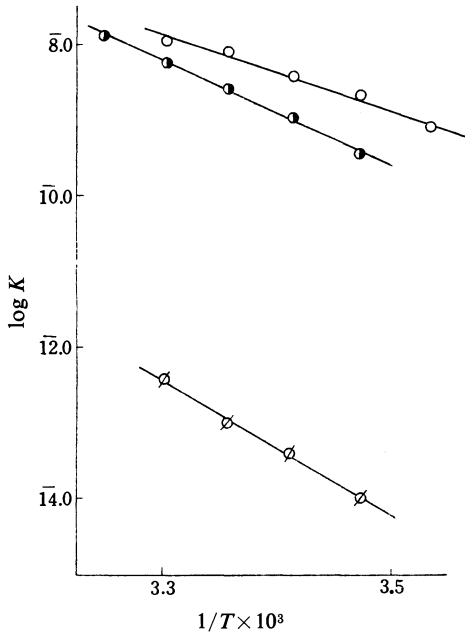

Fig. 2. The relationship between the equilibrium constant of solution and the temperature for $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$ (○), $[Co(NH_3)_5Cl][Co(NH_3)_2(NO_2)_4]_2$ (◑) and $[Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3$ (∅).

The free energy of formation of nitropentamminecobalt(III) ion was obtained in the preceding paper[2] as

$$\Delta G_f^\circ = -153100 + 148.3\,T \quad (11)$$

From Eqs. 2, 10 and 11, that of nitropentamminecobalt(III)-tetranitrodiamminecobaltate(III) is obtained as below:

$$\Delta G_f^\circ = -504300 - 481.3\,T,$$

$$\Delta G_{f\,298}^\circ = -647.8 \text{ kcal.}$$

**Free Energy of Formation of Chloropentamminecobalt(III)-Tetranitrodiamminecobaltate(III).** —The equilibrium constant of solution of this complex is also given by $K = 4\,m^3\gamma^3_\pm$ in the same way as the above. A plot of $\log K$ against $1/T$ gives a straight line in Fig. 2 and its equation is calculated as

$$\log K = 13.93 - 6714/T$$

The free energy change of solution is given by

$$\Delta G^\circ = 30710 - 63.72\,T,$$

$$\Delta G_{f\,298}^\circ = 11710 \text{ cal.} \quad (12)$$

The heat of solution is $\Delta H = 30710$ cal. and the entropy change of solution, $\Delta S^\circ = 63.72$ e. u.

The free energy of formation of chloropentamminecobalt(III) ion is obtained from the solubility data[3] and given by the equation,

$$\Delta G_f^\circ = -156100 + 270.9\,T \quad (13)$$

From Eqs. 2, 12 and 13, the free energy of formation of chloropentamminecobalt(III)-tetranitrodiamminecobaltate(III) in the solid state is calculated as

$$\Delta G_f^\circ = -516600 - 329.4\,T,$$

$$\Delta G_{f\,298}^\circ = -614.8 \text{ kcal.}$$

**Free Energy of Formation of Hexamminecobalt(III)-Tetranitrodiamminecobaltate(III).**— The equilibrium constant of solution of this complex is given by $K = 27\,m^4\gamma^4_\pm$ in the same way as that of the hexamminecobalt(III) salts already reported[15]. The logarithm of $K$ is plotted against $1/T$ in Fig. 1 as a straight line, the equation being

$$\log K = 16.83 - 8873/T$$

The free energy change of solution is given by

$$\Delta G^\circ = 40590 - 76.98\,T,$$

$$\Delta G_{298}^\circ = 17640 \text{ cal.} \quad (14)$$

The heat of solution is obtained as $\Delta H = 40590$ cal. and the entropy change of solution as $\Delta S^\circ = 76.98$ e. u.

TABLE VIII. THERMODYNAMIC FUNCTIONS OF NITROAMMINECOBALT(III) COMPLEXES AT 25°C

| Complex | Solubility | Heat of solution | Equivalent free energy of solution | Entropy change of solution | Lattice energy | Standard free energy of formation |
|---|---|---|---|---|---|---|
| | $m$ | $\Delta H$ cal. | $\Delta G°$ cal. | $\Delta S°$ e.u. | $U$ kcal. | $\Delta G_f^\circ$ kcal. |
| $NH_4[Co(NH_3)_2(NO_2)_4]$ | 0.209 | 3530 | 2305 | | | −286.3 |
| $K[Co(NH_3)_2(NO_2)_4]$ | 0.0684 | 9777 | 4436 | | | −335.8 |
| *cis*-$[Co(NH_3)_4(NO_2)_2]\cdot[Co(NH_3)_2(NO_2)_4]$ | $8.99\times10^{-3}$ | 20350 | 5751 | 48.98 | 101.4 | −434.4 |
| *trans*-$[Co(NH_3)_4(NO_2)_2]\cdot[Co(NH_3)_2(NO_2)_4]$ | $8.38\times10^{-4}$ | 20730 | 8438 | 41.23 | 101.7 | −433.7 |
| $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$ | $1.46\times10^{-3}$ | 21390 | 5565 | | 321.4 | −647.8 |
| $[Co(NH_3)_5Cl]\cdot[Co(NH_3)_2(NO_2)_4]_2$ | $1.00\times10^{-3}$ | 30710 | 5857 | | 323.7 | −614.8 |
| $[Co(NH_3)_6][Co(NH_3)_2\cdot(NO_2)_4]_3$ | $2.84\times10^{-4}$ | 40590 | 5880 | | 664.6 | −863.7 |

In the second paper[15] of this series the free energy of formation of hexamminecobalt-(III) ion was already obtained as

$$\Delta G_f^\circ = -146000 + 307\,T \qquad (15)$$

Therefore, from Eqs. 2, 14 and 15, the free energy of formation of hexamminecobalt(III)-tetranitrodiämminecobaltate(III) in the solid state is given by

$$\Delta G_f^\circ = -681300 - 612\,T,$$
$$\Delta G_{f\,298}^\circ = -863.7 \text{ kcal.}$$

## Discussion

The thermodynamic functions of the nitroamminecobalt(III) complexes at 25°C calculated above are summarized in Table VIII. In this table the free energy of solution is the value for one gram equivalent of each complex, i. e., equivalent free energy of solution.

As shown in this table, the solubilities of these complexes decrease in the order of 1–1, 1–2 and 1–3 valency type salts. In these respects *trans*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2\cdot(NO_2)_4]$ presents a single exception. The equivalent free energies of solution lie within the region between 5500 and 5900 cal. except for *trans*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$, $K[Co(NH_3)_2(NO_2)_4]$ and Erdmann's salt. This corresponds to the free energy required for breaking a bond between the cation and the anion and hydrating each of the ions when the salt is dissolved.

The free energy of solution of *cis*-dinitrotetramminecobalt(III)-tetranitrodiamminecobaltate(III) is remarkably less than that of the corresponding trans salt. This is due to the fact that the entropy change of solution of the former is much greater than that of the latter. In other words, the entropy effect plays an important role when the cis and trans salts are dissolved in water just as in the case of the *cis*- and *trans*-dinitrotetramminecobalt(III) chloride reported in the preceding paper[2].

The heats of hydration of the complex ions concerned are listed in Table IX[16].

TABLE IX. HEAT OF HYDRATION OF COMPLEX IONS

| Complex ion | Heat of hydration (kcal.) |
|---|---|
| $[Co(NH_3)_4(NO_2)_2]^+$ | −40 |
| $[Co(NH_3)_5NO_2]^{2+}$ | −218 |
| $[Co(NH_3)_5Cl]^{2+}$ | −211 |
| $[Co(NH_3)_6]^{3+}$ | −501 |
| $[Co(NH_3)_2(NO_2)_4]^-$ | −41 |

By using these values and the heats of solution of the cobalt(III) nitroammine complexes described above, their lattice energies are computed. These are also shown in Table VIII.

The standard free energies of formation of four cobalt(III) nitroammine complexes in the solid state are given by:

$$2Co(s) + 6N_2 + 9H_2 + 6O_2 = \textit{cis}\text{-}[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2\cdot(NO_2)_4] \quad \Delta G_f^\circ = -434.4 \text{ kcal.} \qquad (a)$$

$$2Co(s) + 6N_2 + 9H_2 + 6O_2 = \textit{trans}\text{-}[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2\cdot(NO_2)_4] \quad \Delta G_f^\circ = -433.7 \text{ kcal.} \qquad (b)$$

$$3Co(s) + 9N_2 + 27/2H_2 + 9O_2 = [Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2 \quad \Delta G_f^\circ = -647.8 \text{ kcal.} \qquad (c)$$

$$4Co(s) + 12N_2 + 18H_2 + 12O_2 = [Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3 \quad \Delta G_f^\circ = -863.7 \text{ kcal.} \qquad (d)$$

16) K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), p, 38.

By dividing a and b by two, c by three and d by four the following values are obtained:

$$Co(s)+2N_2+9/2H_2+3O_2 = 1/2\ cis\text{-}[Co(NH_3)(NO_2)_2]\cdot[Co(NH_3)_2(NO_2)_4]$$
$$\Delta G_f^\circ = -217.2\ \text{kcal.}$$

$$Co(s)+3N_2+9/2H_2+3O_2 = 1/2\ trans\text{-}[Co(NH_3)_4(NO_2)_2]\cdot[Co(NH_3)_2(NO_2)_4]$$
$$\Delta G_f^\circ = -216.9\ \text{kcal.}$$

$$Co(s)+3N_2+9/2H_2+3O_2 = 1/3\ [Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2 \qquad \Delta G_f^\circ = -215.9\ \text{kcal.}$$

$$Co(s)+3N_2+9/2H_2+3O_2 = 1/4\ [Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3$$
$$\Delta G_f^\circ = -215.9\ \text{kcal.}$$

From these values it is found that the free energy of formation of the above-mentioned cobalt(III) nitroammine complexes is proportional to the number of cobalt atoms contained in one molecule of these complexes.

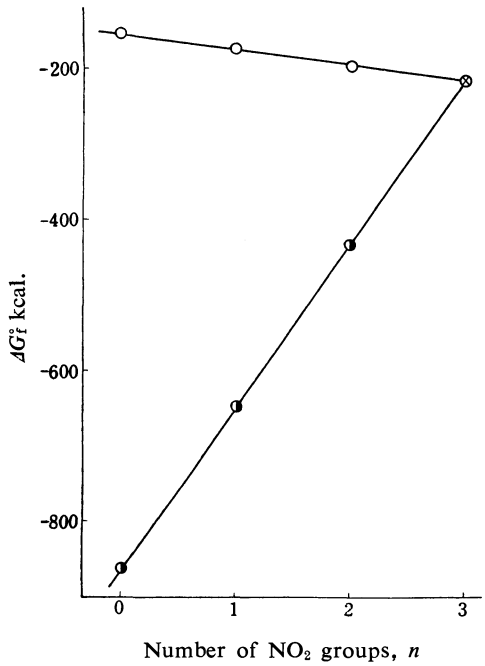

Fig. 3. The relationship between the free energy of formation and the number of nitrogroups co-ordinated in the series of several tetranitrodiamminecobaltates-(III), that is $[Co(NH_3)_{6-n}(NO_2)_n][Co(NH_3)_2(NO_2)_4]_{3-n}$ (◑) and $[Co(NH_3)_{6-n}(NO_2)_n]Cl_{3-n}$ (○).
(⊗) is trinitrotriamminecobalt(III) complex.

When the free energies of formation of the series consisting of $[Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3$—$[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$—$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$ are plotted against the number of $NO_2$ contained in their cations in Fig. 3, a straight line is obtained. This line passes through a point giving the free energy of formation of $[Co(NH_3)_3(NO_2)_3]$. The line for the free energy of formation of the series, $[Co(NH_3)_6]Cl_3$—$[Co(NH_3)_5NO_2]Cl_2$—$[Co(NH_3)_4(NO_2)_2]Cl$, against the number of $NO_2$ also converges to the same point as shown in Fig. 3.

It can be expected that the free energies of formation of $[Co(NH_3)_6][Co(NO_2)_6]$, $[Co(NH_3)_5NO_2][Co(NH_3)(NO_2)_5]$, $[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$ and $2[Co(NH_3)_3(NO_2)_3]$, are almost equal. The latter three are produced by the successive replacement of $NH_3$ in cation and $NO_2$ in anion of $[Co(NH_3)_6][Co(NO_2)_6]$ with $NO_2$ and $NH_3$ respectively, thus forming a set of coordination isomers. Thus the free energy of formation of $2[Co(NH_3)_3(NO_2)_3]$ is $\Delta G_f^\circ = -428.2$ kcal., that of *cis*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$ $\Delta G_f^\circ = -434.4$ kcal. and that of the trans salt $\Delta G_f^\circ = -433.7$ kcal., although those of $[Co(NH_3)_6][Co(NO_2)_6]$ and $[Co(NH_3)_5NO_2][Co(NH_3)(NO_2)_5]$ have not been found. These facts mean that the free energy of formation cobalt(III) nitroammine complexes is additive with respect to the $NO_2$ group.

Furthermore, it is also found that the thermodynamic stability of $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$ is greater than that of $[Co(NH_3)_5Cl][Co(NH_3)_2(NO_2)_4]_2$, since the free energy of formation of the former is less than that of the latter.

## Summary

The solubilities of Erdmann's salt, $NH_4[Co(NH_3)_2(NO_2)_4]$, and the following complexes which have the same complex anion, $K[Co(NH_3)_2(NO_2)_4]$, *cis*- and *trans*-$[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$, $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$, $[Co(NH_3)_5Cl][Co(NH_3)_2(NO_2)_4]_2$ and $[Co(NH_3)_6][Co(NH_3)_2(NO_2)_4]_3$ were measured. Based upon the thermodynamic functions calculated from the above measurement, the free energy of solution, the lattice energy and the free energy of formation of these complexes were calculated and discussed.

# *Oxidizing Action of Hydroperoxides. IV. On the Oxidation of Aryl Alkyl Ketones*

By Kazuhiro MARUYAMA

(Received March 23, 1960)

This research was started with a view to studying the liquid phase autoxidation of *p*-cymene some years ago. In the liquid phase autoxidation of *p*-cymene in the presence of alkali hydroxide, no resinous product was produced and 8-hydroxy-*p*-cymene, cumic acid and *p*-toluic acid were found, accompanied by a negligibly small amount of *p*-methylacetophenone — an interesting contrast to the autoxidation in the absence of alkali hydroxide. From the studies on the autoxidation of some hydrocarbons, it was observed[1] that alkylhydroperoxides act as a strong oxidizing agent on alkylbenzene and also on some carbonyl compounds*, e. g., the primary carbon atom at $\alpha$-position of the side chain is oxidized to alcohol, to aldehyde and finally to carboxylic acid, the secondary carbon is oxidized to carbonyl group and finally decomposes to yield a mixture of acids and the tertiary carbon atom is oxidized to alcohol and/or decomposes to ketone having a fewer number of carbon atoms. Especially, aryl alkyl ketones are easily split by these oxidizing agents into aromatic carboxylic acid and aliphatic alcohol. Further, in all these oxidation reactions, in contrast to peracid oxidation, no phenolic substances are produced. Also diaryl ketones are not affected by these oxidizing agents — an outstanding difference as compared with the case of the cleavage of ketones by peracids** —, whereas aryl alkyl ketones are affected with great ease. In this paper are reported only the oxidation of aryl alkyl ketones.

## Experimental

**Materials.** — *p*-Methylacetophenone was prepared by the action of acethyl chloride on toluene using anhydrous aluminium chloride as a catalyst. The resulting *p*-methylacetophenone was distilled under reduced pressure using Hempel's column, b. p. 94~95°C/12 mmHg: semicarbazone, m. p. 205°C. Propiophenone was prepared by the action of propionyl chloride on benzene suspending anhydrous aluminum chloride. The resulting propiophenone was completely freed from aluminum ions by shaking with acid and alkali, and was distilled under reduced pressure. B. p. 105°C/20 mmHg, m. p. 21°C. *tert*-Butyl phenyl ketone was synthesized from isopropyl phenyl ketone, following Halle's method[2]. B. p. 220~222°C, 104~106°C/17 mmHg, 2,4-dinitrophenylhydrazone; m. p. 166~168°C. Benzophenone was prepared by the action of benzoyl chloride on benzene suspending anhydrous aluminum chloride. M. p. 47~48°C. Fluorenone was synthesized by the oxidation of commercial grade fluorene, following Fanto's method[3]. M. p. 83~84°C. *p*-Nitrobenzophenone was synthesized by the action of *p*-nitrobenzoyl chloride on benzene suspended with anhydrous aluminum chloride, following Schroeter's method[4]. M. p. 138°C. *tert*-Butylhydroperoxide was synthesized by the action of 30% hydrogen peroxide on *tert*-butanol, following Milas and Surgenor's method[5]. The obtained mixture of *tert*-butylhydroperoxide and di-*tert*-butylperoxide was fractionally distilled under reduced pressure. For the purpose of obtaining highly purified hydroperoxide, this process was repeated four times. B. p. 36°C/19 mmHg. $n_D^{27}$: 1.3967. Cumylhydroperoxide was synthesized by the autoxidation of cumene, following Armstrong, Hall and Quin's method[6]. The obtained cumylhydroperoxide was purified by the fractionation under a high vacuum. B. p. 53~54°C/0.0005 mmHg.

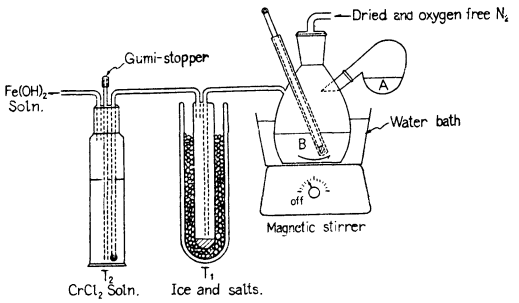

Fig. 1. Reaction apparatus.

**Reaction Apparatus and Procedure.**—The reaction apparatus is shown in Fig. 1. Ketone, monochlorobenzene and finely powdered analytical grade

potassium hydroxide were charged in B and hydroperoxide in A. After the air in the reaction vessel (A and B) was substituted completely with dried and purified nitrogen gas and the temperature of the reaction mixture was made to reach 80°C, and then the hydroperoxide was poured into the reaction mixture by rotating the part A by hand. A flow of the nitrogen gas was maintained constantly to 30 cc./min. during the reaction. A vigorous reaction occurred and the temperature of the reaction mixture was raised to about 90°C. Trap $T_1$ was cooled with ice and salt for condensing therein low boiling substances. The oxygen evolved during the reaction was determined at Trap $T_2$ charged with chromous chloride hydrochloric acid solution[7].

**Oxidation.**—*Acetophenone.*—10 g. of acetophenone were dissolved in 150 cc. monochlorobenzene in which 1.3 g. of finely powdered special grade potassium hydroxide were suspended. As an oxidizing agent, 2.0 g. of *tert*-butylhydroperoxide were used. The reaction mixture was agitated by a magnetic stirrer. After the temperature of the reaction mixture reached 80°C, A was gradually rotated to pour the peroxide into B. Then, a vigorous reaction occurred and a white precipitate appeared immediately. Almost all the peroxide was decomposed in the first hour, but about 6 hr. were required to complete the decomposition. After the end of the reaction, the reaction mixture was extracted with a total of 300 g. of water three times. The water extract was acidified with 2 N sulfuric acid and the precipitated benzoic acid was collected, dried and weighed. The filtrate was neutralized with concentrated ammonia water and concentrated to 10 cc., and then subjected to a paperchromatographic analysis. However, no appreciable amount of formic acid was observed. The substances condensed in Trap $T_1$ were gaschromatographically tested and methanol and *tert*-butanol were found to be the main components.

*p-Methylacetophenone.* — 50 g. of *p*-methylacetophenone suspending 1.3 g. of finely powdered potassium hydroxide were charged in B. As an oxidizing agent, 2.0 g. of *tert*-butylhydroperoxide were used. The reaction procedure was in manner similar to that of the acetophenone. The water extract was acidified. Then, *p*-toluic acid was the main reaction product. *p*-Acetylbenzoic acid and formic acid were paperchromatographically detected in the filtrate, but the amounts of acids were too small to be estimated. *p*-Toluic acid (m. p. 176°C) was confirmed by recrystallization and paperchromatography. The condensate of the Trap $T_1$ was analyzed gaschromatographically to find methanol and *tert*-butanol as the main components.

*Propiophenone.*—10 g. of propiophenone were dissolved in 150 cc. monochlorobenzene in which finely powdered 1.7 g. potassium hydroxide suspended. As an oxidizing agent, 2.0 g. of *tert*-butylhydroperoxide were used. After the temperature of the reaction mixture reached 80°C, A was rotated to pour the peroxide into the mixture and a vigorous reaction took place. Then the temperature of the reaction mixture reached as high as 95°C in a few minutes. Almost all the amount of the peroxide was decomposed in the first half hour, but the reaction continued for 6 hr. to complete the decomposition of the peroxide. The water extract was acidified with 2 N sulfuric acid and the acid precipitated was filtrated, dried and weighed. The filtrate was steamdistilled. Acetic acid was found in the distillate. This was estimated by titration. The acetaldehyde and acetone were also detected as 2,4-dinitrophenylhydrazone on a silicagel chromatostrip, but not estimated. From the condensate in Trap $T_1$, ethanol, *tert*-butanol and methanol were respectively detected gaschromatographically (see Fig. 2), but not estimated. A trace of oxygen was detected in Trap $T_2$.

TABLE I. OXIDATION OF KETONES BY HYDROPEROXIDES AT 80°C, 6 hr.

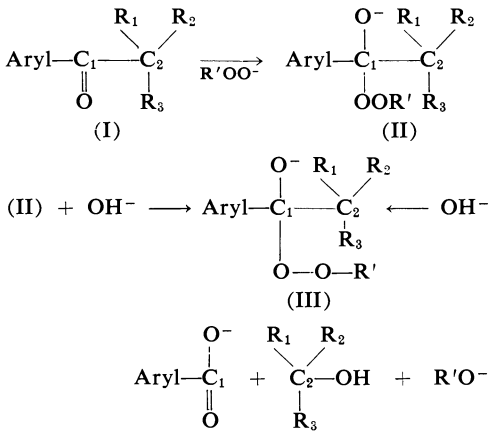
| Ketone g. | | Hydroperoxide g. | Recovered ketone g. | Reaction products, g. Acid | Alcohol | Oxygen |
|---|---|---|---|---|---|---|
| Acetophenone | 10 | *tert*-Butyl 2.0 | 9.1 | Benzoic acid 0.50 | (*tert*-Butanol), methanol | None |
| 〃 | 10 | *tert*-Butyl 2.0 | 8.5 | Benzoic acid 0.71 | (*tert*-Butanol), methanol | None |
| *p*-Methyl-acetophenone | 50 | *tert*-Butyl 2.0 | 45 | *p*-Toluic acid 1.0, *p*-acetylbenzoic acid (trace), formic acid (trace) | (*tert*-Butanol), | None |
| 〃 | 50 | *tert*-Butyl 2.0 | 42 | *p*-Toluic acid 1.5, *p*-acetylbenzoic acid (trace), formic acid (trace) | (*tert*-Butanol), methanol | Trace |
| Propiophenone | 10 | *tert*-Butyl 2.0 | 8.3 | Benzoic acid 1.13, acetic acid 0.34, formic acid (trace) | (*tert*-Butanol), ethanol, methanol | None |
| Propiophenone | 17 | *tert*-Butyl 2.0 | — | Benzoic acid 1.13, acetic acid —, formic acid (trace) | (*tert*-Butanol), ethanol, methanol | None |
| *tert*-Butylphenyl ketone | 10 | Cumyl 10 | 9.5 | Benzoic acid 2.5 | (*tert*-Butanol), methanol, ($\alpha$,$\alpha$-dimethyl-benzylalcohol) | None |
| *tert*-Butylphenyl ketone | 0.5 | *tert*-Butyl 1.0 | — | Benzoic acid 0.05 | (*tert*-Butanol), methanol | Trace |
| Benzophenone | 10 | *tert*-Butyl 2.0 | | None reaction | | $O_2$-evolute |
| *p*-Nitrobenzo-phenone | 10 | *tert*-Butyl 2.0 | | None reaction | | $O_2$-evolute |
| Fluorenone | 10 | *tert*-Butyl 2.0 | | None reaction | | $O_2$-evolute |

(*tert*-Butanol and $\alpha$,$\alpha$-dimethylbenzylalcohol are reduction products of *tert*-butylhydroperoxide and cumylhydroperoxide.)

phenone and $\alpha$,$\alpha$-dimethylbenzylalcohol, if the thermal decomposition would occur. On the other hand, the reduction product which could be expected through the reduction of cumylhydroperoxide by ketone, is $\alpha$,$\alpha$-dimethylbenzylalcohol. Treatment of the reaction mixture was almost the same as in the case of propiophenone. From the water extract was obtained benzoic acid which was confirmed by recrystallization and paperchromatography. *tert*-Butanol was detected and estimated as the main component of low boiling substances condensed in the Trap $T_1$. This was confirmed as phenylurethane (m. p. 136°C; Found: C, 67.4; H, 7.4. Calcd. for $C_{11}H_{16}O_2N$: C, 68.3; H, 7.7%) and also gaschromatographic analysis was made. Besides *tert*-butanol, a small amount of methanol was also found.

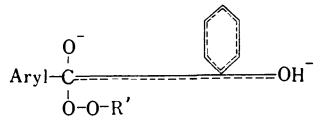
*Benzophenone, p-Nitrobenzophenone and Fluorenone.* —10 g. of each of all the ketones were dissolved separately in 100 cc. monochlorobenzene in which 2.8 g. of finely powdered potassium hydroxide were suspended. 5 g. of *tert*-butylhydroperoxide were used as an oxidizing agent. Oxidation was carried out in the same apparatus as shown in Fig. 1. After the reaction had finished, the same procedure as before was repeated. None of the oxidation products of the ketones was found and the greater part of unchanged ketones were completely recovered during the reaction. Only oxygen—one of the decomposition products of the hydroperoxide—evolved vigorously in all the cases. *tert*-Butanol, acetone and methanol—the remaining decomposition products of the hydroperoxide itself—were found in the reaction mixture. The experimental results were summarized in Table I.

## Discussion



It is likely that for the oxidizing action of hydroperoxides their anions are responsible, because the hydroperoxides themselves can cleave aryl alkyl ketone very slowly or can not do so at all in the absence of alkali hydroxide. Furthermore, in the course of oxidation of alkylbenzenes[8] (*p*-xylene, cumene, ethylbenzene, *p*-cymene and tetralin) by alkali hydroperoxide, the author has observed that potassium hydroxide suspended in alkylbenzene at the beginning of the reaction dissolves nearly completely after the hydroperoxide added and then the oxidation occurs immediately. The alkylbenzenes are oxidized to alcohols, ketones and carboxylic acids. In contrast to this, hydroperoxide alone can not oxidize a side chain of the alkylbenzene in the absence of alkali hydroxide. It may, therefore, be induced

8) K. Maruyama and R. Goto, *Wood Research*, **21**, 12 (1959).



that the anion of hydroperoxide acts as an oxidizing agent. Kharasch et al.[9] asserted that the anion of hydroperoxide is an oxidizing agent in the oxidation of alcohol by hydroperoxide in alkaline solution.

In the oxidation of the above aryl alkyl ketones, the first oxidation products are arylcarboxylc acid and aliphatic alcohol. For example, when propiophenone is oxidized in the above conditions, benzoic acid, ethanol, acetaldehyde and acetic acid are obtained, and it may be seen easily that the latter two products are the second oxidation products. *tert*-Butyl phenyl ketone is also decomposed to benzoic acid and *tert*-butanol (peroxide used, cumylhydroperoxide). Oxidation of both acetophenone and *p*-methylacetophenone yields benzoic acid, *p*-toluic acid and methanol as the main reaction products. However, the methanol provides no direct evidence of alcoholic cleavage originating in the methyl-group of acetophenone or *p*-methylacetophenone, because methanol can be a thermal decomposition product of *tert*-butylhydroperoxide. In spite of the above misgivings, it may be possible to deduce that the methanol would be a cleavage product of acetophenone and also of *p*-methylacetophenone from the estimation of the results of cleavage of propiophenone and *tert*-butyl phenyl ketone; that is, the propiophenone produces ethanol and the *tert*-butyl phenyl ketone produces *tert*-butanol. On the other hand, it seems reasonable to deduce from the experimental results of benzophenone, *p*-nitrobenzophenone and fluorenone that in general diaryl ketones resist the oxidizing agent. This is noticeably different from the cleavage of ketones by peracids, because diaryl ketones are easily cleft by peracids—e. g., peracetic acid—to produce phenols and carboxylic acids[10]. In the cleavage of alkyl aryl ketones by peracids with the exception of cycloalkyl aryl ketones[11], a migration of the aryl group generally occurs, resulting in the formation of phenol.

On the contrary, acetophenone, *p*-methylacetophenone, propiophenone and *tert*-butyl phenyl ketone do not undergo such a cleavage as to yield phenols and carboxylic acids as anticipated from the phenolic cleavage of ketones, that is, the C–C linkage between the carbon atom of benzene and the carbonyl carbon atom resists the attack of hydroperoxide anion and the C–C linkage between the carbonyl carbon atom and the alkyl carbon atom is selectively attacked. For the above reasons, it may be assumed that the oxidation mechanism of ketones by hydroperoxide anion must be kept separated from that of ketones by peracids. Recently, House et al.[12] have reported the cleavage of ketones by alkaline hydrogen peroxide with a poor yield. Based upon the fact that butyrophenone does not cleave to phenol and butyric acid but does cleave to benzoic acid and propionic acid and/or corresponding propanol, they suggest a partly revised oxidation mechanism based on the peracid oxidation mechanism. However, the oxidation mechanism imagined by them hardly explains the results obtained by the present author in the oxidation of diaryl ketones. The author proposes a new oxidation scheme as follows:

In the above assumption, hydroxide anion plays in III a most important role, that is a "pushing action" which is indispensable to the cleavage of ketones. In the case of action of hydroperoxide anion to diaryl ketones resulting in no cleavage, the pushing action of hydroxide anion on $C_2$ which is the benzene ring carbon atom, would not effectively affect it owing to the high potential energy of the transition state represented by IV.

(IV)

Moreover, the fact that with aromatic halides the $S_N2$ type substitution reaction can not easily proceed appears to support a new mechanism, mentioned above. In future, the author has the intention to perform an experiment of oxidation of ketones having an asymmetric carbon atom at $C_2$.

# *Préparation de l'Emulsion à Grand Contraste pour l'Usage Lithographique*

Par Shinichi KIKUCHI et Hirozo UEDA

(Reçu le 13 Février, 1960)

Récemment les pellicules à grand contraste comme Kodalith, Reprolith ont commencé à remplacer les plaques humides dans l'usage lithographique. Les émulsions de cette espèce doivent avoir un grand contraste, une forte densité maximum et une partie inférieure courte de la courbe caractéristique. D-85, dit révélateur contagieux[1] est recommandé pour rendre l'image à grande contraste. Nous avons préparé les émulsions qui s'adaptent à ce révélateur spécial et examiné les conditions de préparation de l'émulsion qui paraissent avoir une influence sur le contraste[2]. Avant d'aborder le développement par D-85 qui est spécial, nous avons essayé de développer les émulsions avec les révélateurs N.S.G. et D-11 dont les formules seront données plus tard.

## Méthode Adoptée

Nous avons pensé qu'un des points les plus importants pour rendre l'image à grand contraste était d'uniformiser les dimensions des grains d'halogénure d'argent. Pour atteindre ce but, nous avons procédé à varier les conditions suivantes:

1. Le mode d'addition du nitrate d'argent dans la solution de bromure de potassium.
2. La concentration en ions argent dans la solution de nitrate d'argent.
3. La vitesse d'addition du nitrate d'argent.
4. L'excès des ions halogènes.
5. Le rapport des concentrations en ions $Cl^-$, $Br^-$ et $I^-$.
6. Le rapport de la concentrations en ions argent à la concentration de gélatine.
7. La concentration de la gélatine.
8. La température.

Nous avons employé dans cette expérience la méthode statistique pour déterminer si quelques-unes de ces conditions ont une influence sur le contraste. La corrélation entre les les conditions et le gamma est jugée par le degré de confiance à 95 et 97%.

## Partie Expérimentale

**Examen des Gélatines Utilisées.**—Dans la première partie de cette étude nous avons examiné les propriétés physico-chimiques et chimiques des gélatines destinées à la préparation de l'émulsion. La teneur en eau de la gélatine a été mesurée par la diminution de poids de la gélatine laissée dans une étuve sèche maintenue à la température constante de 105±5°C. Le point de fusion et le point de congélation ont été mesurés d'après la méthode* recommandée par l'Association des Compagnies Photographiques du Japon. La réaction de Feigl a été examinée de la manière suivante. Environ 1 ml. de la solution de gélatine à 10% qui contient 0.02 g. d'azoture de soude pour 5 ml. de la solution de gélatine, est étendu sur une plaque de verre 2×2 cm. puis laissé à se solidifier. Une heure après, une goutte de solution d'iode (1.268 g. d'iode et 2.5 g. de l'iodure de potassium sont dissous dans 1 litre d'eau distillée) est mise sur la gélatine et cela donne des bulles d'azote suivant la formule: $2NaN_3+I_2=3N_2+2NaI$.

Le nombre de bulle de gaz est compté pendant un quart d'heure et la quantité de bulles est classée entre les valeurs relatives 1 et 10. Cette méthode n'est que qualitative et peut donner une erreur assez élevée quand le nombre de bulles dépasse 40 par 0.5 $cm^2$.

La réaction de Vogel a été examinée de la manière suivante pour montrer le pouvoir réducteur de gélatine. 10 ml. de nitrate d'argent ammoniacal à 6% et 10 ml. de la solution de gélatine à 2% sont mélangés à 32°C et laissés à cette température pendant 24 heures. La couleur de la gélatine est comparée à l'aide d'un colorimètre de Dubosque et le degré de coloration est classé entre les valeurs relatives 1 et 10. Des propriété physico-chimiques des gélatines essayées sont données dans Tableau I.

2) E. J. Wall, "Photographic Emulsions", (1929) pp. 35, 48 et 67; Eder, "Handb. d. Photogrphie", (1927), Bd. 3 Teil I, 3 Aufl; A. Steigmann, "IX e Congré Intern. Photo. Paris", (1936), pp. 372—386.

* Cette méthode est semblable à celle de PAGI qui a paru dans *Bull. Soc. Phot. Sci. Japon*, No. 6, 34 (1956).

TABLEAU I. PROPRIÉTÉS PHYSICO-CHIMIQUES ET CHIMIQUES DES GÉLATINES

| Espèces d'échantillons | Eau % | Point de fusion, °C | Point de congélation, °C | Valeur Feigl | Valeur Vogel |
|---|---|---|---|---|---|
| Nitta No. 3 | 17.7 | 31.9 | 26.0 | 1 | 1 |
| Nippi process | 17.1 | 31.9 | 26.6 | 1 | 2 |
| Nippi ammonia | 16.4 | 30.4 | 25.5 | 10 | 1 |
| Takarazuka 179-5 | 16.5 | 32.5 | 28.5 | 4 | 5 |

**Procédé de Préparation de l'Emulsion.**—*a. Les solutions de réactifs.*—Nous avons préparé les solutions de nitrate d'argent, d'halogénure et de gélatine à température déterminée (45°C). La gélatine est dissoute à 45°C, après d'avoir gonflé dans l'eau. La quantité des solutions est en général de 50 ml.

*b. Addition des solutions et première maturation.*—Les solutions maintenues à 45°C sont mélangées brusquement dans un vase porcelaine et mises à la maturation pendant 20 min. avec agitation. L'appareil d'addition et de maturation est représenté par Fig. 1.

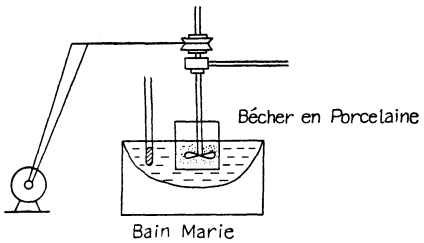

Fig. 1. Bain de maturation.

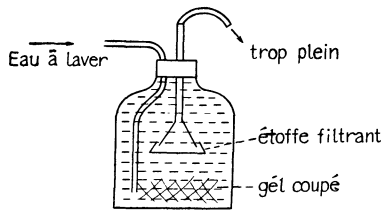

Fig. 2. Appareil de lavage de gél.

*c. Congélation de l'émulsion et son coupage en morceaux.*—Après la première maturation, l'émulsion est mise dans la glace pour la congélation et elle est laissée pendant une nuit dans un frigorifique. Le lendemain matin l'émulsion est coupée par un réseau encadré de bois et formé d'amylan (résine synthétique) dont la maille est de 3 mm. carré. Les émulsions coupées en morceaux sont lavées à l'eau courante dans l'appareil comme dans Fig. 2. La température de l'eau de lavage est maintenue à 14~16°C. La fin de lavage est contrôlée à l'aide du réactif de Nessler qui permet de vérifier s'il reste de l'ammoniaque. Pour 50 ml. d'émulsion une demi-heure de lavage est nécessaire.

*d. 2e Maturation.*—Après le lavage, l'émulsion est mise de nouveau dans un bécher de porcelaine où le gel doit se dissoudre en 1 min. à 45°C. En maintenant l'émulsion à cette température, le plus haut gamma est attteint avec une maturation de 40~70 min. L'agitation mécanique pendant la 2e maturation donne naissance à des bulles quand l'émulsion est étendue sur le verre. On agite donc lentement à la main.

*e. Coulage de l'émulsion sur le verre.*—Le verre de format 119×146 mm. est préalablement lavé, enduit d'une solution d'alun de chrome à 20% et desséché. Avant de coulage, il est porté à 35°C. Le prélèvement de 5 ml. d'émulsion est fait avec une pipette et le coulage est effectué. La couche est nivelée par une tige de verre. La plaque de verre est trans portée sur une planche de verre placée horizontalement et laissée à sécher à l'air à 35°C.

*f. Sensitométrie.*—La sensitométrie se fait par le sensitomètre type I de N.S.G. qui est muni d'un coin ayant une différence de densités successives de 0.15. Les révélateurs employés sont N.S.G. et D-11 à 20°C et ils sont appliqués pendant 4 minutes.

## Résultats

**Propriétés Physico-chimiques et Chimiques des Gélatines Utilisées.** — Les propriétés physico-chimiques et chimiques des gélatines utilisées sont données dans Tableau I. Dans ce tableau les valeurs relatives de Feigl se réfèrent à 1 de Nitta No 3 et 10 de Nippi ammonia et les valeurs de Vogel à 2 de Nippi 61-i et 10 de Nippi FAG 4.

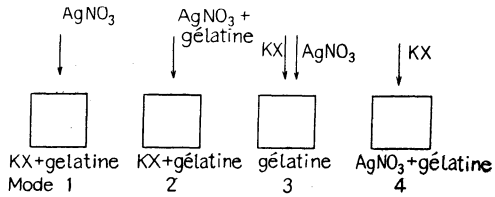

Fig. 3. Différents modes d'addition.

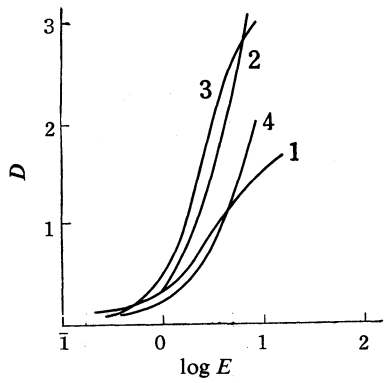

Fig. 4. Courbes caractéristiques.

**Différents Modes d'Addition.** — Nous avons employé quatre différents modes d'addition comme dans Fig. 3. Les résultats sont indiqués dans Tableau II. Prenons un exemple pour illustrer la signification des nombres donnés dans ce tableau. 25 ml. (0.025 g. mole) de la solution de nitrate d'argent 1 M (conc.) sont ajoutés à une solution de gélatine contenant 23.8 ml. de KBr 1.2 M et 1.2 M ml. de KI 1.2 M. Le repport de KBr/KI est de 23.8/1.2=19.8. Cette solution dissout 2.0575 g. de gélatine, ce qui donne le rapport gélatine en gramme/AgX en g. mole 2.0575/0.025=82.3. Dans les conditions où l'iodure est totalement précipité, le rapport AgBr/AgI est 23.56/1.43= 16.3. La quantité totale d'émulsion devient 50 ml. après l'addition.

Dans le mode 2, la quantité de gélatine est divisée en deux parties égales. Les courbes caractéristiques sont données dans Fig. 4 où l'ont voit que c'est le mode 2 qui donne la mailleure courbe avec un gamma élevé.

**Variation de l'Excès d'Halogénure, Rapport des Halogénures et Quantité de Gélatine.**—Dans cette série d'expériences, nous avons fait varier deux facteurs en même temps entre trois qui peuvent influencer les caractéristiques de l'émulsion (Tableaux III et IV). En comparant les résultats, nous avons trouvé qu'une valeur élevée du rapport halogénure d'argent gélatine et un petit excès d'halogénure favorisaient un gamma élevé. La variation du rapport AgCl/AgBr a peu d'effet dans les conditions de ces essais. Si l'on diminue la quantité de gélatine au-delà d'une limite, les grains d'halogénure d'argent sont susceptibles de s'aggroméler avec certaines sortes de gélatine. Nippi Process donne le meilleur résultat. Comme excès

d'halogénure, 25% est le meilleur.

*Manière de traitement des valeurs.*—Pour obtenir les résultats ci-dessus, nous avons employé la manière statistique pour obtenir le gamma probable.

Supposons qu'une relation linéaire existe entre deux valeurs $x$ et $y$ comme suit:

$$y=a_0+b_0x \quad (1)$$

où $a_0$ et $b_0$ sont constants. Les valeurs $y=y_i$ sont obtenues pour $x=x_i$ et $i=1, 2, \cdots\cdots n$. Si $Y_i$ est la valeur obtenue par la méthode de minimum de carrés des valeurs observées,

$$Y_i=a+bx_i$$

L'addition des carrés de déviation entre $y_i$ et $Y_i$ soit minimum:

$$y=\bar{y}+[\sum(x_i-\bar{x})(y_i-\bar{y})/\sum(x_i-\bar{x})^2](x_i-x)$$

$$=\bar{y}+\hat{\beta}(x_i-\bar{x}) \quad (2)$$

où $\bar{y}$ est le moyen de $y_i$, $\bar{x}$ est celui de $x_i$ et $\hat{\beta}$ correspond au gamma. Si l'on prend $S_y$ comme dispersion de $y$ et $n$, comme degré de liberté.

$$S_y=(1/n)\sum[y_i-\{\bar{y}+(\sum(x_i-\bar{x})(y_i-\bar{y})/\sum(x_i-\bar{x})^2)(x_i-\bar{x})\}]^2\equiv\hat{c} \quad (3)$$

Si la fonction $\hat{c}$ (la dispersion du groupe mère) suit la répartition $\chi^2$ du système ayant le degré de liberté $n$, la répartition $t$ est induite de la répartition $\chi^2$ comme suit:

$$t=\sqrt{(n-2)S_x^2}(\hat{\beta}-\gamma)/\sqrt{\hat{c}} \quad (4)$$

d'où

$$\gamma=\hat{\beta}\pm t\sqrt{\hat{c}}/\sqrt{(n-2)S_x^2} \quad (5)$$

où $\gamma$ est le gamma probable et

$$S_x^2=\sum(x_i-\bar{x})^2/n$$

Les auteurs citent un exemple de calcul dans Tableau V.

$$S_x^2=(x_i-\bar{x})/n=2700\times10^{-4}/18=150\times10^{-4}$$

$$\bar{y}=\bar{D}=1.43$$

$$\hat{\beta}=(x_i-\bar{x})(y_i-\bar{y})/(x_i-\bar{x})^2$$

$$=14030\times10^{-4}/2700\times^{-4}=5.20$$

$$\hat{c}=26.9$$

$$n-2=16$$

$t=2.12$ (pour le degré de confiance de 95%)

$$=5.20\pm\frac{2.12\sqrt{26.9}}{\sqrt{16\times150}}=5.20\pm0.22$$

$$=5.42\sim4.98$$

Par cette expérience nous avons voulu examiner l'effet sur gamma en faisant varier la quantité d'excès d'halogénure, du rapport d'ions halogène et la quantité de gélatine. Pour savoir l'effet de trois facteurs il faut faire au moins huit expériences. Mais nous avons fait l'application partielle en employant la méthode du carré latin avec deux niveaux de chaque condition. Le système est schématisé comme Tableau VI.

TABLEAU VI. SYSTÈME DE L'APPLICATION PARTIELLE DU CARRÉ LATIN

| Expérience | Facteurs 1 | 2 | 3 |
|---|---|---|---|
| I | A | C | E |
| II | A | D | F |
| III | B | C | F |
| IV | B | D | E |

Nous avons employé deux niveaux A, B du facteur 1, deux niveaux C, D du facteur 2 et E, F du facteur 3. La valeur obtenue, Val. I de l'équation (6) montre la variation de la différence entre A et B du facteur 1. D'autres facteurs se sont compensés les uns les autres.

Val. I = (Résultat I + Résultat II)/2
− (Résultat III + Résultat IV)/2 (6)

Total des carrés moyens :

$$C.F. = (5.20+3.00+1.84+1.45)^2/4 = 11.49^2/4 = 33.005$$

Influence du facteur 1 :

$$S_1 = \{(5.20+3.00)^2+(1.84+1.45)^2\}/2 - C.F. = 6.027$$

d'où s'obtient le rapport de dispersion 602.7.
Influence du facteur 2 :

$$S_2 = \{(5.20+1.84)^2+(3.00+1.45)^2\}/2 - C.F. = 1.627$$

Influence du facteur 3 :

$$S_3 = \{(5.20+1.45)^2+(3.00+1.84)^2\}/2 - C.F. = 0.819$$

D'où les rapports de dispersion des facteurs 2 et 3 sont respectivement 162.7 et 81.9.

D'après le tableau de répartition de $F$, $S_1$ et $S_2$ montrent que les facteurs 1 et 2 sont significatifs et que $S_3$ ne l'est pas pour varier gamma.

**Variation de Concentration de la Solution.**— Nous avons également essayé de faire varier la concentration de la solution d'argent et de la solution d'halogénure. Les résultats sont donnés dans Tableau VII.

Plus la concentration est grande, plus la sensibilité est grande et le gamma est petit. Au-dessus d'une certaine concentration, le voile

augmente sensiblement trandis que la sensibilité et le gamma diminuent.

**Cas où l'on Ajoute un Excès d'Ammoniaque.** Nous avons essayé d'ajouter un excès d'ammoniaque. Les résultats sont présentés dans Tableau VIII. Dans cette série d'expériences on a également fait varier la quantité de gélatine. Le voile était assez sensible et nous n'avons pas pu obtenir de résultats significatifs et utiles.

**Espèces de Gélatine.**—Nous avons essayé la formule No. 9 avec quatre espèces de gélatine. Nitta No. 3 donne le moindre voile et elle est considérée comme la meilleure parmi ces gélatines (Tableau IX).

**Emploi de Différents Révélateurs.**—Tous les résultats mentionnés jusqu'ici ont été obtenus par le révélateur NSG. D I I donne toujours un gamma plus élevé que le révélateur NSG. Les formules de de deux révélateurs sont données dans Tableau X. La différence entre ces deux gammas dans certains échantillons est donnée dans Tableau XI.

## Conclusion

Dans les conditions que nous avons essayées, le mode 2 d'addition du nitrate d'argent dans KBr avec division de la gélatine en deux parties a donné les résultats les plus conformes au but que nous avous visé proposés. L'observation à microscope électronique semble indiquer que ce mode donne les grains de grandeurs homogènes. Il est préférable de choisir l'excès d'halogénure entre 20 et 30%. Un rapport de la concentration de gélatine à la concentration d'halogénure d'argent voisin de 101 (en unité de gélatine gramme au g. mole de AgX). L'influence de certains autres facteurs n'est pas encore bien déterminée.

By Seizo OKAMURA and Tomonobu MANABE

(Received March 28, 1960)

It has been found by G. Oster that some solid polymers containing photo-sensitizer such as benzophenone could initiate graft polymerization with irradiation by ultra-violet as well as by ionizing rays[1-3]. In those cases, the primary action will be not on the polymer but on the photo-sensitizer, and the decomposed sensitizer fragment may abstract hydrogen atoms from the polymer molecules. The polymer radicals thus formed can initiate graft polymerization or cross-linking reaction.

The ultraviolet pre-irradiation method for graft polymerization or cross-linking reaction cannot be generally applied to thick films or a bundle of fibers because the penetrating power of the rays may be fairly low.

It is found here that some solid polymers containing initiator of radical polymerization of vinyl monomers such as benzoyl peroxide or azobisisobutyronitrile can initiate graft polymerization. This grafting method may be easily applied to thick films or to a bundle of fibres.

## Experimental

A commercial low density polyethylene film of $0.0017\,g.\cdot cm^{-2}$ thickness is soaked for 60 min. in the benzene solution of benzoyl peroxide ($20\,g.\,l^{-1}$) at 50°C, the surface is washed with benzene, and dried. The sample thus obtained contains benzoyl peroxide about 0.2 wt. %. The sample is then heated in air. The sample is sealed with purified methyl methacrylate monomer in a glass tube, and

1) G. Oster and O. Shibata, *J. Polymer Sci.*, **26**, 233 (1957).
2) G. Oster, G. K. Oster and H. Moroson, *J. Polymer Sci.*, **34**, 671 (1959).
3) S. Okamura and T. Manabe, *Isotopes and Radiation*, in press.

then heated in vacuum. After the treatment for graft polymerization, the sample is washed with benzene for about 20 hr. at room temperature in order to extract the homopolymer already formed. The complete extraction, however, will be very hard in such a condition, but some comparison between the graft polymerization conditions may be possible. The sample is then dried and weighed. The amount of graft polymerization will be defined here by

$$\text{graft polymerization \%} = \left( \frac{\text{weight of sample after graft polymerization}}{\text{weight of sample before graft polymerization}} - 1 \right) \times 100$$

The values of grafting thus obtained are rather scattered according to the inhomogeneity of the benzoyl peroxide content and of the sample thickness. Therefore kinetical discussion is omitted here.

## Results

**Time of Pre-heating.**—The effect of time of pre-heating on the graft polymerization is shown in Fig. 1, where the temperature of pre-heating is maintained at 110°C, and the polymerization temperature is 60°C.

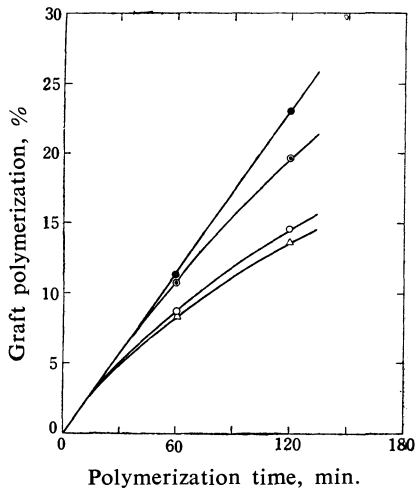

Fig. 1. Effect of time of pre-heating on graft polymerization.
Pre-heating temperature: 110°C
Polymerization temperature: 60°C
Time of pre-heating: -△- 15 min., -○- 30 min., -⊙- 45 min., -●- 60 min.

From the results shown in Fig. 1, it is recognized that the rate of graft polymerization increases with an increase of the time of pre-heating.

**Temperature of Pre-heating.**—The effect of temperature of pre-heating on the graft polymerization is shown in Fig. 2, where the time of pre-heating is maintained at 30 min., and the polymerization temperature is 60°C.

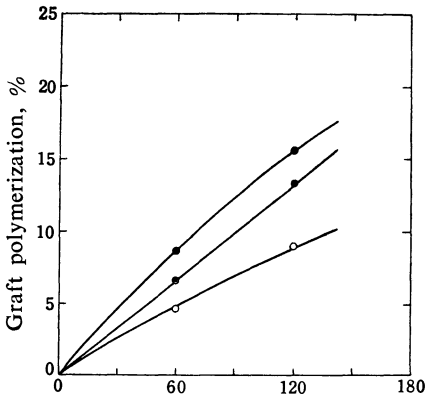

Fig. 2. Effect of temperature of pre-heating on graft polymerization.
Pre-heating time: 30 min.
Polymerization temperature: 60°C
Temperature of pre-heating: -○- 90°C, -⊙- 110°C, -●- 120°C.

From the results shown in Fig. 2, it is found that the rate of graft polymerization increases with the rise of temperature of pre-heating.

**Polymerization Temperature.**—The influence of polymerization temperature on the graft polymerization is represented in Fig. 3, where the pre-heating temperature is maintained at 110°C, and the pre-heating time is 30 min.

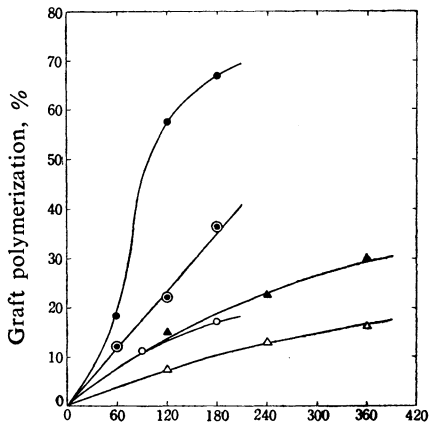

Fig. 3. Effects of polymerization temperature, pre-heating and benzoyl peroxide sensitization on graft polymerization.
Pre-heating: 110°C, 30 min.
-●-
-⊙- No pre-heating
-○- No BPO sensitization
} Polymerization temperature: 70°C
-▲-
-△- No BPO sensitization
} Polymerization temperature: 50°C

**After-effect of Pre-heating.**—The after-effect of pre-heating is shown in Fig. 4, where the pre-heating temperature is maintained at 110°C, the pre-heating time is 30 min. and the polymerization temperature is 60°C.

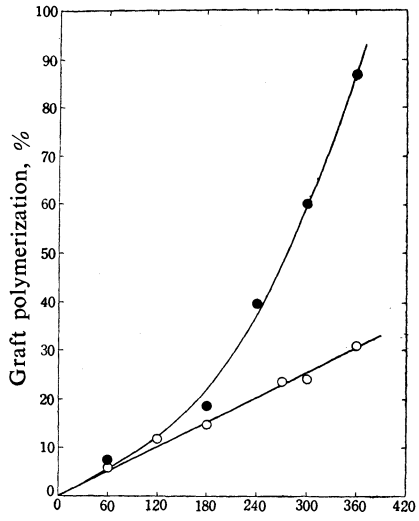

Fig. 4. After effect of pre-heating on graft polymerization.
Pre-heating: 110°C, 30 min.
Polymerization temperature: 60°C
Time interval after pre-heating until polymerization: -○- 4,300 min., -●- 300 min.

From the results represented in Fig. 4, it is shown that the rate of graft polymerization decreases with an increase of time interval after pre-heating until polymerization. And also, the difference of rates between two experiments having different intervals increases with an increase of polymerization time.

## Discussion

The mechanism of graft polymerization reported here may be as follows. I represents the initiator of radical polymerization, P the polymer, M the monomer, and $O_2$ the oxygen respectively.

**Reaction in Pre-heating.**

$I \rightarrow R\cdot$ (1) decomposition of initiator

$R\cdot + P \rightarrow P\cdot + RH$ (2) radical transfer to polymer, production of polymer radical

$P\cdot + O_2 \rightarrow POO\cdot$ (3) production of polymer peroxide radical

$P\cdot + R\cdot \rightarrow$ product (4) disappearence of polymer radical

$P\cdot + P\cdot \rightarrow PP$ (5) cross-linking reaction

$P\cdot + POO\cdot \rightarrow POOP$ (6) production of polymer diperoxide

$POO\cdot + R\cdot \rightarrow POOR$ (7) production of polymer peroxide

**Reaction in Graft Polymerization.**

$I \rightarrow R\cdot$ (8) decomposition of initiator

$POOP \rightarrow PO\cdot + PO\cdot$ (9) decomposition of polymer diperoxide

$POOR \rightarrow PO\cdot + RO\cdot$ (10) decomposition of polymer peroxide

$R\cdot + M \rightarrow RM\cdot$ (11) polymerization by initiator fragment

$PO\cdot + M \rightarrow POM\cdot$ (12) polymerization by polymer diperoxide fragment

$RO\cdot + M \rightarrow ROM\cdot$ (13) polymerization by polymer peroxide fragment

$P\cdot + M \rightarrow PM\cdot$ (14) polymerization by frozen polymer radical at the inside of polymer

$POO\cdot + M \rightarrow POOM\cdot$ (15) polymerization by frozen polymer peroxide radical

The increasing of time and the rise of temperature of pre-heating increase the initiator fragment [R·], and then the increase of graft polymerization may be expected (Figs. 1 and 2). The increase of time interval after pre-heating until polymerization results in the decrease of the concentration of frozen polymer radical (reactions 4 and 5), and then the decrease of graft polymerization may also be expected (Fig. 4). Reaction 14 is expected at the inside of polymer molecule, for the reaction of oxygen with radical (reaction 3) will be very fast.

## Summary

Some solid polymers containing initiator of radical polymerization of vinyl monomers can initiate graft polymerization by heating in air or in vacuo prior to polymerization. In the experiment on polyethylene film containing benzoyl peroxide (monomer: methyl methacrylate), the increase of time (from 0 to 60 min.) and the rise of temperature (from 20 to 120°C) in pre-heating procedure increase the graft polymerization rate. And also, the increase of time interval after pre-heating until polymerization results in the decrease of the graft polymerization rate.

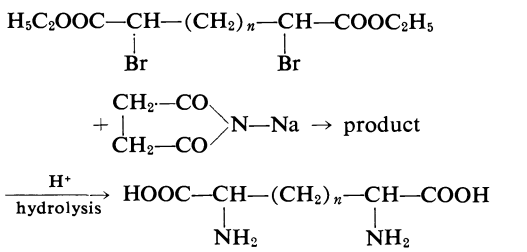
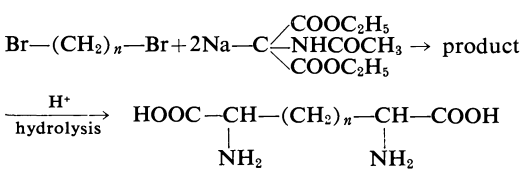
# *Synthesis of a,α'-Diaminodicarboxylic Acids*



By Koji Toi, Kan Mori and Yoshiharu Izumi

(Received April 11, 1960)



A systematic study of the synthesis of a series of $\alpha,\alpha'$-diaminodicarboxylic acids, containing a number of biologically and biochemically important amino acids, was made, mainly by amination of the corresponding $\alpha,\alpha$-dibromo-compounds using succinimide as an aminating reagent (Method I) and by condensation of diethyl acetamidomalonate with $\alpha,\alpha'$-dibromo-paraffin (Method II).

Among the compounds of this type, of particular interest is $\alpha,\alpha'$-diaminopimelic acid because of its presence in bacterial products[1,2], and because of its role as a precursor in the biosynthesis of lysine[3,4]. $\alpha,\alpha'$-Diaminosuccinic acid, with a chemical structure analogous to aspartic acid, asparagine, $C_4$-dicarboxylic acid and other biologically important substances, has recently been isolated from a natural source[5]. The other amino acids in this series have not yet been found in nature. However, $\alpha,\alpha'$-diaminoglutaric acid is regarded as a precursor in the biosynthesis of $\alpha,\gamma$-diaminobutyric acid.[6] Therefore the availability of these amino acids for biological investigations is desirable.

Method I:

Method II:

Succinimide was first used successfully as an aminating reagent by Akabori, Izumi and Fujiwara for the synthesis of $\alpha,\alpha'$-diaminopimelic acid (D. A. Pim.)[7]. In the present work this method was tried for the preparation of $\alpha,\alpha'$-diaminosuccinic (D. A. Suc.), glutaric (D. A. Glu.) and adipic acid (D. A. Adi.). However it was only successful for D. A. Adi. The diethyl acetamidomalonate method was tested in the preparation of D. A. Adi., D. A. Pim., $\alpha,\alpha'$-diaminosuberic (D. A. Seb.), azelaic (D. A. Aze.), and sebacic acid (D. A. Seb.). It was satisfactory for the synthesis of the three last named. Table I shows the results of the above synthesis.

D. A. Suc. has been prepared by reduction of sodium dihydroxytartarate osazone with sodium amalgam.[8-12] Wenner[13,14] and Mckennis et al.[15] prepared it in high yield by hydrolysis of the corresponding bisbenzylamino compound in the presence of Pd-C and hydrogen at high or atmospheric pressure. In the present work a 44 per cent yield of D. A. Suc. was readily obtained by amination of *meso*-$\alpha,\alpha'$-dibromosuccinate, obtained easily by bromination of diethyl fumarate in sunlight, using succinimide as an aminating reagent.

D. A. Glu. has been prepared by Carter et al.[16] by hydrogenolysis of diethyl pyrazoline-3, 5-dicarboxylate at a high pressure. Hellmann et at.[17] prepared it by reacting diethyl $\alpha$-acetamido - $\alpha$ - dimethylaminomethylmalonateiodomethylate with sodium salt of acetamidomalonate, and by hydrolysis of $\alpha,\alpha'$-diphosphiminoglutaric acid. The final product could not be obtained by amination of diethyl $\alpha,\alpha'$-dibromoglutarate with succinimide. Therefore the method of Carter et al. was reinvestigated. A modification of their procedures

Table I

| Compounds to be synthesized | Method I | | Method II | |
|---|---|---|---|---|
| | Starting material | Yield of product | Starting material | Yield of product |
| D. A. Suc. | *meso*-Diethyl $\alpha, \alpha'$-dibromosuccinic acid | 44% | — | — |
| D. A. Glu. | Diethyl $\alpha, \alpha$-dibromoglutaric acid | Trace | — | — |
| D. A. Adi. | Diethyl $\alpha, \alpha'$-dibromoadipic acid | 73% | Ethylene dibromide | Trace |
| D. A. Pim. | Diethyl $\alpha, \alpha'$-dibromopimelic acid | 81%[7] | Trimethylene dibromide | Trace |
| D. A. Sub. | — | — | Tetramethylene dibromide | 62% |
| D. A. Aze. | — | — | Pentamethylene dibromide | 66% |
| D. A. Seb. | — | — | Hexamethylene dibromide | 79% |

was employed and D. A. Glu. was synthesized in a yield of 33 per cent from glycine ethyl ester hydrochloride without separation of the individual intermediates. The method was as follows: to an aqueous solution of glycine ethyl ester hydrochloride was added an aqueous solution of sodium nitrite. An ethereal solution of methyl acrylate was added without separation of ethyl diazoacetate. Since the product could not be crystallized, the substance was reduced in ethereal solution at a high pressure of hydrogen in the presence of Raney's nickel. It was then hydrolyzed in hydrochloric acid.

Simmonds[18] reported the synthesis of D. A. Adi. and D. A. Pim. by the reaction of phthalimide with the corresponding $\alpha, \alpha'$-dibromo-compounds. Using succinimide instead of phthalimide, these two $\alpha, \alpha'$-dibromo-compounds were converted to D. A. Adi. and D. A. Pim. with comparatively good yields of 73 and 81 per cent, respectively. However, the use of diethyl acetamidomalonate resulted in very poor yields.

D. A. Sub., D. A. Aze., and D. A. Seb. were prepared by Neuberg[19] and Abderhalden et al.[20] from the corresponding $\alpha, \alpha'$-dibromo-compounds and ammonia. Simmonds[19] also reported the preparation of D. A. Seb. by a similar method and of D. A. Seb. and D. A. Aze. in 44 and 39 per cent yields, using acetamidomalonate. In the present work the use of acetamidomalonate resulted in yields of 62, 66, and 79 per cent for D. A. Sub., D. A. Aze. and D. A. Seb., respectively. This method seems the most suitable for these three amino acids, since the starting materials are readily available and the required operations are simple.

It is considered that the low yields of D. A. Suc. and D. A. Glu. in the succinimide method, and of D. A. Adi. and D. A. Pim. in the acetamidomalonate method are probably caused by an inhibition of the reaction by steric hindrance.

Table II. The chromatographic behavior of synthetic diaminodicarboxylic acids

| | $R_f$-value | |
|---|---|---|
| | Fee-form | Hydrochloride |
| D. A. Suc. | 0.0312 | 0.0402 |
| D. A. Glu. | 0.0406 | 0.0522 |
| D. A. Adi. | 0.0455 | 0.0600 |
| D. A. Pim. | 0.0570 | 0.0715 |
| D. A. Sub. | 0.0691 | 0.0878 |
| D. A. Aze. | 0.109 | 0.127 |
| D. A. Seb. | 0.157 | 0.186 |

The above seven amino acids and their hydrochlorides prepared as described above have $R_f$-values shown in Table II on paper chromatography using acetic acid-butanol-water (1 : 4 : 1) as solvent.

## Experimental

**D. A. Suc.** — To a solution of 5.5 g. (0.24 mol.) of sodium in 100 ml. of absolute ethanol was added 30 g. (0.30 mol.) of succinimide. This was heated on a water bath to dissolve the succinimide. To this mixture were added 0.5 g. of potassium iodide and 33 g. (0.10 mol.) of *meso*-$\alpha, \alpha'$-dibromosuccinic acid. The mixture was refluxed on an oil bath for 1 hr. It was cooled and filtered. The filtrate was concentrated in vacuo and the residue was hydrolyzed by refluxing in 100 ml. of concentrated hydrochloric acid and 50 ml. of water for 4 hr. The precipitated succinic acid was removed by filtration and the supernatant was concentrated under reduced pressure. The residual material was dissolved in 70 ml. of methanol and filtered to remove sodium chloride. On neutralization with aniline, D. A. Suc. crystallized immediately as paste or block. This crude solid was washed with 90 per cent methanol. It was dissolved in 100 ml. of warm 20 per cent hydrochloric acid and decolorized. The solution was adjusted to pH 6 with aqueous ammonia and 100 ml. of methanol was added to complete crystallization. White crystalline D. A. Suc. decomposing at 305~310°C was obtained in a yield of 6.0 g. (44 per cent).

Found : C, 32.10 ; H, 5.62 ; N, 18.54. Calcd. for $C_4H_8O_4N_2$ : C, 32.43 ; H, 5.44 ; N, 18.91%.

**D. A. Glu.**—A solution of 12 g. (0.15 mol.) of nitrite and 0.5 g. of sodium acetate in 15 ml. of

18) D. H. Simmonds, *Biochem. J.*, **58**, 520 (1954).
19) C. Neuberg, *Z. phys. Chem.*, **45**, 99 (1905).
20) E. Abderhalden and W. Zeisset; *Fermentforschung*, **9**, 336 (1928).

water was cooled to 0°C and a cold solution containing 14 g. (0.1 mol.) of glycine ethyl ester hydrochloride was added with stirring, external cooling being used to keep the temperature at 0~2°C. After 30 min. 13 g. (0.15 mol.) of methyl acrylate in 25 ml. of ether was added, and rapid stirring was continued for 1 hr. Then 4 ml. of acetic acid was added to the mixture dropwise, and stirring was continued for 1 hr. The ethereal layer was separated. The aqueous layer was extracted with 70 ml. of ether, and the combined ethereal solutions were dried over sodium sulfate. The ether was slowly removed by distillation until the total volume became 40 ml. This solution was then reduced at 80 kg./cm$^2$ by hydrogen in the presence of Raney's nickel for 3 hr. at 60°C and for a further 3 hr. at 120°C. After removal of the catalyst, the filtrate was concentrated under reduced pressure. The residue was hydrolyzed for 3 hr. in 50 ml of boiling concentrated hydrochloric acid. The hydrolysate was decolorized with charcoal and concentrated in vacuo. The residual material was dissolved in 50 ml. of 50 per cent methanol and then 20 ml. of aniline was added with vigorous shaking. D. A. Glu. was crystallized. After storing in a refrigerator, the product was filtered and washed with 10 ml. of water, and then twice with 10 ml. of methanol. The dried product weighed 5.3 g. or 33 per cent of the theoretical yield from glycine ethyl ester hydrochloride. It decomposed at 300~310°C without melting.

Found: C, 36.68 H, 6.40; N, 16.54. Calcd. for $C_5H_{10}O_4N_2$: C, 37.03; H, 6.22; N, 17.28%.

**D. A. Adi.** — This was prepared in a manner similar to that of D. A. Suc. using 5.5 g. (0.24 mol.) of sodium, 30 g. (0.3 g. mol.) of succinimide, and 36 g. (0.1 mol.) of diethyl $\alpha$, $\alpha'$-dibromoadipate. The white crystalline product, reprecipitated from hydrochloric acid and aqueous ammonia, weighed 13.6 g. (73 per cent) and decomposed at 275~277°C without melting.

Found: C, 38.99; H, 7.02; N, 15.49. Calcd. for $C_6H_{12}O_4N_2$: C, 40.90; H, 6.87; N, 15.90%.

**D. A. Pim.**—The preparation of this compound was reported in a previous paper.[1] The yield was 81 per cent, and the decomposition point was 307~310°.

**D. A. Sub.**—To 800 ml. of absolute alcohol containing 19 g. (0.825 mol.) of sodium was added 184 g. (0.85 mol.) of diethyl acetamidomalonate. The mixture was dissolved by heating on a water bath. Then 70 g. (0.324 mol.) of tetramethylenedibromide was added and the mixture was refluxed for 10 hr. The hot reaction mixture was filtered, the residue being washed with hot alcohol. The filtrate and the washings were combined and evaporated in vacuo. The residue was hydrolyzed in 1000 ml. of boiling hydrochloric acid for 5 hr. The mixture was concentrated in vacuo and the dry residue was taken up in 100 ml. of water, and again concentrated to dryness. This operation was repeated once more. Then the dry residue was dissolved in 300 ml. of methanol. A mixture of 80 ml. of pyridine and 300 ml. of methanol was added with shaking and the resulting mixture was let stand overnight to precipitate the crude D. A. Sub. This precipitate was washed with methanol and ether and dried. The yield was 53.5 g. This crude compound was suspended in 1000 ml. of water and dissolved by the addition of 10 per cent sodium hydroxide. An aqueous solution containing 100 g. of copper sulphate was added and the mixture was adjusted to pH 5.4 with 10 per cent sodium hydroxide. The precipitate was washed thoroughly with water and was dissolved in 500 ml. of 3 N hydrochloric acid. It was then treated with hydrogen sulfide to remove the copper. The black precipitate was filtered off, and the filtrate was concentrated in vacuo. The residue was taken up in 400 ml. of methanol. A mixture of 80 ml. of pyridine and 200 ml. of methanol was added with shaking and the resulting mixture allowed to stand. After washing with methanol and ether and drying, 41 g. (62 per cent yield) of white crystalline D. A. Sub. were obtained. This did not decompose below 360°C. Paper chromatography showed a single spot with the $R_f$-value given in Table II.

Found: C, 46.89; H, 7.86; N, 13.79. Calcd. for C, 47.05; H, 7.90; N, 13.72%.

**D. A. Aze.**—This was prepared as above by condensation of 160 g. (0.74 mol.) of diethyl acetamidomalonate with 65 g. (0.283 mol.) of pentamethylenedibromide using 16.8 g. (0.73 mol.) of sodium in 700 ml. of absolute alcohol. The crude product (55.5 g.) was dissolved in 2000 ml. of hot water and 80 g. of basic copper carbonate monohydrate was added. The mixture was heated at boiling point for some time. The precipitate was collected on a suction funnel and thoroughly washed with water. It was dissolved in diluted hydrochloric acid. The solution was saturated with hydrogen sulfide to precipitate the copper sulfide completely. The precipitate was removed by filtration and the filtrate was concentrated in vacuo. The residue was dissolved in 300 ml. of methanol. Neutralization with a mixture of 80 ml. of pyridine and 450 ml. of methanol gave a white crystalline product. This was collected on a suction filter, washed with water, methanol and ether, and dried. 40.5 g. (66 per cent yield) of D. A. Aze. was obtained. This decomposed above 320°C without melting. Paper chromatography of this compound gave a single spot with the $R_f$-value given in Table II.

Found: C, 49.74; H, 8.31; N, 12.81. Calcd. for $C_9H_{18}O_4N_2$: C, 49.53; H, 8.31; N, 12.84%.

**D. A. Seb.**—This compound was prepared in the same way as D. A. Sub. from 23 g. (0.106 mol.) of diethyl acetamidomalonate, 10 g. (0.041 mol.) of hexamethylene dibromide, and 2.3 g. (0.10 mol.) of sodium. The yield was 7.5 g. (79 per cent). It did not decompose below 360°C and gave a single spot on paper chromatography with the $R_f$-value given in Table II.

Found: C, 51.73; H, 8.70; N, 11.96. Calcd. for $C_{10}H_{20}O_4N_2$: C, 51.70; H, 8.68; N, 12.06%.

## Summary

A systematic study was made on the synthesis of $\alpha,\alpha'$-diaminodicarboxylic acids mainly by amination of the corresponding $\alpha,\alpha'$-dibromodicarboxylic acids using succinimide as an

aminating reagent and by condensation of diethyl acetamidomalonate with $\alpha, \omega$-dibromoparaffin.

The authors wish to express their sincere thanks to Professor Shiro Akabori for encouragement and valuable advice throughout this work.

# *The Ion-Exchange Behavior of Some Neutral Amino Acids*

By Manabu SENŌ and Takeo YAMABE

(Received May 12, 1960)

In many practical works on the separation of amino acids by means of ion-exchangers, some successful procedures using the ion-exchange chromatography have been established. Above all, the displacement development method has been applied with success to the separation by Partridge et al., and Moore and Stein pointed out that the elution method possessed higher resolving power for analytical purposes[1]. However, few fundamental researches have been carried out on the exchange behavior of amino acids on ion-exchange resins[2]. This problem is interesting, since it is expected that weak amphoteric electrolytes such as amino acids exhibit some characteristic behavior concerning the ion-exchange reaction.

In the present paper, the experimental resuls are described on the ion-exchange behavior of some neutral amino acids, particularly the influence of pH on the ion-exchange reaction and some general remarks are presented in this respect. The behavior of the acidic and the basic amino acids toword the ion-exchange resins will be given in the succeeding paper.

## Experimental

Through the present investigation the following reagents were used; amino acids are glycine, DL-alanine and L-leucine, which are commercial special-grade and were used without further purification. The dissociation constants and the isoelectric points of these amino acids are as follows.

| | $pK_1$ | $pK_2$ | pI |
|---|---|---|---|
| Glycine | 2.34 | 9.60 | 5.97 |
| Alanine | 2.34 | 9.69 | 6.00 |
| Leucine | 2.36 | 9.60 | 5.98 |

The ion-exchange resins used were Amberlite resins, IR-120 (4.24) IRC-50 (10.0), IRA-400 (2.15) IR-4B (8.0), the exchange capacities of these resins being given in parentheses in the unit, meq./g. dry resin.

All the experiments were carried out batch-wise. Through a run of measurements, a constant volume, 50 ml., of a solution containing a constant amount, about 2 meq., of amino acid and being adjusted to a desired pH by adding hydrochloric acid or sodium hydroxide, was added onto a constant quantity, about 1 meq., of the ion-exchange resin. The details for each system are given in the following table.

| Amino acids | Total amounts *a* mmol. | H- or OH-form resins, *w* g. dry resin | | | |
|---|---|---|---|---|---|
| | | IR-120 | IRC-50 | IRA-400 | IR-4B |
| Glycine | 1.95 | 0.169 | 0.094 | 0.330 | 0.101 |
| Alanine | 1.98 | 0.166 | 0.111 | 0.331 | 0.180 |
| Leucine | 2.02 | 0.175 | 0.103 | 0.343 | 0.134 |

After being allowed to stand for a few days, which were long enough for the attaining of the ion-exchange equilibrium, the pH and the remaining amount of the amino acid in the solution phase were measured and the adsorbed amount of the amino acid was estimated herefrom.

Amino acids were measured colorimetrically with ninhydrin[3] and pH of the solutions was measured with a glass-electrode pH-meter, model HM-5, Toa Dempa Kogyo Co., Ltd. All the measurements were made at room temperature, 5~15°C.

## Results and Discussion

Experimental results were shown in Figs. 1–3, in which the adsorbed amounts of amino acids were plotted against the pH of the equilibrium external solution. As anticipated from the amphoteric nature of amino acids, these are adsorbed by the cation-exchange resins in the pH range lower than its isoelectric point and by the anion-exchange resins in the higher pH range.

As seen in these figures, it was revealed that the maximum adsorption of the neutral amino acids by hydrogen- or hydroxyl-form ion-exchange resins takes place in a rather broad pH range near the isoelectric points, while the acidic and the basic amino acid are extensively adsorbed in a relatively narrow pH range near the isoelectric points, as will be presented in the succeeding paper. Furthermore, it was noticed that, in the case of the sodium or chloride form resins, the amounts of amino acids are remarkably diminished in the pH range near the isoelectric point, compared to the case of the hydrogen- or hydroxyl-form resins. In the lower and the higher pH ranges, the adsorbed amounts of all the amino acids decrease sharply owing to the competitive adsorption of hydrogen or hydroxyl ions.

**Adsorption Mechanism of Amino Acids on Ion-Exchange Resins.**—The apparent equilibrium constants defined by

$$\left.\begin{aligned} K_{H}' &= \frac{[A]_r[H^+]_s}{[A]_s[H^+]_r} \\ K_{OH}' &= \frac{[A]_r[OH^-]_s}{[A]_s[OH^-]_r} \end{aligned}\right\} \quad (1)$$

are not constant but depend on pH in the solution phase; $K_H'$ decreases and $K_{OH}'$ increases, with increase of pH, where $[A]_s$, $[H^+]_s$ or $[OH^-]_s$ is concentration in meq./ml. of amino acid, hydrogen or hydroxyl ions in the equilibrium external solution, respectively, and $[A]_r$, $[H^+]_r$ or $[OH^-]_r$ is concentration in meq./(g. dry resin) of amino acid, hydrogen or hydroxyl ions in the resin phase at equilibrium, respectively. It seems that this constancy does not hold, because the dissociation equilibrium of amino acids in the solution is not taken into consideration.

When the neutral amino acid is adsorbed on cation-exchange resin of hydrogen-form,

the amino acid cations that exist in the following equilibrium state,

$$AH^+ \rightleftharpoons A^{\pm} + H^+ \quad \text{(i)}$$

$$A^{\pm} \rightleftharpoons A^- + H^+ \quad \text{(ii)}$$

exchange for hydrogen ions in the ion-exchange resin,

$$RH + AH^+ \rightleftharpoons RAH + H^+ \quad \text{(iii)}$$

and the hydrogen ions are liberated from the cation-exchange resin, resulting in production of more amino acid cations and further exchange of the amino acid cations for the hydrogen ions. The exchange reaction attains the equilibrium through such a repeating process[4].

This adsorption mechanism would be supported by the following empirical facts.

(1) The pH of the external solution remains nearly constant through the adsorption process of amino acids as shown in Table I, in which pH's of the solution phase before and after equilibration of ion-exchange were given in the case of glycine as an example.

(2) The amino acids are adsorbed remarkably on the hydrogen- or hydroxyl-form ion-exchanger in the pH range near the isoelectric points, while the amino acid adsorbed on the salt-form ion-exchanger is small in quantity in this pH range.

It should be noticed that the completion of the above-mentioned two processes, i and iii, lead to the same result as the following mechanism[2],

$$RH + A^{\pm} \rightleftharpoons RAH \quad \text{(iv)}$$

However, there is not any evidence that such a process takes place actually.

**Relations between the Adsorbed Amount of Amino Acid and the pH of the External Solution.**—In a case when the neutral amino acid is adsorbed on the hydrogen-form cation-exchanger, the selectivity coefficient is defined as follows:

$$K_H = \frac{[AH^+]_r [H^+]_s}{[AH^+]_s [H^+]_r} \quad (2)$$

where $[A^+]_s$ is the concentration of ion A in the equilibrium external solution in the unit, meq./ml., and $[A^+]_r$ is that in the resin phase in the unit, meq./g. dry resin. Strictly, the activity should be used instead of the concentration in these equations but was not used in the present paper to avoid the troublesome procedure.

The dissociation constants of the neutral amino acids are given as

$$\left.\begin{aligned} K_1 &= \frac{[A^{\pm}]_s [H^+]_s}{[AH^+]_s} \\ K_2 &= \frac{[A^-]_s [H^+]_s}{[A^{\pm}]_s} \end{aligned}\right\} \quad (3)$$

where the term arising from activity coefficient is also neglected.

Under the present experimental condition, that is;

(1) the total amount of amino acid in the system is constant, $a$ meq.,

(2) the amount of the exchangeable ions in the ion-exchange resin is constant, $c$ meq.,

4) Amino acids are taken up from the solution phase into the resin phase by the other processes, such as Donnan adsorption and physical or chemical adsorption, besides the ion-exchange process. Although it is difficult to estimate the contributions of these processes experimentally, it would be safely said on the basis of the preceding reports listed in Ref. 1, that the ion-exchange is the primary process and the other ones have a small contribution to be neglected to a first approximation, excepting for the case of amino acids with benzene rings.

$c=Cw$, where $C$ is the exchange capacity (meq./g. dry resin) of the resin and $w$ is the weight of the resin used,

(3) the volume of the external solution is constant, $v$ ml., the following relationship holds between the exchanged amount of the amino acid, $[AH^+]_r=y$, and the hydrogen ion concentration in the external solution, $[H^+]_s=x$,

$$\frac{(a-wy)(c-wy)}{y}=\frac{vw}{K_H}\frac{x^2+K_1x+K_1K_2}{x} \quad (4)$$

The similar relation is gained in a case when the neutral amino acid is adsorbed on the hydroxyl-form anion-exchanger, where the selectivity coefficient $K_{OH}$ is defined by

$$K_{OH}\frac{[A^-]_r[OH^-]_s}{[A^-]_s[OH^-]_r} \quad (5)$$

The exchanged amount of the amino acid anion, $[A^-]_r=y$, is related to the hydroxyl ion concentration in the equilibrium external solution, $[OH^-]_s=x'$, by the formula

$$\frac{(a-wy)(c-wy)}{y}=\frac{vw}{K_{OH}}\frac{K_1K_2x'^2+K_1K_wx'+K_w^2}{K_1K_2x'} \quad (6)$$

where $K_w$ is the dissociation constant of water.

It must be noted that these relationships are valid for the two-component systems that contain only hydrogen or hydroxyl ions besides amino acid ions.

**$f(x)$ or $f(x')$ Functions.** — It is found that, in the ion-exchange behavior of the weak amphoteric electrolytes such as amino acids, a function of only the concentration of the hydrogen or the hydroxyl ion in the equilibrium solution phase, $f(x)$ or $f(x')$, which appears in the right hands of the Eqs. 4 and 6, gives the characteristic behavior. This function is, for cation exchange,

$$f(x)=\frac{x^2+K_1x+K_1K_2}{x} \quad (7)$$

and for anion exchange

$$f(x')=\frac{K_1K_2x'^2+K_1K_wx'K_w^2}{K_1K_2x'} \quad (8)$$

The numerical values of these functions for amino acids under investigation are given in Table II and shown against pH of the solution phase in Fig. 4[5,6].

The $f(x)$ or $f(x')$ of each amino acid has a minimum at its isoelectric point. At the minimum of $f(x)$ or $f(x')$, the adsorbed amount of the amino acid is the maximum. This can be shown directly by differentiating the Eqs. 4 and 6. It is supported by the present experiment that the adsorbed amount of the amino acid is the maximum at the isoelectric point.

The adsorbed amount of the amino acid is related inversely to the $f(x)$ or $f(x')$. For

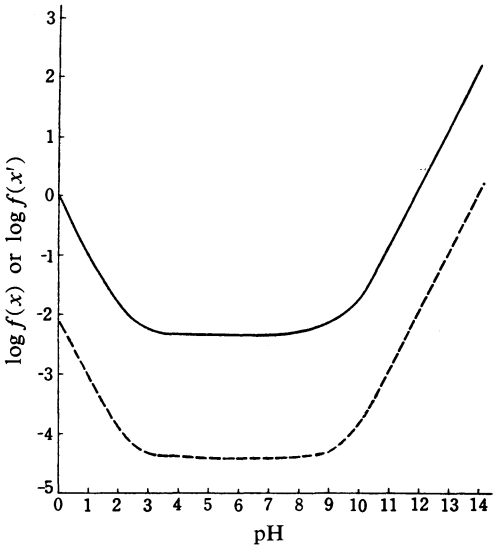

Fig. 4. $f(x)$ and $f(x')$ for glycine, which are shown by a full line and a dotted line, respectively.

5) $f(x)$ is related to $f(x')$ by the formula, $K_wf(x)=K_1K_2f(x')$. Then, for amino acid of which isoelectric point is 7, in this case $K_1K_2=K_w$, $f(x)$ is identical with $f(x')$.

6) $f(x)$ has a practical meaning in the pH range lower than the isoelectric point and $f(x')$ in the higher pH range.

example, the following formula is derived from Eq. 4,

$$y=\frac{ac}{w\left(a+c+\frac{v}{K_H}f(x)\right)}+\frac{a^2c^2}{w\left(a+c+\frac{v}{K_H}f(x)\right)^3}+\cdots\cdots \quad (9)$$

and the similar relation is obtained in another system. From these relations and the dependence of $f(x)$ or $f(x')$ on pH, it is concluded that the maximum adsorption of the neutral amino acids on the hydrogen- or hydroxyl-form exchanger takes place in the broad pH range near the isoelectric point, and this conclusion is also supported experimentally.

**Selectivity Coefficients.**—The selectivity coefficients $K_H$ and $K_{OH}$ were estimated using the above-mentioned experimental data and the formulas and are given in Table III. As for three kinds of neutral amino acids, glycine, alanine and leucine, $K_H$ is very large in comparison with $K_{OH}$. This is partly because the carboxyl group of these amino acids is dissociated more strongly than the amino group and, on this account, the ratio of the concentration of the hydrogen ion to that of the amino acid cation is larger than the ratio of the concentration of the hydroxyl ion to that of the amino acid anion in the equilibrium solution phase[7].

Table III. Selectivity coefficients for ion-exchange of amino acids for hydrogen or hydroxyl ions

| | log $K_H$ | | log $K_{OH}$ | |
|---|---|---|---|---|
| | IR-120 | IRC-50 | IRA-400 | IR-4B |
| Glycine | 0.56 | $\bar{2}.52$ | $\bar{2}.00$ | $\bar{3}.03$ |
| Alanine | 0.41 | $\bar{2}.29$ | $\bar{4}.73$ | $\bar{5}.52$ |
| Leucine | 0.53 | $\bar{2}.43$ | $\bar{3}.24$ | $\bar{4}.38$ |

The order of the selectivity coefficient does not agree with that of the chain length of the amino acid molecule and alanine has smaller $K$ value than that of leucine. This was already reported[8] and it might be considered that a simple adsorption makes a contribution to the uptake of amino acids by ion-exchange resins to some extent in the case of amino acid as glycine which is small in size, and as leucine, which has a long nonpolar chain.

## Summary

The ion-exchange behavior of three kinds of neutral amino acids was examined and the following results were obtained.

1) The ion-exchange behavior of amino acids can be explained when the dissociation equilibrium of amino acids in the solution was taken into account.

2) The maximum adsorption of neutral amino acids on the ion-exchange resins takes place in a rather broad pH range at the isoelectric point.

3) The neutral amino acids are adsorbed more extensively on cation-exchangers than on anion-exchangers. Glycine is adsorbed most extensively and leucine is more adsorbed than alanine.

7) These ratios are given by
$[H^+]_S/[AH^+]_S=f(x)/[A]_S$
$[OH^-]_S/[A^-]_S=f(x')/[A]_S$
where $[A]_S$ is the concentration of amino acid remaining in the equilibrium solution phase, and, for example, $f(x')=0.087\times10^{-2}\ f(x)$ for glycine.

# *Syntheses of Peptides Containing Proline. I. Syntheses of Glycyl-L-prolyl-L-leucyl-glycyl-L-proline and its Related Compounds*

By Shumpei SAKAKIBARA and Yutaka NAGAI*

(Received April 1, 1960)

Collagenase is a proteinase with a very high degree of substrate specificity, and its nature has been the object of keen interest of workers both in the fields of biochemistry and medicine. Very recently several preliminary reports[1-4] have been published and we seem to have some clue to look into the whole picture of the action of collagenase.

It had already been shown by several workers[3,5-8] that when collagen was digested with collagenase, most of the *N*-terminal groups belonged to glycine and several amino acids were found at the *C*-terminal ends. Nagai and Noda[2] found that poly-(L-prolyl-L-leucyl-glycyl)[9] was entirely hydrolyzed by collagenase, mostly into tripeptides, glycyl-prolyl-leucine and peptides from both the ends, prolyl-leucyl-glycyl-prolyl-leucine and glycyl-prolyl-leucyl-glycine. Tripeptides similar to the above were also isolated from collagenase digested collagen[7,10]. From these results and also from the accumulated informations[4,6,11-13] of oligopeptides unsusceptible to the action of collagenase, it was contemplated that the substrate specificity of collagenase requires the presence of two proline residues at a proper distance.

The syntheses of peptides containing two proline residues in the sequence of X-Pro-Leu-Gly-Pro-Y which would be a possible good substrate were carried out in our laboratory. The pentapeptide amide, glycyl-L-prolyl-L-leucyl-glycyl-L-proline amide was split by collagenase into two peptides, glycyl-prolyl-leucine and glycyl-proline amide[2]. This pentapeptide amide was the first example of the synthetic oligo-peptide as a good substrate of collagenase, and furnished a good starting inertia for us to elucidate the substrate specificity of the enzyme. Subsequently, many kinds of peptide containing proline, hydroxyproline or sarcosine were synthesized along this line and a preliminary report on an enzymatic test of those peptides has already been published[14].

In the present series of reports, the synthetic studies of those peptides containing proline will be described successively.

## Syntheses of Peptides

In the planning of the synthetic routes of the pentapeptide, a precaution was taken not to use routes passing through dipeptide esters containing proline because free esters of proline dipeptides are considered to have a great tendency for diketopiperazine formation[15]. In the present study, almost all of the possible routes which conformed with the above precaution, as indicated befow, were tried, and the yield, crystallizability and specific rotation of products were compared for each route. The synthetic routes tested were as follows*:

(1) **a.** Z-Gly-$N_3$ + H-Pro-OEt
$\longrightarrow$ {Z-Gly-Pro-OEt}
$\longrightarrow$ Z-Gly-Pro-OH (I)

**b.** Z-Gly-OH + H-Pro-OEt
M.A.
$\longrightarrow$ {Z-Gly-Pro-OEt}
$\longrightarrow$ Z-Gly-Pro-OH (I)

Methods of peptide-bond formation employed in the present study, were the azide method and the isovaleroyl mixed anhydride method[16]. The azide method is well known to be suitable for keeping the optical purity of peptides in the course of the reaction[17]. The mixed anhydride method is a comparatively simple method of the activation of the carboxyl component, and had been used successfully by Ressler and du Vigneaud[18] for the coupling reaction of carbobenzoxy-L-proline and L-leucyl-glycine ethylester. In every case of the azide procedure used in our present study, it was to be noted that carbobenzoxypeptide azide containing proline residue was insoluble in ether, and chloroform was the most suitable solvent for extracting the azide formed. In regard to the acylation of the proline imino group, the azide method was superior to the mixed anhydride method in view of the synthetic yield, crystallizability and melting point of the products. For example, carbobenzoxyglycyl-L-proline (I) which was prepared by the azide method from carbobenzoxyglycine hydrazide and L-proline ethylester was sufficiently pure without recrystallization, and the yield was also satisfactory (m. p. 155°C, yield 75%). On the other hand, the mixed anhydride method gave the substance I with a lower melting point (153°C) in poorer yield (42%). Similar results were obtained in cases of coupling reactions of carbobenzoxy-L-leucyl-glycine with L-proline ethylester, and of carbobenzoxyglycyl-L-prolyl-L-leucyl-glycine with L-proline ethylester. Recently, Bodanszky and du Vigneard[19] have published an interesting communication, in which they proposed the use of carbobenzoxyamino acid *p*-nitrophenylesters for acylation of peptide esters. If their new procedures would be employed in parts of our procedures, better results might be obtained.

Among the synthetic routes for the carbobenzoxypentapeptide ester (XIV), the best result was obtained by route 7-d. Since the

substance XIV has not been heretofore crystallized, the synthetic yields for those procedures, 7-b, c and d, were compared with each other on the saponified product XV. The route 7-a was eliminated, since the substance VIII which was used as the intermediate in the route was not crystallized, and purification of which was unsuccessful. Substance XV prepared by route 7-d was readily crystallized under the presence of ethyl acetate, but the same substance XV prepared by route 7-b or 7-c was hard to crystallize. The route 7-b was abandoned for the reason that the crystallizability of the intermediate V was poor and of which yield was rather low. Although both intermediate substances XII and XIII were easily crystallized and were obtained from XI in good yields, mixed anhydride route 7-c was somewhat inferior to azide route 7-d as described above. The intermediate XI was prepared through two routes 6-a and 6-b, and the former was somewhat superior to the latter in synthetic yield. In regard to the optical purity, every preparations (XV) obtained by routes 7-b, c and a showed the same specific rotation after recrystallization.

Carbobenzoxy-L-prolyl-L-leucyl-glycyl-L-proline ethylester (VIII) was prepared not only as an intermediate for the substance XIV, but also as a substrate for collagenase. In the synthesis of the substance VIII, two routes, mixed anhydride procedure (5-a) and azide procedure (5-b), were taken into consideration. Since the substances VIII and its saponified product IX were not crystallized, formation of by-products, separation of which seemed to be difficult, was particularly undesirable. In the similar cases of 7-b and 7-d, which corresponded respectively to 5-a and 5-b, it was observed previously that the former was inferior to the latter in the purity and yield of the product. Then, the route 5-a was not explored in this case. Carbobenzoxy-L-prolyl-L-leucyl-glycine hydrazide (VII), which was used in route 5-b, was water-soluble substance and it was very interesting, that this substance was crystallizable only from toluene and this crystal contained crystallization toluene, which could be removed completely when the compound was heated at 50°C in vacuo.

Peptides or their derivatives containing proline residue in general are hydrophilic and peptides containing two or more proline residues, especially, were hard to be crystallized because of the effect of humidity. It was, however, found that carbobenzoxyglycyl-L-prolyl-L-leucyl-glycyl-L-proline (XV) was an exceptional example of readily crystallizable substance as described above. In this case, both ethyl acetate and water were indispensable for crystallization. When the peptide XV was recrystallized from ethyl acetate which contains equimolar amount of water to the peptide, it formed prisms. The crystal contained one mole each of water, and ethyl acetate per mole of the peptide as crystallization solvent and was fairly stable even when it was kept in the open air. In turn, when the same peptide was recrystallized from water-saturated ethyl acetate, different crystals (plates) were obtained, and they were unstable in the open air and gradually transformed into opaque crystals. A crystallographic study on these phenomena is now in progress by Sasada and Kakudo in our laboratory with X-ray diffraction technique.

As described above, the interesting phenomenon that some kinds of peptide derivatives (VII and XV) have affinity with specific substances (toluene or ethyl acetate) seemed to suggest a possible mode of combination in the enzyme-substrate complex formation. Similarly, the penta-peptide amide (XVIII) which was dried azeotropically by using toluene or ethanol occluded the solvents firmly, and complete removal of the solvents was very hard.

The above mentioned carbobenzoxypentapeptide XV was the best substrate for collagenase as described in the previous communication[14]. The substances IX, XV, XVI and XVIII were all hydrolyzed completely by collagenase within a comparatively short period of time. Studies on the enzymatic digestion of these peptides will be published elsewhere in the near future.

## Experimental*

**Carbobenzoxyglycyl-L-proline (I). — a.** Carbobenzoxyglycine hydrazide (11.2 g., 0.05 mol.) was dissolved in a mixture of acetic acid (40 ml.) and water (80 ml.), and 6 N hydrochloric acid (17 ml., 0.1 mol.) was added into the solution. The mixture was cooled to −5°C, shaken well with a small amount of chloroform and carefully treated with sodium nitrite (3.8 g., 0.055 mol.). The carbobenzoxyglycine azide formed was extracted three times with cold chloroform (total 150 ml.). The combined extract was washed with ice water (50 ml.) and acids for a short time over anhydrous sodium sulfate at −5°C. The dried solution was filtered into a mixture of proline ethylester hydrochloride (10 g., 0.055 mol.) and triethylamine (5.6 g., 0.055 mol.) in chloroform (50 ml.) at −5°C, and allowed to stand overnight at 0~4°C. The reaction mixture was washed successively with 0.5 N hydrochloric acid, water and 5% sodium bicarbonate solution and dried over anhydrous magnesium sulfate. The dried solution was concentrated to syrup under reduced pressure and the residue was redissolved in methanol (100 ml.), and then 2 N sodium hydroxide (25 ml., 0.05 M) was added. After the solution was kept for 2 hr. at room temperature, it was neutralized with 6 N hydrochloric acid, and the methanol

* All melting points were uncorrected.

was removed under reduced pressure. As soon as methanol was removed, colorless prisms appeared. After being stored overnight in a refrigerator, the crystals were filtered off, washed with water and ethyl acetate, and dried in a desiccator. The yield of I with m. p. 154.5~155°C was 75% (11.5 g.). This substance was pure enough without recrystallization for preparing higher peptides. Recrystallization from ethyl acetate of the product (1.4 g.) gave prisms (1.2 g.); m. p. 154.5~155°C, $[\alpha]_D^{15}$ −70.4° (c. 6, ethanol); Bergmann et al.[20] reported m. p. 156°C (corr.).

**b.** Carbobenzoxyglycine (2.1 g., 0.01 M) was dissolved in chloroform (40 ml.) by adding triethylamine (1.0 g., 0.01 M), and then toluene (40 ml.) was added into the solution. The mixture was cooled to −10°C and isovaleroyl chloride (1.2 g., 0.01 M) was added slowly into the solution under stirring. After about 1.5 hr. a solution of proline ethylester hydrochloride (2.16 g., 0.012 M) and triethylamine (1.2 g., 0.012 M) in chloroform (40 ml.) was added into the mixed anhydride solution, and the mixture was allowed to stand overnight at 4°C. The reaction mixture was treated as described above. Yield of I was 42% (1.3 g.); m. p. 152~154°C. Recrystallization from ethyl acetate of the product (1.3 g.) gave fine prisms (1.1 g.); m. p. 153~154°C, $[\alpha]_D^{15}$ −70.2° (c. 5, ethanol).

**Carbobenzoxy-L-leucyl-glycine Ethylester (II).**—This substance was prepared according to the procedures of Vaughan and Osato[16]; yield 70%, m. p. 102~104°C, $[\alpha]_D^{15}$ −26.8° (c. 5.5, ethanol).

**Carbobenzoxy-L-leucyl-glycine Hydrazide (III).**—Into a solution of II (10 g.) in ethanol (40 ml.) was added hydrazine hydrate (8 ml.), and then the mixture was allowed to stand overnight at room temperature. The reaction mixture was concentrated to dryness under reduced pressure and the residual crystalline mass was recrystallized from ethanol and ether to give needles; m. p. 130~132°C, yield 89% (8.5 g.).

Found: C, 56.97; H, 7.29; N, 16.71. Calcd. for $C_{16}H_{24}O_4N_4$: C, 57.13; H, 7.19; N, 16.66%.

**Carbobenzoxy-L-leucyl-glycine (IV).**—This substance was prepared from II according to procedures of Bergmann et al.[21]; m. p. 114~115°C, yield 90%, $[\alpha]_D^{15}$ −26.3° (c. 8, ethanol).

**Carbobenzoxy-L-leucyl-glycyl-L-proline Ethylester (V).—a.** A solution of carbobenzoxy-L-leucyl-glycine azide in chloroform, which was prepared from III (3.4 g.) as in the case of I-a was added into a mixture of proline ethylester hydrochloride (2 g.) and triethylamine (1.1 g.) in chloroform (20 ml.) at −5°C, and the mixture was allowed to stand overnight. The reaction mixture was washed successively with water, 1 N hydrochloric acid, water, 5% sodium bicarbonate and water again, and dried. The dried solution was concentrated to syrup and the residue was crystallized in a refrigerator after treatment with petroleum benzine. The crude crystals formed were triturated with a small amount of ethyl acetate and carefully recrystallized with a small amount of petroleum benzine. The crystals were filtered off, washed with ether and dried in a desiccator in vacuo to give fine needles; m. p. 81~85°C, yield 80% (3.6 g.). Recrystallization of the product from ethyl acetate-petroleum benzine gave needles with m. p. 89~91°C; yield 44% (2.0 g.), $[\alpha]_D^{17}$ −78.0° (c. 6, ethanol). A second crop of the recrystallization was obtained in 11% yield (0.5 g.); m. p. 88~91°C.

Found: C, 61.75; H, 7.25; N, 9.64. Calcd. for $C_{23}H_{33}O_6N_3$: C, 61.72; H, 7.43; N, 9.36%.

**b.** Carbobenzoxy-L-leucyl-glycine (IV) (3.2 g.) was dissolved in chloroform (50 ml.) by adding triethylamine (1 g.) and then toluene (50 ml.) was added to the solution. The mixture was cooled to −10°C and isovaleroyl chloride (1.2 g.) was added slowly to the solution under stirring. After about 1.5 hr. a solution of proline ethylester hydrochloride (2.16 g.) and triethylamine (1.2 g.) in chloroform (40 ml.) was added to the mixed anhydride solution, and then the mixture was allowed to stand overnight at 4°C. The reaction mixture was treated as described above to give a crude product; yield 67% (3 g.). Recrystallization from ethyl acetate-petroleum benzine gave fine needles; m. p. 88~91°C, yield 46% (2.1 g.), $[\alpha]_D^{17}$ −77.8° (c. 4, ethanol).

**Carbobenzoxy-L-prolyl-L-leucyl-glycine Ethylester (VI).**—This substance was prepared according to the procedures of Ressler and du Vigneaud[18]; m.p. 148.5~150.5°C, yield 88~90%. Recrystallization from ethanol-water gave 70% yield, m. p. 150~151.5°C, $[\alpha]_D^{15}$ −81.9° (c. 2, ethanol); second crop from the mother liquor gave 13% yield, m. p. 149~150°C.

**Carbobenzoxy-L-prolyl-L-leucyl-glycine Hydrazide (VII).**—Hydrazine hydrate (2 ml.) was added to a solution of VI (2.24 g.) in ethanol (30 ml.) and then the mixture was allowed to stand overnight at room temperature. The reaction mixture was concentrated to syrup under reduced pressure and the residual syrup was dried by the addition of benzene followed by evaporation under reduced pressure. After the drying procedures were repeated, the residue was crystallized by trituration with toluene (about 10 ml.) and dried over sodium hydroxide at room temperature to give fine needles; yield 91% (2.4 g.), m. p. 76~80°C. This substance contained about one mole of crystallization toluene.

Found: C, 62.82; H, 7.44; N, 14.14. Calcd. for $C_{21}H_{31}O_5N_5 \cdot 3/4C_7H_8$: C, 62.73; H, 7.42; N, 13.94%.

After dryness in vacuo at 50°C, the crystallization toluene was removed.

Found: C, 58.27; H, 7.26; N, 16.40. Calcd. for $C_{21}H_{31}O_5N_5$: C, 58.18; H, 7.21; N, 16.16%.

**Carbobenzoxy-L-prolyl-L-leucyl-glycyl-L-proline (IX).—b.** A carbobenzoxy-L-prolyl-L-leucyl-glycine azide solution, which was prepared from VII (toluene-free 2.15 g.) as in the case of I-a, was added to a mixture of proline ethylester hydrochloride (1 g.) and triethylamine (0.56 g.) in chloroform (20 ml.) at −5°C. After being kept overnight at 4°C, the solution was washed successively with water, 1 N hydrochloric acid, water, 5% sodium bicarbonate solution and again with water, and dried. The dried solution was concentrated to syrup under reduced pressure and the residue was

redissolved in methanol (30 ml.). 1 N Sodium hydroxide (8 ml.) was added into the methanol solution, and the mixture was allowed to stand for about 3 hr. at room temperature. After neutralizing the reaction mixture with 6 N hydrochloric acid, it was concentrated to syrup under reduced pressure and the remaining oily material was dissolved in 5% sodium bicarbonate solution. The bicarbonate solution was washed well with ethyl acetate and then acidfied with 6 N hydrochloric acid. The separated oil was extracted with chloroform. On evaporation of the solvent a syrup was obtained and was solidified by trituration with petroleum benzine. After dryness in vacuo at 80°C, the amorphous powder amounted to 54% yield (1.4 g.); m.p. 90~120°C (sintered at 90°C), $[\alpha]_D^{17}$ −106.1° (c. 5.5, ethanol).

Found: C, 61.20; H, 7.29; N, 10.38. Calcd. for $C_{26}H_{36}O_7N_4$: C, 60.45; H, 7.02; N, 10.85%.

**L-Prolyl-L-leucyl-glycyl-L-proline (X).**—Palladium-charcoal (5%, 1 g.) was added to a solution of IX (1 g.) in a mixture of methanol (20 ml.) and water (30 ml.), and hydrogen was introduced into the suspension for 3 hr. under stirring. The catalyst was filtered off and washed three times with hot water (total 30 ml.), and then the combined filtrate was concentrated under reduced pressure. The residual syrup was dissolved in small amount of water, and the solution was filtered. The clear solution was concentrated to syrup and the residue was dried by the addition of benzene followed by evaporation under reduced pressure, and then pulverized. After dryness in vacuo at 110°C for about 3 hr., the product amounted to an 80% yield (0.6 g.); deliquescent powder, m. p. 170~180°C (sintered at 147~150°C), $[\alpha]_D^{15}$ −121.5° (c. 5, water).

Found: C, 55.94; H, 7.86; N, 14.32. Calcd. for $C_{18}H_{30}O_5N_4 \cdot 1/6H_2O$: C, 56.09; H, 7.93; N, 14.54%.

Complete dryness of this substance failed because the substance was partially charred when heated at 135°C for 3 hr. in vacuo.

**Carbobenzoxyglycyl-L-prolyl-L-leucyl-glycine Ethylester (XI).—a.** Palladium-charcoal (5%, 5 g.) and 6 N hydrochloric acid (6 ml.) was added to a solution of VI (13.4 g.) in ethanol (200 ml.), and hydrogen was introduced into the suspension for 3 hr. under stirring. The catalyst was filtered off and washed three times with ethanol (total 60 ml.), and then the combined filtrate was concentrated under reduced pressure. The residual syrup was dried by the addition of toluene followed by evaporation under reduced pressure. A carbobenzoxyglycine azide solution, which was prepared from carbobenzoxyglyciues hydrazide (6.7 g.) according to the procednre in the case of I-a was added into a mixture of the prolyl-leucyl-glycine ethylester hydrochloride and triethylamine (3 g.) in chloroform (100 ml.). After storage overnight in a refrigerator at 4°C, the reaction mixture was washed successively with 1 N hydrochloric acid, water, 5% sodium bicarbonate solution and water again, and dried. Evaporation of the solvent gave a syrupy material which was crystallized by the addition of chloroform and petroleum benzine. The yield of the crude product was 80% (12 g.); m. p. 96~101°C (after dryness in vacuo at 80°C). This substance was used for the preparation of XII and XIII without recrystallization. Melting point of this substance rose to 101~104°C after two recrystallization from chloroform and petroleum benzene; $[\alpha]_D^{15}$ −69.9° (c. 5, ethanol).

Found: C, 59.47; H, 7.10; N, 11.15. Calcd. for $C_{25}H_{36}O_7N_4$: C, 59.51; H, 7.19; N, 11.10%.

**b.** The substance II (10 g.) was hydrogenated in ethanol (50 ml.) containing 6 N hydrochloric acid (5 ml.) with 5% palladium-charcoal (4 g.). The catalyst was filtered off and washed three times with ethanol, and then the combined filtrate was concentrated under reduced pressure. The residual syrup was dried by the addition of toluene followed by evaporation under reduced pressure. A mixture of the leucyl-glycine ethylester hydrochloride and triethylamine (3 g.) in chloroform (30 ml.) was added to a mixed anhydride solution at −10°C, which was prepared from I (8 g.), triethylamine (2.65 g.) and isovaleroyl chloride (3.15 g.) in a mixture of chloroform (100 ml.) and toluene (100 ml.) as in the case of I-b. After being kept overnight at 4°C, the reaction mixture was treated in a similar manner to the case of XI-a and a crude product was obtained in a 78% yield (10.3 g.); m. p. 96~101°C (dried in vacuo at 80°C). After several recrystallizations from chloroform-petroleum benzine, this substance melted at 101~105°C; $[\alpha]_D^{15}$ −70.5° (c. 5, ethanol).

**Carbobenzoxyglycyl-L-prolyl-L-leucyl-glycine (XII).**—The crude product of XI-a (5 g.) was dissolved in methanol (50 ml.) and 1 N sodium hydroxide (11 ml.) was added into the solution, and then the mixture was allowed to stand at room temperature for 2 hr. The mixture was neutralized with 6 N hydrochloric acid, and the methanol was distilled under reduced pressure. The crystals formed were filtered off, washed with water and ethyl acetate, and dried; m. p. 184~187°C, yield 87% (4.1 g.). After recrystallization from ethanol-water (1 : 1), this substance melted at 185~188°C; $[\alpha]_D^{15}$ −60.4° (c. 6.5, pyridine).

Found: C, 58.14; H, 6.90; N, 11.76. Calcd. for $C_{23}H_{32}O_7N_4$: C, 57.97; H, 6.77; N, 11.76%.

This substance was prepared from XI-b (3.2 g.) in a yield of 86% (2.6 g.); m. p. 184~188°C, $[\alpha]_D^{15}$ −60.3° (c. 5, pyridine).

**Carbobenzoxyglycyl-L-prolyl-L-leucyl-glycine Hydrazide (XIII).**—The crude XI-a (10.1 g.) was dissolved in ethanol (50 ml.) and hydrazine hydrate (5 ml.) was added to the solution. After being kept overnight at room temperature, the reaction mixture was concentrated to dryness, and the residual syrup was crystallized from ethanol and ether to give long needles; m. p. 155~157°C, yield 97% (9.5 g.). Recrystallization from ethanol and petroleum benzine gave a 94% yield (9.2 g.); m. p. 157~159°C.

Found: C, 56.34; H, 7.04; N, 17.24. Calcd. for $C_{23}H_{34}O_6N_6$: C, 56.31; H, 6.99; N, 17.13%.

This substance was prepared from XI-b (8.8 g.) in a yield of 94% (8.1 g.); m. p. 157~159°C.

**Carbobenzoxyglycyl-L-prolyl-L-leucyl-glycyl-L-proline (XV). — d.** An azide solution which was prepared from XIII (8 g.) as in the case of I-a,

was added to a solution of proline ethylester hydrochloride (3.2 g.) and triethylamine (1.8 g.) in chloroform (20 ml.) at −5°C. The reaction mixture was allowed to stand overnight at 4°C, and was then washed successively with water, 1 N hydrochloric acid, water, 5% sodium bicarbonate solution and water again, and dried. The dried solution was concentrated to syrup under reduced pressure and the residue was redissolved in methanol (100 ml.). 1 N sodium hydroxide (20 ml.) was added into the methanol solution and the mixture was allowed to stand for about 3 hr. at room temperature. After neutralizing the reaction mixture with 6 N hydrochloric acid, it was concentrated to dryness under reduced pressure and the remaining syrup was dissolved in saturated sodium bicarbonate solution. The bicarbonate solution was washed with ethyl acetate and then acidified with 6 N hydrochloric acid. The separated oil was extracted with chloroform and the extract was concentrated to syrup, which was crystallized by trituration with ethyl acetate containing a small amount of water. After storage overnight in a refrigerator, the crystals were filtered off and dried in vacuo at 80°C for about 3 hr. to give 5.0 g. of the first crop. On evaporation of the ethyl acetate washing described above, a slight amount of residue was obtained. The residue was again saponified in the same manner and a second crop (0.6 g.) was obtained. The total yield was 60%. Recrystallization of the product from ethyl acetate containing an equimolar amount of water to the peptide, gave prisms (6 g.) with m. p. 72°C (dec. at 75~77°C), which were dried in the open air. This material contained one mole of ethyl acetate and one mole of water as crystallization solvents.

Found: C, 56.55; H, 7.44; N, 10.39. Calcd. for $C_{28}H_{39}O_8N_5 \cdot C_4H_8O_2 \cdot H_2O$: C, 56.54; H, 7.27; N, 10.30%.

The crystallization solvents could be removed at 80°C in vacuo to give an amorphous powder; m. p. 130~135°C, $[\alpha]_D^{15}$ −128.2° (c. 4, ethanol).

Found: C, 58.49; H, 6.84; N, 12.23. Calcd. for $C_{28}H_{39}O_8N_5$: C, 58.62; H, 6.85; N, 12.21%.

The route XIV-b-XV gave 35% yield of the amorphous powder; $[\alpha]_D^{15}$ −128.2° (c. 4, ethanol). The route XIV-c-XV gave a 45% yield of the same substance; $[\alpha]_D^{15}$ −128.2° (c. 4, ethanol).

**Glycyl-L-prolyl-L-leucyl-glycyl-L-proline (XVI).** —Palladium-charcoal (5%, 1 g.) was added to a solution of XV (1.7 g.) (amorphous powder) in methanol (20 ml.) and water (30 ml.), and hydrogen was introduced into the suspension for 3 hr. under stirring. The catalyst was filtered off and washed three times with hot water (total 30 ml.), and then the combined filtrate was concentrated under reduced pressure. The residual syrup was dissolved in a small amount of water, and the solution was filtered. The clear solution was concentrated to syrup and the residue was dried by the addition of toluene followed by evaporation under reduced pressure, and then pulverized. After dryness in vacuo at 110°C for about 3 hr., the product amounted to a 51% yield (0.8 g.) of deliquescent powder; m. p. 160~167°C, $[\alpha]_D^{15}$ −160.1° (c. 5.5, water.)

Found: C, 53.72; H, 7.65; N, 15.71. Calcd. for $C_{20}H_{33}O_6N_5 \cdot 1/2H_2O$: C, 53.56; H, 7.64; N, 15.62%.

**Carbobenzoxyglycyl-L-prolyl-L-leucyl-glycyl-L-proline Amide (XVII).**—The syrupy material XIV which was prepared from XIII (4.9 g.) according to the procedure XV-d was dissolved in methanol (40 ml.). After being saturated with dry ammonia gas at 0°C, the solution was allowed to stand one week at room temperature in a sealed tube. The reaction mixture was concentrated to syrup under reduced pressure and the residue was dried by the addition of benzene followed by evaporation under reduced pressure. The dried residue was dissolved in hot ethyl acetate and reprecipitated by the addition of petroleum benzine, and dried over phosphrous pentoxide in vacuo at 80°C; yield 63% (3.6 g.), m. p. 118~128°C (sintered at 102~118°C), $[\alpha]_D^{17}$ −117° (c. 4.5, ethanol).

Found: C, 58.73; H, 7.23; N, 14.60. Calcd. for $C_{28}H_{40}O_7N_6$: C, 58.72; H, 7.04; N, 14.68%.

**Glycyl-L-prolyl-L-leucyl-glycyl-L-proline Amide (XVIII).**—Palladium-charcoal (5%, 1 g.) was added to a solution of XVII (1.5 g.) in ethanol (20 ml.) and water (20 ml.), and hydrogen was introduced into the suspension for 3 hr. under stirring. The catalyst was filtered off and washed three times with hot water (total 30 ml.), and then the combined filtrate was concentrated under reduced pressure. The residual syrup was dissolved in a small amount of water, and the solution was filtered. The clear solution was concentrated to syrup and the residue was dried by the addition of ethanol followed by evaporation under reduced pressure, and then pulverized. This material was dried at 110°C in vacuo for 3 hr. before analysis; deliquescent powder, yield of 82% (0.95 g.), m. p. 135~155°C (sintered at 110~115°C), $[\alpha]_D^{17}$ −147.2°C (c. 3.3, ethanol).

Found: C, 54.25; H, 7.76; N, 19.04. Calcd. for $C_{20}H_{34}O_5N_6$: C, 54.78; H, 7.82; N, 19.17%.

## Summary

Glycyl-L-prolyl-L-leucyl-glycyl-L-proline and its related compounds were synthesized for elucidating the substrate specificity of collagenase. In the synthetic study, almost all of the possible routes were tried and the yield, crystallizability and specific rotation of products were compared for each route. Peptides or their derivatives containing two proline residues in general were hydrophilic and hard to be crystallized, but it was found, that carbobenzoxyglycyl-L-prolyl-L-leucyl-glycyl-L-proline was an exceptional example of a readily crystallizable substance and a good substrate for collagenase.

The authors should like to express their thanks to Professor Shiro Akabori of the Institute and Professor Haruhiko Noda of the University of Tokyo for helpful suggestions and guidance in the course of this work.

# *Crystal Habit Modification of Strontium Sulfate. I. Habit-Modifying Action of Foreign Substances*

By Sadaichi OTANI

(Received March 23, 1960)

Crystals having spherical forms are often found in mineral spherulite which is recognized as a type of radiated crystals. Spherulites have also been prepared artificially by many workers. Popoff[1] studied the two-dimensional spherulites of resorcinol and malonamide, while Lengyel[2] investigated those of several inorganic substances. Three-dimentional spherulites of various inorganic substances were prepared by Morse and others[3] by allowing the reacting solutions to be mixed through diffusion avoiding convection; their best spherulites having spherical forms were obtained in a gelatinous medium. Hence they considered the high viscosity of the medium to be one of the favorable conditions for spherulitic growth. From an ordinary solution, instead of the viscous medium, Patterson[4] obtained spherulitic aggregates of calcium phosphate in the presence of the citrate ion, but the shape of the aggregate was far from being spherical. Recently Miura and his co-workers[5] have succeeded in preparing fine spherical crystals of barium sulfate having nearly uniform size, from an aqueous solution containing citrate ion, and they pointed out the effective utilizations of such crystals in the fundamental study of colloid science and also in the industrial field.

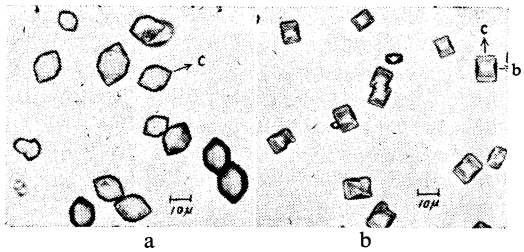
The present author has been interested in the preparation of spherical crystals as well as in the mechanism of their formation, and several attempts have been made regarding these problems. The results obtained will be presented in two parts, of which the first deals with the habit-modifying effect of various substances upon the crystal of strontium sulfate, and the second with the characteristic behavior of the triphosphate ion in the course of deposition and dissolution of strontium sulfate, as well as the mechanism of spherulite formation.

## Experimental

**Reagents.**—Strontium chloride of the reagent grade was purified by repeating three times the alternate crystallization of the dihydrate from a hot solution and then of the hexahydrate from a cold solution. Both potassium sulfate and sodium citrate of the analytical grade were recrystallized from their aqueous solutions. Sodium triphosphate (STP) was prepared by Bell's method[6] and recrystallized from an aqueous solution by adding methanol. Both the EDTA and glycerol used were of the analytical grade. The polyvinyl alcohol (PVA) used had an average molecular weight of $8.5\times10^4$. Both oleylpyridinium chloride and polyethyleneglycol monostearate were furnished by the courtesy of Daiichi Kogyo Seiyaku Co. Ltd. Aerosol OT was of the commercially highest grade.

**Procedure.**—The crystals to be examined were precipitated by mixing a solution of strontium chloride with one of potassium sulfate, in the presence or absence of a third substance in a glass-stoppered flask. To diminish the influence of the container wall upon crystallization, the inside surface of the flask was coated with silicone by the diethyldichlorosilane-treatment. This prevented the precipitate from adhering to the container wall, and thus the crystal growth was not troubled with any steric disturbance of the wall. During mixing and crystallizing, the solutions were violently and continuously shaken with a motor-driven shaker, and the temperature was kept constant within the limits of $\pm0.1$°C.

Foreign substances whose effects were to be examined were added either to the solution of strontium chloride or to one of potassium sulfate, prior to the mixing of these. Sodium citrate, EDTA or condensed phosphates, anyone of which was a complexing agent for metallic cations, was always added to the solution of strontium chloride.



## Results

**Crystals Grown from Mixtures of Strontium Chloride and Potassium Sulfate Solutions.**—First of all, crystals deposited from the solutions prepared by mixing strontium chloride and potassium sulfate solutions without foreign substance were examined. Quite a number of samples were prepared by varying the concentrations and the mixing proportions of the solutions. The concentration range of strontium and sulfate, immediately after mixing, was 0.002~0.1 M.

According to the crystal forms of these samples, they could be classified roughy into

**Effect of Several Additives.** — To inquire whether the viscosity of the medium is an essential factor to the habit modification as reported by Morse and others[3], the effects of glycerol and PVA were tested. In the concentration ranges up to 27% with glycerol and up to 0.4% with PVA, none of these gave any significant influence on the habit of crystals formed.

Then the effects of some surface active agents were examined. Addition of oleylpyridinium chloride or polyethylene glycol monostearate caused a slight increase in the size of the crystals deposited, but the crystal form was hardly influenced by these surface active agents within the concentration limit of 1.0% in each case. Anionic surface active agent Aerosol OT, however, produced a voluminous white precipitate which might be its strontium salt.

**Effect of Sodium Citrate.**—Sodium citrate, even at a very low concentration, has a remarkable effect on the deposition rate and the shape of the crystals. The larger the amount of sodium citrate added, the slower was the deposition rate and the smaller the size of the crystals formed. The shape of the crystals was altered by the addition of sodium citrate in such a way that the edges and corners of the polyhedrons shown in Fig. 1 gradually vanished as the amount of citrate was increased, resulting finally in thin ellipsoids. However, because of the low solubility of strontium citrate, there was a limit to the concentration of the citrate ion in solution, above which the voluminous needle-shaped precipitate appeared.

In Fig. 2 the microphotographs of two samples are shown. These were obtained at 25°C from two separate solutions containing equal amounts of sodium citrate. Both of the solutions from which these crystals were deposited had the same concentration with respect to either of the essential salts as in the previous case (Fig. 1). The electron micrographs of these samples are shown in Fig. 3. Several slenderer figures appearing in Fig. 3a represent the oblique projections of thin ellipsoids (cf. Fig. 7b). Fig. 3b was taken after chromium shadowing at an angle of approximately 22° to the plane of the supporting

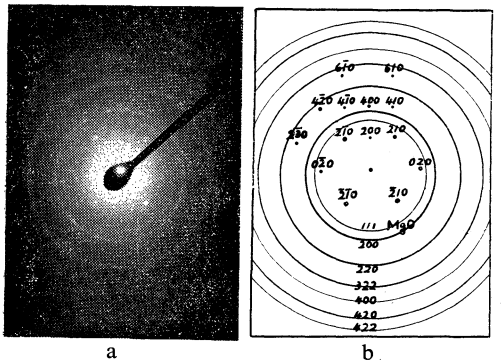
film. This micrograph shows that the crystals are flat and nearly disk-shaped (cf. Fig. 7a).



These crystals were then examined by means of an electron microdiffraction technique. The selected-area diffraction of any particle examined gave always an N-pattern as one shown in Fig. 4b or 5c, indicating that these individual crystals are single crystals. For the analysis of the diffraction patterns, the interplanar spacings were determined by comparing these patterns with the Debye-Scherrer rings of magnesium oxide which were taken under a similar condition. For this purpose, the sample crystals and magnesium oxide smoke were mounted together on a supporting film. That is to say, the film on which the sample crystals had already been mounted was exposed to the smoke of burning magnesium. Fig. 6a represents the diffraction pattern of the selected area where both a sample crystal and a large number of fine crystals of magnesium oxide are involved. The Miller indices corresponding to these spots and rings are indicated in Fig. 6b. From this result it is ascertained that the direction of the electron beam in this case was parallel to the *c* axis of the crystal.

Fig. 4b represents the diffraction pattern of the selected crystal shown in Fig. 4a which shows the electron micrograph of the same sample as the one in Fig. 2b. Fig. 5a represents the electron micrograph of the same sample as the one shown in Fig. 2a, and Fig. 5c shows the diffraction pattern of the selected crystal shown in Fig. 5a. Fig. 5b was taken at a current of the intermediate lens which was a little larger than in the case of Fig. 5c. Comparing these three photographs in Fig. 5 with each other, one can easily understand the relation between the orientation of the particle shown in the electron micrograph and that of the same particle in the diffraction pattern. From the fact that the patterns shown in Figs. 4b and 5c coincide with the N-pattern appearing in Fig. 6a, it is revealed that the nearly flat surfaces of these thin ellipsoidal crystals are parallel to the (001) plane. The direction of the largest

diameter of the crystals shown in Fig. 5a or 2a coincides with that of *b* axis. The axial directions of these crystals are illustrated in Fig. 7.

**Effect of EDTA.**—The crystal habit of strontium sulfate was significantly influenced by EDTA, and it was found that spherulitic aggregates were obtained from a solution containing a relatively large amount of EDTA. One of the remarkable examples is shown in Fig. 8. These photographs were taken with a polarizing microscope with lower nicol only (a) and with the crossed nicols (b). From these photographs, the crystals are seen to be nearly two-dimentional spherulites.

**Effect of Condensed Phosphates.**—The effects of sodium triphosphate (STP) and sodium hexametaphosphate (SHMP) were examined at 25°C. A quite minute amount of these phosphates exerted a great influence on the deposition rate and the crystal habit.

The relation between the composition of the solution and the habit of the crystals obtained in the presence of STP are illustrated in Figs. 9 and 10. Small circles in Fig. 9 indicate the initial concentrations of the three components, strontium chloride, potassium sulfate and STP, the ionic product $[Sr^{2+}][SO_4^{2-}]$ being fixed at 0.001 M$^2$. After examining many solutions having various compositions plotted in the figure, the whole area of the diagram can be divided roughly into six regions A, B,……F. The characteristic behavior of the solution falling in each of these regions is described as follows.

*Region A.*—The effect of STP is insignificant on both the deposition rate and the crystal habit.

*Region B.*—Deposition is retarded noticeably and crystalline aggregates having irregular shapes make their appearance among remarkably modified single crystals (Fig. 10a).

*Region C.*—Retardation of the deposition becomes more significant, and a relatively small number of larger aggregates having irregular shapes (*primary product*) appear in the earlier stage of the process, and later the solution becomes intensely turbid with the deposition of fine single crystals (*secondary product*). Fig. 10b illustrates the primary product.

*Region D.*—Crystal deposition is retarded as well, and crystallization occurs stepwise as in Region C, but the primary product is composed of nearly spherical aggregates as shown in Fig. 10c.

*Region E.*—Spontaneous crystallization is inhibited for a long period of time. However, if the solution was seeded with the crystals obtained from a solution falling in Region D, the seed crystals grow up to larger spheres. The secondary fine crystals also are deposited later.

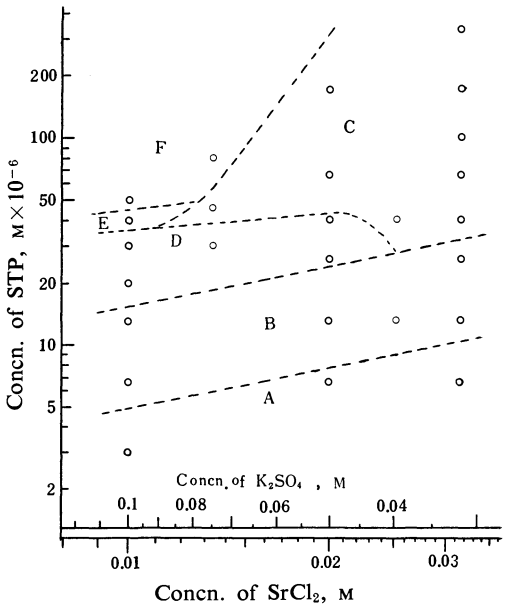

Fig. 9. Composition diagram of $SrCl_2$-$K_2SO_4$-STP-$H_2O$ system.

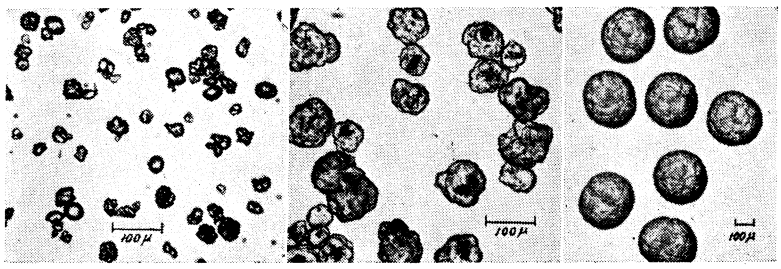

Fig. 10. Crystals grown from solutions containing STP.
a: 0.01 M $SrCl_2$, 0.1 M $K_2SO_4$, $1.3\times10^{-5}$ M STP (Region B)
b: 0.032 M $SrCl_2$, 0.032 M $K_2SO_4$, $6.3\times10^{-5}$ M STP (Region C)
c: 0.01 M $SrCl_2$, 0.1 M $K_2SO_4$, $3.0\times10^{-5}$ M STP (Region D)

*Region F.*—Both spontaneous crystallization and the growth of the seed added are inhibited almost completely.

As the present author was interested in the preparation of spherical crystals, the favorable compositions of the solutions were inquired into for the purpose of examining this process, and it was found that there were the following restrictions on the selection of available compositions. (a) The concentration of STP must be high enough to cause marked habit modification, though there is an upper limit above which no crystallization occurs. (b) The favorable concentration of strontium sulfate is limited to a certain narrow range; below this range crystallization is prevented by so small an amount of STP that the habit-modifying effect does not come into question, while above this range it is impossible to maintain the concentration of STP of sufficiently large value because of the precipitation of sparingly soluble strontium triphosphate. It may be concluded, therefore, that the solution containing a large excess of sulfate ion and a sufficient amount of STP should be recommended for the preparation of well-formed spherical crystals.

Fig. 11, which shows the splinters obtained by crushing the spherical crystal between a pair of microscope slides, makes it clear that the spherical crystal is a kind of spherulite. The arrangement of crystallites can be visualized from microscopic observation of a thin section of the spherulite. Fig. 12a shows a section of a spherulite grown by treating a seed spherulite several times successively with newly prepared solutions of the composition falling in Region E. Fig. 12b illustrates the central portion of the same section in a larger magnification. Fig. 12c shows a micrograph taken with the crossed nicols.

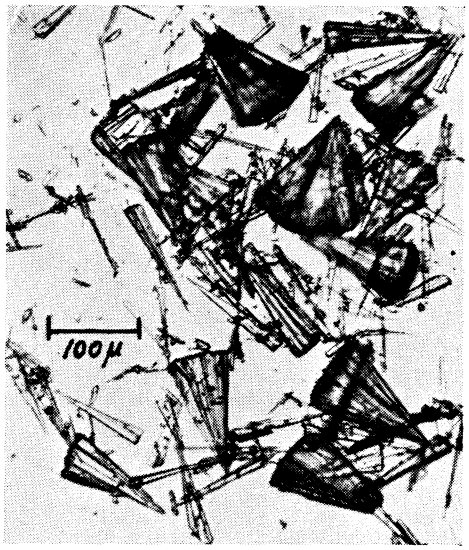

Fig. 11. Splinters of spherulite shown in Fig. 10c.

By certain X-ray examination, it was ascertained that the spherulite was constructed of needle- or wedge-shaped crystallites, each of which was elongated in the direction of *c* axis. The X-ray study was reported in another paper[7].

b: with crossed nicols
c: central portion, with lower nicol only

7) Y. Takano and S. Otani, *J. Sci. Hiroshima Univ., Ser. A*, 23, 109 (1959).

The effect of SHMP was also significant and similar to that of STP, and spherulite was obtained from solutions containing a large excess of sulfate and an appropriate amount of SHMP in its concentration range $(3\sim6)\times10^{-5}$ M.

## Discussion

Lambert and Hume-Rothery[8] studied the crystal habit of strontium sulfate precipitated by mixing the strontium chloride solution with sulfuric acid at various concentrations and temperatures. They also investigated the effect of various foreign ions on the precipitation rate, but did not mention the effect on the habit modification. The crystal habits of their products are somewhat different from what was noticed in the present experiments. This discrepancy may be attributed to the difference in the composition of solutions; particularly the difference in acidity may play a dominant role.

From many experimental evidences which have been reported and those of the present work, it is known that the effect of a foreign substance on the crystal habit is very complicated. For example, the citrate ion caused the formation of spherical crystals of barium sulfate[5] on the one hand, and of nearly disk-shaped single crystals of strontium sulfate on the other hand. Another example is the case of spindle-shaped crystals of barium sulfate obtained by Takiyama[9] in the presence of EDTA, which, in the case of strontium sulfate, caused the formation of nearly two-dimensional spherulites.

It is self-evident that the shape of a crystal depends on the relative growth rate in one direction to that in another direction. The growth rate may be affected by the adsorption of foreign substances on crystal faces. According to the peculiarity of each crystal face, the nature and the degree of adsorption may be varied from face to face. Thus a peculiar habit modification might be interpreted by the relation between the crystal structure of the substance to be crystallized and the molecular or ionic structure of the foreign substance added.

The effect of viscosity itself on the crystal habit seems to be insignificant from the experimental results obtained with glycerol or PVA. Referring to the evidence that spherulite can be obtained from ordinary solutions in the presence of a certain impurity, the adsorption, but not the high viscosity, may be the dominant factor for the spherulitic growth. Morse and others' results[3] that the gelatinous medium favored the spherulitic growth may also be attributed to the adsorption of the gelatin itself or of some other impurities possibly involved in it. The mechanism of the spherulitic growth will be discussed in detail in the following paper.

## Summary

The effect of various impurities on the crystal habit of strontium sulfate were investigated. Solutions containing citrate ion produced a nearly disk-shaped single crystal whose nearly flat surface was parallel to the (001) plane. Nearly two-dimensional spherulite is obtainable from a solution containing EDTA. A minute amount of sodium triphosphate or sodium hexametaphosphate caused the deposition of a relatively large spherulite having a spherical form, which is composed of numerous needle- or wedge-shaped crystallites elongated in the direction of *c* axis. The habit-modifying action of impurities is discussed in detail.

The author wishes to express his sincere thanks to Professor M. Miura of Hiroshima University for his kind guidance and encouragement throughout this work, and to Professor T. Fujiwara of Hiroshima University for his helpful advice. The author is also indebted to Professor T. Sasaki of Tokyo Metropolitan University, Professor M. Shinagawa of Hiroshima University and Dr. M. Kobayashi of Kobe University for their interest in this work and their kindness in furnishing him with various refined condensed phosphates.

# *Crystal Habit Modification of Strontium Sulfate. II. Characteristic Effect of Sodium Triphosphate on Crystallization and Mechanism of Spherulite Formation*

By Sadaichi OTANI

(Received March 23, 1960)

In the preceding paper[1] it was reported that the crystal habit of strontium sulfate was remarkably affected by a quite minute amount of sodium triphosphate (STP) added to the solution from which the crystals were deposited, and that the crystallization was retarded and finally came to be practically inhibited, as the amount of STP was increased, provided the concentration of the strontium ion was not over a given value.

Concerning the similar effect of condensed phosphates on the precipitation of various inorganic salts, many works have been published, mostly from the industrial point of view. For example, the effect of metaphosphates on the deposition of calcium carbonate was studied by several workers[2], and the action of triphosphate, metaphosphate, or Quadrafos on the precipitation of gypsum by Burcik[3]. Because of the minuteness of the amount of the phosphates effective in these cases, the prevention of the precipitation could not be ascribed to the sequestration of the component cations by complex formation. Some of the above authors, therefore, attributed the action of these phosphates to the adsorption of them on the crystal nuclei or the growing crystals.

However, the experimental evidences hitherto reported seem to be still insufficient for the reasonable interpretation of the mechanism of these phenomena, and concerning the effect of pure STP on the deposition of strontium sulfate, no work seems to be available in the literature. For the purpose of studying systematically the peculiar effect of STP on the deposition and the crystal habit of strontium sulfate, measurements were made in the present work on the following: (a) deposition rate and (b) dissolution rate of strontium sulfate at various STP contents, (c) surface adsorption of STP on strontium sulfate crystals, and (d) coprecipitation of STP with strontium sulfate. From the results of these experiments, the mechanisms of the habit modification, of the prevention of crystallization and of the spherulite formation will be discussed.

## Experimental and Results

**Inhibition of Crystallization by STP.**—To estimate quantitatively the retardation of the crystal deposition by STP, the rate of crystallization was measured by a conductance method. The reagents used were the same as those in the preceding work[1]. The solution to be examined was prepared

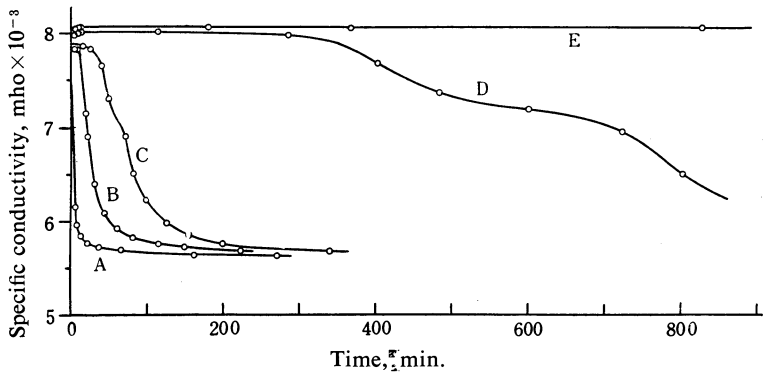

Fig. 1. Conductivity—time curves of 0.02 M $SrSO_4$ solutions containing (A) no STP, (B) $1.0\times10^{-5}$ M STP, (C) $1.5\times10^{-5}$ M STP, (D) $2.0\times10^{-5}$ M STP and (E) $3.0\times10^{-5}$ M STP.

3) E. J. Burcik, *Producers Monthly*, 19, No. 1, p. 42 (1954).

in a conductivity cell by mixing equal volumes of potassium sulfate and strontium chloride solutions of equivalent concentration, the latter containing an appropriate amount of STP. Being continuously shaken, the solution was put to the test as to its conductivity at intervals. The results of five runs with different concentrations of STP are illustrated in Fig. 1. The initial concentration of strontium sulfate was fixed at 0.02 M in all cases.

This figure shows how the deposition rate is reduced by a minute amount of STP. Indeed, when the initial concentration of STP amounted to $3.0\times10^{-5}$ M, no change could be detected for a period more than 70 hr. Even if some fine crystals of strontium sulfate were added to this solution, its conductivity remained unchanged for a long period. These facts show that not only the spontaneous crystallization but also the growth of the crystals added was inhibited by STP at this concentration.

The irregularities seen on curves C and D are caused by the stepwise deposition of crystals of two quite different types, one being spherulite and the other fine single crsytals. The comparatively steep decrease in conductivity in the earlier stage corresponds to the growth of the spherulites and that in the later stage to the deposition of fine single crystals.

**Effect of STP on Dissolution.** — The rates of dissolution of strontium sulfate into water and dilute STP solutions of various concentrations were measured by the conductance method at 25°C. The conductivity of the solvent was first measured with a glass-stoppered conductivity cell with 30.0 ml. of the solvent. Then 1.00 ml. of a solution containing 1.00 mg. of strontium sulfate was pipetted into the cell, and the resultant change in conductivity was traced, the solution being shaken continuously. The result is illustrated graphically in Fig. 2.

**Adsorption of STP on Strontium Sulfate.**—The adsorption of STP on strontium sulfate was measured by a radio tracer method with the aid of STP labeled with $^{32}P$.

The labeled STP was prepared, referring to the result of Edward and Herzog[4], by a thermal treatment of the orthophosphate mixture to which radioactive orthophosphate had been added. The product was then recrystallized from an aqueous solution by adding ethanol, and purity was found to be satisfactory for the purpose from a paper chromatographic test. The strontium sulfate used as the adsorbent was precipitated from an equivalent mixture of strontium chloride and potassium sulfate solutions, washed thoroughly with distilled water by decantation, and dried in an oven at 150°C. The particle size of strontium sulfate thus obtained was 3~5 $\mu$ in diameter.

The adsorbed amount of STP was determined by shaking 30.0 ml. of its solution of a known concentration with 0.1000 g. of the adsorbent for an appropriate period and by measuring the radioactivity of the solution before and after treatment. To avoid the dissolution of the adsorbent during the treatment, the STP solution used was prepared by diluting a measured small volume, say 0.1~1 ml., of a rather concentrated stock solution with a given large volume, say 100~500 ml., of a saturated solution of strontium sulfate.

The adsorption rate was estimated by measuring the radioactivity of the solution under investigation at intervals during the shaking. One of the results obtained at $1.0\times10^{-5}$ M of the initial STP concentration at 30°C is shown in Fig. 3, in which the radioactivity is plotted against the time of shaking. The adsorption isotherm obtained at 30.0°C is also illustrated graphically in Fig. 4. It is ascertained

4) J. W. Edwards and A. H. Herzog, *J. Am. Chem. Soc.*, 79, 3647 (1957).

that this isotherm is in good agreement with Langmuir's equation.

**Coprecipitation of STP with Strontium Sulfate.** —The coprecipitation was studied with the aid of both the conductance method and the radiotracer technique. The procedures were as follows. Appropriate volumes of strontium chloride, labeled STP, and potassium sulfate solutions, all at 25°C, were pipetted into the conductivity cell in the order just mentioned, and shaken. The decrease in the concentration of strontium sulfate in the solution was traced by conductivity measurement. The radioactivity of the supernatant liquid was measured at intervals during precipitation to trace the decrease in STP concentration. Thus, both amounts of the strontium sulfate and STP precipitated within any desired period were determined simultaneously. One of the results obtained at 25°C is shown with curve A in Fig. 5. This curve illustrates how the amount of coprecipitated STP increases as the crystallization proceeds in a solution where the initial concentrations are 0.02 M with respect to both strontium chloride and potassium sulfate and $1.50\times10^{-5}$ M with respect to STP. In this experiment the solution was constantly shaken during crystallization.

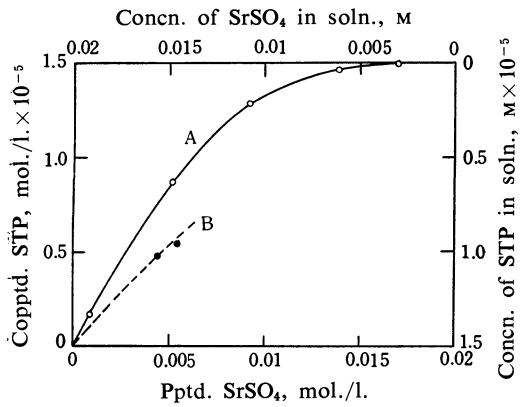

Fig. 5. Coprecipitation of STP with $SrSO_4$.
A: with continuous shaking
B: without shaking

A few measurements were made when solutions were kept unstirred during crystallization. In this case, however, the above-mentioned procedures could not be employed to trace the change in the amount coprecipitated, because the growing crystals were all sedimented at the bottom of the container, thus making the solution inhomogeneous. Therefore, the crystals deposited were filtered off at an appropriate time in the course of crystallization, and weighed after drying. The amount of coprecipitated STP was determined from the radioactivity of the filtrate. The two solid circles in Fig. 5 indicate the values obtained from two runs with solutions having the same composition as that mentioned above.

The mole ratios of STP to strontium sulfate both in the precipitate and the solution were calculated from the data given on curve A in Fig. 5, and are plotted in Fig. 6. The upper curve

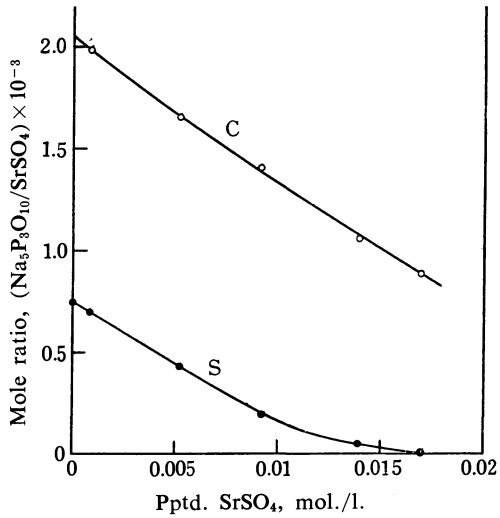

Fig. 6. Mole ratio of STP to $SrSO_4$ during crystallization.
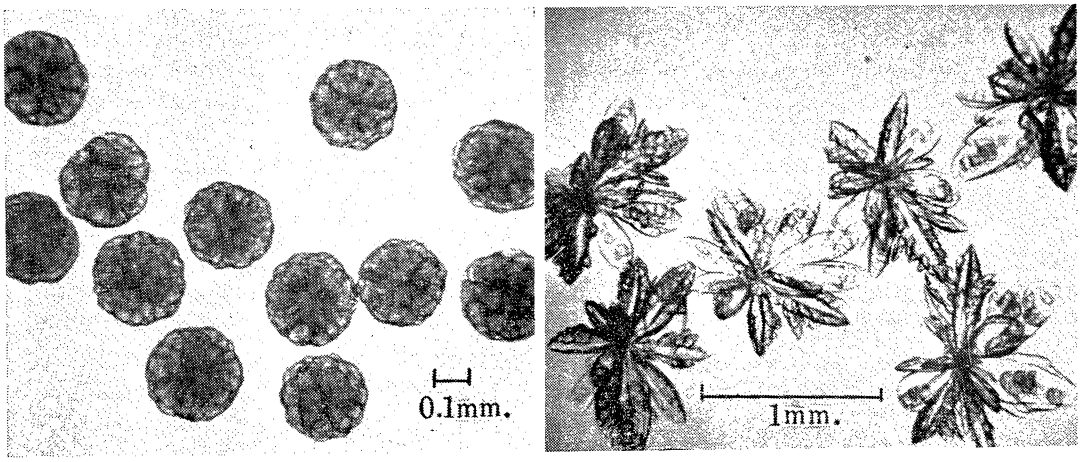
C: in crystal S; in solution



indicates the value in the precipitate and the lower that in the solution.

## Discussion

From the measurements on the crystallization rate, a striking effect of STP was well noticed. As is seen in Fig. 1, an extremely small amount of STP ($3.0\times10^{-5}$ M in its concentration) is quite sufficient to prevent the deposition of crystals from the 0.02 M solution of strontium sulfate. This fact can not be attributed to the complex formation between strontium and triphosphate, in view of the extremely small mole ratio of triphosphate to strontium, namely, 1 : 670.

From the measurements on the dissolution rate, another striking effect of STP was observed. As is seen in Fig. 2, the dissolution of strontium sulfate was retarded by STP even when its concentration was as small as the one in the above-mentioned case. This evidence may possibly be attributed to the adsorption of STP on the crystal surface, because the dissolution can not be hindered directly by the STP existing in the bulk of the solution.

From the measurement of adsorption, the amount of STP adsorbed on strontium sulfate was found to be up to saturation at an extremely low concentration, namely $(2\sim4)\times10^{-5}$ M. Comparison of Fig. 4 with Figs. 1 and 2 reveals the fact that the concentration range within which the amount of adsorbed STP tends to be saturated agrees roughly with the one within which the retardation of crystallization and of dissolution becomes significant. The retardation or prevention of crystallization may accordingly be attributed to the adsorption of STP on the

a b

Fig. 7. Products grown from solutions of $SrSO_4$(0.02 M) containg STP ($1.5\times10^{-5}$ M).
a: with continuous shaking, b: without shaking

crystal nuclei or the growing crystals, and the following mechanism may be considered. The triphosphate ion may be adsorbed preferentially at the active centers of growth on the crystal nuclei or the growing faces of crystals, and the adsorbed triphosphate ion may act as a poison to the layer growth of the crystal faces. The larger the concentration of STP is, the more the active centers will be poisoned and the slower the growth rate will become, and finally, when the concentration of STP exceeds a given value, namely $(3\sim4)\times10^{-5}$ M, at which the adsorption comes to be nearly saturated, all the active centers will be poisoned, and crystallization may be completely inhibited.

Strong interaction between STP and strontium sulfate may be reasonably recognized also from the measurements on coprecipitation. Fig. 6 shows that STP is coprecipitated almost completely with strontium sulfate, the mole ratio of STP to strontium sulfate in the crystal being several times as great as that in the solution.

As is seen from Figs. 5 and 7, agitation of the solution during crystallization has a considerable influence not only on the amount of coprecipitation but also on the crystal habit. Fig. 7a shows the spherulite obtained from a solution with continous shaking (corresponding to curve A in Fig. 5), and Fig. 7b the star-like aggregate from another solution of the same initial composition without shaking (corresponding to curve B in Fig. 5). The difference between the habits of these crystals may be due to the difference in the amount of coprecipitated STP, which can be possibly traced back to the difference in the mode of supply—one by agitation and the other merely by diffusion—of STP from the bulk on the crystal interface.

As already reported[5], the component crystallite of the spherulite or the star-like aggregate is elongated in the direction of *c* axis. This fact means that STP makes the growth rate predominant in the direction of *c* axis. From the above-mentioned poisoning action of the adsorbed STP upon the regular layer growth, it may be concluded that the adsorption of STP is at its minimum on the (001) face as compared with all the other faces, and accordingly the layer growth on this face is least retarded.

Next, the mechanism of spherulite formation will be considered. If radiating fibrillar growth starts from a common center in all directions with an equal growth rate, the growing aggregate will always be spherical. For this to occur, it is necessary to postulate the existence of a cluster of nuclei which has the ability to emit fibrillar crystallites in all directions. In practice, however, the formation of such a cluster of nuclei seems to be improbable, and it may be more acceptable to assume the branching of growing crystallite.

Keller and Waring[6] assumed a periodic branching of fibrils occurring at constant distances with a constant acute angle to explain the "sheaf" formation in the course of spherulitic growth of synthetic high polymers. They proved that the periodicity of branching is a necessary condition for the formation of Popoff's "Zweiblatt"[7] or Morse and Donnay's "sheaf"[8]. Keller and Waring's illustration of

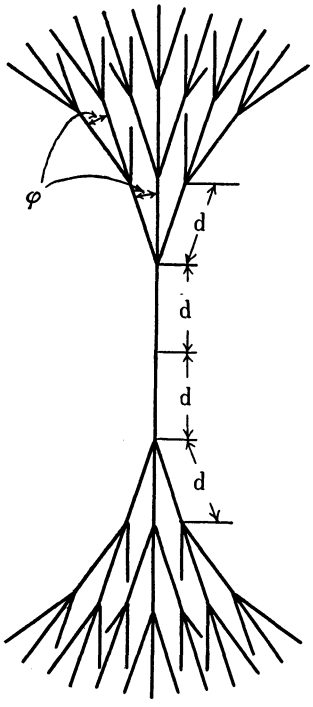

Fig. 8. Schematic diagram showing the sheaf formation through periodic branchings (after Keller and Waring).

the sheaf formation through the periodic branching is reproduced in Fig. 8.

In the present case, the branching of crystallite were recognized from a microscopic observation of the growth process. Fig. 9 shows the development of a seed in a solution containing an appropriate amount of STP. Fig. 9a shows the seed which is one of the splinters obtained by crushing a well-developed spherulite, and Fig. 9b and 9c illustrate the successive stages of its growth. By crushing the product (Fig. 9c), a large number of wedge-shaped smaller crystallites resulted. These are shown in Fig. 9d. By comparing these photographs with each other, it may be seen that radiating crystallization started everywhere on the surface of the seed. This fact may certify that branching of crystallite is induced by STP.

No indication of sheaf formation was observed either in this experiment or in many others mentioned before. However, the formation of spherulite can be interpreted on the basis of the above-mentioned evidence that, under the influence of STP, branchings are accompanied by the growth of strontium sulfate crystal and its growth rate is highly predominant in the direction of *c* axis. Under this condition, the crystal growth must proceed as follows. Starting from a single nucleus, an aggregate crystallites will be formed as a result of successive branchings during the growth, and the number of the crystallites will increase acceleratedly as the growth proceeds. On the other hand, the growth of each crystallite must inevitably be restricted by the steric hindrance of the adjacent ones, and, as a result, only those crystallites of which the direction of the fastest growth happened to coincide nearly with the radial direction may survive. Thus, sooner or later, the aggregate changes to be constructed of a great number of crystallites directed radially, at least near the periphery. Hereafter, the

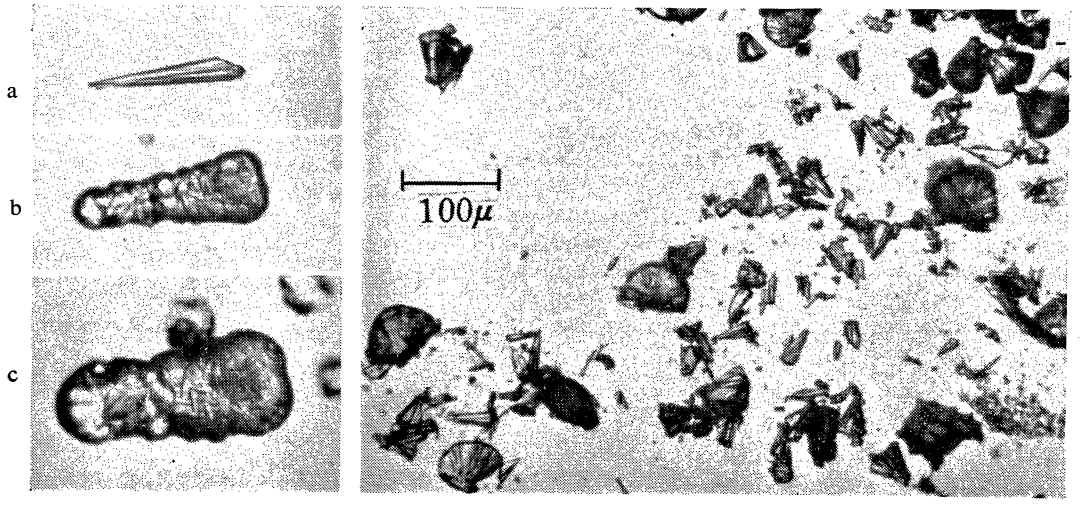

Fig. 9. Spherulitic growth from a seed.
a: seed, b: after 48 min., c: after 190 min., d: splinters obtained by crushing c

shape of the aggregate must gradually approach a sphere, because the growth rate is uniform in all directions in the radial growth.

The above-mentioned concept may explain why such a star-like aggregate as that shown in Fig. 7b is produced, when the solution is kept unstirred. For a moment just after a crystal nucleus begins to grow, it may be supplied with enough STP to cause frequent branchings regardless of the solution being stirred or not. However, as the growth proceeds, the concentration of STP at the immediate vicinity of the growing aggregate may be reduced rapidly because of the consumption of STP due to the selective adsorption (cf. Fig. 6). If the solution is not stirred, STP is supplied merely by diffusion, and hence the branching may ocurr less frequently. Accordingly the resultant aggregate, being composed of a relatively small number of radiated crystallites, gives a star-like appearance.

As to the mechanism of the branching of crystallite, Keller and Waring[6] mentioned twinning and rupture of distorted crystal as possible causes. In the present work, branching is induced by STP, and may be attributed to the adsorption of the latter onto the crystallite. The mechanism of branching may be considered as follows. The adsorbed triphosphate ion could hardly enter into the regular crystal lattice of strontium sulfate because of the unfitness of the size and ionic charge. The crystal lattice may be distorted in the vicinity of the adsorbed triphosphate ion. As the amount of adsorbed triphosphate increases, many ruptures of lattice may appear on the crystal faces owing to the distortions of the lattice. These ruptures may cause branchings of crystallite.

From the above discussion, we may conclude that we shall have a possibility of preparing spherulites of any substance, if we can find an impurity that has the following properties. (1) The impurity is intensely and preferentially adsorbed by the particular crystal faces of the substance in question and (2) the impurity can not make a solid solution or mixed crystal with the substance. A clue to finding such a suitable impurity may possibly be obtained from the knowledge of the relation between the molecular or ionic structure of the impurity and the crystal structure of the substance in question. For the preparation of a spherulite of an inorganic salt, there may be found some suitable impurities among those polyatomic complex ions which have a strong affinity to either of the component ions of the salt.

## Summary

1) The peculiar effect of sodium triphosphate (STP) on the crystallization and the crystal habit of strontium sulfate was studied systematically by measuring (a) the deposition rate and (b) the dissolution rate of strontium sulfate at various STP concentrations, (c) the surface adsorption of STP on strontium sulfate crystal, and (d) the coprecipitation of these salts.

2) The inhibiting action of STP on the deposition and dissolution of strontium sulfate is attributed to the adsorption of STP.

3) The fact that STP makes the growth rate predominant in the direction of *c* axis of strontium sulfate is ascribed to the small adsorption of STP on the (001) faces compared with that on the other faces.

4) The occurrence of the branching of crystallite was ascertained experimentally, and attributed to the ruptures appearing on the crystal faces as a result of the unfitness in the size and ionic charge of the adsorbed triphosphate.

5) The formation process of the spherulite can be interpreted from the fact that the frequent branchings are accompanied by the nearly one-dimentional growth of crystallite.

6) Possibilities of preparing spherulites from other substances are discussed.

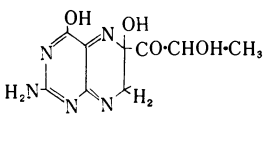
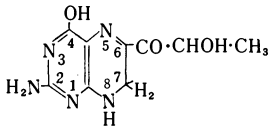
# *The Structure of the Yellow Pigment from Drosophila*



By Saburo NAWA

(Received May 9, 1960)



It has been known that the wild type eye-color of *Drosophila melanogaster* is due to the presence of two pigments, the red and the brown. It is of particular interest to study the chemistry of the eye pigments in order to clarify the relationship between genes and biochemical processes, since the various genetic interrelationships are well established in the group of eye-color mutants of *Drosophila*. Hadorn and Mitchell[1] have mentioned for the first time the presence of a yellow pigment, which was later named Sepiapterin by Ziegler-Günder and Hadorn[2], in *Drosophila* by a simple chromatographic technique and that the mutant *sepia* contained much greater amounts of Sepiapterin in comparison with the wild type. In 1954 Nawa and Taira[3] have reported that the yellow pigment, Xanthopterin-B[4], found in the epidermis of the mutant *lemon* of silkworm is a derivative of 2-amino-4-hydroxypteridine and is indistinguishable from Sepiapterin. In the same year Forrest and Mitchell[5] have isolated Sepiapterin as a crystalline form and proposed the structure I for it, although I was later modified to structure II by Forrest et al.[6] In the light of some new experiments on Sepiapterin, however, its structure will be discussed in this paper. And we now wish to propose the structure III for Sepiapterin on the basis of the following findings.

I

II

III

## Experimental

**Isolation of Sepiapterin.** — One handred grams (wet) of flies (*D. melanogaster*, mutant *sepia*) were homogenized in a Waring Blender in 30% ethanol (500 ml.). The suspension was heated at 80°C for 5 min. and allowed to stand overnight in an ice box. The reddish yellow supernatant obtained by centrifugation was concentrated in vacuo to a small volume (about 50 ml.) and then spread on 8 sheets (40×40 cm.) of heavy filter paper (Toyo Roshi Co. Ltd., No. 26). These were then chromatographed with water. The yellow band was cut off and eluted with water. The eluate was then concentrated and chromatographed again on the heavy filter paper (4 sheets) with a mixture of *n*-butanol, acetic acid and water (4 : 1 : 1). After allowing the chromatogram to dry, the appropriate band corresponding to Sepiapterin was eluted with water. The concentrated solution was applied to a column (6×40 cm.) of cellulose powder and developed with water. The fraction of yellow pigment was collected and evaporated to dryness in vacuo. The residue was dissolved in hot water (8 ml.) and allowed to stand overnight in an ice box, when the product (13 mg.) crystallized as orange needles. All the above procedure was carried out in the dark to avoid photolysis. Eight handred gram of flies gave 105 mg. of crystals in repetition of this procedure.

The ultraviolet absorption spectra are shown in Fig. 1. (At pH 1, $\lambda_{max}$ 281, 410 m$\mu$, $E^{1\%}_{1cm.}$ 440, 340. At pH 11, $\lambda_{max}$ 268, 440 m$\mu$, $E^{1\%}_{1cm.}$ 665. 510.)

**Air Oxidation in Borax Solution.** — Sepiapterin (25 mg.) was dissolved in 5% borax (50 ml.) and shaken at 35°C for 5 hr. in the dark to avoid photodecomposition, when the yellow color of the solution gradually disappeared and the yellow fluorescence changed to green.

**a) Estimation of 7,8-Dihydroxanthopterin (IV).** —When this reaction mixture was allowed to stand overnight in an ice box, the product (14.6 mg.) precipitated. The compound was recrystallized from 0.25 N sulfuric acid as the sulfate (10.7 mg.).

Found: C, 30.0; H, 3.9; N, 29.2. Calcd. for $C_6H_7N_5O_2 \cdot 1/2H_2SO_4 \cdot H_2O$: C, 29.0; H, 4.0; N, 28.2%.

The ultraviolet absorption curves as shown in Fig. 2a. (At pH 1, $\lambda_{max}$ 276, 305 m$\mu$, $E^{1\%}_{1cm.}$, 535, 310. At pH 11, $\lambda_{max}$ 276 m$\mu$, $E^{1\%}_{1cm.}$ 515.) This compound was readily oxidized to xanthopterin (V) with manganese dioxide in alkaline solution. In neutral solution, moreover, the compound was oxidized to V accompanied by consumption of one mole of iodine. These properties, absorption spectra and $R_f$ values of the compound are perfectly identical with those of the authentic 7,8-dihydroxanthopterin (IV)[7-9]. Some $R_f$ values compared with those for authentic IV (in parentheses) are: *n*-propanol, 1% ammonia (2 : 1), 0.16 (0.16); 2% $K_2HPO_4$, 0.32 (0.32), 3% sodium citrate, 0.35 (0.35). The absorption curves of IV obtained from the catalytic hydrogenation of xanthopterin (Nutritional Biochemicals Co., U. S. A.) are shown in Fig. 2b.

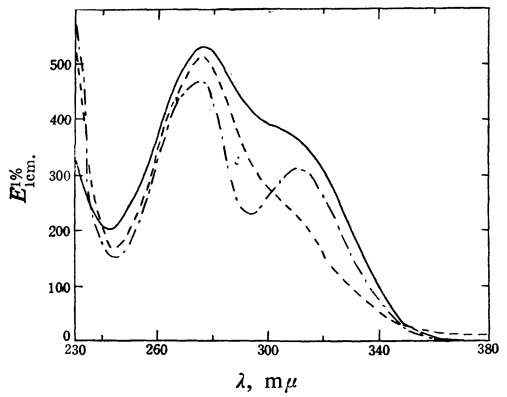

Fig. 2a. The ultraviolet absorption of the product from decomposition of Sepiapterin: ——, at pH 1.0; — — —, at pH 5.0; and - - -, at pH 11.0.

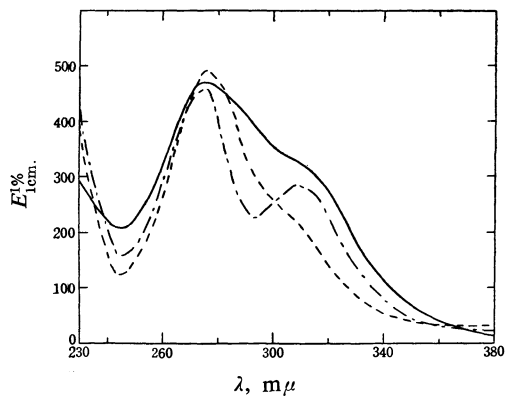

Fig. 2b. The ultraviolet absorption of 7,8-dihydroxanthopterin (IV) obtained from catalytic reduction of xanthopterin: ——, at pH 1.0; — — —, at pH 5.0; and - - -, at pH 11.0.

**b) Characterization of Lactic Acid.** — The supernatant from the reaction mixture mentioned above showed the color reaction[10] characteristic of lactic acid. The supernatant (0.01 ml.) was withdrawn and heated at 100°C for 5 min. with 3 ml. of sulfuric acid and 0.05 ml. of 2% $CuSO_4$. After cooling,, 0.05 ml. of 1.5% *p*-hydroxydiphenyl reagent was added and allowed to stand at 30°C for 30 min. And then the color developed was estimated at 570 m$\mu$ in a Beckman spectrophotometer. From a standard curve obtained from known amounts of lithium lactate, 5 $\mu$g. of Sepiapterin (0.01 ml. of the reaction mixture) was estimated to give 1.5 $\mu$g. of lactic acid (with a molecular weight of 237, the theory for one mole of lactic acid per mole of Sepiapterin is 1.57 $\mu$g.). The remained supernatant was concentrated to a small volume and paper chromatographed in various solvent systems. Some $R_f$ values compared with those for lactic acid (in parentheses) are: *n*-butanol, acetic acid, water (4 : 1 : 1), 0.75 (0.75); ethanol,10% ammonia (4 : 1), 0.77 (0.77); *n*-butanol, pyridine, water (1 : 1 : 1), 0.39 (0.39).

**c) Relationship of Oxygen Uptake, and IV and Lactic Acid Production.** — Sepiapterin (4.7 mg.) was dissolved in 5% borax solution (20 ml.) and each aliquots (2 ml., 0.47 mg.) were shaken in Warburg flasks at 35°C in the dark. At various

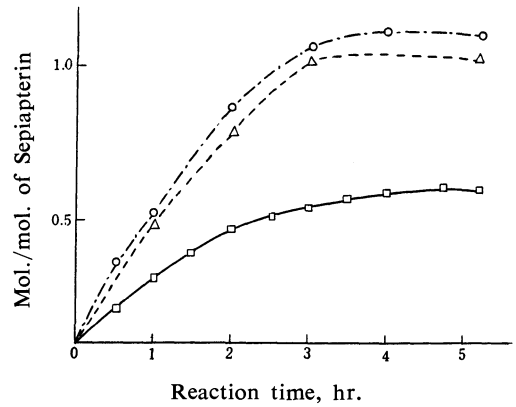

Fig. 3. Air oxidation of Sepiapterin in the presenc of borax: -□-, oxygen consumed; -○-, lactic acid produced; and -△-, 7,8-dihydroxanthopterin produced.

10) S. B. Barker and W. H. Summerson, *J. Biol. Chem.*, **138**, 535 (1941).

time intervals, oxygen uptake was measured, the amounts of IV produced were calculated using the known extinction constant at 310 mμ at pH 7 and the amounts of lactic acid were determined by the procedure described previously. As shown in Fig. 3, the molar ratio of oxygen consumed, and IV and lactic acid produced was 0.5 : 1 : 1 at all reaction intervals. This reaction did not occur in the absence of oxygen. It should be noted that the rate of reaction is variable. Since the reaction is accerelated by addition of small amounts of heavy metal ions and inhibited by chelating agents, it is concluded that the variable rate is due to the presence of metal-ion impurities.

**Periodate Oxidation.**—A solution of Sepiapterin (2.0 mg.) in 2% sodium bicarbonate (1.2 ml.) was treated with 1% sodium metaperiodate (0.8 ml.) in an ice bath. At various intervals the undestroyed periodate was estimated. Aliquots (0.1 ml.) were withdrawn and quenched in 0.001 N sodium arsenite (1.0 ml.) containing potassium iodide (10 mg.). After 15 min. the samples were titrated with standard potassium iodide-iodine (0.002 N) to a starch end-point. Acetaldehyde was determined by the color development[11] with *p*-hydroxydiphenyl in sulfuric acid. To aliquots (0.01 ml.) was added 0.1% sodium arsenite (0.5 ml.). After 15 min. the solution was treated with sulfuric acid (3 ml.), 2% $CuSO_4$ (0.05 ml.) and 1.5% *p*-hydroxydiphenyl reagent (0.05 ml.) at 30°C for 30 min. The color developed was estimated at 570 mμ. As shown in Fig. 4, the

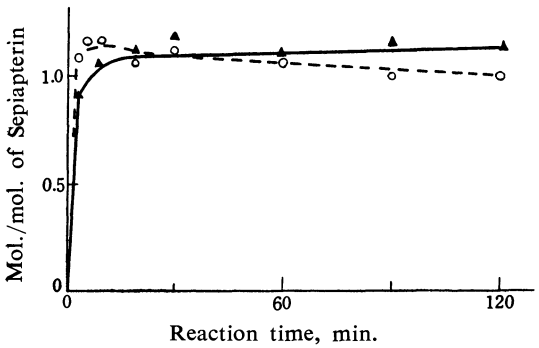

Fig. 4. Periodate oxidation of Sepiapterin: -▲-, periodate consumed; --○--, acetaldehyde produced.

curves of the acetaldehyde production and periodate consumption reached to plateaus as soon as periodate was added to the solution of Sepiapterin. In the reaction the yellow color of the solution rapidly disappeared and the yellow fluorescence changed to green.

**2-Amino-4-hydroxy-7, 8-dihydropteridine-6-carboxylic Acid (VI).**—To a solution of Sepiapterin (20 mg.) in 2% sodium bicarbonate (12 ml.), 1% sodium metaperiodate (8 ml.) was added. After standing 30 min. at 0°C, the reaction mixture was diluted with cold water (20 ml.), applied immediately to a column (5×40 cm.) of cellulose powder and developed with 0.002% ammonia. During the development of the column, the fluorescent products were separated into two bands, major greenish yellow and minor blue fluorescent. The minor blue fluorescent compound (1.6 mg.) was 2-amino-4-hydroxypteridine-6-carboxylic acid (VII) with identity of ultraviolet absorption and its paper chromatographic behavior. The main greenish yellow fluorescent band was collected and a pale greyish residue (7.4 mg.) was obtained by freeze-drying. For convenience, this compound is henceforth referred to as Compound-A.

Found: C, 40.78; H, 3.21; N, 32.75. Calcd. for $C_7H_7N_5O_3$: C, 40.19; H, 3.37; N, 33.48%.

The ultraviolet absorption spectra are shown in Fig. 5. (At pH 1, $\lambda_{max}$ 280, 380 mμ. At pH 11,

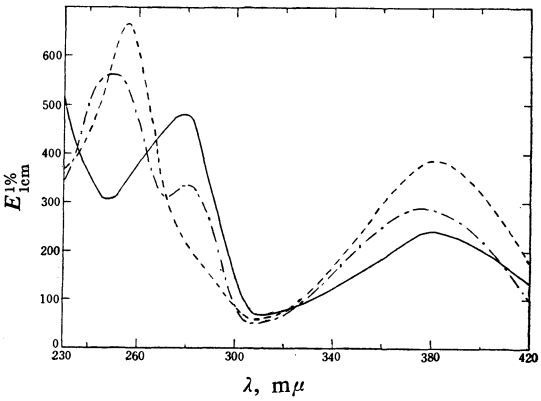

Fig. 5. The ultraviolet absorption of pteridine (VI) obtained from periodate oxidation of Sepiapterin: ——, at pH 1.0; — — —, at pH 5.0; and - - -, at pH 11.0.

$\lambda_{max}$ 255, 380 mμ.) Some $R_f$ values compared with those for VII (in brackets) are: *n*-propanol, 1% ammonia (2 : 1), 0.11 (0.14); *n*-butanol, acetic acid, water (4 : 1 : 1), 0.09 (0.14); 3% sodium citrate. 0.37 (0.53); 5% acetic acid, 0.30 (0.47); 2% $K_2HPO_4$, 0.35 (0.44). Compound-A was comparatively stable to auto-oxidation in neutral solution when stored at 0°C in the dark, but it was readily converted to VII on exposure to light and at that time consumed 0.5 mol. of oxgen. In alkaline solution Compound-A was oxidized into VII with manganese dioxide. In neutral or acidic solution, furthermore, Compound-A consumed 1 mol. of iodine and gave VII. From these results, it is concluded that Compound-A is a dihydro-form of VII, i. e. 2-amino-4-hydroxy-7, 8-dihydropteridine-6-carboxylic acid (VI). This is also confirmed by the following findings.

**a) Reduction of Compound-A with Sodium Borohydride.**—A solution of Compound-A (0.1 mg.) in 0.01 N acetic acid (10 ml.) was treated with sodium borohydride (1 mg.), when the greenish yellow fluorescence of the solution immediately dissappeared. Aliquots of the reaction mixture were adjusted to various pH and the absorption spectra were recorded as shown in Fig. 6. The curves are characteristic of tetrahydropteridies[7,12,13].

13) S. Kaufman, *J. Biol. Chem.*, **234**, 2677 (1959).

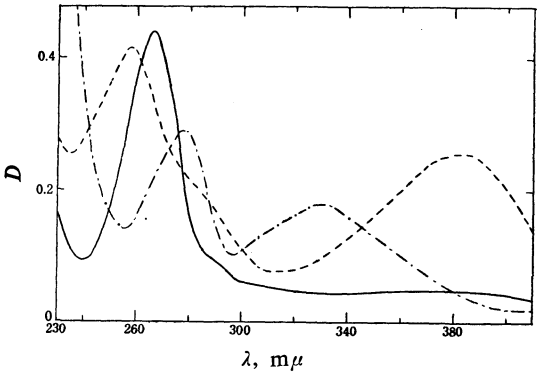

Fig. 6. The absorption of the product resulting from $NaBH_4$ reduction of VI: ——, at pH 1.0; — — —, at pH 5; and - - -, at pH 11.0.

Upon shaking the reaction mixture in air, its fluorescence became blue. Paper chromatography of this solution showed the presence of two blue fluorescent compounds. The major spot was VII and the weaker was 2-amino-4-hydroxypteridine (VIII). Neither VII nor VIII was attacked by $NaBH_4$.

**b) Conversion of Compound-A to 2, 6-Diamino-4-hydroxypteridine (IX).**—A solution of compound-A (0.5 mg.) in 1% ammonia (1 ml.) was heated at 80°C for 30 min. The reaction mixture was applied to a column of cellulose powder and developed with 0.002% ammonia. The main bright green fluorescent band was eluted. The absorption spectra of this eluate in various pH (Fig. 7) correspond to these of 2,6-diamino-4-hydroxypteridine (IX)[14], which were obtained from the catalytic reduction of VIII in dilute ammonia, and the identity of this compound was confirmed by paper chromatographic comparison with the authentic sample. When the compound was incubated with milk xanthine oxidase at pH 8, it was oxidized to a purplish blue

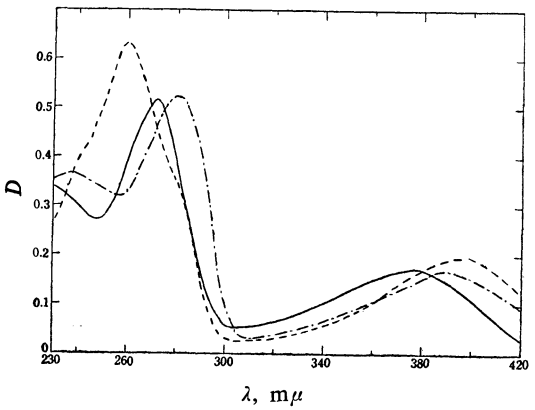

Fig. 7. The absorption of pteridine (IX) obtained from VI by treating with ammonia: ——, at pH 1.0; — — —, at pH 5.0; and - - -, at pH 11.0.

14) C. V. Baalen and H. S. Forrest, *J. Am. Chem. Soc.*, **81**, 1770 (1959).

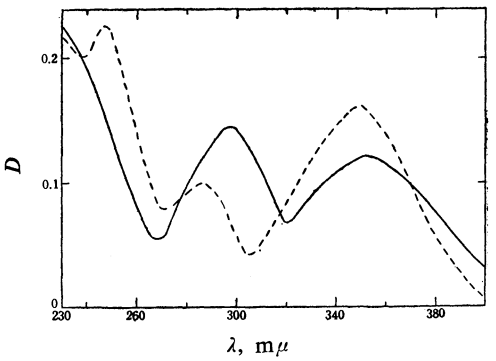

Fig. 8. The absorption of pteridine (X) obtained from IX by treatment with milk xanthine oxidase: ——, at pH 1.0; - - -, at pH 11.0.

fluorescent substance. Its absorption spectra (Fig. 8) resemble those of isoxanthopterin (2-amino-4, 7-dihydroxypteridine)[15]. From the evidence[16,17] that milk xanthine oxidase attacks the 7-position of the pteridine skeleton, it is probable that the substance is 2,6-diamino-4,7-dihydroxypteridine(X).

**Photodecomposition.**—Sepiapterin (0.47 mg., 2.0 μmol.) dissolved in water (2 ml.) was exposed to sunlight in a Warburg flask at 35°C. An oxygen uptake of 50 μl. was observed, when the yellow color of the solution had disappeared. Acetaldehyde (0.086 mg., 1.95 μmol.) was ascertained by the procedure described above. VII (0.39 mg., 1.88 μmol.) was determined using the known optical density for this acid, after separating by paper chromatography.

## Discussion

It has been known that both photodecomposition[3,5] and permanganate oxidation[5] of Sepiapterin gave 2-amino-4-hydroxypteridine-6-carboxylic acid (VII). This shows that Sepiapterin is a 6-substituted pteridine. In connection with the result by Forrest et al.[5], who obtained VII and acetaldehyde from periodate oxidation of Sepiapterin, the present observation that one mole of lactic acid is quantitatively obtained from decomposition of Sepiapterin suggests that the substituent is a lactyl group ($CH_3 \cdot CHOH \cdot CO-$). Since the analytical data indicate that Sepiaterin has three carbon atoms other than its pteridine skeleton, the lactyl group seems to be a sole side chain. The isolation of 7, 8-dihydroxanthopterin (IV) from air oxidation of Sepiapterin suggest whether the 6-hydroxy group of IV is an integral part of the molecule of Sepiapterin or a hydroxylation at the 6-position occurs at

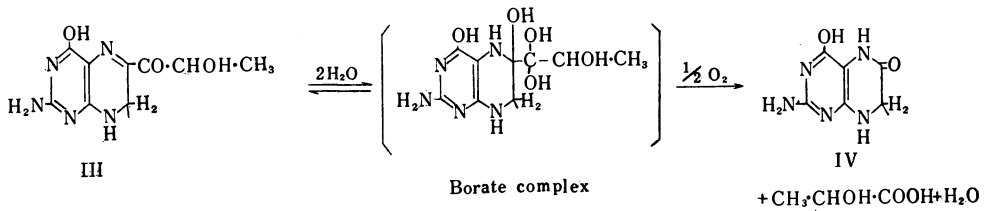

Fig. 9.

the same time as the lactyl side chain is split off. Since this reaction did not occur in the absence of oxygen (0.5 mol. of oxygen were consumed), it is sure that the side chain is split off oxidatively. In this connection, Blakley[18] has reported the production of xanthopterin in aerated solution of dihydro- or tetrahydrofolic acid. It seems reasonable to assume, therefore, that the oxygen atom in the 6-position of IV is oxidatively introduced and then Sepiapterin has no OH group in its 6-position. The finding that the decomposition of Sepiapterin give one mole each of IV and lactic acid accompanied by consumption of 0.5 mol. of oxygen, therefore, suggests that Sepiapterin has the structure 2-amino-4-hydroxy-7, 8-dihydro-6-lactylpteridine (III). From the evidence[19] that polyhydroxy compounds form borate complexes and from the experimental result that 0.5 mol. of oxygen are consumed in the reaction of sepiapterin with borax, the schema shown in Fig. 9 is postulated.

The formation of 2-amino-4-hydroxypteridine-6-carboxylic acid (VII) and acetaldehyde by periodate oxidation of Sepiapterin has been reported by Forrest et al.[5]. However, when in alkaline solution Sepiapterin was treated with periodate, it consumed one mole of periodate to give acetaldehyde and a pteridine different from VII. The pteridine seems to be a dihydro form of VII, i. e. 2-amino-4-hydroxy-7, 8-dihydropteridine-6-carboxylic acid (VI), since it is readily oxidized to VII accompanied by consumption of 0.5 mol. of oxygen or one mole of iodine. Furthermore, the finding that pteridine was converted to 2, 6-diamino-4-hydroxypteridine (IX) by treating with ammonia again supports it to be hydropteridine, in connection with the evidence[14] that the catalytic reduction of 2-amino-4-hydroxypteridine (VIII) in the presence of ammonia gave IX. In progress of our studies, Viscontini and Möhlmann[20] reported that the reduction of Sepiapterin with sodium borohydride give a tetrahydro form of biopterin (2-amino-4-hydroxy-6-(1, 2-dihydroxypropyl)-pteridine )[21-23]. We observed that the sodium borohydride reduction of VI give a compound with a spectrum characteristic of typical tetrahydropteridine[7,12,13], although neither VII nor VIII is affected. Dihydropteridines, therefore, seems to be reduced to the corresponding tetrahydro form by the action of sodium borohydride. It was also found that Sepiapterin is reduced to a tetrahydro form with the enzyme system from chicken liver, which carries out a reaction of dihydrofolic acid to tetrahydrofolic acid. These observations confirm that Sepiapterin is a dihydropteridine. The present result that photodecomposition of Sepiapterin gave one mole each of acetaldehyde and VII accompanied by consumption of one mole of oxygen, is again in accord with the proposed structure III.

Several different pteridines[3,5,6,20,21,23] have already been isolated from *Drosophila*. It has been assumed[3,5,20] that the red pigment found in the wild type has a structure related closely to the yellow pigment (Sepiapterin) and the latter is an intermediate in the synthesis of the former. It is of particular interest that Sepiapterin is a hydropteridine, in connection with the biological significance[24] of hydrofolic acid. Recently, Kaufman[13] reported the role of hydro-form of simple pteridines in the enzymatic oxidation of phenylalanine to tyrosine. It has been, furthermore, known that the mutant *lemon* of silkworm, which accumulates the yellow pigment identical with Sepiapterin in larval epidermis, shows the inhibition of oxidation of phenolic substances in vivo. From these, it may be expected that in the insect the yellow pigment (Sepiapterin) participates in some oxidation-reduction systems, although its biological significance remains to be determined.

## Summary

The yellow pigment (Sepiapterin), occuring in the eyes of *Drosophila melanogaster*,

decomposed to one mole each of 7, 8-dihydroxanthopterin and lactic acid accompanied by consumption of 0.5 mol. of oxygen. From this and from the results of its photodecomposition and periodate oxidation, it is concluded that the compound has the structure 2-amino-4-hydroxy-7, 8-dihydro-6-lactylpteridine (III).

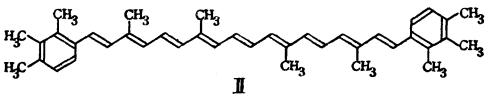
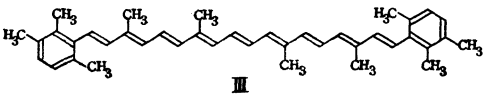
# *Total Syntheses of Renieratene and Renierapurpurin**

By Masaru YAMAGUCHI



(Received May 11, 1960)

In the present paper are described the total syntheses of renieratene, I, and renierapurpurin, the chemical constitution of the latter having been hitherto unknown. By these works, therefore, the chemical constitution of renieratene has been established beyond doubt and the chemical constitution of renierapurpurin, II, has also been clearly established without any degradation studies.



The orange coloration of the sponge *Reniera japonica*, which is considered by zoologists to be identical with *Halichondria panicea*, a species of wide distribution, is mainly due to the presence of a complicated mixture of carotenoids. Fifteen different carotenoids have been isolated from the sponge in crystalline states[1]. The main pigments are, however, carotenoid hydrocarbons which are renieratene, isorenieratene (III), β-carotene and renierapurpurin. Among these pigments, the chemical constitution[2,3] of renieratene and isorenieratene

have been elucidated and the total synthesis of the latter has been carried out by the author[4] and later by M. C. Khosla and P. Karrer[5]. On the other hand, however, little progress has been made on the study of the chemical constitution of renierapurpurin because of the limited quantity of the pigment available. It has so far been known that renierapurpurin forms purple plates of m. p. 230°C, exhibits absorption maxima at 544, 504 and 475 mμ in carbon disulfide, and has the formula $C_{40}H_{48}$ (or $C_{40}H_{50}$)[1]. In regard to its constitution, it has been inferred from its absorption maxima and from an analogy to renieratene, etc., that if it contains two triemthylphenyl groups at both ends of the molecule as in renieratene and isorenieratene, the terminal groups should be ones having small steric hindrance between the polyene chain and annular methyl groups. For example 2, 3, 4-trimethylphenyl group satisfies the condition. However, no experiment has been carried out to draw any conclusion on the problem.

The syntheses were carried out according to Karrer's method[6]. 2, 3, 4-Trimethylbenzaldehyde (IV)[2] was condensed with acetone to give 2, 3, 4-trimethylbenzalacetone (V), which was converted into acetylenic alcohol VI by Grignard reaction. A mixture of this acetylenic alcohol and another acetylenic alcohol VII[4] was condensed with octene-2, 7-dione to give a mixture of three isomeric $C_{40}$-diynetetraols (VIII, IX and X). The mixture was partially hydrogenated and then dehydrated, and the chromatographic separations of the product gave renieratene (I), renierapurpurin (II) and isorenieratene (III) in pure states but in low yields. The identity of these pigments with the natural specimens was verified by mixed melting point determinations, mixed chromatographies, and IR- and UV-determinations.

Renierapurpurin was obtained in a better yield in another experiment starting from acetylenic alcohol VI.

Renierapurpurin is the third carotenoid that is proved to contain benzene rings, and the fact that three possible isomers derivable by combinations of 2, 3, 4-trimethylphenyl and 2, 3, 6-trimethylphenyl groups are all present in the sponge, may be considered to provide an important orientation of the biogenesis of this interesting group of carotenoids.

Furthermore these isomers afford a typical example of steric hindrance, the cause of which has been discussed in the previous paper[3]. The absorption maxima (the longest wavelength, in carbon disulfide solution) of renierapurpurin, renieratene and isorenieratene are at 544, 532 and 520 mμ, respectively[2]. The shifts of maxima (12 and 24 mμ) are proportional to the number of 2, 3, 6-trimethylphenyl group in their molecules.

## Experimental

Solutions were evaporated under diminished pressure unless otherwise mentioned. Anhydrous sodium sulfate was employed for drying solutions.

**4-(2, 3, 4-Trimethylphenyl)-3-buten-2-one (V).**—It was prepared from 2, 3, 4-trimethylbenzaldehyde (IV, 22 g., b. p. 133~135°C/20 mmHg), in the way described in 4-(2, 3, 6-trimethylphenyl)-3-buten-2-one in the previous paper[4]. Colorless solid (17.2 g.), b. p. 125~130°C/3 mmHg. On recrystallization from petroleum benzine it formed thick plates of m. p. 70~71°C.

Found: C, 82.87; H, 8.74. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

From the residue of the distillation, 1, 5-bis-(2, 3, 4-trimethylphenyl)-1, 4-pentadien-3-one (1.6 g.) was obtained in yellow plates when recrystallized from benzene-ethanol, m. p. 150°C.

Found: C, 86.69; H, 8.33. Calcd. for $C_{23}H_{26}O$: C, 86.74; H, 8.23%.

**1-(2, 3, 4-Trimethylphenyl)-3-methyl-1-hexen-5-yn-3-ol (VI).**—Operations of the experiment and the proportions of the reagents are similar to those of the synthesis of 1-(2, 3, 6-trimethylphenyl)-3-methyl-1-hexen-5-yn-3-ol in the previous paper[4]. From $C_{13}$-ketone (V, 13 g.), acetylenic alcohol (VI, 6.1 g.) was obtained as faint colored oil, b. p. 115~120°C (bath temperature)/0.05 mmHg.

Found: C, 84.41; H, 8.92. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

**$C_{40}$-Diynetetraol Mixture (VIII, IX and X).**—An ethereal solution (ca. 30 cc.) of ethylmagnesium bromide prepared from 3.9 g. of ethyl bromide, was added dropwise to a well-stirred mixture of the above acetylenic alcohol (VI, 2 g.), 1-(2, 3, 6-trimethylphenyl)-3-methyl-1-hexen-5-yn-3-ol (VII, 2 g.)[4], cuprous chloride (50 mg.) and dry ether (20 cc.) during one and a half hours, and the mixture was refluxed for an hour. A solution of 4-octene-2, 7-dione (840 mg.) in dry ether (20 cc.) was added dropwise during thirty minutes under stirring. After refluxing for one hour, the mixture was allowed to stand overnight, and decomposed with 1 N sulfuric acid under ice-cooling. The organic layer was extracted with ether and the ethereal solution was washed with dilute sulfuric acid, aqueous sodium hydrogen carbonate and water, dried and evaporated. The residue (4.8 g.) dissolved in benzene (20 cc.) was adsorbed on alumina (Merck, 80 g.) and the column was washed successively with benzene (100 cc., the eluate gave an oily residue 1.95 g.), with ether (60 cc., residue 0.8 g.) and with ether-methanol 10 : 1 (200 cc., residue 1.8 g.). The last fraction was the mixture

4) M. Yamaguchi, ibid., 32, 1171 (1959).
5) M. C. Khosla and P. Karrer, *Helv. Chim. Acta*, 43, 453 (1960).
6) P. Karrer and C. H. Eugster, ibid., 33, 1172 (1950).

of three isomers of $C_{40}$-diynetetraol and formed a yellowish-colored glass-like mass.

Found: C, 79.91; H, 8.80. Calcd. for $C_{40}H_{52}O_4$: C, 80.50; H, 8.78%.

**Renieratene (I), Renierapurpurin (II) and Isorenieratene (III).**—A solution of the above tetraol mixture (1.5 g.) in ethyl acetate (40 cc.) was filtered through a column of active charcoal (0.3 g.) and shaken with palladium-barium sulfate catalyst (1%, 50 mg.) in an atmosphere of hydrogen. Occasional additions of the small amount of catalyst were necessary until 2 mol. of hydrogen (ca. 116 cc., 9°C/760 mmHg) was absorbed. The catalyst was filtered and the solution was evaporated to glassy residue. A boiling solution of toluene-*p*-sulfonic acid (180 mg., dehydrated by melting in vacuo) in toluene (30 cc.) was added at a time to a boiling solution of the above residue in toluene (40 cc.) and the mixture was boiled for ca. eighty seconds. The greenish brown solution was, as soon as possible, poured into a mixture of a saturated aqueous solution of sodium hydrogen carbonate (300 cc.) and petroleum ether (200 cc.). The petroleum ether solution was then washed once with water and thrice with 90% methanol, dried and evaporated. The reddish-brown residue was dissolved in petroleum ether and chromatographed on alumina (4×20 cm.), giving the following zone: i) dark brown zone (most strongly adsorbed), ii) a broad zone, its color changing from red to orange, iii) an orange brown zone, and iv) faint yellow. The residue of the zone ii) was boiled several times with methanol, and the insoluble residue was rechromatographed on alumina giving the following main zones; a) purplish red (uppermost), b) red and c) orange. The pigment of the zone b) was further purified by rechromatography. The residue of the eluate of each zone was boiled with methanol. The insoluble parts were treated with petroleum ether and ethanol, and each pigment which separated out, was recrystallized several times from suitable solvents. The zone a) gave glistening purple plates (2.4 mg.) of renierapurpurin (from chloroform-ethanol), m. p. 229~230°C, its identity with natural pigment being confirmed by mixed melting point, 229~230°C, by mixed chromatography, and by IR- and UV-spectra (Fig. 1 and Fig. 2). The zone b) gave purplish red fine needles (1.4 mg.) of renieratene (from benzene-ethanol), m. p. 184~185°C, the identity with natural pigment being confirmed by mixed melting point, 184~185°C, by mixed chromatography, and by IR- and UV-spectra. The zone c) gave purplish red find needles (2.0 mg.) of isorenieratene (from benzene-ethanol), m. p. 199~200°C, the identity with natural pigment being confirmed by mixed melting point, 199~200°C, by mixed chromatography, and by UV-spectrum.

Because of the small yields of these pigments, no elementary analysis was carried out.

**$C_{40}$-Diynetetraol (IX).**—It was synthesized from acetylenic alcohol (VI, 3 g.) in the way described above. It formed a faint yellow glass-like mass (1.6 g.).

Found: C, 80.12; H, 8.81. Calcd. for $C_{40}H_{52}O_4$: C, 80.50; H, 8.78%.

**Renierapurpurin (II).**—Tetraol (IX, 1.5 g.) was partially hydrogenated and then dehydrated in the way described above. While petroleum benzine solution of the dehydration product was washed, a part of the pigment was crystallized out, which was filtered off (43 mg.). The mother liquor was chromatographed on alumina from a benzene solution, giving three main zones; i) pink, ii) red and iii) orange. From the zone i), 25 mg. of the pigment was obtained, which was combined with the crystals separated during washing. Several recrystallizations from chloroform-ethanol gave pure renierapurpurin (38 mg.), m. p. 230°C.

Found: C, 90.76; H, 8.99. Calcd. for $C_{40}H_{48}$: C, 90.85; H, 9.15%.

# *Flow Properties of Aluminum Soaps-Hydrocarbon Systems*

By Sukekuni SHIBA

(Received May 31, 1960)

It has been known that the aluminum soaps dispersed in hydrocarbon oils make stable gels and exhibit a wide variety of flow behaviors. The polymeric natures of the aluminum soaps have been pointed out by many authors[1-3] from the osmotic pressure and viscosity data on aluminum soaps in benzene. These properties indicate that the soap molecules aggregate to form fibrous micelles and are dispersed polymerically with a network structure in hydrocarbon.

Garner, Nissan and Wood[4], studying thermodynamics and rheological behaviors of the aluminum stearate gels in petrol, found that the apparent viscosity at different rates of shear was at first constant, but at higher rates of shear, the apparent viscosity decreased, reaching approximately constant value at very high rates of shear. Weber and Bauer[5], and also Bauer, Weber and Wiberley[6,7], studying the flow properties of aluminum laurate-toluene gels, the effect of peptizers and entrance effects in capillary, by a pressure capillary viscometer over a wide range of mean rates of shear, ranging from $10^{-3}$ to $10^{+6}$ $sec^{-1}$, obtained the shear stress-rate of shear curves, which showed three types of flow: Newtonian flow at low rates of shear, rapid increase in shear rate with shear stress in the region of shear rate above $10^{-2}$ $sec^{-1}$, and constant slope in log-log plot at shear rate above $10^{-2}$ $sec^{-1}$.

Some of the manifold flow properties were clarified by these investigations; however, many aspects of flow behaviors are not fully explained, due to the variability of flow properties with the nature of soaps, solvents, soap concentrations and physical conditions of measurements especially the rate of shear. Measurements with the capillary type viscometers are liable to be affected by the capillary end effects and the changes in properties during the flow. Therefore, it is desirable to take measures under a uniform rate of shear with specimens not subjected to shear. In this investigation, the flow properties of aluminum soaps of various parent fatty acids in hydrocarbon were measured with a concentric cylinder type rotational viscometer of small clearance; the flow properties and especially the time effects under shear were examined.

## Experimental

**Materials.**—The alminum soaps used in this investigation were prepared from purified fatty acids by an aqueous metathetic process. Stearic and palmitic acids were purified from pure acids (Nihon Yushi Co.) by repeated recrystallization from 80 vol.% ethanol. Myristic and lauric acids were purified from commercial reagents by the same method. Capric and caprylic acids were purified from the commercial reagents by distillation under reduced pressure. The purity of the acids was examined by melting points and neutralization equivalents by titration. The physical constants of fatty acids are shown in Table I.

TABLE I. PHYSICAL CONSTANTS OF FATTY ACIDS

| Fatty acid | M. p., °C | | Neut. equiv. | |
|---|---|---|---|---|
| | Found | Lit.[8] | Found | Calcd. |
| Stearic | 69.5 | 69.6 | 281.9 | 284.5 |
| Palmitic | 62.2 | 62.9 | 258.0 | 256.4 |
| Myristic | 54.5 | 54.4 | 229.1 | 228.4 |
| Lauric | 43.3 | 44.0 | 201.3 | 200.3 |
| Capric | 30.1 | 31.3 | 173.1 | 172.3 |
| Caprylic | 14.3 | 16.3 | 143.8 | 144.2 |

Fatty acid was treated with a 40~50% excess sodium hydroxide solution and distilled water to yield an approximately 5% solution of sodium soap. The mixture was heated to dissolve the soap, and the solution was kept completely transparent at 70~80°C for soaps from stearate to laurate and at 50°C for caprate and caprylate. A hot solution of aluminum sulfate was added slowly while being stirred vigorously, until a slight excess was present and precipitation was complete. The precipitated aluminum soap was filtered and washed with distilled water, until free from sulfate. The test for sulfate ion was made by adding barium chloride solution to the filtrate, which was made slightly acidic with hydrochloric acid. The soaps

were then dried to constant weight at 110°C, and stored in a desiccator over phosphorus pentoxide. Dried soaps were analysed for aluminum by ignition to oxide. The composition of the soaps is shown in Table II.

TABLE II. COMPOSITION OF ALUMINUM SOAPS

| Aluminum soaps | No. of C atoms in acid | Al wt. % (analysed) | Mole acid per mole Al |
|---|---|---|---|
| Stearate | 18 | 5.04 | 1.72 |
| Palmitate | 16 | 5.80 | 1.62 |
| Myristate | 14 | 5.96 | 1.77 |

Nujol was used as a vehicle. It is a liquid paraffin of a commercial grade, a paraffin-rich saturated hydrocarbon. The physical properties are as follows; $d_4^{25}=0.8429$, $n_D^{20}=1.467$, $\eta_{25}=0.217$ poise.

**Preparation of Specimen.**—Nujol was added to a weighed quantity of aluminum soap, and the mixture was heated slowly while being stirred until it became a transparent solution at 110~120°C. After maintaining this temperature for 15min. the solution was cooled and stored in a desiccator over phosphorus pentoxide.

**Apparatus.**—A concentric cylinder type rotational viscometer essentially the same as the apparatus developed by Green[9], was used. The outer cylinder was rotated and the torque necessary to keep the inner cylinder stationary was measured by a torsion spring. When the sample is a Bingham body of plastic viscosity $\eta_{pl}$ and yield value $f$, the relation of angular velocity $\omega$, troque $M$, $\eta_{pl}$ and $f$ is given by the Buckingham-Reiner equation[10];

$$\eta_{pl}\omega=(M/4\pi h)(1/r_i^2-1/r_e^2)-f\ln(r_e/r_i) \quad (1)$$

where $r_i$ and $r_e$ are the radii of inner and outer cylinders; $h$ is the height of the immersed part of inner cylinder; $\eta_{pl}$ and $f$ are obtained by the measurement of $M$ corresponding to $\omega$. The shear stress $\tau$ and the rate of shear $D$ at radius $r$ from the center of the cylinder are given by

$$\tau=M/2\pi hr^2 \quad (2)$$

$$D=2\omega/(1/r_i^2-1/r_e^2)r^2 \quad (3)[11]$$

The dimensions of the apparatus are as follows: $2r_i=29$ mm., $2r_e=30$ mm., $h=50$ mm.. rate of revolution 0~400 rpm, torsion constants of the springs $3\times10^3\sim3\times10^5$ dyn. cm./rad. The apparatus was calibrated with viscosity standard oils. The absolute accuracy of the values obtained from dimensions and force constant of the apparatus was within 2%. The end effect was checked, changing the depth of immersion of the inner cylinder. It was found that the end effect was negligible.

**Procedure.**—The speicmen was placed between the cylinders and kept for 15 min. at the measuring temperature. The rate of revolution was raised stepwise, and at each step the equilibrium points where the deflexion of the torsion spring became constant were determined[12]. The down curve was obtained by reducing the rate of revolution down to zero to obtain the rate of shear-shear stress relation corresponding to the state. Measurements were made for systems containing 0.5~4 wt. % soaps in nujol at temperatures 15~75°C.

## Results and Discussion

The aluminum soap-nujol systems give various types of flow. At room temperature, the system containing soaps above 1% makes a gel, and it changes to paste or liquid state by shear. The more diluted system makes a sol with fluidity, which shows linear or non-linear flow properties. At high temperatures above 80°C, the system becomes a homogeneous transparent elastic solution. Thus, the systems show various flow properties and are unstable in regard to shear and time. Therefore, it is necessary to study the change in properties corresponding to the variables.

**Rate of Shear-Shear Stress Curves.**—Examples of the curves exhibiting the rate of shear-shear stress relations are shown in Fig. 1. The lower curves are the equilibrium curves, which are obtained with the elevated rate of shear, and the upper curves are the $D-\tau$ curves (or down curves) for the states of the specimens equilibrated under the highest rates of shear. Two curves coincide for the dilute systems which behave as Newtonian liquids or Bingham plastic bodies. When the concentration is increased, the two curves make a loop. Plastic viscosity

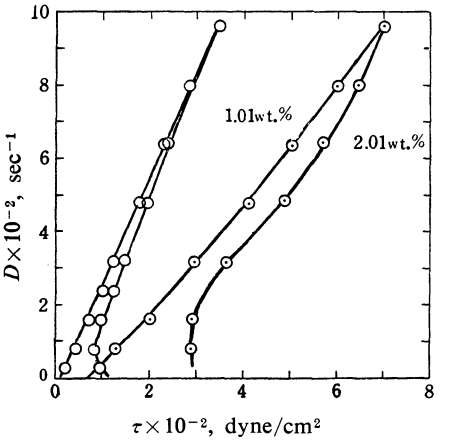

Fig. 1. Rate of shear-shear stress curves for aluminum stearate in nujol at 25°C.

9) H. Green, "Industrial Rheology and Rheological Structures", John Wiley & Sons, Inc., New York (1949), p. 99.

10) M. Reiner, "Deformation and Flow", H. K. Lewis, London (1949), p. 44.

11) For substances which show non-linear flow properties, Eq. 3 can not be used rigorously. In this apparatus, $(r_e-r_i)$ is small enough compared with $r$, so that approximation with Eq. 3 is possible.

12) The specimen was assumed to reach equilibrium when the change in deflexion angle became less than 1/2 deg./min.

and yield value are obtained from the down curve for the state.

Concerning the equilibrium curves, a rapid decrease in viscosity is observed in the range of rate of shear up to 200 $sec^{-1}$. This is in agreement with the results of Weber and Bauer[5], who found a sudden viscosity decrease in the range of rate of shear up to $10^2$ $sec^{-1}$ for aluminum laurate-toluene gels. The curves which they obtained are likely to correspond to the equilibrium curves in this investigation, because the results by these authors will be subject to the effects of shear softening in capillary.

**Ageing.**—The flow properties of the system change with time while standing after preparation. The changes in viscosity and yield value at room temperature (20°C) are shown in Fig. 2. Where the viscosity is obtained from the inclination of the down curve at the rate of shear $5\times10^2$ $sec^{-1}$, for the specimen equilibrated at $10^{-3}$ $sec^{-1}$; the yield values are obtained from the intercepts of the extension of the down curves. Viscosity and yield value increase rapidly with time, exhibiting maximum values at about 4 hr. after preparation, and approach approximately constant values. Therefore, the measurements were carried out between 24~96 hr. after preparation of the specimen. This effect is in agreement with the results of Gray and Alexander[2], and of McBain and Working[1], who obtained the effect of ageing for the benzene solution of aluminum laurate, from flow birefringence and viscosity study. The mechanism of this phenomenon is explained as follows: The system cooled from a hot solution is a metastable jelly containing soap micelles; three dimensional networks of the soap crystallites grow rapidly, and are arranged slowly to the stable state.

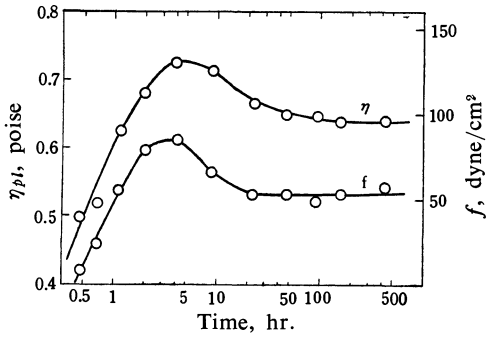

Fig. 2. Ageing of the aluminum stearate in nujol 2.01 wt.%, 25°C.

**Change of Flow Properties under Shear.**—Decrease of shear stress with time under constant rate of shear is shown in Fig. 3. The curve for each rate is obtained for the specimen equilibrated under lower rates of shear. If it is assumed that the contribution of the rheological structures to the shear stress is proportional to the concentration of the structures, $C$, and that the rate of breakdown of the structure is also proportional to $C$, the decrease in shear stress under constant rate of shear is expressed by,

$$\tau-\tau_{eq}=aC \tag{4}$$

$$-\frac{d(\tau-\tau_{eq})}{dt}=-a\frac{dC}{dt}=kC \tag{5}$$

integrating (5)

$$\ln(\tau-\tau_{eq})=\ln(\tau_0-\tau_{eq})-(k/a)t \tag{6}$$

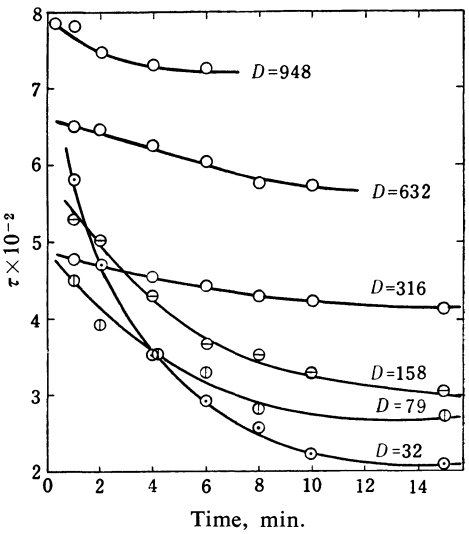

Fig. 3. Decrease of shear stress with time under constant rate of shear.
Aluminum stearate, 2.01 wt.%, 25°C

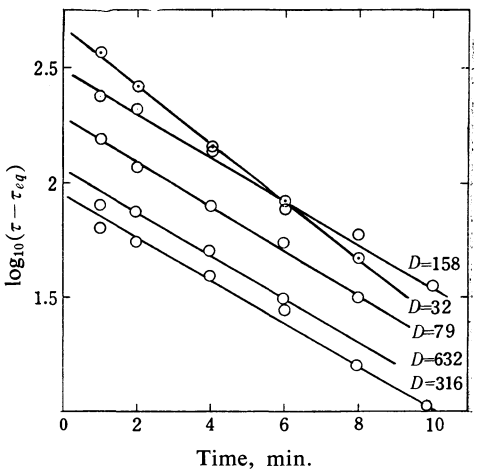

Fig. 4. Rate of degradation of the rheological structure.
Aluminum stearate, 2.01wt.%, 25°C

where $\tau_{eq}$ is the shear stress in quilibrium, $\tau_0$ is the value of $\tau$ at time $t=0$. The decrease in $\log(\tau-\tau_{eq})$ with $t$ is shown in Fig. 4. These results support the assumptions mentioned above. Rates of breakdown under various rates of shear are not constant in general; the rapid breakdown of weak structures under low rate of shear is recognized.

**Examination on Thixotropy**[13].—Flow measurements were repeated to examine the thixotropic recovery, after the specimen was kept standing for some time. The results are shown in Fig. 5. If complete recovery is present, the curves should coincide. However, the curves in subsequent measurements resemble the down curve in the first run, and the breakdown of the structures proceeds by repeated shear. Therefore, in these experimental conditions, thixotropy does not exist even after considerable time.

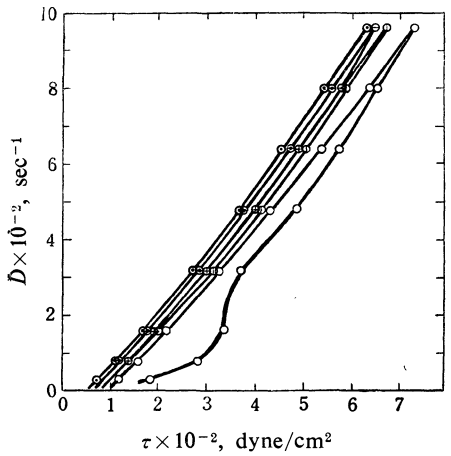

Fig. 5. $D$-$\tau$ curves for repeated shear. Alumium stearate in nujol, 2.01 wt.%, 25°C. ○ 0 hr., ◐ 3 hr., ⊖ 20 hr., ⊙ 72 hr.

Agreements in opinions concerning the time effects of flow behaviors on aluminum soap-hydrocarbon systems have not yet been obtained. Complete recovery was reported by Goldberg and Sandvik[14], and Carver and Van Wazer[15]; whereas, absence of thixotropy was pointed out by Evans and Matthews[16]. Evans states for aluminum greases that the change caused by the applied shearing stress is not thixotropic but

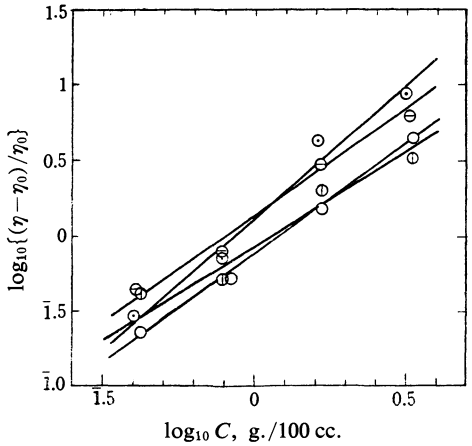

Fig. 6. Concentration dependence of specific viscosity.
○ 15°C, ◐ 25°C ⊖ 50°C, ⊙ 75°C

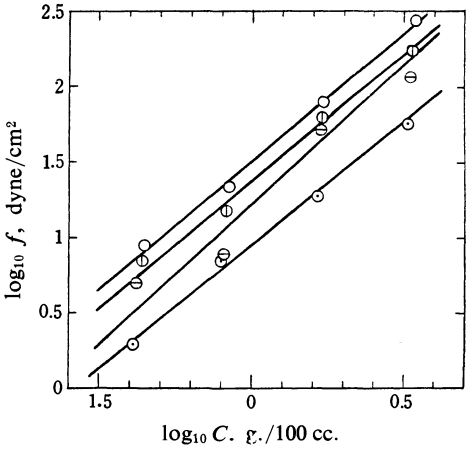

Fig. 7. Concentration dependence of yield values.
○ 15°C, ◐ 25°C, ⊖ 50°C, ⊙ 75°C

appears to be a permanent change in the structure of the grease. Results of this experiment appear to support those of Evans and Matthews. However, the discrepancy of the results obtained by many authors will be ascribed mainly to the experimental conditions; for example, the rate of shear, temperature, concentration and properties of soaps which are not always pure substances. At high temperatures or under a very low rate of shear, it will be possible that the system is thixotropic.

**Effect of Concentration.**—The specific viscosity and yield values for various concentrations and temperatures are shown in Figs. 6 and 7, where the viscosity and yield values are obtained as previously described. These values show an approximately linear relation against $\log C$. That is, the dependence of the viscosity and yield values on concentration is expressed by empirical formulae,

13) It will be adequate to give a general definition of thixotropy in rheological terms as follows: "Thixotropy is the property of a body by virtue of which the ratio of shearing stress to rate of deformation is *temporarily* reduced by previous deformation.", E. K. Fischer, "Colloidal Dispersion", John Wiley and Sons, Inc., New York (1950), p. 183.

$$\eta=\eta_0(1+aC^m) \quad (7)$$

$$f=bC^n \quad (8)$$

where values of $m$, $a$ and $n$ calculated from the data at 15, 25, 50 and 75°C are, $m$=1.47, 1.30, 1.39, 1.73; $a$=0.73, 0.78, 1.33, 1.33; $n$= 1.72, 1.64, 1.72 and 1.61, respectively.

The systems are considered essentially as colloidal suspensions of soap crystallites in oil. If the soap crystallites are non-attractive rod-like ellipsoidal particles of axial ratio over 20, specific viscosity is given by Simha[17], as a function of axial ratio and volume fraction of the particles. The formula gives very high values of axial ratio corresponding to the measured viscosity values. These facts indicate that it is more appropriate to consider the interaction between soap particles and the network structures in the system.

**Effect of Temperature.**—Viscosity-temperature relation is shown in Fig. 8. In this temperature region, approximately linear relations exist. This shows the absence of serious change in rheological structures in this region. Apparent activation energies of flow and constant $A$, calculated from Andrade equation,

$$\eta=A\exp(\Delta E/RT)$$

are shown in Table III. Decrease in $\Delta E$ with increase in concentration is apparent. This tendency, which is in agreement with the results of Carver et al.[15], will be understandable if it is considered that the flow mechanism, is divided into the usual friction and break down of secondary bonding, and the predominance of the latter mechanism in concentrated systems is considered.

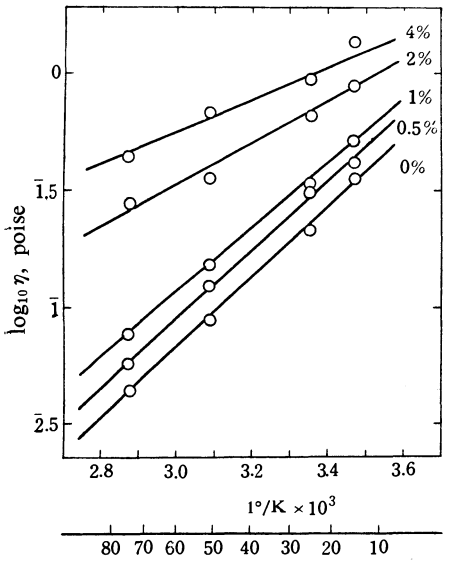

Fig. 8. Viscosity — temperature relations. Aluminum stearate in nujol.

TABLE III. CONSTANTS OF THE ANDRADE FORMULA
(Aluminum stearate in nujol)

| Soap conc. wt. % | $A$ | $\Delta E$, kcal./mol. |
|---|---|---|
| 0.00 | $2.5\times10^{-6}$ | 6.7 |
| 0.50 | $4.3\times10^{-6}$ | 6.6 |
| 0.99 | $9.4\times10^{-6}$ | 6.2 |
| 2.01 | $4.0\times10^{-4}$ | 4.4 |
| 3.99 | $4.7\times10^{-3}$ | 3.2 |

17) R. Simha, *J. Phys. Chem.*, **44**, 25 (1940).

**Effect of the Fatty Acids.**—Results for soaps from various fatty acids are shown in Fig. 9. Soaps from stearate to laurate show similar flow properties, whereas caprate and caprylate show lower values, This fact correlates many other properties of soaps, which change abruptly for soaps below caprate.

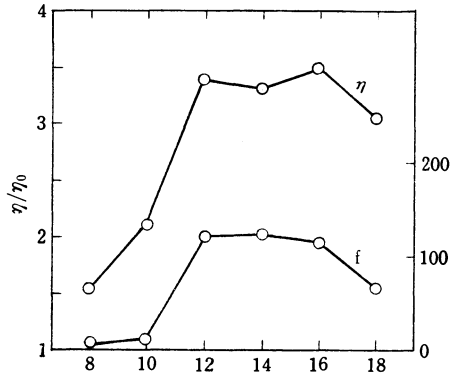

Fig. 9. Viscosity ratio and yield values of various Al soap-nujol gels, 2 wt. %, 25°C.

## Summary

Flow properties of aluminum soap-hydrocarbon systems as viscous liquids or plastic bodies are studied with a concentric rotational viscometer. Results are obtained under the rate of shear up to $10^3$ $sec^{-1}$.

(1) The systems behave as dispersions of soap crystallites with network structures combined by secondary interactions of the particles, and they exhibit marked viscosity increase.

(2) The rheological structures suffer shear breakdown under shear, resulting in decrease in viscosity.

(3) Recovery from the broken structures is impossible, that is, this change is not thixotropic but shear breakdown.

(4) Flow properties change with time while standing at rest.

(5) The effects of concentration, temperature and fatty acids constituting soaps are clarified.

The author wishes to express his thank to Professor H. Akamatu and Dr. T. Nakagawa, both of the University of Tokyo, for their interest and encouragement throughout this investigation.

# *Stress Relaxation of Thermo-reversible Gels. Molecular Weight Dependence of Relaxation Spectrum. Polyvinyl Alcohol-Congo Red-Water System**

By Kiyoshi ARAKAWA

(Received May 24, 1960)

In the previous paper[1] the author reported the results of the stress relaxation study of the gels of polyvinyl alcohol-congo red-water system, where the experiment was intended to obtain some knowledge on the concentration dependence of the relaxation spectrum of the gel which was taken as a typical example of thermo-reversible gels of polymeric nature. As a part of the series of rheological studies of thermo-reversible gels[1,2] a stress relaxation experiment has been made for the purpose of studying the molecular weight dependence of the relaxation spectrum of the gel, and the result is reported in the present paper.

## Experimental

**Apparatus.** — A chainomatic balance relaxometer was used to measure the relaxation Young's modulus of the cylindrical gel, which was the same one as that used previously[1], and the schematic diagram of it is shown in Fig. 1. A specimen is compressed to a given strain between a plate attached to a bar and a bottom plate in a double jacket connected to a screw gauge by the rotation of it. The stress in the specimen is automatically balanced with a chain weight by means of a relay and a balancing motor, the ralaxation Young's modulus $E_r$ is calculated form the vertical length of the suspended chain, as follows.

$$E_r = \frac{l}{\Delta l} \cdot \frac{adhg}{bs}$$

$l$ is the height of the cylindrical specimen without strain, $\Delta l$ the amount of the given compression, $s$ the original sectional area of the specimen, $a$ the distance from the fulcrum to the chain, $b$ the distance from the fulcrum to the center of the pressure plate, $d$ the linear density of the chain, $h$ the vertical length of the suspended chain and $g$ is the acceleration of gravity.

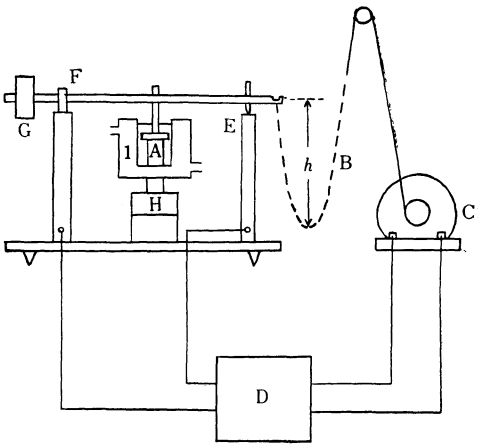

Fig. 1. Chainomatic balance relaxometer.

**Sample.** — Commercial samples of polyvinyl alcohol were purified by precipitation from aqueous solutions with addition of acetone. The amount of residual acetyl group was smaller than 0.7% by mole for all samples used in this experiment. The values of the intrinsic viscosity $[\eta]_{30°C}$ determined by a capillary viscometer and the molecular weight calculated from those using the formula of Nakajima et al.[3] are given in Table I. Congo red

used was Merck's analytical grade chemical. The preparation of testing specimens was made according the same procedure as described in the previous paper[1], except that in the present work an especially designed vessel with a double jacket was used in the dissolution process instead of a conical beaker and a water bath.

The composition of the prepared gel was maintained to be the same for all specimens: polyvinyl alcohol 17.5% and Congo red 1.75% by weight.

TABLE I. MOLECULAR WEIGHT OF POLYVINYL ALCOHOL

| Sample | $[\eta]_{30°C}$(100 cc./g.) | Molecular weight |
|---|---|---|
| I | 0.54 | $3.5\times10^4$ |
| II | 0.66 | $4.9\times10^4$ |
| III | 1.03 | $9.8\times10^4$ |

## Results and Discussion

**Stress Relaxation Data.** — The data of stress relaxation at various temperatures are plotted in the form $(298/T)E_r$ versus $\log t$, where $t$ is time, in Figs. 2a, 2b and 2c. The strain

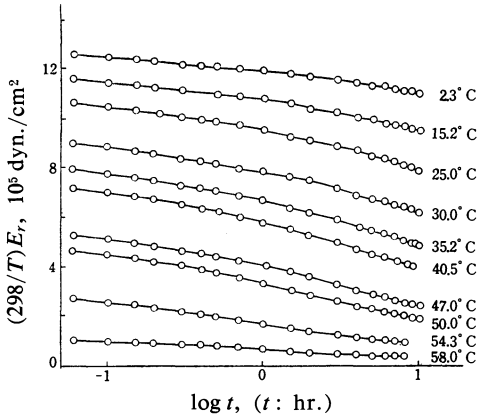

Fig. 2a. Reduced relaxation Young's modulus. Sample I (molecular weight $3.5\times10^4$).

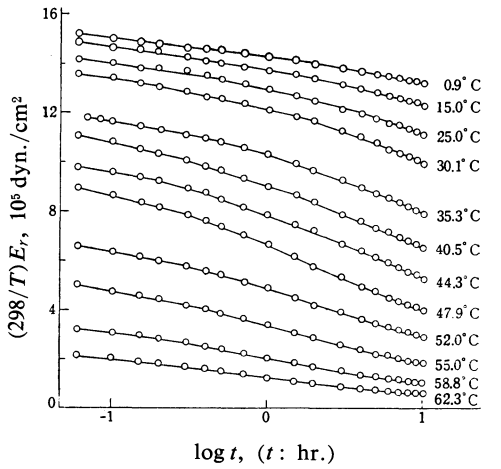

Fig. 2b. Reduced relaxation Young's modulus. Sample II (molecular weight $4.9\times10^4$).

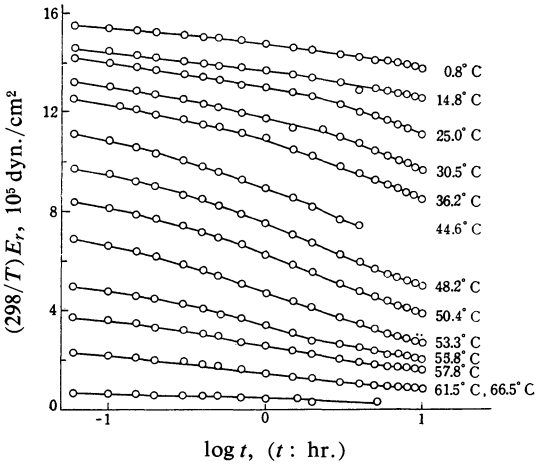

Fig. 2c. Reduced relaxation Young's modulus. Sample III (molecular weight $9.8\times10^4$).

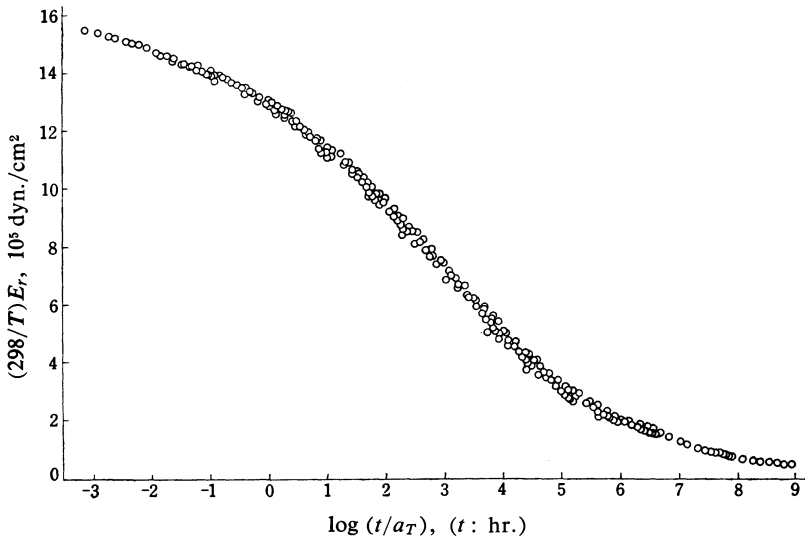

Fig. 3c. Composite relaxation curve at 25°C, Sample III.

applied in this experiment was 15% for all specimens. The data are reduced to 25°C with the multiplication by a factor $298/T$.

According to the time temperature superposition principles[4], each group of relxation curves was superposed to a composite relaxation curve by the horizontal shift of relaxation curves at different temperatures along the $\log t$ axis. The superposition of relaxation curves is good as it is seen in Figs. 3a, 3b and 3c. The density factors was ignored, because its temperature dependence was very small. The shift factors $\log a_T$ are plotted against $T$ in Fig. 4 together with the apparent activation energy $H_a$, which was calculated from the mean $\log a_T$ versus $T$ curve by the following equation.

$$H_a = R\frac{\partial \ln a_T}{\partial(1/T)} \qquad (1)$$

From the Fig. 4 it is seen that $\log a_T$ versus $T$ relation does not obey the W. L. F. equation[5].

**Distribution Functions of Relaxation Times.** —The relaxation spectra $H(\log \tau)$ defined by

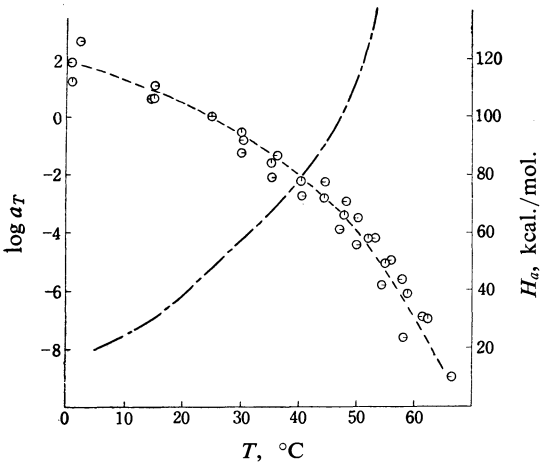

Fig. 4. Temperature dependence of shift factors.
⊖ Sample I, ⊙ Sample II, ⊖ Sample III
----- mean curve of log $a_T$ versus $T$ relation, --- $H_a$

the following Eq. 2 are calculated from the composite relaxation curves shown in Figs. 3a, 3b and 3c by the second order approximation[6].

$$E_r = \int_0^\infty H(\log\tau)\mathrm{e}^{-(t/\tau)}\,\mathrm{d}\log\tau \qquad (2)$$

$$H\left(\log\frac{\tau}{2}\right) = \left[-\frac{\mathrm{d}E_r}{\mathrm{d}\log t} + \frac{1}{2.303}\frac{\mathrm{d}^2E_r}{\mathrm{d}(\log t)^2}\right]_{t=\tau} \qquad (3)$$

The obtained relaxation spectra are plotted against log $\tau$ in Fig. 5. Each spectrum shows the typical box type character, except the structure in details, which is expected to follow a wedge type spectrum at the shorter time region.

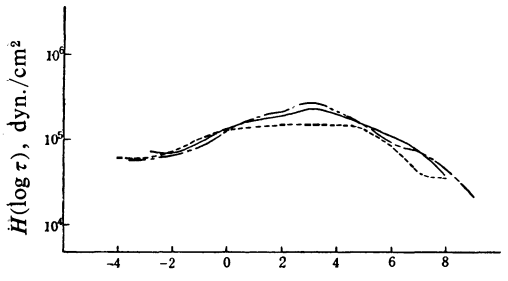

Fig. 5. Relaxation spectra.
----- Sample I
——— Sample II
--- Sample III

They nearly superpose each other at a short time region in Fig. 5. On the longer time side than one hour some difference is seen, and the spectrum goes upwards as the average molecular weight becomes larger, though in the curves of samples II and III the difference is very small and besides, when seen in details, the exchange of the mutual position is found. At the long time end the spectrum of the sample III tends to extend furthest[7].

## Summary and Conclusion

A stress relaxation experiment was made for the gels of polyvinyl alcohol-Congo red-water system using the chainomatic balance relaxometer. Three samples of polyvinyl alcohol whose molecular weight were $3.5\times10^4$, $4.9\times10^4$ and $9.8\times10^4$ were used, and the composition of the gels was maintained to be the same for all specimens: polyvinyl alcohol 17.5% and Congo red 1.75%. The measurement was made to ten hours and the temperature was changed from about 1°C to about 66°C.

The obtained relaxation curves were superposed to a composite relaxation curves for each sample according to the time-temperature superposition principle, and the curves ranging from $10^{-4}$ to $10^9$ hours were obtained, and from those the relaxation spectra were calculated by the second order approximation.

It is seen that the three spectra are nearly all superposed on the shorter time side than one hour and that the maximum value becomes larger as the molecular weight increases, and that the two spectra of the larger molecular weight are very close on the whole, except that at the long time end the spectrum of the largest molecular weight tends to extend further.

It is also seen that the box type spectrum of the gel nearly superposes when the molecular weight is larger than a certain value $M$, where $4.8\times10^4 > M > 3.5\times10^4$, and that the spectrum tends to extend to longer time region as the molecular weight increases.

The author is indebted to Mr. Mineo Watase, Mr. Kokichi Seo and Mr. Hiroshi Osada for their cooperation in carrying out this experiment.

# *Physical Properties and Crystal Structure of 2-Bromo-2, 3, 3-trimethylbutane**

By Tsutomu KOIDE, Yoshihiro KATO** and Tsutomu ODA

(Received May 23, 1960)

It has been shown that the haloethane derivatives such as 1, 1, 1, 2-tetrachloro-2-methylpropane[1] and other compounds whose molecules are similar to hexamethylethane[2] in shape possess polymorphism and for any temperature range below their melting points they possess molecular orientational or rotational freedom. This freedom in the high temperature modification, which is cubic, seems to be responsible for their relatively high melting points.

Since the van der Waals radius of bromine atom is nearly equal to that of chlorine[3], it is of interest to investigate the behavior of molecules in the solid state for bromo-derivatives of ethane in comparison with the same state of its chloro-derivatives[1,4]. As an example, the authors have studied the crystal structure and the behavior of molecules of 2-bromo-2, 3, 3-trimethylbutane by means of optical, X-ray and differential thermal analysis methods.

## Experimental and Results

**Materials.** — The sample of 2-bromo-2, 3, 3-trimethylbutane was prepared by passing gaseous hydrogen bromide through an ethereal solution of pentamethylethanol, which had been obtained by the Grignard reaction of pinacolone with magnesium bromide in ethereal solution. The final product was twice purified by recrystallization, followed by sublimation in high vacuum ($10^{-5}$ mmHg).

The melting point is found to be 151°C in a sealed capillary tube. The liquid phase vaporizes immediately after melting. The solid is soft and shows plasticity. The density is found to be 1.31 g./cc. at 13°C by the flotation method using an aqueous solution of calcium carbonate.

**Optical Observation.**—Under the polarized microscope, the room temperature phase was found to be isotropic, indicating the crystal to be cubic. Observations were extended to the liquid air temperature. The cryostat for this purpose is shown in Fig. 1. Cooling was made by heat conduction through a copper rod dipped in liquid air. The temperature was measured with a copper-constantan thermo-couple and a millivoltmeter. By cooling, it was observed that the crystal transformed at about −117°C into a different crystalline phase which was optically anisotropic.

**X-ray Measurements.**—*The Crystal Structure of the High Temperature Modification.*—Owing to its extremely high volatility, a single crystal of this substance, sealed in a capillary tube for X-ray measurement, sublimes gradually in few days into a number of smaller crystals in the cooler part of the tube. Therefore, in order to prevent this loss of sample due to sublimation, a glass rod just fitting the glass capillary was inserted to make the remaining free space as small as possible.

Using Cu-$K_\alpha$ radiation ($\lambda = 1.54$ Å) filtered through nickel foil, we prepared a series of 20° oscillation photographs covering a range of about 90° with [011] as the axis of rotation.

Laue photographs were taken with X-ray beams parallel to [100], [110] and [111]. All of the Laue spots were split into two or three parts, but the same crystal showed no splitting in its oscillation photographs when rotated through [110]. Thus the crystal used was not a single crystal, but was composed of several crystallites which were slightly different in orientation. All the efforts to get a single crystal have been unsuccessful, as was the case of 2-chloro-2, 3, 3-trimethylbutane[5]. All the Laue spots were successfully indexed, based upon a cubic lattice having holotesseral symmetry. The point group symmetry of the crystal was found to be $T_d$-$\bar{4}3m$, $O$-43 or $O_h$-$m3m$.

The observed spectra in oscillation photographs can be indexed satisfactorily with a body-centered cubic lattice having a unit cell of the side $a = 7.66$ Å. The observed value of density, 1.31 g./cc., is almost equal to the calculated value, 1.32 g./cc., assuming that two molecules are contained in the unit cell.

**Differential Thermal Analysis (D. T. A.).**—The apparatus used for the D. T. A. was described elsewhere[1]. The temperature range of the measurement was from 90°C to the liquid air temperature. Fig. 2 shows the result of the D. T. A. measurement for warming. The time-temperature curve of Fig. 2 shows the temperature of the used reference substance (sodium chloride) and the differential curve shows the temperature difference between the reference

substance and the sample. The temperature differences are plotted on an arbitrary scale. There is an anomalous thermal effect at about −114°C (the peak of the differential curve in Fig. 2) for warming and at about −117°C for cooling. This result is in good agreement with the optical observation.

## Discussion

Since there are two molecules in each unit cell with the body-centered cubic lattice, it is reasonable to place the centers of mass of the molecules at the lattice points 0, 0, 0 and 1/2, 1/2, 1/2. The proper symmetry of these points is $T_d$-$\bar{4}3m$, $O$-43 or $O_h$-$m3m$, so that the symmetry of the molecule should have one of these cubic point groups. On the other hand, if we assume that the molecule has the skew configuration (Fig. 3), the highest symmetry that the molecule could have is $C_s$-$m$, the central C-C bond lying on the plane of symmetry. In order that the molecule, which has the symmetry $C_s$-$m$, attains the cubic symmetry, it is necessary to take into consideration some statistical arrangements for explaining the structure of the crystal, as was done in the X-ray studies of other plastic crystals[6].

One of the possibilities that the statistical symmetry of the molecule is as high as $T_d$-$\bar{4}3m$ is that the molecule orientates its central C-C axis parallel to each one of the four body-diagonals statistically equally, so that the C-C axis acquires at least a statistical symmetry

of 3*m*. Following such a statistical configuration, a calculation of structural factors was carried out, using two models, Ia (Fig. 4) and Ib, which are slightly different from each other. Namely in Ia, the two bromine atoms were assumed to lie statistically on the twenty-four equivalent positions, 24 (*g*)[7] near the three principal axes, and the ten $CH_3$ groups on another set of the same equivalent positions.

7) "International Tables for X-ray Crystallography", Vol. I, Kynoch Press, Birmingham (1952), p. 326.

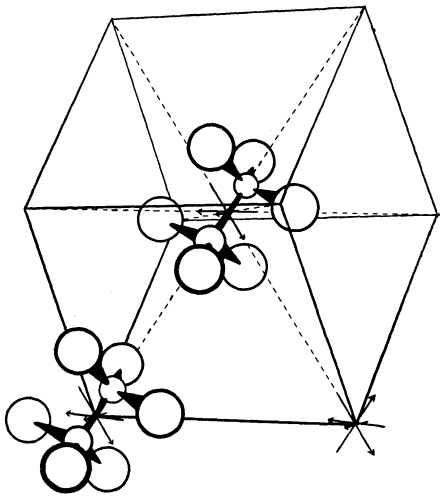

Fig. 4. The model for a statistical configuration, Ia.

In Ib the bromine atoms and the methylic carbon atoms lie separately on two sets of forty-eight equivalent positions, (*h*) with a weight 1/24 for bromine and 5/24 for C. It is to be added here that in these calculations the molecule was assumed to possess the skew form with the C-C and C-Br bond distances, 1.54 and 1.94 Å, and the tetrahedral valency angle.

If half of the molecules, in a statistical sense, rotate their molecular axes around the principal crystal axes through 90°, then the polar molecular axes will be found in eight different directions parallel to the body-diagonals of the crystal. If we add this operation to model Ia, the symmetry of the crystal will become $O^9_h$-*Im*3*m*. We shall call this model IIa. In this model, the polar axes of the molecules will be found in antiparallel orientations, whereas the bromine atoms and methyl groups will remain in almost the same positions as in model Ia. In these two models Ia and IIa, methyl groups and bromine atoms belonging to any two neighbouring molecules are found in trans configuration. By twisting the molecular axis from the positions given by model IIa, we have model IIb (angle of twist ±15°), model IIc (angle of twist ±40°) and model IId (angle of twist ±60°). The symmetry of these three models remains as in IIa.

In addition to these models, which are statistically static, we have also considered model III, in which molecules are rotating spherically around their centers of mass. The crystal will also assume the symmetry of $O^9_h$-*Im*3*m*.

The calculated $|F|$-values based on these models are plotted in Fig. 5, together with the observed data. Curve III is quite different

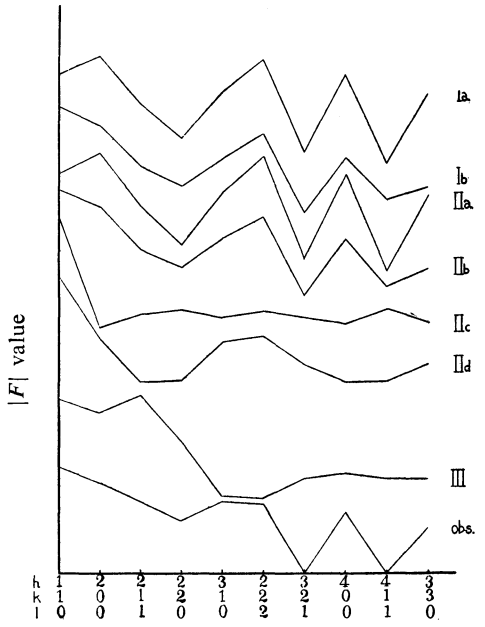

Fig. 5. Observed and calculated values of $|F|$.

from the observed one, suggesting that the free rotation of molecules as a whole in the crystal is ruled out. As a matter of fact, the domain required for the free rotation of the molecules at each lattice point overlaps not only with those of the first neighboring molecules but also with the second neighboring molecules as shown in Fig. 6. The curves for the models IIc and IId also do not agree with the observed one.

The curve Ia agrees fairly well with the observed one. In this model, though there is no appreciable overlap between the first neighboring molecules, there remains the possibility of colliding between the second neighboring molecules (Fig. 6). The agreement between the intensities calculated by model IIb, Ib and the observed ones is the best among all the models so far investigated. In these models, none of the shortest distances between atoms in neighboring molecules exceeds appreciably the sum of the van der Waals radii. It is difficult to decide which one of models, Ib or IIb, is really the case in point. The actual configuration may be expressed by a combination of Ia, Ib, IIa and IIb with appropriate weights.

This statistical structure may throw light on the explanation of the plasticity and rapid decrease of intensity with the increase of diffraction angle.

The orientational disorder of the arrangement of molecules may disappear below the transition temperature. This view is supported by the thermal differential analysis. The change of the optical property from isotropic to an-

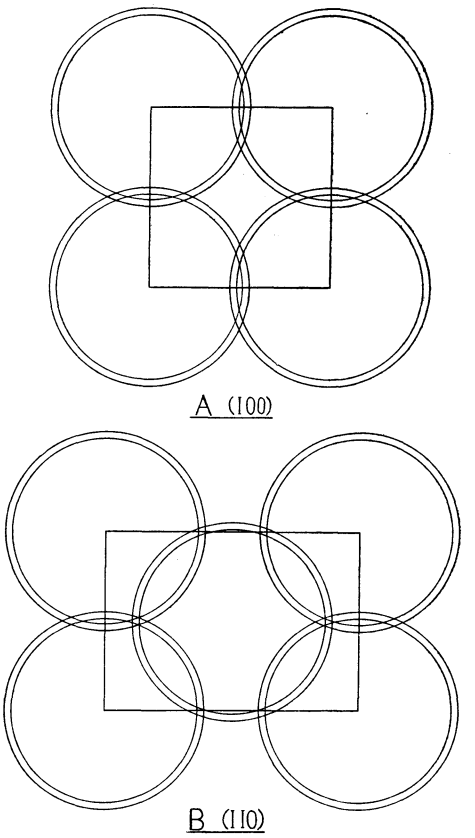

Fig. 6. The required domain for the free rotation of molecule at each lattice point. The radii of these circles are calculated using assumed molecular configuration and van der Waals radii for bromine (outer circles) and methyl groups (inner).
A shows the section parallel to (100).
B shows the section parallel to (110).

isotropic in passing the transition temperature means that the crystal assumes the lower symmetry. This may imply that the arrangement of the molecules becomes more ordered than that of the room temperature phase.

It has been reported that 1, 1, 1, 2-tetrachloro-2-methylpropane[1] and 2-chloro-2, 3, 3-trimethylbutane[4] also give plastic crystals at high temperature. Both of these also belong to the body-centered cubic lattice and the fact that their unit cell dimensions (7.4 and 7.62 Å) are close to the value of the present substance indicates that the free volumes of these molecules are similar.

## Summary

2-Bromo-2, 3, 3-trimethylbutane gives a plastic crystal, which is optically isotropic and has a density of 1.31 g./cc. at 13°C. The X-ray data

can be interpreted on the bases of a body-centered cubic lattice, having $a=7.66$ Å with two molecules in the unit cell. The symmetry interpretation gives a structure of disordered orientation of molecules. It was found, by means of optical and differential thermal analysis methods, that there is a phase transition at about $-114$°C, below which the crystal is of a lower symmetry.

The authors express their hearty thanks to Professor Isamu Nitta, Professor Tokunosuke Watanabé and Dr. Syuzo Seki for their interest during this study. They also express their thanks to Dr. Hiroshi Suga for his help in optical measurements, and to Mr. Yoshiyuki Namba for his discussion. A part of the cost of this research was supported by the Ministry of Education, to which their thanks are due.

# *Variation of Radiocarbon Concentration in Modern Wood*

By Kunihiko KIGOSHI and Yoshio TOMIKURA

(Received May 27, 1960)

It has recently been pointed out by several authors[1-7] that the atmospheric radiocarbon is increasing because of nuclear tests. The present authors have also detected a remarkable change of the atmospheric radiocarbon concentration after 1953. This recent increase of radiocarbon and the Suess effect[8-10], i.e. the dilution effect of atmospheric radiocarbon by combustion of fossil fuel play an important role in the studies on the carbon dioxide cycle in nature. The present paper presents the results of the measurements on the change of the atmospheric radiocarbon contents in recent years using the carbon in tree rings taken from Honshu Island. We used the tree rings of Japanese cedar (*Crytomeria Japonica*) of which the place of growth and the date of cut were known. The measurements of radiocarbon were made with an acetylene filled proportional counter shielded with iron plates and provided by anticoincidence counters.

## Experimental Procedures

**Apparatus.**—A stainless steel tube proportional counter is placed in the middle of eleven anticoincidence Geiger counters inside of an iron shield of 23 cm. in thickness. The pulses from the proportional counter are delaye 10 micro second and are mixed with the pulses of the anticoincidence counters. The background of the proportional counter is $5.46 \pm 0.3$ counts per minute. The proportional counter used for these experiments has the dimensions of 3.5 cm. in inner diameter and of 52 cm. in length. The center anode is stainless steel wire of 0.05 mm. in diameter. The effective volume of the counter is 420 ml.

**Preparation of Acetylene from a Wood Sample.**—A wood sample is heated in a metal crucible in order to remove the volatile organic substance. This procedure makes the sample charcoal. The charcoal is converted into strontium carbonate by the following procedures; combustion in a current of oxygen, absorption of carbon dioxide in 6 N ammonia water, precipitation of calcium carbonate from an ammonium carbonate solution, evolution of carbon dioxide with hydrochloric acid from the calcium carbonate, absorption of carbon dioxide into ammonia water and precipitation of strontium carbonate. The preparation of acetylene from the strontium carbonate is done in a stainless steel tube which is illustrated in Fig. 1.

The mixture of strontium carbonate (8 g.) and magnesium powder (8 g.) is heated in the stainless steel tube by an electric furnace. The tube is connected to a vacuum line and when the temperature rises to 300~400°C the pumping system is cut by the metal cock. The best way to get a good result is to heat the tube up to 800~900°C for more than 4 hr. Very often a kind of explosion was observed during the heating up to 800°C. The

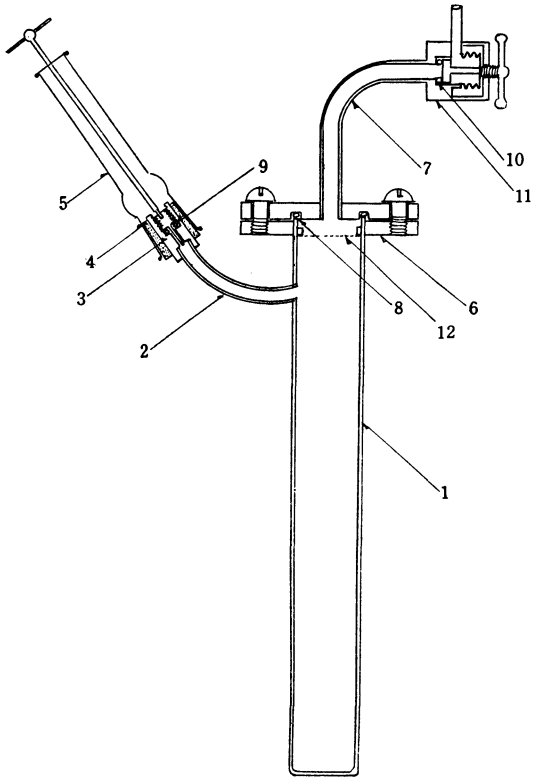

Fig. 1. Tube for preparation of acetylene.
1. Stainless steel tube of 30 mm. in diameter, 780 mm. length
2, 7. Copper tube of 8 mm. in diameter
3. Metal cock for the injection of water
4. Rubber stopper
5. Glass cylinder of 20 mm. in diameter, 150 mm. in length
6. Steel frange
8, 9, 10. O-ring
11. Metal cock
12. Glass filter

explosion can be detected by a sudden temperature rise. The explosion takes place around 450~600°C and if the reaction were stopped just after the explosion, one would get around 60% of acetylene of the calculated value*. Heating up to 800°C after the explosion gives good acetylene yield of 85~95% of the calculated value.

After the preparation of carbide in the stainless steel tube, this is connected to another vacumm line with several cold traps for the purification of acetylene. Acetylene and hydrogen which are evolved by adding water through the side tube to carbide are dried with dry ice in the cold trap. The acetylene is separated from the hydrogen by a trap cooled with liquid nitrogen. The charcoal trap cooled with dry ice removes effectively the contaminated radon from the acetylene. However, since contamination of radon, though it is trace

* When the amount of reaction mixture is large, the temperature rise at the explosion is high enough to produce carbide in fairly good yield.

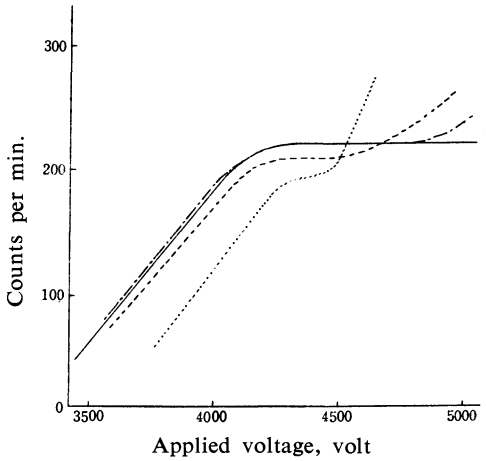

Fig. 2. Characteristic curves of acetylene filled (1 atm.) propertional counter.
——— Pure acetylene
– – – – Acetylene with 0.1% air
– – – 〃 0.2% air
– – – – – – 〃 0.9% air

amount (less than one count per minute), was observed even with these purifications, the acetylene had to be stored in a flask more than three weeks before the activity measurement was made.

**Characteristics of the Acetylene Filled Counter.**—A solid curve in Fig. 2 shows a typical characteristic curve of an acetylene filled proportional counter. The slope of the plateau is constant over the wide range of acetylene pressure within 2% increase per 100 volts. The starting voltage of the plateau is

$$V=(2100+2.98\times P) \text{ volts}, \quad 200<P<800$$

where $P$ is the pressure of acetylene in mmHg. The counter was used with a voltage higher than the starting voltage by 250 volts.

The characteristic curve of the proportional counter changes with the content of impurity of acetylene as is shown in Fig. 2. The allowable maximun amount of impurities such as moisture or air which gives a serious effect on the characteristic curve is abous 0.2% of the total gas. This amount is large enough to operate the counter in a good condition without any special care such as is necessary for the carbon dioxide filled counter that is seriously affected by contaminated air of 0.001% of filling gas[11].

**Effect of the Tritium Activity.**—Fig. 3 shows counts per minute for the different amounts of acetylene gases of modern and dead carbon. There is no change in counts per minute in the case of dead carbon. This indicates that the acetylene produced from dead carbon (from coal or lime) has no activity. The extrapolated values of counts per minute at pressure zero for modern and dead carbon agree with each other within the experimental error of 0.06 count per minute. This shows that the observed activity of the acetyene produced from modern carbon is attributed to the carbon and not to the tritium in acetylene.

11) Hl. de Vries and W. Barendsen, *Physica*, **19**, 987 (1953).

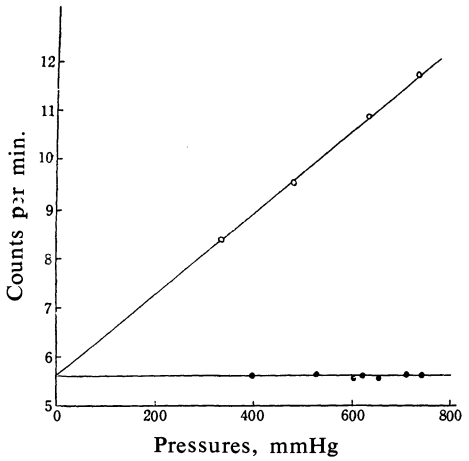

Fig. 3. Relation between counts per minute and pressure of acetylene.
○ Modern carbon, ● Dead carbon

**Counting Procedure.**—Acetylene gas stored more than three weeks is filled in the proportional counter and its characteristic curve is measured. According to the characteristic curve and the pressure in the counter one sets high voltage to be applied. The counting time is usually 48 hr. and the counts are checked every 5 or 10 hr. Background measurements are made for 24 hr. in every two or four days.

## Experimental Results

Table I summarizes the data of the measurements of radiocarbon concentrations in the tree ring samples which were obtained from tree No. 1. Tree No. 1 grew in Akita Prefecture in Honshu Island. This tree has an age of 177 years and was cut in December, 1958. Each tree ring has more than 2 mm. thickness and shows clear boundaries.

The first column of Table I indicates the intervals in which the tree rings grew. The second column shows observed counts per

a) Grown on the campus of Gakushuin University in Tokyo.
b) Grown in Mie Prefecture in Honshu Island.
c) This sample includes the tree rings up to December, 1958.

minute for one gram carbon of each sample. The third column gives the concentrations of C-14 in tree rings at the year indicated in the first column. The concentrations are normalized to the mean value of 18 measured concentrations between 1782 and 1913 (Table I). This mean value will be referred to as a concentration of C-14 in hypothetical modern wood which would not have been affected by industrial effect and nuclear tests.

Table II gives a summary of our data on the tree ring samples after 1950. The second column shows the concentrations of C-14 in the samples which were obtained from tree No. 1. The third and the fourth columns give the results on the trees which grew in Tokyo and Mie Prefecture. Tree No. 2 (the third column) was cut in September, 1959, and No. 3 (the fourth column) in August, 1959. These three series of measurements agree well, and indicate a remarkable increase after the autumn of 1958. The errors indicated in Tables I and II include only statistical counting errors (standard deviations).

## Discussion

The tree ring is a sample formed by constant accumulation of carbon from the atmosphere and is dated by clear boundaries. The examination of the data on the concentration of C-14 in the tree rings gives information on the annual average concentration of C-14 in the atmosphere. Moreover, if samples from the same species of tree were used, the differences of the possible isotopic fractionation among the samples might be negligibly small*. These make the tree ring samples adequate for the studies on the annual variation of C-14 concentration in the atmospheric carbon. However there are some questions about the nature of the sample. First, there is a possibility that the carbon which is taken up through the root could be used for assimilation. Second, the carbon dioxide from the pedosphere might be utilized for assimilation by aerial transport to leaf level. Finally there is a question when the organic substance in a certain part of tree ring was synthesized from the carbon dioxide.

The first and the second question had been discussed by W. Whitaker et al.[12] They suggested a possible influence of the uptake of older carbon by the root system as the most likely explanation of differences in radiocarbon contents of trees from different enviroments. If such an influence plays an important role for a tall tree, the increase in radiocarbon contents in tree rings after 1953 would be less than the increases in atmospheric radiocarbon contents. The authors favor the assumption that this influence is negligibly small because the direct experimental evidences on young pea and barley plants show a small amount of uptake of carbon dioxide through the root system[13]. The experimental results of Whitaker et al. on the effect of the aerial transport for carbon dioxide from pedosphere to leaf level show the absence of any significant amount of old carbon cycling from pedosphere to the leaves of trees.

On the circulation of synthesized organic substances in the tree we have some knowledge which will serve to show when the organic substances in a certain part of the tree ring was synthesized from the atmospheric carbon dioxide. The large cells which are adjacent to the boundary of a tree ring are formed in the spring of the year from the carbon dioxide existing in the atmosphere and from the organic substances, which were synthesized after the summer of the preceding year and have been stored in the older tree rings. The cells which are formed after the middle of the summer of the year become smaller. Finally the smallest cells are formed in September forming the boundary of the tree ring. A large part of the organic substances synthesized during the middle of summer and autumn is stored in a newly formed tree ring[14]. The stored organic substances will be used for the formation of new cells in the next spring. It is therefore desirable to cut down the tree in summer for the measurement.

In general it can be said that the tree ring is made by the atmospheric carbon dioxide during August of the preceding year and September of this year. Although formation of boundaries can be influenced easily by the climate of the place where the sample tree grew, the expected error of the indicated intervals of growth of tree rings in Table I and II may be within one month.

Examination of the results listed in Table I shows a constant concentration of C-14 in the atmosphere between 1782 and 1950 within an error of 2%. Fergusson[10] reported 2% depletion of C-14 concentration in the atmospheric carbon dioxide between 1860 and 1954. Although the limits of statistical counting error of the data are rather broad, the present data seem to support the opinion that the depletion is less than 2% between 1782 and 1950.

* The measurements on the isotopic ratio of $^{13}C/^{12}C$ in tree ring carbon by Fergusson[10] and Broecker et al.[1] show a constant value on the samples from a tree or the trees of same species.

Data of this paper
- ● Akita
- ○ Tokyo
- □ Mie
- —— Interval of growth of tree ring.
- Standard deviation; 1.1~1.5%

Data by Rafter and Fergusson, ×

All the data in Table II as are plotted in Fig. 4 show no essential difference among the three samples except the value of sample No. 1, 1957—1958. Since sample No. 1 was cut in December, 1958 and its last tree ring (1957—1958) was very likely to have incorporated the atmospheric carbon in December, 1958, the higher value corresponds to a sudden increase of atmospheric radiocarbon in the autumn of 1958. It could be concluded that there was no local variation along the south east shore line of Honshu Island from the fact that there is no meaningful difference among the values of the three samples. Bien and Suess[2] reported the variation of C-14 concentration in the tree ring samples up to 1957. These values agree with the present data within the experimental errors. It seems very likely that the local variation of the atmospheric radiocarbon contents is very small, at least in the temperate zone of the northern hemisphere.

In Fig. 4 the plot of the variation of C-14 concentration in the southern atmosphere reported by Rafter and Fergusson[5,6] indicates a systematic delay of the variation to that of the present data. Although the limits of error on the time scale of the present data are rather broad, the delay of the variation of the atmospheric C-14 concentration in the southern hemisphere seems to be several months in length. Broecker and Walton[1] discussed the difference of the atmospheric C-14 concentration between the northern and southern hemispheres. The present result seems to agree with that of Broecker and Walton.

## Summary

1) Using the tree ring samples, the variation of C-14 concentration in the atmosphere since 1782 has been measured by the use of trees growing in Japan. The results show a constant concentration of C-14 in the atmosphere during 1782 and 1950 within the error of 2%.

2) The depletion of C-14 concentration in the atmospheric carbon dioxide between 1782 and 1950 seems to be less than 2%.

3) The observed annual variations on the samples from Tokyo, Akita and Mie Prefectures show almost the same amount of increase after 1953. There is a good agreement between our data and those on the tree ring samples taken in California by Bien and Suess. The concentration of C-14 in the atmosphere averaged over a year seems to have little difference in the temperate zone of the northern hemisphere.

4) The variation of C-14 concentration in the atmosphere of the southern hemisphere seems to follow that of the northern hemisphere with a time lag of several months.

The cooperation of Mr. T. Tokumoto and other officers of the Government Forest Experiment Station and Mr. T. Iwata of the Ise Shrine who supplied the tree samples is gratefully acknowledged. The authors wish to thank Dr. E. Tajima for valuable advice. A part of the expense for this work has been defrayed by the Ministry of Education.

# *Spectrophotometric Determination of Bismuth with Xylenol Orange*

By Hiroshi ONISHI and Nasumi ISHIWATARI

(Received May 24, 1960)

Xylenol Orange was first proposed by Körbl and Pribil[1] as a metal indicator for the EDTA titration. Cheng recently described photometric methods for the determination of zirconium[2], hafnium[3], and iron[4] using Xylenol Orange. It does not appear, however, that a photometric method for determining bismuth with this reagent has been reported.

The present paper reports the conditions for the spectrophotometric determination of bismuth with Xylenol Orange including the effect of foreign substances. The composition and formation constant of the bismuth complex are also discussed.

## Experimental

**Apparatus.**—Absorbance measurements were made with a Hitachi Model EPU-2A spectrophotometer, using 1 cm. cells.

**Solutions.** — L-Ascorbic acid, 10 g. in 100 ml. of water, may be used for several days. A 0.1 g. portion of sodium fluoride was dissolved in 100 ml. of water. A 0.10 g. portion of Xylenol Orange, Dotite XO (Dojindo & Co., Ltd., Kumamoto) was dissolved in 100 ml. of water. This solution can be kept for at least one week. Standard bismuth solution was prepared by dissolving 0.500 g. of pure bismuth metal in a few milliliters of nitric acid, evaporating the solution to dryness on a water bath, dissolving the residue in 1 : 9 nitric acid, and making up to 500 ml. From this stock solution (1.00 mg. Bi per ml.) a working standard solution (e.g., 40 p.p.m. Bi) was prepared by dilution.

**Procedure.**—Transfer the sample solution (dilute nitric acid solution) containing 10~80 $\mu$g. of bismuth to 25 ml. volumetric flask and adjust the nitric acid concentration to make the acidity 0.08~0.12 N after diluting to volume. If the acidity of the sample solution is too high, neutralize excess of acid with sodium hydroxide. Dilute the solution to about 15 ml. with water. Add 1 ml. of ascorbic acid solution and allow to stand at room temperature for about 5 min. Next add 1 ml. of sodium fluoride solution, mix, add 1.0 ml. of Xylenol Orange solution. After diluting to the mark with water and mixing, measure the absorbance of the solution in a 1 cm. cell at 530 m$\mu$. Use the reference solution containing the same amounts of Xylenol Orange and other reagents.

## Results and Discussion

The absorption spectra for Xylenol Orange and its bismuth complex are shown in Fig. 1. When a correction is applied for the reagent blank, an absorption peak is found at about 520 m$\mu$. Because the reagent blank against water at 520 m$\mu$ is about twice as much as that at 530 m$\mu$, the wavelength of 530 m$\mu$ has been adopted for the determination of bismuth.

The effect of nitric acid concentration on the absorbance of bismuth complex is shown in Fig. 2. The absorbances were measured against respective reagent blanks. It is seen that the acidity of 0.08~0.12 N is suitable. Perchloric acid or sulfuric acid also gives the same results as does the nitric acid.

As shown in Fig. 3, a practically constant

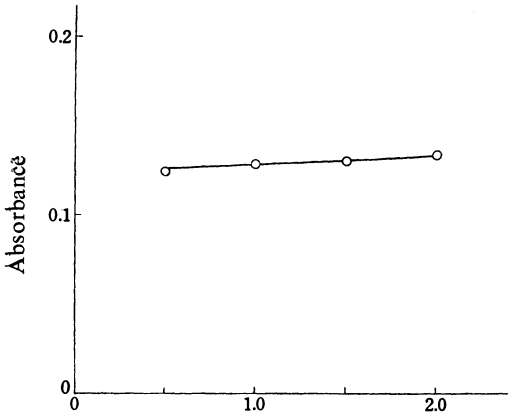

Fig. 3. Effect of Xylenol Orange concentration; 1.6 p.p.m. Bi.

absorbance is obtained by adding more than 0.5 ml. of 0.1% Xylenol Orange solution (final volume=25 ml.). The absorbances were measured against each reagent blank.

Table I shows the stability of the colored solutions. The absorbances remain constant at room temperature for at least 3 hr.

As shown in Fig. 4, absorbance is proportional to bismuth concentration in the range of 0.4 to at least 3 p.p.m. bismuth (10~80 μg. Bi). At 530 mμ the molar extinction coefficient of bismuth is $1.6\times10^4$, or 0.014 μg. Bi/cm² corresponding to $\log I_0/I=0.001$. This sensitivity is comparable to that of the iodide method or the thiourea method[5].

B. In the absence of ascorbic acid and NaF.

The effects of many elements on the determination of bismuth were studied under the conditions used in the procedure (Table II). Most of the metals were in the form of nitrate. Microgram amounts of zirconium and thorium can be masked by fluoride ion. The interference of iron(III) can be eliminated by reduction with ascorbic acid. The effect of niobium is

removed by fuming with perchloric acid and treating the residue with 2 ml. of hot 1.4 N nitric acid. Apparently niobium is precipitated by this treatment. Absorbance measurements must be made within an hour after color development. (The absorbance increases after that time.) Tin and antimony can be volatilized by treating with perchloric, hydrobromic and hydrochloric acids. Five milligrams each of these elements were evaporated to fumes at about 180°C with 1 ml. of 60% perchloric acid and 2 ml. each of concentrated hydrochloric acid and hydrobromic acid (sp. gr. 1.48). After cooling 2 ml. of hydrobromic acid was again added and the solution was evaporated to dryness. The residue was treated with 2 ml. of 1.4 N nitric acid previous to color development. Silver is precipitated by ascorbic acid, but this can be removed by centrifugation after color development. Molybdenum interferes rather seriously and more than 50 μg. of this element can not be permitted.

The proposed method will probably be applicable to lead-base and tin-base alloys

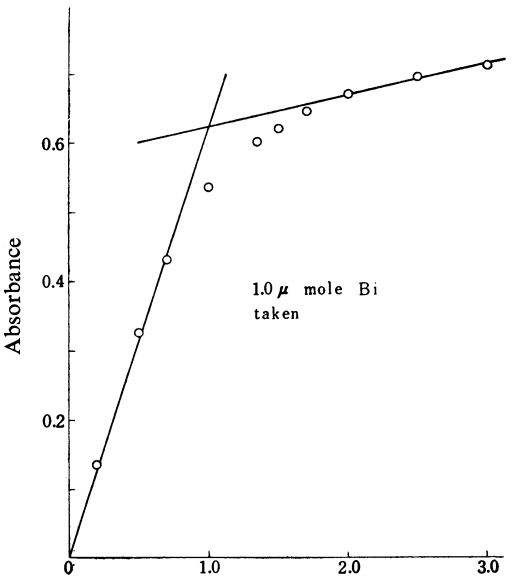

Fig. 5. Mole ratio method.

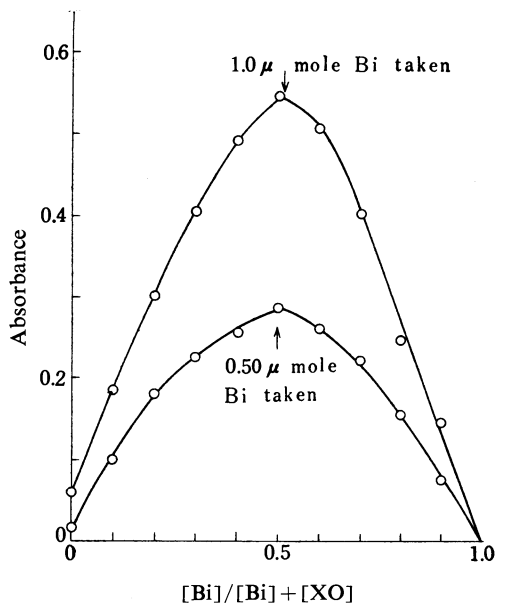

Fig. 6. Method of continuous variation.

after oxychloride precipitation of bismuth[6].

The composition of the bismuth-Xylenol Orange complex was determined by the mole ratio method and by the method of continuous variation (Job's method). The experiments were carried out at room temperatures ranging from 16° to 20°C. From the results obtained (Figs. 5 and 6), a 1 : 1 complex of bismuth with the reagent is indicated. From the fact that Xylenol Orange is an analogue of EDTA, this composition would be expected. On the basis of the data shown in Fig. 6, the formation constant or stability constant of the complex is calculated to be $1\times10^7$ by the method described by Majumdar and Chakrabartty[7] and Cheng[8]. This value is greater than that of the iron(III)-Xylenol Orange complex ($5\times10^5$)[4], and is close to that of the zirconium-Xylenol Orange complex ($4.0\times10^7$)[8].

## Summary

A method is described for the spectrophotometric determination of 10~80 μg. of bismuth with Xylenol Orange. The error is not likely to exceed ±10 per cent. The molar extinction coefficient of bismuth in 0.1 N nitric acid solution is $1.6\times10^4$ at 530 mμ. Instead of nitric acid perchloric acid or sulfuric acid may also be used. The interference of small amounts of zirconium, thorium, and iron can be eliminated by masking. Lead and thallium do not interfere with the determination of bismuth. A 1 : 1 complex of bismuth with Xylenol Orange is suggested.

# *Studies on Polymerizaton and Depolymerization of ε-Caprolactam Polymer. VIII*. The Solution Viscosity of Poly-ε-capramide of Super-high Degree of Polymerization*

By Naoya OGATA

(Received June 6, 1960)

Several equations have been proposed on the relationship between the intrinsic viscosity $[\eta]$ of poly-ε-capramide in sulfuric acid and the polymerization degree $\overline{P}_n$ or the molecular weight $\overline{M}_n$ as follows:

$$\overline{P}_n = 124[\eta] - 5^{1)}$$

$$\overline{P}_n = 119[\eta]^{2)}$$

$$\overline{P}_n = 170[\eta]_{50\%\ H_2SO_4}{}^{3)}$$

$$\log[\eta] = 0.764(\pm 0.016)\log\overline{M}_n - 3.20^{4)}$$

These equations were proposed on the polymer with polymerization degrees below 300 and with broad molecular weight distribution, which was polymerized in the presence of water.

Poly-ε-capramide of a super-high degree of polymerization and with the sharp molecular weight distribution can be obtained by the so-called rapid polymerization of ε-caprolactam in the presence of alkali catalyst[5]. It is expected that the behaviour of the solution viscosity of poly-ε-capramide of a super-high degree of polymerization would be quite different from that of poly-ε-capramide polymerized in the presence of water.

## Experimental and Results

**Polymerization of ε-Caprolactam**[6]. — Sodium hydroxide was dissolved in ε-caprolactam at 100°C at the amount of 1/100, 1/500, 1/750 and 1/1000 mol./mol. and then carbon dioxide gas was introduced for 30 min. into the molten ε-caprolactam. ε-Caprolactam containing colloidally dispersed sodium carbonate was heated at 290°C under normal

pressure in a nitrogen atmosphere or at 250°C under the reduced pressure of 250 mmHg in a nitrogen atmosphere. After the polymerization, polymers were quickly cooled and washed with water.

**Determination of the Solution Viscosity.**—Polymers were dissolved in 98% sulfuric acid at the concentrations of 0.1, 0.2, 0.5, 1.0, 1.5 and 2.0 g./100 cc. and the relative viscosities of the solutions were determined with the Ostwald's viscometer at 25°±0.01°C. The number of carboxyl groups in the polymers was determined by the alkali titration in benzyl alcohol with phenolphthalein as an indicator, and the number of amino groups was determined by potentiometric titration, in phenol-alcohol solvent (1.7/1.0 in volume)[7].

Table I shows relative viscosities $\eta_{rel}$ of the polymer solutions at various concentrations in 98% sulfuric acid. The number of amino groups in the polymers is about twice as great as that of carboxyl groups, as shown in Table II. Although there have been many discussions on the structure[6,8-12] of the end groups of the alkali-catalyzed poly-ε-capramide, it is assumed that the polymerization degree calculated from the number of amino groups may be correct, since the number of carboxyl groups increases by washing the polymer with water, while that of amino groups does not increase[6,11].

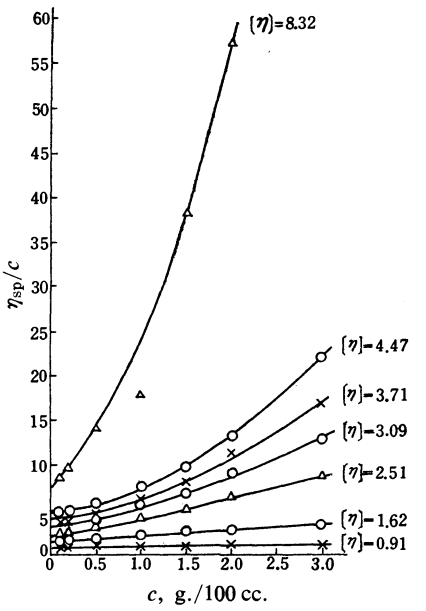

Fig. 1. The relation between $\eta_{sp}/c$ and $c$.

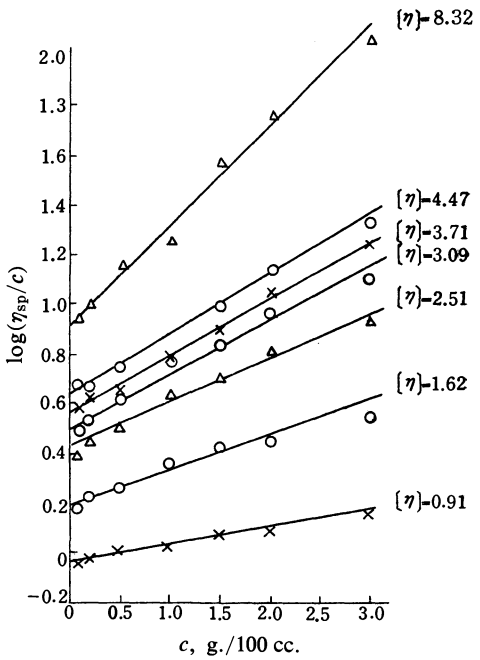

Fig. 2. The relation between $\log(\eta_{sp}/c)$ and $c$.

7) J. E. Waltz and G. B. Taylor, *Anal. Chem.*, **91**, 418 (1947).
8) D. Heikens, *Makromol. Chem.*, **18**, 62 (1956).

11) S. Schaaf, *Faserforsch. u. Textiltech.*, **10**, 224 (1959).
12) A. Hamann, ibid., **9**, 351 (1958).

The relationships between the polymer concentration $c$ (g./100 cc.) in 98% sulfuric acid and $\eta_{sp}/c$ ($\eta_{sp}$ means specific viscosity) shift from a straight line as the polymerization degree increases as shown in Fig. 1. However, as shown in Fig. 2, a linear relation between log ($\eta_{sp}/c$) and $c$ is found and can be expressed as follows:

$$\log(\eta_{sp}/c) = K \cdot c + \log[\eta] \quad (1)$$

where $K$ is a constant and $[\eta]$ the intrinsic viscosity of the polymer, which is obtained by extrapolation of linear log ($\eta_{sp}/c$) vs. $c$ graphs to infinite dilution. The values of $[\eta]$ of the polymers are shown in Table I.

Plotting $K$ against log$[\eta]$, a straight line is obtained as shown in Fig. 3 and the following equation is obtained.

$$K = 0.33 \log[\eta] + 0.05 \quad (2)$$

From Eqs. 1 and 2, Eq. 3 can be derived.

$$\log(\eta_{sp}/c) = 0.05\,c + (0.33\,c + 1)\log[\eta] \quad (3)$$

Plotting $\eta_r$ ($\eta_{rel}$ at $c=1$) against $[\eta]$, a straight line is obtained as shown in Fig. 4, and Eq. 4 is obtained.

$$\eta_r = /2.2[\eta] \quad (4)$$

The relationship between log $\bar{P}_n$ and log $[\eta]$ is in a linear function as shown in Fig. 5, and Eq. 5 is obtained.

$$\bar{P}_{n\,NH_2} = 89[\eta] \quad (5)$$

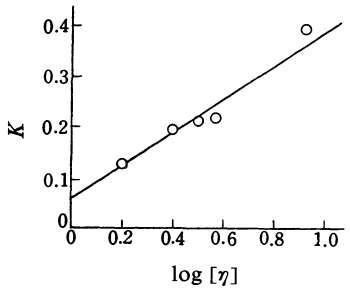

Fig. 3. The relation between $K$ and log $[\eta]$.

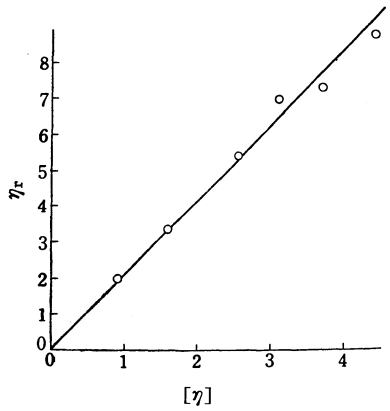

Fig. 4. The relation between $\eta_r$ and $[\eta]$.

From Eqs. 4 and 5, Eq. 6 can be derived.

$$\bar{P}_n = 40.5\,\eta_r \quad (6)$$

Fig. 6 shows the relationship between $\bar{P}_n$ and $\eta_r$ at $c=1$.

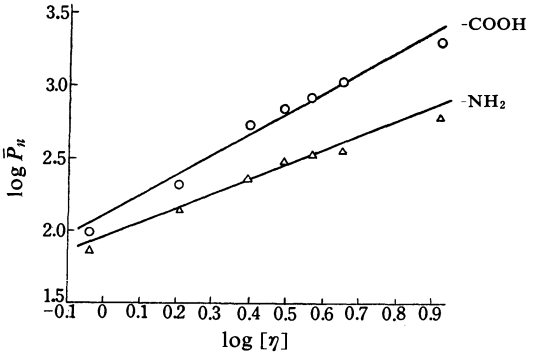

Fig. 5. The relation between log $\bar{P}_n$ and log $[\eta]$.

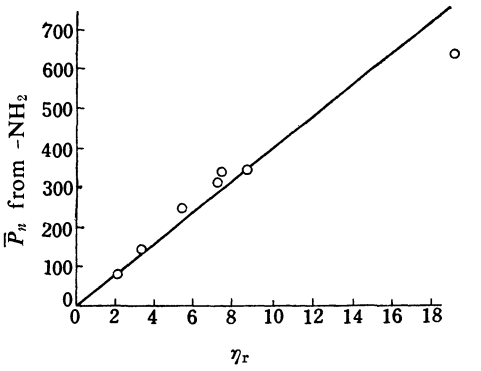

Fig. 6. The relation between $\bar{P}_n$ and $\eta_r$.

**Change in the Polymerization Degree of the Polymer.** — The alkali-catalyzed poly-ε-capramide, which had been washed with water, was preserved in a desiccator with phosphorus pentoxide in a dark place for about 2 years. At that stage, the solution viscosity of the polymers was measured. The polymerization degree of the polymer decreases markedly in comparison with that just after the polymerization and $\bar{P}_n$ becomes about 70, regardless of the initial $\bar{P}_n$.

## Discussion

Generally, it is recognized that the solution viscosity of high polymers can be expressed in the following equation proposed by Huggins,

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c \quad (8)$$

where $k'$ is approximately constant for a series of polymers in a give solvent. Matthes[1] has recognized that the solution viscosity of poly-ε-capramide in concentrated sulfuric acid is well expressed in Huggins' equation and the same results have been attained by Rybnikář[13].

13) F. Rybnikář, ibid., 9, 500 (1958).

TABLE III. CHANGE IN $\bar{P}_n$ OF THE ALKALI-CATALYZED POLY-ε-CAPRAMIDE

| $\bar{P}_n$ of the polymer just after the polymerization | $\bar{P}_n$ of the polymer after 2 years |
|---|---|
| 454 | 71 |
| 254 | 71 |
| 241 | 64 |
| 208 | 72 |
| 190 | 71 |

Dawydoff[14] has also reported that the relationships between $c$ and $\eta_{sp}/c$ or $\ln \eta_{sq}/c$ are in linear functions in the range of the concentrations of less than 0.1 g./100 cc.

Plotting $\eta_{sq}/c$ against $c$, a straight line is obtained for the alkali-catalyzed poly-ε-capramide of $[\eta] < 2.5$, while the shift from a straight line becomes greater in the polymers of $[\eta] > 2.5$. However, a linear relation between $\log (\eta_{sp}/c)$ and $c$ can be found for the polymers in the wide ranges of the polymerization degrees.

It is expected that the interactions among chain molecules occur strongly, as the polymerization degree of the polymer increases, and a simple equation between $\eta_{sp}/c$ and $c$ is not found. The relationship between $\bar{P}_n$ and $[\eta]$ is a simple equation as that derived by Matthes[1] for the polymer polymerized in the presence of water, but the value of the proportionality constant for the alkali-catalyzed polymer is smaller than that derived by Matthes. This is expected to be due to the difference in the molecular weight distribution.

The polymerization degree of the alkali-catalyzed polymer decreases markedly even at room temperature, as stated before, in spite of the fact that the polymers were preserved in a dry state in a dark place. As it is expected that no chemical or photochemical reactions occur in such moderate state, it is very interesting to ascertain whether the amide-interchange reactions would occur in poly-ε-capramide even at room temperature in solid phase, especially in that of a super-high degree of polymerization.

14) W. Dawdoff, ibid., 8, 267 (1957).

## Summary

The solution viscosity of poly-ε-capramide of a super-high degree of polymerization in 98% sulfuric acid has been investigated. A linear relation between $\log (\eta_{sp}/c)$ and $c$ (g./100 cc.) is found for the alkali-catalyzed polymers of $[\eta] > 2.5$, as expressed by the following equation.

$$\log (\eta_{sp}/c) = 0.05\, c + (0.33\, c + 1) \log [\eta]$$

The relationship between $\bar{P}_n$ and $[\eta]$ is expressed by the following equation.

$$\bar{P}_n = 89\, [\eta]$$

The alkali-catalyzed polymer of a super-high degree of polymerization degrades slowly at room temperature in solid phase.

The author wishes to express his gratitude to Dr. K. Hoshino and Dr. H. Kobayashi for their instruction and permission to publish these results. Thanks are also due to Mr. K. Noishiki, Head of the Nagoya Laboratory, and Mr. T. Takayanagi, Chief Research Chemist, for their helpful and discussion. He also thanks Messrs. M. Nakata and T. Ishikawa who collaborated with him in the experiments.

# *Proton Magnetic Resonance of Borazole*[1)]

By Kazuo ITO, Haruyuki WATANABE and Masaji KUBO

(Received June 8, 1960)

The work described in this paper is part of a physicochemical investigation which has as its object the elucidation of the molecular structures and electronic states of borazole and its derivatives. Previous papers of this series have been concerned with the infrared absorptions of some borazole derivatives[2)], the dipole moments of borazole and its derivatives[3)] and the diamagnetic anisotropy of a borazole ring[4)]. The present paper presents the results of investigation on the proton magnetic resonance of borazole. The problem is of particular interest from the standpoint of both chemical shifts and splittings for the following reasons. In the first place, all the NMR spectra which have ever been recorded on compounds having hydrogen atoms attached to boron are outnumbered by the profusion of those on other types of compounds. Secondly, the nuclei of nitrogen $^{14}N$ as well as those of boron isotopes, $^{11}B$ and $^{10}B$, have an electric quadrupole moment capable of affecting through its spin-lattice relaxation the relative broadening of multiplet components. The $^{11}B$ magnetic resonance was also studied in order to facilitate assignments.

## Experimental

**Sample.** — B-Trichloroborazole was prepared by the same method as that described by Brown and Laubengayer[5)]. After being sublimed several times under reduced pressure, it was identified by its melting point 83.5~84.5°C, the value reported in the literature being 83.9~84.5°C [5)]. The infrared spectra[2)] showed absorption bands characteristic of a borazole ring. This compound was reduced to borazole by essentially the same method as that proposed by Schaeffer et al[6)]. differing in that $NaBH_4$ was used as a reducing agent in place of $LiBH_4$ and that triethylene glycol dimethyl ether rather than dibutyl ether was employed as a solvent[7)]. Triethylene glycol dimethyl ether having a boiling point quite different from that of borazole was more suitable than diethylene glycol dimethyl ether suggested by Schaeffer[8)]. Hence, 23.5 g. of sodium borohydride was dissolved in 120 cc. of triethylene glycol dimethyl ether in an atmosphere of dry nitrogen. To this solution, the suspension of 30 g. of B-trichloroborazole in 75 cc. of the same solvent was gradually added at room temperature. Stirring was continued for about 2 hr. After the reaction was over, the product was distilled under reduced pressure and was collected in a trap cooled with dry ice. The yield of crude borazole was about 10 g. Vacuum distillation was repeated several times before use.

**Apparatus and Experimental Procedure.** — The proton magnetic resonance spectrum was recorded at room temperature by means of a JNM-3 high-resolution NMR spectrometer of Japan Electron Optics Laboratory Company operating at 40 Mc./sec. Cyclohexane was used as an internal standard. Accordingly, corrections for the bulk magnetic susceptibility of the sample were not required. It was further confirmed that dilution with carbon tetrachloride did not affect the spectrum in an appreciable manner. The NMR absorption derivative spectrum of $^{11}B$ was also recorded with the same spectrometer operated at 12.6 Mc./sec.

## Results and Discussion

The proton magnetic resonance spectrum obtained is shown in Fig. 1, in which the absorption intensity is plotted against decreasing magnetic field strength. Chemical shifts defined by

$$\delta = 10^6(H_s - H_r)/H_r$$

are also protted along the abscissa. Here, $H_s$ denotes the applied magnetic field for the proton signal of the sample and $H_s$ is that of cyclohexane used as a standard. The signal of cyclohexane was identified by the increase in its intensity on further addition of the standard. Two peaks at $1.4_7$ and $-1.4_9$ were ascribed to spinning side bands, because they shifted depending on the spinning rate.

The spectrum is comprised of a triplet centered at $-4.0_5$ and less intense broad peaks at $2.1_2$, $-1.3_4$ and $-8.2_6$. The triplet was unequivocally assigned to the proton signal of

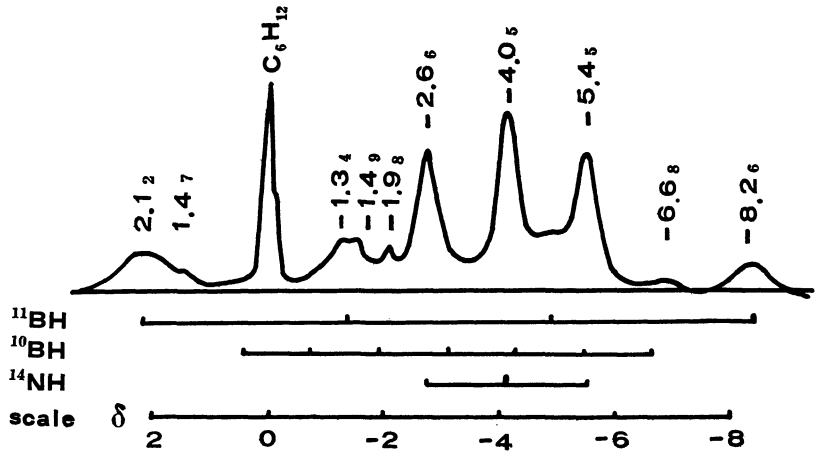

Fig. 1. Proton magnetic resonance spectrum of borazole. The numerical values of shifts are given for major absorption peaks.

$^{14}$NH with a spin coupling constant $J(^{14}NH) = 56$ cps, because the signal is expected to split into three equally spaced peaks owing to the $2I+1$ orientations of a $^{14}$N spin with $I=1$. The spin coupling constant is of the right order of magnitude, since the value for $^{14}NH_3$ is 46 cps[9]. In this triplet pattern, not all of the peaks have the same height, the central line being stronger than the two outer ones, which have the same intensity. Deviation from a simple 1 : 1 : 1 triplet, i. e., the partial collapse of spin multiplets can be ascribed to the presence of $^{14}$N nuclei having an electric quadrupole moment, which gives rise to spin-lattice relaxation in fluctuating electric field gradients. A similar pattern has been shown clearly by Ogg and Ray[9], who compared the proton spectra of anhydrous $^{14}NH_3$ and $^{15}NH_3$. An approximate quantitative theory of this collapse mechanism has been developed by Pople[10], who showed that the broadening of the outer components of the proton triplet spectrum should be three halves as great as that of the central component. Strictly speaking, the outer peaks of the triplet draw together as they broaden. Consequently, the separation between adjacent peaks does not correspond exactly to the spin coupling constant. However, the effect is presumed to be very small in the present case, in which the signals are fairly sharp.

Although the number of hydrogen atoms attached to boron in a borazole molecule is exactly the same as that of hydrogen atoms bonded to nitrogen, the proton signal of BH must be weak, because the abundance ratio of boron isotopes is $^{11}B : {}^{10}B = 81.17\% : 18.83\%$ and also because these isotopes have a greater nuclear spin than that of $^{14}$N, the abundance of which amounts to as much as 99.635%. Therefore, the proton signal of $^{11}$BH must split into four equally spaced peaks in accordance with the spin $I=3/2$ of $^{11}$B. The separation, $3.4_6$, between the two peaks at $2.1_2$ and $-1.3_4$ is equal to half the difference, $6.9_2$, between those at $-1.3_4$ and $-8.2_6$, suggesting the presence of another peak at $-4.8_0$, which, although masked by the $^{14}$NH triplet, appears as a hump between two peaks at $-4.0_5$ and $-5.4_5$ of the triplet. These four peaks complete the proton quartet of $^{11}$BH with $J(^{11}BH) = 138$ cps. This assignment is also consistent with the $^{11}$B NMR spectrum of the same sample. Fig. 2 reproduces the NMR absorption derivative spectrum of $^{11}$B in a borazole molecule. The curve is symmetric across a point, indicating

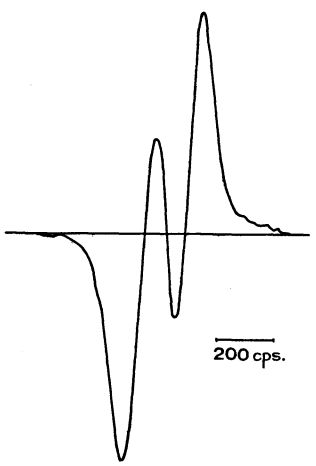

Fig. 2. The NMR absorption derivative spectrum of $^{11}$B of borazole.

9) R. A. Ogg, Jr., and J. D. Ray, *J. Chem. Phys.*, **26**, 1515 (1957).
10) J. A. Pople, *Mol. Phys.*, **1**, 168 (1958).

the presence of two lines of equal intensity separated by 140 cps in good agreement with 138 cps evaluated from the aforementioned proton magnetic resonance spectrum. Philips et al.[11] has carried out the $^{11}B$ magnetic resonance study of boron compounds and reported that $J(^{11}BH)$ was equal to 136 cps for borazole.

The three components of the proton quartet of $^{11}BH$ have practically the same peak height. Although the intensity of the fourth line, which overlaps with the $^{14}NH$ proton triplet, is difficult to estimate exactly, it is very likely that the peak height is the same as those of other members of the quartet. The theory of quadrupole relaxation has already been extended to cover the broadening of multiplet components for protons bonded to nuclei with spin greater than unity[10]. It is predicted that, for spin 3/2, all components of the proton 1 : 1 : 1 : 1 quartet should be broadened equally, instead of showing different peak heights as in the $^{14}NH$ proton triplet. The present results are in agreement with Pople's[10] prediction. A similar quartet pattern having equal spacings and equal peak heights has been shown most clearly for sodium borohydride, $NaBH_4$[12,13]. The partly resolved spectrum of the terminal protons of diborane[13] also appears to be consistent with the prediction.

There are still two weak peaks at $-1.9_8$ and $-6.6_8$ remaining unassigned. A possible interpretation is afforded by the proton signal of $^{10}BH$. If the peak at $-6.6_8$ is assumed to be the outermost low-field member of seven peaks predicted for the signal of protons bonded to $^{10}B$ with its nuclear spin equal to 3, the peak at $-1.9_8$ can be considered to be the third high-field member of the septet, because the center of the $^{11}BH$ quartet must coincide with the central line of the $^{10}BH$ septet. The adequacy of this interpretation is strongly supported by an agreement between the observed spin coupling constant $J(^{10}BH)=48$ cps and the calculated one, 46 cps, based on the observed $J(^{11}BH)=138$ cps and the gyromagnetic ratios $\gamma$ of boron isotopes.

$$\frac{J(^{10}BH)}{J(^{11}BH)}=\frac{\gamma(^{10}B)}{\gamma(^{11}B)}=\frac{4.575}{13.660}$$

where the numerical denominator and numerator are, respectively, the NMR frequencies of $^{11}B$ and $^{10}B$ in Mc. for a 10 kilogauss field. Three peaks between these two observed ones will escape detection owing to overlap with the strong $^{14}NH$ triplet. Two other peaks expected to appear at about $-0.7$ and $+0.5$ have not been observed.

The nuclei of $^{10}B$ have also an electric quadrupole moment. The broadening of multiplet components for protons bonded to nuclei with spin equal to 3 presents an interesting problem from the theoretical point of view. However, it is not feasible to discuss the broadening of the multiplet structure of the septet on the basis of the present investigation.

The proton chemical shifts, $-4.0_5$ and $-3.0_7$, of NH and BH in borazole, as referred to cyclohexane, lead to about $-0.7$ and $+0.3$, respectively, referred to water as a standard[14]. The former differs definitely from the $\delta$ values 4.3~4.5 for secondary alkyl amines[15], and is intermediate between about 2.0 for secondary aryl amines[15] and about $-2.1$ for pyrrole[14]. This is quite reasonable since nitrogen atoms in borazole assume $sp^2$ hybridization and $\pi$-electrons are presumed to migrate to some extent from nitrogen to boron[4,16]. The chemical shift and the spin coupling constant $J(^{11}BH)$ of a BH proton, $+0.3$ and 138 cps, in borazole are closer to those of a terminal proton, $+2.0$ and 125 cps, in diborane, respectively, than to those of a bridge proton, $+6.3$ and 43 cps, in the same molecule[15].

## Summary

The proton and $^{11}B$ magnetic resonances of borazole were recorded at room temperature. The proton magnetic resonance spectrum showed a $^{14}NH$ triplet, a $^{11}BH$ quartet and a part of $^{10}BH$ septet. The broadening of multiplet structure was discussed and the peak heights of the multiplet components were explained in terms of the quadrupole relaxation of nuclei bonded to hydrogen. The chemical shifts and the spin coupling constants were compared with those of related compounds.

The authors wish to thank Dr. T. Seki of Japan Electron Optics Laboratory Company for recording the high-resolution NMR spectra.

# *A Quantum-mechanical Approach to the Theory of Aromaticity*

By Kenichi FUKUI, Akira IMAMURA, Teijiro YONEZAWA and Chikayoshi NAGATA

(Received May 28, 1960)

The term "aromatic" originated from a characteristic odor which was possessed by certain substances isolated from various natural products such as benzoic acid (e. g. from gum benzoin), benzaldehyde (bitter-almond oil), cymene (carraway oil), toluene (tolu balsam) and the like. Hence this terminology essentially involved much ambiguousness since originally it was not based upon any scientific concept of classification. Recently the term "aromaticity" has attracted anew the attention of many organic chemists[1] since the discovery and the synthesis of multifarious non-benzenoid "aromatic" compounds such as tropolone, sydnone, ferrocene and numerous derivatives of these compounds[2].

A quantum-mechanical attack on the problem of aromaticity was for the first time delivered by Hueckel in regard to benzene, who presented the so-called $4n+2$ rule[3]. According to his theory, a conjugated compound has $4n+2$ $\pi$ electrons on its ring should exhibit an aromatic character. Although long years have passed since his report, only a very few attempts have been made to approach this problem theoretically. Recent conspicuous developments in the synthetic organic chemistry of non-benzenoid compounds, however, forced pressingly a re-examination of the significance of aromaticity. Craig investigated the compounds containing $d\pi$ electrons by simple LCAO MO treatment and defined two types of aromaticity according to the type of $d\pi$ orbital involved[4]. One of them obeys the $4n+2$ rule while the other is of a novel type in which the rule does not hold.

The researchers mentioned above, however, considered only the energy of $\pi$ electrons and neglected the internuclear repulsion energy. A more dexterous device should accordingly be desired for the elucidation of aromaticity.

The present authors attempted to investigate the aromaticity more minutely from the quantum-chemical point of view. Prior to entering into the main subject it is desirable to define the term "aromaticity". What is meant by aromaticity is of no clear-cut nature and is usually represented by the following characteristics of aromatic compounds.

Aromatic compounds have a plane structure.

Aromatic compounds show a remarkable stability.

Aromatic compounds have a characteristic reactivity.

Aromatic compounds show a peculiarity in such physical properties as ultraviolet absorption spectra[5], molecular refraction[6], magnetic anisotropy[7], and so forth.

Among these properties some have been already solved and explained satisfactorily, while others have yet been left untouched. The distinguished stability of aromatic compounds aroused the present authors' interest above all other things and is mainly discussed in the present paper.

## Energetical Consideration

Classical explanation of the stability of aromatic compounds had been based upon the strain theory, referring to the proposition that a six-membered ring is stable since it undergoes no strain force. However, by means of this theory we can not understand the reason why some five-membered rings such as furan are stable while others such as cyclopentadiene

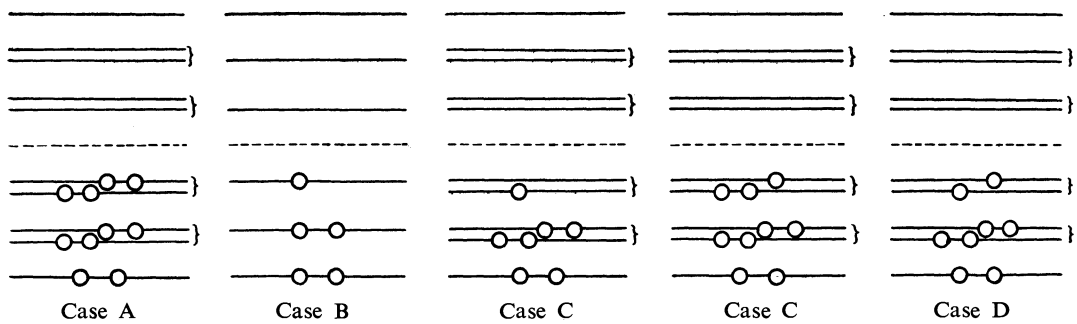

Fig. 2. Electronic configurations which are taken into account in the calculation.
The brace } indicates that two levels are degenerate.

are not. Moreover, recent experiments elucidated that some seven-membered conjugated ring compounds such as tropone and tropolone can exist in a stable form. These facts suggest that, in order to answer the question of aromatic stability, other factors than the strain force, e. g. the magnitude of total $\pi$ electronic energy, should be taken into consideration. For the purpose of attacking this problem, quantum mechanics must obviously be a powerful weapon. Hueckel's $4n+2$ rule was derived by simple LCAO MO treatment[3]. He showed that the electronic configuration of the compound having $4n+2$ electrons on its ring forms a set of closed shells in MO sense analogous to the atomic structure. In the case of $4n$ electrons the complete closed shell structure is impossible as is seen in Fig. 1.

In Hueckel's $4n+2$ rule, however, the effect of electron-electron repulsion and internuclear repulsion had not been taken into account. Accordingly, this rule is not capable of predicting the number of $\pi$ electrons which can exist and be stable on a given membered carbon ring. To overcome this difficulty, the $\pi$ electronic energy is obtained by the formulas utilized by Pople[8]. In the present method the internuclear and electron-electron repulsion energy are considered explicitly and the antisymmetrized product of Hueckel MO were used for the sake of simplicity. Therefore MO is written as

$$\phi_i=\sum_r C_{ir}\phi_r \tag{1}$$

where $\phi_i$ is the $i$th MO and $\phi_r$ represents the AO on the $r$th carbon atom. Electronic configurations which are taken into account are classified into four cases A, B, C and D and these cases are schematically shown in Fig. 2.

For case A Pople gave the total $\pi$ electronic energy including nuclear-nuclear repulsion as follows:

$$\varepsilon_\pi=\sum_r P_{rr}\left(U_{rr}+\frac{1}{4}P_{rr}\gamma_{rr}\right)+2\beta\sum_{r<s}^{*}P_{rs}+\sum_{r<s}\left\{(P_{rr}-1)(P_{ss}-1)-\frac{1}{2}(P_{rs})^2\right\}\gamma_{rs} \tag{2}$$

where $U_{rr}$ is a core matrix element, $\beta_{rs}$ is the resonance integral.

$$\gamma_{rs}=\int\phi_r^*(1)\phi_s^*(2)\frac{e^2}{r_{12}}\phi_r(1)\phi_s(2)\mathrm{d}v_1\mathrm{d}v_2$$

and

$$P_{rs}=2\sum_{i=1}^{n}C_{ir}C_{is} \tag{3}$$

Summation $\sum$ and $\sum^*$ should cover all the atoms and the nearest neighboring atoms, respectively. For the case of regular $n$-membered ring molecules, $U_{rr}$ and $\beta_{rs}$ are constant values represented by $U$ and $\beta$, respectively. In Eq. 2 the internuclear repulsion energy is included in the following form

$$\varepsilon'=\sum_{r<s}Z_rZ_s\gamma_{rs} \tag{4}$$

and $Z_r$ and $Z_s$ are assumed to be unity. For case B the total $\pi$-electronic energy of the non-degenerate system with odd electrons was obtained as follows[8]:

$$\varepsilon_\pi=\sum_r(P^0_{rr}U+P^\alpha_{rr}P^\beta_{rr}\gamma_{rr})+2\beta\sum_{r<s}^{*}P^0_{rs}+\sum_{r<s}\{(P^0_{rr}-1)(P^0_{ss}-1)-[(P^\alpha_{rs})^2+(P^\beta_{rs})^2]\}\gamma_{rs} \tag{5}$$

where

$$P^\alpha_{rs}=\sum_{i=1}^{n}C_{ir}C_{is},\quad P^\beta_{rs}=\sum_{i=1}^{n-1}C_{ir}C_{is}$$

and $$P^\alpha_{rs}=P^\beta_{rs}+P^\beta_{rs} \tag{6}$$

For case C the total $\pi$ electronic energy is obtained by only one electronic configuration for regular $n$-membered ring system, so that the formula for this case is equal to that of case B. For case D the wave functions are chosen as follows.

TABLE I. THE DELOCALIZATION ENERGY OF FIVE-, SIX- AND SEVEN-MEMBERED RING SYSTEMS

| Number of carbon atoms on ring | Number of $\pi$ electrons | Energy of non-conjugated system, e.V. | Energy of conjugated system, e.V. | Difference e.V. |
|---|---|---|---|---|
| 5 | 5 | 5U | 5U− 9.80 | 9.80 |
| | 6 | 6U+10.53 | 6U− 0.48 | 11.01 |
| | 7 | 7U+26.78 | 7U+17.23 | 9.55 |
| 6 | 4 | 4U+ 4.90 | 4U− 6.30 | 11.20 |
| | 5 | 5U | 5U−13.50 | 13.50 |
| | 6 | 6U | 6U−13.88 | 13.88 |
| | 7 | 7U+10.53 | 7U− 2.97 | 13.50 |
| | 8 | 8U+25.96 | 8U+14.76 | 11.20 |
| 7 | 5 | 5U+ 4.38 | 5U−10.17 | 14.55 |
| | 6 | 6U | 6U−17.32 | 17.32 |
| | 7 | 7U | 7U−14.17 | 14.17 |

$$\chi=\frac{1}{\sqrt{2}}\frac{1}{\sqrt{2n!}}\{[\phi_1\bar{\phi}_1\cdots\cdots\phi_n\bar{\phi}_{-n}]-[\phi_1\bar{\phi}_1\cdots\cdots\bar{\phi}_n\phi_{-n}]\} \quad (7)$$

where $\phi_n$ and $\phi_{-n}$ are the molecular orbitals for degenerate levels. In this case we get the total $\pi$ electronic energy by the same method that Pople used as follows:

$$\begin{aligned}\varepsilon_\pi=&\sum_r P_{rr}U+\frac{1}{4}\sum_r\{(P_{rr})^2-(C_{nr})^4-(C_{-nr})^4\\&+6(C_{nr})^2(C_{-nr})^2\}\gamma_{rr}+2\beta\sum_{r<s}{}^{*}P_{rs}\\&+\sum_{r<s}\{(P_{rr}-1)(P_{ss}-1)-\frac{1}{2}(P_{rs})^2\\&-\frac{1}{2}(C_{nr}C_{ns})^2-\frac{1}{2}(C_{-nr}C_{-ns})^2\\&+3(C_{nr}C_{ns})(C_{-nr}C_{-ns})\}\gamma_{rs}\end{aligned} \quad (8)$$

where

$$P_{rs}=2\sum_{j=1}^{n-1}C_{jr}C_{js}+C_{nr}C_{ns}+C_{-nr}C_{-ns} \quad (9)$$

By using these formulas the total $\pi$ electronic energy including internuclear repulsion energy is obtained.

Before performance of calculation it is necessary to consider what kind of quantity can be the measure for aromaticity. In many cases the resonance energy was adopted as the measure for aromaticity[9]. Recently, Craig tried to specify the aromatic character by its symmetry of molecular structures and spin functions[9]. This method, however, is inapplicable to the molecule which lacks sufficient symmetry. In this paper, we intend to compare the stability of the systems of regular $n$-membered ring having $m$ $\pi$ electrons. Since the calculation is restricted to $\pi$ electronic energy and the effect of $\sigma$ bond is neglected, the comparison of stability should be confined to the ring system with the same number of members and variable number of $\pi$ electrons. We, therefore, adopt the energy difference between conjugated regular $n$-membered ring molecule and non-conjugated system that has electrons on each atom as the measure for aromaticity as is shown in Eq. 10.

$$\Delta E=\mathcal{E}\left[\text{⬡}\ \text{or}\ \overset{+}{\text{⬡}}\ \text{or}\ \overset{-}{\text{⬡}}\right]-\mathcal{E}\left[\text{⬡}\right] \quad (10)$$

This measure is nothing but the delocalization energy of the system. The energy of the neutral or ionic non-conjugated system can be given as follows where electron-electron and internuclear repulsions and electron-nuclear attraction are taken into account.

$$\begin{aligned}\varepsilon_{\text{non-conjugated}}=&\sum_{\mu>\nu}(Z_\mu-2)^2\gamma_{\mu\nu}+\sum_{r>s}(Z_r-1)^2\gamma_{rs}\\&+\sum_{r\mu}(Z_\mu-2)(Z_r-1)\gamma_{r\mu}+\sum_{\alpha>\beta}Z_\alpha{}^2\gamma_{\alpha\beta}\\&+\sum_{\alpha,\,r}Z_\alpha(Z_r-1)\gamma_{\alpha r}+\sum_\alpha\gamma_{\alpha\alpha}+nU\end{aligned} \quad (11)$$

where $r$ and $s$ denote the carbon atom which has only one electron on it, $\alpha$ and $\beta$ two electrons, and $\mu$ and $\nu$ none, respectively, and $n$ is the number of $\pi$ electrons. For the sake of simplicity the values of $Z_r$, $Z_\alpha$ and $Z_\mu$ are assumed to be unity. Thus the calculated value is the measure of the stability by delocalization of non-conjugated electrons. Therefore the greater the magnitude of delocalization energy is, the more stable the molecule is. Accordingly this measure is expected to be a good index for aromaticity, since the stability of the molecule is the essential character for aromatic compounds. The atomic integral used in calculation is gained by the semiempirical formulas adopted by Pariser and Parr[5]. For brevity, all the C–C bond distances are assumed to be 1.39 Å referring to that of benzene. Thus

9) D. Ginsburg, "Non-benzenoid Aromatic Compounds", Interscience Publishers Inc., New York (1959).

the obtained results of the delocalization energy are listed in Table I.

As is shown in Table I, infive-, six- and seven-membered ring systems the molecule is most stable when it has six $\pi$ electrons on its ring. In a five-membered ring system this result corresponds to the fact that the five-membered ring molecule with six $\pi$ electrons such as furan, sydnone exists in stable state. Moreover in the seven-membered ring system the stability of tropone and tropolone corresponds to this result. Accordingly, we can explain and extend Hueckel's $4n+2$ rule on the different physical grounds from Hueckel's and combine the rule with the fact that some five- and seven-membered ring molecules with six $\pi$ electrons are stable.

In this connection, it may be worth while to add that another approximate method will contribute to the illustration of $4n+2$ rule. This is the method originally presented by Peter[10] in which the resonance energy is approximately obtained by the perturbation method. The wave function of linear polyenes is utilized as a zero order wave function. The intramolecular bonding between the atoms $r$ and $s$, as is indicated in Fig. 3, is regarded as the perturbation and the stabilization energy due to this bonding is obtained. Result of simple LCAO MO calculation is

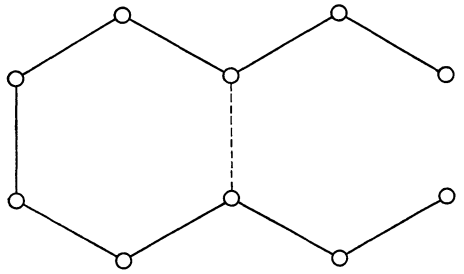

Fig. 3. Scheme for the perturbation method.
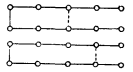
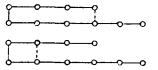
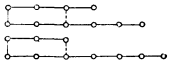
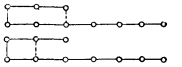
Dotted line indicates the new bonding engendered.
Circle and line represent the carbon atom and the C-C bond constructing the linear polyene.









$$\delta\varepsilon = 2P_{rs}\delta\beta_{rs} + \Pi_{rs,rs}(\delta\beta_{rs})^2 + \cdots\cdots \qquad (12)$$

where $\delta\varepsilon$ is the stabilization energy, $P_{rs}$ and $\Pi_{rs,rs}$ are the order of imaginary bond between the atoms $r$ and $s$ and the selfpolarizability of the imaginary bond $r-s$, respectively, each being of the original polyene, and $\delta\beta_{rs}$ denotes the resonance integral of the bond $r-s$.

A glance at Eq. 4 makes it comprehensible that the magnitude of the stabilization energy predominantly depends on the bond order $P_{rs}$. Peter obtained the resonance energy of various

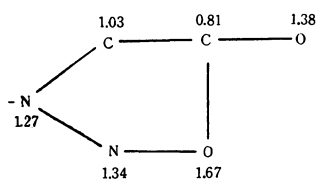
compounds by applying this method and the $4n+2$ rule generally, that is, the molecule in the case that the bond formation makes $4n+2$ ring has the largest resonance energy and therefore more stable than that in the case of $4n$ ring.

If we assume that internuclear repulsion energy stated above does not vary so much according to its geometrical structure, so far as the number of the atoms constituting a molecule does not change, the change of total energy of a molecule may approximately be discussed with an aid of Eq. 4. In many cases that the number of carbon atoms constituting the linear polyene is altered, the value of the bond order was calculated between several carbon-carbon atoms in simple LCAO MO treatment.

The result of calculation is collected in Table II for the cases of four, six, eight, ten, twelve and fourteen carbon atoms. Investigation of this table leads to the conclusion that in a polyene molecule the addition of a bond accompanied with the formation of a $4n+2$ ring stabilizes the molecule, while with the formation of a $4n$ ring it becomes unstable. It may be of interest to examine Table II more carefully to find that in the case of the bond formation with a $4n+2$ ring the corresponding value of bond order increases with the number of describable canonical structures which have alternate single and double bonds, while in $4n$ ring formation the relation is reversed. Hence the number of canonical structures can be a measure for the stability of a $4n+2$ ring molecule but no longer so for $4n$ ring molecules.

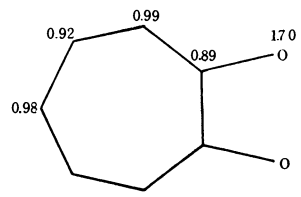
The way of estimating the stabilization energy mentioned above can be replaced by the calculation of conjugation energy per electron in perturbed molecule with simple LCAO MO treatment. The relation between these two methods is shown in Table III, in which a good parallelism is seen.

Table III. The parallelism between bond order and conjugation energy



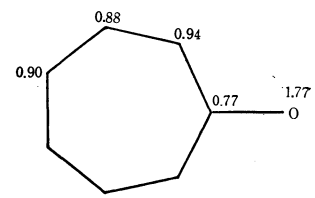
| Molecule | Conjugation energy per electron, $\beta$ | Bond order $P_{rs}$ |
|---|---|---|
|  | 1.100 | −0.3874 |
|  | 1.148 | −0.0866 |
|  | 1.165 | 0.0000 |
|  | 1.244 | 0.0000 |
|  | 1.333 | 0.3019 |

Dotted line indicates the bond formed between atom $r$ and $s$. $\beta$ in parenthesis is the resonance integral of carbon-carbon bond for hydrocarbon.



## Electron Distribution

According to the $4n+2$ rule, it is seen that $\pi$ electron distribution should be correlated closely with the stability of aromatic compounds and molecules with the ring containing $4n+2$ $\pi$ electrons may be more stable than those with $4n$ $\pi$ electrons. Therefore the aromatic compound should have the ring which has $4n+2$ $\pi$ electrons on it. With regard to this rule it is non-benzenoid aromatic compounds with substituents such as sydnone, tropone and so on that attract our interest more strongly.



The sum of $\pi$ electron density on the whole ring was obtained in Fig. 4 in the cases of sydnone, tropone and tropolone. These results suggest that in any cases the aromatic compounds tend to form a ring involving $4n+2$ $\pi$ electrons. When the sum of $\pi$ electron density exceeds 6, the 6-membered ring repels electrons to the substituent, and when it is less than 6, the ring attracts electrons to the ring. Further calculation of the electron distribution in some hydrocarbons containing odd-membered ring is done. The result is shown in Table IV, which illustrates that the $(4n+3)$-membered ring repels electrons and $(4n+1)$-membered ring attracts them independently of the ring size. Thus in azulene the seven-membered ring is positively

The value written in figures is the total $\pi$ electron density at each position.

and the five-membered ring negatively charged representing the Fries' rule[11].

The same tendency can also be ascertained by such a perturbation treatmeat as is described above. A $(4n+1)$- or $(4n+3)$-membered ring can be formed as a result of the bond formation between appropriate two atoms in corresponding polyene molecule, as is shown in Fig. 5. This bond formation is considered as

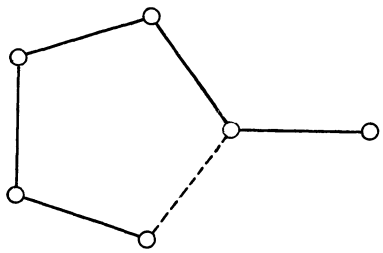

Fig. 5. Adopted model in perturbation method. Circle and line represent the carbon atom and the C-C bond constructing the linear polyene. Dotted line indicates the new bonding engendered.

a perturbation. The wave function for linear polyene is available as a zero order wave function. The total $\pi$ electron density at the $r$th carbon atom, $q_r$, is represented by

$$q_r = 1 + \Pi_{r,st}\delta\beta_{st} + \cdots\cdots \quad (13)$$

where $\delta\beta_{st}$ is the resonance integral of the new bond $s-t$ and $\Pi_{r,st}$ is the atom-bond polarizability of the atom $r$ and the bond $s\cdots\cdots t$ of the original polyene given by

$$\Pi_{r,st} = \frac{\partial q_r}{\partial \beta_{st}} = \sum_{j=1}^{m}\sum_{k=m+1}^{n} \frac{C_{rj}C_{rk}(C_{sj}C_{tk}+C_{tj}C_{sk})}{\varepsilon_j - \varepsilon_k} \quad (14)$$

TABLE V. THE VALUE OF ATOM-BOND POLARIZABILITY AND THE ENERGY DIFFERENCE BETWEEN THE HIGHEST OCCUPIED ORBITAL OF $(4n+1)$- AND $(4n+3)$-MEMBERED RINGS AND $U$

$(4n+1)$-membered ring

| $n$ | $\Pi_{1,2.4n+2}$ $(1/\beta)$ | $\varepsilon_f - U(\beta)$ |
|---|---|---|
| 1 | $\Pi_{1,2.6} = -0.4675$ | 0.6180 |
| 2 | $\Pi_{1,2.10} = -0.3148$ | 0.3474 |
| 3 | $\Pi_{1,2.14} = -0.2383$ | 0.2408 |
| 4 | $\Pi_{1,2.18} = -0.1920$ | 0.1848 |
| 5 | $\Pi_{1,2.22} = -0.1242$ | 0.1474 |

$(4n+3)$-membered ring

| $n$ | $\Pi_{1,2.4n+4}$ $(1/\beta)$ | $\varepsilon_f - U(\beta)$ |
|---|---|---|
| 1 | $\Pi_{1,2.8} = 0.2964$ | −1.2468 |
| 2 | $\Pi_{1,2.12} = 0.2709$ | −0.8310 |
| 3 | $\Pi_{1,2.16} = 0.2127$ | −0.6180 |
| 4 | $\Pi_{1,2.20} = 0.1750$ | −0.4914 |
| 5 | $\Pi_{1,2.24} = 0.1146$ | −0.4068 |

$\Pi_{r,st}$ represents atom-bond polarizability.

$\varepsilon_f$ is energy level of highest occupied orbitals of $(4n+1)$- and $(4n+3)$-membered ring.

$\alpha$ and $\beta$ are Coulomb integral of carbon atom and resonance integral of carbon-carbon bond in polyene, respectively.

11) K. Fries, *Ann. Chem.*, **516**, 248 (1935).

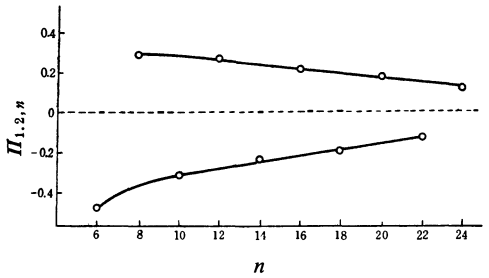

Fig. 6. Atom-bond polarizability and the number of members of linear polyene.

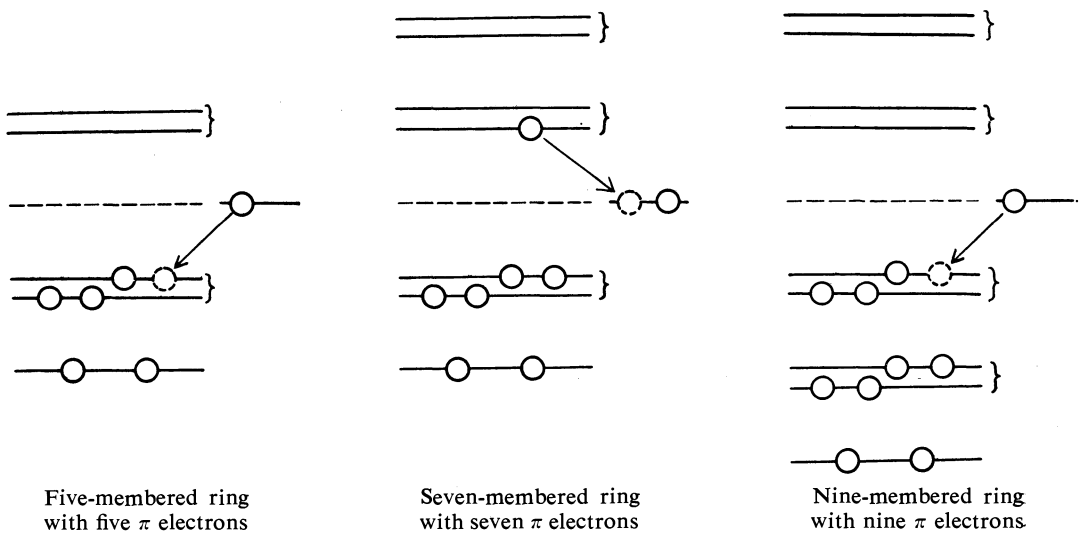
where $C_{rj}$ is the coefficient of the atomic orbital of the $r$th atom in the $j$th molecular orbital in the simple LCAO MO treatment, $\varepsilon_j$ is the energy of the $j$th molecular orbital, and subscript 1, 2, 3,……, $m$ and subscript $m+1$, $m+2$ ……, $n$ denote the occupied and unoccupied molecular orbitals, respectively. The calculated result of $\Pi_{r,st}$ is tabulated in Table V and is also plotted against the number of atoms, $n$, in Fig. 6. In the series of $(4n+3)$-membered rings the value of $\Pi_{r,st}$ is decreased with $n$ and the sum of $\pi$ electron density of the whole ring tends to approach to the limiting value, $4n+2$. A quite reverse tendency is seen in the series of $(4n+1)$-membered rings. That is, $\Pi_{r,st}$ is increased with $n$ and the sum of $\pi$ electron density of the whole ring approaches to the value of $4n+2$. Moreover, it is worth noticing that the absolute value of electronic charge transferred from side chain to ring or in the inverse direction decreases with $n$ in regard to both the $(4n+1)$- and $(4n+3)$-membered rings.

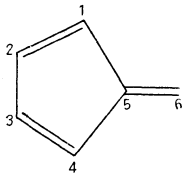
These tendencies may qualitatively be understood from an energetical point of view. The energy levels of $(4n+1)$- and $(4n+3)$-membered rings are given schematically in Fig. 7. In the case of five- and nine-membered rings the charge transfer may occur from side chain to ring and the molecule forms a "closed shell" in a MO sense in order to stabilize itself. On the other hand, in the case of seven-membered ring the direction of the charge transfer is converse.

These circumstances can also be elucidated analytically by using the integral formula for atom-bond polarizability of Coulson[12]. Integral formula for atom-bond polarizability is written as

$$\Pi_{r,st}=(-1)^{s+t}\frac{2}{\pi}\int_{-\infty}^{+\infty}\frac{\Delta_{rt}(iy)\,\Delta_{st}(iy)}{\{\Delta(iy)\}^2}\,dy \tag{15}$$

where $\Delta$ is the secular determinant for the corresponding linear polyene and $\Delta_{rt}$ denotes the secular determinant with row $r$ and column $t$ struck out. Consider a $(4n+1)$-membered ring with a side chain of one carbon atom formed from a $(4n+2)$-membered polyene by a bridging between the 2nd and the $(4n+2)$th atoms of the polyene. The atom-bond polarizability $\Pi_{1,2.4n+2}$ is given by





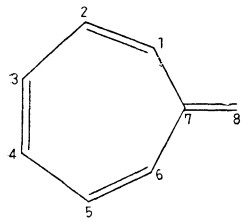


Fig. 7. Energy level of odd-membered ring.
The energy written aside represents that of the side-chain carbon.
The dotted line indicates the $\pi$ electrons transferred and an arrow shows the direction of the electron transfer.

TABLE VI. REACTIVITY INDEXES FOR $(4n+1)$- AND $(4n+3)$-MEMBERED RINGS

| Compound | Position | $f_r$(N) | $S_r$(N) | $q_r$ |
|---|---|---|---|---|
|  | 1 | 0.246 | 0.906 | 1.092 |
| | 2 | 0.156 | 0.784 | 1.073 |
| | 5 | 0.073 | 0.598 | 1.047 |
| | 6 | 1.124 | 2.701 | 0.623 |
| **Compound** | **Position** | $f_r$(E) | $S_r$(E) | $q_r$ |
|  | 1 | 0.223 | 2.049 | 0.942 |
| | 2 | 0.100 | 1.071 | 0.962 |
| | 3 | 0.163 | 1.502 | 0.953 |
| | 7 | 0.046 | 0.756 | 0.976 |
| | 8 | 0.982 | 4.744 | 1.311 |

$f_r$, $S_r$ and $q_r$ are frontier electron density, superdelocalizability and total $\pi$-electron density at position $r$, respectively. (N) and (E) denote the reactivity indexes for nucleophilic and electrophilic reaction, respectively.

$$\Pi_{1,2\cdot 4n+2}=(-1)^{2+4n+2}\frac{2}{\pi}\times\int_{-\infty}^{+\infty}\frac{\Delta_{1,2}(iy)\Delta_{1,4n+2}(iy)}{\{\Delta^{(4n+2)}(iy)\}^2}\,dy \tag{16}$$

Following relations are easily proved[12]

$$\Delta_{1,4n+2}(iy)=1,\quad \Delta_{1,2}(iy)=\Delta^{(4n)}(iy)>0$$

and

$$\Delta^{(4n+2)}(iy)<0 \tag{17}$$

where $\Delta^{(4n)}$ and $\Delta^{(4n+2)}$ denote the secular determinants for $(4n)$- and $(4n+2)$-membered polyene, respectively. From Eqs. 13 and 16 with the aid of Eq. 17 it follows that

$$\Pi_{1,2\cdot 4n+2}>0 \quad \text{and} \quad q_1=1+\Pi_{1,2\cdot 4n+2}\delta\beta<1. \tag{18}$$

Hence the total density at the atom of side chain is less than unity, since $\delta\beta$ is negative. In the case of $(4n+3)$-membered ring originated from a $(4n+4)$-membered polyene the following inequalities are obtained in a similar manner.

$$\Pi_{1,2\cdot 4n}<0 \quad \text{and} \quad q_1=1+\Pi_{1,2\cdot 4n}\delta\beta>1 \tag{19}$$

Thus the total density becomes larger than unity.

Moreover, a close relation is observed between the atom-bond polarizability of a polyene and the highest occupied levels of $(4n+1)$- and $(4n+3)$-membered rings formed from the polyene. Table V illustrates this relation with regard to the cases of $(4n+1)$-membered ring formed from $(4n+2)$-membered polyene and $(4n+3)$-membered ring formed from a $(4n+4)$-membered polyene. In the table it is clearly observed that the lower the highest occupied level of $(4n+1)$-membered ring is, ····· and also the higher the highest occupied level of $(4n+3)$-membered ring is, the larger the amount of charge transferred from ring to side chain is. This result also coincides with the fact that the absolute value of the charge transferred decreases with $n$.

Thus a ring in the molecule has a tendency to approach to a $4n+2$ electron ring by the charge transfer to stabilize the molecule. The position to be attacked by a reagent was predicted for azulene in the paper symposium on aromatic character[13]. The attack of reagent was supposed to occur so as to make the ring possess $4n+2$ electrons by the process of reaction. Similarly, from the consideration stated above, it is predicted that the molecule containing a $(4n+1)$-membered ring and a side chain attached to it such as fulvene may be apt to react with a nucleophilic reagent at the side chain carbon. Inversely, in the case of $(4n+3)$-membered ring, an electrophilic reagent is inclined to attack the side chain carbon. Therefore, $4n+2$ rule can be said to govern the orientation of chemical reaction. Further, this rule also suggests a guiding principle in the syntheses of new aromatic compounds. Namely, we should choose an appropriate substituent attached to the ring that makes the ring possess $4n+2$ electrons. If a molecule

13) D. H. Reid, *Tetrahedron*, 3, 339 (1958).

has excessive electrons on its ring, the substituent to be chosen is electron-attracting, and if it has insufficient electrons, an electron-repelling substituent should be introduced to stabilize it.

This has also been supported by several quantum-mechanical theories of chemical reactivity such as the static method[12] and the frontier electron theory[14]. The reactivity indexes used in these theories have been calculated and tabulated in Table VI, showing that the above-mentioned prediction is correct.

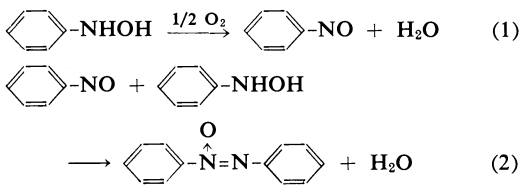
# *Intermediate Compounds in the Catalytic Reduction of Aromatic Nitro Compounds with Raney Nickel Catalyst*[1)]



By Akira SUGIMORI*

(Received June 21, 1960)

There have been some studies on the intermediate compounds in the catalytic reduction of nitro compounds with nickel catalysts. Scholnik, Reasenberg and Smith[2)] reported that in the catalytic reduction of sodium *p*-nitrobenzoate with platinized Raney nickel hydrogen uptake stopped when 2 mol. of hydrogen was consumed (3 mol. of hydrogen is required for the complete reduction of a nitro compound to the corresponding primary amine). This would suggest the existence of an intermediate, but they found only the nitro compound and the *p*-aminobenzoate in the reduction product. Shmonina and Sokolski[3)] reported that nitrosobenzene was formed as an intermediate in the catalytic reduction of nitrobenzene with Raney nickel.

The present author studied the partial reduction of aromatic nitro compounds with neutral Raney nickel. Contrary to the above reports, phenylhydroxylamine derivatives were identified as intermediates.

Nitrobenzene (0.01 mol.) was reduced in ethanol solution at 25°C under ordinary pressure with Raney nickel prepared by treating 1.00 g. of nickel-aluminum alloy (Ni, 40%) with 5 ml. of 20% aqueous sodium hydroxide at 50°C and by washing 10 times with cold water and twice with 20 ml. of ethanol. Shaking was stopped when 0.02 mol. of hydrogen was consumed, the catalyst was filtered off, and the filtrate was poured into 300 ml. of ice water. Light white crystals of phenylhydroxylamine were obtained and they were recrystallized from petroleum ether. The melting point was 76~78°C. Found: C, 66.20; H, 6.73. Calcd. for $C_6H_7ON$: C, 66.03; H, 6.47%. This unstable intermediate was easily converted into azoxybenzene on exposure to air according to the following equations:

(1)

(2)

Therefore, the yield of phenylhydroxylamine was calculated from that of azoxybenzene.

In the same way, the partial reduction of *p*-nitroanisole and of ethyl *p*-nitrobenzoate was carried out and the yields of hydroxylamines and amines were determined. The results are shown in Table I. Nitrobenzene and ethyl *p*-nitrobenzoate gave more hydroxylamines than *p*-nitroanisole.

This agrees with the analysis of the curves

TABLE I. THE PRODUCTS OF PARTIAL REDUCTION

| Compound reduced | Yield of hydroxylamine, % | Yield of amine, % |
|---|---|---|
| Nitrobenzene | 77 | 0 |
| Ethyl *p*-nitrobenzoate | 60 | 0 |
| *p*-Nitroanisole | 22 | 40 |

of the hydrogen consumption rates in the complete reduction to amines. As is shown in Fig. 1, the reduction rate of *p*-nitroanisole is monotonously decreasing, whereas those of nitrobenzene and ethyl *p*-nitrobenzoate have a remarkable increase towards the end of the reaction. It is likely that this increase in the rate takes place when the hydroxylamines are reduced to the amines. The fact that the hydroxylamines which have greater reduction rates than the parent nitro compounds were isolated as the intermediates in the partial reduction, can be understood from the difference in the affinities of the nitro compounds and hydroxylamines to the nickel catalyst. The nitro compounds with stronger affinities repel the hydroxylamines from the catalyst surface. And it can be said that the affinity difference is greater between nitrobenzene and phenylhydroxylamine and between ethyl *p*-nitrobenzoate (with an electron attracting group) and the corresponding hydroxylamine than between *p*-nitroanisole (with an electron repelling group) and its hydroxylamine. This agrees with the result[4] of the catalytic reduction of nitro compounds with a platinum catalyst.

Therefore, the following sequence of processes is presented:

$$ArNO_2 + Ni \longrightarrow ArNO_2\text{-}Ni \quad (3)$$

$$ArNO_2\text{-}Ni + 2H_2 \longrightarrow ArNHOH\text{-}Ni + H_2O \quad (4)$$

$$ArNHOH\text{-}Ni \begin{cases} \xrightarrow{H_2} ArNH_2 + Ni + H_2O & (5) \\ \xrightarrow{ArNO_2} ArNO_2\text{-}Ni + ArNHOH & (5') \end{cases}$$

$$ArNHOH + Ni \longrightarrow ArNHOH\text{-}Ni \quad (6)$$

$$ArNHOH\text{-}Ni \xrightarrow{H_2} ArNH_2 + Ni + H_2O \quad (7)$$

where Ni means the active center of the nickel catalyst.

The author wishes to express his hearty thanks to Professor Y. Urushibara for his kind guidance and encouragement throughout this work. The author is also very grateful to Dr. M. Kobayashi and Dr. S. Nishimura for their kind discussion.

# *Intramolecular Interaction between Hydroxyl Group and π-Electrons. X*[1]*. Tertiary Alcohols Related to Phenethyl Alcohol and 3-Buten-1-ol**

By Michinori Ōki and Hiizu Iwamura

(Received June 16, 1960)

It has been shown in the previous papers[2] that the intramolecular interaction between the hydroxyl group and π-electrons in ω-phenylalkanols and ω-hydroxy-1-alkenes is operative up to phenethyl alcohol and 3-buten-1-ol, respectively. On the other hand, the accumulated data in this laboratory show that there are some alcohols within the above limitation which do not possess the internal interaction, such as 3-cyclohexen-1-ol, and others which have unexpectedly strong O–H stretching absorption ($\nu_{O-H}$) due to the interacting form[3]. The dependence of the occurrence and the

* The summary of this work was presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

2) M. Ōki and H. Iwamura, This Bulletin, 32, 567, 1135 (1959).

3) M. Ōki, H. Iwamura and T. Onoda, Unpublished work.

strength of the interaction on the conformation and the configuration of the molecule may inversely be taken advantage of for elucidation of some problems in the stereochemistry of complex organic compounds including natural products. From the point of the above purpose it will be of value at this stage of investigations to supply further fundamental knowledge relating the strength of the interaction to the conformation of the molecule.

While many authors[4] have recently observed the doublet character of $\nu_{O-H}$ of phenethyl alcohol derivatives and 3-buten-1-ol in the infrared absorption, it has been shown by the present authors[2], that their $\nu_{O-H}$ absorptions separate into three (Fig. 1), each being exemplified by the following conformational isomers in Fig. 2, in the case of phenethyl alcohol. The higher two bands are derived from the rotational isomerism about $C_\alpha$–O bond and observed even in saturated alcohols[5]. The highest absorption at about 3636 $cm^{-1}$ (I) has been assigned to the

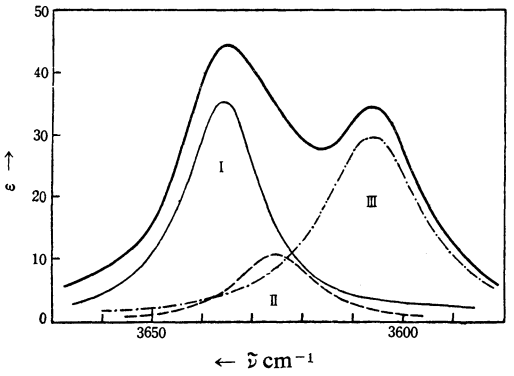

Fig. 1. $\nu_{O-H}$ absorption of phenethyl alcohol.

$\nu_{O-H}$ of the hydroxyl group with its hydrogen atom between two hydrogen atoms attached to the α-carbon atom, while the second at about 3627 $cm^{-1}$ (II) to the $\nu_{O-H}$ with hydroxyl hydrogen between a hydrogen and a carbon atom. The third band at the lowest region of the spectra (III) is of a different kind and has been assigned to $\nu_{O-H}$ of the hydroxyl group having intramolecular interaction with π-electrons of the benzene nucleus. In other words, II and III are the rotational isomers about $C_\alpha$–$C_\beta$ bond.

The triplet nature of the infrared absorption mentioned now, however, does not mean the apparent separation of the absorption curve but that the apparent curve can best be represented by an overlap of three symmetric absorption curves of the type of the Lorentz function[6]. Then nine parameters; $a_i$, $b_i$ and $\nu_i$ ($i=1$, 2 and 3), must be determined in this case and the procedure of the division of the apparent curve is troublesome, whether it is the trial and error method[2] or the least squares method[1]. In the previous paper[1], this difficulty was mentioned and overcome by taking advantage of a tertiary alcohol which shows only doublet $\nu_{O-H}$. The energy of the interaction between an alcoholic hydroxyl group and π-electrons of a benzene nucleus in benzyldimethylcarbinol was thus determined. In the present paper the measurement is extended to the interaction between an alcoholic hydroxyl group and π-electrons of ethylenic double bond in allyldimethylcarbinol. The effect of rotational degrees of freedom on the number of the interacting forms of the molecule and consequently on the apparent $\nu_{O-H}$ curve is also discussed.

## Experimental

**Measurement and Calculation.**—Measurement of the $\nu_{O-H}$ absorption and the calculation of the band properties and the energy of the interaction were carried out as described previously[1,7], for doublet absorption, Eq. 1 being assumed and six parameters determined by means of the least squares method.

$$D(\nu)=\frac{a_i}{(\nu-\nu_i)^2+b_i^2}+\frac{a_f}{(\nu-\nu_f)^2+b_f^2} \quad (1)$$

**Materials.**—Benzyldimethylcarbinol and allyldimethylcarbinol were prepared by action of acetone on benzyl- and allylmagnesium chlorides, respectively, and their physical constants were as follows: benzyldimethylcarbinol b.p. 70°C/3mmHg, $n_D^{25}$ 1.5158. Found: C, 80.10; H, 9.14. Calcd. for $C_{10}H_{14}O$: C, 79.95; H, 9.39%. (lit.[8], b. p. 59~60°C/1.5 mmHg, $n_D^{25}$ 1.5128): allyldimethylcarbinol b. p. 119°, $n_D^{25}$ 1.4250 (lit.[9], b. p. 118~120°C, $n_D^{17}$ 1.4300).

Dibenzylmethylcarbinol and diallylmethylcarbinol were prepared by action of the corresponding Grignard reagents on ethyl acetate: dibenzylmethylcarbinol b.p. 148°C/3 mmHg, $n_D^{23}$ 1.5686 (lit.[10], b. p. 182°C/15mmHg): diallylmethylcarbinol b. p. 74°C/43 mmHg, $n_D^{23}$ 1.4500 (lit.[11], b. p. 158.4°C). Tribenzylcarbinol and triallylcarbinol were prepared through Grignard reaction between diethyl carbonate and benzyl- and allylmagnesium chlorides, respectively: tribenzylcarbinol m. p. 114~115°C (lit.[12], m. p. 115°C): triallylcarbinol b. p. 82°C/16mmHg, $n_D^{23}$ 1.4682 (lit.[13], b. p. 191~192°C, $n_D^{21}$ 1.468).

## Results and Discussion

The apparent $\nu_{O-H}$ curves of allyldimethylcarbinol at several temperatures are shown in Fig. 3. Each curve can be regarded as an overlap of two Lorentz function curves as is exemplified by the curve at 24°C in Fig. 4, and six parameters determined by applying Eq. 1 to the apparent curves are summarized in Table I. The characteristic tendencies of the dependence of some band properties on temperature such as decrease of the total intensity, increase of the half band-width and shift of the wave numbers to the higher side, are again observed in this case.

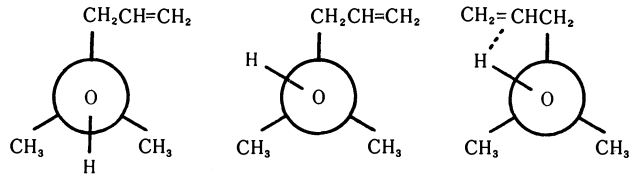

Fig. 6.

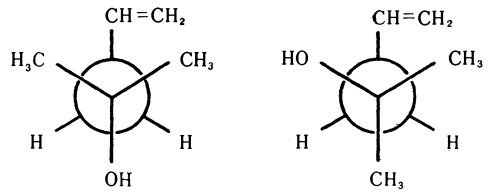
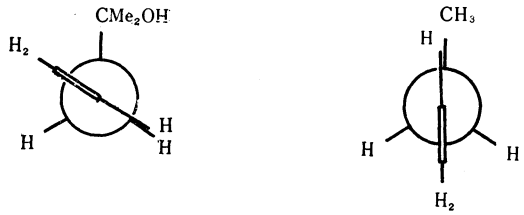


Temperature versus $\ln(A_i/A_f)$ relation is shown in Fig. 5. The values obtained therefrom are tabulated in Table II together with those of benzyldimethylcarbinol reported in the preceding paper[1].

The strengths of the interactions are fairly smaller than those ever estimated. That is, Bamford[14] suggested the energy to be 2~3 kcal./mol. for the interaction between methanol and aromatic nucleus and Schleyer et al.[15] 1.4 kcal./mol. for phenethyl alcohol. However, disappearance of the interacting $\nu_{O-H}$ for 3-cyclohexen-1-ol and β-tetralol seems to suggest, that the energy difference between the free and the interacting molecules is less than 1 kcal./mol. While West[16] has recently shown, that olefins are generally stronger proton-acceptors than simple aromatic hydrocarbons in the intermolecular interaction between the hydroxyl group and π-electrons through measurement of the shift of $\nu_{O-H}$ from free phenol to phenol in hydrocarbons, it is for the first time that the proposition was realized in the intramolecular interaction through the direct energy measurement.

The doublet nature of the $\nu_{O-H}$ of allyldimethylcarbinol as well as benzyldimethylcarbinol shows, that the rotational isomers around $C_\alpha$–O bond can not be distinguished so far as $\nu_{O-H}$ is concerned under the present dispersion of the spectrometer[2]; that is, IV and V in Fig. 6 can not be distinguished and equally give the higher $\nu_{O-H}$ at 3616 $cm^{-1}$. In both forms hydroxyl hydrogen lies between two carbon atoms attached to the α-carbon atom as in *tert*-butyl alcohol[5]. The absorption at 3584 $cm^{-1}$ (VI), on the other hand, can be assigned to the hydroxyl group having internal interaction. In this case, the rotational degree around the $C_\alpha$–$C_\beta$ and $C_\beta$–$C_\gamma$ bonds must be fixed favorably for the interaction, i. e., the hydroxyl group and the group carrying π-electrons must be closely situated.



Although it is usual that the energy difference of about one kcal./mol. between two components in an equilibrium mixture makes one at a lower energy level exceedingly predominant, it does not seem to be the case in allyldimethylcarbinol, the ratio $A_i/A_f$ being only 0.59. This could be explained if the absorption intensity per molecule of the interacting $\nu_{O-H}$ is much weaker than that of free $\nu_{O-H}$ and even small $A_i$ represents a large number of the interacting molecules. However, the assumption is rather contradictory to the knowledge of ordinary hydrogen bonding[17] where the absorption intensity increases on hydrogen bond formation because of increased change of the dipole moment accompanying O–H vibrational motion. The possibility may also be excluded from the fact that, as reported previously[2], the sum of the integrated intensities $(A_i+A_f)$ is almost constant throughout the wide range of substituted phenethyl alcohols. It can preferably be explained by considering the statistical factor contributed from the rotational degree of freedom. Rough computation of the number of the possible conformations for allyldimethylcarbinol was made with the assumption that only the staggered conformations are possible for each bond axis. It may reasonably be assumed that both isomers IV and V have not only the same $\nu_{O-H}$ but also almost the same energy in regard to the conformations of the hydroxyl group. As to the $C_\alpha$–$C_\beta$ axis, three conformations VII, VIII and the mirror image of the latter in Fig. 7 are assumed to have the same energy as a first approximation. Strictly speaking, however, VII and VIII are different in that the former has

14) C. H. Bamford, *Discuss. Faraday Soc.*, **16**, 229 (1954).

VII VIII

Fig. 7.

IX X

Fig. 8.

two gauche type interactions in *n*-butane structure, while the latter a gauche interaction in *n*-butane structure and another gauche interaction in *n*-propyl alcohol. Hence the energy difference between VII and VIII becomes $E_g^{bu.}-E_g^{pr.}$, which may be assumed to be zero[18]. Around the $C_\beta$–$C_\gamma$ bond, only the gauche conformations (IX and its mirror image in Fig. 8) may be permitted as in 1-butene, where two gauche forms are more stable than the trans (X) by 1970 cal./mol.[19] Out of eighteen ($3\times3\times2$) conformations thus possible, only two can take part in the internal interaction and are stabilized by the energy of the interaction. Therefore the ratio, $w_i/w_f=1/8$, must be introduced as a weight in the following Eq. 2;

$$n_i/n_f=w_i/w_f\cdot e^{-(E_i-E_f)/(RT)} \qquad (2)$$

where "$n$" is the number of the molecules. Substitution of the energy of the interaction obtained above gives $n_i/n_f=0.56$ which is in good agreement with $A_i/A_f$ value of 0.59.

The computation was extended to the data of epicholesterol which shows as high $A_i/A_f$ value as 3.14[20]. The molecule has a fairly rigid structure as in Fig. 9 and the freedom of rotation is left only for $C_\alpha$–O axis. Out of three possible conformations, only one can take part

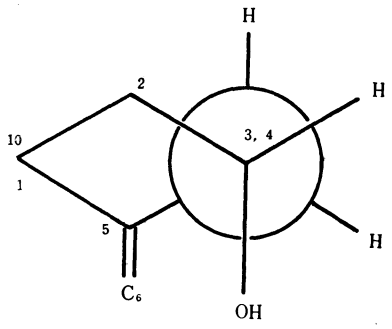

Fig. 9.

in the interaction geometrically, the weight becoming 1/2. As the hydroxyl group is now of the secondary alcohol, it is a stronger proton-donor in hydrogen bonding than those of tertiary alcohols[21], while the ethylenic double bond is regarded to be a stronger proton-acceptor than that of allyldimethylcarbinol, because it possesses three alkyl substituents[14]. The strength of the interaction must therefore be greater than that obtained above and is arbitrarily assumed to be 1.0 kcal./mol[22]. Then $n_i/n_f$ becomes 2.7, which satisfactorily explains why epicholesterol, unlike 3-buten-1-ol, shows larger $A_i/A_f$ value than one.

Benzyldimethylcarbinol may be treated in the same way. The energy difference between two rotational isomers corresponding to VII and VIII would be marked, the latter being more stable, but is neglected for the sake of convenience as no evaluation is possible. As to the $C_\beta$–$C_\gamma$ bond (Fig. 10), every rotational conformation which must be analogous to that of ethylbenzene[23] favors the interaction, and therefore the rotational degree of freedom about this axis is left out of consideration. Thus $w_i/w_f$ becomes 2/7 in all. This value, together with 1/8 in allyldimethylcarbinol, may be regarded to correspond to the entropy terms of the interaction in Table II and well explains the greater absolute value in the latter than in the former, since ln 2/7 is −1.25 and ln 1/8 is −2.08. The energy difference of 0.54 kcal./mol.

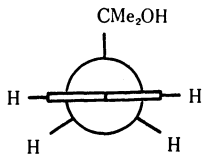

Fig. 10.

18) $E_g^{bu\cdot}$ has been regarded to be 800 cal./mol. (K. S. Pitzer, *J. Chem. Phys.*, **8**, 711 (1940).), while no datum is available for $E_g^{pr\cdot}$, the energy difference between gauche and trans forms in *n*-propyl alcohol.

19) J. G. Aston, S. Isserow and G. J. Szasz, *J. Chem. Phys.*, **12**, 336 (1944); **14**, 67 (1946).

obtained for benzyldimethylcarbinol was used as the energy of the interaction and $n_i/n_f$ of 0.71 was obtained as shown in Table III.

In order to see these statistical effects on $\nu_{O-H}$ absorption curves, the measurements were extended to some tertiary alcohols related to 3-buten-1-ol and phenethyl alcohol. The apparent $\nu_{O-H}$ absorptions are shown in Figs. 11 and 12, respectively, and the numericals are summarized in Table III, the last column being the $n_i/n_f$ values computed as above. The energies of the interaction tabulated in Table II were applied to the same type of compounds, and this procedure may be justified from the constant $\Delta\nu_{max}$ values in the series of allylcarbinols.

In both series the fair agreement between the observed $A_i/A_f$ and the computed $A_i/A_f$ in the lowest homologs does not always hold true in the higher homologs, especially in benzylcarbinol series. The discrepancy can almost exclusively be attributed to the incorrect assumption made in the computation of the weight, that is, to the effect of steric hindrance which disfavors such conformations with the free hydroxyl group as shown in Fig. 13.

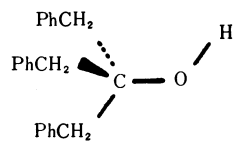

Fig. 13.

It has been shown in this manner, that the ratio of the number of the interacting molecules to the free ones can almost quantitatively be interpreted by considering the statistical or frequency factor of the conformations of the molecules under a given value of the energy of the interaction. In the near future, the computation will be extended to the other organic compounds to explain their $\nu_{O-H}$ absorption curves and the conformations of the molecules.

The authors are indebted to Professor Y. Urushibara and Professor T. Shimanouchi for

their encouragement and discussion throughout this work. The authors' thanks are also due to the Ministry of Education for the Grant in Aid for Fundamental Scientific Research.

# *NMR Spectra of Aliphatic Compounds Containing Oxygen Atoms and the Related Compounds**

By Kenkichi NUKADA

(Received April 13, 1960)

Many works concerning the chemical shifts of functional groups in organic molecules[1-4] have been reported, but the systematic study for the chemical shifts of functional groups containing oxygen atoms has not yet been carried out in detail. In this paper, the author presents the NMR spectra of more than thirty aliphatic compounds containing the oxygen atom and the related compounds such as ethers, formals, acetals, ketal, orthoaliphatic acid esters, polyethylene glycol diethers and cyclic compounds. These compounds contain various types of functional groups such as $CH_3$-O, O-$CH_2$-O, HC$\langle$O, O, etc. Comparing spectra with each other, the author obtained a table of chemical shifts of functional groups. It is also found that there exist some correlations between the chemical shifts of the same type of equivalent protons and the type of alkyl groups bonded to the oxygen atom. The origin of the correlation was considered.

## Experimental

**Measurement of NMR Spectra.**—Spectra were obtained by means of a Varian 4300 B spectrometer (40 Mc). The spectra of both pure liquid benzene solution (volume ratio of solute to benzene equals to 4 : 1) for each sample were obtained and the chemical shifts with respect to proton resonance in benzene were calculated. As a field marker, the spectrum of pure propionic acid was used (Fig. 1). The absolute value of shift was calibrated by the displacement between proton resonances in benzene and cyclohexane (223 cps)[3]. Since it is necessary to maintain all the experimental conditions as stable as possible in the accurate chemical shift measurement, a sweep rate of 1p/$10^7$ per second was used. When necessary to obtain higher resolved spectra, a smaller sweep rate (0.4p/$10^7$) was used. In the latter case, however, the error of chemical shift was considerably increased. The probable error of the measurement in case of rapid passage was within ±2%. Spectra of pure sample were obtained because sometimes it was necessary to check the solvent effect in benzene solution.

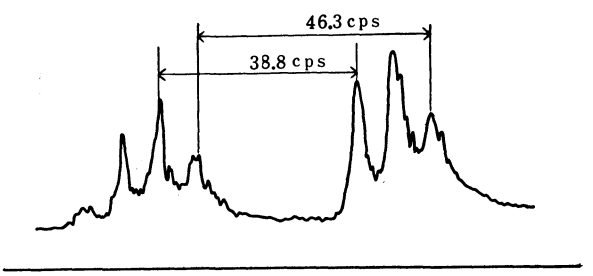

Fig. 1. NMR spectrum of pure propionic acid. This spectrum was used as a field marker, i. e., before and after every chemical shift measurement this spectrum was measured. The absolute values between peaks were calibrated by the displacement between proton resonances in benzene and cyclohexane (223 cps).

**Samples.** — Formals (dimethyl formal, methyl ethyl formal, diethyl formal and diisopropyl formal) and acetals (dimethyl acetal, methyl ethyl acetal and diethyl acetal) were synthesized in the author's laboratory[5]. All the other compounds are commercial products (Tokyo Kasei and Eastman Kodak Co.).

The purity of some compounds (formals, dimethyl acetal, methyl ethyl acetal, ethers except 1, 2-dichloroethyl ethyl ether, polyethylene glycol diethers and cyclic compounds except tetrahydrofuran and epibromohydrin) was checked by gaschromatograph. The other compounds were found to decompose in the column of gaschromatograph, and in this case the purity was checked by the infrared spectra*. The detailed description of the purification was reported elswhere[5,6].

## Results and Discussion

The spectra obtained may be classified into three types as follows:

a) No peaks overlap with each other, so it is quite easy to assign them from the relative intensity and the appearance of the multiplet structures.

b) Some peaks overlap with each other, but referring to the assignment of class a) it is not so difficult to assign them in most cases.

c) Separation of chemical shift is the same order as J-J splitting. In this paper, the assignment of this class is not given since it is impossible to assign them without exact calculation.

In Fig. 2, the assignment and the value of chemical shifts (in cycle per second) are marked on each peak. The separation between peaks is also shown together with that of pure liquid in parentheses.

* Since the infrared spectra of ketal and orthoaliphatic acid esters have not been reported in the literature, it is impossible to check the purity of these compounds merely by the infrared spectra. Since these compounds were known to decompose gradually to alcohols, esters or to aldehydes in air at room temperature, they were distilled (in vacuo) several times until bands at 3500 $cm^{-1}$ and 1700 $cm^{-1}$ completely disappeared.

6) K. Nukada, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 1028 (1960).

The average values of shifts of all functional groups are listed in Table I and these values are consistent with those listed by Chamberlain[3].

Except for halogenated ethers, all functional groups may be divided into four groups, B, A, $A^2$ and $A^3$ according to the approximate value of shift. These groups include sub-groups $\beta$, $\beta^2$ and $\beta^3$, $\alpha\beta$ and $\alpha$, $\alpha^2$ and $\alpha^3$, respectively. The notation of "the type of sub-group" is defined as follows*: $n$ equivalent protons bonded to $\alpha$ or $\beta$ carbon atoms are designated as $\alpha_{CH_n}$ or $\beta_{CH_n}$. If carbon atoms are at $\alpha$ and/or $\beta$ positions with respect to more than two oxygen atoms, several notations are used, i. e., $\alpha^2{}_{CH_n}$ or $\alpha\beta_{CH_n}$, etc. If the carbon atom is at $\alpha$ position with respect to the chlorine atom the notation $\alpha'$ is used. Practically, the chemical shifts of protons bonded to $\gamma$ or far separated carbon atoms are not influenced by the electronegative atoms interested.

The order of shielding is $B > A > A^2 > A^3$ within the main groups. Further in each group, some correlations are recognized. In groups B and A, the order of shielding is $\beta > \beta^2 > \beta^3$ for $CH_3$ protons and $\alpha > \alpha\beta$ for $CH_2$ protons, respectively. In groups A and $A^2$, the order of shielding is $CH_3 > CH_2 > CH$ for $\alpha$ sub-group and $CH_2 > CH$ for $\alpha^2$ sub-group, respectively.

The correlation between the chemical shift and electronegativity of the functional group being directly related to "the type of group" and "the type of sub-group" is quite reasonable.

Let us next consider the change in chemical shift within each sub-group in more detail. The chemical shift of equivalent protons in some functional groups changes, though very slightly, in homologue. The methyl proton shift of the methoxyl group in $R\text{-}C\langle^{O\text{-}Me}_{O\text{-}Me}_{O\text{-}Me}$, for example, goes to a higher field as the alkyl-group R becomes larger. In another example, the methylene proton shift in $CH_2\langle^{OR_1}_{OR_2}$, goes to a lower field as the alkyl groups $R_1$ and $R_2$ become larger. In Tables II and III, the correlations between the chemical shift and the type of attached alkyl group are shown in the former and the latter cases, respectively. Although the change of chemical shift is very slight and some correction of the solvent effect should be considered, surprisingly regular correlations are obtained.

If it is assumed that after a possible correction due to the solvent effect the order of the magnitude of the chemical shift does not change, the result obtained here will give some information concerning the molecular structure and electron density distribution in the molecule.

The possible explanation for the slight change of chemical shift is as follows:

1) **Steric Effect.**—By the steric repulsion between alkyl groups, the X-C-H bond angle changes slightly, following the slight change in hybridization of the carbon atom in C-H bond.

2) **Inductive Effect.** — As R goes from H through $CH_3$ to higher alkyl groups in R'-O-R, the electron affinity of oxygen atom for R' is lowered causing protons in R' to be more shielded*.

3) **Steric and Inductive Effect.**—As R goes from H to higher alkyl groups in R'-O-R, by the steric hindrance the C-O-C bond angle in R'-O-R increases slightly causing a slight change of hybridization of the oxygen atom and further the increase of electron affinity of the oxygen atom.

4) **Direct Effect.** — As R goes from H to higher alkyl groups, the bond angle in molecules change slightly, causing the slight change of magnetic anisotropy of atoms and then shielding for the protons interested.

At present, it is impossible to decide immediately which cause is predominant, since it is quite difficult to estimate the amounts of the influences of these effects on chemical shift quantitatively. The author could say, however, that at least two causes must be considered since opposite senses are obtained in the correlations shown in Tables II and III.

More detailed discussion concerning this problem will be reported in the near future.

The author wishes to express his sincere thanks to Drs. Y. Mashiko and A. Kuboyama of this Institute and Dr. S. Hattori of Kanazawa University for their valuable discussions, and to Dr. H. Honda and Mr. K. Nagata of the Resources Research Institute and Mr. A Suzuki of this Institute, for their help in the laboratory work.

# SHORT COMMUNICATIONS

## *Proton Magnetic Resonance in Cocoon*

By Shizuo FUJIWARA* and Makoto NAKAJIMA**

(Received May 16, 1960)

As the application of the nuclear magnetic resonance, we made a preliminary measurement of the proton resonance in cocoon in order to obtain information about the general features of the thermal motions of molecules. The line shape, the width, and the second moments of the absorption curves were investigated in usual way[1].

### Apparatus and Sample

Most part of the apparatus of NMR measurements is same as described by Gutowsky et al.[2], and has been published elsewhere[2]. The magnetic field applied was about 4000 gauss. The intensity of the rf-field, $H_1$, was about 0.1 gauss. The samples were slightly saturated by this strength of $H_1$, but we could not reduce $H_1$ to the lower level. Measurements were made at room temperature as well as at lower temperatures which were obtained by using the Gutowsky's type[2] Dewar vessel. The temperature of the sample was measured by a copper-constantan thermocouple placed 5 mm. apart from the sample.

Several species of cocoon produced by the Tokyo University of Agriculture and Technology were used as the samples which were hereditally different from each other. Measurements of the temperature dependence of the NMR spectrum were made for the species, Shuka×Ginrei. Samples of four species including two yellow, one white, and one red were measured at the room temperature. They have the genes as shown in Table II, and each of them was divided into two parts of the outer and the inner layers.

### Temperature Dependence of the Line Shape

Fig. 1 shows the results of the measurements for Shuka×Ginrei at different temperatures,

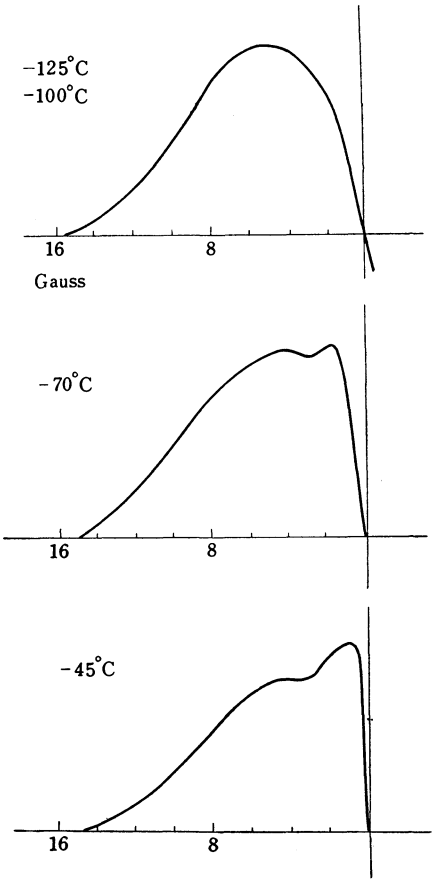

Fig. 1. Proton magnetic resonance in cocoon (species: Shuka×Ginrei). One half of the derivative of the absorption curve is presented as the function of temperature.

where a half of the derivative of each absorption curve is presented. It is noted in the figure that the observed spectrum shows a compound structure, and, moreover, that the relative intensity of the central peak with respect to that of the outer shoulder is much reduced at the lower temperatures, and not detectable at −100°C. The line widths of both the central- and the outer-peaks are not much changed by the temperature.

Besides the principal aminoacids of the silk fibroin, glycine (44%), alanine (26%), and tyrosine (13%), the native cocoon contains sericin. Hence, apart from the amido hydrogens, silk fibroin will contain approximately

36% of the protons in methylene groups, but also about 27% in methyl groups, and 36% in CH, OH, or aromatic positions.

Although one may interpret that the existence of a compound structure (as in the cases of polyethylene and polytetrafluoroethylene[4,5] does not necessarily imply that there are two separate regions differing in their degree of motion as proved for natural rubber[6], polymethylmethacrylate[7] and so on, however, we assume that the structure of the observed spectra is due to the net contribution of the protons in different phases, very motional and rigid, since the relative intensity of the central peak is so strongly temperature dependent, and its width is almost independent.

Table I gives the characteristic figures of the spectrum.

As the component I is observable even at −70°C, it can not be attributed to the sorbed water which might be existent in the sample. The line width of II is invariant with temperature over a range of about 130°C, and if our assumption on the structure of the line

TABLE I. NMR LINE WIDTH OF COCOON (SHUKA×GINREI)

| Component | Line width (in gauss) | | | |
|---|---|---|---|---|
| | <−100°C | −70°C | −45°C | 21°C |
| I(narrow) | (−) | (0.8) | 0.8 | 0.8 |
| II(broad) | 8.0 | 8.0 | 8.0 | 8.0 |

The value for I at −70°C was difficult to determine exactly, since its intensity was low.

shape is correct, this will suggest that the protons in this component are effectively rigid.

The second moments at $-100$ and $-125°C$, where no central peak was observale, were 26.8 and 26.1 gauss$^2$, respectively, and those at $-75°$, $-45°$ and $+21°C$ were 26.1, 24.3 and around 10 gauss$^2$, respectively, which could be explained by the variation of the relative intensities of I and II.

**Line Shapes for Different Species of Cocoon**

Measurements were made for the samples different in species. The results of the measurements were shown in Table II, where the results of the chemical analyses were also shown. Though there is not much difference either in the chemical composition or in the features of the NMR data, among the samples of different species, we notice that the behavior of saturation is different: Fig. 2 shows the normalized derivative curves for the samples, where no saturation effect is observed in the record of Pk, since the each half of the spectrum is completely symmetric with respect to the center of the base line, whereas, in Shuka×Ginrei, the intensity of the right-hand side half is strongly reduced.

Authors thank to Mr. Michio Horinouchi for his assistance in making measurements.

## *Separation of Uranium from Fission Products Using Cellulose*

By Noboru Oi

(Received August 16, 1960)

It has been previously known[1] that cellulose has the property of adsorbing metals such as rare earths from impure uranyl nitrate in ether-nitric acid mixture. We could separate uranium from fission products by dissolving uranyl nitrate in organic solvent and percolating the solution through a column of cellulose pulp. Almost all parts of fission products (99% or more) were retained on the cellulose, while uranyl nitrate passed unadsorbed.

Experimental procedure was as follows. A glass tube, 18 mm. in diameter and 10 cm. long, was packed with 1 g. of activated cellulose (100~200 mesh). Uranyl nitrate (1 g.) which includes fission products (about $10^6$~$10^8$ cpm) was dissolved in 5 ml. of the solvent and was transferred to the top of the column. After washing out uranium with further 25 ml. of the solvent, 30 ml. of 0.2 M nitric acid was passed to elute fission products. The activity of the combined organic solvent, nitric acid and the remained cellulose were analyzed by a $\gamma$-scintillation spectrometer.

Organic solvents suitable for this procedure were oxygen-containing compounds which dissolve uranyl nitrate but have small water-insolubility, perhaps less than 2%. Tri-*n*-butylphosphate was found to elute fission products.

The organic solvent was preferably used without nitric acid. Presence of nitric acid enhanced the elution of fission products, especially ruthenium. For example, from 1-month-cooled irradiated uranium, 1% of fission products were eluted by ethyl ether, while 4.5 and 6.6% were eluted by ethyl ether containing 3 and 5% nitric acid, respectively. In this case the ratio of eluted ruthenium was 1 : 18 : 27.

As regards the influence of water in this procedure, it was shown that fission products were eluted more by decreasing the water content of the system. For example, in the case of uranyl dihydrate, fission products were eluted about twice as much as that of uranyl trihydrate. This fact seems to indicate that this separation method resembles to ordinary liquid-liquid extraction. The cellulose seems to act as the water layer.

Behavior of various nuclides in this separation were as follows. Nuclides which were found to contaminate the organic solvent were mainly iodine, ruthenium and cesium. From these, ruthenium is most troublesome. It was eluted 1% by ethyl ether, 4% by *n*-butyl acetateand 20% by methyl isobutyl ketone. Elution of cesium ceases by lowering the initial uranium concentration. Result of the batch method showed that distribution ratio of cesium-137 between *n*-butyl acetate and the cellulose were 2.1 (1.0 M), 9.5 (0.5 M), 450 (0.1 M), and 6300 (0.0 M) in each uranium concentration written in the parentheses. Zirconium and niobium were eluted only to a small extent. Rare earths remained on cellulose.

Example of treatment of 1 g. of 100 days-cooled irradiated uranium are shown in the table. These results may also be improved by lengthening the column or lowering the initial uranium concentration in the solvent.

It seems that this method is also interesting for handling large amounts of irradiated uranium. In this method mass transfer of

1) F. H. Burstall and R. A. Wells, *Analyst*, 76, 396 (1951).

uranium between two different phases is not performed, so that the contamination of fission products is rather small. Moreover uranium can be easily recovered and fission products are condensed on the small amounts of cellulose.

TABLE

## *The Crystal Structure of Pyridine N-Oxide Hydrochloride and Hydrobromide*

By Yoshiyuki NAMBA, Tsutomu ODA, Hideo ITO and Tokunosuke WATANABE

(Received August 22, 1960)

Pyridine *N*-oxide has recently been a target of investigations by electronic and infrared absorption spectra[1] and by molecular orbital calculations[2], to elucidate its molecular symmetry, bond orders and electronic states, etc. In order to amplify informations about the molecular structure of this compound, the present authors have attempted an X-ray study of its hydrochloride and hydrobromide.

Hydrochloride and hydrobromide of pyridine *N*-oxide were prepared by adding hydrogen chloride or bromide gas to an alcoholic solution of pyridine *N*-oxide. Crystals of these salts were obtained by slow evapolation of alcoholic solutions. They are of a form of a short rod-like prism. The melting points were determined to be 181°C for the hydrochloride and 168°C for the hydrobromide.

No cleavage was observed with both crystals. As these crystals are hygroscopic, we employed a crystal enclosed in a thin-walled capillary made of borosilicate glass for X-ray analyses.

Oscillation and Weissenberg photographs taken with copper $K_\alpha$ radiation ($\lambda=1.54$ Å) indicate that the two crystals are isomorphous and belong to the orthorhombic system. The unit cell dimensions are: $a=11.06\pm0.02$ Å, $b=7.70\pm0.02$ Å, $c=7.25\pm0.02$ Å for the hydrochloride and $a=11.40\pm0.02$ Å, $b=7.87\pm0.02$ Å, $c=7.42\pm0.02$ Å for the hydrobromide. From the density values as determined by the flotation method, each unit cell is found to contain four chemical units. The systematic absences recognized were the $(h\,0\,0)$ reflections with $h$ odd, $(0\,k\,0)$ with $k$ odd and $(0\,0\,l)$ with $l$ odd. Hence the space group was uniquely determined to be $D_2^4$–$P2_12_12_1$. The intensities of $(h\,k\,0)$ and $(h\,0\,l)$ reflections were estimated visually by comparison with calibrated intensity scales, and they were corrected for Lorentz and polarization factors. Approximate temperature and scale factors were obtained by Wilson's method.

From the Patterson projections, $P(uv)$ and $P(uw)$, approximate positions for the halogen atoms were obtained. They are, $x=11/60$, $y=11/60$ and $z=0$. As it was clear that the hydrochloride was more suitable for obtaining atomic positions of light atoms, further analyses were made mainly with the hydrochloride.

A two-dimensional Fourier projection, $\rho(xz)$, was prepared for the hydrochloride using the structure factors whose signs were determined by the chlorine atoms. There appeared in this projection in addition to a predominant peak whose parameter values were those expected for the chlorine atom, a ring-like structure suggesting the location of the skeleton of pyridine *N*-oxide. We calculated the structure factors as a function of the rotation angle of the C···N—O axis of pyridine *N*-oxide within its plane and found that the C···N—O axis is almost parallel with the *c*-axis. In these calculations, we assumed for pyridine *N*-oxide a planar configuration having the symmetry $C_2-2$ with bond lengths, 1.4, 1.4 and 1.3 Å for the C—C, C—N and N—O bonds, respectively. The atomic scattering factors for the carbon, nitrogen and oxygen atoms were those taken from McWeeny's values. In determining the y-coordinates, there remained two possibilites for the orientation of the pyridine *N*-oxide plane referred to the $(0\,1\,0)$ plane. Structure factor calculations for $(h\,k\,0)$ reflections were carried out as a functions of the y-coordinate of the center of the pyridine ring, for the two orientations of its plane ($+30°$, $-30°$), and found a structure which explained fairly well lower order reflections.

1) M. Ito and N. Hata, This Bulletin, **28**, 260 353 (1955).
2) H. H. Jaffe, *J. Am. Chem. Soc.*, **76**, 3527 (1954); **77**, 4441, 4445, 4448, 4451 (1955); T. Kubota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 578 (1959).

Successive refinements were made. However, as the overlap of light atoms did not permit to give individual atomic coordinate accurately. Therefore an effort was made to improve the y-coordinate of each atom, using the least square method. The $\rho(xz)$ and $\rho(xy)$ are illustrated in Figs. 1 and 2. The atomic arrangement projected along the $c$ and $b$ axes are illustrated in Fig. 3.

The configuration of pyridine *N*-oxide is found to be almost planar. Each chlorine atom is surrounded by six pyridine *N*-oxide groups as neighbors. Namely, if we take a chlorine atom marked (A) in Fig. 3, the neighboring pyridine *N*-oxide groups are those designated by (1), (2), ···, (6). If we assume the pyridine *N*-oxide group behaves as a positive ion and the chlorine atom as an anion, as the results of proton transfer, the structure could be described as an ionic structure. However, the chlorine atom has one oxygen atom at a close distance 2.9 Å ((A)·····O atom of

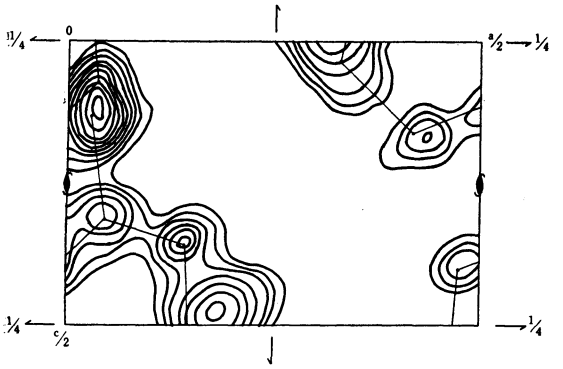

Fig. 1. Electron density map projected on *ac* plane. The intervals of contours for chlorine are twice as much as those for the other atoms.

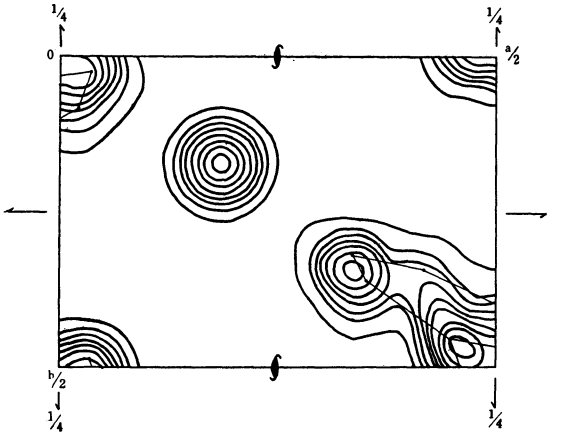

Fig. 2. Electron density map projected on *ab* plane. The intervals of contours for chlorine are twice as much as those for the other atoms.

pyridine *N*-oxide (2)) which suggests a strong interaction between these two atoms, presumably by a hydrogen bond, O—H···Cl. This point of view is supported by the investigation made by the infrared absorption spectra[3]. If this hydrogen bond is strong enough, pyridine *N*-oxide would form a dipolar molecule with hydrogen chloride, leading to a packing of dipolar molecules. The actual state may be just between two extremes.

We shall postpone discussing the precise configuration of the pyridine *N*-oxide molecule concerning to the electronic state of $\pi$ electrons involved in pyridine ring and those of oxygen atom, in conjugation with each other, untill three-dimensional analyses are made.

## *The Crystallization of "Allophane" under Hydrothermal Conditions*

By Mitsue KOIZUMI*, Ryôiti KIRIYAMA** and Wataru MURAYAMA**

(Received September 10, 1960)

Allophane, a hydrous silica-alumina mineral, is classified into mineral allophane, soil allophane and "precipitation allophane"[1] from their ways of occurrence. They are almost X-ray amorphous and show the similar thermal behavior characterized by mullite formation at 900~1000°C under atmospheric condition.

In hydrothermal synthesis experiments, crystallization of some amorphous materials, gels or glasses, occurs at fairly low temperatures. In such a condition, phase assemblages more stable than the reactants may easily be formed. An attempt has been made to observe structural differences of allophane and consequently to establish a picture of structural classification of X-ray amorphous minerals by applying the crystallization method under hydrothermal conditions.

The general procedure was to allow samples of allophane to react with water over the range 200~500°C at 1000 atm. $H_2O$ and then to quench into water. The type of pressure vessel used was of the "test-tube" bomb[2]. Running was made for two weeks at maximum. The products were then examined with an X-ray diffractometer.

Soil allophane from Kanuma[3] and Imaichi[4], mineral allophane from Bihoro[5] and precipitation allophane from Asama[6] and Fukazawa[7] were used for the experiment[8]. Synthetic silica-alumina gels prepared by the homogeneous precipitation method over the chemical composition range of $2SiO_2 \cdot Al_2O_3$-$SiO_2 \cdot 5Al_2O_3$ were kindly supplied for this investigation by

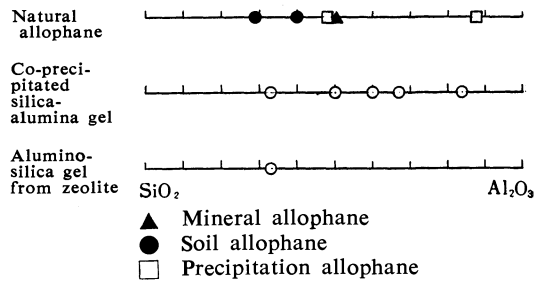

Fig. 1. The chemical composition of the starting materials.

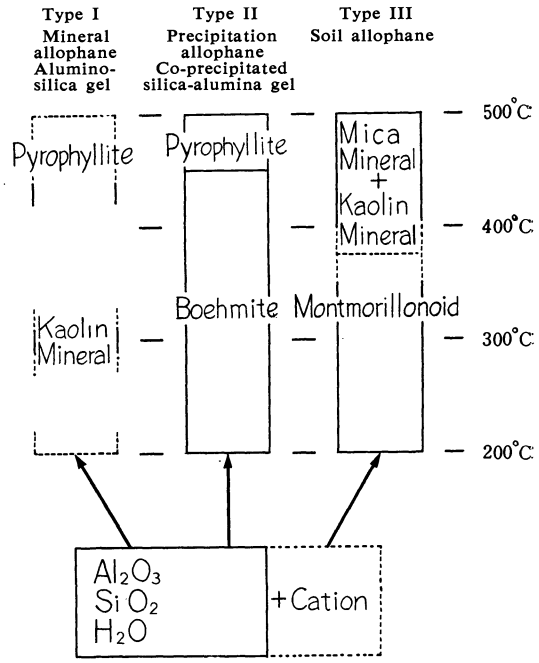

Fig. 2. Diagrammatic representation of phase assemblages obtained from the various starting materials.

Dr. J. Ossaka. The thermal properties of these gels has been studied by Ossaka and found to be identical with those of the natural allophanes[7]. The aluminosilica gel was also prepared from synthetic zeolite, Type A[9], by destructing the framework with hydrochloric acid and then washing sodium ion off with water. The mole ratios of $SiO_2/Al_2O_3$ of these starting materials are illustrated in Fig. 1.

The experimental results are summarized diagrammatically in Fig. 2. Owing to the poor crystallinity of the products, the prcise phase determination was somewhat difficult for several specimens. As indicated in Fig. 2, the crystallization process of the starting materials in this investigation are classified into the following types.

Type I: From the materials of this type, a kaolin mineral was formed at 300°C, and then pyrophyllite was obtained at 430°C. The mineral allophane and the aluminosilica gel appeared to crystallize in this manner.

Type II: The two samples of precipitation allophane and all the co-precipitated silica-alumina gels with various compositions were classified into this type. It should be noted that, from these samples, only a boehmite phase appeared in the temperature range between 200 and 450°C and above 450°C pyrophyllite was formed.

Type III: The three samples of soil allophane yielded a montmorillonoid phase in the region from 200 to 350°C. The (0 0 1) spacing was 15 Å and expanded to 18 Å when treated with glycol. Above 400°C, a mica and a kaolin mineral were obtained together.

Important factors controlling what phases crystallize from the amorphous minerals may be considered to involve (i) $SiO_2/Al_2O_3$ ratio, (ii) impurity cations and (iii) the gel structure. It is probably possible to remove $SiO_2/Al_2O_3$ ratio out of the major factors on the following basis. Each of the three specimens with the almost same ratio of 2:1, including aluminosilica gel, soil allophane and one of co-precipitated silica-alumina gels, gave a product of its own phase. Such was the case also with mineral allophane, precipitation allophane and co-precipitated gel of the same $SiO_2/Al_2O_3$ ratio of 1:1. The products of type III were obtained only from soil allophane. It is considered that their formation may be effected by the presence of a considerable amount of cation impurities which have been contained in every soil allophane. On the contrary, all the starting materials of the types I and II are chemically free from any cations. It is thus reasonable to assume that gel structure plays a role in deciding the product from the starting materials of the similar chemical composition.

From the preparation method previously mentioned, it is suggested that the co-precipitated gels are homogeneous mixtures of the two species of gel particles, silica and alumina, finely dispersed in each other. This concept is supported by the experimental result that the materials of the type II do not yield an aluminosilicate phase but an alumina mineral, boehmite, in the lower temperature range. Thus the precipitation allophane is possibly considered to be structurally identical with the co-precipitated gel.

Mineral allophane showed the same crystallization behavior with an aluminosilica gel prepared from the zeolite. It is obvious, therefore, the mineral allophane is probably an aluminosilicate with four-coordinated aluminum.

As it is well known, our present knowledge is insufficient to discuss the gel structure precisely. From the above results, however, we may now recommend that study on crystallization under hydrothermal conditions will be applicable to deduce a structure of X-ray amorphous mineral. In this way natural allophane of this investigation can be classified into three groups.

The detailed description of this work will be given elsewhere in near future.

## *Hot-atom Chemistry of Radiocobalt in Nitroammine Cobalt Complex Salts**

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO

(Received September 10, 1960)

The present authors had previously reported[1,2] that radiobromine recoil atoms arising from thermal neutron capture in outer anions of various cobaltammine bromides could substitute in the cobalt coordination sphere to form $^{80m}$Br- or $^{82}$Br-labeled complex cations. In this investigation they found that outer anions of nitroammine cobalt(III) nitrates and nitrites could replace ligand $NH_3$ groups in the radiocobalt coordination sphere when cobalt atom was activated by slow neutron bombardment.

Seven kinds of crystalline complex salts listed in Table I were irradiated in an experimental hole in JRR-1 reactor for one to six hours at pile temperature. Thermal neutron flux was approximately $3\times10^{11}$ n/cm$^2$ sec. After standing for one day at room temperature, the irradiated salts were dissolved in water and $^{60}$Co-labeled species were separated by procedures involving paper electrophoresis[3], paper chromatography[4],

| $[Co(NH_3)_3(NO_2)_3]$ | ~0 | ~0 | 0.5 | 55 | ~0 | 44 | 0 |

* "A" denotes an $NH_3$ group in most cases. However, it is possible that small amounts of species with one or two of A's being $H_2O$ may also be present in some cases.

** $R = \frac{\text{Percentage of labeled species containing one more anionic ligand than the target complex}}{\text{Percentage of labeled species containing the same number of anionic ligands as the target complex}}$

ion exchange, or precipitation. The results are summarized in Table I.

As shown in Table I, substitution of ligand $NH_3$ groups by outer anions ($NO_2^-$ or $NO_3^-$) was observed** in most complex salts whenever the substitution product was considerably stable in aqueous solutions. On the contrary, labeled complexes containing less anions in ligands than the target complex were not found in practice after dissolution of almost all the irradiated salts. The factor, *R*, in Table I is the ratio of percentage of labeled species containing one more anionic ligand than the target complex to percentage of labeled species containing the same number of anionic ligands as the target complex. It is interesting that this ratio increases with the increase in electric charge on the target complex ion, or with the increase in number of neighboring outer anions. The results may be generally explained by assuming the electrostatic interaction between the outer anions and the complex ions fragmented more or less during recoil reactions.

It is worth mentioning that cis-trans isomerization of dinitrotetrammine complexes occurs during recoil processes. Cis isomer was found with an enrichment factor of 23±5 in the irradiated *trans*-$[Co(NH_3)_4(NO_2)_2](NO_3)$, while trans isomer with an enrichment factor of 80±10 in the irradiated cis salt.

# *The Electron Spin Resonance Absorption of Molecular Addition Compounds*

By Hiroo INOKUCHI, Kunihiko IKEDA* and Hideo AKAMATU

(Received September 12, 1960)

Recently, a number of molecular complexes formed between electron donors and acceptors have been investigated by the method of electron spin resonance (ESR) and also by the measurement of electrical conductivity[1-3]. On the molecular complexes formed between phenylene diamines and halogenated quinones, Bijl, Kainer and Rose-Innes[3] and also Matsunaga and McDowell[4] reported the existence of unpaired electrons in those complexes. However, it has been found that the observed intensity of ESR absorption fluctuate from specimen to specimen.

In this report, we present the electron spin resonance absorption of the molecular complexes, formed between dimethyl-aniline (I, DMA; liquid) and halogenated benzoquinones (II, *x*-anils) and of those between also tetramethyl-*p*-phenylene diamine (III, TMPD) and *x*-anils as a function of time.

* Observed with freshly prepared specimen.
† Observed with specimen left for 40 days in air.
** Maximum value.

These complexes were made as follows: 50 mg. of purified $x$-anil were dissolved in 5 cc. of DMA, and one-fifth of its volume of ethanol was added into the solution to precipitate the deep colored molecular complex. After filtration, crystals of the complex were sealed up immediately into glass tubings (diameter 2 mm.) under an atmosphere of argon or oxygen. In the case of TMPD-$x$-anil complexes, the solutions of TMPD and of $x$-anil in benzene were mixed with each other to produce the precipitate of the complex. The precipitate was filtered and washed with a small amount of benzene and of ether successively. These complexes were also kept in glass tubings to prevent a decomposition of TMPD by humidity.

The electron spin resonance absorption spectra of these complexes were observed in association with $x$-band microwave spectrometer, Hitachi MPS-1. The spin concentrations in these complexes were measured in comparison with a standard piece of $\alpha,\alpha'$-diphenyl-$\beta$-picrylhydrazyl or 'violanthrone'*. The $g$-values of these complexes possessed near 2.0 and was estimated from the value of ultramarine which is 2.028.

As illustrated in Table I, it was found that DMA-$x$-anil complexes, for which Bijl et al.[3] observed no ESR signals possess definite ESR absorption around $g=2.0$. This fluctuation of intensity of ESR absorption may depend upon preparation techniques of these complexes. The study of $g$-values of DMA-chloranil and also of DMA-iodoanil, which are fairly smaller than the value of free electron itself ($g=2.0023$), is a noteworthy problem.

In the case of TMPD-$x$-anil molecular complexes (Table I), the spin concentrations changed strongly with great regard to the time after preparation as shown in Fig. 1 for TMPD-bromanil. However, the atmospheric gases surrounding the complexes were not so sensitive to the spin concentration of the complexes excepting TMPD-chloranil.

The ESR absorption curve of TMPD-bromanil complex also changed violently with time in its shape. At first, two ESR absorption peaks, their $g$-values were 2.0030 and 2.0043 respectively, were observed for freshly prepared specimen (curve A of Fig. 2). After a couple of days, a new absorption peak appeared (curve B). However, during a next few days, two of them disappeared and only one ESR absorption peak having $g=2.0043\pm0.0004$ remained (curve C). Through a long period observation, the line width of the

■ in air, □ in argon

* Crude violanthrone comprises a small amount of free radicals. This compound can be applied as a substandard piece for the estimation of spin concentration because the free radical is stabilized in the matrix, violanthrone.

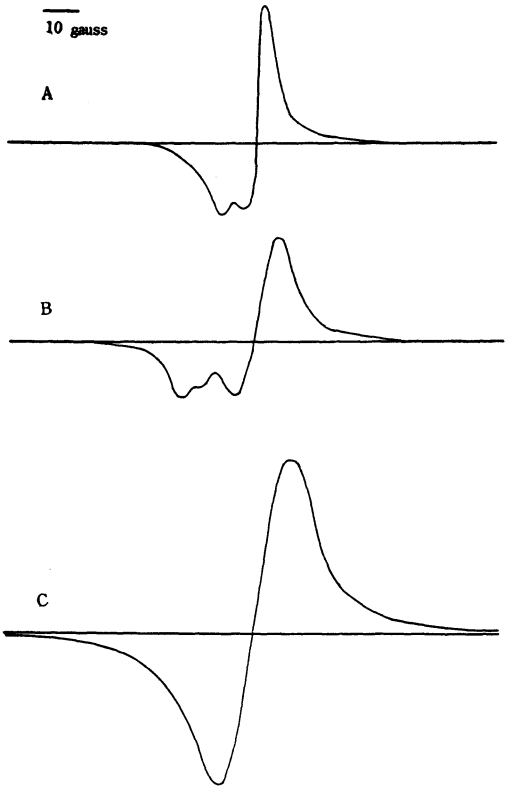

Fig. 2. The derivative curves of electron spin resonance absorption of tetramethyl-*p*-phenylene diamine-bromanil complex in air: (A) for fresh specimen, (B) and (C) for specimen which is exposed in air for 2 days and also for 4 days respectively.

absorption curve was spread from 12~13 gauss to 50 gauss (120 days after preparation).

It seems likely that these changes of spin concentrations and also line widths with time are introduced from the progress of complex formation and/or decomposition of these addition compounds.

# *Detection of End-groups in Polyacrylonitrile by Differential Infrared Spectroscopy*

By Ikuo MATSUBARA

(Received September 19, 1960)

The differential infrared spectroscopy, which is useful for the identification or quantitative estimation of minor constituents in organic substances[1], has been applied to the detection of the end-groups in polyacrylonitrile. As O'Connor et al.[2] have described, the infrared measurements of polymers can be successfully performed with the potassium bromide disk technique, particularly when the samples are obtained in the form of a fine powder or fibers. In the present study the differential analyses of polymers have been carried out with success in combination with the potassium bromide disk technique.

Fig. 1 shows the infrared spectra obtained from the potassium bromide disks of some different polyacrylonitrile samples. The disks were prepared from the mixtures of 400 mg. of potassium bromide and 4 mg. of the sample material, both screened through 250-mesh stainless-steel cloth, by applying a pressure of 8 tons for 10 min. in the evacuated die mount. The infrared spectra were obtained using a Perkin-Elmer model 21 spectrophotometer (with NaCl optics). Samples A and B are polyacrylonitriles of different degrees of polymerization ($\bar{M}_n$=49500 and 11000, respectively)*, both being polymerized by using ammonium persulfate-sodium bisulfite redox system as initiator. Sample C is one polymerized using azo-bis-isobutyronitrile as initiator ($\bar{M}_n$=7000). By inspection of the spectra of samples A and B it has been found that the intensities of the weak shoulder band at 1041 $cm^{-1}$ and the one around 1200 $cm^{-1}$ increase remarkably with the lowering of the degree of polymerization. On the contrary, as is evident from the spectrum of sample C, no such absorption bands of variable intensities are observable at the corresponding frequencies in the case of polyacrylonitrile polymerized using azo-bis-isobutyronitrile as initiator, while the situation is the same for the sample obtained by $\gamma$-ray initiated polymerization. Therefore, it seems that these bands are characteristic of the polymer obtained

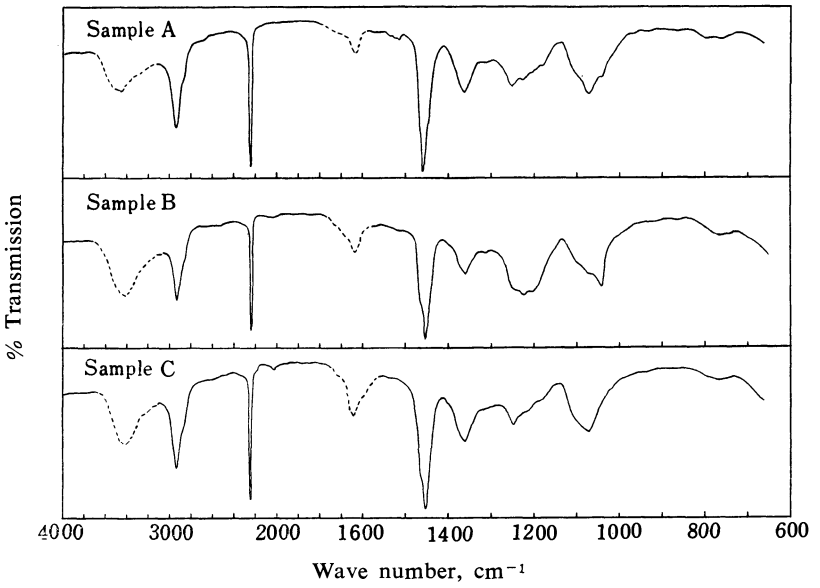

Fig. 1. Infrared spectra of some polyacrylonitriles. Sample A and B were polymerized using ammonium persulfate-sodium bisulfite redox system as initiator ($\overline{M}_n$=49500 and 11000, respectively). Sample C was polymerized using azo-bis-isobutyronitrile as initiator ($\overline{M}_n$=7000). (Dashed lines indicate the absorptions due to water adsorbed by potassium bromide).

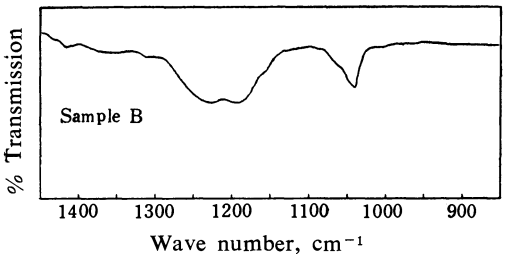

Fig. 2. Differential spectrum of polyacrylonitrile sample B (initiator=ammonium persulfate-sodium bisulfite redox system) against sample C (initiator=azo-bis-isobutyronitrile).

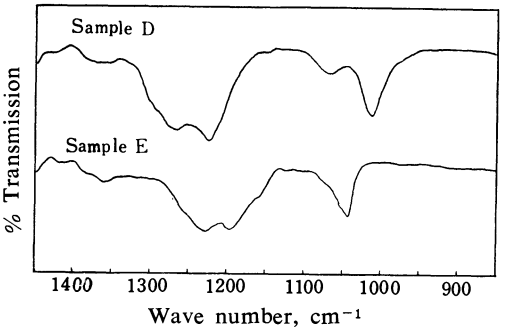

Fig. 3. Differential spectra of polyacrylonitrile sample D (initiator=ammonium persulfate, $\overline{M}_n$=9600) and sample E (initiator=$Fe^{3+}$-sodium bisulfite redox system, $\overline{M}_n$=30300) against sample C (initiator=azo-bis-isobutyronitrile).

using persulfate-bisulfite redox system as initiator. In order to make clear the nature of these bands, the differential method has been applied, in which the disk containing sample B is put in the sample beam of the spectrometer and the absorption bands due to polyacrylonitrile proper are cancelled out by placing the disk containing sample C in the reference beam. The differential spectrum is shown in Fig. 2, in which two independent bands have been separated; one at 1041 $cm^{-1}$ and a doublet with peaks at 1227 and 1190 $cm^{-1}$. It has been predicted from the analyses by tracer methods[3] that, when the persulfate-bisulfite redox system is usedto initiate polymerization, both sulfate and sulfonate end-groups may be introduced into the polymer, and these groups are expected to show characteristic absorptions in the 1200~1000 $cm^{-1}$ region[4]. Therefore, the above two bands are suspected to be due either to the sulfate or sulfonate end-groups. To clarify this point further, two other polyacrylonitrile samples have been examined by the differential method. Sample D was polymerized using ammonium persulfate as initiator ($\overline{M}_n$=9600), and it is expected that the sulfate end-groups

3) Y. Tsuda, *J. Appl. Polymer Sci.*, in press.

4) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules", 2nd Ed., Methuen & Co., Ltd., London (1958), Chapt. 22.

alone may be incorporated in this polymer. Sample E was polymerized using $Fe^{3+}$-sodium bisulfite redox system as initiator ($\overline{M}_n$= 30300), so that the polymer may contain only the sulfonate end-groups. Fig. 3 shows the results of the differential measurements, in which the absorptions due to polyacrylonitrile have been cancelled out by placing sample C in the reference beam. In complete agreement with expectation, the spectrum of sample D corresponds well to those of aliphatic sulfates ($R-O-SO_3^-$), and we may ascribe the doublet with peaks at 1264 and 1224 $cm^{-1}$ to the S-O degenerate stretching vibration, the band at 1065 $cm^{-1}$ to the S-O symmetric stretching vibration of the sulfate ion, while the band at 1011 $cm^{-1}$ may be ascribed to the C-O stretching vibration. In the same way, the spectrum of sample E agrees well with those of aliphatic sulfonates ($R-SO_3^-$)[5], and the doublet with peaks at 1225 and 1195 $cm^{-1}$ may be assigned to the S-O degenerate stretching vibration and the band at 1041 $cm^{-1}$ to the S-O symmetric stretching vibration of the sulfonate ion. Liang and Krimm[6] have reported that there exists a weak shoulder band at 1044 $cm^{-1}$ in the spectrum of polyacrylonitrile and assigned this to a combination or overtone of some skeletal deformation vibrations of this molecule. Although they have not made mention of the initiator by which their polyacrylonitrile sample has been polymerized, it seems quite probable from the above results that this band corresponds to the vibration of the sulfonate end-groups. It is to be wondered why the spectrum of sample B, in which both sulfate and sulfonate end-groups are expected to exist, almost completely agrees with that of sample E and the absorptions due to sulfate end-groups are hardly observable. According to Tsuda's results[3], however, in the polymerization initiated by persulfate-bisulfite redox system the ratio of the concentrations of the sulfate and the sulfonate end-groups produced varies depending on the initial concentrations of the salts and of the acrylonitrile monomer, so that the relative intensities of the absorption bands due to these groups may vary from sample to sample. Therefore, it seems not improbable that the sulfonate end-groups are predominant in the case of sample B.

Quantitative estimations of the end-groups by the differential method were also carried out using the polymers of known end-group contents, and the limit of detectability of both sulfate and sulfonate end-groups by this method is estimated to be about 0.002 millimol./g. polymer.

# *Proton Magnetic Resonance Studies on the Thermally Dehydrated Products of Alumina Trihydrate*

By Tatsuo SAITO*

(Received September 21, 1960)

In our previous communication[1], the thermal decomposition of alumina trihydrate was studied from the change of line shapes of proton magnetic resonance absorption in the thermally dehydrated products. In the present communication, the phase transformations accompanied with the thermal dehydration process of alumina trihydrate have been studied from the variation of second moments of the resonance lines in dehydrated products.

The starting material, bayerite, and the detecting apparatus here employed were the same as those used in the previous experiments[1]. The specimens used for the NMR measurements were prepared from this bayerite by the thermal dehydration at 100~800°C which was carried out for 3 hr. in the air. Each specimen was sealed into an evacuated glass tube which was pumped out to a high vacuum at 110°C for 6 hr.

The variation of the second moments calculated from the experimental derivative curves are shown in Fig. 1 as the function of the temperature. Below 220°C, the second moment was 13~14 gauss$^2$ showing no significant change with the temperature. However, in the range from 220 to 400°C the second moment

* Present address, Government Chemical Industrial Research Institute, Tokyo, Honchō 1-Chome, Shibuya-ku, Tokyo.

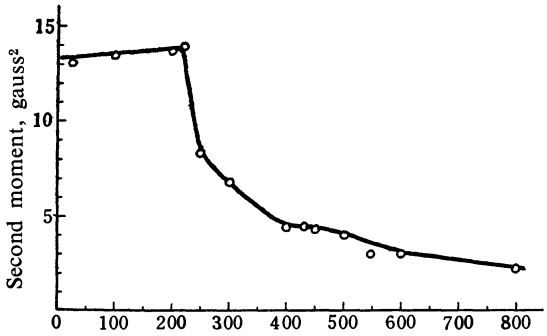

Fig. 1. Variation of the second moments with the temperature in dehydrated products of the starting material.

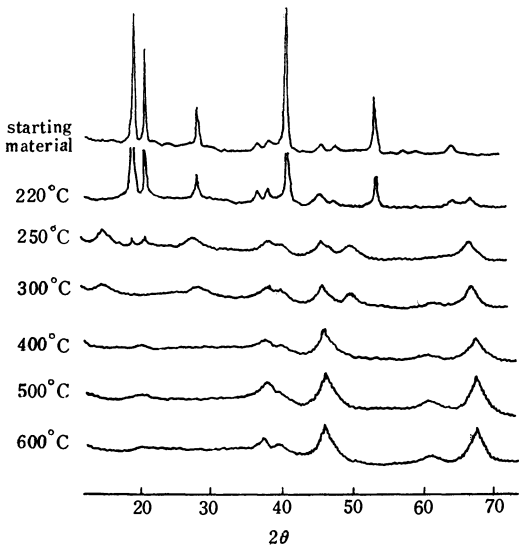

Fig. 2. X-ray diffraction diagrams of the samples dehydrated at various temperatures.

decreases gradually with the rise of temperature, and then at about 400°C the second moment becomes roughly stationary value of 4~5 gauss$^2$. Above 550°C the second moment gradually decreases again.

The above variation of second moments is interpreted as follows:

1) The sudden decrease of second moment at about 220°C seems to show the phase transition from the starting material to the hydrous alumina which has a low value of second moment.

2) The gradual decrease of second moments with the rise of temperature in the range from about 250 to 400°C could be regarded as a result due to the change of mixing ratio of the aluminum hydroxide-hydrous alumina phase.

3) The roughly stationary values of 4~5 gauss$^2$ at about 400~500°C seem to show the phase of hydrous alumina.

The X-ray diffraction study of the compounds was also done. The diffraction diagrams of several specimens which were obtained from this study are shown in Fig. 2. From these diagrams, it is ascertained that the specimens below 220°C having the value of 13~14 gauss$^2$ are crystallographically the same as the starting material, bayerite, and that each specimen at 250° and 300°C shows the diagram of mixed phase of böhmite and $\eta$-alumina, but that the specimens at about 400~500°C having the value of 4~5 gauss$^2$—which are explained to be hydrous alumina—are $\eta$-alumina[2].

It is interesting to note that the transition temperatures of 220 and 400°C are obtained from the variation curve of second moment showing in Fig. 1, while each transition temperature coincides with that of phase transformations obtained from X-ray diffraction studies, respectively.

The author wishes to express his hearty thanks to Professor Tokutaro Hagiwara for his kind direction and also wishes to express his sincere thanks to Professor Tunahiko Shidei and Dr. Syukuro Yano in Kyoto University for their continual guidance and encouragement throughout this study.

## *The Oxygen Effect on Electronic Properties of α, α'-Diphenyl-β-picrylhydrazyl*

By Hiroo INOKUCHI and Minoru KINOSHITA

(Received September 21, 1960)

There is one unpaired electron in each molecule of $\alpha, \alpha'$-diphenyl-$\beta$-picrylhydrazyl. In the study of unpaired spin by means of the method of electron spin resonance (ESR), thereby, this free radical ($g=2.0036\pm0.0003$) is widely used as a standard for estimation of the spin population and also the $g$-value of the applied specimen. However, it has been already known that the ESR absorption spectrum of free radical changes strongly under the influence

of gaseous oxygen[1-3]. Further, the existence of stable addition compound between $\alpha, \alpha'$-diphenyl-$\beta$-picrylhydrazyl and a organic solvent*, such as benzene, cyclohexane or ether, has been reported frequently[4]. In this brief report, we are presenting the effects of oxygen on the spin population and also on the electronic conduction of $\alpha, \alpha'$-diphenyl-$\beta$-picrylhydrazyl itself.

The observation of ESR absorption spectra was carried out at room temperature with association of Hitachi MPS-1 type x-band spectrometer. This prime free radical was made from $\alpha, \alpha'$-diphenyl-$\beta$-picrylhydrazine by oxidation with $PbO_2$ in ether. The dependence of the line width and of the intensity of ESR absorption spectra on the three different samples have been observed. One of them, recrystallized from carbon disulfide solution, was a solvent free powdered sample (D.P.P.H.-Free). The second sample was a large single crystal (1.3 mg.) grown from carbon disulfide solution (D.P.P.H.-Single) and the third sample was deposited from ether solution (D.P.P.H.-Ether).

We found that the spin populations in these samples, keeping in vacuo, were coincident with each other as shown in Table I. When these materials were exposed to air, the line width of ESR spectrum of D.P.P.H.-Free was spread remarkably. However, no change of the integrated intensity of ESR absorptions was found practically in spite of broadening of their line widths. These results indicate that the interaction between $\alpha, \alpha'$-diphenyl-$\beta$-picrylhydrazyl and applied solvent or gaseous oxygen is physical instead of chemical one.

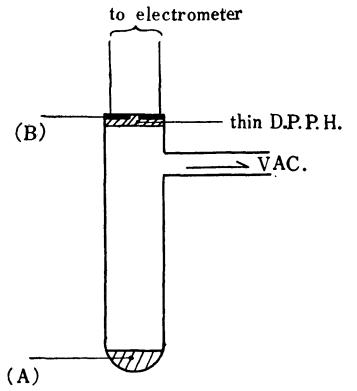

Fig. 1.

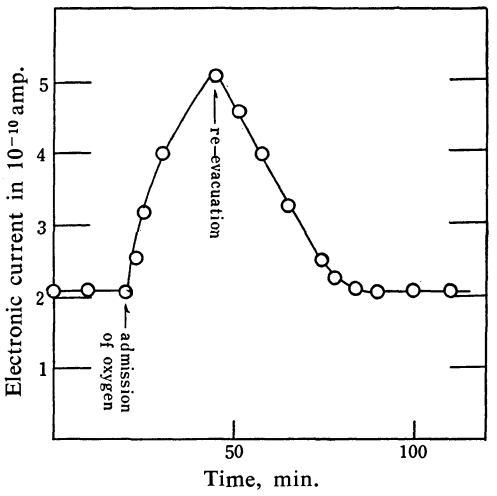

Fig. 2.

We also observed the oxygen effect on the electric conduction of thin D.P.P.H. film. The D.P.P.H. crystal to be evaporated was placed on the bottom (A) of glass vessel as shown in Fig. 1. By heating the vessel, the free radical was evaporated in vacuo to form a continuous thin film inside the top of vessel (B) between the two graphite (colloidal) electrodes. The resistance of this thin film

* No addition compound between D.P.P.H. and carbon disulfide is found.
4) J. A. Lyons and W. F. Watson, *J. Polymer Sci.*, **16**, 141 (1955).

was observed with association of a vibration-reed electrometer. The admission of oxygen into the vessel caused a marked increase of conduction of the film. However, this effect was reversible as on pumping out the oxygen, then, the resistance of the cell returned to its original value. One of these behaviors is illustrated in Fig. 2. These behaviour also suggests that the interaction between D.P.P.H. and oxygen is almostly phyical. The detail of this work may be submitted in elsewhere.

One of the present authors has already found that the absence of the hydrogen deuterium reaction at the surface of the D.P.P.H. crystals shows that the unpaired electrons in the molecules react with adsorbed hydrogens physically[5].

From these observations, the integrated intensity of ESR absorption of D.P.P.H. is independent on the conditions of preparation and also on the exposing time in the air. Therefore, we can conclude that various sorts of the D.P.P.H. crystals are applied as a standard to estimate the spin population of paramagnetic materials.

The authors express their hearty thanks to Professor H. Akamatu for his direction of this study.

# *The Distribution of Recoil Tritium in Benzoic Acid*

By Jiro OKAMOTO

(Received September 13, 1960)

Recently, so-called "Recoil labeling" by tritium has been developed in various organic compounds[1,2]. It is a interesting problem to study replacement of hydrogen at various positions of an aromatic ring by recoil tritium. However this has not been reported by far. Therefore, the author investigated the distribution of recoil tritium produced by $^{6}Li(n, \alpha)^{3}H$ reaction in benzoic acid and found the interesting facts as follows. The mixture of benzoic acid and lithium carbonate as tritium source was sealed in a quartz ampoule, in the presence of air. The irradiation was carried out in No. 15 hole of JRR-I for 15 hr. at $2\times10^{11}$ n/cm$^2$ sec. The irradiated material was dissolved in 150 ml. of pure benzene, then 10 g. of pure benzoic acid was added into the solution as carrier. This solution was refluxed for one hour and was immediately filtered to separate insoluble material from the solution, and then benzene solution was evaporated in vacuo and the crystal was dissolved in hot water to remove the labile tritium of the carboxyl group. A liquid scintillation detector (Tracerlab Model CE-1) was used to assay tritium. High voltage of the instrument was chosen at 1700 V. and temperature was kept at $-10°$C.

An outline of the procedures are shown in Fig. 1. The specific activities of the various

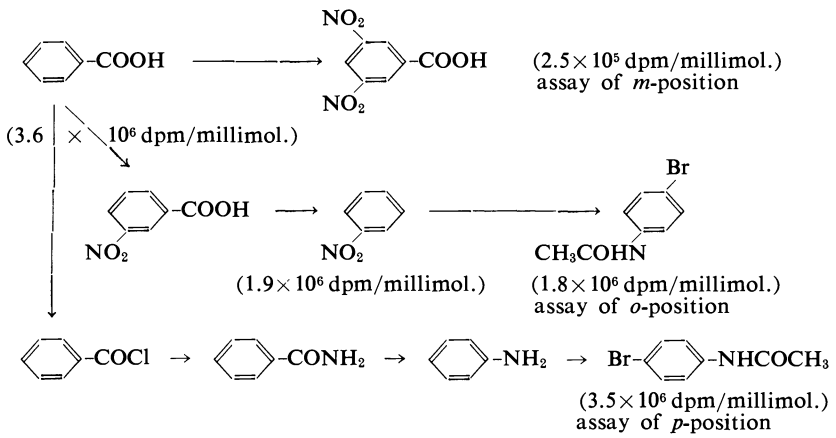

Fig. 1. Derivative and specific activities.

2) F. S. Rowland and R. Wolfgang, *Nucleonics*, **14**, (8) 58 (1956).

compounds which were derived from the irradiated benzoic acid are also shown in Fig. 1. From these results, the percentage of ortho-, meta- and para-positions were determined. In Fig. 2, the values are shown. As is seen in Fig. 2, the replacement of hydrogen at meta-position by recoil tritium is dominant. Therefore, from the replacement process of recoil tritium in the solid phase in this experiment, it is inferred that tritium reacts after being thermalized. Ivanoff[3] stated that in the

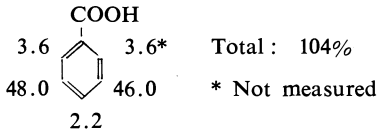

Fig. 2. Distribution of tritium in benzoic acid.

liquid phase, recoil bromine reacts with an aromatic ring after being thermalized. This resulte may support the present author's opinion on the mechanism of replacement reaction of recoil tritium in the solid phase. The furthermore details are to be published later.

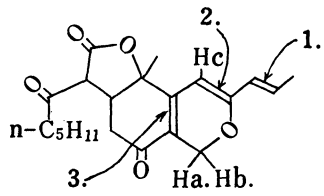
## *Monascoflavin**



By Mamoru OHASHI, Shosuke YAMAMURA, Akira TERAHARA and Koji NAKANISHI

(Received October 6, 1960)

Structure Ia[1] was forwarded as a working hypothesis for monascoflavin[2-4], $C_{21}H_{26}O_5$, $[\alpha]_{700}^{16}+418$ ($c$: 0.0062 in ethanol), plain positive RD curve, one active hydrogen, three C-$CH_3$, no OH and $OCH_3$. However, the NMR spectra[5], especially the AB type quartet around 140 cps (vs. chloroform, at 56.4 Mc) arising from two protons in monascoflavin and dihydromonascoflavin could not be satisfactorily accounted for by the structure. Further studies on new derivatives, corrections of the molecular formula of hydrogenated products, a re-interpretation of the NMR spectra, and considerations of the biogenetic relations with monascorubrin[6] have led to structure I (or Ib). The mentioned quartet is now comfortably assigned to the methylene protons Ha and Hb. Some pertinent compounds are listed in Table I. The dihydro (II), tetrahydro (III) and hexahydro (IV) derivatives are those in which the double bonds (1), (2) and (3) in I have successively been hydrogenated. The 116 cps peak in I and

Ia

I

II is absent in III and IV, and the peak can be assigned to Hc. Presence of the $n$-$C_5H_{11}CO$ side-chain was shown by the production of capronic acid upon ozonolysis, oxidation with potassium permanganate, or fusion with potassium hydroxide, and production of amylamine upon Beckmann rearrangement of the oxime and hydrolysis. The lactone ring is cleaved and amides are formed, though sluggishly, when monascoflavin and hydrogenated products are treated with various amines, i. e., tetrahydromonascoflavin hexyl amide (V, R=$C_6H_{13}$). The amides, unlike the starting materials, no more showed the appearance or intensification of a ca. 288 m$\mu$ peak upon addition of base, and thus an enolizable $\beta$-keto-$\gamma$-lactone moiety is present in monascoflavin. Compound V (R=H) did not consume lead tetraacetate and this suggested it was not

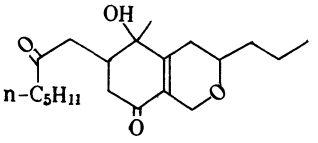
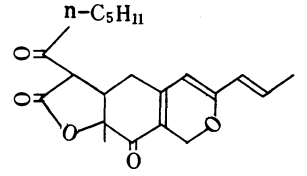
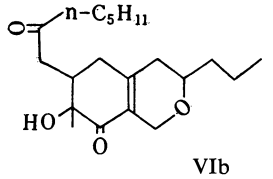
a) Abbreviation for monascoflavin.
b) Tetra- and hexahydromonascoflavin were formulated as the hexa- and octahydro derivatives, respectively, in reference 5.
c) The difference with the calculated $\lambda_{max}$ of 249 m$\mu$ is presumably caused by a transannular effect of the oxygenic *p* electrons on the $\alpha\beta$-unsaturated system. A similar effect has been reported for nitrogen: A. Marchant and A. R. Pinder, *J. Chem. Soc.*, **1956**, 327.
d) This unusually high $\nu_{C=O}$ value for a six-membered ring ketone is due to ring strain imposed by the $\gamma$-lactone. A similar effect is observed when the 1703 $cm^{-1}$ band in III is compared with the 1668 $cm^{-1}$ band in VI.
e) Amide I and II bands at 1665 and 1520 $cm^{-1}$, respectively.



V



VII



an $\alpha$-ketol. Ozonolysis of I and II gave acetaldehyde and butyric acid, respectively, while base hydrolysis of I and II gave crotonic acid and butyric acid, respectively. These results show that a propenyl side-chain is attached to the $\alpha$-position of the pyran ring and that it should be conjugated with the $\alpha$, $\beta$-unsaturated carbonyl group (to permit the occurrence of a vinylogous $\beta$-diketone cleavage). The conspicuous methyl peak at 330 cps in I remains constant and uncoupled in II-IV[5], and the position is lower than ordinary methyl peaks by ca. 30 cps. This, coupled with the production of methylglyoxal from the ozonolysis of I places a methyl group on a tertiary carbon atom bearing a oxygenic function (the lactone ring). Tetrabromomonascoflavin (VII) has no active hydrogen. Furthermore, the +17 $cm^{-1}$ shift of the 1673 $cm^{-1}$ band of I suggests that the $\alpha$-position of the $\alpha$, $\beta$-unsaturated carbonyl group must be substituted by an equatorial bromine. Boiling III in 20% alkali under nitrogen yielded VI. The facts mentioned are best explained by structure I.

VI

Ib

VIb

The alternative structure Ib is also conceivable

but it is difficult to account for the 1690 $cm^{-1}$ band in tetrabromo-monascoflavin and the non-consumption of lead tetraacetate by V(R=H). However, Ib is the conclusion reached by English chemists[7] who base their conclusion on analogies with other azaphilones, e.g., monascorubrin[8], the structure of which also differs from that of the present authors[6,9], and the fact that nortetrahydromonascoflavin (VIb instead of VI) consumed periodic acid with the production of a methyl ketone. These inconsistencies will be settled in the near future.

We are grateful to Professor E. Nishikawa, formerly of Nagoya University, for an abundant supply of starting material and suggestions.

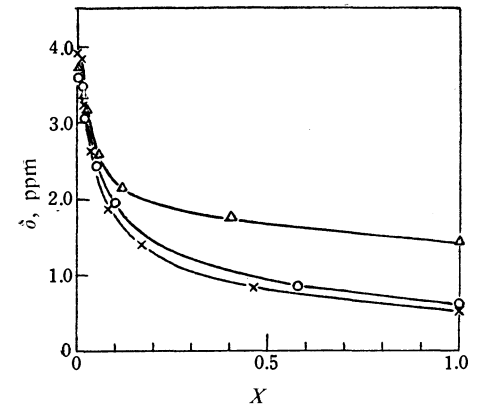
By Michinori Ōki and Hiizu Iwamura

(Received October 8, 1960)

It has been shown through infrared studies[1] that the intramolecular interaction between hydroxyl groups and π-electrons shifts the O–H stretching vibration ($\nu_{O-H}$) to lower frequencies in comparison with an ordinary hydrogn bonding. In connection with recent high resolution nuclear magnetic resonance spectroscopy which has successfully been applied to the study of hydrogen bonding[2], variation of the proton resonance of some alcohols with concentration changes in carbon tetrachloride was studied in order to detect any effect of the aforementioned interaction to the NMR spectra, which must give rise to a different magnetic shielding of hydroxylic proton of the interacting form from that of the free one.

A Varian model V-4300 high resolution NMR spectrometer was operated at 56.4 Mc/sec. Samples include *tert*-amyl alcohol, allyldimethylcarbinol, benzyldimethylcarbinol and tribenzylcarbinol. Preparations and purities of the samples are specified in the preceding paper[1]. Measurements were carried out at 20°C, the samples being dissolved in a given amount of carbon tetrachloride and sealed in glass tubes with the outer diameter of 5 mm. The magnetic field was swept twice in both decreasing and increasing directions and the average of the records of both directions of the sweep taken. The calibration of the sweep rate was made by recording the spectrum of toluene and by reading the separation of the two peaks as 4.90 ppm[3]. The chemical shift ($\delta$) was referred to water as an external standard and corrected for bulk diamagnetic susceptibilities of *tert*-amyl alcohol, allyldimethylcarbinol and benzyldimethylcarbinol, $-\chi_v \times 10^6$ being 0.644, 0.585 and 0.696[4], respectively.



While the absorption lines assigned to hydrogen attached to carbon atom shifted less than 0.5 ppm from thet pure liquid to the sample at infinite dilution, that of hydroxyl proton showed a marked concentration dependence as shown in Figs. 1 and 2. On dilution, the chemical shifts gradually moved to higher magnetic field and at about 0.02 mol. fraction a reversal of the curvature was observed with three carbinols. This phenomenon is understood to be characteristic of a system consisting of monomer, dimer and high polymer[2a]. Tribenzylcarbinol showed, unlike these, no association pattern within the measured concentration range. The curves were extrapolated to infinite dilution and the chemical shifts of pure monomers obtained. Under these conditions, *tert*-amyl alcohol is quite free from association and tribenzylcarbinol possesses only

the hydroxyl group which is intramolecularly interacting with $\pi$-electrons of the benzene nucleus, while allyldimethylcarbinol and benzyldimethylcarbinol are in equilibrium mixtures of free and interacting hydroxyl groups. The composition of the equilibrium estimated from the integrated intensities of infrared absorption is added to the last column in Table I.

TABLE I. CHEMICAL SHIFTS AND THE COMPOSITION AT INFINITE DILUTION IN CARBON TETRACHLORIDE

| | $\delta_{X=0}$ ppm | $\Delta\delta$ ppm | Mole fraction of the interacting form |
|---|---|---|---|
| *tert*-Amyl alcohol | 3.92 | 0 | 0 |
| Allyldimethylcarbinol | 3.61 | 0.31 | 0.37 |
| Benzyldimethylcarbinol | 3.72 | 0.20 | 0.43 |
| Tribenzylcarbinol | 3.49 | 0.43 | 1 |

In contrast with the infrared spectra which show separate $\nu_{O-H}$ bands, the NMR spectra of hydroxyl proton are absolutely single. This must be attributed to the short lifetime and rapid exchange of free and interacting forms of these carbinols. The single proton resonance is therefore observed at the field corresponding to the average shielding of the two forms. When $\delta$ value of *tert*-amyl alcohol is taken as the chemical shift of purely free tertiary alcohols and that of tribenzylcarbinol as that interacting form, the composition of the equilibrium of benzyldimethylcarbinol may be computed from its $\delta$ value. The $\Delta\delta$ (0.20) of benzyldimethylcarbinol is divided by 0.43 and the quotient (0.47 mole fraction) is found to be in good agreement with the infrared datum (0.43). Unfortunately, the true chemical shift of hydroxyl proton taking part in the interaction with $\pi$-electrons of ethylenic linkage can not be determined because of lack of the sample which possesses only the interacting form. Assuming that the observed $\delta_{X=0}$ value of allyldimethylcarbinol is a weighted mean between free and interacting forms, the $\delta$ value of the interacting form can be estimated with use of composition datum (0.37 mole fraction) obtained from the infrared spectra. Thus $\Delta\delta$ is 0.31/0.37 or 0.838 ppm, $\delta$ being 3.08 ppm. Therefore, it may be said that, with the intramolecular interaction of the hydroxyl group with $\pi$-electrons of ethylenic linkage, the magnetic shielding of tertiary hydroxyl proton becomes less and $\delta$ value shifts to the lower magnetic field by less than one ppm. The chemical shift of the hydroxyl proton having interaction with $\pi$-electrons of the benzene nucleus is 0.41 ppm higher than this value. The ring current diamagnetic effect must be operative in the latter case. More precise evaluation is in progress in the hope of obtaining the knowledge about the geometry of the interacting form.

## *Association Shifts of NMR Spectra of Phenylacetylene**

By Naoya NAKAGAWA** and
Shizuo FUJIWARA***

(Received October 15, 1960)

Solvent effects have recently attracted the attention of several workers in the investigations of the chemical shift phenomena of proton magnetic resonance in the -OH, -COOH, -NH, and $-SO_3H$ groups of organic compounds. The results of NMR measurements were interpreted in terms of proton exchange and of hydrogen-bond formation[1]. Some of the most interesting results of these investigations are that obtained by Huggins, Pimentel and Shoolery[2], and by Korinek, Reeves and Schneider[3,4] for chloroform, which revealed us the fact that the association of the chloroform molecules can be studied by the proton resonance shifts of chloroform.

Since this technique is quite useful for the investigations of intermolecular interactions in liquid state, we made measurements of the solvent effects on the proton resonance shifts of phenylacetylene. The apparatus used for NMR measurements was constructed at the University of Electro-Communications and was operated at 27 Mc. In each of these samples, molecules are assumed to be associated with each other (self-association) or with solvent molecules; hence, the results of these measurements can be compared to those of chloroform.

Fig. 1 shows the results of NMR measurements of the solvent effects for the ethinyl proton of phenylacetylene. The resonance position of the ethinyl proton is shifted to lower field by the addition of solvents such as $Et_3N$, $Et_2NH$, $Et_2O$, EtOH, and $Me_2CO$. This can be explained as being due to hydrogen bonding with nitrogen or with oxygen atoms of the solvent molecules. The high-field shift observed in the system with benzene

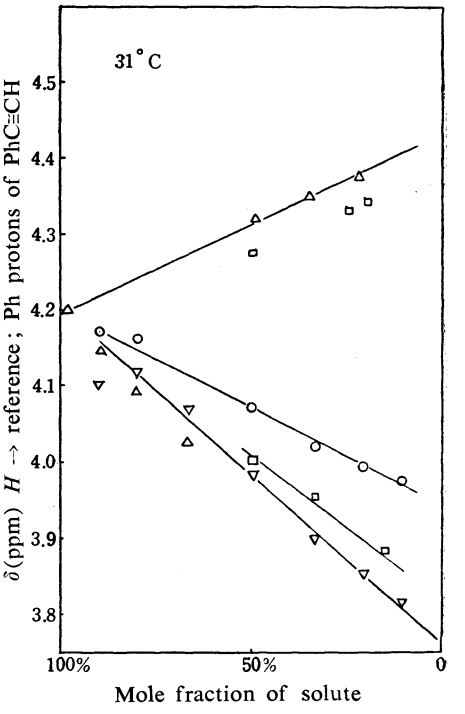

Fig. 1. Chemical shifts of C≡CH of PhC≡CH.
Solvent, △ $C_6H_{12}$, □ $CCl_4$
○ $Et_3N$, □ $Me_2CO$, ▽ $Et_2NH$,
△ EtOH

is explained, as in the case of chloroform, by hydrogen bonding with the $\pi$-electrons of benzene. On the other hand, the high-field shifts observed in the system with carbon tetrachloride and with cyclohexane may be explained by assuming that the self-association of phenyl acetylene molecules is broken by the solvent molecules. This may be regarded as evidence for the proposition that the phenylacetylene molecules are associated with each other through interaction of the triple-bond $\pi$-electrons. This conclusion seems to be consistent with the finding of West in the infrared spectra of triple-bond compounds[5].

The authors thank to Mr. Hiroshi Shimizu of the University of Tokyo for valuable discussions.

# *The Anodic Behavior of Cathodically Prepolarized Bright Platinum Electrode in Sulfuric Acid Solution*

By Shigeo SHIBATA

(Received December 23, 1959)

Numerous accounts[1-19] have been published on the charging curve which is a variation of potential with quantity of electricity passed when a platinum electrode is forced from the equilibrium potential of hydrogen to the oxygen evolution potential with a steady direct current. The curve was distinguished principally into three stages: an initial slow rise of potential which is generally considered to correspond to ionization of hydrogen atoms which have been adsorbed on the electrode surface, rapid linear rise for charging a double layer, and finally a slow linear change to deposition of oxygen which forms an adsorbed or an oxide layer prior to the evolution of gas. In addition, Pearson and Butler[5] and also Hickling[10] found that, when the electrode was first cathodically polarized and anodic current was passed, a new stage, which consists of a horizontal portion of steady potential, which we call stage $\alpha'$, appeared prior to the above-mentioned three stages. Pearson and Butler considered this stage to be attributable to the ionization of free hydrogen in the solution, but Hickling explained that it may be more complex than this simple view. As to the behavior of the stage $\alpha'$, Breiter, Knorr and Völkl[16] found that it is considerably lengthened when the electrode was cathodically prepolarized with high current density (c. d.). They have considered that this phenomenon was ascribed to bubbles which evolved on the surface of the electrode by cathodic prepolarization. Experimental or theoretical studies on the stage $\alpha'$ have been done by these authors, nevertheless the results of those studies are not satisfactory, because they are only qualitative and imperfect. The present investigation was undertaken to throw some light on this problem.

## Experimental

In order to establish a suitable condition for the observation, a network as shown diagrammatically in Fig. 1, similar in principle to that used by Breiter et al.[16], was used. An electrolysis cell can be fed with a steady current from Circuit I as well as from Circuit II, these currents being opposite to each other in direction, with regulated power supplies P and P'. R and R' are variable high

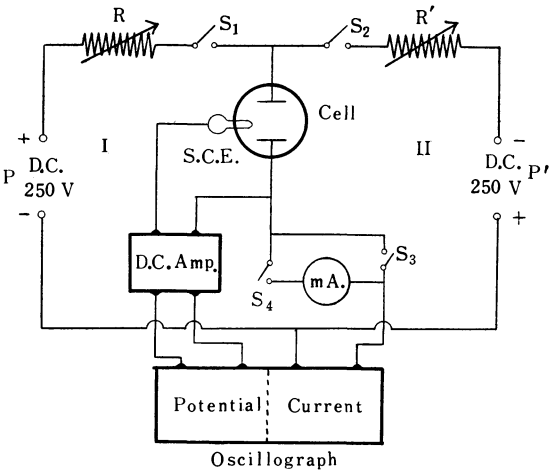

Fig. 1. Circuit diagram.

resistances. When, at first, the switch $S_1$ is closed, a steady current $i_k$ supplied from Circuit I begins to pass through the cell. At a suitable instant the switch $S_2$ is closed, the other switch being left as it is, so that a steady current $i_a'$ supplied from Circuit II, which is opposite in direction and larger in magnitude, superposes with the former, resulting in a current with the same direction as that of the latter and the amount of $i_a = i_a' - i_k$.

The potential changes of the working electrode, measured against a saturated calomel electrode, were recorded by means of a mechanical oscillograph. All potentials referred to are on the hydrogen scale. Switch $S_2$ was geared with a shutter of the oscillograph. The electrolysis cell used was of H type as previously described[20]. The working electrode of bright platinum plate having an area of one square centimeter per side, the back side of which was covered with a thin layer of molten glass, was placed in one compartment, and an antipodal electrode of platinized platinum plate, having an apparent area of 2 cm², was placed in the other compartment. 1 N sulfuric acid solution made with G. R. sulfuric acid and conductivity water redistilled several times with a silica still was used as the electrolyte. Prior to use, the working electrode was carefully cleaned with hot chromic acid, hot concentrated nitric acid and finally with distilled water, and then activated by anodic polarization with a current of 100 mA./cm² for one hour in 1N sulfuric acid solution, reduced cathodically, and introduced into the cell containing the electrolyte saturated with hydrogen. After passing purified hydrogen through the electrolyte for 10 min., the cell was let stand for 5 min. with or without the passing of a given cathodic current, till it was polarized for the oscillographic observation. All experiments were carried out in a thermostat of 15°C.

## Results

It was observed that the horizontal stage $\alpha'$ which is characteristic of the prepolarized electrode could be clearly found also for the nonpolarized electrode in the solution saturated with hydrogen at low anodic polarization c. d. as shown in Fig. 2(A). Fig. 3(A) shows a plot

of $q_{H_2}$, the quantities of electricity required in stage $\alpha'$, against the anodic c. d. As to the relation between the anodic polarization c. d. $i_a$ and the transition time $\tau_{H_2}$ of the stage $\alpha'$, Sand's equation is applicable[21]. As seen in

20) S. Shibata, *J. Chem. Soc. Japan, Pure Chem. Soc. (Nippon Kagaku Zasshi)*, **79**, 239 (1958).

21) H. J. S. Sand, *Phil. Mag.*, **1**, 45 (1901).

Fig. 4(A), $i_a\sqrt{\tau_{H_2}}$ is independent of $i_a$. Taking the diffusion coefficient $D$ as $4.7\times10^{-5}$ cm./sec.[22], we can compute the value of $C^0$, the result being obtained as $7.67\times10^{-4}$ mol./l., which is in good agreement with the solubility of hydrogen $7.3\times10^{-4}$ mol./l.[23] Consequently, the electrode reaction at the stage $\alpha'$ in this case is ionization of hydrogen molecule in the solution and its reaction rate is controlled by diffusion of the hydrogen.

When the electrode was led from a cathodically polarized state with a given c. d. immediately to an anodically polarized state, the stage $\alpha'$ was lengthened considerably, as shown in Fig. 2(B). In Fig. 3(B), $q_{H_2}$ is traced in relation with the polarization c. d. The value of $q_{H_2}$ decreased with the increase of $i_a$ when $i_k$ is kept unchanged, and increased with the increase of $i_k$ when $i_a$ is kept unchanged. It was found that for a given $i_k$ the function $i_a\sqrt{\tau_{H_2}}$ in Sand's equation increased with the increase of $i_a$ in the range of low $i_a$, but tended to a definite value when $i_a$ grew sufficiently. This can be seen in Fig. 4(B). The concentration of hydrogen in the vicinity of the electrode polarized cathodically was computed with Sand's equation, taking the constant value of $i_a\sqrt{\tau_{H_2}}$ at large $i_a$. The results obtained were 4.08, 16.2 and $32.8\times10^{-3}$ mol./l. for the cathodic c. d.'s of 1, 6 and 15 mA/cm$^2$, respectively.

The behavior of $q_{H_2}$ under the turbulence of the electrolyte were studied with the rotated electrode at various rates varying up to 1500 r. p. m., $i_k$ and $i_a$ being kept unchanged. The result thus obtained is shown in Fig. 5. It is seen in this figure that $q_{H_2}$ decreases quickly with the increase of the rate of rotation in the range of low rotations. This can be attributed to the removal of the hydrogen accumulated owing to the prepolarization in the solution in the vicinity of the electrode, but as the rotation becomes vigorous, the rate of this decrease diminishes. As the rate exceeds 1000 r. p. m., the value of $q_{H_2}$ tends to a constant value independent of $i_a$ and $i_k$. This value is coincident to that of the nonpolarized electrode, and suggests the vanishing of the accumulated hydrogen.

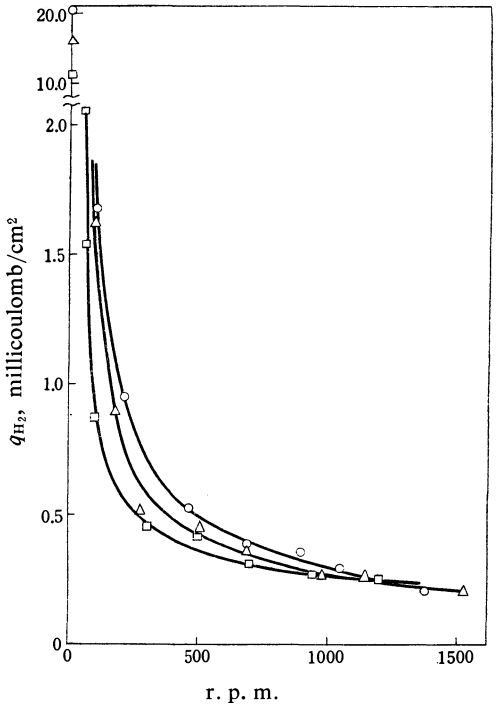

Fig. 5. Variation of $q_{H_2}$ of the prepolarized electrode with number of rotation per min.

## Discussion

The fact that we have found several phenomena which need to be attributed to accumulation of hydrogen in the vicinity of the electrode leads us to assume the existence of temporary supersaturation of hydrogen. It was reported in the experiment performed by Clamroth and Knorr[24] with an active palladium electrode that the maximum value of the diffusion overpotential of the hydrogen on the cathode was $-30\sim-60$ mV. This corresponds to the fact that the concentration of hydrogen in the solution near the electrode is as 10~100 times large as the saturation value at 1 atm. As such a state of high concentration must be very unstable. At the instant of the shut-off of the cathodic current the concentration should begin to fall irreversibly due to the exclusion from the solution. This process is also confirmed in the present results in the behavior of $i_a\sqrt{\tau_{H_2}}$ in reference to $i_a$. As seen in Fig. 4(B) the value of $i_a\sqrt{\tau_{H_2}}$ diminished considerably as $i_a$ decreased. This discrepancy can not be understood unless it is attributed to the spontaneous exclusion of hydrogen from the solution due to the supersaturation. In order to study this point in detail, the following observation was performed. After the steady current which had kept the electrode cathodically polarized, was shut off, the electrode was left as it was for a suitable time elapse—say $t$—till a steady anodic current was switched on,

22) "International Critical Tables", Vol. V, McGraw-Hill Book Co. Inc., New York (1929), p. 63.

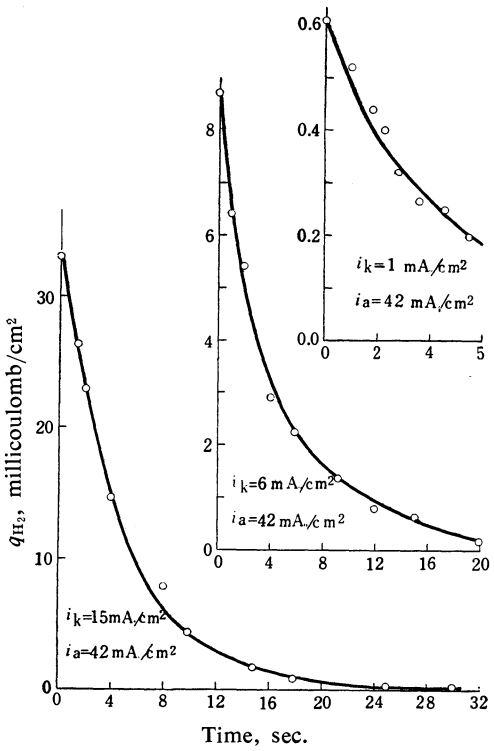

Fig. 6. Decay of $q_{H_2}$ with standing time.

the oscillographic observation taking place simultaneously. Fig. 6 shows the relation between $q_{H_2}$ and $t$. In this figure, we can see the $q_{H_2}$ decreases with the time $t$, in a manner closely resembling that of the decrease of reactant in the usual chemical reaction of first order. That is to say, the spontaneous reduction of the concentration of the hydrogen should obey the following equation

$$-dc/dt = k({}_tC - C^0) \qquad (1)$$

where ${}_tC$ is the concentration of hydrogen in the vicinity of the electrode at the time elapse $t$ from the instant of the shut-off of the polarizing current and $k$ a proportional constant. Solving this equation, we obtain

$$t = -\frac{1}{k} \ln \frac{{}_tC - C^0}{{}_0C - C^0} \qquad (2)$$

where ${}_0C$ is the concentration in the vicinity of the electrode at $t=0$. As the anodic current is sufficiently large (42 mA/cm² in this experiment) for the spontaneous decrease of the concentration of the hydrogen by exclusion during $\tau_{H_2}$ to be disregarded, $\sqrt{\tau_{H_2}}$ is proportional to $C$ as Sand's equation requires. Consequently, the total decrease of $q_{H_2}$ during $t$ can be regarded as corresponding to the decrease of $C$.

$$t = -\frac{1}{k} \ln \frac{\sqrt{{}_t\tau_{H_2}} - \sqrt{\tau^0_{H_2}}}{\sqrt{{}_0\tau_{H_2}} - \sqrt{\tau^0_{H_2}}} \qquad (2')$$

where ${}_t\tau_{H_2}$ is the transition time of stage $\alpha'$ consecutive to the unpolarizing time interval $t$, and ${}_0\tau_{H_2}$ that for $t=0$. When ${}_0C \gg C^0$, also ${}_tC \gg C^0$, Eqs. 2 and 2′ can be simplified as

$$t = -1/k \ln ({}_tC/{}_0C) \qquad (3)$$

$$= -1/2k \ln ({}_t\tau_{H_2}/{}_0\tau_{H_2}) \qquad (3')$$

It is seen from Fig. 7 that a plot of $\log({}_t\tau_{H_2}/{}_0\tau_{H_2})$ against standing time $t$ is linear. From the slope of this line, the value of the rate constant was evaluated as 0.101 sec.

Now, since we can reasonably say that the rate of decay of hydrogen concentration in the vicinity of the electrode, which led from the cathodically polarized state, consists of the superposition of the decay due to the diffusion and the spontaneous decrease due to the supersaturation, it can be expressed mathematically as follows,

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} - k\{C(x,t) - C^0\} \qquad (4)$$

where $C(x,t)$ is the concentration of hydrogen at a point $x$ apart from the electrode surface at time $t$. While the concentration near the electrode polarizing cathodically should fall from the surface toward the bulk solution in macroscopical range, it would be natural to assume that through the thin layer in the vicinity of the surface, in which the diffusion zone would be formed during $\tau_{H_2}$ in the subsequent anodic polarization, the concentration

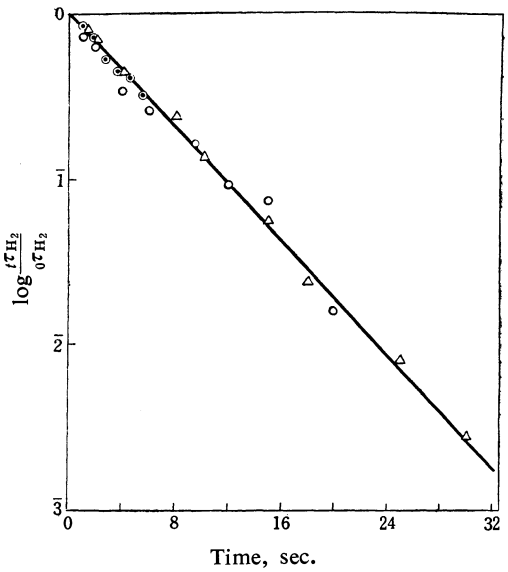

Fig. 7. A plot of $\log \frac{t\tau_{H_2}}{0\tau_{H_2}}$ against standing time.

$i_k$
—⊙— 1 mA/cm²
—○— 6 mA/cm² } $i_a$=42 mA/cm²
—△— 15 mA/cm²

is constant. So the initial condition can be taken as

$$C(x, 0) = {}_0C \tag{5}$$

The boundary condition is

$$D\left(\frac{\partial C(x, t)}{\partial x}\right)_{x=0} = \frac{i_a}{2F} \tag{6}$$

The solution of Eq. 4 which satisfies the conditions 5 and 6 is given by

$$\begin{aligned} C(x, t) = {}&{}_0C \exp(-kt) + C^0\{1-\exp(-kt)\} \\ &- \frac{i_a}{2F\sqrt{Dk}} \exp\left(-\sqrt{\frac{k}{D}}x\right) \\ &+ \frac{i_a}{4F\sqrt{Dk}}\left\{\exp\left(-\sqrt{\frac{k}{D}}x\right)\operatorname{erfc}\left(\sqrt{kt} - \frac{x}{2\sqrt{Dt}}\right)\right. \\ &\left. + \exp\left(\sqrt{\frac{k}{D}}x\right)\operatorname{erfc}\left(\sqrt{kt} + \frac{x}{2\sqrt{Dt}}\right)\right\} \end{aligned} \tag{7}$$

The variation of the concentration at $x=0$ is

$$\begin{aligned} C(0, t) = {}&{}_0C \exp(-kt) + C^0\{1-\exp(-kt)\} \\ &+ \frac{i_a}{2F\sqrt{Dk}} \operatorname{erfc}(\sqrt{kt}) \end{aligned} \tag{8}$$

If we assume that $C(0, \tau_{H_2}) \approx 0$, then

$$\begin{aligned} &{}_0C \exp(-k\tau_{H_2}) + C^0\{1-\exp(k\tau_{H_2})\} \\ &= \frac{i_a}{2F\sqrt{Dk}} \operatorname{erf}(\sqrt{k\tau_{H_2}}) \end{aligned} \tag{9}$$

If $k \to 0$, we obtain Sand's equation. When ${}_0C \gg C^0$ or $\tau_{H_2}$ is sufficiently small, the second term on the left side of Eq. 9 can be neglected against other terms; then we have

$${}_0C \exp(-k\tau_{H_2}) = \frac{i_a}{2F\sqrt{Dk}} \operatorname{erf}(\sqrt{k\tau_{H_2}}) \tag{10}$$

Taking logarithumus of both sides of the equation, this becomes

$$\begin{aligned} \log i_a = {}&\log 2F\sqrt{Dk}\ {}_0C - \{k\tau_{H_2}/2.303 \\ &+ \log \operatorname{erf}(\sqrt{k\tau_{H_2}})\} \end{aligned} \tag{11}$$

$$= \log 2F\sqrt{Dk}\ {}_0C - f(\tau_{H_2}) \tag{11'}$$

where $f(\tau_{H_2})$ in Eq. 11′ expresses the second term on the right hand side of Eq. 11. Eq. 11 is in favour of the experimental results as shown in Fig. 8. If we write ${}_0i_a$ anodic c. d. at $f(\tau_{H_2})=0$, it is obtained, by using Eq. 11′, that

$${}_0i_a = 2F\sqrt{Dk}\ {}_0C \tag{12}$$

By means of Eq. 12 it is possible to calculate the initial concentration ${}_0C$ if ${}_0i_a$ is known. Using the value of ${}_0i_a$ obtained by extrapolating the curve to $f(\tau_{H_2})=0$ in Fig. 8, ${}_0C$ at cathodic c. d.'s of 1, 6 and 15 mA/cm$^2$ was evaluated as 4.0, 14.3 and $30.0\times10^{-3}$ mol./l., respectively. These were in good agreement with the values obtained by calculation with Sand's equation at large $i_a$.

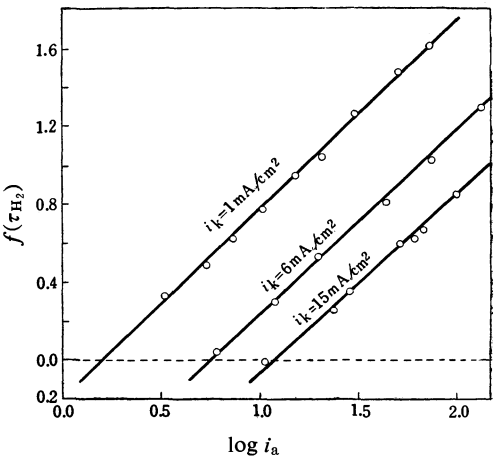

Fig. 8. Relation between $f(\tau_{H_2})$ and log $i_a$.

## Summary

The anodic charging curves of a cathodically prepolarized bright platinum electrode in 1 N sulfuric acid solution saturated with hydrogen have been studied by means of a mechanical oscillograph.

The behavior of stage $\alpha'$ for anodic polarizing c. d. can be explained on the assumption that its stage is due to the molecular hydrogen accumulated in the vicinity of the electrode during the cathodic prepolarization, and that the concentration of the accumulated hydrogen decreases in the same manner as the chemical reaction of first order.

The author's warmest thanks are due to Professor H. Yoshisaki for encouragement and advice, and to Professor T. Terasaki for helpful suggestions.

## Appendix

On writing

$$C_1(x, t) = C(x,t) - C^0 \tag{13}$$

Eq. 4 becomes

$$\frac{\partial C_1(x, t)}{\partial t} = D\frac{\partial^2 C_1(x,t)}{\partial x^2} - kC_1(x,t) \tag{14}$$

and the initial condition is given by

$$\begin{aligned} C_1(x,0) &= {}_0C - C^0 \\ &= B \end{aligned} \tag{15}$$

the boundary condition 6 do not change.

We may attempt to find a solution of Eq. 14 by putting

$$C_1(x,t) = \phi(x) + \varphi(x,t) \tag{16}$$

where $\psi(x)$ is a function of $x$, $\varphi(x,t)$ is of $x$ and $t$. We have to satisfy

$$\frac{\partial\psi(x)}{\partial t}=D\frac{\partial^2\psi(x)}{\partial x^2}-k\psi(x) \tag{17}$$

and

$$\frac{\partial\varphi(x,t)}{\partial t}=D\frac{\partial^2\varphi(x,t)}{\partial x^2}-k\varphi(x,t) \tag{18}$$

The general solution of Eq. 17 is

$$\psi(x)=Ae^{-\sqrt{(k/D)}x} \tag{19}$$

where $A$ is an integration constant. Substitution by the boundary condition 6, yields

$$D\left(\frac{\partial\psi(x)}{\partial x}\right)_{x=0}=-DA\sqrt{\frac{k}{D}}$$
$$=i_a/2\boldsymbol{F}$$

Thus, we obtain

$$\psi(x)=\frac{i_a}{2\boldsymbol{F}\sqrt{Dk}}e^{-\sqrt{(k/D)}x} \tag{20}$$

If we put

$$\varphi(x,0)=\boldsymbol{B}-\psi(x) \tag{21}$$
$$=\phi(x) \tag{21'}$$

the function $C_1(x,t)$ of Eq. 16 satisfy the initial condition (15), i. e.

$$C_1(x,0)=\psi(x)+\varphi(x,0)$$
$$=\boldsymbol{B}$$

The function $\varphi(x,t)$ must satisfy also the boundary condition

$$D\left(\frac{\partial\varphi(x,t)}{\partial x}\right)_{x=0}=0 \tag{22}$$

The general solution of Eq. 18 is

$$\varphi(x,t)=e^{-(D\alpha^2+k)t}\cos\alpha x \tag{23}$$

According to Fourie's integral theorem we obtain

$$\varphi(x,t)=\frac{2}{\pi}\int_0^\infty d\alpha\int_0^\infty\phi(\lambda)e^{-(D\alpha^2+k)t}\cos\alpha x\cos\alpha\lambda d\lambda \tag{24}$$

Summing Eq. 19 and the integrated result of Eq. 24, and using Eq. 13 we obtain the solution 7.

# *Absorption Spectra of Nitrobenzene Derivatives. I. Spectral Features of o-, m- and p-Isomers*

By Kimio SEMBA*

(Received May 26, 1960)

It is well known that molecules having electron attracting groups such as nitro, carbonyl and corboxyl groups exhibit intense absorption spectra in the near ultraviolet or visible region[1]. Recently, Nagakura and Tanaka[2] presented a new theory (molecular energy level diagram method) based on the molecular orbital theory treating the electron migration between two $\pi$-electron systems. According to their theory, it is possible to interpret strong absorption bands of some aromatic nitro compounds in terms of the intramolecular charge transfer spectra.

The intramolecular charge transfer in nitrobenzene means the interaction of the highest occupied orbital of benzene ($H_B$) with the lowest vacant orbital of nitro group ($V_S$). In nitrobenzene derivatives there are appreciable interactions between the molecular orbitals of monosubstituted benzenes and those of the nitro groups[3]. Considering the energy values and symmetry properties of these orbitals, one sees that the interaction between the highest occupied orbital of the monosubstituted benzene and the lowest vacant orbital (anti-bonding $\pi$-orbital) of the nitro group is especially important.

The molecular energy-level diagrams of benzene, aniline and nitromethane[2] are shown in Fig. 1. The intramolecular charge transfer transition may occur as a result of interactions between two split orbitals ($H_{x1}$ and $H_{x2}$) in aniline and the lowest vacant orbital $V_S$ of the nitro group. These transitions are generally accompanied by a large electronic transfer and have been designated as intramolecular charge transfer transition[2].

According to Nagakura and Tanaka's theory, there is no interaction between $H_{x2}$ and $V_S$, and only one transition due to the $H_{x1}$ and $V_S$ interaction can be observed for a *p*-isomer. On the other hand, in *o*- and *m*-isomers the

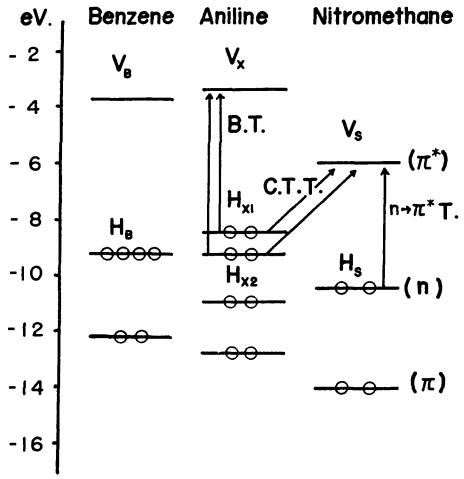

Fig. 1. Molecular energy level diagrams of benzene, aniline and nitromethane.

two orbital $H_{x1}$ and $H_{x2}$ can interact with $V_S$, and two transfer transitions of the charge transfer type may be expected for these isomers.

In this paper the intramolecular charge transfer spectra (250~400 m$\mu$) of *o*-, *m*- and *p*-nitrophenol, -nitroanisole, -nitroaniline and -nitro-*N*-dimethylaniline are measured in *n*-hexane, and their spectral features together with the effect of substituents on them are discussed according to Nagakura and Tanaka's theory.

The migration effects of electron donating groups on absorption spectra of *o*-, *m*- and *p*-nitroaniline are considered in aqueous and hydrochloric acidic solutions and the existence of simple equilibria between these isomers and protons is indicated.

## Experimental

Absorption spectra were recorded by a Hitachi automatic recording spectrophotometer type EPS-2, using quartz cells of 1 cm. in path length. Infrared spectra were obtained by another Hitachi double beam infrared spectrophotometer type EPI-2 with 0.1 mm. rock salt cells.

Solvents, *n*-hexane, methanol, ethanol, chloroform and ethyl ether, were purified by the method recommended by Weissberger and Proskauer[4].

*o*-, *m*- and *p*-Nitrophenol, -nitroanisole and -nitroaniline of Tokyo Chemical Industry Co. special grade were used. *m*- and *p*-Nitro-*N*-dimethylaniline were synthesized according to Fich's method[5] by nitration of *N*-dimethylaniline, and were recrystallized several times from ethanol and benzene, respectively. These samples were thought to be pure enough and no further purification was carried out.

* Intramolecular charge transfer bands.
** Band due to $n\rightarrow\pi^*$ transition.

It is noted from Table I and Fig. 2 (the absorption spectra of *o*-, *m*- and *p*-nitroaniline) that the spectra of *o*- and *m*-nitrobenzene derivatives resemble each other in the point that they show two kinds of absorption bands in the ultraviolet and visible regions, one at 260 m$\mu$ and the other at 350~380 m$\mu$. On the other hand, the *p*-isomer spectrum is quite different from those of the other isomers, except for the band at 220 m$\mu$.

These spectral characteristics have already been pointed out by Kumler[1], and were interpreted on the basis of the "electron oscillation" theory proposed by Lewis and Calvin[6]. However, Kumler's interpretation must be reconsidered from the standpoint of recent theories.

From the positions and intensities of these absorption bands we may assign the bands at 260 and 350~380 m$\mu$ for the *o*- and *m*-isomers and the band at 300 m$\mu$ for the *p*-isomer to the intramolecular charge transfer transitions in these molecules. Thus we have two intramolecular charge transfer bands for *o*- and *m*-isomers and only one for the *p*-isomer (Table I). These characteristic features of the intramolecular charge transfer spectra for the three isomers of nitrobenzene derivatives have been well explained by the molecular orbital theories cited above[3].

6) G. N. Lewis and M. Calvin, *Chem. Revs.*, **25**, 273 (1939).

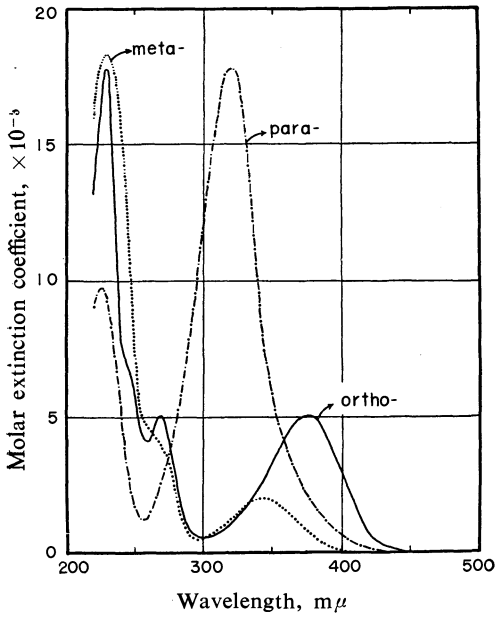

Fig. 2. Absorption spectra of *o*-, *m*- and *p*-nitroaniline, all in *n*-hexane.

The intramolecular charge transfer spectrum of *p*-nitroaniline is much stronger ($\varepsilon \sim 10000$) than those of the *o*- and *m*-nitroaniline (Fig. 2). The coefficient* of the AO at the para-position in the $H_{x1}$-MO of a monosubstituted benzene (aniline) is greater than those of ortho- and meta-AO's, giving rise to stronger absorption for the *p*-isomer than for other isomers[3]. The intensities of the bands at 260 mμ for the *o*- and *m*-isomers are nearly equal ($\varepsilon \sim 5000$) and the longer wavelength band at 350~380 mμ for the *o*-isomer is stronger than the band of the *m*-isomer. The same relations among intensities of the intramolecular charge transfer bands can also be observed for the spectra of other nitrobenzene derivatives studied in this paper.

Absorption bands of *o*-nitrophenol and *o*-nitroaniline, due to transitions of the same type appear at longer wavelengths than those of the *m*-isomers. On the other hand, the bands of *m*-nitroanisole appear at longer wavelengths than those of the *o*-isomer. These facts may be explained in terms of intramolecular hydrogen bondings[3] which can be formed in these ortho compounds as shown in Fig. 3. The formations of these intramolecular hydrogen bondings are evident from infrared absorptions as shown in Figs. 4 and 5. The OH group in *o*-nitrophenol shows a very broad infrared absorption band at 3200 $cm^{-1}$, and the $NH_2$ group in *o*-nitroaniline shows less broad absorptions at 3510 and 3380 $cm^{-1}$. On

* See ref. 3.

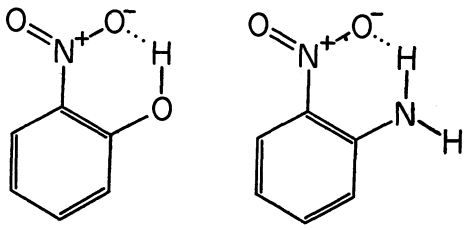

Fig. 3. Intramolecular hydrogen bondings in *o*-nitrophenol and *o*-nitroaniline.

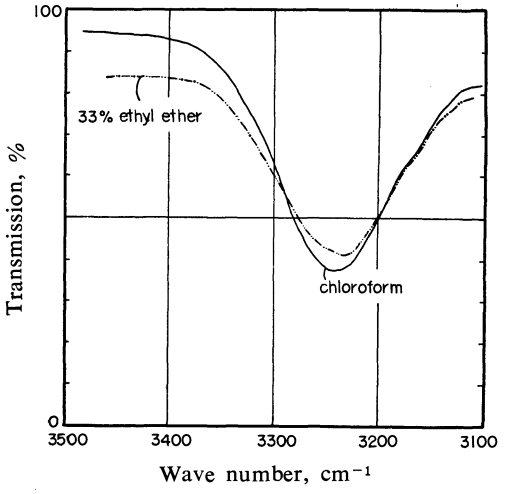

Fig. 4. Infrared absorption of *o*-nitrophenol in chloroform.

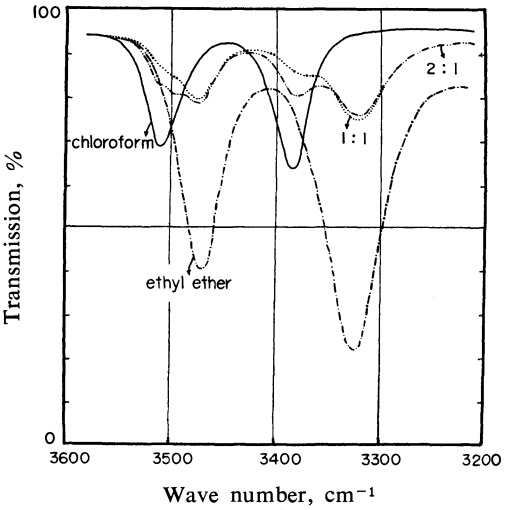

Fig. 5. Infrared absorption of *o*-nitroaniline in chloroform (-·-·- 33% ethyl ether, ····· 50% ethyl ether).

the addition of ethyl ether the former does not shift but the latter groups shift to longer wavelengths. These facts indicate that in *o*-nitrophenol intramolecular hydrogen bonding

is too strong to allow an intermolecular hydrogen bonding between the solute and ethyl ether molecules but in *o*-nitroaniline the intermolecular hydrogen bonding is formed to a large extent, as shown in Fig. 6.

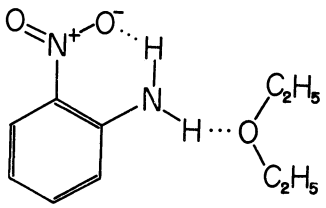

Fig. 6. Intermolecular hydrogen bonding between *o*-nitroaniline and ethyl ether.

The band at 220 m$\mu$ in the spectra of *o*-, *m*- and *p*-isomers may be associated with the transition of another charge transfer type[7]. Absorption shoulders are observed at 240~250 m$\mu$ for *o*- and *m*-nitroaniline (Table I).

**Effect of Substituents on Absorption Spectra.** —Next we shall study the effect of electron donating groups on the absorption spectra in nitrobenzene derivatives. Usually this effect is divided into resonance and inductive effects. In the present case only the resonance effect is of interest, and so we neglect the inductive effect.

According to the perturbation theory the resonance effect is associated with the transfer of an electron from a $\pi$-orbital of the substituent into a vacant orbital of the conjugated system. The effect of the substituents on absorption spectra of benzene derivatives has been explained in terms of the relative stabilization of the ground and excited states[8]. The stabilization energies of these states are closely connected with electron migration from the substituents into the ring, and as generally the stabilization is much greater in the excited state, red shifts of absorption bands are expected with the increasing electron migration.

As seen from Table I, the absorption bands of the *m*- and *p*-isomers shift to the longer wavelengths in the order of OH, $OCH_3$, $NH_2$ and $N(CH_3)_2$ groups. These spectral shifts are very similar to those of monosubstituted benzene derivatives. However, the shifts for *o*-isomers are of somewhat different nature on account of ortho-effects involving effects of intramolecular hydrogen bonding and of steric hindrance.

On comparing nitrophenol with nitroaniline the ionization energy of the $NH_2$ group is much smaller than that of the OH group[9], leading to a much larger electron migration from the $NH_2$ group than from the OH group. Consequently nitroaniline shows a red shift of absorption maximum as compared with nitrophenol. The same type of shifts has been observed for monosubstituted benzenes, phenol and aniline, the latter showing the absorption at the longer wavelength.

On the other hand, we find the absorption maximum of nitrophenol on the blue side of the nitroanisole maximum. Matsen et al.[10] found that the O–O band of phenol is at a longer wavelength than that of anisole and from this they concluded that the resonance of the OH group with the benzene ring is much stronger than that of an alkoxy group ($OCH_3$ or $OC_2H_5$). However, from our result we can assume that the electron migration from the $OCH_3$ group is greater than that from the OH group because of the hyperconjugation effect of the $CH_3$ group. The same consideration may be taken for the $NH_2$ and $N(CH_3)_2$ groups, as the absorption maximum of nitro-*N*-dimethylaniline appears at the longer wevelength than that of nitroaniline.

**Effect of Electron Migration on Absorption Spectra.** — As mentioned above, the shifts of intramolecular charge transfer spectra are very much influenced by the amount of electron migration from electron donating substituents into the benzene ring. For the sake of simplicity we limited our consideration to the case of nitroaniline in aqueous or hydrochloric acidic solution.

The amount of electron migration from the $NH_2$ group of nitroaniline will decrease by addition of hydrochloric acid to the aqueous solution, since the lone pair electrons of the N-atom in the $NH_2$ group will be fixed by a proton according to the following scheme

$$-NH_2 + H^+ \rightleftharpoons -NH_3^+$$

and the electron migration into the ring will be arrested. Then the absorption spectrum of nitroaniline will resemble that of nitrobenzene.

This expectation is satisfactorily supported by the experimental results as shown in Figs. 7, 8 and 9. The absorption spectra of *o*-, *m*- and *p*-nitroaniline in aqueous solutions approach to that of nitrobenzene with the increasing concentration of hydrochloric acid, and finally they all become the same as the spectrum of nitrobenzene with respect to absorption intensities and wavelengths.

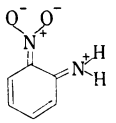
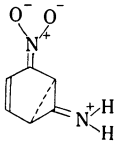
Isosbestic points observed for the spectra of all the isomers can be explained by assuming the following equilibrium



From the experimental results the equilibrium constants and differences of free energy are evaluated, as listed in Table II.

TABLE II. EQUILIBRIUM CONSTANTS AND FREE ENRGY DIFFERENCES FOR *o*-, *m*- AND *p*-NITROANILINE



| Molecule | Equilibrium constant | Free enrgy difference kcal./mol. |
|---|---|---|
| *o*-Nitroaniline | 3.5 | −0.75 (at 29°C) |
| *m*-Nitroaniline | 200 | −3.3 (at 29.5°C) |
| *p*-Nitroaniline | 10.8 | −1.4 (at 26°C) |

The equilibrium constant for the *m*-isomer is much larger than those for other isomers, and the *m*-isomer requires a very small amount of hydrochloric acid to reach equilibrium. This may be due to the meta-directing property of the $NO_2$ group. The meta-position is more negative compared with other positions as the $NO_2$ group has the meta-directing power, and the proton affinity of the N-atom in the *m*-isomer is large (formation of *m*-nitroanilinium ion). The same conclusion may be reached from the viewpoint of the resonance theory. In the *o*- and *p*-isomers the *o*- and *p*-quinoid structures

contribute largely, while in the *m*-isomer the contribution of the *m*-quinoid structure

is expected to be small. From this fact we may conclude that the electron migrations from the $NH_2$ group in the *o*- or the *p*-isomer are large, and that in the *m*-isomer a proton may easily be bonded to the N-atom.

The small value of the equilibrium constant for the *o*-isomer is probably due to steric hindrance.

***n*→*π** Transition**— The absorption band of nitrobenzene due to the $n\rightarrow\pi^*$ electronic transition was observed by Wolf and Herold[11] and by Wenzel[12]. The absorption due to the $n\rightarrow\pi^*$ transition is characterized by its weak intensity and so can not be observed if a strong absorption band lies in the same wavelength region.

In the present work the absorption shoulder with the molar extinction coefficient of about 1000 is observed for *p*-nitrophenol at about 334 m$\mu$. Although this absorption shoulder shifts to the longer wavelengths, in methanol, ethanol and water, it may be assigned to the $n\rightarrow\pi^*$ transition owing to its weakness of intensity. However, we could not observed this weak band in detail owing to the disturbance of the strong intramolecular charge transfer band which overlaps the weak band.

## Summary

The intramolecular charge transfer spectra of some nitrobenzene derivatives were measured in *n*-hexane. The general features of the absorption spectra and the effect of substituents on the absorption spectra were considered from the concept of the intramolecular charge transfer. The migration effect of electron donating groups was discussed for the nitroaniline in aqueous and hydrochloric acidic solutions. Also other absorption due to the $n\rightarrow\pi^*$ transition of nitro group was considered.

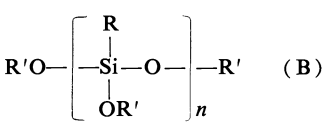
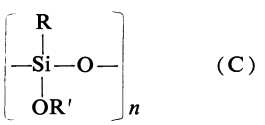
# *Alkylalkoxypolysiloxanes. IX*[1]. *Methylethoxypolysiloxanes Containing the Trimethylsiloxy Group*



By Minoru SAKIYAMA and Rokuro OKAWARA

(Received June 21, 1960)



Many alkylalkoxypolysiloxanes have hitherto been synthesized. They have following general formulas, and each was prepared from only one kind of alkylchlorosilane.

(A)

(B)

(C)

1) Part VIII of this series, R. Okawara and M. Katayama, This Bulletin, 33, 659 (1960).

$$R-\left[\begin{array}{c} OR' \\ | \\ -Si-O- \\ | \\ OR' \end{array}\right]_n-R' \quad (D)$$

R, R'=alkyl group

In this paper, the syntheses and properties of the lower members of linear and branched methylethoxypolysiloxanes involving the trimethylsiloxy group $(CH_3)_3SiO$ are described.

Compounds which belong to series A to D have been synthesized by one of the following methods:

(1) partial hydrolysis of dialkyldialkoxysilane or alkyltrialkoxysilane[2]

(2) sodium hydrogen carbonate treatment of partially alcoholyzed alkylchlorosilanes[3]

(3) thermal condensation between Si–OR and Si–Cl[4]

(4) hydrolysis of partially alcoholyzed alkylchlorosilanes in wet pyridine[5].

Method 4 is different from 1 in that the former takes into account the difference in reactivity toward water between the Si–Cl and the $Si-OC_2H_5$ bonds. It appears that the ethoxy groups reacted quite randomly with $H_2O$ to decrease the yield in method 1, especially when two kinds of methylethoxysilane were used. Therefore, method 1 was not examined. Also the results of some experiments showed that methods 2 and 3 were not conveniently applicable to the preparation. In consequence, method 4 was adopted. Partially ethanolyzed silicon tetrachloride, methyltrichlorosilane and dimethyldichlorosilane were mixed separately with trimethylchlorosilane and cohydrolyzed in wet pyridine in benzene containing the calculated amount of water. The products of hydrolysis were fractionally distilled. The details of the reactions are summarized in Table I. The desired products were obtained in moderate yield. This method is based on the difference of reactivity towards water between the Si–Cl and $Si-OC_2H_5$ bonds. As the $Si-OC_2H_5$ bond is also known to hydrolyze rapidly, particularly in an acidic medium, a slightly basic medium of wet pyridine in benzene was used. The properties of the compounds obtained by the fractionation through a highly efficient Stedman column are given in Table II.

The infrared spectra of these compounds give additional information about the characteristic vibrations of the ethoxy group and the methyl group attached to the silicon atom. Infrared spectra of some types of methylethoxypolysiloxanes have been reported[6]. The spectra obtained for the compounds studied here are similar to those of the methylethoxypolysiloxanes cited above in the region 1300 to 3500 $cm^{-1}$. The spectra in the region 700 to 1300 $cm^{-1}$ are presented on Fig. 1. Frequencies and assignments are shown in Table III.

A sharp band near 1250 $cm^{-1}$ is known to be characteristic of the symmetric deformation of the methyl groups attached directly to a silicon atom. The spectra in Fig. 1 show that, except in $(CH_3)_3SiOSi(CH_3)_2OC_2H_5$, this band is a doublet. The compounds $[(CH_3)_3SiO]_3SiCH_3$ and $[(CH_3)_3SiO]_4Si$ have been reported[7] to show a doublet in the same region.

Wright et al.[7] reported that the characteristic bands of the unit $(CH_3)_3SiO$ lie at 754~756 $cm^{-1}$ and 841 $cm^{-1}$, that of $(CH_3)_2SiO$ at 800~814 $cm^{-1}$ and that of $CH_3SiO$ at 800 $cm^{-1}$. Table III shows that the same bands are observed in the spectra of our compounds containing these particular groups, except that the 800 $cm^{-1}$ band of the $(CH_3)_2SiO$ unit is split into a doublet.

A band near 960 $cm^{-1}$ is connected with the C–C stretching vibration of the $C_2H_5O$ group, and those in the region 1000 to 1150 $cm^{-1}$ are related to Si–O–Si and Si–O–C skeletal vibrations. Of the latter, the band near 1100 $cm^{-1}$ decreases in intensity with the substitution of ethoxy groups by trimethylsiloxy groups. The C–O bond is believed to contribute greatly to this absorption band. A similar tendency in intensity is seen for the bands near 780 $cm^{-1}$ and 1160 $cm^{-1}$.

## Experimental

**Starting Materials.** — Trimethylchlorosilane (I), dimethyldichlorosilane and methyltrichlorosilane were supplied by the Shin-etsu Chem. Ind. Co. Silicon tetrachloride was obtained by the reaction of silicon with chlorine. Those chlorosilanes were partially alcoholyzed with ethanol below 5°C in a three-necked flask with an efficient stirrer, a reflux condenser and a dropping funnel. Then the mixture was warmed to 50°C to complete the reaction and it was fractionally distilled through a Stedman column of about 30 theoretical plates. Boiling points and chlorine content are shown in Table I. The experimental value for the chlorine content of triethoxychlorosilane was considerably less than the calculated value. This is thought to be due to contamination by tetraethoxysilane which has a boiling point close to that of triethoxychlorosilane. This mixture (VII) was used for the source of triethoxychlorosilane without further purification.

**Sodium Hydrogen Carbonate Treatment of the Mixture of I and II.**—To the refluxing mixture of

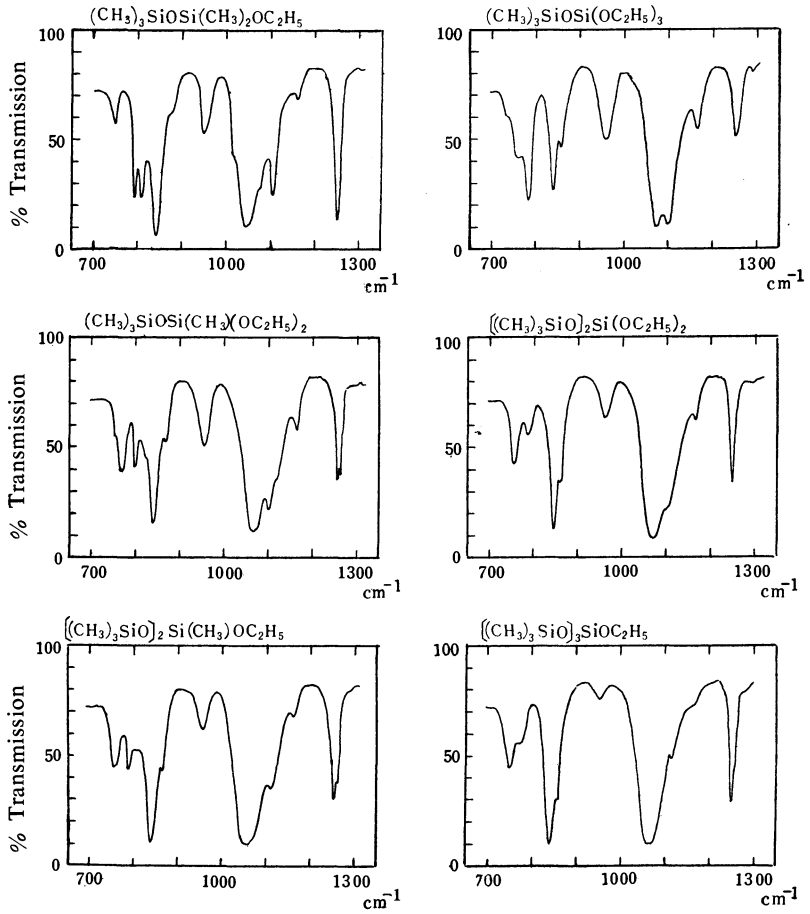

Fig. 1. Infrared spectra of methylethoxypolysiloxanes containing the trimethylsiloxy group.

I (21.8 g., 0.2 mol.) and II (27.8 g., 0.2 mol.), sodium hydrogen carbonate (16.8 g., 0.2 mol.) was added in portions. A reaction occurred violently with the evolution of hydrogen chloride and carbon dioxide. After completion of the reaction, the mixture (20 g.) was fractionally distilled. No plateau was found corresponding to $(CH_3)_3SiOSi(CH_3)_2$-$OC_2H_5$. It was thought from the distillation curve that the product was a complex mixture of methylethoxysilanes and -polysiloxanes.

**Attempts to Condense I and Tetraethoxysilane Thermally.**—A mixture of I (11 g., 0.1 mol.) and tetraethoxysilane (52 g., 0.25 mol.) was refluxed at 124°C for 20 hr., but no reaction occurred. The starting materials were recovered by the fractional distillation of the reaction mixture.

A mixture of I (22 g., 0.2 mol.) and tetraethoxysilane (21 g., 0.1 mol.) was passed through an electrically-heated quartz tube of 40 cm. length and 5 cm. diameter at 300°C for 4.5 hr. The condensate (40 g.) was fractionally distilled. Unreacted tetraethoxysilane was obtained, along with hexaethoxydisiloxane, which could be produced from the partial hydrolysis of tetraethoxysilane by a small amount of water remaining in the reaction tube or formed by oxidation of the ethoxy groups. Between the plateaus of these two compounds, a small plateau having a high refractive index ($n_D^{20}$ 1.3862. reported[8] for $(C_2H_5O)_4Si$: $n_D^{20}$ 1.3837) was found. The thermal condensation: $Si\text{-}Cl + C_2H_5O\text{-}Si \rightarrow Si\text{-}O\text{-}Si + C_2H_5Cl$ might have occurred in this experiment, but the yield was too low to apply this method to the synthesis.

**Hydrolysis of Chlorosilane Mixture in Wet Pyridine.**—The details of each experiment are given in Table I.

The typical operation was as follows. The hydrolyzing mixture consisting of benzene and the calculated amount of pyridine and water was placed in a three-necked flask with an efficient stirrer, a reflux condenser and a dropping funnel. The mixture of I and II to VII was added to the hydrolyzing mixture which was cooled with an ice-bath. The rate of addition was controlled, so that the white smoke of the chlorosilane-pyridine adduct would not be evolved from the top of the reflux condenser. After addition, the mixture was stirred for 1 hr. at room temperature. Whenever

the chlorosilane odor still remained, several drops of wet pyridine were added. The mixture was washed with cold water, and then dried with sodium sulfate. Benzene was removed by distillation, followed by a fractionation through a Stedman type column of about 50 theoretical plates.

**Determination of Silicon Content.**—It is known that when methylpolysiloxanes containing the trimethylsiloxy group are decomposed by the action of concentrated sulfuric acid, volatile decomposition products are evolved. Therefore this method cannot be applied to the determination of silicon content in these compounds. In this study, about 0.5 g. of the sample was decomposed by sodium peroxide in a Paar bomb.

**Infrared Spectra.**—A Hilger H800 spectrometer with a sodium chloride prism was used. Spectra were taken in carbon disulfide solution in the region 700 to 1400 $cm^{-1}$ and in carbon tetrachloride solution in the region 1300 to 3500 $cm^{-1}$. The concentrations were 3% in both cases.

## Summary

(1) Methylethoxypolysiloxanes containing the trimethylsiloxy group have been prepared.

(2) The infrared spectra of these compounds are discussed.

# *Diffusion in Glycerol-Water Mixture*

By Yasunori NISHIJIMA* and Gerald OSTER

(Received June 24, 1960)

When the diffusion coefficient is concentration dependent, the diffusion curve, in which the concentration gradient is plotted against distance, will no longer be symmetric with respect to the position of the original boundary. In such a skewed curve, the maximum position of the concentration gradient is displaced to the solvent side or to the solution side depending on whether the concentration dependence is positive or negative, respectively. The degree of skewness of the curve is a measure of the extent of the concentration dependence of the diffusion coefficient.

The concentration dependence of diffusion coefficient, especially in the case of polymer solutions, has been studied[1-4].

This dependence is attributed to a thermodynamic factor and to a hydrodynamic factor. In most cases, these factors act in opposite directions and partly counterbalance the resultant concentration dependence of the diffusion coefficient. The thermodynamic factor is due to the non-ideality of the solution and usually contributes to the positive dependence, that is, to increase the rate of diffusion with increasing concentration. On the other hand, the hydrodynamic factor tends to slow down the diffusion rate with increasing concentration. This factor is attributed to the concentration dependence of the frictional coefficient of the diffusing particles. When the size and shape of the diffusing particles are independent of the concentration, the hydrodynamic factor can be estimated from the local viscosity of the medium in which the particles are diffusing[5]. It has not been entirely clear, however, how one can determine the local viscosity of the medium. In the case of very dilute solutions, the local viscosity is approximated by the solvent viscosity, whereas, at higher solute concentrations, the local viscosity is apparently somewhere between the solvent viscosity and the solution, or macroscopic, viscosity. In the case of solutions of small molecules such as glycerol-water mixtures, we have found that the local viscosity, obtained from fluorescence measurements of Auramine O, equals the macroscopic viscosity of solution[6].

It is the purpose of the present paper to investigate the concepts mentioned above using the glycerol-water system as an example, and

covering a wide range of concentrations. The diffusion measurements were carried out in an interferometric micro-diffusion apparatus[5].

## Experimental

**Apparatus.**—We have developed a simple interferometric microdiffusion method which employs an ordinary light microscope. The diffusion cell is an optical wedge consisting of two partially-reflecting microscope slides and placed on the microscope stage. Small drops of the liquids are introduced into the cell to form a sharp boundary readily. Since the cell is very thin, convection currents are eliminated and hence rigid temperature control is unnecessary and the temperature was maintained in the vicinity of 25°C. The time required for diffusion measurements in the micro method is reduced by several thousand-fold that required in a conventional diffusion apparatus. The interference fringes produced in the cell are photographed every minute. Since each fringe represents a contour line of constant optical path in the wedge, the refractive index gradient is easily determined. The details of this method have been treated elsewhere[5].

## Results

To insure high accuracy, the diffusion measurements were carried out between several pairs of glycerol-water mixtures varying in concentrations ranging from pure water to 93% glycerol by weight. An example of a normalized diffusion curve obtained by our method is given in Fig. 1. For higher glycerol concentrations the curve is even more skewed in the direction of the higher concentration side.

The diffusion coefficient $D(c)$ as a function of concentration may be calculated from Boltzmann's equation[7]

$$D(c) = -\frac{1}{2t} \cdot \frac{dx}{dc} \int_0^c x dc \qquad (1)$$

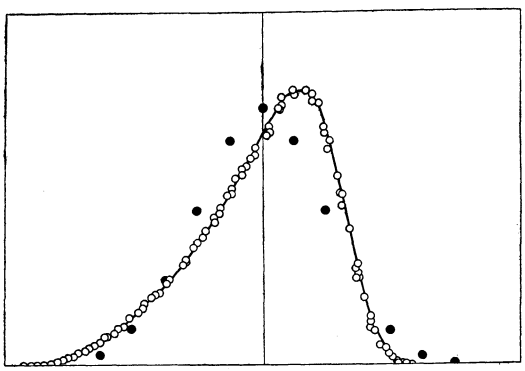

Fig. 1. Normalized diffusion curve: 62% glycerol against pure water (water on left); Open circles: experimental points. Black dots: Gaussian curve.

7) L. Boltzmann, *Ann. Physik*, 53, 959 (1894).

where $c$ is the concentration, $x$ is the distance along the direction of diffusion, and $t$ is the time. In the present study, the diffusion coefficients were calculated from Boltzmann's equation utilizing normalized coordinates. The diffusion coefficient as a function of glycerol concentration is given in Fig. 2. The fact that the slope is negative, shows that the hydrodynamic factor is predominant. Since this curve is not linear, simple graphical methods for evaluating the concentration dependence[3,8] are not valid because such methods assume linearity. A general statistical method for analyzing slightly skewed curves has been developed[9], but is not valid for high glycerol concentration since the diffusion curves are highly skewed (see, for example, Fig. 1).

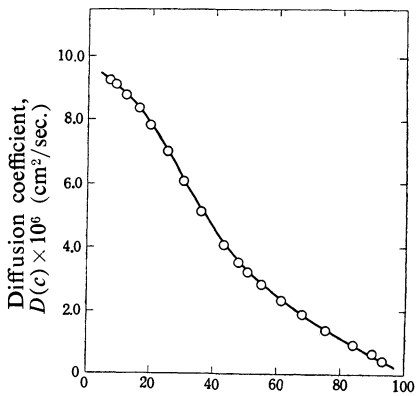

Fig. 2. Diffusion coefficient of glycerol as a function of concentration.

## Discussion

The diffusion coefficient in non-ideal solution is given by the equation[10]

$$D(c) = \frac{RT}{f} \cdot \frac{d \ln a_2}{d \ln c} \qquad (2)$$

where $f$ is the frictional coefficient of the diffusing particles, $a_2$ is the activity of the solute at concentration $c$, $R$ is the gas constant, and $T$ is the absolute temperature. We have calculated the thermodynamic factor, $d \ln a_2 / d \ln c$, in Eq. 2 from literature values of the vapor pressures of glycerol-water mixtures[11]. The frictional coefficient $f$ is proportional to the local viscosity of the medium. Hence, if the local viscosity is identical with the macroscopic, or solution, viscosity this hydrodynamic

TABLE I. CORRECTION FACTORS FOR THE DIFFUSION COEFFICIENT

| Glycerol conc. (wt. %) | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 | 90 |
|---|---|---|---|---|---|---|---|---|---|
| $(d \ln a_2/d \ln c)$ | 1.0 | 1.2 | 1.4 | 1.7 | 2.0 | 2.3 | 2.8 | 3.2 | 3.5 |
| Viscosity | 1.15 | 1.54 | 2.16 | 3.18 | 5.04 | 8.82 | 17.96 | 45.86 | 163.6 |

factor should be proportional to observed viscosities of the glycerol-water mixtures. These correction factors are given in Table I. Applying these correction factors to the data of Fig. 2, we obtain the curve shown in Fig. 3.

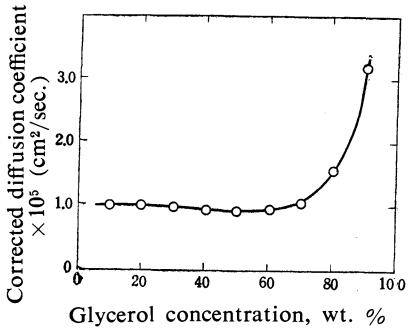

Fig. 3. Corrected diffusion coefficient of glycerol.

The corrected diffusion coefficient illustrated in Fig. 3 is sensibly independent of concentration up to 70% glycerol above which it rises rapidly. The increased mobility at very high glycerol concentrations could be due to a decreased hydration of the glycerol molecules. Vapor pressure measurements of glycerol-water mixtures have been interpreted in terms of a decrease of hydration with increasing concentration of glycerol[12]. More direct measurements, however, such as obtained from nuclear magnetic resonance, could better indicate changes in hydration.

## Summary

Diffusion studies of glycerol in glycerol-water mixtures ranging from zero to 93% glycerol were carried out using the micro-interferometric method. For higher concentration of glycerol the diffusion coefficient decreases strongly with increasing concentration and the diffusion curves are highly skewed. Applying thermodynamic and hydrodynamic correction obtained from vapor pressure measurements and solution viscosities, respectively, the diffusion coefficient was found to be sensibly independent of glycerol concentration up to about 70% after which it rises. The increased mobility at very high glycerol concentrations is attributed to a decreased hydration of the glycerol molecules under these conditions.

# *Formaldehyde Resins. LIII. The Acid-catalyzed Reaction of Acid Amide with Formaldehyde*

By Minoru IMOTO and Mitsue KOBAYASHI

(Received June 23, 1960)

As is well known, acid amides react with formaldehyde to give methylol amides, in the presence of acid- or base-catalysts. Since urea resin is produced by this kind of reaction, many studies have been made[1-3]. Recently, Ugelstadt[4] made a kinetic study of the reactions of propylamide, monochloroacetamide and benzamide with formaldehyde, and concluded that, in acid solution, the reaction rate was represented by

$$v=\frac{-\mathrm{d}[CH_2O]}{\mathrm{d}t}=\text{const.}\,[R\text{-}CONH_2]\,[CH_2O] \quad (1)$$

Furthermore, the following mechanism was

2) G. A. Crowe, Jr. and C. C. Lynch, *J. Am. Chem. Soc.*, **71**, 3731 (1949); **72**, 3622 (1950).
3) A. Iliceto, *Ann. chim. applicata*, **43**, 516 (1953).
4) J. Ugelstadt, The reaction of formaldehyde with amides, and the alkaline hydrolysis of alkoxymethyl ureas. *Dissert. at Norges Tekniske Hogskole* (1955).

proposed for this reaction:

$$\text{i)}\quad CH_2O+HA \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \overset{+}{C}H_2OH+A^-$$

$$\text{ii)}\quad R\text{-}CONH_2+\overset{+}{C}H_2OH \xrightarrow{k_2} [R\text{-}CONH_2CH_2OH]^+$$

$$\text{iii)}\quad [R\text{-}CONH_2CH_2OH]^+ + A^- \rightleftharpoons R\text{-}CONHCH_2OH+HA$$

in which step ii is rate determining. In order to justify this mechanism, it may be useful to examine how the reaction rate is influenced by the polar character of R in $R\text{-}CONH_2$. In the present paper, the acid-catalyzed reactions of ten acid amides with formaldehyde were studied kinetically. The results obtained were as follows: (i) An equation identical with that of Ugelstadt was obtained. (ii) The reaction rate constant ($k$) was estimated for each acid amide, (iii) It was confirmed that the values of $k$ fitted Hammett's equation. (iv) The reaction mechanism was discussed.

## Experimental

**Materials.** — The acid amides were synthesized from the corresponding carboxylic acids according to the following scheme;

$$R\text{-}COOH \xrightarrow[PCl_3]{SOCl_2 \text{ or}} R\text{-}COCl \xrightarrow{NH_4OH} R\text{-}CONH_2$$

The acid amides obtained were purified by repeating recrystalizations. Thus six kinds of substituted benzamides and four kinds of aliphatic amides were prepared; *p*-methoxybenzamide (m. p., 105°C, recrystalized from water-methanol), benzamide (m. p., 128°C, from water-methanol), *p*-chlorobenzamide (m. p., 177.7°C, from water-methanol), *p*-bromobenzamide (m. p., 190°C, from water-methanol), *m*-nitrobenzamide (m. p., 142.5°C, from water-methanol), *p*-nitrobenzamide (m. p., 199°C, from water-ethanol), acetamide (m. p., 80°C from chloroform-ligroin), propylamide (m. p., 79°C, from chloroform-ligroin), *n*-butylamide (m. p., 115°C, from ethylacetate-ligroin) and isobutylamide (m. p., 128°C, from chloroform-ligroin).

The aqueous solution of formaldehyde was prepared by the following procedure; a mixture of para-formaldehyde and water was distilled after refluxing for several hours. The distillate was diluted to a concentration of 1 mol./l.

As catalyst 0.6580 N (in the case of substituted benzamide) or 1.014 N (in the case of aliphatic amide) hydrochloric acid was used.

Commercial dioxane was refluxed for 17 hr. with 10% of its volume of 1 N hydrochloric acid to remove acetaldehyde, under a current of nitrogen. To remove water, the dioxane was treated with a concentrated solution of potassium hydroxide, then allowed to stand over pellets of potassium hydroxides for 1 day and dried over sodium for several hours. It was rectified three times and the fraction above 100.5°C was used.

**Kinetic Procedures.** — All reactions were carried out at 60±0.05°C. The reaction rates were measured according to the following procedures; A required amount of acid amide was weighed into a 50 ml. measuring flask. The acid amide was dissolved in 20 ml. dioxane and then 4 ml. (in the case of substituted benzamide) or 2 ml. (in the case of aliphatic amide) of the catalyst (hydrochloric acid) was added. The flask was placed in a thermostat at 60±0.05°C for at least 30 min. The formaldehyde solution and distilled water were also kept at the same temperature. A required amount of the formaldehyde solution was added to the flask from a hole pipette. Then immediately the solution was diluted to 50 ml. with distilled water. After thorough mixing, the solution was brought into the reaction vessel which was placed in the thermostat. The time when all the reactants were mixed was taken as zero. And 8—10 aliquotes of 5 ml. were taken by a pipette at suitable time intervals. The aliquote was run into a phosphate buffer solution (pH=7.1). The time when the pipette had run empty was taken as zero. Five millilitre of 0.1 N or 0.15 N potassium cyanide was added immediately and the solution was allowed to stand for 10 min. at room temperature. Then were added 10 drops of a diphenyl carbazone solution (1% in methanol), followed by 1 N nitric acid until a light orange-yellow color appeared. The solution was then immediately titrated with 0.03 N or 0.05 N mercuric nitrate until a violet color developed. The consumed amount of $CH_2O$ was calculated for each reaction time.

## Results and Discussion

**Reaction-orders of the Reactants.**—To derive a rate equation of the reaction, the effects of the concentrations of each reactant on the rates were investigated. The study was carried out first on benzamide.

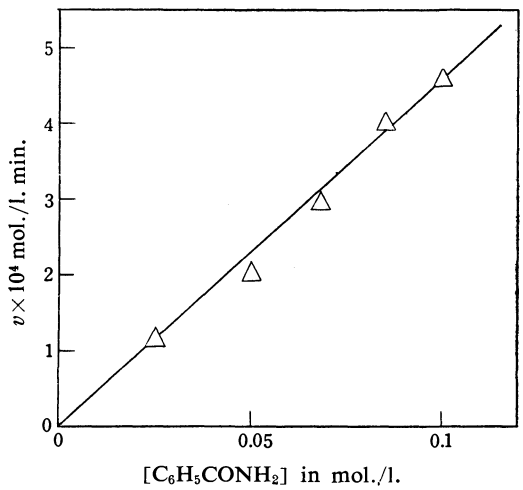

Fig. 1. The relation between the reaction rates and the concentrations of benzamide. Reaction conditions; $[CH_2O]$···0.05 mol./l.; [HCl]···0.05264 N; temp. 60°C.

a) *The Concentrations of Benzamide.*—Keeping the concentrations of formaldehyde and hydrochloric acid constant, the concentration of benzamide was changed from 0.025 to 0.1 mol./l. As shown in Fig. 1, the linear relationship was obtained between the reaction rates and the concentrations of benzamide. The reaction, therefore, was decided to be of first order with regard to the concentrations of benzamide.

b) *The Concentration of Formaldehyde.*—Keeping the concentrations of benzamide and hydrochloric acid constant, the concentration of formaldehyde was changed from 0.015 to 0.05 mol./l. As shown in Fig. 2, the linear relationship was obtained between the reaction rates and the concentrations of formaldehyde. So the reaction was also of first order with formaldehyde.

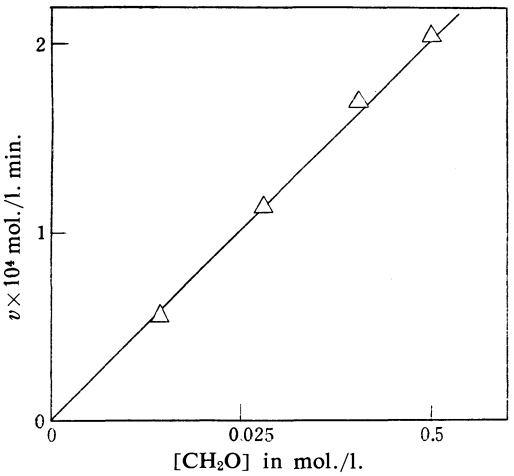

Fig. 2. The relation between the reaction rates and the concentrations of formaldehyde.
Reaction conditions; [$C_6H_5CONH_2$]···0.05 mol./l.; [HCl]···0.05264 N; temp. 60°C.

c) *The Concentrations of Hydrochloric Acid.*—Keeping the concentrations of R-$CONH_2$ and formaldehyde constant, the amount of the catalyst included in 50 ml. of the solution was changed from 2 ml. to 6 ml. The pH of the reaction system and the consumption rate of formaldehyde were measured. As shown in Fig. 3, a linear relationship was observed between the consumption rate of formaldehyde ($v$) and the concentration of hydrochloric acid. But as Fig. 4 shows, the relationship between $v$ and pH is not linear. From the results, it was assumed that this reaction proceeded by a mechanism of general acid-catalysis and the reaction order of hydrochloric acid was unity.

d) *Rate Equation.*—From the results obtained above, the experimental rate equation is represented as follows;

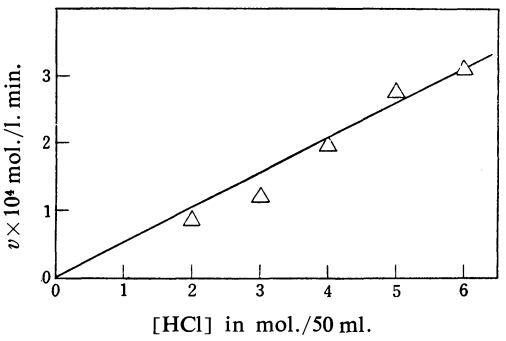

Fig. 3. Plot of the reaction rates against the concentrations of the hydrochloric acid.
Reaction conditions; [$C_6H_5CONH_2$]...0.05 mol./l.; [$CH_2O$]···0.05 mol./l.; temp. 60°C.

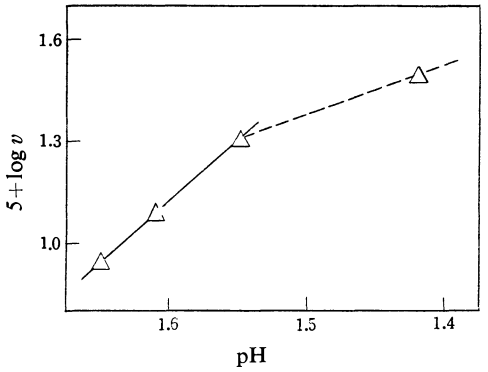

Fig. 4. Plot of the reaction rates against pH.

$$v=\frac{-\mathrm{d}[CH_2O]}{\mathrm{d}t}=k'[HCl]\,[R\text{-}CONH_2]\,[CH_2O] \quad (2)$$

Since [HCl] was assumed to be constant during the reaction, Eq. 2 was simplified to

$$v=k\,[R\text{-}CONH_2]\,[CH_2O] \quad (3)$$

To examine whether the Eq. 3 obtained for benzamide is also applicable to the other amides or not, this equation was tested for acetamide. When the initial concentrations of formaldehyde and acetamide were both a mol./l. and the consumption of formaldehyde was $x$ mol./l., Eq. 4 may be adopted in order to confirm the correctness of Eq. 3.

$$\frac{x}{a(a-x)}=kt \quad (4)$$

A linear relationship was obtained between $\frac{x}{a(a-x)}$ and $t$, at the initial stage of the reaction. (see Fig. 5) Accordingly, Eq. 3 was well supported. The deviation from the linearity at longer reaction time was attributed to the reversed reaction. For the other nine amides, the values of $k$ were estimated by the

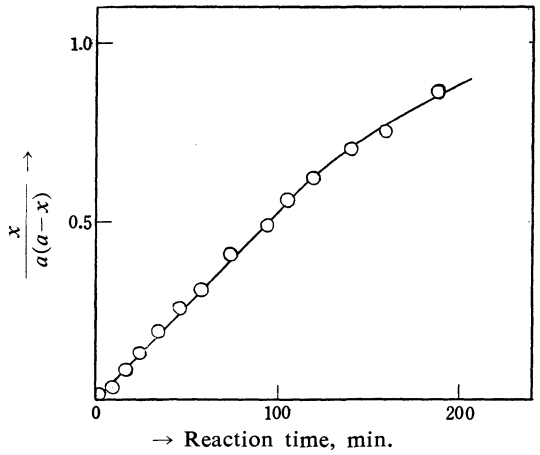

Fig. 5. Plot of $\frac{x}{a(a-x)}$ vs. reaction time.
Reaction conditions; $[CH_3CONH_2]$···0.1 mol./l.; [HCl]···0.02028 N; $[CH_2O]$···0.1 mol./l.; solvent···water; temp. 60°C.

Eq. 3. The results are given in Tables I and II.

**The Effects of the Polar Character on Reaction Rates.**—These values of $k$ were correlated with Hammett's[5] and Taft-Ingold's[6] equations. The linear relationships were obtained as Figs. 6 and 7.

The two equations were as follows;

$$\log \frac{k}{k_0} = -1.10\,\sigma$$

for the substituted benzamides.

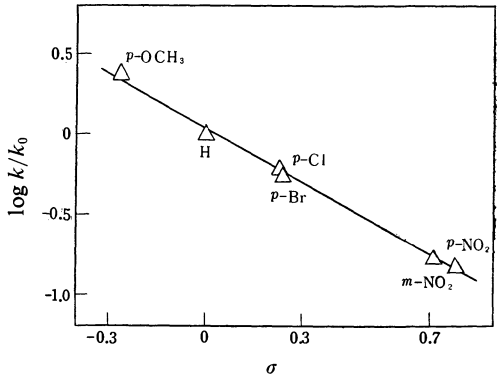

Fig. 6. Hammett equation plot
$\log k/k_0$ vs. $\sigma$ for substituted benzamides.
$\log k/k_0 = -1.10\,\sigma$

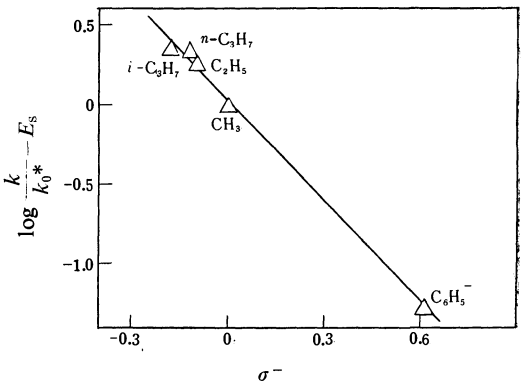

Fig. 7. Taft-Ingold equation plot
$\log \frac{k}{k_0^*} - E_s$ vs. $\sigma^-$ for aliphatic amides.

$$\log \frac{k}{k_0^*} - E_s = -2.16\,\sigma^-$$

$$\log \frac{k}{k_0^*} - E_s = -2.16\,\sigma^-$$

for the aliphatic acid amides. The rate constants for benzamide and acetamide were denoted by $k_0$ and $k_0^*$ respectively.

The negative values of $\rho$ indicate that introducing of the electron releasing groups increases the reaction rate.

**The Effect of the Polar Character on the Activation Energy and the Activation Entropy.**—For *p*-methoxybenzamide, benzamide and *p*-nitrobenzamide, the activation energies were calculated according to Arrhenius equation. (see Table III and Fig. 8). Using the values of the activation energy $\Delta E^+$ thus obtained, the activation entropies $\Delta S^+$ were calculated according to the following equation,

$$k = \kappa \cdot \frac{kT}{h} \cdot e^{-\Delta E^+/RT} \cdot e^{\Delta S^+/R}$$

5) L. P. Hammett, "Physical Organic Chemistry", McGraw-Hill Book Co., New York (1940), p. 184.

6) M. S. Newman, "Steric Effects in Organic Chemistry", John Willy & Sons Inc., New York (1956), p. 586.

where transmission coefficient denoted by $\kappa$ was assumed to be unity. The results are given in the third column of Table III.

It seems reasonable to consider that the higher value of $k$ for the amide having a more electron-releasing group is due mainly to the lower activation energy. The compensation rule is likely to exist for each amide.

Table III. Activation energies and activation entropies for substituted benzamide

| Acid amide | $\Delta E^{\ddagger}$ kcal./mol. | $\Delta S^{\ddagger}$ cal./deg. |
|---|---|---|
| *p*-Methoxybenzamide | 17.1 | −23.86 |
| Benzamide | 20.2 | −16.30 |
| *p*-Nitrobenzamide | 23.5 | −10.16 |

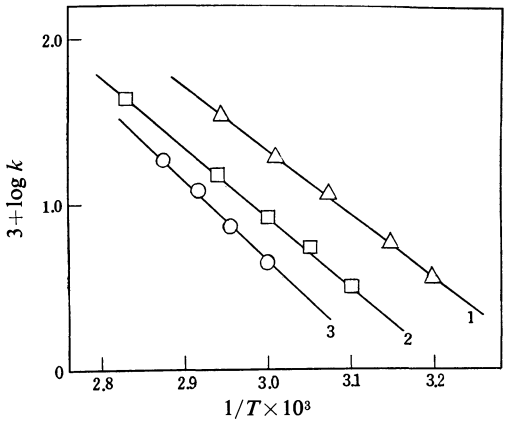

Fig. 8. Temperature dependence of the rate constants.
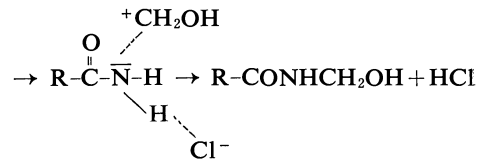
Upper curve; *p*-methoxybenzamide
Middle curve; benzamide
Lower curve; *p*-nitrobenzamide

**Reaction Mechanism of Benzamide with Formaldehyde.**—From the reaction mechanism having been introduced by Ugelstadt, it follows that

$$v=\frac{-d[CH_2O]}{dt}$$



$$=\frac{k_1}{k_{-1}}k_2[HCl][R\text{-}CONH_2][CH_2O]$$

$$=k[CONH_2][CH_2O]$$

Taking into account of his hypothesis that the step of attacking of $^{+}CH_2OH$ on the lone-pair of the nitrogen atom in $-CONH_2$ is rate determining, we could expect that the larger rate constant was observed for the amide having higher electron density at the nitrogen atom. Therefore our results can be well explained with this mechanism. But on the other hand, another mechanism, a $S_E2$ mechanism, may be also possible, as follows:

i) $CH_2O+HCl \rightleftharpoons {}^{+}CH_2OH+Cl^{-}$

ii) $R\text{-}CONH_2+{}^{+}CH_2OH+Cl^{-}$

In this mechanism, the step ii is rate determining.

Which mechanism is more correct remains undetermined.

**On the Existence of $RCONH_3^{+}$.** — Notwithstanding a weak basicity of nitrogen atom of acid amides, it was proved from a spectroscopic study that the addition of a cation to the nitrogen atom was probable.

The infrared spectrum of hydrochloric acid salt of *p*-methoxybenzamide (1 : 1) at solid state (nujol) was compared with that of *p*-methoxybenzamide (see Fig. 9).

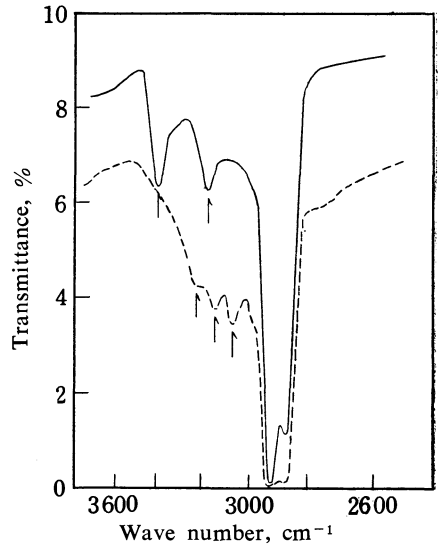


Fig. 9. The infrared spectra of *p*-methoxybenzamide and its hydrochloric acid salt.
Solid line ··· *p*-methoxybenzamide
Dotted line ··· hydrochloric acid salt

The absorption bands at 3382 and 3170 $cm^{-1}$ of the amide may be assigned to the stretching vibrations of the $NH_2$ group under the influence of hydrogen bonding. Comparing with Hopkin's result about urea nitrate[7], the 3237, 3150 and 3068 $cm^{-1}$ bands may be decided as due to the stretching vibrations of $NH_3^{+}$. The disappearance of the 3382 $cm^{-1}$ band in the salt shows an absence of free $NH_2$ group in the molecule.

7) M. Davies and L. Hopkins, *Trans. Faraday Soc.*, 53, 1563 (1957).

From the facts cited above, we may reasonably assume the structure of the salt as $R-\overset{\overset{O}{\|}}{C}-\overset{+}{N}H_3Cl^-$.

# *Formation of Benzenecarboxylic Acids from Bituminous Coal by Means of Oxygen-oxidation in Alkaline Medium*

By Yoshio KAMIYA

(Received June 29, 1960)

The oxidation of coal has been an important method of studying the structure of coal and of obtaining products such as benzenecarboxylic acids. The first systematic work was that of Fischer[1] and Schrader who used air to oxidize suspensions of coal in aqueous sodium carbonate. Oxidation of coal in alkaline permanganate solution was carried out by Bone[2] and coworkers, and most of the benzenecarboxylic acids were isolated. Oxygen-oxidation in aqueous caustic alkali was carried out by Howard[3] and coworkers, who obtained aromatic polycarboxylic acids in good yield from bituminous coal. It is hoped that better reaction methods and conditions will be found by further detailed experiments.

In this paper oxygen-oxidation of coal carried out in aqueous solution of sodium or potassium carbonate, in order to investigate the influence of reaction conditions, is discussed. Various benzenecarboxylic acids were separated from the oxidized product and were identified.

## Experimental

The sample used in the experiment was a Japanese bituminous coal, Shikamachi, the analytical result of which is given below :—

Moisture 1.2% ; Ash 19.8% ; C (d. a. f.) 87.3% ; H(d. a. f.) 5.4%.

*Oxidation Procedure A.*—A suspension of 6 g. of coal (through 100 mesh) in 200 ml. of sodium carbonate aqueous solution of various concentrations was treated with oxygen (initial pressure 30 kg./cm$^2$/0°C) at 250°C for 90 min. in a 600 ml. shaking type autoclave (agitation frequency 100/min.).

*Oxidation Procedure B.* — A suspension of 85 g. of coal in 1.5 l. of aqueous solution of sodium or potassium carbonate was treated with oxygen at 250~280°C in a 3 l. autoclave electro-magnatically agitated ; the reaction gases discharged continuously from the vessel at the rate of 2 l./min. were found to contain about 30% (average) of carbon dioxide.

*Analysis of Oxidation Products.* — The reaction product was filtered to remove residue and the filtrate was acidified with sulfuric acid to pH 1.5. Water-insoluble acids were filtered off and weighed after vacuum drying. The filtrate was saturated with sodium sulfate at 25°C and extracted twice with methyl ethyl ketone equal to 80% of the volume of the total filtrate. The total acids extracted were considered to represent "Aromatic acids" after vacuum drying at 100°C and removal of oxalic acid. Oxalic acid was precipitated with acetic acid and calcium chloride, and the precipitate was decomposed with sulfuric acid and titrated with permanganate solution. The oxalic acid was confirmed as dihydrate by the determination of equivalent weight 64 and melting point 100~101°C.

*Esterification of Aromatic Acid.*—150 g. of aromatic acids were dissolved in a mixture of 450 g. of methanol and 36 g. of sulfuric acid and kept at 110°C for 5 hr. The reaction products were extracted with ethylene dichloride and aqueous solution of sodium carbonate. The acidic esters were re-esterified under similar conditions repeatedly.

## Results and Discussion

**Reaction Conditions.** — The results of procedure A are shown in Fig. 1. An increase in the ratio of sodium carbonate to coal caused an increment in the reaction rate as well as in the yield of aromatic acids. The ratio of 8.7 : 1 corresponds approximately to the weight of sodium carbonate required to convert all the carbon dioxide into sodium bicarbonate. The yield of oxalic acid was 1.4% when the ratio was 10 : 1, but less than 0.5% when it was lower 7 : 1. When sodium hydroxide was used, the yields of products were as shown in Table I.

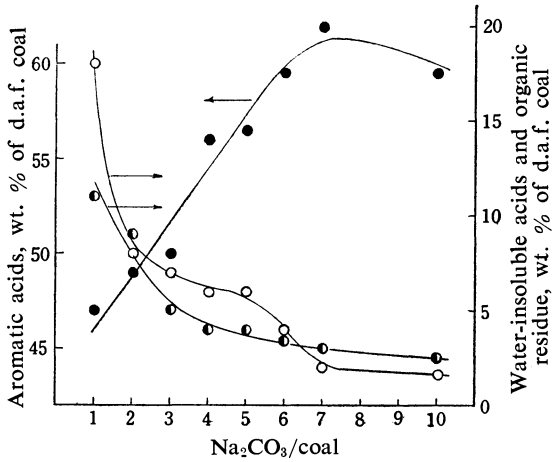

Fig. 1. Influence of the ratio of sodium carbonate to coal.
Procedure A
● Aromatic acids
○ Water-insoluble acids
◐ Organic residue

TABLE I. THE YIELDS OF OXIDATION PRODUCTS USING SODIUM HYDROXIDE AQUEOUS SOLUTION
Procedure A, NaOH/coal=3.4

Yields, wt. % of d.a.f. coal
Aromatic acids 61.3%, Water-insoluble acids 6.8%, Oxalic acid 13.2%, Organic residue 1.2%, Carbon dioxide carbon/coal carbon 0.498

Accordingly, it is seen that if enough sodium carbonate is present, the yield of aromatic acids is the same as in the case of sodium hydroxide.

A portion (200 ml.) of the reaction product from procedure B* was resubmitted to oxidation under two different conditions (Table II)

TABLE II. OXIDATION OF REACTION PRODUCT

| Oxidation condition | Yield of acids, wt. % of d.a.f. coal | |
|---|---|---|
| | Water-insoluble acids | Aromatic acids |
| Before reoxidation | 61.2 | 34.2 |
| Procedure A | 0.8 | 17.0 |
| Procedure A 34 g. of NaOH added | 3.4 | 55.2 |

to investigate the influence of alkali on the decomposition of the acids produced. It was observed that when the ratio of alkali to coal was small the decomposition rate of aromatic acids and water-insoluble acids was high.

During oxidation reaction equilibrium was reached:

$$Na_2CO_3+CO_2+H_2O \rightleftarrows 2NaHCO_3$$

* 250°C, 120 min., $Na_2CO_3$/coal=1, oxygen partial pressure 10 kg./cm², agitation frequency 85/min.

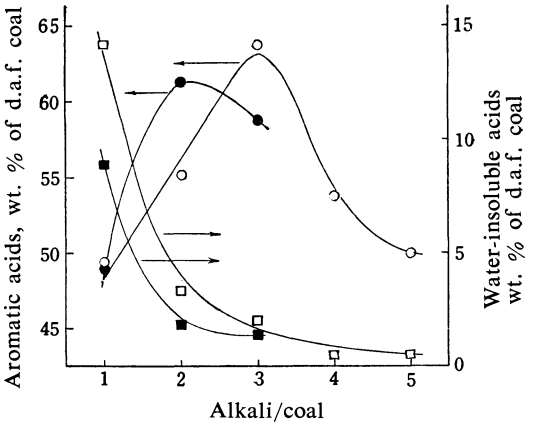

Fig. 2. Influence of the ratio of alkali to coal.
Procedure B, 270°C, 120 min.,
Oxygen partial pressure (average) 14 kg./cm² ($K_2CO_3$), 17 kg./cm² ($Na_2CO_3$),
Agitation frequency 85/min.
● Aromatic acids ($Na_2CO_3$)
○ Aromatic acids ($K_2CO_3$)
■ Water-insoluble acids ($Na_2CO_3$)
□ Water-insoluble acids ($K_2CO_3$)

So it was inferred that bleeding the reactor to remove carbon dioxide would result in good yield of aromatic acids, even when the ratio of alkali to coal was not large. Results of procedure B are shown in Fig. 2. The relations were found to be independent of the kind of alkali at the same molar ratio, when the normality of solution was chosen instead of alkali coal weight ratio. Good acids yields were obtained when the ratio of alkali to coal was higher than 2:1.

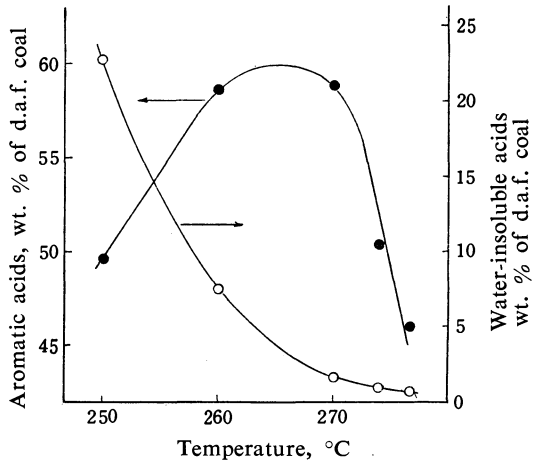

Fig. 3. Influence of temperature.
Procedure B, 120 min. $Na_2CO_3$ 255 g.
Oxygen partial pressure (average) 17 kg./cm², Agitation frequency 85/min.

Procedure B, $K_2CO_3$ 255 g., 270°C, 120 min.,
Oxygen partial pressure (average) 14 kg./cm²
● Aromatic acids
○ Water-insoluble acids

Generally, the reaction rate was doubled for every 10°C rise in temperature. There is also an optimum temperature as shown in Fig. 3. The effect of agitation is also important as shown in Fig. 4.

TABLE III. REACTION CONDITIONS FOR OPTIMUM YIELDS OF AROMATIC ACIDS

| | | |
|---|---|---|
| Reaction conditions | | |
| Alkali used | $Na_2CO_3$ | $K_2CO_3$ |
| Alkali/Coal (wt. basis) | 3 | 3 |
| Temperature (°C) | 270 | 270 |

| Agitation frequency (per min.) | 85 | 85 |
| Yield (wt. % of d.a.f. coal) | | |
| Aromatic acids | 60.8 | 63.9 |
| Water-insoluble acids | 3.8 | 2.1 |
| Oxalic acid | 0.2 | 2.8 |
| Organic residue | 3.1 | 1.5 |

TABLE IV. PROPERTIES OF ACIDS PRODUCED UNDER OPTIMUM CONDITIONS

| Color | | Aromatic acids yellow | Water-insoluble acids dark brown |
|---|---|---|---|
| Elementary analysis | C(%) | 54.5 | 66.0 |
| | H(%) | 3.7 | 3.0 |
| Molecular weight | | 250 | — |
| Equivalent weight | | 80 | 130 |

Remarks: Ash contents of these acids were less than 0.1%.

Details of the optimum reaction conditions and the yield of products are given in Table III. The properties of the acids are given in Table IV.

The coal oxidation process may be expressed as follows: Coal $\xrightarrow{I}$ Water-insoluble acids $\xrightarrow{II}$ Aromatic acids $\xrightarrow{III}$ $CO_2$, $H_2O$. If the ratios of the reaction speeds of these steps are independent of any reaction factors, good correlation between the yields of products should be observed. The relations between water-insoluble acids and aromatic acids are plotted in Fig. 5, and found the mechanism of the reaction is not changed by altering temperature, pressure and agitation. When the alkali coal ratio is 1 : 1, the first step becomes slow and the third fast. The oxidation mechanism depends upon the ratio of alkali to coal.

**Separation of Benzenecarboxylic Acids.**—From the industrial point of view, the most favorable oxidation medium may be sodium carbonate, because of its smaller corrosive effect, low cost and the possibility of its easy recovery. Benzenecarboxylic acids were separated from the aromatic acids which were obtained by the sodium carbonate process under the optimum conditions.

By the first and second esterification 128 g. of neutral esters (Fraction A) were obtained, and by the third and fourth 15 g. (Fraction B) were obtained. Residual acidic materials were completely hydrolysed with alkali and 6 g. of acids (Fraction C) were recovered.

TABLE V. ANALYTICAL CHARACTERISTICS OF ISOLATED ACIDS AND ESTERS

| Component | Elementary analysis (%) C | H | Equivalent weight | Melting point | Remarks |
|---|---|---|---|---|---|
| Phthalic acid | 57.45 (57.45) | 3.66 (3.64) | 83 (83) | Anhydride 131°C *p*-Nitrobenzyl ester 155°C | |
| Isophthalic acid | 57.69 (57.45) | 3.45 (3.64) | 83 (83) | Dimethyl ester 65°C *p*-Nitrobenzyl ester 201~202°C | Barium salt water-soluble |
| Terephthalic acid | 57.53 (57.45) | 3.45 (3.64) | 83 (83) | Dimethyl ester 139~140°C | |

Figures in brackets have been calculated.
* Dissolved in aqueous solution of sodium carbonate and treated at 450°C.

Fraction A was separated into nine fractions by means of vacuum distillation at 120~300°C (packed column, I. d. 10 mm., height 26 cm.). From the distillate nine benzenecarboxylic acids (di-, tri- and tetra-) were isolated by means of solubility difference, using acids, barium salts or methyl esters in solution, and identified (Table V). Infrared spectra of the benzenecarboxylic acids were compared with those of the pure substances and confirmed the identifications. Traces of benzoic acid were isolated by means of counter-current distribution (solvent: ethyl ether and water) from phthalic acid fraction. Naphthalene-carboxylic acid was separated as follows; the ethyl ether soluble part of a distillate (4 mmHg, 225~300°C) was hydrolysed, the filtrate of barium salts in solution was extracted with ethyl ether after acidification, and the extracted acid in ethyl ether solution was purified by washing with water.

Fraction B was submitted to chromatography (column alumina, developer carbon tetrachloride) and recrystallization, and as a result benzene tetra- and penta-carboxylic acids were isolated. From Fraction C mellitic acid was isolated.

The yields of benzenecarboxylic acids from the aromatic acids were as follows:

| | | |
|---|---|---|
| Benzenedicarboxylic acids | | 7.1% |
| Phthalic acid | 5.9% | |
| Isophthalic acid | 1.1% | |
| Terephthalic acid | 0.1% | |
| Benzenetricarboxylic acids | | 16.2% |
| Hemimellitic acid | 4.9% | |
| Trimellitic acid | 10.9% | |
| Trimesic acid | 0.4% | |
| Benzenetetracarboxylic acids mainly 1, 2, 4, 5- and 1, 2, 3, 4- | | 17.3% |
| Benzenepentacarboxylic acid | | 1.9% |
| Mellitic acid | | 0.3% |

The total yield of benzenecarboxylic acids was 43% of aromatic acids and 25% of coal (d.a.f.). The ratio of di- tri- and tetra-benzenecarboxylic acids was approximately 1 : 2 : 2.

Acknowledgment is made to professor S. Ando for his support and advice in the experiments.

# *Charge-transfer Complexes between Iodine and Various Aliphatic Amines*

By Hiroshi YADA, Jiro TANAKA and Saburo NAGAKURA

(Received June 21, 1960)

In 1949 Benesi and Hildebrand[1] found an absorption band characteristic of the iodine complex with benzene. They demonstrated that this absorption band belongs to neither of the component molecules but is due to the interaction between them. Mulliken[2] succeeded in interpreting it as the intermolecular charge-transfer absorption, namely, the absorption inherent to the charge-transfer complex caused by the interaction between an electron donor and an electron acceptor. Since that time complexes of this kind consisting of various combinations of electron donors and acceptors have been studied from both experimental and theoretical points of view[3,4]. Especially, the complexes containing iodine as electron acceptor have been investigated extensively by many authors[3-7].

Nagakura[8] studied spectroscopically the complex between triethylamine and iodine in *n*-heptane. He concluded that the system does not exist as the ammonium salt like $(R_3IN)^+I^-$ but does as the charge-transfer complex represented by the resonance hybrid between the no-bond structure, $R_3N\cdots\cdots I_2$ and the dative (charge-transfer) structure, $R_3N^+-I_2^-$, and also showed that this complex is the most stable among the iodine complexes studied so far, as is seen from its great heat of formation of 12.0 kcal./mol. Further, Nagakura and Tsubomura[9] determined the dipole moment of this complex to be 11.3D in dioxane solution. This fact is conceivably interesting in showing that the contribution of the dative structure amounts to or probably exceeds 50% for this complex and that the complex may be regarded as an intermediate stage for the ammonium salt formation process shown as follows: $R_3N+I_2\rightarrow R_3IN^++I^-$. In fact it has been observed that the complex is easily converted into the corresponding ammonium salt when a slight amount of moisture is present.

In the present paper, the above-mentioned study is extended to iodine complexes with aliphatic amines other than triethylamine. The electron donors used in the present study are ammonia, methylamine, ethylamine, *n*-butylamine, dimetylamine, trimethylamine, tri-*n*-propylamine, tri-*n*-butylamine and piperidine. One of our principal purposes is to discuss the relation between the stability of the complexes and the structures of amine molecules as electron donors, special attention being concentrated on the effect of the alkyl group upon the electron donating power and steric repulsion of various amines. Another principal purpose is to obtain accurate and profound knowledge concerning the spectroscopic properties of the amine-iodine complexes. This is useful for discussing the mechanism of the complex formation.

## Experimental

**Purification of Materials.**—Commercial iodine of G. P. grade was sublimed first with calcium oxide and potassium iodide, and sublimed again under nitrogen atmosphere. It was kept in a desiccator with phosphorus pentoxide as a drying agent. *n*-Heptane of Enjay Co. was shaken with sulfuric acid, dried with calcium chloride and sodium metal successively, and distilled with a distilling column of 60 plates made by Tokyo Kagaku Seiki Co.

Ammonia generated from its aqueous solution by adding concentrated aqueous alkali was liquefied by coolng with dry ice and acetone mixture and dried with a piece of sodium metal. The dry ammonia thus obtained was led into *n*-heptane to prepare the stock solution. This stock solution was diluted to a desired concentration immediately before use. Methylamine, ethylamine, dimethylamine and trimethylamine were purified by distilling at low temperatures with activated alumina immediately before use for spectrophotometric measurements. The concentrations of ammonia, methylamine, dimethylamine and trimethylamine were determined by titration. *n*-Butylamine, diethylamine and piperidine were distilled twice with activated alumina to remove a trace of water. Tri-*n*-propylamine and tri-*n*-butylamine were shaken with acetic anhydride to remove primary and secondary amines contained as impurities, dried with activated alumina and then distilled twice under reduced pressure.

**Method.** — A Cary recording spectrophotometer Model 14 was used for measuring absorption spectra. The temperature of the absorption cell was kept constant during the measurements by using the thermospacer through which water of constant temperature was circulating. A quartz cell with a glass stopper ($10\pm0.01$ mm. light path) was used for the measurements in the ultraviolet region and a quartz cell with $100\pm0.2$ mm. light path was also used for the measurements in the visible region. In the present experiments, the concentrations of iodine and aliphatic amines were taken as low as possible. The actual values of the concentration were in the order of $10^{-5}$ and $10^{-3}\sim10^{-4}$ mol./l. for iodine and aliphatic amines, respectively. Under these conditions, the mixed solutions of iodine and amines were proved spectroscopically to exist in stable equilibrium for several hours. For the system of iodine and ammonia, however, the donor concentration amounted to the order of $10^{-2}$ mol./l., since the equilibrium constant for this system was rather small compared with those the other systems[10]. In this case the shape of the shifted visible band of iodine, which was used for the calculation of equilibrium constants in this case, was observed to be slightly dependent on the donor concentration. It was evident, however, that the effect was not so great as to affect the calculated equilibrium constants. Special care was taken to get rid of moisture in the procedure of preparing the mixed solutions, since even the existence of a slight amount of water is supposed to produce the $I_3^-$ ion whose strong absorption peaks appear in the vicinity of the two kinds of absorption bands, namely the charge-transfer band and the shifted visible band of iodine.

## Results and Discussion

Generally speaking, all the amine-iodine complexes under present consideration show the same spectroscopic features as the triethylamine-iodine complex described in the previous paper does[8]. Some typical examples of the absorption spectra measured in the present study are shown in Figs. 1—4. As is revealed from these figures, the absorption spectra of the iodine-amine systems commonly show two characteristic bands at 410~430 m$\mu$ and 230~280 m$\mu$ wavelength regions. By comparison with the iodine-triethylamine system reported in the previous paper[8], it is evident that the shorter and longer wavelength bands are respectively the charge-transfer band and the blue-shifted one of the visible band of iodine which ordinarily appears at 520 m$\mu$ in *n*-heptane. The maximum wavelengths ($\lambda_{CT}$, $\lambda_{vis}$) of these two kinds of absorption bands are given in Table I, together with the peak intensity ($\varepsilon_{CT}$) for the charge-transfer band. Further, from the analysis of these spectroscopic data, it was concluded that all the electron donors under consideration form stable 1 : 1 complexes with iodine in *n*-heptane. Since the details of the analytical method was described in the previous paper[8], it seems tedious to repeat

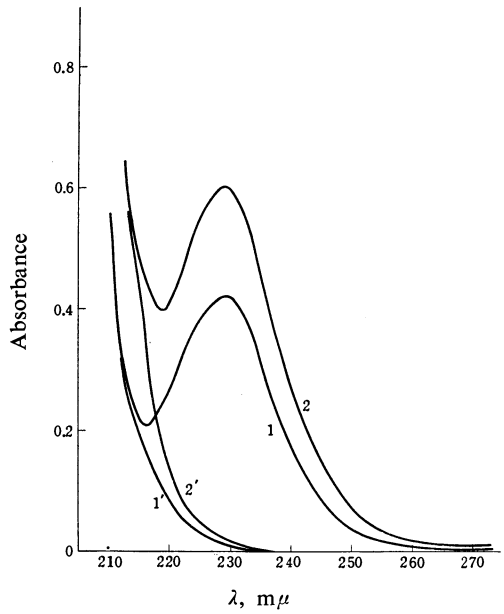

Fig. 1. The near ultraviolet absorption measured at 20°C with mixed solution of ammonia and iodine in *n*-heptane. The concentration of iodine is $7.35\times10^{-5}$ mol./l. The concentrations of ammonia are $5.70\times10^{-3}$ and $1.14\times10^{-2}$ mol./. for curves 1 and 2, respectively. Curves 1′ and 2′ are the absorption curves for the pure ammonia solutions with the concentrations corresponding to curves 1 and 2, respectively. The iodine solution of $7.35\times10^{-5}$ was used as reference with the measurement of curves 1 and 2. The light path was 10 mm. in all cases.

10) With the amine concentration over this limit value the shape of the two bands apparently changed and their peaks seemed to shift towards longer and shorter wavelengths for the charge-transfer band and the shifted visible band of iodine respectively. This phenomenon is the same as that observed by Reid and Mulliken in the case of pyridine-iodine system. In this case it is likely that complicated phenomena other than 1 : 1 equilibrium occur.

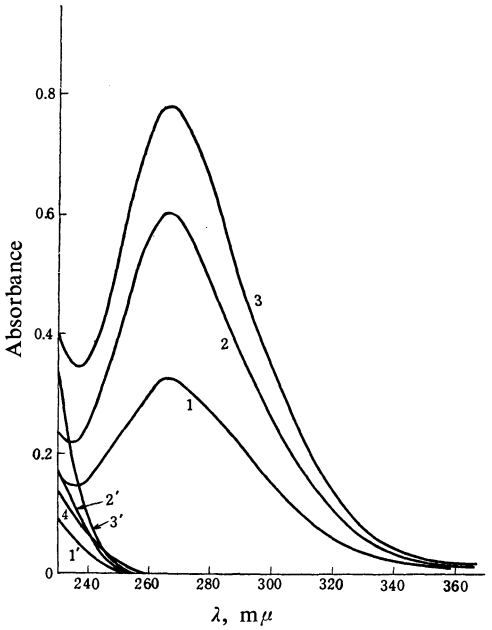

Fig. 2. The near ultraviolet absorption measured at 20°C with the mixed solution of trimethylamine and iodine. The concentration of iodine is $3.00\times10^{-5}$ mol./l. The concentrations of trimethylamine are $2.04\times10^{-4}$, $4.08\times10^{-4}$ and $7.45\times10^{-4}$ mol./l. for curves 1, 2 and 3, respectively. Curves 1', 2' and 3' are the absorptions for the pure trimethylamine solutions with the concentrations corresponding to curves 1, 2 and 3, respectively. Curve 4 is for the pure iodine solution. The light path was 10 mm. in all cases.

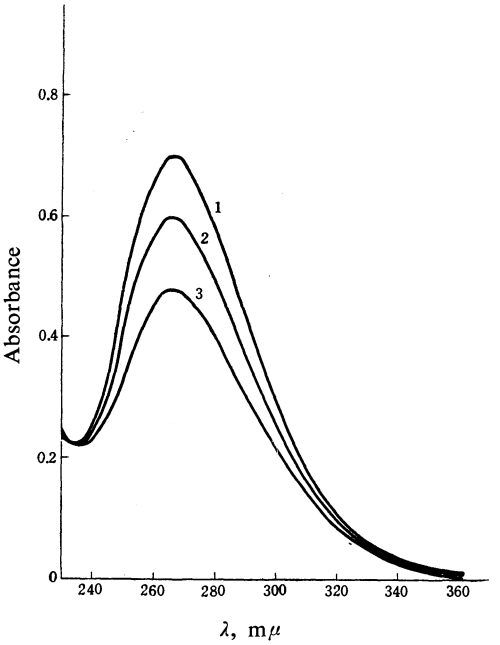

Fig. 3. The temperature dependency of the near ultraviolet absorption of the mixed solution of trimethylamine and iodine. The concentrations of iodine and trimethylamine are $3.00\times10^{-5}$ and $4.08\times10^{-4}$ mol./l., respectively. 10 mm. light path.

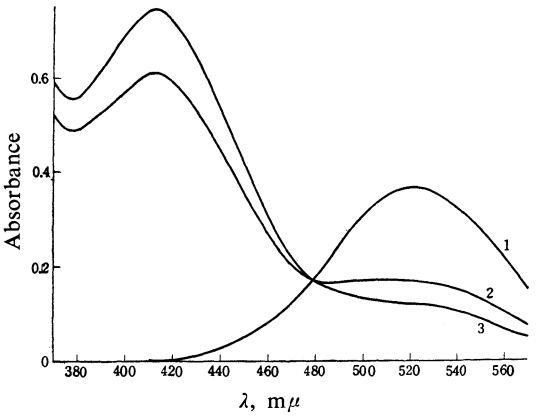

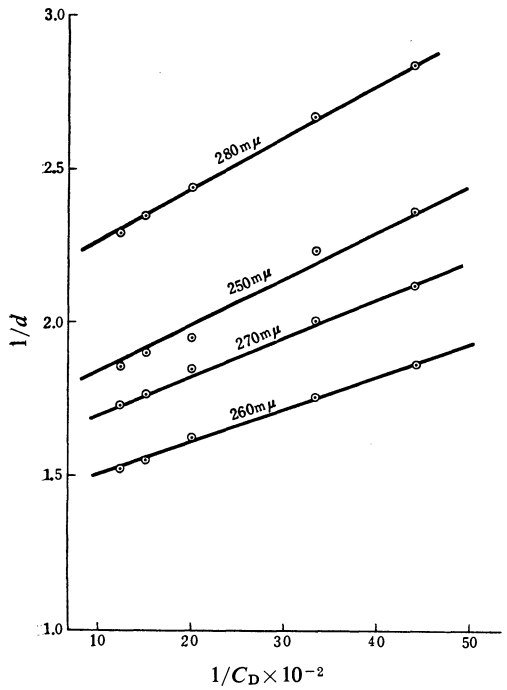

Fig. 4. The visible band of the mixed solution of tri-*n*-butylamine and iodine. The concentration of iodine is $3.97\times10^{-5}$ mol./l. The concentrations of tri-*n*-butylamine are 0, $8.34\times10^{-4}$ and $1.294\times10^{-3}$ mol./l. for the curves 1, 2 and 3, respectively. 100 mm. light path.

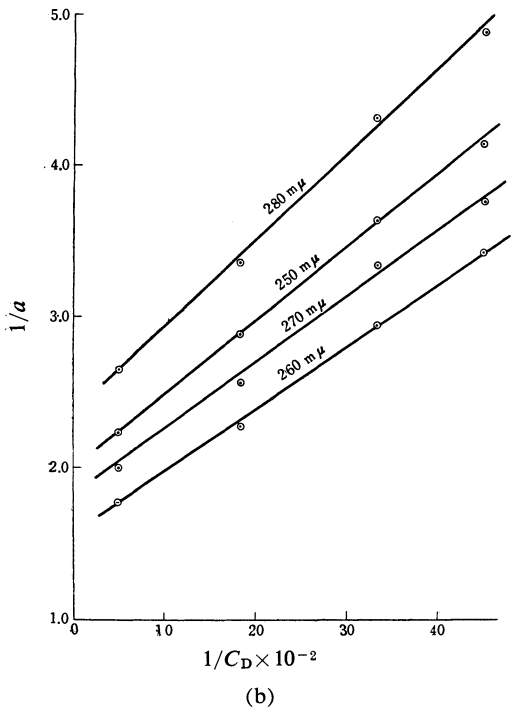

here an account of it. Hence, our description on the evaluation of the equilibrium constants ($K$) will be made only in brief.

The actual evaluation of $K$ was made by the two following methods; one is Benesi and Hildebrand's method and the other is the method which was applied successfully to some hydrogen-bonded systems and also to the triethylamine-iodine system[8,11]. Fig. 5 shows that Benesi and Hildebrand relation is satisfied for the systems under consideration. The $K$ values obtained by these two methods were in complete agreement with each other within the range of experimental errors. For most of the systems under consideration, both the charge-transfer band and the shifted iodine visibie band were used for the evaluation of $K$. However, for the system containing ammonia or methylamine as the electron donor, $K$ was evaluated from the blue-shifted iodine band alone. This is because the charge-transfer bands of these two systems, which appeared at shorter wavelengths compared with those of the other systems, overlap to some extent with the band at some 190 mμ pertinent to the electron donors and therefore are not suitable for the accurate evaluation of $K$. The $K$ values at various temperatures obtained in the present study are given in Table I. Then the values of $R\ln K$ were plotted against the reciprocals of the absolute temperatures ($T$) at which

equilibrium constants were obtained. The linear relationship between these two quantities is shown in Fig. 6 for some typical systems. The heat of formation ($\Delta H$) and the entropy change ($\Delta S$) for the complex formation were obtained from the slope of the straight line and its intersection with ordinate, respectively (actually by the use of the least squares method). The results are shown in Table I, together with the ionization potentials ($I_p$) cited from literatures[12,13] for convenience of discussion. Some notable facts deduced from the results in Table I will be discussed below.

**Heat of Formation and Entropy Change.**— The $|\Delta H|$ values change widely from 4.8 kcal./mol. for the ammonia complex to 12.3 kcal./mol. for the tri-*n*-propylamine complex. A similar tendency can also be seen with $|\Delta S|$. Moreover, it is evident from Table I that both of these quantities generally increase with the decreasing ionization potential of the electron donor. This relationship between $|\Delta H|$ and $I_p$ is completely consistent with the expectation from Mulliken's charge-transfer theory. Therefore this fact certainly supports the interpretation that the iodine-amine complexes under consideration are of Mulliken's charge-transfer type.

It is worthy of notice that the values of $|\Delta H|$ and $|\Delta S|$ increase regularly by replacing

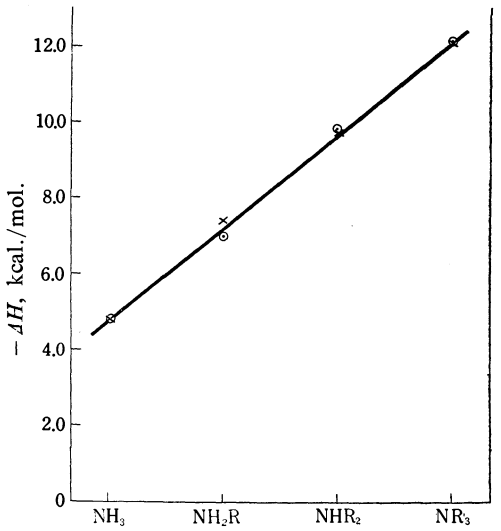

Fig. 7. The effect of successive substitution of alkyl groups for hydrogen atoms of ammonia on the heat of formation.

○: R=Me ×: R=Et

successively hydrogen atoms of ammonia by fixed kinds of alkyl groups. A typical example exhibiting such a tendency is given in Fig. 7. This figure shows that $|\Delta H|$ changes linearly with the number of the methyl or ethyl group introduced into the ammonia molecule. This seems to be interesting in meaning that the effect of the alkyl substitution upon the magnitudes of this quantity may be additive. According to the present experimental results, the $|\Delta H|$ value increases by 2.4 kcal./mol. by replacement of a hydrogen atom of ammonia by a methyl or ethyl group.

Next let us add some notes on the direct relation between $|\Delta H|$ and $|\Delta S|$. As was already pointed out by several authors[14], $\Delta H$'s are often known to change in a linear fashion with $\Delta S$'s for a series of related reactions or equilibria involving moderate changes in structure. For example, Keefer and Andrews[15]

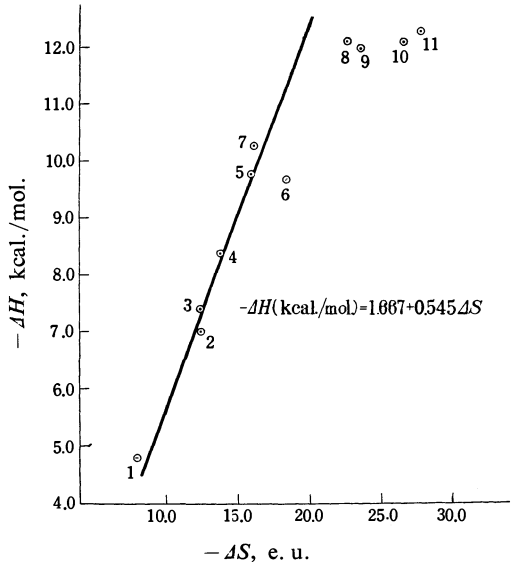

Fig. 8. The relation between the heats of formation and entropies. The numbers in Figs. 8-10 represent the kind of electron donors: 1, ammonia; 2, methylamine; 3, ethylamine; 4, *n*-butylamine; 5, dimethylamine; 6, diethylamine; 7, piperidine; 8, trimethylamine; 9, triethylamine 10, tri-*n*-propylamine; 11, tri-*n*-butylamine. The value for triethylamine is taken from Ref. 11.

14) For example, see J. E. Leffler, *J. Org. Chem.*, **20**. 1202 (1955).

15) R. M. Keefer and L. J. Andrews, *J. Am. Chem. Soc.*, **77**, 2164 (1955).

reported that such a linear relationship holds good for a series of substituted benzene-iodine complexes.

As is clear from Fig. 8, the linear relationship between $|\Delta H|$ and $|\Delta S|$ seems to hold for most amine complexes studied in the present paper, too. However, the points for the complexes including diethylamine and four tertiary amines as electron donors apparently deviate rightwards from the straight line. In the complex formation of iodine with these amines involving bulky substituent groups, the steric strain may actually bring about a great decrease of freedom in the motion of the substituent groups. This is probably the reason why the complexes including these amines as electron donors show greater entropy change than that expected from the linear relationship in Fig. 8. Such deviation from the linear relationship was also observed by Keefer and Andrews with the hexaethylbenzene-iodine complex[15]. Excluding the members deviating from the straight line, one can evaluate the isokinetic temperature[14] to be 545°K for amine-iodine systems.

**The Relation between $|\Delta H|$ and Hammett's Constant.** — When the linear relationship is satisfied between $\Delta H$ and $\Delta S$ in a series of related reactions or equilibria, the same relationship is known to be always satisfied between Hammett's substituent constant $\sigma$ and $\Delta H$, too. In fact, on the basis of the experimental results by Brown et al.[16], Taft[17] pointed out that $\Delta H$ values of $Me_3BNR_3$ complexes change linearly with the $\sigma^*$ values of substituent groups of amines, so far as the steric strain due to the substituent groups may be regarded as small. A similar relation may be expected to hold for the present case. In Fig. 9 are plotted the heats of formation of the iodine-amine complexes against $\sigma^*$ values for alkyl groups of various amine components. The $\sigma^*$ values taken here are the same as those employed by Taft[18] for the trimethylboron-amine complexes. Inspection of the figure reveals to us that, as expected from Hammett's rule, the linear relationship is well satisfied for almost all the points except for those of triethyl-, tri-*n*-propyl-, tri-*n*-butyl-amines. The discrepancy observed with these three tertiary amine complexes may reasonably be thought to be caused by the steric strain. This fact is consistent with the conclusion derived from the $|\Delta H|-|\Delta S|$ relationship mentioned in the preceding paragraph. Taft also pointed out the existence of a similar discrepancy for the $Me_3B\cdot NR_3$ complexes. By excluding the cases of the donors deviating from the straight line in Fig. 9, the value of reaction constant $\rho$ can be calculated to be $-4.84$ for the amine-iodine complexes.

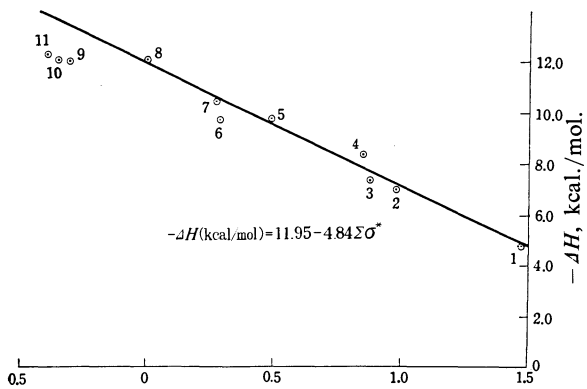

Fig. 9. Hammett's plot between the heat of formation and $\sigma^*$. The straight line is drawn by applying the least squares method to the points 1—5 and 7.

**The Relation between Wavelengths of Charge-transfer Bands and Ionization Potentials of Electron Donors.**—In Fig. 10 the transition energies ($h\nu_{CT}^{obs}$) of the charge-transfer spectra are plotted versus the ionization potentials of electron donors. As is clearly seen from this figure and Table I, the lower the ionization potentials of electron donors are, the smaller the transition energies of the charge-tranfer bands. This tendency can naturally be expected from Mulliken's theory and has already been observed by several investigators for iodine complexes with aromatic hydrocarbons and other electron donors[14,15]. However, the present results are thought to be more reliable and systematic compared with results obtained with some other iodine complexes, because for the present systems the charge-transfer bands appear at the suitable wavelength region where the bands do not overlap with those inherent to the component molecules and therefore the accurate determination of the maximum wavelength is possible.

Concerning the relation between the ionization potential of the electron donor and the transition energy of the charge-trasfer absorption band, Mulliken's charge-transfer theory gives the following formula:

$$h\nu_{CT}=I_p-A+2\beta^2/(I_p-A) \qquad (1)$$

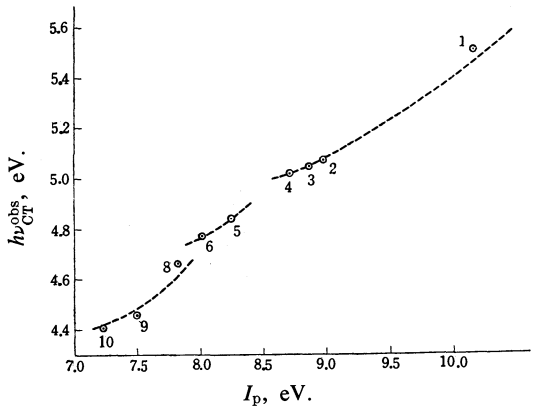

Fig. 10. The relation between the transition energies ($h\nu_{CT}^{obs}$) of the charge-transfer absorption bands and the ionization potentials of the electron donors ($I_p$).

where $\beta$ means the exchange integral between electron donating and electron accepting orbitals, and $A$ represents the electron affinity of the acceptor plus the attraction energy between the component molecules in the charge-transfer structure. Hastings et al.[15] found empirically that Eq. 1 with constant $A$ and $\beta$ fits well the observed $h\nu_{CT}$ values of the complexes of a large number of donor molecules with iodine. However, in the present iodine complexes where the value of $|I_p-A|$ can not be thought to be considerably large as compared with $|\beta|$ and the interaction between the component molecules is apparently great as revealed from the $\Delta H$ values, it looks better to adopt the following equation which can be derived by treating the resonance interaction of the no-bond structure with the dative (charge-transfer) structure with the aid of a variation method:

$$h\nu_{CT}=\sqrt{(I_p-A)^2-4s\beta(I_p-A)+4\beta^2}/(1-s^2) \quad (2)$$

where $s$ means the overlap integral between the electron donating and accepting orbitals, and the other notations in Eq. 2 are the same as those in Eq. 1. From either of these formulas, the linear relationship between $I_p$ and $h\nu_{CT}$ may be expected when the magnitude of $I_p-A$ is overwhelmingly greater than $|\beta|$. In fact, Ham, Platt and McConnell[20] pointed out that the expected relationship is fulfilled for the $h\nu_{CT}^{obs}$ and $I_p$ values observed with a number of iodine complexes.

By the first glance at Fig. 10, it may be revealed that all the points in the figure fit fairly well a straight line. However, in view of the fact that the observed $h\nu_{CT}^{obs}$ values of iodine complexes with various primary or tertiary amines show a tendency to converge to a constant value (5.0 and 4.4 eV. for primary and tertiary amines respectively), it looks better to interpret the results as follows: All the points in Fig. 10 are divided into three parts, according to whether the electron donor is ammonia and primary amines, secondary amines, or tertiary amines. Further, each part of them can conceivably be represented by a hyperbola as expected from Eq. 2.

In other words, it may be said that no parameter in Eq. 2 is a constant commonly used for all the iodine complexes under consideration but rather a constant characteristic of each part. In this connection, it seems interesting to evaluate the actual values of these parameters in such a manner as to fit the observed relationship between $I_p$ and $h\nu_{CT}^{obs}$ as well as possible.

Under the reasonable approximation that the exchange integral $\beta$ is proportional to the overlap integral $s$, namely $\beta=\alpha s$, Eq. 2 can be changed as follows:

$$(1-s^2)h\nu_{CT}=\{(I_p-A)^2-4(I_p-A)\alpha s^2+4\alpha^2 s^2\}^{1/2} \quad (3)$$

Here $\alpha$ is a constant which may be commonly determined independently of the kind of amine. The structure of the trimethylamine–iodine complex was studied by Strømme[22] with the aid of X-ray crystal analysis method and was determined as shown in Fig. 11. On the basis

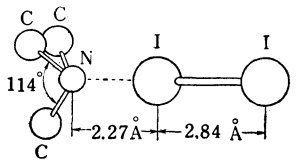

Fig. 11. The spatial configuration for the trimethylamine–iodine complex based on Strømme's X-ray crystal analysis[22].

of this structure, the overlap integral $s_t$ for the tertiary amine–iodine complex system can be evaluated at 0.293. In this case, the 5p $\sigma^*$ antibonding orbital of iodine and the s-p hybridized nonbonding electron orbital of nitrogen are assumed to be electron accepting and donating orbitals, respectively. In that case the proportion of s-p hybridization was determined from the ∠C–N–C bond angle. By the use of the value of $s_t$ and the observed $h\nu_{CT}^{obs}$ and $I_p$ values, the parameter $A_t$ for the tertiary amine complexes and the common

20) H. McConnell, J. S. Ham and J. R. Platt, *J. Chem. Phys.*, **21**, 66 (1953).
21) S. H. Hastings, J. L. Schiller and F. A. Matsen, *J. Am. Chem. Soc.*, **75**, 2900 (1953).
22) O. Strømme, *Acta Chem. Scand.*, **13**, 268 (1959).

parameter $\alpha$ can be evaluated at 7.60 and $-7.14$ eV., respectively. Further, by applying commonly this $\alpha$ value to the secondary and primary amine systems, the parameters for these systems ($s_s$, $s_p$, $A_s$ and $A_p$) can be determined. These results are tabulated in Table II, together with the values of $\beta_p$, $\beta_s$ and $\beta_t$.

Table II. The calculated values of parameter in Eq. 3

| | $A$ (eV.) | $s$ | $\beta$ (eV.) |
|---|---|---|---|
| Primary amines and ammonia | 9.85 | 0.327 | $-2.32$ |
| Secondary amines | 8.21 | 0.308 | $-2.20$ |
| Tertiary amines | 7.60 | 0.293 | $-2.09$ |

From Table II it is clear that $A$, $s$ and $|\beta|$ values decrease in the order of primary amine > secondary amine > tertiary amine. The explanation for this tendency will be given below. The bulky alkyl groups attached to the nitrogen atom of the amine molecule probably cause the increase in the steric repulsion with the opponent iodine molecule. Actually the existence of the steric hindrance for the cases of the triethylamine, tri-*n*-propylamine and tri-*n*-butylamine complexes was shown in the preceding paragraph. This steric repulsion may conceivably bring about the increase in the N–I distance of the complex, in the order of the primary amine<secondary amine < tertiary amine. This means that $s$, $|\beta|$ and the magnitude of the electrostatic attraction in the dative (charge-transfer) structure decrease in the following order: primary amine > secondary amine > tertiary amine. Moreover, $A$ is considered to be the sum of the electron affinity of electron acceptor and the electrostatic attraction between component molecules in the complexed state. Therefore the values of $A$ turn out to decrease in the above order, even if the electron affinity of iodine may be regarded as a constant. Since the latter value is usually assumed to be 1.8 eV.[23], it is easily seen from the $A$ values given in Table II that the absolute values of the electrostatic attraction terms then amount to some 8.0, 6.4 and 5.8 eV. for the complexes including ammonia and primary amines, secondary amines, and tertiary amines, respectively.

## Summary

Mulliken's charge-transfer type molecular complexes between iodine and various aliphatic amines were studied spectrophotometrically in *n*-heptane solutions. The electron donor components used in the present study include ammonia, primary amines (methyl-, ethyl- and *n*-butyl-), secondary amines (dimethyl-, diethyl- and piperidine), and also tertiary amines (trimethyl-, tri-*n*-propyl- and tri-*n*-butyl-). The charge-transfer absorption bands characteristic of molecular complexes of this kind appeared between 229 and 281 m$\mu$ depending on the kind of amines used as electron donors. The stable equilibria of 1 : 1 complex formation were verified for all the systems. The equilibrium constants ($K$) were determined at various temperatures and the heats of formation ($\Delta H$) and entropy changes ($\Delta S$) were evaluated. The values of $\Delta H$ range from $-4.8$ kcal./mol. for ammonia complex to $-12.3$ kcal./mol. for tri-*n*-butylamine complex, and $\Delta S$ also changes from $-8.0$ e. u. for the former and $-27.8$ e. u. for the latter. The effect of successive replacement of hydrogen atoms of ammonia by methyl or ethyl groups on the value of $\Delta H$ was shown to be additive. From the data of $\Delta H$ and $\Delta S$ it was concluded that there exists a linear relation between these two quantities for the iodine complexes with all the primary amines and secondary amines having rather small substituent groups like methyl. The deviation from the linear relation was observed with the complexes including diethylamine and tertiary amines as electron donors. These amines with bulky substituent groups may be expected to exert a great steric hindrance in the case of the molecular complex formation. Further it was shown that the plots of $\Delta H$'s against $\sigma^*$'s (Hammett's substituent constant) fit the straight line, except for those of the iodine complexes with triethylamine, tri-*n*-propylamine and tri-*n*-butylamine. With the aid of the spatial configuration derived from X-ray crystal analysis data for the trimethylamine–iodine complex, one could evaluate the three parameters (overlap integral ($s$), exchange integral ($\beta$) and effective electron affinity ($A$)) which are necessary for explaining reasonably the relation between the transition energies of the charge-transfer bands and the ionization potentials of electron donors. For example, the $\beta$ values thus estimated were $-2.09$, $-2.20$ and $-2.32$ eV. for the complexes with primary, secondary and tertiary amines, respectively.

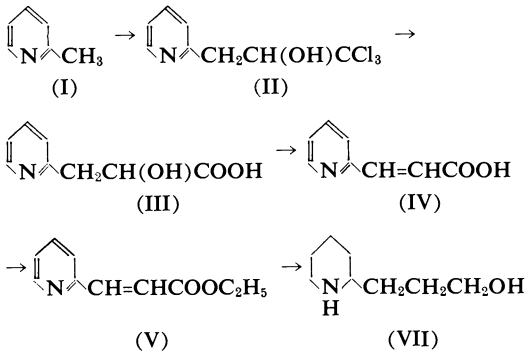
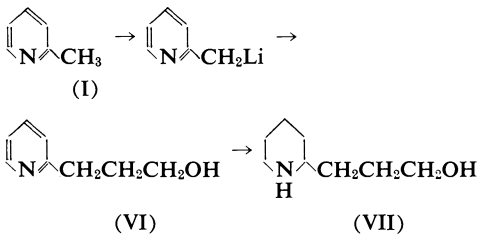
# *Studies on Pelletierine. I. Isolation of Pelletierine from Pomegranate Root Bark**



By Shigeru KUWATA

(Received November 28, 1959)



Pelletierine, an alkaloid which was found in pomegranate bark together with isopelletierine, methylisopelletierine and pseudopelletierine, and long regarded as the most anthelmintic component of the bark-extracts, was assigned the structure 3-(2-piperidyl)-propionaldehyde by Hess and Eichel already in 1917[1]. But no one has been able to succeed in the synthesis of this compound in spite of its very simple structure. This fact has been shedding some doubt upon the reliability of this structure.

According to Hess and Eichel, pelletierine is stable to oxidation and the corresponding propionic acid has never been obtained by the action of chromic acid in sulfuric acid, while part of the base is recovered unchanged and the rest is decomposed under the liberation of ammonia. From general properties of primary alcohol it will be expected that, when 3-(2-piperidyl)-1-propanol is oxidized with chromic acid, the corresponding aldehyde would be formed at least at the first oxidation step, and if this aldehyde is pelletierine as has been assumed, this may not be oxidizable further and must be isolated from the oxidation products. In order to scrutinize this idea, 3-(2-piperidyl)-1-propanol, which was prepared in the scheme of Eq. 1 or 2, was treated with chromic acid. This material, on being oxidized with chromic acid just sufficient to convert it into the aldehyde, gave no product corresponding to the aldehyde either at room temperature or at a higher one. By more drastic conditions using excess chromic acid, a colorless crystalline product was isolated as hydrochloride, which proved to be 3-(2-piperidyl)-propionic acid hydrochloride. These results show apparently that it is very difficult to assign the aldehyde structure to pelletierine.

Equation 1

Equation 2

The alternatively suggested structure for this alkaloid is 1-(2-piperidyl)-2-propanone, i. e., isopelletierine[2-7]. For instance, Galinovsky and Vogl[2], or Wibaut and Hirschel[7] asserted the identity of pelletierine with isopelletierine by comparing the derivatives of both compounds.

But it should be mentioned that the isolation of pelletierine, the most important material for these discussions, has never been attempted by tracing the reports of Hess and Eichel as closely as possible, and its physical properties or chemical behaviors have never been re-examined. Therefore one has been compelled to rely on their reports regarding the properties of this alkaloid. On re-examining their reports, however, a few descriptions are found unacceptable in some respects. For instance, constants of isopelletierine and its derivatives used for the comparison with those of pelletierine and its derivatives[8] are considerably different from those given later by

* This work was partly presented at the 10th and 11th Annual Meetings of the Chemical Society of Japan, April 6, 1957 and April 5, 1958.

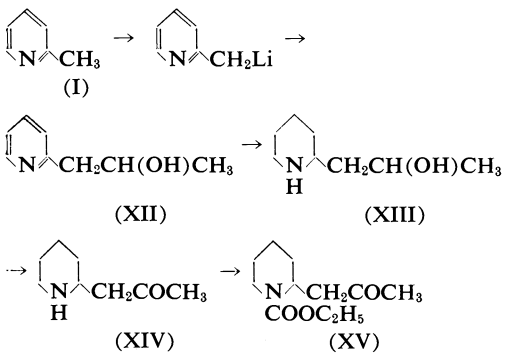
Hess himself[9] or by other researchers[10,11].



In order to compare pelletierine with isopelletierine decidedly, it will be most necessary to isolate the same sample of pelletierine as that which was obtained by Hess, and to re-examine its properties in the first step. Therefore the tracing of the Hess' experiment by using 60 kg. of powder of pomegranate root bark was attempted. The method of isolation was essentially the same as that which had been adopted by Hess and Eichel[8,12], and "pelletierine" was isolated in the form of urethane, having the same boiling point (b. p. 164~166°C at 20 mmHg; lit.[8] b. p. 169~170°C at 21 mmHg). In this method, some procedures were modified with the same results, and these could be confirmed by the preliminaly paper chromatographic test.

3-(2-Piperidyl)-propionaldehyde urethane and isopelletierine urethane, the partners for the comparison, were prepared according to Eqs. 3 and 4, respectively.

Equation 3

Equation 4

9) K. Hess and O. Littmann, *Ann.*, **494**, 7 (1932).
10) J. Meisenheimer and E. Mahler, ibid., **462**, 301 (1928).
11) P. I. Mortimer and W. Wilkinson, *J. Chem. Soc.*, **1957**, 3967.
12) Another method of isolating pelletierine was also reported by Hess, *Ber.*, **52**, 1005 (1919).

Now, "pelletierine urethane", thus obtained from natural sources, was compared with the synthetic samples of 3-(2-piperidyl)-propionaldehyde urethane and isopelletierine urethane.

Table I. Physical constants of the three urethanes

| Urethane | B. p., °C mmHg | $n_D^{20}$ |
|---|---|---|
| 3-(2-Piperidyl)-propionaldehyde urethane | 122~124 (2.5) | 1.4792 |
| 1-(2-Piperidyl)-2-propanone urethane | 131~132 (3.5) | 1.4715 |
| Pelletierine urethane from natural sources | 131~131.5 (3.5) | 1.4711 |

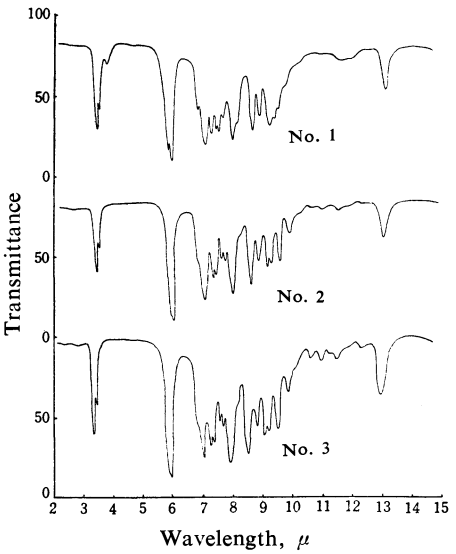


Fig. 1. I. R. of three urethanes.
No. 1: 3-(2-Piperidyl)-propionaldehyde urethane
No. 2: Pelletierine urethane from natural sources
No. 3: 1-(2-Piperidyl)-2-propanone urethane

The physical constants of these urethanes are listed in Table I.

From Table I, it may be recognized that the constants of urethane of pelletierine isolated from natural sources agree well with those of isopelletierine urethane but not with those of 3-(2-piperidyl)-propionaldehyde urethane.

In Fig. 1, in which the infrared spectra of these three urethanes are shown, the spectrum of pelletierine urethane agrees well with that of isopelletierine urethane[13], and not with that of 3-(2-piperidyl)-propionaldehyde urethane. It is remarkable that it never shows

13) This result agrees with the one obtained using hydrobromide by J. P. Wibaut and M. I. Hirschel: Ref. 7.

peaks at 2700 $cm^{-1}$ and 1710 $cm^{-1}$ corresponding to the aldehyde group. Further, these peaks are recognizable in the spectrum of neither the fore-running nor the after-running of "pelletierine urethane".

This fact shows that, in this sample, the compounds having the aldehyde group are never contained even in a small amount. This may be a decided bit of evidence for the absence of 3-(2-piperidyl)-propionaldehyde in the pomegranate bark.

Thus, from the above mentioned points, the author concludes that what has been named pelletierine is nothing but isopelletierine.

## Experimental

**1, 1, 1-Trichloro-2-hydroxy-3-(2-pyridyl)-propane (II).** — 1) 2-Picoline (I) (93 g.) and anhydrous chloral (14 g.) were heated in amyl- or butylacetate (310 g.) for 11~12 hr. at 120~130°C according to Einhorn[14]. The product formed into colorless needle crystals (from ethanol); m. p. 201~202°C (decomp.) (lit.[14] 201~202°C (decomp.)). The yield was 40%.

2) Excess I (1000 cc.) and anhydrous chloral (500 g.) were heated to 110~113°C for 40 hr. according to Tullock and McElvain[15]. The same compound as the above was obtained in 65% yield.

**3-(2-Pyridyl)-lactic Acid (III).**—The compound II was hydrolysed with sodium carbonate as described by Einhorn[14]. III formed into colorless prismatic crystals, m. p. 124~125°C (from ethanol) (lit.[14] m. p. 124~125°C). The yield was 80%.

**3-(2-Pyridyl)-acrylic Acid (IV).**—1) III was dehydrated as described by Einhorn[14]. IV formed into colorless needles, m. p. 204~205°C (decomp.) (lit.[14] m. p. 204~205°C (decomp.)). The yield was 81%.

2) The same compound was obtained from II according to the method of King[16] with some modifications.

A solution of II (341 g.) in ethanol (1100 cc.) was added dropwise with stirring during 5 hr. to a boiling solution of potassium hydroxide (408 g.) in ethanol (2600 cc.). After potassium chloride was filtered off, the filtrate was dried up and kept at 75~79°C at 11~12 mmHg for 24 hr. The cake obtained was dissolved in water and acidified to pH 4 with hydrochloric acid. The precipitate, after being collected and washed with water, gave the acid IV. The yield was 163 g.

**Ethyl 3-(2-pyridyl)-acrylate (V).** — The acid IV was esterified in 67% yield as described in the literature[14]; b. p.$_{14}$ 152.5~153°C; b. p.$_{11}$ 143~147°C (lit.[14] b. p.$_{11}$ 142~145°C).

**3-(2-Pyridyl)-1-propanol (VI).**—2-Picolyl lithium prepared from I (23 g.) and phenyl lithium, which was, in turn, prepared from phenyl bromide (40 g.) and lithium (3.5 g.) in dry ether (200 cc.), was condensed with ethylene oxide (10 g.) as described in Org. Synth.[17]; b. p.$_{7}$ 128~131°C (lit.[17] b. p.$_{4}$ 116~118°C). The yield was 32%.

**3-(2-Piperidyl)-1-propanol (VII).**—1) The ester V was reduced in 28% yield with metallic sodium and ethanol according to Tullock and McElvain[15]. Replacing ethanol with cyclohexanol gave the same result without varying the yield of the reduction product; b. p.$_{3}$ 102~105°C (lit.[15] b. p.$_{3}$ 102~105°C).

2) The alcohol VI (21.5 g.) in dioxane (10 cc.) was hydrogenated over Raney nickel (ca. 0.2 g.) at 130~140°C with hydrogen at an initial pressure of 90 kg./$cm^2$ for about 4 hr.; b. p.$_{5}$ 121~125°C, $n_D^{25}$ 1.4866 (lit.[18] $n_D^{25}$ 1.4863). The yield was 14 g.

**Oxidation of VII with Chromic Acid.**—*1) Mild Oxidation.*—To the propanol VII (8.6 g., 0.06 mol.) in glacial acetic acid (80 cc.) was added chromic acid (4 g., 0.04 mol. = 0.06 equivalent of O) in water (4 cc.) dropwise with stirring at room temperature (30°C), then stirred for 2 hr. more at this temperature. No change of color was observed during this period. The bath temperature was gradually raised, and at about 80°C the color promptly turned green. After being stirred for 10 min. at 80°C and 2 hr. at 50°C, the acetic acid was evaporated. Then the residue was dissolved in water, made alkaline with sodium hydroxide when a considerable amount of tarry material, which dissolved neither in ether nor in water, was separated and the aqueous solution was extracted with ether. After drying, the ether extract was distilled in the stream of hydrogen under reduced pressure. There was obtained 1.7 g. of the fraction of b. p.$_{21}$ 143~145°C, and its refractive index ($n_D^{25}$ 1.4848) was found to be the same as that of the starting material. The residue (2.7 g.) could not be distilled in an oil-bath at 250°C under a pressure of 5 mmHg. No fore-running fraction, the boiling point of which corresponds to that of pelletierine could be recognized.

*2) Violent Oxidation.* — The propanol VII (4 g.) was added dropwise to a mixture of chromic acid (4 g.), concentrated sulfuric acid (16 g.) and water (50 cc.) with shaking. A considerable amount of heat was evolved and the color immediately turned green. Then it was heated with occasional shaking for 1 hr. at 90~100°C. After the inorganic ions were removed by the method of Koenig and Hoppe[19], the aqueous solution was acidified with hydrochloric acid, decolorized and concentrated to dryness. An alcoholic extract of the residue was evaporated in vacuo. From the syrupy residue were separated needle crystals after being allowed to stand in a refrigerator overnight. The crystals were filtered from extremely viscous liquid, washed thoroughly with ethanol and recrystallized from ethanol. The needle crystals thus obtained melted at 186~187°C and were not depressed by admixture with an authentic sample of 3-(2-piperidyl)-propionic acid hydrochloride.

**1, 1-Diethoxy-3-(2-pyridyl)-propane (VIII).**—According to Spielman et al.[20] VIII was synthesized

with the reaction of 2-picolyl lithium and bromoacetal, which was prepared by the method of Org. Synth.[21]; b. p.$_{7}$ 128~129°C (lit.[20] b. p.$_{8}$ 128°C). The yield was 15% (based on lithium).

**1, 1-Diethoxy-3-(2-piperidyl)-propane (IX).**—The acetal VIII (30 g.) in ethanol (200 cc.) was hydrogenated over Raney nickel (ca. 5 g.) at 130~140°C with hydrogen at an initial pressure of 105 kg./cm$^2$ for about 2 hr.; b. p.$_{6}$ 117~120°C, $n_D^{20}$ 1.4540 (lit.[20] b. p.$_{3}$ 101~106°C, b. p.$_{1}$ 91~92°C, $n_D^{25}$ 1.4568). The yield was 20 g.

***N*-Ethoxycarbonyl-1, 1-diethoxy-3-(2-piperidyl)-propane (X).**—The acetal IX was converted into its urethane with ethyl chloroformate and sodium hydroxide by Spielman's method[20]; b. p.$_{3.5}$ 152~156°C, $n_D^{20}$ 1.4612 (lit.[20] b. p.$_{2}$ 146~147°C, $n_D^{25}$ 1.4580). The yield was 74%.

***N*-Ethoxycarbonyl-3-(2-piperidyl)-propionaldehyde (XI).**—The acetal X was hydrolyzed in 95% acetic acid by Spielman's method[20]; b. p.$_{2.5}$ 122~124°C, $n_D^{20}$ 1.4792 (lit.[20] b. p.$_{1}$ 119~121°C, $n_D^{25}$ 1.4771). The yield was 69%.

**1-(2-Pyridyl)-2-propanol (XII).** — According to Org. Synth.[17] the propanol XII was prepared by the condensation of acetaldehyde with 2-picolyl lithium; b. p.$_{17}$ 114~119°C (lit.[17] b. p.$_{17}$ 116~117°C). The yield was 56% based on I.

**1-(2-Piperidyl)-2-propanol (XIII).**—The propanol XII (184.5 g.) in dioxane (100 cc.) was hydrogenated over Raney nickel (ca. 12 g.) at 130°C with hydrogen at an initial pressure of 120 kg./cm$^2$ for 3 hr.; b. p.$_{13}$ 108~113°C (lit.[10] b. p.$_{16}$ 115~120°C). The yield was 158.5 g.

**1-(2-Piperidyl)-2-propanone (Isopelletierine) (XIV).**—The propanol XIII (11.4 g.) was oxidized to isopelletierine with chromic anhydride (6 g.) in glacial acetic acid (80 cc.) by the method of Meisenheimer and Mahler[10]. The fraction distilling below 105°C at 15 mmHg was collected (8 g.). Rectification yielded the fraction of b. p.$_{7}$ 79~80°C, b. p.$_{21}$ 101.2°C, $n_D^{20}$ 1.4661, $d_4^{20}$ 0.9587 (lit. b. p.$_{10}$ 86°C[10], b. p.$_{14}$ 91~92°C[9], $n_D^{20}$ 1.46687[9], $d_4^{20}$ 0.9624[9]).

**"Pelletierine"**

The samples of the pomegranae bark used in this experiment were as follows:

*Powder of Pomegranate Root Bark (Sample I):*—Gathered at the north-bank of the River Yoshino, in Tokushima Prefecture, Japan; dried for several days and ground to fine powder.

*Powder of Pomegranate Root (Sample II).*—From the pomegranate cultured in this laboratory; used immediately after gathering.

*Powder of Pomegranate Bark (Sample III).*—Purchased from drug store; when it was gathered was unknown.

**Preparation of the Sample for Paper-chromatography.** — *1) Method of Wibaut et al.*[5]: — Sample (common to I, II and III) was boiled with methanol, filtered and methanol was distilled off under diminished pressure. The residue was warmed with 10% hydrochloric acid at about 60°C and filtered. The filtrate was washed with chloroform and, after alkalifying with sodium hydroxide extracted with chloroform. The extract was shaken with 10% hydrochloric acid again, then the aqueous layer was condensed under reduced pressure.

*2) Hydrochloric Acid-Methanol Extraction.*—Sample was boiled with methanol containing hydrochloric acid, filtered and condensed under reduced pressure. The syrup thus obtained was extracted with 10% hydrochloric acid and treated as above.

*3) Method of Hess and Eichel*[8],**.—The mixture of sample and sodium hydroxide solution was placed in Soxhlet's apparatus and extracted with ether. The ether extract was treated with 10% hydrochloric acid and the hydrochloric acid extract was condensed.

**Chromatography.** — *Paper:* — Toyo filter paper No. 50 for chromatography (paper was allowed to stand over 24 hr. with saturated vapor of developer before use).

*Developer.* — *n*-Butyl alcohol: con. hydrochloric acid: water=100 : 8 : ca. 20 (in volume) (the upper layer of the mixture was used as developer).

*Method of Development.*—Descending method.

*Colorizing Agent:*—Dragendorf's resgent.

The experimental results are shown in Table II.

Table II. Results of paper chromatographic analyses

| Sample | Method of preparation | $R_f$ | | |
|---|---|---|---|---|
| I | 1 | 0.37 | 0.45 | 0.57 |
| I | 2 | 0.37 | 0.46 | |
| I | 3 | 0.39 | 0.46 | |
| II | 1 | 0.39 | 0.49 | |
| III | 1 | 0.35 | 0.42 | |

**Isolation of Pelletierine.** — Sixty kg. of sample I was extracted by boiling methanol three times, each for 10 hr. The extracts were condensed to syrup and warmed for some time with 10% hydrochloric acid on 60°C and filtered from resinous material. The filtrate was washed with chloroform, the residual aqueous layer was made alkaline with

21) S. M. McElvain and D. Kundiger, *Organic Syntheses*, 23, 8 (1943).

** Instead of calcium hydroxide and chloroform, sodium hydroxide and ether were used, respectively.

sodium hydroxide and extracted with chloroform. The chloroform extract was treated with 10% hydrochloric acid, the aqueous solution was, after condensing, dried up in a desiccator, and thus the mixture of alkaloidhydrochlorides was obtained. The yield was 160 g. This hydrochloride was dissolved in water, and after weakly alkalifying with aqueous sodium bicarbonate solution, extracted with ether. From this ether extract pseudopelletierine was obtainable. The aqueous solution was strongly alkalified with sodium hydroxide and extracted with ether repeatedly until the ether layer became colorless. After drying with sodium hydroxide and distilling off the solvent, the ether extract was distilled under reduced pressure in the atmosphere of hydrogen, then the fraction of 102~113°C at 20 mmHg was collected. The yield was 64.1 g. (The greater part of this fraction was distilled at 104~105°C at 20 mmHg, and, when rectified, the liquid of b. p.$_9$ 86~86.2°C and $n_D^{20}$ 1.4665 was obtained. During distillation in the atmosphere of hydrogen, this liquid kept completely colorless, but it became pink at once when it was allowed to make a contact with air, and then turned dark red in time).

The mixture of the fraction of b. p.$_{20}$ 102~113°C (31.9 g.), sodium hydroxide (45 g.) and water (160 cc.) was stirred and cooled below 10°C. To this suspension, ethyl chloroformate (36 g.) was added gradually. The reaction product was extracted with ether and the extract dried with sodium hydroxide freed from the solvent, and distilled under reduced pressure; thus the fraction which boils at 164~166°C at 19 mmHg was obtained (lit.[8] b. p.$_{21}$ 169~170°C). The yield was 13.3 g. After rectification, viscous colorless liquid of b. p.$_{3.5}$ 131~131.5°C and $n_D^{20}$ 1.4711 was obtained.

**Infrared Absorption Spectra.** — These measurements were taken with a Perkin-Elmer spectrophotometer, Model 21 with sodium chloride prism).

Phase: liquid

Thickness: ca. 0.01 mm.

The author desires to state with sincere thanks that this work was commenced under the direction of the late Professor Ryuzaburo Nodzu and he wishes to express his profound gratitude to Professor Ryozo Goto of Kyoto University and to Professor Hiroshi Watanabe of Kōnan-University for thier invaluable advice and cordial encouragement throughout the work. He also thanks the Research Laboratory of Takeda Pharmaceutical Industries for infrared measurements and Miss. T. Nagahama and Mr. Y. Kaneko for their collaboration with him in the experiments.

# *Studies on Pelletierine. II. On the Structure of the So-called Pelletierine Proposed by Hess**,***

By Sigeru KUWATA

(Received January 6, 1960)

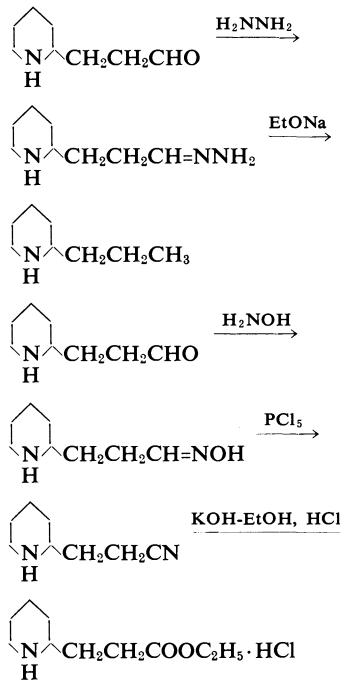
As reported in the previous paper[1], the author has isolated pelletierine by tracing the same method as that of Hess and Eichel and has compared it with synthetic samples of 3-(2-piperidyl)-propionaldehyde and 1-(2-piperidyl)-2-propanone in the form of urethane, as the result of which he has reached the conclusion that pelletierine is the same as isopelletierine, 1-(2-piperidyl)-2-propanone.

But the problem remains that the chemical reactions of pelletetierine, on the basis of which Hess and Eichel have assigned to it the structure of 3-(2-piperidyl)-propionaldehyde, should be explained with isopelletierine.

The most important reactions used by them for the determination of the structure of pelletierine were the following two[2]:

1) $C_8H_{15}ON$ (pelletierine) $\xrightarrow{H_2NNH_2}$ $C_8H_{17}N_3$ $\xrightarrow{EtONa}$ $C_8H_{17}N$ (coniine)

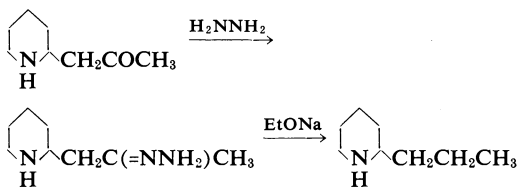
2) $C_8H_{15}ON$ (pelletierine) $\xrightarrow{H_2NOH}$ $C_8H_{16}ON_2$ $\xrightarrow{PCl_5}$ $C_8H_{14}N_2$ (I) $\xrightarrow{KOH\text{-}EtOH,\ HCl\text{-}EtOH}$ the compound II, assumed to be ethyl 3-(2-piperidyl)-propionate hydrochloride



* This work was partly presented at the 12th Annual Meeting of the Chemical Society of Japan, April 4, 1959.

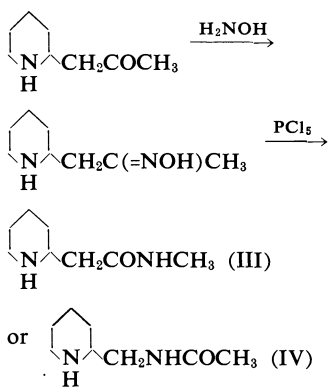
** Immediately before the publication of this paper, the author received a publication of the *J. Am. Chem. Soc.*, in which R. L. Augustine reported the rearrangement of isopelletierine-oxime obtaining the same results; ibid., **81**, 4664 (1959).

1) S. Kuwata, This Bulletin, **33**, 1668 (1960).



2) K. Hess and A. Eichel, *Ber.*, **50**, 1192 (1917).

Assigning the aldehyde structure to pelletierine, they have explained these reactions as follows:



3) 

4) 

In reaction 1, the aldehyde may be replaceable by the ketone (isopelletierine) with the same final reaction product:

But in reaction 2, the product will be entirely different according to the structure of the starting material. Although the production of nitrile is expected from the aldehyde, from the ketone the amide III or IV will be obtainable by the Beckmann rearrangement:

Then, if the compound I is nitrile, as Hess has evaluated, the reaction must involve a skeletal rearrangement which has never been observed hitherto. Or if Hess' evaluation is incorrect, the question as to what structure should be assigned to it remains.

In order to clarify these situations the author has traced reaction 2 using isopelletierine-oxime under the same conditions described by Hess. Thus isopelletierine-oxime was treated with freshly sublimed phosphorus pentachloride in phenetole. The reaction proceeded, as described in the literature[2], with remarkable evolution of heat, and a brown syrupy material was produced, from which, after rectification, the compound which boiled at 104~106°C at 15 mmHg was obtained. When it was purified through picrate, a colorless liquid, boiling at 102~103°C at 10 mmHg, was obtained. This material showed complete agreement with the compound I that Hess and Eichel had obtained from pelletierine-oxime; the comparison between the two is shown in Table I.

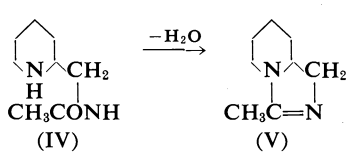


Table I. The properties of the compounds obtained from the reaction of oxime and rhosphorus pentoxide

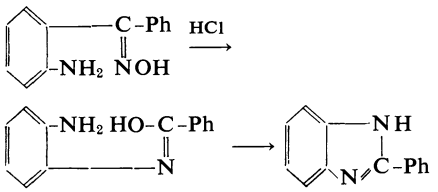
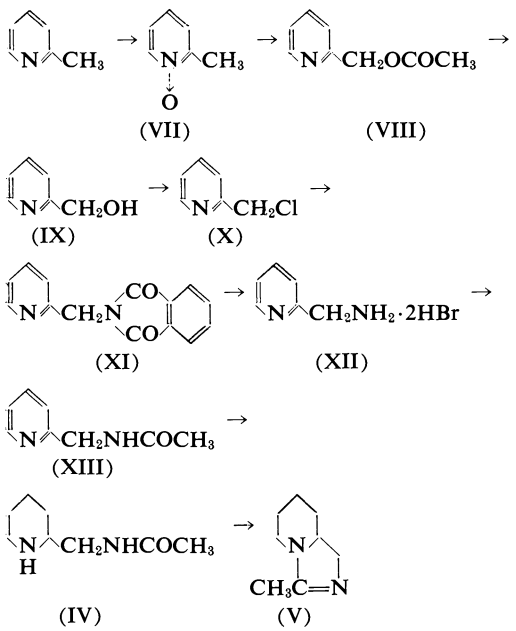
| Oxime | Molecular formula | B. p., °C (mmHg) | M. p. of picrate, °C |
|---|---|---|---|
| Isopelletierine-oxime | $C_8H_{14}N_2$ | 104~106(15)<br>102~103(10)* | 174~175 |
| Pelletierine-oxime[2] | $C_8H_{14}N_2$ | 105~108(15)<br>104~106(15)* | 175~176 |



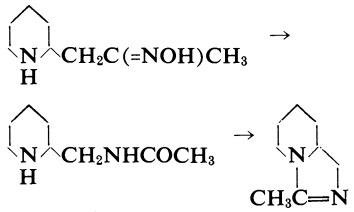
* Purified through picrate.

Thus it was ascertained that the reaction is reproducible with isopelletierine.

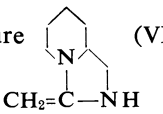
This compound I cannot be nitrile, for its infrared spectrum shows no absorption between 4.0 $\mu$ and 5.0 $\mu$. It is also certain from analytical data that this compound I is neither the amide III nor IV, though the most probable reaction in this case may be the Beckmann rearrangement. On comparing the two formulae, $C_8H_{14}N_2$ of the compound I, and $C_8H_{16}ON_2$ of the amide, it will be easily seen that the difference is just one molecule of water. This fact may allow one to suppose that the compound I may be producible by intramolecular dehydration of the amide, produced by the Beckmann rearrangement of the keto-oxime. Such a dehydration is difficult sterically with formula III, but with formula IV, the following ring closure may be brought on:



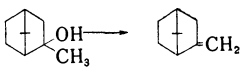
An analogous dehydration has been illustrated, in fact, with *o*-aminobenzophenoneoxime, which provides benzenylphenyleneamidine by the Beckmann rearrangement according to the following scheme[3]:



For the purpose of confirming the correctness of this assumption, 2-acetamidomethylpiperidine (IV) was synthesized by another route, and its dehydrative cyclization was attempted by treating it with phosphorus oxychloride, according to the method of Bower[4] (Eq. 1).

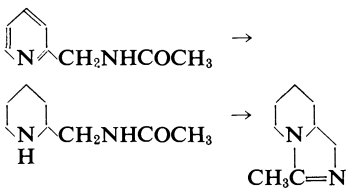


Eq. 1



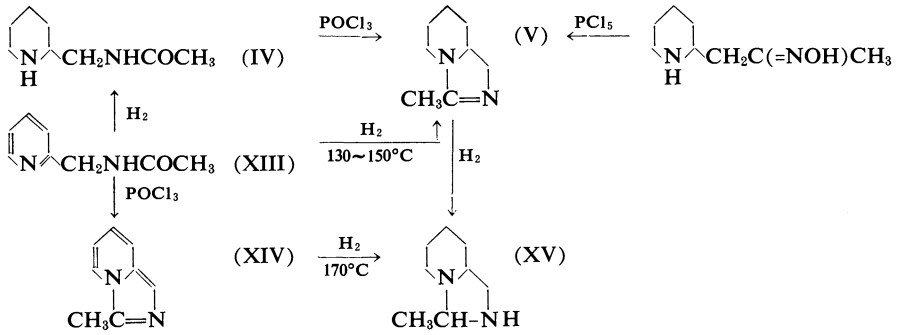
The compound V thus obtained boiled at 103~106°C at 11 mmHg and its picrate melted at 174~175°C. This was never depressed when it was mixed with the picrate of I. The identity of both picrates was also confirmed by the Debye-Scherrer diagram.

From these results, the author thinks that the real structure of the compound I, to which Hess and Eichel assigned 3-(2-piperidyl)-propionitrile, should be represented by V, and the reaction should be explained as shown in the following scheme:



An alternative structure  (VI), however, may also be assumable for the compound I, because such a structure, having the terminal vinyl group, can be seen in some cases as $\alpha$-fenchene from methyl-$\alpha$-fenchocamphorol by intramolecular dehydration[5]:

However, on treating the compound I with ozone, no formaldehyde can be detected, so structure V, and not VI, should be assigned to this compound. The fact that its near infrared spectrum shows no absorption at ca. 1640 m$\mu$ and ca. 2130 m$\mu$ corresponding to $CH_2=C\langle$[6], may also support this conclusion.



Another proof of structure V for this substance was also found in another way. When this compound was reduced catalytically, a colorless liquid, b. $p._{14}$ 85~100°C, which gave crystalline styphnate of m. p. 183~185°C, was obtained. This compound proved identical, by the mixed melting point of both the styphnates, with 2-methyl-1, 3-diazabicyclo[4 : 3 : 0]-nonane obtained by reducing 3-methyl-2; 3a-diazaindene catalytically.

The compound V was also found to be producible when 2-acetamidomethylpyridine was hydrogenated in ethanol at 130~150°C over Raney nickel, the reaction of which would probably be represented by the scheme:

This fact may be a proof that *N*-acetamidomethylpiperidine can be easily cyclized into the bicyclic compound V. The relationship among these bicyclic compounds will be shown diagramatically as follows.

6) Private communication from Mr. M. Nishikawa of the Research Laboratory, Takeda Pharmaceutical Industries, Ltd.; cf. R. H. Holman, *Anal. Chem.*, **28**, 1533 (1956); W. Kaye, *Spectrochimica Acta*, **6**, 257 (1954).

Hess and Eichel treated their "nitrile", the compound I, with alcoholic potash, then with alcoholic hydrochloric acid, and obtained the compound II, which they believed to be ethyl 3-(2-piperidyl)-propionate hydrochloride on the basis of its analytical data and the comparison of the melting points of both the compounds as well as their gold salts. On re-examining their description, one will see that these evidences have some weak points. It is true that analytical data given by them, C, 54.39; H, 9.10, agree well with those for the ester hydrochloride (C, 54.10; H, 9.08), but, those of N and Cl are not given by them. The comparison between the melting points is also not decisive, because it is not dependent on the mixed melting point method. From these situations it seems necessary to re-examine the nature of the hydrolysis product obtained by Hess and Eichel from their "nitrile".

Thus the author wanted to trace their experiments as accurately as possible, but their description of the reaction conditions is not so definite. They state, "Das Nitril wurde mit einer 5-prozentigen alkoholischen Kaliumhydroxydlösung kurze Zeit auf dem Wasserbade erwärmt" and "1 Stunde mit alkoholischer Salzsäure gekocht." In alkali treatment, the volume of alkali solution, the temperature and the reaction time, and in acid treatment the concentration of hydrochloric acid and its volume, are not definite. Thus the reaction was carried out by varying the conditions, and various results were obtained, which are summarized in Table II. Unfortunately in all these cases no crystalline product corresponding to Hess' "ethyl 3 (2-piperidyl)-propionate hydrochloride" could be isolated, but in one case yellow crystalline gold salt (m. p. about 90~95°C, C, 18.51; H, 3.00; Au, 48.40) was obtained from the semisolid hydrolyzate. On recrystallization it gave red needles (m. p. about 120°C, C, 22.30; H, 3.34; Au, 47.05), which seemed to resemble the gold salt of ethyl 3-(2-piperidyl)-propionate hydrochloride (m. p. 128°C, C, 22.87; H, 3.84), as far as the melting point and contents of C and H were concerned, but it was quite apparent from the difference in color (the authentic sample of the gold salt of ethyl 3-(2-piperidyl)-propionate hydrochloride is yellow) as well as from the Au-contents that the two compounds were not identical. Though it is impossible to decide, however, whether the gold salt obtained here was the same compound as Hess and Eichel have isolated, because they have never reported the nature of their compound except its melting point, it may be said at least that by treating the compound I according to their method, a gold salt resembling the one reported by them is obtainable.

On the grounds which have been described hitherto, the author believes that he can deduce the conclusion that pelletierine, to which Hess and Eichel have assigned the structure 3-(2-piperidyl)-propionaldehyde, is nothing but isopelletierine, 1-(2-piperidyl)-2-propanone. By this conclusion can easily be solved many conflicts, arising from the assumption that pelletierine is 3-(2-piperidyl)-propionaldehyde, e. g. a confilict that pelletierine is stable against oxidation, and can not be oxidized into 3-(2-piperidyl)-propionic acid with chromic acid, or a conflct that it can be isolable without any special care, though 3-(2-piperidyl)-propionaldehyde can not be synthesized by any method on account of its extreme instability. The reaction of pelletierine that Hess and Eichel used for the determination of the structure is also easily explainable with isopelletierine, when 3-(2-piperidyl)-propionitrile is replaced by 2-methyl-1, 3-diazabicyclo [4 : 3 : 0]-2-nonene (V) with the same molecular formula. This conclusion also agrees with the finding by Wibaut and Hollstein[7] that 3-(2-piperidyl)-propionaldehyde has no anthelmintic activity, while 1-(2-piperidyl)-2-propanone (isopelletierine) is strongly anthelmintic.

7) J. P. Wibaut and U. Hollstein, *Konincl. Ned. Akad. Wetenschap., Proc. Ser.*, **B59**, 426 (1956); *Chem. Abstr.*, **51**, 11364*i* (1957).

## Experimental

**Isopelletierine-oxime.**—To the solution of $NH_2OH \cdot HCl$ (20 g.) and NaOAc (20 g.) in water (40 cc.) was added isopelletierine (16 g.) in methanol (18 cc.). After standing at room temperature overnight, the solution was made alkaline with sodium hydroxide and was extracted with ether. After drying and distilling off the solvent, the residue (colorless needle crystals, m. p. 97~99°C) was distilled under reduced pressure; b. $p._{10}$ 148~152°C (lit.[8] b. $p._{2.5}$ 134°C, b. $p._{5.6}$ 146°C). The yield was 12.5 g. After boiling the viscous distillate with petroleum ether and cooling, needle crystals were separated; m. p. 105~106°C (from ether). (As to the melting points for the two isomers, Mortimer et al.[8] have reported 105.5°C and 90°C, while Hess and Eichel[2] have reported 96~97°C and 80°C for pelletierine-oxime. The author used the higher melting isomer for the next reaction because it was also the higher one that Hess and Eichel had used for the reaction with phosphorus pentachloride).

**The Reaction of Isopelletierine-oxime with Phosphorus Pentachloride.**—According to a method just the same as Hess and Eichel's[2], isopelletierine-oxime (m. p. 105~106°C) (4.4 g.) was dissolved into freshly rectified anhydrous hot phenetole (10 cc.) and cooled to about 35~40°C, and this solution was added dropwise into a phenetole (30 cc.) solution of freshly sublimed phosphorus pentachloride (9 g.). At the beginning, the oxime precipitated gelatinously, but after some time it turned into a dark brown mass with violent evolution of heat and hydrochloric acid gas, and precipitated to the bottom. After several hours, phenetole was distilled off under reduced pressure at the temperature of 70~85°C, and the residue was dissolved in water while cooling. After the removal of residual phenetole by extraction with ether, the solution was made alkaline with sodium hydroxide and extracted with ether. The ether extract was dried with potassium hydroxide, freed from ether and distilled under diminished pressure. Thus the fraction boiling at 104~106°C at 15 mmHg was gathered. The yield was 1.2 g. After being converted into picrate, recrystallized and regenerated by sodium hydroxide the purified sample was obtained, boiling at 102~103°C at 10 mmHg; $n_D^{25}$ 1.4973.

Found: C, 68.83; H, 10.14; N, 19.17. Calcd. for $C_8H_{14}N_2$: C, 69.52; H, 10.21; N, 20.27%.

The error of the analysis would probably be attributable to the hygroscopicity of this material.

Picrate: yellow needles, m. p. 174~175°C (from ethanol).

Found: C, 45.82; H, 4.72; N, 18.88. Calcd. for $C_{14}H_{17}O_7N_5$: C, 45.77; H, 4.67; N, 19.07%.

**2-Picoline *N*-Oxide (VII).**—The compound VII was obtained in 90% yield from the reaction of 2-picoline and hydrogen peroxide in acetic acid by the method of Boekelheide[9]; b. $p._{25}$ 146~148°C (lit.[9] b. $p._{15}$ 123~124°C).

**2-Pyridylmethanol Acetate (VIII).**—The compound VII was converted into VIII in 79% yield by the action of acetic anhydride according to Boekelheide[9]; b. $p._{18}$ 117~119°C (lit.[9] b. $p._{22}$ 115~118°C).

**2-Pyridylmethanol (IX).**—The acetate VIII was hydrolyzed with 10% hydrochloric acid in 70% yield according to Kobayashi[9]; b. $p._{17}$ 118~121°C (lit[10] b. $p._{16}$ 111~115°C); picrate, m. p. 160~161°C (lit.[9] m. p. 160.5~161°C).

**2-Pyridylmethylchloride (X).**—According to Itai[11], X was obtained by the reaction of the alcohol IX and phosphorus trichloride in 60% yield; b. $p._{21}$ 87°C (lit.[11] b. $p._5$ 70~80°C).

**2-Pyridylmethylamine Hydrobromide (XII).**—The chloride X (35 g.), potassium phthalimide (50 g.) and dimethylformamide (300 cc.) were heated at 90~100°C for about 5 hr. in water bath. When water was added to the reaction product after removal of the solvent under reduced pressure, all the contents of the vessel solidified (solid XI weighed 72 g.) After washing thoroughly with water and dilute sodium carbonate solution, the solid was boiled for 2 hr. with 48% HBr (300 cc.) in oil-bath, and phthalic acid, which separated on cooling, was filtered off. Being decolorized and condensing the filtrate, 60 g. of the crude XII was obtained. From 10 g. of this salt, after treating with sodium hydroxide, extracting with chloroform and distilling the extract, 2.5 g. of the free amine, boiling at 81°C at 5 mmHg, was obtained (lit.[4] b. $p._{20}$ 95~98°C).

**2-Acetamidomethylpyridine (XIII).**—To the mixture of XII (30 g.) and 30% sodium hydroxide solution (240 cc.), acetyl chloride (30 cc.) was added gradually with stirring, keeping the temperature below 20°C. The reaction product was extracted with chloroform, dried with sodium sulfate and distilled under diminished pressure; b. $p._3$ 145~149°C (lit.[4] b. $p._5$ 160~163°C), $n_D^{25}$ 1.5430; picrate, m. p. 169~170°C (Found: N, 18.14%).

**2-Acetamidomethylpiperidine (IV).**—The amide XIII (5 g.) in dioxane (30 cc.) was hydrogenated over Raney nickel with hydrogen of initial pressure of 70 kg./cm² for 2 hr.; b. $p._{14}$ 158~165°C, $n_D^{25}$ 1.5205. This was proved to be a mixture of XIII and IV, because from this distillate two picrates were obtained. One was hardly soluble in ethanol and melted at 169~170°C and was confirmed as the picrate of unreacted XIII by mixed melting point determination. Another, the picrate of IV, was easily soluble in ethanol and melted at 153~155°C.

*Anal. of picrate of IV.* Found: N, 17.85. Calcd. for $C_{14}H_{19}O_8N_5$: N, 18.18%.

The distillate was used for the next reaction without further separation.

**Cyclization of IV by Phosphoryl Chloride.**—A mixture of IV (5.6 g.) and phosphoryl chloride (20 cc.) in benzene (50 cc.) was refluxed for 3 hr. in water bath. Benzene was distilled off, and the residue was dissolved in water, made alkaline with sodium hydroxide and extracted with chloroform.

The extract, dried with sodium sulfate and after removal of the solvent, was distilled under diminished pressure, and was obtained the fraction of b. $p._{11}$ 103~106°C, $n_D^{25}$ 1.5011. The yield was 0.5 g. Its picrate melted at 174~175°C, and showed no depression of the melting point when mixed with the picrate of the reaction product of isopelletierine-oxime and phosphorus pentachloride. Both picrates showed identical Debye-Scherrer diagram.

*Anal. of picrate.* Found: C, 45.66; H, 4.64. Calcd. for $C_{14}H_{17}O_7N_5$: C, 45.77; H, 4.67%.

**Cyclization of XIII to 3-Methyl-2; 3a-diazaindene (XIV) with Phosphoryl Chloride.** — According to Bower and Ramage[4], the compound XIII (4 g.) and phosphoryl chloride (8 cc.) in benzene (24 cc.) were heated under gentle reflux for 4 hr. After distilling off benzene and the remaining phosphoryl chloride under reduced pressure, water was added to the residue, which was made alkaline and extracted with chloroform. After removal of solvent, the residue was distilled under reduced pressure; b. $p._7$ 120~134°C (mainly distilled at b. $p._7$ 134°C) (lit.[4] b. $p._4$ 112~117°C); $n_D^{25}$ 1.5951. The yield was 2.5 g.

Picrate: yellow amorphous crystals, m. p. 210°C (darkened over 200°C) (lit.[4] m. p. 221°C (decomp.)).

Found: C, 46.31; H, 3.46. Calcd. for $C_{14}H_{11}O_7N_5$: C, 46.54; H, 3.07%.

**Reduction of 2-Methyl-1,3-diazabicyclo[4:3:0]-2-nonene (V) to 2-Methyl-1,3-diazabicyclo[4:3:0]-nonane (XV).**—V was hydrogenated over Raney nickel in ethanol with hydrogen having an initial pressure of 95 kg./cm² at 150°C for 3.15 hr. After removal of the catalyst and solvent, the reduction product was distilled under diminished pressure; b. $p._{14}$ 85~100°C. Styphnate: amorphous yellow crystals, m.p. 183~185°C.

*Anal. of styphnate.* Found: C, 43.52; H, 5.06. Calcd. for $C_{14}H_{19}O_8N_5$: C, 43.64; H, 4.97%.

**Reduction of XIV to XV.**—The compound XIV was hydrogenated over Raney nickel in ethanol with hydrogen having an initial pressure of 95 kg./cm² at 170°C for 4 hr. After removal of the catalyst and solvent, the reduction product was distilled under reduced pressure; b. $p._{12}$ 96~98°C, $n_D^{25}$ 1.4600. Styphnate: amorphous yellow crystals, m. p. 183~185°C. This styphnate was identical with the one of XV derived from V, which was confirmed by mixed melting point determination and the comparison of their IR spectra.

**Reduction of XIII in Ethanol.**—The amide XIII (16 g.) in ethanol (20 cc.) was hydrogenated over Raney nickel (ca. 1 g.) with hydrogen having an initial pressure of 130 kg./cm² for 4 hr. at 130~150°C. Distilling the reaction product, after removal of solvent, the following distillates were obtained.

(A) b. $p._{11}$ ~91°C, 4.1 g.

(B) b. $p._{11}$ 91°C~b. $p._{12}$ 158°C, very little.

(C) b. $p._{12}$ 158~163°C (mainly distilled at 162~163°C), 5.6 g.; $n_D^{25}$ 1.5196.

A portion boiling at 102~108°C at 11 mmHg ($n_D^{25}$ 1.4975) in the fraction B formed the picrate, m. p. 174~175°C (needle crystals from ethanol), and this picrate showed no depression of melting point when mixed with the picrate of V, prepared by the action of phosphorus pentachloride upon isopelletierine-oxime. The identitly of both the picrates was also confirmed by the Debye-Scherrer diagram.

*Anal. of the picrate.* Found: C, 46.02; H, 4.79. Calcd. for $C_{14}H_{17}O_7N_5$: C, 45.77; H, 4.67%.

Treating the fraction C with phosphoryl chloride in benzene as mentioned previously, liquid of b. $p._{11}$ 103~106°C and $n_D^{25}$ 1.4985 was obtained, the picrate of which melted at 174~175°C and showed no depression of melting point when mixed with the picrate of V. From the residue, after removal of the liquid (b. $p._{11}$ 103~106°C), the picrate of m. p. 200°C (decomp.) was obtained and showed no depression of melting point when mixed with the picrate of XIV.

Fraction A mainly distilled at 80~83°C at 13 mmHg on redistillation; $n_D^{25}$ 1.4628, $d_4^{25}$ 0.9142. Styphnate melted at 123~125°C (Found: C, 43.69; H, 5.65%).

**Treatment of the Compound V, Obtained from the Reaction of Isopelletierine-oxime with Phosphorus Pentachloride, with Alcoholic Potassium Hydroxide and Alcoholic Hydrochloric Acid.**—V was heated in waterbath with 5% alcoholic potassium hydroxide and the solution was evaporated to

# *Studies on Anti-cancer Agents. V. Desulfurization by Hydrazine Hydrate. II. The Reaction of Benzyl and Piperonyl Disulfide with Hydrazine**

By Tetsuji KAMETANI, Keiichiro FUKUMOTO, Yumiko SATOH**
Takashi TESHIGAWARA and Osamu UMEZAWA***

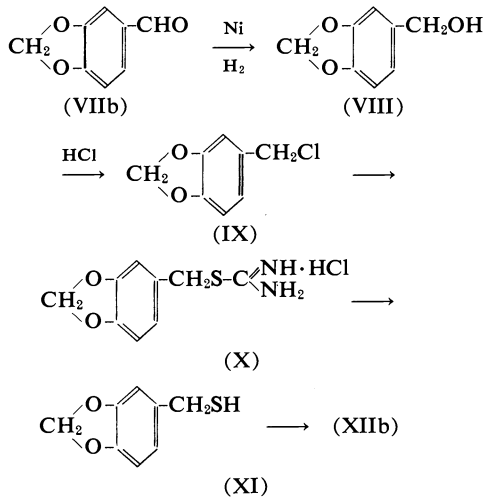
(Received April 20, 1960)

In the preceeding paper[1-3] Kametani and co-workers described the fact that three kinds of alkyl thiolsulfinates, namely, isobutyl, *tert*-butyl and *n*-amyl thiolsulfinates (I) were recognized to be effective against Ehrlich ascites tumor by their screening test among various thiolsulfinates synthesized by us, but almost all of these compounds are unstable for heat and irritative for the skin and eyes, so it is difficult to use them as anti-cancer agents. Among them, only dibenzyl thiolsulfinate (II) was found to form stable crystals, so we tried to synthesize various kinds of dibenzyl thiolsulfinate derivatives, bearing various functional groups in the phenyl nuclei, for instance, nitro, amino and so on.

I: R=isobutyl, *tert*-butyl-, *n*-amyl-
II: R=$C_6H_5$-
III: R=*p*-$NH_2C_5H_4$-

As we reported previously[4], the first attempt to reduce nitrobenzyl disulfide to the corresponding amino derivative (III) by means of hydrazine hydrate resulted in the formation of nitrobenzal hydrazine (V) or nitrobenzaldazine (VI) as the results of an unexpected desulfurization reaction indicated below.

(IV) (V)



(VI)

In this paper desulfurization reaction was examined in the case of benzyl (XIIa) or piperonyl disulfide (XIIb), which has no electron-attractive radical, namely, the nitro group. The piperonyl disulfide (XIIb) was prepared according to the following reaction scheme. In this case, crossed-Cannizzaro reaction was applied the first time to obtain piperonyl alcohol, but the catalytic hydrogenation was found to be more excellent.

When benzyl disulfide was heated with an excess of hydrazine hydrate, desulfurization occurred giving a small amount of yellowish crystals, which agreed with an authentic sample of m. p. 93°C[5] of benzaldazine (XIVa) by a mixed melting point test. As it was known that this compound XIVa turned to benzal hydrazine (XIII) by heating with hydrazine hydrate[6], the former substance was heated with an excess of hydrazine hydrate and it was observed that the color of the reaction mixture changed to colorless from yellow, indicating the formation of benzal hydrazine (XIIIa). This substance is known to be comparatively unstable against moisture in the air and easily decomposes to benzaldazine and hydrazine hydrate[7], therefore it seems possible that the benzal hydrazines initially formed from the disulfides give the corresponding benzaldazines by a prolonged period of reaction. Similarly, dipiperonyliden hydrazine (XIVb) was obtained from piperonyl disulfide and was proved to be identical with an authentic sample which was synthesized from piperonal and hydrazine hydrate[8].

## Experimental

**The Reaction of Dibenzyl Disulfide with Hydrazine Hydrate.** — The mixture of dibenzyl disulfide (1 g.) and 80% $NH_2NH_2 \cdot H_2O$ (2 ml.) was refluxed. After 30 min., an evolution of a gas containing sulfur and the deposition of a small amount of grayish-white substance on the inner tube of the condenser was observed. After 13 hr. of reflux, the reaction mixture was treated with hydrochloric acid and then extracted with ether. Then an ethereal extract was washed with water, dried on sodium sulfate and evaporated, resulting in a yellow viscous substance. This was recrystallized from dilute acetone giving yellow needles of m. p. 91~92°C in poor yield. This was found to be identical with the authentic sample described below.

**Benzaldazine (XIVa).**—To benzaldehyde (2 g.), 1.1 g. of 80% $NH_2NH_2 \cdot H_2O$ was gradually added at room temperature and considerable heat generation which accompanied the separation of yellow needles was observed. After recrystallization from ethanol, 1.3 g. (68.4%) of yellow, long needles (m. p. 93°C)[5] were obtained***.

**Piperonyl Thiuronium Chloride (X).**—Piperonyl chloride (5 g.) was added to thiourea (2.2 g.) in 99% ethanol (33 ml.) and the mixture was heated for 1.5 hr. The solvent was removed by distillation and a small quantity of ether was added to induce crystallization. The solid was collected by filtration. Colorless prisms (m. p. 201°C) were obtained by recrystallization from ethanol. Yield, 5.3 g., 73.6% of theoretical.

Found : C, 43.17 ; H, 4.00. Calcd. for $C_9H_{11}O_2 \cdot NSCl$ : C, 43.81 ; H, 4.49%.

**Piperonyl Mercaptan (XI).** — Thiuronium salt (5 g.) was admixed with 10% sodium hydroxide (34 ml.) and refluxed for 1.5 hr. on an oil bath. In this case an evolution of ammonia gas was observed. After cooling, the mixture was acidified with hydrochloric acid and extracted with ether. After being treated as usual, a fraction of 116~118°C/5 mmHg. (1.5 g., 44.1% of theoretical) was obtained by distillation in vacuo.

**Piperonyl Disulfide (XIIb).**—Iodine (1.2 g.) was gradually added to the stirred mixture of pyridine (1 g.) and piperonyl mercaptan (1.5 g.) at 15°C. After 1.5 hr., the reaction mixture was poured into water (50 ml.) and extracted with benzene, the extract was washed with saturated sodium thiosulfate, hydrochloric acid and water, successively and then evaporated. The residue was recrystallized from ethanol forming yellowish-white crystals (0.5 g., 35.8% of theoretical) of m. p. 68°C[9].

**The Reaction of Piperonyl Disulfide with Hydrazine Hydrate.**—The mixture of piperonyl disulfide (1 g.) and 80% $NH_2NH_2 \cdot H_2O$ (1.5 g.) was heated for 26 hr. and extracted with ether. The ethereal extract was evaporated after drying on sodium sulfate and the residue was recrystallized from acetone giving yellow needles (0.2 g., 22% of theoretical), m. p. 201°C. This was proved to be identical with an authentic sample prepared by the following method.

**** According to Ref. 5, this reaction was carried out in the presence of alkali.
9) W. Manchot and Chr. Zahn, *Ann.*, **345**, 326 (1905).

**Dipiperonyliden Hydrazine (Piperonal Azine) (XVb).**—Hydrazine hydrate (0.1 g.) was added to the mixture of piperonal (0.4 g.) and ethanol (1 ml.). After a few minutes a small amount of water was added, a white crystal separating from it. This was recrystallized from dilute acetic acid giving yellow crystals (0.2 g., 50.1% of theoretical), m. p. 202~203°C.

## Summary

The desulfurization reaction which was reported in the previous paper in case of the reaction of *p*-nitrobenzyl disulfide and hydrazine hydrate was also observed in the similar reaction of benzyl and piperonyl disulfide. The reaction product was found to be benzaldazine derivative instead of the derivative of benzal hydrazine.

# *Behavior of Some Impurities in the Electro-refining of Iron*

By Shumpei OKA*, Takashi MUKAIBO and Hirokazu AIKAWA

(Received April 21, 1960)

Knowledge concerning the behavior of trace impurities during electrolysis is important in preparing high purity electrolytic iron. The production of electrolytic iron has a long history[1,2], but very few investigations have been reported on the behavior of trace impurities[3].

Selecting the sulfate bath as an example, the authors studied the behavior of orthophosphate, sulfate and zinc ions in the electrolyte as well as the behavior of silver plated on anodes. The difficulty of trace analysis was avoided by using phosphorus-32, sulfur-35, zinc-65 and silver-110 as radioactive tracers.

## Experimental

Experiments were carried out separately with phosphate, sulfate and zinc ions in a bath and also with silver plated on anodes. Phosphate, sulfate and zinc ions were added to the electrolyte with corresponding radioisotopes. Silver was plated anodes without applying electricity in the cyanide bath containing silver-110.

After 48 hours' electrolysis, the distribution of the added radioisotope was determined by a suitable radiation counter. The contents of each element in the deposited iron were calculated from the concentration of the carrier.

**Electrolysis.**—An assembly having a high enough scale and the stability to discuss the behavior of impurities during the electrolysis has been constructed. The main features of the equipment are the special cathode frame designed to improve the current distribution on the cathode, liquid suppliers which feed the solution to electrolytic cell, and water bath to make up for the loss due to the evaporation of water. The supply solution for the electrolytic cell contains a sufficient amount of sulfuric acid to keep proper pH-values during long operations. The details of the assembly were reported elsewhere[4] with the results of re-electrolysis of electrolytic iron. In the following experiments the electrolytic iron was also used as an anode material.

The conditions of electrolysis are: temperature 60°C, current density 2 amp./dm$^2$, pH 5~6, 1 M/l. Mohr's salt solution and the period of deposition, 48 hrs. According to Mukai's work[5], sodium *n*-butylsulfonate was added to the bath at the concentration of 1 g./l. in order to protect the deposited metal from dendrite formation and to attain a high current efficiency.

**Measurements of Radioactivity.**—Phosphorus-32 emits a $\beta$-ray of maximum energy 1.71 MeV., which is strong enough to be measured by a liquid immersion type counter. Measurements were carried out by using 20 ml. of the sample solution containing 2 N hydrochloric acid and the correction was made for the absorption due to iron in the solution.

Autoradiography was applied to obtain some information on the distribution of phosphorus in the deposited iron. As the activity of the sample was very weak, X-ray emulsion was selected as a sensitive material. The specimen was moulded in

synthetic resin and an X-ray film was contacted on the polished plane which was coated with thin collodion film. Exposure was continued for three months.

Sulfur-35 emits a $\beta$-ray of maximum energy 0.167 MeV. and a gas flow counter was used for the measurements of its radioactivity. The samples were prepared in the form of barium sulfate precipitates and the self-absorption was corrected. The activity of sulfur-35 in the surface layer of the deposited iron was measured directly by the gas flow counter without separating the iron, because the $\beta$-ray of sulfur-35 has the maximum range of about 0.05 mm. in iron.

Silver-110 and zinc-65 emit $\gamma$-rays and were measured by a well type scintillation counter using liquid samples without the elimination of co-existing iron.

## Results

**Phosphate Ion.** — Electrolysis was repeated several times at different concentrations of the carrier in the electrolyte. Results are illustrated in Table I.

Table I. Distribution of phosphorus after electrolysis

| Concentration of phosphate ion* | 0.00 | 0.66 | 3.30 | 4.96 | 6.60 |
|---|---|---|---|---|---|
| Distribution (%) | | | | | |
| Electrolyte | 1.0 | 1.0 | 1.0 | 0.7 | 0.1 |
| Precipitate | 61.9 | 62.0 | 36.8 | 32.4 | 25.8 |
| Deposited iron | 8.0 | 24.3 | 55.3 | 62.2 | 73.1 |
| Recovery | 70.9 | 87.3 | 93.1 | 95.3 | 98.9 |
| Phosphorus in deposited iron** | + | 0.038 | 0.86 | 1.9 | 2.3 |

* Concentration of the carrier added is expressed in P g./l.
** Weight percentage.
\+ Far less than 0.0004. The value was estimated by using the specific activity of carrier concentration, 0.66 g./l.

When the concentration of phosphate ion was higher than 3 g./l. in the electrolyte as phosphorus, more than half of the added phosphate ions were deposited on the cathode. On the contrary, at the concentration lower than 3 g./l. co-precipitation of phosphate ions with iron hydroxide was dominant over the deposition on the cathode. The recovery of phosphorus-32 became difficult with the decrease of the concentration of the carrier.

The concentration of phosphate ion in the electrolyte decreased rapidly at the beginning of electrolysis and almost all of the added phosphate ions were eliminated by the end of electrolysis.

Autoradiography was applied to the vertical section of the deposited metal. Fig. 1a shows a typical pattern of the autoradiograph obtained from the section illustrated in Fig. 1b. The high concentration of phosphorus near the mother plate was observed, even when pits or dendrites were formed. The distribution coincides with the observed decrease of the concentration of phosphate ion in the bath at the beginning of electrolysis.

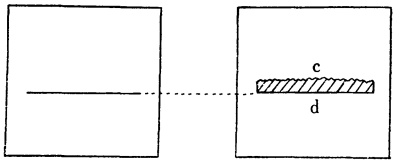

Fig. 1a Fig. 1b

Fig. 1a: Autoradiograph.
Fig. 1b: Section of the specimen.
c: Solution side
d: Mother plate side

By applying the same method of autoradiography on the horizontal plane of the deposited metal, the flat distribution of phosphorus was observed.

**Sulfate Ion.**—The concentration of sulfate ion was about 2 g.-ion/l. in the sulfate bath and sulfur-35 was added to the electrolyte in the form of sulfate ion. The deposited metal from this bath was proved to contain 0.017~0.018 wt. per cent of sulfur by measuring the radioactivity.

Five washing steps were applied to the deposited metal. The effect of washing on the sulfur contents of the surface layer of the metal is illustrated in Fig. 2.

The solution side of the deposited metal had a higher activity than the mother plate side at the beginning of washing. By washing,

Conditions of washing:
(1) Boil in hot water for 5 minutes.
(2) Boil in hot water for 5 minutes.
(3) Immerse in 60°C 0.01 N HCl for 5 minutes.
(4) Immerse in 60°C 0.1 N HCl for 5 minutes.
(5) Boil in hot water for 10 minutes.

the activity of both sides decreased to the same level and the contents of sulfur was reduced from 0.018 to 0.008 wt. per cent.

Autoradiography was tried in vain on the deposited metal. The sulfur seems to have been removed from the surface of the specimen during the wet polishing process.

**Zinc Ion.**—Experiments were carried out at the concentration of added zinc carrier 0.65 and 1.30 mg./l. in the electrolyte. In both cases, nearly 90% of the added zinc-65 ions were deposited on the cathode. A part of the remaining 10% was co-precipitated with iron hydroxide and the rest remained in the electrolyte.

**Silver Plated on Anodes.** — After 48 hours' electrolysis, over 90% of the silver ions that were separated from anodes were precipitated with iron hydroxide and only about 2% were deposited on the cathode. The amount of silver plated on anodes was calculated as 0.47 ppm in iron from the amout of silver separated from anodes by electrolysis. About 0.008 ppm of silver against iron were included in the deposited iron.

**Summary**

Phosphate ions were found to deposit themselves on the cathode like a cation. This phenomenon suggests the formation of a complex ion which has positive charges. The results on sulfur confirms the importance of washing which was pointed out by Schafer and Harr[2] in achieving low values of total sulfur in the deposited metal. Silver was eliminated effectively by electrolysis, but it will be still difficult to remove zinc from iron by electrolysis.

The experiments on radioisotopes were performed in the Radioisotope Laboratory of the University of Tokyo. The authors are indebted to Toho Zinc Co. for financial aid in performing these experiments.

# *Synthesis of Several Ketones from Acetaldehyde and Propylene by Gamma-ray Irradiation**)

By Kozo HIROTA and Motoyoshi HATADA

(Received May 2, 1960)

It has been reported[1] mostly in the patent literature that some ketones are synthetized by a chain mechanism from aldehydes and terminal olefins at 60~100°C, using benzoyl peroxide, acetyl peroxide etc. as initiator. The reaction is believed to involve the sequence,

$$RCHO \rightarrow R\dot{C}O + H$$

$$R\dot{C}O + CH_2{=}CHR' \rightarrow RCOCH_2\dot{C}HR'$$

$$RCOCH_2\dot{C}HR' + RCHO \rightarrow RCOCH_2CH_2R' + R\dot{C}O$$

A similar reaction has been initiated photochemically at room temperature. However, the reaction ought to proceed more easily by use of gamma-ray irradiation without any chemical initiator, because of its powerful action of producing free radicals. Such being the situation, it is interesting to investigate the above expectation in the system of acetaldehyde and propylene, because the yield of ketones was low when a chemical initiator was used[2]. It is the purpose of the present paper to report the result actually carried out.

## Experimental

**Materials.**—*Acetaldehyde* was prepared by heating commercial paraaldehyde at 70°C, which had been purified by distillation, with a small amount of concentrated sulfuric acid. The final product was purified by repeating vacuum distillation twice. *Propylene* was prepared by dehydrating the middle fraction of the distillate of commercial isopropyl alcohol on alumina kept at 400°C. Impurities of the samples were found to be within 0.5% with mass-spectrometry and gas-chromatography.

**Procedure.** — All the samples were carefully deaerated by evacuation, then keeping them at

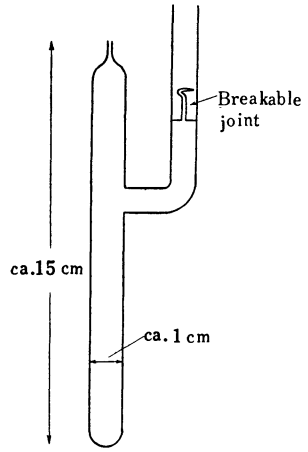

Fig. 1. Irradiation tube.

−190°C, enclosed and irradiated in the glass tube shown in Fig. 1. *Irradiation* was carried out on the samples enclosed in the tube with the Co-60 source (1000 curie) installed at Osaka Laboratory of JARRP. The dose rate was measured with the Fricke dosimeter. After irradiation, products were taken out from the tube by use of a breakable joint and were put to analysis.

**Analysis.**—After the amount of gaseous products was determined with the Saunder-Taylor apparatus, they were analyzed quantitatively by the mass-spectrometric method (apparatus: Hitachi RMU-5). Liquid products were analyzed by the gas-chromatographic method (apparatus: Shimadzu GClA; carrier gas: helium). Final identification of each product was made, however, by resorting to mass-spectrometry and infrared spectrometry on the samples fractionated by the gas-chromatograph except in the case of the higher boiling products, the chemical structure of which was estimated from their retention time.

## Results and Discussion

The gaseous products were hydrogen, methane and carbon monoxide, their $G$ values being small as shown in Table I. From the liquid products, methylpropylketone (MPK), methylhexylketone (MHK), and methylnonylketone (MNK) could be identified by the gas-chromatographic method, using a high vacuum-oil-column (length 2.45 m.) at 180°C. The peak of MPK separated into two parts when the column charged with dioctyl phthalate was used. The peak which was larger in area by several times was found to be normal MPK (M*n*PK), while the other was its isomer, i.e., methylisopropylketone (M*i*PK). It is noteworthy that MPK's, MHK and MNK correspond to the ketones produced by the addition of one, two and three molecules of propylene to an acetaldehyde molecule, respectively.

Table I. Examples of the experiment

Amounts of products are expressed in mol.$\times 10^{-4}$; numbers in parentheses are $G$ values.

| Experiment | 1 | 2 | 3 |
|---|---|---|---|
| Acetaldehyde (mol.) | 0.053 | 0.053 | 0.116 |
| Propylene (mol.) | 0.05 | 0.031 | 0.032 |
| $R$=acetaldehyde/propylene | $1.0_4$ | $1.7_1$ | $3.6_2$ |
| Total dose (r) | $7\times10^7$ | $1\times10^7$ | $2\times10^7$ |
| Dose rate (r/hr.) | $12.2\times10^4$ | $1.9\times10^4$ | $1.4\times10^4$ |
| Products: Hydrogen | 2.24(0.64) | 0.5 (1.4) | — |
| Products: Carbon monoxide | 1.16(0.35) | 0.38(1.0) | — |
| Products: Methane | 0.17(0.05) | 0.11(0.2) | — |
| Products: MPK (M*i*PK) | 6.0 (1.8) | 2.8 (7.0) | 8.7(5.7) |
| Products: MPK (M*n*PK) | 29.0 (9.0) | 2.4 (68) | 128 (83) |
| Products: MHK | 20 (6.0) | 19.5 (60) | 39 (28) |
| Products: MNK | 6.0 (1.8) | 4.3 (1.4) | 5.0(3.3) |

Considering that aldehyde is more sensitive to radiation than propylene and also that irradiation is carried out at room temperature, these ketones may be produced via acetyl radical by the following scheme:

$$CH_3CHO \rightsquigarrow CH_3\dot{C}O$$

$$CH_3\dot{C}O + CH_2{=}CHCH_3 \xrightarrow{k_{p0}} CH_3COCH_2\dot{C}HCH_3$$

$$CH_3COCH_2\dot{C}HCH_3 + CH_3CHO \xrightarrow{k_{p1}} CH_3COCH_2CH_2CH_3 + CH_3\dot{C}O$$

$$CH_3COCH_2\dot{C}HCH_3 + CH_2{=}CHCH_3 \xrightarrow{k_{p1}} CH_3COCH_2\underset{\displaystyle CH_2\dot{C}HCH_3}{\underset{|}{C}}HCH_3$$

$$CH_3COCH_2\underset{\displaystyle CH_2\dot{C}HCH_3}{\underset{|}{C}}HCH_3 + CH_3CHO \xrightarrow{k_{d2}} CH_3COCH_2\underset{\displaystyle CH_2CH_2CH_3}{\underset{|}{C}}HCH_3 + CH_3\dot{C}O$$

$$CH_3COCH_2\underset{\displaystyle CH_2CH_2CH_3}{\underset{|}{C}}HCH_2\dot{C}HCH_3 + CH_2{=}CHCH_3 \xrightarrow{k_{p2}} CH_3COCH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2\dot{C}HCH_3$$

The above scheme coincides with the result that the $G$ values of the produced ketones are higher than that of usual radiation-induced reaction. The produced ketones may therefore be expressed generally by $RCO(C_{3n}H_{6n+1})$, thus M*n*PK, MHK and MNK being the ketones, $n$ of which corresponds to 1, 2 and 3, respectively. However, the presence of a

small amount of M*i*PK indicates a process slightly different from the above; i. e. the addition of acetyl radical to $\beta$-carbon of propylene as follows:

$$CH_3\dot{C}O+CH_2=CHCH_3 \longrightarrow$$

$$CH_3CO-\underset{\cdot CH_2}{\overset{H}{C}}-CH_3 \xrightarrow{RCHO} CH_3CO-\underset{CH_3}{\overset{H}{C}}-CH_3$$

According to the mechanism, higher homologues of the ketone ($n=4, 5, 6\cdots\cdots$) must be produced besides, even though in smaller amount. Actually they could not be identified in the residues of vacuum-distillation of the product, but their existence can be estimated by the following reasoning. In Fig. 2, molar fractions $F_n$ of each ketone produced by the ratio $1:n$ are plotted against aldehyde/propylene ($R$) as the abscissa, making the total dose and dose rate constant, i. e., at $2.3\times10^7$ r and $4.7\times10^4$ r/hr. respectively. The full line denotes the theoretical one[3], calculated by the formula,

$$F_n=\frac{C_nR}{\prod_{i=1}^{n}(C_iR+1)} \qquad (3)$$

where $C_n$'s are transfer constants, $k_{dn}/k_{pn}$. When the following values were adopted, in actual calculation, $C_1=0.84$, $C_2=1.64$ and $C_3=6.1$, good coincidence between theoretical and observed data is obtained. Considering this result, even $C_4$ must be so large that homologues of ketone higher than MNK can be neglected practically, even though they are produced. Actually, if $C_4$ is assumed to be 20 and $F_4$ is calculated, it is very small as shown by the dotted line in Fig. 2.

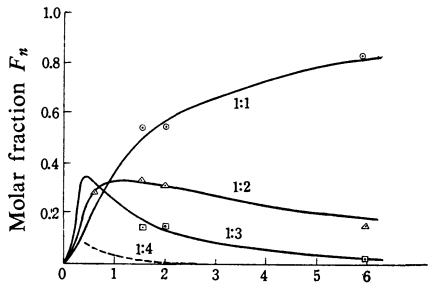

Fig. 2. Molar fraction of produced ketones vs. $R$*.
Dose rate, $4.7\times10^4$ r/hr.
Total dose, $2.3\times10^7$ r.
— Theoretical curves calculated by Eq. 3.

* In Fig. 2~5, $1:n$ means the ketone produced by one mole of aldehyde and $n$ moles of propylene.

3) Cf. p. 245 of Ref. 1.

The terminating processes which follow the above propagating processes in the chain reaction must be ascribed to some recombination processes between radicals, e. g.

$$2CH_3\dot{C}O \longrightarrow (CH_3CO)_2$$

or $$CH_3\dot{C}O+CH_3CO(C_3H_6)_n\dot{C}H_2CHCH_3$$
$$\longrightarrow CH_3CO(C_3H_6)_{n+1}COCH_3$$

Such processes may be reasonable if the fact that the yields of the ketones decrease with increasing dose rate as shown later is taken into account. However the products resulting from the recombination process could not be detected, probably because of their lower yields and of their larger retention time in the gas-chromatogram.

As shown in Fig. 3, where dose rate and total dose were kept constant at $4.7\times10^4$ r/hr. and $2.3\times10^7$ r., respectively, the amount of hydrogen was practically constant, while those of methane and carbon monoxide increased; this tendency is concordant with the expectation that the decomposition products of acetaldehyde increase with $R$.

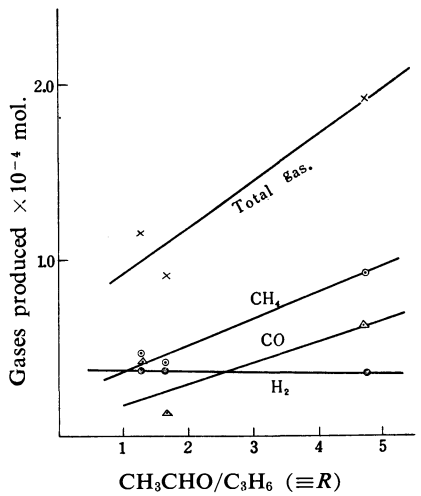

Fig. 3. Gases produced vs. $R$ (molar ratio of acetaldehyde and propylene in the feed).
Total dose, $2.3\times10^7$ r.
Dose rate, $4.7\times10^4$ r/hr.

The effect of total dose on the ketones produced is shown in Fig. 4 where the dose rate and $R$ were kept constant at $15.6\times10^4$ r/hr. and 1.6, respectively. It was found that the amounts of MPK, MHK and MNK increased with the total dose, but not linearly in the cases of MHK and MNK. This result may be explained by the fact the reaction order of propylene was greater than that of aldehyde in the cases of MHK and MNK, considering that the amount of the unreacted

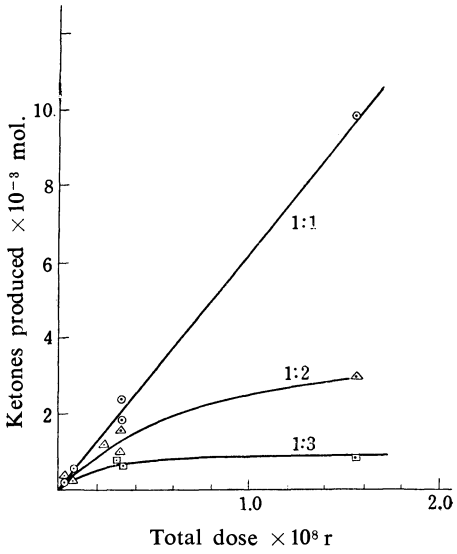

Fig. 4. Ketones produced vs. total dose. $R=1.6$, dose rate, $15.6\times 10^4$ r/hr.

propylene was very small in the case of the highest total dose. The gases produced increased practically linearly against the total dose, but the amounts of hydrogen and methane were the same in the order of magnitude, while the amount of carbon monoxide was much smaller. Of course the order of their magnitude varied according to $R$ as shown in Fig. 3.

In Fig. 5, the logarithm of the amounts of liquid products is plotted against the logarithm of the dose rate where the total dose and $R$ were kept $2.3\times 10^7$ r and 1.6, respectively. As compared with the liquid products, the amounts of the gaseous products were practically not affected by the dose rate, though the amounts of hydrogen and carbon monoxide decreased slightly while that of methane increase. The amounts of ketones decreased markedly against the dose rate, but a linear relation does not exist in Fig. 5. Such a result ought not to be obtained if the bimolecular termination of $CH_3\dot{C}O$ be realized as was done in the above reaction sceeme. However, since the data are still insufficient to derive any conclusion in regard to the mechanism, i. e., the number of measurements was small, and concentration of propylene was not constant during the reaction in some of the measurements, a definite conclusion on the effect of dose rate will be postponed to later research.

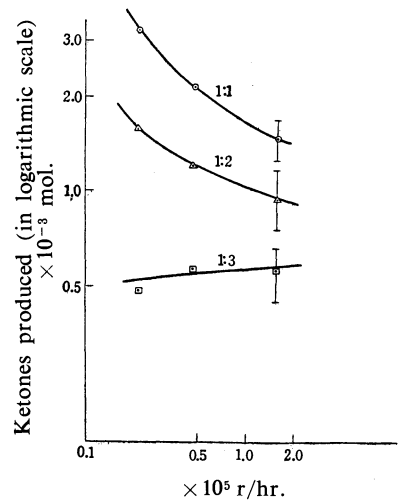

Fig. 5. The amounts of ketones produced vs. irradiation dose rate. $R=1.6$, total dose $2.3\times 10^7$ r.

Finally we will see what can be said about this reaction if it is considered as a synthetic method. First, it is favorable for this method that the total yield of the produced ketones was larger than that of the method by which some chemical initiator is used. For instance in No. 3 in Table I, conversion of propylene into MPK, MHK and MNK amounted to 72%, the sum of their $G$ values being 120. Second, $G$ values will be increased markedly, if the temperature of the system is raised as much as possible. This expectation has been confirmed to some degree in the system of acetaldehyde and isobutylene[4]. However, it is interesting hereafter to determine the upper limit of the reaction temperature, considering that acetyl radical inclines to decompose into $CH_3$ and CO according to the degree of the temperature.

## Summary

It has been found that methylpropylketone and other higher ketones are synthetized with relatively high $G$ values by gamma-ray irradiation on mixtures of acetadehyde and propylene at room temperature, and that the reaction proceeds by a chain mechanism, with acetyl radical produced thereby as the initiator.

We express sincere thanks to Mr. S. Iizuka for his kind advice and also to Mr. J. Takezaki for his assistance in mass-spectrometry.

# *Spectrophotometric Determination of Traces of Boron in Thorium**

By Hiroshi ONISHI, Nasumi ISHIWATARI and Hitoshi NAGAI

(Received May 24, 1960)

Although a few reports[1,2] have been published of the chemical determination of boron in thorium metal, no paper seems to be available pertaining to its determination in thorium oxide. This is probably due to the fact that it is very difficult to dissolve the oxide. Nitric acid or hydrochloric acid in the presence of a small amount of fluoride dissolves the oxide. However, this method of solution will not be directly applicable to the photometric determination of boron because of the interference of fluoride.

The authors have found that strong phosphoric acid[3] dissolves both thorium oxide and metal relatively easily. On the basis of this finding, a method has been developed for the determination of as little as a few tenths of a part per million of boron in thorium oxide or metal. After the dissolution of the sample, boron is separated as methyl borate, and finally determined by the curcumin method[4].

## Experimental

**Apparatus.** — The quartz distilling apparatus and the spectrophotometer were the same as those described before[4].

**Reagents.**—*Strong Phosphoric Acid.*—Prepare from 85% orthophosphoric acid according to the direction of Kiba[3]. The orthophosphoric acid should preferably contain less than 0.05 ppm of B. When such an acid is not obtainable, purify it as follows. Transfer 150 ml. of 85% phosphoric acid, 30 ml. of water (redistilled), and 500 ml. of redistilled methanol to a one-liter quartz distilling flask. Connect the condenser, and heat the flask in a water bath, and continue distillation until no more liquid comes out. Add 150 ml. of water and distil again. Transfer the residue to a 500 ml. quartz beaker, and heat at 150~200°C for several hours. Cool, add 150 ml. of water, and repeat heating as above. Add 100 ml. of water and heat at 200~250°C until boiling ceases. Finally add 100 ml. of water and heat at 200~280°C until boiling ceases. Cool, and prepare the strong phosphoric acid in a suitable apparatus by heating the purified acid to 300°C.

Other solutions used were the same as those described previously[4].

**Procedure.**—Transfer 1.00 g. of thorium oxide or thorium metal sample to the distilling flask and add 5.0 ml. of the strong phosphoric acid using a syringe. Heat the flask on a sand bath at 200~250°C and shake the contents occasionally to hasten the solution of the sample. Stop heating when a clear sample solution has been obtained.

To the cold solution add 3 ml. of water (redistilled) and mix. Connect the flask with the condenser through the adapter, and immerse the flask in a one-liter beaker containing water (this serves as a water bath). Place a 100 ml. platinum dish containing 7.0 ml. of 0.1 N calcium hydroxide suspension and 10 ml. of water under the condenser. Add 20 ml. of methanol (redistilled) and mix the solution with a polyethylene rod and wash the rod with 10 ml. of methanol. Connect the tap funnel, and raise the temperature of the bath slowly to boiling point. Continue heating until no more liquid comes out. (This distillation will take 15~20 min.)

Remove the burner and replace the hot water by cold water. Add 20 ml. of methanol through the tap funnel and distil again. (This second distillation will take 10~15 min.) Lower the dish and wash down the stem of the condenser with water. Mix the distillate and washings and confirm the fact that the solution is alkaline. Evaporate the solution gently to dryness on a water bath.

To the residue add 2 ml. of water and 4.0 ml. of curcumin-oxalic acid solution (0.40 g. of curcumin and 50 g. of oxalic acid in one liter of ethanol). Then continue according to the directions previously described[4]. When the amount of boron is found by referring to the standard curve that has been prepared by omitting the separation step, a correction of +15 per cent is advisable.

*Note.* — Instead of the distilling flask, a quartz dish may be used for the dissolution of the sample. In this case, the process of solution is accelerated by stirring with a quartz rod. The clear sample solution should be transferred to the distilling flask while the solution is hot.

## Results and Discussion

As pointed out by Rodden[5], thorium oxides that have been highly ignited are very difficult to dissolve. In the present work, thorium oxides that had been prepared by heating

thorium nitrate to 500 and 700°C were dissolved in strong phosphoric acid within 1 and 2 hr., respectively (quartz dish). When the distilling flask is used, a longer time is required.

The effects of phosphoric acid and thorium on the determination of boron are shown in Table I. Seven milliliters of 0.1 N calcium hydroxide suspension and the foreign substance, with or without 1 μg. of boron, were evaporated to dryness and then subjected to color development. The addition of 0.18 meq. of phosphoric acid resulted in about a 40 per cent decrease in absorbance. However, as shown below, no significant quantity of phosphoric acid comes out during methanol distillation.

Table I. Effect of phosphoric acid and thorium on the determination of boron*

| Addition | Absorbance | | |
|---|---|---|---|
| | Blank | 1.0 μg. B | Difference |
| — | 0.060 | 0.370 | 0.310 |

* Average of duplicate experiments.

Table II shows the effect of water on the distillation of boron. When water was not added to 5.0 ml. of strong phosphoric acid, methanol distillation was not successful. This was probably due to the formation of methyl phosphate. In the table recoveries were calculated by referring to the standard curve obtained without distillation of boron. In the subsequent work, 3.0 ml. of water was adopted.

Table III summarizes the results of methanol distillation of boron in the absence of thorium. The distillation was made according to the proposed procedure. The reagent blank against the blank of direct color development was about 0.2 μg. of boron. The average recovery

* Other certified values, based on metal (in ppm): 100 each Al, Fe, Mo, P, Si, V, Zn, 35 Be, 10 each Bi, Co, Cu, Mg, Mn, Ni, Pb, Sn, 1 each Ag and Cd.

** Other certified values (in ppm): about 20 Al, about 150 Be, <10 Ca, <5 Cu, 140 Fe, <10 Mg, about 2 Mn, about 10 Ni, about 4 Pb, about 20 Si, about 2 U, 60 N, 230 C.

of 0.2 to 1 μg. of boron is calculated to be 86%. The standard deviation for 1 μg. of boron is 5.6%. The recovery of 86% is comparable to that of the methanol distillation from a sulfuric acid medium[4].

Known amounts of boron were added to thorium oxide (1 g., Société de Produits Chimique des Terres Rares, France) and the boron was determined by the proposed procedure except that +15% were not applied (Table IV). A recovery of about 86% is indicated after correcting for the original boron content of the sample.

The standard samples of thorium oxide and thorium metal, issued by the New Brunswick Laboratory (NBL), were analyzed by the proposed method, and the results are shown in Table V. It is seen that the NBL values for

thorium oxide samples agree quite well with the values obtained by applying the proposed method. Because the NBL value for the thorium metal is very approximate, it is not possible to check the accuracy of the proposed method directly. Duplicate analyses of the thorium metal that was converted into oxide by heating to 600°C for several hours gave 0.67 and 0.59 ppm B (average 0.63 ppm). Since this average agrees within an experimental error with the average of 0.48 ppm (Table V), it is not likely that insoluble boron remains after dissolution of thorium metal in strong phosphoric acid. Furthermore, the average value of 0.48 ppm B agrees reasonably well with the value of 0.35 ppm which was obtained by the spectrochemical determination employing the carrier distillation technique[6]. Consequently, it is considered that the proposed method is successfully applicable to thorium metal. As curcumin can not be used in the method described by Eberle and Lerner[2], the proposed method seems to be more practicable.

6) T. Nakazima and H. Fukushima, *Japan Analyst (Bunseki Kagaku)*, **9**, 830 (1960).

**Summary**

Procedure is described for the spectrophotometric determination of a few tenths of a part per million of boron in thorium oxide or metal. The sample was brought into solution with strong phosphoric acid. After diluting the solution with water, boron was separated by distillation as methyl borate, and finally determined by the curcumin method. The error is not likely to exceed ±0.1 ppm for 0.2~1 ppm of boron.

The authors are indebted to Mr. T. Nakazima and Mr. H. Fukushima of this institute for spectrographic analysis of thorium metal.

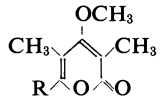
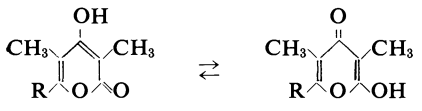
# *Correlation of Reaction Rates and Product Stabilities. I. The Methylation of Pyrononeswith Diazomethane*[1-3]



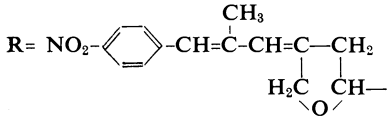
By Hisao NAKATA

(Received February 22, 1960)



The skeletal structures of aureothin and isoaureothin have recently been established as I and II, respectively[1]. The relative stabilities of these two compounds are so different that aureothin isomerizes readily to the more stable isoaureothin derivatives especially under acidic conditions[4]. The isomerization reaction has so far been considered to be an irreversible process involving a certain drastic structural change since the reverse isomerization reaction has not been observed during the course of the structural elucidation studies.

(I) Aureothin



(II) Isoaureothin

(IIIα) (IIIγ)

Desmethylisoaureothin

However, as was shown in the previous paper[1], the constitutional difference between I and II is only in their pyrone rings, and therefore, two tautomeric structures of IIIα and IIIγ are possible for the demethylated product, desmethylisoaureothin. In order to confirm rigorously the structural correlation between

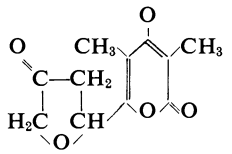
aureothin and isoaureothin, it was felt to be desirable to perform the reverse isomerization reaction.

In the present investigation, desmethylisoaureothin (III$\alpha$) is methylated with diazomethane under the special condition derived from the theory of Arndt's kinetically interplayed methylation reaction. Satisfactory results are obtained.

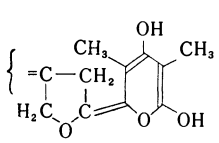


**Tautomerism of Pyronone Derivatives.** — Although previous studies[5] suggest the structure of desmethylisoaureothin as III$\alpha$ having an $\alpha$-pyrone ring, a more definite evidence[1] is now available. Subtraction of the ultraviolet absorption curve of aureothinic acid (IV)[6] from the curve of desmethyl isoaureothin affords the spectrum of the residual pyrone

(IV) Aureothinic acid

(V) Aureonone

(VI) Isoaureonone



fragment. The resultant spectrum does not agree with the spectrum of aureonone (V)[1] but is well superimposable on the spectrum of isoaureonone (VI)[1]. This indicates, that the tautomeric form of the $\alpha$-pyrone structure III$\alpha$ predominates desmethylisoaureothin even in solution. Data of infrared spectra of those compounds[1] also support the conclusion. Therefore, the theoretically conceivable equilibrium III$\alpha$ $\rightleftarrows$ III$\gamma$ lies almost at the III$\alpha$ side[7] and III$\gamma$ is thermodynamically less stable than III$\alpha$. The same is true for their methylated products, aureothin and isoaureothin; the former is less stable than the latter[4]. It was reported also in other pyronone derivatives that the $\gamma$-pyrone isomer is usually less stable and in solution the $\alpha$-pyrone alternative predominates[9-13].

**Theory of Kinetically Interplayed Methylation.** — When a proton transfers from tautomeric acids to bases, it has been observed[14,15] that the proton is lost most quickly from a least stable tautomer. This proton mobility is characterized as the *dynamic acidity*[16,17] and should be differentiated from the so-called acidity in the equilibrium state (*static acidity* in the strict sense)[18,19]. The dynamic acidity correlates with the activation energy of the proton transfer process and the static acidity correlates with the free energy difference between the acid and its conjugated base[20]. The reactivity of a given acid depends on the dynamic acidity of the acid particularly in the reaction, where the proton plays a dominant role; thus, it may be concluded that the reactivity of the acid towards diazomethane is proportional to its dynamic acidity[17,18,23-28]. The less stable isomeric acid has a larger dynamic acidity and is methylated with diazomethane more quickly than the stable isomer,

7) Recently, Yamazaki[8] has ascertained the percentage of enol of desmethylisoaureothin in various solvents. Although she reported the values 46.0 and 41.5% in ethanol and 25.0 and 22.2% in chloroform, no indications of such a result are observed from the infrared spectra[1] of desmethylisoaureothin, and our present conclusion that desmethylisoaureothin exists largely as III$\alpha$ (one of the enol forms) also does not agree with her. Moreover, the reported values in formic acid and in methanol are over 100%, the reason of which attributed to the presence of the dienol form of desmethylisoaureothin. However, it is unlikely to consider any dienol form of this compound. If we were forced to assume the following dienol structure, this would contradict with our previous observation[4] that desmethylisoaureothin is optically active and has a definite sign of rotation in solution.

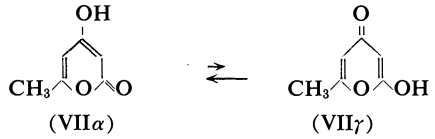
though the equilibrium concentration of the former is less than that of the latter in the solution.

Since the methylation reaction with diazomethane produces an exceedingly stable nitrogen molecule, the process undoubtedly does not have high energy requirements and, indeed, may even be somewhat exothermic[29-31]. The activation energy is correspondingly rather small and the transition state of the methylation reaction would resemble the starting material closely[32,33] in topology[34] and in geometry[34].

When two tautometric acids, A-OH and G-OH, are methylated with diazomethane, the reaction may proceed according to the following mechanistic scheme[16,37] where $A\text{-}OCH_3$ is produced only from A-OH and $G\text{-}OCH_3$ only from G-OH. Because of the resemblance of the transition state to the starting materials it



$$\begin{array}{ccc} CH_2N_2 + A\text{-}OH & \underset{k_-}{\overset{k_+}{\rightleftarrows}} & G\text{-}OH + CH_2N_2 \\ \downarrow k_a & & \downarrow k_g \\ A\text{-}OCH_3 & & G\text{-}OCH_3 \end{array}$$

seems unlikely to consider any other reaction processes of indirect methylation involving the rearrangement of the reaction centre.

Arndt[16,19,38] has discussed in detail the kinetic interplay between methylation reactions (velocities $k_a$ and $k_g$) and prototropic rearrangement reactions (velocities $k_+$ and $k_-$), and drawn the following conclusions. If the concentrated diazomethane solution is added to the tautomeric mixture of A-OH and G-OH, the product proportions $G\text{-}OCH_3/A\text{-}OCH_3$ are not very different from the ratio of G-OH/A-OH, which is the ratio of the initial equilibrium concentrations of the respective acids. On the other hand, if the concentration of diazomethane is maintained at a low level, the ratio of $G\text{-}OCH_3/A\text{-}OCH_3$ will be larger than G-OH/A-OH, provided that G-OH has a larger dynamic acidity than A-OH.

Consequently, it may be expected that the product proportions of the two isomeric methyl ethers depend on the time required for the addition of the diazomethane solution, the more gradually the addition of the diazomethane solution, the more will increase the proportions of the methylated product of the less stable isomeric acid having the larger dynamic acidity.

**Diazomethane Methylation of Pyronone Derivatives.** — Although literatures contain several references to the diazomethane methylation of 2,4-pyronone derivatives such as 6-methyl-2,4-pyronone (triacetic lactone) (VII), the results obtained have been the subject of considerable controversy[9,10,39-41].

(VII$\alpha$) (VII$\gamma$)

6-Methyl-2,4-pyronone (triacetic lactone)

(VIII$\alpha$) 6-Methyl-4-methoxy-$\alpha$-pyrone

(VIII$\gamma$) 6M-ethyl-2-methoxy-$\gamma$-pyrone

Recently, there appeared an extensive study[13] of this methylation reaction and it was concluded that the products were usually mixtures of two possible isomers, the actual proportions depending on the nature of other substituents[42]. Several results in other 2,4-pyronone derivatives were also reported[11,12,43-47]. However,

34) It seems reasonable to distinguish the terms *topology* and *geometry* of the transition state from the term *structure* of reactants or of products, as seen in Refs. 32, 35 and 36. Although the transition state lies somewhere between the reactants and the products, it may not have any definite structure in the ordinary sense, since the arrangement of atoms of the reacting molecules varies with the time in passing over the transition state. The *topology* represents the linkage of atoms of the reacting molecules in the transition state, and may correspond to the *constitution* of the molecule in the static state. The *geometry* represents the spacial orientations of atoms of the reacting molecules in the transition state, and may correspond to the *configuration* and the *conformation* of the molecule in the static state.

as far as the author is aware, little attention has been paid to investigate the relation between the product proportions and the reaction condition employed[48]. Thus, the diazomethane methylation of 6-methyl-2, 4-pyronone (VII) was first examined.

## Results and Discussion

The methylation was carried out by addition of ethereal solution of diazomethane[49] to a suspension of VII in dry ether, and the two isomeric methyl ethers, VIII$\alpha$ and VIII$\gamma$, were separated by the technique of Polish workers[9,50]. Product proportions are calculated as the percentage of the total weight of the methylated products isolated. The results are summarized in Table I.

Table I. Product proportions of diazomethane methylation

| The time required for the addition of the diazomethane solution | Average product proportions | |
|---|---|---|
| i) 6-Methyl-2,4-pyronone (VII) : | VIII$\gamma$ % | VIII$\alpha$ % |
| Very rapidly | 0 | 100 |
| 4 hr. | 26 | 74 |
| 8 hr. | 31 | 69 |
| 18 hr. | 33 | 67 |
| ii) Desmethylisoaureothin (III) : | I, % | II, % |
| Very rapidly | 0 | 100 |
| 2~4 hr. | 0 | 100 |
| 18 hr. | 2 | 98 |

On the basis of these data, it should be emphasized that the more gradually the addition of the diazomethane solution, the more will increase the proportions of the $\gamma$-pyrone methyl ether, VIII$\gamma$.

6-Methyl-2, 4-pyronone (VII) would exist in solution as a tautomeric mixture of VII$\alpha$ and VII$\gamma$. Spectral data[9,10] suggest, that in either solution the tautomeric form of an $\alpha$-pyrone structure (VII$\alpha$) predominates. This means VII$\gamma$ is thermodynamically less stable, and has a larger dynamic acidity, than VII$\alpha$. The observed results presented in Table I are therefore in good agreement with the theoretical prediction that the gradual addition of diazomethane will give rise to the increase of percentages of the less stable isomeric methyl ether in the over-all product.

The same is true in the case of methylation of desmethylisoaureothin (III). As is shown in Table I, aureothin (I) was obtained only when the diazomethane solution was added very gradually. Accordingly, the reverse isomerization reaction was also solved satisfactorily.

From these data the structural correlation of aureothin (I) and isoaureothin (II) was confirmed. It is also indicated that the desmethyl derivative of aureothin does exist in solution as a tautomeric mixture of III$\alpha$ and III$\gamma$[51]. Desmethylaureothin (III$\gamma$) has not been known so far, since its concentration in solution is presumably very small as compared with that of the stable isomer, desmethylisoaureothin (III$\alpha$).

Moreover, the present results support the conclusion[1] that desmethylisoaureothin has the structure III$\alpha$ also in the solid state, since the methylation reaction was carried out for the ether suspension of desmethylisoaureothin[52].

The skeletal structure of aureothin (I) thus being established rigorously, emphasis must be given for the structural peculiarity of this compound. Aureothin has a nitro group which is as yet a rather rare function in natural products. Only few other examples were known, including chloramphenicol[60], hiptagenic acid[61], azomycin[62], and aristolochic acid[63]. Among

48) Herbst et al.[13] reported the product ratio, VIII$\alpha$: VIII$\gamma$ as 64 : 19, which did not agree with the ratio 72 : 20 of Janiszewaka-Drabarek[41]. They also noticed that different proportions were observed under the condition described by Wiley and Jarboe[10] but no explanation of this result was given.

50) I. Chmielewska, J. Cieslak and T. Kraczkiewicz, *Roczniki Chem.*, **30**, 1009 (1956).

51) If III$\gamma$ does not exist in solution, aureothin (I) will not be obtained and the sole product, independently of the reaction condition, will be II, since I is considered to be produced only through III$\gamma$ in the above mechanistic scheme.

52) It seems reasonable to assume that the equilibrium A—OH$\rightleftarrows$G—OH is not held in the solid state. If the crystal consists from the less stable G—OH, the tautomer is first formed when the crystal is dissolved into solution must be G—OH. The next step of the reaction will be either the methylation of this newly formed G—OH to G—$OCH_3$ or its rearrangement to the more stable A—OH. Since G—OH is methylated more rapidly than A—OH, when the methylation takes place immediately by the addition of the concentrated diazomethane solution, the methylation reaction should occur preferentially and the rearrangement reaction will lag behind, so that diazomethane will have little chance to react with A—OH. In this case, therefore, the percentage of the less stable methyl ether, G—$OCH_3$, will increase in the over-all product, when the concentrated diazomethane solution is added rapidly. This is quite contrary to the observed tendency. The method used in Ref. 53 may generally be utilized to show which possible tautomeric structure is represented by the crystals. Several applications have recently been reported. See Refs. 54—59.

them, aureothin is the third nitro compound obtained from nature[64]. Moreover, aureothin has the substituted 2-methoxy-$\gamma$-pyrone structure. All other methylated 2,4-pyrononones which have so far been encountered in nature are 4-methoxy-$\alpha$-pyrones, such as yangonin[11,12,43,44], anibine[65], 4-methoxyparacotoin[65,66] and 5,6-dehydrokavain[66].

## Experimental

**6-Methyl-2,4-pyronone (VII).** — 6-Methyl-2,4-pyronone was prepared from dehydroacetic acid[67].

**Methylation of 6-Methyl-2,4-pyronone.** — About 100 ml. of a dilute ethereal solution of diazomethane prepared[49] from 10 g. of nitrosomethylurea was added, with vigorous stirring, to a suspension of 1 g. of 6-methyl-2,4-pyronone (VII) in dry ether over various periods. All traces of atmospheric moisture were excluded and the temperature of the reaction mixture was maintained at 10~15°C during the addition of the diazomethane solution. After all the diazomethane had been added, stirring was continued for about one hour. All solids gradually dissolved, and finally a light yellow solution was obtained. The resulting mixture was evaporated to dryness in vacuo. The solid was then extracted with seven 50 ml. portions of petroleum ether (b. p. 30~60°C). A small amount of a dark sticky solid remained. The combined extracts were filtered to remove any insoluble impurities and were again evaporated to dryness in vacuo. The crystals thus obtained were dried in a vacuum desiccator over calcium chloride. The procedure for the separation of the two isomeric methyl ethers was the same as that described by Chmielewska et al.[9,50]. The above crystals were dissolved in 50 ml. of anhydrous ether and the solution was cooled below 0°C and was treated with dry hydrogen chloride. The insoluble hydrochloride of VIII$\gamma$ separated immediately and was filtered and dried. The isomeric VIII$\alpha$ remained in solution and was obtained after evaporation of the solvent. The crude 6-methyl-4-methoxy-$\alpha$-pyrone (VIII$\alpha$) exhibited m. p. 84~88°C. Recrystallization from petroleum ether gave pure material, m. p. 87~88°C. The hydrochloride of VIII$\gamma$ was suspended in anhydrous ether, and about 0.5 ml. of diethylamine was added and the mixture was set aside overnight. Insoluble diethylamine hydrochloride was then filtered and the evaporation of the solvent gave free 6-methyl-2-methoxy-$\gamma$-pyrone (VIII$\gamma$), m. p. 88~93°C. After recrystallization from petroleum ether it melted at 94~95°C.

The product proportions shown in Table I are calculated as the percentage of the total weight of the methylated products isolated, data of which are listed in Table II.

TABLE II. PRODUCT YIELDS OF DIAZOMETHANE METHYLATION OF 6-METHYL-2,4-PYRONONE (VII)

| The time required for the addition of the diazomethane solution | Solvent | Product yields mg. | |
|---|---|---|---|
| | | VIII$\gamma$ | VIII$\alpha$ |
| Very rapidly | Ether | 0 | 600 |
| 4 hr. | Ether | 180 | 550 |
| 8 hr. | Ether | 190 | 430 |
| 18 hr. | Ether | 250 | 500 |
| Very rapidly | Acetone | 0 | 400 |
| 4 hr. | Acetone | 120 | 330 |

Table II includes some additional data of the methylation in acetone solvent. The results are essentially the same with those in ether except for the recovery of about 300 mg. of the unchanged starting material (VII).

**Methylation of Desmethylisoaureothin (III).** — To a suspension of 870 mg. of desmethylisoaureothin (III) in 30 ml. of dry ether was added, dropwise, 50 ml. of ethereal diazomethane solution prepared[49] from 1 g. of nitrosomethylurea over a period of 18 hr. with vigorous stirring. During this period, the temperature of the reaction mixture was maintained at 10~15°C and all traces of atmospheric moisture were excluded. After all the diazomethane solution had been added, stirring was continued for 2 hr. The light yellow crystalline solid was then filtered and washed with three 10 ml. portions of ether. The ether washings were combined with the filtrate. The solid separated was recrystallized from ethanol and there was obtained 620 mg. of isoaureothin (II), light yellow needles, m. p. 146~147°C, undepressed upon admixture with an authentic sample.

It is interesting to note that aureothin does not form a hydrochloride, though it has a $\gamma$-pyrone structure. Therefore, two isomeric methyl ethers, I and II, were separated by fractional crystallization from ethanol. Thus, the above ether filtrate and washings were combined and were evaporated to dryness in vacuo. Recrystallization of the resulting solid from ethanol gave a mixture of crystals of yellow prisms and of a small amount of light yellow needles. Two additional recrystallizations from ethanol gave 10 mg. of aureothin (I), yellow prisms, m. p. 152~153°C, undepressed upon admixture with an authentic sample.

The author is indebted to Professor Yoshimasa Hirata of this University for his valuable discussions and encouragement during this investigation. The author wishes to express his gratitude to Mr. Sho Takahashi for technical assistance in some of the experiments reported here. He is also grateful to Mr. Kiyoyuki Yamada for kindly calling the Professor Chmielewska's paper to his attention.

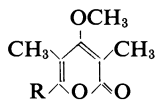
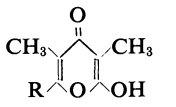
# *Correlation of Reaction Rates and Product Stabilities. II*[1]. *The Methylation of Pyronones with Dimethyl Sulfate*[2,3]

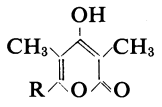


By Hisao NAKATA

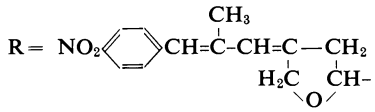
(Received March 22, 1960)



In the previous paper[1] of this series it was reported that the methylation of desmethylisoaureothin (III$\alpha$) with diazomethane under a certain specific experimental condition afforded both aureothin (I) and isoaureothin (II). The product proportion of the two isomeric methyl ethers, viz., I : II, was 1 : 60. A more effective methylation reaction leading to a high yield of aureothin is necessary for preparative purposes since the transformation would be involved in the final stage of the total synthesis of aureothin.



(I) Aureothin



(II) Isoaureothin

(III$\gamma$) Desmethylaureothin

(III$\alpha$) Desmethylisoaureothin

The present investigation is concerned with an experiment on the methylation reaction of enolate anions of 2, 4-pyronone derivatives, the reaction that was chosen for scrutiny for reasons given in the following section. It was shown that the methylation with dimethyl sulfate was successful, and that aureothin was obtained from desmethylisoaureothin in fairly good yield. However, the product proportions of both isomers obtained were incompatible with those predicted by the general rule of this type of reaction. The scope of the reaction and some theoretical implications of the results are briefly discussed.

1) Part I of this series, H. Nakata, This Bulletin, **33**, 1688 (1960).

2) Structure of Aureothin. IX. Part VIII of this series Ref. 1.

3) Presented at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959. A preliminary communication of a part of this work has also appeared. See, H. Nakata, S. Takahashi, K. Yamada and Y. Hirata, *Tetrahedron Letters*, No. 16, 9 (1959).

## Theory of Kinetically Controlled Methylation

The previous investigation[4] on the tautomerism of several 2, 4-pyronones indicates that the $\alpha$-pyrone derivatives are generally more stable than the isomeric $\gamma$-pyrone alternatives. This is well exemplified by the fact[1,5] that isoaureothin (II) and desmethylisoaureothin (III$\alpha$) are, respectively, more stable than aureothin (I) and desmethylaureothin (III$\gamma$.)

Because of this stability sequence of I and II, no equilibrium-controlled[6] methylation reaction of either III$\gamma$ or III$\alpha$ is expected to afford less stable aureothin (I) predominantly, since in the equilibrium-controlled reaction the proportion of the products is a function of only their relative stabilities, and is completely independent of reaction mechanism and rate. On the contrary, in a kinetically controlled reaction relative yields of the products depend only on the relative rates at which they are produced, and are independent of their relative stabilities. Accordingly, an appropriate kinetically controlled reaction must be employed for the purpose of obtaining aureothin (I) in comparatively high yield.

Even in the kinetically controlled reactions, however, there are many instances in which the most stable products are formed at the most rapid rates, and the kinetic control and the equilibrium-control of the reaction frequently give similar product proportions. The reactions of this type are in most cases endothermic processes where the products will provide the best models for the transition

4) For summaries of existing data on the tautomerism of several 2,4-pyronone derivatives, see Ref. 1 and references cited therein.

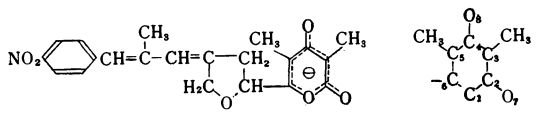
state of the reaction[10,11]. These reactions are usually associated with the production of unstable intermediates from stable starting substances.

On the other hand, if starting substances are of highly reactive unstable species, a different situation occurs. The unstable reactant may probably be destroyed in a very fast, exothermic reaction. The activation energy is correspondingly rather small and the transition state of the reaction may resemble the reactant closely[10,11] in topology and in geometry[12].

When the reactant possesses two different reactive positions, its reaction at one or the other of its reaction centers will give two isomeric products. As is seen in ambident ions[15], such a dual reactivity is best attained when the reactant is an ion, the ionic charge of which spreads over a conjugated system covering these two reaction centers[16,17]. Moreover, the destruction of unstable organic ions, e. g., carbonium ions or carbanions, may be an exothermic process[10]. Thus, of particular importance for the reaction in question will be the fact that the reactant has ionic, conjugatively delocalized electrons distributed between its two reaction centers. Such structural requirements provide the reactant, not only with a dual reactivity, but with an enhanced reactivity as well.

Since the transition states leading to the two products in these reactions have considerable resemblance to the common starting ion, it might be expected that they would resemble each other more than do the two isomeric products[18]. Therefore, the less stable isomer will be obtained in a higher percentage in the kinetically controlled reaction than in the equilibrium-controlled one.

Consequently, the foregoing discussion leads to the conclusion that the following set of conditions is required for a given reaction in which the less stable isomeric product is obtained preferentially.



*1) The reactant must have two different reactive positions mutually conjugated. The reaction upon these affords the two isomeric products.*

*2) The reactant must be a highly reactive unstable species so as to make its reaction exothermic.*

*3) The reaction employed must be kinetically controlled.*

In the present case, methylation of the sodium salt of desmethylisoaureothin seems to be advantageous for the following three reasons.

1) As is the case in other enolate ions of $\beta$-dicarbonyl derivatives, the anion of the salt will probably have the structure IV in which the ionic, conjugatively delocalized electrons are distributed over the pyronone skeleton including the two exocyclic oxygen atoms, $O_7$ and $O_8$. The methylation reaction at one or the other of these oxygens will give either of the two isomeric methyl ethers, viz., I or II.

(IV) Enolate ion of desmethylisoaureothin

2) Although the sodium salt of desmethylisoaureothin is prepared easily and is considerably stable in alkaline solution[5,19], the enolate ion is at any rate a kind of organic ion, and it will have an enhanced reactivity towards any electrophilic reagents[20]. As in ionic inorganic reactions the destruction process of such a reactive ionic species is expected to be a very fast and, presumably, exothermic reaction.

3) Since the methyl ether groupings of aureothin (I) and isoaureothin (II) are relatively stable in neutral or in weakly alkaline mediums[5], no demethylation reaction of either compound will take place under such mild conditions. Therefore, if the methylation reaction is carried out under these conditions, it will be an irreversible, and thus will be a kinetically controlled process.

The next problem was to decide the actual experimental conditions, i. e., the reagent, the

12) The terms *topology* and *geometry* of the transition state[11,13,14] have been defined previously[1], differentiating from the term *structure* of reactants or of products. The *topology* represents the linkage of atoms of the reacting molecules in the transition state, and may correspond to the *constitution* of the molecule in the static state. The *geometry* represents the spacial orientations of atoms of the reacting molecules in the transition state, and may correspond to the *configuration* and the *conformation* of the molecule in the static state. The topology and the geometry reflect the *dynamic* aspect of molecules.

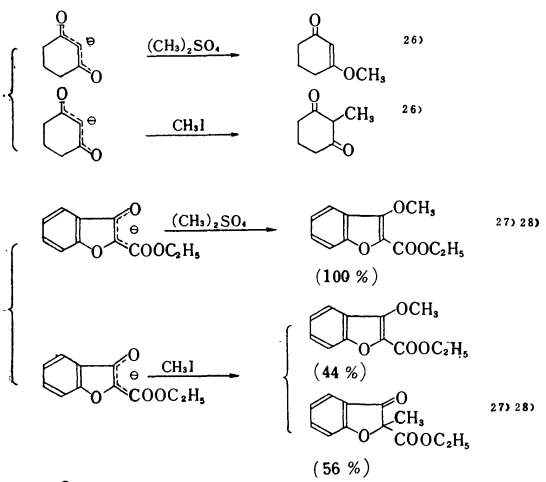
solvent, and the reaction temperature, of the methylation.

In general the alkylation of β-diketones and β-keto-esters is complicated by the possibility that the alkyl group may be introduced either on an oxygen atom (O-alkylation) or on a carbon atom (C-alkylation). As is expected from the structural formula IV, the pyronone enolate ion has at least three reactive positions of $C_3$, $O_7$ and $O_8$. For the present purpose the predominant O-alkylation is desirable and the methylation at the carbon atom $C_3$ must be avoided.

The most important factor affecting the nature of oxygen versus carbon alkylation is the electrophilicity of the alkylating agent. It has been reported[16,17] that when a bond between oxygen and a metal is strongly ionized, e.g., in a typical sodium enolate, a cationic reagent having a strongly electrophilic character will react preferentially at the oxygen atom. This can be generalized[15] in the following way. In the reaction of an ambident ion, the greater is the electrophilicity of the reagent, the greater is the preference for covalency formation with the atom of higher electronegativity[22].



Of available methylating agents, dimethyl sulfate was preferred to methyl iodide on this basis. The fact[25] that dimethyl sulfate usually attacks the more electronegative atom of ambident anions reveals the strongly electrophilic character of the reagent[32].

In the reaction of IV with dimethyl sulfate, the magnitude of the anionic charge will be more or less reduced as the reaction proceeds. Therefore, the less polar solvent, and thus the solvent having a smaller $Y$-value[33,34], may promote the reaction[35,36]. Anhydrous acetone is considered to be a good solvent in this connection[37]. Furthermore, acetone is an aprotic solvent[39] and may prevent solvolytic decomposition of dimethyl sulfate.

The reaction temperature should be low enough to keep the reaction condition mild and less drastic. This is a direct consequence of the requirement that the methylation reaction must be kinetically controlled[40].

## Results

The sodium salt of desmethylisoaureothin was prepared by dissolving the enol III$\alpha$ into 2 N sodium hydroxide solution, and was separated as light yellow needles. The salt had no distinct melting point and decomposed at about 207~210°C without melting. It was insoluble in non-hydroxylic solvents such as benzene. These properties indicated the ionic character of the salt[23,42] as was formulated in IV.

$CN^{\ominus}+(CH_3)_2SO_4 \rightarrow CH_3-CN(75\%)+CH_3-NC(25\%)$[29,30]
$CN^{\ominus}+CH_3I \rightarrow CH_3-CN(100\%)$[29,30]
$NO_2^{\ominus}+(CH_3)_2SO_4 \rightarrow CH_3-NO_2(25\%)+CH_3-ONO(75\%)$[30]
$NO_2^{\ominus}+CH_3I \rightarrow CH_3-NO_2(100\%)$[31]

40) Selectivity of oxygen versus carbon alkylation may probably be affected by temperature. The corresponding rate equation becomes $\ln(k_o/k_c) = -(\Delta\Delta H^{\neq}/RT)+(\Delta\Delta S^{\neq}/R)$. where $\Delta\Delta H^{\neq} = \Delta H_o^{\neq} - \Delta H_c^{\neq}$ and $\Delta\Delta S^{\neq} = \Delta S_o^{\neq} - \Delta S_c^{\neq}$, the subscripts o and c referring to O- and C-alkylation, respectively. In the present case, $k_o/k_c$ will presumably decrease with the increase of the reaction temperature since the choice of the reagent would enable one to assume $\Delta H_o^{\neq} < \Delta H_c^{\neq}$. Accordingly, the low temperature is favored. Dewar[41] has suggested that for very reactive cationic reagents the quantity $\Delta\Delta H^{\neq}$ will be small. If this is actually the case, then the selectivity will have a relatively small temperature dependence. For further detailed discussion and criticism of Dewar's argument, see Ref. 23.

TABLE II. METHYLATION OF 6-METHYL-2,4-PYRONONE (V) AND OF 4-HYDROXYCOUMARIN (VI) WITH DIMETHYL SULFATE

| | Solvent | Time of refluxing hr. | Total yield % | Product proportions % | |
|---|---|---|---|---|---|
| i) 6-Methyl-2,4-pyronone (V): | | | | VII$\gamma$ | VII$\alpha$ |
| V-sodium salt+$K_2CO_3$ | Acetone | 1 | 58 | 0 | 100 |
| V-sodium salt+$K_2CO_3$ | Acetone | 6 | 35 | 0 | 100 |
| V-sodium salt+$K_2CO_3$ | Ether | 6 | >26[a] | 0 | 100 |
| V-triethylammonium salt +$K_2CO_3$ | Acetone | 6 | 34 | 0 | 100 |
| V-silver salt+$K_2CO_3$ | Acetone | 6 | 16 | 0 | 100 |
| V+$K_2CO_3$ | Acetone | 6 | 69 | 0 | 100 |
| V-sodium salt+VII$\gamma$+$K_2CO_3$ | Acetone | 4 | 69 | 0[b] | 100 |
| V-sodium salt+VII$\gamma$+$K_2CO_3$ | Ether | 6 | 36[c] | 0[d] | 100 |
| ii) 4-Hydroxycoumarin (VI): | | | | VIII$\gamma$ | VIII$\alpha$ |
| VI-sodium salt+$K_2CO_3$ | Acetone | 6 | 85 | 0 | 100 |

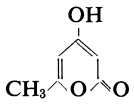
a) A small amount of V was recovered.
b) Recovery of added VII$\gamma$ was 90%.
c) About 40% of V was recovered unchanged.
d) Recovery of added VII$\gamma$ was 71%.

Since the sodium salt was practically insoluble in anhydrous acetone the methylation reaction was first attempted in water-acetone mixture (4 : 1) at 0°C for 1.5 hr. Under these conditions, however, only the starting material III$\alpha$ was recovered unchanged. Consequently, it seemed desirable to employ the more forced condition. Thus, the salt was suspended in anhydrous acetone and the mixture was refluxed with dimethyl sulfate for 6 hr.[44]. Upon employing the fractional crystallization of the resulting mixture, there were actually isolated both aureothin (I) (25% yield) and isoaureothin (II) (37% yield).

This result provided an additional and unambiguous evidence for the reverse isomerization reaction[1] of desmethylisoaureothin derivatives into aureothin, and accordingly, the structural correlation between them was rigorously established.

As might be anticipated from the scrutiny for the reaction conditions discussed in the preceding section, the yield of the less stable isomeric methyl ether I was satisfactory in this methylation reaction. However, attention was called to the relative product proportions of both methyl ethers.

The separation of two isomeric methyl ether derivatives of 2,4-pyrononeses is usually accomplished by taking advantage of the fact that $\gamma$-pyrones form ether-insoluble hydrochlorides[47,48]. In the present case, however, the hydrochloride of aureothin (I) could not be formed, and both isomers were separated by the fractional crystallization from alcohol.



In order to determine more accurately, the relative amounts of isomeric I and II in a

44) Since the reaction was carried out in acetone suspension, the selectivity of oxygen versus carbon alkylation might be affected by the so-called heterogeneity factor[45,46].

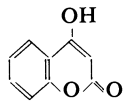
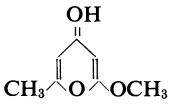
reaction mixture, it seems desirable to use an analytical technique by infrared spectra rather than the troublesome fractional crystallization. Essentially the same method as that described by Zimmerman and his co-workers[49-51] was employed here. The method proved to be accurate to ±2% of aureothin (note Table III in the Experimental Section for analysis of known mixtures of I and II).



Repetition of the methylation experiments showed that the relative amounts of aureothin (I) were always less than those of isoaureothin (II) (Table I). This is incompatible with the general rule of the kinetically controlled reaction[7,8]. The rule states that the less stable isomeric product is formed more rapidly from a given ambident ion, i. e., the less stable isomer should be obtained in a higher percentage over-all product.

Since it appeared of interest to investigate further the general feature of this reaction, the methylations of 6-methyl-2, 4-pyronone (triacetic lactone, V)[4] and of 4-hydroxycoumarin (VI)[52] with dimethyl sulfate were examined. These compounds may probably serve as good models of desmethylisoaureothin (III$\alpha$). 6-Methyl-2, 4-pyrone (V) is expected to afford two possible isomeric methyl ethers, VII$\gamma$ and VII$\alpha$, of which the latter is more stable[4]. Similarly, 4-hydroxycoumarin (VI) will give both VIII$\gamma$ and VIII$\alpha$. The method for quantitative separation of each isomeric methyl ether has been established[47,48], utilizing the hydrochloride formation of VII$\gamma$ and of VIII$\gamma$. The results are shown in Table II.



(V)

(VIII$\alpha$)

4-Methoxy-$\alpha$-chromone

The most striking aspect of the results of the methylation experiments summarized in Table II is the exclusive formation of the more stable methyl ethers under all conditions. This is again quite contrary to the general rule of Ingold[7,8].

Prior to discussion of these contrasted results of methylation reactions, an important point must be established. It is to demonstrate that the methylation reaction is undoubtedly a kinetically controlled process. If the reaction are, not kinetically, but equilibrium-controlled, the preferential formation of the more stable product is understandable, and the results are, of course, far from our problem.

In order to test this possibility, the methylation reaction of the sodium salt of V in acetone and in ether solvent was repeated in the presence of 6-methyl-2-methoxy-$\gamma$-pyrone (VII$\gamma$). From each run there was obtained nearly the same amount of VII$\alpha$ as in the previous experiments and the added VII$\gamma$ was almost quantitatively recovered unchanged (Table II, footnotes b and d). If the methylation reaction had been reversible, the less stable, added VII$\gamma$ would be converted into the more stable VII$\alpha$ by demethylation, isomerization, followed by re-methylation. However, the recovery of VII$\gamma$ and the material balance indicated that this was not the case. Therefore, the two possible products are not interconvertible under the reaction condition, and the possibility that the reaction might be an equilibrium-controlled process is rigorously excluded. Furthermore, it was also shown by these experiments that the absence of VII$\gamma$ in a reaction mixture was not due to any decomposition of it during working-up processes.

Some additional data on the exclusive formation of the more stable methyl ether in 2, 4-pyronone derivatives are available from the literature, though each reaction was not specified as a kinetically controlled process[55-57].

## Discussion

Ingold's rule[7,8] of the kinetically controlled reaction is acceptable for a wide variety of reactions including the recombination of allylic

carbonium ions with anions, the protonation of anions of aliphatic nitro compounds, and those of β-dicarbonyl compounds. From the present results, however, one might conclude that the rule has not entirely general applicability. It will be of interest to re-examine the scope and limitations of the rule in connection with the correlation between reaction rates and product stabilities. This point will be discussed in detail in a subsequent publication of this series, but a brief discussion is given here.

Ingold's rule is based on the consideration[8] that the least stable starting ambident ion is converted into the energetically less different unstable isomeric product with a less drastic electronic reorganization involving less activation energy, than into the electronically and energetically very different stable isomeric product. This seems to be in accordance with Hammond's postulate[10], which states that an interconversion of two states will involve only a small reorganization of the molecular structures if these two states occur consecutively during a reaction process and have nearly the same energy content.

In fact, in most reactions which have so far been associated with the rule, the structure of a given ambident ion has close resemblance to the less stable product. For example, the enolate ion of ethyl acetoacetate has a structure similar to that of the enol[58-60], and thus, treatment of it with dry hydrogen chloride actually gives almost exclusively the less stable enol[61].

If, however, the least stable ambident ion structurally resembles more the stable product than the unstable one, the reverse situation can occur; the most stable isomer will be formed more rapidly than the less stable isomer. The present results of the preferential formation of the more stable methyl ethers in all reactions may be explicable if one considers that the structure of the pyronone enolate ion resembles more the structure of the more stable α-pyrone isomer than that of γ-pyrone isomer. The simple molecular orbital calculation of the charge distributions in the pyronone enolate ion supported this consideration. The details will be reported in a forthcoming paper.

Although the above formulation is in agreement with the orignial idea of Ingold and of Hammond, i. e., the less drastic the structural change the less will be the activation energy of the reaction, it is worthy to note that the structure of the least stable ambident ion does not always resemble the structure of the less stable isomer.

Finally, it may require comment as to why the structure of the ambident ion has resemblance to the more stable isomer in the present special type of compound. Generally, the stabilities of two tautomeric substances depend on two competitive factors[62-65], i. e., *prototropic expenditure of work* and *electronic delocalization*[66], the former being a dominant factor in most keto-enol systems[67]. On the contrary, in the α-pyrone-γ-pyrone system, it seems reasonable to assume that this factor will be more or less of minor importance, since both isomers of a given 2, 4-pyronone have similar O-H functions. Therefore, the relative stabilities of the two isomers will probably be due to the electronic delocalization. This means that the more stable α-pyrone structure is more favorable for the electronic delocalization than the less stable γ-pyrone structure. On the other hand, the electrons should be most favorably distributed in the pyronone enolate ion. Accordingly, the structural resemblance between the ion and the more stable α-pyrone isomer is expected to exist.

## Experimental

**Sodium Salt of Desmethylisoaureothin (IIIα).**— Desmethylisoaureothin (IIIα,) m. p. 196~198°C[5] (1 g.) was dissolved in 30 ml. of hot 2 N sodium hydroxide solution. A clear brown solution was obtained. The crystals which separate on cooling were collected, washed with a small amount of cold alcohol, and dried. Light yellow needles. Yield 1.1 g. The salt had no distinct melting point and decomposed at about 207~210°C without melting.

**Methylation of Sodium Salt of IIIα.** — The sodium salt (1.1 g.) prepared from 1 g. of desmethylisoaureothin (IIIα) was suspended in 40 ml. of anhydrous acetone. Dimethyl sulfate (0.7 g.) was added to the suspension and the mixture was refluxed for 6 hr., and was then set aside overnight. The mixture was again warmed on water bath for 5 min. and was filtered. By concentration of the filtrate to 5 ml. in vacuo a yellow crystalline solid separated, which was filtered. Twice recrystallizations from alcohol gave yellow needles, m. p. 146°C, undepressed upon admixture with an authentic

67) Ref. 21, p. 613.

sample of isoaureothin II. Yield 200 mg. Spontaneous evaporation of each mother liquor of this recrystallization gave 60 mg. of brownish yellow prisms, m. p. 151~152°C, undepressed on admixture with an authentic sample of aureothin I. The infrared spectrum of this material was identical with that of I. The above acetone filtrate was diluted with 30 ml. of water. The separated brown oil crystallized after 2 days. Recrystallization from alcohol gave additional 180 mg. of isoaureothin (II). The mother liquor was evaporated as above, and 205 mg. of aureothin I, m. p. 150~151°C was obtained as brownish yellow prisms. Total yield 62% (aureothin, 265 mg.; isoaureothin, 380 mg.). When the reaction mixture was refluxed for 5 hr., there was obtained 40 mg. of I and 110 mg. of II from 230 mg. of III$\alpha$ (total yield 63%). In another run, the reaction mixture was refluxed with 2 g. of anhydrous potassium carbonate. From 1 g. of the sodium salt, 150 mg. of I and 250 mg. of II were obtained (total yield 41%). In each case, none of the starting material of III$\alpha$ was recovered.

**Attempt on Methylation of Sodium Salt of III$\alpha$ at Low Temperature.** — The sodium salt of III$\alpha$ (500 mg.) was dissolved in 25 ml. of water-acetone mixture (4 : 1). This yellow solution was cooled below 0°C and 4 drops of dimethyl sulfate was added. The mixture was stirred for 30 min. at 0°C and then for another 1 hr. at room temperature. The solution was concentrated to 10 ml. in vacuo and neutralized with dilute acetic acid. A precipitated yellow solid was collected and washed with cold water. Recrystallization from alcohol gave yellow needles, m. p. 195~198°C, undepressed upon admixture with an authentic desmethylisoaureothin III$\alpha$. Recovery 230 mg.

**Quantitative Infrared Analyses.**—Essentially the same analytical technique as that described by Zimmerman and his co-workers[49-51] was employed. All spectra were measured as potassium bromide pellets. It was found that aureothin I exhibited a sharp maximum at 1260 $cm^{-1}$ (optical density= 0.5528; 1.05 mg.-sample) while isoaureothin II had a minimum at this frequency (optical density= 0.0603; 1.06 mg. -sample). The spectrum of isoaureothin II possessed a sharp maximum at 1230 $cm^{-1}$ (optical density=0.3098; 1.06 mg.-sample) while aureothin I had a minimum at this frequency (optical density=0.0969; 1.05 mg.-sample). These two bands were well separated and were selected as the key bands for analysis. Desmethylisoaureothin III$\alpha$ had no intense band in the range 1300~1220 $cm^{-1}$.

The following equation was used: $R = Q \times F$. Here $R$ is the ratio of aureothin I to isoaureothin II, viz., $R$=I/II.

$$Q = \frac{D_m' D_i'' - D_m'' D_i'}{D_m'' D_a' - D_m' D_a''}$$

The $D_m$'s, $D_a$'s and $D_i$'s are optical densities of a given mixture, pure aureothin, and pure isoaureothin, respectively. The superscripts refer to the analytical frequencies of 1260 (') and 1230 ('') $cm^{-1}$. $F$ was determined empirically from the values of $Q$ and $R$ for known mixtures as shown in Table III. The average value of $F$=0.848 was used in calculating the results in the last two columns of Table III. The optical densities used were calculated from the transmittances directly without any consideration of background absorption.

In each case the unknown was prepared by grinding evenly the isomeric mixture with double portions of potassium bromide. An appreciable amount of this well ground mixture was taken as an analytical sample. The sample was ground evenly with 150 mg. of potassium bromide for 5 min. and the mixture was placed under 8 ton/$cm^2$ in a 1.30 cm. diameter casing. The spectra were recorded on a Koken IR-S double beam instrument equipped with sodium chloride optics. The optical density of all mixtures, known and unknown, was taken as zero at 1850 $cm^{-1}$. The best results were obtained when the percentage transmission of both key bands of mixtures was in the range 25~80%. Analyses were made in duplicate in nearly all experiments.

**Repetition of the Methylation Experiment.** — Desmethylisoaureothin III$\alpha$ was converted into its sodium salt (from 400 mg. of III$\alpha$). The salt was suspended in 25 ml. of dry acetone. Nine drops of dimethyl sulfate and 2 g. of anhydrous potassium carbonate were added and the mixture was refluxed for 6 hr. The reaction mixture was worked up as in the foregoing experiment. There was obtained 280 mg. (total yield 68%) of isomeric mixture, which was used for infrared analysis.

The infrared spectrum of this mixture did not exhibit a band at 1195 $cm^{-1}$, indicating the absence of III$\alpha$.

**Methylation of III$\alpha$ with Dimethyl Sulfate and Potassium Carbonate.** — A solution of desmethylisoaureothin III$\alpha$ in anhydrous acetone (500 mg. in 30 ml.) was refluxed with 20 drops of dimethyl sulfate and 2 g. of potassium carbonate for 6 hr. The resulting yellow solution was evaporated to dryness in vacuo. A yellow crystalline solid was obtained. Three recrystallizations from alcohol gave 150 mg. of pure isoaureothin II. From mother liquors of the recrystallization, there was isolated 90 mg. of isomeric mixture, which was subjected to infrared analysis.

No. 1 $D_m'=0.2923$, $D_m''=0.1937$, $Q=1.071$,
Calcd. $R=0.909$, Calcd. I %=47.7%

No. 2 $D_m'=0.4202$, $D_m''=0.2679$, $Q=1.062$,
Calcd. $R=0.900$, Calcd. I %=47.3%
Average I %=47.5%

The infrared spectrum of this mixture did not exhibit a band at 1195 $cm^{-1}$, indicating the absence of III$\alpha$. Therefore, the total yield was 46%, 43 mg. of I and 197 mg. of II.

**Methylation of III$\alpha$ in the Presence of I.** — Desmethylisoaureothin (III$\alpha$) (300 mg.) was methylated as above in the presence of 200 mg. of aureothin (I). There was isolated 390 mg. of isomeric mixture, which was subjected to infrared analysis.

No. 1 $D_m'=0.4953$, $D_m''=0.2840$, $Q=1.252$,
Calcd. $R=1.062$, Calcd. I %=51.4%

No. 2 $D_m'=0.2365$, $D_m''=0.1367$, $Q=1.236$,
Calcd. $R=1.049$, Calcd. I %=51.2%
Average I %=51.3%

The infrared spectrum of the mixture did not exhibit a band at 1195 $cm^{-1}$, indicating the absence of III$\alpha$. The analysis showed that the mixture contained 202 mg. of I and 188 mg. of II. In a separate experiment, 200 mg. of I alone was treated under the same reaction condition as above. It resulted in 83% recovery (165 mg.) of I. Thus, the actual methylation products were 37 mg. of I and 188 mg. of II. Total Yield 72%.

**6-Methyl-2,4-pyronone (V).** — 6-Methyl-2,4-pyronone was prepared from dehydroacetic acid[68].

**Sodium Salt of 6-Methyl-2, 4-pyronone.** — The general procedure for preparation of sodium salts of $\beta$-dicarbonyl compounds was used[69]. Alcoholic sodium ethoxide solution prepared from 0.5 g. of metallic sodium and 15 ml. of ethanol was added to a solution of 3 g. of V in 30 ml. of ethanol. The mixture was concentrated to 20 ml. in vacuo and then 100 ml. of ether was added. The precipitated white solid was collected, washed with acetone, and dried. Yield 2.5 g.

**Methylation of Sodium Salt of V in Acetone.**— One gram of the sodium salt and 2 g. of anhydrous potassium carbonate was suspended in anhydrous acetone, and 1.8 ml. of dimethyl sulfate was added to the suspension. The mixture was refluxed for 1 hr. with occasional shaking. The reaction mixture was filtered while still hot, and the filtrate was evaporated to dryness in vacuo. The resulting solid was extracted with seven 50 ml. portions of petroleum ether (b. p. 30~60°C). A relatively large amount of dark solid remained. The combined extracts were filtered to remove any insoluble impurities and were evaporated to dryness in vacuo, and finally dried in a vacuum desiccator over calcium chloride. The crystalline solid thus obtained was dissolved in 50 ml. of anhydrous ether. The solution was cooled below 0°C and was treated with dry hydrogen chloride. None of the hydrochloride of 6-methyl-2-methoxy-$\gamma$-pyrone (VII$\gamma$) was precipitated. After evaporation of the solvent crude 6-methyl-4-methoxy-$\alpha$-pyrone (VII$\alpha$) was obtained. Recrystallization from petroleum ether gave pure material, m. p. 87~88°C, undepressed upon admixture with an authentic sample[1]. Yield 550 mg. (58%). The above dark solid, which remained from the petroleum ether extraction, was again extracted with anhydrous ether. Treatment of the extracts with dry hydrogen chloride gave no precipitate.

In another run, after the filtration of the initial reaction mixture, the filtrate was concentrated in vacuo over 1 g. of freshly added anhydrous potassium carbonate to prevent any possible acid-catalyzed decomposition of VII$\gamma$ during the working-up process. The final results were essentially the same as those described above, and no VII$\gamma$ was obtained.

When the reaction mixture was refluxed for 6 hr., only VII$\alpha$ was obtained. Yield 330 mg. (35%).

**Methylation of Sodium Salt of V in Ether.**—In 20 ml. of anhydrous ether 1 g. of the sodium salt and 2 g. of potassium carbonate was suspended, to which 2 g. of dimethyl sulfate was added. The mixture was refluxed for 6 hr. After removing the potassium carbonate, the ether filtrate was treated with dry hydrogen chloride. No precipitate was formed. The solution was then concentrated in vacuo. Recrystallization of the resulting solid from petroleum ether gave 250 mg. of VII$\alpha$. Since V was sparingly soluble in ether, unchanged V remained in potassium carbonate residue. The above filtrated solid was dissolved in water and the solution was acidified with dilute sulfuric acid. A small amount of V separated as fine needles, m. p. 186~188°C.

**Triethylammonium Salt of V.** — About 2 ml. of triethylamine was added to a solution of 1 g. of V in 5 ml. of ethanol. Evaporation of the solvent in vacuo gave a colorless oil. Attempts to crystallize the salt from the oil were unsuccessful, and the oil was used without further purification. When the oil was dissolved in water, the initial V was precipitated as a white crystal.

**Methylation of Triethylammonium Salt of V.**— The above oily material (1 g.) was methylated. The procedures used for separation and purification of products were essentially the same as those described above. Only VII$\alpha$ was obtained. Yield 210 mg. (34%).

**Methylation of Silver Salt of V.**—The silver

68) J. Collie, *J. Chem. Soc.*, 59, 607 (1891).

salt of V was prepared according to the directions of Janiszewska-Drabarek[55]. Methylation was carried out as above. The yield was low, VII$\alpha$ 150 mg. (16%).

**Methylation of V with Dimethyl Sulfate and Potassium Carbonate.** — In 15 ml. of anhydrous acetone 850 mg. of V was dissolved. The solution was refluxed with 5 g. of potassium carbonate and 2 ml. of dimethyl sulfate for 6 hr. Concentration of the filtrate of the reaction mixture gave an oily material containing crystals. The procedures for separation of the isomeric methyl ethers were essentially the same as those described above. Only VII$\alpha$ was obtained. Yield 650 mg. (69%).

**Methylation of Sodium Salt of V in the Presence of VII$\gamma$.**—The mixture of 1 g. of the sodium salt, 100 mg. of 6-methyl-2-methoxy-$\gamma$-pyronoe (VII$\gamma$)[1], 2 g. of potassium carbonate, and 2 ml. of dimethyl sulfate was refluxed in anhydrous acetone for 4 hr. The filtrate of the reaction mixture was concentrated in vacuo and the resulting solid was dissolved in 60 ml. of dry ether. A small amount of insoluble material remained and was discarded. The ether solution was cooled and was treated with dry hydrogen chloride. The hydrochloride of VII$\gamma$ was precipitated immediately, and was collected and dried (120 mg.). The isomeric VII$\alpha$ remained in solution and was obtained after evaporation of the solvent. Yield 650 mg. (69%). The free VII$\gamma$ was recovered from the above hydrochloride on treatment with diethylamine[47,48]. Yield 90 mg. (recovery 90%).

In another run, the mixture of 1 g. of the sodium salt, 140 mg. of VII$\gamma$, 2 g. of potassium carbonate, and 2 ml. of dimethyl sulfate was refluxed in anhydrous ether for 6 hr. The ether layer of the reaction mixture was cooled and treated with dry hydrogen chloride. About 130 mg. of hydrochloride of VII$\gamma$ was obtained. This was transformed to free VII$\gamma$ as above. Yield 100 mg. (recovery 71%). The ehter solution was concentrated and the solid thus obtained was recrystallized from petroleum ether. Yield 200 mg. VII$\alpha$ (36%). The filtrated potassium carbonate residue was dissolved in 20 ml. of water. Acidifying with dilute sulfuric acid gave white needles, m. p. 187~189°C, undepressed upon admixture with an authentic sample of V. Recovery 350 mg. (40%).

**4-Hydroxycoumarin (VI).** — Acetylation of 75 g. of methyl salicylate with 75 g. of acetic anhydride in 20 ml. of pyridine gave 80 g. of methyl acetyl salicylate. Treatment of this methyl acetyl salicylate with 9.6 g. of metallic sodium yielded 26 g. of 4-hydroxycoumarin (VI[70].) After recrystallization from water it exhibited m. p. 204~205°C.

**Sodium Salt of 4-Hydroxycoumarin (VI).** — 4-Hydroxycoumarin (VI) (4 g.) was dissolved in 20 ml. of ethanol and alcoholic sodium ethoxide solution prepared from 0.5 g. of metallic sodium and 10 ml. of ethanol was added. The mixture was concentrated in vacuo to 15 ml. and then 100 ml. of ether was added. The precipitated white solid was filtered and dried. Yield 3.4 g.

**Methylation of Sodium Salt of VI.** — One gram of the sodium salt of VI and 2 g. of potassium carbonate were suspended in anhydrous acetone, and the mixture was refluxed with 1.5 ml. of dimethyl sulfate for 6 hr. The acetone layer was treated as described in the literature[55] to separate each isomeric methyl ether. Only 4-methoxy-$\alpha$-chromone (VIII$\alpha$) was obtained. m. p. 125~126°C. Yield 810 mg. (85%).

The author is indebted to Professor Yoshimasa Hirata of this University for his valuable discussions and encouragement during this investigation. The author also wishes to express his gratitude to Mr. Sho Takahashi for technical assistance in some of the experiments reported here.

# *The Transition Phenomenon of Unsaturated Polyester Resin*

By Kōji TANAKA

(Received March 22, 1960)

So far, the author has studied the relationship between the structure and the transition phenomenon of high polymers such as polyethylene and polyvinylalcohol by volume dilatometry and the nuclear magnetic resonance absorption method. As to polyethylene[1], a crystalline polymer, investigation was made of the effect of the degree of crystallinity and of the degree of chain branching on its transition temperature, and on polyvinylalcohol[2] a study was made of the relationship between the hydroxyl group and the transition phenomenon. There is a report[3] that the glass transition temperature of non-crystalline polymer such as atactic polystyrene largely depends upon the degree of polymerization and that the mechanism of the transition phenomenon can be made clear from the standpoint of rate process. Unsaturated polyester resin (unsaturated alkyd resin) crosslinked by a vinyl compound is a non-crystalline polymer having a three dimensional network. Therefore it is expected that the mechanism of the transition phenomenon of the resin differs from that of non-crystalline polymer such as atactic polystyrene, even if the polyester resin itself shows some transition phenomenon.

Polyester resin in a broad sense includes all the high molecular compounds in which the ester linkage between the carboxyl group and the hydroxyl group is the principal element for the formation of high polymer. In the present paper, however, it stands for the polyester resin in a narrow sense; that is, the unsaturated polyester resin crosslinked by a vinyl compound such as styrene and vinylacetate. As is well known, the polyester resin has many good points in comparison with other synthetic resins. For example it excels in such chemical properties as resistance against acid, alkali, water, oil and organic solvent, as well as in electrical property. Above all arc resistance is its distinguishing character. The completely crosslinked polyester resin is hard and brittle at room temperature and below at about $-5°C$ it becomes more brittle, but above 60°C it becomes abruptly flexible. It seems that there is scarcely found any paper describing at what temperature and by what transition mechanism such a change of property occurs. The dilatometric study by the authors showed that this resin had two transition points of second order and the upper transition temperature was charged by the amount of vinyl compound, and in addition it was investigated by nuclear magnetic resonance absorption method from what struct ture and molecular motion these transition phenomena arose.

## Experimental

**Samples.**—MD-S-O: This sample was prepared by mixing maleic anhydride and diethyleneglycol in the mole ratio of 1 to 1 and by heating the mixture at 180°C for six hours with stirring under nitrogen atmosphere.

MAD-S-O: This sample was prepared by mixing maleic anhydride, adipic acid, and diethyleneglycol in the mole ratio of 9 to 1 to 10 and by heating the mixture at 180°C for four hours with stirring under nitrogen gas atmosphere.

These two samples were viscous liquids having no crosslinking structure and were used as starting substances for the preparation of other samples, that is, all other samples were prepared by adding styrene to MD-S-O or MAD-S-O in the ratio shown in Table I and by heating at 80°C for three hours between glass plates, and in addition after-cure treatment was performed at about 100°C for three hours.

TABLE I. THE AMOUNT OF STYRENE IN THE SAMPLES OF POLYESTER RESIN

| Sample | Styrene monomer wt. % | The ratio of C=C group to styrene monomer |
|---|---|---|
| MD-S-0 | 0.0 | 1 : 0 |
| MD-S-1 | 10.0 | 1 : 0.20 |
| MD-S-2 | 20.0 | 1 : 0.45 |
| MD-S-3 | 30.0 | 1 : 0.77 |
| MD-S-4 | 35.9 | 1 : 1 |
| MAD-S-0 | 0.0 | 1 : 0 |
| MAD-S-1 | 10.0 | 1 : 0.22 |
| MAD-S-2 | 20.0 | 1 : 0.50 |
| MAD-S-3 | 30.2 | 1 : 1 |
| MAD-S-4 | 40.0 | 1 : 1.35 |

**Volume Dilatometry.**—The details about this procedure were omitted as they had been described already[1]. Mercury was used as a confining liquid and the temperature range covered was from the

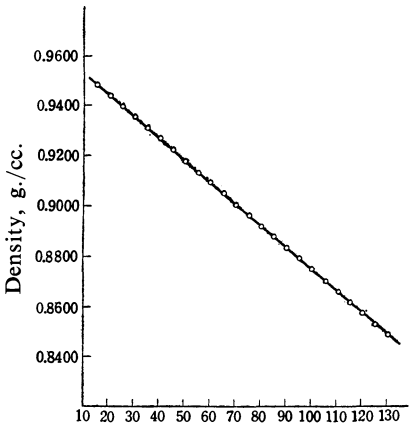

Fig. 1. The density-temperature relationship of silicone oil.

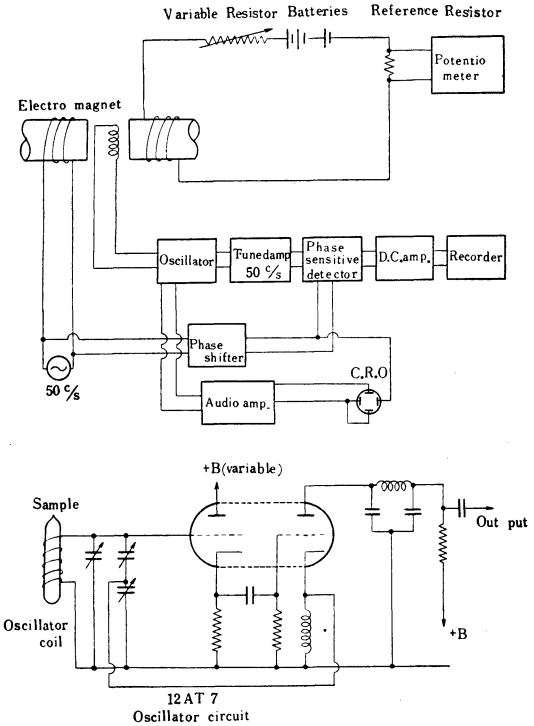

Fig. 2. The constitution of the apparatus for nuclear magnetic resonance absorption.

freezing point of mercury to about 120°C. The bath temperature was varied about five degrees at a time and 20 min. were taken before every measurement in order to let the sample attain equilibrium temperature.

**Hydrostatic Method of Measuring Density.— Apparatus.** — *Balance.* — An ordinary chemical-balance remodeled a little was used. (sensitivity 1/5 mg.)

*Thermostat.*—The chrome-plated vessel with stirrer and two heaters of 500 W. was used. It could accomodate two litters of liquid. Temperature control was performed by connecting the Ostwald-type mercury regulator to micro relay in the range of ±0.05 degree.

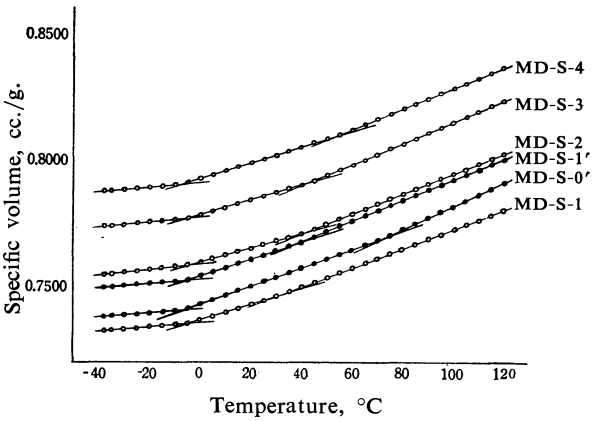

Fig. 3. The volume-temperature curves for the samples of MD series.

*Dipping Liquid.*—As a dipping liquid silicone oil was used. Its qualities were as follows; viscosity 10 c. s. at 25°C, freezing point −65°C, boiling point 200°C, flash point 163°C, and thermal conductivity 0.00032.

*Procedure.*—The sample was connected to the balance with terylene fiber and dipped into silicone oil, and the density was measured in the temperature range from room temperature to 120°C. The temperature was raised five degrees at a time and 15 min. were taken before every measurement.

*Calculation.*—The calculation of density at every temperature, $d_t$ was performed according to the following expression,

$$d_t = \frac{W}{W - W_t} \times \rho_t$$

where $W$ was the weight of the sample in air, $W_t$ that in silicone oil and $\rho_t$ the density of silicone oil at the measured temperature. The density-temperature relationship of silicone oil was determined by volume dilatometry in the temperature range from room temperature to 130°C and shown in Fig. 2.

**Nuclear Magnetic Resonance Absorption Method.** — The usual apparatus consisting of an autodyne oscillator, a lock-in-amplifier, and a recorder was used (Fig. 3). The field intensity was about 3000 gauss. The sample was sealed in the evacuated glass tube.

## Results

Dilatometric study was perfomed for the samples of MD series. Specific volume-temperature curves obtained are shown in Fig. 4. In the figure MD-S-O′ is the sample MD-S-O gelatinized by heating at 110°C for three days and MD-S-1′ the sample MD-S-1 after-cured at 100°C for a day.

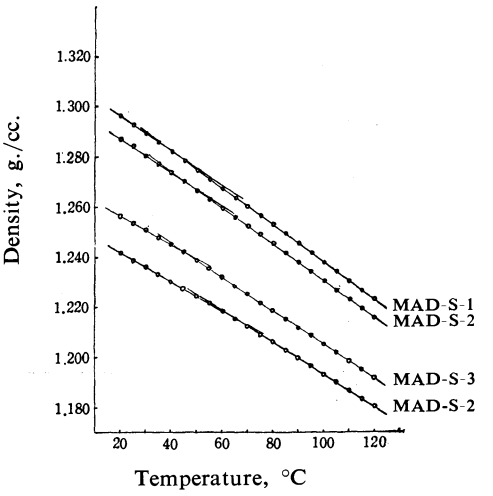

Fig. 5. The density-temperature curves for the samples of MAD series.

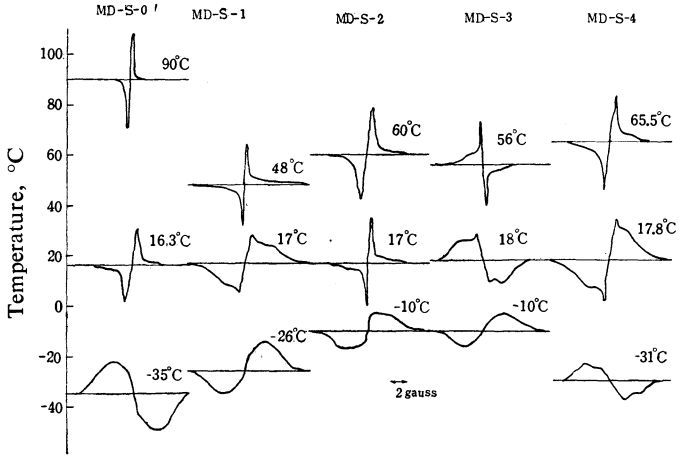

Fig. 6. The derivative absorption curves for the samples of polyester resin.

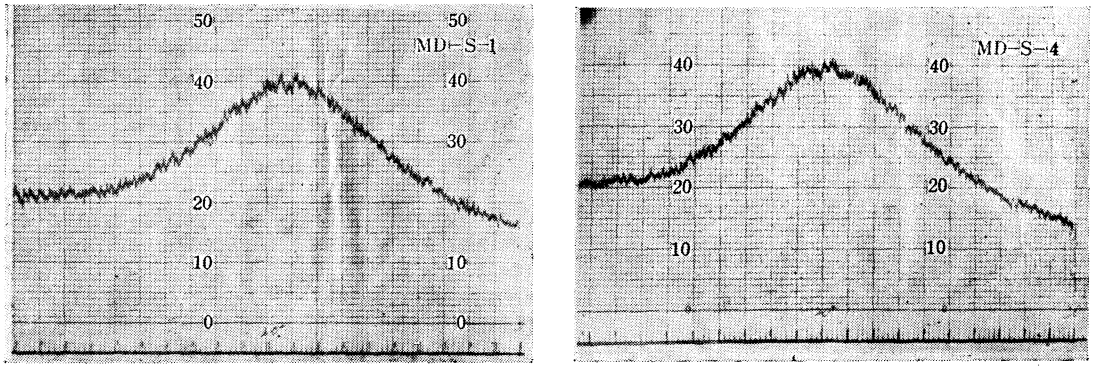

Fig. 7. The X-ray diffraction diagrams for MD-S-1 and MD-S-4.

Hydrostatic study was carried out for all the samples except MD-S-0 and MAD-S-0. Density-temperature curves obtained are illustrated in Figs. 5 and 6.

As is shown in Fig. 2, two second order transition points were observed for each sample of MD series. These temperatures are listed in Table II with the results for MD and MAD series by hydrostatic method.

In Fig. 7 are shown derivative line shapes by nuclear magnetic resonance absorption method for the samples of MD series and the values of second moment, $<\Delta H^2>$, obtained from the derivative curves above and below two second-order transition temperatures for each sample of MD series are listed in Table III.

## Discussion

As was mentioned already, the dilatometric study on the samples of MD series showed that they have two transition points of second-order, and the one was observed below 0°C and the other above room temperature. The transitions below 0°C were observed at nearly equal temperatures for all the samples, while apart from MD-S-0′ and MD-S-1′, those above room temperature were observed at the higher temperature for the sample crosslinked by the larger amount of styrene. Hydrostatic study above room temperature also showed a similar tendency for the samples of MD series and MAD series. Therefore the transition above room temperature is considered to be associated with the crosslinkng structure of the sample. The three dimensional net structure of polyester resin caused by the crosslinking with styrene will become more compact with the increasing amount of styrene until the sample is completely crosslinked. Hence, it is considered that the segmental motion of the polymer is restricted more severely and that the transiton occurs at a higher temperature with the increase of the amount of styrene. This result is well consistent with the result obtained from dielectric measurement by Nakajima and Ishikawa[4] who found two dielectric absorptions at the temperatures above room temperature and below 0°C for the samples of polyester resin. The specific volume of the samples of MD series increases with the increasing amount of styrene. Probably the reason is that the molecular interval is extended by the crosslinking by styrene. Fig. 5 also shows a similar result and the values of density are well consistent with those obtained from Fig. 4.

For MD-S-0′, the lower transition occurs at a temperature almost equal to that of other samples, but the upper transition occurs at 77.9°C, which is higher than that of any other samples. Probably the sample was crosslinked without styrene by the long-time heating and in the sample of this sort the segmental motion was restricted more severely than in the sample completely crosslinked by styrene.

For MD-S-1′, in which the crosslinkings without styrene are considered to exist in addition to those with styrene, only a slight rise of the upper transition temperature was observed. It is likely that the crosslinking without styrene was limited by the styrene contained already in the polymer.

For the samples of MAD series, it was also found that the density decreasing with the increase of the amount of styrene, though it was less affected by the amount of styrene than those of the MD series. In comparing Fig. 6 with Fig. 5, densities and the transition temperature of the sample of MAD series are always lower than those of the sample of MD series containing an equal amount of styrene. Adipic acid does not have C=C bond and is not

4) T. Nakajima and E. Ishikawa, *Bull. Electrotech. Lab. (Japan)*, **20**, 20 (1956).

crosslinked by styrene, so it is considered that an almost constant spaces are always kept at the vicinity of this atomic group and the segmental motion is not so restricted there. For MAD-S-4, the densities are always smaller than those of others of MAD series and the transition temperature is higher. This sample contains an excess amount of styrene and it is considered that it consists of the mixture of MAD-S-3 and styrene polymer or that it is crosslinked by a dimer or trimer of styrene in addition to the crosslinking by the monomer. If the structure of this sample is of the latter type, the molecular interval will be partly wider than that of MAD-S-3, so the decrease of density is reasonable. However, if so, the lowering of the transition point must be observed because the restriction of mobility became smaller than MAD-S-3. The density of polystyrene is about 1.05 at room temperature and the second order transition temperature is around 80°C. Therefore it is considered that the decrease of density and the rise of transition temperature is due to the existence of styrene polymer.

It is considered generally that the second order transition temperature of the crystalline polymer and the non-crystalline one is the point at which the amorphous region of the polymer starts the large-scale segmental motion or at which side chains and molecular terminal groups start the motion. What is, then, the origin of these two second-order transition points of the crosslinked polymer observed? The X-ray diffraction diagrams for the two samples of MD series are shown in Fig. 8. These diagrams did not give any peaks showing the existence of the crystalline part. Therefore the samples investigated are considered to have random network of three-dimensions.

According to Nakajima and Ishikawa[4], polar groups attributed to dielectric absorption at a lower temperature are hydroxyl groups at the molecular terminal and free water contained in the polymer, and those at a higher temperature are ester and ether groups whose mobility is affected by crosslinking by styrene. However, it is not considered that the transition at a lower temperature is attributable only to the molecular-end groups and free water, since, as is shown in Table III, the second moment obtained from the derivative curve in Fig. 7 shows the remarkable change at the vicinity of the lower second-order transition point of each sample. In addition, the amount of protons in the motional state estimated from the derivative curves at the vicinity of room temperature, each of which consists of the absorption curve of protons in the rigid state and that of protons in the motional state, is more than 30% in all the samples investigated and the value of 30% is too large to be considered as protons in the molecular terminal groups and in free water. Therefore it is considered that the second-order transition point at a lower temperature range is the one at which protons in diethyleneglycol located at a place distant from the crosslinking point in the sample of polyester resin start the motion. At the temperature above the upper second-order transition point the narrowing of the movement of protons occurs and a sharp derivative curve was obtained. Therefore the transition point is the temperature at which the Brownian motion of the whole molecule becomes violent. But unlike an amorphous polymer such as atactic polystyrene, it is interesting that the shoulders of the derivative curve are observed at the temperature range above the transition temperature till near the temperature at which thermal degradation of the sample takes place and also that the existence of protons in rigid state (which are considered to be protons at the vicinity of crosslinking points) is recognized.

The author wishes to express his thanks to Professor Masatami Takeda for his able leadership. He is also indebted to Mr. Hiromi Tanno and Miss Masako Yoshida for their assistance in experimental work.

# *On the Thermal Dissociation of Organic Compounds*[1]. *XV. Thermal Dissociation of Urethans in the Presence of Aromatic Amines*

By Teruaki MUKAIYAMA and Toyohiko AKIBA

(Received March 15, 1960)

In the previous papers of this series[2,3] it was shown that, in the presence of amines, urethans dissociate into their component compounds via Eqs. 1 and 2.

$$R\text{-}NHCOOR' \rightleftharpoons R\text{-}N{=}C{=}O + HO\text{-}R' \quad (1)$$

$$R\text{-}N{=}C{=}O + H_2N\text{-}R'' \rightleftharpoons R\text{-}NHCONH\text{-}R'' \quad (2)$$

During the process of dissociation, the nitrogen atom of urethan donates a proton to form an isocyanate, and the oxygen atom accepts a proton to form an alcohol. Therefore, the dissociation reaction involves a double transfer of its protons, namely protonation and deprotonation of urethans by the action of a basic medium.

If Eq. 1 is the rate-determining step of the reactions, the dissociation rate can be followed by measuring the amount of amine remaining at various time intervals. In the case of the dissociation of *N*-phenyl-phenylurethan in the presence of aliphatic amines, such as di-*n*-butyl amine and benzyl amine, the plot for the second order reaction shows a straight line throughout a large portion of the reaction. However, the rate of the dissociation of urethan in weak basic medium, such as anilines, is much slower than in aliphatic amines and shows a tendency of increasing rate as the dissociation proceeds. In this case the rate deviates considerably from the true second-order kinetics.

It seems that the anomalous acceleration of the dissociation is due to the reaction products, urea and phenol. The acceleration of dissociation was therefore examined on the basis of the results obtained from experiments repeated with adding various amounts of urea and phenol in the initial process.

The acceleration of a reaction brought about by the products formed is called "products catalyzed reaction" and in the case of this dissociation, it was found that urea accelerates the dissociation much more than phenol. The products catalyzed reaction found in the thermal dissociation of urethan in aromatic amines makes the mechanism of dissociation of urethan in a weak base more complicated than that in a strong base, such as aliphatic amines.

On the other hand, under the present experimental condition, the dissociation of urethan could not be observed in the absence of anilines, even when urea or phenol is present. And it can be concluded that the coexistence of anilines is a necessary condition for urea or phenol to accelerate the dissociation.

In order to clarify the behavior of urea which accelerate the dissociation, the rates of dissociation of urethans in amine solution in the presence of ureas and analogous compounds, such as amide, were determined. The results can thus be explained by considering the acceptance of a proton by the accelerators from the urethan-amine complex in the transition state and to promote it to dissociate.

## Experimental

**Procedure.** — The experimental procedure was essentially that used in the earlier investigation[2,3]. The amount of amine remaining was determined by titrating with 0.05 N perchloric acid in glacial acetic acid, using Crystal Violet as indicator. The perchloric acid glacial acetic acid solution was prepared according to the method of Markunas[4].

**Materials.**—*N*-Phenyl-phenylurethan, m. p. 122~123°C, and *N*-phenyl-*p*-chlorophenyl urethan, m. p. 120~121°C, were prepared from phenyl isocyanate and the corresponding phenols, and recrystallized from aqueous ethanol.

The physical properties for amines and accelerators are listed in Table I.

Determination of dissociation rate: As described in the introduction, the rates of the dissociation of urethan in the presence of aliphatic amines followed true second-order kinetics. However, the rates of the dissociation in aromatic amines showed anomalous acceleration of the dissociation, as shown in Fig. 1, which might have been caused by the reaction products, urea and phenol. Therfore, the rates of the dissociation, which are the initial

gradiencies, obtained from the titration curve of the residual amine, were measured before appreciable quantities of products, urea and phenol, are formed. The initial rates show substantial variations in their dependence upon the concentration of the amines, or the accelerators, as shown in Tables IV—VI.

## Results and Discussion

As reported in earlier papers[5], the rates of the dissociation of urethan in the presence of amines increased with the basicity of the medium. As shown in Table II, the rates of

the dissociation using aliphatic amines are much faster than those with aromatic ones.

The dissociation rates of urethan in the presence of aromatic amines with electron-donating substituents, such as anisidine and *N*-alkyl aniline, are much greater than those

5) T. Mukaiyama and Y. Hoshino, *J. Am. Chem. Soc.*, **78**, 1756 (1956).

in aromatic amines with electron-withdrawing substituents, such as *m*- and *p*-chloroanilines, as tabulated in Table III.

As shown in Fig. 1, an anomalous acceleration of dissociation occurs after about 20% of the urethan dissociated in the presence of aromatic amines. This phenomenon was not observed, when urethan is dissociated in the presence of aliphatic amines, which are stronger bases than aromatic ones. Assuming that the acceleration might be caused by urea and phenol, which are produced during the dissociation, 2.5 equimolecular proportions of *sym*-diphenylurea and phenol were added to the reaction system in advance. Consequently the amount of amines remaining decreased remarkably by the addition of both urea and phenol, as shown in Fig. 2. The acceleration of the reaction aided by the products is generally called " products catalyzed reaction ".

Similar results are shown by Baker[6] in the addition reaction of isocyanate with alcohol, a reversal of the present type of dissociation.

On the other hand, under the present experimental conditions, the dissociation of urethan could not be observed in the absence of anilines even when urea or phenol is present. It can be concluded that the coexistence of anilines is a necessary condition for urea or phenol to accelerate the dissociation.

In the present experiment, the catalytic activities of products or urea and phenol, adding them individually, were demonstrated by varying molar ratios of urethan, 0.5 to 2.5, as shown in Fig. 3 and Table IV.

$V_0 \times 10^6$ mol./min.

| Added accelerators | Mol. | Aniline 165°C | *p*-Chloro aniline 165°C | *p*-Toluidine 145°C |
|---|---|---|---|---|
| None | | 0.902 | 0.24 | 0.66 |
| *m*-Chlorophenol | 0.5 | 2.61 | 1.5 | 6.3 |
| | 1.0 | 5.42 | 1.25 | 3.13 |
| | 1.5 | 1.63 | 1.5 | 4.10 |
| | 2.0 | 2.19 | 1.67 | 3.58 |
| | 2.5 | | 2.40 | 13.0 |
| *sym*-diphenylurea | 0.5 | 1.97 | 0.28 | 3.57 |
| | 1.0 | 10.38 | 5.06 | 4.60 |
| | 1.5 | 14.5 | 3.16 | 7.92 |
| | 2.0 | 13.32 | 13.7 | 21.4 |
| | 2.5 | 17.65 | 21.5 | 22.4 |
| *sym*-Diphenylurea and *m*-chlorophenol | 0.5 | 6.88 | 3.2 | 11.7 |
| | 1.0 | 12.5 | 3.7 | 4.73 |
| | 1.5 | 9.07 | 9.9 | 24.17 |
| | 2.0 | 9.38 | 21.0 | 14.5 |
| | 2.5 | | 33.3 | 35.0 |

As shown in Table IV, the rate of the catalyzed dissociation is much greater in the presence of urea than of phenol, and it increases concomitantly with increasing concentrations of urea. However, the increase of rate by varying the initial concentration of phenol could be scarcely observed. Therefore, the acceleration of reaction due to the products is caused chiefly by urea. In aromatic amine series, the accelerating action of urea becomes more effective, when a weak base is used. For example, the ratio of the rates in the presence and in the absence of urea in *p*-chloroaniline is 110 : 1, while that in *p*-toluidine, the stronger base, is 40 : 1.

In order to investigate the catalytic activity of ureas, urethans and acid amides, having both an active hydrogen atom and a basic nitrogen atom and exhibiting the same amphoteric character as urea, were used as accelerators.

TABLE V. THE INITIAL RATES OF THE CATALYZED DISSOCIATION OF *N*-PHENYL PHENYLURETHAN WITH ADDED ACCELERATOR IN A *p*-TOLUIDINE —NITROBENZENE SOLUTION

| | Urethan | *p*-Toluidine | *m*-Chlorophenol | Accelerator |
|---|---|---|---|---|
| mol. | 1 | 1 | 2.5 | 2.5 |

| Accelerator | °C | $V_0 \times 10^6$ mol./min. |
|---|---|---|
| $R\text{-}C_6H_4NHCOOCH_2C_6H_5$ | | |
| R: H | 145 | 1.43 |
| *m*-Nitro | 145 | 0.25 |
| *p*-Nitro | 145 | 1.63 |
| *p*-Methoxy | 145 | 2.12 |
| *p*-Chloro | 145 | 2.08 |
| *p*-Methyl | 145 | 5.16 |
| Acetanilide | 165 | 9.00 |
| Benzenesulfonamide | 165 | 5.9 |
| Benzamide | 115 | 2.72 |
| Phthalimide | 145 | 4.98 |

The initial rates of dissociation in the presence of these accelerators (Tables IV—VI) represent the relative catalytic activities and the order of the acceleration ability is as follows;

benzamide$\gg$ *sym*-diphenylurea$\gg$ phthalimide $>$ *N*-phenyl benzyl urethans$>$ acetanilide $>$ benzenesulfonamide.

From this observation, benzamide and *sym*-diphenylurea appear to have greater activity of acceleration as compared to phthalimide and sulfonamide. It can be shown that sulfonamide and phthalimide, having more acidic hydrogen atoms, are less effective than benzamide and urea.

The thermal dissociation of urethan was carried out in various anilines by adding ureas or benzamides substituted with alkyl or aryl groups for hydrogen atom, in equimolecular proportion, as shown in Table VI. Table VI shows that benzamide and *N*, *N*-diphenyl-*N'*, *N'*-diethylurea possess remarkable catalytic activities, while diphenylbenzamide is hardly effective. Accordingly, the relative order of activity of the accelerators is as follows;

benzamide$\gg$ *N*, *N*-diphenyl-*N'*, *N'*-diethylurea $>$ *sym*-diphenylurea$>$ triphenylurea $\geqq$tetraphenylurea$\geqq$diethylbenzamide $>$ benz-*p*-toluidide$>$ benzanilide $>$ diphenylbenzamide$\geqq$none

As presented in the above order, benzamide accelerates the reaction very remarkably. The

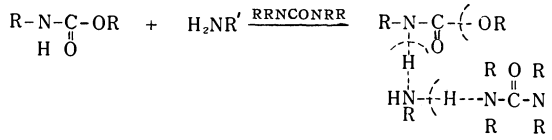
order [*N*, *N*-diphenyl-*N'*-*N'*-diethylurea> tetraphenylurea and diethylbenzamide> diphenylbenzamide] indicates that in similar compounds such as urea and benzamide, diethyl derivatives catalyze more strongly than diphenyl derivatives. Furthermore, the order of urea compounds, *N*, *N*-diphenyl-*N'*-*N'*-diethylurea> *sym*-diphenylurea> tetraphenylurea, indicates that the hydrogen atom attached to the nitrogen atom is not effective in accelerating the dissociation, but the character of the nitrogen atom is the responsible factor. It is considered that the ability of a compound to accelerate the dissociation is attributed to the electrical and structural character of nitrogen atom which is capable of receiving a proton.

In view of the above discussion, it has been observed that the rate of dissociation of urethan, including a double transfer of its proton, in a strong basic or acidic medium is faster than that in a weak basic or acidic medium. This indicates that the rate of dissociation is dependent on the acidic or basic strength of the medium. However, the rate of dissociation is enhanced in a medium containing a mixture of weak base and acid, such as aniline and phenol, rather than in a medium containing the individual compounds.

## Reaction Mechanism



The scheme of the uncatalyzed dissociation of urethan in the presence of an organic base is illustrated as follows;

(I)

In state I, amine behaves as such as to accept a proton which results in the formation of a complex with urethan. State I then dissociates through a shift of a pair of electrons. The catalytic activity of an amine, which assists in the proton transfer of urethan at state I is affected by the basicity of amine as shown in Table II.

The scheme of the dissociation of urethan in an aromatic amine medium in the presence of an accelerator is illustrated as follows;

(II)

In state II, the amine behaves in such a manner as to accept a proton, and the accelerator encourages the deprotonation of the amine to proceed. That is, an accelerator accepts a hydrogen atom from the amine–urethan complex (state II) and induces the amine to take up the hydrogen atom from urethan, hence the dissociation proceeds more readily. Therefore, the accelerator plays an important role in promoting the dissociation of the amine-urethan complex by participating in the proton transfer.

## Summary

*N*-Phenyl phenylurethans dissociate readily into their component compounds in the presence of aliphatic amines and the plot for the second order reaction shows a straight line throughout a large portion of the dissociation. However, the rate of the dissociation of urethans in aromatic amines is much slower than in aliphatic ones and shows a tendency of increasing rate as the dissociation proceeds. The anomalous acceleration of the dissociation is due to the reaction products, urea and phenol.

In order to clarify the behavior of urea which accelerates the dissociation effectively, the rates of the dissociation of urethans in the presence of ureas and analogous compounds, such as urethans and amides, were determined.

The mechanism of the dissociation of urethans in aromatic amines which involve the product catalyzed reaction was discussed.

The authors wish to express their hearty thanks to Professor Toshio Hoshino for his encouragement throughout the course of this experiment and to Mr. Keishi Katsuno and Mr. Yohichi Nakamura for their assistance.

# *The Dehydration Reactions of Aldoximes*

By Teruaki MUKAIYAMA and Tsujiaki HATA

(Received May 4, 1960)

The dehydration reactions of nitroparaffin and aldoxime with isocyanate, carbodiimide, acetylenic ether and ketene acetal have been described in the previous papers[1,2]. In one of the preceding papers, it was proposed that compounds containing a triple bond or a twinned double bond may be used as a useful dehydrating reagent. In addition, the dehydration reaction of aldoxime with ketene acetal containing a double bond and two alkoxyl groups turns out to be also successful. It is also known that iminochloride[3] containing a double bond and a chlorine atom reacts with water much more easily, yielding acid amide rather than nitrile containing a triple bond. These results lead to conclusion that not only the compounds containing a triple bond or a twinned double bond but also the compounds containing a double bond and an atom or atomic group, such as halogen alkoxyl or acyloxyl groups, would become effective dehydrating reagents.

Referring to the above results it appears

1) T. Mukaiyama and T. Hoshino, *J. Am. Chem. Soc.*, **82**, 5339 (1960).

2) T. Mukaiyama and T. Hata, This is now presented to this Bulletin.

3) J. v. Braun, F. Jostes and W. Münch, *Ann.*, **453**, 113 (1927).

feasible to extend the dehydration reactions of nitroparaffin and aldoxime by using vinyl ether or vinyl acetate in place of acetylenic ether described in the preceding paper. Firstly, the reaction of vinyl *n*-butyl ether and aldoxime is tested in the presence of tertiary alkyl amine, but no reaction occurs and the starting materials are recovered quantitatively. The dehydration reaction is also not observed, when vinyl acetate is treated with benzaldoxime under the same condition.

It is known that the addition reaction[4] of vinyl acetate with an alcohol to form an acetal is well conducted in the presence of boron trifluoride and mercuric oxide. Accordingly, vinyl acetate and benzaldoxime are reacted in the presence of a catalytic amount of boron trifluoride and yellow mercuric oxide in place of a basic catalyst. A violent reaction takes place and benzonitrile, acetaldehyde and acetic acid are obtained in good yields.

$$CH_2{=}CH{-}OAc + C_6H_5CH{=}NOH \rightarrow \left[\begin{array}{l} CH_3CH(OAc)(ON{=}CHC_6H_5) \end{array}\right] \rightarrow C_6H_5C{\equiv}N + CH_3CHO + AcOH$$

(I)

Analogous to the explanation used for the dehydration with acetylenic ether, it is reasonable to consider that the reaction proceeds through an intermediate I which gives nitrile and hemiacylal. The latter decomposes to give acetaldehyde and acetic acid.

By the same method, the reaction of vinyl ether and aldoxime gives nitrile in equally good yield along with acetaldehyde and acetal.

$$2CH_2{=}CH{-}OR + R'CH{=}NOH \rightarrow CH_3CH(OR)(ON{=}CHR') \rightarrow R'C{\equiv}N + CH_3CHO + CH_3CH(OR)_2$$

(II)

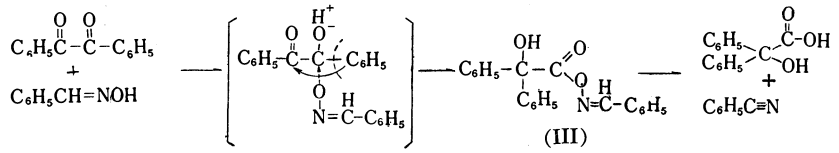
In order to evaluate experimentally the intermediate of the reaction, namely the addition compound of vinyl ether and aldoxime, the isolation of the compound II is tried. Since the catalysts, boron trifluoride and mercuric oxide, may accelerate both the initial addition reaction and the subsequent decomposition reaction, an equimolar amount of triethyl amine to neutralize boron trifluoride is added to the reaction system of vinyl ether and aldoxime immediately after the liberation of heat ceases. By this method the addition compound is isolated in high yield. And the addition compound is observed to decompose on heating in the presence of a catalytic amount of boron trifluonide and mercuric oxide to give 82% yield of nitrile. Consequently, it can be concluded that the coexistence of boron trifluoride and mercuric oxide is effective in accelerating the decomposition of the associated addition compounds with vinylogs, and conducts the dehydration of aldoximes. The decomposition of the adduct II cannot be observed in the absence of the said catalysts and it is recovered quantitatively after refluxing for 7 hr. in benzene.

Further, it is confirmed that benzaldoxime is recovered unchanged, when it is refluxed for 6 hr. in the presence of a catalytic amount of boron trifluoride in benzene. It can be concluded that the dehydration reaction of benzaldoxime is conducted with vinyl ether or vinyl acetate.

In order to examine the possibility of dehydration of aldoximes with vinylogs having an electron-withdrawing substituent which usually show different reactions from vinyl ether or vinyl acetate, acrylonitrile is reacted with benzaldoxime in the presence of a catalytic amount of boron trifluoride and mercuric oxide. No reaction is then observed and the starting materials are recovered. On the other hand, the addition reaction of acrylonitrile with aldoxime is known as an example of cyanoethylation[5] when strong bases are used. The addition compound of acrylonitrile and benzaldoxime is synthesized initially according to the method of Bruson and Riener and it is successfully decomposed to give nitrile and ethylene cyanohydrin on heating in the presence of a catalytic amount of boron trifluoride and mercuric oxide.

$$CH_2{=}CH{-}C{\equiv}N + C_6H_5CH{=}NOH \xrightarrow[\text{or Triton B}]{KOH} C_6H_5CH{=}NOCH_2CH_2C{\equiv}N \xrightarrow{HgO\text{-}BF_3} HOCH_2CH_2C{\equiv}N + C_6H_5C{\equiv}N$$

In the next place, the dehydration reaction of aldoxime with a compound containing carbon-oxygen double bond is studied. It is generally shown that carbonyl compounds react with water to form unstable *gem*-dihydroxy compounds which exist in equilibrium with the starting materials and can scarcely be isolated. On this basis, it is said that these compounds cannot be used as a dehydrating reagent in the present type of reaction. It is, however, known that benzil containing two carbonyl groups reacts with water to form a stable benzilic acid and this is considered to be an example of carbonyl compounds as a dehydrating reagent. The reaction of benzil with aldoxime in the presence of a small



4) W. J. Croxall, F. J. Glavis and H. T. Neher, *J. Am. Chem. Soc.*, **70**, 2805 (1948).

5) H. A. Bruson and T. W. Riener, U. S. Pat., 2352514 *Chem. Abstr.* **38**, 5506 (1944).

amount of potassium hydroxide is tried and nitrile and benzilic acid are obtained as expected.

$$C_6H_5CO—COC_6H_5 + C_6H_5CH=NOH \xrightarrow{KOH} C_6H_5C\equiv N + (C_6H_5)_2(OH)C—COOH$$

The reaction can be shown by the following scheme which involves the initial formation of the addition compound of benzil and aldoxime, and the subsequent rearrangement of the phenyl group to form III. This decomposes to nitrile and benzilic acid by transferring its hydrogen atom.

(III)

Further, in the course of preparing acetylenic ether according to the method of Arens[6], it is found that the intermediate, $\alpha,\beta$-dibromoethyl methyl ether, reacts violently with water to form bromoacetaldehyde and hydrogen bromide. On the consideration that such compounds which readily react with water can be used as a dehydrating reagent of the present type of dehydration, the reaction of $\alpha,\beta$-dibromoethyl methyl ether with aldoxime is tried and nitrile results quantitatively along with hydrogen bromide.

$$CH_2BrCHBr—O—CH_3 + C_6H_5CH=NOH \rightarrow \left[CH_2BrCH(—OCH_3)—ON=CHC_6H_5\right] \rightarrow C_6H_5C\equiv N + (CH_2BrCHO)_3 + HBr$$

(IV)

This reaction can be explained by introducing the intermediate IV which is yielded by the reaction of aldoxime and the ether. The IV, which is similar to the addition compound of vinyl ether and aldoxime, decomposes to give nitrile and hemiacetal. The latter decomposes to aldehyde and alcohol.

Similarly, nitrile is obtained quantitatively when aldoxime is reacted with $\alpha,\beta$-dibromoethyl acetate and $\alpha,\beta$-dibromopropionitrile respectively as shown in the following equations.

$$CH_2BrCHBr—OAc + C_6H_5CH=NOH \rightarrow C_6H_5C\equiv N + AcOH + (CH_2BrCHO)_3 + HBr$$

$$CH_2BrCHBr—C\equiv N + C_6H_5CH=NOH \rightarrow C_6H_5C\equiv N + HBr$$

These reactions are carried out in the absence of a catalyst, and the initially formed hydrogen bromide may be considered to accelerate the reactions.

On the other hand, the treatment of benzaldoxime with $\alpha,\beta$-dibromoethylbenzene yields the dehydrated product of bonzonitril and water in high yields, and the starting material of dibromo compound is unexpectedly recovered. The recovery of the dibromo compound can be satisfactorily explained by considering the replacement reaction of initially formed $\beta$-hydroxy-$\beta$-phenylethylbromide with hydrogen bromide, as shown in the following equations. The unexpected isolation of water is considered to be due to the low reactivity of $\alpha,\beta$-dibromoethylbenzene with water as compared with $\alpha,\beta$-dibromoethylmethyl ether and $\alpha,\beta$-dibromoethyl acetate.

$$CH_2BrCHBr—C_6H_5 + C_6H_5CH=NOH \rightarrow \left[CH_2BrCH(—C_6H_5)—ON=CHC_6H_5\right] + HBr$$

(V)

$$V \rightarrow C_6H_5C\equiv N + CH_2BrCH(—C_6H_5)—OH$$

(VI)

$$VI + HBr \rightarrow CH_2BrCHBr—C_6H_5 + H_2O$$

## Experimental

**Reaction of $\alpha$-Benzaldoxime with Vinyl Acetate.**—A solution of 10 drops of boron trifluoride (40% ether solution) and 0.6 g. of yellow mercuric oxide in 10 ml. dry benzene was added dropwise over a 30-min. period to a solution of vinyl acetate (16 g., 0.186 mol.) and $\alpha$-benzaldoxime (11.3 g., 0.093 mol.) in 20 ml. dry benzene with continuous stirring. Then acetaldehyde and benzene were distilled into a 2, 4-dinitrophenylhydrazine solution. The yield of acetaldehyde 3.6 g., (44% of theoretical) was calculated from the yield of acetaldehyde 2,4-dinitrophenylhydrazone thus obtained. The liquid residue was distilled to give acetic acid 8.1 g., (72% of theoretical), b. p. 55C° (61 mmHg) and benzonitrile 8.7 g., (91% of theoretical), b. p. 85~87°C (23 mmHg) was obtained.

**Reaction of *n*-Heptanaldoxime with Vinyl Methyl Ether.**—To a solution of *n*-heptanaldoxime (5 g., 0.039 mol.) and methyl vinyl ether (5 g., 0.089 mol.) were added 2 drops of boron trifluoride (40% ether solution) and 0.1 g. of yellow mercuric

6) J. F. Arens, *Rec. trav. chim.* Pays-Bas, **74**, 271 (1955).

oxide. After shaking the mixture for 30 min., it became clear, and then it was heated under reflux for 5 hr. After removing acetaldehyde and benzene, acetaldehyde dimethyl acetal 3.5 g., (89% of theoretical), b. p. 64~66C° and heptanitrile 1.7 g., (40% of theoretical), b. p. 54°C (8 mmHg) were obtained.

**Reaction of α-Benzaldoxime with Vinyl Methyl Ether.**—To a solution of α-benzaldoxime (15 g., 0.123 mol.) and methyl vinyl ether (15 g., 0.268 mol.) in 20 ml. dry denzene were added 5 drops of boron trifluoride (40% ether solution) and 0.3 g. of yellow mercuric oxide. After shaking the mixture for 30 min., it was heated under reflux for 6 hr. After removal of acetaldehyde and benzene, acetaldehyde dimethyl acetal 4.0 g., (34% of theoretical), b. p. 62~64°C and benzonitrile 10.2 g., (80% of theoretical), b. p. 48~50°C (3 mmHg) were obtained.

**Addition Compound of α-Benzaldoxime and Ethyl Vinyl Ether.**—To a solution of ethyl vinyl ether (3.6 g., 0.05 mol.) and 0.05 g. of yellow mercuric oxide in 10 ml. dry benzene was added dropwise a solution of α-benzaldoxime (6.1 g., 0.05 mol.) and 2 drops of boron trifluoride (40% ether solution) in 5 ml. dry benzene with continuous stirring over a 10-min. period at room temperature. The reaction mixture became warm and clear soon. After rapid cooling, 4 drops of triethyl amine was added to the solution. After removal of benzene, an attempt was made to distil the liquid residue. Addition compound of benzaldoxime and ethyl vinyl ether 7.8 g., (80% of theoretical), b. p. 92~93°C (4.5 mmHg) was obtained.

Found: C, 68.62; H, 7.86; N, 7.41. Calcd. for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25%.

**Decomposition of the Addition Compound of α-Benzaldoxime and Ethyl Vinyl Ether.**—To a solution of the addition compound of α-benzaldoxime and ethyl vinyl ether (1.9 g., 0.01 mol.) in 10 ml. dry ether were added 5 drops of boron trifluoride (40% ether solution) and yellow mercuric oxide (0.05 g.). Then the mixture was heated under reflux for 7 hr. After removal of acetaldehyde and ether, ethanol 0.4 g., (87% of theoretical), b. p. 77~78°C and benzonitrile 0.85 g., (83% of theoretical), b. p. 69°C (10 mmHg) were obtained.

**Reaction of α-Benzaldoxime with Acrylonitrile.**—To a solution of α-benzaldoxime (8 g., 0.066 mol.) and acrylonitrile (3.5 g., 0.066 mol.) in 15 ml. dry benzene was added 0.2 g. of potassium hydroxide. The mixture was heated under reflux for 5 hr. After removal of benzene, the addition compound of α-benzaldoxime and acrylonitrile 5.2 g., (45% of theoretical), b. p. 150°C (6 mmHg) was obtained.

Found: N, 16.12. Calcd. for $C_{10}H_{10}N_2O$: N, 16.09%.

The same result was obtained when Triton B was used in place of potassium hydroxide.

**Decomposition of the Addition Compound of α-Benzaldoxime and Acrylonitrile.**—To a solution of the above mentioned addition compound (5.2 g., 0.03 mol.) in 10 ml. dry benzene were added 10 drops of boron trifluoride (40% ether solution) and 0.1 g. of yellow mercuric oxide. The mixture was heated under reflux for 12 hr. After removal of benzene, benzonitrile 1.6 g., (44% of theoretical), b. p. 188~189°C and ethylene cyanohydrin 0.7 g., (33% of theoretical), b. p. 221~223°C were obtained.

**Reaction of α-Benzaldoxime with Benzil.**—To a mixture of α-benzaldoxime (1.2 g., 0.01 mol.) and benzil (2.1 g., 0.01 mol.) was added 0.1 g. of well-ground potassium hydroxide. After the mixture was heated on the water-bath for 30 min., it was left on stand for 5 days at room temperature and a large amount of benzilic acid was separated. It was filtered and washed with light petroleum ether and recrystallized from 95% ethanol, 0.5 g., (22% of theroetical), m. p. 150°C. After removal of the low boiling point fractions from the filtrate, benzonitrile 0.2 g., (20% of theoretical), b. p. 78~80°C (18 mmHg) was obtained.

**Reaction of α-Benzaldoxime with α, β-Dibromoethyl Methyl Ether.**—α-Benzaldoxime (6.7 g., 0.055 mol.) was added dropwise to a solution of α, β-dibromoethyl methyl ether in 10 ml. dry benzene with continuous stirring at room temperature. A large amount of white precipitate separated, and then it dissolved with evolving hydrogen bromide, when the mixture was heated under reflux. After heating the mixture for 6 hr., the resulting solution was distilled under reduced pressure and benzonitrile 5.3 g., (93% of theoretical), b. p. 75° (17 mmHg) was obtained. From the residue a small amount of bromoacetaldehyde trimer, m.p. 102~104°C, was obtained.

**Reaction of α-Benzaldoxime with α, β-Dibromoethyl Acetate.**—α-Benzaldoxime (9.9 g., 0.081 mol.) was added dropwise to a solution of α, β-dibromoethyl acetate (20 g., 0.081 mol.) in 20 ml. dry benzene with continuous stirring. After the mixture was heated under reflux for 2 hr., the resulting solution was worked up in the usual manner and acetic acid 2.2 g., (46% of theoretical), b. p. 118°C and benzonitrile 4.8 g., (57% of theoretical), b. p. 61~63°C (7 mmHg) were obtained. From the residue a small amount of bromoacetaldehyde trimer, m. p. 103~104°, was obtained.

**Reaction of α-Benzaldoxime with α, β-Dibromopropionitrile.**—α-Benzaldoxime (11.4 g., 0.094 mol.) was added dropwise to a solution of α, β-dibromopropionitrile (20 g., 0.094 mol.) in 20 ml. dry benzene with continuous stirring. After heating the mixture under reflux for 3 hr., the resulting solution was worked up in the usual manner, benzonitrile 9.7 g., (98% of theoretical), b. p. 77~78°C (15 mmHg) was obtained.

**Reaction of α-Benzaldoxime with α, β-Dibromoethylbenzene.**—α-Benzaldoxime (2.4 g., 0.05 mol.) was added to a solution of α, β-dibromoethylbenzene (5.3 g., 0.05 mol.) in 15 ml. dry benzene. The mixture was heated under reflux for 5 hr. After removal of benzene, water and benzonitrile were distilled and water 2.0 g., (56% of theoretical) and benzonitrile 1.3 g., (65% of theoretical), b. p. 76~78°C (15 mmHg) were obtained. α, β-Dibromoethylbenzene 3.7 g., (70% of theoretical), b. p. 137~139°C (15 mmHg) was recovered.

The authors wish to express their hearty thanks to Professor Toshio Hoshino for his encouragement and to Mr. Senichiro Takeda and Mr. Tomohiko Tsuchiya for their help

throughout the course of this experiment. Thanks are also due to Mr. Asaji Kondo for the microanalyses.

# *A Kinetic Study of Addition Reaction of Vinyl Ether with Carboxylic Acids*

By Teruaki MUKAIYAMA and Hiroyuki NOHIRA

(Received June 1, 1960)

The addition reactions of vinyl ethers with carboxylic acids have been known to give hemiacetal esters (I) in high yields in the presence of a catalytic amount of strong acids, such as hydrochloric acid, sulfuric acid and phosphoric acid.

$$CH_2{=}CH{-}OR + R'COOH \rightarrow CH_3{-}\underset{\displaystyle OCOR'}{\overset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}{-}OR \quad [I] \qquad (1)$$

There are numerous publications in the literature on the addition reactions of vinyl ethers with compounds containing active hydrogen, such as alcohols, phenols and carboxylic acids[1-4]; however, there have been no papers published on the kinetic study of the reactions of vinyl ethers except on their hydrolysis[5,6].

In the present investigation, the rates of the addition reaction of *n*-butyl vinyl ether with carboxylic acids in dioxane and toluene have been measured in order to study the mechanism of the addition reactions.

## Experimental

**Materials.**—*n*-Butyl vinyl ether was obtained from commercial source and purified as follows; the vinyl ether was washed several times with equal volumes of water containing a small amount of sodium carbonate, dried over potassium hydroxide and distilled from metallic sodium through a 30 cm. long column, b. p. 93.0~94.0°C.

Carboxylic acids were also obtained from a commercial source and purified by distillation or recrystallization. Melting points or boiling points and p*K*a of the carboxylic acids used are listed in Table. I.

**Solvent.**—Dioxane (b. p. 101.3°C), toluene (b. p. 111°C) and anisole (b. p. 154°C) were purified by being stored over metallic sodium wire and being distilled from metallic sodium.

**General Kinetic Method.**—In a 50 ml. volumetric flask a solution of *n*-butyl vinyl ether in dioxane was prepared which was exactly 3.00 mol./l. with respect to the vinyl ether. The exact molarity of the solution was determined by iodometry[7]. Similarly, a solution of the corresponding carboxylic acids of appropriate concentration was prepared.

As a typical run, 20 ml. of the carboxylic acid

TABLE I. LIST OF CARBOXYLIC ACIDS USED

| Acid | B. p. | $pK_a^{25°C}$ | Acid | M. p. | $pK_a^{25°C}$ |

solution was placed in a 30 ml. reaction tube, and immersed in a thermostat for 20 min. to obtain a constant temperature. To start the reaction, 5 ml. of the vinyl ether solution was pipetted into the carboxylic acid solution. Two milliliter aliquots of this solution were withdrawn from time to time by means of a pipet and put into the mixture of 15 ml. of standard 0.1 N iodine solution and 15 ml. of methanol in a 100 ml. erlenmyer flask. After the mixture was stirred for 5 min., the excess iodine was titrated with standard 0.1 N sodium thiosulfate solution.

When toluene or anisole was used as the solvent, 0.5 N iodine solution and a large excess of methanol were used to make the titrating mixture homogeneous.

## Results and Discussion

Fig. 1 shows plots of percentage reaction against time (min.) for the reaction of *n*-butyl vinyl ether and monochloroacetic acid in dioxane at 60.0°C with various initial concentrations of reactants. The order of the reaction was determined by van't Hoff's initial rate method, and 0.95±0.1 order with respect to vinyl ether and 2.05±0.1 order with respect to carboxylic acid are obtained. Hence, the kinetic equation of the reaction is expressed by

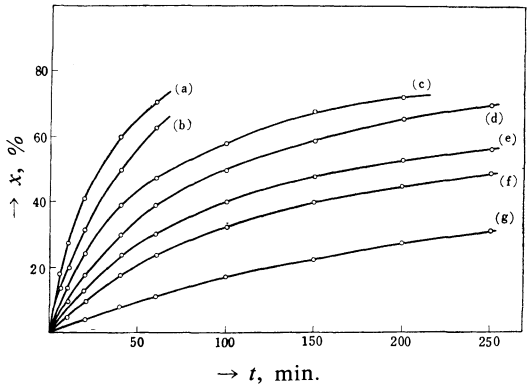

Fig. 1. The addition reactions of *n*-butyl vinyl ether with monochloroacetic acid in dioxane at 60°C.
The plots of percentage reaction *x* against time by various concentration:

| Run | a) | b) | c) | d) | e) | f) | g) |
|---|---|---|---|---|---|---|---|
| *n*-Butyl vinyl ether, mol./l. | 0.6 | 0.5 | 1.2 | 1.0 | 0.6 | 0.5 | 0.3 |
| Monochloro-acetic acid mol./l. | 1.2 | 1.0 | 0.6 | 0.5 | 0.6 | 0.5 | 0.3 |

$$-\frac{dC}{dt}=kAB^2 \qquad (2)$$

where the symbols $A$, $B$ and $C$ represent the concentrations of vinyl ether, carboxylic acid and product, respectively.

Eq. 2 may be integrated to give Eq. 3 or 4.

For $A_0 \neq B_0$,

$$2.303 \log \frac{A_0(B_0-C)}{B_0(A_0-C)}+\frac{B_0-A_0}{B_0}-\frac{B_0-A_0}{B_0-C}=(B_0-A_0)^2kt \qquad (3)$$

For $A_0=B_0$,

$$\frac{2A_0C-C^2}{(A_0-C)^2}=2A_0^2kt \qquad (4)$$

where $A_0$ and $B_0$ represent the initial concentrations of vinyl ether and carboxylic acid, respectively.

For individual runs with varvious initial concentrations shown in Fig. 1, the third order rate constants were calculated by the Eq. 3 or 4 at appropriate percentage reaction. The rate constants are determined along the abovementioned way in such a large range of reaction, i.e. from 10% to 60% completion. Table II shows these rate constants and leads to the fact that these constants are very close together in magnitude (the average value of the rate constant is $4.06\times10^{-4}$ mol$^{-2}$ sec$^{-1}$).

Similarly, the third order rate constants of the reaction of *n*-butyl vinyl ether with aliphatic and aromatic carboxylic acids are obtained (Tables III and IV). The plots of the logarithm of the rate constants vs. threciprocal absolute temperature gave satisfactory straight lines from which activation energies and entropies of activation were obtained (Table IV).

The effects of the substituents of carboxylic acids on this addition reaction are noted as follows:

(1) The rate increases as the acidity of carboxylic acid increases.

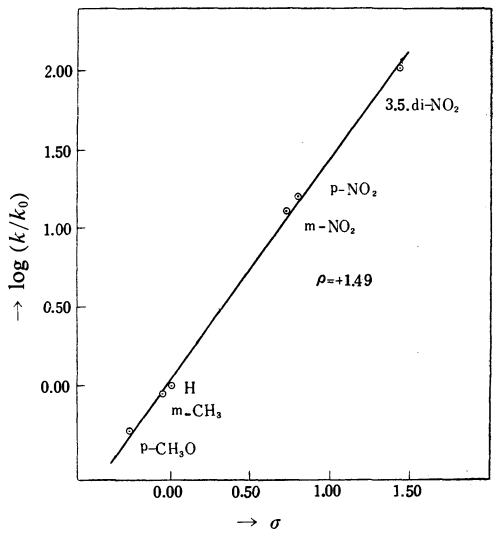

Fig. 2. Plots of log ($k/k_0$) against the Hammett $\sigma$-values.

TABLE IV. THE RATE CONSTANTS OF THE ADDITION REACTION OF *n*-BUTYL VINYL ETHER WITH ALIPHATIC CARBOXYLIC ACIDS IN TOLUENE AT 60°C

| Carboxylic acid | Acetic | Propionic | *n*-Butyric | *n*-Valeric | *n*-Caproic |
|---|---|---|---|---|---|
| $k\times10^{-5}$ mol$^{-2}$ sec$^{-1}$ | 8.70 | 3.66 | 3.05 | 1.67 | 1.01 |

(2) The effect of substituents in meta and para substituted benzoic acids nearly follows the Hammett equation. As shown in Fig. 2, $\log k$ is approximately a linear function of the substituent constants $\sigma$ given by Hammett[8], and the gradient of the plots gave a value for the reaction constant $\rho$ of +1.49.

(3) In ortho substituted benzoic acids, the reaction is not so fast as expected from their acidities, which may be attributed to the steric hindrance of the ortho substituents.

(4) In fatty acids, the rate decreases as the length of carbon chain increases.

These results lead to the conclusion that the reaction takes place in two stages, namely the initial formation of an intermediate complex in equilibrium with vinyl ether and carboxylic acid and followed by the reaction of the complex with another carboxylic acid via rate determining step.

8) L. P. Hammett, "Physical Organic Chmistry", McGraw-Hill Book Co., Inc., New York, N. Y. (1941), p. 188.

$$CH_2{=}CH{-}OC_4H_9 + RCOOH \underset{K}{\rightleftarrows} [RCOOH\cdots CH_2{=}CH{-}OC_4H_9] \quad (5)$$

$$\text{Complex} + RCOOH \xrightarrow[k']{} CH_3{-}\overset{H}{\underset{O}{\underset{|}{\overset{|}{C}}}}{-}OC_4H_9 + RCOOH \quad (6)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad COR$$

For the first stage, the concentration of the complex is found to be

$$[\text{Complex}] = K[CH_2{=}CH{-}OC_4H_9][RCOOH] \quad (7)$$

where $K$ is the equilibrium constant of this stage.

For the second stage, the rate of formation of the product is given by

$$\frac{d[\text{product}]}{dt} = k'[\text{complex}][RCOOH] \quad (8)$$

where $k'$ is the rate constant of this stage.

The over-all kinetic equation, therefore, expressed as

$$\frac{d[\text{product}]}{dt} = k'K[CH_2{=}CH{-}OC_4H_9][RCOOH]^2 \quad (9)$$

It is natural to consider that $K$ is directly proportional to $K_a$, the dissociation constant of the carboxylic acid used. Since a linear Hammett relation is observed, the experimental rate constant $k$ becomes directly proportional to $K_a$,

$$K \propto K_a \quad \text{and} \quad k = k'K \quad (10)$$

The results show that $k'$, the rate constant of the second stage, is not largely influenced by nucleophilic nature of carboxylic acid.

This two-stage mechanism was further ascertained by the following experiments.

Eq. 11 is given, when two kinds of carboxylic acids are reacted competitively with vinyl ether in a kinetic run,

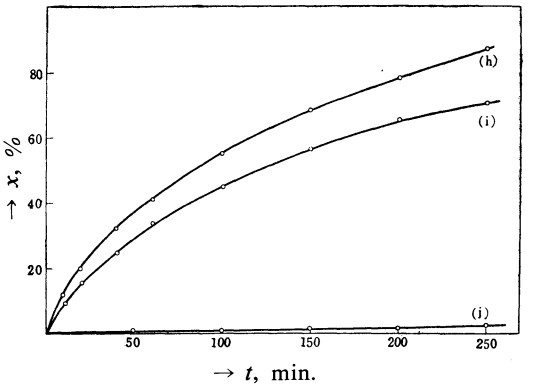
$$-\frac{dA}{dt} = k_1AB_1^2 + k_2AB_1B_2 + k_3AB_2^2 \quad (11)$$

where $A$ is the concentration of *n*-butyl vinyl ether, $B_1$ and $B_2$ are those of two carboxylic acids, respectively.

Fig. 3 shows plots of percentage reaction against time (min.) for the competitive reaction of vinyl ether (0.6 mol./l.) with monochloroacetic acid $B_1$ (0.6 mol./l.) and acetic acid $B_2$ (0.6 mol./l.) in dioxane at 60°C.

From Eq. 11 by use of rate constants, $k_1 = 4.06\times10^{-4}$ mol$^{-2}$sec$^{-1}$ and $k_3 = 4.6\times10^{-6}$mol$^{-2}$ sec$^{-1}$, which have been obtained in the separate experiment listed in Table III, the value of $k_2$ can be estimated graphically by initial rate given in Fig. 3. It is $4.0\times10^{-4}$ mol$^{-2}$ sec$^{-1}$ and the kinetic equation can be expressed as follows.

$$-\frac{dA}{dt} = 4.07\times10^{-4}AB_1^2 + 4.0\times10^{-4}AB_1B_2 + 4.6\times10^{-6}AB_2^2 \quad (12)$$



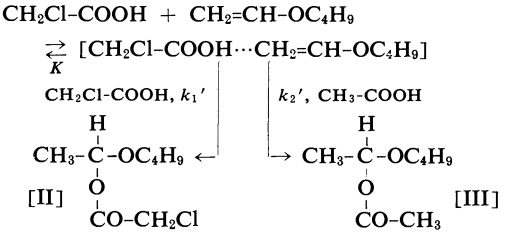


Fig. 3. The competitive addition reactions of *n*-butyl ether with two carboxylic acids in dioxane at 60°C.
The plots of percentage reaction $x$ against time;

| Run | h) | i) | j) |
|---|---|---|---|
| *n*-Butyl vinyl ether, mol./l. | 0.6 | 0.5 | 0.5 |
| Monochloroacetic acid mol./l. | 0.6 | 0.5 | — |
| Acetic acid, mol./l. | 0.6 | 0.5 | 0.5 |

By the separate experiment, it was ascertained that the ratio of the formation of II and III was 4 : 3. Since $k_1$ and $k_2$ are nearly the same values, this gives further experimental support for the above mentioned consideration that the first step, the formation of the complex from vinyl ether and carboxylic acid, is a dominant factor in this reaction and the rates of second step, $k_1'$ and $k_2'$, are nearly equal.

The reaction of *n*-butyl vinyl ether with acetic acid is accelerated by a catalytic amount of phosphoric acid. In a similar fashion as described in the case of the above mentioned competitive reaction of two carboxylic acids, Eq. 11 is also available to this reaction when $A$, $B_1$ and $B_2$ represent the concentrations of the vinyl ether, phosphoric acid and the acetic acid, respectively. Since $B_1$ and $k_3$, the rate constant of self catalyzed reaction of acetic acid, are very small values, both the first term, $k_1AB_1^2$, and the third term, $k_3AB_2^2$, are small compared with the second term, $k_2AB_1B_2$. Then, the kinetic equation is given as follows;

$$-\frac{dA}{dt} = k_2AB_1B_2 \quad (13)$$

Fig. 4 shows plots of $\log\{(200-x)/(100-x)\}$ (where $x$ represents percentage reaction of the vinyl ether) against time for the reaction of *n*-butyl vinyl ether (initial concentration 0.6 mol./l.) and acetic acid (initial concentration 1.2 mol./l.) in dioxane at 50°C with various concentrations of phosphoric acid, a—e.

The rates of reaction increase linearly as the concentration of phosphoric acid increases, and second order plots have a sufficiently straight lines from which the rate constants $k_2$ have been obtained (Table IV). It was confirmed that the reaction is a general acid catalyzed reaction similar to the results obtaind in the case of hydrolysis of vinyl ether[5,6].

TABLE V. THE RATE CONSTANTS OF THE ADDITION REACTION OF *n*-BUTYL VINYL ETHER WITH MONOCHLOROACETIC ACID IN VARIOUS SOLVENTS AT 30°C

| Solvent | $k$, $mol^{-2}\,sec^{-1}$ | Solvent | $k$, $mol^{-2}\,sec^{-1}$ |
|---|---|---|---|
| Dioxane | $3.95\times10^{-5}$ | Toluene 5+dioxane 1 | $9.1\times10^{-3}$ |
| Anisole | $1.34\times10^{-3}$ | Toluene 2+dioxane 1 | $2.1\times10^{-3}$ |
| Toluene | $2.08\times10^{-2}$ | Toluene 1+dioxane 2 | $0.7\times10^{-3}$ |
| | | Toluene 11+ether 1 | $3.3\times10^{-3}$ |

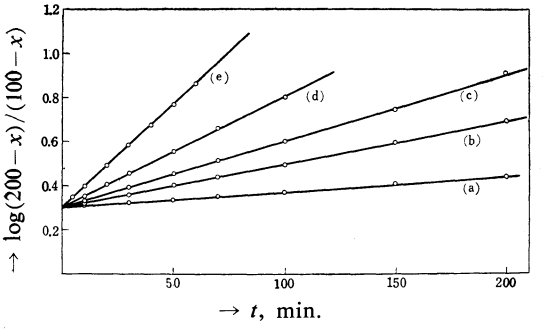
| e | 48.0 〃 | 15.8 〃 | 3.3 〃 |



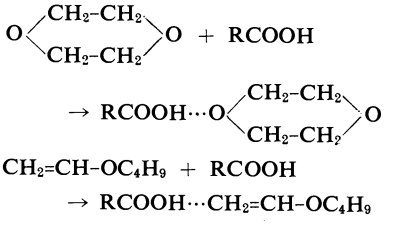


Fig. 4. The addition reaction of *n*-butyl vinyl ether with acetic acid in the presence of a catalytic amount of phosphoric acid in dioxane at 50°C.

In addition, the rates of this reaction are remarkably influenced by the nature of the solvent used. Table V shows the rate constants of the reaction of chloroacetic acid with *n*-butyl vinyl ether in dioxane, anisole and toluene at 30°C. In toluene the reaction is faster by 520 times than in dioxane. In anisole the reaction is not so fast as in toluene but still it is faster by 34 times than in dioxane. It was also observed that the addition of a small amount of dioxane or diethyl ether to toluene solution retards the reaction considerably.

Possible formation of complex from carboxylic acid and solvent containing ether linkage such as dioxane, competes with the formation of the above-mentioned complex from vinyl ether and carboxylic acid, and decreases the concentration of the latter which is the necessary intermediate to form the product, hemiacetal ester. This is a reason why the reaction is very slow in dioxane.

**Summary**

The rate constants, the activation energies and the entropies of activation of the addition reactions of *n*-butyl vinyl ether with carboxylic acids in dioxane, anisole and toluene were determined. It was found that the reaction is first order with respect to vinyl ether and second order with respect to carboxylic acid, and the rate of the reaction increases as the acidity of carboxylic acid increases and a linear Hammett relation is observed in the reaction of meta and para substituted benzoic acids. In the presence of a catalytic amount of phosphoric acid, the rate increases linearly with its concentration. The addition involves two stages, namely the initial formation of intermediate complex from vinyl ether and carboxylic acid, followed by the reaction of the complex with another carboxylic acid. In addition, the solvent effect has been clarified and a general acid catalyzed reaction has been discussed in view of these results.

The authers wish to express their hearty thanks to Professor Toshio Hoshino for his encouragement throughout the course of this experiment.

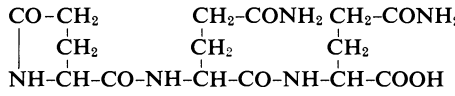
# *Studies on Peptides. VIII. The Synthesis of α,γ-Glutamyl Peptides and the Cleavage Reactions of their γ-Glutamyl Peptide Linkages*[1]



By Tetsuo SHIBA and Takeo KANEKO

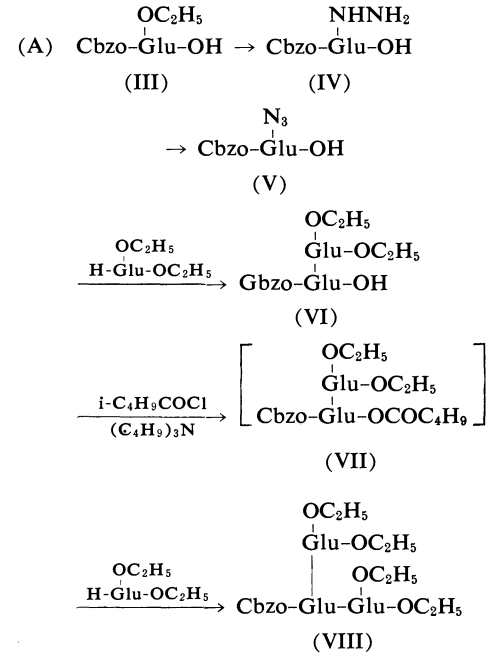
(Received May 13, 1960)

In previous papers[2,3], the structure of eisenine, tripeptide isolated from the brown marine alga *Eisenia bicyclis* Setchell[4,5], had been confirmed by synthesis. Eisenine was thus shown to be L-pyroglutamyl-L-glutaminyl-L-alanine (I). A similar tripeptide, fastigiatine, had been obtained by Fruton and his coworkers from the American marine alga *Pelvetia fastigiata*[6].

(I)

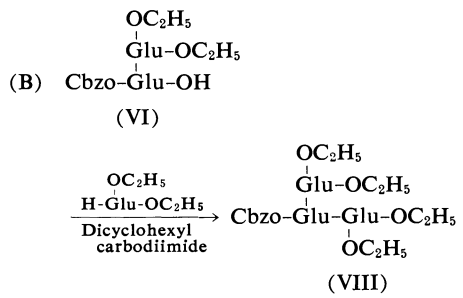
(II)

They suggested that fastigiatine is L-pyroglutamyl-L-glutaminyl-L-glutamine (II)[6]. However, our synthetic results have shown that this structure can not explain the physical constants of natural fastigiatine[1,7]. Nevertheless, even if this structure is not correct, a pyrrolidone ring is certainly present in the molecule of fastigiatine. During the course of our investigations on these two naturally occurring peptides, eisenine and fastigiatine, the fact, that both contain a pyrrolidone ring, seemed to us to be of particular interest.



With regard to the mechanism of formation of such a pyrrolidone ring, two possibilities were considered. One of them is a biosynthetic process in which only the γ-glutamyl peptide linkage of an α,γ-glutamyl peptide existing in the living cell is cleft enzymatically thus forming the pyroglutamyl peptide. With regard to this mechanism, Woodward and Reihart[8] reported that γ-glutamyl transpeptidase obtained from kidney, cleft selectively the γ-glutamyl peptide linkage in glutathione and that pyrrolidone carboxylic acid was produced. Connell and Hanes[9], in discussing this cleavage reaction, suggested that the γ-glutamyl peptide linkage had not been split by pure transpeptidase but by γ-glutamyl lactamase.

The second possibility is a non-enzymatic formation of the pyrrolidone ring. When a powder of the alga is heated in aqueous ethyl alcohol on a boiling water bath in order to extract the peptide, the original α,γ-glutamyl peptide or glutaminyl peptide may be converted to a pyroglutamyl peptide such as eisenine or fastigiatine. In general, the γ-glutamyl peptide bond is much more labile than the α-peptide bond. Ellfolk and Synge[10], as well as Hird and Springell[11], have pointed out that pyrrolidone carboxylic acid was produced from glutathione in a non-enzymatic reaction rather than an enzymatic one. Young and his coworkers[12,13] have observed a similar non-enzymatic reaction in the cases of several γ-glutamyl peptides. Glutamine or glutaminyl peptides are also easily cyclized to pyrrolidone carboxylic acid or to a pyroglutamyl peptide respectively by merely heating their aqueous solutions[7,14,15]. Although the non-enymatic formation of pyrrolidone carboxylic acid from a γ-glutamyl peptide or of a pyroglutamyl peptide from a glutaminyl peptide has been studied, it is not certain whether a pyroglutamyl peptide can be produced by cleavage of α,γ-glutamyl peptide. In the present investigation several α,γ-glutamyl peptides were synthesized and their selective cleavage reactions were studied.



A few methods for the synthesis of α,γ-glutamyl peptides were investigated in a case of the tetraethyl ester of carbobenzyloxy-α,γ-L-glutamyl di-L-glutamic acid. The first method (A) was based on the following reactions.

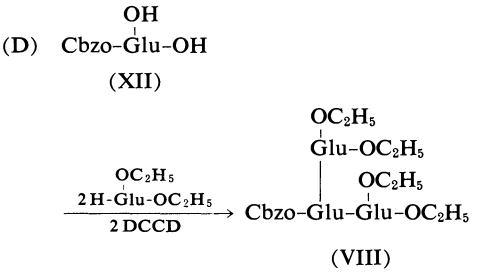
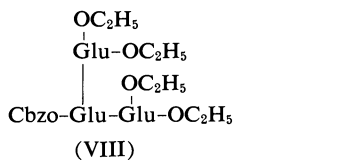
Carbobenzyloxy-$\gamma$-L-glutamyl azide (V) obtained from $\gamma$-ethyl carbobenzyloxy-L-glutamate (III) via the hydrazide (IV), was condensed with diethyl-L-glutamate to give the carbobenzyloxy-$\gamma$-dipeptide diethyl ester (VI). This diester VI was then combined with diethyl-L-glutamate via its mixed anhydride VII with isovaleric acid to obtain tetraethyl carbobenzyloxy-$\alpha$, $\gamma$-L-glutamyl di-L-glutamate (VIII).



In the second method B, diethyl carbobenzyloxy-$\gamma$-L-glutamyl-L-glutamate (VI), synthesized as in method A, was coupled with diethyl-L-glutamate by means of dicyclohexyl carbodiimide. Method B gives a better yield of VIII than method A. However, both methods have the disadvantage of giving poor yields of the intermediate VI from the azide V and of requiring many synthetic steps.

Booth and his collaborators had synthesized the same carbobenzyloxy tetraester (VIII)[16]. Their method was based on the preparation of diethyl carbobenzyloxy-$\alpha$-glutamyl glutamate, followed by its conversion into VIII via the acid chloride method. Their synthesis suffers from similar defects as methods A and B. Later, they succeeded in condensing one mole of *p*-nitrobenzoyl-$\alpha$, $\gamma$-glutamyl diazide with two moles of diethyl glutamate, thus forming in a single reaction tetraethyl *p*-nitrobenzoyl-$\alpha$, $\gamma$-glutamyl diglutamate[17]. In our third method C this diazide method was applied to the carbobenzyloxy derivative. Diethyl carbobenzyloxy-L-glutamate (IX) was obtained in good yield by the direct carbobenzyloxylation of diethyl L-glutamate. This diethyl ester (IX) was then converted into the dihydrazide (X,) and then to the diazide (XI), which was combined with two moles of diethyl L-glutamate to form tetraethyl carbobenzyloxy-$\alpha$, $\gamma$-L-glutamyl di-L-glutamate (VIII). Method C was superior to methods A and B, because the synthetic path became shorter and an overall yield of 48% in reactions X to VIII was obtained.

In our last method D, carbobenzyloxy-L-glutamic acid was directly coupled with two moles of diethyl L-glutamate using two moles of dicyclohexyl carbodiimide. The starting material for this reaction is easily available, only one step is required in order to obtain the desired product and an excellent yield (88%) is obtained. Therefore, this method is superior to the other methods.



The carbobenzyloxy tetraester obtained through such methods, was difficult to crystal-

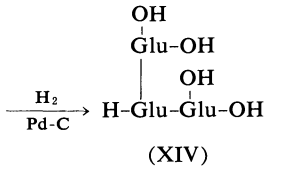
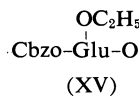
lize, but was obtained as a gelatinous precipitate upon addition of petroleum ether to its solution in ethyl acetate. Several samples of VIII showed varying melting points due to the occlusion of solvent, but their infrared spectra were all identical.

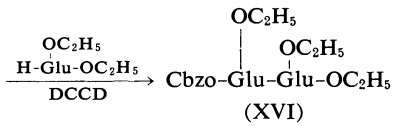


Carbobenzyloxy tetraester (VIII) prepared according to method D, was then hydrolyzed to carbobenzyloxy-$\alpha,\gamma$-L-glutamyl di-L-glutamic acid (XIII), which was obtained as a syrup that did not crystallize. Compound XIII was hydrogenated to $\alpha,\gamma$-L-glutamyl di-L-glutamic

(VIII)

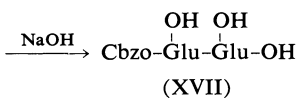


(XIII)

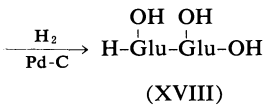


(XIV)

acid (XIV), which had a tendency to decompose during evaporation in vacuo and therefore was lyophilized.

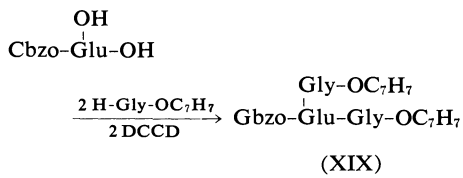


As preliminary experiment for our method D, $\gamma$-ethyl carbobenzyloxy-L-glutamate (XV) was coupled with diethyl L-glutamate using dicyclohexyl carbodiimide. Triethyl carbobenzyloxy-$\alpha$-L-glutamyl-L-glutamate (XVI) was thus obtained in a good yield. Compound XVI was then hydrolyzed to carbobenzyloxy-$\alpha$-L-glutamyl-L-glutamic acid (XVII), which was hydrogenated to $\alpha$-L-glutamyl-L-glutamic acid (XVIII).

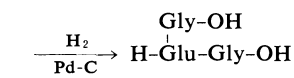


(XV)

(XVI)

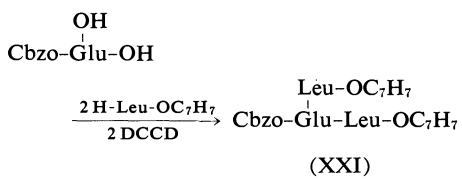


(XVII)



(XVIII)

For the purpose of preparing $\alpha$-glutamyl dipeptides, the method of Bergmann and Zervas[18], in which carbobenzyloxy glutamic anhydride is coupled with an amino acid ester, has hitherto mostly employed. The reaction products, however, always contained a small amount of $\gamma$-peptide as a by-product, which must be separated from the $\alpha$-isomer by means of successive extractions or a countercurrent distribution. Therefore, the anhydride method is not only very tedious, but also disadvantageous as far as its yield is concerned. In contrast, method D is believed to be a better synthetic approach to $\alpha$-glutamyl peptides, since these defects are eliminated.



Subsequently, $\alpha,\gamma$-L-glutamyl diglycine (XX), $\alpha,\gamma$-L-glutamyl di-L-leucine (XXII) and $\alpha,\gamma$-L-glutamyl di-Laspartic acid (XXIV) were also synthesized according to method D except that the amino acid benzyl esters were used in place of the ethyl esters. The benzyl esters of carbobenzyloxy-$\alpha,\gamma$-glutamyl petides (XIX, XXI, XXIII) were hydrogenated to the $\alpha,\gamma$-glutamyl peptides (XX, XXII, XXIV) in one step. The hydrolysis step required for ethyl esters was thus eliminated.

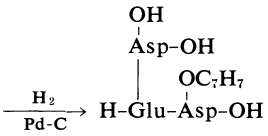
(XX)

(XXI)



(XXII)

(XXIII)

18) M. Bergmann and L. Zervas, *Ber.*, 65, 1192 (1932).

(XXIV)

The hydrogenolysis of the benzylesters (XIX, XXI, XXIII) was carried out in open vessels after the addition of palladium-charcoal (10%). In the case of peptides of glycine XIX and of leucine XXI, this hydrogenolysis took place readily, while tetrabenzyl carbobenzyloxy-$\alpha,\gamma$-glutamyl diaspartate (XXIII) was difficult to hydrogenate, probably owing to its steric structure; the hydrogenated product XXIV could not be obtained in a pure state.

For the purpose of the preparation of $\alpha,\gamma$-L-glutamyl di-L-lysine by a similar synthetic method, $\varepsilon$-carbobenzyloxy-L-lysine methyl ester hydrochloride (XXV) and $\varepsilon$-carbobenzyloxy-L-lysine benzyl ester hydrochloride (XXVI) were synthesized. The former (XXV) had been prepared from $\varepsilon$-carbobenzyloxy-$\alpha$-carboxyl-L-lysine anhydride and methyl alcoholic hydrochloric acid by Bergmann and his coworkers[19]. Our advantageous method or preparation of $\varepsilon$-carbobenzyloxy lysine ester hydrochloride was based on the esterification of $\varepsilon$-carbobenzyloxy-L-lysine obtained from copper lysinate and carbobenzyloxy chloride[20]. $\varepsilon$-Carbobenzyloxy-L-lysine was esterified with thionyl chloride in methyl alcohol for benzyl alcohol to yield the methyl ester hydrochloride (XXV) and the benzyl ester hydrochloride (XXVI) respectively without decomposition of the carbobenzyloxy group. The condensation reactions of these lysine esters with carbobenzyloxy glutamic acid in the presence of dicyclohexyl carbodiimide were not successful. Complex mixtures were obtained in all cases. This failure may be due to the molecular structures of XXV and XXVI. However, these cabobenzyloxylysine ester hydrochlorides (XXV and XXVI) may be useful intermediates in the syntheses of other lysine peptides.

$$\text{Cbzo-NH(CH}_2)_4\text{CH(NH}_2\cdot\text{HCl)COOCH}_3$$

$$\text{Cbzo-NH(CH}_2)_4\text{(NH}_2\cdot\text{HCl)COOCH}_2\text{C}_6\text{H}_5$$

(XXVI)

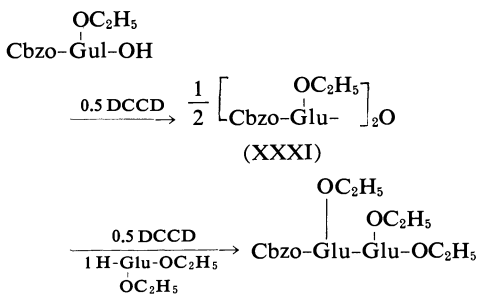
In the course of all condensation reactions in the presence of cyclohexyl carbodiimide, pure dicyclohexyl urea always separated in crystalline form from the reaction mixture. In order to use it repeatedly for other reactions, dicyclohexyl carbodiimide was recovered from dicyclohexyl urea in fair yield according to the method of Amiard and Heymes[21].

Concerning the mechanism of the condensation reaction in the presence of dicyclohexyl carbodiimide, we supposed at first that two moles of amino acid ester would combine simultaneously with one mole of carbobenzyloxy glutamic acid in the presence of two moles of dicyclohexyl carbodiimide. However, when solutions of one mole of carbobenzyloxy-glutamic acid and of two moles of dicyclohexyl carbodiimide were mixed before the addition of any amino acid ester, it was observed that nearly one mole of dicyclohexyl urea separated out immediately. When two moles of amino acid ester were then added to the filtrate from this urea derivative, the expected $\alpha,\gamma$-glutamyl peptide was obtained in good yield and another mole of dicyclohexyl urea was formed at the same time. Therefore, the reactioncan be better explained by a three step mechanism as follows. In the first step, one mole of carbobenzyloxy glutamic acid reacts with one mole of dicyclohexyl carbodiimide to form carbobenzyloxy-glutamic anhydride (XXVII). In the second step, the anhydride ring is opened by one mole of amino acid ester according to the same mechanism as in the method of Bergmann and Zervas[18] with the formation of a mixture of $\alpha$- and $\gamma$-dipeptide derivatives XXVIII and XXIX. In the third step, these condense with another mole of amino acid ester by the action of one mole of dicyclohexyl carbodiimide to give a single product XXX.

(XXVII)

(XXVIII)

(XXIX)



(XXX)

In fact, when one mole of carbobenzyloxy-L-glutamic acid and one mole of dicyclohexyl carbodiimide were mixed, about 0.9 mol. of

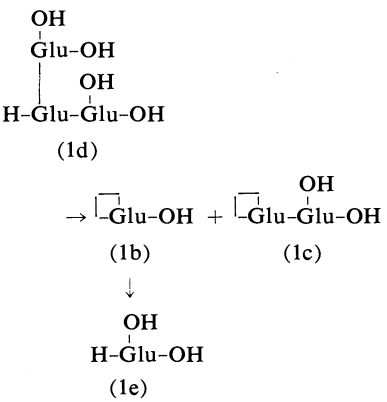
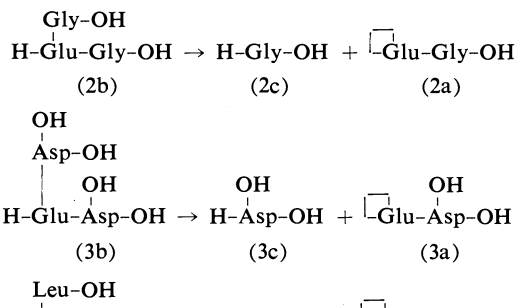
* -AA-=amino acid residue, -NH-CH(R)-CO-.



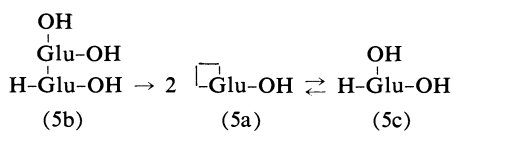
dicyclohexyl urea was always obtained as a precipitate; hence it appears that carbobenzyloxy glutamic anhydride (XXVII) must be formed, but all efforts to crystallize it from the reaction mixture were unsuccessful. Although the formation of the anhydride (XXVII) could not be directly proven, the above mentioned mechanism could be demonstrated indirectly by the following experiment. When one mole of pure carbobenzyloxy-L-glutamic anhydride (XXVII), prepared from carbobenzyloy glutamic acid and acetic anhydride by the usual method, was reacted with two moles of glycine benzyl ester by means of one mole of dicyclohexyl carbodiimide, dibenzyl-carbobenzyloxy-$\alpha$, $\gamma$-L-glutamyl diglycinate (XIX) was obtained in very good yield (92%). This supports the above described three-step mechanism.

When the synthesis of $\alpha$-glutamyl glutamic acid (XVIII) was carried out in a stepwise fashion, i.e. when $\gamma$-ethyl carbobenzyloxy-L-glutamate was mixed with a solution of dicyclohexyl carbodiimide, before diethyl L-glutamate was added, a precipitate of dicyclohexyl urea was also observed. It is assumed, that in this case one mole of the carbobenzyloxy-$\gamma$-ester and a half mole of dicyclohexyl carbodiimide form an intermolecular anhydride XXXI, which then reacts with one mole of diethyl glutamate by means of a half mole of dicyclohexyl carbodiimide in a similar manner as the $\alpha,\gamma$-glutamyl peptide diester (XXX) is assumed to be formed from carbobenzyloxy-glutamic anhydride (XXVII).



Muramatsu and Hagitani[22] have shown that formyl-$\beta$-alanine can also be converted to its bimolecular anhydride by means of dicyclohexyl carbodiimide. Only a small amount of other information on the formation of anhydrides by the reaction of dicyclohexyl carbodiimide with *N*-substituted-$\alpha$-amino acids is available.

Finally, the cleavage of four $\alpha,\gamma$-glutamyl peptides, as well as of $\alpha$-glutamyl glutamic acid and of $\gamma$-glutamyl glutamic acid, caused by heating the aqueous solutions of these peptides, was investigated. The results are presented in Figs. 1—6. In the case of $\alpha,\gamma$-L-glutamyl di-L-glutamic acid (1d), a small amount of pyrrolidone carboxylic acid (1b) was split off after only one week at 40°C. However, at 100°C both pyrrolidone carboxylic acid (1b) and glutamic acid (1e) began to appear already after one hour. The $\alpha,\gamma$-peptide (1d) disappeared completely after nine hours, while a new spot 1c appeared after three hours and became gradually stronger on longer heating. It was not colored by ninhydrin, but colored by Bromothymol Blue, and is supposed to be pyroglutamyl glutamic acid. From the result of this experiment, it was concluded that $\alpha,\gamma$-glutamyl diglutamic acid in aqueous solution was decomposed at 100°C to pyrrolidone carboxylic acid and or glutamic acid and pyroglutamyl glutamic acid by a selective cleavage of its $\gamma$-peptide linkage as shown below.



The cleavage of $\alpha,\gamma$-L-glutamyl diglycine (Fig. 2), $\alpha,\gamma$-L-glutamyl di-L-aspartic acid (Fig. 3), and $\alpha,\gamma$-L-glutamyl di-L-leucine (Fig. 4) proceeded in a similar manner. The decompositions began after one hour at 100°C and were completed after ten to twenty hours. These cleavage reactions may be represented as follows.

22) I. Muramatsu and S. Hagitani, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 1497 (1959).

In the course of the decomposition of γ-glytamyl glutamic acid (Fig. 5), the Bromothymol Blue positive spot (5a) of pyrrolidone carboxylic acid appeared before the ninhydrin spot of glutamic acid (5c). Since Bromothymol Blue is a less sensitive reagent than ninhydrin, this indicates that both glutamic acid residues of the dipeptide were first decomposed to pyrrolidone carboxylic acid, which was then converted to glutamic acid.

On the other hand, α-L-glutamyl glutamic acid was rather stable and began to decompose after only twenty hours (Fig. 6).

From the results of this invesigation it may be concluded that α, γ-glutamyl peptides are subject to the selective cleavage of the γ-peptide bond on heating of the aqueous solutions, with the formation of a pyroglutamyl peptide and an amino acid. The rate of the decomposition was independent of the nature of the amino acid linked to the γ-glutamyl caboxyl group. On the basis of the cleavage reactions described above it is reasonable to assume that the pyroglutamyl peptides of marine algae were formed from glutaminyl peptides or from α, γ-glutamyl peptides in the course of the heating during their isolation.

## Experimental

**Diethyl Carbobenzyloxy-L-glutamate (IX).**—A solution of 83 g. (0.35 mol.) of diethyl L-glutamate hydrochloride in 500 ml. of water was mixed with 44 ml. of an aqueous solution of 4 N sodium carbonate. To this solution of pH 7~8, 70 g. (0.41 mol.) of carbobenzyloxy chloride and 50 ml. of an aqueous solution of 4 N sodium carbonate were added. The reaction mixture was vigorously stirred at room temperature (25°C) for three hours. It was extracted twice with 100 ml. of ether. The combined extract was washed with aqueous sodium carbonate, dried with sodium sulfate, and then evaporated in vacuo to a syrupy residue, which crystallized after two weeks' standing at room temperature; yield 103 g. (89%). It was recrystallized from ethyl alcohol and water, needles, m. p. 39~42°C.

Found: C, 60.91; H, 6.73; N, 4.04. Calcd. for $C_{17}H_{23}O_6N$: C, 60.52; H, 6.87; N, 4.15%.

In order to confirm the optical purity of the product, 4.1 g. was dissolved in 80 ml. of 1 N sodium hydroxide solution at room temperature during two hours. Then, the solution was acidified with 5 N hydrochloric acid and extracted with ethyl acetate. The extract was shaken with an aqueous solution of 1 N sodium carbonate. The aqueous layer was separated, acidified and extracted with ethyl acetate. This extract was evaporated in vacuo to a residue, which was hydrogenated in 20 ml. of methyl alcohol and 20 ml. of water in an open vessel in the presence of 100 mg. of 5% palladium-charcoal. After filtration of the catalyst and evaporation of the filtrate a residue was obtained, which was crystallized from water; yield, 0.4 g. On recrystallization, 255 mg. of pure L-glutamic acid was obtained. The overall yield from carbobenzyloxy diester (IX) was 14 percent. $[\alpha]_D^{25}$ −31.8° (*c*, 2.74, 2 N HCl).

Found: C, 40.34; H, 6.17; H, 9.44. Calcd. for $C_5H_9O_4N$; C, 40.81; H, 6.17; N, 9.52%.

**Carbobenzyloxy-L-glutamic Dihydrazide (X).**—To a solution of 72 g. of diethyl carbobenzyloxy-L-glutamate (IX) in 150 ml. of 99% ethyl alcohol, 100 ml. of 90% hydrazine hydrate was added with stirring during forty-five minutes. The temperature of the reaction mixture was kept below 30°C. When a large amount of a solid product formed during the reaction, another 100 ml. of ethyl alcohol was added. Vigorous stirring was continued for one hour and a half. The white precipitate formed was filtered and then was dissolved in 5 N hydrochloric acid. A solution of sodium acetate was carefully added until a pH of 4 was reached. After standing overnight, 40 g. of fine needles were obtained; yield 60%, m. p. 183~184°C (decomp.). $[\alpha]_D^{21}$ −14.2° (*c*, 3.05, 2 N HCl). Recrystallization from hydrochloric acid and aqueous sodium acetate gave crystals of m. p. 203~204°C (dec.).

Found: C, 50.57; H, 5.91; N, 22.60. Calcd. for $C_{13}H_{19}O_4N_5$: C, 50.49; H, 6.15; N, 22.64%.

**Tetraethyl Carbobenzyloxy-α, γ-L-glutamyl Di-L-glutamate (VIII). Method A.**—Diethyl carbobenzyloxy-γ-L-glutamyl glutamate (VI) prepared from 6.0 g. (0.02 mol.) of carbobenzyloxy-γ-L-glutamyl hydrazide by the azide method[23], was dissolved in 25 ml. of toluene and 25 ml. of chloroform, and 3.7 g. (0.02 mol.) of tri-*n*-butylamine and 2.4 g. (0.02 mol.) of isovaleryl chloride were added with stirring to the solution kept below 5°C. Stirring was continued for two hours while the temperature of the reaction mixture was kept at 0°C. A solution of free diethyl glutamate prepared from 4.8 g. (0.02 mol.) of diethyl L-glytamate hydrochloride and 3.7 g. (0.02 mol.) of tri-*n*-butylamine, in 50 ml. of chloroform, was added dropwise below 0°C within ten minutes. The reaction mixture was stirred for three hours between 0° and −10°C, then permitted to stand at room temperature for a few hours. The reaction mixture was washed with water, 3% aqueous sodium bicarbonate, 0.5% hydrochloric acid and water, and dried with sodium sulfate. Upon addition of petroleum ether crystals formed, which were filtered and dried over phosphorus pentoxide in vacuo; yield, 5.9 g. (45% based on carbobenzyloxy-L-glutamyl-γ-hydrazide), m. p. 133~134°C (sintered at 103~104°C). The melting point could be raised up to 134~136°C* (sintered at 106~108°C) by

23) T. Shiba and S. Imai, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 176 (1959).

* J. H. Mowat, Y. Subborow et al. (*J. Am. Chem. Soc.*, 71, 2308 (1949)) have synthesized tetraethyl carbobenzyloxy-α, γ-L-glutamyl-L-glutamate from tetraethyl *p*-nitrobenzoyl-α, γ-L-glutamyl-L-glutamate by replacing the *p*-nitrobenzoyl group with a carbobenzyloxy group. Their sample had a melting point of 140.5~142.0°C (sintered at 105~107°C).

recrystallization from ethyl alcohol and water. $[\alpha]_D^{23}-15.9°$ ($c$, 3.01, 99% EtOH).

Found: C, 56.62; H, 7.16; N, 6.67. Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.13; H, 6.96; N, 6.45%.

**Method B.**—To a solution of 5.7 g. (0.035 mol.) of diethyl glutamate hydrochloride in 50 ml. of tetrahydrofuran, 1.7 g. of triethylamine was added and the triethylamine hydrochloride formed was filtered off. To the solution of the free ester, 7.6 g. (0.0163 mol.) of diethyl carbobenzyloxy-$\gamma$-L-glutamyl-L-glutamate (VI) and 3.4 g. (0.0163 mol.) of dicyclohexyl carbodiimide in 50 ml. of tetrahydrofuran were added. After stirring for five hours, 0.4 ml. of glacial acetic acid was added and stirring was continued for another hour in order to decompose unreacted carbodiimide. After filtrations of the dicyclohexyl urea, which weighed 3.3 g. (89%) and melted at 228~229°C, the filtrate was evaporated in vacuo. The syrupy residue was dissolved in ethyl acetate, the solution was washed with dilute hydrochloric acid, aqueous potassium bicarbonate and water, dried with sodium sulfate and concentrated in vacuo. The gelatinous residue was recrystallized from ethyl acetate and petroleum ether to give 8.8 g. (83%) of a colorless powder, m. p. 124~127°C (sintered at 92~98°C).

Found: C, 56.85; H, 6.92; N, 6.69. Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.13; H, 6.95; N, 6.45%.

**Method C.**—In a mixture of 50 ml. of water, 15 ml. of concentrated hydrochloric acid and 50 ml. of chloroform, 6.2 g. (0.02 mol.) of carbobenzyloxy-L-glutamic dihyrazide (X) was dissolved. After cooling to 0°C, 30 ml. of an aqueous solution of 5.5 g. (0.08 mol.) of sodium nitrite was added dropwise within ten minutes. The reaction temperature must not exceed 5°C. After stirring for one hour at 0°C, the aqueous layer was separated and extracted twice with 30 ml. of chloroform. The combined chloroform solution was washed twice with cold water and dried with sodium sulfate. A solution of diethyl L-glutamate was prepared by dissolving 24.0 g. (0.10 mol.) of diethyl L-glutamate hydrochloride and 20.5 g. (0.20 mol.) of potassium bicarbonate in 50 ml. of water and extracting this solution three times with 50 ml. of chloroform. The combined extract was washed with water and dried with sodium sulfate. The solution of diazide obtained above was added dropwise during five minutes to this solution, while the temperature was kept at −5°C. The reaction mixture was stirred for two hours between −10°C to 0°C, and then permitted to stand overnight at room temperature. The reaction mixture was washed with dilute hydrochloric acid and then with a small amount of water, dried with sodium sulfate and evaporated in vacuo. The syrupy residue was reprecipitated from ethyl acetate and petroleum ether. The gelatinous precipitate was filtered and crystallized from ethyl alcohol and water to yield crystals, which after drying for a day in vacuo at 65°C weighed 6.3 g. (48%), m. p. 129~131°C (sintered at 99~102°C).

Found: C, 56.88; H, 6.82; N, 6.76; Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.13; H, 6.96; N, 6.45%.

**Method D.**—A solution of 5.6 g. (0.02 mol.) of carbobenzyloxy-L-glutamic acid (XII) in 25 ml. of tetrahydrofuran and a solution of 10.0 g. (0.048 mol.) of dicyclohexyl carbodiimide 25 ml. of tetrahydrofuran were mixed. White crystalline dicyclohexyl urea began to form after a few minutes. Without removing the precipitate, a solution of diethyl L-glutamate was added. This solution had been prepared by adding 6.0 g. (0.06 mol.) of triethylamines to a solution of 14.3 g. (0.06 mol.) of diethyl L-glutamate hydrochloride in 30 ml. of tetrahydrofuran and removing the triethylamine hydrochloride formed by filtration. After the addition of the diethyl L-glutamate, the reaction mixture was stirred for five hours and then allowed to stand overnight. In order to decompose unreacted carbodiimide, 0.5 ml. of glacial acetic acid was added to the reaction mixture and the precipitate of dicyclohexyl urea (8.3 g.) was filtered off. The filtrate was evaporated in vacuo and the residue was dissolved in 100 ml. of ethyl acetate. The solution was washed with dilute hydrochloric acid, aqueous potassium bicarbonate and water and then dried with sodium sulfate. Upon addition of petroleum ether a gelatinous precipitate was obtained, which was filtered and dried in vacuo over phosphorus pentoxide; yield 11.4 g. (88%), m. p. 85~91°C. A recrystaillzed sample melted at 118~120°C (sintered at 102~104°C).

Found: C, 56.89; H, 6.73; N, 6.93. Calcd. for $C_{31}H_{45}O_{12}N_3$: C, 57.13; H, 6.96; N, 6.45%.

**$\alpha,\gamma$-L-Glutamyl Di-L-glutamic Acid (XIV).**—To a solution of 29.5 g. (0.045 mol.) of tetraethyl carbobenzyloxy-$\alpha,\gamma$-L-glutamyl di-L-glutamate in 100 ml. of 1 N sodium hydroxide was added. After standing for one hour at room temperature the reaction mixture was neutralized with 2 N hydrochloric acid, then concentrated to about 100 ml. in vacuo, acidified to Thymol Blue and extracted five times with 100 ml. of ethyl acetate. The extract was shaken five times with aqueous sodium carbonate. The combined aqueous layers were neutralized, concentrated to 200 ml., acidified and extracted again six times with 100 ml. of ethyl acetate. The extracted was dried with sodium sulfate and evaporated in vacuo to 20 g. of a syrup, which did not crystallize; yield 82%.

A solution of 7.0 g. of syrupy carbobenzyloxy-$\alpha,\gamma$-L-glutamyl di-L-glutamic acid in 100 ml. of methyl alcohol and 100 ml. of water, was hydrogenated by the usual method using 1.0 g. of 5% palladium-charcoal. After the catalyst was filtered off, the filtrate was concentrated in vacuo below 35°C to a volume of about 100 ml., and then lyophilized; yield 3.6 g. (96%), m. p. 121~123°C (dec.). $[\alpha]_D^{30}+1.4°$ ($c$, 2.55, 2 N HCl).

Found: C, 42.55; H, 6.27; N, 10.07. Calcd. for $C_{15}H_{23}O_{10}N_3\cdot H_2O$: C, 42.55; H, 5.95; N, 9.93%.

**Triethyl Carbobenzyloxy-$\alpha$-L-glutamyl-L-glutamate (XVI).**—To a solution of 5.8 g. (0.024 mol.) of diethyl-L-glutamate hydrochloride in 50 ml. of tetrahydrofuran, 1.6 g. of triethylamine was added. After removal of the triethylamine hydrochloride formed, the filtrate was poured to a mixture of 5.0 g. (0.016 mol.) of $\gamma$-ethyl carbobenzyloxy-L-glutamate (XV) and 3.6 g. (0.017 mol.) of dicyclohexyl carbodiimide in 50 ml. of tetrahydrofuran. The reaction mixture was stirred for three hours, and

then treated with 0.5 ml. of glacial acetic acid to decompose the excess of carbodiimide. The insoluble dicyclohexyl urea was removed by filtration and washed; Yield 3.2 g. (84%). The solvent was replaced by ethyl acetate and the solution was washed with dilute hydrochloric acid, aqueous potassium bicarbonate and water. After drying with sodium sulfate the solvent was evaporated in vacuo to a residue, which was crystallized from ethyl acetate and petroleum ether; yield 6.5 g. (81%), m. p. 60~64°C (sintered at 45~52°C).

Found: C, 58.72; H, 7.03; N, 5.83. Calcd. for $C_{24}H_{34}O_9N_2$: C, 58.29; H, 6.93; N, 5.67%.

**Carbobenzyloxy-α-L-glutamyl-L-glutamic Acid (XVII).**—To a solution of 6.2 g. (0.0125 mol.) of carbobenzyloxy triester (XVI) in 50 ml. of methyl alcohol, 50 ml. of 1 N sodium hydroxide was added. After standing at room temperature for two and a half hours a small amount of undissolved substance was removed by filtration and the filtrate was acidified with 2 N hydrochloric acid and extracted fou times with ethyl acetate. The dried extract was evaporated in vacuo to a syrup, which was dissolved in 100 ml. of hot water. On cooling, crystals formed which were recrystallized from aqueous ethyl alcohol; yield 2.8 g. (54%), m. p. 161~164°C (decomp.) (sinters at 139°C).

Found: C, 53.13; H, 5.92; N, 7.03. Calcd. for $C_{18}H_{22}O_9N_2$: C, 53.68; H, 5.40; N, 6.83%.

**α-L-Glutamyl-L-glutamic Acid (XVIII).**—A solution of 1.9 g. of carbobenzyloxy dipeptide XVII in 40 ml. of methyl alcohol and 20 ml. of water was hydrogenated using 5% palladium-charcoal. The catalyst was filtered off and washed with hot water. The filtrate and the washings were combined and evaporated in vacuo. The residue was crystallized from water and ethyl alcohol; yield 0.9 g. (61%), m.p. 178~179°C (decomp.). Its infrared spectrum was completely identical with that of α-L-glutamyl-L-glutamic acid prepared from carbobenzyloxy glutamic anhydride according to Bergmann's method.

Found: C, 43.30; H, 5.63; N, 9.99. Calcd. for $C_{10}H_{16}O_7N_2$: C, 43.48; H, 5.84; N, 10.14%.

**Di-benzyl Carbobenzyloxy-α, γ-L-glutamyl Diglycinate (XIX).** — Benzyl glycinate-*p*-toluenesulfonate was prepared according to the method of Izumiya and Makisumi[24]. To a solution of 15.0 g. (0.045 mol.) of this ester salt (m. p. 130~131°C) in 100 ml. of chloroform, 4.5 g. (0.045 mol.) of triethylamine was added. The mixture was poured into a solution of 5.6 g. (0.020 mol.) of carbobenzyloxy-L-glutamic acid in 100 ml. of tetrahydrofuran. Then a solution of 11.0 g. (0.053 mol.) of dicyclohexyl carbodiimide in 100 ml. of tetahydrofuran was added. After the reaction mixture was stirred at room temperature for seven hours, the cyclohexyl urea formed was filtered off; weight 4.4 g. (50%). A small amount of glacial acetic acid was added to the filtrate. After two hours' stirring the reaction mixture was evaporated in vacuo and the residue was dissolved in ethyl acetate. Undissolved dicyclohexyl urea was filtered off. Upon addition of petroleum ether to the filtrate a precipitate was obtained which was recrystallized from ethyl alcohol, and dried in vacuo over phosphorus pentoxide; yield 5.5 g. (48%), m. p. 146~149°C.

Found: C, 64.25; H, 5.76; N, 7.48. Calcd. for $C_{31}H_{33}O_8N_3$: C, 64.68; H, 5.78; N, 7.30%.

**α, γ-L-Glutamyl Diglycine (XX).** — A solution of 5.1 g. of dibenzyl ester XIX in 50 ml. of dioxane, 50 ml. of methyl alcohol and 50 ml. of water, was hydrogenated by the usual method using 1.0 g. of 5% palladum-charcoal. After the catalyst was filtered off, the filtrate was evaporated in vacuo and the residue was lyophilized; yield 1.6 g. (70%), m. p. 73~77°C (sintered at about 68°C). It was dried in vacuo over phosphorus pentoxide for an elementary analysis. $pK'_{a_1}$ 2.70; $pK'_{a_2}$ 3.69; $pK'_{a_3}$ 8.02.

Found: C, 38.75; H, 6.03; N, 14.56; MW, 290. Calcd. for $C_9H_{15}O_6N_3 \cdot H_2O$: C, 38.71; H, 6.14; N, 15.05%, MW, 279.

The molecular weight was calculated from the neutralization equivalent as dibasic acid.

**Diethyl Carbobenzyloxy-α, γ-L-glutamyl Di-L-leucinate (XXI).**—A solution of 7.0 g. (0.025 mol.) of carbobenzyloxy-L-glutamic acid in 75 ml. of tetrahydrofuran and a solution of 3.4 g. (0.065 mol.) of dicyclohexyl carbodiimide in 75 ml. of tetrahydrofuran were mixed. Without removing the precipitate of dicyclohexyl urea which formed, a solution of benzyl L-leucinate was added. This solution had been prepared by adding 6.5 g. (0.065 mol.) of triethylamine to a suspension of 23.6 g. (0.06 mol.) of benzyl L-leucinate-*p*-toluenesulfonate[24] (m. p. 154~155°C) in 150 ml. of chloroform. After the addition of the benzyl L-leucinate, the reaction mixture was stirred for five hours. The precipitate of dicyclohexyl urea was removed by filtration and washed with tetrahydrofuran; weighte 8.3 g. (57%). After addition of a small amount of glacial acetic acid and filtration of a further precipitate (2.2 g.), the filtrate was evaporated to dryness in vacuo. The residue was dissolved in ethyl acetate and washed with water, dilute sodium bicarbonate, dilute hydrochloric acid and water. The solvent was removed and petroleum ether was added to the residue. After cooling, a gelatinous precipitate formed. It was recrystallized from ethyl alcohol and water, and dried in vacuo over phosphorus pentoxide; yield 10.9 g., m. p. 107~116°C (softened at 98°C). From the mother liquor, 3.1 g. of crystals were obtained; total yield 82%.

Found: C, 67.86; H, 7.11; N, 6.53. Calcd. for $C_{39}H_{49}O_8N_3$: C, 68.10; H, 7.18; N, 6.11%.

**α, γ-L-Glutamyl Di-L-leucine (XXII).**—A solution of 5.0 g. of dibenzyl ester XXI in 30 ml. of methyl alcohol, 80 ml. of dioxane and 30 ml. of water was hydrogenated using 1.0 g. of 5% palladium-charcoal. After filtration of the catalyst, the filtrate was concentrated in vacuo to a volume of about 65 ml. The remaining solvent was removed by lyophilization; yield 1.8 g. (67%), m. p. 137~141°C (softened at 134°C, $pK'_{a_1}$ 2.81; $pK'_{a_2}$ 3.75; $pK'_{a_3}$ 8.07). The molecular weight was calculated from the neutralization equivalent as a dibasic acid.

Found: C, 52.65; H, 8.37; N, 10.13; MW, 464. Calcd. for $C_{17}H_{31}O_6N_3 \cdot H_2O$: C, 52.22; H, 8.51; N, 10.75%; MW, 391.

24) N. Izumiya and S. Makisumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **78**, 1768 (1957).

**Tetrabenzyl Carbobenzyloxy-α, γ-L-glutamyl Di-L-aspartate (XXIII).**—To a suspension of 31.0 g. (0.070 mol.) of dibenzyl-L-aspartate-*p*-toluenesulfonate (m. p. 152°C)[24] in 200 ml. of chloroform, 7.0 g. (0.070 mol.) of triethylamine was added to give a clear solution of the free ester. Solution of 7.0 g. (0.025 mol.) of carbobenzyloxy-L-glutamic acid in 100 ml. of tetrahydrofuran and of 14.5 g. (0.070 mol.) of dicyclohexyl carbodiimide in 100 ml. of tetrahydrofuran were added to the solution of the free ester with ice-cooling. The mixture was then stirred at room temperature for nine hours. A gelatinous precipitate was filtered off. This precipitate seemed to be a mixture of the expected tetrabenzyl ester and dicyclohexyl urea. Therefore, it was extracted with tetrahydrofuran and the extract was evaporated. The residue was dissolved in ethyl alcohol and tetrahydrofuran, and crystallized by adding water to the solution. Recrystallization from the same solvents gave 7.6 g. of crystals, m. p. 139~145°C. Some dicyclohexyl urea which had separated out from the mother liquor of the gelatinous precipitate was removed by filtration, and the filtrate was washed with acid, aqueous sodium bicarbonate and water. Upon addition of petroleum ether a precipitate formed which was recrystallized from a mixture of ethyl acetate, tetrahydrofuran and petroleum ether; weighted 4.5 g., m. p. 152~158°C (softened at 145°C). The total yield was 12.1 g. (56%).

Found: C, 67.11; H, 5.75; N, 4.91. Calcd. for $C_{49}H_{49}O_{12}N_3$: C, 67.51; H, 5.63; N, 4.88%.

**α, γ-L-Glutamyl Di-L-aspartic Acid (XXIV).**—A solution of 3.0 g. of compound XXIII in 30 ml. of methyl alcohol, 90 ml. of dioxane and 30 ml. of water, was hydrogenated using 0.7 g. of 5% palladium-charcoal. After filtration of the catalyst, the filtrate and the washings were combined, concentrated in vacuo to about 30 ml. and then lyophilized to a solid, which weighed 1.2 g., m. p. 58~63°C. Elementary analysis, however, indicated that this substance was a mixture of the expected compound XXIV and starting material XXIII. Therefore, 0.7 g. of this substance was again hydrogenated. A paper chromatogram of the reduction product showed only one ninhydrin-positive spot but elementary analysis showed that the substance was still not pure.

**Methyl ε-Carbobenzyloxy-L-lysinate Hydrochloride (XXV).**—To a suspension of 2.0 g. (0.072 mol.) of ε-carbobenzyloxy-L-lysine[20], m. p. 248~250°C (decomp.) in 15 ml. of methyl alcohol, 1.0 g. (0.084 mol.) of thionyl chloride was added dropwise at 0°C. The reaction mixture was permitted to stand one hour and a half in a water bath of 40°C and then twenty hours at 25°C. After evaporated to dryness in vacuo, water was added to a residue and evaporated again in vacuo. Addition of water followed by evaporation was repeated several times to remove the excess of thionyl chloride and hydrochloric acid. The residue was crystallized from 99% ethyl alcohol-ethyl acetate. Pure ester hydrochloride was obtained after recrystallization from the same solvent; weighted 2.0 g. (84%), m. p. 113~114°C (sintered at 111°C).

Found: C, 54.21; H, 6.80; N, 8.41; Cl, 10.99. Calcd. for $C_{15}H_{23}O_4N_2Cl$: C, 54.30; H, 7.24; N, 8.45; Cl, 10.71%.

**Benzyl ε-Carbobenzyloxy-L-lysinate Hydrochloride (XXVI).**—To a suspension of 1.7 g. (0.006 mol.) of ε-carbobenzyloxy-L-lysine[20] in 10 ml. of benzyl alcohol there was added dropwise at −10°C, 0.9 g. (0.0076 mol.) of thionyl chloride. The reaction mixture was permitted to stand at 40°C for four hours, and then at 29°C for twenty three hours. It was then concentrated in vacuo. Upon addition of ether, gelatinous precipitate formed, which was filtered off, washed with ether, and recrystallized from 99% ethyl alcohol-ether; weight 0.5 g., m. p. 131°C. A second crop of ester hydrochloride was obtained from the mother liquor by addition of more ether; weight 0.2 g. The total yield was 24%. A sample recrystallized from the same solvent for elementary analysis melted at 133~134°C.

Found: C, 61.34; H, 6.84; N, 6.98; Cl, 8.55. Calcd. for $C_{21}H_{27}O_4N_2Cl$: C, 61.98; H, 6.69, N, 6.89; Cl, 8.71%.

**Recovery of Dicyclohexyl Carbodiimide from Dicyclohexylurea.**—To 49.5 g. (0.22 mol.) of dicyclohexyl urea, 90 g. of pyridine and 43.9 g. (0.22 mol.) of *p*-toluenesulfonyl chloride were added. The reaction mixture was stirred for one and a half hours at 70~75°C, whereby a faintly yellow precipitate formed. After cooling, petroleum ether was added. The reaction mixture was filtered, and a small amount of triethylamine was added to the filtrate which was then boiled for one hour. A brown precipitate separated out and was filtered off. The filtrate was evaporated in vacuo to a syrup, which was distilled under reduced pressure. It solidified at room temperature; yield 31.8 g. (70%), b. p. 120~130°C/3 mmHg.

**Cleavage Reactions of α, γ-Glutamyl Peptides in Hot Water.**—Solutions of 200~300 mg. samples of α,γ-glutamyl diglutamic acid, α,γ-glutamyl diglycine, α,γ-glutamyl diaspartic acid, α,γ-glutamyl dileucine, γ-glutamyl glutamic acid and α-glutamyl glutamic acid in 20~30 ml. of distilled water were heated in a boiling water bath. An aliquot of each solution was chromatographed using *n*-butyl alcohol-acetic acid-water (4 : 1 : 2) as a developing solvent. The chromatograms were then sprayed first with bromothymol blue in 95% ethyl alcohol and then with ninhydrin in *n*-butyl alcohol. The original peptides were revealed by bromothymol blue as well as by ninhydrin except in the case of α,γ-glutamyl dileucine which showed coloration only with ninhydrin (Figs. 1—6).

In Fig. 1, the spot 1d is the original peptide XIV. After heating the solution for one hour at 100°C, pyrrolidone carboxylic acid (1b) and glutamic acid (1e) were formed. A spot (1c) is supposed to be pyroglutamyl glutamic acid because it was not colored by ninhydrin but only by bromothymol blue. The original peptide (1d) disappeared completely after seven hours. An unknown spot (1a) appeared after twenty-one hours' heating. In another experiment in which the solution was heated at 40°C, the original peptide (1d) was hardly decomposed at all even after one week (Fig. 1).

Fig. 2 shows that the peptide XX (2b) was

○: Ninhydrin coloration, ◌: Bromothymol blue coloration, PCA: Pyrrolidone carboxylic acid.

completely decomposed after eight hours, while glycine (2c) and pyroglutamyl glycine (2a) were formed. Spot 2a was an acidic substance like spot 1c without a free amino group and its structure was shown by the following experiment to be pyroglutamyl glycine. The peptide XX was refluxed with water for eight hours, and then Dowex 50 (H form) was added to the solution until a pH of 1.94 was reached. After filtration the filtrate was evaporated in vacuo to a syrup, which was shown by paper chromatography to be identical with 2a. This syrupy substance was hydrolyzed by 6 N hydrochloric acid at 100°C for eight hours. A two-dimensional paper chromatogram of the hydrolyzate showed two ninhydrin-positive spots of glutamic acid and glycine. Therefore, spot 2a must be due to pyroglutamyl glycine.

Fig. 3 shows the decomposition of the peptide XXIV. It was completely decomposed after twenty eight hours, while aspartic acid (3c) and pyroglutamyl aspartic acid (3a) began to appear after half an hour and three hours respectively.

The cleavage of the peptide XXII is shown in Fig. 4. A spot of the original peptide (4b) disappeared after seventeen hours, while pyroglutamyl leucine (4a) and leucine (4c) appeared.

In Fig. 5, spots 5a, 5b and 5c correspond to pyrrolidone carboxylic acid, original $\gamma$-glutamyl glutamic acid and glutamic acid, respectively. Pyrrolidone carboxylic acid (5a) appeared before glutamic acid (5c).

Fig. 6 shows that in contrast to the peptides in Figs. 1—5 $\alpha$-glutamyl glutamic acid (6b) could not be completely decomposed even after thirty-one hours, and that glutamic acid (6c) and pyroglutamic acid (6a) appeared only after weight and twenty-eight hours respectively.

**Reaction between Carbobenzyloxy Glutamic Acid and Dicyclohexyl Carbodiimide.**—A solution of 3.7 g. (0.018 mol.) of dicyclohexyl carbodiimide in 30 ml. of tetrahydrofuran was added to a solution of 5.0 g. (0.018 mol.) of carbobenzyloxy-L-glutamic acid in 30 ml. of tetrahydrofuran. A precipitate of dicyclohexyl urea separated out immediately. After stirring at room temperature (20°C) for four hours the dicyclohexyl urea was filtered off; weight 3.8 g., m. p. 228~229.5°C. The filtrate was evaporated to dryness in vacuo and the residue was dissolved in ethyl acetate. A small amount (0.2 g.) of undissolved dicyclohexyl urea was filtered off again. The total weight of dicyclohexyl urea obtained in the two crops was 4.0 g. It corresponds almost to the theoretical amount expected from the dehydration reaction. The filtrate was again evaporated to a syrup which could not be crystallized.

**Synthesis of Dibenzyl Carbobenzyloxy-$\alpha,\gamma$-L-glutamyl Diglycinate from Carbobenzyloxy-L-glutamic Anhydride.**—A solution of 2.6 g. (0.010 mol.) of carbobenzyloxy-L-glutamic anhydride[23], synthesized from carbobenzyloxy-L-glutamic acid and acetic anhydride, in 50 ml. of tetrahydrofuran was prepared. Solutions of 7.8 g. (0.023 mol.) of benzyl glycinate-*p*-toluenesulfonate[24] and 4.3 g. (0.023 mol.) of tri-*n*-butylamine in 100 ml. of tetrahydrofuran and of 2.3 g. (0.011 mol.) of dicyclohexyl carbodiimide in 10 ml. of tetrahydrofuran were then

added at room temperature. The reaction mixture was stirred for six hours and the crystal of dicyclohexyl urea was filtered off; weight 1.4 g. (56%), m. p. 228~230°C. While the filtrate was concentrated, a large amount of a crystalline material separated out, which was collected by filtration, suspended in 0.25 N aqueous sodium carbonate, filtered and washed carefully with water; yield 5.3 g. (92%), m. p. 145~149°C. This crystalline material was suspended in 50 ml. of 2 N hydrochloric acid, filtered, washed with water and then recrystallized from ethyl alcohol to give 4.2 g. of pure crystals, m. p. 152~154°C (sintered at 148°C). The infrared spectrum was identical with the one of the ester (XIX) prepared directly from carbobenzyloxy glutamic acid.

Found: C, 64.70; H, 5.84; N, 7.31. Calcd. for $C_{31}H_{33}O_8N_3$: C, 64.68; H, 5.78; H, 7.30%.

The authors wish to thank Mr. Kazunobu Ono for his assistance in the experiments, Dr. Hans J. Cahnmann, National Institutes of Health, U. S. A., for his generous advice on preparing this manuscript and Ajinomoto Co. Inc. for their kind gift of various amino acids.

# *Leaching of Andesite in Acid Media*

By Hiroshi KAMIYA

(Received June 2, 1960)

"Leaching" is a term often used in geology. There is little geochemical study on the leaching process of rocks.

In many epithermal deposits such as sulfur, iron sulfide, opal and alunite ores, the original host rocks have been altered with acid leaching and other processes, and transformed into various altered zones.

Leaching action of surface and ground waters takes part in weathering processes at ordinary temperature and pressure.

As a result, it is important to investigate under natural conditions the behavior of chemical elements, which are abundant in the host rocks as constituents of rock-forming minerals, in order to consider the mechanism of weathering and the alteration of host rocks in the zone of oxidation.

In the study on the behavior of chemical elements, the concept "mobility" has been introduced by many investigators. The relative mobility of some elements in hydrothermal condition has been established by Bakhmutov[1]. Moreover, in weathering processes including leaching, migration and fixation of constituents of the host rocks by actions of ground and surface waters, their mobilities have been discussed[2].

Mobility defined in this way is affected by pH and oxidation-reduction potentional of the environments and many other factors.

Elements may move not only as ions, but as colloids or detrial fragments of original minerals. The movement of the elements as emanation, moreover, may take place, where volcanic gasses take part in the formation of altered rocks.

The above-mentioned discussions are based on no theory or experiments but on field data and observations, as well as on the analysis of natural substances.

The initial processes of both alteration and weathering are chemical and physical decompositions of rocks. Concerning this, solubility of rocks and minerals in water has been measured[3-5].

The present experiment was carried out to investigate what mobility the constituents of rock-forming minerals have, as mainly ions in various acid media in the presence of a sufficient quantity of air.

It is the aim of this study to obtain quantitative data on a leaching action which may play a serious role in weathering and alteration of rocks in the zone of oxidation.

## Experimental

**Sample.**—Like other sulfur deposits, various kinds of altered rocks consisting of secondary minerals, such as opal, alunite and kaoline, were found around sulfur ore bodies of Ogushi Mine in Gumma Prefecture.

It has been recognized there that one of the original host rocks thus hydrothermally altered is augite hypersthene-andesite. The least altered andesite was powdered to 150~200 meshes and used for the present leaching experiment. The chemical composition and mode of the andesite are shown in Tables I and II.

TABLE I. CHEMICAL COMPOSITION OF ANDESITE

| Constituent | Content (%) |
|---|---|
| $SiO_2$ | 55.8 |
| $Al_2O_3$ | 18.8 |
| FeO | 4.1 |
| $Fe_2O_3$ | 3.4 |
| MgO | 3.8 |
| CaO | 7.5 |
| $Na_2O$ | 2.1 |
| $K_2O$ | 1.0 |
| $H_2O$ (−) | 3.0 |
| $H_2O$ (+) | 1.4 |
| Total | 100.9 |

TABLE II. VOLUME PERCENTAGE OF THE CONSTITUTENTS OF THE ANDESITE

| | | |
|---|---|---|
| Phenocryst | Plagioclase | 38 |
| | Hypersthene | 9 |
| | Augite | 8 |
| | Magnetite | 5 |
| Groundmass | | 33 |
| Alteration product | | 7 |
| Total | | 100 |

**Equipment.**—A polyethylene 500 ml. bottle, which contained 200 ml. of leaching acid or water to suspend the powdered sample, was placed on a water bath. This leaching bottle was fitted with a two-hole rubber stopper carrying a polyethylene tube of 5 mm. diameter attached to a flow-meter of air through a washing bottle and reached nearly to the bottom of the leaching bottle so that the leaching acid or water in it would be well stirred by the introduction of air, and also carrying a condenser connected to an aspirator.

For all equipment polyethylene was used because glass could introduce silica and sodium.

**Procedure.**—The flow of air was regulated with the aspirator so that the air would be bubbled through the solution at the rate of 2 l. per minute.

As its temperature was raised up to approximately 90°C, 2 g. of the powdered sample was suspended in it. The leaching experiments were carried out at 90±3°C.

After 5 min., 30 min., 1, 2 and 3 hr. from addition of the sample, the treatment was stopped immediately, and the leachates were centrifuged and analyzed.

For this experiment were used 0.1, and 0.01, 0.001 N sulfuric acids and distilled water.

**Analytical Method.**—The leachates were analyzed for silica, aluminum, iron, calcium, magnesium, sodium and potassium which are abundant in the rock.

1) *$SiO_2$.*—Silica was determined colorimetrically by a molybdenum blue method which would determine only dissolved silica, but no colloidal silica.

2) *Fe.*—Colorimetric estimation of total iron was carried out by reduction of all the iron to ferrous state, using hydroxylamine, and then by measurement of transmittance of a red color developed with $\alpha, \alpha'$-dipyridyl. Ferrous iron was determined by adding $\alpha, \alpha'$-dipyridyl with no reducing agents, reading the transmittance and comparing with a calibration curve. Ferric iron was determined by difference from the sum of the two.

3) *Al.*—Total iron and aluminum was detemined by back titration of a small excess of EDTA with a standard zinc sulfate solution using dithizone as an indicator after addition of sodium acetate buffer. Then, aluminum was determined from the amount of total iron and aluminum after deducting the amount of iron obtained by colorimetric method.

4) *Ca and Mg.*—Total calcium and magnesium were determined by titrating with EDTA in the presence of Eriochrome Black T at pH 10 after removal of iron and aluminum. Next calcium was determined by titration with EDTA using NANA* indicator in strong alkaline solution, and finally the amount of magnesium was calculated by subtracting the amount of calcium from the combined amount.

5) *Na and K.*—Sodium and potassium were determined by means of flame photometry.

## Results and Discussion

**Leaching of Seven Constituents.**—The amounts of seven constituents, $SiO_2$, Al, Fe, Ca, Mg, Na and K leached out of 2 g. sample with sulfuric acid or water at 5 min., 30 min., 1, 2 and 3 hr., respectively, after starting the leaching are arranged in Table III. They are plotted against time in Fig. 1.

As change in pH of the leaching media might have an influence on the leaching, it was desirable to keep the pH of them constant and to maintain the original leaching conditions. However, the experiment under pH-constant condition was not carried out, because the use of buffer solutions, for instance, would make it difficult to detect small amount of constituents leached out of the rock and have an effect on the leaching. Ranges from initial to final pH of the leaching acid or water are given in Fig. 1.

Among the constituents leached, only silicon

* NANA is a commercial name which has chemical formula of 2-hydroxy-1-(2'-hydroxy-4'-sulfo-1-naphthylazo)-3-naphthoic acid.

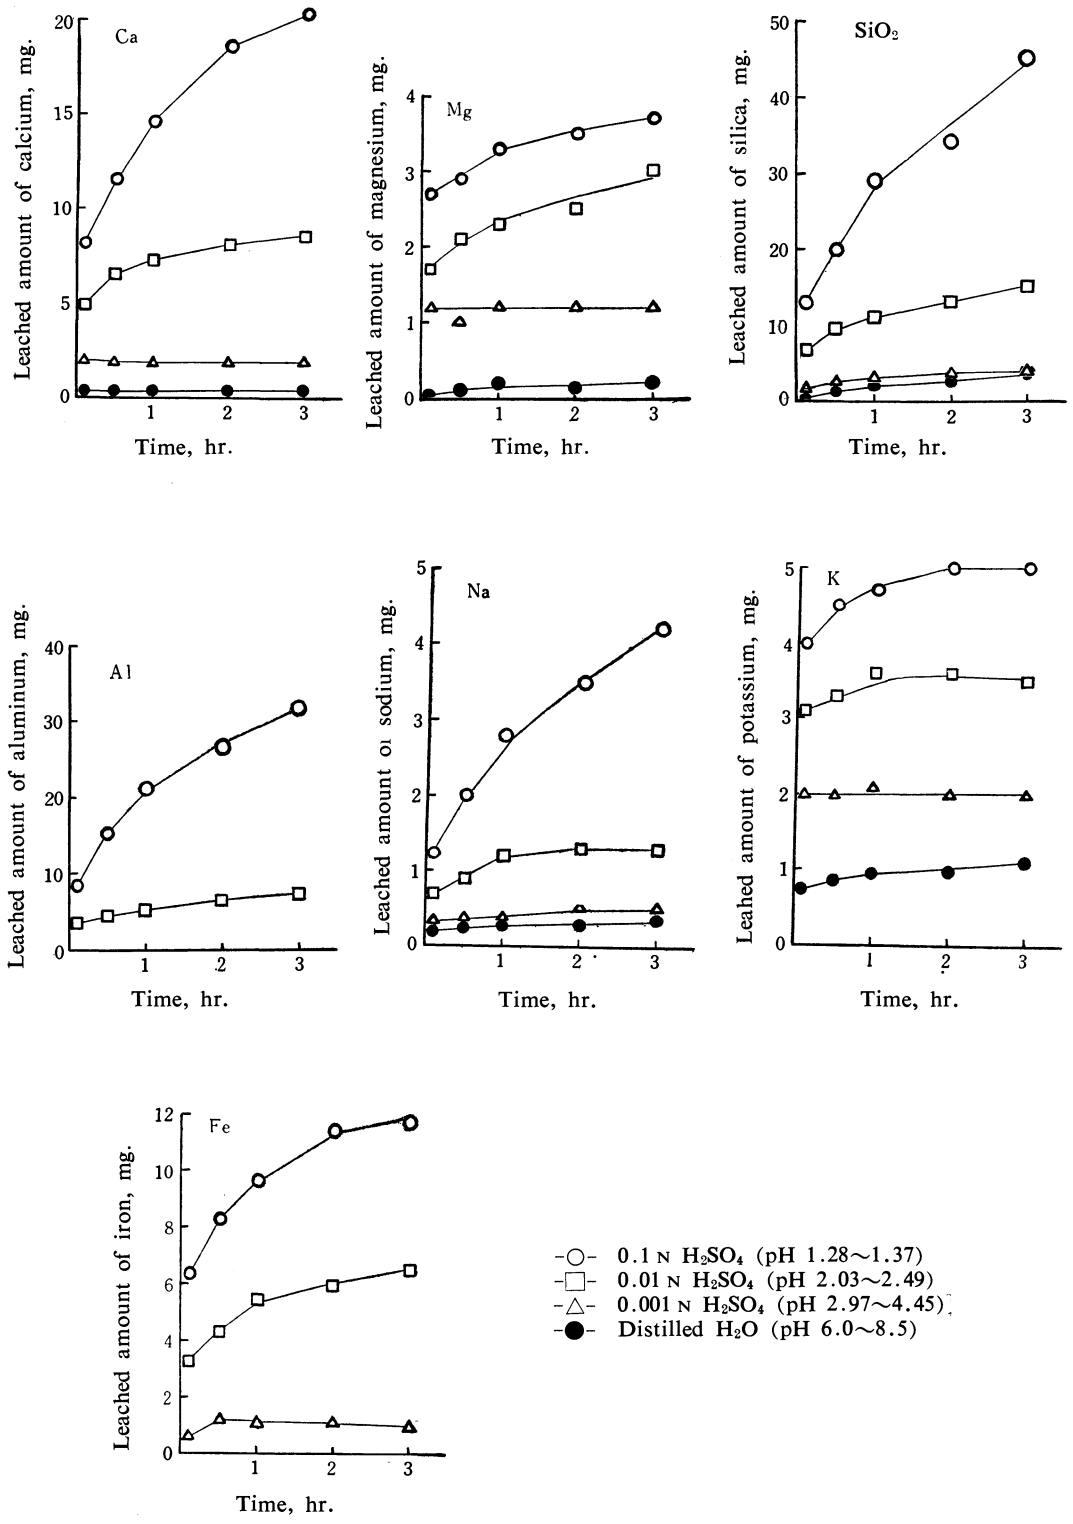

Fig. 1. Leaching-curve of seven constituents plotted against time.

TABLE III. SEVEN CONSTITUENTS LEACHED OUT OF 2 g. POWDERED SAMPLE WITH 200 ml. SULFURIC ACID AND WATER

| | Time | Na (mg.) | K (mg.) | Ca (mg.) | Mg (mg.) | $Fe^{2+}$ (mg.) | $Fe^{3+}$ (mg.) | Al (mg.) | $SiO_2$ (mg.) | pH |

| (pH 6.0) | 1 hr. | 0.28 | 0.95 | 0.2 | 0.2 | <0.05 | — | 0.2 | 2.2 | 8.2 |
| | 2 hr. | 0.28 | 0.97 | 0.3 | 0.1 | <0.05 | — | 0.2 | 2.8 | 8.5 |
| | 3 hr. | 0.34 | 1.1 | 0.3 | 0.2 | <0.05 | — | 0.2 | 3.6 | 8.5 |

is represented as $SiO_2$, because it would be leached in the form of oxide[6].

As shown in Fig. 1, time of leaching, generally, tends to increase the amount of constituents leached. The leaching is very rapid for an initial stage of the experiment, but becomes retarded gradually later, as the concentration of constituents in the leachate appears to approach the limit of their solubility in the leaching acid or water.

The lower pH of the leaching media is, the larger initial leached amount and its increment are. At a high pH of the leaching media such as 0.001 N sulfuric acid and distilled water, time of leaching hardly increases the initial leached amount of several constituents.

The rock contains both ferrous and ferric irons. There existed more ferrous than ferric iron in the leachate of 0.1 N sulfuric acid, and in the leachate of 0.01 N and 0.001 N sulfuric acids and distilled water ferric iron was hardly detected. As the leached ferrous iron might be oxidized to ferric state by bubbled air, it should not be concluded that all the ferric iron in the leachate came only of one kind in the rock. Therefore, the leaching curve of total iron is drawn without a distinction between ferric and ferrous irons in Fig. 1.

With 0.001 N sufuric acid the leaching of iron proceeds during the first 30 min. of the experiment, but prolongation of it decreases its amount in the leachate. This decrease may be caused by reprecipitation of iron once leached owing to an increase of pH.

**Initial Leaching.**—As already described, the initial leaching is very rapid. A considerable amount of constituents was leached out of the rock even during the first 5 min. of experiment.

Each straight line, which is drawn through the first two points representing the leached amount at 5 and 30 min. on the curves given in Fig. 1, does not pass through the origin, but intercepts the axis of the leached amounts. The value of this interception may be thought to correspond to the initial leached amount. In 0.1 N sulfuric acid, for example, this amount of potassium reached 80 per cent of its amount leached up to the end of the experiment.

The initial leaching ratio, that is, the ratio of the initial leached amount of each constituent, obtained in this way, to its content in the original rock was calculated. In Fig. 2 these ratios are plotted against initial pH of the leaching acid or water used for the experiment.

Fig. 2 shows that the initial leaching ratio of every constituent decreases with an increase of pH. The ratio of potassium is the largest among the constituents under the experimental conditions, that is, at pH range 1 to 6. On the contrary, that of silica is the smallest. The ratio of sodium belongs to a rather small

6) H. Mukaiyama, *Min. Geol.*, 4, 195 (1954).

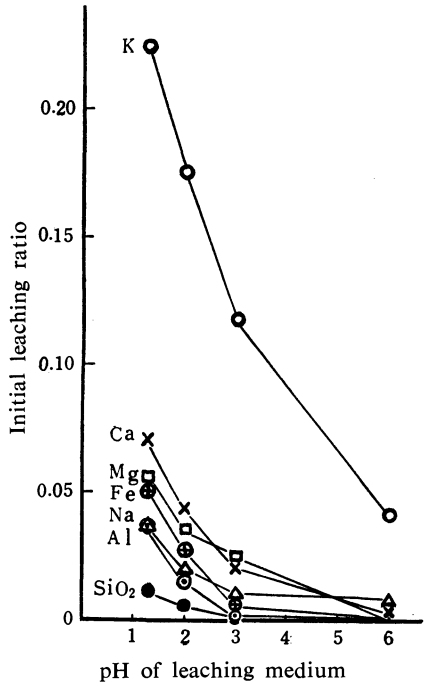

Fig. 2. Relation between initial leaching ratio and pH of leaching medium.

group at low pH, but is large next to that of potassium at pH 6.

Above pH 3 the ratios of aluminum and iron are much the same to that of silica.

**Increasing Rate of Leached Amount.** — The leaching of the constituents out of the rock proceeds at a certain increasing rate, whereupon it becomes gradually retarded.

During three hours of the leaching experiment an average increment per hour of the amount of each constituent excepting the initial leached amount was obtained from the curve in Fig. 1. This increasing rate expresses an average slope of the curve which passes through the five points corresponding to the amount leached at each time.

The ratio of this rate to the content of each constituent in the rock was calculated and plotted against the intermediate value of initial and final pH of the leaching acid or water in Fig. 3.

With an increase of pH, the increasing ratio defined in this way has the same tendency to decrease as the initial leaching ratio has. However, the increasing rate of several constituents is too small to be recognized in 0.001 N

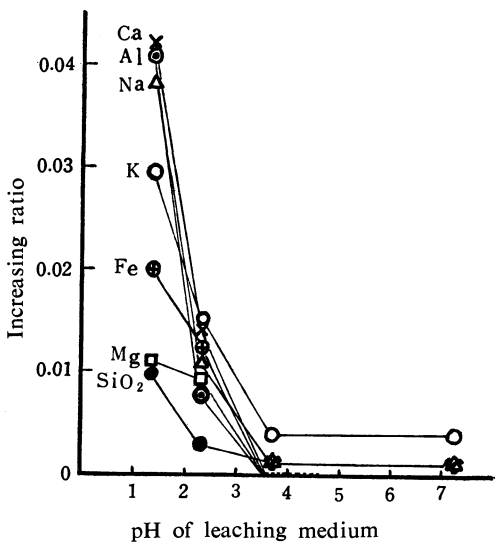

Fig. 3. Relation between increasing ratio and pH of leaching medium.

sulfuric acid and distilled water. In general, the leaching of all the constituents out of the rock is retarded at high pH. For this reason a small increasing rate need not be discussed in detail.

The curves of the increasing ratio in Fig. 3 differ somewhat from the curves of the initial leaching ratio in Fig. 2.

At pH 1 calcium, aluminum and sodium refer to a group of large ratio, next to which are potassium and iron. The ratio of magnesium and silica are small at this pH. Raising of pH changes the order of the ratios at pH 1. At pH 2 aluminum, which has a large ratio at pH 1, belongs to a group of smaller ratio, and on the other hand potassium is the top of them. Magnesium has less difference of the ratio than other constituents at pH range 1 to 2.

**A Comparison between Initial Leaching Ratio and Increasing Ratio.**—In Table IV are given the following ratios of each constituent at pH's 1 and 2.

$$\frac{\text{Increasing ratio (shown in Fig. 3)}}{\text{Initial leaching ratio (shown in Fig. 2)}}$$

Table IV shows that the leaching of potassium is very rapid at an initial stage but becomes retarded soon, that is, the average slope of its leaching curve is less steep than the other constituents in Fig. 1, and that on the contrary

Table IV. Increasing ratio/initial leaching ratio

| | Na | K | Ca | Mg | Fe | Al | $SiO_2$ |
|---|---|---|---|---|---|---|---|
| 0.1 N-$H_2SO_4$ | 1.1 | 0.1 | 0.6 | 0.2 | 0.4 | 1.1 | 0.9 |
| 0.01 N-$H_2SO_4$ | 0.6 | 0.1 | 0.3 | 0.3 | 0.4 | 0.5 | 0.6 |

the increasing rate of sodium, aluminum and silica is superior to the initial leaching.

As a result, every constituent has a characteristic initial leaching ratio and increasing ratio which may depend on mineral composition of the rock or other factors.

The least mobility of silica in the present experiment agrees in Shimada's conclusion that action of sulfuric acid could cause aluminum, iron etc. originally present in rocks to be removed leaving silica to form siliceous rocks[7].

Though a leaching process of rocks would be very complicated under natural conditions, the effect of pH on it is the most important one of many environmental factors.

The writer wishes to express his indebtedness to Professor K. Noguchi for having been good enough to read this manuscript, to Dr. T. Sudo for helpful advice and encouragement and to Dr. J. Ossaka and Mr. M. Ichikuni for help and advice with regard to the analytical techniques. His acknowledgement is also due to the staff of the Ogushi Mine for help in the collection of specimens.

# SHORT COMMUNICATIONS

## *Chlorination of Guaiacol Relating to Bleaching Mechanism of Pulp*

By Koichiro SATO and Hiroshi MIKAWA

(Received September 6, 1960)

To make clear the mechanism of chlorination of lignin by an aqueous chlorine solution, chlorination of lignin and model compounds[1] have been investigated since some years ago.

In advance of the investigation of the behavior of complex lignin-like models against aqueous chlorine solution, guaiacol was investigated first. Because, it is expected that this simple case will show the fundamental principle of the chlorination reaction of the benzene nucleus.

As quite recently C. Dence and K. Sarkanen[2] have reported similar investigations, the results obtained in our laboratory till now are summarized and reported briefly as follows.

A homogenous aqueous solution of guaiacol (128 g. guaiacol in 7 l. of water) was treated 7.5 l. of aqueous chlorine solution (molar ratio 1 : 1) for about 1/2 hr. at 0°C. A small amount of sodium sulphite solution was added to destroy the excess of remaining chlorine or hypochlorous acid if any, and the pH of the solution was adjusted to nine with sodium hydroxide. Sodium borohydride was added in order to reduce the quinoidal structure to pyrocatechol structure to prevent the polymerization of quinoidal structure if any. Then, the solution was acidified, resinous products separated (I), and the whole was extracted continuously with chloroform (II) followed, by ether (III).

I and II were distilled in vacuo into four fractions respectively, each fraction was examined gas chromatographically, and the fractions containing similar components were combined.

From the five fractions thus obtained the following compounds were separated and identified.

1) Guaiacol: The compound was separated as 3, 5-dinitrobenzoate, m. p. 137~139°C, which was not depressed on admixture with the authentic sample. (Found: $OCH_3$, 10.25. Calcd. for $C_{14}H_{10}O_7N_2$: $OCH_3$, 9.75%.)

2) 5-Chloroguaiacol*: The compound was separated as 3, 5-dinitrobenzoate, m. p. 170~171.5°C, which was not depressed on admixture with the authentic sample. (Found: C, 47.71; H, 3.20; Cl, 10.08; $OCH_3$, 8.77. Calcd. for $C_{14}H_9O_7N_2Cl$: C, 47.68; H, 2.55; Cl, 10.07; $OCH_3$, 8.79%.)

3) 4, 5-Dichloroguaiacol: White needles, m. p. 71~73°C, which was not depressed on

2) C. Cence and K. Sarkanen, *Tappi*, **43**, No. 1, 83 (1960).

* Named according to Beilstein's Handbook.

admixture with the authentic sample. (Found: C, 43.68; H, 3.29; Cl, 36.65. Calcd. for $C_7H_6O_2Cl_2$: C, 43.55; H, 3.13; Cl, 36.74%.)

4) Trichloroguaiacol: Pale yellow needles, melting at 103~106°C. (Found: C, 37.58; H, 2.41; $OCH_3$, 13.91. Calcd. for $C_7H_5O_2Cl_3$: C, 36.94; H, 2.21; $OCH_3$, 13.62%.) The positions of chlorine atoms are not settled as yet.

5) 3, 3'-Dimethoxy-4,4'-dihydroxydiphenyl: White prisms, melting at 166~167°C. (Found: C, 67.71; H, 5.73; $OCH_3$, 25.75; Cl, 0.00. Calcd. for $C_{12}H_8O_2(OCH_3)_2$: C, 68.28; H, 5.73; $OCH_3$, 25.21%). Diacetyl derivative, melting at 200.5~202°C. (Found: C, 65.35; H, 5.95; mol. wt. (Rast), 336. Calcd. for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%; mol. wt., 330.32). Dimethyl derivative (biveratrol), melting at 132~133°C. (Found: C, 69.85; H, 6.72; mol. wt. (Rast), 273. Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%; mol. wt., 274.30).

Melting points of the diphenyl and its two derivatives agree well with the values reported in literatures[3,4]. The diphenyl has one phenolic hydroxyl group per methoxyl group, according to the so-called $\Delta\varepsilon$-method of Aulin-Erdtman[5].

From the fraction III the following compounds were separated and identified.

1) Pyrocatechol: White prisms, melting at 103.5~104.5°C, undepressed on admixture with the authentic sample. (Found: C, 65.33; H, 5.54. Calcd. for $C_6H_6O_2$: C, 65.44; H, 5.49%.)

2) 3-Chloropyrocatechol: The compound was isolated as mono carboxymethyl ether, melting at 122~123.5°C, undepressed on admixture with the authentic sample of 3-chlorocatechol monocarboxymethyl ether. (Found: C, 47.70; H, 3.71; Cl, 17.71. Calcd. for $C_8H_7O_4Cl$: C, 47.43; H, 3.46; Cl, 17.52%). The position of the carboxymethyl group of the mono-ether is not determined. Diether was not prepared, as it was found to be difficult to etherify both hydroxyl groups of 3-chloropyrocatechol by an usual method.

Results so far obtained on the effects of aqueous chlorine water on the guaiacol nucleus are summarized as follows:

1) Methoxyl group is demethylated to give methanol in high yield[1].

2) Isolation of pyrocatechol suggests that demethylation can occur without introduction of any chlorine atoms into the nucleus.

3) One to three chlorine atoms are introduced without cleavage of methoxyl groups.

4) It seems therefore to be probable that chlorination of the nucleus and the demethylation of methoxyl group are independent reactions.

5) Guaiacol dimerizes by dehydrogenation.

Details of this work will be published later.

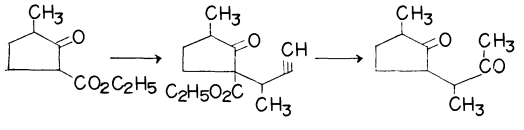
## *The Synthesis of dl-Nepetalactone*

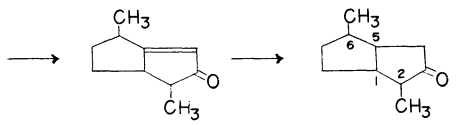
By Takeo SAKAN, Akira FUJINO,
Fujio MURAI, Akio SUZUI
and Yasuo BUTSUGAN

(Received September 10, 1960)

The authors wish to report the synthesis of *dl*-nepetalactone, the levorotatory form of which was first isolated in 1941 from the oil of catnip plant, *Nepeta cataria* L., by S. M. McElvain et al.[1], and was later shown clearly to be I[2,3].



I



Ethyl 3-methyl-2-oxocyclopentanecarboxylate[4] (II) was condensed with 3-bromobutyne[5] to give III, b. p. 99°C/1 mmHg ($\nu_{C\equiv C}$ 4.72 $\mu$, $\nu_{C=O}$ 5.72 $\mu$, 5.86 $\mu$), which was, after hydration, hydrolyzed to diketone IV, b. p. 86°C/1 mmHg (Found: C, 70.97; H, 9.44. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%) ($\nu_{C=O}$ 5.78 $\mu$, 5.86 $\mu$). IV was converted through intramolecular condensation into bicyclic $\alpha,\beta$-unsaturated ketone V, b. p. 66~70°C/1 mmHg ($\lambda_{max}^{EtOH}$ 240 m$\mu$, $\varepsilon=21{,}000$; $\nu_{C=O}$ 5.88 $\mu$, $\nu_{C=C}$ 6.01 $\mu$). Semicarbazone: m. p. 188~189°C; 2, 4-dinitrophenylhydrazone: m. p. 213°C. Catalytic hydrogenation of V afforded saturated ketone VI, b. p. 72~75°/2 mmHg (Found: C, 78.57; H, 10.57. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59%) ($\nu_{C=O}$

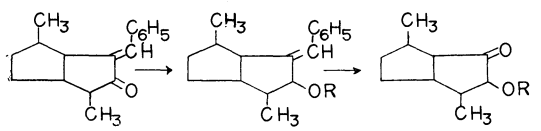
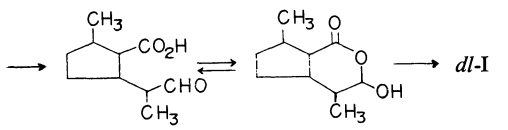
5.78 $\mu$), likely fulfilling the stereochemical requirements ($H_{(C-1)}-H_{(C-5)}-H_{(C-6)}$: cis-trans). 2, 4-Dinitrophenylhydrazone of VI: m. p. 87~88°C.



II III IV

V VI



To make sure the above stereospecificity, the benzylidene derivative (VII), b. p. 110~120°C/0.005 mmHg ($\lambda_{max}^{EtOH}$ 303 m$\mu$, $\varepsilon$=13,000; $\nu_{C=O}$ 5.86 $\mu$, $\nu_{C=C}$ 6.18 $\mu$) (2, 4-dinitrophenylhydrazone: m. p. 181~182°C), of VI was ozonolyzed. A dicarboxylic acid, $C_{10}H_{16}O_4$ (Found: C, 60.29; H, 8.29. Calcd.: C, 59.98; H, 8.05%), m. p. 124.5~126°C, was obtained as an oxidation product. As the IR spectrum of this compound in carbon disulfide was in good accord with that of one (m. p. 85°C[3]) of nepetalinic acids, the acid in hand was distinctly racemic *cis-trans*-nepetalinic acid (m. p. in lit.[6]: 127°C).

Then VII was reduced with sodium borohydride to unsaturated alcohol VIIIa, b. p. 110~128°C/0.015 mmHg ($\nu_{OH}$ 2.98 $\mu$). Acetylation of VIIIa yielded a crystalline acetate (VIIIb), m. p. 120~121°C (Found: C, 79.90; H, 8.55. Calcd. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51%) and an oily one (VIIIb'), b. p. 105~108°C/0.025 mmHg (Found: C, 80.09; H, 9.00%) ($\nu_{C=O}$ 5.77 $\mu$), the latter predominating much over the former.

VII VIII IX

a: R=H, b, b': R=COCH$_3$

$X_A$ $X_B$

When VIIIb was, after ozonolysis and hydrolysis, oxidized with permanganate, a dicarboxylic acid, $C_{10}H_{16}O_4$ (Found: C, 60.11; H, 8.26%), m. p. 158~159°C, was the only product, which showed an IR absorption undoubtedly different from that given by either of the nepetalinic acids (m. p. 85°C and m. p. 117~118°C). Therefore, the crystalline acetate might result from the ketone of cis-cis-series corresponding to VI, formed in a small quantity in the process IV → V → VI.

VIIIb' was ozonolyzed to $\alpha$-acetoxyketone IXb, b. p. 70~73°C/0.05 mmHg (Found: C, 68.17; H, 8.84. Calcd. for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%). On treatment with diluted alkali, IXb afforded $\alpha$-ketol IXa ($\nu_{OH}$ 2.89 $\mu$, $\nu_{C=O}$ 5.80 $\mu$), which was too unstable to be distilled, and was immediately oxidized with periodate to aldehyde carboxylic acid $X_A$. The product, with some charactor of lactol $X_B$, was dehydrated to *dl*-nepetalactone (*dl*-I), b. p. 135°C (bath temp.)/7 mmHg ($\nu_{C=O}$ 5.68 $\mu$, $\nu_{C=C}$ 5.93 $\mu$) by heating at about 200°C. The synthesized lactone accorded in all respects with the natural lactone in their IR charts except only a slight difference of the absorption intensities near 11.4 and 12.2 $\mu$.

The authors are grateful to Professor S. M. McElvain for his kind offer of the spectrum chart of nepetalactone for the identification.

## *Retention of Mn-56 in Neutron-irradiated Potassium Permanganate*

By Hirotoshi SANO

(Received October 27, 1960)

Although the behavior of radioactive manganese atoms produced by $(n, \gamma)$ reaction on permanganate has been studied by several investigators[1,8,9], no information is available on the effect of irradiation temperature on the retention of radio manganese as permanganate. It has been reported that the retention tends to decrease as the irradiation temperature lowers down to dry-ice or liquid-nitrogen temperature in various inorganic salts such as

A seriess of experiments have been carried out by the present author to study the effect of temperature on retention of recoil radio manganese as permanganate. About one-half gram of potassium permanganate in small crystals was placed in separate glass tubes. For low temperature bombardments, the glass tubes were dipped in either liquid nitrogen or dry-ice–etheanol, while they were warmed by preheated oil for high-temperature bombardments. The samples were exposed for two to three hours to neutrons at a flux of ca. $10^7$ $n/cm^2$ sec. The maximum energy of neutrons produced by Be–D reaction was ca. 7 MeV. All bombardments were made in the presence of air. Following the bombardments, the samples were dissolved in distilled water and mixed with a small amount of manganese sulfate solution. The resulting manganese dioxide was filtered through a paper filter without suction. Both the precipitate and the filtrate were reduced with sodium sulfite. The activity of the resulting solution was measured with a dipping type G-M counter, and decay curve was determined. In another series of experiments, the samples were bombarded for 1 to 1.5 hr. at room temperature and then stored for nearly two hours at various temperatures. They were treated in the same way as described above. The results are summarized in Tables I and II.

It is worth mentioning that the bombardment at dry-ice–ethanol or liquid-nitrogen temperature always resulted in slightly higher retentions than the room temperature bombardment did. The results seem to be peculiar as compared with these obtained for other inorganic salts[2-7], in which the retension tends to decrease as the temperature lowers. The bombardment at 90~190°C resulted in highest retentions. This is probably due to an effect similar to thermal annealing. It is seen from Table II that the storage at dry-ice–ethanol or liquid-nitrogen temperature has little effect on the retention.

The author acknowledges the helpful advice given by Professor Nobufusa Saito, and the Institute of Physical and Chemical Research for irradiating samples.

# *Transport Behavior of Some Inorganic Cations across Ion-exchange Membranes. Preferential Impermeability of Barium Ions across Sulfonic Acid Membrane*

By Takeo YAMABE, Manabu SENŌ, Tatuo TANAKA and Ichiro KAMII

(Received September 20, 1960)

It appears to be generally accepted that the permselectivity of a given ion across ion-exchange membranes is closely related to the selectivity of the ion in the ion-exchange equilibria, while the mobilities of ions in solution and membranes are one of the most important factors that have effects on the permeability. In fact, as shown already by one of the authors[1], the order of the permselectivity of cations across a heterogeneous sulfonated styrene cation-exchange membrane[2] is as follows: $H^+ > K^+ > NH_4^+ > Ca^{2+} > Mg^{2+} > Na^+$, and it was recognized that the ion with the larger mobility and the larger selectivity in the ion-exchange reaction possesses the larger permselectivity. In the present communication, it is reported that barium ions show a peculiar transport behavior in the electrodialyses using ion-exchange membranes. As shown in Table I, barium ions show an extraordinarily small permeability, in spite of their very large selectivity in the ion-exchange equilibria.

TABLE I. PERMSELECTIVITIES OF ALKALI-EARTH METAL IONS

| Ions | Permselectivity* | Selectivity of ion-exchange** | Mobility in inf. dil. soln. |
|---|---|---|---|
| M | $T^M_{Na}$ | $K^M_{Na}$ | cm²/V. sec. |
| $Ca^{2+}$ | 1.24[7] | 2.60 | $5.29\times10^{-4}$ |
| $Mg^{2+}$ | 1.13[1] | 1.66 | 4.66 〃 |
| $Ba^{2+}$ | 0.70 | 5.81 | 5.70 〃 |

* Experimental conditions used: Current density 0.02 amp./cm², concentration of stock solution (2-component, ratio 1 : 1) 0.1 N, time 2∼4 hr.

** Data of O. D. Bonner et al. on Dowex 50 X8[8].

This result may be interpreted as follows: The large selectivity of barium ions is owing to the formation of a complex salt with the sulfonated group which dissociates scarecely, resulting in the relatively small concentration of barium ions in unrestricted state[3]. The small concentration of free ions in membranes leads to their small permselectivity. In general, the most predominant factors in determining the permeability of ions across membranes are the mobility and the concentration of unbound ions in membranes, but not the selectivity in the ion-exchange equilibria. The transport behavior of barium ions is one of the confirmative evidences for the deduction and it is also supported by the permeability of some heavy metal ions[6].

The experimental procedure was the same as those given in the preceding papers[1,7], i. e., from the electrodialysis data using a multi-compartment cell with cation- and anion-exchange membranes alternatively, the permselectivity coefficients were calculated according to the equation

$$T^B_A = \left(\frac{t^+_B - t^-_B}{t^+_A - t^-_A}\right) \Big/ \left(\frac{c_B}{c_A}\right) = \frac{r_B - 1}{r_A - 1}$$

where $t^+_A$ and $t^+_B$ are the transport numbers of ion A and B across a cation-exchange membrane, $t^-_A$ and $t^-_B$ are those across an anion-exchange membrane, $c_A$ and $c_B$ are concentrations of ion A and B in the stock solution and $r_A$ and $r_B$ are concentration ratios of ion A and B obtained directly from experimental data. If transport numbers of cations across an anion-exchange membrane are small and remain nearly constant, independently of the kind of cations, this coefficient should be a mesure of the permselectivity of given cations across a cation-exchange membrane. It will be permissible to think that this conditions is fulfilled in this experiment.

## *Molecular Rotations of Polyhydroxycyclohexanes in Relation to their Structures*[1]

By Shukichi YAMANA

(Received November 5, 1960)

Availability of PM-method[2] for the case of $[M]_D^{20}(W)$[3] of polyhydroxycyclohexanes of C1 conformation was tested here. Names of several substances under discussion, together with the orientation of the unit groups, (OH), in their molecules and their $[M]_D^{20}(W)$ are shown in Table I[4]. At first, by using the theoretical

1) Presented at the Symposium on the Structural Chemistry of the Chemical Society of Japan, Sapporo, August 5, 1960.

2) S. Yamana, This Bulletin, **31**, 558 (1958).

3) $[M]_D^{20}$ (W) is a notation which represents the optical molecular rotation of the plane polarized light of wavelength of D-line at 20°C by an aqueous solution of an optically active substance. $[\mu]_{D\,obs}^{20}$ means a corresponding partial molecular rotation which is caused by the dynamical coupling effect between any two members of unit groups in the molecule.

$$\therefore \quad [M]_D^{20}(W) = \sum [\mu]_{D\,obs}^{20} = \sum_{i \neq k} \zeta_i \zeta_k [\mu]_{D\,calcd}^{20}$$

(Ref. Eq. 3 in the previous paper[2]). Here, $[\mu]_{D\,calcd}^{20}$ is the calculated value by using Kirkwood's theoretical formulae and $\zeta_i$ and $\zeta_k$ are adjustable parameters.

4) The central group, cyclohexane-ring, does not appear in the calculation.

TABLE I

| Name Cyclohexane | Orientation of unit group, (OH) | Obs. $[M]_D^{20}$(W)[5] | Calcd. $\sum[\mu]_{Dobs}^{20}$[12] | Calcd. Whiffen[9] |

| 3α | 0 | 0 | $B$ | 0 | 0 | $A$ | | | | |
| 3β | 0 | 0 | 0 | $-B$ | $A$ | $-A$ | | | | |
| 4α | $B$ | 0 | $A$ | $-A$ | | | | | | |
| 4β | 0 | $-B$ | $-A$ | 0 | | | | | | |
| 5α | 0 | $A$ | | | | | | | | |
| 5β | $A$ | $-A$ | | | | | | | | |

Note :

| | $[\mu]_{Dcalcd}^{20}\{3/(n^2+2)\}$ | $[\mu]_{Dobs.}^{20}$ |
|---|---|---|
| $A$ | 11.73 (6.50)[12] | 42.7 (42.7) |
| $B$ | 1.88 (1.66) | 6.8 (10.9) |

formulae of Kirkwood[10], all $[\mu]_{Dcalcd}^{20}\{3/(n^2+2)\}$'s possible in the molecule were calculated[11] and given in Table II. Next, by using these values of $[\mu]_{Dcalcd}^{20}\{3/(n^2+2)\}$ and an adjustable parameter, $\zeta_{OH}$, the following equation was obtained.

$[M]_D^{20}$(W) of (−)1, 3/2, 4 tetrol, −42.7 $\equiv\sum[\mu]_{Dobs}^{20}$ of (−)1, 3/2, 4 tetrol $=(1\beta)\,\bar{\times}\,(2\alpha)+(1\beta)\,\bar{\times}\,(3\beta)+(1\beta)\,\bar{\times}\,(4\alpha)+(2\alpha)\,\bar{\times}\,(3\beta)+(2\alpha)\,\bar{\times}\,(4\alpha)+(3\beta)\,\bar{\times}\,(4\alpha)$[13] $=\{(n^2+2)/3\}\zeta^2_{OH}\{(1\beta)\times(2\alpha)+(1\beta)\times(3\beta)+(1\beta)\times(4\alpha)+(2\alpha)\times(3\beta)+(2\alpha)\times(4\alpha)+(3\beta)\times(4\alpha)\}$[14] $=\{(n^2+2)/3\}\zeta^2_{OH}(-11.73+0+0+11.73+0-11.73)$

$$\therefore\quad \zeta^2_{OH}=3.6402\{3/(n^2+2)\}$$

or

$$\zeta_{OH}=1.9079\{3/(n^2+2)\}^{1/2}$$

The values of $A$ and $B$ for $[\mu]_{Dobs}^{20}$ in Note of table II, can be obtained by multiplying those for $[\mu]_{Dcalcd}^{20}\{3/(n^2+2)\}$ by $\zeta^2_{OH}\{(n^2+2)/3\}$. By using the values of $[\mu]_{Dobs}^{20}$ in Table II, $\sum[\mu]_{obs}$ of all polyhydroxycyclohexanes were calculated and given in the fourth column of Table I. Referring to Table I, it becomes apparent that PM-method is more suitable one to estimate $[M]_D^{20}$(W) of polyhydroxycyclohexanes than Whiffen's method[9], especially when the optical center is located at the center of mass of a bond.

The author wishes to express his sincere thanks to Professor T. Yamamoto, Kyoto University, for his advice and encouragement.

## *Reaction of Enamines. I. The Preparation of Thiocarbonyl Compounds*

By Yujiro NOMURA and Yoshito TAKEUCHI

(Received November 9, 1960)

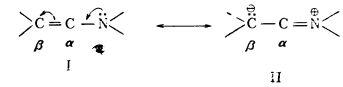
The reactions of enamines[1-3] have been well investigated[4-6]. We have paid attention to the reactivities of enamines and found that thiocarbonyl compounds were obtained by the reaction between enamines and hydrogen sulfide. Thiocarbonyl compounds are usually prepared by the treatment of an acid solution of the corresponding carbonyl compounds with hydrogen sulfide. This method is, however, often likely to lead to the formation of trimers, but our new method is successful in preparing monomeric compounds in good yield.

Twenty grams of 1-morpholino-1-cyclohexene[7] was dissolved in 90 cc. of dimethylformamide and hydrogen sulfide was introduced for six hours with ice cooling. The exothermic reaction occurred and the reaction mixture became faint yellow. Yellow oil separated at once when 100 cc. of 6 N hydrochloric acid was added with stirring and ice cooling.

After adding 100 cc. of water, the oil was extracted with petroleum ether, washed several times with water, dried and distilled in vacuo under nitrogen. The pink liquid, b. p.* 77~78°C/15 mmHg, with disagreeable odour was obtained, whose color was gradually faded away on standing[8].

Yield 10.0 g. (73% theoretical).

The product gave 2, 4-dinitrophenylhydrazone, m. p. 159~160°C, which showed no m. p. depression on admixture with cyclohexanone 2, 4-dinitrophenylhydrazone.

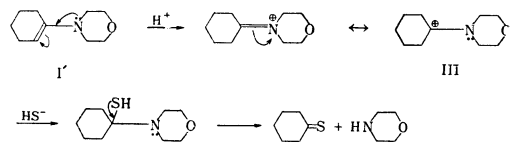


IR spectrum of the product in carbon tetrachloride solution indicated the existence of C=S bond (medium intensity band at 1130 $cm^{-1}$) and the lack of C=O bond of cyclohexanone (strong intensity band at 1705 $cm^{-1}$).

All these facts lead us to identify this product as cyclohexanethione.

By practically the same method, cyclopentanethione was prepared in considerably good yield. From 47.4 g. of 1-morpholino-1-cyclopentene[9] in 200 cc. of dimethylformamide was obtained 23.2 g. (68% theoretical) of cyclopentanethione, b. p.** 63~65°C/8 mmHg. This gave 2, 4-dinitrophenylhydrazone, m. p. 145~146°C, which was found, by means of the mixed melting point test, to be identical with cyclopentanone 2, 4-dinitrophenylhydrazone.

IR spectrum had no absorption at 1740 $cm^{-1}$ ($\nu_{C=O}$ of cyclopentanone).



Enamines have two mesomeric forms, enamine-form I and iminoform II.

I II

The reaction of enamines proceeds in most cases through the attack of electrophilic reagent at $\beta$-carbon atom of imino-form II, but nucleophilic attack at $\alpha$-carbon atom has also been reported[6].

It is postulated that the reaction of enamines and hydrogen sulfide occurs by the nucleophilic attack of $HS^-$ ion on the protonated enamine intermediate (III) as follows.

I' III

We continue to explore the full scope of the reaction of enamines with hydrogen sulfide. The results of the further investigation will be reported in more detail later.
