# *The State of a Small Amount of Magnesium Contained in Calcareous Shells*

By Yasushi KITANO* and Tsuyako FURUTSU

(Received March 23, 1959)

The distribution of magnesium in calcareous parts of marine organisms was studied by K. E. Chave; he listed the factors which controlled distribution of magnesium in the calcareous skeletal formation of marine organisms[1]. He was also the first to succeed in determining the state of magnesium by using X-ray diffraction technique. The magnesium content of the sample in his study was from 2 to 16% $MgCO_3$ in weight. He concluded that magnesium carbonate was present as a solid solution of calcite and dolomite**[,2]. With his own X-ray diffraction technique, however, Chave was not able to determine the state of magnesium, when the content was more than 16% or less than 2% $MgCO_3$. There are a large number of calcareous shells having a magnesium carbonate content less than 2%. One of the authors, Kitano, was the first to devise a new method for determining the state of a small amount of magnesium contained in calcium carbonate deposits from hot springs, as reported in earlier papers[5-7]. This technique was called the "Dissolution Method". In the present paper the same method is applied for calcareous shells. The process greatly simplifies the determination of the state of magnesium in calcareous shells.

## Principle of Dissolution Method

As to the state of magnesium*** in calcareous shells or organisms, there are only three possible forms, magnesium carbonate, dolomite and a solid solution of calcite and dolomite. When the authors closely examine the three forms from the crystallographic point of view, magnesium carbonate can not be expected, and consequently there are only two forms, dolomite and a solid solution, to be determined. When carbon dioxide gas is passed into a suspension of calcite mixed with dolomite or a suspension of calcite with a solid solution of calcite and dolomite, the dissolved quantity of magnesium can be expected to differ for each of the two magnesium compounds. Therefore, the state of magnesium present in calcareous shells can be determined by knowing the quantity of magnesium dissolved by carbon dioxide aerated water.

## Experimental

**Materials.** — *Calcite.* — Commercial reagent of extra pure grade is used without further purification.

*Aragonite.* — The same volume of 1 N $CaCl_2$ solution is added gradually to the boiling solution of 1 N $Na_2CO_3$; the separated precipitate of aragonite is washed with pure water and allowed to dry.

*Magnesium carbonate.* — Since it is difficult to prepare magnesium carbonate, basic magnesium carbonate (extra pure grade) is used instead of magnesium carbonate. When $MgCO_3 \cdot nH_2O$ is suspended in water, it changes quickly into basic magnesium carbonate, which proves that $MgCO_3 \cdot nH_2O$ is more unstable in water than basic magnesium carbonate[8]. Consequently for the purpose of this experiment, the authors use basic magnesium carbonate (MgO 44.2%) instead of magnesium carbonate.

TABLE I. CONTENT OF CALCIUM AND MAGNESIUM IN FOUR KINDS OF SEA URCHINS

| No. | Ca % | $CaCO_3$ % | Mg % | $MgCO_3$ % |
|---|---|---|---|---|
| 1-a | 32.83 | 82.08 | 3.49 | 12.08 |
| 2-a | 34.82 | 87.05 | 3.07 | 11.62 |
| 3-a | 33.51 | 87.78 | 4.05 | 14.01 |
| 4-a | 35.50 | 88.75 | 3.50 | 12.11 |

6) Y. Kitano, ibid., **77**, 215 (1956).

7) Y. Kitano, ibid., **77**, 218 (1956).

*** It seems better to say "magnesium carbonate" instead of "magnesium".

8) Y. Hagino, *Bull. Soc. Salt Science* (*Nippon Shio Gakkai-shi*), 8, 121 (1954).

*Solid solution of calcite and dolomite.*— For this experiment the shells of four kinds of sea urchins are used. The magnesium carbonate in the shells, as found by using X-ray diffraction technique, is contained as a solid solution. The magnesium content of each kind of shell is given in Table I.

*Dolomite.* — Because it is difficult to prepare this material in a laboratory, the authors use the dolomite found in the Kuzuo Mountain District of Tochigi Prefecture.

(*Anal.*: CaO, 33.80; MgO, 19.37; clay, 0.22%.)

An organic substance, a protein, is always present with minerals in shells, and its presence makes the minerals stable. Therefore, when inorganically prepared minerals are suspended in water, they are less stable than minerals containing an organic material. In this experiment the authors would prefer to use minerals which contain an organic material, but since those can not be obtained, inorganic compounds have to be used. Judging from results given in detail later, however, the use of inorganic minerals, calcite and dolomite, is found to be suitable.

**Procedure.** — The best procedure for the determination of the magnesium state is as follows: Two and a half gram of powdered sample, (<325 mesh), are suspended in 200 ml. of pure water. Carbon dioxide gas, washed by passing through water, is passed into the suspension for 25 min., and is allowed to stand for 10 min. After filtering the suspension with No. 6 Toyo filter paper, the magnesium content in the filtrate is determined. By comparing the dissolved quantities of magnesium in shells with those in mixed samples of calcite and possible magnesium compounds in shells, the state of magnesium in calcareous shells can be determined.

## Results

Fig. 1 shows the relationship between the amount of magnesium dissolved by carbon dioxide aerated water and the magnesium content in mixed samples of calcite**** and dolomite[5]. In Table II and Fig. 1 the relationship is given for mixed samples[9] of calcite and four kinds of sea urchin shells. When magnesium is contained as dolomite, it is difficult to find any dissolved quantity of magnesium, as is seen from Fig. 1. It may be expected that dolomite becomes more stable and no dissolved quantity of magnesium can be found when it is present with an organic material in calcareous shells. Therefore, it is quite suitable to use in this experiment native dolomite mineral having no organic material.

## Determination of the State of Magnesium Contained in Calcareous Shells

The above procedure is applied to various kinds of calcareous shells and the results are given in Table III and Fig. 2. Fig. 2 includes the result obtained for mixed samples of calcite and dolomite as well as for mixed samples of calcite and a solid solution of calcite and dolomite. From the results given in Fig. 2, it is inferred that a dissolved quantity of magnesium in calcareous shells comes from a solid solution[10]. Therefore, it can be concluded that magnesium carbonate, having a content less than 2% in weight, is contained in calcareous shells as a solid solution. Meanwhile K. E. Chave reported that magnesium carbonate, having a content from 2 to 16% $MgCO_3$, was present in calcareous shells as a solid solution. Kitano reported previously that magnesium in limestone was always present as dolomite[7]. It is known that limestone in nature comes from calcareous shells. Consequently, it may be expected that the natural state of magnesium changes from a solid solution into dolomite during the process of limestone formation from calcareous shells. This finding is important and useful for an understanding of the formation of limestone in nature.

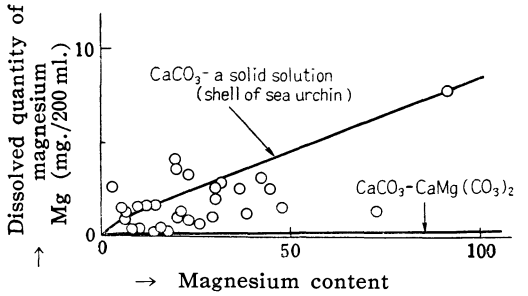

Fig. 2. Relationships between magnesium content and quantity of magnesium dissolved by $CO_2$-aerated water, for various kinds of calcareous shells.

## Summary

An original method (Dissolution Method) for determining small amounts of magnesium contained in calcareous shells has been devised, and the state of magnesium has been determined by this method. As a result, it can be verified that small amounts of magnesium in calcareous shells are always contained as a solid solution of calcite and dolomite.

The authors express their sincere thanks to Mr. Sakae Ichihashi of Osaka City University for his advice given throughout this work.

**** Two kinds of calcium carbonate, viz. calcite and aragonite, are used, and no difference between the dissolved quantities of magnesium for these two calcium carbonates can be found. Almost the same amount of calcium carbonate in shells, coexisting with an organic material, as the amount of inorganically prepared calcium carbonate can be dissolved by carbon dioxide aerated water. Hence, the use of inorganically prepared calcite instead of calcium carbonate coexisting with an organic material, is justified.

9) Fig. 1 also shows the relationship in mixed samples of calcium carbonate and magnesium carbonate[5]. It can be expected that the dissolved quantity of magnesium in the solid solution will be higher than that in magnesium carbonate. However, as seen in Fig 1, the latter is in reality higher than the former. That the solid solution used in this experiment is made stable by a coexisting organic material may be responsible for this discrepancy between the presumed and actual results. (The presence of magnesium carbonate can not be expected in calcareous shells, as mentioned earlier).

10) From Fig. 2, it is clear that the dissolved quantity of magnesium in some calcareous shells is less than that in mixed samples of calcium carbonate and shell of four kinds of sea urchins. This can be understood by the following findings: 1) By mixing calcium carbonate with a sea urchin's shell in which 16% $MgCO_3$ is contained as a solid solution, the authors prepare semples containing a small amount of magnesium as a solid solution. It can be expected that the dissolved quantity in the mixed sample will be higher than that in natural shell samples, because a solid solution is less stable with an increase of magnesium content. 2) Since some calcareous shells are not fresh, it appears possible that a part of the solid solution changes to a stable dolomite.

# *Estrogenic Biphenyls. VIII. Preparation and Estrogenic Activity of 4'-(1-Hydroxyalkyl)-4-methoxybiphenyls*

By Takeo SATO

(Received April 20, 1959)

According to the hypothesis presented by Ōki and Urushibara[1] to account for the estrogenic activity of non-steroidal compounds of the stilbene-bibenzyl type, the activity is closely associated with the molecular structure in that the development of strong action requires not only the presence of two active hydrogens or any groups capable of producing such in vivo at the optimum distance from each other, but also optimum thickness and width of the molecule. Therefore, the problems in studying the relation between the physiological action and the molecular structure in a homologous or an analogous series of compounds will be 1) the distance between the active hydrogen atoms in question, 2) the molecular thickness and width, and 3) the nature of the active hydrogens or the groups carrying them.

As for the biphenyl series Dodds and Lawson[2] reported that 4,4'-dihydroxybiphenyl (I) was almost inactive. As the recent X-ray crystallographical investigation[3] of compound I revealed that the molecule of compound I has the unit cell constants of a=10.54 Å, b=5.36 Å and c=7.59 Å, the distance between the two phenolic groups is apparently less than that between the two hydroxyl groups of steroidal hormones or stilbestrol in which the distance between the two oxygens was reported to be 15.5 Å[1b]. Furthermore, the molecule of compound I is planar or nearly planar[4] owing to the full conjugation of the biphenyl system and this is also considered to be unfavorable for the development of strong estrogenic activity. In this respect, 4-hydroxybiphenyl-4'-carboxylic acid (IIa) and its derivatives with two active hydrogens at a longer distance were prepared and found to be estrogenic[5]. While this manuscript was in preparation, however, Y. Osawa[6] observed that compound I, its dimethyl ether and derivatives were considerably active, compound I being active at 500 $\gamma$ in 100% animals (ovariectomized mice), whereas compound IIa was active in 60% animals at the same level[7]. Though the present author can give no comment on this contradiction in the activity of compound I, there might be another optimum distance of two active hydrogens.

The activity of 4-methoxybiphenyl-4'-carboxylic acid (IIb) was enhanced markedly by alkyl substitution, namely, by increasing the molecular thickness and width, and its dialkyl derivatives, in which positions 3' and either 2 or 6' were substituted, produced full estrus in 100% of the mice at a dose of 100 $\gamma$ in spite of the methylation of the phenolic hydroxyl group[5].

In connection with the third problem, 4'-hydroxymethyl-4-methoxybiphenyl (IIIa) has been prepared to obtain a confirmation for the postulation that a compound with a group other than carboxyl but carrying an active hydrogen will be similarly estrogenic, provided that it has two active groups at a similar distance.

A number of analogues of bisdehydrodoisynolic acid methyl ether (IVa), to which the compounds of the present series are structurally related, including the compounds with hydroxymethyl (IVb) and formyl (IVc) groups instead of the carboxyl, have been prepared[8a] and found considerably active though slightly weaker than the carboxylic compound (IVa). The assumption that they are oxidized in vivo to IVa is quite probable and may serve as an explanation for the somewhat

weaker activity. As methyl ketone IVd was found to be very weakly estrogenic[8b], it would be worthwhile to examine a compound with a secondary hydroxyl group which on oxidation would yield a ketone. Such compounds of the present series, namely, IIIb and IIIc have been synthesized. It appears of interest to note a similarity in the bond arrangement of compound IIIc, which is represented as V, with estradiol (VI). Rubin and Wishinsky[9] have already prepared compound VII as a bicyclic analogue of estradiol but not mentioned the activity.

VI

VII

Compound IIIa was obtained through reduction of methyl 4-methoxybiphenyl-4′-carboxylate (VIII)[10,11], prepared from compound IIb, with lithium aluminum hydride in ether. The alkyl homologues IIIb and IIIc were prepared by sodium borohydride reduction of 4′-acetyl-4-methoxybiphenyl (IX) and 4-methoxy-4′-propionylbiphenyl (X), respectively. The methoxyketone IX was prepared from 4-methoxybiphenyl (XI) by Friedel-Crafts reaction according to the literature[10,12]. Similar treatment of compound XI with propionyl chloride and aluminum chloride in carbon disulfide gave the ethyl ketone X, the structure being confirmed by oxidation to the corresponding carboxylic acid IIb likewise the methyl ketone IX[10].

| IX | $CH_3$ |
| X | $C_2H_5$ |

→ IIIb or IIIc

Ultraviolet absorption spectra of these alcohols are recorded in Table I with the data of compounds IIb and XI. Compound IIIa showed a strong absorption at 264 m$\mu$ whereas the homologues IIIb and IIIc absorbed at 263 m$\mu$. The curves are very similar and the intensities are nearly the same. As the hydroxymethyl group is only very weakly bathochromic[13], the absorption curves resemble that of 4-methoxybiphenyl (XI) and differ markedly from that of IIb, where additional conjugation with the carboxyl group is possible. These data are also taken as a confirmation of the structures.

| IIb | 248~249 | 289 | 4.36 | 1000(50) |
| IIIa | 158~159 | 264 | 4.32 | 1000(60) |
| b | 122~123 | 263 | 4.34 | 200(80) |
| c | 91~ 92 | 263 | 4.34 | 200(80) |
| XI | 89 | 260 | 4.31 | ..... |

Compound IIIa was found to be estrogenic to 20% of mice at the dose of 500 $\gamma$ and to 60% at 1 mg., being nearly equally active as compounds IIa[7] and IIb[14]. In compounds IIIb and IIIc, an increase in activity was encountered and they were active to 80% of animals at 200 $\gamma$ level. It is noteworthy that the compounds which are secondary alcohols and racemic

are more active than the hydroxymethyl compound.

## Experimental[15]

**Methyl 4-Methoxybiphenyl-4'-carboxylate (VIII).**—The methyl ester was obtained as colorless plates, m. p. 172~173°C, on esterification of 4-methoxybiphenyl-4'-carboxylic acid (IIb) in the usual way. Reported[10,11] melting point is 172~173°C.

**4'-Hydroxymethyl-4-methoxybiphenyl (IIIa).**—To an ethereal slurry made from 100 mg. (0.0026 mol.) of lithium aluminum hydride and 20 ml. of ether, a solution of 240 mg. (0.001 mol.) of compound VIII in 100 ml. of ether was added over a period of 10 min. with efficient stirring. The reaction mixture was gently refluxed on a bath for one hour and then allowed to stand. After the excessive reagent was decomposed with water, 50 ml. of 10% sulfuric acid was added and the aqueous layer was extracted with ether. The ethereal solution was successively washed with water, aqueous sodium hydroxide and water. On evaporation of the solution and recrystallization of the residue from benzene yielded 100 mg. of colorless plates, m. p. 158~159°C.

*Anal.* Found: C, 78.80; H, 7.06. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%.

*Phenylurethan.*—It was prepared in the usual way as colorless plates melting at 140~141°C on recrystallization from carbon tetrachloride.

*Anal.* Found: N, 4.42. Calcd. for $C_{21}H_{19}O_3N$: N, 4.20%.

**4'-Acetyl-4-methoxybiphenyl (IX).**—4-Methoxybiphenyl (XI), prepared[16] by decomposition of *N*-nitrosoacetanisidide in benzene, was acetylated with acetyl chloride and aluminum chloride in carbon disulfide. Recrystallization from isopropyl alcohol gave compound IX, m. p. 152~153°C. Reported melting point is 153~154°C[10,12].

**4-Methoxy-4'-propionylbiphenyl (X).**—To a mixture of 15g. (0.082 mol.) of compound XI, 13g. (0.098 mol.) of anhydrous aluminum chloride and 100 ml. of carbon disulfide, 8.0 g. (0.086 mol.) of propionyl chloride was added in the course of twenty minutes, while the reaction mixture was gently refluxed. After stirring and refluxing for additional thirty minutes, the mixture was decomposed with ice water containing hydrochloric acid. The product was washed repeatedly with cold ether and recrystallized from ethanol, colorless plates, m. p. 146~147°C. Yield, 11 g. (56% of the theoretical).

*Anal.* Found: C, 79.86; H, 6.84. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

On oxidation with potassium permanganate and sodium hydroxide, compound X yielded a carboxylic acid, which did not depress the melting point of an authentic specimen of 4-methoxybiphenyl-4'-carboxylic acid (248~249°C).

*2,4-Dinitrophenylhydrazone.*—It was prepared in the usual way and recrystallized from ethyl acetate, deep red plates, m. p. 201~202°C.

*Anal.* Found: N, 13.42. Calcd. for $C_{22}H_{20}O_5N_4$: N, 13.33%.

**4'-(1-Hydroxyethyl)-4-methoxybiphenyl (IIIb).**—To a suspension of 3 g. (0.016 mol.) of compound IX in 200 ml. of methanol, 0.5 g. (0.013 mol.) of sodium borohydride and 50 ml. of methanol was added in the course of 10 min. After the addition was complete, the mixture was warmed to 60°C and stirred for two hours. Aqueous sodium hydroxide was added and a part of methanol was removed on a steam bath. The residue was diluted with water and the solid was collected. Recrystallization from aqueous ethanol gave 2.5 g. (68% of the theoretical) of colorless plates, melting at 122~123°C.

*Anal.* Found: C, 78.62; H, 6.97. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

*Phenylurethan.*—Colorless plates, melting at 162~163°C, on recrystallization from carbon tetrachloride.

*Anal.* Found: N, 3.82. Calcd. for $C_{22}H_{21}O_3N$: N, 4.03%.

**4'-(1-Hydroxypropyl)-4-methoxybiphenyl (IIIc).**—In the same way as described above, 10 g. (0.042 mol.) of compound X in 400 ml. of methanol was reduced with 1.5 g. (0.040 mol.) of sodium borohydride in 100 ml. of methanol to yield 7.5 g. (74% of the theoretical) of colorless plates, melting at 91~92°C on recrystallization from aqueous ethanol.

*Anal.* Found: C, 79.28; H, 7.37. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

*Phenylurethan.*—It was prepared in the usual way and recrystallized from carbon tetrachloride, colorless plates, m. p. 165~166°C.

*Anal.* Found: N, 3.96. Calcd. for $C_{23}H_{23}O_3N$: N, 3.88%.

**Ultraviolet Absorption Spectra.**—The ultraviolet absorption spectra were measured in 95% ethanol with a Hitachi EPU-2 photo-electric spectrophotometer.

# *Effect of Additives on the Hydrogen Reduction of Nickel Oxide*

By Yoshio IIDA and Kenzo SHIMADA

(Received April 30, 1959)

The effect of additives on hydrogen reduction of metal oxide was previously studied in view of the dissociation pressure of the oxide by Grube[1] and Sano[2]. Parravano[3] recently studied the effect of additives on the reductive properties of nickel oxide from the point of view of a semiconductor and concluded that a direct correlation exists between the activation energy and the type of additives for the hydrogen reduction of nickel oxide.

The present investigation has been undertaken to determine the effect of additives on the temperature at which nickel oxide begins to be reduced by hydrogen, and to ascertain whether or not the properties of a semiconductor are related to the reductive properties of nickel oxide.

## Experimental

Nickel nitrate recrystallized four times was heated at 800°C for 10 hr. to obtain nickel oxide powder. The average particle size of nickel oxide powder was about 0.5 $\mu$ according to an electron micrograph. Aluminum oxide powder obtained by heating c. p. aluminum hydroxide at 800°C for 10 hr. Cupric oxide powder was obtained by heating c. p. nitrate salt at 800°C for 10 hr.

Powders were mixed and pressed at a pressure of 1000 kg./cm$^2$ into tablets $10\times10^{\phi}$ mm. The compacts were heated at various temperatures in a silicon carbide furnace with a sintered corundum tubing.

Weight loss during the reduction process was measured by a thermobalance which had a sensitivity of 0.5 mg. and could be used in hydrogen, vacuum and, if necessary, in oxygen. Hydrogen was used from a commercially available tank after being purified with concentrated sulfuric acid, hot platinum asbestos, potassium hydroxide, and phosphorous pentoxide.

Electrical resistance was measured by a Wheatstone bridge in the range of room temperature to 400°C in air.

## Results

**Effect of Additive Aluminum Oxide.**—In order to study the effect of additive aluminum oxide on reduction of nickel oxide, the reduction-temperature curves were obtained at the rate of heating of 100°C/hr. NiO-$Al_2O_3$ mixtures of 99 : 1, 95 : 5, and 50 : 50 mol. were heated at 1100°C for 4 hr. It is seen from Fig. 1 that the mixtures begin to be reduced at 300°C whereas pure nickel oxide begins to be reduced at 200°C. The reduction-temperature curve of the mixture 50 : 50 mol. ratio consisted of two stages. At the first stage the reduction takes place in the range of 300 to 400°C and the second stage reduction begins at 700°C.

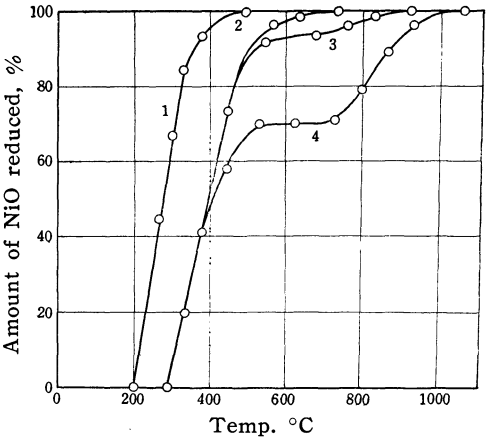

Fig. 1. Reduction-temperature curves of NiO-$Al_2O_3$ mixtures heated at 1100°C for 4 hr. Curve 1 is for pure NiO and curves 2, 3 and 4 are for the mixtures containing 1, 5 and 50 mol. % of $Al_2O_3$, respectively.

**Effect of Additive Lithium Oxide.**—A NiO-$Li_2O$ mixture of 95 : 5 mol. ratio was heated for 4 hr. at 1100°C and the reduction-temperature curve was determined in the same way as described above. It is seen from Fig. 2 that the beginning temperature of reduction of the NiO-$Li_2O$ mixture is about 260°C and is higher that of pure nickel oxide and lower than that of the NiO-$Al_2O_3$ mixture. The temperature at which reduction is completed is 800°C for the NiO-$Li_2O$ mixture and is higher by 400°C than that of pure nickel oxide. It

2) K. Sano, *J. Japan Inst. Metals (Nippon Kinzoku Gakukai-shi)*, **6**, 339 (1942).
3) G. Parravano, *J. Am. Chem. Soc.*, **74**, 1194 (1952).

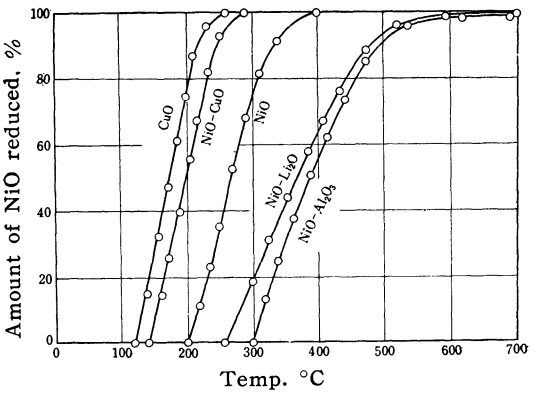

Fig. 2. Reduction-temperature curves of CuO, NiO and mixtures of NiO and 5 mol. % of CuO, $Li_2O$ and $Al_2O_3$, respectively. CuO, NiO and the mixtures were heated at 1100°C for 4 hr.

may be concluded that the heated NiO-$Li_2O$ mixture becomes more difficult to reduce than to do pure nickel oxide.

**Effect of Additive Cupric Oxide.** — The reduction-temperature curve for the NiO-CuO mixture of 95 : 5 mol. ratio heated for four hours at 1100°C was determined at the same rate of heating. It is seen from Fig. 2 that the beginning temperature of reduction for the NiO-CuO mixture is 160°C and is lower than that for nickel oxide. To confirm the fact more evidently, the isotherms of reduction at 160, 140 and 120°C were obtained using the same samples described above. The result is shown in Fig. 3. Pure nickel oxide started to be reduced after an induction period of two hours at 180°C and the amount of nickel oxide reduced was about 80% even after a reducing period of 10 hr. at 180°C. NiO-CuO compact of 95 : 5 mol. ratio heated at 1100°C, however, could be reduced completely after a two hour reducing period at 160°C without an induction period. At 140°C the amount of reduced nickel oxide was 100% after an eight hour reducing period, and even at 120°C the reduction occurred slowly after a two hour induction period. It may be concluded that nickel oxide in the heated NiO-CuO mixture can be reduced at a lower temperature than pure nickel oxide.

In order to see how additive cupric oxide enhances the reduction of nickel oxide by hydrogen, the isotherms of reduction at 140°C for NiO-CuO mixtures of 95 : 5 mol. ratio heated at 700 and 1100°C are compared with the unheated mixtures. The result is shown in Fig. 4. The unheated mixture was reduced by 5% at 140°C for one hour and then ceased to be reduced. Although the mixture heated at 700°C behaves at the initial time of reduction in the same way as the unheated mixture, the one heated at 700°C can be reduced again after a two hour reducing period. The mixture heated at 1100°C can be reduced more rapidly and is reduced by 100% for eight hours at 140°C. It is concluded from the experimental results that cupric oxide in the unheated mixture does not enhance the reduction of nickel oxide but cupric

oxide in the heated mixture enhances the reduction.

## Discussion

In an earlier paper[4] dealing with the solid state reaction of nickel oxide with aluminum oxide, it was shown that when the mixture $NiO$-$Al_2O_3$ was heated, a solid solution of aluminum oxide in nickel oxide and a spinel $NiAl_2O_4$ were formed. From these facts it is concluded that nickel in pure nickel oxide starts to be reduced at 200°C whereas nickel in the solid solution and that in the spinel starts to be reduced at 300 and 700°C, respectively.

Fensham[5] showed that a solid solution is formed when a mixture of nickel oxide and lithium oxide is heated at 1100°C. It was also shown[6] that a solid solution is formed when a mixture of nickel oxide and cupric oxide is heated at 1100°C.

Parravano[3] showed that by incorporation of 5 mol. % of aluminum oxide, the activation energy and the rate of hydrogen reduction of nickel oxide did not differ from those of pure nickel oxide. This result seems to be inconsistent with the result of the present investigation. In Parravano's experiment the mixture of $NiO$-$Al_2O_3$ was heated at 600°C to dissolve aluminum oxide into the nickel oxide crystal, while in this study the mixture was heated at 1100°C. The temperature 600°C seems to be too low to form a solid solution of $NiO$-$Al_2O_3$ completely. This may be the reason for the disagreement.

It was shown by Verwey[7] that nickel oxide is a semiconductor of *p*-type and its electrical conductivity is affected by incorporation of foreign ions. According to the principle of valency control[7], the semiconductivity of nickel oxide decreases by the incorporation of cations with higher valency than two, and increases by the incorporation of monovalent cations. The electrical and reductive properties of nickel oxide incorporated with various additives are shown in Table I. Nickel oxide with various additives was heated at 1100°C for 4 hr. Cationic holes in the nickel oxide lattice increase by the incorporation of $Al^{+3}$ ion and decrease by the incorporation of $Li^+$ ion from the point of view of the electron-neutrality principle.

It can be seen that nickel oxide incorporated with $Li^+$ or $Al^{+3}$ is less readily reducible than pure nickel oxide although $Li^+$ ion has the reverse effect on the semiconductivity compared with $Al^{+3}$ ion. On the other hand, nickel oxide incorporated with $Cu^{+2}$ is more easily reducible than pure nickel oxide, although it has a lower semiconductivity than that of pure nickel oxide. In view of the above facts it is concluded that the effect of impurities on the reductive properties of nickel oxide can not be explained reasonably by the properties of a semiconductor.

Previous reports[1,8] on the effect of additives on hydrogen reduction of oxide showed that the reduction is promoted by the formation of a solid solution of a reduced metal into additives. Niobium could be reduced with hydrogen as an Nb-Ni alloy by the addition of nickel powder[1]. In the present study it is, however, shown that the reductive properties of nickel oxide are not affected merely by the addition of cupric oxide, but affected by the dissolution of a small quantity of cupric oxide into nickel oxide crystal by heating. As the reduced nickel can form no solid solution with unreducible lithium oxide or aluminum oxide, the dissolution of lithium oxide or aluminum oxide should have no influence on the hydrogen reduction according to the above mechanism. The experimental results, however, show that the reduction of nickel

TABLE I. ELECTRICAL AND REDUCTIVE PROPERTIES OF NiO AS A FUNCTION OF IMPURITY DISSOLUTION

oxide is retarded by the dissolution of lithium oxide or aluminum oxide. From these considerations it is concluded that the effect of the dissolution of various oxides on the reduction is not explained completely by the formation of a solid solution.

The reduction of a metal oxide has been considered to be an autocatalytic reaction[9]. Therefore, the accelerated reduction by the addition of cupric oxide is thought to be attributed to the catalytic behavior of metallic copper formed predominantly by hydrogen reduction. It is, however, important to note that cupric oxide does not promote the reduction when cupric oxide is mixed in nickel oxide, but cupric oxide dissolved in the nickel oxide lattice promotes the reduction. From this fact, it is concluded that copper formed predominantly in the reduction process exhibits no catalytic behavior.

In order to know the relation between the reductive properties of nickel oxide incorporated with impurities and the heat of formation of these impurities, the heats of formation of nickel oxide, aluminum oxide, lithium oxide and cupric oxide are given in Table II using the values of Seybolt[10]. It can be seen that the beginning temperature of the reduction of nickel oxide incorporated with other oxides with a greater heat of formation than nickel oxide is higher than that of pure nickel oxide whereas an oxide with a smaller heat of formation than nickel oxide has the reverse effect.

TABLE II. HEAT OF FORMATION OF VARIOUS OXIDES AT 298°K (BY SEYBOLT)

| Oxide | NiO | $Li_2O$ | 1/3 $Al_2O_3$ | CuO |
|---|---|---|---|---|
| Heat of formation kcal./mol. | −51.3 | −134.0 | −126 | −30.4 |

Further, it is seen from Fig. 4 that the induction period of both the unheated mixture NiO-CuO and of that heated at 700°C is shorter than the induction period of that heated at 1100°C. It is evident that the reduction of cupric oxide is retarded by the incorporation of nickel oxide, which has a greater heat of formation than that of cupric oxide.

To see whether this explanation applies to the hydrogen reduction of any other oxide, ferric oxide containing 5 mol. % of aluminum oxide and cupric oxide respectively and pure ferric oxide were heated at 1200°C for 3 hr. and reduced at 350°C isothermally. The results are shown in Fig. 5. It is evident that the dissolution of aluminum oxide which has a greater heat of formation than ferric oxide retards the reduction of ferric oxide and the dissolution of cupric oxide which has a smaller heat of formation than ferric oxide promotes the reduction.

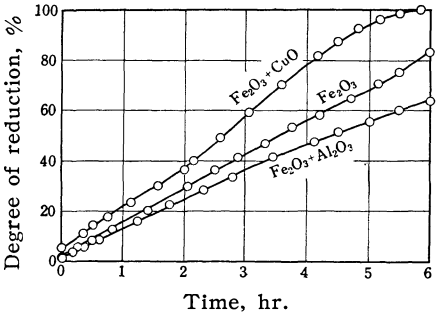

Fig. 5. Isothermal reduction of pure $Fe_2O_3$ and $Fe_2O_3$ containing 5 mol. % of CuO and $Al_2O_3$, respectively. Samples are heated at 1200°C for 3 hr. and reduced at 350°C isothermally.

In view of the above facts the most reasonable conclusion to be drawn from available data is that hydrogen reduction of metal oxide is promoted by the incorporation of another oxide with a greater heat of formation than that of oxide, and is retarded by the incorporation of an oxide with a smaller heat of formation.

## Summary

The effect of additive impurities on the hydrogen reduction of nickel oxide has been studied. The additives have no influence on the reduction unless they dissolve into nickel oxide crystal. The reduction is promoted by the dissolution of cupric oxide and is retarded by the dissolution of lithium oxide and aluminum oxide. The effect of additives on the reduction is not explained reasonably by their catalytic behavior. There is no direct correlation between the reductive properties of nickel oxide and the type of additives from the point of the semiconducting behavior of these materials. The effect of additives on the reduction is related to their heats of formation.

# *Polymerization of Methyl Methacrylate Initiated by N-Nitrosophenylurea*

By Ryoichi UEHARA

(Received May 25, 1959)

*N*-Nitrosophenylurea has been prepared by Huisgen[1] by the following reaction of nitrous fumes (a mixture of NO and $NO_2$) and phenylurea:

$$2C_6H_5NHCONH_2 + N_2O_3 = 2C_6H_5N(NO)CONH_2 + H_2O$$

*N*-Nitrosoacylarylamines which are related to *N*-nitrosophenylurea have been noted as sources of free radicals by many investigators[2]. Blomquist[3] has reported polymerizations of methyl methacrylate, styrene and acrylonitrile initiated by several *N*-nitrosoacylarylamines, and suggested that the polymerizations were initiated by aryl radicals which were produced through the decomposition of the *N*-nitrosoacylarylamines. Although *N*-nitrosoacylarylamines were frequently used as initiators during the early period of studies on radical polymerization, they have never since been employed, owing to the facts that they were not efficient as polymerization-initiators and too labile, i.e. they decomposed spontaneously at room temperature. *N*-Nitrosophenylurea is much more stable than *N*-nitrosoacylarylamines, e.g. the half-value periods of *N*-nitrosoacetanilide and *N*-nitrosophenylurea are respectively 99.5 min. at 20°C and 140 min. at 40°C[1].

It has been found by the present author that *N*-nitrosophenylurea is an efficient initiator of the polymerization of methyl methacrylate. In the present paper, results of experiments on the dependence of the initial rate of polymerization upon the concentration of *N*-nitrosophenylurea and methyl methacrylate are given.

The polymerization was carried out in an atmosphere of nitrogen. In Table I, the conversion versus time and average degree of polymerization of polymethyl methacrylate in the bulk polymerization of methyl methacrylate initiated by *N*-nitrosophenylurea $1.21\times10^{-2}$ mol./l. at 60°C are shown. The conversion in the bulk polymerization initiated by benzoyl peroxide $1.30\times10^{-2}$ mol./l. is also shown in Table I. As an initiator of the polymerization of methyl methacrylate, *N*-nitrosophenylurea is more efficient than benzoyl peroxide.

Dependences of the initial rate of polymerization (R) upon the concentration of *N*-nitrosophenylurea ([NPU]) in solution-polymerization in benzene (methyl methacrylate 50%) at temperatures of 40, 50, 60 and 70°C are shown in Fig. 1. It is evident that the square root dependence holds for each case, i.e. the initial rate of polymerization is linearly proportional to the square root of the concentration of *N*-nitrosophenylurea. The relationship between the initial rate of polymerization and the concentration of methyl methacrylate ([MMA]) in benzene (*N*-nitrosophenylurea $1.24\times10^{-2}$ mol./l.) was studied at 60°C. It is clear that the initial rate

* Polymethyl methacrylate produced by NPU.

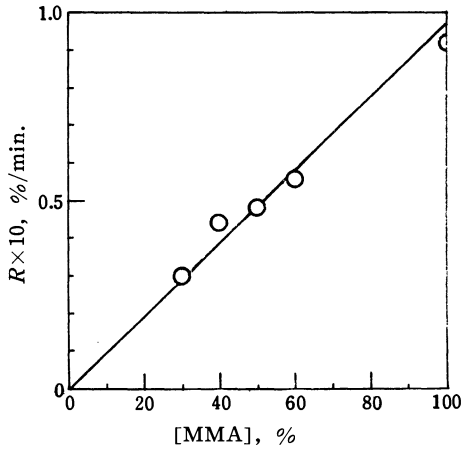

Fig. 2. Correlation of the initial rate of polymerization with the concentration of methyl methacrylate (at 60°C, NPU $1.24\times10^{-2}$ mol./l.)

was linearly proportional to the concentration of methyl methacrylate.

These rate-concentration relationships are quite similar to those which are observed in the polymerizations of vinyl monomers initiated by benzoyl peroxide or $\alpha,\alpha'$-azo-bis-iso-butylonitrile in which unimolecular first order decompositions of the initiators are considered as the initiating reactions by many investigators[4]. Consequently, it is very probable that the polymerization of methyl methacrylate by means of *N*-nitrosophenylurea is initiated by radicals which are produced through the unimolecular first order decomposition of *N*-nitrosophenylurea. The nature of the initiating reaction will be studied in future.

When logarithms of the initial rates of polymerization (methyl methacrylate in benzene 50% and *N*-nitrosophenylurea $1.24\times10^{-2}$ mol./l.) were plotted against reciprocals of temperatures ($1/T$), a good straight line was obtained (Fig. 3). The overall activation energy calculated from the slope in Fig. 3 was found to be 12.8 kcal./mol.

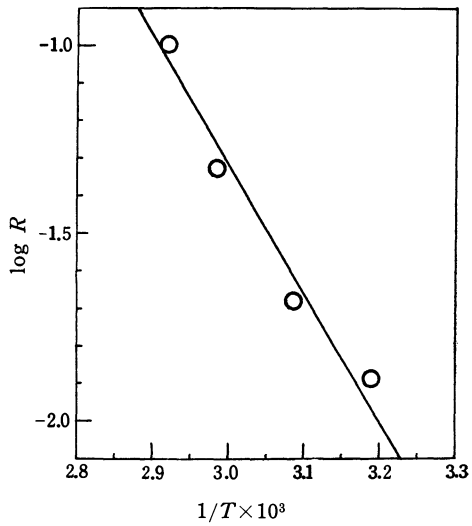

Fig. 3. Correlation of log $R$ with $1/T$ (MMA 50%, NPU $1.24\times10^{-2}$ mol./l.).

## Experimental

**Materials.**—Purification of methyl methacrylate and benzene was carried out as mentioned in a previous paper[5]. *N*-Nitrosophenylurea was prepared through the reaction of nitrous fumes upon phenylurea. Phenylurea (6.8 g.) was suspended in a mixture of glacial acetic acid and acetic anhydride (3 : 1 by volume, 40 cc.) and cooled to 0°C. Nitrous fumes which were produced from arsenious oxide and nitric acid[6] were passed into the suspension until 20 g. of them were absorbed. The crude product was precipitated by pouring the suspension into ice water (200 cc.). The crude product was washed with water (400 cc.) and recrystallized twice from ether, giving pure *N*-nitrosophenylurea (3.1 g.), m. p. 89°C with decomposition. The pure product could be stored in an ice bath for several weeks without any appreciable decomposition.

**Polymerization.**—Details of the procedures of polymerization and the determination of the initial rate of polymerization were given previously[5]. In solution-polymerization, *N*-nitrosophenylurea was dissolved in benzene. Measured amounts of the benzene solution and methyl

methacrylate were placed in a test tube and mixed. The test tube was cooled in a dry ice-methanol bath, flashed with nitrogen, evacuated and sealed. Conversions of the polymerization were measured by precipitating and weighing polymethyl methacrylate formed. Degrees of polymerization of polymethyl methacrylate were estimated from their intrinsic viscosities in chloroform according to Sakurada[7].

**Summary**

*N*-Nitrosophenylurea is an efficient initiator of the polymerization of methyl methacrylate. The initial rate of polymerization of methyl methacrylate was linearly dependent upon the concentration of methyl methacrylate and the square root of the concentration of *N*-nitrosophenylurea. These facts suggest that the polymerization is initiated by radicals which are produced through a unimolecular first order decomposition of *N*-nitrosophenylurea.

# *Electrode Processes of Nickel(II) Ions at the Mercury Electrode in Concentrated Calcium Chloride Solutions*

By Nobuyuki TANAKA, Reita TAMAMUSHI and Mutsuo KODAMA*

(Received June 8, 1959)

The electrode reaction of nickel(II) ions at the mercury electrode seems to proceed with various mechanisms, depending on the kind of supporting electrolyte present in the solution. It has been known that the reduction of nickel(II) ions at the dropping mercury electrode (DME) in the concentrated solution of chloride occurs with a higher degree of reversibility at the potentials much more positive than those at which the reduction of hydrated nickel(II) ions takes place[1]. Reynolds and his coworkers[2,3] pointed out, from the results of the microcoulometry, that the reduction process of nickel(II) ions at the DME in 5 M calcium chloride solution is represented by

$$Ni^{2+} + 2e \rightarrow Ni$$

Recently, Vlček[4] reported that one continuous redox wave is obtained by the Kalousek's method[5,6] with nickel(II) ions in 6 M calcium chloride solution. From this result, he suggested that nickel(II) ions in 6 M calcium chloride solution is reduced at the mercury electrode to a zero-valent nickel complex, $NiCl_4^{4-}$, the life of which is estimated to be longer than 0.01 sec.

In this paper, an extensive and systematic study on the reduction of nickel(II) ions in concentrated calcium chloride solution at the mercury electrode is presented. The number of electrons which participate in the overall electrode reaction has been accurately determined by the coulometry at constant potential. The reduction product has been investigated by means of the controlled potential electrolysis at the mercury electrode. The reversibility of the electrode reaction is discussed from the analysis of the direct current (d. c.), the alternating current (a. c.) and the Kalousek's polarograms, and a possible mechanism for the reaction is proposed.

## Experimental

**Apparatus.**—Current-voltage curves were measured by a manual polarograph similar to that of Kolthoff and Lingane[7] or recorded automatically by a Yanagimoto Galvarecorder Y-GR 2. The Galvarecorder was also used for recording the a. c. and the Kalousek's polarograms and the current-time curves in coulometry.

The Kalousek's circuit used in this study is schematically shown in Fig. 1. The potential of

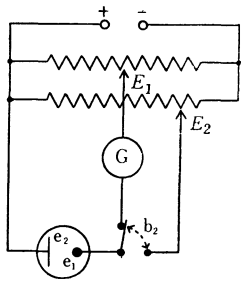

Fig. 1. Circuit of the Kalousek's method: G, Galvarecorder; $e_1$, working electrode (DME); $e_2$, unpolarizable electrode (S. C. E.); $b_2$, exchange switch (contact of relay B in Fig. 2).

the working electrode, $e_1$, is periodically changed from $E_1$ to $E_2$ and vice versa by the exchange switch $b_2$. When the reduction wave is concerned, $E_2$ is usually kept constant at a certain definite value in the potential region of the limiting current plateau. The value of $E_1$ is varied in the same way as in the ordinary polarograph, and only the current which flows when the electrode potential is $E_1$ is recorded. If the reduced substance produced at the electrode is oxidized at the potential of $E_1$, the anodic current is observed.

A simple relay circuit as shown in Fig. 2 was used to exchange the electrode potential instead of a conventional mechanical commutator which consists of a synchronous motor and a rotary switch. Relay B in Fig. 2 has two pairs of contacts, $b_1$ and $b_2$, the latter of which is used for

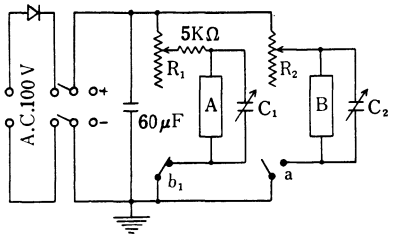

Fig. 2. Circuit of exchange switch: A, B, relay; a, contact of relay A; $b_1$, contact of relay B; $R_1$, $R_2$, 5 kΩ; $C_1$, $C_2$, 5~50 μF.

7) I. M. Kolthoff and J. J. Lingane, "Polarography", Vol. I, Interscience Publishers, Inc., New York (1952), p. 297.

the exchange switch in Fig. 1. The exchange frequency can be easily changed from apporoximately 2 c/s to 30 c/s by adjusting the capacitors $C_1$ and $C_2$. The on-and-off intervals of the switch were made equal by adjusting $R_1$ and $R_2$. This switch proved to be preferable to the conventional mechanical commutator because of the constancy and reliability in its switching action as well as because of its wide range of exchange frequencies. In this study, the exchange frequency of approximately 5.6 c/s was employed unless otherwise stated.

The controlled potential electrolysis was carried out by using a Yanagimoto automatic potentiostat. In the coulometric study the current through the electrolysis cell during the constant potential electrolysis was automatically recorded with a Yanagimoto Galvarecorder[8]. The quantity of electricity was determined by the graphical integration of the current-time curve thus obtained.

A simple beaker type cell was used for all polarographic measurements. A dropping mercury electrode, which had an $m$ value of $1.94_8$ mg./sec. and a drop time $\tau$ of 4.88 sec./drop in an air free 0.1 M potassium chloride solution at −0.60 V. vs. S. C. E., was used for the measurement of current-voltage curves. A saturated calomel electrode of a large surface area was used for the reference electrode, which was connected with the electrolytic solution by a Hume and Harris' type salt bridge[9]. When a. c. polarograms were measured, a platinum plate electrode of a large surface area was inserted in the electrolytic solution as the third electrode, which was terminated at the saturated calomel electrode through a 100 μF capacitor in order to minimize the impedance of the cell[10]. In the controlled potential electrolysis, the cathode was a mercury pool electrode whose surface area was approximately 20 $cm^2$, while the anode was a platinum spiral electrode which was connected with the electrolytic solution through a salt bridge. A saturated calomel electrode was used as a reference electrode, against which the electrode potential of the cathode was controlled.

All measurements were carried out in a thermostat of 25.00±0.01°C, and the dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution. The d. c. and the Kalousek's polarograms given in this paper were corrected for the residual current and the ohmic potential drop of the cell circuit.

**Reagents.** — A standard solution of nickel chloride was prepared by the following procedure. An appropriate amount of pure nickel metal (Yokozawa Chemicals Co.: cobalt content, 0.004%) was dissolved in nitric acid, and the excess of nitric acid was removed by evaporation. By dilution with distilled water a nickel nitrate

solution was obtained, to which a suitable amount of sodium carbonate was added to precipitate nickel(II) as carbonate. The precipitate was filtered off and washed thoroughly with distilled water. The resulting nickel carbonate was dissolved in dilute redistilled hydrochloric acid to prepare the standard solution of an appropriate concentration. The concentration of nickel was accurately determined by the conventional gravimetric method with dimethylglyoxime[11].

Calcium chloride which was free from organic surface-active substances was prepared. Reagent grade calcium chloride dihydrate was heated for 3 hr. at 470°C in an electric oven, and dissolved in redistilled water. After a small amount of insoluble substance was removed by decantation, the pH of the solution was adjusted to about 4.0 by adding hydrochloric acid. The chloride concentration of the solution was determined by the Volhard method[12].

All other chemicals used were of analytical reagent grade. Redistilled water was used to dilute the stock solutions and to prepare the electrolytic solutions.

## Results

In a preliminary investigation, it was found that in 6 M unpurified calcium chloride solution nickel(II) ions are not reduced at the mercury pool electrode at the potentials where they are reduced at the DME. Their reduction at the mercury pool electrode occurred only at much more negative potentials. This phenomenon was not observed when the supporting electrolyte solution was prepared with purified calcium chloride, and therefore it was explained as due to the poisoning effect of surface-active substances which might have been present in the solution prepared with the unpurified reagent. The reduction potential of nickel(II) at the mercury pool electrode was found to shift to negative potentials upon the addition of polyoxyethylene lauryl ether to the electrolytic solution prepared with the purified calcium chloride. This clearly supports the above explanation. In this paper, only the experimental results which were obtained with purified calcium chloride are presented.

The d. c. polarograms of nickel(II) ions which were obtained in the solutions containing various concentrations of calcium chloride are given in Fig. 3. In the presence of 6 M calcium chloride, nickel(II) ions gave a polarogram with a half-wave potential of −0.462 V. vs. S. C. E. A log-

plot, i. e. a plot of $\log i/(i_l-i)$ against $E$, of the polarogram gave a straight line with a slope of 38 mV. (Fig. 4). The limiting current was found to be proportional to the bulk concentration of nickel(II) and also to the square-root of the effective pressure on the DME, as shown in Tables I and II.

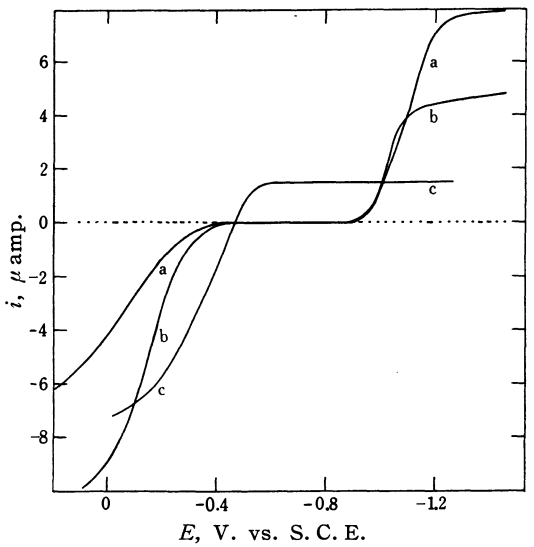

Fig. 5. Kalousek's polarograms of Ni(II) ions obtained at exchange frequency of 5.6 c/s. a; 2.0 mM $Ni(NO_3)_2$ in 0.2 M $KNO_3$, $E_2=-1.45$ V. vs. S. C. E.: b; 1.7 mM $NiCl_2$ in 0.2 M KCl, $E_2=-1.40$ V. vs. S. C. E.: c; 1.7 mM $NiCl_2$ in 6 M $CaCl_2$, $E_2=-0.75$ V. vs. S. C. E.

The Kalousek's polarograms in Fig. 5 were recorded in 6 M calcium chloride, 0.2 M potassium chloride and 0.2 M potassium nitrate solutions. In the 6 M calcium chloride solution one continuous redox wave (Fig. 5, c) was observed as has been reported by Vlček[4], while in the 0.2 M potassium chloride and the 0.2 M potassium nitrate solution no continuous redox wave was obtained, the anodic waves being far separated from the cathodic ones. It may be interesting to note that the potentials at which the anodic waves appear are almost identical in the three different solutions investigated.

In the 6 M calcium chloride solution a typical a. c. polarogram of nickel(II) as shown in Fig. 6 was obtained, the summit potential of which was nearly equal to the half-wave potential of the d. c. polarogram.

An example of the d. c. polarograms of nickel(II) ions obtained at the mercury pool electrode in the 6 M calcium chloride

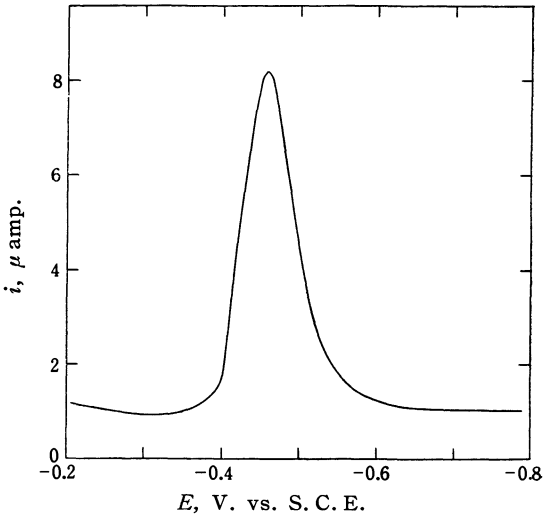

Fig. 6. A. C. polarogram of 3.37$_5$ mM Ni(II) ions in 6 M $CaCl_2$ solution.

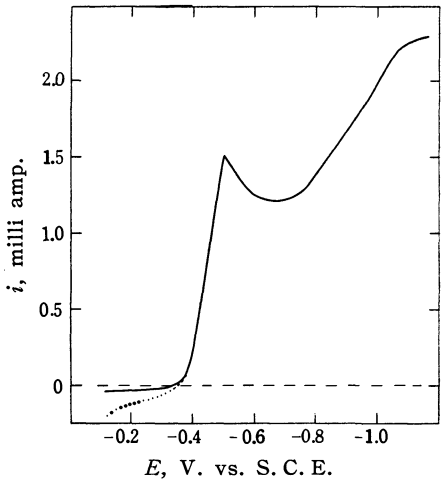

Fig. 7. Current—potential curve of Ni(II) ions in 6 M $CaCl_2$ solution at the mercury pool electrode.

solution is given in Fig. 7. An apparent anodic current was observed when the working electrode was polarized at $-0.1\sim-0.3$ V. vs. S. C. E. immediately after it had been polarized for 20 to 30 min. at the potential where the reduction of nickel(II) takes place (dotted line in Fig. 7). This anodic current remained nearly constant for several minutes if the solution was stirred by nitrogen gas bubbled through it. On the other hand, no anodic current was observed at the dropping mercury electrode with the same solution with which the anodic current was observed at the mercury pool electrode.

The number of electrons $n$ which participate in the overall electrode reaction of

nickel(II) was determined coulometrically by the controlled potential electrolysis. It can be calculated from the relation

$$n = \frac{Q}{FM} \times \frac{(i_d)_1}{(i_d)_1 - (i_d)_2}$$

where $Q$ is the quantity of electricity required for the electrolysis expressed in coulomb, $M$ the initial amount of nickel(II) ions present in the solution expressed in mole, and $(i_d)_1$ and $(i_d)_2$ are the diffusion currents of nickel(II) before and after the electrolysis, respectively. The value of $Q$ was corrected for the quantity of electricity that was measured with the supporting electrolyte solution under the same conditions of actual electrolysis. The results are presented in Table III.

TABLE III. THE NUMBER OF ELECTRONS $n$ CONCERNING THE OVERALL ELECTRODE REDUCTION OF Ni(II) IN 6 M $CaCl_2$ SOLUTION*

| Expt. | $(i_d)_1$, $\mu$ amp. | $(i_d)_2$, $\mu$ amp. | $Q$, coulombs | $n$ |
|---|---|---|---|---|
| 1 | 7.79 | 6.02 | $2.95_9$ | 2.00 |
| 2 | 7.71 | 5.62 | $3.53_2$ | 2.00 |

* The initial amount of Ni(II) was 0.0675 millimol.

In order to know whether the reduced substance of nickel(II) in 6 M calcium chloride solution is contained in the solution or in the mercury of the electrode, the nickel content of the mercury was determined after the electrolysis. Twenty milliliters of $3.37_5$ mM of nickel(II) solution containing 6 M calcium chloride was subjected to the controlled potential electrolysis at −0.80 V. vs. S. C. E. with a mercury pool electrode. After 30 to 40% of the total amount of nickel(II) was reduced, the mercury electrode was separated from the solution, washed carefully with distilled water, and then treated for about 30 hr. with 30 ml. of 3 M hydrochloric acid to extract nickel in the mercury. The precipitate of mercurous chloride produced was filtered off. The volume and pH of the filtrate were adjusted to be about 130 ml. and 6.0~6.5, respectively, by adding distilled water and ammonium hydroxide solution. Then, 15 ml. of 2 M potassium iodide solution was added to the solution, and the solution was kept standing for 30 min. The nickel content of the solution was determined by titration with a 0.01 M ethylenediaminetetraacetate solution using murexide as an indicator[13]. Preliminary experiments indicated that the nickel content can be determined with this procedure in the presence of an excess of mercuric ions. The amounts of nickel(II) ions reduced by the controlled potential electrolysis and those of nickel found in the mercury electrode are given in Table IV.

TABLE IV. DETERMINATION OF THE AMOUNT OF NICKEL IN THE MERCURY POOL ELECTRODE

| 0.0216 | 0.0203 | 94 |

## Discussion

The color of the solution containing nickel(II) ions and 6 M calcium chloride is yellowish green. This suggests the formation of chloronickel(II) complexes. According to Kiss and his coworkers[14] and Kiseleva and Khodeeva[15], the predominant species of these complexes is considered to be $NiCl_4^{2-}$.

The results given in Table II shows that the limiting current of nickel(II) ions in 6 M calcium chloride solution is diffusion-controlled. The relatively low value of the diffusion current for the unit concentration (Table I) is supposed to be due to the high viscosity of the solution. It is known that the diffusion coefficient of ions in the electrolyte solution is inversely proportional to the viscosity of the solution[16]. If the relation

$$D = D^\circ/\eta$$

where $D^\circ$ is the diffusion coefficient of $Ni^{2+}$ ions at infinite dilution and $\eta$ the viscosity of the 6 M calcium chloride solution referred to that of water as unity, is applied to the present case, the diffusion coefficient $D$ of nickel(II) ions in 6 M calcium chloride solution is calculated to be $8.1 \times 10^{-7}$ cm$^2$/sec., when $6.9 \times 10^{-6}$ cm$^2$/sec. is used for $D^\circ$[17] and 8.5 for $\eta$[18]. With the value of $D$ thus obtained, the number of

electrons which participate in the overall electrode reaction is calculated to be 2.0 with the modified Ilkovič equation[19]

$$i_d = 607\, nD^{1/2}m^{2/3}\tau^{1/6}C\left(1+\frac{34\tau^{1/6}D^{1/2}}{m^{1/3}}\right)$$

This value of $n$ is in agreement with that obtained by coulometry at constant potential (Table III), and leads to a conclusion that the nickel(II) ions in 6 M calcium chloride solution are reduced at the mercury electrode to either nickel metal or some chloro complexes of zero-valent nickel.

It has been reported by Vlček[4] that the anodic wave of the Kalousek's polarogram obtained with nickel(II) ions in 6 M calcium chloride solution is due to the oxidation of zero-valent nickel complex, $NiCl_4^{4-}$, formed on the surface of the electrode. On the other hand, it has been known that nickel amalgam is easily obtained by the reduction of aqueous solutions of nickel chloride or sulfate at the mercury electrode[20,21]. Breckpot[22] reported that the oxidation of nickel amalgam occurred at +0.10 V. vs. N. H. E. at 75°C under the current density of 15 amp./m$^2$. This value of oxidation potential agrees approximately with those which were determined from the Kalousek's polarograms given in Fig. 5. The anodic wave is clearly observed on the Kalousek's polarogram which was obtained at the exchange frequency of about 2 c/s. This seems to be an indication that the life of the substance which is actually oxidized by the Kalousek's method must be longer than 0.5 sec. These facts strongly suggest that the anodic current observed with the Kalousek's method is due to the oxidation of nickel amalgam. It should be noted that the oxidation of nickel amalgam proceeds at almost the same potential in all of the solutions (the 6 M calcium chloride, the 0.2 M potassium chloride and the 0.2 M potassium nitrate solution), while the reduction takes place at entirely different potentials in these three solutions depending on the species and the concentration of supporting electrolyte.

Table IV shows that the amount of nickel reduced at the mercury electrode in 6 M calcium chloride solution is almost completely recovered from the mercury electrode. This excludes any possible contribution of the monovalent nickel compounds to the overall electrode reaction, but supports the conclusion that the reduced substance is nickel metal which is dissolved in mercury as nickel amalgam. However, any possibility that the zero- or monovalent nickel complexes exist as the reaction intermediate of very short lives is not excluded.

The experimental results of the a. c. and the Kalousek's polarograms and the log-plot analysis of the d. c. current-voltage curves indicate that the electrode reaction of nickel(II) ions in 6 M calcium chloride solution proceeds with a relatively high degree of reversibility in comparison with that of hydrated nickel(II) ions. It has been pointed out by Senda[23] et al. that the value of $i_p/(n\sqrt{\tau}\, i_d)$, where $i_p$ is the peak current of the a. c. polarogram, represents the degree of reversibility of the electrode reaction. The value for nickel(II) ions in 6 M calcium chloride solution was calculated to be 0.20, which is smaller than the values for the well-known reversible systems such as cadmium(II) or lead(II) ions in potassium nitrate solutions, but nearly equal to those of quasi-reversible systems such as zinc(II) ions in potassium nitrate solutions.

From the foregoing discussion, it can be concluded that the electrode reaction of nickel(II) ions in 6 M calcium chloride proceeds quasi-reversibly at the mercury electrode according to the reaction

$$NiCl_4^{2-} + 2e + Hg \rightleftarrows Ni(Hg) + 4Cl^-$$

## Summary

A typical reduction wave with a half-wave potential of −0.462 V. vs. S. C. E. was obtained with nickel(II) ions in 6 M calcium chloride solution. The a. c. and the Kalousek's polarograms revealed that the electrode reaction is a quasi-reversible one. From the coulometric measurement carried out at the constant potential, the overall electrode reaction proved to be a two-electron reduction. Nearly the total amount of nickel reduced by the controlled potential electrolysis with the mercury electrode was recovered from the mercury, indicating that the nickel(II) ions are reduced to nickel metal to form probably

nickel amalgam. From these experimental results the electrode reaction of nickel(II) ions in 6 M calcium chloride at the mercury electrode was concluded to proceed quasi-reversibly according to the equation

$$NiCl_4^{2-} + 2e + Hg \rightleftarrows Ni(Hg) + 4Cl^-$$

# *Hot-Atom Chemistry of Halogens in Cobaltammine Complex Salts. I. Hot-Atom Chemistry of Bromine in Bromopentammine Cobalt Complex Salts*

By Nobufusa SAITO, Hirotoshi SANO and Takeshi TOMINAGA

(Received June 22, 1959)

Many attempts have already been made to study the hot-atom effect of central atoms in metal complex salts, while very little attention has so far been paid to the hot-atom effect of ligand atoms[1].

The present authors investigated the behavior of radiobromine in ligands of bromopentammine cobalt complex salts following $(n, \gamma)$ process induced by neutron irradiation. The distribution of radiobromine was studied after the salts were irradiated in different phases and at varied temperatures. The authors were especially interested in the irradiation of the complex ion loaded on a cation exchange resin, because some results were already obtained in their laboratory with respect to the behavior of hot-atoms in ion exchange resins[2].

## Experimental

**Samples.**—Five bromopentammine cobalt complex salts were prepared by methods already known:

1. $[Co(NH_3)_5Br](NO_3)_2$[3]
2. $[Co(NH_3)_5Br](C_2O_4)$[4]
3. $[Co(NH_3)_5Br]Cl_2$[5]
4. $[Co(NH_3)_5Br]Br_2$[6]
5. $[Co(NH_3)_5Br]I_2$[7]

Their composition was checked by the spectrophotometric method and by the determination of halogen contents.

For the irradiation in resin phase, $[Co(NH_3)_5Br]^{2+}$ was adsorbed on Dowex 50 W, cation exchange resin in the hydrogen form, 8% cross-linked, consisting of 100~200 mesh beads. As the bromopentammine cobalt complex salts are aquated in the presence of moisture, the resin loaded with complex ion was dried immediately after washing, by means of suction on a sintered-glass filter for a few hours, or by means of heating at 40~60°C under reduced pressure in an Abderhalden's desiccator with phosphorus pentoxide. However, prolonged procedure of drying, especially, of heating in the Abderhalden's desiccator, caused in the meantime considerable aquation. (The remaining moisture caused aquation even after it was reduced to a very small amount by drying.)

Thus, in the case of the complex ion on the resin, not the pure complex ion but the mixture of $[Co(NH_3)_5Br]^{2+}$ and the aquated products, $[Co(NH_3)_5H_2O]^{3+}$ and $Br^-$, was actually irradiated. The ratio of bromo- and aquo-pentammine complex salts was estimated by determining the amount of $Br^-$ liberated in the aquation reaction 1;

$$[Co(NH_3)_5Br]^{2+} + H_2O \rightarrow [Co(NH_3)_5H_2O]^{3+} + Br^- \quad (1)$$

and was shown in Table III. The procedure of determination was as follows: the dried resin with the mixture was washed with water, and $Br^-$ which had been liberated was extracted and determined volumetrically.

**Irradiation.**—The neutrons produced by Be-D reaction in a cyclotron were thermalized. The flux was approximately $10^7$ neutrons/cm$^2$ sec. The samples were irradiated for two to three hours at room temperature or at a lower temperature (−72°C). For the irradiation at room

temperature, the samples were placed in a paraffin block, while for the irradiation at −72°C, they were put in a test tube immersed in a mixture of dry ice and ethanol in a Dewar's vessel.

The complex salts as aqueous solutions or adsorbed on the resin and dipped in water were irradiated with their container immersed in a mixture of ice and water.

**Procedures of Separation.**—Solid samples were dissolved in water one to four hours after the end of irradiation. (The samples irradiated at a lower temperature were kept at room temperature after the irradiation was over.) The solution was poured into a 1.5 cm.×0.8 $cm^2$ column of Dowex 50 W in the hydrogen form*, 8% cross-linked, 100~200 mesh. The column was then washed with water until the total volume of the effluent amounted to 100 ml. The effluent yielded the first fraction containing anions of the sample solution and radiobromine leached out as anions**. The complex ions were adsorbed on the cation exchange resin so firmly that none of them could be detected spectrophotometrically in the first fraction.

The resin loaded with the complex ions was then immersed in water and digested on a bath at 70 to 85°C for about an hour. As the aquation of the bromopentammines was very rapid at elevated temperatures, ligand bromine including radioisotopes was almost completely aquated with this procedure and was extracted by water as the bromide ion. The extract was separated from the resin and aquo complex ion. The extract and the washing yielded the second fraction.

The complex salts irradiated as solutions were treated in the same way as the solids except that precautions were taken to prevent the aquation before the separation process.

The treatment of the complex ion in the resin phase was as follows. The irradiated resin and complex ion were put into a sintered-glass filter of 1 cm. in diameter containing from about a half to an equal volume of Dowex 50 W, 8% cross-linked, (hydrogen form), at the bottom. The size of the column was about 0.8$cm^2$×4~5cm. The column was immersed in water and then washed by suction with 250~300 ml. of cold water. The washing yielded the first fraction. The resin and the complex ion were digested with water, and the extract yielded the second fraction. In this case, the resin with the aquo complex ion still contained considerable activity which could hardly be removed by further digestion with hot water, or by treatment with inorganic acids or with a reducing agent (0.3 M $NaHSO_2$+0.2 M $H_2SO_4$). This was the third fraction.

Measurements were made on each fraction with respect to the gross activity of $^{80m}Br$ (actually, of its daughter, $^{80}Br$, in equilibrium) and $^{82}Br$, and with respect to the content of bromine.

In order to eliminate the hot-atom effect of $^{80}Br$ ($T_{1/2}$=18 min.) following the isomeric transition from $^{80m}Br$, measurements of activity were made more than three hours after the first fraction had been separated. Thus the gross hot-atom effect of $^{80m}Br$ and $^{82}Br$ was observed in this investigation. The ratio of activities of the two isotopes, $^{80m}Br$ and $^{82}Br$, was about 15 : 1 at the end of irradiation, while 5.5 hr. after the end of irradiation it became 8 : 1. The distribution of activity was calculated for each sample by referring to a definite time (5.5 hr. after the end of irradiation).

Activity was measured with either an immersion-type G-M tube or an end-window G-M tube. Silver bromide precipitates were mounted on counting dishes in the latter case.

Bromide was determined volumetrically by Mohr's method or colorimetrically by the method of Stenger and Kolthoff[8]. The amounts of bromine retained in the resin were estimated by radioactivation analysis.

## Results and Discussion

**Hot-Atom Chemistry in Solids.**—The results of measurements on the solid complex salts are shown in Table I. In any of the complex salts investigated, over eighty per cent of radiobromine atoms was leached out into water with an enrichment factor of at least 50. As the maximum recoil energy of radiobromine resulting from slow neutron capture was calculated to be 174 eV.[9], and this is large enough to break Co–Br bond, such a high extractability may not be unexpected.

The column F-2 in Table I is expected to denote the fraction of radiobromine retained in the ligands of the cobalt complex salts. When a bromine atom in $[Co(NH_3)_5Br]^{2+}$ recoils following the neutron capture, the bond between the metal and the bromine is broken and the resulting hot-atom may have several collisions with the surrounding molecules or atoms before it slows down. In the hot reactions with the recoiling bromine or in the recombination reactions which follow them, complex ions such as $[Co(NH_3)_4BrBr^*]^+$ may probably be produced*** as well as $[Co(NH_3)_5Br^*]^{2+}$ (Br* denotes radiobromine). As

* Potassium form was also used, but the results were not significantly different from those obtained with hydrogen form.

** It was reported by Saito, Tomita and Furukawa that most of radiobromine produced in the neutron irradiation of bromates was found in the form of bromide (presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958).

9) A. C. Wahl and N. A. Bonner, "Radioactivity Applied to Chemistry", John Wiley & Sons, Inc., New York (1951), p. 247.

*** The replacement of an ammine group by hot bromine was proved by the fact that ligand yield as $[Co(NH_3)_5Br]^{2+}$ of about 5% was obtained in the irradiation of $[Co(NH_3)_6]Br_3$ with slow neutrons. Details will be published elsewhere.

TABLE I. DISTRIBUTION OF $^{80m}Br$ AND $^{82}Br$ ACTIVITY AND ENRICHMENT FACTOR IN SOLIDS

| Complex salt | Irradiation at room temp. | | Irradiation at −72°C | | Enrichment factor of F-1 |
|---|---|---|---|---|---|
| | F-1 % | F-2* % | F-1 % | F-2* % | |
| $[Co(NH_3)_5Br](NO_3)_2$ | 83.9 | 16.1 | 87.3 | 12.7 | $1\times10^2$ |
| $[Co(NH_3)_5Br](C_2O_4)$ | 82.6 | 17.4 | — | — | $0.5\times10^2$ |
| $[Co(NH_3)_5Br]Cl_2$ | 82.2 | 17.8 | 84.2 | 15.8 | $0.5\times10^2$ |
| $[Co(NH_3)_5Br]Br_2$ | 82.7 | 17.3 | 82.6 | 17.4 | — |
| $[Co(NH_3)_5Br]I_2$ | 87.6 | 12.4 | — | — | $2\times10^2$ |

* Ligand yield as $[Co(NH_3)_5Br^*]^{2+}$. These values were reproducible in at least three runs within 0.4~0.7% standard deviation.

both complex ions are cationic, the second fraction essentially includes the activity in the form of $[Co(NH_3)_4BrBr^*]^+$ besides $[Co(NH_3)_5Br^*]^{2+}$. The probability of the formation of complex ions containing more than two bromine atoms in ligands may be negligibly small.

For the convenience of discussion, the authors defined a quantity $(L.Y.)_A$, "ligand yield in the form of A", which indicated the fraction of total produced activity retained in the form of the complex ion, A. The value in the second fraction is then the summation of ligand yields of all the complex cations; $(L.Y.)_{[Co(NH_3)_5Br^*]^{2+}}$ and $(L.Y.)_{[Co(NH_3)_4BrBr^*]^+}$ (*cis*- and *trans*-isomers).

In this case, however, all the tetrammine complex salts containing radiobromine are much more unstable and are much more rapidly aquated with liberation of bromine than the pentammine complex salts are. The aquation reactions are

$$[Co(NH_3)_4Br_2]^+ + H_2O \rightarrow [Co(NH_3)_4BrH_2O]^{2+} + Br^- \quad (2)$$

$$[Co(NH_3)_4BrH_2O]^{2+} + H_2O \rightarrow [Co(NH_3)_4(H_2O)_2]^{3+} + Br^- \quad (3)$$

Radiobromine in the tetrammine complex salts is liberated and enters the first fraction, through either of these reactions. Half time of the aquation reactions in nearly neutral aqueous solutions were estimated to be a few minutes at 15~20°C, while that of reaction 1 was estimated to be about a hundred hours[10].

In this investigation, the irradiated complex salts were dissolved in water (pH 5~6) at room temperature and kept in solutions for a sufficiently long time in order to eliminate $(L.Y.)_{[Co(NH_3)_4BrBr^*]^+}$ from the second fraction. When all the unstable complex ions were aquated and only the pentammine remained, the curve for the observed activity of the second fraction vs. the period of separation (period of standing in water) leveled off****. Therefore the distribution of activity in the second fraction in Table I may be taken as almost identical with the ligand yield in the form of $[Co(NH_3)_5Br^*]^{2+}$, or so-called "retention".

As seen in Table I, ligand yield as $[Co(NH_3)_5Br^*]^{2+}$ of the complex salts does not vary appreciably as the anionic component is replaced, except that the iodide shows considerably low yield. The irradiation at a lower temperature decreases the yield in some salts, while in the bromide the yield remains almost unchanged. It is interesting to note that the bromide shows almost the same yield as other salts in the irradiation at room temperature: the hot-atoms resulting from the anions may behave in the same way as those from ligands of the complex salts.

**Hot-Atom Chemistry in Aqueous Solutions.**— The results of measurements of aqueous solutions of the complex salts are shown in Table II. In this case, practically all radiobromine was leached out into the first fraction.

**Hot-Atom Chemistry in Resin Phase.** — As shown in Table III, about 80% of the total activity was extracted into the first fraction with enrichment factors of 3~40 when the irradiated resin and complex ion was washed with water. Nine to thirteen per cent of the activity was retained in the ligands (F-2). More than 9% of the total activity remained in the resin even after the aquation of the complex ion on the resin had been brought to completion (F-3).

10) A. B. Lamb and J. W. Marden, *J. Am. Chem. Soc.*, **33**, 1873 (1911); J. N. Bronsted and R. Livingston, ibid., **49**, 435 (1927).

**** By means of extrapolation of the curves to the separation time zero, approximate values of unstable ligand yields (i. e. as $[Co(NH_3)_4BrBr^*]^+$) were roughly estimated to be about 2~5%.

TABLE II. DISTRIBUTION OF $^{80m}Br$ AND $^{82}Br$ ACTIVITY AND ENRICHMENT FACTOR IN SOLUTIONS

| Complex salt | Concentration | Irradiation at 0~3°C | | Enrichment factor of F-1 |
|---|---|---|---|---|
| | | F-1 % | F-2 % | |
| $[Co(NH_3)_5Br](NO_3)_2$ | $7\times10^{-3}$ M | 99.2 | 0.8±0.6 | $0.4\times10^2$ |
| $[Co(NH_3)_5Br](NO_3)_2$ | $8\times10^{-4}$ M | nearly 100 | nearly 0 | $0.4\times10^2$ |

TABLE III. DISTRIBUTION OF $^{80m}Br$ AND $^{82}Br$ ACTIVITY AND PERCENTAGE OF AQUATION IN RESIN PHASE

| Condition of drying | Temp. of irradiation | Distribution of activity | | | Percentage of aquation (aquo-complex %) |
|---|---|---|---|---|---|
| | | F-1 % | F-2 % | F-3 % | |
| Suction | room temp. | 80.0 | 10.7 | 9.3 | 11~20 |
| | −72°C | 81.1 | 9.3 | 9.6 | 5~ 9 |
| Abderhalden | room temp. | 80.2 | 10.7 | 9.1 | 15~42 |
| | −72°C | 80.5 | 8.9 | 10.6 | 9~21 |
| Without drying | 0~13°C (dipped in water) | 76.5 | 13.0 | 10.5 | 2~ 4 |

As mentioned above, the mixture of bromo- and aquo-pentammine complex ions and the liberated bromine was irradiated on the cation exchange resin. The "percentage of aquation" is shown in Table III. Therefore, the interpretation of the activity in the second fraction is more complicated in the resin phase than in solids. The complex cations possibly produced through the hot-atom effect in the irradiation of the mixture are as follows:

a) from $[Co(NH_3)_5Br]^{2+}$,

$$\begin{cases}[Co(NH_3)_5Br^*]^{2+}\\ [Co(NH_3)_4BrBr^*]^{+}\end{cases}$$

b) from $[Co(NH_3)_5H_2O]^{3+}$,

$$\begin{cases}[Co(NH_3)_5Br^*]^{2+}\\ [Co(NH_3)_4Br^*H_2O]^{2+}\end{cases}$$

Radiobromine in ligands of the unstable complex ions other than the bromopentammine may be considerably aquated during the separation process and eluted into the first fraction. However, these aquation reactions do not proceed as rapidly in the resin in the hydrogen form as in the solutions of the irradiated solids, because the rate of reaction 3 is dependent on the pH of solution and it becomes much slower in acid solutions[11].

In the cation exchange resin in the hydrogen form, the pH of the effluent was measured and found to be less than 3, where half time of reaction 3 was several hundred minutes. Therefore, as far as the products of reactions a) are concerned, only about 50% of $(L.Y.)_{[Co(NH_3)_4BrBr^*]^+}$ may be eliminated from the second fraction through the aquation reaction 2 which is almost completed during the period of separation in this investigation, but reaction 3 may not proceed appreciably in the meantime. Similarly, the products of reactions b) may remain without being aquated during the period of separation.

By making suitable assumptions, the authors estimated ligand yields of the above complex ions separately. According to the investigations now being made in their laboratory[12] a considerable fraction of hot bromine resulting from anionic sphere was enriched in ligands of pentammine cobalt complex salts, $[Co(NH_3)_5Y]Br_{(2\text{ or }3)}$, when they were irradiated with slow neutrons. The value of $(L.Y.)_{[Co(NH_3)_5Br^*]^{2+}}$ for $[Co(NH_3)_5H_2O]Br_3$ sample was 7~8%, which was about a half of that in $[Co(NH_3)_5Br]Br_2$. By assuming that $(L.Y.)_{[Co(NH_3)_5Br^*]^{2+}}$ due to aquo- and bromo- pentammine complex ions in the mixture adsorbed on the resin are in the same ratio (i.e. about 1/2) as those separately obtained in the irradiation of solids of these complex salts, the ligand yields in bromopentammine cobalt complex ion corrected for aquation were calculated and are listed in Table IV. These values, however, may be larger than $(L.Y.)_{[Co(NH_3)_5Br^*]^{2+}}$ by about 50% of $(L.Y.)_{[Co(NH_3)_4BrBr^*]^+}$ (i.e. 1~2%)[13].

11) J. N. Brönsted, *Z. physik. Chem.*, **122**, 383 (1926).

12) Results were partly reported at the 12th Annual Meeting of the Chemical Society of Japan, April, Kyoto, 1959. Details will be published elsewhere.

13) Ligand yields of the tetrammine complex salts were estimated as about 1~4%.

TABLE IV. LIGAND YIELDS IN BROMOPENTAMMINE COBALT COMPLEX ION ON THE RESIN CORRECTED FOR AQUATION

| Condition of drying | Temp. of irradiation | Ligand yields* % |
|---|---|---|
| Suction | room temp. | 12.0 |
| | −72°C | 10.4 |
| Abderhalden | room temp. | 13.4 |
| | −72°C | 10.7 |
| Without drying | 0~13°C (dipped in water) | 13.0 |

* Ligand yields may include (L.Y.)$_{[Co(NH_3)_5Br^*]^{2+}}$ and about 1/2 of (L.Y.)$_{[Co(NH_3)_4BrBr^*]^+}$.

As seen in Table IV, the ligand yields in bromopentammine on the cation exchange resin are 10~13% and lower than those obtained in solids. The yields decreased slightly when the samples were irradiated at a lower temperature. It is interesting to note that the presence of water in the samples did not influence the yields appreciably. Even in the case where the complex and the resin were dipped in water during the irradiation, the yields were not greatly different from those for the samples dried in the Abderhalden's desiccator. This may be understood as indicating that the rate of exchange of ligand bromine of bromopentammine with bromide ion in aqueous solutions is very slow and that the aquation reaction 1 does not disturb the mechanism of recombination from which some portion of the ligand yield may result.

Nearly 10% of the total activity was retained in the irradiated resin after the treatments described above. The enrichment factor of radiobromine in this fraction (F-3) was estimated as at least 100. The exchange reaction between the bromine remaining in the resin and bromide ion in water was regarded as being very slow even at elevated temperatures (70~85°C). The reducing agent decreased the activity in the resin only slightly. The irradiation at a lower temperature increased the activity in the resin slightly.

It was presumed from these observations that most of the radiobromine remaining in the leached resin would be organically combined with the resin matrix: some results in favor of this conclusion were reported by Carlson and Koski[14].

## Summary

The hot-atom effect was investigated on $^{80m}Br$ and $^{82}Br$ resulting from $(n, \gamma)$ processes in ligand bromine of bromopentammine cobalt complex salts. The fraction of radiobromine retained in ligand (ligand yield) was compared for samples irradiated in different phases, and it increased in the following order: solution, resin, solid. It is interesting to note that in the irradiation of solids of bromopentammines $[Co(NH_3)_5Br]Br_2$ showed almost the same ligand yield as other salts. The hot-atoms resulting from the anions may behave in the same way as those from ligands of the complex salts. The exchange of ligand bromine in these complex salts with bromide in water was regarded as being very slow at room temperature.

In the irradiation of the complex ion adsorbed on a cation exchange resin, a considerable fraction of radiobromine was trapped in the resin matrix. Treatments with either inorganic acids or a reducing agent did not remove the activity appreciably. Most of the radiobromine remaining in resin was presumed to be organically combined with the matrix.

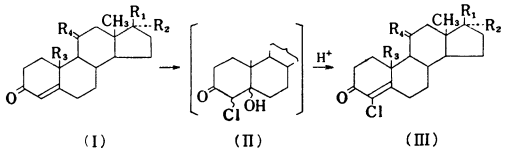
# *The Reaction of 3-Oxo-$\Delta^4$-steroids with Isocyanuric Chloride*



By Fumikazu MUKAWA

(Received May 13, 1959)

It has been reported that 3$\beta$-substituted-$\Delta^5$-steroids gave the corresponding 5$\alpha$-chloro-6$\beta$-hydroxy compounds on treatment with isocyanuric chloride, and that 3-oxo-$\Delta^5$-steroids and their ethyleneketal gave the 6$\beta$-chloro-5$\alpha$-hydroxy compounds[1].

Now, similar studies on the reaction of 3-oxo-$\Delta^4$-steroids (I) with isocyanuric chloride are reported herewith.

Treating the model compound progesterone with isocyanuric chloride in acetone-acetic acid (or perchloric acid) yielded a chloro compound, having an ultraviolet absorption typical for the 4-substituent-4-en-3-one system ($\lambda_{max}^{EtOH}$ 256 m$\mu$, log $\varepsilon$ 4.12)[2-4]. The identity of the product with 4-chloroprogesterone was established by its melting point and the infrared spectrum. Therefore, it appears that 4-chloroprogesterone (Ic) is formed through an intermediate 4$\xi$-chloro-5$\xi$-hydroxy compound (II):

(I) (II) (III)

(a) $R_1$=OAc, $R_2$=H, $R_3$=$CH_3$, $R_4$=$H_2$
(b) $R_1$=$OCOC_2H_5$, $R_2$=H, $R_3$=$CH_3$, $R_4$=$H_2$
(c) $R_1$=$COCH_3$, $R_2$=H, $R_3$=$CH_3$, $R_4$=$H_2$
(d) $R_1$=$COCH_3$, $R_2$=OH, $R_3$=$CH_3$, $R_4$=$H_2$
(e) $R_1$=$COCH_3$, $R_2$=OAc, $R_3$=$CH_3$, $R_4$=$H_2$
(f) $R_1$=OH, $R_2$=$CH_3$, $R_3$=H, $R_4$=$H_2$
(g) $R_1$=$COCH_2OAc$, $R_2$=OH, $R_3$=$CH_3$, $R_4$=O

Extension of this chlorination method to 3-oxo-$\Delta^4$-steroid hormones, led to 4-chloro-derivatives, several of which were characterized by their absorption maximum.

Since this work was completed, Oliveto et al. reported[5] the preparation of 4-chlorocortisone acetate by *N*-chlorosuccinimide and perchloric acid.

4-Chlorotestosterone acetate (IIIa) and 4-chlorotestosterone propionate (IIIb) exhibited greater anabolic and smaller androgenic effect in comparison to administeral testosterone propionate, and showed no inhibitory effects on the gonadotropic secretion upon intraspleenic ovarian transplantation[6].

4-Chloroprogesterone (IIIc) and 4-chloro-17$\alpha$-acetoxyprogesterone (IIIe) showed no progestational activity.

## Experimental*

**5$\alpha$-Chloro-3$\beta$-acetoxy-pregnan-6$\beta$-ol.** — To a mixture consisting of 1.0 g. of pregnenolone acetate, 0.5 g. of isocyanuric chloride and 30 ml. of acetone were added ten drops of 30% acetic acid. The whole was refluxed for 5 min. After cooling to room temperature, the mixture was poured with stirring into 10% aqueous sodium carbonate, and then extracted with ether. The extract was washed with water and dried over magnesium sulfate, after removal of the solvent, the residue was recrystallized from acetone-water to yield 0.6 g. of needles, m. p. 195°C (decomp.), $[\alpha]_D^{17}$ +36 (c. 1.2).

*Anal.* Found: C, 67.26; H, 8.65; Cl, 8.42. Calcd. for $C_{23}H_{35}O_4Cl$: C, 67.37; H, 8.60; Cl, 8.65%.

**Preparation of 4-Chloro-3-oxo-$\Delta^4$-steroids.** — A solution of 0.5 g. of 3-oxo-$\Delta^4$-steroid and 0.3 g. of isocyanuric chloride in 30 ml. of acetone was refluxed for 1 hr. with 3 ml. of acetic acid or 10% perchloric acid. The reaction mixture was then poured into 10% sodium carbonate solution and extracted with ether. Washing of the extract with water, drying over magnesium sulfate, and evaporation of the solvent led to a residue which was purified by recrystallization or chromatography on florisil.

The following 4-chloro-3-oxo-$\Delta^4$-steroids were prepared by this method:

*4-Chlorotestosterone acetate (IIIa)*, needles, m. p. 228°C (from acetone), $\lambda_{max}^{EtOH}$ 255 m$\mu$ (log $\varepsilon$ 4.12);

*4-Chlorotestosterone propionate (IIIb)*, needles, m. p. 164°C (from methanol), $\lambda_{max}^{EtOH}$ 256 m$\mu$ (log $\varepsilon$ 4.12);

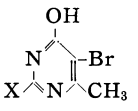
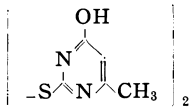
# *Wohl-Ziegler Reaction on 6-Methyluracil and its Homologues*



By Tarozaemon NISHIWAKI and Toshinao GOTO

(Received July 6, 1959)



In general, a free radical mechanism has been presented for the Wohl-Ziegler reaction of allylic methyl groups with *N*-bromosuccinimide, but some abnormal reactions such as aromatic nuclear bromination and addition of bromine to olefinic double bonds by this reagent have been believed to proceed via an ionic mechanism. Since hydroxyl groups in the 2-, 4-, or 6-position of pyrimidines tend to increase electron availability at the 5-position in the ring, it seems very interesting to investigate whether such pyrimidines as 6-methyluracil (I), 2-mercapto-6-methyluracil (II), and 2-amino-6-methyluracil (III) are brominated with NBS at allylic side chain or at a nucleus.

(I) X=OH
(II) X=SH
(III) X=$NH_2$

(IV) X=OH
(VI) X=SH
(VII) X=$NH_2$

(V)

The Wohl-Ziegler reactions on methylpyrimidines are scarecely known. 5-Methyl-barbituric acid[1] and 5-methyl-2,4,6-trichloropyrimidine[2] are brominated at the methyl groups while 2-methyl-4H-pyrido-(1,2-a)-4-pyrimidone[3] are brominated at the nucleus. With *N*-chlorosuccinimide (NCS) uracil, thymine and 2-methylmercapto-6-methyluracil gave nuclear-substituted product in glacial acetic acid and allylic side chain substituted-products in chloroform plus benzoyl peroxide[4].

When the reaction of 6-methyluracil (I) and NBS was undertaken under the classical free radical condition, a halogen-containing product, which decomposed at 251°C, was obtained. Analytical values indicated that this was the brominated compound of I. The melting point of 5-bromo-6-methyluracil (IV), however, was reported to be 247°C (decomp.) by Matsukawa et al.[5] and to be 241°C (decomp.)

by Kurtev et al.[6] The site of the bromine atom in the present compound was concluded to be at $C_5$-position by its unreactive character (e. g. unsuccessful condensation with ethyl malonate)[7] and also by the fact that chlorination of this material yielded 5-bromo-2, 4-dichloro-6-methylpyrimidine[5]. Attempted bromination of 6-methyl-2,4-dichloropyrimidine and 5-bromo-6-methyluracil failed even under illumination with electric light.

2-Mercapto-6-methyluracil (II) was then brominated under the analogous condition. The reaction products were separated by the difference of solubility in ethyl acetate. Ethyl acetate insoluble compound contained no halogen, decomposed gradually over 290°C and could be recrystallized from methanol. From the analytical data, this compound was inferred to be identical with the starting material or with the disulfide (V), solvated with methanol. However, the latter structure was denied because of unsuccessful reduction with sodium borohydride and of the positive reaction for the thiol group with sodium nitroprusside. The reduction of disulfide bond with sodium borohydride was reported by Walton et al.[8] This compound was identified as the starting material by successive benzylation using Bucher's method[9]. From ethyl acetate soluble fraction, a halogen-containing compound with m. p. 256°C (decomp.) was obtained, which was shown to be 5-bromo-2-mercapto-6-methyluracil (VI) by analysis, comparison of its physical data with that reported by Barrett et al.[10,11], positive sodium nitroprusside reaction and failure to brominate this product further, while the expected compound would be susceptible to the further bromination at reactive $C_5$-position, if the bromine had attacked the allylic methyl group. Direct bromination of pyrimidines having alkyl- or aryl-free sulfhydryl group at $C_2$-position had scarecely been reported and Barrett et al. prepared 5-brom-2-mercapto-6-methyluracil (VI) through demethylation of 5-bromo-2-methylmercapto-6-methyluracil by hydrogen iodide. However, it has been revealed that this compound was conveniently prepared by the present method, though in low yield. As 2-methylmercapto-6-methyluracil was substituted at an allylic side chain by NCS, it was also anticipated that this pyrimidine could be brominated at the same position. However, contrary to the authors' expectation, none of the halogen-containing product was obtained, resulting in the quantitative recovery of the starting material.

Under the same condition 2-amino-6-methyluracil (III) was also shown to be brominated at the nucleus by NBS. The reaction product, 5-bromo-2-amino-6-methyluracil (VII), seemed to be unstable in water, because the aqueous solution of this pyrimidine became acidic.

It has also been disclosed that these pyrimidines (I), (II), (III) were brominated at $C_5$-position even in the absence of benzoyl peroxide, in about the same yield as that when benzoyl peroxide was present. From these results it seems possible to conclude that electrophilic attack by NBS took place at $C_5$-position of these three hydroxylpyrimidines.

During the course of this work, the attempt has been made to synthesize 5-bromo-2-benzylmercapto-6-methyluracil. However, this product could not be purified without causing hydrolysis to 5-bromo-6-methyluracil.

## Experimental

**5-Bromo-6-methyluracil (IV).** — Mixtures of 6-methyluracil (12.6 g.), NBS (17.8 g.), benzoyl peroxide (20 mg.) and carbon tetrachloride (100 ml.) were refluxed for 2.5 hr. on a steam bath. After cooling, the solid was collected, and was heated in ethyl acetate (100 ml.) for 50 min. The ethyl acetate insoluble material, after being collected while hot, was successively washed with ethanol (20 ml.), water (10 ml.), and dried at 100°C for one hour, which was recrystallized from glacial acetic acid (charcoal), to give 5-bromo-6-methyluracil, colorless needles, (9.67 g.), m. p. (uncorrected) 251°C (decomp.).

*Anal.* Found: C, 29.61; H, 2.50; N, 13.44. Calcd. for $C_5H_5BrN_2O_2$: C, 29.29; H, 2.45; N, 13.66%.

**5-Bromo-2, 4-dichloro-6-methylpyrimidine.** — The above brominated pyrimidine (IV) (1.50 g.) was heated with mixtures of phosphorous oxychloride (8 ml.) and dimethylaniline (8 ml.) for one hour on an oil bath. The excess of dimethylaniline was removed under reduced pressure, the residue was poured on crushed ice (100 g.). Ether extraction afforded, after removal of the solvent, a compound, b. p. 65~70°C/10 mmHg. It has solidified and then was recrystallized from petroleum ether (b. p. 30~60°C), colorless needles (100 mg.), m. p. (uncorrected) 40~42.5°C. Matsukawa et al. gave m. p. 42~43°C for 5-bromo-2, 4-dichloro-6-methylpyrimidine.

**Bromination of 2-Mercapto-6-methyluracil.**—Mixtures of 2-mercapto-6-methyluracil [12] (1.4 g.), NBS (1.8 g.), benzoyl peroxide (10 mg.) and carbon tetrachloride (20 ml.) were refluxed for 45 min. on a steam bath. After cooling, the solid was collected, which was again heated with ethyl acetate (20 ml.) for 15 min. The ethyl acetate insoluble material, after being collected while hot, was successively washed with ethanol (10 ml.), water (10 ml.) and dried at 100°C for one hour, which was twice recrystallized from methanol (charcoal) to give light cream-colored rectangulars, (300 mg.). This compound began to decompose over 290°C.

*Anal.* Found: C, 42.22; H, 3.98; N, 18.58. Calcd. for $C_5H_5N_2OS \cdot \frac{1}{4}CH_3OH$ (II): C, 41.98; H, 4.69; N, 18.66%.

Ethyl acetate filtrate was evaporated to dryness and the residue was twice recrystallized from a large volume of ethanol (charcoal) to give 5-bromo-2-mercapto-6-methyluracil, in small needles (100 mg.), m. p. (uncorrected) 256°C (decomp.).

*Anal.* Found: Br, 36.20. Calcd. for $C_5H_5BrN_2OS$: Br, 36.15%.

By concentration of the mother liquor, succinimide (300 mg.) was recovered.

Barrett gave m. p. 260°C (decomp.) for 5-bromo-2-mercapto-6-methyluracil (VI) [10].

**2-Benzylmercapto-6-methyluracil.**—Bucher's preparative method for this compound was slightly modified as follows.

A solution of the above ethyl acetate insoluble, bromine-free pyrimidine (m. p. was over 290°C) (210 mg.) in 0.5 N aqueous sodium hydroxide (3 ml.) was refluxed with benzyl chloride (1 ml.) and ethanol (8 ml.) for 20 min. on a steam bath. After being refrigerated overnight, the precipitate was collected, washed with water and recrystallized from ethanol to give 2-benzylmercapto-6-methyluracil in rods (120 mg.), m. p. (uncorrected) 183~184°C.

Bucher gave m. p. 183~184°C for this compound [9].

**5-Bromo-2-amino-6-methyluracil (VII).**—Mixtures of 2-amino-6-methyluracil [13] (1.25 g.), NBS (1.78 g.), benzoyl peroxide (10 mg.) and carbon tetrachloride (20 ml.) were refluxed for one hour on a steam bath. After cooling, the solid was collected, which was again heated in ethyl acetate (20 ml.) for 20 min. on a steam bath. The ethyl acetate insoluble material, being collected while hot, was washed with water (10 ml.) and dried at 100°C for one hour (1.69 g.). Recrystallization from water (charcoal) gave 5-bromo-2-amino-6-methyluracil as cream-colored plates (220 mg.), m. p. (uncorrected) 249~250°C (decomp.).

Todd et al. gave m. p. 250°C (decomp.) for this *pyrimidine* [14]. The recrystallization mother liquor (pH 4.0) was concentrated at reduced pressure to about 5 ml. (pH 2.6), which was adjusted to pH 7 with 1 N aqueous sodium hydroxide to give colloidal substance.

In the bromination of the above three pyrimidines (I)—(III) in the absence of benzoyl peroxide, yields and melting points were shown in Table I.

TABLE I. BROMINATION OF I, II AND III IN THE ABSENCE OF BENZOYL PEROXIDE with NBS

| Pyrimidines examined | | Yield | m. p. (decomp.), °C |
|---|---|---|---|
| I | (0.6 g.) | (400 mg.) | 249 |
| II | (1.4 g.) | ( 50 mg.) | 256 |
| III | (1.2 g.) | (200 mg.) | 246 |

**Bromination of 2-benzylmercapto-6-methyluracil.**—2-Benzylmercapto-6-methyluracil (4.0 g.) was dissolved in glacial acetic acid (50 ml.) containing acetic anhydride (2.5 ml.). To this solution was added bromine (5 ml.) in glacial acetic acid (20 ml.) with stirring during 10 min. After heating on a steam bath for 15 min. with stirring, a yellow precipitate was collected (3.0 g., m. p. 200°C, decomp.) which was recrystallized from 95% ethanol (charcoal) to give colorless rods, m. p. (uncorrected) 249~250°C (decomp.). Recrystallization from absolute ethanol or glacial acetic acid also gave the same hydrolized compound, 5-bromo-6-methyluracil.

*Anal.* Found: N, 13.58; Br, 38.69. Calcd. for $C_5H_5BrN_2O_2$: N, 13.66; Br, 38.98%.

The authors wish to express their sincere gratitude to Professor Noboru Sugiyama of Tokyo University of Education for his helpful advice. Their thanks are also due to Mr. Ken'ichi Kikuchi, director of this company, who has permitted to publish this work.

# *Antioxygenic Activity of Lecithin and its Hydrolysis Products. III. Lecithin, Glycerophosphorylcholine, Phosphorylcholine, Phosphatidic Acids, Choline and Glycerol*

By Chieko URAKAMI and Haru KAMEYAMA

(Received May 4, 1959)

It was reported that choline among other hydrolysis products of phosphatides such as glycerol, oleic and linoleic acids, glycerophosphoric acid, and aminoethyl alcohol was the only one active against oils of plant origin[1]. The opinion of other investigators[2,3], however, was that the active entity in the phosphatide molecule is the phosphoric acid residue and that lecithin in which the hydroxyl of the phosphoryl group is involved in zwitterionic combination should show no activity[2,4]. Olcott and Mattill[2], and also Hilditch and Paul[5] reported that purified lecithin was inactive. However, the purities of the substrates as well as those of the samples of lecithin which were employed by these investigators were doubtful.

It has been known that some minor impurities present in substrates or in samples of phosphatides may act synergistically with a compound which has no activity in itself or conversely inhibit activity of a truly active compound. As the authors have demonstrated with the glycerophosphoric acids[6], the method used for purification of the substrate is important in evaluating antioxygenic activity. In this connection, it is of interest to note the recent paper of Olcott[7]. He demonstrated that a minute amount of free fatty acids added to substrates influenced antioxygenic properties of various compounds. Therefore, those results obtained with substrates which had been purified by mere solvent fractionation and distillation would not be trustworthy.

In regard to purification of lecithin, it is fairly recent[8,9] that the separation of phosphatidylcholines from other components of phospholipids and impurities can be achieved by column chromatography, indicating inadequacy of purification by the acetone precipitation method. Therefore, reinvestigation of natural lecithin is desirable in order to ascertain the varied results reported in the literature. The study on its hydrolysis products such as phosphatidic acids, glycerophosphorylcholine, phosphorylcholine, choline and glycerol is also desirable in elucidating structural requirements of phospholipids for antioxygenic activity.

## Experimental

**Materials.**—*Methyl oleate.*—The ester was prepared from olive oil (Nihon Yushi Co.) essentially in the same manner as described previously[6], except that the treatment with urea preceded the fractionation by low temperature crystallization from acetone. The fraction used as substrate had the following constants: b. p., 203~203.5°C/10 mmHg; $n_D^{20}$ 1.4526; Saponification No., 188.9; Iodine No., 89.9. The ultraviolet absorption spectra of this sample in ether showed $E_{1cm}^{1\%}$ 0.930 at 270 m$\mu$, indicating the presence of a small amount of unsaturated fatty acid esters other than the monoethenoid.

*Orthophosphoric acid.* — The analytical reagent grade (approximately 85%) of Mallinckrodt Chemical Works was dried over phosphorus pentoxide in a vacuum desiccator for four days or until a constant weight was attained.

*Glycerol.*—A fraction distilled at 140°C/3 mmHg was dried over phosphorus pentoxide in a vacuum desiccator.

*Choline.* — Free choline was prepared from choline chloride by shaking its aqueous solution with freshly precipitated silver hydroxide[10]. The yield was over 90% of the theoretical.

*$\alpha$- & $\beta$-Glycerophosphoric acids.*—The free acids were prepared from the corresponding sodium salt in the same manner as described in the previous paper[6].

10) H. W. Dudley, *J. Chem. Soc.*, **119**, 1260 (1921).

*Phosphorylcholine chloride.*—The barium salt of phosphorylcholine chloride was synthesized by H. Okura according to the method described by Baer[11]. The barium ion was precipitated as the sulfate and the clear supernatant liquid separated after removing the sulfate by centrifugation was concentrated to a small volume. The residue was treated with 95% ethanol and any precipitate formed was removed completely by centrifugation. The clear filtrate was concentrated to give syrupy material, which was dried over phosphorus pentoxide. The yield was approximately 83%.

*Phosphorylcholine.* — The chloride ion of the barium salt of phosphorylcholine chloride was removed first by precipitating as silver chloride with freshly prepared silver hydroxide (shaking was continued until the aqueous solution showed negative Beilstein test). The barium cation was removed in the manner described above for the preparation of phosphorylcholine chloride from its barium salt.

*Lecithin.* — Crude lecithin isolated from egg yolk by the conventional method of acetone precipitation was purified by slightly modified method of Rhodes and Led[9].

*Phosphatidic acids.*—The sample was prepared by M. Okada by interacting the lecithin prepared as above with lecithinase C (also called phosphatidase C or phospholipase D) of carrot roots in a manner similar to the method described by Kates[12]. Analysis showed that the sample contained about 70% phosphatidic acids and minor amounts of monoacylglycerophosphoric acids and glyceride-like substances.

DL-α-*Glycerophosphorylcholine.* — This compound was also synthesized by H. Okura according to the method of Baer and Kates[13]. A ratio of α-glyceryl ester to choline was found to be 1.03:1.0.

**Autoxidation.**—Each compound was added to the substrate at a concentration of 0.1% with the use of an appropriate solvent. The rest of the procedure employed was exactly the same as that described previously. The bath temperatures of 45 and 60°C were studied, the latter being chosen for comparison of the efficiencies of those found active.

**Peroxide Determination.** — The method previously described was employed.

## Results

Purified ovo-lecithin, known to be L-α-lecithin, and DL-α-glycerophosphorylcholine were found to be inactive at 45°C as shown in Fig. 1. Both compounds were, however, found to be somewhat active at this temperature when methyl oleate purified by the method of low temperature solvent fractionation alone was used (Fig. 2.). Here again it should be emphasized that

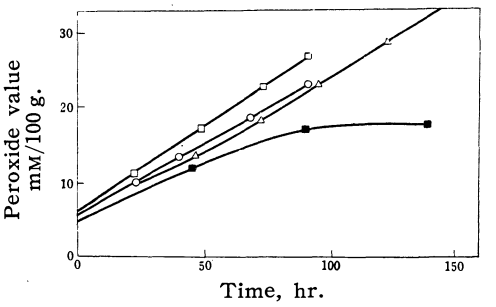

Fig. 1. Peroxide values against time at 45°C.
○: Methyl oleate alone. □: Methyl oleate containing 0.1% ovo-lecithin. △: Methyl oleate containing 0.1% DL-α-glycerophosphorylcholine. ■: Methyl oleate containing 0.1% α-glycerophosphoric acid.

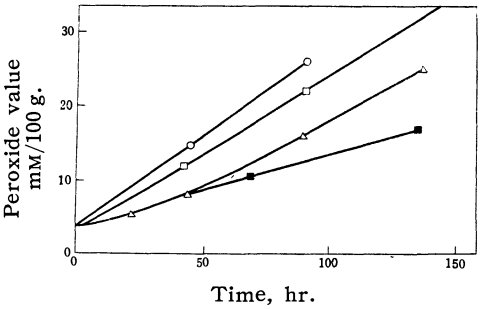

Fig. 2. Peroxide values against time at 45°C, using partially purified methyl oleate.

the method of purification of substrates is very important as the authors have advocated.

Choline was found to be inactive both at 45 (Fig. 3) and 60°C (not shown here). It was also found to be inactive in oleic acid at 50°C. Consequently, choline itsef is definitely inactive contrary to the result reported by Strohecker et al.[1]

Glycerol tested at 60°C exhibited no activity and thus is considered to be an inactive compound in purified methyl oleate.

Phosphorylcholine chloride was found to be active both at 45 (Fig. 3) and 60°C (Fig. 4) and the free phosphorylcholine more active than the chloride at 60°C.

The sample of phosphatidic acids employed in this experiment showed an

activity comparable to that of glycerophosphoric acids (Fig. 5). This result must, however, be considered with some reservation since the control of the purity of the natural free acids was very difficult, just as has been recorded in the literature, i.e. the acids easily lose the fatty acid residues when ethanol or a small amount of moisture is present[14].

The relative efficiencies of the active compounds were compared at 60°C and numerical values obtained by using the following expression: $T_a/T_o$, where $T_a$ is the time required to give 20 mM in peroxide value when 0.1% of an active substance is present and $T_o$ that required to show the same peroxide value by the substrate itself. This method of expression is a modification of that used by Emmanuel et al.[15] As shown in Table I, orthophosphoric acid is the most active one, followed by phosphorylcholine, phosphatidic acid, and phosphorylcholine chloride.

## Discussion

Since glycerol was found to be inactive, the activity observed with the glycerophosphoric acids must be due to the phosphoryl moiety, apparently the glycerol moiety not participating. The absence of activity in DL-α-glycerophosphorylcholine also supports the fact that the glycerol moiety is not involved. This would mean that the alcoholic O-H or C-H linkage of the glycerol moiety is not readily attacked by free radicals, at least not as readily as the α-methylene group of the methyl oleate. This observation is in accord with the order of bond strengths of these three linkages. The bond strength of the O-H linkage is 110 kcal./mol.; that of the C-H of the α-methylene, 80 kcal./mol. or less than 64 when activated by resonance; and that of the C-H in the glycerol moiety, greater than 80 kcal./mol., since an effect produced by the alcoholic hydroxyl group on the C-H linkage is known to be much less than that by the α-double bond.

The activity shown by phosphorylcholine and its chloride is again attributed to the phosphoryl moiety since choline was found to be inactive. It appears that two methylene groups present in the phosphorylcholine molecule are less readily attacked than the α-methylene of the methyl oleate molecule.

It has been reported that ovo-lecithin purified by the method similar to the one the authors employed contained stearic acid in the β-position and an unsaturated acid in the α-position[16]. Since no activity was

14) J. Olley, *Chem. & Ind.*, **73**, 1069 (1954).
15) N. M. Emmanuel et al., *Myasnaya Ind. S. S. S. R.*, **29**, No. 2, 52 (1958); *Chem. Abstr.*, **52**, 177554*h* (1958).

observed with the sample of lecithin used, it appears that the unsaturated fatty acid moiety in the lecithin does not compete with the $\alpha$-methylene group of the substrate molecule. Thus, participation of the fatty acyl groups of ovo-lecithin can be excluded. However, the behavior of the fatty acids present in the sample of phosphatidic acids may differ from that of the lecithin fatty acyl group although the former was prepared from the same sample of lecithin used for the activity study. Kates[12] states that the isolated phosphatidic acids contain $C_{18}$ fatty acids and about 20% of phosphatidic acid derived from the phospholipids present in the chromoplasts. Since the naturally occurring phosphatidic acids are said to be highly unsaturated, the fatty acid residue present in the sample of phosphatidic acids used is considered to be more highly unsaturated than those present in the lecithin originally subjected to the enzymatic action. Therefore, the activity observed with phosphatidic acids may partly be ascribed to autoxidation of the highly unsaturated fatty acyl group. However, it is highly probable that the phosphoryl residue has played a major role since the glycerophosphoric acids have been shown to be active, almost as active as phosphatidic acids (Fig. 5).

The foregoing discussion leads to the conclusion that the phosphoryl moiety is responsible for antioxygenic activity. A question arises, however, as to the absence of activity in ovo-lecithin and DL-$\alpha$-glycerophosphorylcholine despite the presence of the phosphoryl group in both molecules, The authors tentatively attribute this to the zwitterionic forms of the molecules, as suggested earlier by Olcott and Mattill[2] and Calkins[4]. No definite conclusion concerning this can be drawn at this stage of investigation, for it is necessary to reveal true behavior of cephaline under identical conditions. It is said to be active according to the earlier investigators.

It would be of interest to examine whether the activity ratios, $T_a/T_o$, relate to some characteristics of the molecules of those found to be active such as acidity, the number of the free hydroxyl of the phosphoryl group or the ratio of the molecular weight of phosphoric acid to that of each of the active compounds.

As shown in Table I, an order of acidity is $\beta$-glycerophosphoric acid > $\alpha$-glycerophosphoric acid > orthophosphoric acid phosphatidic acid > phosphorylcholine and its chloride, but this is not in accord with the order of activity ratio, orthophosphoric acid > phosphatidic acid and phosphorylcholine > phosphorylcholine chloride > $\alpha$-glycerophosphoric acid > $\beta$-glycerophosphoric acid. Similarly, no significant relations can be found between the activity ratios and the number of the free hydroxyl of the phosphoryl group in each molecule, e. g. phosphorylcholine which is considered to have only one free hydroxyl, shows a stronger activity than does its chloride or $\beta$-glycerophosphoric acid although orthophosphoric acid with three free hydroxyl groups is exceptionally strongly active. Interaction of the alcoholic hydroxyl with the oxygen and hydroxyl of the phosphoryl group in the $\beta$-glycerophosphoric acid should, of course, be taken into consideration in this connection, but this will be dealt with in a later paper. The ratios of the molecular weight of phosphoric acid to that of each of the active compounds also bear no relation to the activity ratios.

Thus, it appears that other factors must be sought to understand how the phosphoryl group participates in exhibiting antioxygenic activity or in other words to

TABLE I. RELATION OF ACTIVITY RATIOS OF ACTIVE COMPOUNDS WITH SOME OF THEIR CHARACTERISTICS

| | $H_3PO_4$ | PA | PC | PCCl | $\beta$-GP | $\alpha$-GP |
|---|---|---|---|---|---|---|
| $T_a/T_o$ at 60°C | 2.48 | 1.39 | 1.40 | 1.27 | 1.31 | d |

PA represents phosphatidic acids; PC, phosphorylcholine; PCCl, phosphorylcholine chloride; $\alpha$- and $\beta$-GP, $\alpha$- and $\beta$-glycerophosphoric acids. a) This is expected to be somewhat weaker than that of $\alpha$-GP. b) and c) These are weaker than any of the rest of the compounds listed due to the presence of the choline base in their molecules. d) It is expected to be somewhat higher than 1.31 of $\beta$-GP according to the result obtained at 45°C[6].

understand mechanisms involved. For this, the authors have porposed that an oxygenated substrate molecule interact with the phosphoryl group to give highly conjugated compounds which undergo autoxidation much more readily than does the substrate molecule. Further investigation on this problem is underway.

Incidentally, Hanahan et al.[17] reported that phosphorylcholine and glycerophosphoric acids (in conjunction with choline) stimulated oxygen consumption of the isolated rat liver mitochondria, the former being particularly strongly active. Lecithin and glycerophosphorylcholine were found to stimulate some oxygen consumption but only under special conditions. The enzymatic system such as this is far more complex than the system under consideration and in no way should these two systems be compared. However, one can not deny a possibility that reactions taking place in both systems may be found to be related, in view of the recent finding that free radicals are present in biological systems[18,19].

**Summary**

Purified ovo-lecithin, DL-α-glycerophosphorylcholine, choline and glycerol were found to exhibit no antioxygenic property against carefully purified methyl oleate. Phosphorylcholine, its chloride and natural phosphatidic acids, on the other hand, showed activity.

The order of activity efficiency at 60°C was found to be orthophosphoric acid > phosphatidic acid and phosphorylcholine > phosphorylcholine chloride > α-glycerophosphoric acid > β-glycerophosphoric acid. The discussion is presented to show that the phosphoryl moiety is predominantly responsible for antioxygenic activity.

The authors are indebted to Misses M. Ishida, J. Kondo, K. Yamaguchi and K. Sakamoto for their technical assistance.

By Takeshi MATSUMOTO and Akira SUZUKI

(Received February 20, 1959)

Since the elucidation of the structures of Garrya alkaloids by K. Wiesner[1], a number of alkaloids have been shown to be related to the tricyclic diterpenoid[2]. Lycoctonine[3] as well as lucidusculine[4], both of which have been studied in this laboratory under the leadership of Professor H. Suginome for the past several years, are supposed to belong also to this class. Mainly in this connection, the authors became interested in constructing model compounds with the 2-aza-perhydro-1,4a-(propano)-phenanthrene ring system (I). In the present paper the authors describe the preparation of 2-methoxy-5-hydroxy-1-naphthylacetic acid (II) and of other suitably substituted 1,2,5-naphthalene derivatives, which appeared to be potentially useful building blocks for the synthesis of the above skeleton (I). At first, the synthesis of 1-hydroxymethyl-2-methoxy-5-hydroxynaphthalene (III), which would form the B, C ring of the hydrophenanthrene, was attempted.

The starting material for this purpose was 1-acetoxymethyl-2-acetoxy-5-acetamidonaphthalene (V), which was prepared from 1-piperidino-methyl-5-acetamido-2-naphthol (IVa) by a slight modification of Cornforth and Robinson's method[5] from 5-acetamido-2-naphthol.

b, R=CH₃

Attempts to hydrolyze the triacetyl compound V with aqueous alkali however resulted in the formation of an amorphous product VI which could not be caused to crystallize by any means. After methylation with dimethyl sulfate a crystalline methyl derivative was obtained. The derivative was not, however, the expected compound VIIIb. The elemental analysis, determination of the methoxyl group, and measurement of molecular weight of the methyl derivative indicated that its formula corresponds to $C_{26}H_{21}N_2O_2(OMe)_3$. In addition, the compound exhibited infrared absorption in nujol at 3280 (N-H), 1645 (amide I), 1510 (amide II), 1275 (aryl ether), 1100 (alkyl ether), 800 (three adjacent H), 805 $cm^{-1}$ (three adjacent H)[6]. On these grounds formula VII is proposed as a likely structure for this compound, the point of attachment (dotted line) of disubstituted naphthylmethyl moiety however being uncertain. Fromation of this coupled product may be interpreted as follows:

Reaction behaviors of certain phenolic Mannich bases have already been explained in a similar manner[7]. According to the above view, the formation of the coupled product should be controlled through replacement of the phenolic hydroxyl by a methoxyl group. 1-Piperidinomethyl-5-acetamido-2-naphthol methyl ether (IVb), which would form a methoxyl derivative (VIIIb) through acetolysis and hydrolysis, however could not be obtained by treatment of IVa with diazomethane, probably because compound IVa exists almost completely as a zwitter ion. The

9) Reported infrared spectra of anoboline (i) and the compound (ii) exhibit very weak absorption bands at N-H and O-H stretching vibration region and broad absorption band at 2260~2800 $cm^{-1}$ region. The assignment of 3440 and 3400 $cm^{-1}$ bands of compoud IVa is however not conclusive. One of them might be responsible for the hydroxyl group.

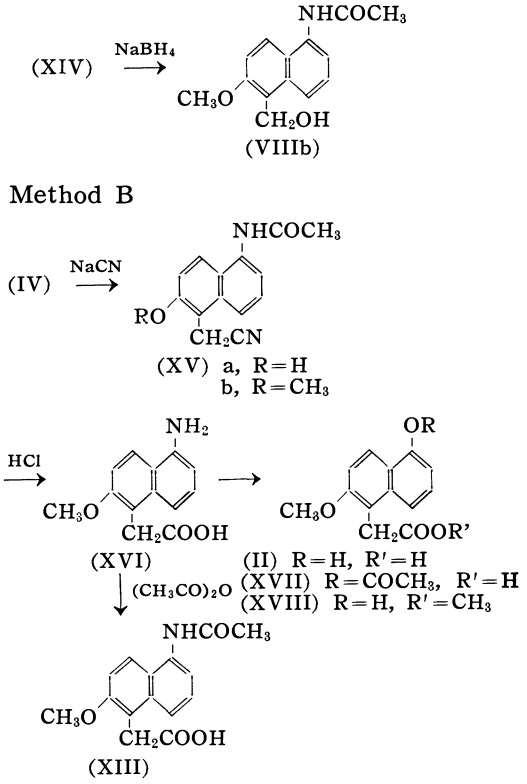
dipolar character seems to be reflected by the infrared absorption of IVa.



The compound in chloroform exhibited twin secondary amide N-H absorption bands[8] at 3400 and 3440 $cm^{-1}$, a broad weak band extending from 2260 to 2800 $cm^{-1}$, and no absorption band characteristic of the hydroxyl group[9].

Since the first attempt to synthesize 1-hydroxymethyl-2-methoxy-5-naphthol was thus unsuccessful, and moreover, since it was felt that hydronaphthalene (IX) or hydrophenanthrene (X) derived from the naphthol might be likely to undergo carbon-carbon bond cleavage at a certain later stage as illustrated above, the present authors abandoned attempts to find conditions to effect conversion V→VIIIa and turned attention to the preparation of 2-methoxy-5-hydroxy-1-naphthylacetic acid (II) which contains two, rather than one, side chain carbon atoms. Introduction of the carboxymethyl group to naphthalene nucleus has been achieved by two methods. Steps involved are summarized as follows:

Method A

Method B

Of these, method B gave an excellent result.

The reaction of 5-acetamido-2-naphthol with allyl bromide in boiling acetone afforded the allyl ether (XI) in quantitative yield. The latter compound, on being heated in an atmosphere of nitrogen for an hour at 185~195°C, was converted into 1-allyl-5-acetamido-2-naphthol (XIIa) in a yield of 99.5%. The methylation of XIIa with dimethyl sulfate in the presence of alkali proceeded without difficulty (yield, 81.7%). For the formation of naphthylacetic acid, the methyl ether (XIIb) was then treated with potassium permanganate. Oxidation at room temperature resulted in the formation of a difficultly separable mixture, but at below −10°C in ethanol, even though in a yield of 13%, the desired acid (XIII) was obtained along with a non-acidic product (20%). The latter compound was characterized as 2-methoxy-5-acetamido-1-naphthaldehyde (XIV) on the basis of elemental and infrared spectral analyses. The aldehyde was smoothly reduced in a good yield (94%) to the corresponding alcohol (VIIIb) by the use of sodium borohydride. Two promising intermediates, XIII and VIIIb, have thus been obtained. However, for the present purpose, the yield of the oxidation stage

a) amide I b) amide II c) shoulder

was too low. Therefore, plans were again changed and exploration was made of an alternative route, method B.

On treatment of IV with sodium cyanide in aqueous ethanol for 12 hr. under reflux, 1-cyanomethyl-5-acetamido-2-naphthol was obtained in almost quantitative yield[10].

Methylation of XVa to XVb (yield, 93%) by dimethyl sulfate in sodium hydroxide solution, followed by hydrolysis with hydrochloric acid in aqueous ethanol afforded the amino acid hydrochloride (XVI·HCl). In this case, when an excess of dimethyl sulfate and of alkali was used, 1-cyanomethyl-2-methoxy-5-(*N*-methyl)-acetamidonaphthalene was formed as a by-product. The reaction of the amino acid (XVI) with acetic anhydride gave 2-methoxy-5-acetamido-1-naphthylacetic acid, which should be identical with compound XIII obtained by method A. The identity of these products was proved by melting and mixed melting point determinations. Finally, the amino acid hydrochloride (XVI·HCl) was treated under Bucherer conditions. The expected product, 2-methoxy-5-hydroxy-1-naphthylacetic acid (II) was obtained in a 91% yield.

10) In the reaction of 1-dimethylaminomethyl-2-naphthol with sodium cyanide the diarylmethane (iii) is formed at least in 20% yield [J. Brewster, "Organic Reactions", Vol. VII, John Wiley & Sons, Inc., New York (1953), p. 109] clearly through the process outlined below. It is interesting that in the present case, no dinaphthylmethane was produced, although its formation was expected.

(iii)

## A Note on the Infrared Spectra of 1, 2, 5-Trisubstituted Naphthalenes

In the course of the above work, infrared spectra of all the prepared 1,2,5-trisubstituted naphthalenes have been measured. Data on absorption bands at 1650~1500 $cm^{-1}$ (skeletal vibration) and at 900~700 $cm^{-1}$ (C–H out-of-plane vibration) are presented in Table I.

It can be seen that all the 1,2,5-trisubstituted naphthalenes so far examined show a fairly strong band within a narrow frequency range of 800±8 $cm^{-1}$. This band may be attributed to the presence of three

aromatic vicinal hydrogen atoms in these compounds. It is to be expected that these compounds exhibit also a band at 860~800 $cm^{-1}$ (two vicinal hydrogen atoms), but this latter band is obscured owing to the complexity at this region.

In the range of 1650~1500 $cm^{-1}$ the naphthalene derivatives listed above show in common *four* bands. It has been stated[11] that aromatic compounds, in general, exhibit *three* absorption bands in this range[12]. The results given in Table I indicate that the examined naphthalene derivatives present two strong bands at ca. 1620 and ca. 1510 $cm^{-1}$ and two subsidary absorption bands between these wave numbers. Scope and limitation of this generalization are not yet clear. However, it may be mentioned at this point that a number of, of course if not all, naphthalene derivatives except these with electronegative nitro and halogen substituents, exhibit the characteristic four absorption bands between 1650~1500 $cm^{-1}$. Naphthalene itself[13], 1-naphthol[14], 2-naphthol[14], 1,6-dihydroxynaphtalene[14], 1-acetamido-6-hydroxynaphthalene[14] and 1-acetamido-6-allyloxy naphthalene[14] present the above feature. The following naphthalenes, spectra of which appear in the API[15] and DMS[16] cards, fall also in this category (kind and position of substituents, and serial number[17] are given):

1-methyl (762), 2-methyl (763) (1530$cm^{-1}$: weak), 1-ethyl (764), 2-ethyl*,[18] (765), 1,3-dimethyl* (767), 1,5-dimethyl* (769), 1,6-dimethyl* (770), 2,3-dimethyl* (773), 2,7-dimethyl* (775), 2-*n*-propyl* (777), 1-*n*-buthyl (778), 2-*n*-buthyl* (779), 1-*n*-amyl (780), 2-*n*-amyl* (781), 2-methoxy (*1766*), di-1-naphthylmethane (*2777*), 1-cyanoethyl-2-hydroxy (*2640*), di-1-naphthylketone (*2527*) (1621 $cm^{-1}$: sh), 1-benzyl (*2287*) (an extra band at the 1500 $cm^{-1}$ region; attributable to phenyl vibration?), 2-benzyl* (*2288*) (an extra band like 1-isomer), di-2-naphthylketone (*2528*) (1515 $cm^{-1}$: weak).

In the following compounds the subsidary absorption band- or bands- are obscure:

1,4-dimethyl (768), 1,7-dimethyl* (771), 1,8-dimethyl (772), 2,6-dimethyl* (774), 1-*n*-propyl (776), 2,4-dimethyl* (1209).

## Experimental[19]

**1-Piperidinomethyl-5-acetamido-2-naphthol (IVa).**—The procedure of Cornforth and Robinson[5] was slightly modified as follows: Formaldehyde (16.5 ml., 37% solution) was added to a mixture of piperidine (22.5 ml.) 5-acetamido-2-naphthol (37.5 g.) and ethanol (350 ml.). After being kept at room temperature for three days, the crude product, which separated, was collected, washed with a small amount of ethanol and dried. A yield of 88% (49 g.) of piperidino-base was obtained. Recrystallization from isoamyl alcohol gave colorless plates, m. p. 198~199°C. *o-Methylation* of the piperidino-base was attempted by the addition of ethereal solution of excess diazomethane to the base dissolved in chloroform. No generation of nitrogen was observed. On removal of volatile substances after 24 hr., the piperidino-base was recovered in an almost quantitative yield.

**1-Acetoxymethyl-2-acetoxy-5-acetamidonaphthalene (V).**—A mixture of the piperidino-base (IVa) (20 g.) and acetic anhydride (160 cc.) was heated on a steam bath for 3 hr. After addition of water during warming until the solution became clear, the solution was extracted three times with chloroform. The extract was then washed successively with 5% sodium bicarbonate and water, dried and the chloroform removed. The residue was crystallized on being triturated with ether. Recrystallization from ethanol-water gave colorless clustered prisms, m. p. 170~171°C (5.2 g., 24.6%).

**Hydrolysis of V.**—A suspension of 2 g. of V in 20 ml. of 5% aqueous potassium hydroxide was heated at 100°C for several minutes, and then a homogeneous solution was obtained. The solution was then cooled to 0°C and acidified to pH 2 with 6 N hydrochloric acid; an amorphous solid (1.4 g.), which separated, was collected. Methylation was effected as follows: A mixture of the above amorphous solid, sodium hydroxide (0.3 g.) and water (4.2 ml.) was shaken with dimethyl sulfate (0.66 cc.) for half an hour. Additional amount of sodium hydroxide and dimethyl sulfate was then added and shaking continued for a further half hour. The excess of dimethyl sulfate was

11) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen & Co., Ltd., London (1958), p. 69—79.

12) Since the measurement presented in the table was taken by the nujol mull method, the fourth aromatic skeletal absorption at ca. 1450 $cm^{-1}$ was not taken into account.

16) Documentation of Molecular Spectroscopy, Butterworths Scientific Publications, London (1956—1958).

17) Serial numbers of the DMS cards are given in italics.

18) In the compounds marked with an asterisk, absorption band at the highest frequency (ca. 1620 $cm^{-1}$) splits into two bands of comparable intensity. It may be noted that most of these compounds possess a 2-alkyl group.

19) All melting points are uncorrected. Infrared spectra were taken on a Koken model DS-301 infrared spectrophotometer. The authors wish to thank Mr. O. Yonemitsu of the Pharmaceutical Institute of Hokkaido University for the spectral data and Miss N. Fujino for the microanalyses.

destroyed by gentle heating on a steam bath. Crude methoxyl compound, which separated, amounted to 1.34 g. The product was then dissolved in tetrahydrofuran and chromatographed on alumina (ca. 30 g.). A portion eluted with ethanol was crystallized. For analysis a sample was recrystallized from ethanol; m. p. 285°C (decomp.), colorless small needles.

*Anal.* Found: C, 71.01; H, 6.33; $OCH_3$, 19.07; mol. wt. (Rast), 443.5. Calcd. for $C_{26}H_{21}O_2N_2(OCH_3)_3$: C, 71.58; H, 6.22; $OCH_3$, 19.13%; mol. wt., 486.6.

**5-Acetamido-2-naphthyl Allyl Ether XI.**—5-Acetamido-2-naphthol was converted into allyl ether by heating a mixture of the material (20g.) with allyl bromide (14.4 g.), finely powdered potassium carbonate (28 g.) and purified acetone (600 ml.) for 12 hr. on a steam bath with mechanical stirring. After evaporation of the solvent, the residue was diluted with water and the precipitated allyl ether (24 g., 100%) was collected; m. p. 130~132°C. A portion, recrystallized from aqueous ethanol, gave a pure specimen of XI as colorless needles, m. p. 136°C.

*Anal.* Found: C, 74.96; H, 6.31. Calcd. for $C_{15}H_{16}O_2N$: C, 74.66; H, 6.27%.

**1-Allyl-5-acetamido-2-naphthol (XIIa).**—The crude ether (XI) (18 g.) was heated in an atmosphere of nitrogen for 1 hr. in an oil bath maintained at 185~195°C. The reaction product was then completely dissolved in 10% sodium hydroxide (360 cc.), and the solution was acidified with 6 N hydrochloric acid, the product (17.5 g., 99.5%) being precipitated. Recrystallization from aqueous ethanol gave the naphthol (XIIa) as colorless needles, m. p. 176~177°C.

*Anal.* Found: C, 74.53; H, 6.35. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27%.

**1-Allyl-2-methoxy-5-acetamidonaphthalene(XIIb).**—A mixture of XIIa (4.4 g.), dimethyl sulfate (4 g.) and aqueous 10% sodium hydroxide (14.5 ml.) was shaken for 0.5 hr., and the precipitated product was filtered, washed with water and dried; yield, 3.8 g. (81.7%). The crude methyl ether was recrystallized from aqueous ethanol as colorless needles, m. p. 147~147.5°C.

*Anal.* Found: C, 75.09; H, 6.85. Calcd. for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.71%.

**1-(2,3-Dibromopropyl)-2-methoxy-5-acetamidonaphthalene.**—To a solution of the methyl ether (XIIb) (0.5 g) in 6 ml. of chloroform, 0.31 g. of bromine dissolved in 4 ml. of chloroform was added drop by drop with shaking. After standing for 1 hr. at room temperature, the solvent was evaporated. The thick sirupy residue solidified upon scratching and was purified by recrystallization from aqueous ethanol; colorless needles, m. p. 168.5~170°C.

*Anal.* Found: C, 45.87; H, 4.41. Calcd. for $C_{16}H_{17}O_2NBr_2$: C, 46.29; H, 4.13%.

**Dihydro Derivative of XIIb.**—Another portion of XIIb (0.8 g.) in ethyl acetate (35 ml.) was hydrogenated over 10% palladized charcoal (0.2 g.). Uptake of hydrogen was completed after about 3 hr. The solution was filtered from the catalyst which was washed with ethyl acetate. The solvent was removed from the combined filtrate and washings under reduced pressure. *1-Propyl-2-methoxy-5-acetamidonaphthalene* was obtained from aqueous ethanol as colorless needles, m. p. 151.5~152.5°C.

*Anal.* Found: C, 74.20; H, 7.71. Calcd. for $C_{16}H_{19}O_2N$: C, 74.68; H, 7.44%.

**Oxidation of XIIb with Potassium Permanganate.**—The methyl ether (XIIb) (5 g.) dissolved in 300 ml. of 95% ethanol and potassium carbonate (1.25 g.) in 12.5 ml. of water were placed in a flask surrounded with an ice-salt bath. A solution of potassium permanganate (10 g.) in 240 ml. of water was then run into the flask at such a rate that the temperature did not rise above −10°C with constant stirring. After the completion of the oxidation, manganese dioxide was filtered off and washed with hot ethanol. The filtrate and washings are combined, the whole was concentrated to about 130 ml., and the residue was extracted three times with chloroform. The combined chloroform extracts were then washed with water, dried and evaporated. A neutral product, *2-methoxy-5-acetamido-1-naphthaldehyde* (*XIV*) was obtained; yield, 1 g. (20%). A pure sample was obtained on recrystallization from ethanol as pale yellow needles and had an m. p. 232~233°C, $\nu_{max}^{nujol}$ 3265 (N-H), 1668 (CHO) and 1655 $cm^{-1}$ (NHCO).

*Anal.* Found: C, 69.18; H, 5.63. Calcd. for $C_{14}H_{14}O_3N$: C, 69.12; H, 5.39%.

To the above aqueous alkaline solution, separated from the chloroform layer, concentrated hydrochloric acid was added in excess to precipitate acidic products; the crude acid was collected (0.5 g.). The filtrate was extracted three times with chloroform, the extracts were combined, dried and evaporated. An additional amount (0.2 g.) of the above acid was obtained. Recrystallization from ethanol gave *2-methoxy-5-acetamido-1-naphthylacetic acid* (*XIII*) as colorless needles, m. p. 245°C.

*Anal.* Found: C, 65.80; H, 5.84. Calcd. for $C_{15}H_{15}O_4N$: C, 65.92; H, 5.53%.

**1-Hydroxymethyl-2-methoxy-5-acetamidonaphthalene (VIIIb).**—The aldehyde (XIV) (190 mg.) was dissolved in 5 ml. of methanol containing a small amount of sodium methoxide and the solution was cooled to produce a fine suspension. On addition of sodium borohydride, the aldehyde dissolved, crystallization of the reduction product began after several minutes, and was completed after 12 hr. The product was collected, washed with water and dried. Removal of the solvent from the filtrate gave further a small quantity of the hydroxymethyl compound. The product weighed 172 mg. (94%) and was purified by recrystallization from ethanol, m. p. 214~215°C.

*Anal.* Found: C, 68.41; H, 6.37. Calcd. for $C_{14}H_{15}O_3N$: C, 68.55; H, 6.16%.

**1-Cyanomethyl-5-acetamido-2-naphthol (XVa).**—A mixture of the piperidino-bass (IV) (9 g.), sodium cyanide (15 g.), ethanol (220 ml.) and water (30 ml.) was refluxed for 12 hr. Water was then added to the reaction mixture, and the solution was concentrated under reduced pressure

to expel ethanol, and acidified with concentrated hydrochloric acid. The solid (7.2 g., 99.5%) which separated was filtered. For analysis a sample was recrystallized from ethanol; m. p. 239°C (decomp.), $\nu_{max}^{nujol}$ 3350 (OH), 3210 (N—H), 2240 (C≡N), and 1660 $cm^{-1}$ (NHCO).

*Anal.* Found: C, 69.54; H, 5.17; N, 11.57. Calcd. for $C_{14}H_{12}O_2N_2$: C, 69.95; H, 5.03; N, 11.66%.

**1-Cyanomethyl-2-methoxy-5-acetamidonaphthalene (XVb).**—The above naphthol (XVa) (6 g.) in aqueous 10% sodium hydroxide (12.5 ml.) was shaken with dimethyl sulfate (3 ml.) for 1 hr., and the reaction mixture was allowed to stand overnight. The methyl ether, which separated, was collected; yield, 5.9 g. (93%); m. p. 211～215°C. Upon recrystallization from ethanol, it formed colorless small needles, m. p. 226～227°C, $\nu_{max}^{nujol}$ 3270 (NH), 2240 (C≡N), and 1660 $cm^{-1}$ (NHCO).

*Anal.* Found: C, 70.70; H, 5.73. Calcd, for $C_{15}H_{14}O_2N_2$: C, 70.85; H, 5.55%.

When a large excess of dimethyl sulfate and of alkali was used, *1-cyanomethyl-2-methoxy-5-(N-methyl)-acetamidonaphthalene* was obtained. Recrystallization from ethanol gave colorless prisms, m. p. 172～173.5°C, $\nu_{max}^{nujol}$ 2240 (C≡N) and 1660 $cm^{-1}$ (NHCO); no appreciable band in the N-H stretching vibration region.

*Anal.* Found: C, 71.58; H, 6.32; N, 10.32. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%.

**Hydrolysis of XVb to 2-Methoxy-5-amino-1-naphthylacetic Acid (XVI).**—A mixture consisting of XVb (1.5 g.), ethanol (7.5 ml.), water (5 ml.) and concentrated hydrochloric acid (20 ml.) was refluxed on a steam bath for 5 hr. and was then cooled well with ice. The precipitates were filtered and dried. A yield of 1.52 g. of the amino acid (XVI)·HCl with m. p. 253°C (decomp.) was obtained. The acetate of compound XVI was prepared through the addition of 10% sodium hydroxide solution and acetic anhydride to the aqueous solution of XVI · HCl. The pure sample of the acetate formed colorless needles, m. p. 245°C. No depression in the melting point was observed on admixture of XIII.

**2-Methoxy-5-hydroxy-1-naphthylacetic Acid (II).**—A mixture of the amino acid (XVI) hydrochloride (1.5 g.) and 40% sodium bisulfite solution (85 ml.) in a three-necked flask provided with a reflux condenser and mechanical stirrer, was heated at 95～100°C for 20 hr. At the end of this time 60% aqueous sodium hydroxide (30ml.) was slowly added to the boiling solution with vigorous stirring and the mixture was heated under slightly reduced pressure until the evolution of ammonia had ceased (ca. 3 hr.). After cooling, concentrated hydrochloric acid (85 ml.) was added drop by drop to expel sulfur dioxide and the mixture was heated on a steam bath for 1 hr. The solution was allowed to stand overnight. The crude naphthol (II) (1.23 g., 91%), which separated, was recrystallized from glacial acetic acid as small colorless prisms, m. p. 229～230°C (decomp.), $\nu_{max}^{nujol}$ 3200～3400 (OH), 1710 ($CO_2H$) and 1687 $cm^{-1}$ ($CO_2H$)[20].

*Anal.* Found: C, 67.04; H, 5.32. Calcd. for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

*The methyl ester (XVIII)* was prepared as follows: Fifty milligrams of II was dissolved in 2.5 ml. of 5% methanolic hydrogen chloride. The solution was kept at room temperature. After 48 hr., water and ethyl acetate were added. The ethyl acetate layer was washed with sodium bicarbonate solution, dried and evaporated. The crystalline residue (50 mg., 94.4%), m. p. 150～153°C, was recrystallized from benzene to give a pure sample, m. p. 155.5～156.5°C, $\nu_{max}^{nujol}$ 3400 (OH) and 1720 $cm^{-1}$ (ester).

*Anal.* Found: C, 68.15; H, 5.95. Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

**2-Methoxy-5-acetoxy-1-naphthylacetic Acid (XVII).**—The above hydroxy acid (II) (920 mg.) was dissolved in a mixture of anhydrous pyridine (10 ml.) and acetic anhydride (4.5 ml.). After being kept at room temperature overnight, the reaction mixture was concentrated to dryness in vacuo, and the residue was washed with water and dried. Crude acetate (1.02 g., 94%) with m. p. 180～183°C was obtained. The sample for analysis was prepared by recrysallization from benzene; it had m. p. 185.5～186.5°C, $\nu_{max}^{nujol}$ 1755 (phenolic acetate CO), 1200 (phenolic acetate), 1716[20] (carboxyl group) and 1685 $cm^{-1}$ (carboxyl group).

*Anal.* Found: C, 65.31; H, 5.25. Calcd. for $C_{15}H_{14}O_5$: C, 65.69; H, 5.15%.

## Summary

A synthesis of 2-methoxy-5-hydroxy-1-naphthylacetic acid has been described.

The authors are indebted to Dr. Tozo Kubota, Director of the Dyestuffs Division of the Nippon Kayaku Chemicals Co., Ltd. for a generous supply of 1,6-Cleve's acid, from which 2-hydroxy-5-acetamidonaphthalene was prepared.

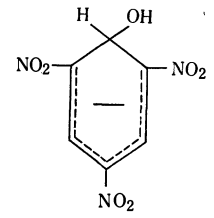
20) It is interesting to note that both acids, II and XVII, exhibit in nujol two carbonyl bands of comparable strength. Two examples of the similar splitting of carboxyl carbonyl band have been reported in the literature (M. St. C. Flett, *J. Chem. Soc.*, **1951**, 962). This abnormal absorption is probably due to the hydrogen bond of the carboxyl group in the solid state, since i) both the acids exhibit a single absorption in dioxane solution at 1715 $cm^{-1}$ and ii) the abnormal absorption band disappears in the methyl ester (XVIII) of II.

# *Visible and Ultraviolet Absorption Spectra of 1,3,5-Trinitrobenzene in Water in the Presence of Sodium Hydroxide*

By Takehiro ABE

(Received July 1, 1959)

In the previous paper[1,2], the author has reported an absorption spectrum of a red-colored solution produced by adding a few drops of sodium hydroxide solution into an aqueous solution of 1,3,5-trinitrobenzene. In the present paper, an attempt has been made to investigate the interaction of 1,3,5-trinitrobenzene with hydroxyl ion in detail by measuring the absorption spectra of the colored solution at various concentrations of sodium hydroxide, together with an effect of hydrochloric acid on the colored solution.



## Experimental

Commercial pure 1,3,5-trinitrobenzene was purified by recrystallizing three times from methanol-water; m. p. 123.1°C. Each colored solution of trinitrobenzene and sodium hydroxide in water was freshly prepared by adding an aqueous solution of sodium hydroxide into an aqueous solution of trinitrobenzene before each measurement. The spectra of the solution were measured with a Hitachi Model EPU-2 spectrophotometer at 25°C or at room temperature. Path length of absorption cells was 1 cm.

## Results and Discussion

**Absorption Spectra of Trinitrobenzene in Water at Various Concentrations of Sodium Hydroxide (Fig. 1).**—As Fig. 1 shows, the aqueous solutions of trinitrobenzene in the presence of sodium hydroxide show absorption bands at 260, 300 and 400~500 mμ. The absorption curve of the colored solution with a sodium hydroxide concentration of 0.393 N resembles that of the red complex between trinitrobenzene and ammonium hydroxide in water[3]. The visible absorption curves of the colored solutions of trinitrobenzene and sodium hydroxide in water are different from that of the solution in acetone, which shows absorption bands at two regions of 450 and 510~590 mμ[4]. The visible absorption curves appreciably resemble that obtained by Caldin et al.[5,6] for the colored solution of trinitrobenzene and ethoxide ion in ethanol, for which a different absorption curve has been obtained by Foster[7].

The color produced by the reaction of trinitrobenzene with sodium hydroxide in water seems to be due to the following structure which is the same as that presented by Meisenheimer[8] for the red product of trinitrobenzene with sodium ethoxide, although the question pointed out in the previous paper[2] still remains.

The structures of Meisenheimer's type have recently been supported for the colored products of many polynitro aromatic hydrocarbons with alkalies[2-4,6,7,9-13].

The absorbances of the visible absorption bands increase with the increasing concentration of sodium hydroxide below the sodium hydroxide concentration, about 0.6 N, but reversely decrease above the sodium hydroxide concentration. The color finally disappears at very high concentration of sodium hydroxide. On the other hand, the bands at 260 and 300 mμ, observed distinctly above the sodium hydroxide concentration, about 0.4 N, become intense, as the sodium hydroxide

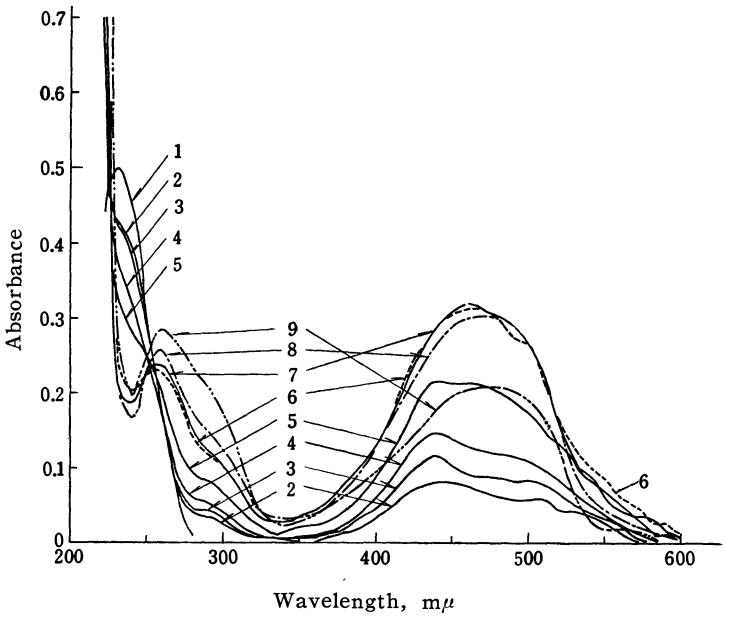

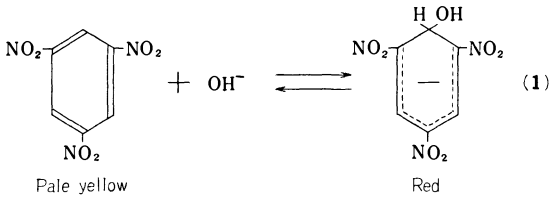

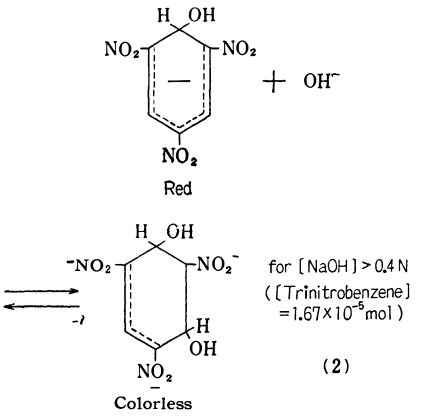

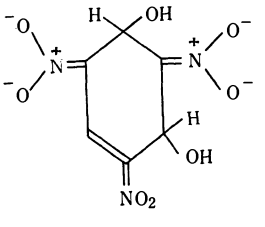

Fig. 1. Absorption spectra of 1,3,5-trinitrobenzene ($1.67\times10^{-5}$ mol.) in water containing various concentrations of sodium hydroxide at 25°C (path length of cells, 1 cm.).
Concentrations of sodium hydroxide:
1) 0; 2) $5.89\times10^{-2}$ N; 3) $7.86\times10^{-2}$ N; 4) $1.18\times10^{-1}$ N; 5) $1.97\times10^{-1}$ N; 6) $3.93\times10^{-1}$ N; 7) $5.89\times10^{-1}$ N; 8) $9.60\times10^{-1}$ N; 9) 1.92 N.

concentration increases. The 260 and 300 mμ bands, as mentioned below, can not be ascribed to a product produced by a further reaction of the colored species, and disappear by addition of an acid. From the above results, the absorption bands may be interpreted as follows. The decrease in the absorbances of the visible absorption bands, considered to be due to [Trinitrobenzene·OH]$^-$, seems to lead to the suggestion that interaction of [Trinitrobenzene·OH]$^-$ with hydroxyl ion results in the formation of [Trinitrobenzene·2OH]$^{2-}$ above the sodium hydroxide concentration, about 0.4 N. The increase in the absorbances of the 260 and 300 mμ bands can be explained by attributing these bands to [Trinitrobenzene·2OH]$^{2-}$. Accordingly, the following reactions may possibly be expected for the interaction of trinitrobenzene with sodium hydroxide in water.

The p$K$ values of 1,3,5-trinitrobenzene solution were determined by Schaal[14] by ultraviolet absorption measurement in an ethylenediamine-water mixture of a known

14) R. Schaal, *Compt. rend.*, **239**, 1036 (1954).

acidity function, with the result of $pK_1=14.40$ and $pK_2=18.00$. The two $pK$ values may support the formations of [Trinitrobenzene·OH]$^-$ and [Trinitrobenzene·2OH]$^{2-}$. Schaal also supposed the formation of the following complex for the $pK_2$.

**An Equilibrium Constant for the Colored Reaction of Trinitrobenzene with Hydroxyl Ion.**—In the previous paper[2] the author has found that the red-colored species of 1,3,5-trinitrobenzene and 2,4,6-trinitrotoluene with sodium hydroxide in water are more stable than those of picryl chloride and 2,4,6-trinitrophenylmethylnitramine (Tetryl). The colored solution of trinitrobenzene and ethoxide ion has been found by Caldin and Long[5] and by Foster[7] to obey Beer's law. An attempt has, therefore, been made to obtain the equilibrium constant $K$ for the colored reaction 1 of trinitrobenzene with sodium hydroxide in water from the result in Fig. 1.

As [NaOH]$\gg$[Trinitrobenzene] in the present measurements, Benesi and Hildebrand's equation[15] can be written as

$$\frac{l[\text{Trinitrobenzene}]}{d}=\frac{1}{\varepsilon K}\cdot\frac{1}{[\text{NaOH}]}+\frac{1}{\varepsilon} \quad (3)$$

Here $l$ represents the path length of absorption cells (1 cm.) and $d$ and $\varepsilon$ are respectively an absorbance and a molar extinction coefficient for the colored species. Fig. 2 is obtained by plotting [Trinitrobenzene]$/d$ against 1/[NaOH]. Although the colored species of trinitrobenzene and hydroxyl ion is comparatively stable, it slowly reacts with hydroxyl ion, as mentioned below. Moreover, the molar extinction coefficient of the colored species may be affected by the concentration of sodium hydroxide, since the absorption curves of the red complexes of trinitrobenzenes with ammonium hydroxide are apt to be greatly influenced with any solvent, as shown in the previous paper[3]. As Fig. 2 shows, [Trinitrobenzene]$/d$, however, is nearly proportional to 1/[NaOH] below the sodium hydroxide concentration, about 0.6 N. The linearities of Benesi and Hildebrand's plots indicate the formation of the 1:1 colored complex between trinitrobenzene and hydroxyl ion, because Benesi and Hildebrand's Eq. 3 is derived for the 1:1 complex. Therefore, the visible absorption bands are undoubtedly owing to the formation

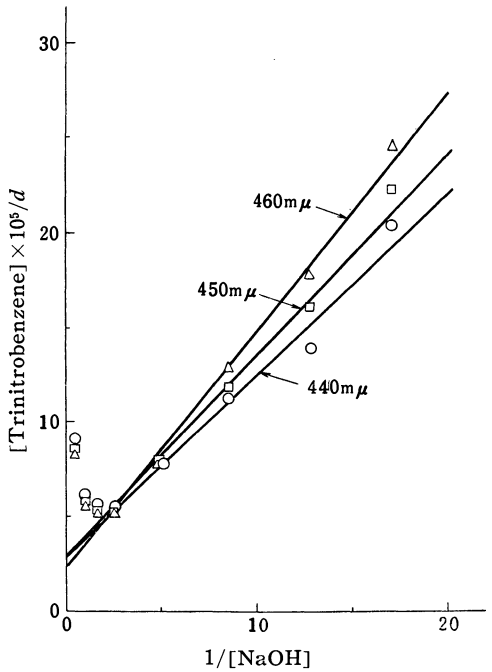

Fig. 2. Benesi and Hildebrand's relation for the result in Fig. 1.

of [Trinitrobenzene·OH]$^-$. Deviations of the plots from the linearities above the sodium hydroxide concentration, about 0.6 N can be interpreted to be owing to the formation of [Trinitrobenzene·2OH]$^{2-}$ according to reaction 2. By Eq. 3 the intercept at 1/[NaOH]=0 and the ratio of the intercept to slope give $1/\varepsilon$ and $1/\varepsilon K$, respectively. From the best straight line for the 450 m$\mu$ absorption band, it is possible to find $\varepsilon_{450}=3.5\times10^4$ and $K=2.7$ at 25°C. The value of $3.5\times10^4$ is larger than the molar extinction coefficient of $9.4\times10^3$ for the maximum absorption band (at 480 m$\mu$) of the red complex of trinitrobenzene with ammonium hydroxide in water[3]. The equilibrium constant of 2.7 is very much smaller as compared with that ($2.4\times10^3$) obtained by Caldin and Long[5] for the color reaction of trinitrobenzene with ethoxide ion in ethanol at 25°C.

**Time Dependence of Absorption Spectra of the Colored Solutions of Trinitrobenzene and Sodium Hydroxide in Water (Fig. 3).**—On standing the colored solutions of trinitrobenzene and sodium hydroxide in water, the absorbances of the visible absorption bands gradually decrease, while an increase in absorbance can be observed at about 350 m$\mu$. The 350 m$\mu$ band is probably due to a product in which [Trinitrobenzene·OH]$^-$ and [Trinitrobenzene·2OH]$^{2-}$ result.

15) H. A. Benesi and J. H. Hildebrand, *J. Am. Chem. Soc.*, **71**, 2703 (1949).

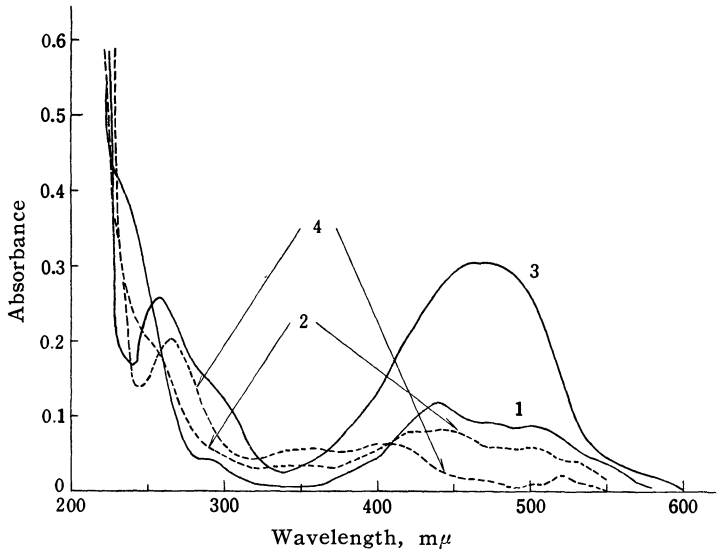

Fig. 3. Absorption spectra of the colored solutions of trinitrobenzene ($1.67\times10^{-5}$ mol.) and sodium hydroxide in water, stood for long hours (at room temperature).
1) A solution with a sodium hydroxide concentration, $7.86\times10^{-2}$ N;
2) The same after two days;
3) A solution with a sodium hydroxide concentration, $9.60\times10^{-1}$ N;
4) The same after a day.

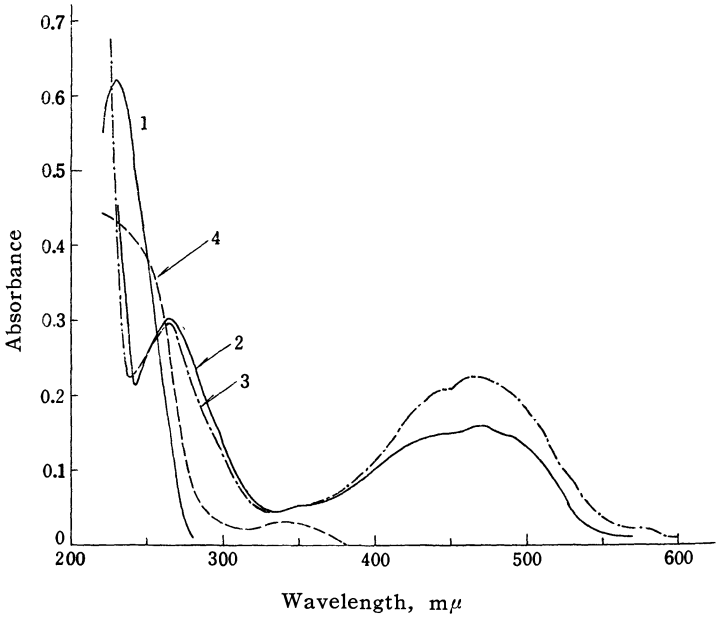

Fig. 4. An effect of hydrochloric acid on the spectrum of the colored solution of trinitrobenzene and sodium hydroxide in water (at room temperature).
1) A solution obtained by adding 2 cc. of water into 2 cc. of an aqueous solution of trinitrobenzene ($4.18\times10^{-5}$ mol.);
2) A solution obtained by adding 2 cc. of water into 2 cc. of a colored solution of trinitrobenzene ($4.18\times10^{-5}$ mol.) and sodium hydroxide (2.88 N);
3) A solution obtained by adding 2 cc. of a 1.77 N aqueous solution of hydrochloric acid into 2 cc. of the same colored solution as in 2);
4) A solution obtained by adding 2 cc. of a 3.55 N aqueous solution of hydrochloric acid into 2 cc. of the same colored solution as in 2).

The 260 and 300 mμ bands and the visible absorption bands may, therefore, be considered to be due to intermediates, that is, [Trinitrobenzene·OH]$^-$ and [Trinitrobenzene·2OH]$^{2-}$ in the reaction of trinitrobenzene with hydroxyl ion to the product giving the 350 mμ band. The absorbances of the visible absorption bands decrease faster in the colored solution with a high sodium hydroxide concentration than in that with a low sodium hydroxide concentration. This suggests that sodium hydroxide plays an important role for the further decoloration reaction of [Trinitrobenzene·OH]$^-$, as mentioned in the previous paper[3].

**An Effect of Hydrochloric Acid on the Spectrum of the Colored Solution of Trinitrobenzene and Sodium Hydroxide (Fig. 4).**—It has been reported by Caldin and Long[5], by Nagakura and Oosawa[12], and by the author[2] that the colored solutions formed on adding alkalies to solutions of aromatic polynitrocompounds are reversibly decolorized by the addition of acids. As Fig. 4 shows, when 2 cc. of 1.77 N aqueous solution of hydrochloric acid is added to the colored solution with a sodium hydroxide concentration, 2.88 N, in which reaction 2 is expected to occur according to the appearance of the distinct 260 mμ band, the absorbances of the visible absorption bands increase, while that of the 260 mμ band slightly decreases. This seems to be due to a reverse reaction of [Trinitrobenzene·2OH]$^{2-}$ to [Trinitrobenzene·OH]$^-$ by addition of hydrochloric acid. If a higher concentrated solution of hydrochloric acid is added to the colored solution, the visible absorption bands disappear and a weak absorption band can be observed 350 mμ. The 350 mμ bands seems to be due to the final product of the reaction between trinitrobenzene and hydroxyl ion, as mentioned above. From the above results, [Trinitrobenzene·2OH]$^{2-}$ may be considered to change into [Trinitrobenzene·OH]$^-$ reversibly by the addition of an acid.

## Summary

(1) Absorption spectra of the colored solutions of 1,3,5-trinitrobenzene and various concentrations of sodium hydroxide in water have been measured at 25°C. The colored solution shows absorption bands at 260, 300 and 440~500mμ. The absorbances of the visible absorption bands increase below the sodium hydroxide concentration, about 0.6 N, but decrease above the sodium hydroxide concentration, as the concentration of sodium hydroxide increases. On the other hand, the 260 and 300 mμ bands, observed above the sodium hydroxide concentration, about 0.4 N, increase their absorbances with an increase in concentration of sodium hydroxide. These lead to the suggestion that the visible absorption bands are due to [Trinitrobenzene·OH]$^-$ and the 260 and 300 mμ bands are due to [Trinitrobenzene·2OH]$^{2-}$.

(2) Below the sodium hydroxide concentration, about 0.6 N, Benesi and Hildebrand's equation holds for the colored solutions, giving an equilibrium constant of 2.7 for the reaction between trinitrobenzene and hydroxyl ion in water at 25°C.

(3) On keeping the colored solution to stand for long hours, the 260 and 300 mμ bands and the visible absorption bands decrease their absorbances, while an absorption band appears at about 350 mμ.

(4) When an aqueous solution of hydrochloric acid is added into the colored solution with a high concentration of sodium hydroxide, the absorbances of the visible absorption bands increase. The 260 mμ band and the visible absorption bands disappear by adding a solution of hydrochloric acid, enough to neutralize the sodium hydroxide contained in the solution. By the addition of acids, [Trinitrobenzene·OH]$^-$ and [Trinitrobenzene·2OH]$^{2-}$ seem to change into trinitrobenzene reversibly.

The author is particularly indebted to Professor Y. Nomura for his suggestions and encouragement throughout this work.

# *An Electron Diffraction Investigation on the Molecular Structure of Hydrazine*

By Yonezo MORINO, Takao IIJIMA, and Yoshitada MURATA

(Received July 1, 1959)

The molecular structure of hydrazine was studied in 1943 by Giguére and Schomaker[1] with the visual method of electron diffraction and the N–N distance was found to be 1.47±0.02 Å. Recently Yamaguchi et al.[2] in this Department studied the infrared vibration-rotation spectrum of the molecule and recognized a difficulty in interpreting the spectrum by the use of this distance. Strictly speaking, the moment of inertia can not be fixed uniquely by the vibration-rotation spectrum alone, for there is a wide choice in selecting the $J$ and $K$ numbering without any other information. Thus, precise determination of the N–N distance was desirable for the proper assignment of the spectral lines. The principal object of the research is to determine the N–N distance as accurately as possible by the sector-microphotometer method, and, if possible, to measure the root mean square amplitudes of thermal vibration.

## Experimental

The sample of hydrazine was kindly provided by Dr. Yamaguchi. The apparatus for electron diffraction was the same as that reported in the preceding paper[3]. An $r^3$-sector was used. The camera length was 11.82 cm. and the accelerating voltage used was about 45 kV. The nozzle was heated to about 60°C and the sample holder to about 30°C. The measured range was from 17 to 100 in $q$-unit. The diffraction patterns were traced on a Rigaku-Denki MP-3 microphotometer. During the tracing the photographic plates were rotated rapidly about the center of the diffraction pattern.

## Structure Analysis

Karle's method[4] was applied to a pair of photographs of different exposure (1 : 1.5). The density-intensity calibration curve was found to be linear in the whole range of the measurement. The ratio of density between the two photographs was consistent with the ratio of the time of exposure.

The molecular intensity curves, $qM(q)$, were obtained by the procedure developed by Karle and Karle. The result is shown in Fig. 1. The radial distribution curve (Fig. 2) was calculated by the Fourier transformation of the observed molecular

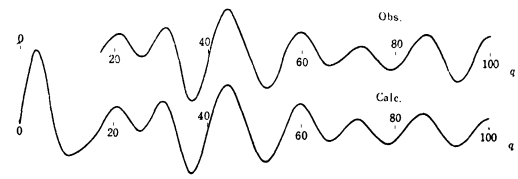

Fig. 1. Observed and calculated molecular intensity curves, $qM(q)$, of hydrazine.

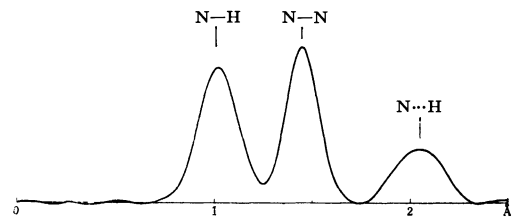

Fig. 2. The modified radial distribution curve of hydrazine.

intensity multiplied by an artificial factor $\exp(-bq^2)$ with $b=0.0002303$, which was assumed so as to reduce the intensity to one tenth of the original at $q=100$. In order to diminish the effect of series termination, the observed intensity curve was spliced with a curve calculated for an assumed model, below 20 and from 90

TABLE I. MOLECULAR PARAMETER OF THE MODEL ASSUMED FIRST FOR THE CALCULATION OF THE SUPPLEMENTARY PART OF THE RADIAL DISTRIBUTION CURVE

| | Atomic distance | Root mean square amplitude |
|---|---|---|
| N–N | 1.47 Å | 0.052 Å |
| N–H | 1.04 Å | 0.074 Å |
| N···H | 2.05 Å | 0.100 Å |

to 120 in $q$-scale. The molecular parameters of the starting model are given in Table I. The equilibrium distances were taken from the paper of Giguére and Schomaker. For the mean amplitude of N-N, that of C-O pair in methanol, 0.052 Å, was adopted. The mean amplitude for the pair of N-H, 0.074 Å, was calculated with an N-H diatomic molcule having the frequency of the symmetric stretching vibration of $NH_3$, 3337 $cm^{-1}$. Finally, for the pair of non-bonded N···H the observed value of a C···H pair in $n$-butane, 0.100 Å, was used. The model was refined by successive approximation. The calculations of the molecular intensity curve and of the radial distribution curve were performed with the aid of a parametron computer PC-1.

The index of resolution was found to be about 95%. Each peak of the radial distribution curve was fitted with a Gaussian in shape to obtain $r_m(f)$ from the position of the maximum of the Gaussian peak, and $<\Delta r^2>^{1/2}$ from the width of the peak. The failure of Born approximation was corrected by Bartell-Brockway method[5]. Using the values of $r_m(f)$, $<\Delta r^2>^{1/2}$, and the index of resolution, thus obtained, the theoretical intensity curve was computed. It is compared with the observed in Fig. 1. Agreement is very well up to 90 in $q$-scale. The final values of the molecular constants listed in Table II were established by taking average over the values obtained by four photographs.

TABLE II. FINAL OBSERVED VALUES OF ATOMIC DISTANCES AND THEIR MEAN SQUARE AMPLITUDES

| | $r_m(f)$ | $<\Delta r^2>^{1/2}$ | $r_0$ (spectroscopic)[2] |
|---|---|---|---|
| N-N | 1.449 ±0.004 Å | 0.051 ±0.005 Å | 1.453 ±0.005 Å |
| N-H | 1.022 ±0.006 Å | 0.074 ±0.007 Å | 1.025 ±1.020 Å |
| N···H | 2.063 ±0.015 Å | 0.103 ±0.015 Å | — |
| N-N-H | 112.0 ±1.5° | — | 112 ~112.5° |

## Calculation of Mean Amplitudes

As was shown by one of the present author[6], the mean square amplitude of a distance between a pair of atoms is given by

$$<\Delta R_i^2> = \sum_k L_{ik}^2 <Q_k^2>$$

where $<Q_k^2>$ is the mean spuare amplitude of the $k$-th normal vibration and is given by the normal frequency as follows:

$$<Q_k^2> = \frac{h}{8\pi^2\nu_k} \coth \frac{h\nu_k}{2kT}$$

$L_{ik}$ is the element of the $\boldsymbol{L}$ matrix which transforms the internal coordinates to the normal coordinates. $L_{ik}^2<Q_k^2>$ indicates the contribution of the $k$-th normal vibration to the mean square amplitude of $R_i$.

The $\boldsymbol{L}$ matrix elements of the hydrazine molecule were calculated by Yamaguchi by the use of the frequencies of the normal vibrations obtained by the Raman and infrared spectra. The temperature of the sample was estimated to be 333°K. The calculated values are shown in Table III, with a reference to the observed values.

TABLE III. CALCULATED VALUES OF MEAN SQUARE AMPLITUDES IN THE UNIT OF $10^{-4}$ Å$^2$

| Total | | | 21.8 | 54.2 | 97.4 |
| Observed mean square amplitude | | | 26 | 55 | 106 |

## Discussion

The N-N bond distance was found to be 1.449±0.004 Å. It is apparently smaller than that by Giguére and Schomaker, 1.47 Å, although the difference is of the same order of magnitude as the error of their value. The final assignment of the spectral lines of the infrared spectrum provided 1.453±0.005 Å[2], in good agreement with the value newly obtained. The N-H distance and the angle of N-N-H obtained by both methods are compared in Table II. For the infrared spectrum, it is the moment of inertia that gives the spacings of the spectral lines, and the

5) L. S. Bartell and L. O. Brockway, *Nature*, **171**, 978 (1953).

6) Y. Morino, K. Kuchitsu and T. Shimanouchi, *J. Chem. Phys.*, **20**, 726 (1952); Y. Morino, K. Kuchitsu, A. Takahashi and K. Maeda, *J. Chem. Phys.*, **21**, 1927 (1953).

moment of inertia strongly depends upon the position of the hydrogen atoms which are located at both ends of the molecule. Hence the N–H distance and the N–N–H bond angle may be obtained more accurately by the infrared spectrum. It must be admitted that the non-bonded N···H distance might contain a fairly large error in the electron diffraction measurement, because the halos in the inner region ($<17$ in $q$-scale) have not been measured. In fact, the N···H peak in the radial distribution curve was found to be appreciably deformed from the Gaussian.

For the mean square amplitudes, the agreement between the observed and the calculated is quite satisfactory, as shown in Table III. Large systematic errors would be contained in the observed values, because the effects of non-nuclear scattering and of finite sample size were not corrected for the observed values. It would be of interest to note that the contribution of the N–N stretching mode to the mean amplitude of N–N pair and that of the N–H stretching modes to the bonded N–H mean amplitude are the most predominant, whereas for the non-bonded N···H pair many modes contribute in comparable order of magnitude.

**Summary**

By the sector-microphotometer method of electron diffraction the molecular structure of hydrazine was obtained as shown in Table II. The bond distances are in good agreement with the values obtained by the infrared vibration-rotation spectrum. The mean amplitudes agreed with the calculated values within the limits of errors.

The authors wish to express their gratitude to Professor H. Takahashi and his coworkers, Department of Physics, the University of Tokyo, for the use of the PC-1 Computer, and to Dr. A. Yamaguchi for her kind offer of hydrazine sample and for many helpful discussions. They are also indebted to the Ministry of Education for the research grant.

# *Oxide Formation on Iron Surface Corroded in Non-Oxidizing Acids*

By Jiro KATO and Yoshi ARAI

(Received August 5, 1959)

On corroding an iron specimen in hydrochloric acid solution with an inhibitor, such as propargyl alcohol, it is possible to observe the formation of ferrous oxide on its surface by means of electron diffraction with good reproducibility of results. The propargyl alcohol is known to be an efficient inhibitor for steel against hydrochloric acid solution[1]. Yamamoto[2] assumed that the propargyl alcohol is able to inhibit the dissolution of iron, since it is adsorbed onto the iron surface with its triple bond. A formation of complex compound, such as $HC{=}\underset{\underset{\text{Fe}}{|}}{\overset{\cdot\cdot}{C}}CH_2{-}\underset{\underset{\text{Fe}}{|}}{O}H$, was also suggested by Lüthringhous and Goetz[3]. In their suggestion, they pointed out the effect of hydrochloric acid from the stand point of the organic chemistry. It is of interest, therefore, to examine experimentally whether their assumptions are true or not.

In this investigation the determination of the corrosion products was carried out by means of electron diffraction. The mechanically polished specimens (5×5 mm.) were immersed in 2 N HCl solution with or without propargyl alcohol about 4 hr. at 70°C. The concentration of propargyl alcohol added was about 10 mM. After the corrosion test, the specimens were washed with distilled water, ethanol and petroleum ether successively, and then immediately examined in an electron

diffraction camera working with 50 kV. electrons. The lattice parameters of the oxide film were determined in reference to those of gold foil. The reflection pattern obtained from the specimen corroded in 2 N HCl solution containing the propargyl alcohol is shown in Fig. 1.

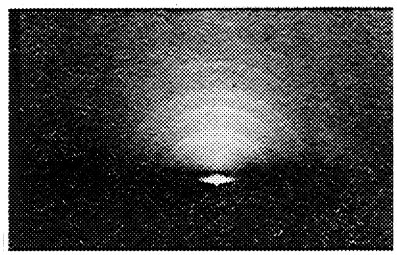

Fig. 1. Diffraction pattern from the iron specimen corroded in 2 N HCl solution containing the propargyl alcohol.
Temperature: 70°C, Immersion time: 4 hr.

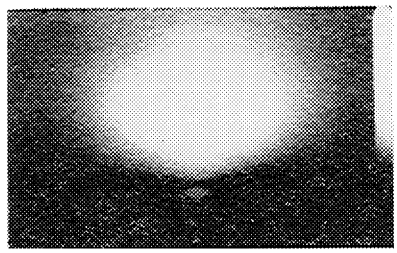

Fig. 2. Diffraction pattern from the iron specimen corroded in 2 N HCl solution containing the propargyl alcohol.
Temperature: 70°C, Immersion time: 8 hr. at 70°C and thereafter 12 hr. at room temperature.

When the specimen was corroded for longer time (about 8 hr.) followed by standing for 12 hr. at room temperature, its surface was coated by $Fe_3O_4$ (or $\gamma$-$Fe_2O_3$). (See Fig. 2.)

Only the iron pattern was observed on the surface of the specimen exposed to 2 N HCl without the propargyl alcohol.

The inhibition mechanism of propargyl alcohol may be explained by considering that oxide films formed on iron surface are protected by the adsorbed propargyl alcohol from a further attack of acid. The oxide films may be always created on the iron surface by dissolved oxygen or OH ions formed at the iron dissolution[4].

In the present investigation the oxide film formation is experimentally observed with the electron diffraction (reflection method). From these results, it is suggested that the oxidation of iron is carried out at the dissolution even in the non-oxidizing acid, such as hydrochloric acid.

The authors wish to express their sincere thanks to Mr. T. Akiba and Dr. A. Nakatuchi for their kind permission to publish this work.

# *The Bischler-Napieralski Reaction in Liquid Sulfur Dioxide. Formation of N, N'-bis-β-Phenethyl Acet- and Benz-amidines and N, N'-Diphenyl Acet- and Benz-amidines*

By Ritsuro TADA, Hisanori SAKURABA and Niichiro TOKURA

(Received May 2, 1959)

It has been shown in a previous paper[1] that dihydroisoquinoline and phenanthridine-derivatives may be produced from the corresponding ketone oximes by simultaneous Beckmann rearrangements and cyclodehydrations in liquid sulfur dioxide under appropriate conditions. As shown in Chart I, the *syn-* and *anti-*configurations of the starting materials should be taken into account in considering the reaction process.

Chart I

In the above-mentioned simultaneous rearrangement and cyclodehydration, the total yield of the condensed ring compound was lower than forty-five per cent and this low yield was apparently due to the presence of a considerable amount of the Ia (*syn*) isomer.

In order to clarify this point, the expected intermediate from the *anti* oxime (I), viz. the acid amide (II), was subjected to the Bischler-Napieralski reaction with phosphorus pentoxide in liquid sulfur dioxide by modifying Bradsher and Sinclair's method of cyclodehydration[2]. In a preliminary examination, it was ascertained that 1-methyl-3,4-dihydroisoquinoline (R=$CH_3$, III) was obtained from *N*-phenethyl acetamide (R=$CH_3$, II) in a maximum yield of 24.5%, and that 10.7% of the acid amide (I) was recovered.

In addition, it was found that the procedure gave a basic substance besides usual Bischler-Napieralski reaction product III.

This result aroused the authors' interest in examining the general behavior of acid amides toward condensing reagents in liquid sulfur dioxide.

Among various reagents examined, phosphorus oxychloride, polyphosphoric acid and thionyl chloride gave no reaction product and only phosphorus pentoxide was effective. The results are shown in Table I.

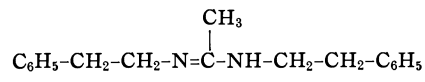
As is shown in Table I, the relation between the dihydroisoquinoline and the basic substance produced at 20°C in liquid sulfur dioxide explains that the side reaction was induced in preference to the

TABLE I. SYNTHESES OF 1-METHYL-3,4-DIHYDROISOQUINOLINE FROM *N*-β-PHENETHYL ACETAMIDE IN LIQUID $SO_2$[a,b]

| No. | Molar ratio of amide to $P_2O_5$ | Reaction | | Amide, recovered, yield, % | 1-Methyl-3,4-dihydro isoquinoline, yield, % | Basic substance, yield, % |
|---|---|---|---|---|---|---|
| | | Temp. °C | Time hr. | | | |
| 1 | 1 : 5 | 20 | 6 | 35.3 | 3.5 | 23.0 |
| 2 | 1 : 5 | 70 | 6 | 10.7 | 24.5 | 33.8 |
| 3[c] | 1 : 17 | 210 | 0.5 | — | 83 | 0 |

a) Reactions were carried out with 6.5 g. (0.04 mol.) of amide in 100 ml. of liq. $SO_2$ under shaking.

b) $POCl_3$, polyphosphoric acid, or $SOCl_2$ used as the reagent in liq. $SO_2$ (molar ratio of amide to reagent was 1 : 5) at 20°C for 6 hr. or at 70°C for 6 hr., caused no reaction.



c) Reaction was carried out in tetralin[8].

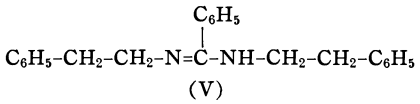
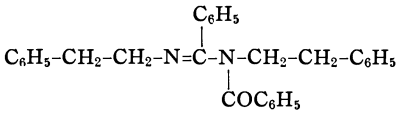
2) C. K. Bradsher and E. F. Sinclair, *J. Org. Chem.*, **22**, 79 (1957).

Bischler-Napieralski reaction.

This basic substance produced was assumed to be the hitherto unknown *N*,*N'*-bis-β-phenethyl acetamidine (IV).



(IV)

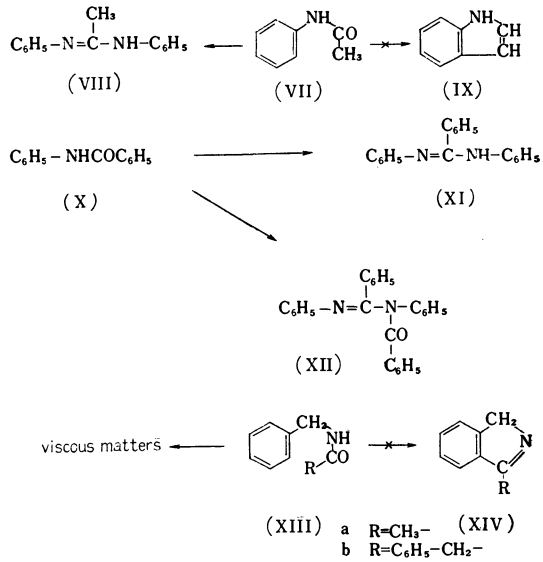


This amidine (IV), distilling at 205~215°C (6~7 mmHg) or 180~190°C (2~3 mmHg) was obtained as a pale yellow oil ($n_D^{15}=1.5748$) and yielded a picrate of m. p. 118~119°C. The elementary analyses of both the base and the picrate satisfied formula IV. The ultraviolet spectrum of the base showed a maximum at $\lambda_{max}^{MeOH}=250\ m\mu$ ($\varepsilon_{max}=385$), indicating the presence of a nonconjugated benzene ring. Its infrared spectrum showed absorption at $\nu_{max}^{KBr}=1635$ (>C=N-), 3440 (>NH), 1352 (methyl), 2915 and 2860 (methylene), and 745 and 695 $cm^{-1}$ (benzene, mono-substituted). The hydrolysis of this base with ten per cent aqueous sodium hydroxide solution, yielded *N*-β-phenethyl acetamide and *N*-β-phenethylamine. Thus the structure of the base was etablished as being IV.

Similarly, it was also shown that a basic substance was afforded by the reaction of *N*-β-phenethyl benzamide (R=$C_6H_5$, II) with phosphorus pentoxide in liquid sulfur dioxide. This basic matter produced was identified as the known *N*,*N'*-bis-β-phenethyl benzamidine (V).

Further, it was also found that another substance was present in the reaction mixture in the latter case. This substance was assumed to be the hitherto unreported *N*-benzoyl-*N*,*N'*-bis-β-phenethyl benzamidine (VI).

(V)



(VI)

This amidine (VI), melting at 110~110.5°C, was obtained as faintly orange crystals. The elementary analysis satisfied formula VI. The ultraviolet spectrum of the amidine showed a maximum at $\lambda_{max}^{MeOH}=241\ m\mu$ ($\varepsilon_{max}=18647$). Its infrared spectrum showed absorptions at $\nu_{max}^{KBr}=1626$ (>C=N-), 1643 (>N-CO-), 2935 and 2860 (methylene), and 747 and 695 $cm^{-1}$ (benzene, mono-substituted). The hydrolysis of this neutral substance with 2 N sulfuric acid gave benzoic acid, *N*-β-phenethyl benzamide and *N*,*N'*-bis-β-phenethyl benzamidine. Thus its structure may be represented by VI.

It was further examined in cases of the other acid amides whether such amidine formations might be encountered generally in liquid sulfur dioxide. When acetanilide (VII) was subjected to this reaction, a similar basic substance was afforded and identified as the known *N*,*N'*-diphenyl acetamidine (VIII). Moreover, when benzanilide (X) was subjected to this reaction, similar substances were obtained and identified as the known *N*,*N'*-diphenyl benzamidine (XI) and *N*-benzoyl-*N*,*N'*-diphenyl benzamidine (XII), respectively. However, when benzyl acet- (XIIIa) and benz-amide (XIIIb) were used, the corresponding amidines were not produced, and viscous substances which were difficult to identify were afforded. The ring closure to IX or XIV was also difficult (Chart II).

Chart II

These results are listed in Table II.

The reason why the formation of dihydroisoquinolines is limited is thus well elucidated as the result of the competitive formation of *N*,*N'*-bis-β-phenethyl amidines. The present authors are not sure that the viscous substances produced from XIII (R=$CH_3$ or $C_6H_5$) might be the polymerization products of the isoindole derivatives which have been known to be very unstable.

## Experimental

**Reagents.**—Amides were prepared by acetylation or benzoylation of the corresponding amines according to methods indicated in references; the amides were *N*-β-phenethyl acetamide[3] (b. p. 147~148°C/3~4 mmHg), *N*-β-phenethyl benzamide[3] (m. p. 114.5~115.5°C), *N*-benzyl acetamide[4] (m. p. 61~63°C) and *N*-benzyl benzamide[5] (m. p. 104~105°C). Acetanilide (m. p. 113.5~114.5°C) and benzanilide (m. p. 162.5~163°C) were commercial ones of extra pure grade.

Liquid sulfur dioxide was used as a solvent. A commercial material was dried with sulfuric acid and distilled before use.

The commercial phosphorus -pentoxide, -oxychloride and thionyl chloride of extra pure grade were used. Polyphosphoric acid was prepared by the known method[6].

**Apparatus and General Procedure.**—Glass pressure vessels (300 ml. capacity) equipped with metal joints and needle valves were used as before[1]. A liquid sulfur dioxide solution of an amide was added to a mixture or a solution of the condensing reagent in liquid sulfur dioxide with ice-cooling. Since benzanilide is sparingly soluble in liquid sulfur dioxide, sulfur dioxide was added to the mixture of this amide and phosphorus pentoxide. Then the whole set was thoroughly shaken and kept for a definite time at a definite temperature.

When the reaction was over, the reaction mixture turned into a gelatinous mass. The excessive solvent (sulfur dioxide) was evaporated and the mixture was decomposed with chilled water. Then the products were treated for further examination.

**Reaction of *N*-β-Phenethyl Acetamide (II) (R=$CH_3$) in Liquid Sulfur Dioxide.**—To 50 ml. of sulfur dioxide containing the condensing reagent (five times moles against that of the amide) as indicated in Table I was added a solution of 6.5 g. (0.04 mol.) of *N*-β-phenethyl acetamide (II) (R=$CH_3$) in 50 ml. of sulfur dioxide. After the reaction under a definite condition with shaking, the solvent was evaporated and water was added to the solution with chilling. The acidic mixture was extracted with benzene. The benzene solution, after washing with sodium bicarbonate solution and drying with anhydrous sodium sulfate, was condensed and the residue was distilled in vacuo. The acid amide (II) (R=$CH_3$) was recovered as a pale yellow oil boiling at 160~170°C (6~7 mmHg). Hydrolyzing this acid amide to β-phenethyl amine with hydrochloric acid, a picrate of the amine was prepared, m. p. 167~168°C. Reported melting point is 171°C[7]. The mixed melting point with an authentic sample showed no depression.

3) A. Bischler and B. Napieralski, *Ber.*, **26**, 1903 (1893).
4) J. Strakosch, ibid., **5**, 697 (1872).
5) E. Beckmann, ibid., **23**, 3334 (1890).
6) R. C. Gilmore and W. J. Horton, *J. Am. Chem. Soc.*, **73**, 1412 (1951).
7) H. Decker and W. Kropp, *Ber.*, **42**, 2078 (1909).

The residual aqueous solution was made alkaline with caustic alkali and was extracted with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, was evaporated and the residue was distilled in vacuo. A colorless oil boiling at 100~105°C (7~8 mmHg) was obtained. This was 1-methyl-3,4-dihydroisoquinoline (III) (R=$CH_3$). Picrate, yellow needles, m. p. 188~189°C. Reported melting point is 188~190°C[8]. No melting point depression was observed when the sample was mixed with an authentic sample.

*Anal.* Base Found: N, 9.72. Calcd. for $C_{10}H_{11}N$: N, 9.65%. Picrate Found: N, 15.10. Calcd. for $C_{16}H_{14}O_7N_4$: N, 14.97%.

Moreover, following the above fraction, a pale yellow oil boiling at 205~215°C (6~7 mmHg) was obtained. This oil was assumed to be *N,N'*-bis-*β*-phenethyl acetamidine (IV), b. p. 180~190°C (2~3 mmHg), $n_D^{15}$=1.5748, I. R. $\nu_{max}^{KBr}$: 3440, 2915, 2860, 1635, 1352, 745 and 695 $cm^{-1}$, U. V. $\lambda_{max}^{MeOH}$: 250 m$\mu$ ($\varepsilon_{max}$ 385). Picrate, yellow needles (from 95% ethanol) m. p. 118~119°C, mol. wt. (by the Counningham method)[9]: 464 (the molar ratio of picric acid : base=1 : 1, calcd. as $C_{24}H_{25}O_7N_6$ 495).

*Anal.* Base Found: N, 10.99. Calcd. for $C_{18}H_{22}N_2$: N, 10.52%. Picrate Found: C, 57.92; H, 4.78; N, 14.29. Calcd. for $C_{24}H_{25}O_7N_5$: C, 58.17; H, 5.09; N, 14.14%.

No production of dihydroisoquinoline or amidine were observed with phosphorus oxychloride, polyphosphoric acid or thionyl chloride in liquid sulfur dioxide from II. Yields obtained with a variety of conditions are listed in Table I.

**Hydrolysis of IV.**—Two grams of this base was heated for 3.5 hr. under refluxing with 20 g. of 10% sodium hydroxide solution, then the mixture was acidified with hydrochloric acid. The mixture was extracted with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, was concentrated and the residue was distilled in vacuo. A pale yellow oil (0.4 g.), boiling at 154~155°C (4~5 mmHg), was obtained. This was *N*-*β*-phenethyl acetamide. Hydrolyzing this acid amide to *β*-phenethyl amine with hydrochloric acid, a picrate of the amine was prepared. The melting point and the mixed melting point with an authentic sample were 167~168°C[7]. The residual solution was made alkaline with caustic alkali again and the product was extracted with benzene. The benzene extract, after washing with water and drying with anhydrous sodium sulfate, was concentrated and the residue was fractionated in vacuo. Two oils, boiling at 110~115°C (50~51 mmHg) and 205~215°C (6~7 mmHg) were obtained. The first colorless oil (0.4 g.) was *N*-*β*-phenethyl amine. A picrate of the amine was prepared. The melting point and the mixed melting point with an authentic sample were 167~168°C[7]. The second pale yellow oil (0.2 g.) obtained was the recovered *N,N'*-bis-*β*-phenethyl acetamidine. A picrate of the amidine was prepared. The melting point and the mixed melting point with the picrate of the amidine (reaction product in liquid sulfur dioxide) were 118~119°C.

**Preparation of IV from II with Hydrogen Chloride.**—*N*-*β*-Phenethyl acetamide was subjected to a reaction with hydrogen chloride stream at 150°C for two hours according to the preparation method of Wallach[14]. A basic pale yellow oil ($n_D^{15}$=1.5718) boiling at 175~185°C (1~2 mmHg) was obtained and yielded a picrate of m. p. 118~119°C. This melting point was not depressed on mixture with the picrate of the basic substance (b. p. 180~190°C/2~3 mmHg) obtained from *N*-*β*-phenethyl acetamide in liquid sulfur dioxide and assumed to be *N,N'*-bis-*β*-phenethyl acetamidine (IV).

**Reaction of *N*-*β*-Phenethyl Benzamide (II) (R=$C_6H_5$) in Liquid Sulfur Dioxide.**—A solution of 9 g. (0.04 mol.) of *N*-*β*-phenethyl benzamide in 50 ml. of sulfur dioxide was added to 50 ml. of sulfur dioxide containing the reagent (molar ratio of amide to $P_2O_5$ was 1 : 5). After the reaction for six hours and at 20°C with shaking, the solvent was allowed to evaporate and water was added with chilling. The acid mixture was extracted with benzene. The benzene solution, after washing with ammonia water and then with water, was dried with anhydrous sodium sulfate and was evaporated. The residue gave crystals melting at about 115°C. The crystals 4.4 g. (48.8%) were recrystallized from ethanol as colorless leaflets, melting at 116~116.5°C and were identified as the recovered *N*-*β*-phenethyl benzamide. When the reaction was carried out at 70°C, the benzene extract gave crystals of m. p. 110~110.5°C, faintly orange prisms (from ethanol). The crystals (1.1 g., 12.7%) were assumed to be *N*-benzoyl-*N,N'*-bis-*β*-phenethyl benzamidine (VI). I. R. $\nu_{max}^{KBr}$: 2935, 2860, 1643, 1626, 745 and 695 $cm^{-1}$, U. V. $\lambda_{max}^{MeOH}$: 241 m$\mu$($\varepsilon_{max}$ 18647), mol. wt. [Rast's method (camphor)]: 423, calcd. as $C_{30}H_{28}ON_2$, 432.

*Anal.* Found: C, 83.08; H, 6.05; N, 6.41. Calcd. for $C_{30}H_{28}ON_2$: C, 83.30; H, 6.53; N, 6.41%.

The residual acid aqueous solution after benzene extraction was made alkaline with ammonia water and was again extracted with benzene. The benzene solution was dried and concentrated. When 2 N sulfuric acid was added to the residue, an oil was precipitated. The supernatant solution was decanted and ammonia water was added to the oil. The oil changed into crystals. The crystal (0.8 g., 12.3%, reaction at 20°C and 0.6 g., 9.2%, reaction at 70°C) obtained by filtration was recrystallized from ligroin (b. p. 100~120°C) as colorless needles, melting at 79.5~80°C (picrate, yellow plate, m. p. 170~170.5°C) and was identified as *N,N'*-bis-*β*-phenethyl benzamidine[10] (V) (m. p. and mixed m. p. 79.5~80°C) (picrate[11], m. p. and mixed m. p. 170~170.5°C).

The supernatant solution decanted was made alkaline with ammonia water and was again extracted with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, was concentrated and the residue was distilled in vacuo. A pale yellow oil ($n_D^{18}=1.6293$) boiling at 150~160°C (2~3 mmHg) was obtained. This base (1.2 g., 14.6%, reaction at 20°C and 6.6 g., 80.4%, reaction at 70°C) was 1-phenyl-3,4-dihydroisoquinoline (III) (R=$C_6H_5$). Picrate, yellow needle, m. p. 173.5~174°C. Reported melting points 173~174°C[12]. No melting point depression was observed when mixed with an authentic sample.

*Anal.* Base Found: N, 6.31. Calcd. for $C_{15}H_{13}N$: N, 6.76%. Picrate Found: N, 12.82. Calcd. for $C_{21}H_{16}O_7N_4$: N, 12.84%.

The results and the related facts observed were shown in Table II.

The residual ammoniacal solution after extraction was acidified with sulfuric acid and was extracted again with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, yielded a crystal after evaporation. This crystal (0.2 g., 8.3%, reaction at 20°C and 0.2 g., 8.3%, reaction at 70°C) was recrystallized from 50% ethanol to an m. p. of 121~121.5°C and was identified as benzoic acid by a mixed melting point determination.

**Hydrolysis of VI.**—Six tenths gram of VI was heated for two hours on a boiling water bath with 2 N sulfuric acid, then the mixture was made alkaline with ammonia water and was extracted with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, was concentrated and was triturated with ether. The ether-insoluble residue (0.3 g.) melted at 114~115°C. This was *N*-β-phenethyl benzamide. From the ether solution, a viscous liquid (0.1 g.) was obtained and changed to a crystal melting at 69~70°C (recrystallization from ligroin, b. p. 100~120°C). A picrate of this basic matter was prepared. The melting point and the mixed melting point with the picrate[11] of the *N,N'*-bis-β-phenethyl benzamidine (V) were 170~170.5°C. The residual aqueous solution after extraction was acidified with sulfuric acid and was extracted with benzene. The benzene solution gave a crystal (0.1 g.) melting at 121~121.5°C. This was identified as benzoic acid by a mixed melting point procedure.

**Preparation of VI.**—*N,N'*-bis-β-phenethyl benzamidine[10] was subjected to a reaction for four hours with benzoyl chloride in boiling benzene according to the method[13] of Oxley and Short. A neutral faintly orange prism melting at 110~110.5°C was obtained. This melting point was not depressed on mixture with the neutral substance (m. p. 110~110.5°C) obtained from *N*-β-phenethyl benzamide in liquid sulfur dioxide, thus establishing the structure of the latter to be *N*-benzoyl-*N,N'*-bis-β-phenethyl benzamidine (VI).

**Reaction of Acetanilide (VII) in Liquid Sulfur Dioxide (Table II).**—A solution of 5.4 g. (0.04 mol.) of acetanilide in 50 ml. of sulfur dioxide was added to a mixture of reagent (molar ratio of amide to $P_2O_5$ was 1 : 5) in 50 ml. of sulfur dioxide. When the reaction at 20°C for six hours with shaking was over, the reaction mixture was treated as in the previous case. From the benzene extract of the reaction mixture (acidic condition) there was recovered 3.1 g. (57.4%) of acetanilide, m. p. 113.5~114°C (recrystallization from benzene). No melting point depression was observed when mixed with an authentic sample.

The residual solution was made alkaline by sodium hydroxide solution. From the benzene extract of the solution, there was separated an oil, which changes to a crystalline matter. The crystal (0.8 g., 19.0%) was recrystallized from 50% ethanol as a colorless needle, melting at 131.5~132°C and was identified as *N,N'*-diphenyl acetamidine[14] (VII) (m. p. and mixed m. p. 131.5~132°C). I. R. $\nu_{max}^{KBr}$: 3220, 1637, 1380, 757 and 690 $cm^{-1}$, U. V. $\lambda_{max}^{MeOH}$: 265 mμ ($\varepsilon_{max}$ 18827), mol. wt. [Rast's method (camphor)]: 208, calcd. as $C_{14}H_{14}N_2$, 210. Picrate, yellow needle (from 95% ethanol): m. p. 168.5~169°C[15], mol. wt. (by the Cunningham method)[9]: 475, calcd. as $C_{20}H_{17}O_7N_5$ (the molar ratio, picric acid : base=1 : 1), 439.

*Anal.* Base Found: C, 79.76; H, 6.53; N, 13.55. Calcd. for $C_{14}H_{14}N_2$: C, 79.96; H, 6.71; N, 13.32%. Picrate Found: C, 54.86; H, 4.12; N, 15.76. Calcd. for $C_{20}H_{17}O_7N_5$: C, 54.67; H, 3.90; N, 15.94%.

From the filtrate, 0.3 g. (5.5%) of an oil was obtained by distillation in vacuo. Colorless oil, b. p. 96~102°C (49~50 mmHg) was identified as aniline by its benzoylation[16], m. p. and mixed m. p. 160°C.

When the reaction was conducted at 70°C for six hours, 1.9 g. (35.1%) of the acid amide was recovered and 1.3 g. (30.9%) of the amidine and 0.6 g. (11.1%) of aniline were obtained.

**Reaction of Benzanilide (X) in Liquid Sulfur Dioxide (Table II).**—To a mixture of benzanilide 7.9 g. (0.04 mol.) and the reagent (molar ratio of amide to $P_2O_5$ was 1 : 5), was added 100 ml. of sulfur dioxide. When the reaction at 20°C for six hours with shaking was over, the solvent was allowed to evaporate and water was added with chilling. The acid mixture was filtered. The filtrate was extracted with benzene. From the benzene solution, after washing with water and drying with anhydrous sodium sulfate, a trace of crystal was obtained. The crystal was recrystallized from 50% ethanol as a colorless needle, melting at 121~121.5°C and was identified as benzoic acid by a mixed melting point. The residue, after filtration, was washed with water and dried. Fractional crystallization of the residue from ethanol gave two kinds of crystals melting at about 160 and about 170°C, respectively. The first crystal 3.3g. (41.7%) was recrystallized from ethanol as a colorless leaflet, melting at

162.5~163°C and was identified as the recovered benzanilide.

The second crystal was recrystallized from benzene-ethanol as a faintly yellow prism, melting at 172~172.5°C. This crystal (3.5 g., 46.6%) was identified as *N*-benzoyl-*N*,*N'*-diphenyl benzamidine[13] (XII) (m. p. and mixed m. p. 172~172.5°C). I. R. $\nu_{max}^{KBr}$: 1650, 1626, 763 and 690 $cm^{-1}$, U. V. $\lambda_{max}^{MeOH}$: 255 m$\mu$ ($\varepsilon_{max}$ 20890), mol. wt. [Rast's method (camphor)]: 366, calcd. as $C_{26}H_{20}ON_2$, 376.

*Anal.* Found: C, 83.31; H, 5.25; N, 7.21. Calcd. for $C_{26}H_{20}ON_2$: C, 82.95; H, 5.36; N, 7.44%.

The residual acid aqueous solution was made alkaline with ammonia water and was extracted again with benzene. The benzene solution, after washing with water and drying with anhydrous sodium sulfate, was evaporated and the residue was given as a crystal. The crystal (0.1 g., 1.8%) was recrystallized from benzene as a colorless needle, melting at 146~146.5°C (picrate, yellow plate, m. p. 216.5~217°C with decomp.) and was identified as *N*,*N'*-diphenyl benzamidine[17] (XI) (m. p. and mixed m. p. 146~146.5°C, picrate[18], m. p. and mixed m. p. 216.5~217°C with decomp.).

When the reaction was conducted at 70°C for six hours, 0.4 g. (5.0%) of the acid amide was recovered and 0.4 g. (16.6%) of benzoic acid, 1.4 g. (18.6%) of *N*-benzoyl-*N*,*N'*-diphenyl benzamidine and 2.5 g. (46.2%) of *N*,*N'*-diphenyl benzamidine were obtained.

**Reaction of *N*-Benzyl Acetamide (XIII) (R=$CH_3$) in Liquid Sulfur Dioxide.**—To a mixture of the reagents ($P_2O_5$, 29 g., molar ratio of amide to $P_2O_5$ was 1 : 5) in 50 ml. of liquid sulfur dioxide was added a solution of 5.9 g. (0.04 mol.) of *N*-benzyl acetamide in 50 ml. of liquid sulfur dioxide. The reaction mixture was treated as described above after shaking for six hours at 70°C. A small amount of basic substance and a viscous residue were obtained in the reaction mixture (Table II).

**Reaction of *N*-Benzyl Benzamide (XIII) (R=$C_6H_5$) in Liquid Sulfur Dioxide.** — A solution of 8.4 g. (0.04 mol.) of the *N*-benzyl benzamide in 50 ml. of liquid sulfur dioxide was added to 50 ml. of sulfur dioxide containing the reagent ($P_2O_5$ five times moles against that of the amide). The reaction mixture was treated as in the previous case after shaking for six hours at 20 or 70°C. A small amount of resinous basic substance and a large amount of viscous acidic or neutral substance were separated from the viscous reaction mixture. But they were not further examined.

## Summary

The Bischler-Napieralski reaction of *N*-$\beta$-phenethyl acetamide in liquid sulfur dioxide resulted in the formation of *N*,*N'*-bis-$\beta$-phenethyl acetamidine in addition to the expected 1-methyl-3,4-dihydroisoquinoline. And the reaction product from *N*-$\beta$-phenethyl benzamide were *N*,*N'*-bis-$\beta$-phenethyl benzamidine and *N*-benzoyl-*N*,*N'*-bis-$\beta$-phenethyl benzamidine in addition to the expected 1-phenyl-3,4-dihydroisoquinoline. In the case of acetanilide, *N*,*N'*-diphenyl acetamidine was produced. Benzanilide afforded *N*,*N'*-diphenyl benzamidine and *N*-benzoyl-*N*,*N'*-diphenyl benzamidine under a similar condition. The similar reaction of benzyl acylamides in liquid sulfur dioxide failed to yield such amidines.

The financial support of this project was granted by the Ministry of Education. Liquid sulfur dioxide was donated by the Befu Chemical Industries Co., Ltd. Ultraviolet absorption spectra were measured by Professor T. Nozoe and his associates of the Department of Chemistry. Infrared absorption spectra were measured by Professor S. Kinumaki and his associates of this Institute. The elementary analyses were performed by Mr. Shinichi Oyama and Miss Yoko Endo. The authors wish to express their thanks to these helps and donations.

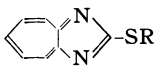
# *Some Reaction of 2-Mercapto-1, 3-diazaazulene*

By Ichiro MURATA

(Received May 20, 1959)

Nozoe, Mukai and Murata[1] reported that the reaction of tropolone methyl ether and thiourea in ethanol, in the presence of sodium alcoxide, resulted in the condensation to form 2-mercapto-1, 3-diazaazulene (I). Later, the same condensation reaction was carried out on tropolones with methyl[2], isopropyl[3], phenyl[4] and styryl[5], and oxidative desulfurization reaction on 2-mercapto-1,3-diazaazulene thereby formed. No studies, however, have been made on the nature of the mercapto group in 2-position of these compounds and it seemed of interest to examine reactivity of a mercapto group in this kind of new, nitrogenous heterocyclic compound. Therefore, examinations were made with I which has no carbon-containing side chain.

Oxidation of I with nitric acid or 10% hydrogen peroxide with heating affords 1,3-diazaazulene (II)[1] in over 80% yield. Application of 10% hydrogen peroxide at room temperature or of sodium nitrite in acetic acid affords only the 2-disulfide (III)[1] in almost quantitative yield. Application of hydrogen peroxide to III with heating produces II, but the possible intermediate in this reaction, the sulfonic acid or sulfinic acid[6], was not isolated. III is easily reduced to I by aqueous solution of sodium sulfide.



The sodium salt of I undergoes facile reaction in ethanol with various alkyl iodides, polynitrochlorobenzenes, benzyl chloride, chloroacetone, phenacyl chloride, chloroacetic acid, and 2-chloro-1,3-diazaazulene[7] to form the corresponding thioethers (Table I).

| XV | 248(4.72), 275(sh.), 368(4.41) |

The ultraviolet absorption maxima of these thioethers are presented in Table II.

The nucleophilic substitution reaction of I was then examined. Examples of nucleophilic substitution of a mercapto group are extremely rare and only the reaction with ammonia or amine[8] is known. Heating of I with 40% aqueous ammonia or methylamine in a sealed tube for a few hours at 170~180°C only results in quantitative recovery of I. Heating of I with concentrated hydrochloric acid in a sealed tube for 6 hr. at 160°C results in its hydrolysis and 2-hydroxy-1,3-diazaazulene (XVI)[1,7] is obtained in a good yield.

The methylthio group may be considered to undergo more facile nucleophilic substitution than the mercapto group and there is a comparatively large number of examples[9]. Actually, IV reacts with a number of nucleophilic reagents to form the corresponding 2-substituted derivatives (Table III).

## Experimental[10]

**2-Mercapto-1, 3-diazaazulene (I).** — Synthesized from tropolone methyl ether and thiourea according to the method described earlier[1]. Reddish orange microneedles, m. p. >300°C.

**Oxidation of I.**—a) To a suspension of 1 g. of I in 10 cc. of water, 5 cc. of 30% hydrogen peroxide was added and the mixture was warmed on a water bath, by which the reaction proceeded immediately with effervescence to form a clear, orange solution. After cooling, the mixture was rendered weakly alkaline with sodium hydrogen carbonate and extracted with chloroform. The extract was washed with water, dried, and chloroform was evaporated. The residue was dissolved in benzene and passed through a short column of alumina from which 620 mg. of yellow needles, m. p. 110~112°C, was obtained. Mixed fusion with 1,3-diazaazulene (II) showed no depression of the melting point.

b) To a suspension of 100 mg. of I in 1 cc. of water, 1.2 cc. of 10% hydrogen peroxide was added dropwise with stirring at room temperature and the mixture was stirred for further 3 hr. The precipitate formed was collected by filtration and 80 mg. of yellow microneedles (III), m. p. 203°C (decomp.), was obtained.

c) A solution of 45 mg. of sodium nitrite dissolved in 0.5 cc. of water was added dropwise to 100 mg. of I suspended in 2 cc. of glacial acetic acid, cooled in ice. The precipitate formed changed from orange to yellow. After stirring for 2 hr., the precipitate was collected by filtration to 85 mg. of III, m. p. 204°C (decomp.).

**Reaction of Disulfide (III).**—*a) Oxidation with hydrogen peroxide.*—A mixture of 100 mg. of III suspended in 0.5 cc. of water, with 1 cc. of 30% hydrogen peroxide added, was heated on a water bath by which effervescence occurred immediately to form an orange solution. The mixture was neutralized with sodium hydrogen carbonate, extracted with chloroform, and the extract was washed with water. After drying, chloroform was distilled off and 70 mg. of yellow needles, m. p. 110~113°C, was obtained. This showed no

10) All melting points are uncorrected. Ultraviolet absorption spectra were used for identification of high-melting substances and decomposition products. Measurement was made with a Beckman Model DU spectrophotometer. The microanalyses were carried out by Mr. S. Ohyama and Miss A. Iwanaga, to whom the author's deep gratitude is hereby expressed.

depression in the melting point on admixture with II.

*b) Reduction with sodium sulfide.* — Aqueous solution of 200 mg. of sodium sulfide was added to 65 mg. of III, suspended in 1 cc. of ethanol by which the precipitate disappeared to form an orange solution. The mixture was diluted with 2 cc. of water, acidified with glacial acetic acid, and the precipitate was collected by filtration to give 50 mg. of I, m. p. >300°C.

**Reaction of Sodium Salt of I and Halides.**—*a) General procedure for preparation of methyl- (IV), ethyl- (V), n-propyl- (VI), n-butyl- (VII), allyl- (VIII), benzyl- (IX), phenacyl- (XII) and acetonylthio-1,3-diazaazulene (XIII).* — Ethanolic solution of 1.1 molar equivalents of halide was added to the sodium salt of I dissolved in ethanol and the mixture was refluxed for 0.5~1.0 hr. Ethanol was distilled off, the residue was dissolved in benzene, and the benzene solution was passed through a short column of alumina. The crystalline residue obtained on evaporation of benzene was recrystallized 2~3 times from the solvent listed in Table I.

*b) General procedure for preparation of 2,4-dinitrophenyl- (X), 2,4,6-trinitrophenyl- (XI) and 2-(1,3-diazaazulenylthio)-1,3-diazaazulene (XV).*— Sodium salt of I was mixed with halide in ethanol and the precipitate formed after some time was recrystallized twice from a solvent as listed in Table I.

*c) 2-Carboxymethylthio-1,3-diazaazulene (XIV).* —To a solution of 500 mg. of I dissolved in 2 cc. of 2 N sodium hydroxide, 300 mg. of monochloroacetic acid neutralized with sodium hydrogen carbonate was added and the mixture was heated on a water bath at 90°C for 15 min. After cooling, the mixture was acidified with acetic acid, the yellow precipitate was collected by filtration, and washed with water and then with ethanol, affording 640 mg. of crystalline powder, m. p. >300°C.

**2-Hydroxy-1, 3-diazaazulene (XVI).**—*a) From I.* — A mixture of 100 mg. of I and 2 cc. of concentrated hydrochloric acid was sealed in a tube and heated at 160°C for 6 hr. Evaporation of hydrochloric acid left 120 mg. of colorless crystals, m. p. >300°C, which was dissolved in a small amount of water, and the solution was neutralized with a saturated solution of sodium hydrogen carbonate. The crystalline precipitate thereby formed was collected by filtration and 95 mg. of pale yellow needles, m. p. 234°C, was obtained. Recrystallization from dilute ethanol raised the melting point to 244°C, undepressed on admixture with XVI.

*b) From IV.*—A mixture of 50 mg. of IV and 1 cc. of concentrated hydrochloric acid was refluxed, in an oil bath for 2 hr., hydrochloric acid was evaporated, and the residue was treated as in a) from which 30 mg. of XVI was obtained.

**Nucleophilic Substitution Reaction of IV.**—*a) 2-Amino-1,3-diazaazulene (XVII).*—A mixture of 50 mg. of IV and 1 cc. of ammonia water was sealed in a tube and heated at 100°C for 6 hr. The mixture was allowed to cool overnight and crystals that formed were collected by filtration to 15 mg. of crystals melting at 290°C with decomposition. Recrystallization from hot water afforded yellow needles (XVII), m. p. 294°C (decomp.). Ammonia mother liquor was diluted with 3 cc. of water and extracted with chloroform from which 20 mg. of IV was recovered.

*b) 2-Methylamino- (XVIII) and 2-dimethylamino-1,3-diazaazulene (XIX).*—A mixture of 50 mg. of IV and 40% aqueous solution of monomethylamine or dimethylamine was sealed in a tube and heated at 100°C for 6 hr. The reaction mixture was diluted with water, extracted with chloroform, and the chloroform residue was recrystallized from the benzene-petroleum ether mixture to XVIII, m. p. 173~174°C, or XIX, m.p. 134°C. There was no recovery of IV in this case.

*c) 2-Hydrazino-1,3-diazaazulene (XX).* — To a solution of 70 mg. of IV dissolved in 1 cc. of ethanol, 0.5 cc. of 80% aqueous solution of hydrazine was added and the mixture was refluxed for 2 hr. When cooled, crystals formed, they were collected by filtration and recrystallized from ethanol to 45 mg. of XX, m. p. 187°C (decomp.).

*d) 2-Anilino- (XXI) and 2-benzylamino-1,3-diazaazulene (XXII).*—A mixture of 70 mg. of IV dissolved in 1 cc. of ethanol and 50 mg. of aniline or benzylamine was heated in a sealed tube at 160~170°C for 8 hr. The crystals formed on cooling were recrystallized from benzene to yellow needles (XXI), m. p. 238~239°C, or yellow scales (XXII), m. p. 175°C.

*e) 2-Methoxy-1,3-diazaazulene (XXIII).* — To a solution of 30 mg. of sodium methoxide dissolved in 3 cc. of dehydrated methanol, 90 mg. of IV was added and the mixture was refluxed on a water bath for 25 hr. After evaporation of methanol, the benzene-soluble portion afforded 30 mg. of XXIII and the benzene-insoluble portion afforded 15 mg. of XVI.

The author expresses his deep gratitude to Professor Tetsuo Nozoe of the Faculty of Science of this University for kind and unfailing guidance throughout the course of this work. He is also indebted to Mr. Shinji Iizuka for technical assistance.

# *On the Structure of Condensation Products of o-Aminophenols with α-Dicarbonyl Compounds. II*

By Ichiro MURASE

(Received June 1, 1959)

It has been reported in the previous paper[1] that 2,2′-bibenzoxazoline and its 2,2′-dimethyl derivative were formed by the condensation of *o*-aminophenol (2 mol.) with glyoxal (1 mol.) and with diacetyl (1 mol.), respectively.

Now, condensation of skeletal derivatives of *o*-aminophenol with several kinds of α-dicarbonyl compounds was studied and the structures of these condensation products were determined.

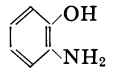
The condensation reaction proceeded generally in the same way as in the case of 2,2′-bibenzoxazoline previously reported. However it was found that the products were classified into two groups according to the molar ratio of the reactants.

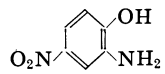
The following investigation led to the conclusion that the compounds of the first group were the condensation products of two moles of *o*-aminophenols with one mole of α-dicarbonyl compounds and the structures proved to be 2,2′-bibenzoxazoline derivatives as in the case previously reported. The second group was equimolar condensation products of each component and the structures proved to be 2-hydroxy 2,3-disubstituted 1,4-benzoxazine derivatives. The structures of these two groups are summarized in Tables I and II, respectively, together with their infrared and ultraviolet absorption spectra. The melting points and analytical data of both groups are listed in Tables III and IV, respectively.

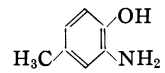
It was found that the more bulky the alkyl groups in the dicarbonyl compounds were, the poorer the yield of the condensation product became. In some cases, such bulky groups affected only benzoxazine type products as the single ones. Acetylisobutylyl reacted only with 4-nitro-2-aminophenol to give a benzoxazine type condensation product. On the other hand, it proved that phenylglyoxal reacted with all *o*-aminophenols examined to give products of the same type in good yields. It was exceptional that acetylbenzoyl despite the bulky groups and though it did not react with any other skeletal derivatives, condensed with two moles of *o*-aminophenol to give a bibenzoxazoline type product. Benzil did not react at all with any of *o*-aminophenols examined.

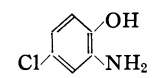
5-Nitro-2-aminophenol and picrylamine did not react with any α-dicarbonyl compounds examined, while 4-nitro-2-aminophenol was very reactive.

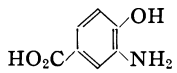
Thus, the ease and the type of the condensation are affected by the basicity of the amino group and the acidity of the hydroxyl group of the *o*-aminophenols and further by the steric factor of the α-dicarbonyl compounds.

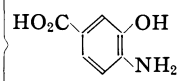












It is interesting to note that in place of methylglyoxal and diacetyl, their monoximes reacted with *o*-aminophenol and 4-nitro-2-aminophenol with elimination of the oximino groups to produce the same condensation products as those obtained from the mother dicarbonyl compounds. But dimethyl glyoxime did not react with them.

The 2,2′-bibenzoxazoline structures were established by means of their infrared and ultraviolet absorption spectra; the sharp NH band and the anilino band were present in each infrared spectrum, which were the same as those of an authentic 2,2′-bibenzoxazoline, and the features of the ultraviolet spectra excellently agreed with each other regarding those of the compounds derived from the same aminophenols (refer to Table I).

Among these bibenzoxazoline derivatives, those which were derived from glyoxal, methylglyoxal and diacetyl were stable toward the cold dilute solution of both mineral acid and aqueous alkali, while higher homologues were more sensitive to these reagents and were hydrolyzed gradually on standing at room temperature. The carboxylic derivatives dissolved in sodium hydrogen carbonate solution to give a colorless solution, and in sodium hydroxide solution with orange coloration.

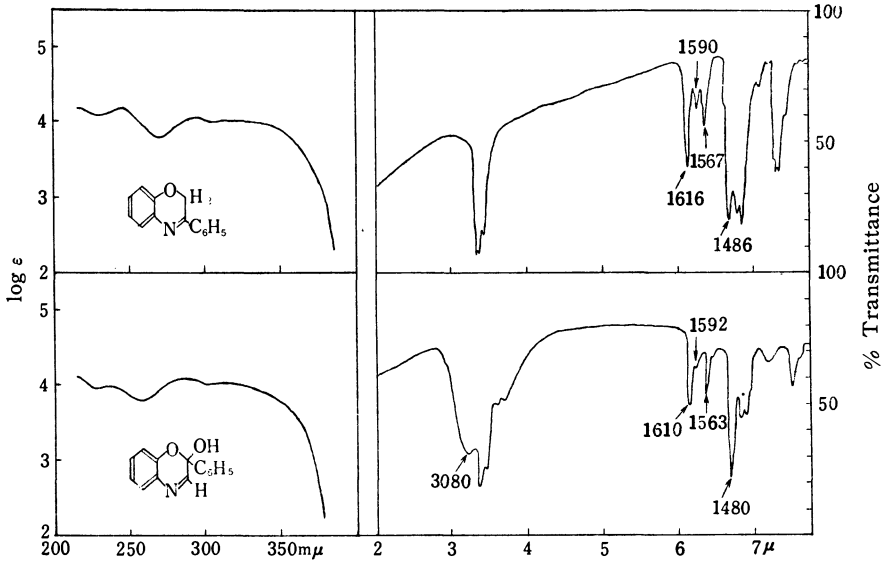
It is apparent that they were tautomerized to Schiff bases in the latter case as indicated in the previous paper[1].

Concerning the equimolar condensation products (the second group), benzoxazoline structure A was considered at first, since the compounds of this group were insoluble in aqueous alkali except carboxylic derivatives.

(A)

The broad infrared absorption bands found near 3000 $cm^{-1}$ in all spectra indicate the presence of hydrogen bonded OH or NH groups. However carbonyl absorption, the presence of which was expected from formula A, was not found in any spectra, and instead comparatively weak absorptions were present in the 1600 $cm^{-1}$ region. Further, the fact that, in the case of $\alpha$-iminoketones such as $C_6H_5NHCH_2COCH_3$ and $C_6H_5NHC(CH_3)_2COCH_3$, the sharp NH band at 3413 $cm^{-1}$ in the both compounds and the strong C=O band at 1706 $cm^{-1}$ in the former and at 1709 $cm^{-1}$ in the latter existed, excluded the possibility of $\alpha$-iminoketonic formula A.

Therefore, the author proposed the 1,4-benzoxazine structure C and the mode of the reaction indicated.



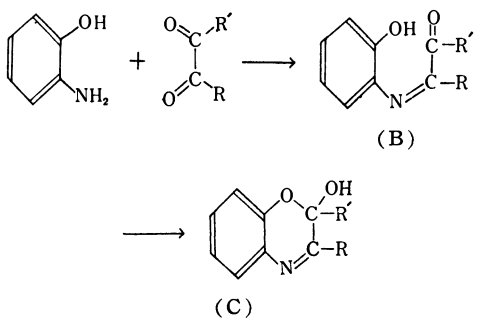


Fig. 1. Ultraviolet (in ethanol) and infrared (Nujol mull) spectra of 19 (bottom) and 3-phenyl-1,4-benzoxazine (top).

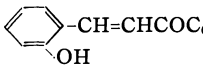
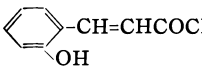
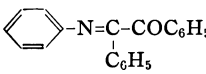




(B)



(C)

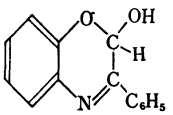
The intermediate Schiff base structure B was also excluded because the C=O absorption was absent in their infrared spectra and they were insoluble in alkali. This was further supported by the fact that the following compounds of which structures were closely related to B, showed very strong C=O absorptions:

 1645 cm$^{-1}$

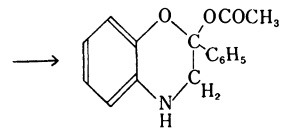
 1642 cm$^{-1}$

 1667 cm$^{-1}$
(1645 cm$^{-1}$, C=N)

Thus, the 1,4-benzoxazine structure C carrying no carbonyl group is most favorable and is further supported by the comparison with the known 1,4-benzoxazine structure. While such 2-hydroxyl substituted 1,4-benzoxazines as C have not been reported in literatures so far, 3-phenyl-1,4-benzoxazine is known[2] as one of a few 1,4-benzoxazine compounds and it was found that the condensation product of *o*-aminophenol with phenylglyoxal (19) resembled 3-phenyl-1,4-benzoxazine in the infrared and ultraviolet spectra as shown in Fig. 1.



Acetylation of 19 with acetic anhydride gave the acetyl derivative (19a), m. p. 92°C, and the catalytic hydrogenation of 19a afforded the dihydro derivative (19b), m. p. 147°C, one mole of hydrogen being absorbed. The reaction can be explained as follows and the structures of the resulting compounds were consistent with their infrared spectra shown in Fig. 2.



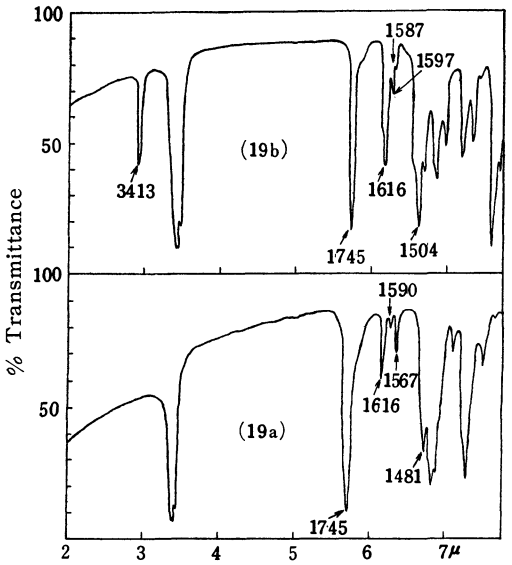
(19) (19a)

2) E. Lellmann and A. Donner, *Ber.*, **23**, 173 (1890).

* In the case of the condensation of *o*-aminophenol with phenylgyoxal, if the amino group reacts with the ketonic carbonyl group to form a Schiff base type product in the first step, and then it undergoes ring-closure to form benzoxazine, the structure should be given as follows:

This isomeric strcuture of 19 was excluded, however, because on potassium permanganate oxidation in boiling acetone, 19 was recovered and the 2-hydroxyl group proved to be attached to a tertiary carbon atom as indicated in the scheme.

(19b)



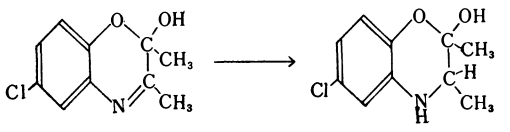


Fig. 2. Infrared spectra of 19a and 19b (Nujol mull).

(25) (25a)

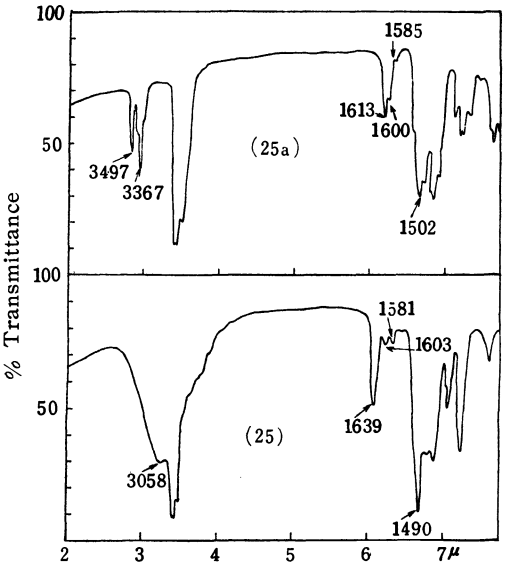

Fig. 3. Infrared spectra of 25 and 25a (Nujol mull).

Definite assignment of C=N absorptions of these 1,4-benzoxazines has remained unsolved, because phenyl ring absorptions were overlapped by other bands in this region, however the bands which were commonly observed in 1,4-benzoxazine derivatives at 1567 $cm^{-1}$ (3-phenyl-1,4-benzoxazine, Fig. 1), 1563 $cm^{-1}$ (19, Fig. 1) and 1567 $cm^{-1}$ (19a, Fig. 2) disappeared by hydrogenation (19b, Fig. 2), and thus the author tentatively assigned these bands to C=N absorptions and other bands in this region which remained even after hydrogenation to phenyl ring absorptions (refer to Table II).

Further, the broad absorption bands in the 3000 $cm^{-1}$ region (19, Fig. 1) should be due to intermolecular hydrogen bond of the hydroxyl group**, because it disappeared by acetylation and the *O*-acetate carbonyl band appeared at 1745 $cm^{-1}$ (19a, Fig. 2).

In the case of the condensation product of 4-chloro-2-aminophenol with diacetyl (25), catalytic hydrogenation was conducted and dihydro derivative (25a), m.p. 135°C, was obtained.

** Because the solubility of 19 in the suitable solvent was very small, it could not be confirmed by taking the infrared spectra with a dilution method.

The structures of 25 and 25a were also consistent with features of their infrared absorption spectra shown in Fig. 3.

Since the others of this second group gave quite similar infrared spectra concerning the 3000 $cm^{-1}$ and the 1600 $cm^{-1}$ regions as shown in Table II, it can be recognized that they should also have the benzoxazine structures.

Thus, it has been concluded that the compounds resulting from the condensation of equimolar *o*-aminophenols and *α*-dicarbonyl compounds have the structure of 2-hydroxy-1,4-benzoxazine derivatives.

The condensation products of asymmetric *α*-diketones such as acetylpropionyl and acetylisobutylyl (20, 22, 26) have not been worked out as regards the position 2- or 3- of the alkyl group in 1,4-benzoxazine. The author tentatively proposed the 3-methyl substituted structure, considering that the carbonyl attached to the methyl group is more reactive than others and reacts with the amino group at first, as shown in the above scheme proposed.

The 2-phenyl derivatives were stable toward 6 N hydrochloric acid at 100°C and dilute alkali at room tempreature, but in the case of 19 it was hydrolyzed to *o*-aminophenol by boiling with 10% sodium

hydroxide solution. On the other hand, 2,3-dialkyl homologues were sensitive to acid and alkali and hydrolyzed gradually even at room temperature.

On applying semicarbazide to 25 and phenylhydrazine to 19, diacetyl disemicarbazone and phenylglyoxal phenylosazone were obtained respectively. Hydrolysis must have occurred in these cases.

## Experimental

**General Procedure of the Condensation Reaction of o-Aminophenols with α-Dicarbonyl Compounds.** —The procedure was equally conducted both in the bibenzoxazoline type and the benzoxazine type condensations.

Freshly prepared *o*-aminophenols were dissolved in a large amount of distilled water which was previously boiled and cooled at 80°C. To this solution, a slight excess of calculated amount of α-dicarbonyl compounds dissolved in a little amount of water was added and mixture was held at this temperature with occasionally shaking for about 1 hr. Precipitates were soon or gradually formed. After cooling, they were filtered and washed with water. Recrystallization from alcohol or dilute alcohol using a Norit gave pure crystalls.

**2-Methyl-2'-ethyl-2, 2'-bibenzoxazoline (2).** — A mixture of *o*-aminophenol (2 g.) and acetylpropionyl (1.5 g.) dissolved in a little amount of alcohol was boiled for 3 hr. The solvent was then distilled off and the remaining tarrish residue was extracted several times with petroleum benzine (80~120°C). The combined extract was decolorized using a Norit and concentrated to form crystals. Recrystallization from dilute alcohol gave prisms, m. p. 142°C.

**2-Methyl-2'-phenyl-2, 2'-bibenzoxazoline (4).** — A solution of *o*-aminophenol (1 g.) and acetylbenzoyl (1.5 g.) in dioxane (15 ml.) was boiled for 2 hr. and then the solvent was distilled off under reduced pressure. The remaining oil soon solidified and was recrystallized from alcohol to give long needles, m. p. 218°C. Mol. wt. (Rast), Found: 329, Calcd.: 330.

**2-Hydroxy-2-isopropyl-3-methyl-7-nitro-1, 4-benzoxazine (20).** — An equivalent portion of 4-nitro-2-aminophenol and acetylisobutylyl was well mixed and heated on a hot plate about at 120°C for 20 min. On cooling, the oily product solidified which was pressed on a clay plate and recrystallized from benzene to give needles, m. p. 131°C.

**Condensation of o-Aminophenol with Isonitrosoacetone; 2-Methyl-2,2'-bibenzoxazoline (1).**—To a solution of *o*-aminophenol (1 g.) in hot water (50 ml.), isonitrosoacetone (1 g.) was added and the mixture was boiled for 1 hr. Precipitates gradually formed and they were recrystallized from alcohol to give fine needles, m. p. 220°C.

The condensations of isonitrosoacetone with 4-nitro-2-aminophenol and diacetyl monoxime with *o*-aminophenol were carried out in the same manner and 5,5'-dinitro-2'-methyl-2,2'-bibenzoxazoline (6) and 2,2'-dimethyl-2,2'-bibenzoxazoline were obtained respectively.

**2-Acetoxy-2-phenyl-1, 4-benzoxazine (19a).** — A solution of 2-hydroxy-2-phenyl-1,4-benzoxazine (19) (1 g.) in acetic anhydride (60 ml.) was boiled for 2 hr. and then the solution was concentrated under reduced pressure. The remaining oily product solidified on standing and was recrystallized from dilute alcohol to give fine prisms, m. p. 92.3°C.

*Anal.* Found: C, 72.12; H, 5.01; N, 5.37. Calcd. for $C_{16}H_{13}NO_3$: C, 72.01; H, 4.88; N, 5.22%.

**Hyrogenation of 19a: 2-Acetoxy-3-phenyl-3,4-dihydro-1,4-benzoxazine (19b).**—A solution of 19a (0.5 g.) in acetic acid (25 ml.) was hydrogenated using Adams calalyst at atmospheric pressure and room temperature. A slightly excessive amount of hydrogen was absorbed after 3 hr. The solvent was removed under reduced pressure and the residue was recrystallized from alcohol to give colorless needles, m. p. 147°C.

*Anal.* Found: C, 71.29; H, 5.71; N, 5.47. Calcd. for $C_{16}H_{15}NO_3$: C, 71.38; H, 5.58; N, 5.20%.

**Action of Phenylhydrazine on 19: Phenylglyoxal Phenylosazone.**—To a suspension of 19 in a little amount of acetic acid, an excess of phenylhydrazine was added and the mixture was heated on water bath, the contents being gradually dissolved. After 30 min., water was added and the resulting precipitates were recrystallized from alcohol. Yellow prisms, m. p. 150~151°C; showed no depression with an authentic phenylglyoxal phenylosazone, m. p. 151°C.

**Hydrogenation of 25: 2-Hydroxy-2,3-dimethyl-6-chloro-3, 4-dihydro-1, 4-benzoxazine (25a).** — A solution of 25 (1 g.) in alcohol (60 ml.) was hydrogenated using Adams catalyst at atmospheric pressure and room temperature. A slightly excessive amount of hydrogen was absorbed after 5 hr. The resulting colorless solution was concentrated under reduced pressure and then water was added. The crystals obtained on cooling of the mixture in an ice box were recrystallized several times from dilute alcohol to give fine plates, m. p. 135°C.

*Anal.* Found: C, 55.92; H, 5.23; N, 6.56. Calcd. for $C_{10}H_{12}NO_2Cl$: C, 56.21; H, 5.62; N, 6.56%.

**Alkali Hydrolysis of 19.**—A suspension of 19 in 5% sodium hydroxide solution was boiled for 20 min., the contents were gradually dissolved and reddish brown solution was obtained. To this solution an excess of acetic anhydride was added and the mixture was evaporated to dryness on a water bath. The resulting residue was washed with water and recrystallized from hot water. Needles, m. p. 201°C, showed no depression with *N*-acetyl-2-aminophenol, m. p. 201°C.

**Action of Semicarbazide on 25: Diacetyl Disemicarbazone.**—To a warm solution of 25 (0.35 g.), semicarbazide hydrochloride (0.3 g.) dissolved in water (1 g.) containing 0.3 g. of sodium acetate was added and the mixture was allowed to stand at room temperature. White precipitates soon formed and they were filtered and well washed

with alcohol. The white crystals, m. p. 279°C, which were almost insoluble in most organic solvents showed no depression with an authentic diacetyl disemicarbazone, m. p. 279°C.

The author wishes to express his thanks to Professor Tokuichi Tsumaki and Professor Takeichi Nishikawa for their exceedingly kind directions to this work. The author also thanks Dr. Yo Ueda and Mr. Hiroshige Yano of the Department of Pharmacy for their measurement of infrared spectra and Mr. Michio Shido and Miss Sachiko Indo for microanalysis. The cost of this research was partly defrayed from the Research Grant of the Ministry of Education, to which the author's thanks are also due.

# *Resolution of Amino Acids. II. Resolution of Racemic ε-Acyllysine and δ-Acylornithine Amides by Leucine Aminopeptidase*

By Nobuo IZUMIYA, Hakaru UCHIO and Tetsuo KAMATA

(Received June 8, 1959)

In a previous communication[1], it was shown that racemic phenylalanine and γ-phenyl-α-aminobutyric acid amides can be resolved by leucine aminopeptidase. In this paper, a similar method is described, which is based upon the asymmetric hydrolysis of the amides of ε-benzoyl-DL-lysine, δ-benzoyl-DL-ornithine and δ-carbobenzoxy-DL-ornithine by a partially purified leucine aminopeptidase derived from swine kidney[2].

For the resolution, the initial substrate concentration was set at 0.05 mol., and the course of hydrolysis was followed measuring evolved ammonia. After analysis reveals the theoretical 50% hydrolysis, ω-acyl-L-amino acid was collected by filtration, and ω-acyl-D-amino acid amide in the filtrate was separated by means of ion-exchange resin. In this way, ε-benzoyl-DL-lysine amide was resolved in a good yield. δ-Benzoyl-DL-ornithine amide was hydrolyzed in the same manner. However, the difference of the solubilities in water of δ-carbobenzoxy-L-ornithine and -D-ornithine amide hydrochloride is bigger than that of the corresponding benzoyl derivatives, and therefore the amide of δ-carbobenzoxy-DL-ornithine may be in some cases more suitable for the purpose.

## Experimental

**Preparation of Leucine Aminopeptidase.** — A partially purified enzyme solution of Step 4 by Smith was prepared as described[2]. Its activities against ω-acyl-amino acid amides are shown in Table I, the proteolytic coefficient ($C_1$) of L-leucine amide being included for comparison. The rates of hydrolysis were measured by titration of 0.2 to 0.6 ml. samples with 0.005 N hydrochloric acid by means of the Conway microdiffusion method[3].

As shown in Table I, ω-acyl-L-amino acid amides are hydrolyzed at 1/4~1/7 times the rate

TABLE I. PROTEOLYTIC COEFFICIENT ($C_1$) OF AMINO ACID AMIDES BY PARTIALLY PURIFIED LEUCINE AMINOPEPTIDASE*

| Substrates | $C_1$ at different initial concn. of substrates** | | |
|---|---|---|---|
| | 0.01 M | 0.025 M | 0.05 M |
| L-Leucine amide | 5.6 | 3.2 | 2.0 |
| ε-Benzoyl-DL-lysine amide | 1.3 | 0.84 | 0.49 |
| δ-Benzoyl-DL-ornithine amide | 1.1 | 0.73 | 0.50 |
| δ-Carbobenzoxy-DL-ornithine amide | 0.82 | 0.49 | 0.32 |

* Enzyme was preincubated in 0.1 M Tris buffer of pH 8.0 with 0.008 M manganese chloride for one hour at 38°C. Assays were conducted in 0.1 M Tris buffer of pH 8.0 at 38°C with preincubated enzyme added. $C_1 = \log[100/(100 - \%\ \text{hydrolysis})]/(\text{min.} \times \text{mg. protein } N \text{ per ml. test solution})$.

for L-leucine amide, a most sensitive substrate for the enzyme. However, the efficient resolution would be still possible with the susceptibilities of ω-acyl-amino acid amides in the orders described above.

**Synthesis of Compounds.** — *ε-Benzoyl-DL-lysine ethyl ester hydrochloride.* — ε-Benzoyllysine[4,5] (200 g.) was suspended in ethanol (4 l.) and dry hydrogen chloride was introduced to saturation at room temperature. The solution was refluxed for one hour and evaporated in vacuo. The residue was dissolved in ethanol (2 l.), and the same procedure was repeated again. Treatment of the residue with dry ether yielded crystals*. These orystals were recrystallized from ethanol-ether; yield, 236 g. (94%); m. p. 91~94°C.

*Anal.* Found: N, 8.82. Calcd. for $C_{15}H_{23}O_3N_2Cl$: N, 8.90%.

*ε-Benzoyl-DL-lysine amide hydrochloride.* — The above compound (189 g.) was dissolved in methanol (3.4 l.) previously saturated with dry ammonia at 0°C, the solution was kept at room temperature for three days and then concentrated in vacuo to dryness. The residual crystals were collected by the aid of methanol and acetone. This was dissolved in hot water, the solution was concentrated, and additions of methanol and acetone yielded crystals; yield, 108 g. (63%); m. p. 235~237°C (decomp.).

*Anal.* Found: C, 54.73; H, 6.73; N, 14.46. Calcd. for $C_{13}H_{20}O_2N_3Cl$: C, 54.64; H, 7.05; N, 14.71%.

*δ-Benzoyl-DL-ornithine ethyl ester hydrochloride.*— This compound was prepared from δ-benzoyl-ornithine[4-6] (236 g.) in the same way as that for benzoyllysine ethyl ester hydrochloride; yield, 288 g. (96%); m. p. 175~177°C.

*Anal.* Found: N, 9.33. Calcd. for $C_{14}H_{21}O_3N_2Cl$: N, 9.31%.

*α-Carbobenzoxy-δ-benzoyl-DL-ornithine ethyl ester.*— To a suspension of the above compound (9.0 g.) in chloroform (90 ml.) was added triethylamine (9.4 ml.). The compound went into solution immediately, and carbobenzoxy chloride[7] (4.8 ml.) was added to the solution under cooling. The mixture was allowed to react at room temperature overnight, washed with water, dilute bicarbonate solution, dilute hydrochloric acid, and water; the organic layer was dried over sodium sulfate and concentrated in vacuo to yield a syrup which was crystallized by the addition of petroleum ether. This was recrystallized from ethyl acetate-petroleum ether; yield, 10.3 g. (86%); m. p. 110°C.

*Anal.* Found: N, 7.24. Calcd. for $C_{22}H_{26}O_5N_2$: N, 7.03%.

*α-Carbobenzoxy-δ-benzoyl-DL-ornithine amide.* — This compound was prepared from the above compound (6.0 g.) by the same procedure as that for benzoyllysine amide hydrochloride and recrystallized from methanol-ether; yield, 4.7 g. (85%); m. p. 205~206°C.

*Anal.* Found: N, 11.52. Calcd. for $C_{20}H_{23}O_4N_3$: N, 11.38%.

*δ-Benzoyl-DL-ornithine amide hydrochloride.*—This compound was prepared from benzoylornithine ethyl ester hydrochloride (150 g.) in the same way as that for benzoyllysine amide hydrochloride and recrystallized from methanol-ether; yield, 87 g. (64%); m. p. 195~197°C.

*Anal.* Found: C, 53.24; H, 6.68; N, 15.24. Calcd. for $C_{12}H_{18}O_2N_3Cl$: C, 53.04; H, 6.68; N, 15.46%.

This compound was also prepared as follows. α-Carbobenzoxy-δ-benzoylornithine amide (3.7 g.) dissolved in 0.3 N methanolic hydrochloric acid (36 ml.) was treated with dry hydrogen in the presence of palladium black in the usual manner[8]. The filtrate from the catalyst was evaporated in vacuo, and the residual syrup was crystallized easily; yield, 2.5 g. (92%); m. p. 196~197°C.

*Anal.* Found: N, 15.41. Calcd. for $C_{12}H_{18}O_2N_3Cl$: N, 15.46%.

*δ-Carbobenzoxy-DL-ornithine.*—This compound was prepared from ornithine hydrochloride (101 g.) by the same procedure as that for the L-isomer[4,9]; yield, 121 g. (76%); m. p. 250~253°C (decomp.).

*Anal.* Found: N, 10.71. Calcd. for $C_{13}H_{18}O_4N_2$: N, 10.52%.

*δ-Carbobenzoxy-DL-ornithine amide hydrochloride.*— The above compound (106 g.) was treated with 1.5 N methanolic hydrochloric acid (4.4 l.) as described in the case of the L-isomer[10], and the hygroscopic crystalline carbobenzoxyornithine methyl ester hydrochloride obtained was amidated with methanolic ammonia in the usual manner. The product was recrystallized from methanol-acetone; yield, 86 g. (71%); m. p. 153~154°C.

***Rf* Values of Compounds.**—The $R_f$ values of the reference compounds are given in Table II.

**Resolution of ε-Benzoyl-DL-lysine Amide.** — *ε-Benzoyl-L-lysine.* — ε-Benzoyl-DL-lysine amide hydrochloride (86.4 g.) was dissolved in water (2 l.) containing manganese chloride tetrahydrate (0.60 g.). The pH was adjusted to about 7.5 with 1 N aqueous ammonia (150 ml.), the enzyme solution containing the equivalent of 16.4 mg. of protein nitrogen was added, and the volume was made up to 6.0 l. After about ten hour incubation at 38°C, the results of ammonia determination indicated complete hydrolysis of the L-amide, when the pH of solution was found to be near 8.5. In the course of the digestion, benzoyl-L-lysine was partly precipitated. The course of hydrolysis is shown in Fig. 1.

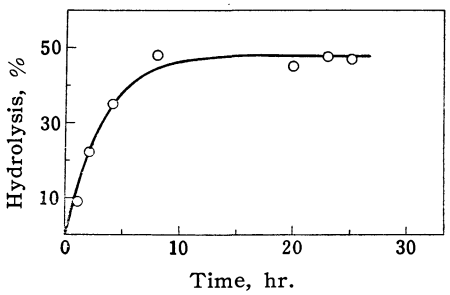

Fig. 1. Time-course of hydrolysis of ε-benzoyl-DL-lysine amide.

It was incubated for another fifteen hours, and its paper chromatography in this stage showed two spots with several solvent systems. The incubation mixture was evaporated in vacuo to a small volume, and the crystals were collected and washed with water (combined filtrate and washings saved for the D-amide). This was recrystallized from hot water; yield, 33.1 g. (88%); m. p. 244~246°C (decomp.); $[\alpha]_D^{15}$ +22.0° ($c$=2, in 5 N hydrochloric acid) (lit.[11] $[\alpha]_D^{25}$ +22.3°).

*Anal.* Found: N, 11.10. Calcd. for $C_{13}H_{18}O_3N_2$: N, 11.29%.

*L-Lysine hydrochloride.* — The above compound (10 g.) was refluxed with 6 N hydrochloric acid (150 ml.) for ten hours, and benzoic acid produced was removed in the usual manner[12]. The solution was evaporated in vacuo, and the residual syrup was dissolved in water. The solution, adjusted to pH 6.4~6.6 by the addition of triethylamine, was evaporated to dryness, and the residue was recrystallized from water-ethanol; yield, 6.7 g. (92%); $[\alpha]_D^{15}$ +20.5° ($c$=2, in 5 N hydrochloric acid) (lit.[13] $[\alpha]_D$ +20.7°).

*Anal.* Found: N, 15.50. Calcd. for $C_6H_{15}O_2N_2Cl$: N, 15.34%.

*ε-Benzoyl-D-lysine amide hydrochloride.* — The filtrate and washing** described already were passed through a column of Amberlite IRA-400 (5 cm.×50 cm.) in the alkaline phase, a strongly basic anion-exchange resin, and water (9 l.) was successively added to the top of the column. The fractions were combined and evaporated to dryness in vacuo. The evaporation was repeated several times with addition of methanol, the residue was dissolved in 1 N methanolic hydrochloric acid (150 ml.), and the solution was concentrated to a small volume, acetone being added. The crystals collected were recrystallized from hot methanol-acetone; yield, 35.5 g. (83%); m. p. 220~221°C (decomp.); $[\alpha]_D^{15}$ −16.8° ($c$=2, in water).

*Anal.* Found: C, 54.61; H, 7.16; N, 14.58. Calcd. for $C_{13}H_{20}O_2N_3Cl$: C, 54.64; H, 7.05; N, 14.71%.

*ε-Benzoyl-D-lysine.*—The above compound (14.3 g.) was refluxed with 2 N hydrochloric acid (210 ml.) for one hour, the solution was evaporated in vacuo, and the residue was dissolved in water, triethylamine being added to neutralization. The crystals collected were recrystallized from hot water; yield, 8.5 g. (68%); m. p. 246~247°C (decomp.); $[\alpha]_D^{15}$ −21.8° ($c$=2, in 5 N hydrochloric acid) (lit.[11] $[\alpha]_D^{30}$ −22.1°).

*Anal.* Found: N, 10.97. Calcd. for $C_{13}H_{18}O_3N_2$: N, 11.19%.

*D-Lysine hydrochloride.*—Benzoyl-D-lysine amide hydrochloride (8.6 g.) was refluxed with 6 N hydrochloric acid for ten hours, benzoic acid was removed, and the solution was evaporated to dryness in vacuo. The evaporation was repeated several times with addition of water and of some triethylamine until free of ammonia, this procedure replacing ammonium chloride with triethylamine hydrochloride which is soluble in ethanol. The product remained was recrystallized from water-ethanol; yield, 4.7 g. (86%); $[\alpha]_D^{15}$ −20.3° ($c$=2, in 5 N hydrochloric acid) (lit.[14] $[\alpha]_D$ −20.7~−21.0°).

*Anal.* Found: N, 15.71. Calcd. for $C_6H_{15}O_2N_2Cl$: N, 15.34%.

**Resolution of δ-Benzoyl-DL-ornithine Amide.**— *δ-Benzoyl-L-ornithine.* — To δ-benzoyl-DL-ornithine amide hydrochloride (54.4 g.) and manganese chloride tetrahydrate (0.40 g.) dissolved in water, pH being brought to 7.5, was added the enzyme

containing 12.5 mg. of protein nitrogen. The mixture was made up to 4.0 l. and incubated at 38°C, the course of hydrolysis being shown in Fig. 2. The solution was then evaporated to a small volume, and the resulting crystals were collected and washed with water; yield, 12.8 g. The combined filtrate and washings were passed through a column of Amberlite IRA-400 (4.5 cm.×40 cm.), and the column was washed with water (6 l.) (combined fractions saved for the D-amide). Elution of the additional L-amino acid from the column was accomplished with 2 N hydrochloric acid (7 l.) The eluate was evaporated, the residue was dissolved in water, and the solution was neutralized with triethylamine; yield, 9.7 g. The combined crystals (22.5 g.) were recrystallized from hot water; yield, 20.3 g. (86%); m.p. 243~245°C (decomp.); $[\alpha]_D^{15}$ +26.0° ($c$=2, in 5 N hydrochloric acid) (lit.[15] $[\alpha]_D^{10}$ +19.8°).

*Anal.* Found: N, 11.61. Calcd. for $C_{12}H_{16}O_3N_2$: N, 11.86%.

*L-Ornithine hydrochloride.*—This was prepared from the above compound (11.8 g.) as that for L-lysine hydrochloride; yield, 7.6 g. (90%); $[\alpha]_D^{20}$ +22.0° ($c$=2, in 5 N hydrochloric acid) (lit.[13] $[\alpha]_D$ +22.1°).

*Anal.* Found: N, 16.57. Calcd. for $C_5H_{13}O_2N_2Cl$: N, 16.60%.

*δ-Benzoyl-D-ornithine amide hydrochloride.*—The combined fractions described already were treated in the same way as that for benzoyl-D-lysine amide hydrochloride; yield, 23.4 g. (86%); m. p. 208~210°C; $[\alpha]_D^{15}$ −16.5° ($c$=2, in water).

*Anal.* Found: C, 52.41; H, 6.77; N, 15.38. Calcd. for $C_{12}H_{18}O_2N_3Cl$: C, 53.04; H, 6.68; N, 15.46%.

*δ-Benzoyl-D-ornithine.*—This was prepared from the above compound (13.6 g.) as that for benzoyl-D-lysine; yield, 5.3 g. (45%); m. p. 242~245°C (decomp.); $[\alpha]_D^{15}$ −25.8° ($c$=2, in 5 N hydrochloric acid).

*δ-Carbobenzoxy-D-ornithine amide hydrochloride.*— The combined filtrate and washings described already were treated in the same way as that for benzoyl-D-lysine amide hydrochloride. The product obtained was recrystallized from hot methanol-ether; yield, 25.7 g. (85%); m. p. 175~176°C; $[\alpha]_D^{18}$ −8.7° ($c$=2, in water).

*Anal.* Found: C, 51.32; H, 6.71; N, 14.04. Calcd. for $C_{13}H_{20}O_3N_3Cl$: C, 51.68; H, 6.68; N, 13.92%.

*D-Ornithine hydrochloride.* — The above compound (6.0 g.) was treated as that for L-ornithine hydrochloride in this section and D-lysine hydrochloride; yield, 2.9 g. (86%); $[\alpha]_D^{20}$ −22.2° ($c$=2, in 5 N hydrochloric acid) (lit.[14] $[\alpha]_D$ −20.1°).

*Anal.* Found: C, 35.91; H, 7.76; N, 15.97. Calcd. for $C_5H_{13}O_2N_2Cl$: C, 35.58; H, 7.77; N, 16.60%.

## Summary

ε-Benzoyl-DL-lysine amide, δ-benzoyl-DL-ornithine amide and δ-carbobenzoxy-DL-orithine amide were resolved to ω-acyl-L-amino acids and ω-acyl-D-amino acid amides by the partially purified leucine aminopeptidase preparation. ω-Acyl-L-amino acids and ω-acyl-D-amino acid amides were hydrolyzed to L- and D-amino acid hydrochlorides, respectively. The parts of ω-benzoyl-D-amino acid amides were changed to ω-benzoyl-D-amino acids by acid hydrolysis.

# *Determination of Methyl and Phenyl Groups in Methyl-Phenyl-Siloxane Polymer by NMR Spectroscopy*

By Tsutomu KUBOTA and Tsutomu TAKAMURA

(Received June 22, 1959)

Chemical applications of NMR spectroscopy have been developed rapidly during recent few years. Although many reports have been published on its application to the molecular structure investigation and to the qualitative analysis, quantitative analysis using the NMR method has scarcely been reported[1] at all.

It has already been known that under an appropriate experimental condition the peak area of the resonance spectrum is directly proportional to the number of resonating atoms irrespective of their chemical nature[2,3]. Since the peak area depends both on the volume of specimen inserted in an effective part of a high frequency coil and on whether or not the specimen is placed at the right position in the coil, a calibration must always be performed with the identical sample container if the outer reference method is adopted. If, however, a suitable inner reference is used instead of an outer one, such a disadvantage can be avoided; and in addition to this, the authors have a great advantage that no standard substance is required. The inner reference method is done by mixing a sample material homogeneously with a known amount of any substance which produces a resonance peak and by referring to the peak area produced by the substance as a standard.

Shoolery et al. have pointed out the usefulness of the method, but have not made the actual application[4]. Muller and Goldenson have used the peak area method for their kinetic study of phospher compound[5] and Shaw and Elsken have shown that the peak height of differential form of spectrum can be applied to the quantitative analysis[6], but their purposes seem not to be in the complete examination of the inner reference method.

It is the purpose of the present study to examine the inner reference method and to bring it to a practical use, in which determination of methyl and phenyl groups in methyl-phenyl-siloxane polymer has been carried out. The linear relationship between the peak area and proton concentration has been found to exist in a wide range of experimental conditions, the determination being made without difficulty. The analytical results were compared with those obtained from the infrared analysis and it was found that they were in good agreement within the experimental error.

## Experimental

**Materials.**—Dioxane and benzene of commercial guaranteed reagents were used without further purification. Acetone was purified by drying a commercial guaranteed reagent with unhydrous calcium chloride and by distilling twice. Water was purified by distilling the de-ionized water. All of the organosiloxanes were those synthesized and purified in the Tsurumi Research Laboratory of Tokyo Shibaura Electric Co. The boiling or melting point ranges of siloxanes were within $\pm 0.5°C$.

**Measurements.**—Approximately 0.6 ml. of each sample was poured by means of a syringe into a glass tube of 5 mm. in outer diameter which then was sealed off. If necessary, a glass tube of 2 mm. in outer diameter containing pure water was sealed in the outer tube at the coaxial position. These sealed tubes were offered to measurements. Since according to a preliminary examination, there exists no difference between the proton chemical shift obtained by using a soft lead glass tube as a sample container and that obtained by using a borosilicate glass tube, soft lead glass tubes were used throughout this work becauce of the ease of sealing them.

Proton NMR spectra were recorded with a Japan Electron Optics Laboratory NMR Spectrometer Model JNM-3. The applied resonance frequency was 40 Mc, the field sweep width, 87.5 and 175 milligauss, the sweep rate being controlled to 5 to 10 milligauss per second. All the measurements were carried out in a room whose air temperature was regulated to $25 \pm 1°C$.

The proton chemical shift described in $\delta$ value was calibrated as follows: The spectrum was recorded for pure acetone using pure water as a reference. The distance between the peaks due to acetone and water was measured from the center of the peaks, the field width corresponding to the distance being decided by using the $\delta$ value of acetone, $\delta = -0.334$, which was given by Allred and Rochow[7]. All the measurements were repeated ten times for one sample, the data being averaged. The proton chemical shift of the methyl group attached to the silicon atom was found to be $\delta = -0.49$ for hexamethylsiloxane and methyl-phenyl-siloxane polymer, and that of the phenyl group to be $\delta = +0.22$ for cyclooctaphenyltetrasiloxane and methyl-phenyl-siloxane polymer.

The infrared spectrum was recorded with an automatic recording spectrometer which was specially designed by Professor H. Yoshinaga of Osaka University. Measurements were carried out with the carbon disulfide solutions of sample at various concentrations and by means of a rock salt cell of 0.1 mm. optical path length for quantitative use. The key bands taken for methyl and phenyl groups were the absorption bands at wave numbers of 2970 and 3030 $cm^{-1}$, respectively.

## Results and Discussion

Prior to the quantitative determination on methyl-phenyl-siloxane polymer, calibration curves were drawn with some standard substances to ascertain that the proportionality really exists between a peak area due to methyl or phenyl group and the number of protons contained in the group. Hexamethylsiloxane and cyclooctaphenyltetrasiloxane were chosen as standards, because the chemical constitution of these substances is similar to that of the siloxane polymer. Although the most favorable case would be one where these substances could be mixed homogeneously at various mixing ratios, the solid of phenyl siloxane is only slightly soluble in methyl siloxane; therefore, benzene and dioxane were used as auxiliary standards. The peak area was measured by varying the mixing ratio for three binary systems, namely, hexamethylsiloxane-benzene, cyclooctaphenyltetrasiloxane-dioxane and benzene-dioxane, where each characteristic peak is well separated. The examples of spectra are shown in Fig. 1.

In the case of the hexamethylsiloxane-benzene system two peaks appeared; the one is due to proton of benzene and the other to that of siloxane. The concentration of siloxane was obtained from the experimental results by taking the ratio of the peak area of benzene to that of siloxane and by multiplying the ratio by

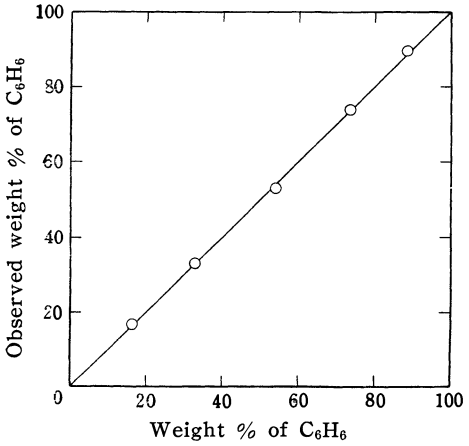

Fig. 4. Plotting of concentration of benzene in dioxane obtained from NMR spectra against that obtained from the mixing ratio.

a factor of 1/2, since benzene and siloxane molecules have six and twelve equivalent hydrogen atoms, respectively. The concentration of siloxane thus obtained was plotted against that determined by the mixing ratio. As seen in Fig. 2, the plots are well on the straight line whose slope is unity, the direct proportionality being confirmed. Similar plottings made on cyclooctaphenyltetrasiloxane-dioxane and benzene-dioxane systems gave also straight lines, the proportionality being ascertained as shown in Figs. 3 and 4. With the results of these experiments parallelly performed the direct proportionality was proved to be maintained in the mixture of hexamethylsiloxane and cyclooctaphenyltetrasiloxane.

The fact that the chemical shift of any respective group shows no difference whether the group is attached to simple siloxane or siloxane polymer shows these compounds to be nearly identical regarding the chemical construction. Therefore, the proportionality is supposed to be maintained also in the case of siloxane polymer.

Since the peak area measured at a definite recording condition depends on the sample volume located in the high frequency coil effectively, as already mentioned, the absolute number of protons can hardly be determined when outer reference is used. Such a difficulty is eliminated by mixing a known amount of a substance having proton with the sample homogeneously. Dioxane was chosen as a suitable reference. The actual measurement was made on the mixture of methylphenylsiloxane polymer and dioxane by varying the mixing ratio. Three well separated peaks appeared in this case as shown in Fig. 1, two from methyl and phenyl groups of siloxane polymer and one from dioxane. The peak area due to one proton can be obtained from the observed area of dioxane whose concentration is known, then, the numbers of methyl and phenyl groups involved in 100 g. of siloxane polymer can be calculated for each mixing ratio from the peak areas. The obtained values are listed in the second and fourth columns in Table I to show the constant value over a wide range of mixing ratio.

On the other hand, the number of each group was also determined with the infrared technique. Cyclooctamethyltetrasiloxane and cyclooctaphenyltetrasiloxane were used as standard substances for methyl and phenyl groups, respectively. Assuming that each extinction coefficient of a respective group in siloxane polymer is identical with that of the corresponding standard substance, the number was

TABLE I. NUMBERS OF METHYL AND PHENYL GROUPS PER 100 g. OF METHYL-PHENYL-SILOXANE POLYMER DETERMINED BY NMR AND INFRARED METHOD

| Weight % of methyl-phenyl-siloxane polymer in dioxane | Number of methyl group | | Number of phenyl group | |
|---|---|---|---|---|
| | NMR | Infrared | NMR | Infrared |
| 84.1 | 1.21 | — | 0.56 | — |
| 54.5 | 1.16 | — | 0.55 | — |
| 44.0 | 1.14 | — | 0.57 | — |
| 30.1 | 1.15 | — | 0.56 | — |
| mean | 1.17 | 1.21 | 0.56 | 0.56 |

determined from the absorptions in carbon disulfide solution of known concentrations. The results averaged are cited in the third and fifth columns of Table I. Agreement of these results obtained from the two different methods is good within the experimental error.

The great advantage of NMR spectroscopy on the quantitative analysis is that no standard to the respective specimen is required because the peak area depends only on the number of protons and, under an appropriate experimental condition, is independent of the nature of molecular configuration. A comparatively large experimental error in the method caused by the crude reproducibility of the spectrum is now being reduced by the rapid development of instrumentation. The group type analysis on the relatively complicated molecule will then be systematized with the accumulation of chemical shift data, each number of atoms having nuclear spin would be determined for each group with the inner reference method, and therefore, the NMR method will display more power in the determination of molecular structure.

## Summary

Proton spin resonance spectra were recorded for the three binary mixtures, benzene-dioxane, benzene-hexamethylsiloxane and dioxane-cyclooctaphenyltetrasiloxane whose mixing ratios were varied. The peak area due to resonating proton of methyl or phenyl group was found to be directly proportional for all systems to the number of protons which give the peak of respective groups over a wide range of recording conditions.

With the results obtained, the determination of methyl and phenyl groups in methyl-phenyl-siloxane polymer was carried out by the use of the inner reference method using dioxane. Siloxane polymer was mixed with dioxane and the spectrum was recorded for the mixture, the number of each group being calculated from the obtained peak area. The results were compared with those obtained from the infrared analysis and they were in good agreement within the experimental error.

The authors express their thanks to Dr. T. Harada, the Manager of Matsuda Research Laboratory, for his permission to publish this paper, to Dr. H. Miyazawa for his advice on the measurement of the NMR spectra and Mr. K. Kawazumi for the preparation and purification of organosilicon compounds.

# *The Volume Change on Formation of Water from its Ions*[1]

By Akira TSUJIOKA

(Received July 3, 1959)

The reaction between the hydrogen ion and the hydroxyl ion is given by

$$H^+ + OH^- = H_2O \qquad (1)$$

It was noticed by Geffcken et al.[2] that the volume change associated with this reaction in aqueous solution is about 23 cc. per mole at infinite dilution and at 25°C. But there has been no investigation to provide the data at various concentrations and to correlate quantitatively the volume change with concentration. Although the volume changes on formation of water are not susceptible of direct measurement, these values can be determined by using the data on changes of volume on neutralization of a strong acid with a strong base.

In the concentration range of high dilution, there is little or no difference between the volume change on neutralization of aqueous sodium hydroxide with hydrochloric acid and that with hydrobromic or hydroiodic acid[3]. The expansion

1) Presented at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959.

2) W. Geffcken and D. Price, *Z. physik. Chem.*, **B26**, 81 (1934).

3) J. D'Ans and E. Lax, "Taschenbuch für Chemiker und Physiker", 2nd Ed., Springer-Verlag, Berlin (1949), p. 821; Landolt-Börnstein, "Physikalisch-Chemische Tabllen", Erg. B. II, Springer-Verlag, Berlin (1931), p. 274.

in total volume in such cases may be explained as mainly due to the disappearance of electrostriction of charged ions[4], which is caused by the fact that the hydrogen ion combines with the hydroxyl ion to form water. In the higher concentration range, however, the magnitudes of volume change per mole commonly decrease with three different series of reactions mentioned above and the differences among them becomes larger (see the second column in Table II). In order to explain these subjects, it is necessary to derive the relationship between the volume change on formation of water from its ions and the concentrations of acid and base.

With reference to the method employed by Rossini[5], who calculated the heat of ionization of water, i.e. the negative of the heat evolved in reaction 1 at infinite dilution, by combining the data on heats of neutralization and those on heats of dilution, the author has evaluated changes of volume on formation of water from its ions at constant temperature. On the other hand, the author has shown that the volume change on formation of one mole of water from its ions at moderate concentrations is represented by a linear function of the square root of the concentration of ions, by using the Masson-Geffcken relationship[2,6] on the apparent molar volume of electrolytes in solution. The relationship so obtained has been checked with the calculated data. The agreement of the results has been found very satisfactory.

In the present paper the author has utilized the data on changes of volume on neutralization recently obtained by the present author[7], and also the data of Saslawsky et al.[3,8]

## Calculation and Results

In considering the volume changes on neutralization of various acids and bases, the author will deal with both uni-univalent strong electrolytes.

The reaction between a strong acid and a strong base at finite and equal concentrations, $C$ mol./l., is given by

$$HB + MOH = MB + H_2O \qquad (2)$$

This reaction represents the formation of one mole of water from its ions at the initial concentration $C$, and also the dilution of one mole each of $M^+$ and $B^-$ ions from $C$ to $C'$, by which the concentration in moles per liter of the resulting salt solution is denoted.

The volume change for the process is

$$\Delta V_N = \Delta V_F + \Delta V_D \qquad (3)$$

where $\Delta V_N$ is the volume change on neutralization, $\Delta V_F$ is that on formation of water and $\Delta V_D$ is that on dilution. The value of $\Delta V_F$ can be obtained from that of $\Delta V_N$, which is directly measurable, if the corresponding value of $\Delta V_D$ is known. Then, it is assumed that the volume change on dilution of one mole each of $M^+$ and $B^-$ ions from $C$ to $C'$ is equal to that on dilution of one mole of salt MB from $C$ to $C'$. In other words, it is assumed that the sum of the apparent molar volumes of $M^+$ and $B^-$ ions, in the basic and acid solutions respectively, is equal to the apparent molar volume of MB in the neutral salt solution. It will be permissible at the range of concentration here studied, because it would be rightly considered that the difference between $B^-$ ion—$H^+$ ion interaction and $B^-$ ion—$M^+$ ion interaction is small and can be ignored at low or moderate concentrations. Again, a similar assumption is made not only regarding $M^+$ ion, but also regarding $H^+$ and $OH^-$ ions, respectively.

Thus, values of the volume change on formation of water from its ions at various concentrations at 20°C have been computed from those of the volume change, obtained by the present author[7], on neutralization of a hydrochloric acid with a sodium hydroxide solution of equal concentration. In computing these values

TABLE I. CHANGES OF VOLUME ON FORMATION OF WATER FROM ITS IONS AT 20°C[a]

| Initial concn. $C$ mol./l. | Vol. change on neutralization $\Delta V_N$ ml./mol. | Concn. of the resulting soln. $a^*$ % | Vol. change on dilution ($C \rightarrow a^*$) $\Delta V_D$ ml./mol. | Vol. change on formation of water $\Delta V_F$ ml./mol. |
|---|---|---|---|---|
| 1 | 20.04 | 2.841 | −0.58 | 20.62 |
| 2 | 18.16 | 5.530 | −1.00 | 19.16 |
| 3 | 16.91 | 8.093 | −1.25 | 18.16 |

given in Table I, the author has taken $\Delta V_D$ as equivalent to the difference between the apparent molar volume of sodium chloride in the aqueous solution, of which the concentration is similar to the one of the acid or the basic solution, and that in the resulting solution, because both the density of the solution to be diluted and that of the resulting salt solution have been known[7,9].

TABLE II. VALUES OF $\Delta V_F$ CALCULATED FROM SASLAWSKY'S DATA[3,8] AT 20°C

(1) Calculated from values of $\Delta V_N$ on reaction: $HCl+NaOH=NaCl+H_2O$.

| Initial concn. $C$ mol./l. | Vol. change on neutralization $\Delta V_N$ ml./mol. | Concn. of the resulting soln. $C^*$ ml./mol. | Vol. change on dilution ($C \rightarrow C^*$) $\Delta V_D$ ml./mol. | Vol. change on formation of water $\Delta V_F$ ml./mol. |
|---|---|---|---|---|
| 1 | 19.6 | 0.495 | −0.7 | 20.3 |
| 2 | 18.0 | 0.982 | −1.0 | 19.0 |
| 3 | 16.7 | 1.463 | −1.2 | 17.9 |
| 4 | 15.9 | 1.938 | −1.4 | 17.3 |
| 5 | 15.0 | 2.409 | −1.6 | 16.6 |

(2) Calculated from values of $\Delta V_N$ on reaction: $HBr+NaOH=NaBr+H_2O$.

| $C$ | $\Delta V_N$ | $C^*$ | $\Delta V_D$ | $\Delta V_F$ |
|---|---|---|---|---|
| 1 | 20.0 | 0.495 | −0.6 | 20.6 |
| 2 | 18.5 | 0.982 | −0.9 | 19.4 |
| 3 | 17.5 | 1.462 | −1.1 | 18.6 |
| 4 | 16.7 | 1.935 | −1.2 | 17.9 |
| 5 | 15.9 | 2.405 | −1.4 | 17.3 |

(3) Calculated from values of $\Delta V_N$ on reaction: $HI+NaOH=NaI+H_2O$.

| $C$ | $\Delta V_N$ | $C^*$ | $\Delta V_D$ | $\Delta V_F$ |
|---|---|---|---|---|
| 1 | 19.4 | 0.495 | −0.5 | 19.9 |
| 2 | 18.4 | 0.982 | −0.7 | 19.1 |
| 3 | 17.9 | 1.461 | −0.9 | 18.8 |
| 4 | 17.1 | 1.934 | −1.0 | 18.1 |
| 5 | 16.0 | 2.404 | −1.1 | 17.1 |

Then, in Table II are shown values of $\Delta V_F$, which have been calculated from the data, obtained by Saslawsky et al.[3,8], on changes of volume on three different series of reactions. In this calculation, the author has evaluated the concentration of the resulting salt solution from the value of $\Delta V_N$, and computed the corresponding value of $\Delta V_D$ by the Masson-Geffcken relationship on the apparent molar volume of electrolyte*. Because the apparent molar volumes of these salts, i. e. sodium chloride, bromide and iodide, confirm satisfactorily this relationship over the range of concentration here treated[10,11].

In Tables I and II-1, the agreement of the results has been found very satisfactory. It is just as predicted from the fact that each of the values of volume change on neutralization obtained by the present author is in good agreement with the corresponding one by Saslawsky et al.[7] Furthermore, each of the values of $\Delta V_F$ shown in Tables II-2 and II-3 is in tolerable agreement with the corresponding one given in Table I or II-1, without an error greater than one or two per cent.

## Discussion

The volume change per mole on reaction 2 is given by[7]

$$\Delta V_N = \Phi_s^* + \Phi_w + \Phi_a - \Phi_b \qquad (4)$$

where $\Phi$ is the apparent molar volume of the solute. The subscripts refer to salt, water, acid and base, respectively, and the asterisk indicates that the salt concentration is $C^*$ mol./l. As has been fully discussed in the previous section, this reaction represents the formation of one mole of water from its ions at the initial concentration, and also the dilution of one mole each of $M^+$ and $B^-$ ions from the initial concentration $C$ to the final one $C'$. Therefore, the changes of volume for these two processes are represented by means of the following equations, respectively.

$$\Delta V_F = \Phi_w - (\Phi_H + \Phi_{OH}) \qquad (5)$$

$$\Delta V_D = \Phi_s^* - (\Phi_M + \Phi_B) = \Phi_s^* - \Phi_s \qquad (6)$$

where $\Phi_H$, $\Phi_{OH}$, $\Phi_M$ and $\Phi_B$ are the apparent molar volumes of $H^+$, $OH^-$, $M^+$ and $B^-$ ions at the initial concentration, respectively.

Substitution of Eqs. 4—6 into Eq. 3 gives the following equation.

$$\Phi_H + \Phi_{OH} = \Phi_a + \Phi_b - \Phi_s \qquad (7)$$

If the apparent molar volumes of these three electrolytes confirm the Masson-Geffcken relationship, $\Phi = \Phi^\circ + S\sqrt{C}$, Eq. 7 can be reduced to

$$\Phi_H + \Phi_{OH} = (\Phi_a^\circ + \Phi_b^\circ - \Phi_s^\circ) + (S_a + S_b - S_s)\sqrt{C} \qquad (8)$$

* The limiting slopes are $S_{(NaCl)}=2.32$, $S_{(NaBr)}=2.04$ and $S_{(NaI)}=1.64$ (cf. Ref. 10).

10) A. Tsujioka, *Proc. Faculty Eng., Keio Univ.*, **10**, 63 (1957).

11) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions", 2nd Ed., Reinhold Publishing Co., New York (1950), p. 252.

where $\Phi^\circ$ is the apparent molar volume of a solute at infinite dilution, and $S$ is the limiting slope. Again it is the same as in Eq. 4 that the subscripts refer to acid, base and salt, respectively.

It has been found valid for most electrolytes that the Masson-Geffcken relationship holds over a wide range of concentration except on high dilution[2,12]. For aqueous solutions of some acids or lithium salts, however, the apparent molar volumes of the solutes show an unusual dependence on the concentration, especially at high concentrations[13,14]. Hydrogen iodide which has been treated in the present paper is one of these electrolytes, but its deviation from the Masson-Geffcken relationship would be rightly considered to be negligibly small at moderate concentrations[14].

At high dilution, on the other hand, the apparent molar volumes of strong electrolytes in solution confirm the limiting law derived from the Debye-Hückel theory[15,16]. That is, the apparent molar volumes, $\Phi$, of strong electrolytes in solution at high dilution are represented by the following equation.

$$\Phi = \Phi^\circ + S_v\sqrt{C} + kC \qquad (9)$$

where $\Phi^\circ$ is the apparent molar volume of a solute at infinite dilution, $S_v$ is the universal limiting slope which is 1.86 at 25°C for 1—1 electrolyte[17], and $k$ is constant and specific for each electrolyte. If the apparent molar volumes of acid, base and salt confirm Eq. 9**, Eq. 7 can be reduced to

$$\Phi_H + \Phi_{OH} = (\Phi_a^\circ + \Phi_b^\circ - \Phi_s^\circ) + S_v\sqrt{C} + (k_a + k_b - k_s)C \qquad (10)$$

where the subscripts refer to acid, base and salt. Therefore, the sum of the apparent molar volumes of $H^+$ and $OH^-$ ions confirm the limiting Debye-Hückel law at high dilution as same as the 1—1 strong electrolytes.

Now, by using the values of the parameters*** of Masson-Geffcken equations for sodium chloride, hydrogen chloride and sodium hydroxide, Eq. 8 can be reduced to

$$\Phi_H + \Phi_{OH} = -5.47 + 3.10\sqrt{C} \qquad (11)$$

Using Eq. 5, therefore, one obtains the following equation:

$$\Delta V_F = 23.52 - 3.10\sqrt{C} \qquad (12)$$

where $\Delta V_F$ is the volume change in ml./mol. which occurs on reaction 1, and $C$ is the concentration in mol./l. of hydrogen and hydroxyl ions. This equation can be applied to moderate concentrations, i.e. 1~5 mol./l., at 20°C. Again, the numerical term in Eq. 12 does not refer to the value of volume change on formation of water from its ions at infinite dilution.

In Figs. 1 and 2, values of $\Delta V_F$ shown in Tables I and II, as well as those calculated by Eq. 12, have been plotted against the square root of the concentration. The agreement of the results has been found very satisfactory in Fig. 1. In Fig. 2, values of $\Delta V_F$ computed from values of the volume change on neutralization of hydroiodic acid with sodium hydroxide solution are considerably different from the corresponding ones computed from the data in other cases.

The apparent molar volume of hydrogen iodide, at concentrations above 1.5 N, deviate from the values predicted by the Masson-Geffcken relationship[18]. This behavior was attributed to incomplete ionization by Fajans[18], while to ion-ion and

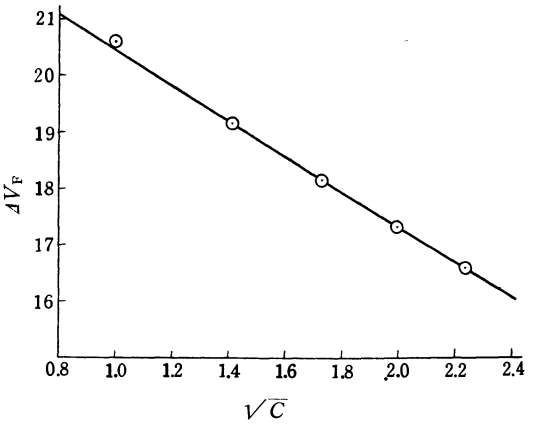

Fig. 1. Volume changes on formation of water, given in Table I, plotted against the square root of the concentration. (——, calculated by Eq. 12).

** The limiting law of the molar volume has not been experimentally confirmed for sodium hydroxide. But the limiting slope appears to be the same for NaOH, HCl, NaCl and for other electrolytes of the 1—1 charge type. Because there is no reason to assume any anomaly in NaOH, in view of the theoretical derivation of Eq. 9.
17) O. Redlich and J. Bigeleisen, *J. Am. Chem. Soc.*, **64**, 758 (1942).

*** $\Phi_{(NaCl)} = 15.82 + 2.32\sqrt{C}$; $\Phi_{(HCl)} = 17.80 + 0.87\sqrt{C}$; $\Phi_{(NaOH)} = -7.45 + 4.55\sqrt{C}$ (cf. Ref. 7).
18) K. Fajans, *J. Chem. Phys.*, **9**, 281 (1941).

ion-solvent interactions by Bigeleisen[13]. But it appears to leave much room for discussions[19]. Nevertheless, it would be rightly considered that the less satisfactory linearity of HI, shown in Fig. 2, is due to a reason similar to the one to which its deviation from the Masson-Geffcken rule must be ascribed.

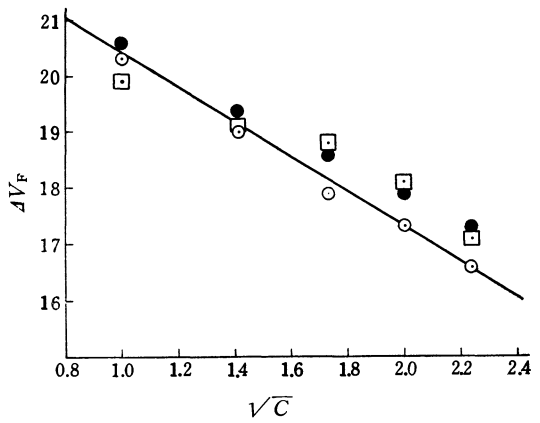

Fig. 2, Concentration dependence of $\Delta V_F$, given in Table II.
(——, calculated by Eq. 12; ○, HCl+NaOH; ●, HBr+NaOH; □, HI+NaOH)

Thus, by using the results obtained in the present work, it is readily possible to predict changes of volume on neutralization of a strong acid with a strong base. The difference among values of the volume change, obtained in different series of reactions between acids and bases at the same conditions, is mainly due to that among the corresponding ones of $\Delta V_D$. Values of $\Delta V_D$ are generally negative, so the expansion in total volume on neutralization gets smaller as the numerical value of $\Delta V_D$ gets larger. The diminution in total volume on dilution ($\Delta V_D$) is proportional to the limiting slope of the salt[10] (cf. Eq. 6). Therefore, the larger the limiting slope for a salt, the smaller the expansion in volume on neutralization is. The correctness of this prediction has been found very satisfactory in Table II*.

## Summary

Values of the changes of volume on formation of water from the hydrogen and hydroxyl ions in aqueous solutions, at various concentrations at 20°C, have been calculated, by combining the data of volume change on neutralization of a strong acid with a strong base and those on dilution of electrolyte solutions. Furthermore, the dependence of the volume change on the concentration has been derived and checked with the calculated data. The volme change on formation of water from its ions at moderate concentrations at 20°C is given by the equation: $\Delta V_F = 23.52 - 3.10\sqrt{C}$ ml. per mole, where $C$ is the concentration of ions in mol./l.

Thus, the author has made it easy to analyze the volume changes on neutralizations of various acids and bases.

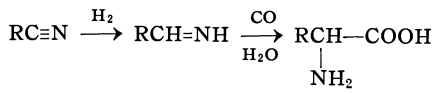
# *Studies on the High Pressure Reaction of Carbon Monoxide. I. On the Reactions of Schiff Bases and Azocompounds with Synthetic Gas*

By Shunsuke MURAHASHI and Shigeki HORIIE*

(Received July 3, 1959)



From considerations of the chemical formula, it might be conceivable that if an addition of carbon monoxide to the double bond of Schiff base could occur, there are possibilities of synthesizing α-amino acid on hydrolysis of the addition products with water or peptide with a restricted quantity of water, as indicated below:

The following work was undertaken in the light of such a consideration.

It is well known that the reduction of nitrile proceeds to amine via éte intermediate of Schiff base, and that cobalt carbonyl is able to catalyze oxo-reaction, and furthermore it also catalyzes hydrogenation of aldehyde to alcohol in the presence of carbon monoxide and hydrogen.

On such an account the authors attempted to prove the possibility of obtaining amino acid or polypeptide directly from nitriles.

At the time when the authors started the work, chemical reaction of nitriles under an oxo-condition had not been explored and so benzonitrile and benzylcyanide were subjected to the present examination. The experiments resulted only in giving a small quantity of amines (mixtures of primary and secondary ones) and it revealed that reduction of nitrile would be very difficult to be realized and no reaction product was obtained in which carbon monoxide had been involved. Therefore, the authors have turned the subject to the Schiff base itself and studied to see whether the reaction in this case would take place, giving α-amino acid or peptide as was postulated above.

The general conditions adopted for the experiments are as follows: Catalyst, cobaltcarbonyl; Solvent, benzene or benzene-alcohol (1 : 1); Gas, $CO+H_2$ (1 : 1), 200 atm.; Reaction temperature, 120~130°C.

The results with Schiff bases were shown in Table I which shows conclusively that a reduction of C=N double bond had occured and no reactions were found in which carbon monoxide has participated.

The reduction proceeded very smoothly and did not present any marked difference even when the reactions were carried out at varied conditions, i. e. pressure, temperature and reaction time. As to the effect of reaction medium it was found, that the reaction was faster and began at a somewhat (10~20°C) lower temperature when alcohol-benzene mixture (1 : 1) was used instead of aromatic hydrocarbons.

Benzaldehyde phenylhydrazone did not give any definite result with synthetic gas. The authors, then, studied the reaction of synthetic gas on double bond having nitrogen atom, such as the N=O and N=N-group as well as C=S double bond.

Nitrobenzene and azobenzene was allowed to react with carbon monoxide and was ascertained to give aniline as a principal product. Hydrazobenzene was also subjected to this reaction for reference and it was confirmed that aniline was again the principal product. In all cases the authors found the formation of a considerable quantity of diphenylurea, as shown in Table II.

Thus, it has been confirmed that the four kinds of bond, C=N, N=N, C=S and N=O were all reduced by synthetic gas in the presence of cobalt carbonyl catalyst. The formation of urea derivatives observed in all cases except for the compound involving C=S linkage is

* Present address: Institute of Scientific and Industrial Research, Osaka Univ., Sakai, Osaka.

Reaction conditions are the same in Table I.

noteworthy, because it demonstrates, that some new kind of CO-reaction has occurred, and especially the fact that a formation of symmetrically substituted urea derivatives were observed from asymmetrically substituted azo-compounds was of special note.

As the reaction appeared to be a new one, the authors planned further experiments so as to obtain more detailed information about the high pressure reaction of carbon monoxide.

Hydrazobenzene gave 50% yield of azobenzene under the similar condition, at the reaction temperature which was lower than that required for the reduction (80～90°C). From this experiment it could be postulated that urea could have formed from hydrazobenzene via azobenzene. However, the yields of diphenylurea were in all cases higher when hydrazobenzene was used instead of azobenzene. In the case of nitrobenzene, the formation of urea derivative was also observed and its formation could be interpreted by the intermediate formation of either hydrazobenzene or azobenzene.

In order to discuss the possible mechanism for the formation of urea derivative, one has to consider either 1) fission of hydrazo linkage followed by addition of CO, or 2) that the azo group remains without cleavage until CO is added across the double bond and then the -N-N- bond is subjected to fission by hydrogenolysis as will be shown below (Eq. 2). Eq. 1 was suggested earlier by W. Reppe[1] as a possible mechanism of the oxo-reaction and the carboxylation of olefins. Accordingly one might propose Eq. 2 for the urea formation.

$$RCH{=}CH_2 \xrightarrow{CO} RCH(\text{-}CH_2\text{-}C(=O)\text{-}) \longrightarrow RCH(CHO)\text{-}CH_3 \text{ or } RCH_2CH_2CHO \quad (1)$$

$$RN{=}NR' \xrightarrow{CO} RN(\text{-}NR'\text{-}C(=O)\text{-}) \xrightarrow{H_2} RNHCONHR' \quad (2)$$

Since azobenzene is reduced for the most part to aniline, it would be an acceptable argument that the formation of urea could have resulted from the reaction of

1) W. Reppe, *Ann.*, **582**, 40 (1953).

aniline and carbon monoxide. Pino[2] discussed the possibility of formation of urea derivatives from two moles of aniline and one mole of carbon monoxide under a dehydrating condition, and Buckley[3] reported the formation of formylaniline by the reaction of aniline and carbon monoxide.

However, all the authors' tests with aniline and with formylaniline failed to show that the urea-formation is the result of the reaction of aniline and carbon monoxide.

An alternate mechanism would presumably be a fission of the azo-compound by means of carbon monoxide and hydrogen, leading to the primary formation of phenylisocyanate and aniline. However, the authors failed to isolate such an intermediate to prove this mechanism.

As another possibility, hydrazobenzene might well be accounted for the reaction. In this regard the authors will discuss it in later papers.

## Experimental

**1) Reduction of Benzaldehydeanil with Synthetic Gas.** — Benzaldehydeanil (5 g.) was dissolved in 50 ml. of benzene or benzene-alcohol mixture (1:1) and charged in an autoclave of 100 ml. content made of 18-8 stainless steel together with cobalt carbonyl (1.0 g.). After replacement of air, the synthetic gas was compressed up to 200 atm. (CO, 100 atm. and $H_2$, 100 atm.). The autoclave was heated at 120~130°C, when the pressure began to descend, and after completion of gas absorption it was allowed to cool. The content of the autoclave was heated in a flask on a water bath and after decomposition of the cobalt catalyst and filtration the filtrate was distilled in vaccuo, affording 4 g. of benzylaniline, m. p. 38°C, which was identified by the mixed melting point test with an authentic sample.

The essential feature of the experimental procedures are all the same as described above, and thus *p*-chloro, *p*-methyl-, *p*-methoxy- and *p*-nitro-benzaldehydeanil were subjected to examination. The results are given in Table I. The melting points and the boiling points all agree with the values described in the literatures. *p*-Nitrocompound was reduced under the present condition selectively at the anil double bond and the nitro group remained unchanged.

**2) Reaction of 3-Phenyl-2-thioxopropionic Acid and Carbon Monoxide.**—3-Phenyl-2-thioxopropionic acid (3 g.) in benzene (50 ml.) was allowed to react with carbon monoxide and hydrogen of 200 atm. in the presence of cobalt catalyst (1 g.) at 120~130°C for 2 hr. No gas absorption was observed, but after cooling and degassing, it was found that hydrogen sulfide gas had formed. A definite product could not be isolated except 2-phenylpropionic acid amide melting at 102°C.

**3) Formation of Diphenylurea as a By-product in the Reaction of Azobenzene and Synthetic Gas.**—Azobenzene (5 g.) yielded 1.1 g. of diphenylurea (20% yield) in a form of a difficultly soluble product, which was recrystallized from alcohol.

**4) Urea Derivatives from *p*-Chloroazobenzene.** —*p*-Chloroazobenzene (5 g.) was treated as in exp. 1 and from the reaction product 0.6 g. (12%) of a mixture of urea compounds was obtained, and was separated into two parts: *p,p'*-dichlorodiphenylurea as the difficultly soluble part in alcohol in colorless prisms, m. p. 286°C (with decomposition), and as the soluble part *p*-chlorodiphenylurea in scaly crystals, m. p. 244°C.

*Anal.* Found: C, 56.66; H, 3.70; Cl, 25.20; N, 10.36. Calcd. for $C_{13}H_{10}Cl_2N_2O$: C, 56.93; H, 3.64; Cl, 25.26; N, 10.21%.

*Anal.* Found: C, 64.06; H, 4.64; Cl, 14.32; N, 11.55. Calcd. for $C_{13}H_{11}ClN_2O$: C, 64.19; H, 4.52; Cl, 14.40; N, 11.52%.

**5) Urea Derivatives from *p*-Methylazobenzene.** —*p*-Methylazobenzene (5 g.) was treated as in exp. 4 and from the filtrate of the reaction mixture a mixture (1.2 g., 22%) of urea was separated. From a difficultly soluble portion *p,p'*-dimethylphenylurea (0.3 g.) was obtained in colorless needles, m. p. 262°C and from the soluble portion *p*-dimethyldiphenylurea (0.7 g., 12%) was obtained, and further a small quantity of unsubstituted diphenylurea was obtained from the last portion of the soluble residue.

*Anal.* Found: C, 74.81; H, 6.70; N, 11.78. Calcd. for $C_{15}H_{16}N_2O$: C, 75.00; H, 6.66; N, 11.66%.

*Anal.* Found: C, 74.15; H, 6.20; N, 12.51. Calcd. for $C_{14}H_{14}N_2O$: C, 74.33; H, 6.19; N, 12.38%.

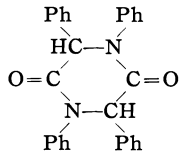
# *Studies on the High Pressure Reaction of Carbon Monoxide. II. Synthesis of Phthalimidine*

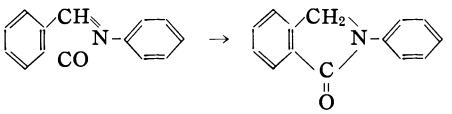
By Shunsuke MURAHASHI, Shigeki HORIIE** and Takashi JŌ**

(Received July 3, 1959)



In Part I the reaction of Schiff bases and azobenzene derivatives with synthetic gas was described and it was found that in the case of azobenzene, no insignificant amount of diphenylurea had been formed besides aniline which was the main product.

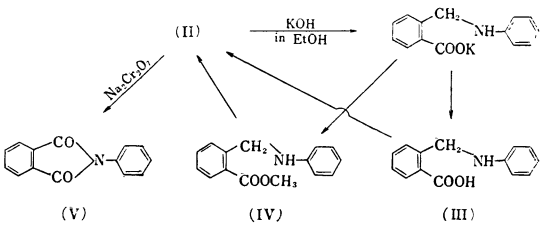
With the object of obtaining more information on the cause of diphenylurea-formation as well as on the knowledge of reactivity of carbon monoxide with -N=N- bond, the authors studied the reaction with carbon monoxide alone instead of with synthetic gas as reported in Part I. There, it was found that new reactions took place which afforded phthalimidines when Schiff bases were subjected to the reaction with carbon monoxide under the cobalt catalyst, and quinazolones when azocompounds were used. The present paper describes the synthesis of phthalimidine.



When benzaldehydeanil was dissolved in an aromatic hydrocarbon such as benzene or toluene and heated under carbon monoxide pressure of 100 to 200 atm. at 200~230°C in the presence of cobalt catalyst, it afforded white scaly crystals, m. p. 200°C.

The result of the analysis of these crystals indicated that it had an experimental formula ($C_{14}H_{11}ON$), indicating that 1 mol. of carbon monoxide had entered into every 1 mol. of benzaldehydeanil.

It appeared at the outset to have achieved the synthesis of amino acid in the form of anhydride and to have obtained tetraphenyldiketopiperazine of the following formula:



But a detailed study of this substance soon revealed that it was the derivative of phthalimidine (II) and was probably synthesized according to the following scheme:

(I) (II)

Compound II gave on hydrolysis an acid (III) which are so unstable on standing as to return to the original compound. In order to get a stable product, compound II was hydrolyzed with alkali and then the hydrolyzate was esterified directly with dimethylsulfate without acidification. Although the ester of III was separated as an oil, it also returned to its original compound II very easily.

These behaviors did not correspond to the one of diketopiperazine.

The formation of phthalic anhydride by oxidation with potassium permanganate and the formation of *N*-phenylphthalimide by sodium bichromate-oxidation demonstrated eventually that compound II was a phthalimidine derivative as illustrated above.

A conclusive evidence was established by comparison with the authentic sample prepared by other means.

Thus a novel reaction was found, in which CO-attack had taken place on both the benzene rings and on the *N*-atom with simultaneous ring formation. In order to establish the necessary conditions for the achievement of this reaction, several runs were carried out and the results were shown in Table I. The essential features

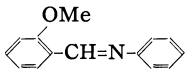
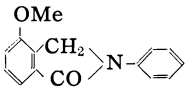
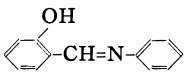
Concn. of Catalyst: 0.03 millimol./cc.
a) Benzaldehydeanil: 0.028 mol.
b) $[Co(CO)_4]_2$: 0.0015 mol.
c) $[Co(CO)_4]_2$: 0.0045 mol.

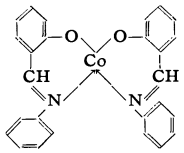
of the results are as follows:

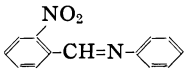
a) No reaction without the catalyst (Expt. No. 1). b) Cobalt compound such as dicobalt octacarbonyl, iron pentacarbonyl (less active), metallic cobalt, and cobalt salt or complex and so on, which have the potentiality of forming metal carbonyl, would be effective in promoting the reaction (Expts. No. 2–5). c) Nickel carbonyl is ineffective (Expt. No. 7). d) As a solvent, aromatic hydrocarbons are appropriate and protonic solvents inhibit the reaction (Expts. No. 13–17). e) Temperature of about 200°C is necessary and appropriate temperature of reaction lies in the range of 220～230°C (Expts. No. 10–12). f) Since the change of carbon monoxide pressure in the range of 30～300 atm. did not show any appreciable effect on the reaction, the necessary pressure seems to be that which suffices to maintain the concentration of cobalt carbonyl at the reaction temperature (Expts. No. 10–12). g) Since cobalt carbonyl is decomposed by contact with oxygen, it was inevitably needed to exclude oxygen (Expts. No. 18–19). h) The effect of the inner wall of an autoclave generally was not noticed except at the beginning of its use, when sometimes an irregular behavior was observed.

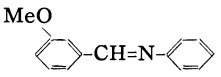


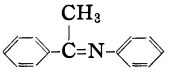


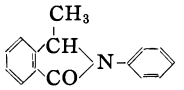


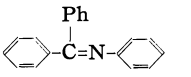


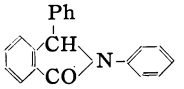


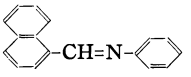


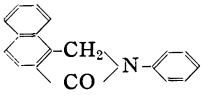


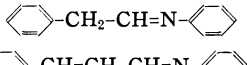


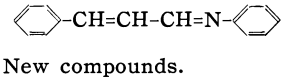












As this reaction is expected to give useful intermediates for dyestuffs and synthetic chemical reagents, the reactions between carbon monoxide and varieties of Schiff bases having various substituents were examined, as shown in Table II.

In both the cases of benzaldehydeanils with substituents (H, OMe, OH, Cl) in the *p*-position of aniline nucleus and those with substituents (OH, $Me_2N$) in the *p*-position of benzaldehyde side, all gave phthalimidines in good yields by the reaction with carbon monoxide, and no appreciable effect of the substituents was observed (Expts. No. 1–4 and 6–7). *o*-Methoxybenzaldehydeanil gave the expected phthalimidine though in a comparatively low yield. (Expt. No. 8).

In the case of salicylaldehydeanil, a stable red-colored complex containing cobalt was formed, and therefore, cobalt compound used as the catalyst did not promote the reaction but appeared only to have been converted to the stable complex compound II with salicylaldehydeanil (Expt. No. 9).

*m*-Methoxybenzaldehydeanil yielded a low yield of phthalimidine. The expected

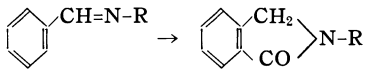
* New compounds.

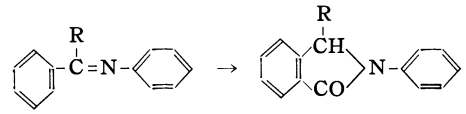


** Yield based on anil consumed.

products could be either VI or VII. Since the product was oxidized with sodium bichromate in acetic acid to yield 4-methoxyphthalic acid anilide (VIII), it was identified as a new compound, *N*-phenyl-5-methoxyphthalimidine (VI) (Expt. No. 11).

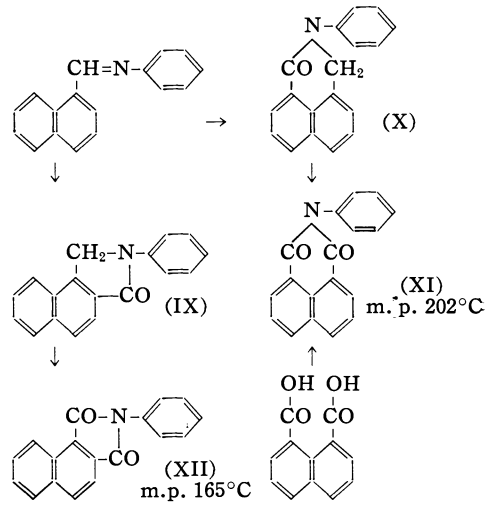
The ring closure is expected to take place at these asterisk positions.

Schiff base derived from aliphatic amine and benzaldehyde also gave the phthalimidine by the reaction with carbon monoxide (Expts. No. 12 and 13).



R: $CH_3$ and $PhCH_2$

Benzaldoxime did not give phthalimidine, but gave benzamide. This fact suggests that a part of cobalt carbonyl had been converted to cobalt hydrocarbonyl in the reaction condition and since this is a strong acid*** it might have promoted the Beckmann rearrangement.

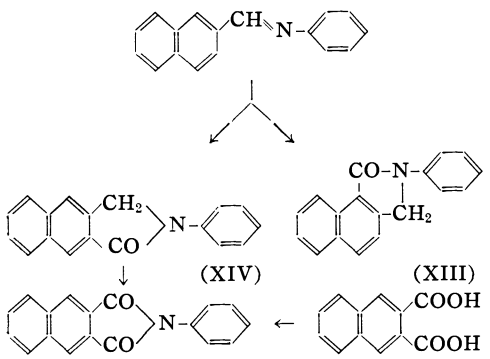


In the case of Schiff base having a nitro group, either on the side of aniline or on the benzaldehyde nucleus, the reaction became very complicated, yielding a deep violet infusible solid**** instead of the expected nitrophthalimidine (Expts. No. 5 and 10). As the model experiment on nitrobenzene (see *Experimental*) shows, the reaction was complicated owing to the presence of the nitro group, but the presence of phthalimidine grouping in the product was demonstrated by the occurrence of phthalic acid among the oxidation products.

Schiff bases, obtained from ketone such as acetophenone and benzophenone and aniline, reacted smoothly with carbon monoxide, yielding the expected phthalimidines (Expts. No. 15 and 16).

R: Me and Ph

Naphthaldehydeanils yielded the corresponding derivatives of phthalimidine in good yields. As 1-naphthaldehydeanil can be expected to ring-close with carbon monoxide at a 2- or 8-position, either one or a mixture of two (IX), (X) will be formed as the product. The product obtained, however, was not a mixture but a pure substance, and was converted to *N*-phenylnaphthalimide (m. p. 165°C) by oxidation with sodium bichromate in acetic acid. *N*-Phenyl-1, 8-naphthalimide (XI) synthesized from 1, 8-naphthalendicarboxylic acid and aniline, which has the melting point of 202°C, does not coincide with the oxidation product. Therefore, the phthalimidine obtained here would be IX and the oxidized product XII. Thus, the ring closure takes place at the 2-position to yield 2-phenylbenz [*e*] isoindolin-1-on (VI),

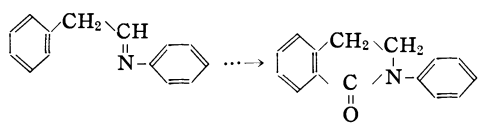


Although the chemical structure of compound IX has not yet been fully

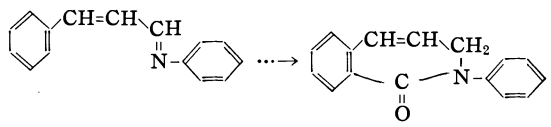
*** Since this rearrangement by cobalt carbonyl or more probably cobalt hydrocarbonyl was considered to be a new fact, the same method was attempted to apply to aliphatic oximes. However, aliphatic oximes were merely reduced and by cyclohexanone oxime, gave dicyclohexylurea besides an amino compouond.

**** It is apparent that the reducing power of carbon monoxide led to the formation of azo-linkage (G. D. Buckley, N. H. Ray; *J. Chem. Soc.*, **1949**, 1154) or of diphenylurea linkage (S. Horiie, unpublished) by the reduction of the nitro group. Reactions as these might be responsible for the reaction between carbon monoxide and the nitrocompound leading to the formation of an insoluble, infusible and deep violet substance.

ascertained by a direct comparison with the synthesized sample, its identity is considered to be well confirmed by the comparison with XV, and this will be described below.



Since, in the case of 2-naphthaldehydeanil, the ring closure takes place at the 1- or 3-position of naphthalene nucleus, the expected product is either XIII of XIV. Only one kind of reaction product was also obtained here and, through the oxidation by sodium bichromate, it gave a *N*-phenylnaphthalimide, which coincided with *N*-phenyl-2, 3-naphthalimide (V), synthesized from 2, 3-naphthalene dicarboxylic acid and aniline. Therefore, the reaction product obtained with 2-naphthaldehydeanil was proved to be 2-phenylbenz[*f*]-isoindolin-1-on (XIV), which occurred as the result of the ring closure at the 3-position.



(XV) mp. 278°C

This ring closure by carbon monoxide at the 3-position of the naphthalene derivatives is a very peculiar case and of interest in comparison with the fact that the ring closure usually occurs at the 1-position of 2-substituted naphthalene derivatives.

Starting from phenylacetaldehydeanil and cinnamaldehydeanil, the reaction should analogously be expected to lead to the formation of 6- and 7-membered rings, respectively, but the experiments were carried out in vain. This would suggest that the reaction with carbon monoxide seems to be characteristic of the azomethine group, conjugated with the aromatic ring and is limited to the formation of a 5-membered ring.

## Experimental

**1) Reaction between Benzaldehydeanil and Carbon Monoxide.**—Five grams of benzaldehydeanil was dissolved in 50 ml. of benzene, and placed in an autoclave of 100 ml. content together with a catalytic amount of cobalt carbonyl solution (concn., 0.03 millimol./ml.) and carbon monoxide was pressed after replacement of air up to 100~200 atm., then the autoclave was heated at 220~230°C for 5~6 hr. with constant shaking. After cooling, the excess of carbon monoxide was purged and a greater part of *N*-phenylphthalimidine, which is produced, emitted as crystalline needles or scales and were collected on a filter and washed with a small amount of benzene, the crystal (4.1 g., 72% of theoretical) is almost pure, m. p. 163°C.

*Anal.* Found: C, 80.26; H, 5.47; N, 6.92. Calcd. for $C_{14}H_{11}ON$: C, 80.38; H, 5.26; N, 6.70%.

**2) Hydrolysis of *N*-Phenylphthalimidine and Alkylation of the Hydrolyzed Product.**—One gram of *N*-phenylphthalimidine was boiled with an alcoholic solution of potassium hydroxide (2 g. of potassium hydroxide in 20 ml. of alcohol-water (1 : 1) solu ion) and after 3 hr. the alcohol was distilled off and the remaining water solution was devided into two parts.

When one part of the solution had been made slightly acidic with dilute hydrochloric acid, the oil was separated out, which then crystallized after a while. This crystal (0.45 g.) was proved to be identical with *N*-phenylphthalimidine.

When the other portion of the solution was methylated with 0.6 g. of dimethylsulfate, an oil which gradually changed into crystalls, and which was identified as *N*-phenylphthalimidine, m. p. 162°C oozed out.

**3) Oxidation of Phthalimidine with Bichromate.**—The oxidation carried out referred to the work of Maxwell and Allen[1]. Thus, *N*-phenylphthalimidine (0.5 g.) was dissolved in anhydrous acetic (30 ml.) acid under stirring and warming at 90°C. Sodium bichromate in fine powder was charged slowly until no more color change was observed. After half an hour when the mixture was poured into water, a white crystalline precipitate, which was recrystallized from alcolol, in colorless needles (0.2 g.), m. p. 205°C separated out. The mixed melting point test with an authentic sample proved to be identical with *N*-phenylphthalimide.

**4) *N*-Phenylphthalimidine.** — *N*-Phenylphthalimide, which is obtained by fusion of aniline and phthalic anhydride was reduced with Zn-dust according to the method of Graebe[2] in an acetic acid solution at 80~90°C.

1) C. S. Maxwell and X. F. Allen, "Organic Syntheses", Vol. 24, John Wiley & Sons, Inc., New York (1944), p. 1.
2) C. Graebe, *Ann.*, **247**, 288 (1888).

After reduction, the solution was poured into a large amount of water, and the white crystals separated. The crystals, after recrystallization from alcohol, were found to be identical with the sample obtained from benzaldehydeanil, m. p. 163°C.

**5) Synthesis of *N*-(*p*-Methoxyphenyl)phthalimidine.** — *N*-Benzyl-*p*-methoxyaniline (5 g.) was caused to react with carbon monoxide in the same manner as in the previous paper (Expt. Part 1) in Paper II). After being cooled, the reaction mixture was filtered to yield 4.8 g. of the colorless scaly crystals, m. p. 137~138°C (from methanol). A literature reported the m. p. of 135°C[3].

*Anal.* Found: N, 5.79. Calcd. for $C_{15}H_{13}O_2N$: N, 5.85%.

This crystals (1 g.) suspended in 50 ml. of 1 N sodium hydroxide and oxidized with potassium permanganate, yielded 0.2 g. of phthalic acid which was identified by the mixed melting point test with the authentic sample.

**6) Synthesis of *N*-(*p*-Hydroxyphenyl)phthalimidine.**—The colorless crystals (3.7 g.) were obtained in needles in a similar manner starting from benzal-*p*-hydroxyaniline (5 g.). The product was recrystallized from alcohol, m. p. 224~245°C.

*Anal.* Found: C, 74.65; H, 4.92; N, 6.22. Calcd. for $C_{14}H_{11}O_2N$: C, 74.56; H, 5.12; N, 6.42%.

The crystals (1 g.) were oxidized to phthalic acid (0.2 g.) by alkaline potassium permanganate.

**7) Synthesis of *N*-(*p*-Chlorophenyl)phthalimidine.**—Benzal-*p*-chloroaniline (5 g.) gave in a similar manner 4.2 g. of colorless scaly crystals, which was recrystallized from alcohol, m. p. 181~182°C.

*Anal.* Found: C, 69.14; H, 4.11; N, 5.19. Calcd. for $C_{14}H_{10}ONCl$: C, 69.40; N, 4.44; N, 5.99%.

The crystals (1 g.) were oxidized to phthalic acid (0.25 g.).

**8) Reaction of Carbon Monoxide with Benzal-*p*-nitroaniline.**—In a similar manner, there was obtained an amorphous deep purple substance, which was insoluble in organic and inorganic solvents and was infusible. The fact that oxidation of this substance by potassium permanganate yielded a minor amount of phthalic acid seems to show that the general reaction between benzal-*p*-nitroaniline and carbon monoxide has taken place to some extent.

**9) Synthesis of *N*-Phenyl-6-dimethylaminophthalimidine.**—*p*-Dimethylaminobenzaldehydeanil (5 g.) gave 4.6 g. of colorless needles, which were recrystallized from alcohol, m. p. 154°C.

*Anal.* Found: C, 76.00; H, 6.13; N, 11.30. Calcd. for $C_{16}H_{16}ON_2$: C, 76.16; H, 6.39; N, 11.10%.

**10) Synthesis of *N*-Phenyl-6-hydroxyphthalimidine.** — *p*-Hydroxybenzaldehydeanil (5 g.) also gave 4.4 g. of colorless needles, which were then recrystallized from alcohol, m. p. 215~216°C.

*Anal.* Found: C, 74.65; H, 4.88; N, 6.45. Calcd. for $C_{14}H_{11}O_2N$: C, 74.65; H, 4.92; N, 6.22%.

**11) Synthesis of *N*-Phenyl-4-methoxyphthalimidine.** — The reaction mixture from *o*-methoxybenzaldehydeanil (5 g.) and carbon monoxide, after distillation of benzene and after being kept for several days, gave 1 g. of brownish black crystals, which were then recrystallized from alcohol several times into colorless needles, m. p. 145~146°C.

*Anal.* Found: C, 75.70; H, 5.36; N, 5.96. Calcd. for $C_{15}H_{13}O_2N$: C, 75.30; H, 5.48; N, 5.86%.

**12) Formation of 3-Methoxyphthalic Acid Anil.** —Onto a boiling mixture of *N*-phenyl-4-methoxyphthalimidine (0.4 g.) and glacial acetic acid (10 ml.), sodium bichromate was added portionwise until the color of bichromate ion no longer disappeared, and then the whole mixture was poured onto water. White crystals were filtered off, washed with water and recrystallized from alcohol into colorless scaly crystals (0.2 g.), m. p. 188~189°C, which agreed well with m. p. of a literature[4].

*Anal.* Found: C, 71.00; H, 4.45; N, 5.75. Calcd. for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.37; N, 5.53%.

**13) Formation of Salicylaldehydeanil-cobalt Complex.** — Salicylaldehydeanil (5 g.) gave in a similar manner, after removal of benzene and addition of a small amount of alcohol, 2.1 g. of red crystals, which were recrystallized from alcohol, m. p. 190~191°C. The existence of cobalt was ascertained qualitatively by the borax bead test.

*Anal.* Found: C, 68.55; H, 4.73. Calcd. for $(C_{13}H_{11}ON)_2Co$: C, 68.72; H, 4.84%.

Identification of this compound was carried out by the mixed melting point test with the sample, which was synthesized in the following way: a mixed solution of salicylaldehydeanil (1 g.) in benzene and cobalt carbonyl (1.5 g.), after being kept at room temperature for 3 days, was refluxed in a water bath to decompose the remaining carbonyl and then filtered. After removal of benzene from the filtrate, the remaining brown oil was kept standing with the addition of a small amount of alcohol to yield red crystals, m. p. 190~191°C. This compound showed the same melting point as the one which has been obtained from salicylaldehydeanil and cobalt acetate (m. p. 191°C)[5].

**14) Reaction between *o*-Nitrobenzaldehydeanil and Carbon Monoxide.**—*o*-Nitrobenzaldehydeanil yielded an amorphous deep purple substance just like the one of benzal-*p*-nitroaniline.

**15) Reaction between Nitrobenzene and Carbon Monoxide.**—The reaction mixture of nitrobenzene (40 g.) and cobalt carbonyl (0.5 g.) was subjected to steam distillation, yielding 15 g. of apparently amorphous and deep purple solid as residue, which was insoluble and infusible. An extraction of the solid with alcohol for a prolonged time gave 1.2 g. of diphenylurea.

3) A. T. Peters, G. T. Pringle and F. M. Rowe, *J. Chem. Soc.*, **1948**, 597.

4) W. H. Benteley, R. Robinson and C. Weizmann, ibid., **1907**, 111.

5) Endō, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **65**, 428 (1944).

**16) Synthesis of *N*-Phenyl-5-methoxyphthalimidine.**—The reaction mixture of *m*-methoxybenzaldehydeanil (5 g.) and carbon monoxide was refluxed to effect the decomposition of the catalyst, filtered, and evaporated to a brownish oil, which crystallized after standing in a vacuum dessicator (0.3 g.). Repeated recrystallizations from alcohol gave colorless needles, m. p. 145~146°C.

*Anal.* Found: C, 75.10; H, 5.68. Calcd. for $C_{15}H_{13}O_2N$: C, 75.30; H, 5.48; N, 5.86%.

*m*-Methoxybenzaldehydeanil (2.4 g.) was recovered by distillation of the mother liquor at a reduced pressure.

**17) Formation of 4-Methoxyphthalic Acid Anilide.**—*N*-Phenyl-5-methoxyphtalimidine (0.2 g.) in glacial acetic acid (4 ml.) was refluxed with sodium bichromate (2 g.), and the whole mixture was poured into-water, resulting in the formation of white crystals. After washing with water, the crystals were recrystallized from alcohol into colorless needles (0.1 g.), m. p. 177~178°C, which agreed well with the reported melting point of 4-methoxyphthalic acid anilide (179°C)[6]. The crystals showed a depression of melting point with 3-methoxyphthalic acid anilide, and so it was identified as 4-methoxyphthalic acid anilide.

*Anal.* Found: C, 71.32; H, 4.65. Calcd. for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.37%.

**18) Synthesis of *N*-Benzylphthalimidine.** — Starting from benzalbenzylamine (5 g.), crystalline *N*-benzylphthalimidine (4.7 g.) was obtained in a similar manner, m. p. 90~91°C (from alcohol), which agreed well with Gabriel's value (m. p. 90~91°C)[7].

*Anal.* Found: C, 80.40; H, 5.49; N, 6.22. Calcd. for $C_{15}H_{13}ON$: C, 80.69; H, 5.87; N, 6.27%.

Oxidation of the crystals (0.5 g.) by potassium permanganate gave phthalic acid (0.2 g.), which was identified by the mixed melting point test with the known sample.

**19) Synthesis of *N*-Methylphthalimidine.** — Benzalmethylamine (5 g.) was reacted with carbon monoxide in a usual manner, giving *N*-methylphthalimidine (3.0 g.), which was recrystallized from alchohol in colorless cubic crystals, m. p. 114~115°C.

*Anal.* Found: C, 73.15; H, 6.36; N, 9.97. Calcd. for $C_9H_9ON$: C, 73.45; H, 6.16; N, 9.52%.

The crystals (0.5 g.) were oxidized by potassium permanganate to phthalic acid (0.1 g.), which was identified by the mixed melting point test with the known sample.

**20) Reaction between Benzaldoxime and Carbon Monoxide.**— Benzaldoxime (5 g.) gave 1.3 g. of colorless needles by the reaction with carbon monoxide, m. p. 127~128°C (from chloroform). The analytical data showed a good agreement with the composition of the original benzaldoxime, indicating that an additional reaction with carbon monoxide had not taken place. The crystal was considered as benzamide from the fact that its melting point does agree with that of benzamide and that it afforded benzoic acid by hydrolysis. Identification was carried out by the mixed melting point test with a known sample of benzamide.

*Anal.* Found: C, 69.07; H, 6.01; N, 14.01. Calcd. for $C_7H_7ON$: C, 69.40; H, 5.83; N, 11.56%.

**21) Synthesis of *N*-Phenyl-3-methylphthalimidine.**—Acetophenoneanil (5 g.) was reacted with carbon monoxide in a usual manner and, after removal of catalyst and benzene, the residue was extracted with hot petroleum ether. On cooling the extract, there were obtained crystals, which were recrystallized from petroleum ether into colorless needles (315 g.), m. p. 81~82°C.

*Anal.* Found: C, 81.10; H, 5.97; N, 6.21. Calcd. for $C_{15}H_{13}ON$: C, 80.69; H, 5.87; N, 6.27%.

A literature reported the same melting point (80°C)[8].

**22) Synthesis of *N*-Phenyl-3-phenylphthalimidine.**—Benzophenoneanil (5 g.) gave, after the treatment similar to Expt. 17, 2.2 g. of the product in colorless needles (from petroleum ether), m. p. 195~196.5°C.

*Anal.* Found: C, 84.20; H, 5.20; N, 4.98. Calcd. for $C_{20}H_{15}ON$: C, 84.18; H, 5.30; N, 4.91%.

**23) Synthesis of 2-Phenylbenz[*e*]isoindolin-1-on.**—1-Naphthaldehydeanil (2.0 g.) gave, in the usual way, a crystalline product (2.1 g.), m. p. 177°C (from alcohol).

*Anal.* Found: C, 83.68; H, 4.98; N, 5.65. Calcd. for $C_{18}H_{13}ON$: C, 83.38; H, 5.01; N, 5.40%.

**24) Oxidation of 2-Phenylbenz[*e*]isoindolin-1-on.** — The crystals (0.5 g.) were dissolved in 30 ml. of boiling glacial acetic acid and sodium bichromate was added gradually until the color of bichromate ion no longer disappeared. After cooling, the reaction mixture was poured into water, giving white crystals, which was then washed with water and recrystallized from alcohol into colorless needles (0.3 g.), m. p. 165°C.

Since these crystals showed a marked depression of the melting point when mixed with *N*-phenyl-1, 8-naphthalimide (m. p. 202°C), which was synthesized from the known sample of 1, 8-naphthalenedicaboxylic acid and aniline, the product was confirmed to be different from the latter compound.

**25) Synthesis of 2-Phenylbenz[*f*]isoindolin-1-on.** — From the reaction mixture of 2-naphthaldehydeanil (4.0 g.) and carbon monoxide there separated crystals which were recrystallized from alcohol into scaly crystals (1.5 g.), m. p. 254°C.

*Anal.* Found: C, 83.55; H, 5.05; N, 5.28. Calcd. for $C_{18}H_{13}ON$: C, 83.38; H, 5.01; N, 5.40%.

The unreacted 2-naphthaldehydeanil (2.2 g.) was recovered from the filtrate after removal of catalyst and benzene.

**26) Oxidation of 2-Phenylbenz[*f*]isoindolin-1-on.** — The crystal (0.5 g.) was dissolved in 30 ml. of boiling glacial acetic acid, and sodium bichromate added in portions until the color of bichromate ion no longer disappeared. After cooling the reaction mixture was poured into a large quantity of water, yielding white crystals, which

# *Studies on the High Pressure Reaction of Carbon Monoxide. III. Reaction between Azocompounds and Carbon Monoxide**

By Shigeki HORIIE** and Shunsuke MURAHASHI

(Received July 3, 1959)

As was reported in Part I of this series, reaction of synthetic gas with Schiff base and with azobenzene principally results in reduction of "C=N" and "N=N" linkage. In the case of azobenzene, however, the principale product aniline was accompanied with a considerable amount of diphenylurea, indicating that azobenzene had reacted in some way with carbon monoxide in the presence of cobalt carbonyl[1]. During the study of the mechanism of diphenylurea-formation, the authors found another new reaction of carbon monoxide, that is, azobenzene gave indazolone and quinazolone by the reaction with carbon monoxide.

The authors wish to report in this paper on the formation of indazolone and quinazolone by the new reaction.

Azobenzene and 100~200 atmospheric pressures of carbon monoxide were heated at 220~230°C in the presence of cobalt carbonyl in aromatic hydrocarbon solvents such as benzene and xylene, resulting in the formation of 3-phenyl-2, 4-dioxo-1, 2, 3, 4-tetrahydroquinazoline (II) (69.2%) (for which, the authors later on will use an abridged expression, quinazolone or quinazolones in general). When the reaction was carried out at the temperature range of 170~190°C, 49.1% of 2-phenylindazolone (I) was obtained.

2-Phenylindazolone thus obtained was reacted again with carbon monoxide according to the condition used for the formation of quinazolone (230°C), yielding a high yield of quinazolone (II) (81.8%). Hence 2-phenylindazolone (I), is considered as an intermediate product in the formation of quinazolone (II) from azobenzene.

Since the formation of 2-phenylindazolone from azobenzene and carbon monoxide was expected from the analogy of formation of phthalimidine from benzaldehydeanil and carbon monoxide, product I was synthesized from another route that is, an azo compound was synthesized by the condensation of anthranilic acid amide and nitrosobenzene, hydrogenated to hydrazo-compound, and then deaminated to 2-phenylindazolone and identified***.

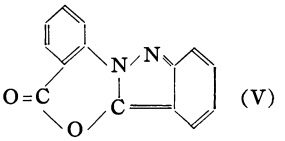
*** The author synthesized 2-phenylindazolone starting from anthranilic acid amide according to the method of Auwers and Hüttenes[2].

2) K. V. Auwers and K. Hüttenes, *Ber.*, **55**, 2680 (1922).

Identification of 3-phenyl-2, 4-dioxo-1, 2, 3,-4-tetrahydroquinazoline (II) was carried out in the series of reactions which follows: compound II was dissolved in 10% aqueous solution of sodium hydroxie, and was hydrolyzed by boiling the solution for 2~3 hr. to yield anthranilic acid (III) almost quantitatively. Alcoholic potassium hydroxide decomposed compound II to *o*-carboxydiphenylurea (IV), which coincided with the known sample obtained from anthranilic acid and phenylisocyanate. Moreover, compound IV was converted to quinazolone (II) either by fusion of IV or by saturating the alcoholic solution of IV with dry hydrogen chloride.

Compound II was definitely identified as 3-phenyl-2, 4-dioxo-1, 2, 3, 4-tetrahydroquinazoline by comparing with the authentic sample that was synthesized from authranilic acid and phenylurea[3].



It was found that this new reaction was of value for the synthesis of large varieties of quinazolone derivatives to be elucidated later.

A survey of literatures reveals that the synthetic study of 2-phenylindazolone was meager and the yields were usualy rather low. Although at present our method does not allow high yield of indazolone selectively, being always accompanied with quinazolone and diphenylurea, the method is yet promising for the synthesis of indazolones.

Details of the scope of the reactions with varieties of azobenzene derivatives is described below. Generally, the reaction did not take place in the absence of catalysts. The effective catalysts are iron carbonyl, cobalt carbonyl, or cobalt compound, such as metallic cobalt, cobalt soap, and organic cobalt complex that can be converted into cobalt carbonyl under the reaction condition. Nickel carbonyl did not promote the reaction****. The solvents are preferably aromatic hydrocarbons, such as benzene, toluene, and xylene. The presence of polar substances such as water and alcohol inhibits the reaction[4]. The reaction temperature is preferably in the range of 220~230°C. Below 200°C the proportion of indazolone, which is the intermediate to quinazolone, was pre dominant. Initial charge of carbon monoxide pressure of 100 atmospheric pressures is sufficient for the reaction. As oxygen decomposes the catalyst, it needs to be excluded from the system.

Since quinazolone(III)affords by hydrolysis anthranilic acids in a good yield, the reaction leads to a new and important preparative route of anthranilic acid.

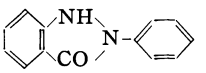
As another by-product in this reaction besides diphenylurea, lactone of 2-(3-hydroxyindazol-2-yl)-benzoic acid (V)[5], and a neutral crystalline substance that has the melting point of 165°C, were obtained. The structure of the latter substance is now under study.

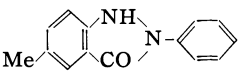
Next, the authors took up the problem of viewing the scope and the extent of this reaction. For this purpose azobenzenes and various kinds of compounds, which seem to be related, were subjected to the reaction. Table II shows the results on the formation of indazolones from substituted azobenzenes RN=NR′, and Table III shows the results of quinazolone-formation. As will be seen from the

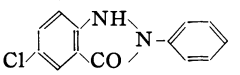
3) F. Kunckell, *Ber.*, 43, 1234 (1910).

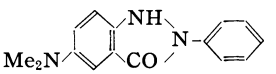
**** The content of the study was presented at the Meeting of Yūkigōsei-kyokai, November, 1955. In the following year 1956, Prichard and others published a patent (U. S. Pat. 2,769,003), in which they claimed that the reaction of azobenzene with nickel carbonyl yielded mainly lactone of 2-(3-hydroxyindazole-2-yl) benzoic acid being accompanied with small amount of quinazolone and diphenylurea.

4) The effects of various solvents on the reaction will be published in detail in the next paper.









5) The lactone (V) was proved to be identical to the one that was obtained from azobenzene and nickel carbonyl according to the process of Prichard and others.

TABLE I. SYNTHESIS OF QUINAZOLONE*

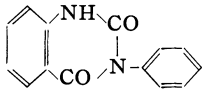
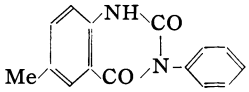
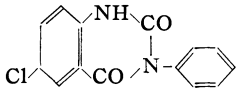
Azo-compound, 5 g.; $[Co(CO)_4]_2$, 0.05 m mol/cc.; CO 150 atm.; solvent, benzene; reaction temperature, 180~190°C; reaction time, 2 hr.; reaction vessel, a 100 ml. rocking autoclave made of 18:8 stainless steel.

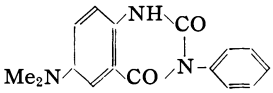
tables, the reaction can be applied to various derivatives of azobenzenes. It is interesting to note here that when one of the benzene ring has a substituent of electron-repelling character, the ring closure always occurs on the side of the nucleous having the substituent and where the substituent is electron-attracting the reaction does not take place. This fact suggests strongly that electronegativity of the nitrogen atom, which seems to be the site for the primary act of catalyst, is deeply influenced by these substituents.

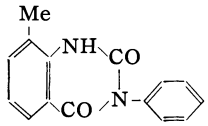
The formation of 3-phenyl-2, 4-dioxo-1, 2-3, 4-tetrahydroquinazoline from indazolone is a new reaction, where a five membered ring was enlarged to a six-membered ring under the incorporation of a carbon monoxide molecule. This reaction appears to be formally quite similar to the formation of diphenylurea from hydrazobenzene.

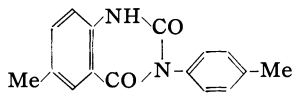


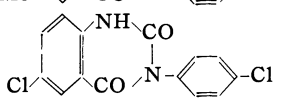


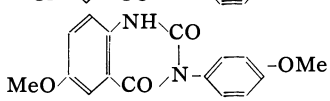


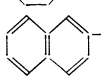


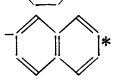












To obtain a further information of the reaction the authors studied several ring compounds with a 5-membered ring under the same condition described as above. Indazol[6], indazolone[6], 2-phenyl-benzoxazol[7] and 2-phenyl-benzimidazole[8] were tested for this purpose. But none of them was found to be feasible for the ring enlargement.

A pyridine and a quinoline derivative, VI and VII[9], which are closely related to

* A small amount of dinaphthylurea was formed.

benzaldehydeanils were studied also under the similar condition.

(VI)

(VII)

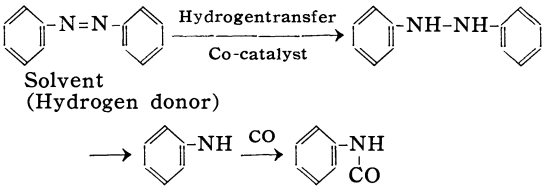
In both cases, reactions took place with an uptake of carbon monoxide, but the reaction products thus obtained were colored deep violet-red and unstable solid and could not be crystallized into definite products.

In all cases quinazolone derivatives obtained gave, in good yield, anthranilic acid derivatives. (see *Experimental*)

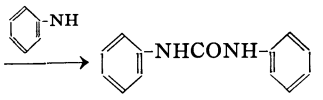
### On the By-product of the Reaction

As an example shows the following reaction products were obtained by the reaction where benzene was used as the reaction medium.

| | |
|---|---|
| Quinazolone | 64.1% |
| Diphenylurea | 17.2% |
| Lactone | 3.1% |
| Neutral substance | a small quanity |
| Aniline | 〃 |

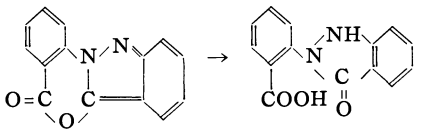


The formation of diphenylurea is significant, and so it would be necessary to learn the cause of its formation and to minimize its formation so as to obtain a complete information on the reaction and to improve the yield of quinazolone. From the result of the experiments it was shown that the formation of diphenylurea could not be observed in the decomposition reaction of quinazolone, and so was the quinazolone formation from diphenylurea and carbon monoxide. Hence it may be concluded that these two reaction products originate from different reaction courses.



In order to account for the formation of diphenylurea from azobenzene, it is necessary for azobenzene to get one mole of hydrogen from somewhere, since the reactions are carried out with carbon monoxide alone in an anhydrous condition, none of the hydrogen atoms were available except from solvent molecules.

According to the gaschromatographic analysis of carbon monoxide used, the hydrogen in the gas was found to be 0.1% or less, and this quantity was proved to be too low to balance the urea-formation. Therefore, it was considered that solvent molecules are responsible for hydrogen supply. As an approach to this question various solvents were tested, including cyclohexane, *n*-hexane, dioxane, ether, acetonitrile, ethylalcohol, benzene, and naphthalene. Among these, cyclohexane found to produce diphenylurea in much abundance as campared to benzene and the same is also held in a comparison of *n*-hexane and benzene.



In both of the cases the quantity of urea and also the proportion of urea to quinazolone were increased. These seem to show that the solvent had contributed to the formation of urea by giving up its hydrogen necessary for the formation of urea.

As was described earlier in Part I of this series, the formation of urea was easier by hydrazobenzene than by azobenzene. From this and other facts in early parts of this paper, the authors tentatively propose the possible formation of urea derivatives as to proceed according to the following scheme:

The presence of this lactone [2-(3-hydrooxyindazol-2-yl) benzoic acid lactone] was easily confirmed through its hydrolysis and fomation of 2-(*o*-carboxyphenyl) indazolone. Prichard[10] obtained it by the reaction of azobenzene and carbon monoxide in the presence of nickel carbonyl catalyst and the authors' product was proved to be identical with this.

As was previously stated, the formation of quinazolone is strongly favored in the presence of cobalt catalyst in benzene solution, and the reaction proceeded via indazolone derivative as the intermediate. The same reaction failed when nickel carbonyl was used in a benzene solution.

Prichard has disclosed in his patent that he could observe the formation of this lactone as the main product and of small amount of quinazolone as a by-product, when nickel carbonyl was used as the catalyst in a cyclohexane solution. But, he did not observe anything about the intermediate formation of indazolone.

From the differences of reaction conditions including solvent and of the products which were formed, in quantity as well as in quality, it might be appropriate to conclude that the approach to quinazolone in the authors' experiments was not the same as that of Prichard.

It is well known that cobalt carbonyl is readily convertible to hydrocarbonyl, and so the very nature would be responsible for a hydrogen-transfer reaction. On the other hand, it is not known that nickel carbonyl possesses such a behavior of easy conversion to hydrocarbonyl and such a difference of the property between these two catalysts would be the main cause of differences observed in the authors' and Prichard's results. The authors will consider in detail this point later.

## Experimental

**1) Synthesis of 2-Phenylindazolone by the Reaction of Azobenzene with Carbon Monoxide.** —A solution of azobenzene (5 g.) and cobalt

10) W. W. Prichard, U. S. Pat., 2,769,003 (1956).

carbonyl (1 g.) in benzene (25 ml.) was placed in an autoclave of 100 ml. capacity made of 18:8 stainless steel, and carbon monoxide was charged in up to 150 atmospheric pressures. The autoclave was heated at 180~190°C for 4 hr. under constant shaking. After being cooled, a crystalline substance in the reaction mixture was filtered (3.0 g.). From the filtrate, after removal of catalyst by refluxing on a water bath followed by filtration and removal of benzene, 1.5 g. of azobenzene was recovered. The crystalline substance was treated with 5% aqueous solution of sodium hydroxide, and filtered. The insoluble crystals were to be mainly of diphenylurea (0.65 g., 16%) containing, as contamination, some amount of yellow crystals, which were found to be lactone of 2-(3-hydroxyindazol-2-yl) benzoic acid, m. p. 296°C. Diphenylurea was recrystallized from alcohol (m. p. 240°C) and identified by the mixed melting point test with the sample prepared by an alternative way. The alkaline solution was acidified by either carbon dioxide, hydrochloric acid, or sulfuric acid, and a white crystalline substance separated. The crystalline substance, after filtration, was recrystallized from alcohol, yielding 0.8 g. of quinazolone (17.5%) as the insoluble part and 2.8 g. of 2-phenylindazolone (49.1%) as the soluble part. The latter were colorless needles, m. p. 204°C, and identified by the mixed melting point test with the sample synthesized as described below.

*Anal.* Found: C, 74.03; H, 4.82; N, 13.55. Calcd. for $C_{13}H_{10}N_2O$: C, 74.28; H, 4.76; N, 13.33%.

**2) Synthesis of 2-Phenylindazolone.**—Anthranilic acid was converted to isatoic anhydride[11], which was then treated with 20% aqueous ammonia, and converted to anthranilic acid amide[12] and was used as the starting material of this synthesis. Into a solution of anthranilic acid amide (8.0 g.) in 100 ml. of acetic anhydride, freshly distilled nitrosobenzene[13] (6.2 g.) was added in small portions. The mixture, after being kept at room temperature overnight, was diluted with equal volume of alcohol, and refluxed. Under vigorous stirring zinc powder (20 g.) was added portionwise. The red color of the solution faded out completely after about 1.5 hr. The solution was filtered and poured into a large quantity of water. The separated crystals were filtered off, and recrystallized from alcohol to yield pure 2-phenylindazolone (3.0 g.), m. p. 202~204°C.

**3) Synthesis of 3-Phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline by the Reaction of 2-Phenylindazolone with Carbon Monoxide.**—A mixture of 2-phenylindazolone (2 g.), cobalt carbonyl (1.0 g.) and benzene (50 ml.) was caused to react with 150 atmospheric pressures of carbon monoxide at 230°C for 2 hr. The crude crystals, that were obtained by filtering the reaction mixture after cooling, was recrystallized from alcohol to yield 1.8 g. of pure II (81.8%). Identification was carried out by the melting point test with a known sample.

*Anal.* Found: C, 70.29; H, 4.12; N, 11.66. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.20; N, 11.76%.

**4) Synthesis of 3-Phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline by the Reaction of Azobenzene with Carbon Monoxide.**—(i) A mixture of azobenzene (5.0 g.), cobalt carbonyl (2.0 g.) and benzene (45 ml.) was reacted with 150 atomspheric pressures of carbon monoxide at 220~230°C for 0.5 hr. After cooling, a crystalline mass (5.2 g.) in the reaction mixture was filtered off. The filtrate was refluxed on a water bath to effect the decomposition of the catalyst, and removed from inorganic substance by filtration. Yellow crystals, lactone of 2-(3-hydroxyindazol-2-yl) benzoic acid (0.1 g.) was obtained as a comparatively soluble part in benzene. The crystalline mass obtained above was treated with cold 5% aqueous solution of sodium hydroxide[14]. As the insoluble residue, diphenylurea (0.7 g., 12.1%) was obtained, and white crystals precipitated from the alkaline solution by acidifying (pH 4.0) with either carbon dioxide, hydrochloric acid, or sulfuric acid. The crystal was recrystalized from alcohol in colorless needles, m. p. 275°C, which was identified as 3-phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline by the mixed melting point test with the authentic sample.

*Anal.* Found: C, 70.63; H, 4.18; N, 11.90. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.20; N, 11.76%.

(ii) A mixture of azobenzene (5.0 g.), iron carbonyl (3.0 g.) and benzene (50 ml.) was heated with 180 atmospheric pressures of carbon monoxide at 240°C for 4 hr. to yield 3-phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (0.8 g., 12.3%).

(iii) A mixture of azobenzene (5.0 g.), acetylacetone cobalt complex (1.0 g.), and benzene (50 ml.) was heated with 150 atmospheric pressures of carbon monoxide at 240°C for 5 hr. to yield 3-phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (1.9 g., 29.2%).

(iv) A mixture of azobenzene (5.0 g.), cobalt stearate (2.0 g.) and benzene (50 ml.) was reacted with 160 atmospheric pressures of carbon monoxide at 230°C for 2.5 hr. to yield 1.9 g. of 3-phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (29.2%).

**5) Hydrolysis of 3-Phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline by Sodium (or Potassium) Hydroxide.**—A solution of quinazolone (2.0 g.) in 10 ml. of 10% sodium (or potassium) hydroxide was refluxed. After 20 min. an oil began to separate, and the mixture was kept boiling for 2.5 hr. After cooling, aniline was removed by extraction with a small amount of ether. The aqueous solution was neutralized to pH 4.0 by diluted hydrochloric acid, and then a white solid precipitate was formed, which was filtered off, washed with water, and dried to yield 0.95 g. of gray crystalline anthranilic acid, m. p. 140°C (86.4%). Identification of the anthranilic was

carried out by the mixed melting point test with a known sample.

The filtrate gave by the addition of copper acetate 0.2 g. of copper anthranilate, which corresponds to 0.16 g. of anthranilic acid (10.1%).

**6) Hydrolysis of 3-Phenyl-2, 4-dioxo-1, 2, 3, 4-tetrahydroquinazoline by Alcoholic Potassium Hydroxide.**—A solution of quinazolone (2 g.), potassium hydroxide (8 g.) and 96% alcohol (40 ml.) was refluxed for 20 hr. After removal of alcohol, the residue was dissolved in water and acidified by concentrated hydrochloric acid, when a white solid precipitated. The solid was recrystallized from alcohol yielding as the insoluble part the recovered quinazolone (0.4 g.) and as the soluble part colorless needles, *o*-carboxydiphenylurea (0.8 g., 46.5%). The latter compound was identified by the mixed melting point test with a known sample prepared in the following manner.

*Anal.* Found: C, 65.28; H, 4.70; N, 10.86. Calcd. for $C_{14}H_{12}N_2O_3$: C, 65.62; H, 4.68; N, 10.93%.

**7) Synthesis of *o*-Carboxydiphenylurea.** — A solution of anthranilic acid (2 g.) in dry ether (10 ml.) and a solution of phenylisocyanate (1.8 g.) in dry ether (10 ml.) were combined under ice-cooling and stood at room temperature overnight. Crystals were filtered off and recrystallized from alcohol in colorless needles, *o*-carboxydiphenylurea (3.4 g., 90%), m. p. 187~188°C.

*Anal.* Found: C, 65.60; H, 4.72; N, 10.81. Calcd. for $C_{14}H_{12}N_2O_3$: C, 65.62; H, 4.68; N, 10.93%.

**8) Synthesis of *o*-Carboethoxydiphenylurea.**—Ethyl anthranilate (2 g.) was added gradually into phenylisocyanate (1.5 g.). The reaction was vigorously exothermic. The mixture was heated on a boiling water bath for about 0.5 hr. and the solid thus formed was recrystallized from alcohol in colorless needles, *o*-carboethoxydiphenylurea (3.3 g., 94.3%), m. p. 148°C.

*Anal.* Found: C, 67.30; H, 5.31; N, 10.15. Calcd. for $C_{16}H_{16}O_2N_3$: C, 67.60; H, 5.63; N, 9.86%.

**9) Synthesis of 3-Phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (II).**—(i) *o*-Carboxydiphenylurea (1.0 g.) was heated for 30 min. at 190°C which is slightly above its melting point. The reaction mass was recrystallized from alcohol in colorless needles, II (0.05 g.), m. p. 273~275°.

(ii) When dry hydrogen chloride was introduced into a solution of *o*-carboxydiphenylurea (1.0 g.) in alcohol (30 ml.) at room temperature (20°C), the temperature of the content rose up to 30~40°C. Introduction of hydrogen chloride was continued for a while and the mixture was kept standing, and then colorless scaly crystals were formed. The crystals, after removal of alcohol and hydrogen chloride, were recrystallized from alcohol into colorless needles (0.9 g., 96.8%), m. p. 274~275°C.

(iii) *o*-Carboethoxydiphenylurea (0.2 g.) was heated at 200°C for 3 hr. in a sealed glass tube. After cooling, the reaction product was solidified at the bottom of the tube and the unreacted starting material was sublimed off on the upper wall of the tube. The product was recrystallized from alcohol into colorless needles (0.03 g., 18.1%), m. p. 273°C.

(iv) A mixture of anthranilic acid (5.0 g.) and phenylurea (5.0 g.) was heated at 200°C for 5 hr. in a sealed glass tube. The reaction product was treated with 100 ml. of 5% sodium hydroxide to remove the insoluble phenylurea. The alkaline solution was acidified by diluted hydrochloric acid, precipitating white crystalline acidic substance which was recrystallized from alcohol into colorless needles (2.5 g., 28.6%), m. p. 274°C.

TABLE IV. FORMATION OF ANTHRANILIC ACIDS FROM QUINAZOLONES

| R | R' | g. | R | Yield g. | Yield % | m. p. °C |
|---|---|---|---|---|---|---|
| H | H | 2.2 | H | 1.1 | 95.6 | 145 |

**10) Reaction of α-Styrylpyridine and Carbon Monoxide.**—A solution of 3 g. of α-styrylpyridine and 1 g. of dicobalt octacarbonyl in 20 ml. of benzene was heated at 135~145°C under 130 atmospheric pressures of carbon monoxide for one hour to give 1 g. of amorphous product. This product was extracted with dimethylformamide and a reddish purple-colored amorphous substance melted at 200~250°C was obtained.

*Anal.* Found: C, 68.03; H, 5.24; N, 6.59; ash, 11.43%.

A similar experiment with α-styrylquinoline has failed to obtain any definite crystalline product, but resins.

**11) Effect of Solvents.**—For the purification of both naphthalene and *p*-dichlorobenzene, they were recrystallized from ethyl alcohol, and the crystals melting at 80 and 53°C respectively were collected.

Carbon tetrachloride and *n*-butylacetate were carefully fractionated and the fractions boiling at 76 and 126°C respectively were collected. Other solvents such as *n*-hexane, cyclohexane, benzene, toluene, tetraline, dioxane, ether, tetrahydrofuran, chlorobenzene, acetonitrile and ethylalcohol are, after drying over metallic sodium, fractionated. The fractions boiling at 69, 81, 80, 110, 207, 102, 34, 64, 122, 81 and 78°C respectively were collected.

**12) Reaction of Hydrazobenzene and Carbon Monoxide.**—A solution of 2 g. of hydrazobenzene and 1 g. of dicobalt octacarbonyl in 30 ml. of benzene was heated at 220~230°C under 120 atmospheric pressures of carbon monoxide for 4 hr. to give 0.95 g. of diphenylurea (41.3% yield) and 0.2 g. of 3-phenyl-2, 4-dioxo-1, 2, 3, 4-tetrahydroquinazoline (7.7% yield).

# *Synthetic and Analytical Studies on Color Reagents. VIII. o-Halogeno-o'-hydroxyazo Compounds*

By Tadashi IWACHIDO*, Haruo MIYATA and Kyoji TOEI

(Received July 3, 1959)

In the previous papers[1-5], a series of *o*-substituted-*o'*-hydroxyazo compounds, having various groups in ortho position were synthetized and their identification limits for various metal ions were determined, and thus the usefulness of these reagents for metal indicators and colorimetric reagents was discussed.

The present paper describes the preparation of *o*-halogeno-*o'*-hydroxyazo compounds and their identification limits for calcium, magnesium and thorium. Especially absorption spectra of *o*-halogenophenylazo-chromotropic acids and their magnesium complexes are determined, and the relation between the absorption spectra and their structures is discussed.

## Experimental

**Syntheses of Reagents.**—*o*-Iodoaniline was prepared by the method of Baeyer[6]. *o*-Iodonitrobenzene was prepared from diazotized *o*-nitroaniline with iodine-potassium iodide solution, and then it was converted into *o*-iodoaniline by the reduction with stannous chloride and purified by the steam distillation. White needles, m. p. 59.5~60°C.

*o*-Bromoaniline[7] was obtained by the reduction of *o*-bromonitrobenzene which was prepared by Sandmeyer's reaction of diazotized *o*-nitroaniline, m. p. 33°C.

*o*-Chloroaniline and aniline were reagent grade products and *o*-fluoroaniline was kindly supplied from Dr. K. Inukai**.

Aniline and *o*-halogenoanilines were dissolved in 6 N hydrochloric solution respectively, cooled in ice, diazotized with an equivalent weight of sodium nitrite, and filtered off when necessary. Coupling reaction had to be carried out immediately. The stability of these diazonium salt solutions seems to decrease in the order of *o*-fluoro-, chloro-, bromo- and iodoaniline.

β-Naphthol, 2-hydroxy-3-naphthoic acid, Scheffer's acid and R-acid were dissolved in about 1 N sodium hydroxide solution, N-W-acid and chromotropic acid in a solution of sodium acetate and G-acid in concentrated aqueous ammonia. These solutions were separated from any insoluble matter by filtration, and then cooled below 5°C. Coupling reaction was carried out by adding the diazonium salt solution into the cooled naphthol or naphtholsulfonic acid solution and the azo compound thus obtained was recrystallized from acetic acid or dilute hydrochloric acid.

**Identification Limits.** — Identification limits for calcium, magnesium and thorium were determined by the method of the previous paper[1]. The reagents coupled with β-naphthol or G-acid indicate no color change with concentrations of 50 γ/ml. magnesium, calcium and thorium, whilst those with Scheffer's acid or N-W-acid change a little or not at all. The identification limits of the reagents coupled with R-acid, 2-hydroxy-3-naphthoic acid and chromotropic acid are relatively low. R-acid reagents do not indicate any color change for 50 γ/ml. thorium, but the identification limits for calcium and magnesium are 5~50 γ/ml. Reagents prepared from 2-hydroxy-3-naphthoic acid for magnesium, calcium and thorium have a limit of 0.1~25 γ/ml. and those from chromotropic acid 0.1~10 γ/ml.

Identification limits of one series of these reagents increase with the atomic weight of the halogen atom at the ortho position. But the values for magnesium and calcium are far greater than those of *o,o'*-dihydroxyazo compounds[1], and are almost the same as those of *o*-trifluoromethyl- or *o*-methyl-*o'*-hydroxyazo[4] and *o*-sulfo-*o'*-hydroxyazo compounds[3]; for thorium they are larger than those of *o*-arsono-*o'*-hydroxyazo compounds[5].

**Absorption Spectra of *o*-Halogenophenylazo-chromotropic Acids and their Magnesium Complexes.** — *Reagent solution.* — The reagents being very hygroscopic, they were dried at 110°C in weighing bottles, cooled in phosphorus pentoxide desiccator, and weighed. A $2.5\times10^{-4}$ mol./l. solution was prepared and stored in the dark.

A 0.25 M magnesium sulfate solution was made from recrystallized $MgSO_4\cdot7H_2O$.

*Procedure and apparatus.*—A series of the reagents and their magnesium complex solutions of varying pH were prepared in the following manner. All solutions were made in a dark room, for the absorption of reagents was retarded by the daylight, especially at a higher pH.

Five milliliters of the reagent solution was placed in a 50 ml. volumetric flask, followed by addition of an adequate volume of 1 N hydrochloric acid, 1 M aqueous ammonia, 1 M ammonium chloride or 0.1 N sodium hydroxide to adjust the pH to the desired value and then the volume was made up to 50 ml. with water.

Magnesium complex solutions were similarly prepared with 5 ml. of 0.25 M magnesium sulfate solution. Above pH 11, magnesium hydroxide

was formed, so the determination could not be made. The pH was measured with Shimadzu Glass Electrode Model GU-1 pH meter and the absorbancy with Shimadzu Spectrophotometer QR-50 type, with 1 cm. cells. Absorption spectra over various pH values are shown in Figs. 1—5.

## Results and Discussion

**Spectral Properties of the Reagents.**—Between pH 2 and 6, the same reagent gives the identical absorption spectra having two absorption maxima at 510~520 and 530~540 mμ (Fig. 1—5). It is considered that electrolytic dissociation of naphtholic OH does not occur. Above pH 7, these maxima shift to form one maximum (at pH≧12) with increasing pH.

From the presence of an isosbestic point in each figure, two structures are expected, and from the electrolytic dissociation of chromotropic acid[8,9] the following structures are presented.

8) H. Zollinger and W. Büchler, *Helv. Chim. Acta*, **34**, 591 (1951).
9) J. Heller and G. Schwarzenbach, ibid., **34**, 1876 (1951).

X=H, F, Cl, Br and I.

Formula I corresponds to the acidic form and II exists at pH more than 12. Azo grouping seems to be *trans*-form. Structure I has two hydrogen bridges; the one between *peri*-oxygen atoms is too strong to dissociate even at pH 12, but the other begins to dissociate at pH 7~8 and completely dissociates at pH 12 to give II. Formula I has a higher co-planarity than formula II.

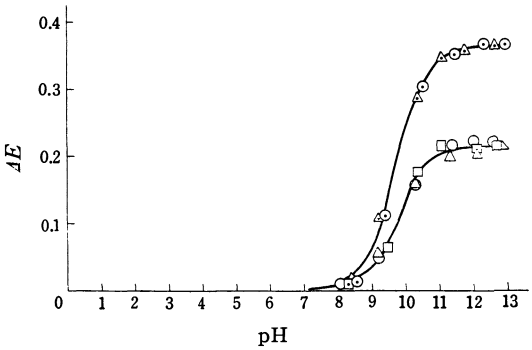

Fig. 6. Relationship between pH and absorption differences at 510 mμ.
⊙, *o*-H-compound; △, *o*-F-compound;
○, *o*-Cl-compound; △, *o*-Br-compound;
□, *o*-I-compound.

Absorption differences at 510 mμ are plotted against pH (Fig. 6). There are two series; the one consists of *o*-hydrogen and *o*-fluoro-compounds, and the other *o*-chloro, *o*-bromo and *o*-iodocompounds. The difference seems to spring from steric hindrance. Namely, in formula II, *o*-halogenophenyl group and chromotropic acid can rotate around each single bond of N-C axis, and hydrogen and fluorine atoms at ortho position are not hindered, but chlorine, bromine and iodine atoms are hindered by the sulfonic group of chromotropic acid according to Stuwart model.

**Spectral Properties of Magnesium Complexes.** —Absorption curves of the mixtures of the reagent and the magnesium solutions are the same as those of the reagent over pH 2~6. This indicates that magnesium complexes can not be formed in an acid medium. Absorption maxima of magnesium complexes at a higher pH are shifted to longer wavelength and to higher absorbancy with increasing amount of magnesium, and thus 1000 times magnesium

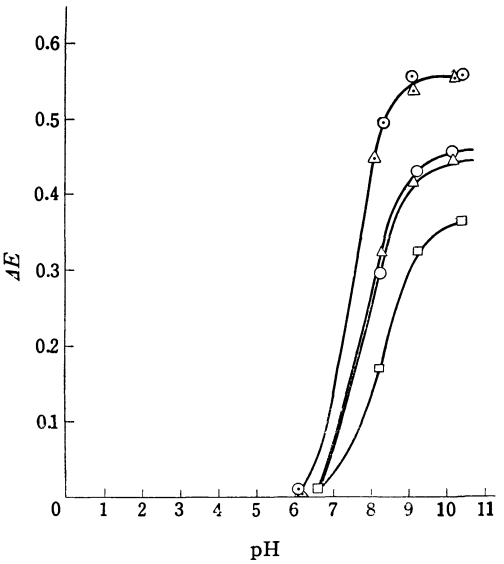

Fig. 7. Relationship between pH and absorption differences at 570 mμ.
⊙, *o*-H-complex; △, *o*-F-complex;
○, *o*-Cl-complex; △, *o*-Br-complex;
□, *o*-I-complex.

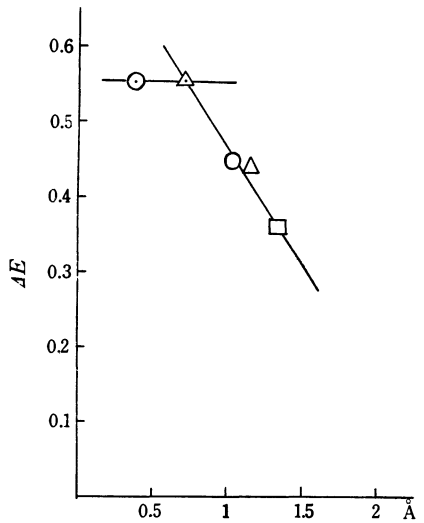

Fig. 8. Relationship between covalent radii of halogen atoms and absorption differences of magnesium complexes at 570 mμ.

○, *o*-Cl-complex; △, *o*-Br-complex;
□, *o*-I-complex.

was used for the measurement (broken lines in Figs. 1—5).

Absorption differences at 570 mμ are plotted against pH (Fig. 7) and against covalent radii of halogen atoms[10,11](Fig. 8). Absorption differences of *o*-hydrogen and *o*-fluoro-complexes are the same, and the others decrease with the atomic weight of halogen atoms. This also means the presence of steric hindrance.

The authors wish to express their thanks to Professor M. Ishibashi and Professor K. Emi for their encouragement. Also the authors express hearty thanks to Dr. K. Inukai who kindly supplied *o*-fluoroaniline.

# *Spectrochemical Study of Microscopic Crystals. XX*[1]*. The Dichroism of Tris(ethylenediamine)-cobalt(III) and -chromium(III)*[2]

By Shoichiro YAMADA and Ryutaro TSUCHIDA

(Received July 21, 1959)

Knowledge about the electronic state of metallic complexes is important in understanding theoretically their optical activity, which is quite well-known in the history of the chemistry of coordination compounds. Since the dichroism is closely related to the electronic state of the metallic compounds, the experimental determination of the dichroism with tris-(ethylenediamine)-cobalt(III) and -chromium(III) ions is thought to be useful for elucidating the optical rotatory dispersion as well as the electronic state of the metallic coordination compounds.

In this work, the authors have determined the dichroism with tris(ethylenediamine)-cobalt(III) and -chromium(III) halides in the crystalline state and discussed about the results of the measurements in relation to the above problems.

## Experimental

**Materials.**—Crystals of *d,l*-$[Co\,en_3]Cl_3\cdot 3H_2O$ and *d,l*-$[Co\,en_3]Br_3\cdot 3H_2O$ were prepared according to the method of Grossman and Schück[3]. The hexagonal, prismatic crystals of the compound usually show the well-developed $(10\bar{1}0)$-plane[4]. The crystals show a discernible dichroism on the prism face; they are orange yellow with polarized light having its electric vector along the *c*-axis, and pale yellow with the electric vector perpendicular to the *c*-axis. The dichroism measurements were made on the well-developed prism face.

The optically active *d*-$[Co\,en_3]Br_3\cdot 2H_2O$ was prepared by resolution of the racemic *d,l*-$[Co\,en_3]\cdot Cl_3\cdot 3H_2O$ according to the method of Werner[5]. A slight but definite dichroism was observed under the microscope on the prism face (101), on which the dichroism measurement was carried out.

The racemic *d,l*-$[Cr\,en_3]Cl_3\cdot 3H_2O$ was prepared in yellow, hexagonal prismatic crystals by the method of Rollinson and Bailar[6]. The crystal of the compound appears to be isomorphous with that of *d,l*-$[Co\,en_3]Cl_3\cdot 3H_2O$. It appears yellow with the polarized light having its electric vector along the *c*-axis, and very pale yellow with the electric vector perpendicular to the *c*-axis. The dichroism measurement was carried out on the well-developed prism face.

**Measurements.**—Quantitative dichroism measurements in the visible and ultraviolet regions have been carried out at room temperature by Tsuchida and Kobayashi's microscopic method[7].

The symbols used in the present paper are the same as those in the former papers of this series. Thus the molar absorption coefficient, *K*, was estimated from the following expression: $K=10M\alpha/\rho$.

## Results

**Dichroism of the Tris(ethylenediamine)-cobalt-(III) Ion.**—The present dichroism measurements with $d,l$-$[Co\,en_3]Cl_3\cdot 3H_2O$ and $d,l$-$[Co\,en_3]Br_3\cdot 3H_2O$ are shown in Figs. 1 and 2, and Tables I and II. Formerly Kobayashi[7a] reported the absorption spectrum of tris(ethylenediamine)-cobalt(III) bromide trihydrate in the crystalline state using natural light. The absorption maxima determined in the present work agree with those formerly reported by Kobayashi, excepting for the region of the short wavelength. According to the crystal structure analysis[8], the $c$-axis in the crystal of $d,l$-$[Co\,en_3]Cl_3\cdot 3H_2O$ is found to be coincident with the threefold axis of the $[Co\,en_3]^{3+}$ ions. Although the crystal structure analysis of $d,l$-$[Co\,en_3]Br_3\cdot 3H_2O$ is not available at present, the bromide trihydrate presumably has the crystal structure of the same type as that of the chloride trihydrate. The $c$-absorption in Figs. 1 and 2, therefore, represents the $z$-absorption of the complex ion, that is, the absorption with the electric vector along the threefold axis of the complex ion.

$\nu$: $10^{13}\,sec^{-1}$.

From the present measurement, the following relationships are obtained about the dichroism of the $[Co\,en_3]^{3+}$ ion.

(1) For the band at about $64\times10^{13}\,sec^{-1}$ (469 mμ), the $z$-absorption of the complex ion is somewhat stronger than the $x$-absorption.

(2) For the band at about $88\times10^{13}\,sec^{-1}$ (341 mμ), the $x$-absorption is about 2.5

times stronger than the $z$-absorption. The $z$- and the $x$-absorption refer to the directions shown in Fig. 3.

The $[Co\,en_3]^{3+}$ ions in the crystal of $d,l$-$[Co\,en_3]Cl_3\cdot 3H_2O$ are subjected to the field formed by the surrounding ions. However, the dichroism, as here determined, may be assumed in approximation to represent the dichroism of the isolated $[Co\,en_3]^{3+}$ ion itself.

TABLE III. ABSORPTION MAXIMA OF $d$-$[Co\,en_3]Br_3\cdot 2H_2O$

| | $\nu$ | log $\alpha$ | $K$ | $\nu$ | log $\alpha$ | $K$ |
|---|---|---|---|---|---|---|
| $c$-Abs. | 63.9 | 1.54 | $9.07\times10^4$ | 88 | 1.27 | $4.86\times10^4$ |
| $a$-Abs. | 64.1 | 1.43 | $7.03\times10^4$ | 88 | 1.67 | $12.2\times10^4$ |

$\nu$: $10^{13}\,sec^{-1}$.

The dichroism with a crystal of $d$-$[Co\,en_3]Br_3\cdot 2H_2O$ is shown in Fig. 4 and Table III. The arrangement of the complex ions in the crystal of the optically active form is expected to be different from the arrangement in the crystal of its racemic compound, but the dichroism observed with $d$-$[Co\,en_3]Br_3\cdot 2H_2O$ is regarded to represent the main features of the dichroism characteristic of the $d$-$[Co\,en_3]^{3+}$ ion. Comparison of the dichroism of $d$-$[Co\,en_3]Br_3\cdot 2H_2O$ with the dichroism of $d,l$-$[Co\,en_3]Br_3\cdot 3H_2O$ indicates unanimously that the $c$- and the $a$-absorption of the former crystal represent, respectively, the main characteristics of the $z$- and the $x$-absorption of the $d$-$[Co\,en_3]^{3+}$ ion.

From the dichroism with the three compounds above presented, the following relationships may be induced about the dichroism of the $[Co\,en_3]^{3+}$ ion.

(1) For the first absorption band, the $z$-absorption is somewhat stronger than the $x$-absorption.

(2) For the second absorption band, the $x$-absorption is a few times stronger than the $z$-absorption. The polarization is more marked for the second absorption band than for the first band.

(3) The optically active form of the $[Co\,en_3]^{3+}$ ion exhibits the same type of dichroism as the dichroism shown by its racemic complex compounds.

**Dichroism of the Tris(ethylenediamine)-chromium(III) Ion.**—The result of the dichroism measurements with $d,l$-$[Cr\,en_3]Cl_3\cdot 3H_2O$ is shown in Fig. 5 and Table IV. The structure analysis of the crystal has not been reported as yet. The external form and optical property, however, are so closely similar to those of $d,l$-$[Co\,en_3]Cl_3\cdot 3H_2O$ that the crystal of the chromium(III) complex is supposed to be isomorphous with the crystal of the corresponding cobalt(III) compound. Therefore, the $c$-absorption in Fig. 5, the absorption with the electric vector along the $c$-axis, may be regarded as corresponding with the $z$-absorption of the complex ion. Based

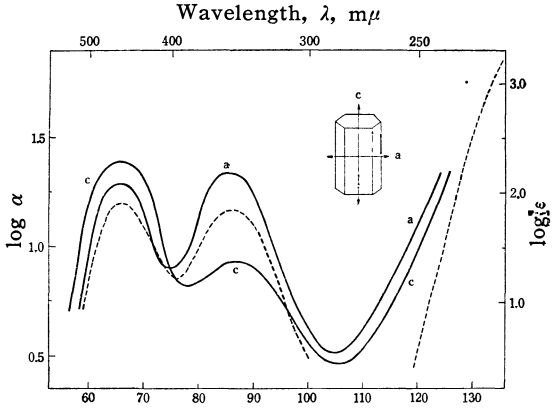

Fig. 5. Absorption spectra of $d,l$-$[Cr\,en_3]\cdot Cl_3\cdot 3H_2O$ in the crystallined state (——) and in solution (-------). The curve of the solution is taken from Ref. 14.

TABLE IV. ABSORPTION MAXIMA OF $d,l$-$[Cr\,en_3]Cl_3\cdot 3H_2O$

| | $\nu$ | log $\alpha$ | $\nu$ | log $\alpha$ |
|---|---|---|---|---|
| $c$-Abs. | 66 | 1.40 | 86 | 0.86 |
| $a$-Abs. | 66.3 | 1.25 | 85.6 | 1.24 |
| | $\nu$ | log $\varepsilon$ | $\nu$ | log $\varepsilon$ |
| Solution[a] | 65.6 | 1.90 | 85.5 | 1.84 |

a) M. Linhard, *Z. Elektrochem.*, **50**, 224 (1944).

$\nu$: $10^{13}\,sec^{-1}$.

on this assumption of the arragement of the complex ions in the crystal, the following relationships are derived about the dichroism of *d,l*-$[Cr\,en_3]Cl_3 \cdot 3H_2O$.

(1) For the band at about $66 \times 10^{13}\,sec^{-1}$ (454 m$\mu$), the *z*-absorption is about 1.5 times stronger than the *x*-absorption.

(2) For the band at about $85.6 \times 10^{13}\,sec^{-1}$ (350 m$\mu$), the *x*-absorption is about 3 times stronger than the *z*-absorption.

These relationships are found to be of a similar type to those for the corresponding cobalt(III) complexes, as is expected from close similarity in absorption spectra between cobalt(III) and chromium(III) complexes in general. The similarity is also expected from consideration on the symmetry of the electronic state as well as the external form of the complex ions.

## Discussion

**Dichroism of the First and the Second Absorption Band.**—The $[Co\,en_3]^{3+}$ ion has symmetry $D_3$, but its spectrum shows that the effective symmetry is much higher and approximates $O_h$. Thus, the absorption curve bears a close resemblance to those of the hexammine-cobalt(III) complexes with $O_h$ symmetry. The ligand field around the $Co^{3+}$ in the $[Co\,en_3]^{3+}$ ion may be represented by the overall symmetry of $O_h$ with a trigonal field of $D_3$ symmetry as a small perturbation term. In the case of the hexammine-cobalt(III) ion, the absorption bands in the long wavelength region are forbidden owing to the $g \leftarrow\!\!|\!\!\rightarrow g$ selection rule, and become allowed in combination, with the vibrational motion of the complex. The $[Co\,en_2]^{3+}$ ion, however, has no center of symmetry, and the unsymmetrical field will allow the slight electric dipole transitions even in the absence of vibrational distortion.

The two absorption bands in the long wavelength region of the $[Co\,en_3]^{3+}$ ion correspond to those of the $[Co(NH_3)_6]^{3+}$ ion, which are due to the electronic transitions $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$. On grounds of energy[9] and from a consideration of the rotatory dispersion[10] of the $[Co\,en_3]^{3+}$ ion, the longer wavelength band around 4700 Å is ascribed to the transition $^1A_{1g} \rightarrow {}^1T_{1g}$ and the shorter wavelength band around 3400 Å to the transition $^1A_{1g} \rightarrow {}^1T_{2g}$, the complex ion being assumed to be approximately of $O_h$ symmetry. It is known that the chromium(III) complexes show absorption spectra quite similar to those of the corresponding cobaltic compounds. The first and the second absorption bands of the hexammine-chromium(III) ion are ascribed to the $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}$ transitions, respectively. On the basis of Moffitt's theory, the assignment is found to be in agreement with the rotatory dispersion of the chromium(III) complex ion[11].

In the $D_3$ group, species $A_{1g}$, $A_{2g}$ and E of the $O_h$ group go over into $A_1$, $A_2$ and E, respectively, whereas $T_{1g}$ splits itself into $A_2+E$ and $T_{2g}$ into $A_1+E$. In practice, the degeneracies of the threefold $T_{1g}$ or $T_{2g}$ levels in the hexammines are not perceptibly resolved in their ethylenediamine analogues. The splitting due to the $D_3$ symmetry in these complexes is quite small, as is seen from the present dichroism measurements. Thus the splitting, if any, of the first absorption band under the field of $D_3$ symmetry is found to be very small. Nevertheless the dichroism of the $[M\,en_3]^{3+}$ ion is surely due to the effect of the field with the $D_3$ symmetry.

It might be interesting to point out that the dichroism of the $[Co\,en_3]^{3+}$ and the $[Cr\,en_3]^{3+}$ ion agree, on the basis of the above-mentioned assignment of the absorption bands, with the selection rule which was given by Moffitt[10] from discussion taking only the symmetry of the ground and the excited electronic state into consideration and discarding vibrational modes of the complex ion. This agreement, however, may be rather fortuitous. For complete analysis of the ultraviolet dichroism, account is to be taken of the vibrational modes of the complex ions.

Recently Sugano and Tanabe[12] experimentally determined optical anisotropy with the chromium ruby, in which the field around the $Cr^{3+}$ ion is represented by $C_3$ symmetry and is quite similar to the field encountered in the $[Cr\,en_3]^{3+}$ ion. It was found from their measurements with the chromium ruby that for the first absorption band the *z*-absorption is stronger than the *x*-absorption, and that for the second band the *x*-absorption is stronger than the *z*-absorption, where the *z*- and the *x*-absorptions represent the absorption with polarized light having its electric vector along and perpendicular to the *c*-axis, respectively. This observation was shown to be in good agreement with

9) L. Orgel, *J. Chem. Phys.*, **23**, 1004 (1955) etc.
10) W. Moffitt, ibid., **25**, 1189 (1956).
11) J. P. Mathieu, *J. chim. phys.*, **33**, 78 (1936).
12) S. Sugano and Y. Tanabe, *J. Phys. Soc. Japan*, **13**, 880 (1958).

their theoretical interpretation, which also predicted the same type of dichroism for the $[Cr\,en_3]^{3+}$ and the $[Co\,en_3]^{3+}$ ion. This, however, is not the case with these complex ions. The present measurements indicate that the dichroism with the $[Cr\,en_3]^{3+}$ ion is reverse to the dichroism of thd chromium ruby. The difference in dichroism between the two types of the compounds show that the explanation for one case does not apply, at least in its original form, to the other. The dichroism with the $[Cr\,en_3]^{3+}$ ion may be understood, if this is assumed to belong, for some reason, to the case where the second term of $F_{2u}$ type in the expansion of the hemihedral perturbation field, $V_{trig}$, is much greater than the first term of $F_{1u}$ type in Sugano and Tanabe's treatment[13]. It is expected theoretically that the first term may be much larger than the second term in ordinary cases. The anomaly with the $[Cr\,en_3]^{3+}$ ion is not explained at present.

**Dichroism and Optical Rotatory Dispersion of the Complex Ions.**—The information about the dichroism of the complex ions is expected to be useful for the understanding of the rotatory dispersion[10]. The complex ions of the type here considered show two component absorptions corresponding to the "first absorption band", both of which may possibly be active, at least partly, in the optical rotation. In this case, superposition of the two inversive dispersions due to the component absorptions may be observed in the wavelength region of the first absorption band. In the tris(ethylenediamine)-cobalt(III) and -chromium(III), the splitting of the first absorption band is found from the present dichroism measurements to be quite small, so that the two sorts of Cotton effect due to the two components of the first band are not observed separately, but their superposition appears with only one maximum. On the other hand, the *d*-trioxalatochromate(III) ion shows in the wavelength region of the first absorption band a small, negative component of Cotton effect, in addition to a much larger component of a positive sign[11]. This may be explained qualitatively on the basis of the dichroism. The dichroism measurements, the details of which will be reported later, indicate that the $[Cr\,ox_3]^{3-}$ ion unambiguously shows two maxima at 51.0 and $51.8\times10^{13}\,sec^{-1}$, the splitting of the first band being much greater than in the tris-(ethylenediamine)-cobalt(III) or -chromium(III). The appearance of the small, negative component of Cotton effect may be understood, if it is assumed that the electronic transitions corresponding to the above two component absorptions give rise to Cotton effect of their own, the sign for one being reverse to the sign for the other.

**Comparison of the Crystal Spectra with the Spectra of the Solution.** — It is shown that difference is scarcely recognizable in maximum wavelength between the crystal and the solution. On the other hand, difference is observed in intensity of the first and the second absorption band, the difference being greater for the latter band than for the former. If the authors compare the average of $K_z$ and $K_x$, as the value for the crystal, with $10^3\varepsilon$, which is regared as representing absorption coefficient by the compounds of one formula weight in solution, the present measurements show that intensity is greater for the solution than for the crystal, even when reflection from the surface of the crystal is taken into account. The difference seems to be definite, though it is generally small. This is readily understandable, since the perturbation due to the solvent molecules apparently contributes to absorption coefficient in solution, whereas this kind of contribution to the intensity is lacking in the crystal. The Schwarzschild-Villiger effect might be responsible partly for the difference, but is probably very small in the wavelength region under consideration.

**Absorption Band due to Association of Ions.** —Linhard[14] formerly found a new type of absorption bands in addition to the first and the second absorption band with the tris(ethylenediamine)-cobalt(III) and -chromium(III) complexes in solution. The new absorption band, which appears in the region of wave length slightly shorter than the second absorption band, is found to become stronger as the concentration of the halide ion increases, and is regarded by Linhard and others as due to association of the halide ions with the $[M\,en_3]^{3+}$ ion. The absorption band of this kind is evidently observed in the absorption curves of the complexes in the crystalline state, as reported in the present measurement with a single crystal. The present

13) See Ref. 12. The present authors are indebted to Dr. S. Sugano for the suggestion concerning the difference between the chromium ruby and the complex ions examined in the present work.

14) M. Linhard, *Z. Elektrochem.*, **50**, 224 (1944).

measurements indicate that the tris-(ethylenediamine)-cobalt(III) complexes in the crystalline state show an absorption band in the region of longer wavelength than does $[Co\,en_3](ClO_4)_3$ in solution. Thus *d,l*-$[Co\,en_3]Br_3\cdot 3H_2O$ shows the band at about $100\times 10^{13}\,sec^{-1}$, which is seen to superpose partly on the shorter wavelength side of the second absorption band. The X-ray study shows that in the crystals of the racemic tris(ethylenediamine)-cobalt(III) chloride trihydrate a complex ion is surrounded by nine chloride ions at about 3.2 Å from a nitrogen atom of the complex ions. A similar arrangement of ions is expected for the racemic bromide trihydrate in the crystalline state. The present measurements, therefore, may be regarded as evidence for the view that the new band is due to association of the complex ion with the surrounding halide ions. It is interesting to note here that the interaction takes place at such a distance, which seems to be comparatively great for the interaction. This type of the group composed of the complex ion and the halide ions surrounding it was formerly established to exist from the measurements of rotatory dispersion[15] and absorption spectra with the complex compounds in solution[14].

From the present dichroism measurements, the following relationships are derived about the absorption band due to the association of the ions.

(1) This kind of absorption band lies in the case of the bromide at longer wavelength than in the case of the chloride.

(2) The absorption is stronger with the electric vector along the trigonal axis of the complex than with the electric vector perpendicular to the axis.

(3) The first or the second absorption band undergoes very little effect even when the association band shifts to a longer wavelength region.

(4) The chromium(III) complex shows the association band in much shorter wavelength region than does the corresponding cobalt(III) complex.

15) R. Tsuchida, *J. Chem. Soc. Japan (Nippon Kwagaku Kwaishi)* 58, 621 (1937).

The relationships 1, 3 and 4 are essentially the same as those obtained by Linhard[14] with the complexes in aqueous solution, and in agreement with Linhard's assumption that the association band be ascribed to the electronic transitions due primarily to the halide ions which are deformed under the field of the complex ion.

Since the halide ions without the specific field from the outside absorb in a shorter wavelength, it may be assumed that the absorption of the halide ions is displaced to a longer wavelength in the presence of the field by the complex ions as in the crystals of the compounds here examined. Rrelationship 4 shows that the $[Cr\,en_3]^{3+}$ ion has smaller effect upon the halide ions than has the $[Co\,en_3]^{3+}$ ion, being in agreement with Linhard's observation with the complexes in solution.

## Summary

The dichroism in the visible and ultraviolet region has been quantitatively determined at room temperature by Tsuchida and Kobayashi's microscopic method with a single crystal of *d,l*-$[Co\,en_3]Cl_3\cdot 3H_2O$, *d,l*-$[Co\,en_3]Br_3\cdot 3H_2O$, *d*-$[Co\,en_3]Br_3\cdot 2H_2O$ and *d,l*-$[Cr\,en_3]Cl_3\cdot 3H_2O$.

It has been found that the $[Co\,en_3]^{3+}$ and the $[Cr\,en_3]^{3+}$ ion show a similar type of dichroism. For both the complex ions, the *z*-absorption is slightly stronger than the *x*-absorption in the wavelength region of the first absorption band and much weaker than the *x*-absorption in the region of the second absorption band.

The results of the measurements are discussed in relation to the electronic state and the optical rotatory dispersion of the complex ions.

The present authors wish to thank Dr. S. Sugano of the University of Tokyo for helpful discussion and the Ministry of Education for a grant-in-aid.

# *L'effet photovoltaïque des halogénures d'argent*

Par Shinichi KIKUCHI, Hiroshi NOZAKI, Yushi HAMANO et Seiya SAKAINO

(Reçu le 10 juillet 1959)

Quand une électrode métallique est exposée à la lumière dans un liquide ou dans une solution convenable, il se produit un changement du potentiel d'électrode, qui s'appelle l'effet photovoltaïque. Ce phénomène qui s'appelle aussi l'effet Becquerel, d'après le nom de celui qui le mit en évidence, a été étudié par beaucoup de chercheurs[1]. Les raisons de cet effet peuvent être divisées en quatre catégories: a) l'électrode métallique exposée à la lumière donne le potentiel photovoltaïque sans aucun changement macroscopique; b) la réaction photochimique des matières colorantes ou d'autres substances sensibles à la lumière, couvrant l'électrode, donne le potentiel; c) le liquide ou la solution est la cause du potentiel photovoltaïque; d) le semiconducteur solide couvrant la surface du métal donne le potentiel. Le travail de Becquerel doit être classé dans la 2e catégorie, car il traite la production du potentiel par l'électrode d'halogénure d'argent mise dans la solution d'électrolyte. La présente étude doit être classée dans la 3e catégorie, car elle traite l'effet photovoltaïque dans la solution colloïdale d'halogénure d'argent. Sheppard et Vanselow[2] ont étudié en 1938 l'effet photovoltaïque de l'électrode d'halogénure d'argent dans la solution d'électrolytes et développé la théorie de la sensibilisation photographique à partir des résultats de cette étude. Mais le potentiel était de l'ordre de quelques millivolts à quelques dizaines de millivolts. D'ailleurs il était instable et non reproductible surtout quand il y a en suspension des grains d'halogénure d'argent. Nous avons donc adopté l'électrode de platine au lieu de l'électrode d'halogénures d'argent et l'avons mise dans la solution colloïdale d'halogénure d'argent. Dans ce cas le potentiel photovoltaïque était très grand et reproductible et nous a permis d'étudier d'une manière détaillée la vitesse de la réaction photochimique des halogénures d'argent et l'application de cet effet dans les autres domaines.

## Expériences

L'appareil que nous avons utilisé dans le présent travail est montré sur la figure 1; les halogénures d'argent sont mis dans une cuve à électrolyse (1), ainsi que la solution colloïdale, et mélangés avec un agitateur magnétique (2). Au-dessus d'une certaine vitesse d'agitation, les halogénures peuvent être considérés comme une suspension homogène. Le bromure et l'iodure d'argent sont préparés en mettant du nitrate d'argent 1 N dans un excès de solution d'halogénures de potassium 1 N. Les précipités sont lavés à l'eau, desséchés et broyés en poudre fine dans le mortier. Une quantité pesée de poudre est mise dans la solution d'électrolyte (la solution d'halogénures alcalins). Quant au chlorure d'argent, une certaine quantité de solution de nitrate d'argent est ajoutée à un petit excès de chlorure de potassium. Le précipité est légèrement chauffé, puis filtré et lavé. Il est entrainé par une solution de KCl 0.1 N dans la cuve à électrolyse à travers un petit trou percé au fond du filtre sur entonnoir. Nous avons essayé de maintenir la même répartition de grains d'halogénures d'argent, en contrôlant les conditions de traitement dans chaque lot d'expériences. Une lampe à mercure (3) est employée comme source. Quelque temps après l'allumage de la lampe, en maintenant la stabilité de luminosité, l'on ouvre l'obturateur (4) et la lumière traverse une distance constante dans l'espace, la paroi du thermostat en résine acrylique (3 mm. d'épaisseur) et ensuite une couche d'eau de 2 cm. avant d'arriver dans la cuve à électrolyse. Dans ce

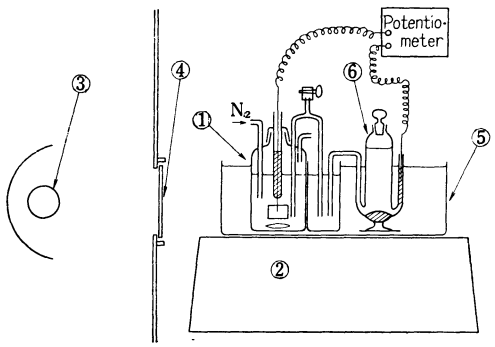

Fig. 1. Le système d'expériences.

rapport, la distance entre le centre de la cuve à électrolyse et celui de la source était maintenue à 20 cm., sauf autre indication, afin qu'une lumière constante entre la cuve. La luminosité de la lampe à mercure a été vérifiée de temps à autre avec un posemètre à sélénium. La cuve à électrolyse est un cylindre de verre de 50 mm. de diamètre. La paroi de verre ne laisse pas passer les rayons plus courts qu'environ 3500 Å. Le potentiel de l'électrode de platine a été mesuré d'une manière potentiométrique en se référent à une électrode au calomel saturé (6). La température du thermostat était de 25°C. Nous avons fait passer de l'azote dans la cuve à électrolyse préalablement à la mesure, afin de chasser l'oxygène dissous dans la solution. Le potentiel de l'électrode de platine peut varier sensiblement, même avant l'exposition à la lumière. Le traitement préalable est donc très important pour obtenir une valeur reproductible. Dans ce travail, l'électrode de platine est trempée dans une solution de soude caustique et de chlorure stanneux pendant 5 min. et mise dans l'acide nitrique concentré. Elle est complètement lavée à l'eau avant l'usage. Quand le potentiel du platine prend sa valeur stable, l'obturateur est ouvert et le potentiel est mesuré de temps à autre jusqu'à ce que le potentiel atteint une valeur constante.

## Résultats des expériences et observations

**1. Allure du potentiel photovoltaïque.**—Au cours de l'exposition, le potentiel de l'électrode de platine mise dans la solution colloïdale d'halogénures d'argent varie le côté positif du potentiel comme l'indique la figure 2 assez rapidement dans les prmières minutes, puis lentement, et il tend vers une valeur de saturation. Même si le potentiel avant l'exposition est différent, il tend vers une valeur déterminée après un certain temps d'exposition.

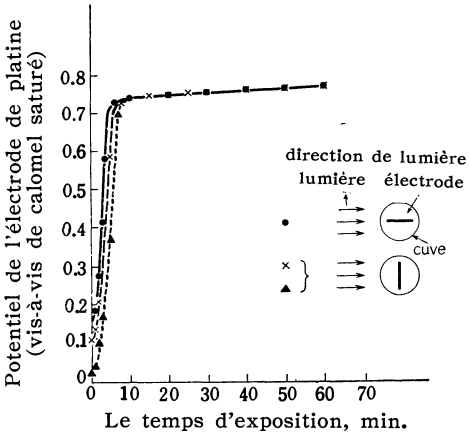

Fig. 2. L'effet photovoltaïque de AgBr 0,1 mol./l. en suspension dans la solution de KBr 0,1 N.

Nous appelons désormais le potentiel du platine mis dans la solution des halogénures d'argent le photopotentiel. Après le moment où le potentiel atteint, la valeur de saturation il ne baisse presque pas, même si l'on cesse d'illuminer la cuve. Il n'y a qu'une diminution de quelques millivolts au bout de 20 heures de repos. Le potentiel reste constant même si l'on arrête l'agitation et si l'halogénure d'argent se dépose au fond de la cuve. La variation de l'aire de l'électrode perpendiculaire à la direction de la lumière n'affecte pas le potentiel de saturation. Le potentiel de l'électrode de platine ne change pas par l'exposition à la lumière s'il n'y a pas d'halogénure d'argent dans la solution d'électrolyte. Ce résultat permet de penser que le photopotentiel ne dépend pas de l'exposition de l'électrode et que la réaction photolytique dans la solution est la raison du changement de potentiel.

**2. Les différents halogénures et le photopotentiel.** — Si l'on suppose que le photopotentiel dépend du potentiel d'oxydation des halogènes, l'ordre des potentiels doit être $AgCl > AgBr > AgI$ et le fluorure d'argent, insensible à la lumière visible, ne doit pas donner le changement du potentiel. Les potentiels normaux des halogènes vis-à-vis de l'électrode à hydrogène normale sont donnés dans le tableau I.

TABLEAU I

| | $\varepsilon_h$ |
|---|---|
| $1/2\,F_2(g)+e \rightleftarrows F^-$ | 2,85 volt |
| $1/2\,Cl_2(g)+e \rightleftarrows Cl^-$ | 1,359 |
| $1/2\,Br_2(a=I)+e \rightleftarrows Br^-$ | 1,085 |
| $1/2\,I_2(s)+e \rightleftarrows I^-$ | 0,536 |

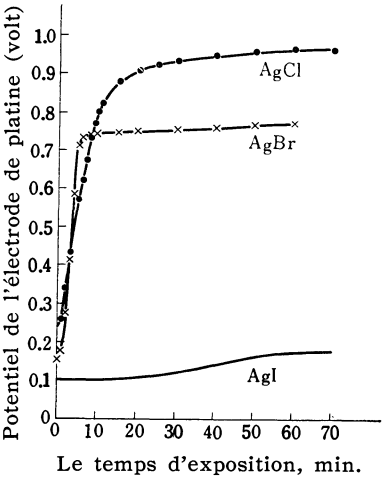

Fig. 3. L'effet photovoltaïque de AgX 0,1 mol./l. en suspension de la solution de KX 0,1 N.

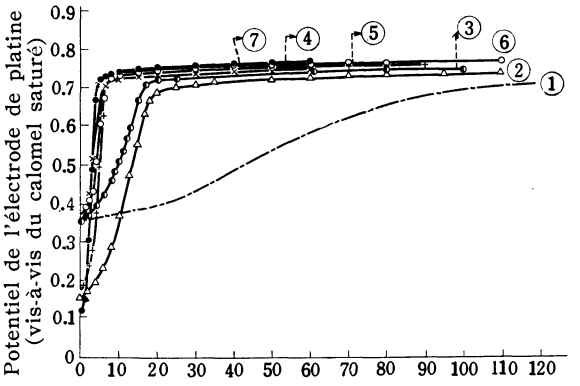
Dans une première série d'expériences, les solutions d'halogénures de potassium 0,1 N contenant 0,05 mol./l. des halogénures d'argent ont donné les photopotentiels comme la figure 3. Le système du fluorure d'argent n'a pas donné d'effet photovoltaïque.

**3. La relation entre la concentration des halogénures dans la solution et l'effet photovoltaïque.**—Si le photopotentiel indique le potentiel d'oxydation d'halogène selon l'équation $1/2\,X_2+e \rightleftarrows X^-$, le potentiel $E$ doit dépendre des concentrations de l'halogène et de l'ion halogène.

$$E=E_0+\boldsymbol{R}T/\boldsymbol{F}\ (\ln [X_2]^{1.2}/[X^-])$$
$$=E_0+\boldsymbol{R}T/2\boldsymbol{F}\ln [X_2]-\boldsymbol{R}T/\boldsymbol{F}\ln [X^-] \quad (1)$$

Si l'on suppose que la concentration des halogénures d'argent en suspension est constante et que la concentration de l'halogène libéré est constante, la formule 1 devient la formule 2.



$$E=E_0'-0{,}059\log [X^-] \quad (2)$$

Dans 2e série d'expériences où les auteurs font varier la concentration d'ion, les résultats ont été ceux de la figure 4. La relation entre le photopotentiel mesuré après 60 min. d'exposition et la concentration de l'ion d'halogène est semblable à l'équation 2. Cependant cette relation n'est plus valable au-dessus d'une concentration de 0,3 N. Dans le cas du bromure, la couleur de la solution après l'exposition est sensiblement brune et la couleur du bromure d'argent est aussi grise. Cela montre qu'il y a une certaine quantité de brome dans la solution. Les auteurs supposent que le photopotentiel plus faible dans la solution concentrée de bromure provient de la réduction de la concentration en brome par formation d'ion complexe.

$$Br_2+Br^- \rightleftarrows Br_3^-$$

**4. La relation entre la concentration des halogénures d'argent et le photopotentiel.**—Dans la série suivante, les auteurs ont mesuré le photopotentiel en faisant varie la concentration d'halogénure d'argent, en tenant constante la concentration de l'ion brome. Plus la concentration en bromure d'argent est petite, plus la vitesse de formation du brome est petite et la vitesse d'augmentation du potentiel est également petite (Fig. 5). De la formule 1 on peut tirer la formule 3 en prenant $Br^-$ const.

$$E=E_0''+0{,}0296\log [Br_2] \quad (3)$$

1. $1\times10^{-3}$ mol./l.
2. $3\times10^{-3}$ mol./l.
3. $7\times10^{-3}$ mol./l.
4. $1\times10^{-2}$ mol./l.
5. $5\times10^{-2}$ mol./l.
6. $7\times10^{-2}$ mol./l.
7. $1\times10^{-1}$ mol./l.

Fig. 5. La concentration de AgBr et le photopotentiel (concentration 0,1 N).

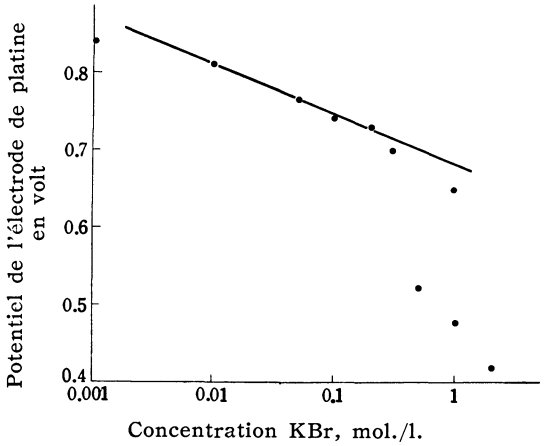


Fig. 4. Photopotentiel de AgBr en suspension 60 min. après l'exposition dans la solution KBr (AgBr 0,05 mol./l.).

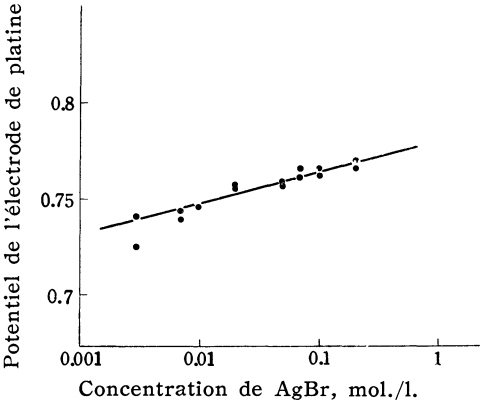

Fig. 6. La concentration de AgBr et le photopotentiel 60 min. après l'exposition (dans KBr 0,1 N).

Comme il y a une réaction de recombinaison d'argent et de brome un effet de filtre de lumière actinique par l'argent déposé, la concentration de brome libéré ne doit pas être proportionnelle à la concentration de bromure d'argent. Mais quand ces effets sont petits, on peut supposer que ces deux concentrations sont proportionelles et la formule 4 devient,

$$E \fallingdotseq E_0''' + 0{,}0296 \log (\mathrm{AgBr}) \qquad (4)$$

En fait la figure 6 montre que le photopotentiel est à peu près une fonction linéaire du logarithme de la concentration de bromure d'argent (Fig. 6).

**5. L'effet de l'intensité de la lumière et de la grandeur des grains d'halogénure d'argent sur le potentiel.** — Quand l'intensité de la lumière qui entre dans le système colloïdal d'halogénure d'argent faiblit, la vitesse d'augmentation du photopotentiel devient moindre et le potentiel final est aussi plus faible (Fig. 7). Il y a un effet identique. Quand la grandeur des grains d'halogénures d'argent augmente, la vitesse d'augmentation du photopotentiel diminue. La figure 8 montre l'allure du photopotentiel pour deux grandeurs de grains de chlorure d'argent, celles de diamètre moyen de moins de 0,1 mm. et de 0,7 mm. On peut en expliquer la raison en disant que la diffusion de chlore libéré dans le gros grain exige plus de temps que dans le petit grain.

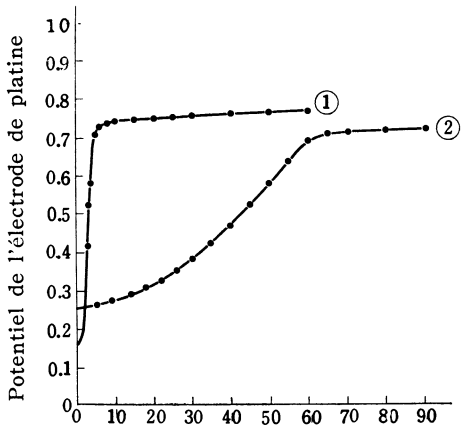

Fig. 7. L'intensité de lumière et l'effet photovoltaïque (0,1 mol./l. AgBr dans 0,1 N KBr).
1) Distance de la source 20 cm.
2) 〃 100 cm.

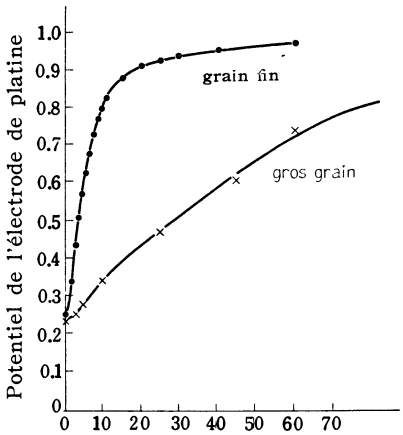

Fig. 8. Grandeur des grains et le photopotentiel (0,1 mol./l. AgCl dans 0,1 N KCl).

**6. Le potentiel après l'arrêt de l'exposition.** —Quand on arrête l'exposition après un certain temps, l'allure du photopotentiel est celle de la figure 9. Quand le potentiel se trouve sur la courbe montante, l'augmentation du potentiel continue même après l'arrêt de l'exposition, puis il commence à redescendre. L'explication est que l'halogène libéré ne se recombine pas tout de suite après l'arrêt de l'exposition et continue à venir dans la solution à cause de la différence de concentration d'halogène entre le cristal et la solution. La redescente peut s'expliquer par la recombinaison du brome avec l'argent. Mais cette explication n'est pas suffisante. Parce qu'une fois que le potentiel se trouve dans la partie de courbe près de la valeur saturée, il ne descend presque pas même après l'arrêt de l'exposition dans le cas du bromure et de l'iodure d'argent. Mais le potentiel de chlorure

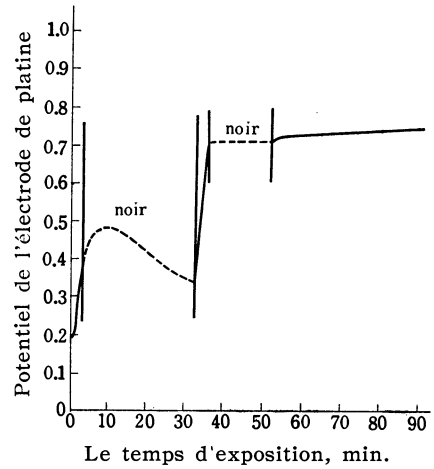

Fig. 9. L'effet photovoltaïque en cas d'interruption de lumière (0,1 mol./l. AgBr dans 0,1 N KBr).
—— exposition, ------ dans le noir

d'argent montre une descente du potentiel. On peut expliquer le phénomène dans le bromure et dans l'iodure d'argent en disant que la quantité d'halogène qui se recombine est minime par rapport à l'halogène libéré dans la solution.

**7. La comparaison du photopotentiel et du potentiel d'électrode d'halogène.**—Les auteurs ont calculé la concentration du brome libéré après 1 heure d'exposition du système colloïdal 0,1 N KBr-AgBr comme dans le tableau II.

TABLEAU II

| Concentration de AgBr mol./l. | Photopotentiel 60 min. après l'exposition vis-à-vis de calomel saturé | Concentration de brome libéré mol./l. |
|---|---|---|
| 0,2 | 0,766 | 2,02 $\times 10^{-5}$ |
| 0,1 | 0,764 | 1,77 〃 |
| 0,07 | 0,761 | 1,37 〃 |
| 0,05 | 0,756 | 0,926 〃 |
| 0,02 | 0,756 | 0,926 〃 |
| 0,01 | 0,746 | 0,424 〃 |
| 0,007 | 0,739 | 0,246 〃 |
| 0,003 | 0,725 | 0,0824 〃 |

On voit que la quantité de brome libéré est minime par rapport à la suspension de AgBr. Pour vérifier si l'électrode de platine indique le potentiel d'oxydoréduction par la réaction,

$$1/2\,Br_2 + e = Br^-$$

dans une solution diluée comme dans le tableau II, nous avons mesuré le potentiel en dissolvant une quantité connue du brome dans des solutions de KBr 0,1 N, 1 N et 3 N. Les résultats se voient sur la figure 10. Dans la solution à 0,1 N de KBr, le potentiel suit la formule 3 au-dessus de 0,72 volt (vis-à-vis du calomel saturé) et au-dessus de la concentration $2\sim3\times10^{-6}$ mol./l. de brome. Au-dessus de 0,72~0,73 volt, le potentiel dévie grandement de la formule 3. Au-dessous de cette concentration de brome, le potentiel est instable à cause du potentiel naturel par suite de l'adsorption d'ions étrangers et pour d'autres raisons. Aux plus fortes concentrations de KBr, comme 1 N ou 3 N, le potentiel devient moindre que le potentiel calculé par la formule 3.

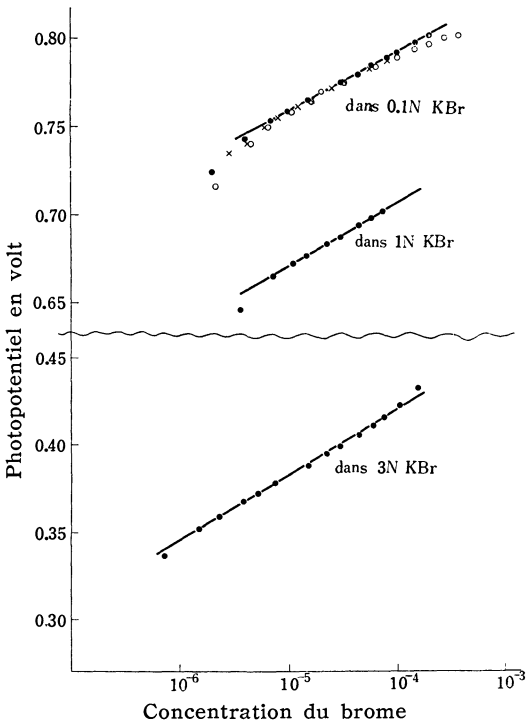

Fig. 10. La concentration du brome et le photopotentiel.

## Conclusion

1. L'exposition à la lumière d'une suspension d'halogénures d'argent dans une solution d'électrolyte donne un grand effet photovoltaïque.

2. Nous avons trouvé par certaines expériences que ce potentiel provient de l'halogène libéré du cristal vers la solution.

3. L'électrode de platine mise dans la solution colloïdale d'halogénure d'argent indique au commencement le potentiel naturel donné par l'état initial de l'électrode. Par l'exposition de AgX à la lumière, l'halogène est libéré vers la solution et il donne le potentiel défini par :

$$1/2\,X_2 + e \rightleftarrows X^-$$

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. IV. Polyphenyls*

By Hiroshi SUZUKI

(Received July 7, 1959)

In this part of the series, the electronic absorption spectra and the spatial configurations of polyphenyls are briefly surveyed, and the relation between them is discussed especially for *o*- and *p*-terphenyls, the method applied being analogous to the one for the treatment of biphenyl presented in Part I[1] of this series.

**p-Polyphenyls.**—It is well known that the first intense band in *p*-polyphenyl is shifted progressively toward longer wavelengths and increases in its intensity as the number of benzene rings is increased, no limit having been reached with the first six members which have been studied experimentally[2]. The band is regarded as the conjugation band, and the bathochromic shift and the intensification of this band with the increasing number of benzene rings may be attributed to the increasing extent of conjugation due to the elongation of the conjugated system. It may be stated in this connection that the first four members have been proved to be planar in the crystalline states[3].

The relation between the position of the conjugation band and the number of benzene rings in *p*-polyphenyl has been discussed by several workers on various grounds. Thus, for example, Davydov[4] has treated this problem quantum-mechanically, and derived the following equation:

$$\Delta E_{\min} = A - 2|M||\cos[\pi/(n+1)]|$$

where $\Delta E_{\min}$ is the transition energy corresponding to the conjugation band, $M$ is the matrix element of the interaction between neighboring benzene rings, and $n$ is the number of benzene rings in the molecule. Hence, with increasing $n$, the band should shift toward longer wavelengths, and the magnitude of the shift should decrease. From the experimental data of Gillam and Hey[2] for biphenyl and for sexiphenyl, the values of $A$ and of $M$ have been estimated at 50060 $cm^{-1}$ and at 10300 $cm^{-1}$, respectively, in chloroform, and at 50900 $cm^{-1}$ and at 10200 $cm^{-1}$, respectively, in hexane. Accordingly, when $n$ is $\infty$, the band should be expected to be at about 339 m$\mu$ in chloroform and at about 328 m$\mu$ in hexane. A somewhat similar equation has been derived empirically by Hirayama[5].

Further, Dewar[6] has calculated the wavelengths of the conjugation bands of *p*-polyphenyls by his NBMO method, and obtained values which are in excellent agreement with the experiment.

**m-Polyphenyls.** — The spectra of linear *m*-polyphenyls form a system quite different from that of *p*-polyphenyls. In the meta-series there is virtually no change in the position of the first intense band after biphenyl up to the highest member of the series yet prepared, in which the number of benzene rings is 16, in marked contrast to the para-series. On the other hand, the intensity of the band increases as the series ascends, being roughly proportional to the number of benzene rings in the molecule[2].

The different characteristics of the spectra of the two series have been ascribed to the presence of conjugation which covers the whole molecule in the para- but not in the meta-series. Thus Dewar[6] has considered the *m*-polyphenyls as the cross-conjugated systems according to his definition, and stated that the largest non-cross-conjugated unit present in them is biphenyl. In addition, Dale[7] has described it in line with Dewar's theory as follows; in *m*-terphenyl, one orbital of each of two sets of doubly degenerate $\pi$-orbitals in the central benzene ring will interact mainly with the orbitals in one of the benzene rings

attached to the parent benzene ring, while the other orbital interacts mainly with the orbitals in another benzene ring. These explanations seem considerably satisfactory.

In spite of this, however, Murrell and Longuet-Higgins[8] have proposed a different explanation. They have attempted to account for the main features of the spectra of *m*- and *p*-polyphenyls by electron interaction between the chromophores in these series, and stated that the different characteristics of the spectra of the two series can be interpreted without reference to conjugation between the aromatic rings.

While data of the spatial configurations of linear *m*-polyphenyls appear to have not been available yet, it is of great interest that 1,3,5-triphenylbenzene has been found to be non-planar not only in the vapor state but also in the crystalline state. According to Bastiansen[9], the angle between two adjacent benzene ring planes in this compound in the vapor phase is $46\pm5°$, which is almost completely identical with the value found for biphenyl in the vapor phase[10]. 1,3,5-Triphenylbenzene has been found to have the non-planar configuration even in the crystalline state, in which the interplanar angles are about 25° according to Lonsdale[11] or +34°, −27° and +24° according to Farag[12], in striking contrast to biphenyl which is known to be planar in the crystalline state[13].

**o-Polyphenyls.**—While *p*-polyphenyls have been proved to be planar in the crystalline states, *o*-polyphenyls can not be planar owing to the steric necessities. Actually it has been found that *o*-terphenyl is non-planar in the crystalline state[14]. Consequently, *o*-terphenyl should be less conjugated than the *p*-isomer, and hence the electronic absorption spectrum of the former should be appreciably different from that of the latter. In fact, this has been shown to be the case[15].

**o-Terphenyl, p-Terpheny and Some Related Compounds.**—Now, the relation between the spectra and the most probable spatial configurations of *o*- and *p*-terphenyls and of some related compounds will be discussed below by application of a method analogous to the one used in the treatment of the similar problem of biphenyl in Part I of this series.

The $\pi-\pi$ resonance integral for each of the co-annular bonds in *o*- and *p*-terphenyls is denoted by $\mu\beta$, and by the parameter $\mu$ an allowance is made for a change of the resonance integral associated with changes of the interplanar angle and of the bond length, quite similarly to the case of biphenyl.

*o*-Terphenyl is considered to belong to the symmetry group $C_2$. Seven of nine orbitals belonging to each of the representations $A$ and $B$ vary with $\mu$, and the other two orbitals of each set do not vary with $\mu$ (one of which has energy of $+\beta$, and the other $-\beta$). The highest occupied orbital belongs to $B$, and the lowest vacant one to $A$. The transition between these two orbitals is allowed. On the other hand, *p*-terphenyl is considered to belong to $D_2$. To each of the representations $B_1$ and $B_3$, there belong five orbitals which vary with $\mu$ and one orbital which does not vary with $\mu$ ($B_1$, $+\beta$; $B_3$, $-\beta$). In addition, to each of $A_1$ and $B_2$, three orbitals whose energies do not vary with $\mu$ ($A_1$ $+\beta$, $-\beta$, $-\beta$: $B_2$; $+\beta$, $+\beta$, $-\beta$) belong. The highest occupied orbital belongs to $B_3$, and the lowest vacant one to $B_1$. The transition between these two orbitals is allowed.

The transition between the highest occupied orbital and the lowest vacant one in each compound is considered to correspond to the conjugation band in the spectrum of each compound, and the corresponding transition energy $\Delta E_A$ can be evaluated as a function of $\mu$ by the simple LCAO molecular orbital method. The results of calculations are shown in Table I, in which the data for biphenyl reported previously[1] are included for comparison.

It is evident that the value of $\Delta E_A$ increases in each of the systems as the value of $\mu$ decreases, indicating that the conjugation band should be shifted toward shorter wavelengths with decreasing $\mu$. When $\mu$ is 0, $\Delta E_A$ in each system is $2(-\beta)$, and coincides with the value for benzene.

The difference between the value of $\Delta E_A$ for *o*-terphenyl and that for *p*-terphenyl at the same value of $\mu$ is much smaller than the difference between the

Symbols $p$-T, $o$-T and B represent $p$-terphenyl, $o$-terphenyl, and biphenyl, respectively.

value for biphenyl and that for $o$- or $p$-terphenyl. This fact seems to give some support to the assumption in the treatment of $o$-alkyl- and of $o,o'$-dialkylbiphenyls in the earlier part[16] of this series that the normal electronic bathochromic effect of an $o$-alkyl substituent and that of the corresponding $p$-substituent are approximately of the same magnitude.

According to Dale[15], the ultraviolet absorption spectra of $p$- and of $o$-terphenyls in the crystalline states measured by the pressed KCl-disk technique do not significantly differ from the respectively corresponding solution spectra. Only a normal, or slightly larger than normal, red-shift is observed for each compound. This fact is considered to indicate that the interplanar angles in each compound in solution are not much larger than in the crystalline state. Thus, the spectrum of $p$-terphenyl in hexane shows an intense absorption band without fine structure at 276 m$\mu$ ($\varepsilon$=32100), which is considered to be the conjugation band. (According to the present measurement[17] $\lambda_{max}$ is 276.5 m$\mu$ and $\varepsilon$ is 31800 in $n$-heptane. According to Gillam and Hey[2], $\lambda_{max}$ is 276 m$\mu$ and $\varepsilon$ is 35000 in hexane, and $\lambda_{max}$ is 280 m$\mu$ and $\varepsilon$ is 25000 in chloroform.) On the other hand, the spectrum of the crystalline $p$-terphenyl shows an intense band at 284 m$\mu$. The spectrum of $o$-terphenyl in hexane exhibits a maximum at 232 m$\mu$ ($\varepsilon$=26900), and the spectrum of the crystal at 237 m$\mu$. In addition, the spectra of $o$-terphenyl in both the states show a diffuse maximum or inflection at about 250~260 m$\mu$ (in the hexane solution, $\lambda_{max}$ is about 252 m$\mu$ and $\varepsilon$ is about 11400). Dale has regarded this vestigial band as the $\lambda_1$-band, namely, the "main band" which covers the full chromophore, and the band at 232 m$\mu$ or 237 as the $\lambda_2$-band, namely, the "overtone" or "minor" band.

It is undertaken by applying the author's method to infer the most probable spatial configurations of $o$-terphenyl and of $p$-terphenyl in solution from their spectra. In that case, $p$-terphenyl in the crystalline state is taken as the longer-wavelength-side reference compound, because it has been known to have the planar configuration with the co-annular bond length ($R$) of 1.48 Å [18]. This value of $R$ is equal to that in biphenyl in the crystalline state[13]. Therefore, the value of $\mu$ for the planar $p$-terphenyl molecule is 0.858. This is quite similar to the case of the planar biphenyl[1], and the correspnding value of $\Delta E_A$ is estimated at 1.282($-\beta$), which is referred to as $\Delta E_L$ as usual. The peak wave number of the conjugation band in the spectrum of $p$-terphenyl in the crystalline state measured by the pressed KCl-disk technique, corrected for the normal red-shift[1,15], is taken as the value of the wave number corresponding to $\Delta E_L$ (viz. $\nu_L$). The magnitude of the normal red-shift may be estimated to be about 6 m$\mu$ at 284 m$\mu$ according to the regular relation between the position of the band and the magnitude of the corresponding normal red-shift determined by Dale[15]. Accordingly, the value of $\nu_L$ may be assumed to be 35971 cm$^{-1}$ (278 m$\mu$).

On the other hand, benzene is taken as the shorter-wavelength-side reference compound, similarly to the case of biphenyl. That is, the value of $\Delta E_A$ when $\mu$ is 0 is 2($-\beta$) (viz. $\Delta E_S$), and the corresponding value of $\nu$ (viz. $\nu_S$) is assumed to be 48000 cm$^{-1}$ (the center of gravity of singlets of benzene).

From the positions of the conjugation bands of $o$-terphenyl and of $p$-terphenyl in solution, the respectively corresponding values of $\Delta E_A$ are obtained by the usual procedure (cf. Ref. 1, Eq. 8). (As the conjugation band of $o$-terphenyl the inflection at about 252 m$\mu$ is taken, accepting

Symbols p and s represent the "isolated" planar molecule and the molecule in solution, respectively. Wavelength in parentheses denotes an inflection.

the assignment by Dale, although this would appear to be open to question.) From these values of $\Delta E_A$ the corresponding values of $\mu$ are estimated according to the relations shown in Table I between $\mu$ and $\Delta E_A$ for *o*-terphenyl and for *p*-terphenyl. Then, the corresponding values of $\theta$ (the interplanar angle) and of $R$ are computed according to the relation between $\mu$ and $\theta$ as well as $R$ postulated in Part I of this series (cf. Eqs. 1—7 in Ref. 1). The results of calculations are shown in Table II, being denoted by symbol a.

The fact that the length of the co-annular bonds in the planar molecule of *p*-terphenyl is equal to that in biphenyl would appear to be rather surprising, for it would be expected that the length of the "single" bond might be contracted with the increasing extent of conjugation. This problem will be discussed later. Here, it is tentatively assumed that the co-annular bond length in planar *p*-terphenyl were equal to the "single" bond length, 1.445 Å, in planar *trans*-stilbene, considering that terphenyl as well as stilbene can be regarded as a "tri-conjugated system"[19]. The results of calculation carried out on the basis of this assumption are also shown in Table II, being denoted by symbol b. It is to be noted that the change of the value of the length of the pivot bond of the reference compound from 1.48 to 1.445 Å does not significantly affect the calculated values of the interplanar angles.

According to the result of the X-ray crystal analysis[14], the configuration of *o*-terphenyl in the crystalline state is the one in which the planes of the two outer phenyl groups are turned approximately 50° or less (probably 45~50°) out of the plane of the parent nucleus. Since the interplanar angle in the molecule in solution is considered to be not significantly different from that in the crystalline state in view of the spectral similarity between both the states, it may be said that the calculated value is in considerably good agreement with the experimental value. The interplanar angle in *o*-terphenyl in the vapor phase has been very roughly determined by the electron diffraction method to be about 90°[20].

The most probable configuration of *p*-terphenyl in solution has been inferred to be slightly non-planar, in accordance with the infrared spectroscopic evidence by Dale[21]. It may be noteworthy that the calculated value of the interplanar angle in *p*-terphenyl in solution is considerably smaller than the corresponding one in biphenyl in solution (about 20°)[1]. Furthermore, the value in *p,p'*-quaterphenyl is inferred to be still smaller than that in *p*-terphenyl. According to Dale[15], the position of the conjugation band in the pressed KCl-disk spectrum and that in the hexane solution spectrum (in parentheses) are as follows (wavelengths are in mμ): biphenyl, 253 (246); *p*-terphenyl, 284 (276); *p,p'*-quaterphenyl, 303 (294). On the other hand, the magnitude of the normal red-shift may be estimated to be about 3.5 mμ at 253 mμ, about 6 mμ at 284 mμ, and about 8 mμ at 303 mμ. Accordingly, the position of the conjugation band of the "isolated planar molecule" may be presumed to be 249.5 mμ for biphenyl, 278 mμ for *p*-terphenyl, and 295 mμ for *p,p'*-quaterphenyl, and consequently the differences between the positions of the conjugation bands of the assumed isolated planar molecules and those of the corresponding molecules in solutions are 3.5, 2 and 1 mμ, respectively. This fact may be considered to indicate

that the degree of the deviation of the most probable configuration of the molecule in solution from the planarity decreases in the order biphenyl > *p*-terphenyl > *p,p'*-quaterphenyl, although it may be somewhat doubtful whether much significance can be attached to the numerical values of these differences themselves mainly because of inevitable uncertainty in the estimation of the magnitude of the normal red-shift.

*o,p'*-Quaterphenyl has two bands at 284 mμ and at 255 mμ in the pressed KCl-disk spectrum, and at 276 mμ and at 248 mμ in the solution spectrum. Dale has interpreted these two bands as $\lambda_1$- and as $\lambda_2$-bands, respectively, on the basis of his concept of the "overtone" band. At any rate, it is of interest that the band at 284 mμ (276 mμ) appears to correspond to the conjugation band of *p*-terphenyl and the band at 255 mμ (248 mμ) to the conjugation band of biphenyl.

**On the Bond Length.**—Lastly, the length of the "single" bond in conjugated systems is briefly discussed. It is noteworthy that the length of the co-annular bond has been proved to be 1.48 Å in each of biphenyl, *p*-terphenyl, and *p,p'*-quaterphenyl[22] in the crystalline state. This fact appears to be in contrast to the expectation that the length of the "single" bond might be contracted with the increasing extent of conjugation, or in other words, with the increasing elongation of the conjugated system, and would be considered to support the striking hypothesis proposed recently by Dewar and coworker[23] that when the distinctions between the bond radius and the energy of bond formation of an $sp^3$ carbon atom and those of an $sp^2$ carbon atom are made it appears that bond lengths and heats of formation can be predicted without considering resonance at all. According to Platt[24], one of the important evidence contributory to Dewar's hypothesis is that the length of the "single" bond 1.48 Å in butadiene represents no shortening of Dewar's $sp^2$–$sp^2$ single bond distance. Butadiene in the vapor phase has been found probably to have almost exclusively the planar *trans*-configuration in which the length of the 2—3 bond is 1.483±0.01 Å [25].

On the other hand, *trans*-stilbene is known to have the planar or nearly planar configuration in which the length of the α-1 "single" bond is 1.44±0.02 Å or 1.45±0.02 Å in the crystalline state[26]. That is, the further shortening of the $sp^2$–$sp^2$ bond occurs in *trans*-stilbene as compared with those in polyphenyls and in butadiene. In addition, Cook[27] has pointed out that the length of the $sp^2$–$sp^2$ "single" bond varies from about 1.44 to about 1.55 Å with the angle between the planar groups joined by such a bond, in accordance with the assumptions made previously by the present author[1,28]. Therefore, in spite of Dewar's new hypothesis, it seems evident that the length of the "single" bond depends on the extent of conjugation, or in other words, on the extent of the π—π interaction across the bond. Hence, the bond length may be to be correlated with the π-bond order as usual after all.

When the actual bond lengths are taken into account, the value of the π-bond order is estimated at 0.319 for the co-annular bond of biphenyl[1] and at 0.384 for the α-1 bond of *trans*-stilbene[29]. On the other hand, when the π—π resonance integral is taken as β for all the bonds, the value of the π-bond order is 0.370 for the co-annular bond of biphenyl[1], is 0.375 for that of *p*-terphenyl[30], and is 0.431 for the α-1 bond of *trans*-stilbene[30]. In view of these values it may not be surprising that the length of the co-annular bond of *p*-terphenyl as well as that of *p,p'*-quaterphenyl is not substantially different from that of biphenyl in spite of the elongation of the conjugated system, and that the length of the "singe" bond of *trans*-stilbene is considerably shorter than those of these polyphenyls. It may be of interest in this connection that Syrkin and Dyatkina[31] have shown by calculations by the molecular orbital method that there is an increase of 0.38(−β) in the resonance energy for each Ph–Ph bond in the formation of biphenyl, terphenyl, or quaterphenyl.

**Summary**

The ultraviolet absorption spectra and the spatial configurations of polyphenyls have been briefly surveyed, and then the most probable spatial configurations of *p*-terphenyl and of *o*-terphenyl have been inferred from the spectra by application of the method analogous to the one for biphenyl in the first part of this series, resulting in the interplanar angle of about 10° for *p*-terphenyl and in that of about 43° for the *o*-isomer. Some related compounds have also been discussed. Further, it has been shown that the length of the "single" $sp^2$–$sp^2$ bond of the conjugated system depends on the extent of the $\pi$—$\pi$ interaction across the bond, contrary to Dewar's recent hypothesis.

# SHORT COMMUNICATIONS

## *Temperature Dependence of Ceric-cerous Gamma-ray Dosimeter*

By Hiroshi HOTTA and Kazuo SHIMADA

(Received August 20, 1959)

The 0.8 N sulfuric acid aqueous solution of ceric sulfate is usually recommended as a gamma-ray dosimeter for high dose. On the other hand, the temperature of irradiated solutions is apt to be raised at high dose rate owing to the absorption of gamma-ray energy. Therefore, in order to examine the temperture effect on the yield of cerous ion, the above solution was irradiated for one or two hours in a water thermostat under various dose rate between about $7\times10^4$ *r*/hr. and $6\times10^6$ *r*/hr. at the Co-60 Irradiation Laboratory of JAERI, and the yield was determined from the decrement of optical density at 314 m$\mu$. Ceric sulfate (Frederick Smith Chem. Co.) without further purification was dissolved in water, distilled triply as usual, in a test tube of hard glass (Hario Glass). A series of the samples was put carefully under the same condition for various temperatures between about 20 and 90°C.

The logarithm of the decrement of optical density of the sample irradiated

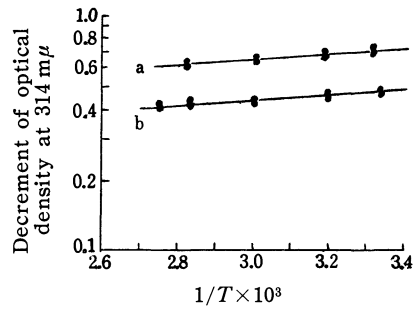

Fig. 1. The observed decrement of optical density of ceric ion by irradiation for 1 hr., against the inverse absolute temperature at (a) $5.6\times10^5$ *r*/hr. and (b) $1.7\times10^6$ *r*/hr. For measuring, the sample was diluted to the suitable concentration, for convenience.

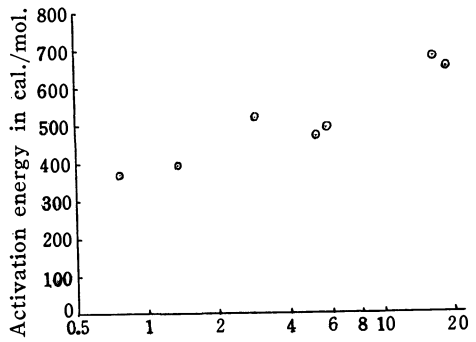

Fig. 2. The apparent activation energy of the reduction of cerous ion at various dose rates.

for one hour at $5.6\times10^5$ and $1.7\times10^6$ $r$/hr., among the observed values at various dose rate is plotted against inverse absolute temperature in Fig. 1. The value at higher dose rate was more reproducible than at the lower one owing to the property of this system. The decrement of the optical density, namely, the yield of cerous ion decreses with the increase of temperature as shown in Fig. 1.

The interpretation of the result is not so easily given, for the various elementary reactions are surposed. According to Hardwick, the apparent activation energy is about −300 cal./mol. at very low dose rate (600 millicurie radium source)[1].

## *Gas-Liquid Partition Chromatography of m- and p-Xylenes on α-Naphthylamine*

By Takeo ARAKI and Ryozo GOTO

(Received November 27, 1959)

Recently, Zlatkis, Ling and Kaufman[1] reported the resolution of isomeric xylenes by gas-liquid partition chromatography, and a good separation of *m*- and *p*-xylene was attained by using 1-chloronaphthalene as the liquid substrate. The isomers, *m*- and *p*-xylene have now been resolved. The stationary liquid phase used was α-naphthylamine which is expected to show an ionic character similar to that of 1-chloronaphthalene in the partition of xylenes. A value for the relative peak separtion[2] ($S_{12}=0.085$) for α-naphthylamine was better than the reported value for 1-chloronaphthalene ($S_{12}=0.060$)[1].

Since α-naphthylamine is known to be quite unstable, the end of the column (approximately 7 cm.) was packed with a bare solid support C-22 to maintain a stable base line. When ethylbenzene was present in the aromatic samples, this stationary liquid would not separate *p*-xylene from ethylbenzene. A chromatogram is illustrated in Fig. 1, and experimental conditions and data are listed in Table I.

More detaitled information on this subject will be published elsewhere.

The authors wish to thank the support of Yawata Chemical Industry Co. for assembling the gas-chromatograph instruments used in this study. This work has been carried out by the Scientific Research Grant-in-aid of the Ministry of Education.

## *The Szilard-Chalmers Effect of Calcium and Tungsten Oxinates*

By Hiroshi EBIHARA and Kenji YOSHIHARA

(Received September 30, 1959)

The enrichment of radioactive calcium or tungsten by the Szilard-Chalmers process has not been successful so far. Bruno and Belluco[1] could not find the Szilard-Chalmers effect of calcium ethylenediaminetetraacetate complex. The present authors found enrichment of $^{45}Ca$ and $^{185}W$ during their studies on the Szilard-Chalmers effect of calcium and tungsten complexes of 8-hydroxyquinoline (oxine).

*n*-Butylamine is the best solvent tested for calcium oxinate, but is water-miscible. A preliminary tracer study on the cation exchange behavior of $^{45}Ca$ as bivalent cation in the solvent showed a very high recovery (nearly 100%) of $^{45}Ca$ on the resin. Accordingly the ion-exchange in *n*-butylamine was used in order to catch $^{45}Ca$ in a cationic form leaving the oxinate in the solution. In each experiment about 5.0 g. of dehydrated calcium oxinate irradiated in JRR-1 for about 15 or 60 hr. (neutron flux: $10^{11}$ $n/cm^2 \cdot sec.$, about 95% thermal neutron) was dissolved in *n*-butylamine. The solution was passed through a cation exchange resin column (7.0 mm.$\phi$ $\times$100 mm. of Diaion SK-1, H-form, 100~200 mesh, 1.1 ml./min.). After washing the column with a sufficient volume of *n*-butylamine and water, $^{45}Ca$ on the resin was eluted with 6 N hydrochloric acid. Calcium was precipitated as phosphate for the measurement of radioactivity. The results listed in Table I show that about 6~8% of $^{45}Ca$ is separated in a cationic form from the complex with an enrichment factor of 40~120.

TABLE I. SEPARATION OF $^{45}Ca$ BY THE SZILARD-CHALMERS EFFECT

| Irrad. time | Yield** | Ca taken* | Ca found in the cationic fraction* | Enrichment factor |
|---|---|---|---|---|

* The quantity of calcium was determined by the phosphate method.

** Yield=the amount of $^{45}Ca$ in the cationic form/total amount of $^{45}Ca$.

To investigate the Szilard-Chalmers effect of $^{185}W$, about 1.0 g. of dehydrated tungsten oxinate irradiated in JRR-1 for about 15 hr. was dissolved in 150 ml. of chloroform, and the solution was shaken with the buffer solution of various pH values. Thus $^{185}W$ separated from the complex by the Szilard-Chalmers effect was collected in the aqueous solution. The quantities of tungsten were determined colorimetrically. The results are listed in Table II.

TABLE II. EXTRACTION OF $^{185}W$ FROM TUNGSTEN OXINATE

| pH | Yield | W taken*** | W found in the extracted fraction | Enrichment factor |
|---|---|---|---|---|
| | % | mg. | mg. | |
| 1.01 | 37.3 | 38.0 | 0.24 | 59 |
| 2.98 | 34.2 | 38.0 | 0.09 | 144 |
| 4.02 | 33.5 | 38.0 | 0.07 | 196 |
| 5.00 | 33.7 | 38.0 | 0.06 | 233 |
| 5.96 | 33.1 | 38.0 | 0.07 | 194 |
| 7.01 | 33.9 | 38.0 | 0.03 | 429 |
| 9.02 | 38.0 | 38.0 | 0.18 | 80 |
| 10.06 | 44.0 | 38.0 | 0.39 | 43 |

*** The quantity of tungsten was determined by the thiocyanate method.

High enrichment factors were obtained in the pH range between 3~7, and the maximum enrichment factor was 429 at pH 7. The extraction yield was almost constant (34%) in this pH range.

## *Sorption of Benzene by Isotactic and Atactic Polystyrenes*

By Hisashi Odani, Michio Kurata and Mikio Tamura

(Received November 6, 1959)

In recent years there has been much interest in the physical properties of stereo-specific synthetic polymers. The present authors have recently studied the absorption and desorption of benzene by three isotactic polystyrenes of different degrees of crystallinity and one atactic

polystyrene at 35°C[1]. Sorption isotherm data have been obtained for these systems from both integral and differential kinetic runs*.

An isotactic polystyrene (isotactic-PS) used a sample that had been prepared by stereo-specific polymerization with Ziegler's catalyst. After the purified polymer had been boiled in heptane for thirty hours, the polymer was separated into isotactic and atactic fractions, by extracting the latter with cold methyl ethyl ketone. The isotactic-PS films were obtained by the same procedure reported elsewhere[1]. The polymer films of different degrees of crystallinity were then prepared by annealing these films at three different combinations of temperature and period. These annealing conditions are summarized in Table I, in which the degree of crystallinity of each specimen estimated roughly by the X-ray method are also given. An atactic polystyrene (atactic-PS) sample used was a commercial sample, "Lustrex hi-flow 77-234", and a benzene of A. R. grade was used as penetrant. The sorption apparatus and procedure were practically the same as those reported elsewhere[1].

TABLE I. ANNEALING CONDITIONS AND DEGREES OF CRYSTALLINITY OF ISOTACTIC PS's

| | Annealing condition | | Degree of crystallinity |
|---|---|---|---|
| | Temp. °C | Period hr. | |
| Isotactic PS-I | 120 | 2 | 0.08 |
| Isotactic PS-II | 180 | 0.5 | 0.45 |
| Isotactic PS-III | 160 | 1.5 | 0.50 |

Fig. 1 gives absorption isotherms obtained for the three isotactic-PS's and for the atactic-PS at 35°C. Here the ordinate represents the mass of benzene in grams sorbed per gram of a given polymer at dry state and the abscissa the relative pressure of a given vapor in the external phase. It is seen that the isotherm in the region of medium relative pressure is much steep for atactic-PS and becomes less steep with increase of crystallinity for isotactic-PS's. This feature is analogous to that for isotherms on systems water vapor-celluloses having different

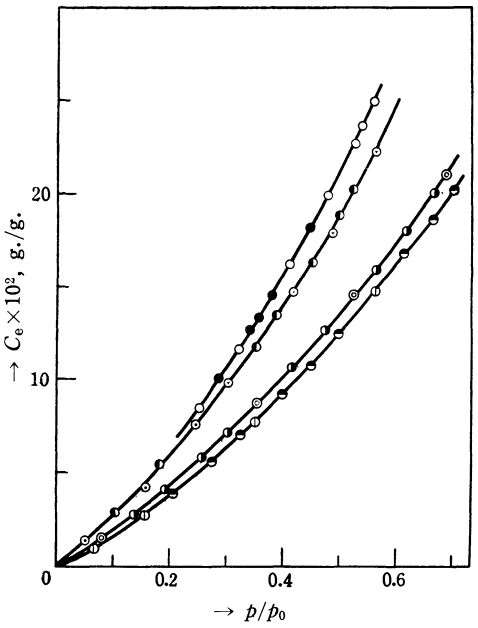

Fig. 1. Absorption isotherms of isotactic PS's and atactic PS-benzene at 35°C.

| | Integral absorption | Differential absorption |
|---|---|---|
| Isotactic PS-I | ⊙ | ◐ |
| Isotactic PS-II | ◎ | ◑ |
| Isotactic PS-III | ⓘ | ◓ |
| Atactic PS | ○ | ● |

degrees of crystallinity[2]. It is also seen that the data from integral absorption experiments and those from differential ones fall well on a single curve for each system.

For any given relative pressure the equilibrium amount of benzene in dry polystyrene decreases with increase in crystallinity. This suggests that benzene is mainly absorbed in amorphous regions of a given sample. If this is the case, there should hold

$$(C_e)_i = (C_e)_a(1-\phi) \qquad (1)$$

where $(C_e)_a$ and $(C_e)_I$ are the equilibrium concentrations of benzene at a given relative pressure in an atactic-PS and in an isotactic-PS in which the volume fraction of crystal region is $\phi$, respectively. The values of $\phi$ may be calculated as a function of relative pressure by applying Eq. 1 to the data of Fig. 1. Within the range where the calculations are possible, $\phi$ is practically independent of $p/p_0$ for each isotactic-PS, giving an average value $0.10_7$, $0.36_4$ and $0.41_0$ for the isotactic-PS-I,

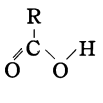
## *Intramolecular Hydrogen Bonding in α-Keto- and α-Alkoxy-carboxylic Acids*[1]

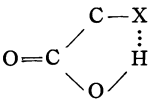


By Michinori Ōki and Minoru Hirota

(Received November 9, 1959)

A number of hydroxylic compounds which carry a proton accepting group at a suitable position have been verified to form an intramolecular hydrogen bonding, but only a few examples of intramolecular hydrogen bonding involving the hydroxyl group of a carboxyl group as a proton donor have been known. The structure of a normal carboxyl group has been suggested to be non-planar, the O–H bond being 30° away from *cis*-planar conformation[2]. However, when an acid has a proton accepting group at α- or β-position to the carboxyl group, the *trans*-structure will be stabilized owing to the formation of an intramolecular hydrogen bonding and will be allowed to exist in spite of the otherwise unfavorable conformation.

(I) *cis*-Structure



(II) *trans*-Structure

In this regard, the infrared spectra of such compounds including monomethyl oxalate, pyruvic acid, methoxyacetic acid, phenoxyacetic acid, and their homologues were examined with a Perkin Elmer 112G Spectrophotometer in carbon tetrachloride solution[3]. The concentration of the solution was less than 0.002 mol./l. in order to minimize the effect of dimeric association. As summarized in Table I, the results

Table I. $\nu_{O-H}$ Absorption of the carboxyl group of various carboxylic acids

| Acid | $\nu_{O-H}$ Absorption frequencies | | | |
|---|---|---|---|---|
| | Free form | | Hydrogen-bonded form | |
| | $\nu_{max}$ | $\varepsilon_{max}$ | $\nu_{max}$ | $\varepsilon_{max}$ |
| Monomethyl oxalate | 3516.3 | 34 | 3461.1 | 72 |
| Monomethyl malonate | 3529.9 | 58 | | |

| β-Phenoxypropionic | 3531.7 | 68 | | |

show that a carboxylic acid which carries a proton accepting group at α-position bear two $\nu_{O-H}$ bands. The results may be interpreted as an evidence for the existence of a hydrogen bonding and consequently for structure II. The peaks at higher frequencies appear between 3550 and 3500 $cm^{-1}$ and are assigned to the $\nu_{O-H}$ bands of free monomeric acids. The peaks at lower frequencies can be assigned to the $\nu_{O-H}$ bands of the intramolecularly hydrogen-bonded forms. It may be also pointed out that the intramolecular hydrogen bonding is observed only when a five membered ring is formed (structure III).

(III)

Since the proton accepting power of an atom is largely influenced by the electron density, the authors expected some electronic effects to be exerted on the hydrogen bonding ability; the spectra of various substituted phenoxyacetic acids were thus measured. The results are in accordance with the expectation, as shown in Table II, where apparent integrated absorption intensities of the two bands

| $NO_2$ | 3521.8 | | Not found. | | 0 |

* The ratio is a more important factor than the individual integrated intensity in discussing the properties of the bands, since the effect of the dimeric form can not be completely neglected.

were obtained graphically instead of taking the absorption coefficient because of the closeness of the two bands.

Another evidence for the existence of the hydrogen bonding may be obtained from the measurement of the carbonyl region. The measurement revealed that two bands are also found for the monomeric acid when it carries a proton accepting group at the $\alpha$-position and that the higher frequency absorption disappears when no hydrogen bonding is observed in the O-H stretching region. Thus, the peak at about 1790 $cm^{-1}$ is assigned to the $\nu_{C=O}$ band of structure II and that between 1735 and 1730 $cm^{-1}$ to structure I.

The details will be reported in the near future.

## *Behavior of Energetic Radiobromine Atoms Arising from $(n, \gamma)$ Reaction in Cobalt Complex Salts*

By Nobufusa Saito, Takeshi Tominaga and Hirotoshi Sano

(Received November 10, 1959)

In the course of the investigation on the behavior of hot radiobromine atoms ($^{80m}$Br and $^{82}$Br) in bromopentammine cobalt complex salts[1], the present authors found that some of such energetic radiobromine atoms arising from $(n, \gamma)$ reaction either in ligand bromine or in anionic bromine eventually entered ligands of the complexes through formation of chemical bond with the cobalt atom. When solid complex salts, $[Co(NH_3)_5Y]Br_{2,3}$ and $[Co(en)_2Y_2]Br_{1,3}$, were irradiated, the fraction of total produced radiobromine finally retained in ligands (hereafter defined as "ligand yield") was found to vary with changing ligand group, Y. In order to clarify the mechanism of hot-atom behavior of radiobromine in these systems, the present authors investigated the effects of various ligands on the ligand yields in these complex salts.

Experimental procedures were similar to those described in the previous paper[1]. Distribution of radiobromine was determined by a procedure involving separation with a cation exchange resin.

As shown in Tables I and II, enrichment of radiobromine in ligands was observed with these complex salts. On the irradiation of the salts $[Co(NH_3)_5Y] \cdot Br_{2,3}$, several complexes labeled with Br* ($[Co(NH_3)_5Br^*]^{2+}$, $[Co(NH_3)_4YBr^*]^{1,2+}$, etc.) might possibly be produced through reactions of hot radiobromine atoms with the target complex. However, almost all labeled complexes other than $[Co(NH_3)_5 \cdot Br^*]^{2+}$ were extremely unstable to aquotization in aqueous solutions, and it was possible with adequate procedures of separation to obtain the ligand yield without appreciable contribution of yields in the forms of unstable labeled complexes, $[Co(NH_3)_4YBr^*]^{1,2+}$ etc. Therefore, the ligand yield in Table I may be taken as almost identical with the fraction of radiobromine stabilized in the form of $[Co \cdot (NH_3)_5Br^*]^{2+}$, or that obtained through replacement of Y by Br*. On the irradiation of the salts $[Co(en)_2Y_2]Br_{1,3}$, the probability of replacement of ethylenediamine in ligands seemed to be very small. Thus, the ligand yield in Table II may be taken as indicating the fraction of radiobromine in the form of $[Co(en)_2YBr^*]^{1,2+}$. It is interesting that no significant differences were observed between the ligand yields of *cis*- and *trans*-isomers of both $[Co(en)_2(NCS)_2]Br$ and $[Co(en)_2Cl_2]Br$.

To explain the relationship between ligand yield and Y, the present authors proposed a model in which collisions of

| Cl | Cl | 0.85 |
| I | I | 0.95 |
| Br | Br | 1.00 |

hot bromine atom with the donor atom in Y played an important role. When the masses of the donor atom in ligand Y, and of bromine atom are $M$ and $M'$, respectively, the fraction of the maximum possible loss in the recoiling energy of a hot bromine atom for an elastic collision with the donor atom is given by $\gamma = 4MM'/(M+M')^2$. Calculated values of $\gamma$ for donor atoms in different ligands, Y, are shown in Table III. Fig. 1 shows the relationship between the ligand yield and the $\gamma$ value for the complex salts listed in Tables I and II. As each complex molecule of the salts $[Co(en)_2Y_2]Br_{1,3}$ contains more Y's in ligands than that of $[Co(NH_3)_5Y]Br_{2,3}$, the probability of the collision of a hot bromine atom with Y may be somewhat larger for the former

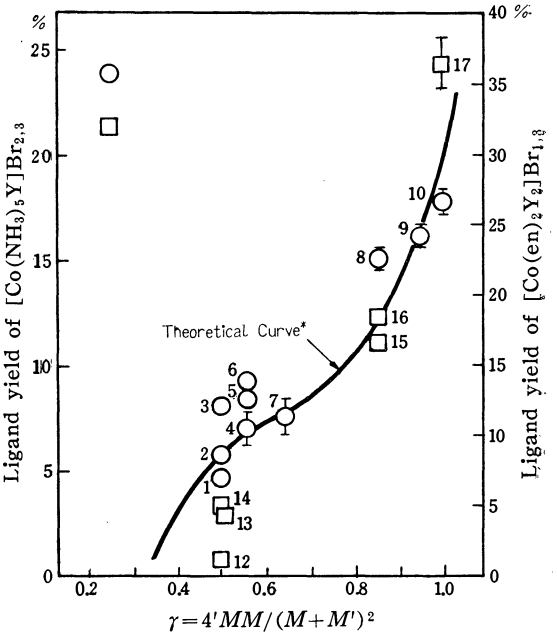

Fig. 1. The relationship between the ligand yield and the value of $\gamma$.
○ $[Co(NH_3)_5Y]Br_{2,3}$
□ $[Co(en)_2Y_2]Br_{1,3}$
* The shape of this curve was theoretically predicated on the basis of the model proposed by the present authors. Details will be published elsewhere.

salts. Based on the crystallochemical data, the ratio of relative collision cross sections of a bromine atom with Y in ligands was estimated as about 1.5 : 1 for $[Co(en)_2Y_2]Br$ and $[Co(NH_3)_5Y]Br_2$. Therefore, different ligand yield scales were used for the two series in Fig. 1 where both are shown together. It is seen in Fig. 1 that the ligand yield seems to increase as the value of $\gamma$ of the donor atom in ligand Y increases: the efficiency of replacement of Y by hot bromine depends mainly on $\gamma$. Therefore, it may be presumed that the kinetic processes play an important role to determine the fate of hot bromine atoms in these systems.

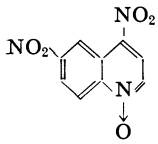
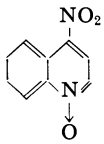
## *Electronic Structure and Antifungal Activity of Quinoline- and Pyridine-N-oxide Derivatives*

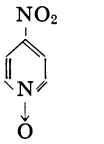
By Kenichi FUKUI, Akira IMAMURA and Chikayoshi NAGATA

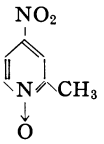
(Received December 9, 1959)

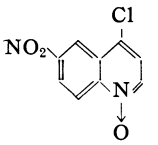
Many studies have ever been undertaken in order to elucidate the mechamism of action of fungicides or antifungal substances. Albert et al., through the experiments on 8-hydroxyquinoline, concluded that a chelate formation may be involved in the process of fungicidal action[1]. Ikeda found some parallelism between the reduction potential and the fungicidal activity of 1,4-naphthoquinone derivatives and assumed that the binding ability of fungicides with SH group in the body of fungi may be the main factor determining the fungicidal activity[2].

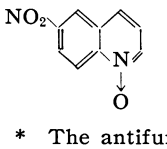












For the purpose of the elucidation of the reaction mechanism involved in the early stage of fungicidal action of quinoline- and pyridine-*N*-oxide derivatives, the present authors have calculated the reactivity indexes, namely, the approximate superdelocalizability ($S'_r$) which is one of the reactivity indexes used in the frontier electron theory and proved to be a good index for discussing the biological actions of carcinogenic compounds and plant growth compounds[3,4].

**Result and Discussion.**—In the present paper the authors dealt with *N*-oxides containing the nitro group such as 4-nitroquinoline-*N*-oxide, 6-nitroquinoline-*N*-oxide, 4,6-dinitroquinoline-*N*-oxide, 4-chloro-6-nitroquinoline-*N*-oxide, 4-nitropyridine-*N*-oxide, and 2-methyl-4-nitropyridine-*N*-oxide whose antifungal activities were tested recently by Okabayashi et al.[5]

From an organic chemical point of view, the most probable reaction is the nucleophilic replacement of the nitro group, since this group is very susceptible to the attack by nucleophilic reagent. If any reaction of this type plays a dominant role in the fungicidal action, the order of antifungal activity must be parallel with the reactivity index of the attacked position. The result of the authors' calculation supports this assumption. That is, the order of approximate superdelocalizability for the nucleophilic attack ($S'^{(N)}$) at the most reactive position in the molecule is nearly parallel with antifungal activity as is seen in Table I. The signs + and − indicate the degree of antifungal activity. The larger the number of + sign is, the greater the activity is. The sign − indicates that the compound has no activity. One exception is inactive 4,6-dinitroquinoline-*N*-oxide whose $S'^{(N)}$ value at position 4 is far larger than the most potent fungicide, 4-nitro-quinoline-*N*-oxide. In order to obviate this difficulty, one can assume that the upper threshold value of reactivity index for occurrence of activity as well as the lower one might exist. Such an interpretation has frequently been made in the theoretical study of biological phenomena, for instance, the carcinogenic action of polycondensed aromatic hydrocarbons and azo compounds. Inactiveness of 4,6-dinitroquinoline-*N*-oxide, therefore, may be understood if the authors suppose that this compound is so reactive that it would react with various groups in the body of fungi before it reaches the reaction center connected with the fungicidal action.

TABLE I. RELATION BETWEEN REACTIVITY INDEX AND ANTIFUNGAL ACTIVITY OF QUINOLINE- AND PYRIDINE-*N*-OXIDE DERIVATIVES

| Compound | Approximate superdelocalizability for nucleophilic ($S_r'^{(N)}$) attack | Antifungal activity* |
|---|---|---|
|  | 1.014(4)** | − |
|  | 0.630(4) | +++ |
|  | 0.297(4) | ++ |
|  | 0.279(4) | + |
|  | 0.205(6) | + |
|  | 0.168(6) | − |

* The antifungal activity was tested for Aspergillus oryzae, Tolura utilis, Saccharomyces sake and Zygosaccharomyces soja by Okabayashi, and the signs + and − are given by the present authors considering the experimental activity.

** The figures in the parentheses indicate the position at which the nucleophilic substitution is assumed to take place.

On the other hand, Okabayashi's *in vitro* experiment showed that the nitro group of 4-nitroquinoline-*N*-oxide was easily substituted by the SH group of cystein and the substituted compound lost its antifungal activity. Bearing this fact in mind together with the theoretical result obtained by the present authors, it may be possible to correlate the easiness of nucleophilic substitution at the carbon atom to which the nitro group is attached with the antifungal activity of nitro group-containing quinoline- and pyridine-*N*-oxides.

Parameters for chloro, methyl and nitro groups used in the calculation are the same as those of a previous paper[4]. Since there seem to exist no unambiguous values used for Coulomb integrals of *N*-oxide, the present authors adopt, according to the result of analyses of the ultraviolet spectrum[6], the values $\alpha+\beta$ and $\alpha+1.8\beta$ for nitrogen and oxygen, respectively.

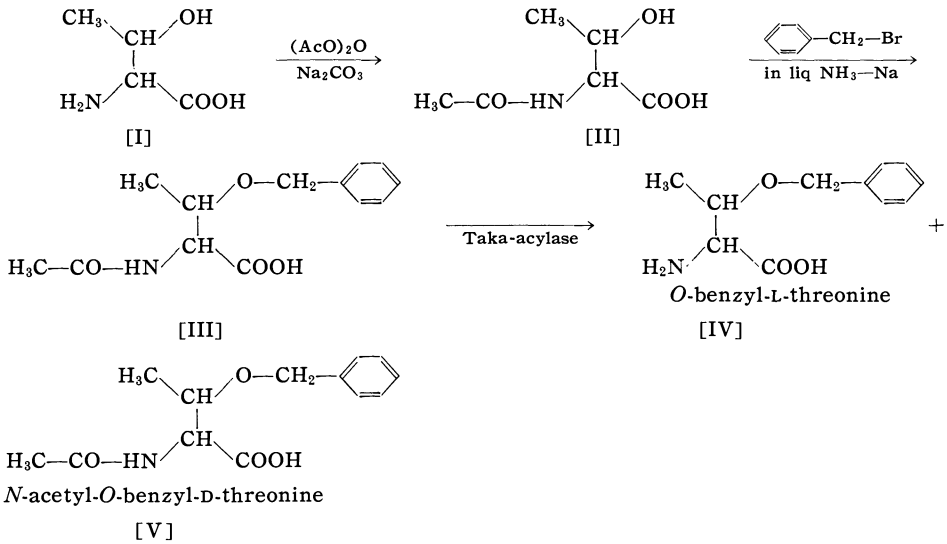
## *Synthesis of N-Acetyl-O-benzyl-DL-threonine and O-Benzyl-L-threonine*

By Yasuhiro Murase*, Kenji Okawa and Shiro Akabori

(Received December 11, 1959)

Difficulties are encountered in the synthesis of the peptides containing serine or threonine owing to the presence of the hydroxyl group that induces an unexpected side reaction during the synthetic procedure.



In order to avoid an undesirable side reaction, one of the authors[1] had already synthesized *O*-benzyl-L-serine in which the free hydroxyl group was protected with the benzyl rest.

In this communication, the authors will describe the synthesis of the *O*-benzyl-L-threonine from *N*-acetyl-DL-threonine, which was prepared by the direct acetylation of the DL-threonine with the acetic anhydride method.

**Synthesis of *N*-Acetyl-DL-threonine [II].**—DL-Threonine (12 g.) was dissolved in 200 ml. of an aqueous solution containing sodium carbonate (13.5 g.). Into the above solution was added dropwise acetic anhydride (12 g.) under vigorous stirring at +5°C. After the addition was over, the stirring was continued for about 30 min. at room temperature. When the reaction was over,

about 100 ml. of Dowex 50 (H-form) was added to the reaciton mixture under stirring until the evolution of the carbon dioxide ceased. The resulting mixture was passed through the Dowex 50 (H-form) ion exchange column (7 $cm^2 \times 30$ cm.). By elution with water, the effluent was collected and concentrated in vacuo. The resulting syrupy materials were crystallized with ethylacetate. The crude products weighed 14 g., 87% yield. The recrystallization from ethylacetate containing alcohol gave a pure material (12.9 g.) in 80% yield, m. p. 132~133°C.

*Anal.* Found: C, 44.73; H, 6.96; N, 8.78. Calcd. for $C_6H_{11}O_4N$: C, 44.75; H, 6.88; N, 8.70%.

***N*-Acetyl-*O*-benzyl-DL-threonine [III].** — *N*-Acetyl-DL-threonine (8.5 g.) was dissolved in liquid ammonia (200 ml.), followed by portionwise addition of methallic sodium (2.3 g.) at −60°C. After benzylbromide (18 g.) was added into the above solution, the reaction vessel was taken out from the cooling Dewar's bottle; then the temperature of the reaction mixture raised to −28°C and ammonia was gradually evolved off at this temperature for 2.5 hr. The resulting mixture was dissolved in an aqueous solution of sodium bicarbonate, the aqueous solution extracted with ether being acidified with 6 N hydrochloric acid. The crystals produced were extracted with ethylacetate, and the organic layer was washed with water and dried. By removing the solvent, the crude product (2.0 g.) was obtained in 16% yield. Recrystallization from hot water gave a pure material (1.3 g.), m. p. 141~142°C.

*Anal.* Found: C, 61.69; H, 6.67; N, 541. Calcd. for $C_{13}H_{17}O_4N$: C, 62.13; H. 6.82; N, 5.57%.

**Optical Resolution of *N*-Acetyl-*O*-benzyl-DL-threonine.**—*Preparation of enzyme solution.*—Takadiastase (1 g.) was extracted with 10 ml. of water at 0°C. for 2 hr. and an insoluble part was filtered off using Cellite. The crude enzyme solution was used for the resolution without further purification.

*Enzymic resolution of N-acetyl-O-benzyl-DL-threonine.* — *N*-Acetyl-*O*-benzyl-derivative (1 g.) was dissolved in an aqueous solution of 2 N sodium hydroxide containing a slight excess of sodium hydroxide which brought the solution to pH 7.4. The above enzyme solution, together with the substrate, was incubated at 36.5°C for 24 hr. After incubation was over, the mixture was passed through the Amberlite IR-120 column (H-form). By the first elution with water, the acidic component was removed off, and then the amino acid component was liberated by the second elution with an aqueous 1 N ammonia (about 150 ml.). The latter eluate collected was concentrated in vacuo. The resulting product was dissolved in a small amount of hot water, boiled for 10 min. to remove the contaminant and filtered. The filtrate was concentrated and dried in vacuo. The residual weighed about 330 mg., 79% yield. Crystallization from hot water gave fine crystals of *O*-benzyl-L-threonine which melted at 197°C with decomposition. $[\alpha]_D^{19°} -3.04$ ($c$=1, 1 N HCl).

## *Molecular Configuration of Poly(m-methylstyrene) and Poly(p-trimethylsilylstyrene)*

By Isamu NITTA, Yōzō CHATANI and Yoshiaki SAKATA*

(Received October 19, 1959)

Syntheses and infrared studies of poly(*m*-methylstyrene) (PMMS) and poly(*p*-trimethylsilylstyrene) (PPTMSS) have already been reported by Murahashi, Nozakura and Tadokoro[1]. In this communication, molecular configuration of these polymers will be reported on the basis of X-ray diffraction evidence.

The fiber period calculated from the layer line spacing is 57.1 Å for PMMS and 60.6 Å for PPTMSS. And by taking photographs of tilted specimens, axial maximum intensity on the 29th layer line was observed (see Fig. 1). The repeat distance of successive monomers along the fiber axis (1.97 Å for PMMS and 2.09 Å for PPTMSS) is much shorter than 2.53 Å found in the case of fully extended chain of singly linked carbon atoms. Therefore, it would be appropriate to conclude that these polymers construct uniform helices in their crystalline regions, indicating one of characteristic features of isotacticity.

To analyze further the helical structure, the authors used the method of Cochran

and others[2]. Taking the fiber axis as the $c$ axis and using cylindrical coordinates $R, \phi, l/c$ in the reciprocal space, the structure factor of a helical molecule can be given as follows :

$$F(R, \phi, l/c) = \sum_j \sum_n f_j J_n(2\pi R r_j) \times \exp\left\{i\left[n\left(\phi - \varphi_j + \frac{\pi}{2}\right) + 2\pi l z_j/c\right]\right\} \quad (1)$$

where $r_j, \varphi_j, z_j$ represent the cylindrical coordinates of the $j$-th atom of a monomer, and $J_n$'s are Bessel functions, the order $n$ of which are to be obtained properly for the reflexions on each layer line $l$ by solving the equation ;

$$l = un + vm \quad (n, m ; \text{integers}) \quad (2)$$

where $u$ and $v$ are, respectively, the number of turns and that of monomers in the repeat distance.

Trial consideration** on various possibe types of helices shows that the helix of 8 turns ($u=8$, $v=29$) for PMMS and 9 turns ($u=9$, $v=29$) for PPTMSS will be taken as to account qualitatively for average intensity of each layer line (see Table I). The helical model thus obtained seems to be quite reasonable, because, from the observed value of fiber period and the assumed 1.54 Å of the C-C single bond length, the standard tetrahedral angle (109.5°) comes out in the permissible region of C-C-C bond angle calculated for the C helix. Moreover, the region of intense reflexions conforms to the properties of the selected Bessel function for each layer line. After all such considerations the authors are led to the probable configuration shown in Fig. 2. Although precise orientations of side groups have not been determined from such considerations alone, it would be imagined reasonable that the plane of phenyl radical is so inclined as to be influenced by steric hindrances of neighboring hydrogen atoms.

** From Eq. 1, it is shown that on a particular layer line a strong reflexion can occur in a region where $R$ is small only if the corresponding Bessel function is of a low order, so long as a helix dose not take too large a value of any $r_j$.

# *The Abnormality in the Mechanical Behavior of Polyvinyl Acetate-Carbon Tetrachloride Gel*

By Kazuyoshi OGINO

(Received February 23, 1959)

It is well known that many polymeric substances are typically visco-elastic: their stress under constant strain decreases continuously with time; i. e. stress relaxation is observed. In this case, it is usual that the stress deteriorates with time, and this is expected from the following consideration: when a specimen is held under a constant strain, the relative position or the configuration of the molecules changes with time so as to attain a more unstrained position, and thus the stress which corresponds to this strain decreases with time. This is the stress relaxation in "normal" condition.

On the other hand, Tobolsky et al. found[1] that some abnormalities in the stress relaxation under constant elongation appear at about 100°C when natural and several synthetic polymers are heated in the air. Further, they thought that the structural or chemical changes are reflected in the visco-elastic behavior of these substances. This phenomenon is known as the chemorheological process.

Many examples of abnormalities in the mechanical properties of polymeric substances have been interpreted as the result of the scission of the network chain or the cross-linking reaction by oxygen in the air*,[2].

The author found that the mechanical behavior of swollen polyvinyl acetate gels, which were cross-linked slightly with diallyl adipate and swollen in several organic solvents, shows abnormality when carbon-tetrachloride was used as a solvent; i. e. their stress *increases* continuously with time when the temperature was raised above 50°C. When one chooses polyvinyl acetate, polymethyl acrylate, polymethyl methacrylate or polystyrene as the polymeric substance, and chloroform, benzene, toluene, carbon tetrachloride or methanol as the solvent, the combination of polyvinyl acetate and carbon tetrachloride is the only system which causes an increase in stress under constant strain. The purpose of this paper is to report this abnormality, and to make a possible interpretation for this phenomenon.

## Experimental

**Materials.**—Commercial monomeric vinyl acetate was shaken several times with aqueous alkaline solution, and with distilled water. This process was repeated three times. The monomer was then distilled under reduced pressure.

Diallyl adipate was synthesized by esterification of allyl alcohol with adipic acid, and was purified by fractional distillation under reduced pressure**.

Carbon tetrachloride was purified by washing with aqueous alkaline solution and by distillation.

Vinyl acetate monomer mixed with cross-linking agent was polymerized thermally in bulk in a sealed glass tube under the presence of benzoyl peroxide as initiator (about 0.5 wt. %). This had been purified by recrystallization. At the beginning of polymerization, the temperature was kept at about 50°C until the contents were solidified, and was then held at 100°C for 12 hr.

The polymer rod was cut into several pieces, about 1 cm. in length, and was brought to the swelling equilibrium in carbon tetrachloride.

**Apparatus.** — The apparatus used in this

experiment is the same as the one used in the previous work[3], and is shown in Fig. 1.

The temperature of the sample was controlled by circulation of water from a water bath, and was read directly by a thermometer immersed in the solvent. The temperature was so high (about 50°C) that in some cases the fluctuation was observed to some extent, but this did not exceed 1°C.

## Results and Discussion

Fig. 2 shows the relation between stress and time at about 50°C under 20% strain. It is clear from this figure that the stress in these gels decreases slightly in the first step and then increases. The degree of this increase in stress becomes larger as the degree of swelling diminishes.

Oxygen from the air can not be considered to be the cause of this abnormality, because this occurs only in the system of polyvinyl acetate and carbon tetrachloride, and does not occur in any other polymer-solvent combinations. It is difficulty to find any reason for the effect of atmospheric oxygen being found in this system alone. The structural difference between vinyl acetate and methyl acrylate is only in the position of the carbonyl group. There must consequently be some special meaning for the vinyl acetate system. This can be interpreted as follows.

It is well known that in the solution polymerization, especially when carbon tetrachloride, carbon tetrabromide, chloroform, sulfur dichloride or mercaptane is chosen as solvent, the chain transfer with solvent molecules occurs very easily and each polymer molecule contains fragments of the solvent[4]. Such a compound is known as telomer, and the reaction is called telomerization. Fig. 3 shows the mechanism of the chain transfer with carbon tetrachloride as an example.

On the other hand, the chain transfer with monomeric vinyl acetate takes place in the scheme as shown in Fig. 4.

$$Mn\cdot + CCl_4 \rightarrow MnCl + \cdot CCl_3$$
$$\cdot CCl_3 + M \rightarrow M\cdot CCl_3\cdot \rightarrow MnCCl_3\cdot$$
$$MnCCl_3\cdot + CCl_4 \rightarrow \underset{\text{(Telomer)}}{Cl\cdot Mn\cdot CCl_3} + \cdot CCl_3$$

Fig. 3. The chain transfer with carbon tetrachloride.

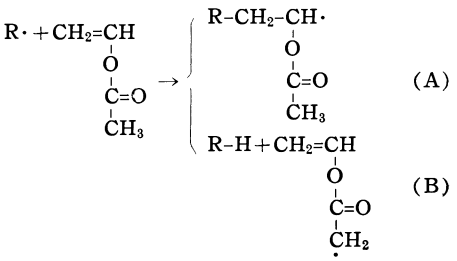

Fig. 4. The chain transfer with vinyl acetate.

In this case, it is noticeable that the radical of type B is produced. This is considered to be the cause of the existence of vinyl groups which are connected to the end of the branching along the long chain molecule of polyvinyl acetate[5]. In the case of the other monomers, such as methyl acrylate, methyl methacrylate or styrene, radicals of this type rarely exist. The existence of this radical, and consequently the possibility of the existence of vinyl groups at the end of each branching in polymer is the characteristic feature of vinyl acetate.

Hence, the polymer which has a structure like that shown schematically in Fig.

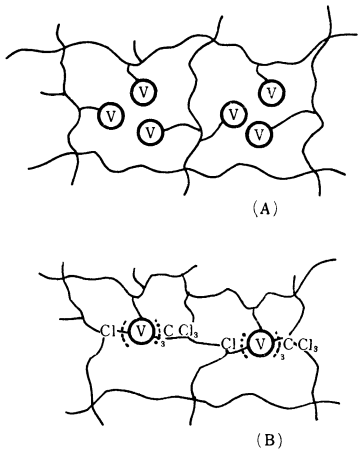

Fig. 5. The schematic diagram to show the internal structure of polyvinyl acetate. ($V$=Vinyl group)

5A will be produced when vinyl acetate is polymerized thermally in bulk in a sealed tube under the presence of benzoyl peroxide as an initiator. Therefore, when this polymer is brought to the swelling equilibrium with carbon tetrachloride, and is maintained at about 50°C, telomer will be formed between carbon tetrachloride and vinyl groups present at the end of each branching. This feature is shown in Fig. 5B. If this reaction occurs, the effective molecular weight between junction points decreases, and so the stress will increase. In order that this reaction, telomerization, may take place, it is necessary that radicals exist in this system. This postulation seems to be satisfied because the initiator which was added initially into the monomer will still remain undecomposed in the polymer, and further, it is demonstrated, for example, by Ingram[6], that radicals which are created in the course of polymerization will remain unchanged.

To confirm this postulation, the mechanical property of polyvinyl acetate, which was swollen at room temperature in carbon tetrachloride with 5% bromine added, was investigated. By this treatment, vinyl groups may be saturated and radicals may be consumed by bromine; i. e. it may be considered that the cause which provokes telomerization will be removed. This result is shown in Fig. 6. It is clear that after the treatment with bromine solution the "normal" relaxation

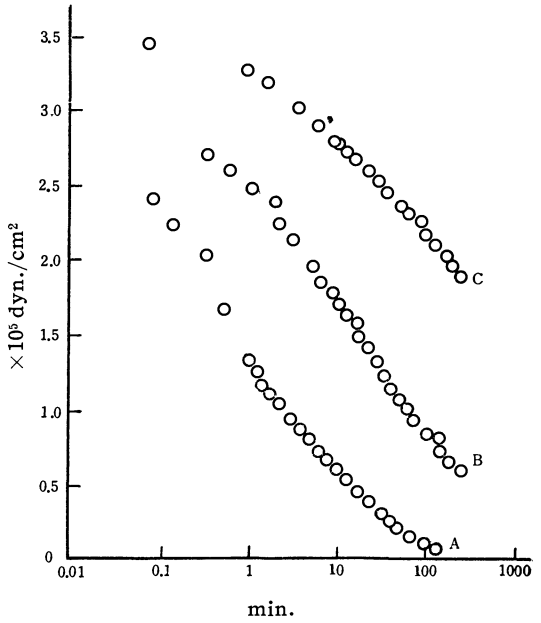

Fig. 6. The relation between stress and time under 20% strain after the treatment by bromine solution in carbon tetrachloride.

of stress is observed. The volume fraction of polymer in bromine solution is larger than that in carbon tetrachloride. This may be due to the polar effect of substituted bromine atoms.

If it may be assumed that the abnormality observed in the system polyvinyl acetate-carbon tetrachloride gel arises from telomerization between vinyl groups and solvent, it is expected that when chloroform is used as a solvent a similar abnormality will be observed. But, as shown in Fig. 7, this was not observed. This may be due to the fact that chloroform is a good solvent for polyvinyl acetate and the degree of swelling becomes very great, so the chain molecules will be fairly far apart from each other in this solvent compared with the case in carbon tetrachloride***.

Tobolsky et al. showed that the splitting or reforming reaction of cross-linkages by oxygen occurs between chain molecules[7], and that if the number of splits per cubic centimeter is a linear function of time, the decay of stress follows the Maxwellian

6) D. J. E. Ingram et al., *Trans. Faraday Soc.*, **54**, 409 (1958).

*** Tobolsky et al. found that the effect of oxygen upon the mechanical property was not observed in swollen polymer, and thought that this might be due to the greater distance of chain molecules in the swollen state than in the dry state[1].

7) A. V. Tobolsky, D. Metz and R. B. Mesrobian, *J. Am. Chem. Soc.*, **72**, 1942 (1950).

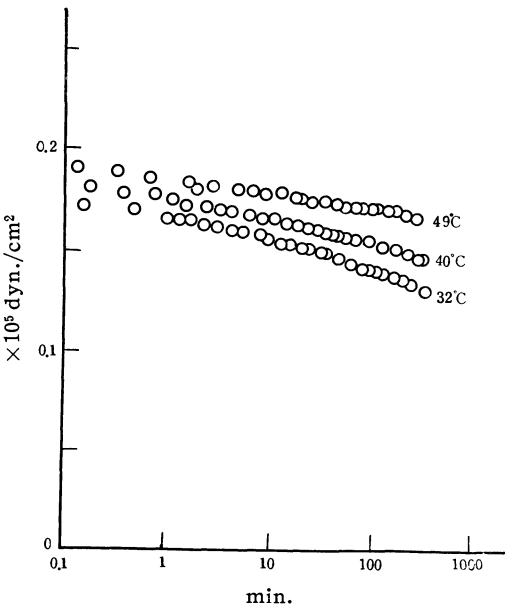

Fig. 7. The relation between stress and time in chloroform. (The volume fraction: 0.020)

decay law[8], or

$$f(t) = f(0) \exp(-kt)$$

where $f(0)$ is the stress at time zero, $f(t)$ the stress at time $t$, and $k$ the rate constant.

Now, for the system polyvinyl acetate-carbon tetrachloride gel, if $a$ is the number of vinyl groups at time zero between junction points, and $x$ of this group are consumed at time $t$ by telomerization, the following equation can be postulated because the rate of telomerization, $dx/dt$, will be primarily dependant upon the distance between chain molecules[1], and as the reaction proceeds, the chance of two vinyl groups meeting with each other will increase by the presence of newly formed cross-linkage. Thus, the rate of reaction will be proportional to the number of vinyl groups which have been cross-linked; i. e.

$$dx/dt = kx$$

therefore,

$$\ln(x/a) = kt$$

The stress at time $t$ can be considered to be proportional to the number of cross-linkages, $x$, which are formed between junction points, and so,

$$\ln\{f(t)/f(0)\} = kt$$

Thus, if one plots the results of Fig. 2 as $\ln(f/f_0)$ against $t$, the curves of Fig. 8 are obtained. The slope in each curve is identical with the rate constant, $k$, if the term of stress relaxation is neglected.

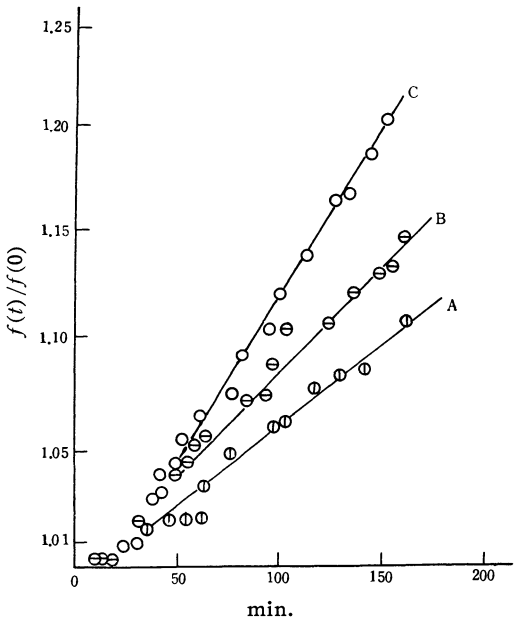

Fig. 8. The plot of $\ln\{f(t)/f(0)\}$ against $t$ at about 50°C.

The abnormality in the mechanical behavior of polyvinyl acetate-carbon tetrachloride gel was interpreted here by telomerization between vinyl groups and solvent.

The author wishes to express his indebtedness to Professor H. Akamatu and Assistant Professor T. Nakagawa for their interest and support, and to Dr. N. Inamoto for his helpful advice and criticism concerning this experiment.

# *Effect of Ionization on the Behavior of Insoluble Monolayers*

By Shoichi IKEDA and Toshizo ISEMURA

(Received March 23, 1959)

It has been observed experimentally that an insoluble monolayer of electrolyte is more condensed on an aqueous subphase of higher concentration of salt while it is more expanded on that of lower concentration. Such an effect of salt on the behavior of ionized monolayer was first elucidated by Davies[1] in the light of the theory of electric double layer, which was based on the Gouy-Chapman's theory of diffuse double layer developed by Derjaguin and Landau[2] and Verwey and Overbeek[3]. Investigations on ionized monolayers have been carried out further along this line[4,5].

In the present paper the authors will show that the same results can be derived from a simpler thermodynamic consideration as well as from the electrostatic theory. The present theory is not only more intuitive and tractable but also is a more general approximation, although it assumes an uncertified model.

An insoluble monolayer may be supposed to be a two-dimensional solution in a surface phase, in which the monolayer substance behaves as a solute, apart from its non-polar side chains. It exerts a surface pressure for maintaining thermodynamic equilibrium with the bulk phase. Thus, for an electrolyte monolayer it may be assumed that its ionized groups are dissolved uniformly in a "surface phase" with a definite thickness, $\delta$, and ions of salt in the aqueous subphase are distributed between the surface and bulk phases, counter ions being concentrated in the surface phase and co-ions being repelled from there into the bulk phase. The distribution of ions between the two phases will be first evaluated by an analogy to the membrane equilibrium and then by an improved approximation. The difference in ionic concentrations between the two phases resulting from the ionization of monolayer contributes to both surface pressure and potential. These contributions will be calculated by means of a thermodynamic procedure.

Consider a uni-univalent type of salt and a monolayer substance whose molecule dissociates into an insoluble cation carrying $i$-univalent ionized groups and $i$ univalent anions common with those of the salt. The ionized groups of the monolayer are assumed to be uniformly distributed in the surface phase. Since the surface phase can not be defined from the present theory alone, its thickness, $\delta$, must be assigned so as to cover the effective thickness of the diffuse double layer, as seen later.

## Membrane Equilibrium for Ionized Monolayer

In the present model it is assumed that the boundary between the surface and bulk phases behaves like a semipermeable membrane in osmotic equilibrium and, to the first approximation, the distribution of diffusible ions between these phases is governed by conditions similar to those in Donnan's membrane equilibrium in colloidal solution[6]. That is, electrochemical potentials of each diffusible ion in both phases are put equal. In the expression of the electrochemical potential functions, activities may be substituted by concentrations, unless they are very high.

Let the concentrations of cation and anion of salt be $\bar{n}_+$ and $\bar{n}_-$ (ions per cm$^3$) in the surface phase, respectively, and those of both ions equally $n$ in the bulk phase. If the electrostatic potential of diffusible ions in the surface phase relative to that in the bulk phase is $\psi_D$, conditions for equilibrium are given by

$$\begin{aligned} kT\ln\bar{n}_+ + e\psi_D &= kT\ln n \\ kT\ln\bar{n}_- - e\psi_D &= kT\ln n \end{aligned} \qquad (1)$$

where $e$ is the elementary charge, $k$ the

6) F. G. Donnan and E. A. Guggenheim, *Z. physik. Chem.*, **A162**, 346 (1932).

Boltzmann constant and $T$ the absolute temperature. Furthermore, it is assumed that the surface phase remains electrically neutral, i.e.

$$\bar{n}_+ + \frac{i\Gamma_M}{\delta} = \bar{n}_- \tag{2}$$

where $\Gamma_M$ (ions per cm$^2$) is the surface concentration of non-diffusible cations, each with $i$ univalent ionized groups, in the surface phase. From Eqs. 1 and 2 the equilibrium concentrations of diffusible ions are obtained as

$$\begin{aligned}\bar{n}_+ &= \frac{1}{2}\left\{-\frac{i\Gamma_M}{\delta} + \sqrt{\left(\frac{i\Gamma_M}{\delta}\right)^2 + 4n^2}\right\} \\ \bar{n}_- &= \frac{1}{2}\left\{\frac{i\Gamma_M}{\delta} + \sqrt{\left(\frac{i\Gamma_M}{\delta}\right)^2 + 4n^2}\right\}\end{aligned} \tag{3}$$

They can also be written as

$$\begin{aligned}\bar{n}_+ &= n\exp(-e\psi_D/kT) \\ \bar{n}_- &= n\exp(e\psi_D/kT)\end{aligned} \tag{4}$$

where

$$i\Gamma_M = 2n\delta\sinh\frac{e\psi_D}{kT} \tag{5}$$

The surface excesses of diffusible ions may be defined as

$$\begin{aligned}\Gamma_+ &= \delta(\bar{n}_+ - n) \\ \Gamma_- &= \delta(\bar{n}_- - n)\end{aligned} \tag{6}$$

and the surface concentration of the ionized group is

$$i\Gamma_M = 1/A \tag{7}$$

where $A$ is the area per ionized group.

In order to determine the thickness of the surface phase, $\delta$, and the potential of ionized groups of monolayer, $\psi_M$, one must take account of the results of the theory of diffuse double layer. According to the theory, concentrations of diffusible ions at the depth, $x$, below the surface, where the electrostatic potential is $\psi$, are given by

$$\begin{aligned}n_+ &= n\exp(-e\psi/kT) \\ n_- &= n\exp(e\psi/kT)\end{aligned} \tag{8}$$

where $n$ is the concentration of each ion or salt far away from the surface. Their surface excesses may be defined by

$$\begin{aligned}\Gamma_+ &= \int_0^\infty (n_+ - n)\mathrm{d}x \\ \Gamma_- &= \int_0^\infty (n_- - n)\mathrm{d}x\end{aligned} \tag{9}$$

which lead to

$$\begin{aligned}\Gamma_+ &= \frac{2n}{\kappa}\left\{\exp\left(-\frac{e\psi_G}{2kT}\right) - 1\right\} \\ \Gamma_- &= \frac{2n}{\kappa}\left\{\exp\left(\frac{e\psi_G}{2kT}\right) - 1\right\}\end{aligned} \tag{10}$$

Here $\psi_G$ is the potential at the surface, $x=0$, and $\kappa$ is the Debye-Hückel parameter

$$\kappa^2 = \frac{8\pi ne^2}{\varepsilon kT} \tag{11}$$

$\varepsilon$ being the dielectric constant. As for the distribution of diffusible ions, the present treatment corresponds to an averaged procedure of the theory of diffuse double layer. Thus, equating Eq. 6 to Eq. 10, it follows that

$$\delta = 2/\kappa \tag{12}$$

and

$$\psi_D = \psi_G/2 \tag{13}$$

The electrostatic potential of ionized groups of monolayer, $\psi_M$, should be equal to the Gouy potential, $\psi_G$. Hence, it is twice as high as the electrostatic potential of diffusible ions, or the membrane potential, $\psi_D$.

$$\psi_M = 2\psi_D \tag{14}$$

It may be assumed generally in the treatment of ionized monolayers based on the present model of surface phase that the thickness of surface phase is given by $2/\kappa$ and the electrostatic potential of ionized groups is twice as high as that of diffusible ions.

### Improved Approximation for the Distribution of Ions

The distribution of diffusible ions obtained in the previous section has been derived from a simple assumption that the surface phase is electrically neutral. In this section one will develop an approximate method when this assumption is removed.

When the surface and bulk phases are distinguished from each other, the electrostatic potential, $\psi$, of diffusible ions follows the Poisson equations

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = -\frac{4\pi e}{\varepsilon}\left(\frac{i\Gamma_M}{\delta} + n_+ - n_-\right)$$

for $x \leq \delta$ (surface phase) (15)

$$= -\frac{4\pi e}{\varepsilon}(n_+ - n_-)$$

for $x \geq \delta$ (bulk phase) (16)

where $\delta = 2/\kappa$, and their concentrations are given by equations formally identical with

Eq. 8. Eqs. 8 and 15 imply that the surface phase is not always electrically neutral.

In order to solve the Poisson-Boltzmann equations, Eqs. 15 and 16 with Eqs. 8, it will be assumed that the surface phase deviates slightly from being electroneutral. In such a case the "$\lambda$-method", which was devised for solving the problem of polyelectrolyte solution[7], might be applied to the present equations. Then a quantity $\lambda$ is defined as

$$\frac{i\Gamma_M}{\delta}+n_+-n_-=\frac{i\Gamma_M}{\delta}\lambda \tag{17}$$

$$\lambda \ll 1 \tag{18}$$

Evidently, the problem is reduced to that of the membrane equilibrium, if $\lambda=0$. From Eqs. 8 and 17, it follows that

$$\sinh\frac{e\psi}{kT}=\frac{i\Gamma_M}{2n\delta}(1-\lambda) \tag{19}$$

Expanding $e\psi/kT$ in a series of $\lambda$ using Eq. 19 and ignoring the terms higher than $\lambda$, one obtains

$$\frac{e\psi}{kT}=\ln\frac{i\Gamma_M+\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{2n\delta}-\frac{i\Gamma_M\lambda}{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}} \tag{20}$$

and

$$\lambda=\frac{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{i\Gamma_M}\left[-\frac{e\psi}{kT}+\ln\frac{i\Gamma_M+\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{2n\delta}\right] \tag{21}$$

Then, instead of Eq. 15, one has a linear equation

$$\frac{d^2\lambda}{dx^2}=\chi^2\lambda \tag{22}$$

or

$$\frac{d^2\psi}{dx^2}=\chi^2(\psi-\psi_D) \tag{23}$$

where

$$\chi^2=\frac{4\pi e^2}{\varepsilon kT}\sqrt{\left(\frac{i\Gamma_M}{\delta}\right)^2+4n^2} \tag{24}$$

and

$$\frac{e\psi_D}{kT}=\ln\frac{i\Gamma_M+\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{2n\delta} \tag{5a}$$

The most general boundary conditions for Eqs. 15 and 16 are given by

$$(d\psi/dx)_{x=0}=0 \tag{25}$$

$$\psi \text{ and } d\psi/dx \text{ : continuous at } x=\delta \tag{26}$$

and

$$\psi_{x=\infty}=(d\psi/dx)_{x=\infty}=0 \tag{27}$$

Under these conditions one can obtain solutions which correspond to those derivd by Lifson[8] and Nagasawa and Kagawa[9] for the polyelectrolyte solution. For the sake of simplicity, however, a simpler condition

$$\psi_{x=0}=0 \tag{26a}$$

is chosen here instead of the second condition (26). This means that $\psi=0$ and $n_+=n_-=n$ in the bulk phase ($x\geq\delta$). Thus the surface phase ($x\leq\delta$) may be treated separately. The solutions of Eqs. 22 and 23 are found to be

$$\lambda=\frac{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{i\Gamma_M}\frac{e\psi_D}{kT}\frac{\cosh\chi x}{\cosh\chi\delta} \tag{28}$$

and

$$\psi=\psi_D\left(1-\frac{\cosh\chi x}{\cosh\chi\delta}\right) \tag{29}$$

respectively.

After this, one will be concerned with the mean concentrations and the mean potential of ions in the surface phase. By a simple averaging procedure or by Gauss's theorem of electrostatics, the mean value of $\lambda$ is calculated to be

$$\langle\lambda\rangle=\frac{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}{i\Gamma_M}\frac{e\psi_D}{kT}\frac{\tanh\chi\delta}{\chi\delta} \tag{30}$$

The mean concentrations of cation and anion in the surface phase are then represented by

$$\begin{aligned}\langle n_+\rangle&=\frac{1}{2}\left\{-\frac{i\Gamma_M}{\delta}+\sqrt{\left(\frac{i\Gamma_M}{\delta}\right)^2+4n^2}\right\}\times\left\{1+\frac{i\Gamma_M\langle\lambda\rangle}{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}\right\}\\ \langle n_-\rangle&=\frac{1}{2}\left\{\frac{i\Gamma_M}{\delta}+\sqrt{\left(\frac{i\Gamma_M}{\delta}\right)^2+4n^2}\right\}\times\left\{1-\frac{i\Gamma_M\langle\lambda\rangle}{\sqrt{(i\Gamma_M)^2+4(n\delta)^2}}\right\}\end{aligned} \tag{31}$$

respectively, and their surface excesses are defined by

$$\begin{aligned}\Gamma_+&=\delta(\langle n_+\rangle-n)\\ \Gamma_-&=\delta(\langle n_-\rangle-n)\end{aligned} \tag{32}$$

respectively. The mean electric potential of diffusible ions in the surface phase is given by

$$\langle\psi\rangle=\psi_D\left(1-\frac{\tanh\chi\delta}{\chi\delta}\right) \tag{33}$$

7) F. Oosawa, N. Imai and I. Kagawa, *J. Polymer Sci*., 13, 93 (1953).

8) S. Lifson. *J. Chem. Phys.*, 27, 700 (1957).

9) M. Nagasawa and I. Kagawa, This Bulletin, 31, 961 (1958).

The potential of ionized groups of monolayer is assumed to be defined by

$$\psi_M = 2\langle\psi\rangle \tag{34}$$

as described before. Then one has

$$\langle n_+\rangle/n = n/\langle n_-\rangle = \exp(-e\psi_M/2kT) \tag{35}$$

### Contribution of Ionization to Surface Pressure and Potential

When a monolayer is ionized and charged positively, diffusible ions in aqueous subphase become distributed between the surface and the bulk phase, as given by Eq. 3 or 31, and the electrostatic potential of the monolayer becomes higher than that of the diffusible ions in the bulk phase by the amount $\psi_M$, as given by Eq. 14 or 34. The thermodynamic equilibrium is established by accompanying the decrease in surface free energy, i.e. the increase of surface pressure. The relationship between the increment of surface pressure and the ionic concentrations will be described by an equation such as the Gibbs absorption isotherm. At a constant surface concentration of monolayer, the surface pressure, $\Pi_i$, due to the ionization of monolayer can be expressed by

$$\mathrm{d}\Pi_i = kT(\Gamma_+ + \Gamma_-)\mathrm{d}\ln n + i\Gamma_M \mathrm{d}(e\psi_M) \tag{36}$$

In the following formula one will carry out the integration of Eq. 36 in the case of the $\lambda$-approximation, since the results from the treatment of membrane equilibrium can be derived as a limiting case. Inserting Eqs. 31 and 32 into Eq. 36 and neglecting the terms higher than $\lambda$, it may be written as

$$\mathrm{d}\Pi_i = kT\left\{-2n\delta + \sqrt{(i\Gamma_M)^2 + 4(n\delta)^2} - \frac{(i\Gamma_M)^2\langle\lambda\rangle}{\sqrt{(i\Gamma_M)^2 + 4(n\delta)^2}}\right\}\mathrm{d}\ln n + i\Gamma_M \mathrm{d}(e\psi_M) \tag{37}$$

Integration leads to

$$\Pi_i = 2kT\left\{-2n\delta + \sqrt{(i\Gamma_M)^2 + 4(n\delta)^2} - \frac{(i\Gamma_M)^2\langle\lambda\rangle}{\sqrt{(i\Gamma_M)^2 + 4(n\delta)^2}}\right\} - kT(i\Gamma_M)^2 \int_\infty^n \frac{\langle\lambda\rangle}{\sqrt{(i\Gamma_M)^2 + 4(n\delta)^2}} \frac{\mathrm{d}n}{n} \tag{38}$$

provided that the integration constant is chosen so as to be $\Pi_i = 0$ at the infinite salt concentration. If the last term with a complicated integral is ignored, it follows that

$$\Pi_i = 2kT(\Gamma_+ + \Gamma_-) \tag{39}$$

$$= 2kT\delta(\langle n_+\rangle + \langle n_-\rangle - 2n) \tag{40}$$

In the approximation of membrane equilibrium, $\langle\lambda\rangle = 0$, Eq. 40 reduces to

$$\Pi_i = 2kT\delta(\bar{n}_+ + \bar{n}_- - 2n) \tag{41}$$

Eqs. 40 and 41 represent a colligative nature of surface pressure at a low surface concentration of monolayer. Eqs. 40 and 41 can be rewritten by the use of measurable quantities as

$$\Pi_i = 2kT\left\{-\frac{4n}{\kappa} + \sqrt{\frac{1}{A^2} + \left(\frac{4n}{\kappa}\right)^2} - \frac{1}{A^2}\frac{\langle\lambda\rangle}{\sqrt{\frac{1}{A^2} + \left(\frac{4n}{\kappa}\right)^2}}\right\} \tag{42}$$

and

$$\Pi_i = 2kT\left\{-\frac{4n}{\kappa} + \sqrt{\frac{1}{A^2} + \left(\frac{4n}{\kappa}\right)^2}\right\} \tag{43}$$

respectively, and by the use of the electrostatic potential of monolayer the above two equation become as follows:

$$\Pi_i = 4n\delta kT\left(\cosh\frac{e\psi_M}{2kT} - 1\right) \tag{44}$$

Eq. 44 in the case of $\langle\lambda\rangle = 0$ is in complete agreement with the equation derived from the theory of diffuse double layer

$$\Pi_i = \frac{8nkT}{\kappa}\left(\cosh\frac{e\psi_G}{2kT} - 1\right) \tag{45}$$

which should be expected if Eqs. 12—14 hold.

The situation that the same results follow both from the treatments of membrane equilibrium and of diffuse double layer has also been noticed in the theory of polyelectrolyte solution[9,10]. Further, it would be more plausible to assume that $\delta = 2/\kappa$, although it had always been assumed that $\delta = 1/\kappa$[11].

If the surface pressure of unionized monolayer is $\Pi_0$, the observed surface pressure of ionized monolayer can be expressed by

$$\Pi = \Pi_0 + \Pi_i \tag{46}$$

Thus, the surface pressure of ionized

monolayer is higher at lower salt concentration, and, conversely, it is lower at higher salt concentration. At sufficiently high salt concentrations, $\Pi_i=0$ and, accordingly, $\Pi=\Pi_0$. (A polyelectrolyte monolayer exerts an additional surface pressure due to the elastic deformation of polymer chains on ionization, but the inference mentioned here remains unaltered.)

The surface potential of ionized monolayer measured experimentally has the form[1,12]

$$\Delta V=\frac{4\pi\mu}{A}+\psi_M \tag{47}$$

where $\mu$ is the surface moment per ionized group. At sufficiently high salt concentrations, $\psi_M=0$ and, accordingly, $\Delta V=4\pi\mu/A$. At low salt concentrations,

$$\left(\frac{\partial\Delta V}{\partial\ln n}\right)_{i\Gamma_M \text{ or } A}=\left(\frac{\partial\psi_M}{\partial\ln n}\right)_{i\Gamma_M \text{ or } A}=-\frac{Tk}{e} \tag{48}$$

as already found by Crisp[13].

### Comparison with Experiments

The results obtained above from either treatment for ionized monolayers, the approximation of membrane equilibrium or the $\lambda$-method, can be readily examined with experimental data, by comparing the values of $\Pi_0$ and $\mu$ at various salt concentrations, which can be evaluated by subtracting the calculated values of $\Pi_i$ and $\psi_M$ from the observed values of $\Pi$ and $\Delta V$, respectively. If the treatments were valid, the $\Pi_0$ and $\mu$ values should be independent of salt concentration. One has applied the procedure to the available data on surface pressure of two typically different monolayers, i. e. those of octadecyltrimethylammonium chloride*,[1] and of copoly-1 : 3 : 1-(L-lysine, L-phenylalanine, L-glutamic acid)**,[4].

For the approximation of membrane equilibrium, using Eq. 43 for $\Pi_i$, the results as shown in Table I are obtained. It can be seen that the $\Pi_0$ values are not independent of salt concentration. Further, all these values are found to be negative. The negative $\Pi_0$ values imply that the corresponding unionized monolayers would contract in themselves rather than spread on aqueous surfaces. Davies' suggestion that the ionized monolayers would be condensed into "islands" or micelles is not valid, since the ionized monolayers do not contract but only form condensed films on strong salt solutions. This inconsistency may be ascribed to an overestimate of $\Pi_i$ values. The too high contribution of ionization to monolayer properties

12) J. H. Schulman and A. H. Hughes, *Proc. Roy. Soc.*, **A138**, 430 (1932).

13) D. J. Crisp, Research, "Surface Chemistry", Butterworths Scientific Publications, London (1949), p. 65.

* For this monolayer, a constant value of $\mu$ was noticed by Davies[1]. However, the $\mu$ value appears to be insensitive to salt concentration.

** If the deformation of polymer chains on ionization is taken into account, the $\Pi_0$ values would be lower than those in Table I, in which this contribution is not involved.

comes from the distribution of counter ions being too much concentrated in the surface phase and of co-ions being too much repelled from there. Indeed, the present approximation sometimes leads to concentration of counter ions in the surface phase being more than ten times as high as that in the bulk phase.

It can be expected that this difficulty will be partly avoided by removing the assumption of the electroneutral surface phase. The $\lambda$-approximation has led to the surface pressure due to ionization given by Eq. 42, which is lower than that obtained by the approximation of membrane equilibrium, Eq. 43, by the amount

$$\frac{kT}{A}\ln\left[\frac{1/A+\sqrt{(1/A)^2+(4n/\kappa)^2}}{-1/A+\sqrt{(1/A)^2+(4n/\kappa)^2}}\right]\times\frac{\kappa}{2\chi}\tanh\frac{2\chi}{\kappa}$$

To confirm this, the data for the monolayer of octadecyltrimethylammonium chloride has been treated by Eq. 42 in a manner as previously. The results are shown in Table II. It can be seen that the $\Pi_0$ values are independent of salt concentration and are always positive. Thus, the inconsistency which was encountered previously in the method of membrane equilibrium is not revealed in the $\lambda$-approximation.

TABLE II

*Octadecyltrimethylammonium chloride on* NaCl, $T=293°K$, $\varepsilon=80$, $A=85\ A^2$ per long chain ion

| $n$ mol./l. | $\Pi_i$(Eq. 42) dyn./cm. | $\Pi$ | $\Pi_0$ | $\langle\lambda\rangle$ |
|---|---|---|---|---|
| 0.033 | 3.87 | 5.8 | 1.93 | 0.487 |
| 0.100 | 2.99 | 5.3 | 2.31 | 0.509 |
| 0.50 | 1.40 | 3.8 | 2.40 | 0.539 |
| 2.0 | 0.34 | 2.7 | 2.36 | 0.523 |

The advantage of the $\lambda$-method is, however, only superficial. When the surface concentration of monolayer is not low enough, the last term of an integral in Eq. 38, which can not be easily estimated, becomes significant. Moreover, it is found from Table II that all the $\langle\lambda\rangle$ values are about 0.5 and incompatible with the fundamental assumption, Eq. 18. It may, therefore, be stated that the $\lambda$-method, as well as the approximation of membrane equilibrium, can not explain completely the effect of ionization on the typically expanded monolayer of octadecyltrimethylammonium chloride. The method is also found to be insufficient to elucidate consistently the ionization behavior of the condensed monolayer of copoly-1 : 3 : 1-(L-lysine, L-phenylalanine, L-glutamic acid).

The main purpose of the theory consists in a description of the experimental fact that an ionized monolayer is more condensed on concentrated salt solutions and is more expanded on dilute solutions. The present theory has, however, given explanations of only a part of the observations that higher salt concentrations reduce surface pressure of an ionized monolayer more than lower salt concentrations do. Generally, an ionized monolayer has an area where the reversal of surface pressure occurs, which is independent of salt concentration but dependent on salt species[5]: at the area larger than this, the surface pressure is lower at higher salt concentrations and at the smaller area it is reversed. Hence, the present theory concerns only the region of large area. It seems likely that for a comprehensive interpretation of the behavior of ionized monolayers the assumption of uniformly distributed ionized groups in the surface phase should be modified and penetration of ions into the surface phase, finite dimension of ions, association effect and other individual characteristics of ions should be taken into account.

## Summary

The effect of salt on ionized monolayers is treated with a model of "surface phase", in which ionized groups of monolayers are dissolved uniformly. To obtain the distribution of diffusible ions between the surface and bulk phases, the method of membrane equilibrium and the $\lambda$-approximation are employed. The former method is a special case of the latter. The contribution of ionization to surface pressure is calculated thermodynamically. The results derived from the former method are found to be in complete agreement with those derived from the theory of diffuse double layer, if the thickness of surface phase is chosen as $2/\kappa$ and the electric potential of ionized groups is twice as high as the membrane potential. On examining two typically different monolayers, the former method reveals some contradiction, although it explains experimental data qualitively. The latter method, which is more general, can overcome the difficulty and gives reasonable values for surface pressure of an expanded monolayer. It is

found, however, that even the $\lambda$-approximation is still unsatisfactory to describe the behavior of ionized monolayers in the range of area with which they are ordinarily concerned.

A part of the expense for this work was defrayed by the Ministry of Education, to which the authors' thanks are due.

# *The Roles of Prolyl Residue in Polypeptide Monolayers. III. Surface Films of Gelatin*

By Shoichi IKEDA and Toshizo ISEMURA

(Received June 23, 1959)

Collagen and gelatin are unusually rich in prolyl and hydroxyprolyl residues as compared with ordinary globular proteins. Because of the specific structures of these imino acid residues, the configurations of polypeptide chains in these proteins are expected to be quite different from those in other proteins. In fact, such characteristics have been observed in solutions of collagen[1-3] and gelatin[4,5] as well as in collagen fiber[6]. In surface films, if they are spread on aqueous surfaces, collagen and gelatin will likewise show a characteristic behavior.

It was established with synthetic polypetides[7,8] that the presence of prolyl residues in a polypeptide chain makes their surface films more expanded, chiefly due to the decrease in number of hydrogen bonds and, accordingly, the condensed nature of films of ordinary synthetic polypeptides may be ascribed to the hydrogen bonding in films. It has been noticed that most globular proteins form condensed films. If the roles of prolyl residue in polypeptide monolayers are reproduced in protein films, collagen and gelatin should form expanded films on aqueous surfaces.

In the present paper it will be examined by the measurements of surface pressure, potential and viscosity, whether these considerations are valid or not for the surface films of gelatin.

## Experimental

**Materials.**—Gelatin was purified from leaf gelatin of Nihon Hikaku Co., Ltd., by desalting it in acetate buffer at pH 4.8 and then washing it with distilled water. The pH of the solution of gelatin thus obtained was 4.9. Concentrations of gelatin solutions were determined by measuring the dry weight of 0.5% stock solution. Spreading solutions were prepared by diluting the stock solution ten times with distilled water.

**Methods.** — Surface pressure, potential and viscosity were measured by a surface balance of float type, a vibrating electrode and an oscillating rotatory disk, respectively. Surface moment was calculated from surface potential, using the Helmholtz equation.

To adjust pH of aqueous subphases to 2.0, 5.6 and 11.2, 0.01 N hydrochloric acid, distilled water and 0.01 M potassium carbonate were used, respectively. Purified potassium chloride was added to prevent the film from dissolving into aqueous subphases.

## Results

curves of gelatin films on salt-free subphases at three different pH's. Surface pressures of gelatin films on distilled water were scarcely influenced by the temperature of spreading solution and the nature of spreading solvents. Besides a gelatin solution in distilled water at room temperature, a solution in distilled water at 48°C, and solutions in 0.1 M potassium rhodanate, in 40% ethanol and in a mixture of dichloroacetic acid-isopropanol-water (5 : 2 : 3) were examined. Fig. 2 shows the $\Pi$-$A$ and $\mu$-$A$ curves of gelatin films on 1 M potassium chloride solutions at three different pH's. On the alkaline side the film had a slight tendency to dissolve into aqueous subphase, when spreading solution was freshly prepared. The surface viscosity-area ($\eta$-$A$) curve of the film on 1 M potassium chloride is also shown in Fig. 2.

## Discussion

Both collagen and gelatin are composed of about 30% glycyl residues and about 30% prolyl and hydroxyprolyl residues. In solution a collagen molecule exists as a rigid rod-like particle[1,2] which is also found in collagen fiber from X-ray diffraction studies[6]. On the other hand, a gelatin molecule behaves as a random coil like ordinary polymer molecules but unlike a collagen molecule[4,5].

It was reported, however, that, if collagen and gelatin are spread as surface films, they are indistinguishable from each other: collagen spread from its formic acid solution and gelatin from its aqueous and formic acid solutions give identical $\Pi$-$A$ and $\mu$-$A$ curves on 30% ammonium sulfate solution[9]. This fact is consistent with the present observations that $\Pi$-$A$ curves of gelatin films are independent of the nature of the spreading solutions.

In spite of its hydrophilic nature, gelatin formed a stable film on distilled water, as already noted[10]. The extent of the spreading of film was very incomplete and not very much influenced by the acididity and alkalinity of aqueous subphases. Such behavior of gelatin film is quite different from those of other protein films[11]. Further, molecular expansion of gelatin as was observed in aqueous solutions[12] was not reflected in its surface films. The surface moment of gelatin was higher on distilled water at pH 5.6 than on aqueous subphases at both sides of this pH. This is not consistent with the idea of titration of surface films[13,11], but is in agreement with the result for collagen film on aqueous solutions, the pH's of which were adjusted by hydrochloric acid[9]. Addition of salt into aqueous subphases caused gelatin films to spread more[14]. Even on 1 M potassium chloride, however, gelatin spread still incompletely and appeared to dissolve on compression. The surface pressures at different pH's were nearly identical on such a concentrated salt solution, as was generally expected from the theory of ionized

monolayers. Apart from these facts, all the surface films of gelatin were found to be of expanded types.

It has been observed that globular proteins, when spread as monolayers, form condensed films, at least, at the isoelectric point and occupy an area of about 15 $A^2$ per residue, which would mean that the protein films are in the $\beta$-configuration[15,11]. The expanded nature of gelatin films may be attributed to the roles of prolyl residues such as are found in the polypeptide monolayers, i. e. to the reduced number of hydrogen bonds[7]. In surface viscosity behavior was exhibited the general property of expanded films showing that the surface viscosity is only manifest at high surface pressure region[8]. The incomplete spreading and pressure-solubility of gelatin films may come from its hydrophility and specific configuration of polypeptide chains.

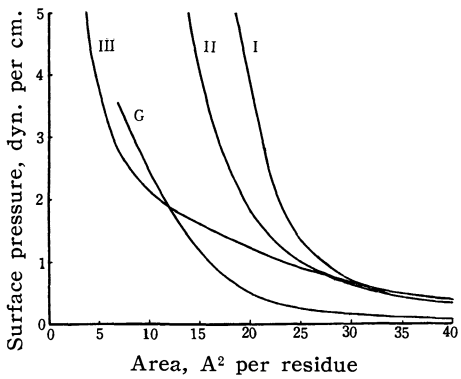

Fig. 3. Comparison of surface pressure-area curve of gelatin with those of some synthetic polypeptides. G: gelatin, I: poly-L-prolyl-L-leucylglycine, II: copoly-1:1:1-(L-proline, L-leucine, DL-alanine), III: poly-L-proline. G and III on 1 M potassium chloride.

Collagen and gelatin molecules were once regarded as consisting of L-prolyl-glycyl-R sequences, on which basis Astbury and Bell[16] suggested a chain configuration in collagen fiber. Recently, Millionova and Andreeva[17] proposed from their X-ray study on poly-glycyl-L-proline that glycyl-L-prolyl sequences are repeated in a collagen molecule. The amino acid analysis on partial hydrolysates of gelatin[18] and collagen[19] has, however, shown that a considerable amount of L-prolyl-L-hydroxyprolyl sequences are found in them, and now it is generally recognized that gelatin and collagen contain these sequences abundantly. At present, a configuration of polypeptide chain in collagen fiber has been established on the basis of the repeated structure of L-prolyl-L-hydroxyprolyl-glycyl sequences[6].

It appears that the surface pressure behavior of gelatin film also supports the presence of these sequences. In Fig. 3 the *II-A* curves of some polypeptide films reported in a previous paper[7] are summarized together with that of gelatin film on 1 M potassium chloride. It will be seen that the extent of expansion or the surface compressibility of gelatin film lies near that of copoly-1 : 1 : 1-(L-proline, L-leucine, DL-alanine) and is lower than that of poly-L-proline. In the former copolypeptide L-prolyl-R-L-prolyl sequences are possible and in the latter polypeptide the successive L-prolyl residues exist. Thus, it is considered that a gelatin molecule consists of L-prolyl-R-L-prolyl or L-prolyl-L-prolyl-R sequences. Since some of the prolyl residues in gelatin are substituted by hydroxyprolyl residues and the presence of hydroxyprolyl residues makes a surface film somewhat condensed, the latter sequence, i. e. L-prolyl-L-hydroxyprolyl-glycyl, may be favorable to explain the extent of expansion of gelatin film, in accordance with the results of chemical analysis.

If L-prolyl-L-hydroxyprolyl bonds are assumed to exsist in a gelatin molecule, the effect of salt on gelatin films can be well interpreted following Harrington's suggestion[20], that most of these bonds are *trans* in distilled water and the addition of salt causes the *trans-cis* transformation of these bonds. If the parts of *cis* bond in a gelatin molecule remain on the surface while the parts of *trans* bond dissolve in aqueous phase and the other parts are either on or in aqueous subphase according as their own hydrophility and their surrounding chain configurations, it can be explained why gelatin can form a stale film even on distilled water in spite of its hydrophilic nature. Further, the presence of salt in subphases would stabilize the *cis* bond more than the *trans* bond, causing the *trans-cis* transformation, and make

films spread more easily. There considerations are consistent with those made for poly-L-proline film previously[7].

## Summary

Surface films of gelatin, which is very rich in L-prolyl and L-hydroxyprolyl residues, were examined on salt-free and 1 M potassium chloride solutions at three different pH's by the measurements of surface pressure, potential and viscosity. They were found to spread incompletely but to be of expanded types. The incomplete spreading and the other properties of the films were regarded as a manifestation of the specific configuration of gelatin in films. The expanded nature of the films was attributed to the roles of prolyl residue in gelatin such as observed in polypeptides. The extent of expansion of the films appeared to give evidence to support the results from chemical analysis that a gelatin molecule is composed of a large amount of L-prolyl-L-hydroxyprolyl bonds. The behavior of gelatin films was adequately explained by assuming that the parts of *cis* L-prolyl-L-hydroxyprolyl bond form the film and the parts of *trans* bond dissolve in aqueous subphase.

# *Studies on the Mannich Reaction. III. On the Formation of Piperidine Derivatives (3)*

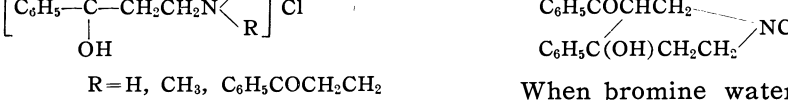
By Norito UCHINO

(Received May 4, 1959)

In the previous papers of this series[1], tautomerism of the Mannich compound involving prototropy was proposed as indicated below.

R=H, $CH_3$, $C_6H_5COCH_2CH_2$

The present experiment shows a fact which seems to support the above scheme.



The β-benzoylethylamines[2-4] used are: bis-(β-benzoylethyl)-amine(II), tris-(β-benzoylethyl)-amine(III), 4-oxy-4-phenyl-5-benzoyl-1-(β-benzoylethyl)-piperidine(IV), bis-(β-benzoylethyl)-methylamine(VI) and 4-oxy-4-phenyl-5-benzoyl-1-methyl-piperidine(VII).

$(C_6H_5COCH_2CH_2)_2NH$ (II)

$(C_6H_5COCH_2CH_2)_3N$ (III)

 (IV)

$(C_6H_5COCH_2CH_2)_2NCH_3$ (VI)

 (VII)

When bromine water was added to an aqueous solution of hydrochloride of the above Mannich base, yellow precipitates were produced almost quantitatively. The precipitates thus obtained had an irritative odor, probably that of bromine originated from the compounds. The bromine as molecule was also partly removed by washing with water.

In general, bromine may add to a free amine as the following scheme:

1) N. Uchino, This Bulletin, **32**, 1009 (1959).
2) C. Mannich and S. M. Abdullah, *Ber.*, **68**, 113 (1935).
3) J. T. Plati and W. Wenner, *J. Org. Chem.*, **14**, 543 (1949).
4) C. Mannich and G. Heilner, *Ber.*, **55**, 356 (1922); F. F. Blicke and J. H. Burckhalter, *J. Am. Chem. Soc.*, **64**, 451 (1942).

In the present study, such an addition of bromine seems impossible, because the amine is treated as a hydrochloride. Substitution in a benzene nucleus or addition to a double bond which is formed by enolization of a carbonyl group is not probable, considering the ease of evolution of bromine from the addition products and negative ferric chloride test regarding II·HCl or III·HCl.

The bromine compound from the hydrochloride of the Mannich base could be recrystallized from alcohol if the recrystallization was carried out within a little while, bright yellow crystals being obtained which were of an indistinct melting point. When the crystals were heated to a higher temperature, they decomposed and melted to a dark-brown liquid. The recrystallized addition compound still had a smell of bromine, and reduced potassium iodide.

The acid value, the halogen content and the oxidizing power of the recrystallized bromine addition product of II·HCl are summarized in Table I.

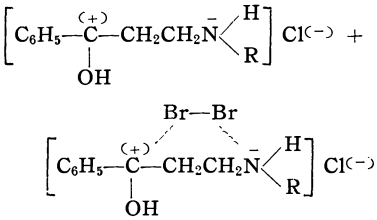
Table I. Analytical results of bromine addition product of II·HCl

| | Found ml./g. | Calcd. ml./g. |
|---|---|---|
| Acid value (N/10-NaOH) | 50.7 | 21.0[c] |
| Oxidizing power[a] (N/10-$Na_2S_2O_3$) | 24.1 | 42.0[d] |
| Halogen content[b] (N/10-$AgNO_3$) | 52.6 | 63.0[d] |

a) The bromine addition product was dissolved in alcohol, and potassium iodide was added to the solution. Iodine produced was titrated with sodium thiosulfate solution.

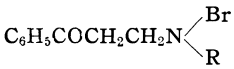
b) Bacon's method was used.

c) Theoretical value of N/10-NaOH consumed for hydrochloric acid which is present as hydrochloride of the addition compound of one mole of bromine with one mole of II·HCl.



d) Theoretical value for the addition compound of one mole of bromine with one mole of II·HCl.

From the above results, it is considered that at least one mole of bromine is added to one mole of the hydrochloride.



The yellow color of the product from II·HCl or III·HCl disappeared on refluxing the alcoholic solution. On cooling, compound II·HCl was recovered from the solution. When the addition product of II·HCl or III·HCl was treated with alcoholic alkali, base IV was obtained[5]. To obtain the free base of the bromine compound by the alkali treatment, a suspension in water of the additional product of II·HCl or III·HCl was rapidly treated with alkali and the assumed free base produced was immediately extracted with ether. However, the colorless crystals formed proved to be the hydrobromide of II (II·HBr).

The compound II·HCl or III·HCl, however, gave no crystals on the brief treatment with alkali; the ether solution was evaporated to give base IV[5].

On the brief treatment of the bromine addition compound with alkali, a free base containing bromine thus dissolves in ether, and the bromine is partially removed from the original addition product, because the yellow color disappears. Thus the mechanism of the addition of bromine is considered as the following scheme:

The bromine links, in the form of linking astride, on the carbonium ion and on the lone pair of electrons of the nitrogen atom, both of which are formed by the prototropy. When the product is treated with alkali for a little while, the hydrogen chloride and the hydrogen bromide are removed. The free base thus produced may be *N*-bromo-*β*-benzoylethylamine.

The compound of *N*-halogenamine type seems to have an oxidizing power. In the present case, the unstable *N*-bromo-bis-(*β*-benzoylethyl)-amine oxidizes contaminants in the solvent (ether), changing into base II. Base II combines with hydrobromic acid produced, and separates as a hydrobromide.

In order to isolate the unstable *N*-bromoamine, extraction with ether, benzene or carbontetrachloride was attempted without success; the only product obtained was the reduced one II·HBr.

Bromine likewise adds to the free Mannich base. For example, the yellow precipitates readily formed on addition of excessive bromine to an ether solution of base II or III. This product on brief treatment with alkali also yielded the colorless compound II·HBr.

It is known that an amine yields an *N*-bromoamine on treatment with sodium

5) Even if base II or III is produced by the alkali treatment, it changes into base IV; cf. Ref. 2.

hypobromite[6]. Here, compound II·HCl was treated with sodium hypobromite to give II·HBr. This fact also shows the existence of the unstable *N*-bromo-β-benzoylethylamine.

The bromine addition product of III·HCl also gives II·HBr on brief treatment with alkali, probably because of the unstability of the *N*-bromoamine derivative.

## Experimental

**Addition of Bromine to the Salt of the Mannich Base.**—One gram of compound II·HCl or III·HCl was dissolved in 200~300 ml. of water. To the solution was added 500 ml. of bromine water. The yellow precipitates were filtered and dried in vacuo at room temperature in the presence of phosphorous pentoxide; 1.3 g. of bromine addition product of II·HCl or 1.2 g. of that of III·HCl was obtained.

**Recrystallization of the Bromine Addition Product.**—The bromine addition product, which was obtained from 2.0 g. of II·HCl, was recrystallized from alcohol within a little while to give yellow crystals; yield, 1.5 g. The crystals were analyzed after vacuum-drying at room temperature in the presence of phosphorous pentoxide (Table I).

**Decomposition of the Bromine Addition Product by Alcohol.**—In boiling alcohol was dissolved 1.5 g. of bromine addition product of II·HCl, and the solution was refluxed for thirty minutes. After being cooled, 1.2 g. of colorless crystals were obtained, which were recrystallized from alcohol acidified with hydrochloric acid to give II·HCl; m. p. and mixed m. p. 173°C.

*Anal.* Found: C, 67.80; H, 6.52; N, 4.47. Calcd. for $C_{18}H_{20}O_2NCl$: C, 68.02; H, 6.34; N, 4.40%.

The bromine addition product obtained from 1.0 g. of III·HCl was also treated with alcohol giving 0.5 g. of II·HCl; m. p. and mixed m. p. 171~173°C.

**Treatment of the Bromine Addition Product with Alcoholic Alkali.**—The bromine addition product obtained from 1.0 g. of II·HCl was dissolved in hot alcoholic sodium hydroxide, and the solution was poured into a great volume of water. The aqueous solution which became turbid was allowed to stand for one day. The turbid matter coagulated to a resinous matter. The product was dissolved in hot alcohol, and the free base was converted into hydrochloride by adding hydrochloric acid. After being cooled, the hydrochloride was separated by adding a little ether, filtered, and washed with ether. Yield, 0.1 g. The hydrochloride was recrystallized twice from alcohol giving compound IV·HCl; m. p. and mixed m. p. 196~198°C.

*Anal.* Found: C, 71.79; H, 6.05; N, 3.18. Calcd. for $C_{27}H_{28}O_3NCl$: C, 72.06; H, 6.27; N, 3.11%.

The bromine addition product obtained from 1.0 g. of III·HCl was also treated with alcoholic alkali to give 0.2 g. of IV·HCl; m. p. and mixed m. p. 197~199°C. The residual alcohol solution was evaporated giving only a dark-brown resinous matter.

**Short Treatment of the Bromine Addition Product with Alkali.**—The bromine addition product obtained from 2.0 g. of III·HCl was suspended in 100 ml. of water, and an excess of dilute solution of sodium hydroxide was added. The colorless matter produced was quickly extracted with 400 ml. of ether. The organic layer was kept at room temperature; colorless crystals began to separate from the solution. After one day, the crystals were filtered and washed with ether; yield, 0.8 g.; m. p. 166~167°C (from alcohol). The crystals showed a remarkable flame reaction of halogen, and gave precipitates of silver bromide with silver nitrate.

*Anal.* Found: C, 60.30; H, 5.86; N, 3.88. Calcd. for $C_{18}H_{20}O_2NBr$(II·HBr): C, 59.67; H, 5.56; N, 3.86%.

The crystals were converted into hydrochloride by repeated recrystallization from alcoholic hydrogen chloride to give II·HCl; m. p. and mixed m. p. 172~173°C. From these results, the crystals separated from the ether solution were confirmed to be II·HBr.

The residual ether solution was evaporated only to give a dark-brown resinous matter which could not be distilled at the usual reduced pressure. The resinous matter decomposed at a higher temperature.

The bromine addition product obtained from 2.0 g. of II·HCl gave 1.5 g. of II·HBr in the same way as above; m. p. 166~167°C.

*Anal.* Found: C, 60.80; H, 5.72; N, 3.89. Calcd. for $C_{18}H_{20}O_2NBr$: C, 59.67; H, 5.56; N, 3.86%.

In the above reaction, ether, benzene or carbontetrachloride was used as an extracting solvent. All these solvents were sufficiently purified just before use. In this case, compound II·HBr was also separated from the solvent, and the yields were 0.8, 0.2 and 0.3 g., respectively.

**Reaction of the Salt of the Mannich Base with Alkali.**—To 200 ml. of water was added 2.0 g. III·HCl, and an excess of solution of sodium hydroxide. The free base produced was extracted with ether. No crystals separated even when the ether solution was allowed to stand. When the ether solution was evaporated, an oily matter was obtained which solidified after a while. Recrystallization from alcohol gave 1.5 g. of base IV; m. p. and mixed m. p. 149~150°C.

*Anal.* Found: C, 78.63; H, 6.75; N, 3.65. Calcd. for $C_{27}H_{27}O_3N$: C, 78.42; H, 6.58; N, 3.38%.

Two grams of II·HCl gave 1.1 g. of base IV in the same way as above; m. p. and mixed m. p. 149~150°C.

**The Bromine Addition Product of the Free Mannich Base.**—To an ether solution of free base III, which was obtained by treating 3.0 g. of III·HCl with a dilute solution of sodium hydroxide for a little while, was added 1.1 g. of bromine.

6) Cf. R. Willstätter and V. Hottenroth, *Ber.*, **37**, 1783 (1904); F. Rashig, *Ann.*, **230**, 223 (1885).

Yellow precipitates produced were filtered, washed, and dried to give 3.5 g. of yellow powder which emitted an irritating odor of bromine. The bromine content of the precipitates was 26.0% [Theoretical $(C_6H_5COCH_2CH_2)_3NBr_2$, 27.9%]. One gram of this addition product was suspended in ether, and an excess of dilute solution of sodium hydroxide was added with shaking. The bromine addition product turned colorless, and dissolved in ether. The ethereal portion was allowed to stand to give 0.2 g. of II·HBr; m. p. 168~169°C (from alcohol).

*Anal.* Found: C, 59.43; H, 5.63; N, 3.59. Calcd. for $C_{18}H_{20}O_2NBr$: C, 59.67; H, 5.56; N, 3.86%.

The residual ether solution was evaporated to give 0.7 g. of base IV; m. p. and mixed m. p. 149~150°C (from alcohol).

A bromine addition product of base II was produced by the same process as the above one. The bromine content was 44.1% [Theoretical $(C_6H_5COCH_2CH_2)_2NH·Br_2$, 36.2%]. From 0.2 g. of this addition product was obtained 0.1 g. of II·HBr; m. p. 169~170°C (from alcohol).

*Anal.* Found: C, 59.84; H, 5.68; N, 4.08. Calcd. for $C_{18}H_{20}O_2NBr$: C, 59.67; H, 5.56; N, 3.86%.

In the case of bromine addition product of base VI, the results were somewhat different from those of the above reaction. The bromine addition product of base VI, which was obtained from 5.0 g. of VI·HCl, was suspended in ether, and an excess of dilute solution of sodium hydroxide was added to the suspension with shaking. The addition product turned somewhat pale-yellow, but it was hardly soluble in ether. The pale-yellow matter was filtered and dried; yield, 3.5 g. Its bromine content was 27.5%, which is lower than the [theoretical value of $(C_6H_5COCH_2CH_2)_2·NCH_3·Br_2$ (35.1%), and higher than that of VI·HBr (21.2%). Two grams of the above matter was dissolved in 50 ml. of alcohol and refluxed for one hour to give 1.4 g. of VI·HBr; m. p. 188~189°C (from alcohol). The mother liquor was slightly condensed to give an additional amount (0.2 g.) of VI·HBr.

*Anal.* Found: C, 60.65; H, 6.03; N, 3.79. Calcd. for $C_{19}H_{22}O_2NBr$: C, 60.64; H, 5.89; N, 3.72%.

The above crystals were converted into VI·HCl by repeated recrystallization from alcoholic hydrogen chloride; m. p. and mixed m. p. 169~170°C.

The ether layer, which was separated from the bromine addition product, was kept at room temperature to give the same product VI·HBr; m. p. 188~189°C; yield, 0.1 g.

*Anal.* Found: C, 60.36; H, 6.14; N, 3.89. Calcd. for $C_{19}H_{22}O_2NBr$: C, 60.64; H, 5.89; N, 3.72%.

**Reaction of Bis-(β-benzoylethyl)-amine Hydrochloride (II·HCl) with Sodium Hypobromite.**— One gram of II·HCl was added to 100 ml. of water. To this solution was added a solution of sodium hypobromite which was prepared by adding excessive sodium hydroxide to bromine water. The free base produced was extracted with ether. The ether solution was left to stand to produce crystals; yield, 1.0 g. The crystals were recrystallized from alcohol giving II·HBr; m. p. 170°C.

*Anal.* Found: C, 59.96; H, 5.65; N, 3.76. Calcd. for $C_{18}H_{20}O_2NBr$: C, 59.67; H, 5.56; N, 3.86%.

## Summary

i) The addition of bromine to β-benzoylethylamine hydrochloride was studied. It was concluded that bromine molecule was added to β-benzoylethylamine hydrochloride in the form linking astride to the carbionium ion and the lone pair of electrons of the nitrogen atom, both of which were formed by prototropy.

ii) The bromine addition product of β-benzoylethylamine hydrochloride was treated with alkali for a little while to give *N*-bromo-β-benzoylethylamine which was very unstable and decomposed to give β-benzoylethylamine hydrobromide.

The author is particularly indebted to the late Professor Ryuzaburo Nozu and to Professor Ryozo Goto for their discussions and encouragement throught this investigation, and also to Professor Seishi Machida for his encouragement.

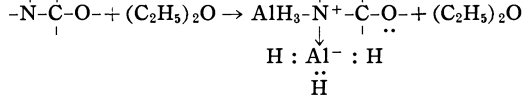
# *Selective Reduction of Phosphatides with Lithium Aluminum Hydride. I. Ovolecithin*

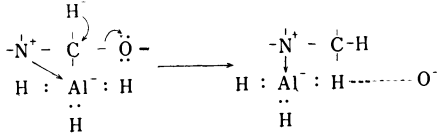
By Chieko URAKAMI, Hirochika OKURA and Mitsuko OKADA

(Received May 19, 1959)



For determination of the structures and the configurations of phosphatides, the following two methods were available. Long and Magure[1] carried out the reactions to derive L-α-glycerylphosphoric acid as described below:

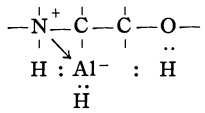
L-α-Lecithin —(Phospholipase C)→ 1,2-Diglyceride
—(Phosphorylation)→ L-α-Phosphatidic acid
—(Hydrolysis)→ L-α-Glycerylphosphoric acid



Baer and Maurukas[2] devised the so-called "diazomethol ysis" giving the phosphatidic acid dimethyl ester. In both methods, unsaturated fatty acids, if present, should be hydrogenated before carrying out these reactions. These two methods are, however, not always convenient for general application. The former is far more complicated and would require a sufficient amount of purified phosphatides for analysis of the final product. The latter is, on the other hand, simpler, but it is applicable to those containing the free amino group such as phosphatidyl serine and phosphatidylethanolamine and not to phosphatidylcholine.

The reaction of lecithin with lithium aluminum hydride was carried out by Karrer and Jucker[3] under drastic conditions, at the boiling point of ether. Inorganic phosphorus, phosphine, glycerol and a substance with an amine-like odor were reported to be present in the reaction mixture. Apparently, all ester linkages of the lecithin molecule were cleaved. A number of instances of selective reduction by this reagent were reported, e. g. methyl 4-nitrovalerate was reduced to the corresponding alcohol at −35°C in 20 min., the nitro group being unattacked[4]. A selective reduction similar to this example may possibly be achieved with lecithin under carefully controlled conditions.

The authors' attention was focused on an ionic character of the coordinate covalences of the sulfonyl, nitro and phosphoryl groups. Under mild conditions approach of a hydride ion of lithium aluminum hydride present in ether solution to these groups may encounter some difficulty due to the presence of negatively charged oxygen atoms which are stabilized by resonance. If this plays a part in reduction of the lecithin molecule, the cleavage of the two fatty acid ester linkages would be easier than that of the two ester linkages of the phosphoryl group. However, the nitrogen atom of the choline may also play a role since Trevoy and Brown[5] showed the reaction to be a bimolecular nucleophilic substitution by a hydride ion and Gaylord[6] proposed a mechanism for the reduction of an –N–C–O– group, utilizing the ionic species, $AlH_4^- \rightleftharpoons AlH_3 + H^-$, and the concept of ether participation which have been proposed by Paddock[7], as shown below:



The coordination of $AlH_3$ with the lone pair on nitrogen can occur in the initial step. By analogy with Grignard reaction, the formation of a five-membered quasi-ring is suggested. As the result, nitrogen would become deficient in electron and tend to withdraw electron from the adjacent carbon giving the latter a positive character. The hydride ion could then displace the ethereal oxygen resulting in cleavage of the C–O bond:

1) C. Long and M. F. Magure, *Biochem. J.*, **57**, 223 (1954).
2) E. Baer and J. Maurukas, *J. Biol. Chem.*, **212**, 39 (1955).
3) P. Karrer and E. Jucker, *Helv. Chim. Acta*, **35**, 1586 (1952).
4) H. Feuer and T. J. Kucera, *J. Am. Chem. Soc.*, **77**, 5740 (1955).
5) L. W. Trevoy and W. G. Brown, ibid., **71**, 1675 (1949).
6) N. G. Gaylord, *Experientia*, **10**, 351 (1954).
7) N. L. Paddock, *Nature*, **167**, 1070 (1951).

This mechanism can possibly be applied to the choline moiety of the lecithin molecule, as far as the formation of a six-membered quasi-ring is concerned:

However, an electrostatic effect on the $\beta$-carbon atom would be not as strong as that on the $\alpha$-carbon. The nitrogen atom in this case is already in the cationic form and has no lone pair available for coordination with $AlH_3$ but approach of $AlH_4^-$ would be possible, resulting perhaps in a complex formation*. This may also encounter some difficulty, particularly at low temperatures at which the molecule exists in its ground state, because a hydride ion must overcome zwitterionic and possibly steric effects of the trimethyl group in its approach to the cationic nitrogen. Thus, a higher amount of energy would be required for the cleavage of the phosphoryl-choline linkage than that for the cleavage of the fatty acid ester linkage where no such obstacle exists.

By similar qualitative examination the following speculations may be made on relative ease of cleavage of the two phosphoryl ester linkages. The cleavage of the phosphoryl-glyceryl linkage depends on an attack by a hydride ion on the phosphoryl group only. On the other hand, in the cleavage of the phosphoryl-choline linkage a mechanism involving nitrogen may also participate; this may operate independently of the mechanism involving the phosphoryl group or assist the latter by making oxygen somewhat deficient in electron as a result of the formation of a six-membered quasi-ring. Accordingly the phosphoryl-choline linkage is considered to be cleaved somewhat more readily than the linkage between the phosphoryl and glycerol.

Thus, a step-wise cleavage of the lecithin molecule may be possible, i. e. the cleavage of the fatty acid ester linkages, giving the corresponding alcohols and glycerylphosphorylcholine (with retention of the configuration); or the cleavage of the choline moiety, following the removal of the fatty acids, giving choline and a reduced form of glycerylphosphoric acid**. Accordingly, attempts were made to find suitable reaction conditions to achieve either one of the two possibilities by controlling temperature, time and amounts of lithium aluminum hydride.

* The authors used "$AlH_3$" in a preliminary report on this subject, This Bulletin, **31**, 779 (1958), but presently consider that it must be reserved as such.

## Experimental

**Materials.**—*Lecithin.*—Crude egg yolk lecithin was purified according to Hanahan's method[8], (P : N, 1 : 1.10 and 15.8% choline).

*DL-α-Glycerylphosphorylcholine.*—This compound was synthesized according to the method of Baer and Kates[9], ($\alpha$-glyceryl ester: choline, 1.03 : 1.0).

**Analytical Methods.** — *Choline.* — Choline in glycerylphosphorylcholine was determined by Schmidt's method[10] and in lecithin by Glick's method[11].

*Phosphorus.*—The conventional method of wet incineration, with 10 N sulfuric acid and hydrogen peroxide, was used to convert organic phosphorus to the orthophosphate. The inorganic phosphate was then determined spectrophotometrically according to the method described by Burmaster[12] or by Ernester et al.[13] Concentrations of the reagents were altered, however, as circumstances required.

*Ester.*—The method described by Bauer and Hirsch[14] was employed.

*α-Glycol.*—The periodate oxidation method of Voris et al.[15] was used.

**Reaction of Lecithin with Lithium Aluminum Hydride.**—One hundred milligrams of lithium aluminum hydride was dissolved in 50~60 ml. of dry ether (0.1~0.2% solution). The solution was filtered first through glass wool packed in a glass tubing of about 6 mm. in diameter and then through a sintered glass filter sealed in a glass tubing of about the same diameter and transferred into a specially constructed burette. The filtration and transfer were carried out by applying pressure with dry nitrogen gas. Calcium chloride tubes were provided to keep the entire system in a dry state. A flask of about 100 ml. capacity containing a cooled ether solution of lecithin was attached to the burette and a calculated amount of the reducing agent*** was added in small portions so that the temperature

** A trivalent phosphorus compound may be formed as a result of an attack of $AlH_4^-$ on the positively charged phosphorus atom. This sort of interaction was shown to occur under drastic conditions (the formation of phosphine was recognized)[3] and it may be possible that even under mild conditions this may occur to a certain extent.

*** Concentrations of the ether solution were determined from time to time by the conventional method of hydrogen gas liberation. Aliquots were delivered from the burette.

of the reaction mixture could be maintained constant. Stirring with the magnetic stirrer was continued for a desired length of time. The reaction mixture was cooled and decomposed with wet ether. A sufficient amount of water was added to separate the organic layer. The aqueous phase was shaken twice with a small portion of fresh ether and the ether extracts were combined. The aqueous layer was then washed with chloroform to remove lysolecithin (this step was omitted in later experiments since no lysolecithin was found to be present in the chloroform extract). The ether extract was made up to a known volume, usually 25 ml., and aliquots were taken for analyses of organic phosphorus and esters. The aqueous phase was made acid with 10 N sulfuric acid to dissolve the precipitate, the solution filtered and made up to a known volume, usually 50 ml., for analyses of inorganic phosphorus, total phosphorus, free choline and total choline.

**Isolation of L-α-Glycerylphosphorylcholine.** — Lecithin (about 400 mg.) was reduced under the optimum conditions (14°C, Table V). After decomposing the reaction mixture with water, the precipitate formed was removed by centrifugation. The clear solution was passed through a column of IRC-50 and the eluate was analyzed for choline and α-glycol (α-glycol: choline, 1.02: 1.00). The eluate was then concentrated under reduced pressure in the atmosphere of nitrogen and the amorphous cadmium chloride addition complex was prepared according to the procedure described by Baer[9] (Found: P, 5.24%). A solution of the complex was passed through a mixture of 4 ml. of Dowex 3 and 2 ml. of IRC-50 and the solution analyzed for α-glycol, total P and choline (Found: α-glycol : P : choline, 0.97 : 1.00 : 1.02). α-Glycerylphosphorylcholine recovered after passing the resin column was found to be 94%. The crystalline cadmium chloride complex was prepared and analyzed (Found: C, 21.56; H, 4.80) after drying over phosphorus pentoxide at 56°C for 8 hr. under 3 mmHg. The infrared spectrum of this compound was found to be identical with that of the synthetic DL-α-glycerylphosphorylcholine. Its optical rotation was determined on the concentrate of the aqueous solution freshly prepared by repeating the reduction and purification in the same manner as described above [Found: $[\alpha]_D^{24}-2.96\pm0.2°$ (c, 2.2 water); $[\alpha]_D^{23}-2.85\pm0.1°$ (Baer)].

Preliminary experiments with α- and β-glycerylphosphoric acids in the same manner as described for the reduction of lecithin showed that no migration of the phosphoryl group occurred. Similar experiments with glycerylphosphorylcholine was not possible due to technical dfficulties. The migration of the phosphorylcholine groups is, however, unlikely to occur under such mild reaction conditions.

## Results and Discussion

The results shown in Tables I and II indicate that the reaction proceeds through

a) Calculated values based on the analytical results.

Ch. stands for choline and m. e. for milliequivalent. The figures in parentheses are percentages based on choline or ester content of each sample taken.

the formation of glycerylphosphorylcholine and not phosphorylcholine, since choline containing substances in the aqueous phase release the total amounts of choline present in the samples on acid hydrolysis. Therefore, the experiments under much milder conditions were carried out so that only glycerylphosphorylcholine would be produced. These results are shown in Tables III—V.

It was of interest to see if ether insoluble glycerylphosphorylcholine itself would release the choline moiety by lithium aluminum hydride in ether, the synthetic glycerylphosphorylcholine was, therefore, reacted at 20°C for 3 hr. with 15 mol. of lithium aluminum hydride per mole of the compound. It was found that about 21% free choline was released.

From the results shown in Tables III—V,

the optimum conditions for the reductive cleavage of lecithin giving a 100% yield of glycerylphosphorylcholine appears to be 20 min. at 10°C with a mole ratio of lecithin to lithium aluminum hydride 1 : 2 (Table V). Some phosphorus and ester were found to be present in the ether phase, but this is considered to be due to some impurities present in the sample employed as indicated by its analytical results. According to its optical rotation observed, the glycerylphosphorylcholine formed in the reaction has the L-α-configuration. This method is, therefore, not only simple for the determination of configurations of lecithin, but also a useful method for the preparation of L-α-glycerylphosphorylcholine.

Tables III and V show that the reaction involving the release of the choline moiety is quite sensitive to temperature. With the temperature difference of only four degrees, 18, 14 and 10°C, amounts of choline released decrease from 30 to 4% and finally to 0%, respectively. On the other hand, it is not affected much by reaction time as shown in Tables III, IV and II. It appears then that temperature must be raised higher than 20°C for a complete release of the choline moiety as shown in Table I. The fact that the reaction is sensitive to temperature would mean that an amount of energy required for the cleavage of the phosphoryl-choline linkage is significantly higher than that required for the cleavage of the fatty acid ester linkage. It is quite in accord with what the authors have anticipated.

In those cases where considerable amounts of choline are formed, the total amounts of phosphorus recovered in the aqueous phase are only 62~68% of the calculated amounts (Table II), despite the absence of phosphorus in the organic phase. It is also noticed in the same table that the amounts of the inorganic phosphorus in the aqueous phase are not equivalent to that of the choline moiety released; only 0~3% of the inorganic phosphorus are detected where 41~69% free choline are formed. These results may indicate that some complex mechanisms are involved in the cleavage of the choline moiety.

If a mechanism similar to that proposed by Gaylord[5] operates in the cleavage of the choline moiety, trimethylethylamine should be formed. If, on the other hand, a mechanism involving the phosphoryl moiety participates, choline and a reduced form of α-glycerylphosphoric acid, which may not be detected by the method of analysis employed must be produced. In Table IV, 79 and 73% of phosphorus found in the aqueous phase can be considered to have been derived from 77 and 75% of glycerylphosphorylcholine, respectively. Therefore, 21 and 27% of undetected phosphorus may be ascribed to a reduced form of glycerylphosphoric acid, indicating that the latter mechanism may have played a role. Under such mild conditions, liberation of phosphine would not be possible, for an amount of lithium aluminum hydride used is far less than that required for reduction of the phosphoryl group to its ultimate stage. When three moles of the reducing agent is used (Table II), of 62% total phosphorus detected in the aqueous phase after three hours of reaction time 59% can be accounted for glycerylphosphorylcholine and the remaining 3% may have come from glycerylphosphoric acid (since no inorganic phosphorus is found to be present). Similarly, with 5 and 10 hr. of reaction time 25 and 34%, respectively, may have been derived from glycerylphosphoric acid. Undetected phosphorus would then amount to 38, 36 and 32% for 3, 5 and 10 hr., respectively, of the reaction time in these instances. Therefore, under these conditions, the two mechanisms mentioned above appear to have participated simultaneously, though participation of the latter mechanism seems to predominate in the three hour run. This may indicate that energy requirements for the formation of an intermediary complex with the cationic nitrogen are somewhat higher than that with the phosphoryl group.

Suppose that the formation of the inorganic phosphate is the only indication available for the cleavage of the glycerylphosphoryl linkage, this ester linkage is considered to be the most stable one in the lecithin molecule against lithium aluminum hydride. It may also be pointed out that " free choline " given in the tables constitutes of a mixture of choline itself and the quarternary amine according to the foregoing discussions.

## Summary

The optimum conditions for cleavage of the fatty acid ester linkages in the lecithin molecule were found to be 20 min. at 10°C with the use of two moles of lithium aluminum hydride per mole of lecithin.

The product formed under these conditions was identified to be L-α-glycerylphosphorylcholine when ovolecithin which was shown to be L-α-lecithin[8] was used.

Discussion has been presented as to two mechanisms possibly participating in the cleavage of glycerylphosphorylcholine, one involving a complex formation with the phosphoryl group and the other with the cationic nitrogen atom of the choline base.

# *Electrode Kinetics of Indium (III) at the Dropping Mercury Electrode*

By Senkichi INOUYE and Hideo IMAI

(Received May 28, 1959)

The polarographic behavior of indium-(III) has been investigated in various media by many authors. In these investigations two typical electrode processes are noticeable: One is a reversible process which proceeds at about −0.5 V. vs. S. C. E. in the chloride, bromide, iodide or organic acid solution[1,2]. The other is an irreversible process which proceeds at about −1.0 V. vs. S. C. E. in the perchlorate[2] or phosphate[3] solution*. In this report is presented the evaluation of the rate constant of the irreversible electrode process of indium(III) in the perchlorate medium, and the temperature dependence of the rate constant is discussed.

## Experimental

The apparatus used was described in the previous report[4] and was not modified in any detail.

All the reagents were of analytical grade. The stock solution of indium perchlorate was prepared by dissolving indium oxide (weighed as $In_2O_3 \cdot 3H_2O$) in perchloric acid. Indium oxide was prepared from indium chloride by precipitating indium hydroxide with ammonium hydroxide and by desiccating the precipitate to a constant weight at 130°C.

In order to avoid the overlap of the hydrogen wave on the indium wave, the hydrogen-ion concentration was controlled by adding sodium hydroxide. The concentration of the perchlorate ion in the test solution was 0.5 F.

Purified nitrogen was bubbled to remove dissolved oxygen in the test solution prior to submission to polarography.

The temperature was kept constant within the change of ±0.1°C by a thermostat.

## Results and Discussion

**Irreversible Current-Voltage Curve of Indium-(III).**—The irreversible current-voltage curve of indium(III) in the perchlorate medium is illustrated in Fig. 1. Usually, this irreversible wave is accompanied by a pronounced maximum of the first kind. This maximum wave can be suppressed by the addition of a surface active material such as gelatine, methyl red or methyl cellulose. The adsorption of the surface active material on the surface of the dropping mercury electrode (DME), however, seems to change the potential distribution on and near the electrode surface, and this effect results in the variation of the transfer coefficient[3,5]. Moreover, the adsorptive concentration will vary with the change of temperature. Accordingly, the use of a surface active material is not desirable for the purpose of investigating

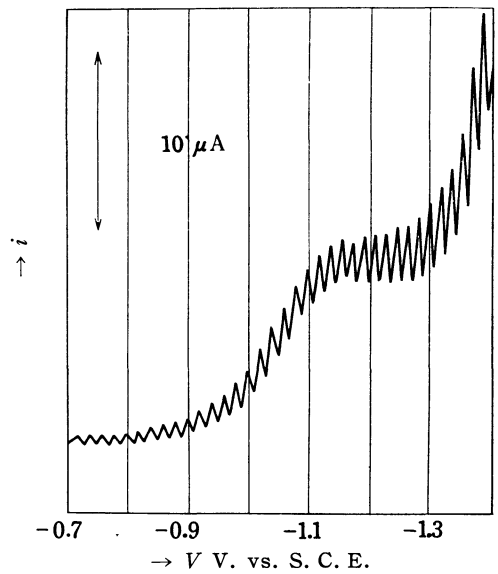

Fig. 1. The current-voltage curve of indium(III) in 0.5 F perchlorate.
Temp.=20°C, $m$=1.8$_1$, $t$=4.9$_0$ (open circuit), [$In^{3+}$]=1 mF.

the temperature dependence of the reaction rate. In this experiment, the lifetime of the DME was elongated by lowering the mercury head, and the supporting electrolyte was appreciably concentrated. Under these conditions, the maximum wave could be satisfactorily minimized. The test solution may be contaminated by the trace of surface active materials which have been accidentally intermixed. After this trace was removed by adding active charcoal, the maximum could not be suppressed in any way. The presence of this trace, however, scarcely affects the value of the transfer coefficient in the temperature range examined, as is illustrated in Table I.

When the hydrogen-ion concentration was too small, the test solution became turbid owing to the formation of indium hydroxide. Even when perchloric acid was added until the turbidity had just disappeared, the current-voltage curve of indium was too greatly extended, from −0.5 to −1.3 V. vs. S. C. E. On the other hand, when the acidity was too great, the hydrogen wave overlapped on the indium wave in question. Therefore, the perchloric acid concentration as great as 0.04 F was preferable.

**Evaluation of Diffusion Constant.** — The value of the diffusion constant of the indium ion is required for the calculation of the rate constant. This value was evaluated from the diffusion-controlled limiting current by Ilkovic's equation, i. e.

$$D^{1/2}=i_d/607\,nCm^{2/3}t^{1/6} \quad (1)$$

where $D$ is the diffusion constant in cm$^2$/sec., $i_d$ is the mean diffusion-controlled current in μA, $n$ is the number of electrons transferred per an ion, $C$ is the bulk concentration of indium(III) in mF, $m$ is the average mass of mercury flowing in mg./sec. and $t$ is the life-time of the DME in sec. The evaluation of the number of electrons transferred per an ion was carried out as follows: When chloride, iodide or acetate was added to the test solution, the irreversible wave was changed to the reversible one, the half-wave potential being simultaneously changed from −1.0 to −0.5 V. vs. S. C. E. It was confirmed that the diffusion-current constants of the two waves were practically equal[3]. In the reversible electrode process the value of $n$ was evaluated to be three from the inclination of the $\log[i/(i_d-i)]$ versus $E$ (the potential of the DME) plot. Accordingly, the value of $n$ in the irreversible electrode process will also be three. The evaluated value of the diffusion constant is given in Table I.

**Evaluation of Transfer Coefficient and Rate Constant.**—The value of $\log[i/(i_d-i)]$ was plotted versus the potential of the DME from the irreversible current-voltage curve. This polt gave a straight line near the half-wave potential. According to Matsuda and Ayabe's theory[6], the inclination of the linear portion of this plot is a function of the transfer coefficient as is given in Eq. 2, i. e.

$$E=\frac{RT}{\alpha nF}\{2.3\log(k_f^\circ f^\circ t^{1/2}D^{-1/2}) -0.12-2.2\log[i/(i_d-i)]\} \quad (2)$$

where $f^\circ$ is the activity coefficient of the depolarizer in the solution and the other symbols are used with their usual significance. The evaluated value of $\alpha n$, which is the product of the transfer coefficient by the number of electrons involved in the rate-determining reaction, is illustrated in Table I.

The rate constant, $k_f^\circ$, referred to 0 V. vs. N. H. E. was evaluated from Eq. 3[6], i. e.

$$E_{1/2}=\frac{RT}{\alpha nF}[2.3\log(k_f^\circ f^\circ D^{-1/2}) +1.15\log t-0.12] \quad (3)$$

6) H. Matsuda and Y. Ayabe, This Bulletin, 28, 422 (1955).

where $E_{1/2}$ is the half-wave potential of the irreversible wave in volts vs. N. H. E. The values of the rate constant at various temperatures ranging from 20 to 30°C are illustrated in Table I.

TABLE I. THE DIFFUSION CONSTANT, THE TRANSFER COEFFICIENT AND THE RATE CONSTANT OF THE ELECTRODE PROCESS OF INDIUM-(III) IN 0.5 F PERCHLORATE

| Temperature $T$°K | Diffusion constant $D$, cm²/sec. | Transfer coefficient $\alpha n$ | Rate constant $k_f^\circ$, cm./sec. |
|---|---|---|---|
| 293.2 | $8.0\times10^{-6}$ | 0.66 | $2.2\times10^{-12}$ |
| 299.7 | $9.6\times10^{-6}$ | 0.66 | $4.7\times10^{-12}$ |
| 303.2 | $10.8\times10^{-6}$ | 0.65 | $7.3\times10^{-12}$ |

**Temperature Dependence of Rate Constant.**— From Table I, the logarithm of the rate constant was plotted versus the reciprocal of the absolute temperature. This plot is satisfactorily linear as is illustrated in Fig. 2. From the inclination of this plot, the heat of activation at constant pressure ($\Delta H^*$) was calculated by Arrhenius's equation, i. e.

$$d\ln k_f^\circ/dt = \Delta H^*/\boldsymbol{R}T^2 \quad \text{or}$$

$$\log k_f^\circ = c - \Delta H^*/2.3\,\boldsymbol{R}T \qquad (4)$$

where $c$ is a constant. The heat of activation at constant volume ($\Delta H^{\ddagger}$) was calculated by Eq. 5 in order to apply the absolute rate expression.

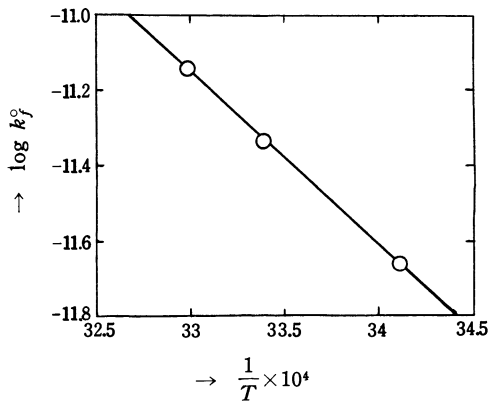

Fig. 2. The temperature dependence of the rate constant of the electrode process of indium(III) in 0.5 F perchlorate.

TABLE II. THE HEAT OF ACTIVATION IN THE ELECTRODE PROCESS OF INDIUM(III) IN 0.5 F PERCHLORATE

| The heat of activation at constant pressure $\Delta H^*$, kcal./mol. | The heat of activation at constant volume $\Delta H^{\ddagger}$, kcal./mol. |
|---|---|
| 21.1 | 20.5 |

$$\Delta H^* = \Delta H^{\ddagger} + \boldsymbol{R}T \qquad (5)$$

These data are illustrated in Table II.

On applying the absolute rate theory to an electrode process, it is noteworthy that the applied potential plays a role as the activation energy of the electron transfer, and that the electrode reaction is a heterogeneous reaction. It is well known that a spontaneous potential difference exists at the mercury-solution interface. Accordingly, the value of the applied potential as the activation energy must be referred to the zero-charge potential, i. e. the Lippmann-potential. Delahay[7] has given a modified expression of the absolute rate theory for an electrode reaction which involves no kinetic complication, as is given in Eq. 6, i. e.

$$k_f^\circ = \frac{e\boldsymbol{k}T}{\boldsymbol{h}}\cdot\rho\cdot\exp(-\Delta H^{\ddagger}/\boldsymbol{R}T) \times\exp(\alpha n\boldsymbol{F}E_m/\boldsymbol{R}T)\cdot\exp(\Delta S^{\ddagger}/\boldsymbol{R}) \qquad (6)$$

where $e$ is the transmission coefficient, $\boldsymbol{k}$ is the Boltzmann constant, $\boldsymbol{h}$ is the Planck constant, $\rho$ is an arbitrary factor in cm., $E_m$ is the Lippmann potential referred to N. H. E.** and $\Delta S^{\ddagger}$ is the entropy of activation in e. u. Eq. 6 involves two arbitrary factors. One of them is the transmission coefficient, the value of which was assumed to be 1 in this calculation. The other arbitrary factor is $\rho$, which was introduced to equalize the dimension of the right side of Eq. 6 to the dimension of the rate constant (cm./sec.).

Delahay has proposed a value as great as that of $2.0\times10^{-8}$ cm. as the mean distance between two depolarizer ions in the bulk solution. It is noteworthy that this value is of the order of the atomic radius. Supposing that the depolarizer at the vicinity of the electrode surface pertains to the rate of the electrode reaction, the above mentioned value of $\rho$ seems to be impossibly small. Accordingly, the value of $\rho$ was evaluated from the depolarizer concentration at the vicinity of the electrode surface. The value amounts to $5.7\times10^{-6}$ cm. as the mean interionic distance between the two depolarizer ions at the vicinity of the electrode surface.

The transmission coefficient does not

7) P. Delahay. *J. Am. Chem. Soc.*, **75**. 1190 (1953); "New Instrumental Methods in Electrochemistry", Interscience Publishers, Inc. New York (1954), p. 41.

** The Lippmann-potential of the DME in 0.5 F perchlorate was evaluated by the "VDME" method[8] as great as $-0.23_7$ V. vs. N. H. E.

8) H. Imai, S. Inouye and S. Chaki, This Bulletin, **31**, 767 (1958); ibid., **32**, 994 (1959).

inherently vary in the order of its magnitude, and accordingly, it does not seriously affect the value of the entropy of activation, while the possible variation of the order of $\rho$-value seriously affects the value of the entropy of activation. In Table III is presented the value of the entropy of activation evaluated in correspondence to the values of $\rho$ as great as $5.7\times10^{-6}$.

TABLE III. THE ENTROPY OF ACTIVATION AND THE FREE ENERGY OF ACTIVATION IN THE ELECTRODE PROCESS OF INDIUM(III) IN 0.5 F PERCHLORATE

| Arbitrary factor $\rho$, cm. | Entropy of activation $S^{\neq}$, e. u. | Free energy of activation $F^{\neq}$, kcal. |
|---|---|---|
| $5.7\times10^{-6}$ | $-5.7$ | 22.2 |

In the above mentioned case the entropy of activation is appreciably negative. Accordingly, it can be assumed that the randomness or disorder in the atomic arrangement of the activated state is less than that of the original state. Lingane[2] has reported that indium(III) is supposed to exist in the form of the aquo complex in the perchlorate solution. Hence, it can be concluded that, when the indium(III) aquo ion enters into the electric field of the electrode surface, the possible coordination of water dipols will be more or less deprived of its randomness prior to the electron transfer.

The reasonable evaluation of $\rho$-value is reserved for the future.

The authors wish to express their hearty gratitude to Professor M. Shinagawa for his valuable advice and to Professor M. Miura for his encouragement throughout this study.

# *Density Measurement in Dilute Aqueous Solution of Polyvinyl Alcohol*

By Koichiro NAKANISHI* and Michio KURATA

(Received June 30, 1959)

Precise determination of solution density has an important bearing on the measurements of various physicochemical properties of high polymers in dilute solution. Fragmentary data can be found in literature, but the density measurement itself was scarcely ever chosen as the subject of studies on dilute high polymer solutions, except in the case of a few studies concerning polystyrene[1-5].

Recently a suggestion was made by Kobatake[6] on the possibility of elucidating the polymer-solvent interaction from the density data of dilute solution. According to an equation proposed by Kobatake[6], the polymer-solvent interaction $B_{12}$ can be best estimated from the molecular weight dependence of the solution density. An analysis of Schulz and Hoffmann's data[5] on the apparent specific volume of polystyrene and polymethyl methacrylate was carried out by Kobatake and Inagaki[7] along with this line of approach. Some interesting data concerning molecular interactions in solution were obtained from the values of $B_{12}$. It would seem, therefore, that systematic accumulation of density data should contribute to the problems in dilute high polymer solutions.

In this paper, the density of an aqueous solution of polyvinyl alcohol (PVA) is measured by the use of well defined and fractionated samples, and some analysis

of the results are made on the basis of Kobatake's equation[6,7].

In order to determine the solution density, the authors adopted the method of floating equilibria which is the same as that used for the quantitative analysis of heavy water concentration[8,9]. This method was proved to be applicable also to polymer solution. It was rather easy to obtain the solution density and polymer concentration with the same accuracy as that obtained by other methods[2,3,5].

## Experimental

**Preparation of Materials.**—The PVA fractions were obtained by the saponification of polyvinyl acetates which were polymerized in solution under various conditions and fractionated in acetone-water system. Acetyl group content in the resulting PVA samples was less than 0.2%.

The molecular weight of PVA samples was determined from the intrinsic viscosity in water. The viscosity average molecular weight calculated from Nakajima's equation[10] is shown in Table I. In the same table, experimental conditions for polymerization are also tabulated since they have an important bearing on the molecular weight dependence of density.

Unfractionated samples of PVA were also used in the preliminary experiments.

Water as solvent was obtained by the careful distillations of conductivity water.

**Apparatus and Float.**—The apparatus used for the measurement of floating equilibria is based on the one described by Harada[9] for the quantitative analysis of heavy water. The float, made of silicate glass, is spindle-shaped and 2~3 cm. long. The upper spherical part of the float is hollowed, and the apparent specific weight of the whole float is adjusted to a value of the solvent density (water, in this case) near room temperature. The temperature at which the measurements run is always regulated within the accuracy of 0.005°C by a large outer thermostat.

The motion of the float in the sample liquids was followed by a traveling microscope and the equilibrium temperature of the float was read on a Beckmann thermometer.

**Density Measurement.** — (*a*) *Preparation of sample solution.* — The PVA samples, after the saponification, were purified by extraction with methanol in a Soxhlet extractor for three days or longer and dried in vacuo. These samples were dissolved into water in a flask which was placed on a boiling water bath for more than eight hours and about 1% solution was prepared. The solution was then filtered through the glass filters Nos. 2 and 4, and again heated on a boiling water bath. This stock solution was diluted by weight and/or by volume to obtain required concentrations and each solution was stored in a closed tube. Before use, each solution was kept overnight in a thermostat at 80°C. Concentrations of the solution were determined by evaporating the solvent and drying in vacuo at 60°C to constant weight.

(*b*) *Measurement of equilibrium temperature.*— The equilibrium temperature, $T_0$, of the float in water—the temperature which keeps the float both from sinking and floating—is first measured for each float. The "apparent density" of the float is next obtained by comparing this temperature with the density-temperature curve of water (chain-dotted line in Fig. 1). Thus, when the equilibrium temperature in solution, $T$, is again measured for each float of known density, the density-temperature curve of the solution (solid line in Fig. 1) is immediately obtained. The density of solution at any temperature is also determined from this curve.

In practice, the sensitivity of the float to

temperature variation was higher than the constancy of the thermostat. The equilibrium temperature was then measured in the following two ways; namely, the "quasi-static" and the "dynamic" method[11]. In the former, floating equilibrium is determined directly by a fine adjustment of temperature, while the latter is based on the interpolation of the floating and sinking velocity of the float near the equilibrium temperature.

When the difference between the equilibrium temperature of the solution and that of the solvent is large, a correction for the thermal expansion of the float is required. In this case, the following equation was used,

$$d_t = d_0/(1+\alpha\cdot\Delta T) \quad (1)$$

$$\Delta T \equiv T - T_0 \quad (2)$$

where $d_t$ and $d_0$ are the density of the float at $T$ and $T_0$, respectively, and $\alpha$ is the coefficient of cubic expansion of silicate glass[12].

(c) *Apparent and partial specific volumes.*—Following the procedure given above, the solution density $d_{12}$ can be obtained as a function of polymer concentration $c_2$ (g./cc.) and temperature. For the discussion of experimental data, however, it is convenient to use the apparent specific volume $\phi_2$ (cc./g.) and the partial specific volume $V_2$ (cc./g.) of solute polymer in solution. They can be calculated from the solution density by the following equations,

$$\phi_2 = 1/d_1 - d_{sp}/c_2 \quad (3)$$

$$V_2 = \phi_2 + w_2(1-w_2)\cdot\partial\phi_2/\partial w_2 \quad (4)$$

$$V_2 \cong \phi_2 + c_2\cdot\partial\phi_2/\partial c_2$$

(for dilute aqueous solution) (5)

where $d_1$ is the density of solvent (g./cc.), $w_2$ is the weight fraction of solute polymer and $d_{sp} = (d_{12}-d_1)/d_1$.

**Discussion of the Experimental Error.**—Although the float is sensible to the temperature change of 0.001°C, fluctuation in excess of 0.003°C is inevitable in the determination of equilibrium temperature in both the two methods, quasi-static and dynamic. The error in the density determination, even when the work is very carefully done, is accordingly expected to be about $\pm 2\times 10^{-6}$. In practice, such a degree of precision was easily obtained in the measurement with water in which the "apparent density" of the float was quite stable.

While in PVA solutions, the "apparent density" of the float becomes somewhat unstable, though the cause is uncertain. PVA may be adsorbed to the float and sometimes an insoluble film may be formed on the surface. Under this circumstance, calibration with water is frequently required. Thus, the actual error found in PVA solution was not in excess of $\pm 4\times 10^{-6}$.

Finally, it was often observed that foam grows on the surface of the float and that the quasi-equilibrium of the float is attained especially in the measurement near 20°C. In the temperature region from 25 to 30°C with which the authors' experiment is concerned, however, the appearence of foam was rare and there was practically no experimental difficulty.

## Results and Discussion

**Equilibrium Temperature as Function of Polymer Concentration.** — Fig. 2 shows the temperature difference ($\Delta T$) vs. concentration relationship of PVA aqueous solution up to 1.0 g./100 ml. Each curve in the figure corresponds to the values obtained with using different floats. It is seen at once that the $\Delta T$ vs. concentration relationship can be regarded as almost linear below 0.5 g./100 ml., but convex in the more concentrated region. It can be also observed that the larger the "apparent density" of the float is (namely, the lower the $T_0$ of the float is), the more magnified the temperature difference is for the same sample solution. The molecular weight of PVA affects $\Delta T$, though very minutely and can not be seen in the figure. This point will be discussed later.

The $\Delta T$ vs. concentration curve in Fig. 2 may be used as a calibration curve for the determination of polymer concentration in dilute solution. The temperature difference $\Delta T$ for PVA aqueous solution of 1.0 g./100 ml. reaches to about 9~10°C, while the equilibrium temperature itself can be obtained with a precision of 0.003°C. In this case, accordingly, a concentration difference of at least 0.003 g./100 ml. (i. e.

0.003 wt. %) will be detectable by the present method.

**Solution Density as Function of Polymer Concentration and Molecular Weight.**—In Fig. 3, the solution density vs. polymer concentration relationship is shown for aqueous solution of fractionated PVA. The data of $d_{12}/d_1$ (specific weight to solvent water) vs. $c_2$ fall on a straight line at least below the polymer concentration of 1.0 g./100 ml., and are slightly dependent on the molecular weight of PVA.

For a clear detection of this dependence, it is convenient to calculate the apparent specific volume $\phi_2$ of PVA in solution. Fig. 4 shows the experimental values of

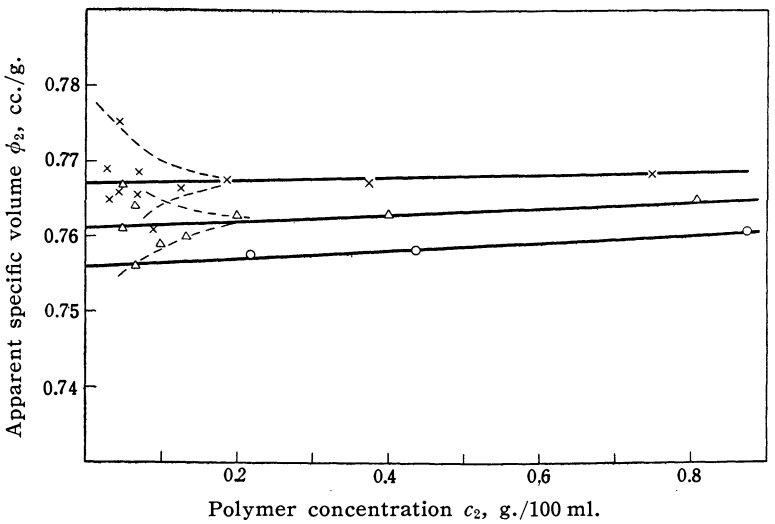

Fig. 4. Apparent specific volume of PVA in aqueous solution, as function of polymer concentration, $c_2$, at 30°C.
○ B-5 $P$=1600 △ T-2 $P$=550 × E-2 $P$=190

$\phi_2$ calculated by Eq. 3 at each concentration. It is seen from the figure that $\phi_2$ increases slightly with $c_2$ for every case concerned, though the data at extreme dilution are somewhat uncertain. It may be thus concluded that a negative second order term, though very small, does exist, if the $d_{12}$ vs. $c_2$ relationship, as usual, is represented by a power series (see Eq. 6).

Another remarkable result seen on Fig. 4 is the clear dependence of $\phi_2$ on the molecular weight of PVA. This dependence is expected from the simple qualitative consideration that the presence of the end-group which is different from the intermediate segment will affect the spatial configuration of the polymer molecule. It is seen that $\phi_2$ decreases with increasing molecular weight, and the fifth decimal place of the solution density $d_{12}$ is influenced by the molecular weight of the solute polymer. As is shown immediately after, $\phi_2$ and the partial specific volume $V_2$ seem to be inversely proportional to the molecular weight of PVA. Taking this molecular weight dependence into account, the experimental formula for the solution density of a dilute solution of PVA at 30°C is proposed as follows:

$$\frac{d_{12}}{d_1} = 1+\left(0.249-\frac{2.47}{P}\right)\cdot c_2 -\left(0.64-\frac{88}{P}\right)\cdot c_2^2 \qquad (6)$$

where $P$ is the polymerization degree of PVA and $c_2$ is the polymer concentration in g./cc. This equation could reproduce the experimental data very well.

Eq. 6 should prove useful for predicting the density of an aqueous solution of PVA, irrespective of the origins of the PVA samples, if the polymerization degree is not too low. However, it is to be remarked here that, if $P$ is lower than 500, the solution density of PVA which is polymerized under different initiators may not be represented by this equation.

From Eq. 4 or 5, the partial specific volume $V_2$ of PVA is easily obtained. Because of scattering in the observed values of $\phi_2$, the accurate determination of $V_2$ and its concentration dependence becomes difficult at concentrations lower than 0.2 g./100 ml., and $V_2$ only at the concentration of 0.5 g./100 ml. was estimated by interpolation. Plotting the experimental values of $V_2$ against $1/P$, a nearly linear relationship is obtained as in Fig. 5.

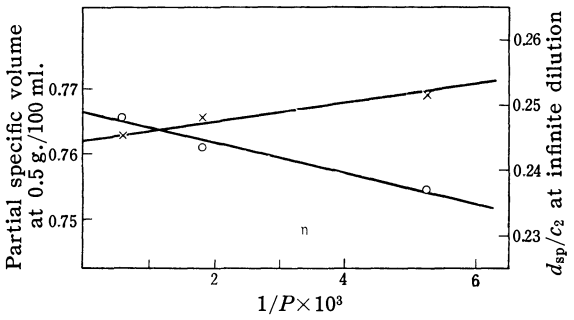

Fig. 5. Molecular weight dependence of $(d_{sp}/c_2)_{c_2\to0}$ and $V_2$ at 0.5 g./100 ml., at 30°C.
○ $\left(\frac{d_{sp}}{c_2}\right)_{c_2\to0}$ × $V_2$ at 0.5 g./100 ml.

In the same figure, the values of $d_{sp}/c_2$ at infinite dilution $(d_{sp}/c_2)_{c_2\to0}$ are also plotted against $1/P$. A linear relationship is observed here. This dependence of $(d_{sp}/c_2)_{c_2\to0}$ on $P$ must be the same as that of $\phi_{2(c_2\to0)}$ as is easily seen from Eq. 3. Thus, one may write

$$\phi_2 = \phi_{2(P\to\infty)}+K/P \qquad (7)$$

at infinite dilution. Here, $\phi_{2(P\to\infty)}$ is the apparent specific volume of the polymer whose polymerization degree $P$ is infinity and $K$ is a constant.

**Estimation of Polymer-Solvent Interaction.**— If the end-segments in the polymer molecule are different in size from the intermediate segments, it is to be expected that $\phi_2$ (or $V_2$) may change inversely proportional to the molecular weight of the polymer.

In fact, Kobatake[6] has derived theoretically an equation which is quite the same in form as Eq. 7. According to his theory, two constants in Eq. 7 can be correlated with the parameters of intermolecular potential as follows:

$$\phi_{2(P\to\infty)} = -\beta_{12}/m_2 \qquad (8)$$

$$K = -2\beta'_{12}+\frac{2\rho_1 B_{11}+1}{\rho_1} \qquad (9)$$

$$B_{12} = 2\beta'_{12}+P\beta_{12} \qquad (10)$$

where $B_{11}$ is the excluded volume (or McMillan-Mayer's "irreducible integral"[13]) between two solvent molecules, $B_{12}$ is the excluded volume between solvent- and polymer molecules, $\beta_{12}$ is the excluded volume between solvent molecule and intermediate segment, $\beta'_{12}$ is the excess excluded volume representing the end-group effect, $m_2$ is the molecular weight

13) W. G. McMillan, Jr. and J. E. Mayer, *J. Chem. Phys.*, **13**, 276 (1945).

TABLE II. EXPERIMENTAL VALUES OF APPARENT AND PARTIAL SPECIFIC VOLUMES AND POLYMER-SOLVENT EXCLUDED VOLUMES

| $P$ | $(d_{sp}/c_2)_{c_2\to 0}$ | $\phi_{2(c_2\to 0)}$ | $V_2$ | $-B_{12}(\times 10^{-3})$ | $-\beta_{12}$ | $-\beta'_{12}$ |
|---|---|---|---|---|---|---|
| 1600 | 0.248 | 0.756 | 0.763 | 1.21 | | |
| 550 | 0.243 | 0.761 | 0.766 | 0.415 | 0.755 | 1.20 |
| 190 | 0.237 | 0.767 | 0.769 | 0.143 | | |

of monomer, and $\rho_1$ is the density (number density) of the solvent.

According to Orstein and Zernike[14], the $B_{11}$ in Eq. 9 is correlated with the isothermal compressibility $\kappa_1$ as follows:

$$\frac{2\rho_1 B_{11}+1}{\rho_1} = kT\kappa_1 \qquad (11)$$

where $k$ is the Boltzmann constant and $T$ is the absolute temperature in °K. One can then calculate $\beta_{12}$ and $\beta'_{12}$ by Eqs. 8 and 9, and finally $B_{12}$ by Eq. 10.

The authors will first estimate the second term $(2\rho_1 B_{11}+1)/\rho_1$ in Eq. 9. Using Eq. 11, the value of $(2\rho_1 B_{11}+1)/\rho_1$ for water is estimated to be 0.068 cc./g. from the experimental data of $\kappa$ at ordinary pressure[15]. Thus, Eq. 9 can be reduced to

$$K = -2\beta'_{12}+0.068 \qquad (12)$$

Using the experimental results of $\phi_{2(c_2\to 0)}$ (extrapolated values of $\phi_2$ to infinite dilution) and its molecular weight dependence, the authors calculate the values of $\beta_{12}$, $\beta'_{12}$ and $B_{12}$, which are listed in Table II.

The value of $\beta_{12}$ represents the "free volume" of PVA molecule per monomer unit, while $\beta'_{12}$ is related to the excess contribution by end-segments. It may be concluded from the comparison between them that the contribution of the end-group in the polymer molecule to total interaction differs markedly from that of the intermediate segment and can not be neglected.

Furthermore, it is to be remarked here that a linear relationship between $\phi_2$ and $1/P$ can also be expected from Eq. 9 even when the end-group effect is negligible. However, for the present case, $\beta'_{12}$ have a large value in comparison with the second term in Eq. 9; the experimental value of $K$ is estimated to be 2.47 cc./g., $-2\beta'_{12}$ is thus estimated to be 2.40 cc./g. which is to be compared with 0.068 cc./g. for the second term. Therefore, a greater part of molecular weight dependence of $\phi_2$ may be attributed to the end-group effect.

Finally, the authors will make a comparison between $V_2$ (see Table II) and the specific volume of solid PVA, $V_2^\circ$. The specific volume of completely amorphous PVA is estimated to be 0.787 from the extrapolation of the experimental values for PVA-film having different crystallinity[16]. A volume contraction in solution is clearly observed in the present case.

## Summary

The solution density of polyvinyl alcohol dilute aqueous solution is measured by the use of the method of floating equilibria. This method is proved to be useful for the purpose of precise density and concentration determination of PVA dilute solution. An experimental formula for the density of PVA aqueous solution both as a function of the concentration and polymerization degree of PVA is proposed. The excluded volumes between solute and solvent are estimated from the molecular weight dependence of apparent and partial specific volumes obtained.

The authors wish to express their hearty thanks to Dr. Y. Kobatake of Tokyo Institute of Technology who calls their attention to the present problem; also to thank Professor M. Tamura of Kyoto University for his interest and guidance. They are also thankful to Dr. A. Nakajima of Kyoto University for his valuable suggestions in preparing the materials.

# *Microwave Spectrum of Malononitrile, $CH_2(CN)_2$. I. The Molecular Structure in the Ground Vibrational State*

By Eizi HIROTA and Yonezo MORINO

(Received July 7, 1959)

The vibration-rotation interaction in polyatomic molecules has been studied extensively by Nielsen and others[1]. The interaction manifests itself in several ways in the observed spectra; for example, the rotational constant differs slightly in each vibrational state and the centrifugal force results in the elongation of molecules. An interesting feature of the interaction is given by the Coriolis force which can be observed most clearly in the degenerate vibrational states. Microwave investigation has been made on the Coriolis interaction in linear and symmetric top molecules, in the name of *l*-type doubling[2]. However, it may be pointed out that, if the two vibrational states are nearly or accidentally degenerate, the Coriolis interaction is expected to become large. Malononitrile has been studied for this purpose, since the Coriolis interactions are expected between four low-lying C—C≡N bending modes[3].

The Raman effect of malononitrile was observed by Kohlrausch and Ypsilanti[4] and the infrared absorption spectrum was measured by Halverson and Francel[5]. The latter authors assigned the spectra and carried out the normal coordinate analysis. However, no data have yet been reported on the structure of the molecule. The present paper will give the molecular structure in the ground vibrational state. The vibration-rotation interaction will be treated in the near future.

## Experimental

The apparatus used was a conventional Stark modulation spectrograph, a 100 kc. sine wave being used for simplicity[6]. In addition to the normal molecule, three kinds of molecules isotopically substituted, $CHD(CN)_2$, $CD_2(CN)_2$, and $CH_2CNC^{15}N$, were synthesized to observe their rotational spectra. The hydrogen atoms of malononitrile exchange readily with the hydrogen of water; thus, the deuterated molecules were obtained by mixing the normal malononitrile with heavy water, made slightly alkaline by adding a small quantity of anhydrous sodium carbonate. The $^{15}N$ substituted molecules were obtained as follows. Ammonium sulfate containing 23.5% $^{15}N$ was mixed with barium hydroxide and heated. The ammonia thus evolved was led into cold water. The reaction of aqueous ammonia with ethylcyanoacetate gave cyanoacetic amide, which was dehydrated by phosphorous oxychloride to $CH_2CNC^{15}N$[7].

## Rotational Spectra and Rotational Constants

The malononitrile molecule has a two-fold symmetry axis and the moment of inertia about this axis is of an intermediate magnitude. Thus, the selection rule allows only the *b*-type rotational transitions. The *a*-axis lies on a plane made by the two cyano groups and the central carbon atom. The *c*-type transitions are allowed for $CHD(CN)_2$ and the *a*-type transitions for $CH_2CNC^{15}N$, but neither of them was observed. Microwave absorption was observed only at room temperature since the vapor pressure is low. Owing to the large dipole moment (~3.6 D), the small rotational constants, and the presence of many vibrational states of low energies, the molecule was found to have many rotational lines: at least, one absorption line was observed in every 10 Mc./sec. Hence, the assignment seemed at first to be difficult. Fortunately, a *Q*-branch series $J_{0,J} \rightarrow J_{1\,J-1}$ was found to be assigned most easily*: the Stark effects are large and the intensities, in particular of high $J$ members, are very strong. It was possible to resolve three or four Stark components of $J=5$, 6 and

7 lines and thus to check the $J$ numbers of these lines by the technique of Golden and Wilson[8)]. Six low $J$ transitions of $P$- and $R$-branches were also observed for $CH_2(CN)_2$, and two $R$-branch transitions for isotopically substituted molecules. The $Q$-branch members, $9_{09} \rightarrow 9_{18}$ and $10_{0,10} \rightarrow 10_{19}$ of the $CH_2CN^{13}CN$ molecule in natural abundance were measured and assigned. The measured frequencies are listed in Table I.

The rotational constants given in Table II were determined by four $Q$-branch ($J=$ 1 to 4) and two $R$-branch ($0_{00} \rightarrow 1_{11}$ and $1_{01} \rightarrow 2_{12}$) transitions, the centrifugal distortion being neglected. $A-(B+C)/2$ and $(B-C)/2$ were obtained for $CH_2CN^{13}CN$. The results are also given in Table II. The frequencies calculated by using the constants obtained above are compared with the observed frequencies in Table I.

### Structure Analysis

The structure of malononitrile is specified by five parameters: the C—H, the C—C, and the C≡N bond length, and the HCH and the CCC bond angle. If the linearity of the C—C≡N group is abandoned, an additional parameter, ∠CCN, is necessary.

For convenience a Cartesian coordinate system is fixed in the molecule; its origin coincides with the center of gravity and the $x$-axis is taken along to the $c$-axis, the $y$-axis to the $a$-axis, and the $z$-axis to the $b$-axis, respectively (see Fig. 1). For isotopically substituted molecules the origin is shifted to the new center of gravity,

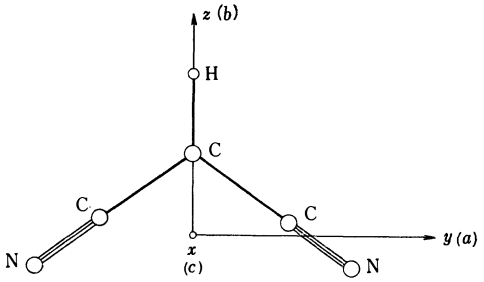

Fig. 1. Schematic diagram of malononitrile molecule.

but the $x$-, $y$-, and $z$-axes are kept parallel to those in the original molecule. For $CD_2(CN)_2$ the ($x$, $y$, $z$) system evidently coincides with the principal axes of moment of inertia, but for $CHD(CN)_2$ and $CH_2CNC^{15}N$ a slight rotation of axes is necessary, in transforming from the ($a$, $b$, $c$) system to the ($x$, $y$, $z$) system. Thus, in evaluating $\sum m_i x_i^2$, $\sum m_i y_i^2$, and $\sum m_i z_i^2$ (which are called the $x$-moment, the $y$-moment, and the $z$-moment, respectively) from $I_a$, $I_b$ and $I_c$ for the latter two molecules, some minor corrections are necessary and they are easily calculated by assuming a structure close to the real one. The $x$-, $y$- and $z$-moments thus obtained are listed in Table III.

**a) $x$-Coordinates.** — The $x$-moment is a function only of the $x$-coordinate of the hydrogen atom, $x_H$: that is,

$$\sum m_i x_i^2 = 2m x_H^2 \qquad (1)$$

where $2m = 2m_H$ for $CH_2(CN)_2$ and $CH_2CN\cdot C^{15}N$, $2m = [(3m_C + 2m_N)(m_D + m_H) + 4m_D m_H]/(3m_C + 2m_N + m_D + m_H)$ for $CHD(CN)_2$, and $2m = 2m_D$ for $CD_2(CN)_2$. The value of $x_H$, given in Table IV, increases with the mass of hydrogen, just as in the case of methylene chloride. Laurie[9] has explained this effect by the inertia defect, in analogy with planar molecules. By taking into consideration the inertia defect $\Delta$, Eq. 1 is modified as follows:

$$\sum m_i x_i^2 + (1/2)\Delta = 2m x_H^2 \qquad (1')$$

where a single value of the inertia defect $\Delta$ is assumed for all molecules, since the inertia defect is considered to originate from the in-plane vibrations of low frequencies. In fact, four observed $x$-moments can be reproduced by Eq. 1′, if two parameters, $x_H$ and $\Delta$, are assumed to be 0.8847 Å and 0.3379 amu Å$^2$, respectively. The calculated $x$-moments are compared with those observed in Table V. The

TABLE IV. VALUES OF $x_H$ DETERMINED WITHOUT THE INERTIA DEFECT CORRECTION (Å)

| Molecule | $x_H$ |
|---|---|

| $CH_2CNC^{15}N$ | 0.8364 |
| $CHD(CN)_2$ | 0.8514 |
| $CD_2(CN)_2$ | 0.8610 |

TABLE V. OBSERVED AND CALCULATED $x$-MOMENTS (amu Å$^2$)

| Molecule | $\sum m_i x_i^2$ | |
|---|---|---|
| | obsd. | calcd.[a] |
| $CH_2(CN)_2$ | 1.4124 | 1.4091 |
| $CH_2CNC^{15}N$ | 1.4106 | 1.4091 |
| $CHD(CN)_2$ | 2.1805 | 2.1851 |
| $CD_2(CN)_2$ | 2.9872 | 2.9848 |

a) $x_H = 0.8847$ Å and $\Delta = 0.3379$ amu Å$^2$ are assumed.

inertia defect $\Delta$ of 0.3379 amu Å$^2$ is large compared with that of methylene chloride 0.167 amu Å$^2$, or of other molecules[9]. It is consistent with the fact that there are more normal modes of low frequencies in malononitrile.

Myers and Gwinn[10] have analyzed their data on methylene chloride by plotting $x_H$ against $1/2m$. The meaning of this procedure is evident from Eq. 1′; if $\Delta \ll \sum m_i x_i^2$ is assumed, $x_H$ is given by $(\sum m_i x_i^2/2m)^{1/2} \cdot (1 + \Delta/4\sum m_i x_i^2) = x_H^0 + (\Delta/4x_H^0)(1/2m)$, where $x_H^0 = (\sum m_i x_i^2/2m)^{1/2}$ means the value of $x_H$, when $\Delta$ is ignored. Thus, the $x_H$ obtained here corresponds to $x_H^0$ in the limit of $1/2m \to 0$.

**b) $y$-Coordinates.** — If the effect of zero-point vibration is negligible, the same $y$-moment should be obtained for three molecules; $CH_2(CN)_2$, $CHD(CN)_2$ and $CD_2(CN)_2$, since the $y$-moment is a function depending only upon the coordinates of the cyano groups. The observed $y$-moments,

9) V. W. Laurie, ibid., 28, 704 (1958).

10) R. J. Myers and W. D. Gwinn, ibid., 20, 1420 (1952).

170.3922, 170.3564 and 170.3236 amu Å$^2$, show a small discrepancy, presumably due to zero-point vibration, but the effect is not so large as in the $x$-moment.

By combining the $y$-moment for $CH_2CN\cdot C^{15}N$, $(\sum m_i y_i^2)_{15}$, with that of $CH_2(CN)_2$, $(\sum m_i y_i^2)_{14}$, the $y$-coordinate of nitrogen, $y_N$, in the normal molecule is obtained as follows:

$$y_N^2 = [(M+\Delta m_N)/M\Delta m_N] \times [(\sum m_i y_i^2)_{15} - (\sum m_i y_i^2)_{14}] \quad (2)$$

where $M$ is the total mass of $CH_2(CN)_2$, and $\Delta m_N$ is the mass difference of $^{15}N$ and $^{14}N$. Then $y_N$ is found to be 2.1943 Å.

In order to determine the $y$-coordinate of the carbon atom in a cyano group, $y_C$, it is desirable to substitute the carbon atom with its isotope, $^{13}C$[11]. As mentioned earlier, two $Q$-branch transitions have been observed for $CH_2CN^{13}CN$ molecule, but the rotational constants could not be determined accurately enough for the structure analysis. Hence $y_C$ is evaluated through the $y$-moment combined with the value of $y_N$ obtained above. Three values of the $y$-moments for $CH_2(CN)_2$, $CHD(CN)_2$, and $CD_2(CN)_2$ give accordingly three $y_C$'s: 1.2161, 1.2155 and 1.2149 Å, respectively. As the difference between them is not large, the average of the three values is used for $y_C$: that is, 1.2155 Å.

**c) $z$-Coordinates.** — The $z$-moments of $CH_2(CN)_2$, $(\sum m_i z_i^2)_2$, and of $CHD(CN)_2$, $(\sum m_i z_i^2)_3$, give the $z$-coordinate of hydrogen in the normal molecule, $z_H$, by the relation similar to Eq. 2:

$$z_H^2 = [(M+\Delta m_H)/M\Delta m_H] \times [(\sum m_i z_i^2)_3 - (\sum m_i z_i^2)_2] \quad (3)$$

where $\Delta m_H$ is the mass difference of D and H. If the $z$-moment of $CD_2(CN)_2$, $(\sum m_i z_i^2)_4$, is used in place of $(\sum m_i z_i^2)_3$, the equation

$$z_H^2 = [(M+2\Delta m_H)/2M\Delta m_H] \times [(\sum m_i z_i^2)_4 - (\sum m_i z_i^2)_2] \quad (4)$$

must be applied. Eq. 3 gives $z_H$ of 1.5384 Å, whereas Eq. 4 gives 1.5357 Å. The average value, 1.5371 Å, is used in the following analysis of the structure.

A similar procedure is used to determine the $z$-coordinate of the nitrogen atom, $z_N$. The relevant equation is

$$z_N^2 = [(M+\Delta m_N)/M\Delta m_N] \times [(\sum m_i z_i^2)_{15} - (\sum m_i z_i^2)_{14}] \quad (5)$$

where $(\sum m_i z_i^2)_{14}$ means $(\sum m_i z_i^2)_2$ in Eqs. 3 and 4. It may be noted that, since the effect of zero-point vibration entering in $\sum m_i x_i^2$ is probably similar for the two molecules $CH_2(CN)_2$ and $CH_2CNC^{15}N$, $I_{yy}$ is used in place of $(\sum m_i z_i^2)$. In doing so, the accuracy attained becomes considerably better, for the value of $I_{yy}$ is determined by the rotational constant $A$, whereas $\sum m_i z_i^2$ is evaluated by three rotational constants, $A$, $B$ and $C$. Under this assumption $z_N$ is found to be $-0.5427_3$ Å.

Since adequate substitutions are not yet available, a procedure similar to that used for the determination of $z_H$ and $z_N$ can not be applied to the $z$-coordinates of carbon atoms. Moreover, whatever substitution is possible, the $z$-coordinate of the carbon atom of the cyano group is close to zero, and the procedure becomes less powerful. Hence the first moment equation and the relation giving the $z$-moment of $CH_2(CN)_2$ are used to evaluate the $z$-coordinates of the apex carbon atom, $z_0$, and of the carbon atom in the cyano group, $z_C$[11]. They are 0.8994 and 0.0545 Å, respectively.

All the coodinates necessary for the structure determination are thus obtained and listed in Table VI. The bond length

Table VI. Coordinates of atoms in $CH_2(CN)_2$ and molecular structure

| Atom | $x_i$ | $y_i$ | $z_i$ |
|---|---|---|---|
| H | ±0.8847 Å | 0 Å | +1.5371 Å |
| C (apex) | 0 | 0 | +0.8994 |
| C (cyano) | 0 | ±1.2155 | +0.0545 |
| N | 0 | ±2.1943 | $-0.5427_3$ |

| | | | |
|---|---|---|---|
| C—C | $1.480_3$±0.0056 Å | ∠CCC | 110°24′±24′ |
| C≡N | $1.146_6$±0.0064 Å | ∠HCH | 108°26′±26′ |
| C—H | $1.090_6$±0.0034 Å | ∠CCN | 180°−(3°24′±26′) (outside) |

of C—H is found to be 1.091 Å, that of C—C 1.480 Å, and that of C≡N 1.147 Å. The bond angle of CCC, 110°24′, is about 1° wider than the tetrahedral angle, whereas that of HCH, 108°26′, is smaller than the tetrahedral angle by the same order of magnitude. Myers and Gwinn[10] reported the C—H bond length and the HCH bond angle in methylene chloride to be 1.082 Å and 112°58′, respectively, whereas Lide, Jr.[12], obtained 1.092 Å and 111°52′, for the corresponding quantities in methylene fluoride. The C—H bond length of malononitrile, 1.091 Å, is closer to that of methylene fluoride, rather than to that of methylene chloride, but the

12) D. R. Lide, Jr., *J. Am. Chem. Soc.*, **74**, 3548 (1952).

HCH bond angle 108°26′ is definitely smaller than those of methylene halides. It is noteworthy that the linearity of C—C≡N groups does not hold, the cyano groups being bent outside by about 3.5°. Though zero-point vibration may modify considerably the equilibrium configuration, it seems reasonable to assume an electrostatic repulsion between two electronegative groups such as cyano radicals. Somewhat longer C—C, somewhat shorter C≡N bond length, and the bent C—C≡N indicate that the electron configuration in the cyano groups might be more or less different from that in acetonitrile. In fact, Casabella and Bray[13] found, in the solid state, a quadrupole coupling constant and an asymmetry parameter, definitely larger than those of acetonitrile and of ethyl cyanide.

### Dipole Moment

The dipole moment of $CH_2(CN)_2$ was obtained from the Stark effects of the six transitions: four $Q$-branch lines of $J=1$ to 4 and two $R$-branch transitions, $0_{00} \rightarrow 1_{11}$ and $1_{01} \rightarrow 2_{12}$. The field strength was calibrated by the $J=1 \rightarrow 2$ transition of OCS, the dipole moment of OCS being assumed to be 0.7124 D[14]. The values of the dipole moment obtained from the six transitions agree well with each other (Table VII). The average of them is 3.735 D, which is compared with 3.6 D obtained by the dielectric constant measurement in benzene solutions[15].

# *The Adsorption of Dye Mixtures by Cellophane Sheet. I. Temperature and Concentration Dependence of Adsorption from Some Binary Mixtures*

By Yukio HORIKI, Yoshié TANIZAKI and Noboru ANDO

(Received July 13, 1959)

It is well known that the amount of adsorption of dyes from binary mixtures of a direct dye with others is commonly reduced as compared with the adsorbed dye amount when dyed singly[1-3]. Some factors of such reduction of adsorption in mixture dyeing have been variously discussed, and it seems to be most appropriate to consider a mutual interaction between dyes in solution as a principal factor. Neale and Stringfellow have considered that such interaction is attributed to the complex formation[2]. This concept, however, has failed to be accepted, because there is no direct evidence of complex formation in solution at such a high temperature as is practically applied[4]. Derbyshire and Peters[3] have recently shown by the spectroscopic measurements that Chlorazol Sky Blue FF and Chrysophenine G form a 1 : 1 complex in aqueous solution containing no salt at 60°C, and further concluded by the thermodynamic treatment that the complex formation occurs even at a usual dyeing temperature 90°C. Based on this conclusion, they have discussed in a semi-quantitative way the results of mixture dyeing.

In the hope of finding a method to obtain some quantitative information about the interaction between dyes in mixture dyebath, necessary to explain the reduction in adsorption, the authors have studied the single and the mixture dyeings of Chlorazol Sky Blue FF and Chrysophenine G, and of Chlorazol Sky Blue FF and a monoazo acid dye.

## Experimental

Chlorazol Sky Blue FF and Chrysophenine G were used as direct dyes, and *p*-nitroaniline→γ acid (α-coupling) as a monoazo acid dye. Chlorazol Sky Blue FF (called Blue dye for short) and the monoazo acid dye (Acid dye) were the same as those used in the authors' previous works[5,6], and Chrysophenine G (Yellow dye) was prepared by purifing the commercial dye by Robinson and Mills' method[7].

The Cellophane sheet used was that made by Tokyo Cellophane Co., Ltd. It was washed with distilled water at 90°C for 30 min. Pieces of the sheet weighing 15~25 mg. were dyed in 75 g. portions of the dye solution at 50, 70 and 90°C for 24 hr.* The dyed sheets were rinsed in ice-cold water (about 6°C) and then left in a desiccator with 50% sulfuric acid for two days. An accurate weight of the dyed sheet was obtained by dividing its weight under the constant humidity by a known humidity coefficent (e. g. 1.07 at 15°C and 1.10 at 30°C)[8].

Check measurements on solutions of known density in 25% aqueous pyridine showed that the dyes obeyed Beer's law both singly and in mixture, and that the absorption spectra in the mixture were additive. Based on this fact, the dye adsorbed by the sheet was stripped with 25% aqueous pyridine and the dye content of the strip solution was measured by a Shimadzu QR-50 spectrophotometer.

In case of the mixture dyeing, the initial concentration of Blue dye was about $1\times10^{-5}$ mol./l. for every dyebath, and those of Yellow dye and Acid dye were varied from zero to about $35\times10^{-5}$ and $90\times10^{-5}$ mol./l., respectively. The concentration of sodium chloride was 2.0 g./l. for every dyebath.

## Results

The relation between the amount of adsorption of Blue dye and the dyebath concentration of its partners was examined, 24 hr. after mixture dyeing, by the

adsorption measurements of binary mixtures containing a constant amount of Blue dye. The results are shown in Figs. 1 and 2; the one denotes the pair of Blue dye and Acid dye, and the other Blue dye and Yellow dye. Comparison between these figures shows that the adsorption of Blue dye is not so decreased with an increase in the dyebath concentration of Acid dye (Fig. 1), while it is markedly reduced by the addition of a very small amount of Yellow dye until it rapidly converges to zero (Fig. 2). Furthermore, under the present condition, the adsorption of Blue dye from a dyebath, containing several times as much Yellow dye as Blue dye, slightly increases with a raise in temperature; this is the same tendency as that reported by Neale and Stringfellow[2]. This situation can be recognized by the relation between the adsorption of Blue dye and temperature in Fig. 3.

In case of mixture dyeing with Blue dye the adsorption of the partner, i. e. Yellow dye or Acid dye, is also reduced, as compared with that in the case of its single dyeing. For instance, adsorption curves of Yellow dye from single and mixture dyebaths at 70°C, corresponding to Fig. 2, are shown in Fig. 4a.

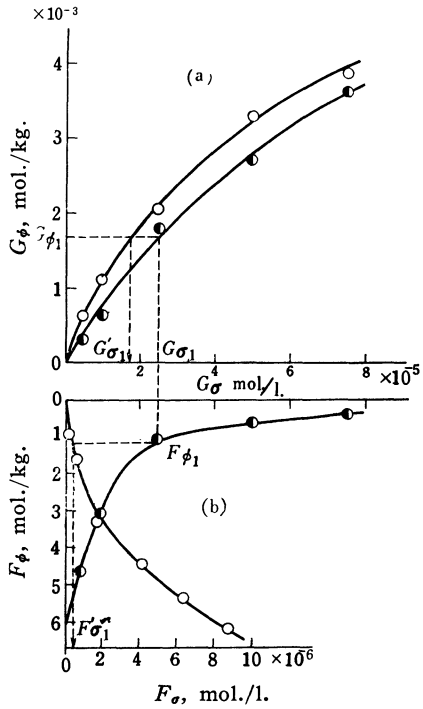

Fig. 4. The adsorptions of Blue dye and Yellow dye from single and mixture dyebaths at 70°C. Here the results of mixture dyeing correspond to those of Fig. 2. Scale ($F_\sigma$) on the abscissa (b) refers to the white circles.

○ Single ◐ Mixture

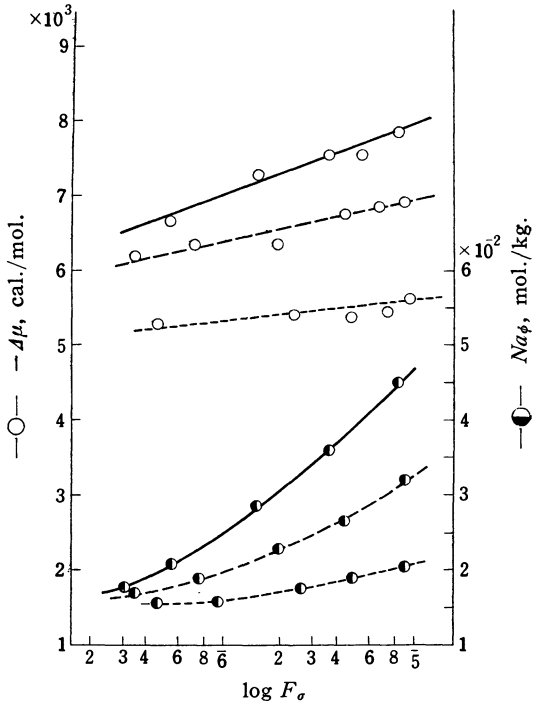

Fig. 5. The relations of the affinity ($-\Delta\mu^0$) of Blue dye for Cellophane (white circles) and of the concentration of sodium ion ($Na_\phi$) in Cellophane (half solid circles) to the logarithm of final dyebath concentration of Blue dye ($F_\sigma$, mol./l.).

—— 50°C, ---- 70°C, ------ 90°C

It has been seen that the affinity of Blue dye**, obtained from its single dyeing (corresponding to the white circles in Fig. 4b), is more or less dependent on its dyebath concentration at constant temperature. The relation between the affinity of Blue dye and its final dye bath concentration at various temperatures in single dyeing is shown in Fig. 5. This figure shows that the affinity, $-\Delta\mu^0$, is approximately proportional to the logarithm of the final dyebath concentration of Blue dye, $F_\sigma$. In this figure is also shown the relation between $\log F_\sigma$ and the concentration of sodium ion in Cellophane, $Na_\phi$**.

## Discussion

Based on the assumption that the reduction of the amount of dyes resulting from the mixture dyeing is due to an interaction between the two dyes, the results described in the preceding section will be discussed. Now, let us assume simply that:

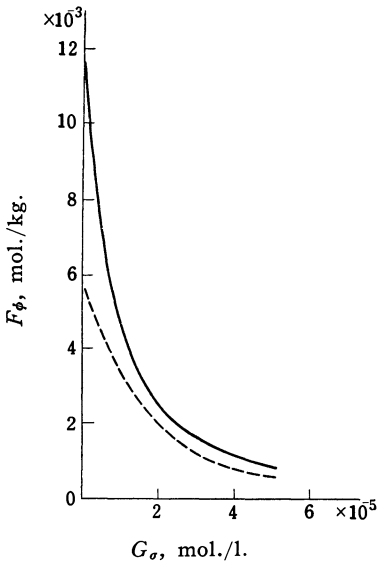

Fig. 6. The relation between the dyebath concentration of Yellow dye and the adsorption of Blue dye calculated from Eqs. 1 and 3. $F_\sigma = 1\times10^{-5}$ mol./l., $K_{50°} = 6\times10^{-7}$ mol./l., $K_{70°} = 1\times10^{-6}$ mol./l.

—— 50°C, ---- 70°C

** $Na_\phi$ and $-\Delta\mu^0$ were calculated from Eqs. 7.19 (p. 200) and 7.26 (p. 206) in Ref. 4. $V$ (surface layer volume) =0.45 l./kg. for each dyeing temperature.

1) The effective dyebath concentration which contributes to adsorption is reduced by an interaction between both dyes in mixture.

2) The amount of the dye adsorbed from the mixture dyebath corresponds to this effective dyebath concentration, and the adsorbing behavior of the dye in mixture dyeing is just the same as that in its single dyeing, so it behaves independently. Consequently, concerning the effective dyebath concentration, the additivity in adsorption comes into being.

These assumptions may be appropriate under the condition that no competition of dyes for the available surface occurs. If the assumptions are accepted, the effective dye bath concentration will be calculated by the following equation, using the amount of dye adsorbed from mixture dyeing and its affinity obtained from single dyeing,

$$D_\phi = Na_\phi^{-z} Na_\sigma^{+z} V^{z+1} D_\sigma' \exp(-\Delta\mu^0/\boldsymbol{R}T) \quad (1)$$

where $D_\phi$ (mol./kg.) is the amount of a dye adsorbed by Cellophane, $D_\sigma'$ (mol./l.) the effective dyebath concentration, $Na_\phi$ (mol./kg.) the sodium ion concentration in Cellophane, $Na_\sigma$ (mol./l.) the sodium ion concentration in dyebath, $V$ (l./kg.) the surface layer volume, $-\Delta\mu^0$ (cal./mol.) the standard affinity, $\boldsymbol{R}$ and $T$ the gas constant and the absolute temperature, respectively, and $z$ the number of sulfonic groups per molecule. The difference $D_c$ (mol./l.) between the total dyebath concentration $D_\sigma$ (mol./l.) and the effective dyebath concentration may be attributed to the interaction of dyes in mixture solution; in other words, $D_c$ may be regarded as the dyebath concentration ineffective to adsorption. If the amount of a dye adsorbed in this mixture dyeing is known, it would be expected that its effective dyebath concentration would be calculated by Eq. 1. However, as the calculated affinity of dyes generally varies more or less with the dyebath concentration, it is undesirable to calculate it directly by Eq. 1. Therefore, it was obtained graphically from the observed values in single and mixture dyeings. Concerning the pair of Blue dye and Yellow dye, for example, its effective dyebath concentration is obtained from Figs. 4a and 4b as follows: when the final total dye bath concentrations of Blue dye and Yellow dye are $F_{\sigma 1}$ and $G_{\sigma 1}$, respectively***, as shown in the figure, the amounts of adsorption of the dyes $F_{\phi 1}$, $G_{\phi 1}$ correspond to $F_{\sigma 1}'$, $G_{\sigma 1}'$ in single dyeing, respectively, which may be regarded as their effective dyebath concentrations. $F_{\sigma 1}-F_{\sigma 1}' \equiv F_{c1}$ and $G_{\sigma 1}-G_{\sigma 1}' \equiv G_{c1}$ may be regarded as the concentrations participated in the interaction, and it follows that $G_{c1}/F_{c1}$ means the mole ratio of both dyes contributed to the interaction. Values obtained in such a way are shown in Tables I and II. Table I shows that $G_c/F_c$ tends to about unity when the relative concentration of Yellow dye to Blue dye increases to a certain value. If it is assumed that the interaction in this range of concentration means the formation of a 1:1 complex, it is possible to calculate the instability constant $K$ of the complex, according to the mass action law,

$$K = \frac{F_\sigma' G_\sigma'}{F_c} = \frac{(F_\sigma - F_c)(G_\sigma - G_c)}{F_c}, \quad (F_c = G_c) \quad (2)$$

Values of $K$ calculated by the equation are shown in Table I.

When the value of $K$ is known, the effective dyebath concentration will be obtained from Eq. 2. For example, $F_\sigma'$ can be given as a function of $F_\sigma$ and $G_\sigma$, by the following equation which was derived from Eq. 2,

$$F_\sigma' = F_\sigma - F_c = \frac{1}{2}\{(G_\sigma - a)^2 + (b^2 - a^2)\}^{1/2} + \frac{1}{2}(a - G_\sigma) \quad (3)$$

where $a = F_\sigma - K$ and $b = F_\sigma + K$. Since $a$ and $b$ are constant when $F_\sigma$ is fixed, $F_\sigma'$ is the function of $G_\sigma$ alone. Further, the value of $F_\phi$ in the mixture of Blue dye and Yellow dye can be obtained by substituting $F_\sigma'$ into Eq. 1.

In order to check the validity of the assumption described above, values of $F_\sigma'$ corresponding to various values of $G_\sigma$ were calculated by Eq. 3; here were used $6\times10^{-7}$ and $1\times10^{-6}$ mol./l. as the values of $K_{50°}$ and $K_{70°}$, respectively, and $1\times10^{-5}$ mol./l. as that of $F_\sigma$ and $0.5\times10^{-5}\sim5\times10^{-5}$ mol./l. as that of $G_\sigma$. The values of $F_\phi$ are also calculated by Eq. 1, using the obtained values of $F_\sigma'$, where $Na_\phi$ and $-\Delta\mu^0$ were obtained graphically from Fig. 5, and $3.42\times10^{-2}$ mol./l. and 0.45 l./kg. were used as the values of $Na_\sigma$ and $V$, respectively. These calculated values of $F_\phi$ against

*** Since the total concentration of Blue dye is nearly constant ($1\times10^{-5}$ mol./l.), $G_{\sigma 1}/F_{\sigma 1}$ is dependent only on $G_{\sigma 1}$. Suffix 1 denotes some fixed values of $F_\sigma$, $G_\sigma$, etc.

| | 9.73 | 1.1 | 2.5 | 7.2 | 3.3 | 24 | 4.6 | 1.9 | 7.0 |
| | 9.76 | 1.1 | 2.5 | 7.3 | 3.5 | 25 | 6.5 | 2.3 | 9.0 |

Notations, $F_\sigma$ etc. and $A_\sigma$ etc., refer to Blue dye and Acid dye, respectively.

$G_\sigma$ are given in Fig. 6. Good agreement between the calculated (Fig. 6) and the measured (Fig. 2) values shows that the behavior of dyes in mixture dyeing may be qualitatively explained by the knowledge of single dyeing, if it is possible to know the instability constant.

If the composition of complexes remains constant over the whole concentration range, $K$ should be determined in principle even when the composition is not 1:1. In this way the amount of dyes adsorbed from mixture dyeing may be predicted. In the case of the mixture of Blue dye and Acid dye, however, the composition is gradually varied****, so the instability constant could not be obtained. Therefore, the amount of adsorption of the dyes from mixture dyeing can not be calculated by the above method. But it is expected that the difference between Fig. 1 and Fig. 2 may be understood qualitatively as follows: it is dependent directly on the extent of decrease in the effective dyebath concentration of Blue dye whether the reduction in adsorption of this dye is slow (Fig. 1) or rapid (Fig. 2) with an increase in the dyebath concentration of its partners. This fact may be attributed to the following two factors:

(a) The mole ratio of components in complexes.

(b) The instability constant of the complexes.

It is clear that the smaller the mole ratio ($G_c/F_c$ or $A_c/F_c$), the greater the

**** The spectroscopic measurements for the same mixture free from sodium chloride at room temperature show the same tendency: $A_c/F_c$ gradually increases with an increase in the relative concentration of Acid dye.

TABLE III. EFFECT OF TEMPERATURE ON THE ADSORPTION OF BLUE DYE

| | 90 | | | | |

decrease in effective dyebath concentration of Blue dye. If one considers only this point, it will apparently be expected from Tables I and II that the reduction of $F_\phi$ is slower in the case of the pair of Acid dye and Blue dye than that of Yellow dye and Blue dye. On the other hand, when the complexes have the same composition, the smaller $K$ is, the greater should be the decrease in the effective dye bath concentration. For instance, it will be expected that in the case of the pair of Acid dye and Blue dye the value of $K$ at a given temperature is greater than in the case of that of Yellow dye and Blue dye in a concentration range, in which only a 1:1 complex seems to be formed in both pairs[9]. Concerning the effect of temperature, the reduction in adsorption of a dye on addition of its partner will become smaller with temperature, since the value of $K$ increases in general with the rise of temperature. This is clearly seen in Figs. 1 and 2.

The relation between the amount of Blue dye adsorbed from the mixture with Yellow dye and dyeing temperature, as shown in Fig. 3, is also remarkable. That is, the amount of Blue dye adsorbed from the mixture, which contains several times as much Yellow dye as Blue dye, tends to increase slightly with the rise of temperature. The interpretation of this result is rendered difficult, but it may be explained at least by the hypothesis of complex formation and the knowledge of single dyeing. In other words, if $Na_\sigma$ and $V$ are independent of temperature, the partial differentiation of Eq. 1 with respect to $T$ leads to

$$\frac{\partial \ln F_\phi}{\partial T} = -4\frac{\partial \ln Na_\phi}{\partial T} + \frac{\partial \ln F_\sigma'}{\partial T} + \frac{\partial}{\partial T}\left(\frac{-\Delta\mu^0}{\boldsymbol{R}T}\right) \tag{4}$$

To see the correspondence of the equation with the results in Fig. 3, the value of each term at the right side of Eq. 4 was calculated for the interval of 20°C (50~70 and 70~90°C). If one takes $1\times10^{-5}$ mol./l. as $F_\sigma$, 1:0.5, 1:5 and 1:10 as $F_\sigma/G_\sigma$, and $5\times10^{-7}$, $1\times10^{-6}$ and $5\times10^{-5}$ mol./l. as $K$ of the 1:1 complex at 50, 70 and 90°C, respectively, then $F_\sigma'$ at each temperature can be calculated from Eq. 3, and $Na_\phi$ and $-\Delta\mu^0$ can be obtained from Fig. 5, also. Therefore, the value of $\Delta \ln F_\phi/\Delta T$ can be obtained from Eq. 4. They are listed in Table III. The result agrees qualitatively with the relation between $F_\phi$ and the temperature shown in Fig. 3. It will be recognized here that the sign of $\partial \ln F_\phi/\partial T$ may be dependent chiefly on the relation between the second and the third terms. In other words, it may mostly be influenced by the dependence of the instability constant and the affinity on temperature.

## Summary

1) The amount of dyes adsorbed by Cellophane from two mixture dyeings of Chlorazol Sky Blue FF and Chrysophenine G, and Chlorazol Sky Blue FF and *p*-nitroaniline→γ acid (α-coupling) was measured. Further, the amount in case of single dyeing was also measured.

2) It was assumed that the reduction in adsorption of dyes from mixture dyeing is due to an interaction between the two dyes in the dyebath, and that this interaction means only the formation of complexes. On this assumption, the instability constant in the case of the pair of Blue dye

9) A value of $K$ of the mixture in aqueous solution of Blue dye and Acid dye calculated at room temperture for a concentration range, in which only a 1:1 complex seems to be formed, is $1.25\times10^{-5}$ (Ref. 6) and that of the mixture of Blue dye and Yellow dye is $4\times10^{-6}$ at 60°C (Ref. 3). If these values are compared with each other at the same temperature, the difference between them will become greater: $K$ of the former may be much greater than that of the latter.

and Yellow dye was calculated, according to the mass action law, but it was impossible to calculate it in the case of the pair of Acid dye and Blue dye, because the composition of complexes of this pair was not constant.

3) How the amount of Blue dye adsorbed from mixture dyeing varies with the sort and the concentration of its partner dye and with the dyeing temperature was discussed from the standpoint of the instability constant and the affinity.

The authors wish to express their sincere thanks to Professor Ikuzo Tanaka and Dr. Tsuneo Yoshino of this Institute for their kind advice, to Assistant Professor Yoshiji Ishii, Gumma University, who gave them Chrysophenine G purified, and to Assistant Professor Kenzo Nishida, Yamagata University, for his helpful suggestion for the treatment of the Cellophane sheet.

# *Chemical Behaviors of the Intermediates Produced during the Reductive Photobleaching of Eosin in the Evacuated Alcoholic Solution*

By Kengo UCHIDA, Shunji KATO and Masao KOIZUMI

(Received July 13, 1959)

One of the present authors (Koizumi) and Imamura[1] investigated kinetically the photobleaching of eosin in the deaerated ethanol solution and concluded that the reaction proceeds via the following primary processes:

$$D \xrightarrow{h\upsilon} D^* \quad \text{(i)}$$

$$D^* \rightarrow D^t \quad \text{(ii)}$$

$$D^t + RH \rightarrow DH\cdot + R\cdot \quad \text{(iii)}$$

$$(DH\cdot \rightarrow \text{final products})$$

Where D: dye ion; $D^*$: singlet excited state of dye ($S^*$); $D^t$: triplet state of dye (T); RH: ethanol; DH·: semiquinone of eosine; R·; radical produced from ethanol.

Now, in order to make clear the details of these elementary reactions, it is essential to study about the chemical behaviors of the intermediates, $D^t$ and DH·. Experiments by the flash technique have already been commenced in the authors' laboratory. However, the ordinary kinetic studies, for example, the investigation about the effect of added substances on the reaction rate are expected to be useful for this purpose to some extent. In the present research, isopentane, *n*-hexane, benzene, cyclohexene, *n*-hexene and cyclooctatetraene (COT) were added to the reaction system and the variation of the rate of photobleaching was examined.

1) M. Koizumi and M. Imamura, This Bulletin, **28**, 117 (1955); **29**, 899 (1956); M. Imamura, ibid., **30**, 249 (1957).

## Experimental

**Materials.**—*Eosine.*—Grübler's product was used. Stock solution $1\times10^{-4}$ M was kept in the dark and this was diluted to $1\times10^{-5}$ M for each experiment. Isopentane, *n*-hexane and benzene were purified by the usual methods. COT prepared kindly by Dr. N. Hagiwara of Osaka University, was further distilled under vacuum three times and was stored in an evacuated ampule.

*n*-Hexene-2 and cyclohexene of Tokyo Kasei were distilled two or three times and were reserved in vacuo.

Ethanol, after being treated with concentrated sulfuric acid, was made free from aldehyde by the addition of silver oxide and dehydrated by calcium oxide.

**Apparatus and Procedures.**—A tungsten projection lamp (75 V. 500 W.) was used as a light source. The voltage was fixed at $45.0\pm0.5$ V. and the intensity was checked by measuring the bleaching rate of the aqueous eosine solution (not deaerated) throughout all the experiments[1]. A yellow glass filter cutting off $< 450$ m$\mu$ and a reaction cell was attached to the metallic case surrounding a glass tube, 6 cm. in diameter, in which the lamp was placed. Degassing of the sample was performed carefully by repeating the vacuum distillation. A Terrex cell for measuring the absorption spectra was used as a reaction vessel, the upper part of which was fused to a tube of hard glass for the cell to be attached to the

above distillation set. After the deaerated sample was poured into the cell it was fused off at a suitable position. The sample was irradiated in a thermostat usually at 25°C and at suitable time intervals the absorption spectra were measured by a Hitachi spectrophotometer (EPU-2A). The measurement of fluorescence spectra was done by the fluorescence attachment of the spectrophotometer.

## Results

**Rate Formula.**—Throughout all the experiments, the absorption spectra of the irradiated solution gradually declined keeping the same shape and particularly with the maximum at the same position as in the original solution. The situations are exactly the same as in the case of the pure alcoholic solution of eosine[1]. One example is shown in Fig. 1.

The rate of bleaching can be expressed by the same formula presented by Koizumi and Imamura[1],

$$-\frac{dc}{dt}=\frac{k}{d}I_0(1-e^{-\alpha cd})\times 10^3 \qquad (1)$$

where $c$ is the concentration of dye in mol./l., $I_0$ the intensity of illuminating light (mol. $cm^{-2}$ $sec^{-1}$), $\alpha$ the average or effective molar absorption coefficient and $d$ the thickness of the solution in cm.

Integrating Eq. 1, one obtains

$$\ln(e^{\alpha c_0 d}-1)-\ln(e^{\alpha cd}-1)=10^3 kI_0\alpha t \qquad (2)$$

By using the properly determined value of $\alpha$, one can obtain $k$ from the inclination of the linear plot of $\ln(e^{\alpha cd}-1)$ against $t$.

**The Effect of the Added Substance.**—*a) Isopentane, n-hexane, benzene and COT.* — The addition of these substances does not affect appreciably the absorption spectra of eosin in the visible region nor the fluorescence spectra. In the case of high concentration there is a slight decrease

* Isopentane purified with utmost caution.
** In these two runs, $k$-value in the pure alcoholic solution is markedly different from that of the other runs (including those in Table II). The cause for this is unknown though it may perhaps be due to the pretreatment of alcohol employed. The effect of the added substance will certainly not be affected seriously by this, since it is essentially related with a relative quantity to the reference alcohol.

in the fluorescence intensity. As an example, the influence of the addition of isopentane upon the fluorescence spectra is shown in Fig. 2. Other substances show more or less similar effects. In Fig. 3 rate constants $k$'s are plotted against the concentration and the data are given in Table I. It is apparent that the above four substances have a retarding effect and among them, COT is by far the most significant inhibitor for the bleaching reaction.

*b) n-Hexene and cyclohexene.* — Neither absorption spectra nor the fluorescence intensity is affected essentially. At higher concentration, the intensity of fluorescence increases slightly as shown in Fig. 4. The values of $k$ are plotted against mole fraction in Fig. 5, which shows that $k$ linearly increases with the concentration of the added substance. The data are given in Table II.

## Discussion

The primary processes were already described in the introduction. The fate of DH· and R· is not yet quite certain but the effect of the added substance on the rate is expected to be due to their interference with one of the above three steps i—iii. Since the mechanism would naturally be different for two groups, the retarding substances (isopentane, *n*-hexane, benzene and COT) and the promoting substances (*n*-hexene and cyclohexene), they will be considered separately.

**The Retarding Effect.**—Since either the absorption spectrum or the intensity of fluorescence is scarcely affected by the addition of the retarding substances, the first two processes in these systems have a rate almost equal to what they have when they are not added. Hence the remaining process iii ought to be eventually retarded by the interference of the added substance. There are two possibilities to be considered for this; the one is the deactivation of $D^t$ and the other is the recovery of D by the removal of hydrogen from DH·. But the latter possibility may safely be ignored from the fact that the above retarders have no tendency to be hydrogenated or scarcely any. Hence the conclusion is that the triplet state of eosin is deprived of its excess energy by the added substance, resulting in the decrease of the bleaching rate. Thus the only process which must be taken into account is the following one

which competes with process iii,

$$D^t + Q \rightarrow D + Q \qquad k_Q[Q] \qquad \text{(iv)}$$

where Q represents an added retarder.

Assuming the steady-state concentration for D* and $D^t$ one can write for $k$ the following:

$$k = \varphi_{S\rightarrow T} \frac{k_a[RH]}{k_a^S[RH] + k_Q[Q]} \qquad (3)$$

where $\varphi_{S\rightarrow T}$ gives the fraction of the singlet state going to the excited triplet, $k_a$ is the rate constant for the effective hydrogenating reaction iii, $k_a^S$, the sum of the rate constants for the genuine reaction and the deactivation of $D^t$ by alcohol. From Fq. 3

$$\frac{1}{k} = \frac{1}{\varphi_{S\rightarrow T}} \frac{k_a^S}{k_a} + \frac{1}{\varphi_{S\rightarrow T}} \frac{k_Q[Q]}{k_a[RH]} \qquad (4)$$

Thus, the plot of $1/k$ against $[Q]/[RH]$ gives a straight line as shown in Fig. 6. From the inclination $k_Q/\varphi_{S\rightarrow T}k_a$ and the intersect with the ordinate $\left(\frac{1}{\varphi_{S\rightarrow T}} \frac{k_a^S}{k_a}\right)$, one can easily evaluate a value of $k_Q/k_a^S$, which gives a measure for the efficiency of the added substances in deactivating $D^t$. The results are shown in Table III.

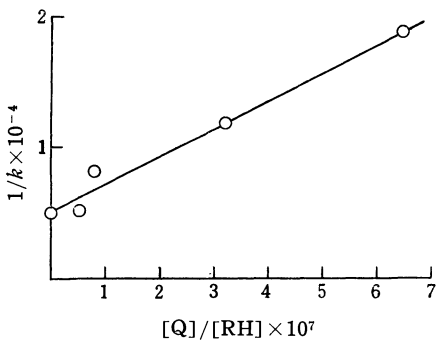

Fig. 6. Plot of $1/k$ against $[Q]/[RH]$ where Q is cyclooctatetraene.

TABLE III. THE KINETIC DATA FOR THE RETARDING SUBSTANCES

| Retarder | $k_Q/\varphi_{S\rightarrow T}\cdot k_a$ | $k_a^S/\varphi_{S\rightarrow T}\cdot k_a$ | $k_Q/k_a^S$ |
|---|---|---|---|
| Isopentane | $5.0\times10^3$ | $1.7\times10^3$ | 2.9 |
| *n*-Hexane | $4.4\times10^3$ | $2.4\times10^3$ | 1.9 |
| Benzene | $3.4\times10^4$ | $5.4\times10^3$ | 6.3 |
| COT | $2.0\times10^{10}$ | $5.5\times10^3$ | $3.7\times10^6$ |
| Water | | | 0.053[1] |

It is interesting that saturated hydrocarbons which are chemically inactive are rather better deactivators than water. The value for COT is enormously large, the result being consistent with that of Schenck[2]. It may be that the electronic excess energy can effectively be transferred to the vibrational energy of COT which has various modes of bending and torsion due to the nonplanarity of its structure.

**The Promoting Effect.** — Cyclohexene and *n*-hexene which promote the bleaching rate have a single double bond. These two substances also give scarcely any influence on the absorption spectrum and fluorescence intensity of eosine, so that they do not have much effect upon the rate of processes i and ii. Furthermore in view of their promoting effect, their action on the T-state of the dye is not thought to be an essentially deactivating one. At first sight, the promoting action might be attributed to the same kind of reaction between D and the added substance (P) as that between D and alcohol represented by iii. But if so, it is very curious that COT, which is exceedingly unsaturated, shows a quite opposite effect. Moreover, since much of the deactivating process would certainly occur along with the genuine reaction (dehydrogenation of P), the overall rate constant $k$ should be represented as follows:

$$k = \varphi_{S\rightarrow T} \frac{k_a[RH] + k_P[P]}{k_a^S[RH] + k_P^S[P]} \qquad (5)$$

where $k_P[P]$ refers to the rate of reaction leading to bleaching and $k_P^S[P]$ is the sum of $k_P[P]$ and that for the deactivating process. Eq. 5 never gives linearity between $k$ and $[P]$ since $k_P^S[P]$ most certainly can not be neglected in view of the rather large value of $k_P[P]$.

Thus, it seems that a plausible interpretation can never be given on the basis of the reaction scheme presented by Koizumi and Imamura[1].

Now, according to the unpublished results for the bleaching reaction of eosine in alcohol by the flash-technique which have been obtained in the authors' laboratory[3], there are two intermediates spectroscopically observed, other than $D^t$, and these have different durations though in the same order of magnitude (few millisec.).

As another intermediate besides semiquinone, the most probable one would be a certain kind of intermolecular complex between $D^t$ and RH, or alternatively, (DH·.....R·) trapped in the same cage. In either case the introduction of another

2) G. O. Schenck and K. Kinkel, *Naturwissenschaften*, 38, 355 (1951).
3) To be published in the near future.

intermediate of this kind modifies the reaction scheme in such a manner that process iii must now be divided into the following ones,

$$D^t + RH \rightarrow X \qquad (iii')$$

$$X \rightarrow D + RH \qquad (iii'')$$

$$X \rightarrow DH\cdot + R\cdot, \quad k_X \qquad (iii''')$$

where X represents either the complex between $D^t$ and RH, or DH· and R· exisitng in the same cage.

In view of a small quantum yield of photobleaching, a large part of X would perhaps decompose into D and RH (process iii'') resulting only in the dissipation of excess energy of $D^t$, while a small fraction of X would complete the bleaching reaction by step iii'''. It is of course undecided whether X is some kind of molecular complex or a transient state in which DH· and R· exist in the same cage, but the two alternatives give exactly the same kinetics.

Now, if one modifies the reaction scheme as above, one can interpret quite rationally the promoting action of the added substance. Thus, if the added substance P attacks X in such a manner that it detaches the R-part from the latter, producing a more stable radical PR· and leaving behind a metastable DH·, then the rate of bleaching would be increased. This type of attack may perhaps be so specific that it would not be accompanied with much of the deactivating process. The process can formally be written as follows:

$$X + P \rightarrow DH\cdot + RP\cdot \qquad (v)$$

Taking into account iii', iii'', iii''' and v instead of iii, one can give the expression for $k$ as follows:

$$k = \varphi_{S\rightarrow T}\varphi_{T\rightarrow X}\frac{k_X + k_P[P]}{k_X^S + k_P[P]} \qquad (6)$$

where $k_X^S$ is the sum of the rate constants for reaction iii'' and iii'''. If one assumes that the action of P on X consists mainly of reaction v and is not of such a nature as to promote reaction iii'' and moreover that $k_X^S \gg k_P$ holds as already discussed above, then Eq. 6 is approximately rewritten as

$$k = \varphi\frac{k_X + k_P[P]}{k_X^S} \quad (\varphi = \varphi_{S\rightarrow T}\varphi_{T\rightarrow X}) \qquad (7)$$

which explains the linear relationship between $k$ and [P] experimentally obtained. From the plot of $k$ against [P], one can evaluate the values of $k_X/k_P$, which are shown in Table IV.

Table IV. The kinetic data for the promoting substances

| Promotor | Inclination | Intersection | $k_P/k_X$ |
|---|---|---|---|
| Cyclohexene | $21.4\times10^{-4}$ | $2.15\times10^{-4}$ | 10.0 |
| *n*-Hexene-2 | $15.3\times10^{-4}$ | $2.50\times10^{-4}$ | 6.1 |

It is to be added that the same relation as Eq. 7 would be obtained, if P attacks $D^t$ in such a specific manner as to produce DH· far more rapidly than to dissipate the excess energy in vain. A relation similar to Eq. 4 would also be obtained for retarding substances if one assumes that X instead of $D^t$ is selectively decomposed by Q into D and RH·. But the assumption is highly improbable that the retarding substances and the promoting substances attack the same one molecular species in a quite different and peculiar fashion. A more natural picture would be that the two groups of the added substances act on different molecular species in a different way as described above. Of course, in order to make the above remark more definitely, it is necessary to study further about the chemical behavior of $D^t$, X and DH· toward many other substances and especially to use the flash technique.

## Summary

The effect of the addition of isopentane, *n*-hexane, benzene, cyclohexene, *n*-hexene and cyclooctatetraene was examined upon the rate of the reductive photobleaching of eosine in the evacuated alcoholic solution. It was found that the saturated hydrocarbons, benzene and COT retard the reaction more or less, COT being most prominent in its effect, while the hydrocarbons with a single double bond (cyclohexene and *n*-hexene) act, contrary to the authors' expectation, as the promotors of the bleaching. The retarding effect of the first group was interpreted to be due to the deactivation of the T-state of dye ion by the added substances, but the promoting action of the second group could not be accounted for rationally on the basis of the above scheme. To fit the present results, therefore, a modified scheme was newly proposed in which a certain kind of molecular complex between $D^t$ and RH is formed prior to DH··

# *Molecular Structure of Acrylonitrile by Electron Diffraction*

By Takahide SAITO and Takeshi UKAJI*

(Received July 20, 1959)

The shortening of a single bond between two multiple bonds has been studied in various cases[1], but not yet in the cases with the structure,

$$C{=}C{-}C{\equiv}N$$

The authors wish to report some results on acrylonitrile (Fig. 1) by the electron diffraction.

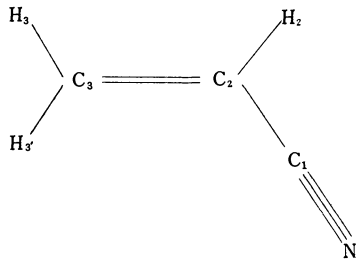

Fig. 1. Molecular scheme of acrylonitrile.

## Experimental

The apparatus of electron diffraction is the same as in the previous reports from the authors' laboratory[2], with the exception of the use of two camera lengths, 9.1 and 10.1 cm. The electron wavelength, about 0.055 Å, was calibrated by gold foil diffraction.

The sample is kindly supplied to the authors' by Professor S. Kambara, b. p.=78°C.

Measurements were carried out by the usual visual method.

## Procedure and Results

The experimental visual curve from eight photographs is shown in Fig. 2. The dotted line for $q>80$ means less accurate observation due to the obscurities of photographs and that for $q<10$ is an assumed line to help the calculation of the radial distribution curve.

The radial distribution curve has been calculated from the visual intensity curve according to the equation[3],

$$r\cdot D(r)=\sum_{q=1,2\cdots}^{q_{max}} I(q)\exp(-aq^2)\sin \pi/10\cdot qr$$

$$q=(4\pi/\lambda)\sin(\theta/2)$$

$$\exp(-aq^2{}_{max})=0.1$$

in which $\theta$ is the scattering angle, and $\lambda$ is the wavelength of the beam. The curve obtained shows the still remaining ghosts. However, it is convenient to assign each peak in this curve for the following trial and error method.

The first peak of 1.16 Å is attributed to the C≡N bond from the consideration of weight**. The second peak of 1.38 Å corresponds to the overlapped contribution of C=C and C—C bonds. The peaks at 2.12 and 3.46 Å correspond to the interatomic distances of nonbonded C···H and C···N, respectively.

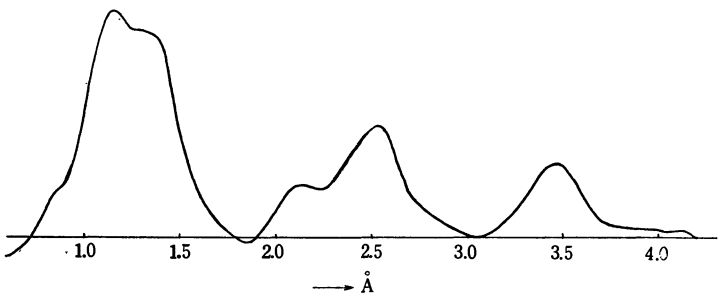

Fig. 2. Radial distribution curve.

The theoretical intensity curve for assumed models has been calculated by the use of the equation[3]

$$I(q)=\sum_{ij}(Z_iZ_j/r_{ij})\exp(-a_{ij}q^2)\sin \pi/10\cdot qr_{ij}$$

$$a_{ij}=(\pi^2/200)l_{ij}$$

where $r_{ij}$ is the distance between the $i$-th and $j$-th atom, $Z_i$ is the atomic number of $i$-th atom and $l_{ij}$ is the mean amplitude of $r_{ij}$.

The coefficient of thermal vibration, $a_{ij}$, is roughly estimated with reference to the calculated data [4-6]. The coefficients used

TABLE II. THE COMPARISONS WITH EACH MODEL

| Atomic pair | I | II | III | IV | V |
|---|---|---|---|---|---|
| C—C | 1.42 | 1.44 | 1.44 | 1.46 | 1.44 |
| C≡N | 1.16 | 1.16 | 1.16 | 1.16 | 1.16 |
| $C_1$···$C_3$ | 2.44 | 2.43 | 2.41 | 2.43 | 2.43 |
| $C_3$···N | 3.51 | 3.50 | 3.47 | 3.49 | 4.49 |
| $C_2$···N | 2.58 | 2.60 | 2.60 | 2.58 | 2.60 |
| Average of $q_{calcd.}/q_{obsd.}$ | 0.995 | 0.992 | 1.000 | 0.996 | 0.995 |
| Root mean deviation | 0.014 | 0.015 | 0.017 | 0.013 | 0.017 |

The length of atomic pair is given in Å unit.

are shown in Table I. The theoretical curve was calculated to cover the following ranges of parameters, $C_3{\equiv}N$ 1.16, $C_2{=}C_3$ 1.42~1.46, $C_1{\cdots}C_3$ 2.41~2.47 and $C_3{\cdots}N$ 3.46~3.53 Å. In the above calculations, $Z_H$ 1.25 and C—H 1.08 Å were used and each term of H···H was neglected. The theoretical curves, agreeing well with the visual intensity curve and having the values of parameters close to the interatomic distances obtained from the radial distribution curve, are shown in Fig. 2.

In Table II are shown the values of principal parameters in these models. Although these models are more appropriate rather than the others, the agreements with the visual curve are not sufficiently satisfactory. For example, there are considerable disagreements in the following aspects: (1) the relationships of intensity of max. 3 and 3', (2) the relative intensity of max. 7 and 7', (3) the location of min. 5 (the experimental has larger $q$ than all the theoreical), (4) the relationships of intensity of max. 6, 6' and 6''. Therefore, it is difficult to prefer a model to the other form. However, the following ranges for the parameters may be supported in reference to values of the similar molecules (Table III), C≡N 1.15~1.17, C=C 1.32~1.36, C—C 1.42~1.46 and $C_1{\cdots}C_3$ 2.41~2.44 Å. The difficulty in determining the best model may be the result of the uncertain observation of intensity, especially in the range of larger $q$ values.

However, it is probable from the considerations of the parameter charts that the molecule of acrylonitrile has the following interatomic distances:

| | |
|---|---|
| C≡N | 1.16±0.01 Å |
| C=C | 1.34±0.02 Å |
| $C_2{\cdots}C_3$ | 2.43±0.02 Å |
| C—C | 1.44±0.02 Å |

TABLE III. THE INTERATOMIC DISTANCES (Å UNIT) OF SIMILAR COMPOUNDS

# *Determination of Reducing Sugars by Means of Back Titration against Alkaline Copper Solution. I**

By Masahito TAKAHASHI

(Received May 23, 1959)

Since the determination by means of Fehling solution has become used so generally for sugar analysis, different chemists have devised, in consequence of its importance in both practice and research, so many modifications that there is probably no method in analytical chemistry which suffers more from variety of procedure. Numerous modifications have been described which differ in analytical details. Fehling solution is rather unstable, so efforts have been made to improve its stability, and to establish a simpler and more practical procedure.

The amount of copper which is reduced by various sugars has been found to vary according to the alkalinity, the temperature, the rate of ebullition, the time of heating, the type of tartrate, the amount of contact with air, etc. Among them the most important variables are the temperature, the time of heating, and the rate of ebullition. Consequently some methods have devised for heating because it is difficult to standardize the temperature and the rate of ebullition. The indirect heating is frequently employed as in the case of Main's pot method where the temperature is regulated by a boiling water bath and the reduction is carried out in a test tube provided with floats. But this is not a fine procedure, because it requires a complicated operation and demands skilfulness in analyst. Then, the results should be corrected according to the variation of variables rather than a strict standardization of the reacting condition is demanded. Blank titration with a standard sugar solution, which checks the variation of conditions and corrects the results, is most suitable for the present purpose.

Numerous procedures already devised for the determination of the quantity of reduced copper can briefly be divided into a partial reduction method and a total reduction method. In the former a certain volume of Fehling solution is brought into a reaction with a given amount of sugar which does not reduce all the copper, and the cuprous oxide produced is weighed directly or estimated by means of redox titration. The other is a method which, in principle, involves the determination of the volume of sugar solution required to reduce completely a measured volume of alkaline copper solution, the end point being indicated by a spot test or an internal indicator. This is indeed one of the earliest procedures for the determination of the reducing power. Soxhlet heated a known volume of Fehling solution to boiling in an open dish and added the sugar solution until the copper was completely reduced. No great accuracy was possible by this procedure, even in highly skilled hand. The degree of accuracy of this method was considerably increased by various devices, namely, by boiling the solution in a flask instead of an open dish, to diminish back-oxidation, and by using a suitable indicator. Lane and Eynon[1] found that the end point was internally indicated by the reduction of methylene blue to methylene white by minute excess of reducing sugar and determined the weight of each sugar required to reduce the copper completely. These weights, which varied with nature of sugar and with its concentration, constituted their table for analysis. This method, described as "the most convenient, most expeditious, and frequently the most accurate method"[2], has been adopted for industrial and scientific purposes, but seems still to be a complicated and time-consuming procedure with some disadvantages. For instance, it consumes a large volume of sugar solution, and is not available for the determination of a small quantity of sugar, etc.

In general, the total reduction method,

* Partly presented at the Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1957.

1) J. H. Lane and L. Eynon, *J. Soc. Chem. Ind. (London)*, **42**, 32T, 143T (1923); **44**, 150T (1925); **46**, 434T (1927).

2) F. J. Bates et al., "Polarimetry, Saccharimetry and the Sugars", U. S. Government Printing Office, Washington (1942), p. 185.

represented by Lane and Eynon's method, is simpler, more practical, and more accurate than the partial reduction method, represented by the gravimetric method and Bertrand's method. In view of this advantageous quality, the author has endeavored to improve the former procedure and to establish a more convenient method of procedure with a high accuracy on such a way as to confer the maximum possible simplicity of procedure and to eliminate the personal factor as far as possible. To this end a back titration method has been devised.

## Experimental

**Materials.**—The following substances were used for the present investigation. An anhydrous glucose was obtained by recrystallizing a commercial glucose (monohydrate, the Japanese Pharmacopoeia) from water and acetic acid. A pure commercial lactose was recrystallized from water. A pure commercial galactose was recrystallized from water and alcohol. Crystalline copper sulfate ($CuSO_4 \cdot 5H_2O$) of reagent grade was recrystallized from water. A 50% solution of sodium hydroxide (reagent grade) was prepared and allowed to stand until a precipitate of sodium carbonate appeared. By filtering it through asbestos a clear solution was obtained. Benzoic acid, Rochelle salt and methylene blue were all of reagent grade.

**Reagents.** — *I) Standard sugar solution.* — One gram of crystalline benzoic acid and 2.046 g. of crystalline glucose were dissolved in water and made up 1 l. with water.

*II) Copper solution.*—Sixty-six grams of caystalline copper sulfate was dissolved in water and made up to 1 l. with water.

*III) Alkaline solution.*—The calculated amount of sodium hydroxide solution containing 110 g. of sodium hydroxide and 345 g. of Rochelle salt were dissolved in water and made up to 1 l. with water.

*IV) Indicator.*—Half a gram of methylene blue was dissolved in 100 ml. of water.

**Procedure.** — In Soxhlet's method, Lane and Eynon's method and others, a measured volume of the boiling alkaline copper solution is titrated with a sugar solution, the end point being indicated by a spot test or an internal indicator, and the concentration of the sugar solution is estimated from the volume of the sugar solution required to reduce the alkaline copper solution completely. On the other hand, in this back titration method a boiling mixture of a measured volume of the alkaline copper solution and a measured volume of the sugar solution is back-titrated with the standard sugar solution, and the concentration of the sugar solution is estimated from the volume of the standard sugar solution required to reduce the mixture completely.

It is well known, for example, that if the sugar solution is added in portions 5 ml. and the liquid boiled for 10 sec. after each addition, the total volume required will not be exactly the same as if the whole of the sugar solution is added at once. Now in this method nearly the whole of the standard sugar solution is added at once and after boiling the rest quantity is added (normal titration). As in the Lane and Eynon's method, a preliminary titration system is adopted, by which the required volume of the standard sugar solution is found approximately in order that almost the whole of it may be added at one time simultaneously with heating. In the case of the blank titration the required volume is known approximately, so that a preliminary titration is unnecessary.

In a blank titration, a mixture of 20 ml. of water and 10 ml. of an alkaline copper solution is titrated with the standard sugar solution. In the normal titration, the volume of the standard sugar solution can be obtained, which is required to reduce a mixture of the alkaline copper solution (10 ml.) and 20 ml. of the sugar solution. The difference between the two quantities obtained thus represents the concentration of the sugar solution.

*a) Blank titration.*—Equal volumes of solutions II and III are mixed thoroughly. Ten milliliters of the mixed solution and 20 ml. of distilled water are measured into a 100~300 ml. flask and heated over an asbestos wiregauze with a 300~500 W. electric heater charged full voltage. About 23.5 ml. of the standard sugar solution delivered from a 25 ml. burette is added into the flask as soon as possible. For this purpose an automatic burette is very convenient, the outlet of which is connected by melting with a glass tube (about 10 cm.) bent twice at right angles so that the solution in the burette is not heated by the reaction mixture. After the liquid has begun to boil vigorously, it is kept in moderate ebullition by lowering the working voltage. After boiling for two minutes, 3 to 6 drops of the methylene blue indicator are added, and the standard sugar solution is added in small quantities, that is to say, several drops or less at a time, and after the commencement of decolorization, drop by drop. The liquid is boiled for about ten to fifteen seconds between successive addition, and the titration is continued until the color of the indicator is discharged. The titration is completed in about one minute, so that the reaction liquid is boiled altogether for 3 min. without interruption. The decolorization of the methylene blue is easily detected, since the blue color of copper ion has already vanished. The rate of heating is regulated carefully so as to make the precipitate as much as possible. The end point can be determined with accuracy of less than one drop of the standard sugar solution. At the end point the blue color of the methylene blue vanishes suddenly, and the faint purple tint is still observable. The methylene white is rapidly reoxidized by air, particularly at the high alkalinity of this reaction mixture. Hence it is essential that air is excluded during the titration.

This is accomplished by making an uninterrupted current of steam issue from the neck of the flask on which the analysis is performed.

So long as solutions II and III are mixed correctly, the titer of the blank titration is constant; so that the blank titration is unnecessary at each time of mixing. When the sample solution contains materials other than sugars to be determined, a blank titration should be made against the solution containing these materials.

*b*) *Preliminary titration.*—Ten milliliters of the mixed copper solution is boiled in a 100~300 ml. flask after adding 20 ml. of the sample sugar solution. Usually after ten seconds of ebullition the reduction of the copper solution is nearly completed, which can easily be seen from the disappearance of the blue color of cupric ion and the bright red color imparted to the boiling liquid by the suspended cuprous oxide. If it is judged that nearly all the copper has been reduced, boiling is continued for about one minute from the beginning of ebullition, 3 to 5 drops of the methylene blue indicator are added, and then the standard sugar solution is added in small quanties, that is to say, 0.2 ml. or less at a time at regular intervals, the liquid being allowed to boil, until the color of the indicator is discharged. When unreduced copper is still found to be there in large quantity after boiling a mixture of 20 ml. of the sample solution and the copper solution about ten seconds, 3 ml. of the standard sugar solution is added and the whole is allowed to boil for ten seconds and so on, until it is considered unsafe to add a further large increment of the standard sugar solution. Boiling is continued further thirty seconds, after which the indicator is added and the titration is completed by small additions of the standard sugar solution as already mentioned. The indicator should not be added until the end point is nearly reached.

When maximum accuracy is not required, a single preliminary titration gives satisfactory results; the error will, as a rule, not exceed 0.6 mg. per 20 ml. of the sample solution.

*c*) *Normal titration.*—Ten milliliters of the mixed copper solution and 20 ml. of a sample sugar solution are measured into a 100~300 ml. flask, and, as soon as the mixture is heated, almost the whole of the standard sugar solution is added, which required to reduce all the copper, so that if possible not more than 1 ml. is required later to complete the titration. The approximate volume of the standard sugar solution required is estimated by a preliminary titration. After the liquid has begun to boil, it is kept in moderate ebullition for 2 min., and then 3 to 6 drops of the methylene blue indicator are added, and the titration is then completed in 1 min.

## Results

The author has measured the volume of the standard sugar solution required to reduce a mixture of 10 ml. of the alkaline copper solution and 20 ml. of water (*blank titration*), and that of the standard sugar solution required to reduce a mixture of 10 ml. of the alkaline copper solution and 20 ml. of the solution of sugars of various concentrations (*normal titration*). The relationship among the weight ($W$) of sugar in mg. in 20 ml. of sugar solution, the volume ($B$) in ml. of the standard sugar solution required in the blank titration, and the volume ($m$) of the standard sugar solution in the normal titration, has been found to be;

$$W=2(B-m)tf$$

where $t$ is a correction term, and $f$ is a factor of the standard sugar solution.

For the purpose of calculating the weight of sugar from difference ($B-m$), a correction term $t$ has been introduced, which varies with the nature of the sugar and the term ($B-m$). The term $t$ is 1.000 over widely different concentrations, viz. from 1 to 48 mg. per 20 ml. in the case of glucose, but in case of lactose and galactose it varies with the difference ($B-m$), the values of which are shown in Table I.

In the titrations on which Table I is based, the volume of the standard sugar solution added to the reaction mixture after heating was about 0.3~0.5 ml. less than the total volume required, and during the last third minute of ebullition, this complementary quantity was added, two

drops at a time at intervals of about 10~15 sec. until the end point was reached.

Operating in this way consistent results have been attained with all the reducing sugars tested, viz. glucose, lactose and galactose. On the basis of these results Table I was prepared. Over the whole of these ranges it is possible to attain a higher degree of precision, and the consistent results may be obtained, the error being within 0.06 ml., namely, 0.12 mg. in the case of glucose.

In the case of the sugar solutions containing other materials whose influence can not be overlooked, blank titration was made against the mixture of 10 ml. of the alkaline copper solution and 20 ml. of a solutions containing all materials of the same concentrations except for reducing sugars to be determined.

Some examples of glucose in solutions containing 5 and 20 g. of sucrose per 100 ml. are shown in Table II. It is important that, in all cases which have been investigated, the correction term $t$ is not affected noticeably by contamination with other materials.

The experimental factor of the standard sugar solution should be 1.000, but a small deviation is inevitable according to the variations of the experimental conditions and personal differences in judging the end point. It is advisable to standardize the standard sugar solution, after its preparation, by titrating against a weighed pure glucose. If the deviation be large, adjustment of the standard sugar solution should be made so as to make the value of the factor approximately equal to one by adding glucose or water to the standard sugar solution.

On the other hand, it is possible to estimate the sugar content in a solution of unknown concentration. The quantity $2(B-m)tf$ gives the weight in mg. of the sugar in 20 ml. of the solution.

Some remarks should be made. Very stable and reproducible heating is possible by use of an electric heater. A reagent grade preparation of sodium hydroxide ordinally containing carbonate may be used, although the decolorization of methylene blue is somewhat slower than it is in the presence of carbonate free sodium hydroxide.

## Summary

A new volumetric method determining reducing sugars has been developed by titrating a boiling mixture of modified Fehling solution and sugar solution with a standard sugar solution. By the method the concentration of sugar solution can be determined rapidly with high degree of precision.

Errors caused by variables of analytical conditions automatically being corrected, the maximum degree of accuracy will be possible by this procedure even in an unskilled hand.

There are several advantages over Lane and Eynon's method and other methods; the method is applicable over a wide range of sugar concentrations, especialy dilute solution, and in addition the difficulty in changing or washing a burette for a new solution, etc., is eliminated.

The author wishes to express his sincere thanks to Professor Y. Tsuzuki of Tokyo College of Science for his kind advice, and to Professors S. Kusunoki and T. Kinugasa of Kobe University for their encouragement throughout this work.

# *Biochemical Studies on Pearl. VIII. Occurence of Calcite, Aragonite and Dolomite in Pearl and Shell*

By Shozo TANAKA, Hiroyuki HATANO* and Osamu ITASAKA**

(Received July 20, 1959)

Among many kinds of bivalved molluscs which are available in the pearl culture industry, *Pinctada martensii* (Dünker), the Japanese pearl oyster, is one of the most important species in Japan. In the previous papers of biochemical studies on pearl, physiological properties of the pearl oyster were reported to have a marked resemblance to the ordinary oyster[1,2] and the chemical mechanism of pearl formation was discussed from a view-point of comparative biochemisrty upon the calcification of invertebrata and vertebrata[3-5].

Several analytical results on the pearl and the shell materials of the pearl oyster have been reported[1-10], but few observations have been made on the nature of chemical constituents in the pearl and the shell.

In the present work, investigations have been made on the chemical compositions of the nacre of pearl, the nacreous portion of the shell or "mother-of-pearl", which forms an innermost layer of the shell, and the prismatic substance of an outer layer of the shell (Fig. 1). Furthermore, crystalline forms of calcium carbonate in the pearl and the shell were determined by the X-ray diffraction method. Also, a minute amount of magnesium was found in the shell and occurrence of dolomite was ascertained by a chemical method.

## Experimental

**Materials.**—Cultured pearls used in the following experiments were collected from three-year old Japanese pearl oysters, while shell samples were obtained from pearl oysters of two winters***.

The cultured pearls were separated into nacres and nuclei mechanically, the latter being put aside. By scraping off the outer layers with a grinding-wheel, a nacreous substance of the inner layers of shells was prepared. A prismatic substance of the outer layers was obtained mechanically from thin posterior shell margins. These materials were first crushed into pieces by means of a porcelain mortar and, then, pulverized after drying at room temperature for a few days.

Calcium carbonate crystals for the X-ray diffraction analysis were prepared from the pearls and the shell substances by immersing the pulverized materials in one per cent sodium hypochlorite solutions for a few hours to remove organic substances.

**Methods.**—The chemical compositions of the

pearl and the shell materials were determined by the methods reported in the previous papers[1,2]; moisture was determined by measuring the decrease in weight on drying at 105°C for about 24 hr. until the weight came to a definite constant; total nitrogen was determined by a semi-micro-Kjeldahl's technique; total ashes were determined by igniting any sample to a constant weight at approximately 700°C and making a correction for the ignition loss of carbonate. Inorganic constituents in the ashes were determined as follows: phosphate as ammonium phosphomolybdate, calcium as calcium oxalate, sulfate as barium sulfate, and magnesium as ammonium magnesium phosphate after being separated from calcium, respectively; the carbonate content was calculated from the amount of carbon dioxide determined by the Conway's microdiffusion method[11].

Conchiolin, a screloprotein contained in the pearl and the shell, was estimated from the amount of residue remaining after the inorganic constituents were dissolved in dilute hydrochloric acid[12].

X-ray diffraction patterns of crystalline calcium carbonate in the pearl and the shell were recorded by the Norelco's X-ray diffractometer and were compared with those of the standard crystals of calcite and aragonite.

The state of chemical combination of a minute amount of magnesium which was found in the pearl as well as the shell was determined by the chemical method established by Kitano[13]. The principle of his method is as follows. When a small amount of magnesium is contained in calcareous shells, it is expected to be present in one of the only two possible forms, i.e. dolomite $CaMg(CO_3)_2$ and a solid solution of calcite and dolomite. Now, when carbon dioxide gas is passed into mixed suspensions of calcium

a) Into a suspension containing 2.5 g. of magnesium preparation in 200 ml. of distilled water, purified carbon dioxide was passed for 25 min. After being allowed to stand for 10 min., the suspension was filtered through a sheet of Toyo Roshi No. 6 filter paper. Total quantities of calcium and magnesium ions in the filtrate were determined by the volumetric method using EDTA, while the amount of calcium ion was estimated as calcium oxalate, and then the amount of magnesium ion was calculated from these two values, or was determined directly by the volumetric method using oxim reagents.

b) Extra pure reagents of calcite and aragonite prepared by Y. Kitano were used in this experiment.

c) As a standard preparation of a solid solution of calcite and aragonite, were used shells of four kinds of sea urchins, in which the magnesium had been found to be present in the form of a solid solution by X-ray diffraction techniques.

d) A dolomite preparation found at Kuzuo, Tochigi-ken, was used. The analytical results are as follows: CaO, 33.80; MgO, 19.37; clay, 0.22%.

e) [g. of $Ca^{2+}(Mg^{2+})$ dissolved into 200 ml. of a suspension] × 100/[g. of $Ca^{2+}(Mg^{2+})$ in 2.5 g. of a suspension].

carbonate with dolomite or into those of calcium carbonate with a solid solution of calcite and dolomite, the quantities of magnesium dissolved into the suspensions are not the same for two cases. The data obtained by Kitano[13] are given in Table I. On the basis of these results, therefore, the state of chemical combination of magnesium present in calcareous shells can be determined by measuring the quantity of magnesium dissolved in water saturated with carbon dioxide.

## Results and Discussion

**Chemical Composition.** — The chemical compositions of the pearl and the shell of the pearl oyster are shown in Table II, which indicates that the pearl as well as the shell contain about ninety per cent of calcium carbonate and a few per cent of conchiolin. It seems to be noticeably

characteristic that, contrary to various calcareous tissues of vertebrata, there are little or only minute amounts of phosphate and sulfate in the pearl and the shell of the pearl oyster. Less content of conchiolin and a larger amount of calcium carbonate in the nacre than in the prismatic substance are observed. Scant amounts of pigments are present in the pearl and the nacreous oyster, while plenty of coloring substances can be found in prismatic substances[14]. Compared with the case of the nacre, relatively large amounts of magnesium are contained in the prismatic layer of the shell.

The curves shown in Fig. 2 indicate the X-ray diffraction patterns, recorded by

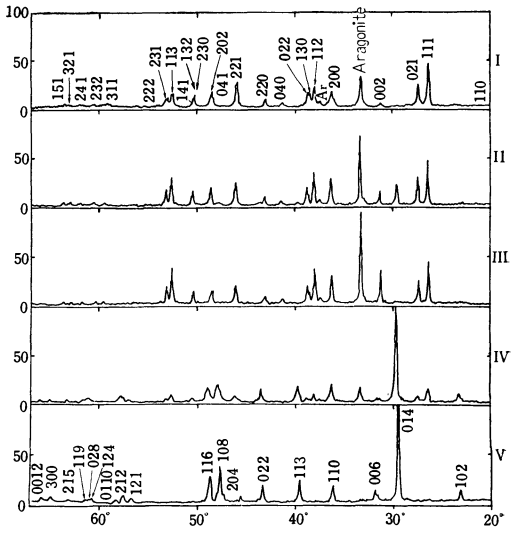

Fig. 2. X-ray diffraction patterns of calcium carbonate crystals in the nacre of pearl and in the shell material of the pearl oyster, *Pinctada martensii*. Norelco's apparatus****, of crystalline preparations of calcium carbonate from the pearl and shell materials. The crystals of calcium carbonate existing in the nacre of pearl and in the nacreous layer of shell were identified as aragonite crystals of a rhombohedral lattice, and those in the prismatic layer as calcite crystals of a rhombic lattice.

Calcite is known to form the most stable lattice of calcium carbonate while aragonite is less stable under usual crystallographical conditions. For aragonite crystal to be produced, therefore, certain special conditions should be given such as higher temperature, higher pH value of surrounding media, or a larger growing rate of crystals due to sudden supply of materials[15,16]. In connection with these requirements, it may be considered that the presence of relatively large amounts of magnesium ion is favorable to the formation of aragonite crystals.

Magnesium preparations prepared from the pearl and the shell were treated by the same procedure and the results obtained

are presented in Table III. Comparing these results with the data in Table I, it has been determined that magnesium in the nacre of pearls and in the nacreous layer of shells exists as dolomite and that in the prismatic layer as a solid solution of calcite and dolomite.

Several experiments have been carried out on the formation of calcareous skeletons in marine organisms and it is demonstrated that the temperature is one of the most effective factors on differentiation of the composition of calciferous skeleton in some marine invertebrates[17,18]. Any other possible factors may be expected to alter the modification and the chemical composition of a crystal.

According to the experimental data in Table III, the fact that magnesium carbonate is difficult to crystallize in a rhombic lattice owing to a geometrical correlation of constituent atoms, seems to have some relations with the mode of crystallization of calcium carbonate in the pearl oyster.

## Summary

The chemical compositions of the pearl and the shell of the Japanese pearl oyster were investigated from a crystallographical and biochemical point of view.

By the X-ray diffraction analysis, crystals of calcium carbonate in the nacre of pearl and in the nacreous layer of shell were determined to be aragonite, while those in the prismatic layer were shown to be calcite.

The state of chemical combination of minute amounts of magnesium present in the pearl and the shell materials was examined by a chemical method. In the nacreous substances, magnesium is present as dolomite, while in the prismatic material it exists as a solid solution of calcite and dolomite.

The state of crystals of calcium carbonate and magnesium carbonate occurring in the pearl oyster has been discussed with respect to the formation of the pearl and the shell of the pearl oyster.

The authors wish to express their gratitude to Dr. Y. Kitano, Nagoya University, Nagoya, for his kind permission to quote his unpublished data in Table I and also for his advice which was given throughout the course of this research.

# *Ionic Character and Hybridization in the Hydrogen Cyanide Molecule*

By Yoshifumi KATO*, Utaro FURUKANE and Haruo TAKEYAMA

(Received July 20, 1959)

It is well known that the nuclear quadrupole coupling constant $eQq$ is intimately related to the electronic structure near the nucleus of a molecule. Townes and Dailey[1] have explained especially the ionic character and the hybridization of an atom from the analysis of the experimental values of the nuclear quadrupole constants. They have considered that the existence of a field gradient $q$ is attributable to unbalanced electrons, i.e. $p$ or $d$ electrons in the valence shell.

Schatz has studied the ionic character and the hybridization of chlorine in discussing the chlorine, hydrogen chloride and methyl chloride molecules[2], using the experimental values of the dipole moment besides the quadrupole coupling constant, and has stressed the importance of including the overlap integral for the estimation of the quadrupole coupling constant. However, his calculations of the field gradient are essentially based on the theory by Townes and Dailey[1]. Namely, he assumed the total quadrupole coupling constant dependent upon only the $3p$ and $3d$ electrons of chlorine and ignored the effects of other electrons and nuclei in the molecule.

In this paper, the ionic character and the $s$ character of the nitrogen atom in a hydrogen cyanide molecule have been investigated by means of the theoretical evaluation of the dipole moment and the quadrupole coupling constant taking into account the effects of all the electrons and nuclei in a hydrogen cyanide molecule.

## Calculation Method

**Basic Wave Function.** — The hydrogen cyanide molecule is a linear molecule having an NC bond distance equal to 1.156 Å and a CH bond distance equal to 1.1064 Å as determined by microwave measurements[3]. The hydrogen cyanide molecule is taken to lie along the $Z$ axis with its nitrogen atom at the origin. The total wave function used is the following valence bond function including an ionic term ($N^-=C^+$), that is,

$$\Psi_T = A\left[\Psi_{cov} + \lambda_1 \Psi_{\sigma ion} + \lambda_2(\Psi_{\pi x ion} + \Psi_{\pi y ion})\right] \quad (1)$$

Where $A$ is the normalization factor and four state functions appearing in Eq. 1 are taken as simple products of the following electron pair bond functions with the Heitler-London type:

$$\left.\begin{aligned}
\Psi_{cov} &= (NC:\sigma)^2(CH:\sigma)^2(N_2:\sigma)^2 \\
&\quad \times (NC:\pi_x)^2(NC:\pi_y)^2 \\
\Psi_{\sigma ion} &= (N_1:\sigma)^2(CH:\sigma)^2(N_2:\sigma)^2 \\
&\quad \times (NC:\pi_x)^2(NC:\pi_y)^2 \\
\Psi_{\pi x ion} &= (NC:\sigma)^2(CH:\sigma)^2(N_2:\sigma)^2 \\
&\quad \times (N:\pi_x)^2(NC:\pi_y)^2 \\
\Psi_{\pi y ion} &= (NC:\sigma)^2(CH:\sigma)^2(N_2:\sigma)^2 \\
&\quad \times (NC:\pi_x)^2(N:\pi_y)^2
\end{aligned}\right\} \quad (2)$$

and

$$\left.\begin{aligned}
(NC:\sigma)^2 &= A_1[n_1(i)c_2(j) + c_2(i)n_1(j)] \\
(CH:\sigma)^2 &= A_2[c_1(i)h(j) + h(i)c_1(j)] \\
(NC:\pi_x)^2 &= A_3[n_{\pi x}(i)c_{\pi x}(j) \\
&\quad + c_{\pi x}(i)n_{\pi x}(j)] \\
(N:\pi_x)^2 &= n_{\pi x}(i)n_{\pi x}(j) \\
(N_1:\sigma)^2 &= n_1(i)n_1(j)
\end{aligned}\right\} \quad (3)$$

$(NC:\pi_y)^2$, $(N:\pi_y)^2$ and $(N_2:\sigma)^2$ are taken with the analogous definitions to $(NC:\pi_x)^2$, $(N:\pi_x)^2$ and $(N_1:\sigma)^2$, respectively. Therefore, in the wave function used, the higher order permutation of the electrons is neglected; that is, the orthogonarity among the electron pair bonds is assumed. The coefficients $A_1$, $A_2$ and $A_3$ of the electron pair bond functions are easily shown to be

* Present address: Osaka Municipal Technical Research Institute, Kita-ku, Osaka.

3) J. W. Simmon, W. E. Anderson and W. Gordy, *Phys. Rev.*, **77**, 77 (1950).

$$\left.\begin{aligned} A_1&=[2(1+S_{n_1c_2}{}^2)]^{-1/2}\\ A_2&=[2(1+S_{c_1h}{}^2)]^{-1/2}\\ A_3&=[2(1+S_{n_\pi c_\pi}{}^2)]^{-1/2}\\ S_{n_1c_2}&=\int n_1c_2\mathrm{d}v \qquad Sc_1h=\int c_1h\mathrm{d}v\\ S_{n_\pi c_\pi}&=\int n_\pi c_\pi \mathrm{d}v \end{aligned}\right\} \quad (4)$$

Futhermore $h$, $c_{\pi x}$, $c_{\pi y}$, $n_{\pi x}$ and $n_{\pi y}$ are atomic orbitals (AO), and $n_1$, $n_2$, $c_1$ and $c_2$ are the following $s-p$ hybridized orbitals:

$$\left.\begin{aligned} n_1&=\alpha^{1/2}(N:2s)+(1-\alpha)^{1/2}(N:2pz)\\ n_2&=(1-\alpha)^{1/2}(N:2s)-\alpha^{1/2}(N:2pz)\\ c_1&=2^{-1/2}[(C:2s)+(C:2pz)]\\ c_2&=2^{-1/2}[(C:2s)-(C:2pz)] \end{aligned}\right\} \quad (5)$$

All the AO's except the $2p$ orbitals of nitrogen are the Slater orbitals[4] (assumed effective nuclear charge $\delta_h=1.17$, $\delta_c=1.625$ and $\delta_n=1.95$). The $2p$ orbitals of nitrogen have a great effect on the field gradient at the nitrogen nucleus. Then, the following analytic function derived from the Hartree-Fock field calculation of the ground state $^4S$ of the nitrogen atom[5] is used for its radial function instead of the Slater orbital,

$$R_{2p}=r[1.809\exp(-1.387r)+6.620\exp(-2.950r)] \quad (6)$$

**Dipole Moment.**—The experimental value of the dipole moment of hydrogen cyanide has been known to be 3.00 D[3] and also it is given by the expression

$$\mu_T=e(\sum_{i=1}^{2} r_i-\sum_{j=1}^{10}\overline{Z}_j) \quad (7)$$

$$\sum_{i=1}^{2} r_i=6.7440\ \text{Å} \quad \overline{Z}_j=\int|\Psi_T|^2Z_j\mathrm{d}v \quad (8)$$

Where $e$ is the protonic charge ($4.80288\times10^{-10}$ esu), the first and the second term in Eq. 7 are, respectively, the contributions of the nuclei and the electrons. When the latter are calculated by the wave function given in Eq. 1, the expression is easily shown to be

$$\sum_{j=1}^{10} Z_j=M_{cov}+M_{\sigma ion}+M_{\pi ion}+M_{trans} \quad (9)$$

where

$$\left.\begin{aligned} M_{cov}&=2[M(NC:\sigma)+M(CH:\sigma)+2M(NC:\pi)+M_{n_2n_2}]\\ M_{\sigma ion}&=2\lambda_1{}^2[M(CH:\sigma)+2M(NC:\pi)]\\ M_{\pi ion}&=4\lambda_2{}^2[M(NC:\sigma)+M(CH:\sigma)+M(NC:\pi)+M_{n_2n_2}]\\ M_{trans}&=4\lambda_1A_1[M_{n_1c_2}+2S_{n_1c_2}\{M(CH:\sigma)+2M(NC:\pi)+1/2M_{n_2n_2}\}]\\ &+8\lambda_2A_3[M_{n_\pi c_\pi}+2S_{n_\pi c_\pi}\{M(NC:\sigma)+M(CH:\sigma)+M(NC:\pi)+M_{n_2n_2}\}]\\ &+16\lambda_1\lambda_2A_1A_3[S_{n_\pi c_\pi}M_{n_1c_2}+S_{n_1c_2}M_{n_\pi c_\pi}+2S_{n_1c_2}S_{n_\pi c_\pi}\times\{M(CH:\sigma)+M(NC:\pi)+1/2M_{n_2n_2}\}] \end{aligned}\right\} \quad (10)$$

and the following abbreviations are adopted:

$$\left.\begin{aligned} M(NC:\sigma)&=A_1{}^2(M_{n_1n_1}+M_{c_2c_2}+2S_{n_1c_2}M_{n_1c_2})\\ M(CH:\sigma)&=A_2{}^2(M_{c_1c_1}+M_{hh}+2S_{c_1h}M_{c_1h})\\ M(NC:\pi)&=A_3{}^2(M_{c_\pi c_\pi}+2S_{n_\pi c_\pi}M_{n_\pi c_\pi}) \end{aligned}\right\} \quad (11)$$

Also the normalization factor $A$ is shown to be

$$A=(1+\lambda_1{}^2+2\lambda_2{}^2+4A_1S_{n_1c_2}\lambda_1+8A_3S_{n_\pi c_\pi}\lambda_2+16A_1A_3S_{n_1c_2}S_{n_\pi c_\pi}\lambda_1\lambda_2)^{-1/2} \quad (12)$$

The necessary integrals of the dipole moment matrices: $M_{ab}=\int\chi_aZ\chi_b\mathrm{d}v$ and the overlap integrals: $S_{ab}=\int\chi_a\chi_b\mathrm{d}v$ are given to Table I. These values are obtained by the ordinary method[6].

**Quadrupole Coupling Constant.**—The experimental value of the nuclear quadrupole coupling constant has been known from the microwave datum to be $-4.58$ Mc.[3] On the other hand, the quadrupole coupling constant is shown to have the following expression:

$$eQq_T=eQ(q_n+q_{el}) \quad (13)$$

$$q_n=0.79295e\ e\ \text{a.u.}$$

$$q_{el}=-e\int|\Psi_T|^2(3\cos^2\theta_z-1)/r^3\mathrm{d}v \quad (14)$$

Where $q_T$ is the average value of $(\partial^2V/\partial Z^2)_{z=0}$, $V$ being all the electrostatic potentials and $Q$ the nuclear quadrupole moment of nitrogen ($=2\times10^{-26}$ cm$^2$)[1]. In Eq. 13, the

TABLE I. VALUES OF MOLECULAR INTEGRALS:

$$S_{ab}=\int \chi_a \chi_b \mathrm{d}v, \quad M_{ab}=\int \chi_a Z \chi_b \mathrm{d}v$$

(in Angstrom as unit)

| | | | |
|---|---|---|---|
| $S_{c_sh}$ | 0.50876 | $M_{c_sh}$ | 0.012501 |
| $S_{c_\sigma h}$ | 0.49357 | $M_{c_\sigma h}$ | 0.16891 |
| $S_{n_sc_s}$ | 0.47011 | $M_{n_sc_s}$ | −0.040613 |
| $S_{n_sc_\sigma}$ | −0.49979 | $M_{n_sc_\sigma}$ | 0.18131 |
| $S_{n_\sigma c_s}$ | 0.39765 | $M_{n_\sigma c_s}$ | 0.13353 |
| $S_{n_\sigma c_\sigma}$ | −0.30254 | $M_{n_\sigma c_\sigma}$ | −0.026792 |
| $S_{n_\pi c_\pi}$ | 0.29880 | $M_{n_\pi c_\pi}$ | −0.020225 |
| | | $M_{c_sc_\sigma}$ | 0.47003 |
| | | $M_{n_\sigma n_s}$ | 0.39169 |

The following abbreviated notations for AO's are used; $h=(H:1s)$, $c_s=(C:2s)$, $c_\sigma=(C:2pz)$, $c_\pi=(C:2px$ or $2py)$, $n_s=(N:2s)$, $n_\sigma=(N:2pz)$ and $n_\pi=(N:2px$ or $2py)$. The one-center and the two-center integrals are respectively evaluated with the nucleus in question and the center of internuclear distance as the origin.

first and the second term on the right are, respectively, the contributions of the nuclei except the nitrogen nucleus and the electrons to the field gradient $q_T$. $q_{el}$ is calculated by Eq. 1 as follows:

$$\begin{aligned}
q_{el}=&2[q(NC:\sigma)+q(CH:\sigma)\\
&+2q(NC:\pi)+q_{n_2n_2}]\\
&+2\lambda_1^2[q(CH:\sigma)+2q(NC:\pi)+2q_{n_1n_1}]\\
&+4\lambda_2^2[q(NC:\sigma)+q(CH:\sigma)+q(NC:\pi)\\
&+q_{n_2n_2}+q_{n_\pi n_\pi}]\\
&+4A_1\lambda_1[q_{n_1c_2}+2S_{n_1c_2}\{q(CH:\sigma)\\
&+2q_{n_\pi c_\pi}+3/2\,q_{n_1n_1}\}]\\
&+8A_3\lambda_2[q_{n_\pi c_\pi}+2S_{n_\pi c_\pi}\{q(NC:\sigma)\\
&+q(CH:\sigma)+q_{n_2n_2}+q_{n_\pi c_\pi}+1/2\,q_{n_\pi n_\pi}\}]\\
&+16A_1A_3\lambda_1\lambda_2[S_{n_\pi c_\pi}q_{n_1c_2}+S_{n_1c_2}q_{n_\pi c_\pi}\\
&+2S_{n_1c_2}S_{n_\pi c_\pi}\{q(CH:\sigma)\\
&+q(NC:\pi)+3/2\,q_{n_1n_1}+1/2\,q_{n_\pi n_\pi}\}] \qquad (15)
\end{aligned}$$

Here the following abbreviations are adopted:

$$\left.\begin{aligned}
q(NC:\sigma)&=A_1^2(q_{n_1n_1}+q_{c_2c_2}\\
&\quad+2S_{n_1c_2}q_{n_1c_1})\\
q(CH:\sigma)&=A_2^2(q_{c_1c_1}+q_{hh}+2S_{c_1h}q_{c_1h})\\
q(NC:\pi)&=A_3^2(q_{n_\pi n_\pi}+q_{c_\pi c_\pi}\\
&\quad+2S_{n_\pi c_\pi}q_{n_\pi c_\pi})
\end{aligned}\right\} \qquad (16)$$

All $q_{ab}=-eq_{ab}'=-e\int \chi_a(3\cos^2\theta_z-1)/r^3\chi_b\mathrm{d}v$ are calculated by using the methods of Barnett and Coulson[7]. These values are given in Table II.

TABLE II. VALUES OF FIELD GRADIENT INTEGRALS:

$$q_{ab}'=\int \chi_a(3\cos^2\theta_z-1)/r^3\chi_b\mathrm{d}v \text{ (in atomic unit)}$$

| | | | |
|---|---|---|---|
| $q_{n_\sigma n_\sigma}'$ | 2.36606 | $q_{c_sc_s}'$ | 0.098460 |
| $q_{n_\pi n_\pi}'$ | −1.18303 | $q_{c_sc_\sigma}'$ | −0.048937 |
| $q_{n_sc_s}'$ | 0.030116 | $q_{c_\sigma c_\sigma}'$ | 0.133908 |
| $q_{n_sc_\sigma}'$ | −0.045963 | $q_{c_\pi c_\pi}'$ | 0.080736 |
| $q_{n_\sigma c_s}'$ | 0.102260 | $q_{hh}'$ | 0.011326 |
| $q_{n_\sigma c_\sigma}'$ | −0.160130 | $q_{c_sh}'$ | 0.027928 |
| $q_{n_\pi c_\pi}'$ | −0.012108 | $q_{c_\sigma h}'$ | 0.035842 |

The three-center integrals $q_{c_sh}'$ and $q_{c_\sigma h}'$ are evaluated by Ruedenberg-Mulliken's approximation[8];

$$\int \chi_a 1/r_c^3 \chi_b \mathrm{d}v \approx 1/2\, S_{ab}\left(\int |\chi_a|^2 1/r_c^3 \mathrm{d}v + \int |\chi_b|^2 1/r_c^3 \mathrm{d}v\right)$$

## Results and Discussion

The parameters to be determined are the ionic characters $\lambda_1$, $\lambda_2$ and the $s$—$p$ hybridization of nitrogen $\alpha$. Now, in use of Eqs. 7 and 13, the relation of $\lambda_1$ and $\lambda_2$

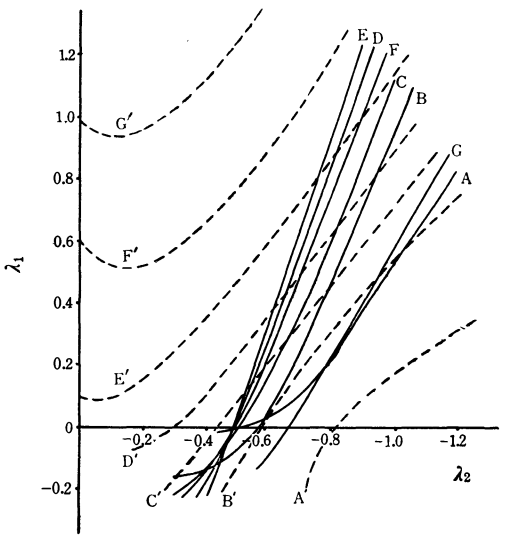

Fig. 1. The relationship between $\lambda_1$ and $\lambda_2$, being chosen in all cases to give the experimental values. $\alpha$ is taken as a parameter. The full and dotted lines are respectively the curves of the dipole moment and the quadrupole coupling constant.

| G: | $\alpha=0.8$ | G': | $\alpha=0.60$ |

7) M. P. Barnett and C. A. Coulson, *Trans. Roy. Soc. (London)*, **243**, 221 (1951).

8) R. S. Mulliken, *J. chim. phys.*, **46**, 497 (1949); K. Ruedenberg, *J. Chem. Phys.*, **19**, 1433 (1951).

which are taken to coincide with the experimental values is shown in Fig. 1, in which the hybridization $\alpha$ is taken as a parameter. From Fig. 1, it is seen that the dipole moment is not much affected by the *s* character between $\alpha=0.3$ and 0.7, but it depends on the ionicity as a considerable extent. This will explain the well-known fact that there is a possibility to take up the ionic character as a measure of the dipole moment[9]. On the other hand, the *eQq* curves are intensely dependent upon the *s* character, too. The $\alpha$, $\lambda_1$ and $\lambda_2$ values are not determined simultaneously, but it will be clear from Fig. 1 that the region of allowed $\alpha$ value is between about 0.3 and 0.5. Now, it is possible to calculate the NC bond moment under the same scheme as above. The NC bond moments for the reasonable set of $\alpha$, $\lambda_1$ and $\lambda_2$ obtained from Fig. 1 are as follows:

| $\alpha$ | $\lambda_1$ | $\lambda_2$ | NC bond moment |
|---|---|---|---|
| 0.50 | 1.81 | −1.16 | 2.57 D |
| 0.45 | 1.04 | −0.94 | 3.38 D |
| 0.40 | 0.61 | −0.80 | 1.61 D |
| 0.35 | 0.35 | −0.72 | 1.59 D |
| 0.30 | 0.04 | −0.60 | 1.42 D |

The NC bond moment has been estimated to be about 3.5 D by Smyth[10]. If his estimation is correct, a reasonable set of three parameters would be taken to be $\alpha=0.45$, $\lambda_1=1.04$ and $\lambda_2=-0.94$. Then, the experimental value of total molecular dipole moment of the hydrogen cyanide molecule 3.0 D can be explained to be 3.4 D ($N^-C^+$ bond moment) plus −0.4 D ($C^+H^-$ bond moment). The value −0.4 D for the $C^+H^-$ bond moment may be acceptable taking into account the inclusion of the atomic dipole term by Coulson[11].

From the *eQq* data, Townes and Dailey[1] and separately Dailey[12] have estimated the structure of HCN as follows:

| Structure | | Assumed *s* character | Assumed *eQq* per *p* electron** | |
|---|---|---|---|---|
| Covalent | Ionic | | | |
| 90% | 10% | 25% | −24 Mc. | Townes & |
| or 90% | 10% | 50% | −10 Mc. | Dailey |
| 90% | 10% | 45% | — | Dailey |

In both estimates, obviously some arbitrariness exists in the determination of the parameters because of several having been obtained from only one experiment value. On the other hand, Pauling[13] has presumed that the ionicity of the NC bond would probably have about 57% from the experimental values of the dipole moment of alkyl cyanides. The relative weights of structures are expressed in the following two ways; the one is due to the definition that the weights of the covalent and two ionic parts are given in the ratio $1:\lambda_1^2:2\lambda_2^2$ by Coulson[14] (I), and the other includes a transitional structure as well as covalent and ionic by Syrkin and Dyatkina[15] (II). Then, the following results are obtained from the present calculation:

| Structure | | Weight of structure, % By I | By II |
|---|---|---|---|
| Covalent | (A) | 26.0 | 10.2 |
| $\sigma$ ionic | (B) | 28.1 | 11.2 |
| $\pi_x$ & $\pi_y$ ionic | (C) | 45.9 | 18.1 |
| Transitional | (A)—(B) | | 21.3 |
| 〃 | (A)—(C) | | 19.3 |
| 〃 | (B)—(C) | | 20.0 |

Following the definition by Coulson, the present result with 74% as the ionic structure seems rather to support Pauling's conclusion. Here it is interesting to note that in a triple bond NC, each structure with the $\sigma$ or $\pi$ polarized bond has nearly equal weight, notwithstanding the fact that $\sigma$ bond has larger overlap (~0.7) and, on the other hand, $\pi$ bond smaller overlap (~0.3). However, it is probably impossible in the present calculation to state anything about the relationship between the degree of the overlap of each bond in the multiple bond and the polarization of the bond or the mobilities of electron in bond.

Fig. 2 shows the curves of the quadrupole coupling constants calculated, taking into account only *p* electrons of nitrogen and all the charges for the field gradient at the nitrogen nucleus with $\alpha=0.45$. Now, being taken to fix $\lambda_1$ and $\lambda_2$ values, the *eQq* values taking into account the contribution of all the charges are always larger than ones for only *p* electrons. This difference probably depends upon whether or not the charge distribution in the overlap

D & D': $\lambda_2 = -1.1$

region is taken into account in evaluating the field gradient. Gordy[16] has argued that the overlap effects should be ignored and has pointed out the merits of his simple relation between the ionicity and quadrupole coupling constant in which the $s$ character is neglected entirely. Certainly the field gradient is proportional to $1/r^3$, but at the same time to the charge density. Therefore, it should be naturally required for the evaluation of the nuclear quadrupole coupling constant to take into account not only the redistribution of the charge near the nucleus due to the formation of the chemical bond, but also the distribution of the charge in bonding region because of its larger density.

In this point, the present results will support Schatz's calculation of $eQq$ including the overlap effects.

# *Spectrophotometric Determination of Nitrous Acid with Disodium 1-(4'-Aminobenzeneazo)-amino-8-hydroxy-naphthalene-2', 6-disulfonate*

By Yukiteru KATSUBE and John H. YOE

(Received July 27, 1959)

Colorimetric methods in general use for a small quantity of nitrous acid are based on the formation of intensely colored azo dyes. Nitrous acid reacts with primary aromatic amines in acid solution to form diazonium salts, which react with a second molecule of the amine to produce colored cations of an aminoazo compound. Although the intense color of the azo dyestuffs formed in this way is available for the determination of nitrous acid, the coupling reagent used has an important influence on the determination.

The best amine that has been used for the determination of nitrous acid is sulfanilic acid (*p*-anilinesulfonic acid), with subsequent coupling of the resulting diazonium compound with $\alpha$-naphthylamine to give the red dyestuff *p*-benzene sulfonic acid-azo-$\alpha$-naphthylamine[1-6].

This paper describes a new method for the determination of trace quantities of nitrous acid based on the formation of a colored compound with disodium 1-(4′-aminobenzeneazo)-2-amino-8-hydroxy-naphthalene-2′, 6-disulfonate.

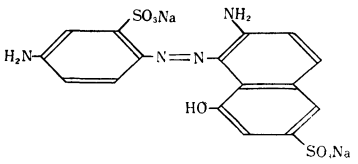

Fig. 1. Disodium 1-(4′-aminobenzeneazo)-2-amino-8-hydroxy-naphthalene-2′, 6-disulfonate.

## Experimental

**Apparatus and Reagents.** — *Spectrophotometer.* — A Shimazdu Spectrophotometer with matched 1 cm. glass cells, was used.

*Standard solution of nitrous acid.* — The standard solution of nitrous acid was prepared according to Treadwell[4]. His instructions are as follows. Add silver nitrate to a concentrated solution of commercial potassium nitrite, filter off the precipitated silver nitrite and wash it several times with cold distilled water. To obtain pure silver nitrite, dissolve the precipitate in as little distilled water as possible and cool quickly. Drain off the mother liquor through a funnel provided with a platinum cone using gentle suction. Wash the silver nitrite on the funnel with a small volume of cold distilled water. Place the washed silver nitrite in a calcium chloride desiccator and allow to dry in the dark. Dissolve 1.5388 g. of the dried silver nitrite in a liter volumetric flask with hot distilled water and add 0.8 g. of pure sodium chloride to convert the silver nitrite into silver chloride and sodium nitrite. After cooling, make the solution up to volume with distilled water and allow the precipitate to settle. Pipet 10 ml. of the clear solution into a second liter-volumetric flask, make up to the mark with distilled water and thoroughly mix. One milliliter of this solution contains 4.7 mg. of nitrous acid.

*Reagent solution.* — Prepare the reagent solution by dissolving disodium 1-(4′-aminobenzeneazo)-2-amino-8-hydroxy-naphthalene-2′, 6-disulfonate in distilled water to give a 0.05% solution. (The reagent may be obtained from the LaMotte Chemical Products Co., Chestertown, Maryland, U. S. A.)

*0.4% Ethylenediaminetetraacetic acid (disodium salt) solution.*

*6 N Hydrochloric acid.*

**Procedure.** — Transfer 20 ml. of EDTA solution to a 25 ml. volumetric flask and add 1 ml. of the sample solution, which has been adjusted so as to contain 5 to 60 p. p. m. of nitrous acid. Add 2.5 ml. of the reagent solution, and 0.3 ml. of 6 N hydrochloric acid and shake well. Make up to the mark with distilled water, thoroughly mix and, after ten minutes, measure the absorbance at 625 mμ, using a reagent blank solution as a reference. Determine the weight or the concentration of nitrous acid in the sample from a calibration curve.

## Results and Discussion

**Absorption Spectra.** — Disodium 1-(4′-aminobenzeneazo) - 2 - amino - 8 - hydroxy - naphthalene-2′, 6-disulfonate is a red-brown solid, soluble in water. It is stable indefinitely in the solid state, and for, at least, three months when dissolved in water. The aqueous solution of the reagent is red; the nitrite ion in hydrochloric acid reacts with it to give a blue solution. Absorption spectra of the reagent solution and of the blue solution produced by the color reaction between the reagent and nitrite in diluted hydrochloric acid solution are given in Fig. 2.

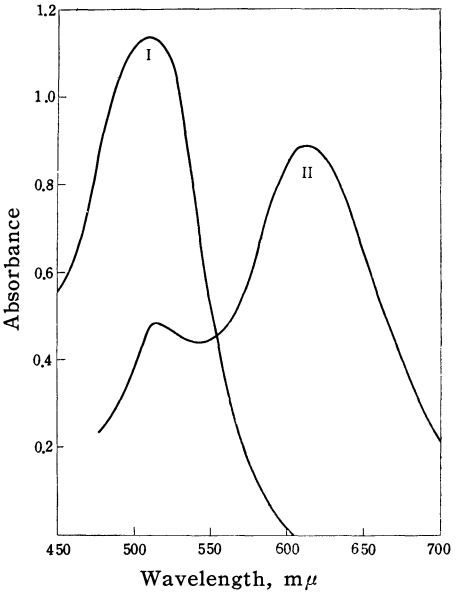

Fig. 2. Absorption spectra.
I. Reagent, 50 p. p. m.
II. Reagent (50 p. p. m.) + $HNO_2$ (2.3 p. p. m.)

As seen in Fig. 2, the compound produced by the color reaction has a maximum absorption at 625 mμ; the reagent solution does not absorb light at this wavelength. Hence, for analytical use absorbance measurements are made at 625 mμ. A large exess of the reagent must be avoided because its solution has a slight absorption at 625 mμ when the reagent concentration is greater than 50 p. p. m. It is not necessary to use exactly the same concentration of the reagent for standards and unknowns so far as the concentration of

unreacted reagent is below 50 p. p. m. and water is used as reference solution. However, color intensities measured with the reagent solution as a blank obey Beer's law better than those with a water blank.

Application of the method of continuous variations[7,8] to this color reaction indicates that the mole ratio of reagent to $NO_2^-$ is 1 to 1. The result is shown in Fig. 3.

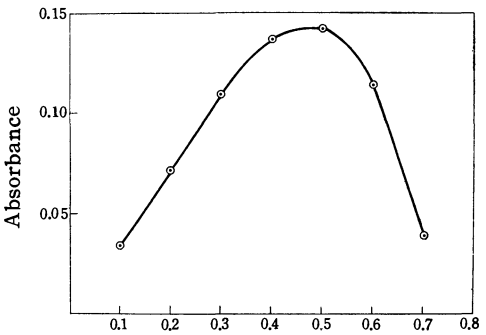

Fig. 3. Application of method of continuous variations: The nitrite and the reagent solutions were mixed in proportion to give the $x$ to $(1-x)$ ratio of component in 1.0 ml. total volume in a 100 ml. volumetric flask, where $x$ is equivalent to ml. of $10^{-3}$ M reagent and $(1-x)$ is equivalent to ml. of $10^{-3}$ M nitrite ion (the concentration of hydrochloric acid in the mixed solution was adjusted to 0.1 N).

**Effect of Concentration of Hydrochloric Acid.** — In order to determine the effect of the concentration of hydrochloric acid on the color reaction, the blue colored solution containing 2.8 p. p. m. of nitrous acid and 50 p.p.m. of the reagent were prepared with hydrochloric acid of various strengths, and absorbances of these solutions were measured. The results are shown in Fig. 4.

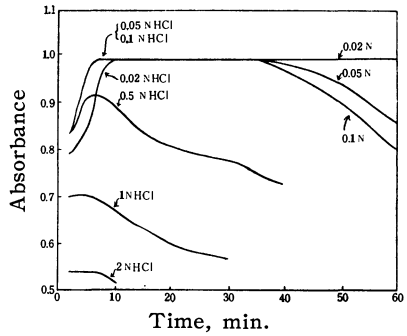

Fig. 4. Effect of hydrochloric acid.

It is seen that the optimum concentration of hydrochloric acid is between 0.05 and 0.1 N and hence, the solution containing nitrite must be adjusted to within this concentration range. Additional acid decreases the color intensity, causing rapid decolorization. With less acid, the color does not attain a maximum intensity within a reasonable time. In the optimum acid concentration, the color increases during the first ten minutes after the preparation of the blue solution, and then remains constant for about thirty minutes. It is necessary, therefore, to allow the solution to stand ten minutes and then to measure the absorbance within thirty minutes.

When sulfuric, phosphoric and acetic acid are used in place of hydrochloric acid, a less intense color is obtained.

**Effect of Temperature.** — There is no variation in the absorbance of the color system over a temperature range of 15 to 30°C. Hence, normal temperature changes in the laboratory introduce no error.

**Interfering Ions.** — The reagent was tested with 67 ions on a spot plate to determine the effect of other ions. The tested ions are given in Table I as the periodic table style.

Sixteen ions shown by italics in Table I were found to cause interference ($As^{+3}$,

TABLE I. EFFECT OF OTHER IONS

8) W. C. Vosburgh and G. R. Cooper, *J. Am. Chem. Soc.*, **63**, 437 (1941).

$Br^-$, $Fe^{+3}$, $Ce^{+3}$, $CeO_3^{-2}$, $F^-$, $Hg^{+,2+}$, $I^-$, $Mn^{+2}$, $MnO_4^-$, $MoO_4^{-2}$, $Sn^{+2,+4}$, $Ti^{+4}$, $Zr^{+4}$). Ferric ions cause a serious error and must be removed before the addition of the reagent. Chemical methods of separation of ferric ions did not yield good results. However, when EDTA solution is added to the sample solution before the addition of the reagent, interference of ferric ions is effectively eliminated. EDTA has no influence on the absorption spectrum of the blue colored solution. The effect of some common ions was tested spectrophotometrically; Table II summerizes the tolerance.

In Table II, the limiting concentration of an ion is taken to be the concentration that causes a deviation of more than 0.01 unit in the absorbance of a solution containing 0.94 p. p. m. of nitrous acid.

Table II. Interferences

| Ion | Added as | Limiting concn., p. p. m. |
|---|---|---|
| $Co^{+2}$ | $CoCl_2$ | 300 |
| $Cr^{+3}$ | $Cr_2(SO_4)_3$ | 200 |
| $Cu^{+2}$ | $CuSO_4$ | 300 |
| $Fe^{+3}$ | $Fe_2(SO_4)_3$ | 100 |
| $Ni^{+2}$ | $NiSO_4$ | 300 |

Table III. Accuracy and precision of the method

| Nitrous acid | | Absorbance** at 625 mμ | Standard deviation*** in absorbance unit | Error % |

| 2.26 | | 0.864 | 0.002 | |
| 2.63 | | 0.95 | 0.010 | |
| 2.82 | | 0.99 | 0.013 | |
| 3.38 | | 0.15 | 0.018 | |

* These values were calculated by use of 0.405 of average value, from 0.19 to 1.88 p. p. m. $HNO_2$, of absorbances calculated per one p. p. m. $HNO_2$.

** These values are the averages of six replicate determinations.

*** The standard deviations were calculated by the equation, $\sigma = \sqrt{\sum d^2/(n-1)}$, $d$ being the deviation of each absorbance measured from the average and $n$ the number of measurements.

**Calibration Curve and Precision.** — In order to construct a calibration curve and to determine the precision of the method, fifteen series of six replicate determinations were made. The precision, expressed as the standard deviation from the mean for each of the fifteen series, is shown in Table III.

The spectrophotometric sensitivity of the color reaction is 0.004 $\gamma$ of nitrous acid per sq. cm. A more practical sensitivity may be taken as one part of nitrous acid in 10,000,000 parts of solution. A solution containing this concentration has an absorbance of 0.040 unit.

**Beer's Law.** — Beer's law is obeyed up to about 2 p. p. m. of nitrous acid and the absorbances are sufficiently reproducible to allow the range of the determination to be extended to about 3 p. p. m. (see Fig. 5).

**Determination of Nitrous Acid in Synthetic Solutions Containing Various Ions.** — The determination of nitrous acid in the presence of certain other ions has made. The results are given in Table IV.

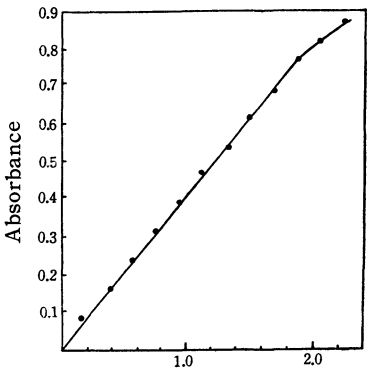

Fig. 5. Beer's law plot.

**Summary**

A procedure has been developed for the spectrophotometric determination of trace amounts of nitrous acid with disodium 1-(4′-aminobenzeneazo)-2-amino-8-hydroxynaphthalene-2′, 6-disulfonate. The method is accurate and precise and has a sensitivity of 0.004 $\gamma$ of nitrous acid per sq. cm. Beer's law is obeyed up to about 2 p. p. m. of nitrous acid. A study of the effect of many ions on the color reaction has been made. The interference of ferric ions is eliminated by the use of EDTA.

# *Estimation of the Energy of Hydrogen Bonds Formed in Crystals. II. Phenols*

By Ariyuki AIHARA

(Received July 20, 1959)

The OH···O bonding is the most familiar of the hydrogen bonds and has already been widely explored; the phenomena in ice (or water), alcohols and acids have been studied in special detail. Nevertheless, data on hydrogen bonds in phenols are not so ample in literatures as those of alcohols and acids, at least so far as the crystalline state is concerned. In this connection the author has chosen, as the first of the series of investigation on the strength of hydrogen bond formed in crystals, a number of phenols of various kinds, and examined them following the procedure proposed in a previous paper[1]. The materials here examined include those the molecules of which have bulky substituents close to hydroxyl groups, preventing the formation of hydrogen bonds, such as *o*-hydroxydiphenyl or 2,4,6-tri-*tert*-butylphenol, and also 1- and 2-naphthols, which may be classified as phenols in a wider sense.

## Experimental

The apparatus used for the measurement of sublimation pressures is the same as was used before[1].

Most of the materials dealt with in this paper are commercial products and purified by fractional sublimation before use. Four of them, i. e. 4-*tert*-butylphenol, 2-*tert*-butyl-4-methylphenol, 2-methyl-4-*tert*-butylphenol and 2,4,6-tri-*tert*-butylphenol were kindly sent by Professor M. Davies, Univ. Wales; these were purified in the same way as the others except 2-methyl-4-*tert*-butylphenol, which was fractionally distilled and measured in liquid state.

## Results and Discussion

**Sublimation Pressures.** — Results of the measurements of sublimation pressures of thirteen phenols are shown in Tables I—XIII, respectively, together with vapor pressure equations obtained by the method of least squares.

m. p. 123°C: t. p. 39.1°C

The linear relation between $\log P$ and $1/T$ has been found quite satisfactory for all the measurements except those of 1- and 2-naphthols, both of which have shown transitional changes of $\log P \sim 1/T$ curves at about 39°C. To confirm this change, careful measurements of sublimation pressures were made repeatedly, and from the intersections of two lines representing $\log P \sim 1/T$ relations for both phases, 39.4 and 39.1°C have been obtained as transition points of 1-naphthol and 2-naphthol, respectively (Fig. 1). As it is not proper to conclude the existence of a transition by the measurement of sublimation pressures alone, especially when the heat of transition is small, a thermal analysis of these substances is now in progress and the results will be published later.

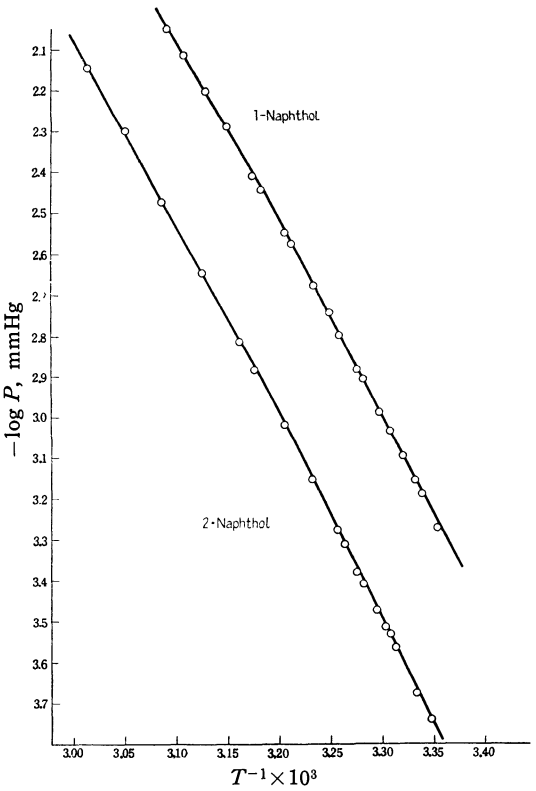

Fig. 1. Sublimation pressures of 1- and 2-naphthols.

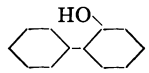

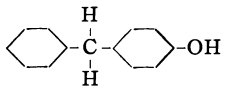

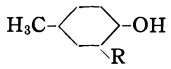

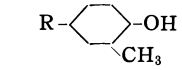

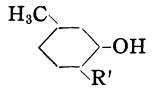

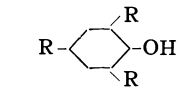

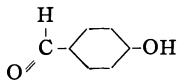

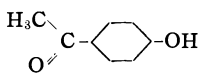

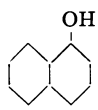

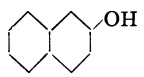

Balson[2] has also measured the sublimation pressure of thymol. However, his result, $\log P = 14.201 - 4766/T$, $\Delta H = 21.8$ kcal./mol., differs appreciably from the author's, the sublimation pressure being lower and the heat of sublimation being greater than the author's in the temperature range of the author's measurement. Considering the structure of this molecule Balson's value for the heat of sublimation of thymol seems to be too large.

**Energy of Hydrogen Bond.**—In Table XIV, the heats of sublimation of thirteen phenols, hypothetical lattice energies obtained assuming the additivity of lattice energies, and the energies of hydrogen bonds estimated by the procedure proposed before are shown by letters, $\Delta H$, $\Delta H'$ and $E$, respectively. The changes of standard free energies at 298.2°K, $\Delta G^{298.2}$, and of entropies, $\Delta S$, on sublimation are also shown in the table.

Let us first consider the case where the formation of OH···O bond seems rather difficult or almost impossible due to the presence of bulky substituted groups, such as phenyl and *tert*-butyl, in the vicinity of OH groups. Four compounds, i. e. *o*-hydroxydiphenyl, 2-*tert*-butyl-4-methylphenol, thymol and 2,4,6-tri-*tert*-butylphenol may fall in this category. As can be seen in Table XIV, the estimated values of hydrogen bonds for *o*-hydroxydiphenyl and 2-*tert*-butyl-4-methylphenol are negligibly small, being in fair agreement with the experimental results of infrared and ultraviolet absorption by Mecke[3], Coggeshall[4] and Josien[5]. According to Coggeshall[4], a phenol with one ortho position occupied by a *tert*-butyl and the other unoccupied, such as 2-*tert*-butyl-4-methylphenol, is partially hindered in forming a hydrogen bond. This means that one might expect, at least, a small

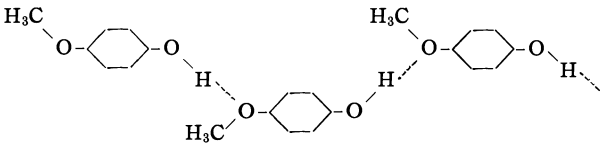
R=C(CH$_3$)$_3$, R′=CH(CH$_3$)$_2$



* For liquid state.

value of hydrogen bond energy for this compound instead of zero as shown in Table XIV. This discrepancy must be partly due to the difference in the states of the compound when it was examined, the one being solid and the other in solution, and partly due to the uncertainty of the method of estimation of hydrogen bond energy in this work. Thymol is a phenol with one ortho position occupied by an isopropyl group which is less powerful than *tert*-butyl in hindering the access of OH group of other molecules. Therefore, the energy of hydrogen bond in this compound, 1.4 kcal./mol., would be reasonable. A large negative value was obtained for 2,4,6-tri-*tert*-butylphenol. There will be no objection against believing that the OH group of this molecule is quite free from any intermolecular hydrogen bond, being protected by *tert*-butyl groups on both ortho positions, as was confirmed by Coggeshall[4] and Davies[6], by means of

6) M. Davies and R. J. Meakins, *J. Chem. Phys.*, **26**, 1584 (1957).

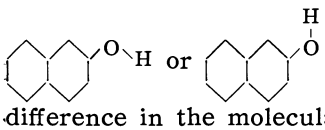
or

infrared technique and dielectric method in microwave region, respectively. Therefore, the large difference between $\Delta H$ and $\Delta H'$ for 2,4,6-tri-*tert*-butylphenol must be ascribed to the failure of the assumption, for this compound, of the additivity of lattice energy. This is understandable when the fact is taken into consideration that three *tert*-butyl groups of this molecule are bulky enough to screen a phenyl nucleus, to which they are attached, from the others, thereby causing the decrease of the effect of dispersive force due to the phenyl group to a greater extent. It is likely, therefore, that the *tert*-butyl groups are mainly responsible for dispersive attraction in this case, as was found with a system of $SF_6$ and $CF_4$, where the intermolecular attraction was discussed as due to halogen atoms of the molecules exclusively[7,8].

The heat of vaporization of 2-methyl-4-*tert*-butylphenol, 18.1 kcal./mol., is almost the same as the heat of sublimation of 2-*tert*-butyl-4-methylphenol, 18.5 kcal/mol.; this means that the OH···O bond in the crystal of the former should be stronger than that of the latter, as predicted from their molecular structures.

The hydrogen bond energies for *p*-hydroxydiphenyl and *p*-*tert*-butylphenol, 3.2 and 3.6 kcal./mol., respectively, are almost of the same order of magnitude, but somewhat smaller than the value obtained for phenol by Nitta and Seki, 4.5 kcal./mol.[9] This is probably due to a steric effect of large substituents in para positions rather than to any change of proton donating (or accepting) power of the OH groups. This effect is much more enhanced in the case of *p*-benzylphenol, obtained energy being 1.2 kcal./mol.

Comparatively large values of the energies of hydrogen bonds were obtained for *p*-formylphenol, *p*-acetylphenol and *p*-methoxyphenol, i.e. 7.3, 6.4 and 6.2 kcal./mol., respectively. It is interesting to note that these molecules have a possibility of making head-to-tail associations by hydrogen bonds.



Then, the proton-donating power of OH and, at the same time, the proton-accepting power of O atoms of O=C and O–$CH_3$ groups must be increased appreciably, resulting in the increase of the strength of hydrogen bonds formed. As the crystal structures of these substances have not been analyzed as yet, a definite conclusion can not be drawn with regard to the mode of association of these molecules. Still, it will be quite safe to say that the OH···O bonds formed by these molecules are much stronger than those by other molecules mentioned above. The values for OH···O bonds obtained here can be compared with the energies of association of carboxylic acids in gaseous state, ~7 kcal./mol. (monomer), obtained by Taylor[10] and Nash[11]. Incidentally the $pK_a$ values[12] of *p*-formylphenol, *p*-acetylphenol and *p*-methoxyphenol, which can be taken as the measure of proton-donating power of these molecules, 7.66, 7.95, 10.20, respectively, (in water at 25°C), support the correctness of the order of strength of

hydrogen bonds for these phenols as revealed here; the $pK_a$ value of phenol is 9.95[12].

The hydrogen bond formed in the crystal of 2-naphthol is stronger than that in 1-naphthol, while the latter seems to be of the same order of strength as the bond in phenol[9]. A similar result was obtained by Nagakura[13] when he studied the proton-donating power of phenols and naphthols by the measurement of near ultraviolet absorption of these substances in appropriate solvents to which some proton-acceptors, such as methylacetate or dioxane were added; his values of the energies of OH···O bonds for phenol, 1-naphthol, and 2-naphthol are 5.3, 5.7 and 6.1 kcal./mol., respectively. These results are rather strange, as Nagakura pointed out, if the fact is considered that the extent of electron migration into the naphthyl ring from oxygen atom is almost of the same order as that into a benzene ring in the case of phenol, and therefore, that the $pK_a$ values[12] and the dipole moments[14-16] of these three compounds are identical; $pK_a$=9.95, 9.85, 9.93 in water at 25°C, $\mu$=1.5, 1.4, 1.5 D, respectively.

The author is inclined to presume that the main factor differentiating 1-naphthol from 2- with regard to the power of forming hydrogen bond is steric hindrance due to a hydrogen atom at 8-position in case of 1-naphthol. Thus, the OH group must be obliged to take only such a direction as to be opposite to the 8-position of the naphthyl nucleus. On the other hand, the OH group in 2-naphthol is quite free from such hindrance as mentioned above, and can take either of the directions,

difference in the molecular structure.

In this connection a comment will be made of the transitions found with 1- and 2-naphthol. The fact of interest is that the transition points of these substances, 39.4 and 39.1°C, respectively, are very close to the melting point of phenol, 40.8°C, and that the heats of transition, 2.2 and 2.4 kcal./mol., respectively, are almost of the same order as the heat of fusion of phenol, 2.7 kcal./mol.[17] This would mean that the transitions and melting of the above substances might occur under the same mechanisms. It is most likely that intramolecular rotation about C–O bond[18] takes place at the melting point of phenol thereby leading to a less ordered state of liquid. As the O–H groups are bound to each other through chains of hydrogen bonds, a rotating part of the molecule will be mostly phenyl nucleus. That the change of entropy on melting at 40.8°C, 8.6 cal./deg. mol.[17], is almost the same as that of benzene at 5.5°C[17], and smaller than that of thiophenol, 10.5 cal./deg. mol. at −14.9 °C[17], may support the above argument. In the case of 1- and 2-naphthol, the onset of intramolecular rotations would lead to a transition in the crystalline states, but not to melting, because the effect of dispersive forces due to naphthyl rings is strong, as was found in the present experiment. Detaits will be published later.

## Summary

The energies of hydrogen bonds formed in the crystalline state of twelve phenols have been estimated by a procedure proposed in a previous paper. The values of energy range from zero to 7 kcal./mol. depending upon the difference of molecular structures: the phenols with bulky substituents in the vicinity of OH groups are non- or weakly-hydrogen-bonded, while those with carbonyl or methoxy groups at para positions are strongly bonded presumably by head-to-tail association. The other phenols fall between the two extremes. Incidentally it is interesting that the highest values of OH···O bond are rather close to the energies of association of carboxylic acids in the gaseous state.

With 1- and 2-naphthols, a parallel relation between the transitions of the above substances and the melting of phenol has been pointed out.

The author is grateful to Professor M. Davies for sending some of the samples

# *Die absolute Konfiguration des Phyllodulcins*

Von Hisao ARAKAWA

(Eingegangen am 30. April 1959)

Es sind verhältnismässig geringere Dihydroisocoumarinderivate in der Natur gefunden worden; als erstes hatten Asahina und Asano[1] 1931 die Struktur des Phyllodulcins (I), des Süßstoffs der Blätter von *Hydrangea macrophylla* Seringe var. *Thunbergii* MAKINO („Amacha"), festgestellt; seither sind Hydrangenol[1,2], Ochracin[3] (Mellein)[4,5], 3-Me-6-MeO-8-hydroxy-3,4-dihydroisocoumarin[6] und Bergenin[7] als Dihydroisocoumarinderivat charakterisiert und synthetisch sichergestellt worden.

Zur Aufklärung der Beziehung zwischen der optischen Aktivität und der absoluten Konfiguration der Verbindungen dieser Reihe, wählte der Verfasser als Repräsentanten das Phyllodulcin zuerst aus, und beabsichtigte die absolute Konfiguration ihres C-3-Atoms zu bestimmen.

Anderseits hatten vor einigen Jahren Hardegger et al.[8] durch erschöpfende Ozonisierung die absolute Konfiguration des (+)-Catechins, eines Naturstoffs von $C_6$-$C_3$-$C_6$-Gerüst, ähnlich wie I sichergestellt, also wünschte der Verfasser I dieser Methode zu unterwerfen.

Aber es ist schwer, optisch reinstes Präparat von I zu gewinnen. Das von Asahina et al.[1,9] als stärkst drehbares erhaltene Phyllodulcin zeigte den Schmerzp. 120° und $[\alpha]_D$ +67.7~69.70, aber da hatte man nur eine geringere Masse; und es ist dem Verfasser gelungen als stark drehbares Präparat Prismen von Schmerzp. 119~121°C und $[\alpha]_D$ +70.7~80.8°, ausserdem als schwach drehbare Kristalle von $[\alpha]_D$ +22.4° zu erhalten.

Deshalb wurde Phyllodulcin von $[\alpha]_D$ +70.7~80.8° in Essigsäure einer Ozonisierung unterworfen und Oxydation mit Peressigsäure, Entfernung der Oxalsäure und kontinuierliches Extrahieren mit Äther führten zu Äpfelsäure*. Die Veresterung der Säure mit Diazomethan lieferte Methylester von $[\alpha]_D$ +6.5°**, dessen IR-Spektrum mit solchem der authentischen DL-Äpfelsäure identisch ist. Schließlich führte Ammonolyse des Esters zu prismatischem Kristall von Schmerzp. 154~155°C, $[\alpha]_D$ +56.7°. Durch Mischprobe, Vergleichen des IR-Spektrums mit solchem des authentischen Präparates von *R*-Äpfelsäure und spezifische Drehung, ist es sichergestellt, daß das *R*-Äpfelsäure diamid gewonnen worden ist.

Mit der Isolierung der *R*-Äpfelsäure (II) ist es nun bestimmt, daß die absolute Konfiguration des C-3 in Phyllodulcin *R*-Konfiguration ist.

* Papierchromatographisch charakterisierte man als Äpfelsäure. Noch dazu wurde aus dem Kristall von $[\alpha]_D$+22.4° Äpfelsäure als Kristalle erhalten und ihre IR-Spektren stimmten mit solchen der authentischen DL-Äpfelsäure überein und ihre Drehungen in 10-proz. Ammoniummolybdat zeigten links drehend bis $[\alpha]_D$−46.3°. Darum ist die erhaltene Säure ein Gemisch von DL-Körper mit wenigem D-Körper, denn es ist bekannt[10], daß der Drehungssinn einer optisch aktiven Äpfelsäure sich in der Lösung von Ammoniummolybdat umkehrt und ihr Drehungsvermögen mehr als 10-mals vergrößert worden ist.

10) H. D. Dakin, *J. Biol. Chem.*, **59**, 9 (1924).

** Aus dem Phyllodulcin von $[\alpha]_D$+22.4° wurde Methylester von $[\alpha]_D$+2.3° erhalten. (s. Versuche).

## Beschreibung der Versuche

**Extrahieren des Phyllodulcins.**—Der zu 5.5 kg käufliche „Amacha" wurde mit essigsäurehaltigem wässer. Methanol extrahiert (einmal, einige Tage lang). Nach im Vakuum Abdampfen des Methanols ausgeschiedene grüne rohe Kristalle wurden mit Äther, Chloroform, Äthanol und Methanol gereinigt. Die Kristalle jeder Fraktion wurden mehrmals fraktioniert aus Äthanol umkristallisiert. Es wurden die Prismen erhalten, die rein süß schmecken (Tabelle I).

Die IR-Spektren von B, C, D in Nujol stimmen überein. Die IR-Spektren von A und B in Chloroform sind identisch.

**Ozonspaltung von Fraktion A $[\alpha]_D$ +22.4°.**—Durch eine Lösung von Fraktion A (10 g) in 100 ccm 90-proz. Essigsäure wurde bei 5°C Ozon geleitet. Die Lösung färbte sich bald dunkelbraun und hellte dann auf, schließlich wurde sie nach 67 Stdn. ganz farblos und teils kristallisierte Oxalsäure, die bei 98～100°C schmolz und durch Mischprobe mit authentischem Präparat identifiziert wurde. Nach Zugabe von 15 ccm Perhydrol wurde die Lösung 24 Stdn. lang stehen gelassen und mit 50 ccm Wasser versetzt, dann wurde die Lösung nach Hardegger et al.[8] behandelt und von Oxalsäure befreit und dann im Vakuum eingedampft. Der erhaltene Rückstand wurde nach Zugabe von Wasser wiederholt im Vakuum eingedampft, und der getrocknete Rückstand (6 g) in warmem Wasser gelöst, und dann mit Äther kontinuierlich extrahiert.

Nach Abdampfen von Äther und nack Trocknen dann abfiltriert. Der erhaltene gelbe Rückstand betrug 470 mg. Dreimaliges Umkristallisieren aus Methanol gab 60 mg fast farblose Prismen von Schmerzp. 154～155°C, $[\alpha]_D^{13}$ +56.7° (c=1.18 in Methanol).

war der Extrakt größtenteils kristallisiert. Fraktioniertes Umkristallisieren aus Essigester gab farblose Kristalle (Tabelle II).

TABELLE II

| Schmerzp. C° | Ausbeute g | Spezifisches Drehungsvermögen in 10-proz. Ammoniummolybdat |
|---|---|---|
| 131～132 | 0.3 | —*** |
| 125～127 | 0.2 | $[\alpha]_D^{13}$ −4.9° (c=3.05) |
| 119～121 | 0.4 | $[\alpha]_D^{25}$ −11.7° (c=5.03) |
| 113～116 | 0.1 | $[\alpha]_D^{12}$ −46.3° (c=1.12) |

*** Misch-Schmerzp. mit authentischer DL-Äpfelsäure: 131～132°C.

Nach Trocknen des Kristalls von Schmerzp. 113～116°C bei 80°C im Vakuum.

$C_4H_6O_5$

| | | | | |
|---|---|---|---|---|
| Ber. | C | 35.83 | H | 4.51 |
| Gef. | C | 35.85 | H | 4.63 |

Die Mutterlauge wurde in Vakuum-Exsiccator abgedampft, wonach der Rückstand in Methanol gelöst, mit Diazomethan verestert und mit Natriumsulfat getrocknet. Nach Vorlauf von Kochp. 62°C/2 mmHg wurde 490 mg Hauptfraktion von Kochp. 110～111°C/10 mmHg, $[\alpha]_D^{13}$ +2.7° (c=16.3 in Methanol) erhalten.

$C_6H_{10}O_5$

| | | | | |
|---|---|---|---|---|
| Ber. | C | 44.44 | H | 6.22 |
| Gef. | C | 44.19 | H | 6.42 |

Das IR-Spektrum stimmte mit solchem des authentischen DL-Äpfelsäuredimethylesters von Kochp. 115～117°C/14 mmHg (in $CS_2$, $CCl_4$) überein.

**Abbau der Fraktionen B, C und D von $[\alpha]_D$ +70.7～80.8° mit Ozon und Isolierung von *R*-Äpfelsäure als Diamid aus dem Ätherextrakt.**—Durch eine Lösung von 5.2 g Kristalle (0.9 g B+2.7 g C+1.6 g D) in 50 ccm 95-proz. Essigsäure wurde 3-proz. Ozon 31 Stdn. lang eingeleitet, wonach sie mit 7.5 ccm Perhydrol versetzt, 18 Stdn. lang stehen gelassen und dann wie oben behandelt, mit Äther 20 Stdn. extrahiert. Der erhaltene Rückstand wog 3.3 g und sein Papierchromatogramm (Xylol, Phenol, 85-proz. Ameisensäure, 5:5:2)[11] lieferte die Flecke der Äpfelsäure. Seine Methanollösung wurde dann verestert. Die Destillation des getrockneten Methylesters ergab bei 111～112°C/10 mmHg 700 mg von $[\alpha]_D^{9}$ +6.5° (c=12.89). Das IR-Spektrum stimmt mit solchem von DL-Äpfelsäuredimethylester überein.

666 mg Methylester wurde in verzweigtem Reagenzrohr (unter Abkühlung durch eine Mischung von fester Kohlensäure mit Äthanol) mit 12 ccm von verflüssigtem Ammoniak aus der Bombe versetzt und dann das Reagenzrohr in einem Autoklav geschlossen. Nach Stehenlassen bei Zimmertemperatur 24 Stdn. lang, dampfte man Ammoniak ab und mischte mit Äther und

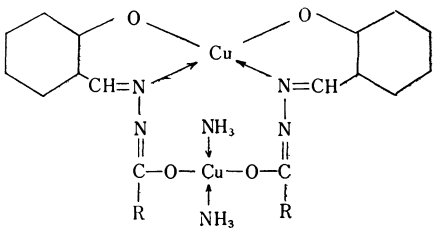
Werden die Aroylreste mit den Acylresten ersetzt, so lassen sich die Salicylaldehyd-acylhydrazone erhalten, die auch, als Chemotherapeutica, in Frage kommen. Durch Anfügen der Acylreste mit längeren Ketten sollen Salicylaldehyd-acylhydrazone lipophile Eigenschaft gewinnen, die den Angriff der Substanzen auf wachsgepanzerte Bakterien erleichtern könnte.

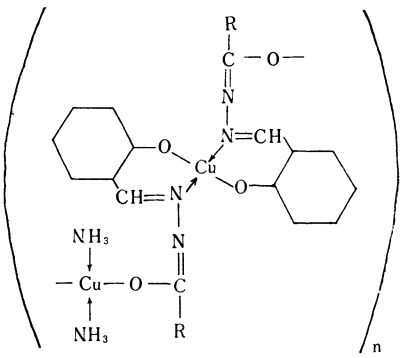
In der vorliegenden Mitteilung sollen die Salicylaldehyd-acylhydrazone, worunter einige noch nicht berichtet worden sind, und deren Kupferkomplexsalze beschrieben werden.

Neue Acylhydrazine und Salicylaldehyd-acylhydrazone wurden in üblicher Weise dargestellt; Acylhydrazine durch Erhitzen der Fettsäureester mit Hydrazinhydrat, Salicylaldehyd-acylhydrazone durch Gemisch des Salicylaldehydes und der Acylhydrazine. Als Ausgangsstoffe für die Komplexsalzdarstellung wurden Salicylaldehyd-formylhydrazon, -acetylhydrazon, -propionylhydrazon, -*n*-butyrylhydrazon, -*n*-valerylhydrazon, -*i*-valerylhydrazon, -*n*-capronylhydrazon, -*n*-caprylylhydrazon, -*n*-caprinylhydrazon, -*n*-palmitylhydrazon, -phenylacetylhydrazon und -phenoxyacetylhydrazon herangezogen. Alle diese Hydrazone sind schneeweiß, und in Äthanol und anderen organischen Lösungsmitteln sehr leicht löslich; sie lassen sich aus Äthanol leicht umkristallisieren.



Die Komplexsalze wurden, wie im Versuchsteile näher beschrieben, durch Gemisch der Hydrazone in Äthanol und des Kupferacetats in wässrigem Ammoniak dargestellt. Sie bilden hell- bzw. dunkelgrüne Kristalle, und nach den analytischen Daten kommt ihnen eine allgemeine empirische Formel $[C_8H_5O_2N_2RCu\cdot(NH_3)_{0\text{ oder }1}]$ zu. Die Komplexsalze des Salicylaldehyd-*n*-palmitylhydrazons, -phenylacetylhydrazons und -phenoxyacetylhydrazons enthalten je 1 Mol. Ammoniak und geben es (mit Ausnahme vom Komplexsalze des Salicylaldehyd-phenoxyacetylhydrazons) beim Erhitzen im Vakuum leicht ab; deren

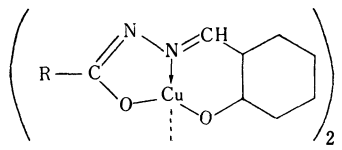
* Organische Metallkomplexsalze III. Vorgetragen in Kyoto auf der XII. Jahresversammlung der Japanischen Chemischen Gesellschaft, am 3. April 1959.



1) II. Mitteilung: H. Ohta, Dieses Bulletin, **31**, 1056 (1958).

2) Ng. Ph. Buu-Hoï und Mitarbb., *J. Chem. Soc.*, **1953**, 1358.

Farbe schlägt vom Hellgrün nach Olivgrün um. Das Ammoniak muß daher koordinativ mit dem Kupferatom gebunden sein. Aus Rücksicht auf die Koordinationszahl des Kupfers und die Struktur des Liganden können diese Komplex salze mit der Formel I formuliert werden. Die Formeln II und III werden als unwahrscheinlich ausgeschlossen, weil 1) die Ausbildung der



II

III

Salze von der Formel II bzw. III sterisch nicht oder sehr schwer möglich ist, und 2) die Salze der Formel III nur als amorphes Pulver erhalten würden.

Die anderen übrigen Komplexsalze enthalten kein Ammoniak und sind dunkelgrün gefärbt. Diese und diejenigen, die durch Erhitzen im Vakuum das Ammoniak verloren haben, gehören zu den „Kupferkomplexsalzen der Koordinationszahl 3". Von ihnen sind die des Salicylaldehyd-*n*-caprinylhydrazons und -*n*-palmitylhydrazons in Campher löslich. Die Molekulargewichte beider Salze wurden nach Rast durch die kryoskopische Methode bestimmt. Die Resultate zeigten, daß sie dimer sind. Da die Formel II undenkbar ist, könnten diese Komplexsalze mit der Formel IV zum Ausdruck gebracht werden. Wahrscheinlich zwischen den beiden Kupferatomen wäre irgendeine Art Wechselwirkung vorhanden. Auch die magnetischen Messungen

IV

wurden mit diesen zwei Verbindungen in festem Zustand ausgeführt. Wegen der technischen Schwierigkeiten — *N*-Salicyliden-*N'*-*n*-palmityl-hydrazino-kupfer (II) konnte nicht, *N*-Salicyliden-*N'*-*n*-caprinil-hydrazino-kupfer(II) konnte nur äußerst schwer, pulverisiert werden — wurden jedoch keine befriedigenden Ergebnisse erhalten.

## Beschreibung der Versuche

**Acylhydrazine und Salicylaldehyd-acylhydrazone.** —Acylhydrazine können in üblicher Weise durch Kochen von Fettsäureestern mit etwas überschüssigem Hydrazinhydrat leicht synthetisiert werden. Die neuen Acylhydrazine wurden als Salicylidenderivate (Salicylaldehydacylhydrazone) charakterisiert.

Salicylaldehyd-acylhydrazone werden durch Gemische berechneter Mengen Salicylaldehyd und Acylhydrazine in Äthanol dargestellt und daraus umkristallisiert.

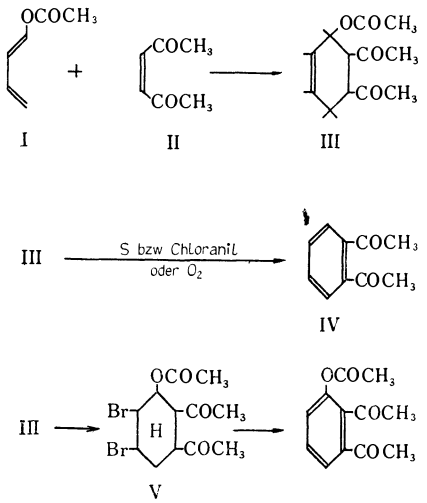
# *Darstellung von o-Diacetylbenzol durch Diels-Alder-Reaktion*

By Eturô MAEKAWA

(Eingegangen am 1. August, 1959)

*o*-Diacylbenzole sind nicht nur als Ausgangsprodukte der Naphthochinonsynthese[1] von präparativer Bedeutung, sondern bilden auch wegen ihrer intensiven Farbreaktion mit Aminosäuren[2,3] und auch mit primären Aminen[4,5] sehr interessante Verbindungen. Die Farbreaktion von *o*-Diacylbenzolen ist so stark, daß man mit ihnen z. B. 20~50 $\gamma$ Aminosäuren[2] oder 1 $\gamma$ aromatische primäre Amine[44] auf Papierchromatogrammen einwandfrei nachweisen kann. Sie lassen sich darstellen aus *o*-*n*-Alkylacylbenzolen durch Oxydation mit Permanganat[1,2] oder aus 3-Alkylphthaliden durch Umsetzung mit Alkylmagnesiumhalogeniden und durch direkte Oxydation



1) F. Weygand, H. Weber und E. Maekawa, *Chem. Ber.*, **90**, 1879 (1957).

des gebildeten Magnesiumsalzes der 1-Oxy-1.3-dialkylphthalane mit Permanganat[1]. Obgleich die Darstellung von *o*-Diacylbenzolen stark verbessert wurde[4,5], geht sie noch immer in ziemlich schlechter Ausbeute vor sich. Außerdem sind die Oxydationsbedingungen bei der ersten Methode so stark, daß diese auf die Ausgangsprodukte mit leicht oxydierbaren Substituenten schwer anwendbar ist. Das zweite Verfahren wird unter milderen Bedingungen durchgeführt, liefert aber nur unreine Produkte.

Wie von F. Weygand u. a. berichtet wurde[1], aromatisiert das Addukt aus 1-Acetoxybutadien-(1.3)[6] und 2.3-Dimethoxy-*p*-benzochinon in siedendem Alkohol automatisch unter Abspaltung von Essigsäure und Wasserstoff zu 2.3-Dimethoxynaphthochinon-(1.4). Diese Tatsache erweckte die Hoffnung, *o*-Diacetylbenzol aus 1-Acetoxybutadien-(1.3) und $\alpha.\beta$-Diacetyläthylen[7,8] durch Diensynthese herstellen zu können. 1-Acetoxybutadien-(1.3) und $\alpha.\beta$-Diacetyläthylen geben beim Kochen der alkoholischen Lösung in guter Ausbeute des Addukt, 3-Acetoxy-1.2.3.6-tetrahydro-1.2-diacetylbenzol, das gegen Erwarten stabil und bei 15 Torr ohne Zersetzung destillierbar ist.

Erhitzt man das Addukt mit Schwefel auf etwa 180°C, so wird zuerst Schwefelwasserstoff- und später Essigsäureentwicklung deutlich bemerkt. *o*-Diacetylbenzol müßte also in zwei Stufen entstanden sein. Aus dem Reaktionsgemisch wird eine schwach gelbe, klebrige Flüssigkeit mit demselben Siedepunkt wie *o*-Diacetylbenzol herausdestilliert. Diese Flüssigkeit, deren Elementaranalyse mit den für *o*-Diacetylbenzol berechneten gut übereinstimmt, zeigt sehr intensive violette Farbreaktion mit Anilin in essigsaurer Lösung in der Kälte und gibt ein Disemicarbazon, das beim Mischschmelzpunkt mit dem reinen *o*-Diacetylbenzol[5] keine Depression zeigt. Obgleich weitere Reinigung dieser Flüssigkeit sehr schwierig war, kristallisierte sie bei längegerem Stehen im Eisschrank—etwa über ein Jahr—zum Teil in schönen Nadeln, die nach einer Umkristallisation aus Petroläther einen Schmelzpunkt von 37°C zeigten[9]. Auch beim Erhitzen des Adduktes in der Luft unter normalem Druck bildete sich *o*-Diacetylbenzol, das als Disemicarbazon identifiziert werden konnte.

Chloranil und dessen Homologe werden oft als Aromatisierungsmittel empfohlen[10,11]. Wenn man das Addukt, 3-Acetoxy-1.2.3.6-tetrahydro-1.2-diacetylbenzol mit zwei molekularer Menge Chloranil in Xylol erhitzt, wird Essigsäureentwicklung beobachtet. Obwohl das Produkt auch starke Farbreaktion mit Anilin in essigsaurer Lösung zeigte und das erwartete *o*-Diacetylbenzol als Disemicarbazon identifiziert werden konnte, ließ es sich noch nicht genügend reinigen. Andere Versuche, z. B. Erwärmen mit Natriumhydrogencarbonat oder mit Selendioxyd, zerstörten die Substanz mehr oder weniger.

Ein Versuch zur Bromierung des Adduktes in der Allylstelle mit *N*-Bromsuccinimid in Tetrachlorkohlenstoff führte nur zur Harzbildung. Während sich beim Versetzen des Adduktes mit Brom in Tetrachlorkohlenstoff ein Harz unter Entwicklung des Bromwasserstoffs bildete—das Reaktionsgemisch zeigte jedoch mit Anilin violette Farbreaktion — wurde durch Versetzen mit Brom unter Zusatz von Pyridin eine kristallinische Dibromverbindung erhalten, die beim Aromatisieren unter Abspalten von Bromwasserstoff 3-Acetoxy-1.2-diacetylbenzol ergeben könne. Das aus der Dibromverbindung durch Erhitzen mit Pyridin hergestellte Produkt zeigte mit Anilin eine violette Farbreaktion und scheint nach Elementaranalyse ein noch unreines Präparat von 3-Acetoxy-1.2-diacetylbenzol zu sein.

11) U. Eisner und R. R. Linstead, ebenda, **1955**, 3753.

Bemerkenswert ist, daß das Addukt selbst mit Anilin in essigsaurer Lösung beim Kochen eine intensive rote Farbreaktion zeigt. In der Kälte gibt es in verdünnter Essigsäure nach längerem Stehen mit Anilin eine rote Färbung, die sehr langsam in violette übergeht. Unter Erhitzen der Mischung findet die Veränderung der Farbe viel schneller statt als in der Kälte. Sowohl verschiedene Amine als auch Aminosäuren, die mit *o*-Diacetylbenzol eine violette Farbreaktion zeigen[5], reagierten auch mit dem Addukt zuerst unter einer Rotfärbung: die Farbe wurde beim Stehen langsam tiefer. Mit diesem Addukt konnten $10^{-4}$ bis $10^{-5}$ g primäre Amine auf Papierchromatogramme nachgewiesen werden. Zwar ist die Grenze des Nachweises praktisch gleicher Ordnung wie beim Nachweis mit *o*-Diacetylbenzol, es besteht aber der Nachteil des Adduktes als Nachweisreagens darin, daß für die Färbung längere Zeit benötigt wird. Der Nachteil ist jedoch nicht sehr entscheidend, weil das Addukt als *o*-Diacetylbenzol viel leichter und auch in viel größerem Maßstab hergestellt werden kann.

$\alpha.\beta$-Diacetyläthylen ergab Diels-Alder-Addukte weder mit Furan noch mit 2.3-Dimethoxybutadien-(1.3), soweit versucht wurde.

### Beschreibung der Versuche

**1. $\alpha.\beta$-Diacetyläthylen (I)**[7,8].—Fp. 75.5～76.5°C (Lit.[8] 75.5～76.5°C) (aus Petroläther schwach gelbe Nadeln).

**2. 1-Acetoxybutadien-(1.3)(II)**[6].—$Kp._{30}$ 51～52°C.

**3. 3-Acetoxy-1.2.3.6-tetrahydro-1.2-diacetylbenzol (III).**—40 g I wurden in 300 ccm Äthanol mit 50 g II 24 Std. am Rückfluß in Abwesenheit von Feuchtigkeit gekocht, das Lösungsmittel im Vakuum abgedampft und der Rückstand im Vakuum zweimal fraktioniert, $Kp._{12}$ 156～159°C, Ausbeute 65 g (82%).

$C_{12}H_{16}O_4$ (224.2)

Ber. C 64.27 H 7.19
Gef. C 65.50 H 7.43

Diese Verbindung zeigt mit Anilin in essigsaurer Lösung in der Kälte eine rote Farbreaktion. Die Farbe wird langsam violett.

**4. Versuch zur Aromatisierung von III zu *o*-Diacetylbenzol (IV).**—(a) Mit Schwefel 25 g III wurden 5 Std. mit 3.5 g Schwefel bei 100 Torr auf 160～180°C erhitzt, wobei rege Schwefelwasserstoff- und Essigsäureentwicklung beobachtet wurden. Bei der Destillation des Reaktionsgemisches im Hochvakuum gingen 18 g schwach gelbes Öl bei 105°C und 0.05 Torr über.

$C_{10}H_{10}O_2$ (152.2) (*o*-Diacetylbenzol)

Ber. C 73.92 H 6.21
Gef. C 73.68 H 6.34

Dieses Öl zeigte eine intensive violette Farbreaktion mit Anilin-Essigsäure in der Kälte und kristallisierte zum Teil bei längerem Stehen im Eisschrank (über ein Jahr bei −5°C) in Nadeln, die aus Petroläther umkristallisiert wurden, Fp. 37°C (Lit.[3] 38°C), Ausbeute 2.3 g Disemicarbazon, Fp. 150°C (Lit.[3] 150°C).

(b) Mit Chloranil 4.5 g III wurden 40 Std. mit 9.4 g Chloranil in 500 ccm Xylol am Rückfluß erhitzt, wobei Essigsäureentwicklung beobachtet wurde. Das Reaktionsgemisch wurde abfiltriert, das Filtrat eingeengt und der Rückstand mit Petroläther ausgezogen. Die Petrolätherlösung zeigte eine intensive violette Farbreaktion mit Anilin-Essigsäure in der Kälte. Obgleich keine Kristalle von IV nach dem Abdampfen des Petroläthers erhalten wurden, konnte IV als Disemicarbazon (0.13 g) identifiziert werden.

(c) Mit der Luft 4.5 g III wurden 48 Std. auf ca. 150～160°C erhitzt. Obgleich der Petrolätherauszug des Reaktionsgemisches eine intensive violette Farbreaktion mit Anilin in essigsaurer Lösung zeigte und Disemicarbazon (0.25 g) von IV gibt, blieb der Versuch zur Reinigung des Produktes erfolglos.

(d) Mit Selendioxyd 1 g III wurde 1 Std. mit 200 mg Selendioxyd in 20 ccm Äthanol am Rückfluß erhitzt. Es wurde keine Farbreaktion mit Anilin mehr beobachtet.

(e) Mit Natriumhydrogencarbonat 450 mg III wurden 10 Min. mit 150 mg Natriumhydrogencarbonat in Äthanol-Wasser (1:1) erhitzt. Nach dem Ansäuern mit Essigsäure zeigte das Gemisch nur schwache violette Farbreaktion mit Anilin.

**5. 3-Acetoxy-4.5-dibrom-1.2-diacetylcyclohexan (V).**—1.6 g III wurden in 30 ccm Tetrachlorkohlenstoff mit Brom bei Raumtemperatur versetzt, wobei das Gemisch unter Bromwasserstoffentwicklung ein Harz bildet. Das Produkt zeigte jedoch mit Anilin in essigsaurer Lösung eine intensive Farbreaktion. Unter Zusatz von Pyridin und unter Eiskühlung findet aber beim Versetzen mit Brom Harzbildung kaum statt. Das Gemisch wurde nach Stehenlassen über Nacht abfiltriert, das Lösungsmittel im Vakuum abgedampft und der Rückstand aus Methanol umkristallisiert, farblose Nadeln, Ausbeute 0.9 g (35%), Fp. 90～92°C (Zers.).

$C_{12}H_{16}Br_2O_4$ (384.1)

Ber. C 37.52 H 4.20 Br 41.61

Das Produkt scheint ein noch unreines Präparat von 3-Acetoxy-1.2-diacetylbenzol, zu sein konnte

jedoch wegen sehr schlechter Ausbeute nicht mehr gereinigt werden.

## Zusammenfassung

1-Acetoxybutadien-(1.3) gibt mit $\alpha.\beta$-Diacetyläthylen das Addukt: 1-Acetoxy-1.2.3.6-tetrahydro-1.2-diacetylbenzol, das durch Schwefel zu *o*-Diacetylbenzol aromatisiert werden konnte. Die Synthese ist in großem Maßstab leicht durchzuführen. Das Addukt reagiert mit primären Aminen unter einer roten Färbung und die Farbe geht langsam in violette über. Es wurden noch Reaktionen des Adduktes mit Brom untersucht.

Herrn Prof. Dr. F. Weygand, München, sage ich an dieser Stelle meinen aufrichtigsten Dank für Anregung und Anleitung zu vorstehender Arbeit.

# *Studies on Arsenic Trisulfide Glass*

By Jiro MATSUDA

(Received August 11, 1959)

The arsenic trisulfide glass has been studied as one of the new optical materials, because it can transmit infrared rays very well and has marked resistance to water and acid, and is more easily manufactured than single crystals[1-5].

The author once studied some different methods of preparation for technical arsenic trisulfide glass, and found the transmission value to be about 70% between 2 and 12 $\mu$ for 1 mm. thickness[6]. This figure is the maximum of the transmission value of this glass and the rather low transparency in this case results from the surface reflection and high refractive index[7]. If this glass can be properly coated on the surface, it will be more suitable for optical purposes, for this process must assist in reducing the reflection at the surface and raising the poor resistance to alkali.

Apart from the question of optical materials, the arsenic trisulfide glass is the interesting experimental glass composed of one component which melts at low temperature (about 300°C). Since the publication of the theory by Zachariasen[8] and the introduction of the X-ray analysis by Warren[9], glassy substances are explained as homogeneous polymers which characterize the amorphous substances consisting of network formers and modifiers, but some writers have insisted that glass is composed of a microheterogeneous system by microcrystalline structure[10]. These different views are closely related to the process of the transition of solids[11]. What process of transition occurs in glassy substances? The solution of this problem is very interesting and necessary in investigating the structure of glass. The various physical properties have frequently been studied on this point. The color of arsenic trisulfide has been found to be remarkably sensitive to changes in temperature. When it is heated yellow arsenic trisulfide is transformed to red and then to black. At 100°C, red aesenic trisulfide and at 170°C black substances can be obtained[12,13].

The author studied the thermal expansion values of red arsenic trisulfide glass

at transition temperatures by the quenching method and investigated the process of the transition.

## Experimental

The preparation of techincal arsenic trisulfide, the casting and the polishing of the glass were done by the same methods as mentioned in the previous report (Ref. 6).

Terylene film was used to coat the surface of the glass, because it can form the transparent, thin and filmy state easily at fairly low temperature and has a proper refractive index to remove the surface loss peculiar to the arsenic trisulfide glass. Terylene was dissolved in *o*-chlorophenol and this dilute solution was dropped on the glass which was horizontally rotated by an electric motor. Such treated glass was dried at 80°C in an air bath. The chemical durability of the glass to alkali was measured by spectroscopic method; that is, some pieces of glass were experimentally dipped in aqueous solution of sodium hydroxide for a limited time. After such etching they were washed and dried and measured on the falling of the transmittance at 2 $\mu$ wavelength.

The thermal expansion was measured by the ordinary optical lever method. Throughout the measuring, the samples were heated in succession at the constant rate of 2°C a minute. Before heating they were annealed at the constant temperature (187°C) for three days and allowed to cool very slowly to room temperature about 60 hr. in the electric annealing oven. They were then reheated for several hours at various temperatures ranging from 153 to 180°C and were quenched in the air.

The heating was made always in an mobile oil bath to prevent arsenic trisulfide from oxidizing.

## Results and Discussion

**Coating of the Surface.** — As shown in Fig. 1, the effect of the coating is very remarkable in the range of short wavelengths, while it gradually decreases in the wavelengths which are over 7 $\mu$ and many absorption bands of surface film appear. If the film coated on the surface is so thin that interference color can be seen, the efficacy of the treatment in the rays of the short wavelengths is very conspicuous. In that case the transmittance is 75 to 95% between 2 and 5.7 $\mu$. Moreover, even such a thin film markedly increases durability to alkali. As shown in Fig. 2, when dipped in 0.05 N alkaline solution, the coated glass is hardly affected at all. After 15 hr. etching the transmittance decreases by about only 4%.

In the case of 0.1 N, the coated glass is affected in some degree, but even after dipping for 30 min. the transmittance decreases by only 1~2%. All these decreases of the transmission were observed to be caused by etching pits which grew up from mechanical scratches on the film. These results mean that terylene film has sufficient protecting action against alkaline etching in such concentrations. As these results show, such coated arsenic trisulfide glass is of good use as optical material of the cell in the infrared between 2 and 5.7 $\mu$ and as seen in Fig. 1, the uncoated glass can be utilized as basic glass to study infrared absorption of various substances. Besides the terylene film, by proper coating of other materials the arsenic trisulfide glass seems to be the more valuable optical material.

**Thermal Expansion.** — The physical properties of glass are affected remarkably by different thermal histories. The abnormal thermal expansion of borosilicate

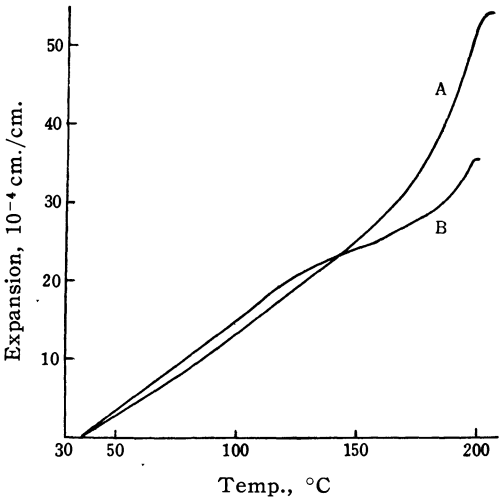

Fig. 3. Thermal expansion.
A: annealed, B: chilled.

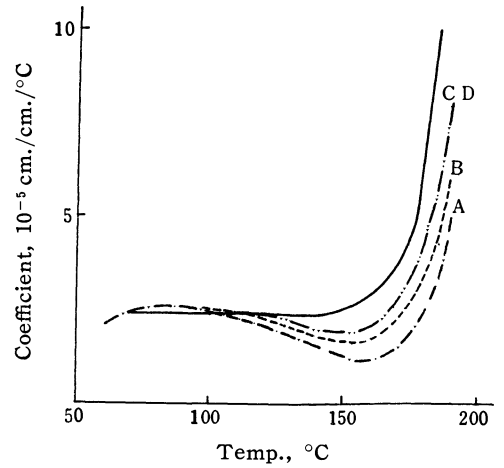

Fig. 4. Different coefficients among annealed and chilled glass.
——: annealed glass.
A, B, C and D are quenched at 180, 174, 164, and 153°C, respectively.

glass is one of the well-known examples of these sorts. As shown in Fig. 3, the annealed arsenic trisulfide glass shows transformation point at 170°C. The meaning of the transformation point in glass is not always the same in crystallography, but it is an undoubted fact that the structure of glass may change to a certain extent near the point. On the other hand, the precipitated arsenic trisulfide is said to have transformation points near 100 and 170°C[12-14]. However, in the case of the glassy state, the transformation appeared only at 170°C. Accordingly in order to study the common transformation point of these different solid states, the various coefficients of expansion were measured by the quenching method. A, B, C and D shown in Fig. 4. represent respectively the quenched specimens at 180, 174, 164 and 153°C. In Fig. 4, both A and B indicate larger values of the coefficients than in annealed glass below 100°C, but C and D almost the same values as annealed glass; that is, the quenching effect does not appear in the case of C and D.

In the high temperature range, the higher the quenching temperature becomes, the smaller the coefficient becomes, arriving at the minimum value near 160°C, but no substantial difference can be found among A, B, C and D curves and these results suggest that there is no intrinsic difference among the internal structures of the four specimens; that is, the difference of the coefficients shows the extent of their polymerization, and the higher the quenching temperature becomes, the more insufficient the polymerization becomes. This fact is guessed also from the difference among their exact temperatures at which the graduation of the dilatometer begins to show shrinking.

TABLE I. QUENCHING EFFECT ON THE EXACT TEMPERATURE AT WHICH THE ELONGATION CURVE ON THE DILATOMETER BEGINS TO SHOW SHRINKING

| Sample | Temp., °C |
|---|---|
| A | 200 |
| B | 200 |
| C | 202 |
| D | 206 |
| annealed | 209 |

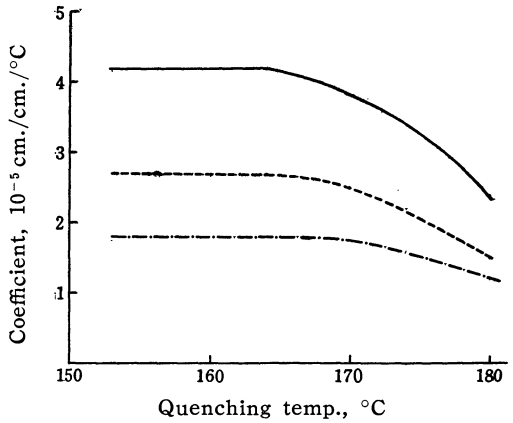

Fig. 5
——, ----, and —·—: measured at 180, 170 and 160°C, respectively.

14) W. A. Jonker, *Z. anorg. u. allgem. Chem.*, **62** 89, (1909).

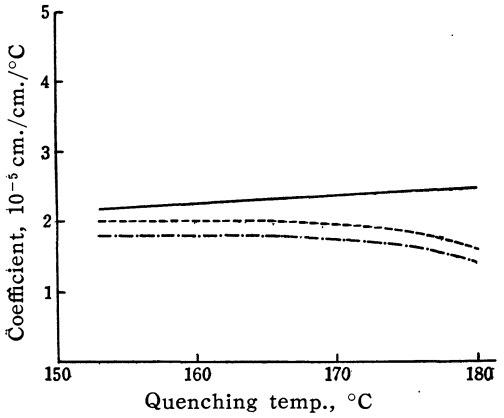

Fig. 6

——, ----, and —·—: measured at 100, 140 and 150°C, respectively.

These results are given in the table. As can been seen, the higher the quenching temperature becomes, the lower the exact temperature becomes; that is, the less sufficient the polymerization becomes.

Figs. 5 and 6 show the interrelation between the quenching temperature and the temperature in measuring of the coefficients. The abscissa means the quenching temperature. The differences among four specimens are notable at 180°C of measuring-temperature and become smaller at low temperature and at 100°C almost disappear. In all specimens the coefficients measured above 160°C, increase as the temperature rises, but this phenomenon appears in reverse below 150°C. Consequently all specimens show the minimum coefficient between 150 and 160°C. However, while the quenching temperature rises, the coefficients decrease in all cases above 100°C.

## Summary

Arsenic trisulfide glass shows 70% of transmittance between 2 and 12 $\mu$. This transmittance is somewhat insufficient for the optical cell in the infrared. Moreover, the chemical durability to alkali is very weak. These defects can be removed by proper coating on the surface. For instance, it can be of good use between 2 and 5.7 $\mu$ by using terylene film.

In thermal expansion, the transformation point of glassy arsenic trisulfide is nearly 170°C. In order to study what process of transformation occurs in the glass, the quenching method was applied. Some pieces of annealed glass were experimentally quenched at 180, 174, 164 and 153°C. Thermal expansion was measured on these quenched glasses.

Because of their various controls of expansion by temperature, glassy transformation at 170°C has no connection with transformation at the same temperature in arsenic trisulfide.

The author wishes to express his thanks to Mr. S. Matsuzaki for valuable cooperation and to Maruzen Oil Co., Ltd. for their kindness in the measuring of transmittance in the infrared.

# *Surface Tension and Spinnability of Molten Poly-ε-capramide*

By Naoya OGATA

(Received August 13, 1959)

Surface tension of a liquid means the tension in the boundary between a liquid and a gas or the free energy of the surface. As surface tension tends to make the area of surface as small as possible, it is expected that the spinnability of a liquid would have relation with its surface tension and hence physical properties concerning its surface can be estimated. Surface tension of molten ε-caprolactam and poly-ε-capramide has been measured and their surface properties have been studied.

## Experimental

**Polymerization of ε-Caprolactam.** — ε-Caprolactam was polymerized at 257°C for 15 hr. in the presence of 5% of ε-aminocaproic acid and 2, 1 or 0.5 mol. % of benzoic acid. The degree of polymerization of polymers was estimated from the solution viscosity in *m*-cresol at 25°C by the following equation[1].

$$\bar{P}=127[\eta]^{1.435} \quad (1)$$

**Measurement of Surface Tension.** — Surface tension of molten ε-caprolactam or poly-ε-capramide was measured by the method of maximum bubble pressure[2]. When a capillary is immersed in a liquid and gas pressure is raised slowly, a bubble is formed at the tip of the capillary. If gas pressure is further raised, the bubble breaks away from the tip and the pressure decreases. Hence, the pressure passes through a maximum. When the main radius of curvature at the largest bubble is $R$ and the depth of the tip of the capillary is $h$, the maximum pressure is given by the following equation.

$$P=2\gamma/R+Dgh \quad (2)$$

where $\gamma$, $g$ and $D$ mean surface tension, gravity constant and density, respectively. If the radius of a capillary is narrow enough, $R$ can be approximated to the capillary radius $r$.

The tip of the capillary of 0.02~0.05 cm. radius was immersed in the melted substance at 1 cm. in depth and nitrogen gas was introduced slowly at the pressure rate of 0.1 cm. $H_2O$/min. and the maximum bubble pressure was measured.

**Measurement of Spinnability.**—The apparatus is shown in Fig. 1. A glass stick of radius of 0.2 cm. was immersed in molten poly-ε-capramide at 0.5 cm. in depth and was pulled up at the constant rate. The clutch was cut off immediately at the break of the thread and the length was measured.

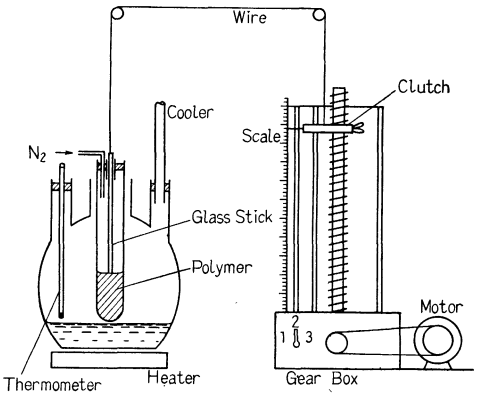

Fig. 1. Apparatus for the measurement of spinnability of poly-ε-capramide.

## Results

**Surface Tension of Molten ε-Caprolactam and Poly-ε-capramide.** — Surface tension values of molten ε-caprolactam and *N*-acetyl-ε-aminocaproic acid to nitrogen gas at various temperatues are shown in Fig. 2.

Surface tension values of poly-ε-capramide of various polymerization degrees and at various temperatures are shown in Figs. 3 and 4. The poly-ε-capramide

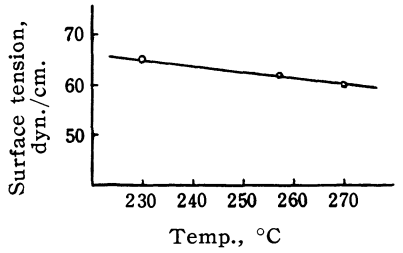

Fig. 4. Surface tension of poly-ε-capramide ($\bar{P}_n$=120) at various temperatures.

used was an equilibrium polymer containing about 10% of ε-caprolactam and its oligomers.

**Thread Length of Poly-ε-capramide.**—The thread lengths of poly-ε-capramide of various polymerization degrees at 230 or 257°C and at various pulling rates are shown in Fig. 5. The thread length of poly-ε-capramide ($\bar{P}$=120) at 257°C and at the pulling rate of 0.74 cm./sec. is proportional to the radius of a glass stick as shown in Fig. 6. Each polymer contained about 10% of ε-caprolactam and its oligomers.

## Discussion

Ramsay and Shields[3] found a linear relation between surface tension of a liquid and temperature as the following equation:

$$\gamma(M/D)^{2/3}=k(T_c-T-6) \qquad (3)$$

where $\gamma$ is surface tension, $M$ is molecular weight, $D$ is density, $T_c$ is critical temperature and $k$ is a constant characteristic for a liquid.

3) W. Ramsay and J. Shields, *Z. physik. Chem.*, **12**, 433 (1893).

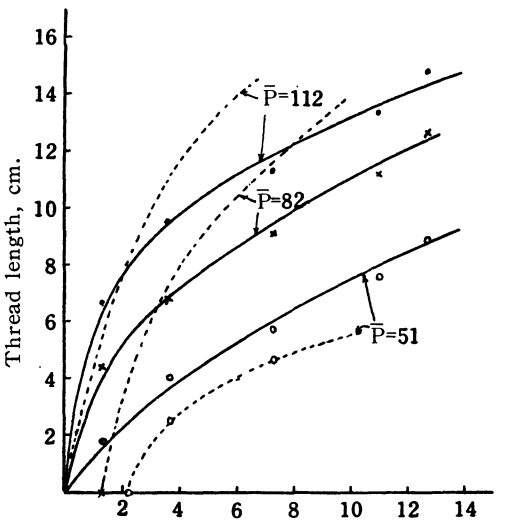

Fig. 5. Thread length at various pulling rates.
—— 230°C, ------ 257°C.

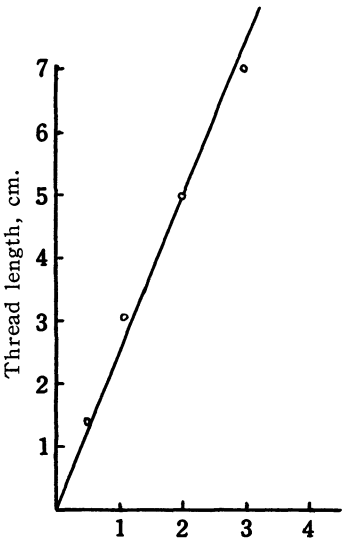

Fig. 6. The relation between thread length and radius of glass stick.
($\bar{P}$=120, $V$=0.74 cm./sec., $t$=257°C)

The value of $k$ for a normal liquid is usually about 2.12. The value of $k$ and the critical temperature of ε-caprolactam is estimated to be 2.77 and 463°C, respectively.

Surface tension of poly-ε-capramide increases as the degree of polymerization increases. When the logarithms of surface-tension $\gamma$ are plotted against the polymerization degree $\bar{P}$, a linear relation is

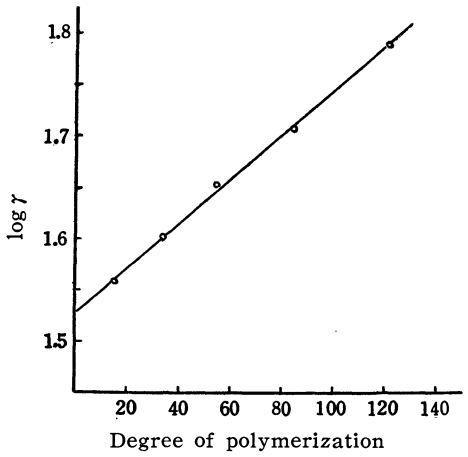

Fig. 7. Relation between $\log \gamma$ and $\bar{P}$.

obtained as shown in Fig. 7 and the following equation is obtained at 257°C.

$$\log \gamma = 0.0022\bar{P} + 1.53 \quad (5)$$

As the surface tension of poly-ε-capramide ($\bar{P}=120$) is nearly proportional to temperature from Fig. 4, the value of $d\gamma/dT$ is about −0.06 dyn./cm. deg. and that of *N*-acetyl-ε-aminocaproic acid is also −0.06 dyn./cm. deg. Therefore, the value of $d\gamma/dT$ of linear poly-ε-capramide is expected to be −0.06 dyn./cm. deg. independent of the polymerization degree, and the following equation is obtained, where $t$ is temperature in degrees centigrade.

$$\gamma = 10^{(0.0022\bar{P}+1.53)} + 0.06(257-t) \quad (6)$$

Surface tension of ε-aminocaproic acid at 252°C is estimated from Eq. 6 to be about 34 dyn./cm. This value is not consistent with the surface tension value of ε-caprolactam (18 dyn./cm.), but is nearly approximated to that of *N*-acetyl-ε-aminocaproic acid (32 dyn./cm.). Therefore, it is expected that the surface tension of ε-aminocaproic acid is about 16 dyn./cm. greater than that of ε-caprolactam.

Since surface tension means intermolecular forces among molecules, this result suggests that the intermolecular force of ε-aminocaproic acid is greater than that of ε-caprolactam.

The total surface energy $U$ is given[2] by

$$U = \gamma - T\partial\gamma/\partial T \quad (7)$$

The total surface energies of ε-caprolactam, *N*-acetyl-ε-aminocaproic acid and poly-ε-capramide are shown in Tables I and II.

The total surface energy of ε-aminocaproic acid is estimated to be about 66 erg/cm² from Table I and is 16 erg/cm² smaller than that of ε-caprolactam. This result is very interesting in relation to the exothermic reaction of the ε-caprolactam polymerization[4,5].

Table I. Total surface energy of ε-caprolactam, *N*-acetyl-ε-aminocaproic acid and poly-ε-capramide

| Sample | Temp. °C | γ(dyn./cm.) | ∂γ/∂T | U(erg/cm²) |
|---|---|---|---|---|
| ε-Caprolactam | 76 | 40 | −0.12 | 82 |
| | 100 | 37 | −0.12 | 82 |
| | 140 | 35 | −0.12 | 85 |
| | 208 | 25 | −0.12 | 83 |
| | 252 | 18 | −0.12 | 81 |
| Mean value | — | — | −0.12 | 82 |
| *N*-Acetyl-ε-aminocaproic acid | 116 | 40 | −0.06 | 63 |
| | 152 | 39 | −0.06 | 65 |
| | 205 | 35 | −0.06 | 64 |
| | 252 | 32 | −0.06 | 64 |
| Mean value | — | — | −0.06 | 64 |
| Poly-ε-capramide ($\bar{P}$=120) | 230 | 65 | −0.06 | 95 |
| | 257 | 62 | −0.06 | 94 |
| | 270 | 60 | −0.06 | 93 |
| Mean value | — | — | −0.06 | 94 |

Table II. Total surface energy of poly-ε-capramide

| $\bar{P}$ | γ(dyn./cm.) | U(erg/cm²) |
|---|---|---|
| 15 | 38 | 70 |
| 34 | 40 | 72 |
| 54 | 45 | 77 |
| 84 | 51 | 83 |
| 121 | 62 | 94 |

It is presumed that the increase in surface tension of poly-ε-capramide with the increase of its polymerization degree may be caused by the difference in thermal movement of macromolecules.

It is assumed that the thread of molten poly-ε-capramide may be broken at the point at which the surface energy reaches equilibrium with the friction energy of viscous liquid. Hirai[6] introduced the following equation in relation to surface tension $\gamma$ and thread length $L$, and ascertained this equation for the thread length of glycerine.

$$L = R_0 V\mu/\gamma \quad (8)$$

4) S. M. Skuratov et al., *Kolloid Zhur.*, **14**, 185 (1952); *Faserforsch. u. Textiltech.*, **4**, 390 (1953).
5) H. Yumoto, This Bulletin, **28**, 94 (1955).
6) N. Hirai, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **75**, 1019 (1954); *Chem. Abstr.*, **46**, 9357*h* (1955).

In this equation $R_0$ is the radius of a glass stick, $\mu$ is the viscosity and $V$ is the pulling rate. In case of poly-ε-capramide, $L$ is not proportional to $V$ as shown in Fig. 5. However, a linear relation is obtained by plotting $\log L$ against $\log V$, as shown in Fig. 8.

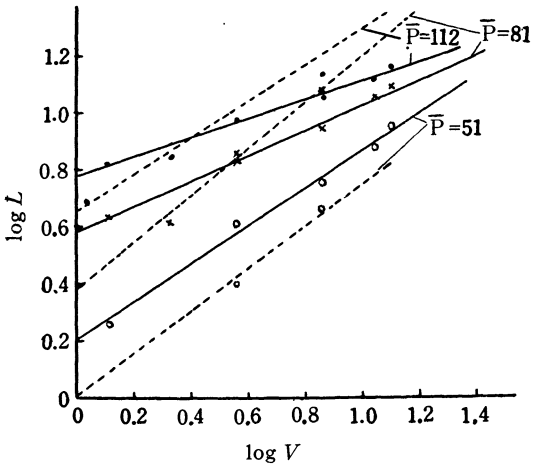

Fig. 8. Relation between $\log L$ and $\log V$.
—— 230°C, ------ 257°C.

Since $L$ was proportional to the radius $R_0$ of a glass stick, the following equation is given:

$$L=kR_0V^a \tag{9}$$

The values of $k$ and $a$ at various polymerization degrees and temperatures are shown in Table III, where $R_0$ and $V$ are given in cm. and cm./sec. units, respectively.

TABLE III. THE VALUES OF $k$ AND $a$ IN $L=kR_0V^a$

| Temp., °C | $\bar{P}$ | $k$ | $a$ |
|---|---|---|---|
| 230 | 51 | 8 | 0.6 |
| | 82 | 16 | 0.4 |
| | 112 | 30 | 0.4 |
| 257 | 51 | 5 | 0.7 |
| | 82 | 12 | 0.7 |
| | 112 | 23 | 0.6 |

The value of $a$ is almost invariable and its mean value is 0.5. Therefore, the thread length is proportional to the square root of the pulling rate.

The values of $\mu/\gamma$, which are shown in Table IV, were estimated from the following equation derived by K. Hoshino[7].

$$\log\mu=-7+2300/T+6.2([\eta]^{25°C}_{cresol})^{1/2} \tag{10}$$

7) K. Hoshino and S. Fujii, *Chem. High Polymers (Kobunshi Kagaku)*, **1**, 14 (1944); *Chem. Abstr.*, **44**, 5147*b* (1950).

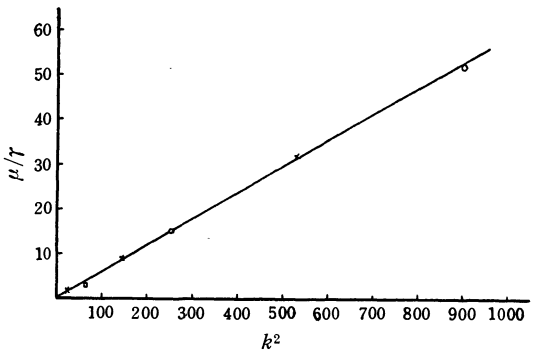

Fig. 9. The relation between $k^2$ and $\mu/\gamma$.

TABLE IV. THE VALUE OF $\mu/\gamma$

| Temp. °C | $\bar{P}$ | $[\eta]^{25°C}_{cresol}$ | $\mu$(poise) | $\mu/\gamma$ | $k^2$ |
|---|---|---|---|---|---|
| 230 | 51 | 0.53 | 123 | 3 | 64 |
| | 82 | 0.74 | 810 | 15 | 256 |
| | 112 | 0.92 | 3240 | 52 | 900 |
| 257 | 51 | 0.53 | 73 | 2 | 25 |
| | 82 | 0.74 | 480 | 9 | 144 |
| | 112 | 0.92 | 1900 | 32 | 529 |

When the value of $k^2$ is plotted against $\mu/\gamma$, a linear relation is obtained as shown in Fig. 9 and the following equation is given.

$$\mu/\gamma=0.059k^2 \tag{11}$$

From Eqs. 9 and 11, the thread length of poly-ε-capramide can be represented as follows:

$$L=4.13R_0(\mu V/\gamma)^{1/2} \tag{12}$$

It can be estimated from the above-mentioned results that the thread length of molten poly-ε-capramide of $\bar{P}=100\sim120$ at 257°C may be approximately 12 cm., when the polymer is spun at the rate of 400 m./min. from a nozzle of 0.02 cm. radius, and the fiber must be cooled within this length to obtain a continuous filament.

## Summary

Surface tension of molten ε-caprolactam and poly-ε-capramide has been measured by the method of maximum bubble pressure. Surface tension of ε-caprolactam at 252°C is 18 dyn./cm. and it is 16 dyn./cm. smaller than that of ε-aminocaproic acid (34 dyn./cm.). It is estimated from the Ramsay-Shields' equation that the critical temperature of ε-caprolactam is 463°C. Surface tension of poly-ε-capramide of the polymerization degree $\bar{P}$ is given by the following equation.

$$\gamma=10^{(0.0022\bar{P}+1.53)}+0.06(257-t)$$

The thread length of molten poly-ε-capramide has been measured by pulling up a glass stick and is represented by the following equation, where $L$ (cm.) is thread length, $R_0$ (cm.) radius of a glass stick, $\mu$ (poise) melt viscosity, $\gamma$ (dyn./cm.) surface tension and $V$ (cm./sec.) pulling rate:

$$L=4.13R_0(\mu V/\gamma)^{1/2}$$

The author wishes to thank Dr. K. Hoshino and Dr. H. Kobayashi who instructed him in this study and permitted the publication of these results. He also thanks Mr. M. Nakata who collaborated with him in experiments.

# *Phase Equilibrium on Liquidus Surface of the System $3CaO \cdot P_2O_5$-$CaO \cdot MgO \cdot 2SiO_2$-$MgO \cdot SiO_2$*

By Toshiyuki SATA

(Received August 15, 1959)

As a continuation of the author's preceding reports, which were on the phase relationship in the systems $3CaO \cdot P_2O_5$–$MgO \cdot SiO_2$–$SiO_2$[1] and $3CaO \cdot P_2O_5$–$CaO \cdot MgO \cdot 2SiO_2$–$SiO_2$[2], an equilibrium study on the system $3CaO \cdot P_2O_5$–$CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$, a side plane of a tetrahedron of a system $3CaO \cdot P_2O_5$–$CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$–$SiO_2$, was carried out by the usual quenching method. On the phase relationship of this 3-component system, no paper has ever been presented.

Of the three component system concerned, data of the two partial systems, $3CaO \cdot P_2O_5$–$CaO \cdot MgO \cdot 2SiO_2$ and $3CaO \cdot P_2O_5$–$MgO \cdot SiO_2$, were already given by the author's reports. Another partial system $CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$ was investigated by Bowen[3]. In his phase diagram, it is characterized that forsterite is a primary phase at 22~100% of $MgO \cdot SiO_2$. However, in the phase diagram published in 1952 by Atlas[4], who studied the matter by adding LiF, the primary phase may be a solid solution at overall range, which is decomposed to a clinoenstatite, diopside, protoenstatite or rhombic enstatite solid solution in a crystalline phase. In this report the author followed Bowen's diagram, and constructed the phase diagram on the liquidus surface of this system.

## Experimental

The nine compositions taken on the system $CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$ are listed in Table I. Then on the line joining these nine compositions with $3CaO \cdot P_2O_5$ point, thirty-two sample points were taken in the system $3CaO \cdot P_2O_5$–$CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$ and plotted in Fig. 1.

Powdered batches of these compositions, prepared by quenching into a glass after being kept at above their melting points, were again held at constant temperatures in a silicon carbide resister furnace and then quenched in water. Thenceforth the equilibrium phases found therein were determined by optical and X-ray examination. For measuring the temperature a thermocouple of platinum-platinum rhodium (10%) was used. Details of the experimental procedures are similar to those already described in the preceding report[1].

TABLE I. COMPOSITIONS OF SAMPLES TAKEN FROM THE SYSTEM $CaO \cdot MgO \cdot 2SiO_2$–$MgO \cdot SiO_2$

| No. | $CaO \cdot MgO \cdot 2SiO_2$ | $MgO \cdot SiO_2$ |
|---|---|---|

## Results

Data on the quenching runs for this 3-component system are listed in Table II,

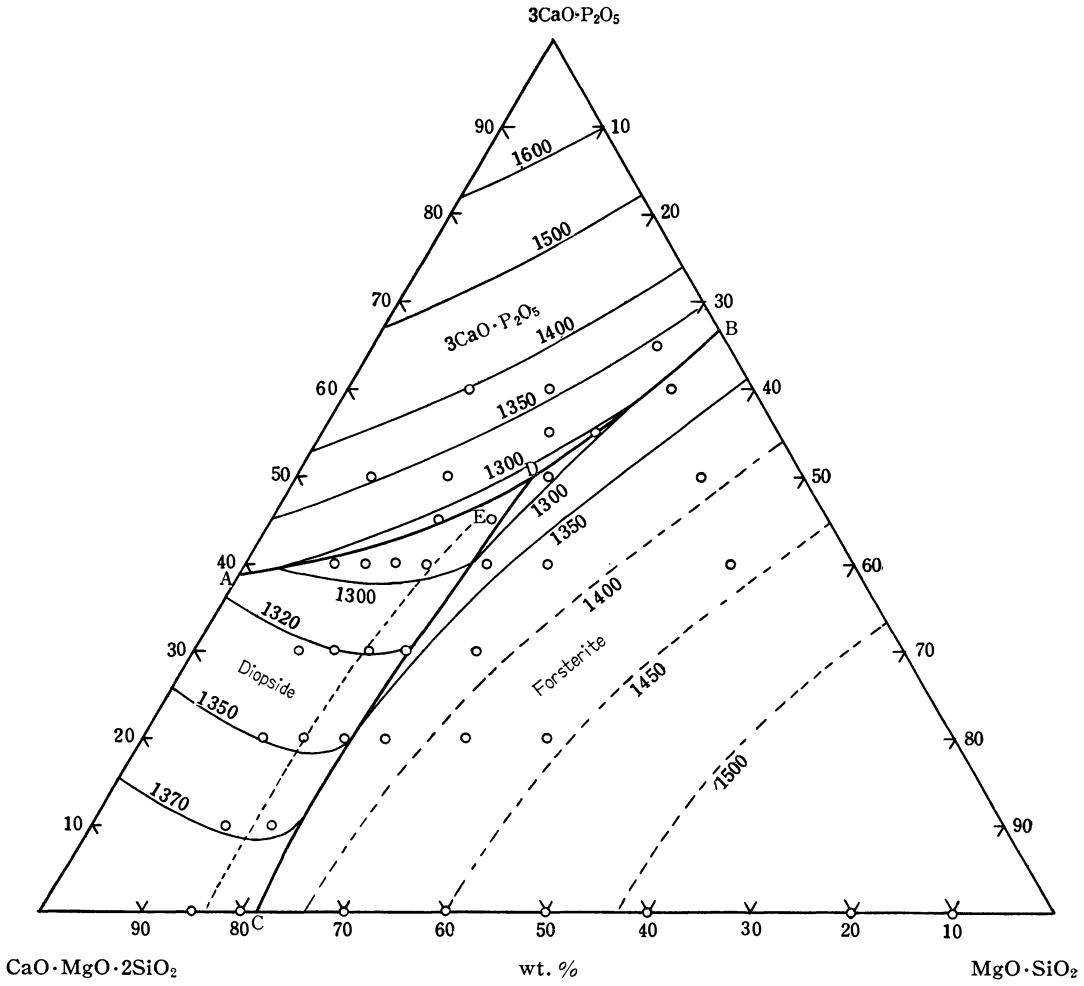

Fig. 1. The system $3CaO \cdot P_2O_5$-$CaO \cdot MgO \cdot 2SiO_2$-$MgO \cdot SiO_2$.
(A: 1314°C, B: 1308°C, C: 1390°C)

from which the equilibrium diagram on the liquidus surface was constructed as shown in Fig. 1. Primary crystals in this system are tricalcium phosphate ($\alpha$ or $\beta$), diopside and forsterite, respectively, and forsterite occupies a wide field. Accordingly it is found that this system is not a ternary one.

A lower liquidus temperature range is located in the center of this triangle, its minimum temperature being 1277±5°C. A temperature minimum at 1389°C in the system $CaO \cdot MgO \cdot 2SiO_2$-$MgO \cdot SiO_2$ falls slowly toward the neighborhood of this lowest point as shown by a dotted line. However, it can not be decided in this report whether this valley of temperature attains to this point or not. Clinoenstatite does not appear as a primary crystal on the liquidus surface. Hence a decomposition of pyroxene solid solution to colinoenstatite may occur under the liquidus.

## Summary

The phase relationship on the liquidus surface of the system $3CaO \cdot P_2O_5$-$CaO \cdot MgO \cdot 2SiO_2$-$MgO \cdot SiO_2$ was investigated by the usual quenching method. The three primary crystals are $\alpha$- or $\beta$-tricalcium phosphate, diopside and forsterite, and the range of the lowest temperature is located at the center of this triangle (1277°C). From these results, it is found that this system should be considered as a partial system in the 4-component system $3CaO \cdot P_2O_5$-$CaO \cdot MgO \cdot 2SiO_2$-$2MgO \cdot SiO_2$-$SiO_2$.

# *Ultraviolet Absorption Spectra of o-, m- and p-Dinitrobenzene*

By Takehiro ABE

(Received May 15, 1959)

Introduction of a substituent group for hydrogen in a benzene nucleus has been considered to shift in general the spectrum of the original benzene derivative to longer wavelengths. In the previous papers[1,2], however, the author found that absorption maximum bands of *m*-dinitrobenzene, 1,3,5-trinitrobenzene and 2,4,6-trinitrotoluene shifted to the blue as compared with the intense 260 m$\mu$ band of nitrobenzene.

In the present paper, an attempt has been made to investigate the influence of the introduction of one more nitro group in the ortho-, meta-, or para-position upon the spectrum of nitrobenzene.

## Experimental

**Materials.**—*o*-Dinitrobenzene, Tokyo Kasei Co. guaranteed reagent, was used directly; m.p. 118.1°C (lit. 118°C). Commercial pure *m*-dinitrobenzene was recrystallized three times from ethanol; m.p. 90.4°C (lit. 90°C). *p*-Dinitrobenzene, Tokyo Kasei Co. guaranteed reagent, was recrystallized once from methanol; m.p. 174.7°C (lit. 174°C). Commercial guaranteed ethanol was fractionally distilled after the usual treatment.

**Spectra.**—The spectra of the dinitrobenzenes in ethanol were measured with a Hitachi quartz spectrophotometer, Model EPU-2 at room temperature. Path length of absorption cells was 1 cm.

## Results and Discussion

As indicated in Fig. 1 and Table I, the maximum absorption band of *m*-dinitrobenzene is at a shorter wavelength and has a greater molar extinction coefficient than that of nitrobenzene, while the

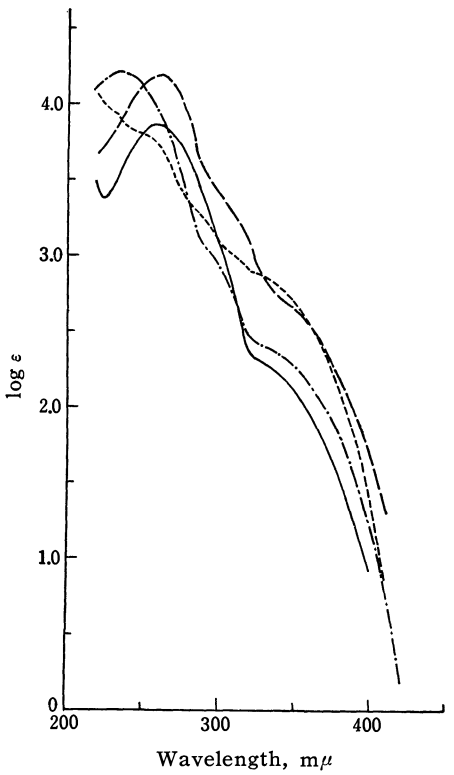

Fig. 1. Absorption spectra of nitrobenzene (——), *o*-dinitrobenzene (------), *m*-dinitrobenzene (—·—), and *p*-dinitrobenzene (— —), all in ethanol.

TABLE I. VALUES OF THE ABSORPTION MAXIMA OF DINITROBENZENES IN ETHANOL

| | $\lambda_{max}$, m$\mu$ | $\varepsilon$ |
|---|---|---|
| Nitrobenzene | 260 | 8140 |
| *o*-Dinitrobenzene | — | — |
| *m*-Dinitrobenzene | 233 | 17200 |
| *p*-Dinitrobenzene | 261 | 15600 |

1) T. Abe, This Bulletin, **31**, 904 (1958).
2) T. Abe, ibid., **32**, 339 (1959).

absorption maximum of *p*-dinitrobenzene gives a more intense absorption band at the same region as the 260 m$\mu$ band of nitrobenzene. The 260 m$\mu$ band of nitrobenzene has been interpreted by Doub and Vandenbelt[3] and later by Wenzel[4] to correspond to the 200 m$\mu$ band of benzene which has the same intensity, but has been interpreted by Nagakura and Tanaka[5] in terms of the intramolecular charge transfer involving an excitation of a bonding electron of the highest occupied energy-level of benzene to the vacant energy-level of the nitro group.

From the concept of the intramolecular charge transfer, the maximum absorption bands of *m*- and *p*-dinitrobenzene will be discussed by considering interactions between the highest occupied energy-levels of nitrobenzene and the vacant level of the nitro group on substituting the second nitro group in the meta- or para-carbon atom of nitrobenzene. According to the energy level diagrams given by Nagakura and Tanaka[6,7], the vacant energy-level ($V_{NO_2}=-6.85$ eV.) of the nitro group is lower than the lowest vacant energy-level ($V_N=-4.65$ eV.) of nitrobenzene, to which the $V_{NO_2}$ mainly contributes. On introducing one more nitro group in nitrobenzene, the energy-levels of nitrobenzene, indicated in Fig. 2, may be approximately affected by only the vacant level ($V_{NO_2}$) of the nitro group with such interaction as was given by Nagakura and Tanaka[5], because interactions with other occupied levels of the nitro group, which are remote or of different symmetry, are negligibly small. According to Nagakura and Tanaka's theory, as a result of the interaction with the $V_{NO_2}$, an energy-level ($E=H_{N1}$ or $H_{N2}$) of nitrobenzene shifts below by the following magnitude:

$$\Delta E=1/2[(E-V_{NO_2})+\{(E-V_{NO_2})^2+4C_N^2C_{NO_2}^2\beta^2\}^{1/2}] \quad (1)$$

Here $C_N$ and $C_{NO_2}$ are a coefficient of an atomic orbital of a carbon atom in the molecular orbital of $E$ and a coefficient of an atomic orbital of the nitrogen atom in the molecular orbital of $V_{NO_2}$, respectively, where the carbon atom and the nitrogen one are joined together. The $\beta$ is the resonance integral between the atomic orbital of the carbon atom and the orbital of the nitrogen atom. It is obvious that the $\Delta E$ increases as $C_N$ increases or as $(E-V_{NO_2})$ decreases. On the other hand, the $V_{NO_2}$ of the nitro group similarly interacts with the levels of nitrobenzene, especially with the $H_{N1}$, $H_{N2}$ and the $V_N$ that is nearest to the $V_{NO_2}$. When the nitro group is substituted in the meta-position of nitrobenzene, two intense absorption bands of intramolecular charge transfer can be expected to appear at longer wavelengths for *m*-dinitrobenzene owing to transitions involving excitations of bonding electrons of the occupied levels ($H_{m1}$ and $H_{m2}$) to the lowest vacant level ($V_m$), because the $V_{NO_2}$ interacts with both the levels of $H_{N1}$ and $H_{N2}$, as in the case of some disubstituted benzenes[6]. On substituting the nitro group in the para-position of nitrobenzene, a transition of a bonding electron in $H_{p2}$ to the lowest vacant level ($V_p$) can be predicted to show only an intense band of intramolecular charge transfer at a longer wavelength, the $B_1$-level ($H_{N1}$) in nitrobenzene being intact. The blue shift of 260 m$\mu$ band of nitrobenzene for

*m*-dinitrobenzene means the great interaction of $V_{NO_2}$ with $H_{m_1}$ and $H_{m_2}$. Consequently, these levels will shift in nitrobenzene as indicated Fig. 2. In this case, the occupied $B_1$-level ($H_{N_1}$) as well as the $A_1$-level ($H_{N_2}$) in nitrobenzene may be predicted to become low in *m*-dinitrobenzene, because the coefficient of the atomic orbital belonging to the meta-carbon atom in the molecular orbital of the occupied $B_1$-level ($H_{N_1}$) of nitrobenzene is greater than the corresponding coefficient in the $A_1$-level, although the $H_{N_1}$ is slightly higher than the $H_{N_2}$. In the molecular orbital of the occupied $A_1$-level ($H_{N_2}$) of nitrobenzene, the coefficient of the atomic orbital for the para-carbon atom is apparently greater than that for the meta-carbon atom. Accordingly, the $A_1$-level ($H_{N_2}$) of nitrobenzene can be considered to become lower in *p*-dinitrobenzene than in *m*-dinitrobenzene, as given from Eq. 1. The maximum absorption band of *p*-dinitrobenzene lies at the wavelength close to that of nitrobenzene. From these it may be expected that the $V_{NO_2}$-level shifts below to the same extent, as compared with the $H_{N_2}$, in *p*-dinitrobenzene, owing to the great interaction between the $V_{NO_2}$ and the $V_N$. In comparison with the case of *m*-dinitrobenzene, it is known that the coefficient of the atomic orbital of the para-carbon atom is probably much greater than that of the meta-carbon atom in the molecular orbital of the vacant $A_1$-level ($V_N$) of nitrobenzene. From the above discussion, the maximum absorption bands of dinitrobenzenes may be interpreted to be owing to the electronic transitions illustrated in Fig. 2.

An ortho-substituted benzene usually shows a spectrum resembling that of a meta-substituted benzene[6], while the absorption curve of *o*-dinitrobenzene is different from that of *m*-dinitrobenzene, giving only shoulders at 250, 290, 310 and 360 m$\mu$. This may be understood in terms of steric hindrance by the adjacent large nitro groups of *o*-dinitrobenzene. This steric hindrance may interfere with a coplanar arrangement of the nitro groups with benzene nucleus.

The weak shoulder of nitrobenzene at 290 m$\mu$, which has been interpreted by Nagakura and Tanaka[6,8] to be related to the 260 m$\mu$ band of benzene, becomes more distinct in *m*- and *p*-dinitrobenzene.

The molar extinction coefficients of the 360 m$\mu$ bands for *o*- and *p*-dinitrobenzene are greater than those of *m*-dinitrobenzene, which are slightly larger than the corresponding molar extinction coefficient for nitrobenzene. The 360 m$\mu$ band of nitrobenzene has been interpreted by Wenzel[4] to be due to the nitro group.

## Summary

In ethanol, *m*-dinitrobenzene shows the maximum absorption band at shorter wavelengths than nitrobenzene, while *p*-dinitrobenzene gives the absorption maximum at the wavelength near to that of nitrobenzene. These bands have briefly been discussed from the concept of the intramolecular charge transfer. The absorption curve of *o*-dinitrobenzene, indicating no absorption maximum but shoulders, are different from those of the other dinitrobenzenes, probably owing to steric hindrance by the adjacent large nitro groups.

The author is particulary indebted to Professor Yōkan Nomura for his suggestion and encouragement.

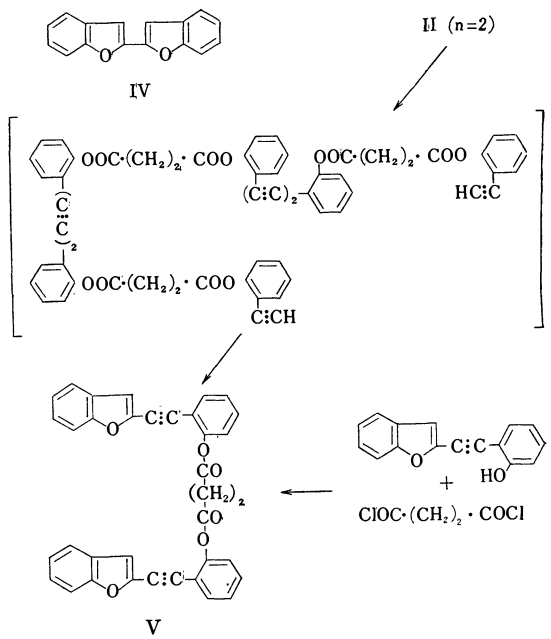
# *Cyclic Acetylenes. I. Cyclic Derivatives of o,o'-Dihydroxydiphenyldiacetylene. An Example of a Strained Cyclic Diacetylene**

By Fumio TODA and Masazumi NAKAGAWA

(Received July 21, 1959)



It is of interest to compare the physical and chemical properties of a strained acetylenic compound with that of a strainless analogue in relation to the reactive nature of benzyne intermediate[1]. Along with this line the authors have studied the synthesis of a cyclic diacetylene in which the structure of the molecule forces to bend the diacetylenic linkage. Recently a fairly large variety of cyclic polyacetylenes have been synthesized by several investigators[2], but most of these macrocycles seem to be strainless with regard to the triple bond.

A series of cyclic derivatives of *o,o'*-dihydroxydiphenyldiacetylene have been synthesized according to the following scheme. *o*-Hydroxyphenylacetylene (I)[3] was converted into the polymethylene dicarboxylate (II) by the reaction with the corresponding diacid dichloride in alkaline media. By oxidative coupling of II ($n$=2, 3, 4, 5, 7 and 8) according to the procedure of Eglinton[2] the authors have obtained $III_a$, $III_b$, $III_c$, $III_d$ and $III_{d'}$ in 20, 40, 21 and 7.5% ($III_d$+$III_{d'}$) yield, respectively. Two isomers were found in the case of $n$=7. The low-melting isomer ($III_d$, m. p. 111°C) completely changed to the high-melting isomer ($III_{d'}$, m. p. 125~127°C) on standing at room temperature for two weeks.

The structures of compounds III were inferred from analyses, molecular weight determinations, ultraviolet and infrared spectroscopy. The cyclic nature of III was also confirmed by the absence of free ethynyl absorption in infrared spectra (ca. 3300 $cm^{-1}$) and by titration against silver nitrate.

In the case of $n$=3, 2, 2'-dibenzofuranyl (IV)[4] was isolated in 25% yield together with $III_a$. IV was also obtained from the products of the coupling reaction of II ($n$=2) in 57% yield together with a small amount of compound V. The ultraviolet spectrum of V closely resembles that of 2-(2'-benzoyloxyphenylethynyl)-benzofurane[4] as illustrated in Fig. 1. The structure of V was confirmed by the

----: V

The mechanism of the formation of IV is not yet clear, but it may be formed from highly strained III cleaving the ester linkages simultaneously accompanying the benzofurane ring formation. It has been reported by the present authors that IV is formed in a quantitative yield from *o*, *o'*-dihydroxydiphenyldiacetylene on treatment with alkali[4]. IV and adipic acid are formed on the alkaline hydrolysis of $III_b$, but the formation of IV from *o*, *o'*-dihydroxydiphenyldiacetylene under the condition of Eglinton's oxidative coupling was not observed. Therefore, the simple interpretation such as the intramolecular cyclization to IV of *o*, *o'*-dihydroxydiphenyldiacetylene which is formed by the ring fission of the cyclic diyne is not acceptable as the mechanism of the formation of IV under the condition of the coupling reaction. Also the formation of V may be attributed to the fission of the ester linkages presumably in the course of cyclic trimerization of II ($n=2$).

The attempt to prepare III ($n=8$) have failed. In this case the only identified product was VI, and the formation of VI is also probably associated with the fission of the ester linkages during the course of cyclic dimerization of II ($n=8$).

VI

The most striking property of $III_a$ is its high sensitivity to light in the solid state making a sharp contrast to the photostable nature of $III_b$, $III_c$, $III_d$ and $III_{d'}$. The surface of the colorless crystals of $III_a$ was rapidly coated with red colored, insoluble and high melting point material when the solid was exposed to a diffused light in the laboratory. But the solution of $III_a$ was found to be fairly stable. These properties are closely related to those of some polyacetylene compounds[5].

Examination of the scale models of III indicates that $III_b$ is a rigid and planar molecule with the two phenyl groups held in the same plane. On the other hand, the phenyl groups in $III_c$ are not readily able to become coplanar on account of the bridging chain. The model of $III_a$ clearly shows that the diacetylenic linkage is forced to bend owing to the short methylene chain holding its phenyl groups in a coplanar position. The anomalous photosensitivity of $III_a$ may be attributed therefore to the bending of the diacetylenic bond. It has already been suggested by Bohlmann that the stabilization of a certain polyacetylenic compound bearing two bulky terminal groups is associated with the steric effect of the bulky groups retarding the formation of cross linkings[6]. The diacetylenic linkage in $III_a$ seems to be more exposed to the outer environment of the molecule on account of its bending as compared with that linkage of the corresponding less strained cyclic diynes. Therefore the intermolecular approach to form cross linkings which is facilitated

by the presence of the distorted diacetylenic bond is, though it is not decisive, a possible cause of the unstable nature of $III_a$.

The catalytic reduction of 2,2′-diacetoxydiphenyldiacetylene (VII), $III_a$ and $III_b$ were carried out using a palladium on charcoal catalyst. It was hoped that $III_a$ might exhibit some abnormalities in the course of hydrogenation resulting from the ring strain, but the experimental results indicated no marked difference in the rates of hydrogenation as illustrated in Fig. 2. The fact that the hydrogenation of $III_a$ stopped after absorption of ca. 90% of theoretical amount of hydrogen is probably ascribed to the formation of minor amount of the above mentioned photopolymer during the course of reduction.

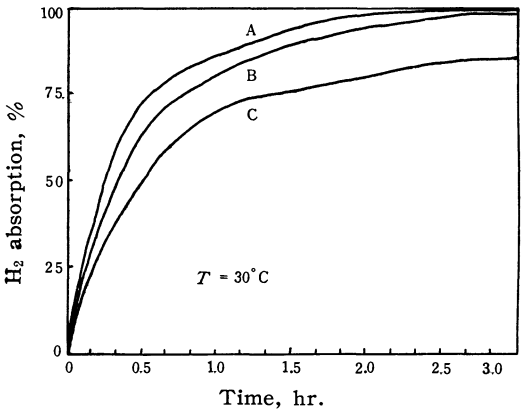

Fig. 2. The rates of hydrogenation of VII, $III_a$ and $III_b$.
A: VII B: $III_b$ C: $III_a$

These situations seem to be reflected in the ultraviolet spectra of $III_a$, $III_b$, $III_c$ and $III_d$. VII was used as a comparison for an open chain analogue of III. As indicated in Table I and Fig. 3, the ultraviolet spectra of these diacetylene are closely related and are different only in the absorption intensities without any significant wavelength displacements. The extinction coefficients $\varepsilon$ of $\lambda_{max}$ of the long wavelength region (290~340 m$\mu$) of $III_b$ are larger than that of VII, but the $\varepsilon$ values of $III_a$, $III_c$, $III_d$ and $III_{d'}$ in the same region are smaller than that of VII.

TABLE I

| Compound | Absorption | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| VII | | | | 250 (479) | 260 (483) | 275 (240) | 291 (337) | 310 (445) | 331 (398) | |

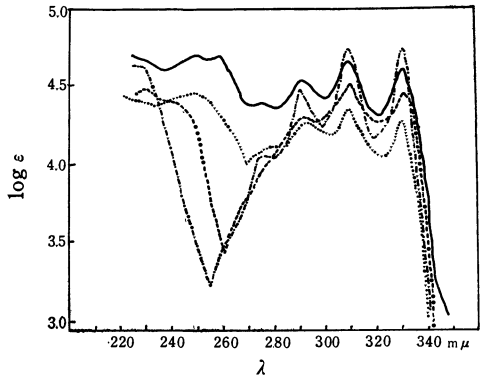
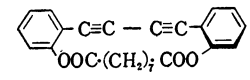
The figures indicate the $\lambda_{max}$ in m$\mu$.
The figures in parentheses are $\varepsilon_{max} \times 10^{-2}$.
Asterisk indicates the $\varepsilon$ value of per dyne unit.
The bold figures indicate shoulders.
All spectra were measured in 95% ethanol.





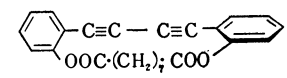


Fig. 3. The ultraviolet spectra of VII and the cyclic diacetylenes ($III_a$, $III_b$ and $III_c$).
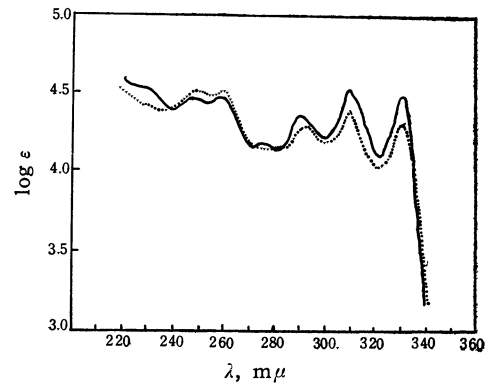
——: VII -----: $III_a$
-·-·-: $III_b$ ·····: $III_c$

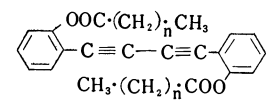
The decrease of the ε values are in the sequence of $III_b > VII > III_a > III_c$ indicating the important role of the uniplanar phenyl groups in affecting the intensity of absorption. This fact suggests that the spectra associate with transitions between non-planar ground states and near planar excited states[7]. The largest ε values of $III_b$ in this region may be due to the rigid and planar structure of the molecule having maximum conjugation between the two phenyl groups and the acetylenic bonds. On the other hand, the smaller ε values of $III_a$ as compared with VII may be attributed to the diminished probability of excitation of the molecule to an excitation state in which the diacetylenic linkage should take a linear configuration. The low intensity of absorption of $III_c$, $III_d$ and $III_{d'}$ may also be regarded as the twisted position of the phenyl groups in these molecules affecting to reduce the probability to a uniplanar state of excitation.

The ultraviolet spectra of $III_d$ and $III_{d'}$ are different as shown in Table I and Fig. 4. The absorption intensity in the long wavelength region of $III_{d'}$ is much lower than that of $III_d$ indicating the presence of a larger degree of twist of the phenyl groups in $III_{d'}$ as illustrated in the following formulae. Examination of the scale models of $III_d$ and $III_{d'}$ indicates that the methylene chain in $III_d$ is much more crowded than in $III_{d'}$. Therefore, the relief of compression energy of methylene chain seems to be responsible to the

$III_d$

$III_{d'}$





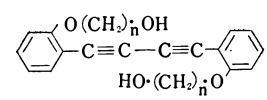


Fig. 4. The ultraviolet spectra of the isomeric cyclic diacetylene ($III_d$ and $III_{d'}$).
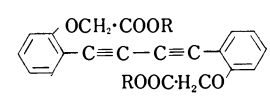
——: $III_d$ ·····: $III_{d'}$

stabilization of $III_d$ to $III_{d'}$. The isolation of $III_d$ and $III_{d'}$ may be regarded as the first example of the presence of a new type of conformational isomers in which the diacetylenic linkage behaves as pivot bond.



The low absorption intensity in the ultraviolet spectrum of VI is also explained by the hypochromic effect of non-coplanar

VII : n=0

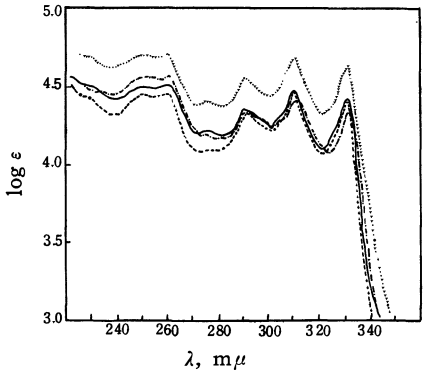

Fig. 5. The ultraviolet spectra of 2,2'-diacyloxydiphenyldiacetylenes.
·····: VII ——: $VIII_a$
----: $VIII_b$ -·-·: VI

phenyl groups. Further examples of the effect are obtained in the series of VIII, IX and X. As illustrated in Fig. 5 and Table I, the increase in the number of methylene group in VIII resulted in the decrease of the intensity of absorption. The steric effect of the acyl group affecting the hypochromic shift of the ultraviolet spectra of VIII seems to show a tendency approaching to a definite value when the steric requirement of the group reaches a certain degree, namely, the differences of $\varepsilon$ values between VII and $VIII_a$, $VIII_b$ and the differences between VII and VI are quite large, while the difference between $VIII_a$ and $VIII_b$ and that of VI and $VIII_a$, $VIII_b$ are relatively small.

The same trend is also observed in the case of $IX_a$, $IX_b$, $X_a$ and $X_b$ as indicated in Figs. 6 and 7 and in Table I.

The characteristic feature in the ultraviolet spectra of $III_a$ and $III_b$ are the presence of a sharp and intense $\lambda_{min}$ at ca. 260 mμ, the $\varepsilon$ values are only one-

tenth of the corresponding $\varepsilon$ of $III_c$ and $III_d$. The proximity effect of *o,o'*-bridging chain which is held closely parallel with the diacetylenic linkage may be a possible explanation of this fact, but it is premature to deduce a conclusion from these few examples.

Further studies in the same direction are now in progress.

## Experimental**

**General Procedure of the Preparation of Di-*o*-ethynyl-phenyl Polymethylene Dioate (II, $n=2$, 3, 4, 5, 7 and 8).**—Polymethylene dioic acid chloride (2 mol.) was added to the solution of *o*-hydroxy-phenylacetylene[4] (I, 1 mol.) in 10% aqueous solution of potassium hydroxide (7 equiv.). The mixture was shaken under ice cooling. The oily material separated was extracted with ether, washed with aqueous potassium hydroxide and water successively. The colorless viscous oil obtained on evaporating the solvent was used without further purification. For example, in the case of $n=7$, azelaic acid chloride (9.0 g., 0.04 mol.) was added in one portion to the solution of I (2.4 g., 0.02 mol.) in 10% aqueous solution of potassium hydroxide (7.8 g., 0.14 mol.), and the mixture was shaken for 1 hr. The reaction mixture was extracted with ether, washed with aqueous potassium hydroxide and water. The ether extract was dried over anhydrous magnesium sulfate. A colorless oil was obtained by the evaporation of the solvent (3.3 g., 85%). The crude II [$n=7$, I. R. max., 3260 (-C≡CH), 2860, 2920 ($-CH_2-$), 1762 $cm^{-1}$ (ester)] gave yellow cuprous acetylide by Ilosvay's reagent, and gave white silver salt by an alcoholic silver nitrate solution.

**Oxidative Coupling of Di-*o*-ethynylphenyl Adipate ($n=4$).** — The mixture of II ($n=4$, 1.5 g.), cupric

** Not all melting points are corrected. Infrared spectra were measured using liquid film or nujol mull method.

acetate monohydrate (15 g.) and pyridine (150 g.) was stirred for 4 hr. at 55°C. The stirring was continued for additional 1 hr. at room temperature. Most of the pyridine was removed from the reaction mixture under reduced pressure. Water (1000 ml.) was added to the residue and extracted with ether (1000 ml.). The ether extract was washed with aqueous cupric acetate and water, successively. The ethereal solution was dried over anhydrous magnesium sulfate. The solvent was removed and the residual solid was recrystallized from ethanol giving $III_b$ (0.6 g., 40%) as colorless needles, m. p. 123.5°C.

*Anal.* Found: C, 76.83; H, 4.54; mol. wt. (Rast), 325. Calcd. for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%; mol. wt., 344.

I. R. max., 1758 $cm^{-1}$ (ester).

$III_b$ gave no precipitation with alcohlic silver nitrate solution.

**Hydrolysis of $III_b$.** — $III_b$ (0.1 g.) was dissolved in an aqueous alcoholic solution of potassium hydroxide (ethanol 15 ml., water 2 ml. and potassium hydroxide 0.3 g.). The solution was refluxed for 3 hr. on a boiling water bath. The crystals were recrystallized from ethanol yielding colorless needles, m. p. 194.5~195.5°C which showed no depression of the mixed melting point with an authentic sample of 2,2'-dibenzofuranyl (IV)[4]. The filtrate was washed with ether and the aqueous layer was acidified with 2 N hydrochloric acid, extracted with ether. Treatment of the ether extract gave adipic acid, m. p. 148~150°C. The mixed melting point with pure adipic acid showed no depression.

**Oxidative Coupling of Di-*o*-ethynylphenyl Glutarate (II, $n=3$).** — II ($n=3$, 2.5 g.) was mixed with cupric acetate monohydrate (20 g.) and pyridine (200 g.). The mixture was agitated for 4 hr. at 55°C. The insoluble precipitate was removed from the reaction mixture by filtration and was washed with ether. The filtrate was distilled under reduced pressure to remove pyridine. The residue was extracted with ether (600 ml.). The ether extract and the ethereal washing was combined and washed with a saturated aqueous solution of cupric acetate and water. The ether solution was dried over anhydrous magnesium sulfate and concentrated to 100 ml. The crystals deposited at this stage were filtered (m. p. 194.5~195.5°C, 0.2 g.). The crystals were identified as 2,2'-dibenzofuranyl (IV) by the mixed melting point determination. The solvent was removed from the filtrate and the residue was recrystallized from ethanol employing active charcoal, giving colorless needles mixed with hexagonal plates. Further recrystallization of the mixed crystals from ethanol (50 ml.) gave 0.2 g. of IV. The total yield of IV was found as 0.4 g. (25%). Slightly impure $III_a$ was obtained as hexagonal plates (m. p. 133~134°C, 0.5 g., 20%) on standing the alcoholic filtrate. Recrystallization of this material gave pure $III_a$, m. p. 135~136°C.

*Anal.* Found: C, 76.33; H, 4.08; mol. wt. (Rast), 350. Calcd. for $C_{21}H_{14}O_4$: C, 76.35; H, 4.27%; mol. wt., 330.

I. R. max., 1755 $cm^{-1}$.

The surface of the crystals of $III_a$ changed to red on exposure to a diffused light in the laboratory. An amorphous, high melting material remained when the colored crystals were dissolved in ethanol.

**Oxidative Coupling of Di-*o*-ethynylphenyl Pimelate (II, $n=5$).** — II ($n=5$, 1.4 g.) was oxidized with cupric acetate monohydrate (1.5 g.) in pyridine (150 g.) at 55°C. After 3 hr., the reaction mixture was treated similarly as described above yielding a viscous oil (1.3 g.). The mixture of the oil with methanol (2 ml.) gradually solidified on standing. Repeated recrystallization from methanol using active charcoal gave $III_c$ as colorless needles, m. p. 120.5~121.5°C, 0.3 g (21%).

*Anal.* Found: C, 76.94; H, 5.06; mol. wt. (Rast), 364. Calcd. for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%; mol. wt., 358.

I. R. max., 1760 $cm^{-1}$.

$III_c$ gave no precipitation with alcoholic silver nitrate.

***o,o'*-Diacetoxydiphenyldiacetylene (VII).** — Acetic anhydride (2.0 g.) was introduced in one portion to the solution of *o,o'*-dihydroxydiphenyldiacetylene (0.4 g.) in aqueous potassium hydroxide (water 40 ml., potassium hydroxide 1.4 g.). The mixture was shaken under ice cooling. The solid deposited was collected by filtration and recrystallized from ethanol yielding VII as colorless needles, m. p. 134°C.

*Anal.* Found: C, 75.33; H, 4.31. Calcd. for $C_{20}H_{14}O_4$: C, 75.46; H, 4.43%.

I. R. max., 1755 $cm^{-1}$ (ester).

**Oxidative Coupling of Di-*o*-ethynylphenyl Succinate (II, $n=2$).** — The mixture of II ($n=2$, 2.5 g.) was stirred for 3 hr. at 55°C and the stirring was continued further 30 min. at room temperature. The most of pyridine was removed under reduced pressure. Water was added to the residue and the mixture was extracted with ether (1000 ml.). The extract was washed with saturated solution of cupric acetate and water, successively. The dried ether extract was reduced to 100 ml. and the needle-like crystals deposited (0.4 g., m. p. 194.5~195.5°C) were collected by filtration. This was identified as IV by mixed melting point determination. The solvent was removed from the filtrate resulting in a mixture of viscous oil and crystals. The crystals separated by filtration were washed with hot ethanol, giving IV (0.7 g.). The recrystallization of the combined IV from benzene using charcoal, yielded 1.0 g. (57%) of IV. The oily filtrate gradually solidified on standing. The solid was treated with ethanol and charcoal to result in V, colorless needles, m. p. 157.5~158.5°C, 20 mg. (ca. 1%).

*Anal.* Found: C, 78.23; H, 4.09; mol. wt. (Rast), 517. Calcd. for $C_{36}H_{22}O_6$: C, 78.54; H, 4.03%; mol. wt., 550.

I. R. max., 1755 $cm^{-1}$ (ester).

V gave a negative test against alcoholic silver nitrate.

**Synthesis of Di-2-(2'-benzofuranylethynyl)-phenyl Succinate (V).** — 2-(2'-Hydroxyphenylethynyl)-benzofurane[4] (50 mg.) was dissolved in the solution of potassium hydroxide (0.35 g.) in water (10 ml.). Succinoyl chloride (0.31 g.) was added in one portion to the alkaline solution and was shaken to result in a crystalline solid. The solid was collected by filtration, washed with water and alcohol. Recrystallization from ethanol gave colorless needles, m. p. 157.5~158.5°C, 30 mg. (51%). The mixed melting point with V, the product of the oxidative coupling of II ($n$=2), showed no depression. The infrared spectra of these two substances were found as identical over the entire region of wavelength.

**Oxidative Coupling of Di-*o*-ethynylphenyl Nonanedioate (II, $n$=7).** — The mixture of II ($n$=7, 2.0 g.), cupric acetate monohydrate (15 g.) and pyridine (150 g.) was stirred for 3.5 hr. at 55°C. Pyridine was removed under reduced pressure. Water (1000 ml.) was added to the residue and the mixture was extracted with ether (1000 ml.). The ethereal layer was washed with saturated solution of cupric acetate and water, successively, and dried over anhydrous magnesium sulfate. A viscous oil (0.5 g.) obtained by removing the solvent was mixed with ethanol (2.0 ml.). The mixture was kept to result crystallization. The crystals were collected by filtration (filtrate A). The crystals were recrystallized from ethanol and separated by filtration (filtrate B). Further recrystallization from ethanol gave $III_{d'}$ as colorless needles, m. p. 125~127°C, 50 mg. (2.5%).

*Anal.* Found: C, 77.20; H, 5.73. Calcd. for $C_{25}H_{22}O_4$: C, 77.70; H, 5 74%.

The crude crystals obtained by the concentration of the combined filtrates A and B were treated with ethanol and charcoal and recrystallized from ethanol, resulting in $III_d$ as colorless needles, m. p. 111°C, 100 mg. (5%).

*Anal.* Found: C, 77.56; H, 5.68; mol. wt. (Rast), 399. Calcd. for $C_{25}H_{22}O_4$: C, 77.70; H, 5.74% mol. wt., 386.

After being kept for two weeks at room temperature the melting point of $III_d$ raised to 125~127°C and the mixed melting point of the material with $III_{d'}$ showed no depression. The ultraviolet spectra of $III_d$ and $III_{d'}$ measured after 4 days from the isolation are listed in Table I.

**Oxidative Coupling of Di-*o*-ethynylphenyl Decanedioate (II, $n$=8).** — II ($n$=8, 2.5 g.) was treated with cupric acetate monohydrate (15 g.) in pyridine (200 g.) at 55°C for 4 hr. The same treatment of the reaction mixture as stated in the case of II ($n$=7) resulted a crystalline solid. Recrystallization of the solid from ethanol employing charcoal yielded VI as amorphous powder, m. p. 149~151.5°C, 0.3 g. (16%).

*Anal.* Found: C, 72.29; H, 6.83. Calcd. for $C_{36}H_{42}O_8$: C, 71.74; H, 7.02%.

I. R. max. (measured in hexachlorobutadiene), 2920, 2850 (-$CH_2$-), 2650 (carboxyl OH), 1755 (ester) and 1703 $cm^{-1}$ (carboxyl CO).

VI is readily soluble in aqueous sodium hydrogen carbonate and sodium hydroxide solution and gave a negative test against an ethanolic silver nitrate.

**2,2'-Dipropionyloxydiphenyldiacetylene ($VIII_a$).** — Propionic anhydride (2.6 g.) was added in one portion to the solution of 2,2'-dihydroxydiphenyldiacetylene[4] (0.47 g.) in water (20 ml.) and potassium hydroxide (1.6 g.). The mixture was shaken with occasional cooling with ice water. The solid separated was recrystallized from ethanol to result in $VIII_a$, m. p. 56°C, 0.5 g. (70%).

*Anal.* Found: C, 76.06; H, 5.29. Calcd. for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24%.

I. R. max., 1770 $cm^{-1}$ (ester).

**2,2'-Dibutyloxydiphenyldiacetylene ($VIII_b$).** — 2,2'-Dihydroxydiphenyldiacetylene (1.2 g.) was reacted with butyric anhydride (8.0 g.) according to the same procedure described above for the preparation of $VIII_a$. The reaction mixture was extracted with ether and the extract was washed with aqueous alkali and water. The solvent was evaporated from the dried extract yielding crude crystals. Recrystallization of the crude material from aqueous ethanol resulted in $VIII_b$, m. p. 51°C, 1.4 g. (75%).

*Anal.* Found: C, 76.61; H, 5.93. Calcd. for $C_{24}H_{22}O_4$: C, 76.98; H, 5.92%.

I. R. max., 1755 $cm^{-1}$ (ester).

**2,2'-Di-(β-hydroxyethoxy)-diphenyldiacetylene ($IX_a$).** — The reaction of *o,o'*-dihydroxydiphenyldiacetylene with ethylenechlorohydrine in the presence of sodium ethoxide gave $IX_a$. $IX_a$ thus obtained was separated into two forms, labile form (m. p. 75~76°C) and stable form (m. p. 90~91°C). The labile crystals readily changed to the stable form on standing at room temperature.

*Anal.* Found: C, 74.64; H, 5.57. Calcd. for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

I. R. max., 3350 (-OH), 2145 (-C≡C-) and 1244 $cm^{-1}$ (=C-O-).

**2,2'-Di-(γ-hydroxypropoxy)-diphenyldiacetylene ($IX_b$).** — *o*-(γ-Hydroxypropoxy)-phenylacetylene (b. p. 142~143°C/7 mmHg) which was obtained in 88% yield by the reaction of *o*-hydroxyphenylacetylene[1] and 3-bromo-1-propanol in the presence of sodium ethoxide was oxidatively coupled according to the method of Sörensen[8]. Treatment of the reaction mixture resulted in $IX_b$ as colorless needles in 57% yield, m. p. 103°C.

*Anal.* Found: C, 75.54; H, 6.01. Calcd. for $C_{22}H_{22}O_4$: C, 75.41; H, 6.33%.

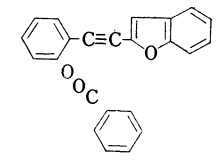
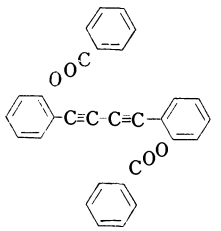
# *Cyclic Acetylenes. II. Attempted Synthesis of Cyclic Terephthalate of o, o'-Dihydroxydiphenyldiacetylene*

By Fumio TODA and Masazumi NAKAGAWA

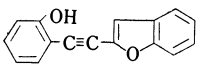


(Received July 21, 1959)

Cyclic terephthalate of *o, o'*-dihydroxydiphenyldiacetylene (III) may offer a suitable model substance for the investigation of transannular phenomena between the $\pi$-electron system of the benzene nucleus of terephthalic acid residue and that of diacetylenic linkage, because the scale model of this molecule indicates that the molecule is rigid, holding the terephthalate group closely in parallel with the diacetylenic linkage.



The synthesis of III has been attempted according to the following series of reactions. Di-2-ethynylphenyl terephthalate (II) was obtained in good yield by the reaction of *o*-hydroxyphenylacetylene (I)[1] with terephthaloyl chloride in aqueous acetone in the presence of sodium hydroxide.



The oxidative coupling according to the Eglinton's procedure[2] at a reaction temperature of 55°C resulted in 2-(2'-benzofuranylethynyl)-phenyl hydrogen terephthlate (IV) in 5% yield. 2, 2'-Dibenzofuranyl (V)[3] and IV were isolated from the reaction products in 15 and 3% yield, respectively, when the reaction was carried out at a temperature of 60°C.

2) G. Eglinton and A. R. Galbraith, *Chem. & Ind.*, **1956**, 737.
3) F. Toda and M. Nakagawa, This Bulletin, **32**, 514 (1959).

The ultraviolet spectra of VIII[3] have three maxima in the long wavelength region (290~340 mμ), whereas the spectra of VI and di-2-(2'-benzofuranylethynyl-phenyl succinate[4] have only two peaks in the same region lacking the maximum at ca. 290 mμ indicating that the presence of the free hydroxyl group is responsible for the appearance of the maximum at ca. 290 mμ in the ultraviolet spectra of 2-phenylethynylbenzofurane type compounds. On the other hand, ester derivatives of *o,o'*-dihydroxydiphenyldiacetylene such as VII and *o,o'*-diacetoxydiphenyldiacetylene have

TABLE I

| Compound | Absorption, mμ | | | | |
|---|---|---|---|---|---|
| IV | 242 (282) | | | 311 (253) | 332 (245) |
| VI | 230 (308) | | | 311 (364) | 332 (371) |
| VII | 230 (815) | **275** (229) | 293 (265) | 311 (346) | 332 (299) |
| II | 240 (1075) | **270** (146) | | | |
| VIII | 250 (79) | | 298 (265) | 318 (297) | 340 (284) |

All spectra were measured in 95% ethanol. The figures in parentheses are $\varepsilon_{max} \times 10^{-2}$. The bold figures indicate shoulder.

always three $\lambda_{max}$ in the long wavelength region. The ultraviolet spectrum of IV is closely related to that of VI lacking the absorption near 290 mμ (cf. Table I; Figs. 1 and 2). The infrared spectrum of IV indicates the presence of a carboxyl group ($\nu_{OH}$, 2655, 2520 $cm^{-1}$; $\nu_{CO}$, 1696 $cm^{-1}$) and ester group ($\nu_{CO}$, 1735 $cm^{-1}$). From these findings the structure of hydrogen terephthalate of VIII was assigned to IV. Presumably internal strains resulting from steric or a dipolar replusion between the terephthalate group and the diacetylenic bond caused the cleavage of one or both of the ester linkage of III yielding IV or V. The same type of fission of ester linkage during the course of intramolecular oxidative coupling of a series of dialkynyl terephthalate was recently reported by Eglinton and Galbraith[5].

It is interesting to note that the infrared spectrum of VIII shows the absorption of disubstituted acetylenic bond at 2207 $cm^{-1}$, but the corresponding absorption disappears in the spectra of IV, VI and VII. The low intensity of absorption in ultraviolet region of IV, as compared with that of VI, is attributable to the hypochromic influence of the more bulky terephthalic acid group as discussed in the previous paper of the series[4].

Further studies on the synthesis of cyclic derivatives of *o,o'*-dihydroxydiphenyldiacetylene containing a para-disubstituted benzene as the *o,o'*-bridging chain are now in progress.

## Experimental*

**2-Ethynylphenyl Terephthalate (II).**—*o*-Hydroxyphenylacetylene (I, 0.6 g) was dissolved in a mixture of sodium hydroxide (0.2 g.), acetone (10 ml.)

II gives yellow cuprous acetylide with Ilosvay's reagent and white silver salt with ethanolic silver nitrate solution.

**Oxidative Coupring of II at 55°C.**—II (2.0 g.) in pyridine (50 g.) was added to the solution of cupric acetate monohydrate (15 g.) in pyridine (100 g.). The mixture was kept at 55°C for 5 hr. The precipitate was removed and most of the solvent was removed under reduced pressure. The residue was mixed with water (1000 ml.) and extracted with ether (1000 ml.). The extract was washed with a saturated solution of cupric acetate and water, successively. The dried ethereal solution was concentrated to 100 ml., and the greenish yellow precipitate formed was removed. Concentration of the filtrate yielded crude crystals. After treatment with acetone and charcoal, the crude material was repeatedly recrystallized from xylene to give pure IV, colorless needles, m.p. 222.5~223°C (decomp.), 0.1 g. (5%).

*Anal.* Found: C, 75.38; H, 3.86; mol. wt. (Rast), 343. Calcd. for $C_{24}H_{14}O_5$: C, 75.39; H, 3.69%; mol. wt., 382.

**Oxidative Coupling of II at 60°C.**—II (3.0 g.) in pyridine (150 g.) was added through a Hershberg type dropping funnel to the vigorously stirred solution of cupric acetate monohydrate (15 g.) in pyridine (150 g.) at 60°C over a period of 4 hr., and stirring was continued for additional 1.5 hr. at the same temperature. The precipitate formed was removed by filtration. After removal of pyridine in vacuo, the residue was diluted with water and extracted with benzene (400 ml.). The benzene layer was treated according to the usual manner. Evaporation of the solvent gave a greenish black solid. The solid was digested with ether, and the solvent was removed to give crystals, which were refluxed with ethanol (20 ml.) and the insoluble material was removed by filtration. The filtrate was cooled to yield crystals, which were repeatedly recrystallized from xylene to yield IV, m.p. 222.5~223°C (decomp.), 100 mg. (3%). On concentration of the mother liquor, V, colorless needles, m.p. 190~194°C, 0.3 g. (15%) was obtained, which undepressed the melting point of an authentic sample[3].

The authors wish to thank Messrs. T. Shiba and M. Okumiya and Miss K. Koike for performing the elementary analyses.

# *High Pressure Reduction of Organic Compounds with Urushibara Catalyst. VI*[1]*. A New Type of Urushibara Nickel Catalyst*

By Izumi MOTOYAMA

(Received August 15, 1959)

In 1952 Urushibara and Chuman discovered a new catalyst, which was prepared from precipitated nickel. Aqueous nickel chloride solution was treated with zinc dust, and the precipitated nickel was digested with caustic alkali to obtain the active catalyst for hydrogenation[2]. The procedure for the preparation of this catalyst has been successively modified to obtain the more active catalyst. It was also found that a highly active catalyst can be obtained by digesting the precipitated nickel with either aqueous caustic alkali or aqueous acetic acid, and the former was named Urushibara nickel B or U-Ni-B in abbreviation[3], and the latter Urushibara nickel A or U-Ni-A in abbreviation[4]. Recently it was proved that the activity of the U-Ni-B is comparable with that of Raney nickel catalyst for hydrogenation under ordinary pressure[5].

An application of Urushibara nickel catalyst to the hydrogenation of various organic compunds under high pressure

1) Part V: K. Hata, S. Taira and I. Motoyama, This Bulletin, **31**, 776 (1958).
2) Y. Urushibara, ibid., **25**, 280 (1952).
3) Y. Urushibara and S. Nishimura, ibid., **27**, 480 (1954).

has been investigated since 1954. During the successive investigations it was noticed that this catalyst could not hydrogenate aromatic compounds such as benzene, aniline, etc., even under severe conditions, although it was very effective for the hydrogenation of ethylenic compounds, aldehydes, ketones, nitro compounds, oximes, nitriles and simple phenols[6-9]. To get rid of this defect, an attempt was made to prepare a new type of Urushibara catalyst from nickel chloride and aluminum instead of zinc. Some information on the new Urushibara catalyst thus obtained, named Urushibara nickel BA or U-Ni-BA in abbreviation, was reported briefly in the preceding paper[1].

In the present paper, the hydrogenation of several aromatic compounds with this new catalyst and certain useful modifications of procedure for the preparation of this new catalyst are described.

## Hydrogenation of Aromatic Compounds

The Urushibara nickel BA was found to be effective for the hydrogenation of aromatic nucleus which had not been hydrogenated with U-Ni-B or U-Ni-A. The results of the hydrogenation of some aromatic compounds are summarized in Table I. The hydrogenation of phenol can also be attained with either U-Ni-B or U-Ni-A, but it takes much time to complete the reaction with these catalysts even under considerable high temperature. With U-Ni-BA, however, phenol can be easily hydrogenated at lower temperature. It is evident from these results that the U-Ni-BA has a high activity for the hydrogenation of aromatic nucleus, and that the use of aluminum grains instead of zinc dust brings about a favorable change on the property of Urushibara catalyst. It is obvious that the difference between the properties of these two kinds of Urushibara catalysts is due to the difference of the metal combined with nickel in each catalyst.

## Preservability of Urushibara Catalyst

Preparation of catalyst has been generally thought to be troublesome and difficult, but it is not true for the preparation of Urushibara nickel catalyst, because it is prepared by simple operations in only an hour or less. However, the preparation of U-Ni-BA from nickel chloride and aluminum grains requires somewhat longer time than that of the other Urushibara catalysts from nickel chloride and zinc dust. A certain useful modification has been made in the procedure for the

preparation of U-Ni-BA catalyst, so as to shorten the time required for the preparation. The principle of the modification is to prepare the U-Ni-BA catalyst from preserved nickel precipitate, which is previously made in large quantities. After the ion-exchange reaction between nickel chloride and aluminum grains, the precipitated nickel is preseved in a proper manner, and then treated with aqueous alkali to make up the U-Ni-BA catalyst when it is used for hydrogenation. Such preservation of the precipitate, however, was expected to cause deactivation of the catalyst, because it is presumed that active nickel surface are inherently present in the precipitate but are covered with certain water-insoluble substances, and consequently the precipitated nickel itself, as it is precipitated, is ineffective as catalyst, unless it is treated with alkali or acid[4].

The activity of the catalyst prepared from the preserved precipitate was examined by the hydrogenation of phenol. The precipitate was preserved from a day to three months in the following three ways: in distilled water, in 99% ethanol and in dry state. Each preserved precipitate was then treated with 20% aqueous sodium hydroxide solution to prepare the catalyst. The results of the hydrogenation of phenol are summarized in Table II. As shown in Table II, each 3 mol. of hydrogen were absorbed with the catalyst prepared from the preserved precipitate as well as with that immediately treated with alkali after the ion-exchange reaction, although the time required for hydrogenation was somewhat longer with the former catalyst. About 8 g. of cyclohexanol were isolated similarly from every reaction mixture. Thus, contrary to expectation, no remarkable deactivation was found with U-Ni-BA catalyst by any preservation of the precipitated nickel. The precipitate preserved in dry state is more convenient for use than those preserved in water or ethanol.

When the dried precipitate is exposed to air under ordinary pressure, it is rapidly oxidized generating a considerable amount of heat. Therefore, it is desirable to keep it under reduced pressure, especially in case of a large scale operation.

Additional results of the hydrogenation with the catalyst prepared in this way are summarized in Table III. It can be seen from these results that this catalyst still maintains the similar catalytic activity as the catalyst prepared from precipitated

TABLE IV. PHYSICAL CONSTANTS OF THE PRODUCTS

| Compound | b. p. °C/mmHg. | Refractive index (°C) | Derivative (m.p., °C) |

nickel immediately after the ion-exchange reaction (cf. Table I).

It is quite interesting that the U-Ni-BA catalyst prepared from the precipitated nickel being kept in air for a long time maintains its high catalytic activity for the hydrogenation of aromatic compounds.

The modification in this way can be applied not only to the new Urushibara catalyst but also to the old ones.

## Experimental

**Apparatus.**—Hydrogenation was carried out in an autoclave of stainless steel with a magnetic stirrer (capacity: 200 cc., rate of stirring: about 60 strokes per min.).

**Catalyst.**—Catalyst was prepared according to the procedure previously reported[1] and washed thrice with 99% ethanol, when the hydrogenation was carried out in ethanol. When another solvent was employed, the catalyst was washed first thrice with 99% ethanol and then thrice with the solvent.

**Preservation in Dry State.** — The precipitate, obtained from 100 ml. of aqueous nickel chloride solution containing 40 g. of $NiCl_2 \cdot 6H_2O$ and 50 g. of aluminum grains (40~80 meshes), was washed well with distilled water, then collected on Büchner funnel and dried under reduced pressure. Final weight of the precipitate was about 70 g.* in all. Each 14 g. of the dry precipitate, which contains 2 g. of nickel, was treated with 250 g. of 20% aqueous sodium hydroxide solution before the application for hydrogenation.

**Materials.**—All substances used for hydrogenation were purified by redistillation or recrystallization except those with special indication.

Methyl salicylate, ethyl benzoate and diethyl phthalate were respectively prepared by usual esterification[11] from corresponding acids.

Benzene was purified by treatment first twice with anhydrous aluminum chloride[12], then with a large amount of U-Ni-A[13]. The purified benzene was redistilled before hydrogenation.

**Products.**—Reduction products were fractionally distilled except those with special indication, and were identified through appropriate derivatives. When the products were liquid, their refractive indices were measured. Physical constants of the products are summarized in Table IV.

Cyclohexane and ethylcyclohexane were respectively separated from the solvent by adding a large quantity of water to the reaction mixture, dried over anhydrous calcium chloride and distilled.

Piperidine was converted to its hydrochloride by adding an excess of concentrated hydrochloric acid to the reaction mixture after removal of catalyst. The solvent was distilled off and the residue was completely dried up under reduced pressure. Then, the resulting piperidine hydrochloride was purified by recrystallization from 99% ethanol.

## Summary

A new Urushibara nickel catalyst, U-Ni-BA, was prepared from nickel chloride and aluminum grains. This new catalyst was found to be highly active for the hydrogenation of aromatic nucleus, contrary to the older Urushibara nickel catalyst, U-Ni-A or U-Ni-B.

The preservability of the catalyst was examined: the precipitate, obtained by the reaction of nickel chloride with aluminum grains (or zinc dust), was kept for a long time in solvent or in dry state, and a similarly active catalyst could be obtained by digesting the preserved precipitate with aqueous caustic alkali.

# *An Approximate Method of Calculating Localization Energies in Alternant Hydrocarbons*

By Hiroaki BABA

(Received August 18, 1959)

Since the localization theory was first proposed by Wheland[1], it has been one of the most effective means of dealing with the chemical reactivity in conjugated organic compounds. The only fault found with this theory is that the calculation of localization energies is frequently an arduous task, especially when one is treating a large molecule. By taking into consideration the characteristic property of nonbonding molecular orbitals, Dewar[2] developed a convenient method of obtaining approximate values of localization energies for alternant hydrocarbons, and successfully applied it to some organic reactions[3]. However, the values obtained by this method of approximation are in general numerically far from being the exact values.

In a previous paper[4] it was made clear that in an alternant hydrocarbon the exact value of localization energy has an intimate correlation with Dewar's approximate one, and also with the value of free valence, the latter quantity being an important index of chemical reactivity[5]. In connection with this problem, another approximate method of computing localization energies in alternant hydrocarbons will be described in the present article.

## Definition

The present treatment is based on the simple LCAO molecular orbital method with neglect of overlap integrals; the notation is the same as that used in the preceding papers[4,6].

Consider a carbon atom $r$ in an alternant hydrocarbon, and denote the carbon atoms adjacent to atom $r$ by $t$, $t'$, ……. Suppose that $\beta_{rt}$, $\beta_{rt'}$, …… simultaneously change from their initial value $\beta$ to a certain value $\beta_r$, and that the other coulomb and resonance integrals remain unchanged. Then, bond number $N_r$ can be regarded as a continuous function of $\beta_r$. If this function is represented by $N_r(\beta_r)$, the localization energy of atom $r$ is expressed as[4]

$$L^{(r)}=\int_{\beta}^{0} 2N_r(\beta_r)\mathrm{d}\beta_r. \tag{1}$$

Next, reference will be made to two known approximate values[4] of $L^{(r)}$. One is

$$L^{(r)\prime}=-2N_r{}^0\beta \tag{2}$$

where $N_r{}^0[\equiv N_r(\beta)]$ is the bond number in the initial state, and is connected with free valence $F_r{}^0$ by the relation $N_r{}^0=\sqrt{3}-F_r{}^0$. The other is

$$L^{(r)\prime\prime}=-2N_r(0)\beta \tag{3}$$

where

$$N_r(0)=\lim_{\beta_r\to 0} N_r(\beta_r)$$

As was proved in the previous paper[4], $L^{(r)\prime\prime}$ defined by Eq. 3 agrees with Dewar's approximate value mentioned in the introductory paragraph.

In the simple molecular orbital procedure, the total energy for the ground state of a system of electrons is obtained as the sum of the energies of the ground-state molecular orbitals to which the individual electrons belong. If the orbital energies are determined by the usual variation method, the total energy obtained in this way corresponds to its absolute minimum under the restriction that the orbitals form

an orthonormal set. If one keeps this fact in mind, it is easily verified that $N_r$ decreases monotonously as $\beta_r$ increases. Hence

$$N_r^0 > N_r(\beta_r) > N_r(0) \quad (\beta < \beta_r < 0) \tag{4}$$

so that from Eqs. 1—3

$$L^{(r)\prime} > L^{(r)} > L^{(r)\prime\prime} \tag{5}$$

Let us now consider a new quantity $\boldsymbol{L}^{(r)}$ defined as follows:

$$\boldsymbol{L}^{(r)} = -(N_r^0 + N_r(0))\beta \tag{6}$$

Then, from Eqs. 2 and 3

$$\boldsymbol{L}^{(r)} = \frac{1}{2}(L^{(r)\prime} + L^{(r)\prime\prime}) \tag{7}$$

Since both $L^{(r)\prime}$ and $L^{(r)\prime\prime}$ are approximate values of $L^{(r)}$, $\boldsymbol{L}^{(r)}$ will also be an approximation of $L^{(r)}$.

The relation of $\boldsymbol{L}^{(r)}$ with other quantities may be understood by Fig. 1, where the full line curve aeb represents the relation between $\beta_r$ and $2N_r(\beta_r)$. $L^{(r)}$ is, of course, equal to the area under the curve, $L^{(r)\prime}$ to the area of rectangle agcd, and $L^{(r)\prime\prime}$ to that of rectangle hbcd, while $\boldsymbol{L}^{(r)}$ is equal to the area of trapezoid afbcd.

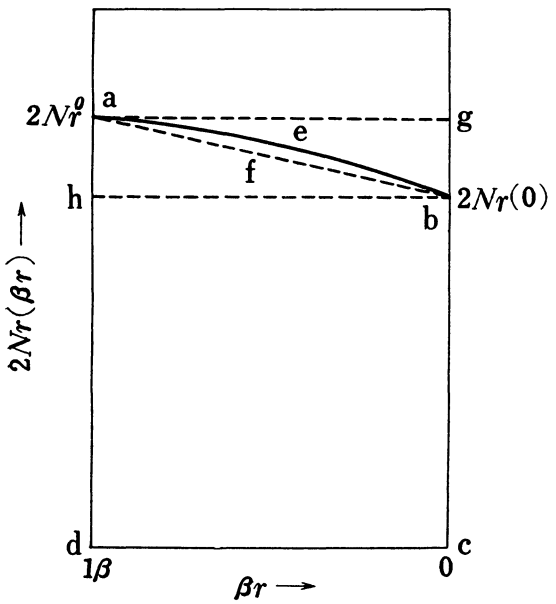

Fig. 1.

## Examples and Discussion

In Table I are listed the values of $\boldsymbol{L}^{(r)}$ and other related quantities for three positions of anthracene. In Fig. 2 $\boldsymbol{L}^{(r)}$, $L^{(r)\prime}$ and $L^{(r)\prime\prime}$ are plotted against $L^{(r)}$ for a number of alternant hydrocarbons. The values of $L^{(r)}$ for primary, secondary and tertiary carbon atoms fall within the ranges 1.0 to 1.8, 1.8 to 2.6 and 2.6 to 3.1, respectively. The examples presented in this table and figure clearly show that $\boldsymbol{L}^{(r)}$ is superior to $L^{(r)\prime}$ and $L^{(r)\prime\prime}$ as an approximation of $L^{(r)}$.

TABLE I. LOCALIZATION ENERGIES IN UNITS OF $-\beta$ FOR ANTHRACENE

| Position | $L^{(r)}$ | $\boldsymbol{L}^{(r)}$ | $L^{(r)\prime}$ | $L^{(r)\prime\prime}$ |
|---|---|---|---|---|
| 1 | 2.25 | 2.06 | 2.55 | 1.57 |
| 2 | 2.40 | 2.27 | 2.65 | 1.89 |
| 9 | 2.01 | 1.84 | 2.42 | 1.26 |

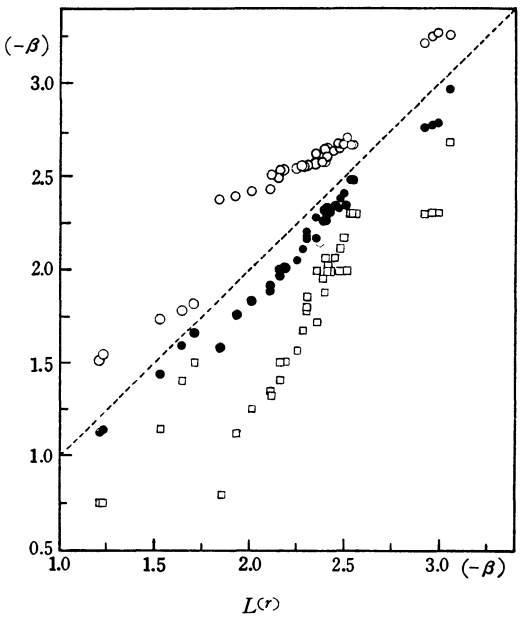

Fig. 2. Relations between $L^{(r)}$ and $\boldsymbol{L}^{(r)}$, $L^{(r)\prime}$ and $L^{(r)\prime\prime}$.
●, $\boldsymbol{L}^{(r)}$; ○, $L^{(r)\prime}$; □, $L^{(r)\prime\prime}$.
$L^{(r)}$ and $L^{(r)\prime}$: Taken from references 5 and 6, and "Dictionary of Values of Molecular Constants", Vol. II, edited by C. A. Coulson and R. Daudel.
$L^{(r)\prime\prime}$: Taken from reference 2, and calculated by the present author.

Previously it was shown by the present author[4,6] and also by Fukui et al.[7] that under certain conditions there is a definite parallelism among the quantum mechanical quantities, including $L^{(r)\prime}$ and $L^{(r)\prime\prime}$, which are related to the reactivity of an alternant hydrocarbon. Considering the definition of $\boldsymbol{L}^{(r)}$, one may at once reach the conclusion that the same parallelism exists between $\boldsymbol{L}^{(r)}$ and any other quantity mentioned above.

# *Tropones. IV.* Ultraviolet Absorption Spectra of Reaction Products of Tropones and Carbonyl Reagents***

By Toshio MUKAI

(Received June 8, 1959)

The reaction products of tropone and carbonyl reagents, such as oxime, semicarbazone, thiosemicarbazone, phenylhydrazone, and nitrophenylhydrazone form peculiar conjugation systems and they are of interest in the study of ultraviolet spectrum. These compounds generally have deep color, ranging from orange to dusky purple. The present paper describes observations on the ultraviolet spectra of products obtained on the reaction of tropone and tropones possessing the methyl, phenyl, naphthyl, *o*-tolyl, or benzyl group in 2-position, and carbonyl reagents, measured in methanol, acidic and alkaline solutions.

The ultraviolet spectrum of tropone oxime[1], of tropone semicarbazone[1] and of tropone thiosemicarbazone are shown in Figs. 1—3, respectively. These three compounds possess a C=N- group in place of the carbonyl group in tropone and show two typical absorption maxima as tropone itself does[1]. The maximum absorption in methanol solution shifts to longer wavelengths in the order of the oxime, semicarbazone and thiosemicarbazone, and this tendency is the same as that in the case of unsaturated ketone derivaives in general[2]. All three compounds have fairly deep color which must be due to the broad absorption appearing at the wavelength region above 400 m$\mu$.

The ultraviolet spectra of the oxime and semicarbazone in hydrochloric acid solution show a shift to a longer wavelength region and that of the thiosemicarbazone to slightly shorter wavelengths. The absorption maxima lie near 240 and 330 m$\mu$ in all three compounds and the value of their intensity is also similar.

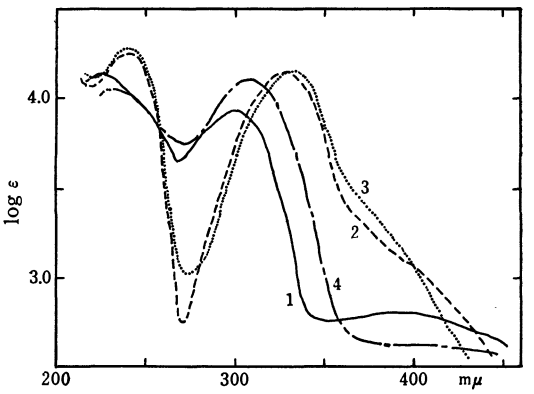

Fig. 1. Ultraviolet absorption spectra of tropone oxime: (1) in methanol, (2) in 0.1 N HCl, (3) in 6 N HCl and (4) in 0.1 N NaOH solution.

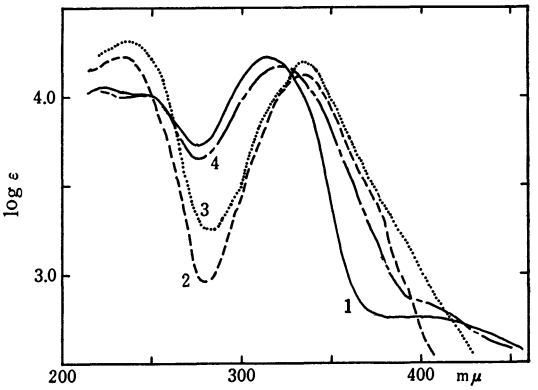

Fig. 2. Ultraviolet absorption spectra of semicarbazone of tropone: (1) in methanol, (2) in 0.1 N HCl, (3) in 6 N HCl and (4) in 0.1N NaOH solution.

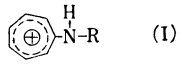

This fact indicates that they all have a structure of conjugate acid like I and that their absorptions are not so greatly affected by group R. The fact that there is no shift of the absorption curve according to the concentration of hydrocholric acid (in 0.1 or 6 N), suggests that the formation of the conjugate acid (I) is almost complete even in dilute acid solution such as 0.1 N solution.

R=OH.NHCONH$_2$.NHCSNH$_2$

In alkaline solution, the absorption curves of the oxime, semicarbazone and thiosemicarbazone, all show a shift to a longer wavelength region. It has already been pointed out that the oxime has an amphoteric property, is stable, and dissolves both in acids and in alkalis[1], and this shift is assumed to be due to the formation of an anion (II). Similarly, formation of anions (III) and (IV) can be expected for the semicarbazone and thiosemicarbazone.

(II) (III)

(IV)

Ultraviolet absorption spectra of the phenylhydrazone[1] and *p*-bromophenylhydrazone[1] of tropone are shown in Table I and Fig. 4 and those of *p*-nitrophenylhydrazone[1] and 2,4-dinitrophenylhydrazone[1] of tropone in Table I and Fig. 5. These phenylhydrazones exhibit absorption maximum at a longer wavelength region than the oxime and semicarbazone do. Further it is seen that the introduction of a nitro group in the

* Broad band. These bands can not be compared with each other.

ortho- or para-position of the phenyl ring results in a further shift of the maximum to a longer wavelengths (above 400 mμ).

In hydrochloric acid solution, they all show a shift originating in the formation of a conjugate acid [I: R= $-NH-C_6H_5$, $-NH-C_6H_4Br(p)$, $-NH-C_6H_4NO_2(p)$, $-NH-C_6H_3(NO_2)_2(2,4)$]. In *p*-nitro- and 2,4-dinitrophenylhydrazones, there is a shift of 6~10 mμ when the concentration changes from 0.1 to 6 N hydrocholric acid. This is probably due to the weakened basicity of these compounds by the introduction of a nitro group which has an effect on the formation of the conjugate acid (I).

In alkaline solution, the absorption maxima of *p*-nitro and 2,4-dinitrophenylhydrazone shift to a longer wavelength region (above 500 mμ) and this is due to the formation of an anion (V) with a long chain of conjugation. The formation of an anion (V) is supported by the fact that phenylhydrazone and *p*-bromophenylhydrazone hardly show any shift in alkaline solution (see Fig. 4).

(V) X=H, $NO_2$

The ultraviolet absorption spectra of *p*-nitrophenylhydrazone in methanol and alkaline solution exhibit maxima at somewhat longer wavelength than that of 2,4-dinitrophenylhydrazone and this is due to the steric hindrance of the nitro group in 2-position of the phenyl ring. However, the maximum of 2,4-dinitrophenylhydrazone appears in a longer wavelength than that of *p*-nitrophenylhydrazone in acid solution. This is probably due to the fact that resonance represented by V occurs only to a small extent in acid solution and consequently the interference of the nitro group in 2-position of the phenyl group does not give an effect on the spectrum.

Of these products from reaction with carbonyl reagents, oxime and 2,4-dinitrophenylhydrazone are easily formed in tropones possessing alkyl or aryl radical in its 2-position. Effect of a substituent on the ultraviolet spectrum was examined with oximes. Ultraviolet spectra of oximes are shown in Table II.

The absorption maxima of 2-methyltropone oxime[3] in longer wavelength region shift to a slightly shorter wavelengths than those of tropone oxime when measured in methanol or 0.1 N sodium hydroxide solution but conversely shift to a longer wavelength in hydrochloric acid solution. Of these oximes, the interesting thing is the absorption of 2-phenyltropone oxime[4]. As will be seen from Fig. 6, the curve appears different since new absorption maxima appear at

260 and 265 mμ in methanol and alkali solution. It is considered that the absorption in this region is due to the coplanarity of the seven-membered ring and phenyl ring, as in the case of 2-phenyltropone itself[3,7].

On the other hand, the absorption of 2-benzyltropone oxime[5] is very similar to that of 2-methyltropone by the introduction of a methylene group, while the absorption of 2-α-naphthyltropone oxime does not exhibit the maximum at around 260 mμ seen in the case of 2-phenyltropone oxime, irrespective of the presence of the naphthyl group. Moreover, the second absorption maximum of 2-naphthyltropone oxime have shifted to a shorter wavelength region than the corresponding absorption maximum of 2-phenyltropone oxime in methanol solution (Table II) and a steric interference between the tropone ring and the naphthyl group at peri-position may be considered at its cause. The absorption maximum at 222~224 mμ of strong intensity seen in 2-α-naphthyltropone oxime is thought to be the absorption of naphthalene itself[8]. The ultraviolet spectrum of 2-o-tolyltropone oxime[3] also suggests the presence of a steric hindrance by the methyl group in the ortho-position of the phenyl ring. Owing to this effect, this compound has a maximum at 295 mμ which is considerably shifted toward shorter wavelength compared with a maximum of phenyltropone oxime at 307 mμ.

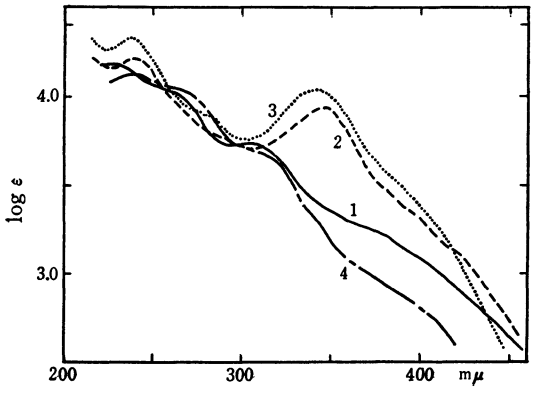

Fig. 6. Ultraviolet absorption spectra of oxime of 2-phenyltropone: (1) in methanol, (2) in 0.1 N HCl, (3) in 6 N HCl and (4) in 0.1 N NaOH solution.

Ultaviolet absorption spectra of 2,4-dinitrophenylhydrazones of various tropones are shown in Table III. In these cases also, the direction of the shift in hydrochloric acid and alkali solutions are the same as in the case of 2,4-dinitrophenylhydrazone of tropone, but the relationship between the shift of absorption and kind of substituents is complicated and conclusive explanation is difficult. The marked tendency of these is the small of shift in the absorption of 2-phenyl-, 2-benzyl- and 2-α-naphthyl-tropone derivatives measured in 0.1 N hydrochloric acid solution. The reason for this is the smallness in basicity and it may be considered that the stronger the basicity, the larger will be the shift. In 6 N hydrochloric acid solution, all the compounds

have absorption maximum at about 360 mμ and formation of conjugate acids of similar structure may, therefore, be assumed. The absorption maximum of 2-α-naphthyltropone derivative at 222~223 mμ of strong intensity is that of naphthalene itself[8], as was stated earlier.

The author takes this opportunity to express his sincere gratitude Professor Tetsuo Nozoe for his kind guidance throughout the course of this work, and to Professor Shuichi Seto and Assistant Professor Yoshio Kitahara for much helpful advice.

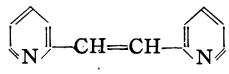
# *Geometrical Isomers of α-Stilbazole*

By Takumi KATSUMOTO

(Received August 8, 1959)



There is a series of stilbene derivatives which are substituted by one or two α-pyridyl groups for the phenyl groups of the stilbene. They are stilbene (I), α-stilbazole (II) and α-pyridostilbene, i.e. 1-2-bis-(α-pyridyl)-ethylene (III).

(I)

(II)

(III)

They are expected to exist in *cis*- and *trans*-structures as they are all 1,2-disubstituted ethylenes. Among the six isomers, *cis*- and *trans*-stilbene (I) are well known and recently the author reported two geometrical isomers of α-pyridostilbene (III)[1]. However, regarding α-stilbazole hitherto only one species which melts at 91°C has been known to us.

The author presumed that in the course of the preparation of the known species of α-stilbazole, the other isomer would be prepared as one of the by-products and then removed in some processes. The course was re-examined and it was found that the last recrystallization process removed completely the other isomer from the main product. Now, he has recovered the other isomer from the the filtrate, and then determined that the known species of α-stilbazole is a *trans*-isomer and the other is a *cis*-isomer on the basis of the data of the elementary analyses, the melting points, the ultraviolet and the infrared spectra.

## Experimental

**Syntheses of *cis*- & *trans*-α-Stilbazole.**—A mixture of freshly purified benzaldehyde (b.p. 179~180°C), α-picoline (b.p. 129.3°C) and anhydrous zinc chloride in the ratio 3 : 2 : 1 was heated in in an autoclave at 200°C for 24 hr.[2] After being cooled, the dark brown and viscid product was dissolved in aqueous hydrochloric acid, steam distilled to remove benzaldehyde and basified with sodium hydroxide, followed by steam distillation to remove the residual α-picoline. The solution separated raw and purplish red stilbazole, which was extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate. After the chloroform was evaporated, the residue was distilled under 10 mmHg pressure. Pale yellow liquid passed over the interval 170~180°C and condensed in a receiver. No α-stilbazole could be found in the fore-run which was collected separately in three traps kept at 0, −20 and −80°C, respectively. The main distillate in the receiver was recrystallized from boiling ethanol. The precipitate (**A**) melts at 91°C and corresponds to the known species of α-stilbazole. The yield was 60% theoretical. After ethanol was evaporated from the filtrate, there remained the brown oil. It was purified repeatedly by the elution chromatography (alumina, 2×40 cm., chloroform) until it showed the constant ultraviolet absorption spectrum. The purified oil (**B**) is colorless and melts at −50.0°C. The yield was nearly 3% theoretical.

**Other Materials.**—*cis*- & *trans*-*Stilbene.*—*cis*-Stilbene[3] was prepared from *cis*-α-phenylcinnamic

1) T. Katsumoto, This Bulletin, **32**, 1019 (1959).
2) G. H. Lénárt, *Ann.*, **410**, 95 (1915).

acid and *trans*-stilbene[4] from benzoin, according to the methods of "Organic Syntheses". They were purified by the same method as the above. Their melting and boiling points are shown in Table II.

*cis- & trans-α-Pyridostilbene.*—The same samples that were synthesized in the preceding experiment[1] were used.

**Analyses and Measurements.**—Analytical data of the elementary analyses were determined by the Elementary Analyses Center of Kyoto University.

Melting points below the room temperature were measured in the following method, because the samples were so transparent even in the solid state as in the liquid state that the appearances did not change at the melting points. A liquid sample was packed as usual in a capillary tube which was then attached to a thermometer centered in a methanol bath. Dry air was sent into the bath to stir the methanol. A very thin and long glass wire was inserted in the capillary tube. As the bath was cooled in a dry ice-acetone mixture to −70°C, the sample solidified and the glass wire was fixed in it. Then, the methanol bath was transferred to an acetone bath that had been cooled near −40°C. The melting point was clearly observed as the glass wire could not be pulled out until the sample began to melt. *cis*-Stilbene and *cis*-stilbazole were viscid near the melting point.

Boiling points under reduced pressure were measured by Garcia's method[5] as described in the preceding paper[1].

The ultraviolet absorption spectra (in cyclohexane) were made with a Shimadzu QB-50 quartz spectrophotometer. The wavelengths of this photometer were calibrated with the absorption band at 301 mμ of an aqueous potassium nitrate solution. The infrared absorption spectra were obtained with a Hilger or a Leitz spectrophotometer equipped with a rock-salt prism. Readings were taken in the region of 1700~670 $cm^{-1}$ and always calibrated with the absorption bands of polystyrene.

## Results and Discussion

As described above, the colorless liquid (**B**) was recovered from the filtrate of the recrystallization of the known species of α-stilbazole (A). The analytical data of the elementary analyses of the liquid (**B**) are shown in Table I and are in good

agreement with the calculated values for stilbazole $C_{13}H_{11}N$. It seems that **B** is also a species of $\alpha$-stilbazole. **B** melts at $-50.0°C$, which is much lower as compared with the melting point of **A** (91°C). As a *cis*-isomer always melts at much lower temperature than a *trans*-isomer does (Table II and Ref. 6), **A** is a *trans*-isomer and **B** is a *cis*-isomer.

Fig. 1 shows the infrared absorption spectra of **A** and **B** in carbon tetrachloride or in cyclohexane. Each band of **A** is in good agreement with corresponding band of **B**, except two bands at 1330 and 965 $cm^{-1}$ which will be discussed later. The good agreement indicates that **B** is the other isomer of **A**. Furthermore, this determination is made sure by the assignments of these absorption comparing their absorptions with those of the related compounds, stilbene (I) and $\alpha$-pyridostilbene (III) as shown in Table III.

The fundamental studies[7-9] on benzene vibrations have shown that the characteristic skeletal stretching modes of the semi-unsaturated carbon-carbon bonds lead to the appearance of a group of four bands between 1650~1450 $cm^{-1}$. Four absorptions corresponding to them are also expected theoretically in the case of pyridine and have been found in the similar range of the spectra of many pyridine derivatives[10,11], although the vibrations are mostly found to shift to somewhat lower frequencies on passing from benzene to pyridine. In these ranges each of **A** and **B** shows seven absorptions due to BR-1, 3, 4 and PR-1, 2, 3, 4 vibration modes (Table III). The letters B and P in the table denote the vibrations arising from a benzene and a pyridine ring, respectively. These spectra show that **A** and **B** each consist of a benzene and a pyridine ring. Randall et al.[12] regarded a bond in the range 1587~1575 $cm^{-1}$, namely, BR-2 in Table III, as an indication of the conjugation of an ethylenic double bond with an aromatic ring. In the spectra of $\alpha$-stilbazole the BR-2 vibration is obscure, because the absorption range is very similar to that of the PR-1 vibration and they overlap one another, but the PR-2 vibration corresponding to the BR-2 vibration in the sense of the conjugation, is clearly seen. This shows that a pyridine ring in the $\alpha$-stilbazole is conjugated with an ethylenic double bond.

In the range 1225~950 $cm^{-1}$, aromatic compounds all show a series of relatively weak but sharp bands, the positions of which vary with the type of substitution and are independent of the nature of substituents[11]. Randle and Whiffen[13,14] have shown that they arise from the CH in-plane bending modes. Generally, mono-substituted benzenes show three absorptions in the ranges 1175~1125, 1110~1070 and 1070~1000 $cm^{-1}$ [11,14,15]. In the case of $\alpha$-substituted pyridines the similar absorptions also appear in the ranges 1151~1140, 1050~1040 and 998~986 $cm^{-1}$ [10]. Five absorptions at **A** and **B** are located in the above absorption ranges of the mono-substituted benzenes and the $\alpha$-substituted pyridines, and correspond to the BHI-2, 3 and the PHI-1, 2, 3 vibration modes. The absorptions due to the BHI-1 seem to be masked with those due to the PHI-1 mode (Table III). These absorptions show that the benzene and the pyridine ring of **A** and **B** are a mono-substituted benzene and an $\alpha$-substituted pyridine ring.

Mono-substituted benzenes show two strong absorptions in the ranges of 770~730 $cm^{-1}$ [11,12] and 710~690 $cm^{-1}$ [11,12,15]. They are assigned to the out-of-plane CH bending vibrations of five adjacent ring hydrogen atoms remaining on the benzene ring, and the absence of the latter band is a strong evidence of the latter band is a strong evidence of the absence of a mono-substituted benzene. On the other hand, $\alpha$-substituted pyridines having four adjacent hydrogen atoms on the ring behave like an ortho-substituted benzene and absorb strongly in the range of 780~740 $cm^{-1}$ [10,11]. The three strong bands corresponding to the above bands appear in the spectra of **A** and **B** (BHO-1, 2 and PHO in Table III).

Thus, **A** and **B** are both disubstituted ethylenes with a phenyl and an $\alpha$-pyridyl radical, i.e. $\alpha$-stilbazole.

Generally, *trans*-ethylenic double bonds give rise to two medium to strong bands in the ranges of 990~965 $cm^{-1}$ [11,16] and 1310

| α-Pyridostilbene (III) | 211 | 9920 | 257 | 5790 | 221 | 8770 | 267 | 15750 |
| | | | 262 | 5910 | 226 | 6620 | 316 | 28470 |
| | | | 268 | 4420 | | | 331 | 20510 |

~1290 $cm^{-1}$ [11]. The former band was assigned by Kilpatrick and Pitzer to the out-of-plane bending vibration[11], while the latter was assigned by Sheppard and Sutherland[17] to the in-plane bending vibration, of the hydrogen atoms remaining on the *trans*-disubstituted ethylene. Especially the absence of the former band can be regarded as the conclusive evidence of the *trans*-ethylenic linkage. Not any absorptions corresponding to the above absorptions are found in the spectrum of **B**, while **A** gives rise to the two strong absorptions at 965 and 1330 $cm^{-1}$ due to the *trans*-substituted ethylene (EHO, EHI in Table III). Thus, **B** is *cis*-α-stilbazole and **A** is *trans*-α-stibazole.

The ultraviolet spectra of **A** and **B** are compared with those of *cis*- and *trans*-isomers of stilbene (I) and α-pyridostilbene (III) in Table IV and Figs. 2–4. Each spectrum of stilbene and α-pyridostilbene consists of the E(ethylenic)-band and the K(conjugated)-band (Figs. 2 and 3). All the E-bands of both *cis*- and trans-isomers lie near 220 mμ. However, every K-band of the *trans*-isomer lies at a longer wavelength than that of the *cis*-isomer does. In addition, the intensity of the K-band is always much stronger in the *trans*-isomer than in the *cis*-isomer. The bathochromic displacements and much increase of the absorption intensities arise from the coplanarity of the molecular structure and then from the high degree of resonance on passing from the *cis*-structure to the

17) N. Sheppard and G. Sutherland, *Proc. Roy. Soc.*, **A196**, 195 (1949).

*trans*-structure[18]. Robertson and Woodward[19] indicated that, as the results of X-ray diffraction measurements, in *trans*-stilbene the bond joining the phenyl groups to the ethylenic group are 1.45 Å long. As the bond is considerably shorter than the usual saturated carbon-carbon bond (1.54Å), it is therefore a hybrid type, and two phenyl groups in *trans*-stilbene must exist almost in the plane in which ethylenic carbon and hydrogen atoms lie. Such configurations are expected in the cases of α-stilbazole (II) and α-pyridostilbene (III).

The spectra of **A** and **B** are typical of the *trans*- and the *cis*-structure (Fig. 3) and make sure of the above determination.

The conclusion is that a known species of α-stilbazole (**A**) is the *trans*-isomer and the other species (**B**) which was separated by the present author is the *cis*-isomer.

The author wishes to thank Professor S. Kimura of Kyoto University for encouragement, Professor T. Matsu'ura of Hiroshima University and Dr. H. Murata of the Osaka Municipal Technical Research Institute for recording infrared spectra, and Mr. M. Yamaguchi of this laboratory for his helpful assistance.

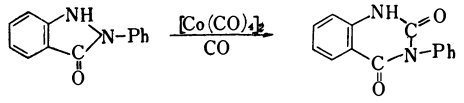
# *Studies on the High Pressure Reaction of Carbon Monoxide. IV. On the Mechanism of Phthalimidine and Indazolone Formation*

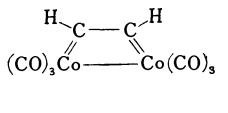
By Shigeki HORIIE* and Shunsuke MURAHASHI



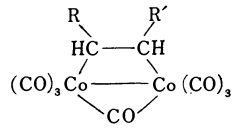
(Received July 3, 1959)

Both the formation of phthalimidines and of indazolones from Schiff bases or azocompounds are considered formally to be the same type of reactions, in which one molecule of carbon monoxide was incorporated into, and then underwent ring closure.

The formation of quinazolons from indazolone is considered to proceed via the reaction of ring enlargement, and has to be considered as another type of reaction and will be mentioned later.



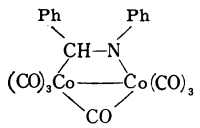
In view of avoiding confusion arising from by-products formation, the reaction of Schiff base was preferably chosen as the subject of this investigation because of the simplicity of the reaction—in the latter case the only reaction product was phthalimidine. From an experiment with Schiff base in continuous run, there could be observed the formation of a complex compound, which was soluble in benzene and was appreciably stable. It was shown in the previous reports that both in the cases of Schiff bases and azobenzenes the more electronegative the "C=N" or "N=N" bond is, the easier the reaction proceeds. These observations seem to indicate that some relation could exist between the ease of complex formation and the feasibility of reaction, and if this argument holds true, the two alternative methods of thinking on the attachment of catalyst on the reactive center of the substrate might be conceivable.



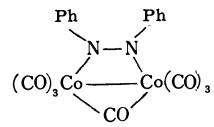
a) The one is that complex formation gives rise to the attachment of cobalt carbonyl across the $\pi$-bond of C=N or N=N. In this case a steric requirement

* Present address: Institute of Scientific and Industrial Research. Osaka Univ., Sakai, Osaka.

should necessarily be considered as was reported by Wender et al. in the case of oxo-synthesis. They observed the formation of a definite complex[1] from acetylene and cobalt carbonyl of the following constitution and, from this fact they postulated the same kind of complex formation by oxo-reaction, when olefins and cobalt carbonyl were reacted II[2],



(I)



(II)

and they reasonably explained the observed differences of reaction velocity on various olefins on the steric ground, which inevitably affects the ease of intermediate complex formation.

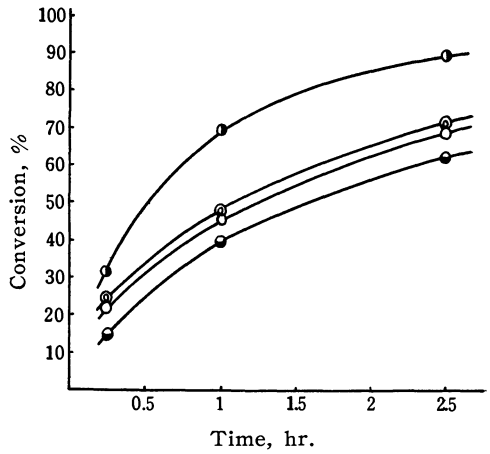
If the same arguments are accepted in the authors' case, the intermediate complex would be such as III or IV, and marked steric effect might well be consiedered when Schiff bases or azocompounds were subjected to the experiment.

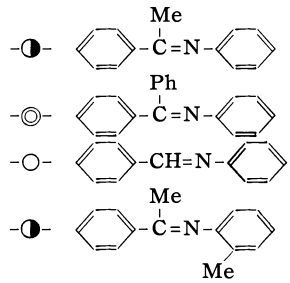
(III)

(IV)

On this account, the authors have compared the velocity of phthalimidine formation reaction, taking benzaldehyde-anil, acetophenone and benzophenone-anil as reactants, and the results are illustrated in Fig. 1. There has been no difference on the velocity and no sterically hindered effect of the phenyl group was discernible. Hence, the formation of this type of complex III would hardly be acceptable.

b) An alternative way of thinking would be that, an attachment of cobalt carbonyl takes place on the lone pair of nitrogen, which gives rise to the formation of a complex, acting as an intermediate for the reaction. Such consideration seems to explain much better the experimental facts which are described below. Although in the case of benzalcyclohexylamine gave in good yield phthalimidine as shown in





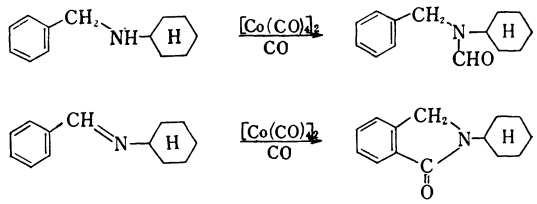


Fig. 1. Reactions of acetophenone-anil and benzophenone-anil with carbon monoxide.

Concn. of Schiff bases: 0.55 millimol/cc.
Concn. of $[Co(CO)_4]_2$: 0.03 millimol/cc.
Pressure of CO : 150 atm.
Solvent : benzene
Reaction temp. : 230°C

formula below, benzyl cyclohexylamine did not give rise to phthalimidine, but only gave *N*-formyl compound by the treatment with carbon monoxide in the presence of cobalt catalyst, under the same condition. Recently, Wender and his collaborators[3] also observed the formation of formyl compounds by the reaction of dimethylamine or piperidine with carbon monoxide, in the presence of cobalt carbonyl catalyst.

In those cases it seems to be appropriate to postulate that an intermediate

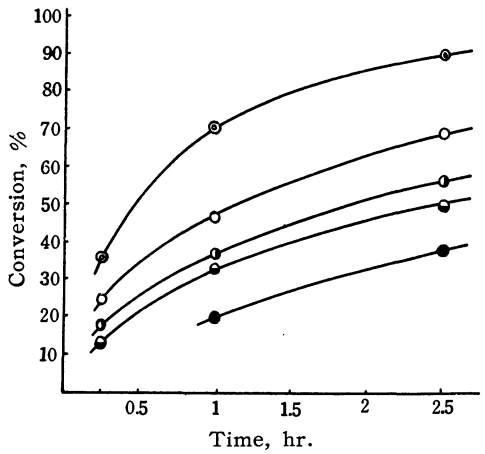
2) I. Wender, S. Metlin, S. Ergun, H. W. Sternberg and H. Greenfield, ibid., **78**, 5401 (1956).

3) H. W. Sternberg, I. Wender. R. A. Friedel and M. Orchin, ibid., **75**, 3148 (1953).

$$\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!NH \xrightarrow[CO]{[Co(CO)_4]_2} \begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!N\text{-}CHO$$

formation of a complex occurred resulting from the coordination of the lone pair of the nitrogen atom with cobalt carbonyl, which in turn stabilized to yield formyl compound. Then, as a possible mechanism for the formation of phthalimidine and indazolone, the same argument would be worth while for consideration and for experimentation.

That is, in this case the initial step of the reaction is the coordination of cobalt carbonyl and nitrogen atom of anil bond CH=N, and the steric effect of ortho-position, which are marked with asterisks,



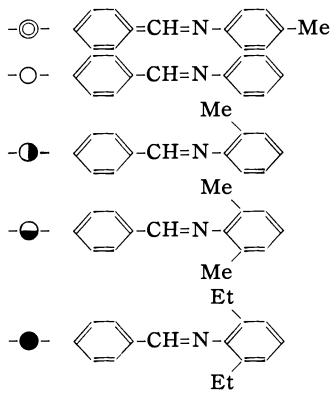


Fig. 2 Reactions of substituted benzaldehyde-anil and carbon monoxide.

Concn. of Schiff bases : 0.55 millimol./cc.
Concn. of $[Co(CO)_4]_2$ : 0.03 millimol./cc.
Solvent : benzene

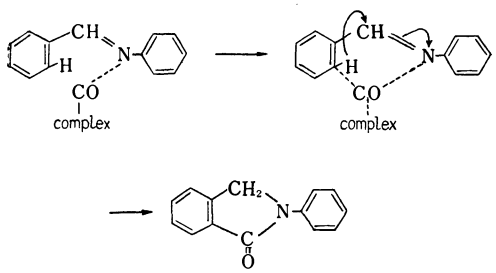
Reaction temp. 230°C

would become very influential to the reaction. Thus, several *o*-substituted anils were subjected to the reaction so as to see whether the steric effect of the substituents was operative. The results of the experiments were illustrated in Fig. 2, where the effect caused by the methyl or ethyl substituent group were visualized in percentage of conversion of anils to phthalimidines, which were followed by the reaction time. It was expected mono-ortho-substituted anil yields lower conversion than unsubstituted one and ortho-dimethyl substituted anil would exhibit a still lesser conversion



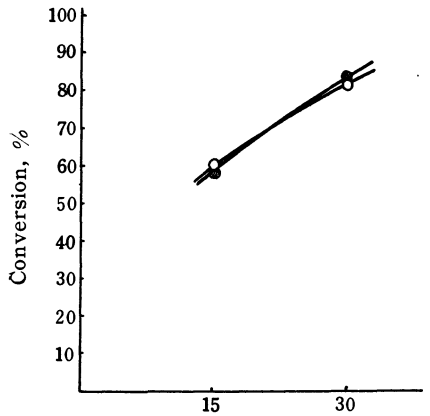
The experiment with *p*-methyl substituted anil has shown that methyl group had rather promoting effect, when it comes on para position, free from steric effect. The fact that in the case of ortho-substituted anil had shown marked low conversion in spite of having a methyl group of promoting action, shows that the steric effect is pronounced in these reactions. Hence it appeared as mentioned above, the primary step would be the addition of cobalt-carbonyl on the lone pair of nitrogen which is hindered by *o*-substituent of large steric requirement.

On the other hand, the reduction of a double bond of anils by means of synthetic gas and cobalt carbonyl go generally smoothly even if in the case where the substituents at the ortho position had shown to exhibit greatest resistance for the formation of phthalimidine, and no distinct steric effect was observed here.

The clear distinction of both reactions should indicate that the fundamental differences might exist in both reactions on the behavior of catalytic action. From the consideration above, the phthalimidine or indazolone formation can eventually be explained as follows.

1) Some kind of complex formation occurred at first between a lone pair of nitrogen atom of the anil or of azo-double bond, and here a steric effect was operative.

2) The formation of N-CO bond was then stabilized with the formation of a 5-membered ring with the carbon atom of benzene with simultaneous transfer of the hydrogen atom of ortho position of benzene to the unsaturated bond of C=N or N=N. Here the presence of such suitable acceptor of hydrogen atom was essential, and these might, side by side, have assisted the ring formation. In the case of benzyl cyclohexylamine as stated above, there is lacking such an accepting group and hence



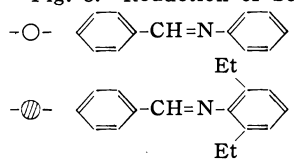


Fig. 3. Reduction of Schiff bases.

after the formation of the complex would stabilize by converting to formyl benzyl amine.

Concerning the formation of quinazolone from indazolone as the authors stated earlier, it is believed to have formed by a ring-enlargement reaction, and such a reaction, as far as the authors are aware, has not yet been described. A glance at this reaction seems to be similar to the reaction of the formation of diphenylurea from hydrazobenzene, but the mechanism of this enlargement is not yet fully understood.

## Experimental

**1) Reactions of Schiff Bases and Carbon Monoxide.** — *General procedure.* — A solution of 0.0275 mol. of Schiff base and 1.5 millimol. of dicobalt octacarbonyl in 50 ml. benzene was heated at 230°C under 150 atmospheric pressure of carbon monoxide. After the reaction, benzene solution was heated under atmospheric pressure in a water bath so as to decompose cobalt carbonyl and filtered. After removal of benzene by distillation and then under reduced pressure, the residue was analyzed.

On each run, conversions from Schiff base into phthalimidine was determined for every 15, 60 and 150 min.

*(i) On benzaldehyde-anil.* — Conversions (%) into 2-phenylphthalimidine were 22.9, 46.2 and 68.1, respectively.

*(ii) On acetophenone-anil.* — Conversions (%) into 2-phenyl-3-methylphthalimidine melted at 82°C were 31.5, 68.5 and 89.0, respectively.

*Anal.* Found: C, 80.29; H. 5.99. Calcd. for $C_{15}N_{13}ON$: C, 80.69; H, 5.87%.

*(iii) On benzophenone-anil.*— Conversions (%) into 2,3-diphenyl-phthalimidine melted at 196.5°C were 24.8, 48.6 and 70.2, respectively.

*(iv) On acetophenone o-tolylimide.*—Conversions (%) into 2-*o*-tolyl-3-methylphthalimidine melted at 108°C were 14.3, 10.0 and 63.5, respectively.

*Anal.* Found: C, 80.68; H, 6.15. Calcd. for $C_{16}H_{15}ON$: C, 80.98; H, 6.37%.

*(v) On benzaldehyde p-tolylimide.*—Conversions (%) into 2-*p*-tolylphthalimidine were 36.8, 69.9 and 87.9, respectively.

*(vi) On benzaldehyde o-tolylimide.*—Conversions (%) into 2-*o*-tolylphthalimidine were 18.2, 36.0 and 53.0, respectively.

*(vii) On benzaldehyde o, o-xylidylimide.* — Conversions (%) into 2-*o*, *o*-xylidylphthalimidine melted at 103°C were 14.5, 32.8 and 49.8, respectively.

*Anal.* Found: N, 5.85. Calcd. for $C_{16}H_{15}ON$: N, 5.90%.

*(viii) On benzal-o, o-diethylaniline.*—Conversions (%) into 2-*o*, *o*-diethylphthalimidine melted at 140°C were 18.6 and 35.9, respectively.

*Anal.* Found: N, 5.02. Calcd. for $C_{18}H_{19}ON$: 5.28%.

**2) Reactions of Benzylcyclohexylamine and Carbon Monoxide.**—A solution of 5 g. of benzylcyclohexylamine and 1 g. of dicobalt octacarbonyl in 45 ml. of benzene was heated at 230°C under 140 atmospheric pressure of carbon monoxide to give 1.6 g. (28.1%) of benzylcyclohexylformylamine boiling at 135~140°C/3 mmHg.

*Anal.* Found: N, 5.99. Calcd. for $C_{14}H_{13}ON$: N, 6.63%.

**3) Reaction of Schiff Base and Water Gas.**— *General procedure.*—A solution of 0.025 mol. of Schiff base and 1.5 millimol. of dicobalt octacarbonyl in 50 ml. of benzene was heated at 120°C under 180 atmospheric pressure of synthetic gas (CO : H=1 : 1).

A benzene solution obtained was hydrolyzed with 4 N sulfuric acid. Benzaldehyde liberated was determined by the method of Bennett and Salamon[4] (hydroxylamine) to get the amount of unreacted Schiff base.

4) C. T. Bennett and M. S. Salamon; *Analyst*, **52**, 693 (1927).

The percentage conversions of benzal compound to benzyl compound were estimated from the value of Schiff base remaining after 15 and 30 min. in each run.

*(i) On benzaldehyde-anil.* — Conversions (%) from benzaldehyde-anil into benzylaniline were 59.8 and 80.0, respectively.

*(ii) On benzal-o, o-diethylaniline.*—Conversions (%) from benzal-*o*, *o*-diethylaniline into benzyl-*o*,*o*-diethylaniline were 58.0 and 81.9, respectively.

# *Radiation-induced Polymerization of α-Methylstyrene**

By Kozo HIROTA, Kenji MAKINO, Keiji KUWATA and Gisuke MESHITSUKA

(Received July 31, 1959)

It has been considered till recently that α-methylstyrene (αMS) is not easily polymerizable, i. e. it can not be polymerized by radical initiators, but can be polymerized by cationic[1] or anionic initiators[2] at low temperatures. Therefore, it will be interesting to study the effect of ionizing radiation on αMS, i. e. to investigate the possibility of radiation-induced polymerization*, and to make clear the kind of mechanism, if it can be polymerized. After the research was advanced to some extent[3], it was found, however, that the first problem was answered affirmatively, and also that the polymerization seemed to proceed by a radical mechanism[3b]. Therefore, a new problem was encountered. This was why αMS did not polymerize by use of such a radical initiator as benzoyl peroxide. It is the object of the present paper to investigate the three problems mentioned above.

## Experimental

**Materials.** — α-Methylstyrene of guaranteed grade of Tokyo Kasei Kogyo K. K. was used. It was treated with aqueous solutions of 20% NaOH and of 20% $NaHSO_3$ successively. Then, it was dried with dehydrated calcium chloride and also with potassium hydroxide freshly fused, and vacuum-distilled under nitrogen atmosphere. The sample thus purified was stored in a closed vessel. According to gas chromatographic analysis, the water content in it was negligible (<0.002%). Naphthalene of chemical pure grade was used after repeated recrystallization. Other reagents (carbon tetrachloride, benzoquinone, cyclohexane and nitrobenzene) were of guaranteed grade and were used without further purification.

**Procedure of Irradiation.**—Two γ-ray irradiation sources of Co-60 were used; one was 350 curie source, while the other 1000 curie source**. Samples will therefore be classified in series B or J, according as the irradiation was carried out at the former or at the latter. In order to avoid direct contact with air and water, αMS was always vacuum-distilled ($10^{-4}$ mmHg) into irradiation tubes. However, as it is known that the presence of oxygen and water brings about an undesirable effect on polymerization, one of the samples (J 9) was distilled over an evaporated film of sodium in advance of irradiation for the sake of comparison. The irradiation tube was made of hard glass and could contain 5~16 g. of αMS. Being required by the discussion on the mechanism of polymerization, ultraviolet irradiation was also attempted by utilizing the sunlight in summer, enclosing the sample in a quartz ampoule.

**Treatment of the Irradiated Samples.** — The irradiated sample was taken out by opening the tube and was poured into methanol, which was five times as much as the sample in volume. White polymers thus precipitated were filtered, washed with methanol, and dried in vacuo at room temperature until the weight became constant. The molecular weight of the polymer was determined with the osmotic pressure method or the viscosity method. In the latter method,

* When the authors' preliminary research was announced at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958, they could not find any research of this kind in literature.

b) Total dose of $7.3\times10^6$ $r$; dose rate of $5.3\times10^4$ $r$/hr.

the following viscosity formula was used[4].

$$[\eta]=3.50\times10^{-5}(\bar{M}_n) \quad (1)$$

$\bar{M}_n$: average molecular weight

As the molecular weight of the polymer was low in case of photopolymerization, the cryoscopic method was adopted.

## Results

**Preliminary Experiments.** — As shown in Table I, it has been found that αMS polymerizes with total dose of $6\times10^6$ $r$, dose rate being $1.2\times10^5$ $r$/hr. The polymer obtained is of fairly high molecular weight. Its melting point is also high if compared with the polymer obtained by photo-polymerization[5]. Moreover, it has been found that polymerization was sensitized by the addition of carbon tetrachloride, but was retarded by the presence of naphthalene and perfectly inhibited by oxygen and benzophenone. Such effects of additives seem to suggest that the polymerization proceeds by the radical initiation of γ-rays.

**Effect of Total Dose.** — In Table II, the effect of total dose on conversion and intrinsic viscosity is shown by keeping the dose rate constant. Conversion of polymerization increases linearly with the total dose after an induction period (ca. 5 hr.). On the other hand, judging from the relation between the intrinsic viscosity and total dose, the molecular weight of the polymer seems to be constant.

5) C. E. Schildknecht, *Ind. Eng. Chem.*, **50**, 107 (1958).

**Effect of Dose Rate.** — In Table III, the effect of dose rate on conversion is shown. In order to investigate the effect of dose rate on velocity of polymerization in detail, the conversion rate $V_p$ is plotted against dose rate $I$ in Fig. 1. It is clear that the velocity of polymerization of αMS is first order of $I$ on the assumption that it is proportional to the rate of conversion. For the sake of comparison, the result of

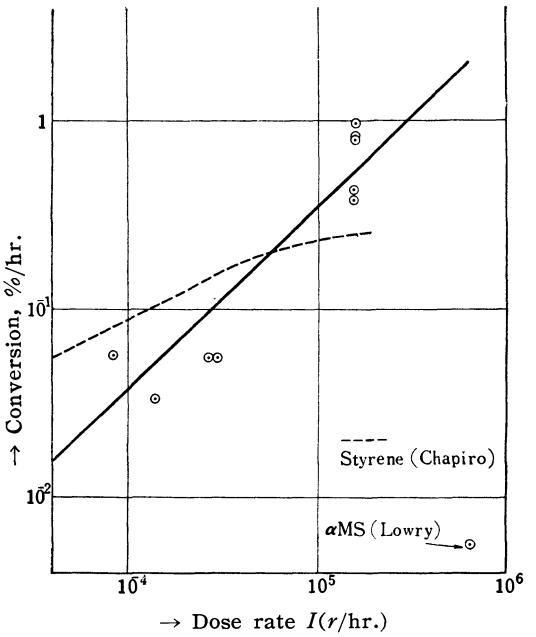

Fig. 1. Conversion per hour vs. dose rate.

Chapiro[6] on styrene is plotted as a broken line, by which it is shown that the order of polymerization of styrene is one half if the dose rate is small. The same order is often reported in the γ-ray-induced polymerization. Therefore, it may be noteworthy that an exceptional order of reaction has been obtained in the present research. This problem will be taken up again in the part of discussion in relation to the mechanism of polymerization. However, the polymerization velocity seems of the same degree in both monomers, while the recent data of Lowry[7] on αMS is very small as compared with that of the present research. The intrinsic viscosity $[\eta]$ is shown to be independent of dose, i. e. 0.110, being similar to that of Lowry. The molecular weight of poly-α-methylstyrene is smaller than that of polystyrene by Chapiro.

**Effect of Solvent.** — As mentioned in the part of the preliminary experiment, effect of several solvents on the reaction rate was already investigated. However, an additional experiment was carried out in other solvents, in order to make the mechanism of polymerization clearer. To meet this requirement, nitrobenzene and cyclohexane were selected as the solvents to be studied, each dielectric constant being 36 and 1.9, respectively. If the reaction proceeds by an anionic or cationic mechanism, αMS will polymerize very rapidly in a solvent of high dielectric constant[8] such as nitrobenzene, while if the reaction proceeds by a radical mechanism, the polymerization must be inhibited by the solvent on the contrary. According to the result shown in Table IV, nitrobenzene behaves as an inhibitor, while cyclohexane behaves as a simple diluent. The result, in addition to the preliminary experiments, confirms the conclusion that the reaction proceeds by a radical mechanism.

**Effect of Temperatures.**—Hitherto, radical polymerization of αMS has been attempted at higher temperatures, but the result was found always negative. Though the data here obtained seem to contradict the above results, the situation may be brought about by the condition that the irradiation was carried out at ordinary temperature. Such being the case, the effect of temperature on radiation-induced polymerization was investigated over the range 9~72°C, the result being summarized in Table V.

As shown by the value of intrinsic

viscosity, it seems that the degree of polymerization $\overline{DP}$ decreases linearly with temperature, and will became practically zero at 77°C. This tendency may be clearly shown by Fig. 2 where conversion and $[\eta]$ are plotted against temperature. It may be estimated that the degree of polymerization at 77°C will be less than five, because telomers of such low polymerization degree are soluble in methanol. On the other hand, the amount of conversion has a maximum and will be zero at 72°C (cf. Fig. 2). The phenomenon here observed must be ascribed to the peculiar property of αMS, and will serve as a key to the mechanism of polymerization***.

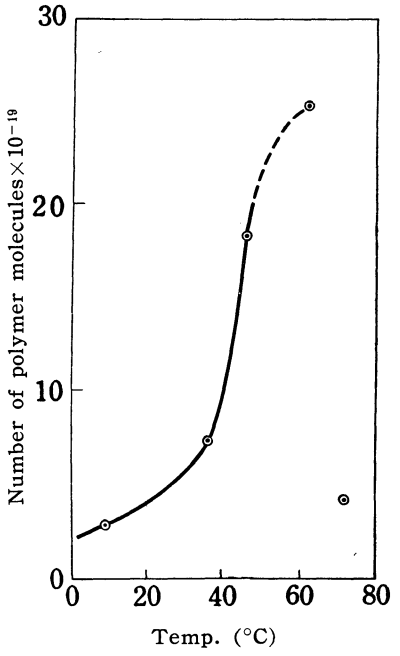

Fig. 3. The effect of temperature on the number of polymer molecules.

Assuming that Eq. 1 can be applied on the poly-αMS, as far as the relative value of average molecular weight is concerned, the number of polymer ($n$) produced at each temperature was calculated, and it was found that $n$ increases very rapidly if temperature decreases as shown in Fig. 3.

**Photopolymerizations.** — Recently, it was reported that Schildknecht[5] succeeded to polymerize αMS by irradiating it with ultraviolet light, the detail being not described. Therefore, similar research was carried out by use of the sunlight for the sake of confirmation. Polymers of 0.38 g. in weight could be obtained from the starting material of (αMS 15.7 g.+di-*tert*-BPO 4.0 g.). The molecular weight of the polymers was ca. 640 (cryoscopic method).

## Discussion

**Mechanism of Polymerization.**—Considering the effects of additives and solvents on the yield of polymers, it may be reasonable to conclude that the radiation-induced polymerization of αMS proceeds by a radical mechanism, as already mentioned. Polymerizing power of ultraviolet light also supports the mechanism, though telomers obtained are of low molecular weight. In the course of the present research this conclusion has been justified independently by Lowry[7] who could obtain polymers having the molecular weight of 50000 at 0°C by the redox polymerization method.

Thus, the present research seems merely to have added an example of radiation-induced polymerization, but it may be noteworthy to have found that the polymerization of this monomer has a peculiar dependency upon temperature, especially it will practically stop at higher temperatures than ca. 70°C. Now, it may be clear why the attempts to polymerize αMS did not succeed hitherto. In these attempts the temperatures to supply radical initiators to the sample were too high to obtain polymers. The phenomenon of this kind called "ceiling temperature" was already pointed out experimentally by Snow and Frey[9] in the copolymerization of olefins and sulfur dioxide. Later Dainton and Ivin[10] explained it by assuming the equilibrium

$$M_j + M \rightleftarrows M_{j+1}$$

and derived the existence of a temperature beyond which the reaction chains will fail to grow. Thermodynamically the ceiling temperature $T_c$ may generally be given by

$$T_c = -\Delta H_p / -\Delta S_p = \frac{\Delta H}{\Delta S^\circ + 2.30 \boldsymbol{R} \log_{10}[M]} \quad (2)$$

where $\Delta H_p$ and $\Delta S_p$ denote, respectively, changes of enthalpy and entropy of polymerization, [M] denotes the concentration

*** Detailed discussion on the relations of conversion and intrinsic viscosity with temperature will be omitted, because it was published already [K. Makino, G. Meshitsuka, K. Kuwata and K. Hirota, *Isotopes and Radiation (Tokyo)*, 2, 322 (1959)].

9) R. P. Snow and F. E. Frey, *Ind. Eng. Chem.*, **30**, 176 (1938); *J. Am. Chem. Soc.*, **65**, 2417 (1943); cf. F. E. Mathews and H. M. Elder, Brit. Pat., 11,635 (1914).

of monomer, and $S^\circ$ denotes the quantity referred to monomer in a standard state of pure liquid. Recently McCormic[11] determined $T_c$ of αMS to be 61°C from the polymerization in tetrahydrofuran solution by use of a sodium naphthalene complex as initiator. Though the temperature is slightly lower than that of the present research, the discrepancy can be explained by Eq. 2, if it is considered that the degree of polymerization of the present sample is lower than that of McCormic (cf. the formula[12] giving the relation between $\Delta H_p$ and average molecular weight $\overline{M}_n$: $-\Delta H_p = 8.424 + 2194/\overline{M}_n$). It is rather interesting that $T_c$ of such a low temperature is obtained in both experiments, notwithstanding the fact that the active species are different in the course of polymerization. Now, a problem remains why $T_c$ of poly-α-methylstyrene is much lower than that of polystyrene. It may be ascribed to the small values of $-\Delta H_p$ for this monomer as compared with other monomers: e. g. αMS 9.0, styrene 16.0 and ethylene 22, respectively in kcal./mol. per monomer, in spite of the order of magnitude of its $\Delta S_p$ comparable to the other monomers[13].

**Kinetic Formula of Polymerization.** — From the above discussion, it seems to be without ambiguity that radiation-induced polymerization of αMS proceeds by a radical mechanism, but an important experimental result still remains to be unexplained. In the pioneer work of Chapiro[6] on the gamma-ray-induced polymerization of styrene and other monomers, he found that velocity $V_p$ of the polymerization can be expressed by the formula

$$V_p \propto I^{1/2} \qquad (3)$$

where $I$ is the dose rate. The formula is generally accepted to be applicable to all the radiation-induced polymerization. Nevertheless, in the present research as shown in Fig. 1, the velocity derived from the conversion (%) is not proportional to $I^{1/2}$ but rather to $I$. The above result, though it seems to be exceptional, can be understood by the mechanism in which a degradative chain transfer proceeds more frequently than the chain termination between radicals. Therefore, each step of the elementary processes of the present reaction will be summarized as follows:

Initiation: $\mathrm{M} \xrightarrow{\phi I} \mathrm{R}\cdot$

$\mathrm{R}\cdot + \mathrm{M} \xrightarrow{k'_i} \mathrm{M}^*$

Propagation: $\mathrm{M}^*_j + \mathrm{M} \xrightarrow{k_p} \mathrm{M}^*_{j+1}$

Depropagation: $\mathrm{M}^*_{j+1} \xrightarrow{k_d} \mathrm{M}^*_j + \mathrm{M}$

Chain transfer to monomer:

$\mathrm{M}^*_j + \mathrm{M} \xrightarrow{k_{tr}} \mathrm{M}_j + \mathrm{M}^*$

Degradative chain transfer:

$\mathrm{M}^*_j + \mathrm{M} \xrightarrow{k_t} \mathrm{M}_j + \mathrm{M}$

where $\mathrm{M}^*_j$ denotes active polymers of $j$ subunits and $\phi$ radicals produced per unit $I$ in unit volume of monomers. Applying the steady state treatment to the mechanism mentioned above, the kinetic formula may be derived easily:

$$V_p = (\phi I/k_t)(k_p[\mathrm{M}] - k_d)$$

i. e. $V_p$ is proportional to $I$.

## Summary

It has been shown that (a) α-methylstyrene polymerizes at room temperatures by gamma-ray irradiation; that (b) the reaction proceeds by a radical mechanism, considering from the effect of solvents, additives and ultraviolet light; that (c) ceiling temperature for this monomer is exceptionally low (ca. 70°C) among vinyl monomers, so that it is hard to obtain high polymers by the usual method; that (d) the experimental fact that the velocity of polymerization is proportional to dose rate and not to square root of dose rate can be explained by the assumption that degradative chain transfer occurs more frequently than the termination between active polymers.

A part of the expense for the present experiment has been defrayed from a grant given by the Ministry of Education, to which the authors' thanks are due.

# *Solvent Effect on the Intrinsic Viscosity of Polymers*

By Tetsuya ISHIKAWA

(Received July 7, 1959)

It is well known that the intrinsic viscosity, $[\eta]$, of a polymer takes high values in good solvents and low values in poor solvents. If the experimental precautions to be observed in order to obtain reliable data are taken, such difference may be attributed quantitatively to the solvent character which the existing theories of dilute solution viscosity of polymers do not deal with.

## Analytical Procedure

In the last report[1], the author derived from his ideal mixture law for viscosity the following form for $[\eta]$, $cm^3\,g^{-1}$:

$$[\eta]=\frac{(K_v)_0}{d_2}\left(\frac{\eta_2}{\eta_1}\right),$$

$$(K_v)_0=\left|\frac{(1-z_v)(\eta-\eta_1)}{z_v(\eta_2-\eta)}\right|_{z_v\to 0} \qquad (1)$$

in which $\eta_1$, $\eta_2$ and $\eta$ denote the viscosities of a solvent, solute of high molecular weight whose density is $d_2$, and the solution respectively, and $z_v$ is the volume fraction of the solute before mixing.

For an ideal mixture composed of two liquids of low molecular weights, $(K_v)_0=(K_v)_1=K_v$, a constant for all concentrations, and the probable values of $K_v$ relative to benzene of 32 liquids can be computed from $K$ values relative to benzene obtained before[2], by means of the equality:

$$K_v=K\frac{M_1d_2}{M_2d_1} \qquad (2)$$

where $M_1$, $M_2$, and $d_1$, $d_2$ are the molecular weights and densities of components 1 and 2, respectively, benzene being taken as component 1 in this case.

Combining Eq. 1 with Eq. 2, the following assumption is made:

Since $[\eta]$ is an extrapolated value at infinite dilution of a polymer with a given solvent where solvent molecules suffer presumably no change in association, $(K_v)_0$ of polymer/solvent may be inversely proportional to $K_v$ of solvent/benzene, and therefore $[\eta]$ may be inversely proportional to the product

$$\eta_1\times(K_v \text{ of solvent/benzene})$$

so long as $(K_v)_0\times(K_v$ of solvent/benzene) which signifies the solute character term at infinite dilution retains a constant value in different solvents.

In other words, between the intrinsic viscosities of the same polymer in solvent 1 and in solvent 2, there may exist the equation:

$$\frac{[\eta] \text{ in solvent 1}}{[\eta] \text{ in solvent 2}}=\frac{(\eta\times K_v \text{ rel. to benzene) of solvent 2}}{(\eta\times K_v \text{ rel. to benzene) of solvent 1}} \qquad (3)$$

## Verifications

In order to verify Eq. 3, one quotes from Wales, Marshall and Weissberg's report on the intrinsic viscosities of dextran in water and in formamide at 25°C[3], as one has $K=0.67$ for water and $K=0.34$ for formamide at 25~40°C[2].

Now, one has for benzene ($M=78.11$) $d=0.87875$(20/4), 0.86805(30/4); for water ($M=18.02$) $d=0.99823$ (20/4), 0.99568 (30/4), $\eta=0.01005$ poise (20°C), 0.00802 poise (30°C); and for formamide ($M=45.04$) $d=1.1349$ (20/4), 1.1266(30/4), $\eta=0.0375$ poise (20°C), 0.0294 poise (30°C)[4,5].

From these values one obtains

$$\frac{(\eta\times K_v \text{ rel. to benzene) of water}}{(\eta\times K_v \text{ rel. to benzene) of formamide}}=1.16(20°C),\ 1.19(30°C)$$

On the other hand, the inverse ratios of intrinsic viscosity values, $100\,cm^3\,g^{-1}$, in formamide to those in water taken from

1) T. Ishikawa, This Bulletin, **31**, 791 (1958).
2) T. Ishikawa and T. Baba, ibid., **11**, 64 (1936); see also T. Ishikawa, ibid., **31**, 524 (1958).
3) M. Wales, P. A. Marshall and S. G. Weissberg, *J. Polymer Sci.*, **10**, 229 (1953).
4) "International Critical Tables", III, (1928), pp. 25, 27—30.
5) F. Henning, "Wärmetechnische Richtwerte", Vdi-Verlag G.m.b.H. (1938), pp. 40—45.

Wales, Marshall and Weissberg's data for dextran of four different molecular weights, $M$, are:

$$\frac{[\eta] \text{ in formamide}}{[\eta] \text{ in water}} = \frac{0.121}{0.097} = 1.25 \text{ for } M = 11000$$

$$= \frac{0.341}{0.271} = 1.26 \text{ for } M = 71000$$

$$= \frac{0.446}{0.384} = 1.16 \text{ for } M = 153000$$

$$= \frac{0.492}{0.421} = 1.17 \text{ for } M = 185000$$

Comparing these values with the above obtained values, it is seen that the coincidence is satisfactory, especially for dextran of higher molecular weights.

The following is another test applied to the data of the toluene and methyl ethyl ketone (MEK) solutions of one polystyrene sample distributed to several laboratories from the International Union of Pure and Applied Chemistry (IUPAC)[6]. The average values of $[\eta]$, $cm^3g^{-1}$, assembled by Frank and Mark were 148.3±2.3 for toluene at an average temperature 25.5°C (25°C in eight laboratories, 30°C in one laboratory, and 24.7°C in one laboratory), and 82.9±2.8 for MEK at an average temperature 25.5°C (25°C in seven laboratories, 30°C in one laboratory, and 24.7°C in one laboratory).

For toluene one has $\eta=0.00551$ poise (25°C)[7], and $K=1.24$ (15~35°C)[2], from which one gets $K_v=1.03$ (25°C) by putting toluene ($M=92.13$) and benzene ($M=78.11$) densities to be 0.86122 (25/4) and 0.87340 (25/4), respectively; for MEK one has $\eta=0.00383$ poise (25°C) but $K$ is unknown because of lack of binary mixtures composed of this liquid as one component in the literature, and, under the author's direction, viscosity measurements on the binary system of benzene (1)-MEK(2) have been carried out by M. Ikeda, lecturer of Nagasaki Prefectural Junior College.

Benzene and MEK used for the present measurements were the guaranteed reagents of Kanto Chemical Co., Inc., the former having test No. 4E033294 and the latter having test No. 3E088722, and both were used without further purification.

Densities and viscosities were measured at 25°C with an automatically regulated thermostat, T-3 type of Shimadzu Seisakusho Ltd., with a Gay-Lussac pycnometer of 25 $cm^3$, and with a Ostwald viscometer with 10 $cm^3$ efflux volume which has given efflux time of 54.70 sec. for water.

To convert density (25/25) to density (25/4) and relative viscosity to absolute viscosity, the author used density of water at 25°C=0.99707[4], and viscosity of water at 25°C=0.008941 poise[8].

The experimental results are given in Table I. As seen from the observed $K_v$ values in Table I, this system belongs to the case where the association degree of either of the components decreases with the dilution of the other, and either of the extrapolated values of $K_v$ at $z_v=0$ or $z_v=1$ gives the normal $K_v$ for the mixture. Mixtures of phenol, guaiacol, or benzyl benzoate with benzene or toluene in which the former components suffer molecular dissociation are examples for this case. The formulation of viscosity vs. composition curves of such mixtures can not be generally done, yet a particular case can be solved by a particular means, that is to say, $K_v$ or its reciprocal at each composition to test whether they are in linear relationship with composition or not[9]. For the present case, reciprocal values of $K_v$ against $z_v$ appear to lie nearly on a straight line, $1/K_v=0.56-0.18z_v$, hence one has obtained $(K_v)_0=1.79$ and $(K_v)_1=2.63$. Compare the observed and calculated viscosity values in Table I, the deviations being at most less than 1%. It is doubtful, however, that either of components, benzene or MEK, suffers molecular dissociation, so the author refers to the results by making use of Fischler's viscosity data on benzene

(1)-acetone(2) system[10] as found in the literature (see Table II). Since in this system benzene suffers no molecular change throughout the concentration, giving a constant value 2.06±0.05 which is an intermediate value between $(K_v)_0$ and $(K_v)_1$ for MEK/benzene, the same liquid in the benzene(1)-MEK(2) system may also be considered to suffer no molecular change, and therefore $(K_v)_1=2.63$ can be decided as the normal value, $K_v$, for MEK/benzene, the corresponding association degree of MEK being estimated to be 2.78.

Taking $K_v=2.63$ and $\eta=0.00383$ poise at 25°C for MEK and the above values for toluene, one obtains

$$\frac{(\eta\times K_v \text{ rel. to benzene) of MEK}}{(\eta\times K_v \text{ rel. to benzene) of toluene}}=1.77$$

whereas

$$\frac{[\eta] \text{ in toluene}}{[\eta] \text{ in MEK}}=\frac{148.3}{82.9}=1.79$$

for $M=560000\sim590000$

Also from the similar data on four polystyrene fractions in the previous report[11] from IUPAC, the same ratios in respective laboratories are:

$$\frac{[\eta] \text{ in toluene}}{[\eta] \text{ in MEK}}=1.88,\ 1.99 \text{ for } M=860000$$
$$=2.11,\ 2.01 \text{ for } M=655000$$
$$=1.54,\ 1.61 \text{ for } M=234000$$
$$=1.64,\ 1.60 \text{ for } M=82500$$

with an average of 1.80 which is nearly equal to the preceding result. Hence the coincidence is fairly good between the ratios taken from intrinsic viscosity data and from the present theory.

## Conclusion

The foregoing verifications lead us to the conclusion that an intrinsic viscosity equation $[\eta]=(K_v)_0(\eta_2/\eta_1)/d_2$ is valid for polymer solutions, and therfore that $[\eta]$ of a polymer in a solvent can be converted to $[\eta]$ of the same polymer in a standard solvent, e. g. benzene, or toluene, or acetone; this procedure will give a reliable value to be further analyzed, if normal $K_v$ values of these solvents relative to the standard solvent are known.

The author is indebted to Nagasaki American Cultural Center for having made it possible for him to obtain, by mail from Tokyo, Journal of Polymer Science, Vol. X, 1953; and also to Mr. M. Ikeda for his viscosity measurements on the binary system of benzene and methyl ethyl ketone.

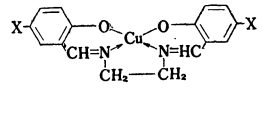
# *Some Addition Compounds of Salicylaldehyde-ethylenediimine-copper*. IV.*

By Tsuguo TANAKA



(Received August 17, 1959)

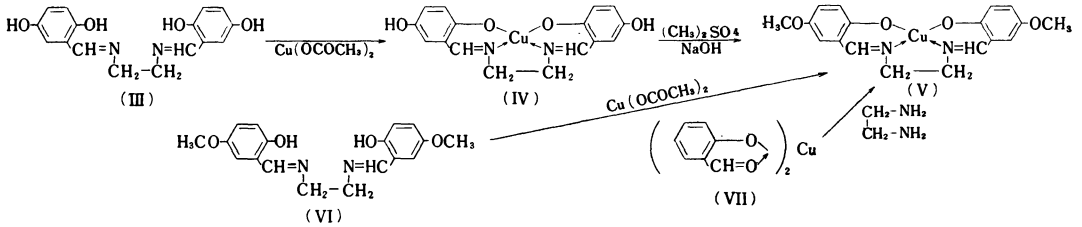
Recently, some observation have been reported[1] about the influence of substituents in the ligand molecules on the physical and chemical properties of their metal chelates. Calvin et al.[2] presented the following order about the stability of the chelates, which he explained on the basis of mesomeric effect, among the substituents A in a metal chelate of salicylaldehyde-anil (I) by the measurement of their half wave potential.

$$OCH_3 > OH > CH_3 > H > C_6H_5 > SO_3Na > NO_2$$

(I)

(II)

An analogous but not identical order of substituents was also observed by the present author[3] about the tendency of the formation of the addition compounds of 5,5′-disubstituted salicylaldehyde-ethylenediimine-copper (II) with propionic acid, phenol and chloroform; the order was



$$5,5'\text{-}CH_3 > 5,5'\text{-}H > 5,5'\text{-}NO_2 > 5,5'\text{-}Cl$$

Now, it was attempted to obtain a further illustration about the influence of the 5,5′-substituent groups in salicylaldehyde-ethylenediimine-copper on the formation of the addition compounds.

5,5′-Dibromo-, 5,5′-diiodo- and 5,5′-dimethoxy-salicylaldehyde-ethylenediimine-copper were synthesized according to the usual procedure[3,4]. 5,5′-Dibromosalicylaldehyde-ethylenediimine-copper was obtained as a purple addition compound with chloroform when it was recrystallized from chloroform, which was eliminated on standing in the air to give a pure green 5,5′-dibromo-salicylaldehyde-ethylenediimine-copper.

The metal chelate which was obtained by the reaction of 5-iodosalicylaldehyde-copper with ethylenediamine-monohydrate in an ethanolic solution was a purple addition compound of 5,5′-diiodosalicylaldehyde-ethylenediimine-copper with ethanol which lost ethanol, when heated at 110°C for thirty minutes, to give dark green 5,5′-diiodosalicylaldehyde-ethylenediimine-copper. Free 5,5′-diiodosalicylaldehyde-ethylenediimine-copper formed addition compounds with ethanol and chloroform.

But the reaction of 5-hydroxysalicylaldehyde with copper acetate in an ethanolic solution resulted in the formation of a black polymeric copper salt, which could not be converted into 5,5′-dihydroxysalicylaldehyde-ethylenediimine-copper by a reaction with ethylenediamine in ethanol. Therefore, 5-hydroxysalicylaldehyde was treated with ethylenediamine-monohydrate in an ethanol to give 5,5′-dihydroxysalicylaldehyde-ethylenediimine (III), which on warming in ethanol with an aqueous solution of copper acetate produced dark blue crystals of the copper salt (IV)[5]. The structure of 5,5′-dihydroxysalicylaldehyde-ethylenediimine-copper (IV) was

(III) (IV) (V) (VI) (VII)

a) Powdered sample. b) Recrystallization.

confirmed by the following synthesis.

5,5'-Dihydroxysalicylaldehyde-ethylenediimine-copper (IV) was methylated by treating it with dimethylsulfate and aqueous sodium hydroxide[6], when 5,5'-dimethoxysalicylaldehyde-ethylenediimine-copper (V) was obtained. V was also obtained either by the reaction of 5,5'-dimethoxysalicylaldehyde-ethylenediimine (VI) with an aqueous solution of copper acetate in ethanolic solution, or by the reaction of 5-methoxysalicylaldehyde-copper (VII) with ethylenediamine-monohydrate. Identity of these products was proved by the observation of the absorption spectra.

The formation of the addition compounds of these metal chelates with propionic acid, phenol, chloroform and ethanol was examined and the results were summarized in Table I.

Peculiar behavior of 5,5'-diiodosalicylaldehyde-ethylenediimine-copper was noted; it formed addition compounds with propionic acid as well as with chloroform and ethanol in contrast to other derivatives.

Comparing these results with those already reported, the tendency of the formation of addition compounds is in the following order,

$$5,5'\text{-}CH_3 \underset{(+)}{>} 5,5'\text{-}OCH_3 \underset{(-)}{>} 5,5'\text{-}I \underset{(-)}{>} 5,5'\text{-}H >$$
$$5,5'\text{-}OH \underset{(-)}{>} 5,5'\text{-}Br \underset{(-)}{>} 5,5'\text{-}NO_2 \underset{(-)}{>} 5,5'\text{-}Cl$$

where (+) indicates electron releasing and (−) electron attracting inductive effects[7].

## Experimental

5-Iodosalicylaldehyde was obtained as its sodium salt by the reaction of *p*-iodophenol (10 g.) with chloroform (9 g.) in aqueous sodium hydroxide[8] (9.1 g. sodium hydroxide in 40 ml. water) at 55~65°C. Yield, 14%.

**5, 5'-Dihydroxysalicylaldehyde - ethylenediimine.** —To a solution of 5-methoxysalicylaldehyde (1.6 g. in 41 ml. ethanol) was added ethylenediamine-monohydrate (520 mg. in 5 ml. ethanol). In the meantime a yellow precipitate separated, which was filtered and dried (1.5 g.). It was dissolved in ethanol and water was added to it drop by drop until turbidity occurred; the product was left to stand for a while, until yellow needles separated, which were filtered and dried. Yield, 0.9 g.; m. p. 250°C (decomp.). It is easily air-oxidized in an ethanolic solution, when left to stand for one day and the color changes into orange to red.

*Anal.* Found: C, 60.63; H, 5.77; N, 8.00. Calcd. for $C_{16}H_{16}O_4N_2$-$H_2O$: C, 60.37; H, 5.70; N, 8.80%.

**5,5'-Dimethoxysalicylaldehyde - ethylenediimine.** —To a solution of 5-methoxysalicylaldehyde (900 mg. in 20 ml. ethanol) was added ethylenediamine-monohydrate (100 mg. in 3 ml. ethanol). In the meantime the whole mass solidified, which was filtered, washed with a little water and recrystallized from ethanol. Yield, 700 mg.; m. p. 165°C.

*Anal.* Found: C, 65.95; H, 6.38; N, 8.29. Calcd. for $C_{18}H_{20}O_4N_2$: C, 65.84; H, 6.14; N, 8.53%.

5,5'-Dibromo-, 5,5'-diiodo-, 5,5'-dimethoxysalicylaldehyde-ethylenediimine-copper were obtained by the usual procedure[3,4].

**5, 5' - Dibromosalicylaldehyde - ethylenediimine - copper.** — Gold orange 5-bromosalicylaldehyde-copper was converted into green 5,5'-dibromosalicylaldehyde-ethylenediimine-copper. Recrystallization of the product from chloroform produced a purple addition compound with chloroform which, upon standing in air, gradually (in two days) lost chloroform to yield the green, pure 5,5'-dibromo-complex.

*Anal.* Found: C, 39.99; H, 2.86; N, 5.91; Cu, 13.04. Calcd. for $C_{16}H_{12}O_2N_2Br_2Cu$: C, 39.42; H, 2.48; N, 5.75; Cu, 12.97%.

**5, 5' - Diiodosalicylaldehyde - ethylenediimine - copper.**—Gold yellow 5-iodosalicylaldehyde-copper suspended in boiling ethanol was treated with ethylenediamine-monohydrate; immediately transient green coloration was observed, but the color turned purple and the purple addition compound of 5,5' - diiodosalicylaldehyde - ethylenediimine-copper with ethanol precipitated, which was filtered and recrystallized from ethanol. By heating the addition compound at 110°C for thirty minutes, dark green pure 5,5'-diiodosalicylaldehyde-ethylenediimine-copper was obtained.

*Anal.* Found: C, 33.25; H, 2.42; N, 4.17; Cu, 10.40. Calcd. for $C_{16}H_{12}O_2N_2I_2Cu$: C, 33.04; H, 2.08; N, 4.82; Cu, 10.93%.

**5, 5'-Dimethoxysalicylaldehyde - ethylenediimine-copper.**—(a) It is obtained from yellow 5-methoxysalicylaldehyde-copper as described above. Recrystallization from chloroform gave green plates. $\lambda_{max}^{C_5H_5N}$ 400, 585 m$\mu$[9].

*Anal.* Found: C, 53.74; H, 4.59; N, 6.77; Cu, 16.91. Calcd. for $C_{18}H_{18}O_4N_2Cu$: C, 54.45; H, 4.65; N, 7.19; Cu, 16.30%.

(b) 5,5'-Dimethoxysalicylaldehyde - ethylene - diimine (600 mg.) in boiling ethanol (80 ml.) was treated with a saturated aqueous solution containing copper acetate (400 mg.) and the mixture was boiled for thirty minutes on a water bath. After cooling, the precipitates were filtered and recrystallized from chloroform.

(c) To an intimate mixture of 5,5'-dihydroxysalicylaldehyde-ethylenediimine-copper (400 mg.) and dimethylsulfate (400 mg.) was added 0.8 ml. of 10% aqueous sodium hydroxide solution; it reacted exothermically at once, stirred thoroughly to complete the reaction. After an hour, the paste was filtered, washed with water, dried and recrystallized from chloroform.

**5, 5'-Dihydroxysalicylaldehyde-ethylenediimine-copper.**—To a boiling solution of 5,5'-dihydroxysalicylaldehyde-ethylenediimine (1.2 g. in 215 ml. ethanol) was added copper acetate (0.96 g. in 20 ml. water) and the mixture heated for twenty minutes on a water bath. After the mixture was cooled, the precipitate was filtered and recrystallized from ethanol. It showed blue purple as needles but a gray green color appeared when powdered. Yield, 1 g.

*Anal.* Found: C, 50.15; H, 4.47; N, 6.64; Cu, 17.27. Calcd. for $C_{16}H_{14}N_2O_4Cu$-$H_2O$: C, 50.61; H, 4.25; N, 7.38; Cu, 16.74%.

**Addition Compound with Propionic Acid**[3].—*5, 5'-Diiodosalicylaldehyde-ethylenediimine-copper.*

*Anal.* Found: C, 33.49; H, 2.70; N, 4.53. Calcd. for $C_{16}H_{12}O_2N_2I_2Cu$-$C_3H_6O_2$: C, 34.79; H, 2.77; N, 4.27%.

# *Primary Processes in the Photobleaching of Eosin as Revealed by the Flash Technique*

By Shunji KATO, Teiko WATANABE, Shigeo NAGAKI and Masao KOIZUMI

(Received August 17, 1959)

A few years ago, Imamura and Koizumi[1] investigated kinetically the reductive photobleaching of xanthen dyes and proposed a reaction scheme which involved the formation of semiquinone radical with a lifetime of millisecond order. Now, techniques of flash photolysis and flash spectroscopy have been introduced in order to get direct evidence for their conclusion and to obtain more detailed information about the primary processes. The present paper is concerned chiefly with the spectra of the transient intermediates and their assignment along with some discussions about the reaction scheme. A rather remarkable result was that two types of intermediates with a lifetime of millisecond order were observed spectroscopically. One of these was assigned to semiquinone and the other to a certain kind of complex between dye and ethanol.

## Experimental

**Flash Lamps.** — A photolysis flash lamp, six turn helical Terex tube, 10 mm. in diameter, the total length of which was about 1 m., was filled with argon at 4.5 cmHg pressure. It was surrounded by a cylindrical magnesia reflector. A spectroflash lamp was a Terex tube, 20 cm. in length and 15 mm. in diameter, having a flat quartz window, the argon pressure being 20 cmHg. Five 10 $\mu$F oil condensers were used for photolysis flash and one condenser of the same capacity for spectroflash, and both of them were charged up to 4 kV. Flashes were triggered by induction coils operated by strobo discharge tubes. The interval of firing was controlled from 0.3 to 700 millisec. by an electronic device. The half height widths of the flashes were measured by an oscilloscope and found to be approximately 60 and $<20$ $\mu$ sec., respectively, a crystal oscillator being used as a time measure.

**Spectroscopic.**—A Shimazdu QF-60 quartz spectrograph and Fuji Neopan plates were used.

**Reaction Vessels.** — The vessels were of 10 cm. length and 1 cm. diameter glass tubes with quartz plates cemented on both ends. The glass part of the vessel cuts off shorter wavelengths than 300 m$\mu$.

**Materials.** — Merck eosin and Wako Pure Chemical Industries G. R. grade ethanol were used. The latter was transparent up to 260 m$\mu$ for a 10 cm. path. Throughout the investigation, $1\times10^{-5}$ mol./l. ethanolic solution of eosin was degassed by repeated distillation in high vacuum, sealed in a reaction vessel and then was placed at the center of the helical flash lamp.

**Calibration of the Flash Intensity.** — Although the flashing condition was made as nearly the same as possible by monitoring the condenser voltage, some variation in intensity could not be avoided. To evaluate correctly the absorption spectra of the transient species from the trace of a microphotometer, the variation of the spectro-flash intensity was taken into account in the following way. From the readings of the trace for the solvent and solution, the logarithm of exposure was determined in the usual way. When the difference in the logarithm of exposure was plotted against the molar extinction coefficient ($\varepsilon_\lambda$) of eosin, a linear relationship was found to hold in the wavelength region above 480 m$\mu$, where the transient species had no absorption. Since the relation

$$\Delta S_\lambda = \log I_\lambda - \log I'_\lambda + \varepsilon_\lambda cd$$

holds, where $\Delta S_\lambda$ is the difference in logarithm of exposure, $I_\lambda$ and $I'_\lambda$ are the intensity of the spectro-flash for solvent and solution, respectively; the intercept of the ordinate gives the value $\log I_\lambda - \log I'_\lambda$, which allows one to calibrate the intensity variation of the spectro-flash.

## Results

The absorption spectra are shown in Fig. 1. The spectra of the initial solution were obtained by a Hitachi spectrophotometer EPU-2A. The time interval written is that between the start of the two flashes. As seen from the figure, after 0.6 millisec., the main absorption of eosin decreases to 60% of the initial solution, and at the same time a definite transient absorption comes into existence. Substracting from this the absorbance due to the remaining eosin, the quantity of which

1) M. Koizumi and M. Imamura, This Bulletin, **28**, 117 (1955); **29**, 899 (1956).

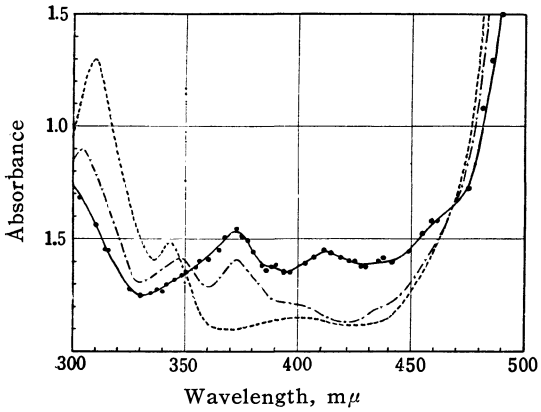

Fig. 1. Transient spectra of eosin.

—·—: 5 millisec.
----: before flash

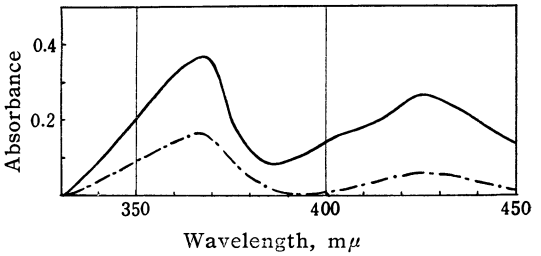

Fig. 4. Absorption spectra of transient species of ulanin.
——: 0.6 millisec.
—·—: 5 millisec.

can be evaluated from the depression of the absorbance in the region longer than 480 mμ, one can obtain the genuine spectra of transient species, which are shown in Fig. 2.

Three peaks are seen at 373, 410 and about 450 mμ. After 5 millisec., the 373 and 450 mμ peaks, which will be called A band from now on, still maintain considerable intensity, whereas the 410 mμ peak (B band) has disappeared. After several minutes, these transient absorption bands thoroughly vanish and the eosin spectra are recovered up to about 88% of the original solution. Twelve per cent loss is attributable, without doubt, to permanent bleaching.

In the presence of air, neither transient spectral change nor permanent bleaching was observed. The deaerated aqueous solution of eosin showed a slight transient depression of eosin absorption spectra, but no new spectra were observed in the region of the above mentioned A and B bands.

For uranin in ethanol also, transient spectra were observed by the flash illumination, but at 0.6 millisec. no clear peak corresponding to the 410 mμ peak of eosin was found (Figs. 3 and 4).

It is worth adding here that when only a photolysis flash is fired, a fluorescence spectrum can be taken on a plate, and it is to be noted that the fluorescence intensity varies markedly according to whether the sample is aerobic or not. On the contrary, the measurement by an ordinary fluorimeter (an accessory of the spectrophotometer), shows no such difference.

TABLE I. RELATIVE FLUORESCENCE INTENSITY AT THE PEAK WAVELENGTH

| | Flash | Fluorimeter |
|---|---|---|
| Aerobic | 100 | 100 |
| In vacuo | 5 | 100 |

## Discussion

The appearance of two spectral bands A and B with different lifetimes indicates that at least two transient species are formed in the initial stage of the reductive photobleaching of eosin.

As regards the assignment of these two bands, there scarcely exists any doubt that the A band is due to the semiquinone radical of eosin on the basis of the kinetic studies of Imamura and Koizumi. The assignment of band B, however, is not so clear-cut. A question may arise whether this absorption is caused by the triplet state of dye, but this possibility can be denied from the following two reasons. The first reason is that the lifetime of the band, being some tenths of a millisecond, would be too long for a triplet. Considered from the results already published in literature, for instance, as reported by Porter et al.[2], triplet states have usually too short a lifetime at room temperature and in ordinary solvents of common fluidity, to be observed by the present apparatus. The second reason is that if it were due to triplet state, the similar band should be observed in aqueous solution because of lower reactivity of water to the triplet state than ethanol, a fact which has been established by kinetic studies of photobleaching[1].

The B band must, therefore, be attributed to some unknown molecular species which perhaps is formed prior to semiquinone. Now, as reported elsewhere[3], the influence of added substances on the bleaching rate of eosin strongly suggests the formation of a certain kind of molecular complex between the excited state of the dye and ethanol. If this scheme is accepted, it is quite natural to attribute the B band to the complex in question.

Furthermore, in order to interpret the other experimental results reported in this paper, it is quite desirable, indeed it seems rather indispensable, to introduce such a complex in the reaction scheme, as will be shown below.

1) From the result that at 0.6 millisec. after the firing of the main flash the quantity of the existent dye drops to about 60% of that of the initial solution, it is very natural to consider that at a certain early period after flashing, nearly all the dye molecules exist as intermediates whose lives are in the order of $10^{-3}$ sec. or so.

Supposing that a semiquinone is the only one species as such an intermediate, then nearly 50% of dye would be bleached permanently, if one assumes, as is plausible, that semiquinone is stabilized by a dismutation process, $2DH \rightarrow D + DH_2$. Contrary to this expectation, only 12% permanent bleaching is produced by a single flash. In other words, about 24% of the dye is converted into semiquinone by one flash, hence this result necessitates that some other transient species like the complex considered above be existent, and that most of this transient species be deactivated without going to the reaction product.

2) The absence of photobleaching as well as of transient spectrum in aerobic condition is intimately connected with the fact formerly reported, that the reductive photobleaching is completely inhibited by the existence of a very small quantity of oxygen[1]. Imamura and Koizumi who at that time did not conceive of the formation of the complex, estimating the lifetime of the species attacked by oxygen to be $10^{-3}$ sec. or so from the quantity of oxygen necessary to suppress completely the bleaching reaction, concluded that semiquinone be mainly destroyed by oxygen, rejecting the possibility of the triplet state (with much shorter lifetime) being deactivated. But if so, B band should still be observed in flashing the aerated alcoholic solution. Thus, their scheme is not consistent with the present results and it is necessary to consider that the molecular complex now introduced be deactivated effectively by oxygen.

3) The results of fluorescence measurements are also consistent with the formation of such a complex. Thus by flash illumination in vacuo, a major part of the dye is converted into the complex at an early stage and survives at the end of the flash. Consequently, the illumination has poor efficiency for the fluorescence, since only a little part of dye remains in the ground state throughout the later period of flash. Whereas the complex is rapidly destroyed into its components by the attack of oxygen, yielding the dye molecule in the ground state. This process enables each molecule of dye to emit fluorescence repeatedly many times in the duration of the flash, resulting in a large increase of the fluorescence intensity. Such a situation is not expected if one assumes that

3) K. Uchida, S. Kato and M. Koizumi, This Bulletin, **33**, 169 (1960).

oxygen mainly attacks the semiquinone radical. In measurements by an ordinary fluorimeter on the other hand, the low intensity of exciting light causes almost no change in the population of the ground state irrespective of whether a sample is free from air or not, hence the same fluorescence intensity results in the two cases.

The above qualitative discussion, though it seems quite plausible, is in fact not conclusive so long as only the fluorescence experiments for ethanol solutions are concerned, because the results are equally well interpreted if one assumes that the triplet state instead of the complex is efficiently deactivated by oxygen. The problem will be clarified if a quantitative comparison is made for the fluorescence intensity of the evacuated and aerated aqueous solution, where neither semiquinone nor complex is formed. At the present stage of investigation, the complex-decomposition-scheme may be said, in view of the discussion in 2), to be more plausible than the triplet state-deactivation-scheme, although the latter process may perhaps take place to some extent.

Summarizing the above discussion one can conclude the following reaction scheme for the reductive photo-bleaching of eosin.

$$D + h\nu \rightarrow D^* \quad (1)$$

$$D^* \rightarrow D + h\nu' \quad (2)$$

$$D^* \rightarrow D^t \quad (3)$$

$$D^t + RH \rightarrow X \quad (4)$$

$$X \rightarrow D + RH \quad (5)$$

$$X \rightarrow DH\cdot + R\cdot \quad (6)$$

$$2DH\cdot \rightarrow D + DH_2 \quad (7)$$

In the presence of air

$$X + O_2 \rightarrow D + RH + O_2 \quad (8)$$

and in addition to reaction 8, perhaps, $D^t$ may also be deactivated to a lesser extent. The process of reaction 8 is faster than reaction 5 or 6 even when the oxygen content is very small.

For uranin also, a similar scheme may hold, but the lifetime of X seems to be much shorter.

## Summary

Reductive photobleaching of eosin and uranin in ethanol solutions was studied by the flash technique. Transient spectra of semiquinone with a lifetime of millisecond order was established. In addition, another transient spectra with a life of the same order was observed in the case of eosin. This was interpreted to be due to a certain complex intermediate between ethanol and eosin, formed prior to semiquinone. The aerated alcoholic solution and the evacuated aqueous solution, when illuminated by a flash, showed no transient spectra in the wavelength region of the above two intermediates. The fluorescence of the aerated ethanol solution produced by the flash had about twenty times as large intensity as that of the evacuated solution induced under otherwise similar condition. A scheme for the primary processes of the reductive photobleaching involving the above complex can interpret all these results satisfactorily.

The authors express their gratitude to the Mainichi Press for a grant of subsidy.

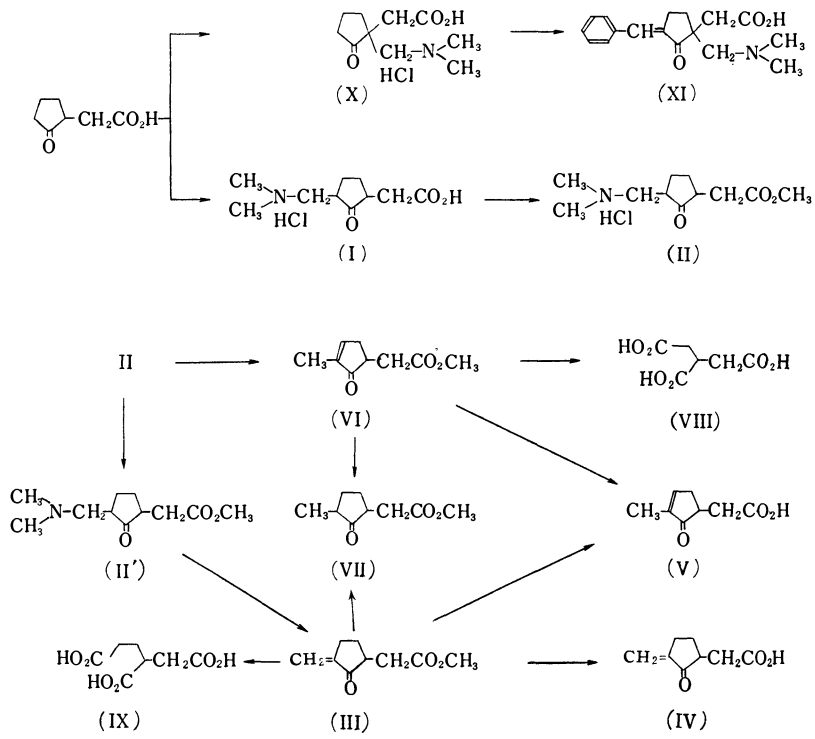
# *Studies on Antibiotics and Related Substances. IX. Synthesis of Methyl 5-Methylenecyclopentanone-2-acetate, an Antitumor Substance and Related Compounds*

By Sumio UMEZAWA and Mitsuhiro KINOSHITA



(Received September 3, 1959)

Recent publication[1] from this laboratory described the syntheses and antitumor activities of the methylene derivatives of cyclopentanone-3-carboxylic acid, relating to sarkomycin[2], an antitumor antibiotic. The present paper is concerned with an extention of this work in which the syntheses and antitumor activities of 5-methylenecyclopentanone-2-acetic acid and its ester are described.

Cyclopentanone-2-acetic acid was prepared by the Linstead and Meade's method[3]. A mixture of cyclopentanone-2-acetic acid, paraformaldehyde and dimethylamine hydrochloride was fused to give two kinds of Mannich base hydrochlorides; 2-(dimethylaminomethyl)cyclopentanone-2-acetic acid hydrochloride (X) crystallized at first from the absolute ethanol solution of the reaction mixture and 5-dimethylaminomethyl isomer (I), the desired product, was obtained from the mother liquor in a 24.2% yield.

On treating with benzaldehyde in the presence of sodium hydroxide, the 2-dimethylaminomethyl isomer (X) afforded a benzylidene derivative (XI), indicating[4] the presence of an activated methylene group in VIII.

Thermal decomposition of the methyl

4) Benzaldehyde condenses readily on the two activated methylene groups of cyclopentanone; C. Mentzel, *Ber.*, **36**, 1499 (1903); R. Cornubert, *Compt. rend.*, **190**, 440 (1930).

ester (II) of 5-dimethylaminomethyl isomer (I) afforded a colorless oil (48%) which gave analyses for $C_9H_{12}O_3$ but had neither antitumor nor antibacterial activity. The product contained a carbonyl group as shown by the formation of a semicarbazone of m. p. 162~163°C. The ultraviolet absorption suggested the presence of an $\alpha,\beta$-unsaturated carbonyl group, showing maxima at 228 and 307 m$\mu$ and the infrared spectrum also indicated a conjugated carbonyl system (Figs. 1 and 2). Ozonolysis yielded tricarballylic acid (VIII) but no formaldehyde. These data led to the conclusion that the destructive distillation of II produced a rearrangement of the exocyclic double bond formed by elimination of dimethylamine to a more stable conjugated system to give methyl 5-methyl-4-cyclopenten-1-one-2-acetate (VI).

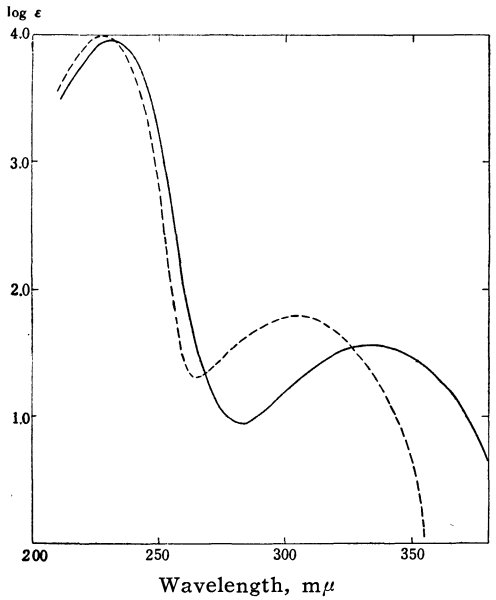

Fig. 1. Ultraviolet absorption spectra of methyl 5-methylenecyclopentanone-2-acetate (——) and methyl 5-methyl-4-cyclopenten-1-one-2-acetate (----) in methanol.

When the free base (II') obtained from II by treatment with ammonia in chloroform was subjected to destructive distillation, the desired methyl ester (III) of 5-methylenecyclopentanone-2-acetic acid was obtained in a 42.7% yield.

Acid hydrolysis of III with 5% hydrochloric acid-acetone solution produced a rearrangement of exocyclic double bond as well as hydrolysis, giving 5-methyl-4-cyclopenten-1-one-2-acetic acid (V) which was found to be identical with the product obtained from VI by alkaline hydrolysis, as judged by mixed melting point determination and by comparison of ultraviolet and infrared absorption spectra. Hydrogenation of III with platinum catalyst in methanol solution afforded methyl 5-methylcyclopentanone-2-acetate (VII); the semicarbazone, m. p. 149~149.5°C, of VII was found to be identical with the semicarbazone of the product obtained from VI by catalytic hydrogenation, as judged by mixed melting point determination. Ozonolysis of III gave formaldehyde (isolated as the methone derivative) and butane-1, 2, 4-tricarboxylic acid (IX); formation of the former established the presence of an exomethylene group in III.

The infrared absorption spectrum of III indicated a conjugated carbonyl system and the ultraviolet absorption data also suggested the presence of the $\alpha,\beta$-unsaturated carbonyl group, showing maxima at 232 and 333 m$\mu$ (Figs. 1 and 3). The accumulated data provided definite proof that the decomposition product III from the free base of II was methyl 5-methylenecyclopentanone-2-acetate.

Mild hydrolysis of III with dilute sulfuric acid followed by extraction with ethyl acetate and evaporation of the solvent in vacuo gave a 16.8% yield of a crude product of 5-methylenecyclopentanone-2-acetic acid

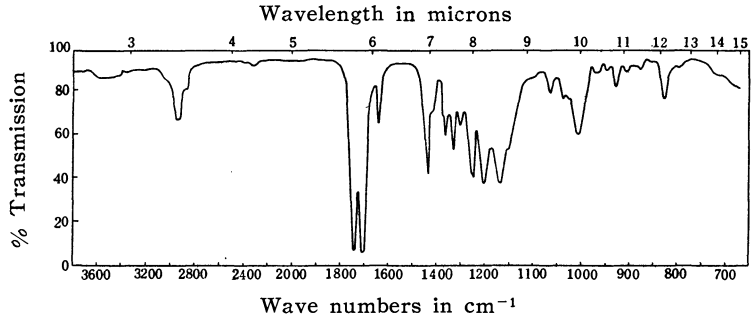

Fig. 2. Infrared absorption spectrum of methyl 5-methyl-4-cyclopenten-1-one-2-acetate (liquid).

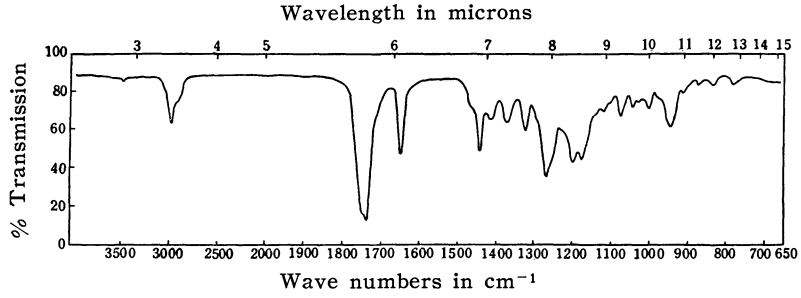

Fig. 3. Infrared absorption spectrum of methyl 5-methylenecyclopentanone-2-acetate (liquid).

(IV), a pale yellow, viscous liquid, which spontaneously polymerized so readily that further purification could not be accomplished. With the crude product, absorptions in the infrared spectrum indicated a conjugated carbonyl system, and the ultraviolet absorption data also suggested the presence of the $\alpha,\beta$-unsaturated cabonyl group, showing a maximum at 230 m$\mu$.

Both 5-methylenecyclopentanone-2-acetic acid and its ester (III) were found to possess antitumor and antimicrobial activities. As in the case of 5-methylenecyclopentanone-3-carboxylic acid[1], the methyl ester (III) was more potent than the corresponding free acid (IV).

## Experimental

**2-(Dimethylaminomethyl)cyclopentanone-2-acetic Acid Hydrochloride (X).** — A mixture of cyclopentanone-2-acetic acid[3] (14.2 g.) and dimethylamine hydrochloride (8.2 g.) was heated to 75°C. To the resulting melt was added paraformaldehyde (3.0 g.) and the mixture stirred at 75°C for 3 hr. and evaporated in vacuo to remove moisture. The resulting syrup was dissolved in hot absolute ethanol and filtered. After cooling, some seeds of pure X were added to the filtrate and the mixture was stored in an ice box. The first crystalline crop was separated, and washed with acetone-ethanol (3 : 1). The product (5.5 g.) was triturated with hot absolute ethanol (10 cc.). After standing at room temperature, filtration followed by washing with cold ethanol (5 cc.) gave 3.4 g. (14.4%) of 2-(dimethylaminomethyl)-cyclopentanone-2-acetic acid hydrochloride (X), m. p. 145~147°C (decomp.). An analytical sample was obtained by recrystallization from methanol, m. p. 150~150.7°C (decomp.).

*Anal.* Found: C, 51.05; H, 7.42; N, 5.72. Calcd. for $C_{10}H_{18}O_3NCl$: C, 50.95; H, 7.64; N, 5.95%.

**5-Benzylidene-2-(dimethylaminomethyl)cyclopentanone-2-acetic Acid (XI).** — To a solution of 2-(dimethylaminomethyl) cyclopentanone-2-acetic acid hydrochloride (X) (200 mg.) in 2.5 N sodium hydroxide (1.6 cc.) was added benzaldehyde (100 mg.) and the mixture stirred at 20°C for one hour. The resulting yellow solution was adjusted to pH 3 with 3 N hydrochloric acid, and shaken with ether. The water-layer was evaporated to dryness in vacuo and then extracted with absolute ethanol. Evaporation of ethanol solution afforded a crude hydrochloride of XI, very hygroscopic yellow amorphous powder; yield, 210 mg. (77%); characteristic strong absorption in ultraviolet spectrum at $\lambda_{max}^{MeOH}$ 308~309 m$\mu$ ($E_{1cm}^{1\%}$ 304). To a solution of the crude hydrochloride (200 mg.) in methanol (1.6 cc.) was added picric acid (200 mg.) in hot methanol (2.4 cc.). Water was added until the solution appeared turbid, and the mixture was allowed to stand overnight in a refrigerator to afford short prisms of picrate of XI; yield, 183 mg. (42% based on the crude hydrochloride of XI), m. p. 149~150°C (decomp.). Two recrystallizations from methanol-water gave a pure sample, m. p. 150~151°C (decomp.).

*Anal.* Found: C, 53.65; H, 4.45; N, 10.82. Calcd. for $C_{23}H_{24}O_{10}N_4$: C, 53.49; H, 4.68; N, 10.85%.

**5-(Dimethylaminomethyl)cyclopentanone-2-acetic Acid Hydrochloride (I).** — The mother liquor of the above-mentioned first crop (X) was stored in an ice box for 3 days to afford the second crop, which was collected, washed with acetone-ethanol (3 : 1) and dried; yield, 6.6 g.; m. p. 130~135°C (decomp.). Recrystallization from ethanol-acetone gave 5.6 g. of 5-(dimethylaminomethyl)cyclopentanone-2-acetic acid hydrochloride (I) (24.2%), m. p. 135~137°C (decomp). An analytical sample was obtained by recrystallization from methanol, m. p. 137~138.5°C (decomp.).

*Anal.* Found: C, 51.31; H, 7.56; N, 6.08. Calcd. for $C_{10}H_{18}O_3NCl$: C, 50.95, H, 7.64; N, 5.95%.

**Methyl 5-(Dimethylaminomethyl)cyclopentanone-2-acetate Hydrochloride (II).** — A mixture of 5-(dimethylaminomethyl)cyclopentanone-2-acetic acid (I) (6.1 g.) and absolute methanol (60 cc.) was saturated with dry hydrogen chloride and allowed to stand overnight. The solvent was removed by distillation at about 40°C in vacuo and the residue was dried in vacuo over phosphorus pentoxide. The resulting crystals were dissolved in a small quantity of absolute methanol by warming and the solution was diluted with absolute ether, whereupon there separated a crystalline precipitate of methyl 5-(dimethylaminomethyl)cyclopentanone-2-acetate hydrochloride (II), m. p. 117~121°C. Yield, 6.0 g. (93%). Two recrystallizations from methanol-ether, m. p. 123.5~124.5°C.

*Anal.* Found: C, 52.54; H, 7.87; N, 5.76. Calcd. for $C_{11}H_{20}O_3NCl$: C, 52.88; H, 8.07; N, 5.61%.

**Methyl 5-Methylenecyclopentanone-2-acetate (III).** — To a solution of methyl 5-(dimethylaminomethyl)cyclopentanone-2-acetate hydrochloride (II) (3.0 g.) in chloroform (10 cc.) was added saturated ammonia-chloroform solution (6.3 cc.), whereupon ammonium chloride immediately precipitated. The chloroform-layer was separated and concentrated under reduced pressure. The residue was heated at 108°C in an oil bath under highly reduced pressure (0.1~0.01 mmHg). Colorless distillate (1.4 g.), which was collected in a receiver cooled in a dry ice-methanol bath, was dissolved in ether (6.5 cc.) and shaken with dilute hydrochloric acid to remove dimethylamine and unreacted free amine-ester (II'). The ether-layer was dried over anhydrous sodium sulfate, and the solvent was removed in vacuo to afford a crude product of methyl 5-methylenecyclopentanone-2-acetate (III) (810 mg., 42.7%). Vacuum distillation of the crude product gave a low yield of pure sample of III, b. p. 60~65°C (bath temp.)/0.01 mmHg. There was much residue in the distillation flask, indicating the ready polymerization of III.

*Absorption spectra*: ultraviolet, $\lambda_{max}^{MeOH}$ 232 ($\varepsilon$ 9100) and 333 m$\mu$ ($\varepsilon$ 36.9); infrared, $\nu_{max}^{liq}$ 1733 (ester and conjugated carbonyl) and 1643 cm$^{-1}$ (C=C).

*Anal.* Found: C, 63.81; H, 7.16. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

**Catalytic Hydrogenation of III.** — A solution of freshly prepared III (300 mg.) in methanol (3 cc.) was shaken with platinum oxide (24 mg.) and hydrogen; 44 cc. (11°C, 766.1 mmHg, 95% based on theoretical amount) of hydrogen was absorbed in 18 min. The mixture was filtered and concentrated under reduced pressure and distilled in vacuo to give methyl 5-methylcyclopentanone-2-acetate (VII) (235 mg., 77.6%), b. p. 62°C (bath temp.)/0.01 mmHg.

*Anal.* Found: C, 63.84; H, 8.63. Calcd. for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

*Semicarbazone* of methyl 5-methylcyclopentanone-2-acetate; colorless needle from ethyl acetate, m. p. 149~149.5°C.

*Anal.* Found: C, 52.95; H, 7.37; N, 18.63. Calcd. for $C_{10}H_{17}O_3N_3$: C, 52.85; H, 7.54; N, 18.49%.

**Ozonolysis of III.** — a) A solution of 100 mg. of III in ethyl acetate (5 cc.) was treated with an approximately 2% (by weight) ozone-oxygen mixture at 0°C at a rate of 500cc./min. for 2 hr. The resulting solution was mixed with water (5 cc.) and zinc dust (150 mg.) and the mixture was refluxed for 30 min. The reaction mixture was filtered while hot into a solution of methone (150 mg.) in 5 cc. of ethanol. Dilution with 10 cc. of water afforded the needles of formaldehyde methone, m. p. 185~187°C. Recrystallization from methanol-water; m. p. 188~189°C; yield, 30 mg. Admixing with an authentic specimen of formaldehyde methone showed no change of melting point.

b) A solution of 300 mg. of freshly prepared III in ethyl acetate (14 cc.) was treated with ozone as mentioned above a) at −15°C. The resulting yellow solution was concentrated in vacuo below 10°C to afford a viscous yellow oil, which was heated with 1.6 cc. of 30% hydrogen peroxide at 90°C for one hour. The colorless solution was evaporated under reduced pressure. Addition of water to the residue followed by evaporation was repeated to remove excess of hydrogen peroxide. The final residue was refluxed with 3.5 cc. of 10% methanolic potassium hydroxide for 2 hr. Methanol was removed, acidified to pH 2.4 with dilute hydrochloric acid, saturated with ammonium sulfate and extracted with ether continuously for 3 hr. After the extract was dried over anhydrous sodium sulfate, the ether was distilled off. The residue immediately crystallized; yield, 200 mg. (59%); m. p. 108~112°C. A paper chromatography of this product with xylene-phenol-85% formic acid (7 : 3 : 1) showed only the distinct spot which had the same $R_f$ value as that of an authentic butane-1,2,4-tricarboxylic acid[5] (IX). Recrystallization from ethyl acetate gave 51 mg. of pure butane-1,2,4-tricarboxylic acid, m. p. 119.5~120.8°C, mixed m. p. 120~120.8°C.

**5-Methylenecyclopentanone-2-acetic Acid (IV).** — A mixture of freshly prepared methyl 5-methylenecyclopentanone-2-acetate (III) (994 mg.) and 1.5 N sulfuric acid (20 cc.) was stirred at 28~32°C for 2.5 hr. After removal of a considerable amount of resinous material (527 mg.) by decantation, the resulting solution was adjusted to pH 8.0 with a saturated solution of sodium bicarbonate, and shaken with two 15 cc. portions of ether to remove any unchanged ester. The water-layer was adjusted to pH 2.4 with 1.5 N sulfuric acid and extracted with two 15 cc. portions of ethyl acetate. After the extract was dried over anhydrous sodium sulfate, the ethyl acetate was removed by distillation in vacuo at about 0°C to yield a crude product of IV, a pale yellow viscous oil; yield, 153 mg. (16.8%). The freshly prepared sample was soluble in water and methanol. However, on standing at room temperature, the product rapidly polymerized and became much less soluble in water and methanol. It resisted attempts to recrystallize it. The ultraviolet absorption spectrum of the product showed a strong absorption at 230 m$\mu$ ($E_{1cm}^{1\%}$ 197) in methanol, indicating the presence of an $\alpha,\beta$-unsaturated ketone group. Infrared spectrum in liquid showed maxima at 1735 (carboxyl and conjugated carbonyl), 1642 (C=C) and 2700~2500 cm$^{-1}$ (carboxyl OH).

**5-Methyl-4-cyclopenten-1-one-2-acetic Acid (V).** — a) A mixture of methyl 5-methyl-4-cyclopenten-1-one-2-acetate (VI) (200 mg.) and 10% sodium hydroxide solution (0.45 cc.) was stirred at 17°C for one hour. The resulting solution was acidified to pH 2.0 by addition of dilute hydrochloric acid, saturated with ammonium sulfate, and extracted with three 1 cc. portions of ether. The dried extract was concentrated to afford a pale yellow oil (160 mg.) which, on standing, slowly

5) This was prepared by the method of Tawney and Prill: P. O. Tawney and E. J. Prill, *J. Am. Chem. Soc.*, **70**, 2828 (1948).

turned to a solid mass of crystals intermixed with oil. The crude crystals were drained on porous porcelain to remove an oily material; yield, 50 mg. (27%), m. p. 43~47°C. A pure sample of 5-methyl-4-cyclopenten-1-one-2-acetic acid (V) was obtained by recrystallization from ether-benzine, colorless prism, m. p. 48~49°C.

*Absorption spectra*: Ultraviolet, $\lambda_{max}^{MeOH}$ 228~229 (ε 9850) and 310 mμ (ε 48.4); infrared, $\nu_{max}^{Nujol}$ 1670 (conjugated carbonyl), 1630 (C=C), 2700~2500 (carboxyl OH) and 1738 $cm^{-1}$ (carboxyl C=O).

*Anal.* Found: C, 62.21; H, 6.69. Calcd. for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

b) A solution of freshly prepared methyl 5-methylenecyclopentanone-2-acetate (III) (1.4 g.) in 14.5 cc. of acetone-hydrochloric acid mixture (6 : 1 by weight) was allowed to stand at 20°C for 10 hr. To a resulting solution, water (30 cc.) and sodium bicarbonate (3 g.) were added under ice-cooling. After removal of acetone under reduced pressure below 5°C, the aqueous layer was extracted with two 10 cc. portions of ether, acidified to pH 2.4 with 3 N hydrochloric acid and again extracted with three 10 cc. portions of ethyl acetate. The dried ethyl acetate solution was concentrated under reduced pressure to afford a pale yellow oil (560 mg.) which crystallized gradually on standing. Treatment on a porous porcelain gave crude crystals (70 mg.), which was recrystallized from ether-benzine, m. p. 48~49°C and mixed m. p. with V obtained in a) 48~49°C. The ethereal extract was concentrated, and then treated in the same manner as described above in a) to afford a viscous oil (500 mg.). Distillation gave a fraction (70 mg.) of b. p. 125~128°C (bath temp.)/0.005 mmHg, which crystallized immediately. Recrystallization from ether-benzine yielded a pure sample of V, m. p. and mixed m. p. 48~49°C.

**Methyl 5-Methyl-4-cyclopenten-1-one-2-acetate (VI).** — Methyl 5-(dimethylaminomethyl)cyclopentanone-2-acetate hydrochloride (II) (1.0 g.) was placed in a round-bottom flask and heated in an oil bath at 150°C for 15 min. The resulting orange colored product was cautiously distilled at 150°C/0.01 mmHg to afford a colorless liquid (VI) in a receiver cooled in a dry ice-methanol bath. By redistillation of the liquid, pure sample of VI was obtained; yield, 325 mg. (48%); b. p. (bath temp.) 80°C/0.01 mmHg.

*Absorption spectra*: Ultraviolet, $\lambda_{max}^{MeOH}$ 228 mμ (ε 9750) and 307 mμ (ε 62.7); infrared, $\nu_{max}^{liq}$ 1712 (conjugated carbonyl), 1640 (C=C) and 1745 $cm^{-1}$ (ester C=O).

*Anal.* Found: C, 63.85; H, 7.41. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

*Semicarbazone* of VI; colorless needles, m. p. 162~163°C.

*Anal.* Found: C, 53.15; H, 6.49; N, 18.45. Calcd. for $C_{10}H_{15}O_3N_3$: C, 53.25; H, 6.72; N, 18.64%.

**Catalytic Hydrogenation of VI.** — A sample (300 mg.) in methanol (3 cc.) absorbed theoretical amount of hydrogen in the presence of platinum oxide (24 mg.) in 12 min. The reduced product was purified by distillation under reduced pressure to give methyl 5-methylcyclopentanone-2-acetate (VII) (282 mg., 93%), b. p. (bath temp.) 85~89°C/0.03 mmHg. The sample readily afforded a *semicarbazone*, m. p. 149~149.5°C, which did not depress the melting point of the corresponding derivative of the hydrogenation product of III.

Ozonolysis of VI was carried out in the same manner as described in the ozonolysis of III: a) The compound (200 mg.) did not give any formaldehyde methone, indicating the absence of a terminal methylene group. b) The compound (200 mg.) gave a crude crystalline product (117 mg. 56%) which afforded only the distinct spot of tricarballylic acid (VIII) by paper chromatography. Recrystallization from ether gave pure tricarballylic acid; m. p. and mixed m. p. 161~162°C.

**Bioassays.** — Preliminary results have indicated that methyl 5-methylenecyclopentanone-2-acetate (III) completely inhibits the growth of *M. pyogenes var. aureus* 209-p, *E. coli*, *Saccharomyces sake* and *Penicillium* 408,701 in a dilution of 1 : 16000. 5-Methylenecyclopentanone-2-acetic acid (IV) completely inhibited the growth of *Trichophyton mentagrophytes* in a dilution of 1 : 32000, but had comparatively weak activities against other fungi and bacteria tested.

5-Methyl-4-cyclopenten-1-one-2-acetate had no antimicrobial and antitumor activity, as expected from the fact that 2-methyl-2-cyclopenten-1-one-3-carboxylic acid obtained from sarkomycin (2-methylenecyclopentanone-3-carboxylic acid) by thermal isomerization had no biological activity[6].

It is interesting to find that III and IV possess antitumor activity[7]. The minimum necessary concentrations of III and IV for the anti-HeLa-cell effect were 15.6 and 125 μg/cc.

A detailed report on the biological activities of III and IV will be published elsewhere.

## Summary

1) 5-(Dimethylaminomethyl)cyclopentanone-2-acetic acid hydrochloride (I) and 2-dimethylaminomethyl isomer (X) have been synthesized from cyclopentanone-2-acetic acid by means of the Mannich reaction.

2) Methyl 5-(dimethylaminomethyl) cyclopentanone-2-acetate (II′) has been degraded to give methyl 5-methylenecyclopentanone-2-acetate (III), which has been hydrolyzed into 5-methylenecyclopentanone-2-acetic acid (IV), a homologue of isosarkomycin.

3) Destructive distillation of the hydrochloride (I) afforded methyl 5-methyl-4-cyclopenten-1-one-2-acetate (VI), an isomer of III.

6) I. R. Hooper, L. C. Cheney, M. J. Cron, O. B. Fardig, D. A. Johnson, D. I. Johnson, F. M. Palermiti, H. Schmitz and W. B. Wheatley, *Antibiotics & Chemotherapy*, 5, 590 (1955).

7) Private communication from Prof. H. Umezawa of National Institute of Health, Tokyo.

4) It has been found that III and IV possess antitumor and antimicrobial activities.

The authors are indebted to Professor H. Umezawa, National Institute of Health, Tokyo, for antitumor assays.

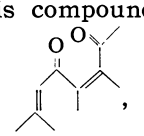
# SHORT COMMUNICATIONS



## *Chemical Structure of Miliacin*

By Shokichi ABE

(Received October 7, 1959)

A crystalline substance (I, $C_{31}H_{52}O$, m.p. 282°C, $[\alpha]_D$+8.0°) was isolated from *Panicum miliaceum L.* and from *Syntherisma sanguinalis Dulac var. calialis Honda* by Ito[1] and was named miliacin.

Its ultraviolet absorption spectrum did not indicate the presence of conjugated double bond system, but the color reaction with tetranitromethane suggested the presence of double bond. From its infrared absorption spectrum (9.0 $\mu$) its oxygen linkage was supposed to be an ether type. The oxidation product, miliacin oxide (II, $C_{31}H_{52}O_2$, m.p. 285.5~286°C, $[\alpha]_D$+52.3°) was obtained by the action of perbenzoic acid in chloroform, this oxide did not show the color reaction with tetranitromethane. It follows that miliacin is a pentacyclic compound having a double bond.

Upon oxidation with selenium dioxide, miliacin and miliacin oxide afforded a diendione (III, $C_{31}H_{46}O_3$, m.p. 253°C, $[\alpha]_D$−87.6°, $\lambda_{max}$ 281 m$\mu$ log $\varepsilon$ 4.2), whose infrared absorption spectrum (9.0 $\mu$) revealed the existence of the ether linkage. The ultraviolet absorption spectrum of this compound was similar to that of $\beta$-amyradiendionol. This fact means that this compound contains a partial structure,  , characteristic of compound derived from $\beta$-amyrin-oleanane series. Therefore, it may be concluded that miliacin is a member of $\beta$-amyrin-oleanane series and its ester linkage does not participate with the carbon atoms at positions 9, 11—13, 18 and 19.

Upon treatment with hydrogen chloride in chloroform, miliacin oxide afforded compound (IV, $C_{31}H_{50}O$, m.p. 210~211°C, $[\alpha]_D$ −63.0°, $\lambda_{max}$ 243 m$\mu$ log $\varepsilon$ 4.3, 250 m$\mu$ log $\varepsilon$ 4.4, 260 m$\mu$ log $\varepsilon$ 4.2). Its infrared (9.0 $\mu$) and ultraviolet absorption spectrum and optical rotation difference suggested the presence of an ether linkage and $\Delta^{11:13(18)}$ conjugated double bond. On the other hand, miliacin was changed to its isomer (V, $C_{31}H_{52}O$, m.p. 189°C, $[\alpha]_D$−23.4°) by the same treatment. This isomer gave an oxide (VI, $C_{31}H_{52}O_2$, m.p. 262°C, $[\alpha]_D$+42.7°), which showed no color reaction with tetranitromethane. From the infrared absorption spectrum and the optical rotation difference of this isomer, it was assumed that the double bond of miliacin had rearranged to $\Delta^{13(18)}$ by this treatment.

By the action of boron trifluoride-acetic acid or *p*-toluenesulfonic acid in acetic anhydride-acetic acid, miliacin afforded a diene hydrocarbon (VII, $C_{30}H_{48}$, m.p. 125°C, $[\alpha]_D$+41.2°), which gave a dioxide (VIII, $C_{30}H_{48}O_2$, m.p. 203°C, $[\alpha]_D$+73.5°) by the oxidation with perbenzoic acid. This diene was prepared by David[2] from germanicol and has the structure 8 : 10 : 14-trimethylnovoleana-3(5) : 8-diene. By the action of *p*-toluenesulfonic acid miliacin oxide gave 5 : 8 : 14-trimethylnovoleana-9(10) : 11 : 13(18)-triene[3] (IX, $C_{30}H_{46}$, m.p. 137°C).

Isosawamilletin[4] (X, 3$\beta$-methoxyolean-12-ene) was oxidized with selenium dioxide to a diendione, which was identical with compound III.

It was deduced from the foregoing experimental results that miliacin was 3$\beta$-methoxygermanicene (I, 3$\beta$-methoxyolean-18-ene), the conjugated diene was 3$\beta$-methoxyoleana-11 : 13(18)-diene [IV], and the isomer derived from miliacin by the action of hydrogen chloride was 3$\beta$-methoxyolean-13(18)-ene [V], as indicated in the next figure.

# *On the Model Form of the Catalytic Wave of Proteins**

By Mutsuaki Shinagawa
and Hiroyuki Nezu

(Received December 8, 1959)

In order to extend the knowledge about the nature of the catalytic wave of protein[1,2] a model experiment was undertaken, and the following three points were emphasized in this experiment: 1) hydrogen sulfide and cystine were used as typical sulfhydryl compounds; 2) the influence of methyl cellulose and gelatin on the catalytic wave of cystine was examined polarographically; and 3) the influence of glucose, sucrose, glucosamine and glycogen on the cystine wave was similarly examined. In the latter case, these sugars were used as model compounds for the carbohydrates contained in the mucoprotein molecule, which is said to be an effective substance for the demonstration of the serum filtrate.

From such experiments, the various wave patterns analogous to those of the protein wave were obtained by regulating the amounts of each of the constituents in the test solutions (Table I).

**Single Rounded Cystine-like Wave.**—Hydrogen sulfide, which may be considered as one of the simplest of the sulfhydryl compounds, was examined polarographically over a large range of concentrations in the buffered cobaltous solutions, i.e. 0.1 M $NH_4OH$, 0.1 M $NH_4Cl$ and $10^{-3}$ M $CoCl_2$. When hydrogen sulfide was added to the solution containing gelatin, the single rounded wave analogous to the cystine wave appeared and the diffusion current of cobalt disappeared. When hydrogen sulfide was added to the solution, and then gelatin was added, the single rounded wave did not appear. If the solution contains large amounts of gelatin, the wave analogous to that of cystine did not appear and the diffusion current of cobalt disappeared (Fig. 1A). This cystine-like wave was observed even at the limiting concentrations of hydrogen sulfide as low as $10^{-7}$ M.

| 12 | — | Gs | C | −1.75 | poorly defined | −1.0 |
| 13 | — | Gg | C | −1.75 | poorly defined | −1.0 |

C: $10^{-3}$ M Cystine Gl: 0.1% Glucose M: 0.1% Methyl cellulose
G: 0.1% Gelatin Gs: 0.1% Glucosamine S: 0.1% Sucrose
Gg: 0.1% Glycogen H: Hydrogen sulfide

**Protein-like Wave.**—When methyl cellulose was added to the buffered cobaltous solution, the polarographic double wave similar to the protein double wave appeared as shown Fig. 1B. Other carbohydrates such as glucose, sucrose, glucosamine and glycogen were examined in order to determine whether their activities were similar to that of methyl cellulose on the formation of the wave analogous to the protein wave (Table I). Further quantitative experiments were initiated in order to examine the influence of methyl cellulose and gelatin on the cystine wave (Fig. 2).

It seems that Brdicka's mechanism[3], generally accepted since 1933, is unsatisfactory to explain these phenomena for the following reasons: 1) It might be difficult to supply hydrogen ions to the electrode surface from the bulk of an ammoniacal buffered solution at about pH 9. 2) At a potential of about −1.6 V. where the two peaks of the double wave appear, the cobalt-ammine ion is rapidly reduced to metallic cobalt at the electrode surface but the cobaltocysteinate ion may not be reduced to metallic cobalt. So the most delicate point in the interpretation of the whole catalytic electrode process involved in the polarographic "protein wave" consists in the elucidation of the role of cobalt. 3) Even if these waves depend on the catalytic reduction of hydrogen it is difficult to explain how, in the case of protein, two maxima are observed.

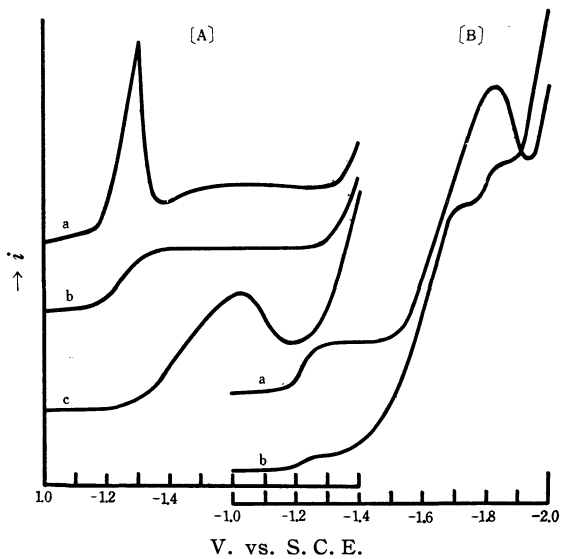

Fig. 1. Polarograms demonstrating the catalytic wave.
(A) a) $1 \cdot 10^{-2}$ M $CoCl_2$ + 1 M $NH_4OH$ 1 ml. + 1 M $NH_4Cl$ 1 ml. + $H_2O$ 7 ml.
b) (a) + 1% gelatin 5 drops
c) (b) + $H_2S$
(B) a) (A, b) + $1 \cdot 10^{-2}$ M cystine 1 ml.
b) (a) + 1% methyl cellulose 10 drops

However, the coexistence of constituents (cobalt ion, cystine, carbohydrate, gelatin and ammonia) in the ammoniacal buffered solution is necessary to obtain the wave analogous to the protein wave. In view of the above experimental facts, it seems reasonable to assume that these five essential constituents in the ammoniacal buffered

system make a certain contribution to the electrode reaction either through their chemical interactions in the vicinity of the electrode surface and their adsorptive activities at the surface.

In conclusion, this mechanism may be considered in terms of the two following ideals: a) There may be some competition among the constituents which react with the cobaltous ions to yield complex ions or salts of extremely low solubility. Such competition in the vicinity of the electrode surface has a great effect on the currents of electroreduction and reoxidation of cobalt. b) The surface activities of these competing constituents have characteristic effects on the currents.

# *Note on the Monomeric Friction Coefficient of Poly-n-butyl Methacrylate in Diethyl Phthalate*

By Hiroshi FUJITA and Akira KISHIMOTO

(Received December 19, 1959)

From dynamic mechanical measurements encompassing the glass to rubber transition region Saunders et al.[1] have recently shown that the monomeric friction coefficient $\zeta_0$ (in dyne sec./cm.) of poly-*n*-butyl methacrylate in diethyl phthalate at 0°C varied with the polymer concentration $c$ (in g./ml. of solution), according to the relation:

$$\zeta_0 = 5.8 \times 10^{-10} \exp(24c) \qquad (1)$$

They state that there appears to be no theoretical expectation for the form of this relation. The purpose of the present communication is to show that their $\zeta_0$ data can be interpreted reasonably in terms of a free volume theory described recently by Fujita and Kishimoto[2], if the original theory is modified so that the diluent concentration $C$ (in grams of diluent per gram of dry polymer) is replaced by the volume fraction of diluent $v$[3]. Thus, the starting assumption of the modified theory is that the fractional free volume, $f$, in the polymer-diluent mixture at a fixed temperature $T$ is a linear function of $v$, i.e.

$$f = f(T, 0) + \beta'(T)v \qquad (2)$$

where $f(T, 0)$ is the free volume fraction in the pure polymer at temperature $T$ and

1) P. R. Saunders, D. M. Stern, S. F. Kurath, C. Sakookim and J. D. Ferry, *J. Colloid Sci.*, **14**, 222 (1959).
2) H. Fujita and A. Kishimoto, *J. Polymer Sci.*, **28**, 547 (1958).
3) The modification of the original theory, involving derivations of the new equations, and applications of the modified theory to viscosity data on concentrated polymer solutions will be described in detail in a forthcoming publication.

$\beta'(T)$ is a parameter (dependent on temperature) similar in nature to the parameter $\beta$ defined previously[2]. The physical meaning of the new parameter $\beta'$ will be given in a forthcoming article[3].

If one starts with Eq. 2 and uses a similar procedure to that described in Ref. 2, one can derive the relation:

$$-\frac{2.303[f(T,0)]^2 \log a_v}{1+2.303f(T,0)\log a_v}=\beta'(T)v \qquad (3)$$

Here $a_v$ is the concentration shift factor with the pure polymer as a standard and may be evaluated, in a manner described previously[2], from appropriate viscoelastic measurements obtained as a function of diluent concentration. Eq. 3 may be rewritten in the form:

$$-(1/\log a_v)=2.303f(T,0)+\{2.303[f(T,0)]^2/\beta'(T)\}(1/v) \qquad (4)$$

This indicates that plots of $-1/\log a_v$ vs. $1/v$ form a straight line and $f(T, 0)$ and $\beta'(T)$ can be determined from its slope and intercept at $1/v=0$.

Under the assumption that all the relaxation mechanisms—at least, those contributing to the mechanical behavior in the particular region concerned—have the same dependence on diluent concentration in the polymer, the shift factor $a_v$ may be evaluated from the ratio of the monomeric friction coefficient of the mixture at diluent concentration $v$ to that of the pure polymer ($v=0$) at the same temperature. The authors calculated $a_v$ for the system poly-*n*-butyl methacrylate+diethyl phthalate at 27°C (this is the glass transition temperature of pure poly-*n*-butyl methacrylate[4]) from the $\zeta_0$ data of Saunders et al.[1] and of Child and Ferry[4]. The latter study gives the $\zeta_0$ values for the pure polymer at 27°C. The former data, which were originally given for the temperature 0°C have been converted to the desired temperature by using the WLF equation[5] with the numerical constants recorded in Table II of Ref. 1. Fig. 1 shows the plot of $-1/\log a_v$ vs. $1/v$ obtained from these data. It is seen that the plotted points follow a straight line reasonably well, in agreement with the prediction of Eq. 4. From the solid line drawn one finds that $f(T_g^0, 0)=0.023$ and $\beta'(T_g^0)=0.05_0$; here $T_g^0$ denotes the glass transition temperature of the pure

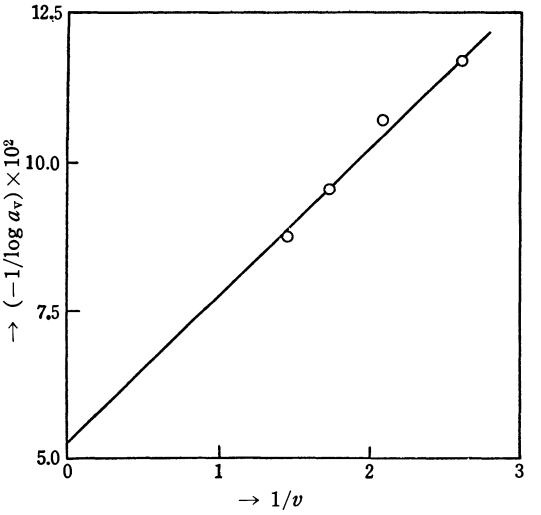

Fig. 1. Plot of $-1/\log a_v$ vs. $1/v$ for the system poly-*n*-butyl methacrylate + diethyl phthalate at 27°C; $v$ is the volume fraction of diethyl phthalate in the mixture.

polymer. It is of interest to see that the value of $f(T_g^0, 0)$ obtained, which was denoted by $f_g^0$ in Ref. 2, is quite close to the approximately) universal value 0.025.

Eq. 4 may be used to evaluate $f(T, 0)$ and $\beta'(T)$ when the steady-flow viscosity, $\eta$, of the polymer-diluent mixture is known as a function of diluent volume fraction $v$. In this case the shift factor $a_v$ may be taken as the ratio $\eta/[(1-v)\eta_0]$, where $\eta_0$ is the value of $\eta$ for the pure polymer at the same temperature $T$. The authors applied Eq. 4 to Bueche's data[6] for the steady-flow viscosity on the system polymethyl methacrylate+diethyl phthalate at 100°C, the glass transition temperatue of this polymer[7]. A very satisfactory straight line was obtained between $-1/\log a_v$ and $1/v$ and yielded $f(T_g^0, 0)=0.017$ and $\beta'(T_g^0)=0.051$, where $T_g^0=100$°C. This low value of $f_g^0$ is consistent with a similar low value obtained previously[7] for this methacrylate polymer. Of interest is the result that the $\beta'$ value derived here is very close to the one obtained above from the analysis of the friction coefficient data for the poly-*n*-butyl methacrylate+diethyl phthalate system. Although the definite conclusion must be reserved, it appears that to a first approximation the parameter $\beta'(T)$ is characteristic of the diluent

# *Evolution of Atomic Oxygen from Platinum Surface Treated Previously with Discharged Oxygen Gas*

By Kazuo MITANI and Yoshio HARANŌ

(Received January 5, 1960)

Fryburg[1] investigated an enhanced oxidation of platinum by treating a platinum strip with discharged oxygen gas at a temperature of 1000°C. He found that when the temperature of a platinum strip is higher than 800°C, a brown deposit of platinum dioxide appears on the wall of the enclosing glass tube in the immediate vicinity of the heated platinum strip.

After treating platinum surface with discharged oxygen gas, it is found that atomic oxygen evolves from it when heated in vacco.

The main part of the apparatus is shown in Fig. 1. D is a discharge tube. The reaction vessel V contains a platinum ribbon (0.024×0.28×363 mm.) capable of being heated by electric current. Atomic oxygen given off is detected by the change of color of molybdenum trioxide deposited on a glass plate P according to the following equation[2]:

$$3\,MoO_3 + O = Mo_3O_8 + O_2$$

Discharged oxygen gas is made to pass through the reaction vessel at a pressure of 0.1~1 mmHg for 20 min., without heating the platinum ribbon by electric current. Then the discharge being stopped, the

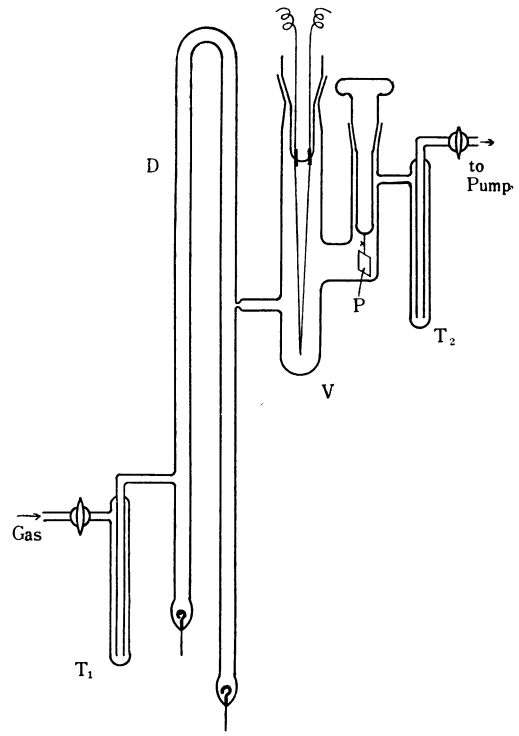

Fig. 1

reaction vessel is evacuated by a diffusion pump through a trap cooled by dry ice. In this condition, molybdenum trioxide remains to be pale yellow. While the evacuation is continued, the platinum ribbon is heated to 1400°C. Then, molybdenum trioxide in the side tube changes its color distinctly from pale yellow to deep blue within 20 min. This is an evidence that atomic oxygen is given off from the platinum surface. The authors will report in a later paper that adsorbed oxygen atoms desorb in molecular form when heated in vacuo. Therefore, taking account of Fryburg's experement[3], it is believed that the platinum surface covered with platinum dioxide, and that atomic oxygen is given off by the decomposition of platinum dioxide when the ribbon is heated to a high temperature in vacuo.

# *Determination of Thallium(I) with Iodate in the Presence of Mercuric Ions and with Iodate and Permanganate via Bromide*

By Bechu SHARMA

(Received August 31, 1959)

Most of the current methods, to determine thallium(I), have certain inherent defects. Willm's method[1] based upon titration of thallium(I) in hydrochloric acid with permanganate has been used extensively, but various authors reported unfavorable results. The procedure used by Marshall[2] is tedious. Kolthoff[3], Zintl and Rienacher[4], however, titrated it accurately with bromate in hydrochloric acid using methyl orange as indicator. Willard and Young[5] determined it against ceric sulfate. Berry[6] titrated various thallous salts with iodate using iodine monochloride end point and reported low results by about 2%. Swift and Garner[7] employed iodine monochloride procedure in the determination of thallium(I) with iodate, permanganate and ceric sulfate, but precise results were obtained only with iodate. Recently a general application of the amperometric Dead Stop End Point to direct and indirect determination with iodate in the presence of mercuric ions has been reported. Arsenious oxide and hydrazine sulfate are used as direct primary standards and thiosulfate, thiocyanate and thiourea are determined by excessive iodate[8]. Investigations were therefore carried out to adopt the above procedure (iodate procedure in the presence of mercuric ions) in the determination of thallium. Oxidation titration of hydrazine sulfate with permanganate and ceric sulfate in hydrochloric acid via bromide has been carried out amperometrically using "Dead Stop End Point" written as D.S.E.P.[9] This also suggested a similar oxidizability of thallium.

## Experimental

A 0.1 N (0.025 M) solution of potassium iodate was prepared from E. Merck (G. R.) reagent. Its strength was checked against 0.1 N arsenious oxide prepared from E. Merck (G. R.) reagent using iodine monochloride end point. Approximately 0.1 N potassium permanganate solution, prepared from British Drag House (L. R.) reagent, was standardized against 0.1 N arsenious oxide. A 1% thallous acetate solution was prepared from B.D.H. reagent and its strength was determined against potassium iodate using iodine monochloride procedure.

**Direct Titration Procedure.** — An aliquot of iodate solution was transferred to a 100 ml. titrating vessel, 25～35 ml. of mercuric chloride (8～9%) solution was added followed by such a volume of 12 N hydrochloric acid as to adjust the overall acidity between 0.7～1.5 N. The contents of the vessel were cooled to 25°C completely. The reaction mixture was finally titrated against thallous acetate using the amperometric D.S.E.P. A potential of 0.1 V. was impressed across the indicator electrodes. The indicator current increased toward a maximum as the addition of thallous acetate solution was continued and finally decreased to a minimum at the equivalence point. As iodate is reduced to iodide, the equivalent weight in these titrations is 1/6 the formula weight.

**Reverse Titration Procedure.** — An aliquot of thallous acetate was taken in a titrating vessel, and mixed with 30～35 ml. mercuric chloride solution (8～9%) and 12 M hydrochloric acid (to maintain overall acidity between 1～2 N). The contents of the vessel were cooled to 25°C completely. The reaction mixture was finally titrated against standard iodate solution using the same electrometric end point. Near the equivalence point the indicator current showed a sudden increase in its value.

A series of experiments in which the acidity and mercuric chloride concentration were varied over a wide range, revealed that 1～2 N overall acid concentration and 25～35 ml. mercuric chloride gave accurate results. The results of one typical series of experiments are summarized in Tables I and II. Direct as well as reverse procedure may be extended to iodine monochloride end point (second end point), the acidity (hydrochloric acid) of the reaction mixture being raised at the iodide end point (first end point) to about 5～6 N.

**Determination of Thallium(I) with Iodate and Permanganate via Bromide.**—An aliquot of thallous

acetate was taken in a titrating vessel and 25~35 ml. 12 M hydrochloric acid was added to maintain the final acidity as indicated in Tables III and IV followed by 2~3 g. of potassium bromide. The reaction mixture was then titrated againt standard permanganate or iodate using the amperometric D.S.E.P. A potential of 0.1 V. was impressed across the indicator electrodes. The indicator current remained constant throughout the titration and finally at the equivalent point it showed a sudden increase in its value. Series of experiments in which the acidity was varied over a wide range revealed that the method is accurate for the determination of thallium(I) with iodate and permanganate via bromide at an overall acidity between 3~5 N. In the titration of thallous salt with permanganate at a high acid concentration (above 4 N), the amount of permanganate solution consumed was too high owing to (catalytic) oxidation of hydrochloric acid by permanganate.

## Summary

Oxidation of thallium(I) is carried out with iodate in the presence of mercuric ions using the amperometric D.S.E.P. Thallium is oxidized to thallium(III) and iodate is quantitatively reduced to iodide. The procedure is valuable because it gives correct determination for thallium(I) at

a low acid concentration. Oxidation of thallium(I) with permanganate and iodate in hydrochloric acid via bromide is also found to be accurate and quantitative.

# *Pre-oxidation by Iodine Monochloride—Potassium Hydroxide and Use of Iodine Monochloride End Point in the Determination of Hydrazine, Thiocyanate, Thiosulfate and Glucose*

By Bechu SHARMA

(Received August 31, 1959)

Iodate procedures introduced by Andrews[1] and later developed by Jamieson[2] and Lang[3], involve essentially the formation of iodine (+). Although applicable to a variety of common reductants, in a number of cases, iodate is not capable of bringing about direct oxidation. Thus ferrous iron and ferrocyanide bring about an apparent state of equilibrium which changes only slowly. Lang[3-4] proposed for such reductants a preoxidation by iodine monochloride solution prepared from iodide and iodate in the presence of chloride. Lang further found applicability of this method to an alkaline medium, wherein some cases hypoiodite acts more efficiently, e. g. for the determination of hydrogen peroxide[4] and formaldehyde[5]. An additional advantage of this procedure is that the back titrations can as well be followed with permanganate and ceric sulfate which are standared volumetric oxidizing agents. This point has been emphasized by Swift[6] and his coworkers in the determination of arsenic(III) wherein excessive iodine monochloride was followed in an acid medium. An earlier communication described the "iodine monochloride+sodium hydroxide" oxidation and iodine monochloride end point using iodate, permanganate and ceric sulfate for the determination of thiourea and its derivatives[7]. Subsequent investigations revealed that thiosulfate which is oxidized by alkaline hypoiodite could as well be determined. In an alkaline medium, thiosulfate is oxidized to sulfate which provides an advantage of a high conversion factor. The direct oxidation of thiocyanate by iodate, stops at cyanide stage alone while by alkaline hypoiodite it is converted into cyanate. Herein then, the modified procedure would provide an advantage of higher molecular ratio. Again, the oxidation of hydrazine sulfate, which is an ideal primary standard on account of its stability, ease of purification and various acidimetric and oxidimetric applications, was subjected to restricted conditions of acidity when titrated by iodine monochloride procedure. On the other hand, however, it could be easily oxidized by hypoiodite. Glucose is not oxidized by iodate in an acid medium, but iodine in weakly alkaline medium is capable of oxidizing it to gluconic acid. This principle was therefore applied to the determination of glucose as well. It may be pointed out that there are no direct titrimetric procedures for glucose, whose oxidation, except by iodine, hardly stops at the gluconic acid stage and the complete oxidation by drastic oxidants like permanganate and ceric sulfate in an acid medium and by ferricyanide in an alkaline medium, requires critical operative conditions for quantitative conversion into carbon dioxide and water.

## Experimental

A 0.5 M iodine monochloride solution was prepared by dissolving 17.5 g. of potassium iodate, and 22.7 g. of potassium iodide in 250 ml. of water to which 150 ml. 12 M hydrochloric acid was added. The solution was titrated with iodate or iodide solution using carbon tetrachloride till the organic layer was colorless. A 0.1 M potassium thiocyanate solution was prepared and standardized as usual by titration with standard silver nitrate solution. Sodium thiosulfate solution was standardized against potassium dichromate as well as with 0.1 N potassium iodate using iodine monochloride end point. The latter was found to be a better check due to the oxidation of thiosulfate to sulfate, which was subsequently achieved by hypoiodite oxidation. A 0.1 N hydrazine sulfate solution was prepared from British Drng House (L.R.) reagent recrystallized from water twice and dried at 140°C. A 1% glucose solution was prepared from E. Merck (L.R.) sample and was standardized by iodimetric determination. Potassium permanganate and ceric sulfate solutions were prepared and standardized as usual. Except for glucose the following

The order of mixing was thiocyanate, iodine monochloride and alkali, in order to utilize the oxidant in acid and alkali medium.

general procedure was adopted. An aliquot of the reductant solution was taken in an Erlenmeyer flask to which an amount of iodine monochloride (at least 3/2 times that calculated on the reduction to iodide) and finally 25% (potassuim hydroxide solution were added to render the solution 1~2 N in alkali. Advantage of the addition of iodine monochloride was that the oxidant was available in an acid as well as in an alkaline medium. However, with thiosulfate, sulfur precipitates and the oxidation hardly goes to completion. The addition of alkali prior to iodine monochloride avoided this and the oxidation was found to be smooth. After being kept for 5~10 min. the solution was transferred to a 150 ml. beaker, acidified with 12 M hydrochloric acid to give an overall 5~6 N acidity and was titrated with iodate, permanganate or ceric sulfate by

10 ml. of 1% glucose require 11.05 ml. 0.025 M iodate.

* As in the presence of excess of alkali, hypoiodite does not act smoothly on glucose, the order of mixing was "glucose+iodine monochloride", to which only just sufficient alkali was added to dissolve the liberated iodine. Finally little more alkali was added to convert iodine into hypoiodite.

the amperometric "Dead Stop End Point". The unit was the simple form of the one described by Foulk and Bawden[8]. One tenth volt was the impressed potential across the indicator electrodes between which a mechanical stirrer served to mix thoroughly the reaction mixture. The current measurements were made by a sensitive galvanometer with a lamp-and-scale arrangement. The current increased to a maximum and then decreased to a minimum where the conversion of iodine and iodide to iodine (+) was complete. In the oxidation of glucose, the control of alkalinity was most critical. This was achieved by careful addition of alkali to the mixture of glucose and iodine monochloride to the point where the iodine that separated just dissolved. The reverse order glucose-alkali-iodine-monochloride was found to give variable results. In glucose determination, the final titration was possible only with iodate because other oxidants, permangante and ceric sulfate, attacked the gluconic acid. The results of one typical series of experiments are summarized in Tables I—IV.

8) C. W. Foulk and A. T. Bawden, *J. Am. Chem. Soc.*, 48, 2045 (1926).

**Summary**

The principle of hypoiodite (iodine monochloride+potassium hydroxide) pre-oxidation and iodine monochloride end point has been adopted to the determination of hydrazine, thiocyanate, thiosulfate and glucose. The availability of alternative standard titrating solutions (iodate, permanganate and ceric sulfate) and applicability over a range of reductant concentrations are essential features of this procedure.

# *Heats of Formation of Lower Members of Dimethyl- and Methylisopropoxy-cyclopolysiloxanes*

By Toshio TANAKA

(Received July 30, 1959)

From the investigation on the redistribution equilibrium between dimethylcyclopolysiloxanes and linear polysiloxanes catalyzed by sulfuric acid, it was concluded by Scott that the ring in the trimer of cyclosiloxanes had a slight strain, while the ring structures of tetramer and the polymer of larger size were probably free from strain. He attributed this strain to the deformation of normally large Si-O-Si angle in forming the small-membered ring[1]. Before and after that, it was indicated from X-ray[2,3] and electron[4] diffraction studies that the six-membered ring in the trimer was planer or nearly planar. While, the siloxane rings of the tetramer[5] and the octamer[6] were reported to have *zigzag* form from X-ray diffraction study, and the former ring was supposed to have *cradle* (rather than *crown*) form from electron diffraction study[7]. As the results of these studies, the difference between the molecular structures of the cyclic trimer and the cyclic tetramer exist in the Si-O-Si angle, which is 125° for the former and 140° for the latter, and it has been supposed that a value of about 140° would be probable for a strain free Si-O-Si valency angle[7].

In this paper, the heats of combustion of the members represented by $C_n$ and $D_n$ (see below) have been measured at 20°C and a constant volume, and the corresponding heats of combustion and formation in isobaric process have been calculated. From the results, it will be indicated

## Experimental

**Materials.**—The members of $C_n$ were prepared by hydrolyzing methylisopropoxydichlorosilane with considerable dropping rate using pyridine as an acid acceptor and were characterized*. The physical constants and the analytical data are shown in Table I.

The members of $D_n$, supplied from Shin-etsu Chem. Ind. Co., have been rigorously fractionated through a semi-micro Stedman column of about 20 theoretical plates and the physical constants have been compared with them reported in the literature of the subject. The results are shown in Table II.

TABLE II. PHYSICAL CONSTANTS OF $D_n$[a]

| Compound | b.p. °C/mmHg | $d_4^{20}$ | $n_D^{20}$ | Mol. wt. Found[b] (Calcd.) |

a) The values in brackets are those reported in the publication; E. G. Rochow, "An Introduction to the Chemistry of the Silicones", 2nd Ed., John Wiley & Sons, Inc., New York (1951), p. 185.
b) Cryoscopic measurements in benzene.

**Calorimetry.**—The apparatus used in this experiment was described elsewhere[8]. Each liquid sample has been weighed in a gelatine capsule and it has been burned by electrical ignition, as described in the case of methylethoxypolysiloxane in the previous paper[9]. After the burning of the samples, a bulky product, consisting of silica and incomplete combustion products of a part, are yielded in the combustion vessel. The incomplete combustion products in the experiments of $C_3$, $C_4$ and $D_4$ have been found to contain amorphous carbon and, sometimes, a trace of carborundum**. In addition to these products, a polymer-like substance containing a silicon atom has been yielded in the combustion experiment of $D_5$, as in the case of 1,3,5,7,9-pentamethylcyclopentasiloxane[10]. The incomplete combustion products included in the silica have been determined in quantities and the thermal corrections for them have been calculated according to the method in the previous paper[9,10].

## Results and Discussion

Five to six combustion experiments have been carried out with each liquid sample of the same material, and the results are shown in Table III, excepting that of $D_5$.

The result of the combustion experiment of $D_5$ is shown in Table IV.

In Table IV, the energy evolved per gram at 20°C and a constant volume is represented by $-\Delta U_B^{low}$, in which the thermal corrections for carbon and, sometimes, for carborundum have been made, but the correction for the polymer-like substance only is not taken into account;

TABLE III. EXPERIMENTAL RESULTS OF $C_3$, $C_4$ AND $D_4$

| Compound | cal./g. Heat of combustion | | | | | | Mean | Relative mean deviation % |
|---|---|---|---|---|---|---|---|---|
| $C_3$ | 6140 | 6133 | 6121 | 6126 | 6113 | 6138 | 6129 | ±0.14 |
| $C_4$ | 6099 | 6077 | 6096 | 6088 | 6090 | — | 6090 | ±0.06 |
| $D_4$ | 6357 | 6336 | 6355 | 6346 | 6332 | — | 6345 | ±0.09 |

* Details of the preparation of these compounds will soon be published by Dr. Ōkawara.
8) T. Tanaka and T. Watase, This Bulletin, **28**, 258 (1955).
9) T. Tanaka, ibid., **32**, 1258 (1959).
** In the combustion experiment of $D_4$, polymer-like substance, though only a trace in quantity, has sometimes been found in the combustion product, as in the case of $D_5$ described below, but such an experimental result of $D_4$ has been rejected here.
10) T. Tanaka, *Technol. Repts. Osaka Univ.*, **8**, 437 (1958).

TABLE IV. EXPERIMENTAL RESULTS OF $D_5$

| Wt. of sample | $-\Delta U_B^{low}$ | Amount of $SiO_2$ produced from the polymer-like substance | | $-\Delta U_B^{high}$ |
|---|---|---|---|---|
| g. | cal./g. | mg. | $\alpha$(%) | cal./g. |
| 0.45543 | 6326 | 1.90 | 0.52 | 6359 |
| 0.45763 | 6277 | 2.75 | 0.74 | 6323 |
| 0.44446 | 6317 | 2.03 | 0.56 | 6352 |
| 0.45899 | 6292 | 1.79 | 0.48 | 6322 |
| 0.45121 | 6311 | 1.48 | 0.41 | 6337 |
| 0.45404 | 6321 | 1.52 | 0.41 | 6347 |
| Mean | 6307 | | | 6340 |
| Average value | | 6324 | | |

$-\Delta U_B^{low}$, will be therefore considered as underestimated value for the heat of combustion of $D_5$. The third column in this table is the number of grams of silica produced from the polymer-like substance by the further ignition in the course of analysis of incomplete combustion product, and the fourth column indicated by $\alpha$ is its percentage for the amount of silica equivalent to the weight of the sample in each run. As the thermal correction for the formation of the polymer-like substance could not be evaluated exactly in this experiment, it has been calculated under the assumption that the amount of sample equivalent to the amount of silica produced from the polymer-like substance remained, not burned at all, and $-\Delta U_B^{high}$ in th last column of the Table IV has been obtained by the following expression:

$$-\Delta U_B^{high} = -\Delta U_B^{low}(1+\alpha\cdot 10^{-2}).$$

This will be evidently overestimated value for its heat of combustion. Accordingly, the average value of these $-\Delta U_B^{low}$ and $-\Delta U_B^{high}$ values has here been adopted as the reasonable one for the heat of combustion of $D_5$.

Table V is a summary of thermal data of $C_n$ and $D_n$ calculated from the combustion results.

Notations in this table are as follows: $-\Delta U_R$, the heat of combustion at standard constant volume process, where the reactants are one atmospheric pressure; $-\Delta H_f$, the heats of formation of the members of $C_n$ and $D_n$ in the liquid state from standard elements; $-\Sigma E$, the heats of formation of those in the gaseous state from mono-atomic gases. These energy values have been calculated by the method described in the previous paper[8]. In the calculation of $-\Sigma E$, values of 52.1, 59.2, 171.7 and 89.9 kcal./g.-atom have been adopted for the heats of atomization of hydrogen, oxygen, carbon and silicon, respectively, which are the same values used in the previous paper[8]. And then, values of 10.9[11] and 11.2[12] kcal./mol. have been used for the heats of vaporization of $D_4$ and $D_5$, respectively, and the corresponding energy values of $C_3$ and $C_4$ have been estimated to be 10.1 and 11.0 kcal./mol. from the Trouton's rule, respectively. The $-\Sigma E/n$ in the last column of the Table V, derived in this manner, will be considered as the sums of bond energies in structural units*** of $\left[\begin{matrix}CH_3\\ i\text{-}C_3H_7O\end{matrix}\!\!>\!Si\!<\!\begin{matrix}O\\ O\end{matrix}\right]$ for $C_n$ and of $\left[\begin{matrix}CH_3\\ CH_3\end{matrix}\!\!>\!Si\!<\!\begin{matrix}O\\ O\end{matrix}\right]$ for $D_n$.

**No Strain in the Cyclic-tetramer and -pentamer.** —If the $-\Sigma E/n$ of $D_5$ in Table V, though involving a considerable uncertainty, will be accepted as the reasonable value for the sum of bond energies in its structural unit, this is somewhat higher than the corresponding value of $D_4$. Such an energy difference between these compounds will perhaps be attributed to the difference between their polymer sizes, as in the case of methylmethoxypolysiloxanes, $CH_3O\cdot[(CH_3)(CH_3O)SiO]_nCH_3$[9], and methoxy end-blocked dimethylpolysiloxanes, $CH_3O\cdot[(CH_3)_2SiO]_nCH_3$[13], in which the values of

*** For example, in $D_n$, the term of "structural unit" will be used for $[(CH_3)_2SiO_2]$, but not $[(CH_3)_2SiO]$, on the number of each chemical bond in the compounds.
13) T. Tanaka, to be published in *J. Inorg. & Nuclear Chem.*

$-E\left[\begin{smallmatrix}C\\O\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$**** and $-E\left[\begin{smallmatrix}C\\C\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$**** were found to be increasing with their polymer sizes, respectively.

If the value of 98.8 kcal./mol.[9,10] is here adopted for C–H bond energy in $D_n$, the values of $-E\left[\begin{smallmatrix}C\\C\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ for $D_4$ and $D_5$ result in 339 and 341 kcal./mol., respectively. While, the corresponding values in methoxy end-blocked dimethylpolysiloxanes, which are linear compounds, were obtained to be 329, 335 and 336 kcal./mol. for the monomer, the dimer and the trimer, respectively[13]. The value of $-E\left[\begin{smallmatrix}C\\C\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ in the cyclic tetramer is somewhat larger than that in the linear trimer, and the energy difference between them will be attributed to the difference between their polymer sizes and, if possible, partly to the difference between the cyclic and the linear structures. As the linear polysiloxanes under consideration will probably have no strain in their molecular structures, the ring structures of the cyclic-tetramer and -pentamer may also be free from strain, when one compares the $-E\left[\begin{smallmatrix}C\\C\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ with those in the linear compounds.

**Strain in the Cyclic Trimer.**—The value of $-\Sigma E/n$ in $C_3$ is 5 kcal. lower than that in $C_4$, as shown in Table V. The energy difference will not by itself correspond to the strain per the structural unit of $\left[\begin{smallmatrix}CH_3\\i\text{-}C_3H_7O\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ in $C_3$, because it must be taken into consideration that the value of $-\Sigma E/n$ in $C_n$ will also increase with increasing of the polymer size, as in the case of $D_n$. Now, if it is assumed that the $-\Sigma E/n$ for $C_3$ should be 2 kcal. lower than that for $C_4$, by applying the energy difference in $-\Sigma E/n$ between $D_4$ and $D_5$, the extra lowering energy in $C_3$ comparing from $C_4$, 3 kcal. per the structural unit, will be due to the strain in the cyclic trimer; the ring of cyclic trimer, then, will be anticipated to have a strain corresponding to 9 kcal./mol. as a whole. However, the incremental change in $-\Sigma E/n$ between the cyclic-trimer ($C_3$) and -tetramer ($C_4$), attributed to the difference of their polymer sizes, will perhaps be larger than that between the cyclic-tetramer ($D_4$) and -pentamer ($D_5$), because the incremental change in energy between the neighboring members will be decreasing as their polymer sizes increase, as observed in the previous works on the linear polysiloxanes[9,13]. It has also been found in the previous paper[9] that the value of $-E\left[\begin{smallmatrix}C\\O\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ in the first member of methylmethoxypolysiloxanes were 4 kcal. lower than that in the second member. As the cyclic trimer is the smallest-membered ring in the cyclopolysiloxanes, the larger part of the incremental change (5 kcal.) in $-\Sigma E/n$ between $C_3$ and $C_4$ may be attributed to the difference of their polymer sizes. Thus, the ring of the cyclic trimer will be considered to have a strain corresponding to a few or several kcal./mol. at most, being fairly smaller than 9 kcal./mol.

Though the Si–O–Si angle in the cyclic trimer has been considered to be subjected to a considerable distortion in comparing with its normal angle, the magnitude of energy due to strain obtained here seems to be too small. Such a slight strain in the six-membered ring will however be explained as due to the siloxane linkage having the nature represented by the term of "*ball and joined socket*", as explained previously by Roth and Harker[3].

The energy due to strain derived here comes out from the small difference between large quantities, so that it may not be a conclusive value. Notwithstanding, it may be said that the above results are parallel with the conclusions obtained from the investigation on redistribution equilibrium[1] and on molecular structures of cyclopolysiloxanes[2-7].

**** Sums of bond energies in the structural units of $CSiO_3$ and $C_2SiO_2$, in which C-H and C-O bonds are excepted, in methylmethoxypolysiloxanes and methoxy end-blocked dimethylpolysiloxanes, respectively. These sums were obtained under the assumption that the C-H and the C-O bond energies were not varied from molecule to molecule in the previous papers[9,13].

## Summary

Heats of combustion of lower members of dimethyl- and methylisopropoxy-cyclopolysiloxanes have been measured at 20°C and a constant volume, and the corresponding heats of combustion and formation in isobaric process have been calculated. From the results, the heats of formation of structural units, $\left[\begin{smallmatrix}CH_3\\CH_3\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$ and $\left[\begin{smallmatrix}CH_3\\i\text{-}C_3H_7O\end{smallmatrix}\!\!>\!Si<\!\!\begin{smallmatrix}O\\O\end{smallmatrix}\right]$, of these compounds from mono-atomic gases have been derived, and it has been found that the ring structures

of the cyclic-tetramer and pentamer would be free from strain. Further, the effect of distortion of Si–O–Si valency angle in the cyclic trimer on the heat of formation has been discussed.

The author wishes to express his sincere thanks to Professor T. Watase, Dr. R. Ōkawara and Dr. M. Kakudo for their helpful discussions, and to Mr. H. Mimura for his aid in a part of this work.

# *Studies on Organic Reagents for Inorganic Analysis. VI. Absorption Spectrum of Phenylfluorone-Metal Chelate and the Nature of the Chelating Bond*

By Hirotoshi SANO

(Received July 2, 1959)

For many organic dyes used for the colorimetry of metals, the color change is ascribable to the shift of the $\pi \rightarrow \pi'$ absorption spectra of the organic system caused by the chelating. With respect to the nature of such color change, there have been many papers published recently. Molecular orbital (LCAO) method was applied successfully by Belford, Martell and Calvin[1] to compute the effect of metal ion upon the $\beta$-diketone-metal chelate. The absorption spectra of metal oxalates were interpreted by Graddon[2] on the basis of a simple electrostatic effect. Dortashaeppi, Hürzeler and Treadwell[3] tried to apply a free electron gas model method to the alizarin chelates of several metals. Based on the amperometric titration data, the absorption spectra of alizarin S and its metal chelate were also discussed by Larsen and Hirozawa[4].

In the treatment of the problem, however, the effect of the nature of the chelating bond has been almost neglected, although it seems sometimes to have considerable influence on the absorption spectra. The author reported previously that the maximum wavelengths of the absorption spectra of phenylfluorone metal chelates shift toward the longer side with the decrease in the electronegativity of the metal chelated[5]. In this paper, the correlation of the maximum wavelength with the ionic character of the chelating bond was treated theoretically with the aid of the free electron gas model approximation.

## Fundamental Consideration

The author has adopted Kuhn's free electron gas model method[6,7] for the present purpose, because the model can be conveniently applied to the subject although the value of the model must not be overestimated. According to Kuhn, the electron gas suffers a disturbance in the case of polyenes, unsymmetrical cyanines, etc., and the $\pi$-electrons are thought to be placed in a one-dimensional potential having a sine curve periodicity. The wavelength of absorption maximum is expressed by the following equation.

$$\frac{1}{\lambda_{\max}} = \frac{V_0}{\boldsymbol{h}\cdot\boldsymbol{c}}\left(1-\frac{1}{N}\right)+\frac{\boldsymbol{h}}{8m\boldsymbol{c}}\cdot\frac{N+1}{L^2} \qquad (1)$$

where, $L$ is the length of the path of the free $\pi$-electron measured along the conjugated chain, $N$, the number of $\pi$-electrons, $m$, the mass of the electron, $\boldsymbol{c}$, the velocity of light, $\boldsymbol{h}$, Planck's universal constant, and $V_0$, the amplitude of the sine-shaped potential along the chain.

Suppose that the dye is resonating between two limiting structures Ia and Ib. When each of the two structures makes the same contribution to the normal state of the dye, as seemed to be the case for symmetrical polymethine dyes, each conjugated C–C bond should have an equal bond length*, and the value of $V_0$ should be zero.

$$\cdots\text{-}\underset{1}{C}=\underset{2}{C}\text{-}\underset{3}{C}=\underset{4}{C}\text{-}\underset{5}{C}=\cdots \leftrightarrow \cdots=\underset{1'}{C}\text{-}\underset{2'}{C}=\underset{3'}{C}\text{-}\underset{4'}{C}=\underset{5'}{C}\text{-}\cdots$$

Ia Ib

On the other hand, when Ia and Ib do not make equal contribution to the normal state, as seemed to be the case for polyene etc., a longer C–C bond (so-called "single bond") and a shorter bond (so-called "double bond") appear alternatively along the conjugated chain, and $V_0$ has a definite value.

If the mean bond length of the longer C–C bond and the shorter bond is represented with $\overline{R}'$ and $\overline{R}''$, respectively, the relation mentioned above is summarized as follows:

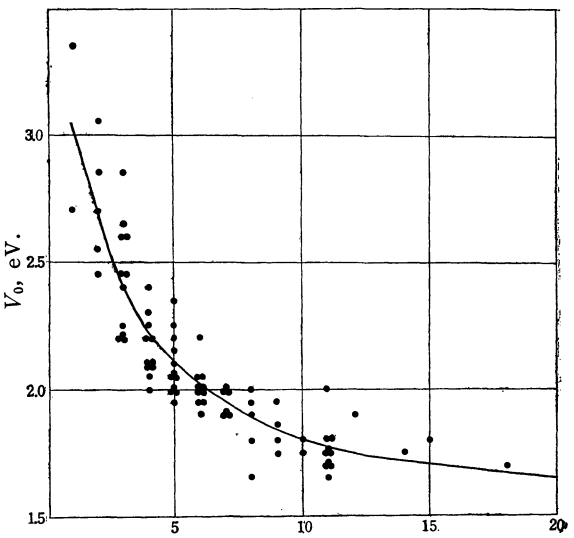
$$V_0=0, \text{ when } \overline{R}'-\overline{R}''=0 \quad (2)$$

$$V_0>0, \text{ when } \Delta R=\overline{R}'-\overline{R}''>0 \quad (3)$$

**The Relation between $V_0$ and $\Delta R$.**—It was difficult to obtain theoretically the relation between $V_0$ and $\Delta R$. Therefore, the problem was solved with the aid of empirical treatment. The difference between the mean "double-" and mean "single-" bond length in polyenes, $\Delta R$, was obtained by calculation based on Coulson's semi-empirical theory[8], because few observed values for the bond length of polyenes were reported. The results are shown in Table I**.

TABLE I. CALCULATED VALUES OF $\overline{R}'$, $\overline{R}''$ AND $\Delta R$

| $j$ | $\overline{R}'$, Å | $\overline{R}''$, Å | $\Delta R$, Å |
|---|---|---|---|
| 1 | — | 1.330 | — |
| 2 | 1.432 | 1.347 | 0.085 |
| 3 | 1.424 | 1.356 | 0.068 |
| 4 | 1.420 | 1.362 | 0.058 |
| 5 | 1.415 | 1.365 | 0.050 |
| 6 | 1.414 | 1.369 | 0.045 |
| 7 | 1.412 | 1.371 | 0.041 |
| 8 | 1.411 | 1.373 | 0.037 |
| 9 | 1.410 | 1.375 | 0.034 |
| 10 | 1.409 | 1.376 | 0.032 |
| 11 | 1.408 | 1.377 | 0.030 |
| 12 | 1.407 | 1.378 | 0.029 |
| — | — | — | — |
| 22 | 1.402 | 1.384 | 0.017 |



The values of $V_0$ calculated from the experimentally determined absorption maxima of a number of polyenes*** have been collected in Fig. 1, which shows the relationship between $V_0$ and the number of conjugated double bonds. It is found that the values of $V_0$ distribute in a narrow range hyperbolically with the increasing number of the conjugated double bonds.

Based on the values $\Delta R$ obtained in Table I and the values of $V_0$ estimated from Fig. 1, an empirical equation for the $\Delta R$-relation is derived as follows:

$$V_0=3-3\left(1-\frac{\Delta R}{0.21}\right)^5 \quad (4)$$

Fig. 2 illustrates the value of $V_0$ as a function of $\Delta R$.

In practice, the small value of $V_0$ is useful for the following discussion, because the value of $V_0$ is smaller than one electron volt in the dye-metal chelate. Therefore, Eq. 4 can be reduced to

Number of conjugated double bond ($j$)

Fig. 1. Relation between $V_0$ and the number of conjugated double bond.

* This approximation is not strictly correct, but no objection is found in the following consideration, because the corresponding bond length in both structures strictly equal, namely, $C_1$-$C_2$, $C_2$-$C_3$, $C_3$-$C_4$,.....equal to $C_{1'}$-$C_{2'}$, $C_{2'}$-$C_{3'}$, $C_{3'}$-$C_{4'}$,....., respectively.

** The value of bond length for the "single" bond is underestimated, because the calculation used here includes no self-consistent treatment, whereas that of "double" bond is considered to be practically equal to the true value.

*** The absorption maxima were taken from the follwing: A. E. Gillam and E. S. Stern, "An Introduction to Electronic Absorption Spectroscopy in Organic Chemistry", Edward Arnold Publishers, Ltd.. London (1954); Y. Urushibara, "Organic Chemistry II (Yûki Kagaku)", Kyôritsu Shuppan, Tokyo (1955).

8) C. A. Coulson, *Proc. Roy. Soc.*, **A169**, 413 (1939).

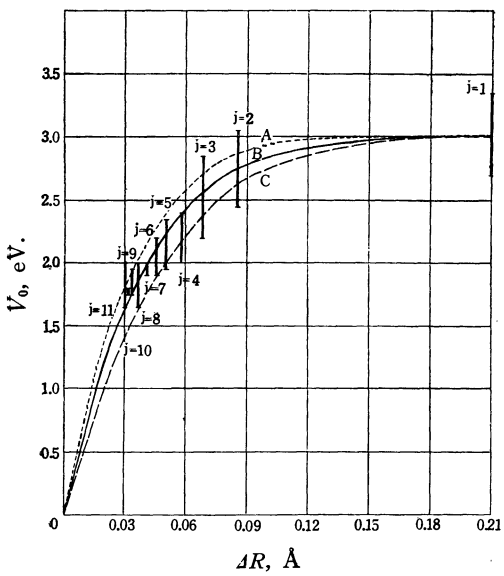


Fig. 2. Relation between $V_0$ and $\Delta R$.
Curve A: $V_0=3-3(1-\Delta R/0.21)^6$
Curve B: $V_0=3-3(1-\Delta R/0.21)^5$
Curve C: $V_0=3-3(1-\Delta R/0.21)^4$

$$V_0 \simeq 71.4\Delta R - 680\Delta R^2 \qquad (5)$$

Deviation from Eq. 4 is 5%, at $\Delta R<0.03$Å, $V_0<1.8$ eV.,

$$\text{or} \qquad \Delta R \simeq \frac{V_0}{71.4}\left(1+\frac{680}{71.4^2}\cdot V_0\right) \qquad (6)$$

**The Relation between $V_0$ and the Ionic Character of the Chelating Bond.**—As is well known, a bond length, $R$, is expressed as follows:

$$R=R_1-(R_1-R_2)\frac{3x}{2x+1} \qquad (7)$$

where $R_1$ is the C-C bond length of pure single bond of ethane, $R_2$ is that of pure double bond of ethylene and $(1+x)$ is the bond order of the C-C bond in question based on the valence bond theory[9]. For instance, $x$ should be expected to be 0.5 when $\Delta R$ is zero.

Suppose that $(1+x)$ represents the bond order of the "double" bond, the bond length, $R''$, is

$$R''=R_1-(R_1-R_2)\frac{3x}{2x+1}, \quad x>0.5 \qquad (8)$$

Similarly, the bond length corresponding to "single bond", $R'$, is

$$R'=R_1-(R_1-R_2)\frac{3(1-x)}{3-2x} \qquad (9)$$

Then,

$$\Delta R=3(R_1-R_2)\frac{2x-1}{4-(2x-1)^2} \qquad (10)$$

substituting numerical data for $R_1$ and $R_2$ in Eq. 10, it is seen that

$$\Delta R=0.63\frac{2x-1}{4-(2x-1)^2}$$
$$(R_1: 1.54\text{Å}, R_2: 1.32\text{ Å}) \qquad (11)$$

By rewriting this expression it is seen that

$$x=\frac{1}{2}+\frac{2}{0.63}\Delta R-\frac{8}{0.63^3}\Delta R^3+\frac{64}{0.63^5}\Delta R^5-\cdots \qquad (12)$$

$$x\simeq\frac{1}{2}+\frac{2}{0.63}\Delta R, \qquad \Delta R<0.16\text{ Å} \qquad (12')$$

On the other hand, the value of $x$ may be connected with the ionic character of the bond between the metal and the donor atom of the dye as follows:

IIa IIIa

O=C-C=···=C-O$^-$ M$^+$ $\leftrightarrow$ O=C-C=···=C-O-M

$\updownarrow$ $\updownarrow$

$^-$O-C=C-···-C=O M$^+$ $^-$O-C=C-···-C=O$^+$-M

IIb IIIb

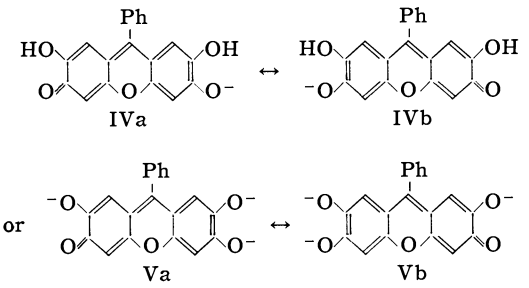
In the four formulae, IIa and IIb represent two limiting structure of the metal-dye compound combined with a pure ionic bond, whereas IIIa and IIIb represent two limiting structures of compound combined with a pure covalent bond.

When the metal-donor bond has a pure covalency, the conjugated system is considered to be similar to that of polyene ($V_0=V_{0n}$, $\Delta R=\Delta R_n$, and $x=x_n$) which has the same number, $N$, of conjugated $\pi$-electron, whereas it becomes equal to that of symmetrical polymethine ($\Delta V_0=0$, $\Delta R=0$, $x=0.5$) when the bond is pure ionic.

On the whole, therefore, each of two structures, II and III, contributes to the normal state of the dye-metal compound, in proportion to the ionic character and covalent character, respectively. The mean bond order for "double" bonds of the dye-metal chelate, $1+x$, will be expressed as follows:

$$1+x=(1-i)(1+x_n)+1.5i \qquad (13)$$

where $i$ is the ionic character. The value of $x_n$, the mean bond order of the polyene, is obtained from Table 1, Eq. 9 or 10, and the mean bond length $\overline{R'}$ or $\overline{R''}$ of the polyene, which possesses the same number of conjugated $\pi$-electron as the system. Based on Eqs. 6, 12' and 13, the relation between $i$ and $V_0$ can be derived as follows:



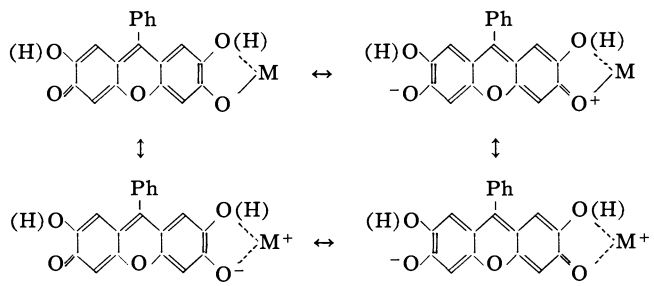
9) L. Pauling, "The Nature of the Chemical Bond", Cornell Univ. Press, Ithaca, N. Y. (1939).

$$1-i=(0.044\ V_0+0.006\ V_0^2)/(x_n-0.5) \quad (14)$$

The absorption maximum of the dye-metal complex is also connected with the ionic character of the dye-metal bond through $V_0$ in Eqs. 1 and 14.

### Application to Experimental Results

It is necessary to know the conjugated system responsible for the absorption maximum of the dye anion to calculate the length of the conjugated chain, $L$, based on the number of $\pi$-electrons in the system. The phenylfluorone anion is considered to be resonating between IVa and IVb or Va and Vb, each of which makes the same contribution to the normal state of the anion, because of its symmetrical structure.



In the present study, $L$ was calculated from the observed wavelength of the absorption maximum of the phenylfluorone anion ($N=12$, and $V_0=0$ based on the following equation,

$$\lambda_{max}=\frac{8mc}{h}\cdot\frac{L^2}{N+1} \quad (1')$$

and this value was used in calculating the value of $V_0$ for the metal chelates.

The possible structures of phenylfluorone metal chelate**** are

The wavelength of absorption maxima of the 2,3,7-trihydroxy-9-phenylfluorone chelates were shown in Table II together with other properties.

As is found in Table II, the shift of the absorption maximum is rather independent of the ionic radii of metals. This suggests that the electrostatic effect on the shift is not predominant in this case.

In the previous work[5] the author showed empirically that $V_0$ of each phenylfluoronate increased with the decrease in the ionic character estimated from the difference of electronegativity between metal and oxygen atoms. The value of the ionic character obtained through the process

b) H. O. Pritchard and H. A. Skinner, *Chem. Revs.*, **55**, 745 (1955).

mentioned above is shown in Fig. 3, together with the results obtained from the nuclear quadrupole coupling data by Dailey and Townes[11], for comparison.

The agreement between two independent results is too close to be accidental. This will be due to the fact that the metal-dye chelate has the structure in which the electrostatic effect by metal is negligibly small, and the effect of the perturbation caused by metal is predominant.

Some phenylfluorone derivatives which possess some substituent in the phenyl group react with metals, and the relationship among the absorption maxima of the metal chelates is similar to that in the phenylfluorone metal chelates[12].

## Experimental

Metal solutions were prepared from metal oxides (germanium, titanium), chloride (tin), or oxychloride (zirconium), and standardized gravimetrically. These stock solutions contain sufficient amounts of hydrochloric acid to prevent the hydrolysis of metals, being free from foreign ions. A working solution was prepared by dilution of an aliquot of each stock solution with water or dilute hydrochloric acid.

Phenylfluorone solution was prepared by dissolving 0.120 g. of phenylfluorone in 150 ml. of ethanol containing 1 ml. of 5.0 N hydrochloric acid, and the resulting solution was diluted to 200 ml. with ethanol.

Absorbance values of the sample and the blank solution were measured with a Beckman Model DU spectrophotometer, using 1 cm. glass cells. Distilled water or blank solution was used as a reference solution. The absorption maxima show practically no variation with the change in the acidity of the solution or the amount of the dyes and metals in solution[14].

## Summary

The absorption spectra of phenylfluorone-fourth group metal chelates were investigated by the acid of Kuhn's free electron gas model method. If the chelating bond formation does not cause an essential change in the $\pi$-electron system of the dye molecule, in the more ionic chelating bond, the absorption maximum of the chelate must be closer to the maximum wavelength of the dye anion. Based on the conception in valence-bond method and ionic-covalent resonance, it was theoretically and experimentaly shown that there was a certain relationship between the absorption maximum wavelength of the chelate and the ionicity of the chelating bond. (The ionicity of the bond was estimated from the difference of electronegativity between the metal and the terminal oxygen atom). The results obtained here for the relationship between the ionicity and the electronegativity difference show too close an agreement with the results obtained from the nuclear quadrupole coupling data by Dailey and Townes.

The author is indebted to Dr. Kenjiro Kimura, Professor Emeritus, and Professor Nobufusa Saito in this laboratory, for their generous encouragement in carrying out this study. The author is also grateful for a grant from the Ministry of Education.

# *Studies on the Chemical Constitution of Agar-agar. XXI*[1]. *Re-investigation of Methylated Agarose of Gelidium Amansii*

By Choji ARAKI and Susumu HIRASE

(Received August 24, 1959)

It has been suggested by Araki[2], one of the present authors, that agar is a mixture of at least two different polysaccharides, one of which is termed agarose having a linear structure composed alternatively of β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose residues. The structure assignment to the agarose has been partly based on the fact that complete methanolysis of methylated agarose led to the isolation of methyl 2,4,6-tri-*O*-methyl-D-galactoside[3,4] and 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal[5]. But the separation of the cleavage fragments was incomplete and the latter fragment was isolated only in a yield insufficient to interpret the whole molecule of agarose. This paper is concerned with the examination of the agarose structure by carefully re-investigating the methanolysis products of methylated agarose prepared from the *Gelidium amansii* agar.

Following the complete methanolysis of the methylated polysaccharide with 3% methanolic hydrogen chloride, the products were separated into neutral and acidic components by means of ion-exchange resins. The acidic component was obtained in too small a yield to be of structural significance. The mixture of neutral sugar derivatives was solved into its components by fractionation with petroleum ether followed by chromatography on charcoal-Celite columns. The mixture was found to contain methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside in addition to the previously isolated 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal and methyl 2,4,6-tri-*O*-methyl-D-galactoside. It was of significance to observe that, well in agreement with the fore-going Araki's formula of agarose, the 2-*O*-methyl-3,6-anhydro-L-galactose derivatives could be obtained in molar quantities equivalent to the 2,4,6-tri-*O*-methyl-D-galactose derivative.

The methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside, a new compound, was obtained as crystals, melting at 67~69°C and showing a specific rotation $[\alpha]_D^{12}$ +66° in water. Its structure was assigned by the rotation, by the hydrolysis to give 2-*O*-methyl-3,6-anhydro-L-galactose, which was identified as crystalline 2-*O*-methyl-3,6-anhydro-L-galactonic acid and its methyl ester and amide, and by further methylation to give crystalline methyl 2,4-di-*O*-methyl-3,6-anhydro-β-L-galactoside. The finding of the methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside among the methanolysis products of the methylated agarose accounts for the direct origin of methyl 2,4-di-*O*-methyl-3,6-anhydro-β-L-galactoside, which had been isolated[6] after methanolysis and subsequent re-methylation of the methylated polysaccharide.

If the agarose molecule were branched, it would be expected that either methyl di-*O*-methyl-D-galactoside or 3,6-anhydro-L-galactose dimethylacetal or both would be derived from units of branch points when the methylated polysaccharide was subjected to methanolysis. In spite of careful examination, however, neither of them could be detected among the methanolysis products under investigation. It is therefore convincing that the molecule is a chain as previously suggested by Araki[2]. As for the non-reducing end of the chain, repeated experiments failed to detect any of the fully methylated component sugars among the methanolysis products of the methylated polysaccharide with the exception of only one experiment, in which 2,3,4,6-tetra-*O*-methyl-D-galactose was isolated as its crystalline aniline derivative in a yield of twelve milligrams from fifteen grams of the methylated polysaccharide. This exception, however, suffers from the

possibility that the polysaccharide molecule might have been degraded before or during the methylation process. Percival and his coworkers reported, that no tetra-*O*-methyl-D-galactose could be detected among the products of hydrolysis of the methylated polysaccharide[7]. Consequently, it may be still difficult at this time to decide whether D-galactose and 3,6-anhydro-L-galactose constitutes the non-reducing end of the molecule. In any case, since the end group, if present, would exist only in a trace quantity, it seems likely that agarose is a chain with a very high degree of polymerization, although the possibility is not completely excluded yet that the polysaccharide may have an endless, closed loop-structure.

In connection with the methylation data mentioned above, the information concerning the paper chromatography of the methylated derivatives of 3,6-anhydro-L-galactose is also reported here in. Cyclohexanol saturated with water was found to serve as an effective solvent for separating the anhydrosugar derivatives, the spots of which could be easily revealed when chromatograms were sprayed with an *o*-aminophenol reagent previously reported from this laboratory[8]. Table I shows the $R_f$ values and the colors of spots observed by this method for some available samples of the anhydrosugar derivatives.

TABLE I. PAPER CHROMATOGRAPHY OF SOME 3,6-ANHYDRO-L-GALACTOSE DERIVATIVES

| Compound | $R_f$ | Color |
|---|---|---|
| Methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside | 0.77 | brown |
| 2-*O*-Methyl-3,6-anhydro-L-galactose dimethylacetal | 0.67 | brown |
| Methyl 2,4-di-*O*-methyl-3,6-anhydro-$\beta$-L-galoctoside | 0.84 | brown |
| 2,4-Di-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal | 0.84 | yellow |
| 2,5-Di-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal | 0.84 | brown |

Filter paper used: Tōyō Filter Paper No. 52.
Developing solvent: cyclohexanol saturated with water.
Spraying reagent: *o*-aminophenol in aqueous ethanol acidified with phosphoric acid[8].

## Experimental

**General Procedure.**—Evaporation and concentration of solutions were carried out below 40°C under reduced pressure. Specific rotations were measured in aqueous solutions unless otherwise stated. Melting points are uncorrected.

**Paper Chromatography.**—Paper chromatograms were run in cyclohexanol saturated with water and sprayed with *o*-aminophenol in aqueous ethanol acidified with phosphoric acid[8] for the purpose of identifying 3,6-anhydro-L-galactose derivatives; while, they were run in *n*-butanol-ethanol-water (4 : 1 : 2 V./V.) and sprayed with aniline hydrogen phthalate in moist *n*-butanol[9] for the purpose of identifying reducing D-galactose derivatives.

**Methylated Agarose.**—Methylated agarose was prepared by acetylating the *Gelidium amansii* agar with acetic anhydride and pyridine, extracting the agarose acetate from the resulting acetylation products with chloroform and then treating the agarose acetate repeatedly with dimethylsulfate and sodium hydroxide as previously described by Araki[10], one of the present writers. The methoxyl value found was 33.8% in reasonable agreement with the value 34.3% calculated for $[C_{12}H_{14}O_5(OCH_3)_4]_n$.

**Methanolysis of Methylated Agarose and Separation of Neutral and Acidic Components.**—Methylated agarose (15.0 g.) was suspended in 3% methanolic hydrogen chloride (100 ml.) and heated under reflux for 35 hr. The resulting brown solution was neutralized with silver carbonate, filtered and evaporated to a sirup. It was then dissolved in 0.2 N barium hydroxide solution (100 ml.) and heated for 2 hr. at 60°C to saponify the methyl ester of the acidic component. After removal of the excess of barium hydroxide by neutralization with carbon dioxide and subsequent filtration, the solution was allowed to pass through columns of Amberlite IR-120 (80 ml.) and IR-4B (100 ml.) in succession, and the columns were thoroughly washed with water. The effluent and washings were combined and evaporated to dryness, when the mixture of neutral sugar derivatives was obtained as a colorless sirup; yield, 15.2 g., $[\alpha]_D^{20}+60.0°$ ($c$ 1.20).

The anion-exchange resin used above was transferred to a beaker, stirred with 2 N sulfuric acid (100 ml.) for a few minutes under ice-cooling to displace the acidic component, and re-transferred to a glass tube to form a column. After the excess of the liquid was allowed to drain from the column, the resin was washed with additional 40 ml. of 2 N sulfuric acid followed by water (600 ml.). All the effluents and washings were combined and immediately neutralized with a saturated barium hydroxide solution, the precipitates of barium sulfate were removed by filtration, and the filtrate was evaporated to dryness. The acidic component in a barium salt form was obtained as a thick sirup; yield, 0.42 g., $[\alpha]_D^{20}$ +2.7° ($c$ 0.75). It showed positive color reactions both for ketose and uronic acid. But the yield was so small that no further investigation was carried out.

**Fractionation of the Neutral Components with Petroleum Ether.**—The mixture of the neutral

7) E. G. V. Percival and T. G. H. Thomson, *J. Chem. Soc.*, **1942**, 750.
8) S. Hirase, C. Araki and S. Nakanishi, This Bulletin, **26**, 183 (1953).
9) S. M. Partridge, *Nature*, **164**, 443 (1949).
10) C. Araki, *J. Chem. Soc. Japan* (*Nippon Kwagaku Kwaishi*), **58**, 1338, 1351 (1937).

sugar derivatives (15.2 g.) obtained above was dissolved in water (80 ml.). The solution was continuously extracted with petroleum ether (b. p. 30~37°C) for 30 hr. in a Soxhlet's apparatus. The extract was evaporated to a thin sirup, which on standing crystallized partly; yield, 2.05 g., $[\alpha]_D^{22}$ +76.1° (*c* 0.71). The residual aqueous solution was also evaporated to a sirup; yield, 13.0 g., $[\alpha]_D^{22}$ +56.0° (*c* 1.0).

**Chromatographic Separation of the Components Insoluble in Petroleum Ether.**—One third quantity of the petroleum ether-insoluble components obtained above was chromatographed at 20~22°C on a column (5.2×22 cm.) packed with a mixture of charcoal (50 g.) and Celite (40 g.). The solvents used for elution were water and ethanol of successively increasing concentrations in water. The effluents were collected of every one liter in separate receivers and concentrated to give 100 ml. fractions, which were then examined both polarimetrically and paper chromatographically. The fractions showing the same contents were combined and evaporated to recover components, which were then purified by dissolution in acetone, filtration and re-evaporation to a constant weight. The total recovery amounted to 4.12 g. or 93% of the applied sample. The recovered components were determined for methoxyl content and specific rotation. The results are shown in Table II. None of the fractions showed on a paper chromatogram the presence of non-methylated or fully methylated 3,6-anhydro-L-galactose derivatives, which might be, derived from units of branch points or the non-reducing end of the methylated polysaccharide molecule, respectively.

**Identification of the Components Insoluble in Petroleum Ether.**—*(a) 2-O-Methyl-3,6-anhydro-L-galactose Dimethylacetal.*—Fraction II in Table II was a colorless sirup showing a refractive index $n_D^{25}$ 1.4620. When examined on a paper chromatogram, it showed a single spot having $R_f$ 0.67. The methoxyl value found was in good agreement with the value 41.90% calculated for $C_6H_9O_3 \cdot (OCH_3)_3$. The fraction was therefore considered to be pure 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal. One of the present writers has reported $[\alpha]_D^{8}$ −13.79° and $n_D^{25}$ 1.4647 about the previously isolated sample of 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal[5].

Fraction III in Table II was a colorless sirup, which on standing crystallized partly. When examined on a paper chromatogram, it showed the presence of two spots having $R_f$ 0.67 and 0.77, respectively, one agreed with the dimethylacetal obtained above, the other with methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside. Since the optical rotations of these pure compounds are −30.7° and +66.0°, respectively, as reported herein, the fraction was considered to be a mixture of 28% of the dimethylacetal (0.14 g.)

TABLE II. CHROMATOGRAPHIC SEPARATION OF THE COMPONENTS INSOLUBLE IN PETROLEUM ETHER

D: Methyl 2,3,4,6-tetra-*O*-methyl-D-galactoside.

and 72% of the methyl glycoside (0.36 g.). This proportion is in agreement with that calculated on the basis of methoxyl values. For the actual separation, the fraction was re-chromatographed on a column (2.5×20 cm.) of charcoal-Celite at 20~22°C. The dimethylacetal was eluted from the column chiefly with 4% ethanol in water; yield, 0.10 g., $[\alpha]_D^{17}$ −30.3° (*c* 0.54), $n_D^{25}$ 1.4615, $OCH_3$ 41.27%; while, the methyl glycoside was removed from the column with 6% ethanol in water and was obtained as crystals; yield, 0.31 g., m. p. 65~67°C, $[\alpha]_D^{17}$ +66.0° (*c* 0.50). Admixture with the sample obtained from fraction IV described below showed no depression of the melting point.

For the identification of 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal, the following experiments were carried out:

*i) 2-O-Methyl-3,6-anhydro-L-galactose.* — 2-*O*-Methyl-3,6-anhydro-L-galactose dimethylacetal (0.40 g.) in 0.02 N sulfuric acid (20 ml.) was heated in a boiling water bath for 2 hr., at which time the rotation of the solution reached a constant value ($[\alpha]_D$ −31°→−10°). The solution was neutralized with barium carbonate, filtered and evaporated to a sirup which was then dissolved in acetone. Filtration and evaporation of the acetone solution afforded 2-*O*-methyl-3,6-anhydro-L-galactose as a colorless sirup; yield, 0.35 g., $[\alpha]_D^{12}$ −14.3° (*c* 0.63), $n_D^{25}$ 1.4870, $OCH_3$; found: 17.45% (calcd. for $C_6H_9O_4(OCH_3)$: 17.59%). It reduced a Fehling solution at room temperature and restored the color to a Schiff's reagent. One of the present writers has reported $[\alpha]_D^{34}$ +33.9° of the sugar[5]. The previously reported value in a positive direction seems to be ascribed to some contaminants.

*ii) 2-O-Methyl-3,6-anhydro-L-galactonic acid.*— The reducing sugar (0.30 g.) obtained above was dissolved in water (5 ml.) and bromine (0.4 ml.) was added dropwise during 4 hr. to the solution kept at 40°C. The treatment of the solution in the usual manner afforded 2-*O*-methyl-3,6-anhydro-L-galactonic acid; yield, 0.35 g., m. p. 137~140°C. Recrystallization twice from ethyl acetate furnished the pure compound; m. p. and mixed m. p. 141~142°C, $[\alpha]_D^{12}$ −70.3° (*c* 0.84). One of the present writers has reported m. p. 142°C and $[\alpha]_D^{12}$ −70.0° for 2-*O*-methyl-3,6-anhydro-L-galactonic acid[5].

Found: C, 43.63; H, 6.32; $OCH_3$, 16.34. Calcd. for $C_6H_9O_5(OCH_3)$: C, 43.75; H, 6.27; $OCH_3$, 16.15%.

*iii) Methyl 2-O-methyl-3,6-anhydro-L-galactonate.* —The acid obtained above was converted to the methyl ester by the reaction with methanolic hydrogen chloride in the usual manner. The resulting methyl ester was recrystallized from benzene, forming stout needles; m. p. 90~91°C, $[\alpha]_D^{12}$ −70.8° (*c* 1.06). One of the present writers has reported about m. p. 91°C[1,5] $[\alpha]_D^{10}$ −55.3°[5] and $[\alpha]_D^{24}$ −61.6°[1].

Found: C, 46.54; H, 7.02; $OCH_3$, 30.23. Calcd. for $C_8H_{14}O_6$: C, 46.60; H, 6.84; $OCH_3$, 30.12%.

*iv) 2-O-Methyl-3,6-anhydro-L-galactonamide.* — The amide was prepared from the methyl ester obtained above by the reaction with methanolic ammonia and purified by recrystallization from ethanol; m. p. 171~172°C, $[\alpha]_D^{12}$ −75.4° (*c* 0.53). Araki and Arai have reported m. p. 170~171°C and $[\alpha]_D^{23}$ −74.3° for the amide[1].

Found: C, 43.88; H, 6.95; $OCH_3$, 16.01. Calcd. for $C_7H_{13}O_5N$: C, 43.97; H, 6.85; $OCH_3$, 16.23%.

*(b) Methyl 2-O-Methyl-3,6-anhydro-β-L-galactopyranoside.*—Fraction IV in Table II crystallized completely on standing and melted at 64°C. It showed on a paper chromatogram as a single spot having $R_f$ 0.77. This was combined with the crystals obtained by re-chromatography of fraction III described above and was recrystallized twice from petroleum ether, affording pure methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside as elongated prisms; m. p. 67~69°C, $[\alpha]_D^{12}$ +66.0° (*c* 1.00).

Found: C, 50.49; H, 7.46; $OCH_3$, 32.55; mol. wt. (Rast), 190. Calcd. for $C_6H_8O_3(OCH_3)_2$: C, 50.52; H, 7.42; $OCH_3$, 32.65%; mol. wt., 190.2.

The structure assignment to this compound has been based on the following experiments:

*i) 2-O-Methyl-3,6-anhydro-L-galactose.* — The methyl glycoside (0.20 g.) obtained above was hydrolyzed with 0.02 N sulfuric acid (20 ml.) for 2 hr. during which time the specific rotation of the solution changed from +66° to −11°, the final value being in good agreement with that observed when 2-*O*-methyl-3,6-anhydro-L-galactose dimethyl-acetal was hydrolyzed. The resulting 2-*O*-methyl-3,6-anhydro-L-galactose was isolated in the same manner as described already; yield, 0.15 g., $[\alpha]_D^{12}$ −15.0° (*c* 0.50), $n_D^{25}$ 1.4867; $OCH_3$ found 17.50%. The sugar was identified as 2-*O*-methyl-3,6-anhydro-L-galactonic acid and its methyl ester and amide in exactly the same manner as described already.

*ii) Methyl 2,4-di-O-methyl-3,6-anhydro-β-L-galactoside.* — Methyl 2-*O*-methyl-3,6-anhydro-β-L-galactopyranoside (0.08 g.) was dissolved in methyl iodide (4 ml.), silver oxide (3 g.) added, and the mixture was refluxed for 6 hr. The reaction mixture was diluted with dry acetone and filtered. Evaporation of the filtrate afforded methyl 2,4-di-*O*-methyl-3,6-anhydro-β-L-galactoside melting at 81~82°C, which was then recrystallized from petroleum ether; yield, 0.07 g., m. p. and mixed m. p. 83°C, $[\alpha]_D^{10}$ +76.7° (*c* 0.60). Methyl 2,4-di-*O*-methyl-3,6-anhydro-β-L-galactoside has been recorded as: m. p. 83°C and $[\alpha]_D^{14}$ +78.1°[6a]; m. p. 82~83°C and $[\alpha]_D$ +73.0°[6c] and m. p. 81°C and $[\alpha]_D$ +75.0°[6d].

Found: C, 53.02; H, 7.88; $OCH_3$, 45.45. Calcd. for $C_6H_7O_2(OCH_3)_3$: C, 52.93; H, 7.90; $OCH_3$, 45.59%.

*(c) Methyl 2,4,6-Tri-O-methyl-α,β-D-galactoside.* —All fractions VI—VIII in Table II were obtained as crystals with ill-defined melting points. Examination on paper chromatograms using the *o*-aminophenol reagent revealed no spot, indicating thereby the absence of any 3,6-anhydro-L-galactose derivative. The methoxyl values found were in good agreement with the value 52.52% calculated for $C_6H_8O_2(OCH_3)_4$. These fractions

were therefore composed entirely of methyl 2,4,6-tri-*O*-methyl-$\alpha,\beta$-D-galactoside.

Fraction V in Table II showed a spot corresponding to methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside on a paper chromatogram. When the fraction was hydrolyzed with 1 N sulfuric acid for 5 hr. at 98°C, the product showed a single spot corresponding to 2,4,6-tri-*O*-methyl-D-galactose on a paper chromatogram, the anhydrosugar derivative being completely destroyed during the hydrolysis. Fraction V was therefore a mixture of 40% of methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside (0.09 g.) and 60% of methyl 2,4,6-tri-*O*-methyl-$\alpha,\beta$-D-galactoside, the proportion being calculated on the basis of the methoxyl values.

*i) 2,4,6-Tri-O-methyl-α-D-galactose.*—Fractions VI—VIII were combined and hydrolyzed with 1 N sulfuric acid (20 ml.) for 4.5 hr. at 98°C. The reaction solution was then treated in the usual manner, when 2,4,6-tri-*O*-methyl-D-galactose was obtained; yield, 1.40 g., m. p. 104~105°C. Paper chromatographic examination indicated the presence of 2,4,6-tri-*O*-methyl-D-galactose only. Recrystallization, twice from ether, furnished the pure compound; m. p. and mixed m. p. 110~111°C, $[\alpha]_D^{15}$ +115.9° (initial)→+90.7° (after 24 hr., constant) (*c* 1.07). The physical constants are in good agreement with literature values[3,4].

Found: C, 48.56; H, 8.30; $OCH_3$, 41.78. Calcd. for $C_6H_9O_3(OCH_3)_3$: C, 48.64; H, 8.16; $OCH_3$, 41.90%.

*ii) 2,4,6-Tri-O-methyl-N-phenyl-D-galactosylamine.*—The tri-*O*-methyl-D-galactose recovered from the mother liquor of recrystallization mentioned above was converted into its aniline derivative in the usual manner[3,4]; m. p. and mixed m. p. 174°C, $[\alpha]_D^{14}$ −120.0° (initial)→−82.0° (constant) in acetone (*c* 0.50).

*(d) Unidentified Components.*—Fractions IX and X in Table II seemed to be methylated disaccharide derivatives having molecular weight, respectively, 423 and 398. The structures will be studied in the subsequent paper.

**Separation and Identification of the Components Soluble in Petroleum Ether.**—*(a) Separation.*—The sirup (2.05 g.), which had been obtained by extracting the neutral components of the methanolysis products with petroleum ether, was chromatographed at 22~24°C on a column (5.0×15 cm.) packed with charcoal (40 g.) and Celite (28 g.) in exactly the same manner as in the separation of the components insoluble in petroleum ether. The results are shown in Table III.

*(b) Identification.*—Fraction II was a colorless sirup, showing a spot corresponding to methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside on a paper chromatogram. When it was hydrolyzed with 1 N sulfuric acid for 5 hr. at 98°C, the resulting product showed a spot corresponding to 2,4,6-tri-*O*-methyl-D-galactose on a paper chromatogram, the anhydrosugar derivative being completely destroyed during the hydrolysis. From these facts, fraction II was considered to be a mixture of 70% of methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside (0.42 g.) and 30% of methyl 2,4,6-tri-*O*-methyl-D-galactoside (0.18 g.), the proportion being calculated on the basis of the methoxyl values.

Fraction III was proved to be entirely methyl 2,4,6-tri-*O*-methyl-$\alpha,\beta$-D-galactoside in exactly the same manner as in the case of fractions VI—VIII in Table II.

Fraction IV in Table III gave no spot on a paper chromatogram sprayed with an *o*-aminophenol reagent, indicating thereby the absence of any 3,6-anhydro-L-galactose derivative. On hydrolysis it produced 2,4,6-tri-*O*-methyl-D-galactose which was identified on a paper chromatogram. Fraction IV contained therefore methyl 2,4,6-tri-*O*-methyl-$\alpha,\beta$-D-galactoside only. However, a similar fraction obtained from the other batch was found to contain methyl 2,3,4,6-tetra-*O*-methyl-D-galactoside in addition to the tri-*O*-methyl-D-galactose derivative as described below.

**Confirmation of Methyl 2, 3, 4, 6-Tetra-*O*-methyl-D-galactoside.**—From the other batch of methylated agarose (15 g.), there was obtained a fraction similar to fraction IV of Table III; yield, 0.07 g. Paper chromatographic examination indicated the absence of any 3,6-anhydro-L-galactose derivative. The sirup was hydrolyzed with 1 N sulfuric acid (1 ml.) for 4.5 hr. at 98°C and the product was isolated in the usual manner as a colorless sirup; yield, 62 mg. Examination on a paper chromatogram indicated the presence of both 2,4,6-tri-*O*-methyl-D-galactose and 2,3,4,6-tetra-*O*-methyl-D-galactose. The mixture was resolved into the components on a column (2.5×32 cm.) packed with filter paper powder, a 2-butanone-water azeotrope being used as a mobile phase. A faster moving fraction containing the tetra-*O*-methyl-D-galactose was obtained as a sirup; yield, 20 mg., $[\alpha]_D^{10}$ +44.0° (*c* 0.50). It was dissolved in ethanol (1 ml.), aniline (20 mg.) added, and the solution was refluxed for 3 hr., when 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosyl amine was obtained; yield, 12 mg., m. p. 186~189°C. Recrystallization from ethanol afforded the pure compound; m. p. and mixed m. p. 192°C, $[\alpha]_D^{13}$ −75.8° (initial) in acetone (*c* 0.132).

Found: $OCH_3$, 40.18. Calcd. for $C_{16}H_{25}O_5N$: $OCH_3$, 40.51%.

**Yields of the Components.**—As shown in Tables II and III, the yields of 2-*O*-methyl-3,6-anhydro-L-galactose dimethylacetal, methyl 2-*O*-methyl-3,6-anhydro-$\beta$-L-galactopyranoside and methyl 2,4,6-tri-*O*-methyl-$\alpha,\beta$-D-galactoside are 3.72, 2.34 and 7.02 g., respectively, when calculated on the basis of the whole neutral components (15.2 g.). Consequently, the molar proportion of the sum of the former two to the last one is 1 : 1.03.

The authors wish to express their hearty thanks to Mr. K. Arai for micro-combustion and to Mr. T. Itō for assistance.

# *Studies on the Vibrated Dropping Mercury Electrode. II. Electrocapillary Characteristics of the Current-Voltage Curve*

By Hideo IMAI, Shōkichi CHAKI and Senkichi INOUYE

(Received June 8, 1959)

The theory of the limiting current of the vibrated dropping mercury electrode (VDME) has been given in the previous report[1], and it was shown that the limiting current increases about ten times when the mean velocity of the vibration is of the order of several centimeters per second. This result suggests the potentiality of the "VDME" method for improving the sensitivity of polarographic determinations. The surface charge density of the dropping mercury electrode (DME), however, exerts an influence on the velocity of the vibration, and accordingly, it controls the limiting current. Thus, the linear relation of the limiting current with the depolarizer concentration was not always obtained. Moreover, the remarkable effect of surface active materials on the limiting current and the effect of the vibration on the summit potential of a polarographic maximum or on potential of the electrocapillary maximum (the Lippmann-potential) were observed. These results are presented and discussed in this report.

## Experimental

The apparatus used was described in the previous report[1] and was not modified in any detail.

All the reagents were of analytical grade, and were used after the recrystallization. The test solution was prepared in the same way as that described in the previous report[1].

When the reduction potential of a depolarizer was adjoining the Lippmann-potential, the plateau of the limiting current was not well-defined. On this occasion, the limiting current was measured at a potential optionally determined.

The increase in the current-sensitivity owing to the vibration was expressed by the ratio, $(i_l/i_d)$, of the limiting current against the diffusion-controlled current measured at the same potential. All measurements were made at 25.0±0.1°C.

## Results and Discussion

**1. Variation of Limiting Current with Depolarizer Concentration.**—This relation was investigated in the cases of the mercuric, thallous, cadmium, nickel and zinc ions. The concentration ranged from 0.005 to 10 mF. The test solution contained 0.1 F potassium chloride or potassium nitrate as the supporting electrolyte, and a small

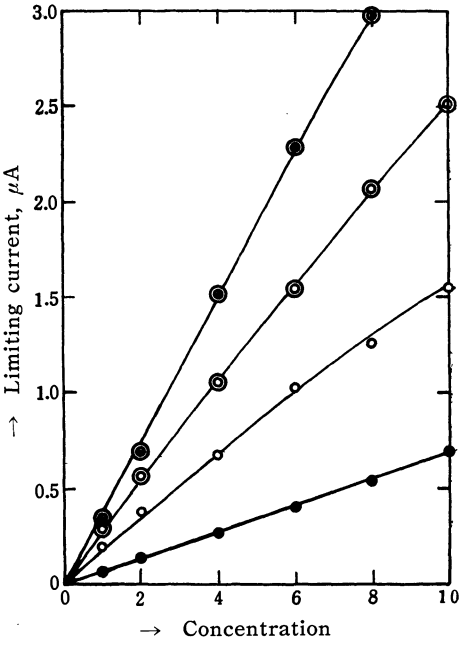

Fig. 1. The variation of the limiting current with the concentration of the zinc ion.
●: $i_d$ of $10^{-3}$, $10^{-4}$ and $10^{-5}$ F order
○: $i_l$ of $10^{-3}$ F order
◎: $i_l$ of $10^{-4}$ F order
◉: $i_l$ of $10^{-5}$ F order
The value of the current in the ordinate must be multiplied by the factor of 100, 10 and 1 μA for the concentration order of $10^{-3}$, $10^{-4}$ and $10^{-5}$ F, respectively. $E$= 0.38 V./cm. (25 c. p. s.). $m$=1.81 mg./sec. $t$=4.1$_9$ sec. (open circuit). The supporting electrolyte=0.1 F KCl. The limiting current was evaluated at −1.2 V. vs. S. C. E.

TABLE I. THE VARIATION OF THE RATIO, $i_l/i_d$, WITH THE DEPOLARIZER CONCENTRATION (25°C)

| Depolarizer concentration, mF | $i_l/i_d$ | | | | |
|---|---|---|---|---|---|
| | $Hg^{2+}$ in KCl | $Tl^{+}$ in $KNO_3$ | $Cd^{2+}$ in KCl | $Ni^{2+}$ in $KNO_3$ | $Zn^{2+}$ in $KNO_3$ |
| 10 | — | — | — | — | 2.0 |
| 5 | — | — | — | — | 2.5 |
| 1 | 5.7 | 3.0 | 3.2 | 3.3 | 3.5 |
| 0.5 | 5.6 | 2.8 | 3.4 | 3.8 | 4.3 |
| 0.1 | 5.7 | 2.8 | 3.3 | 4.0 | 5.0 |
| 0.05 | 5.6 | 2.7 | 3.2 | 4.3 | 6.0 |
| 0.01 | — | 2.8 | 3.2 | 4.6 | 7.0 |
| 0.005 | — | 2.6 | 3.4 | 4.8 | — |
| $E$, V./cm. | 0.4 | 0.38 | 0.38 | 0.38 | 0.38 |
| $t$, sec. | 8.3 | 6.2 | 6.2 | 6.1 | 4.2 |
| $m$, mg./sec. | 0.74 | 1.33 | 1.34 | 1.48 | 1.81 |

$E$ is the intensity of the a. c. electric field (25 c. p. s.), $t$ is the life-time of the DME and $m$ is the rate of mercury flow.

quantity of the sodium sulfite solution was added to remove the trace of dissolved oxygen.

In the cases of the mercuric ion, the thallous ion and the cadmium ion, the plateau of the limiting current was not obtained. This is because the surface charge density of the DME markedly varies near Lippmann-potential which is adjacent to the reduction potential of the depolarizer in question. On the contrary, the nickel ion and the zinc ion developed a fairly well-defined wave except for the increase of the residual current.

The variation of the ratio, $i_l/i_d$, with the depolarizer concentration is given in Table I.

In the former three depolarizers of Table I, the value of $i_l/i_d$ does not appreciably change with the depolarizer concentration. On the contrary, the value of $i_l/i_d$ is inversely proportional to the depolarizer concentration in the latter two depolarizers, and a curvilinear plot of the limiting current versus the concentration is obtained as is shown in Fig. 1.

In this connection, the variation of the life-time of the DME with the depolarizer concentration was investigated, and the result is illustrated in Table II.

TABLE II. THE VARIATION OF THE LIFE-TIME OF THE DME WITH THE CONCENTRATION OF THE ZINC ION (25°C)

| Concentration of the zinc ion, mF | Life-time of the DME, sec. | |
|---|---|---|
| | Open circuit | At −1.2 V. vs. S. C. E. |
| 8 | $4.5_6$ | $4.4_2$ |
| 1 | $4.5_6$ | $4.3_7$ |
| 0.2 | $4.5_7$ | $4.3_4$ |
| 0.01 | $4.5_7$ | $4.2_4$ |
| 0.001 | $4.5_7$ | $3.8_4$ |

In Table II the life-time measured in the open circuit is independent of the depolarizer concentration, while the life-time measured at the more negative potential than the reduction potential of the zinc ion increases as the depolarizer concentration is increased.

The increase of the life-time can be assigned to the increase of the surface tension of the DME.

The surface tension increases as the surface-charge density decreases and the decrease of the surface charge density results in the retardation of the vibration. Thus, the curvilinear relation of Fig. 1 is attributable to the effect of the reductant on the surface charge density of the DME.

**2. Effect of Surface Active Materials.**—*2-i. Variation of limiting current with concentration of surface active materials.*—The variation of the limiting current of 1 mF zinc ion with the concentration of the surface active material such as gelatine, methyl cellulose or polyoxyethylene lauryl ether (LEO, the mean molecular weight= 862) was investigated. The result is illustrated in Fig. 2. In every case the effect of the vibration diminishes by the addition of the surface active material, the limiting current being reduced to the value of the diffusion-controlled current by the addition up to about 0.01%. This effect is attributable to the retardation of the vibration due to the decrease of the surface-charge density. The effect of gelatine is more pronounced than that of methyl cellulose, and the difference of the curvilinear relation in Fig. 2 seems to relate to the adsorption mechanism of the surface

active material on the mercury surface.

*2-ii. Current-voltage curve accompanied with adsorption and desorption of surface acitve material.* — The effect of *n*-octyl alcohol on the current-voltage curve of 1 mF mercuric ion in 0.1 F potassium chloride was investigated. The limiting current markedly changes at two potentials which lie in the region of the anodic polarization and in the region of the cathodic polarization as is illustrated in Fig. 3. The potential of the current change at about −0.2 V. vs. S. C. E. and that of the current change at about −1.5 V. vs. S. C. E. correspond to the potential of the adsorption and that of the desorption of *n*-octyl alcohol, respectively, as is seen in comparison with the tensammetric curve appended in Fig. 3. From the fact that the limiting current changes with the adsorption or the desorption of the surface active material as is previously described in *2-i*, it is concluded that the change of the limiting current at about −0.2 V. vs. S. C. E. and that at about −1.5 V. vs. S. C. E. correspond to the decrease of the anodic current of the chloride ion owing to the adsorption of *n*-octyl alcohol and to the increase of the cathodic current of the mercuric ion owing to the desorption of *n*-octyl alcohol, respectively.

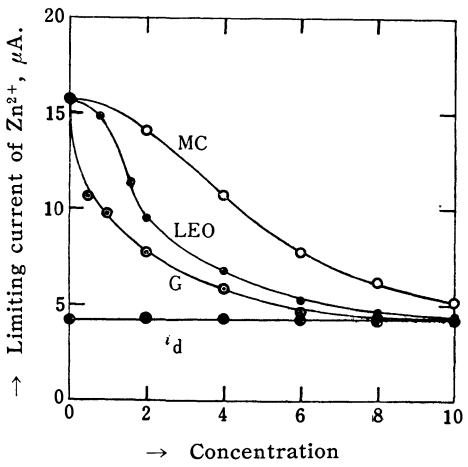

Fig. 2. The variation of the limiting current of the zinc ion with the concentration of the surface active material. The value of the concentration in the abscissa must be multiplied by the factor of $10^{-3}$ % for gelatine (curve G) and methyl cellulose (curve MC) or by the factor of $2.5\times10^{-6}$ F for LEO. $(Zn^{2+})=1\times10^{-3}$ F. Refer the illustration given in Fig. 1 to the other experimental conditions.

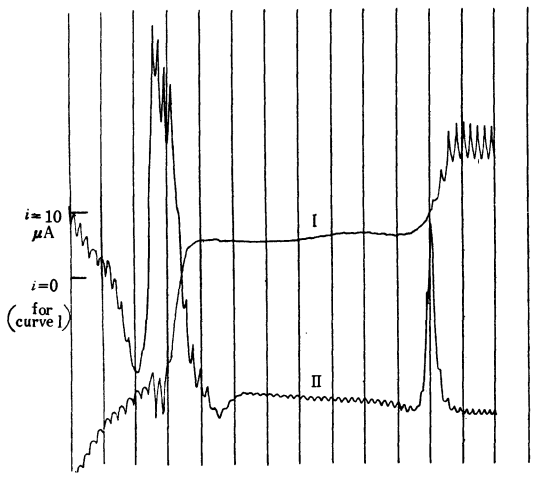

Fig. 3. The "VDME" current-voltage curve of the mercuric ion in the presence of *n*-octyl alcohol (curve I). $(Hg^{2+})=1\times10^{-3}$ F. The supporting electrolyte=0.1 F KCl. Curve II is the tensammetric curve of the same solution. The applied voltage starts from +0.2 V. vs. S. C. E., and each voltage interval corresponds to 0.15 V.

*2-iii. Dependence of limiting current to frequency of vibration and to concentration of*

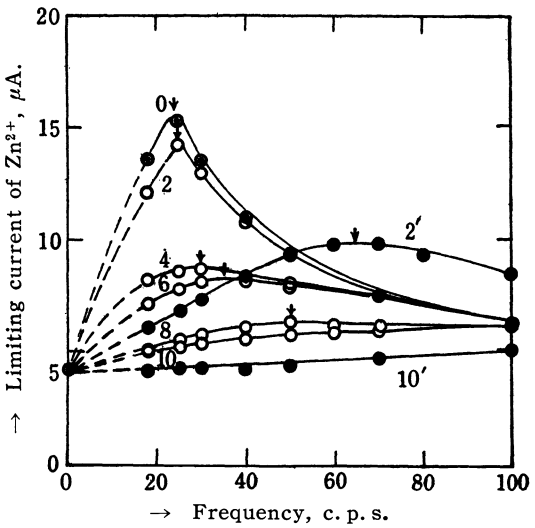

Fig. 4. The effect of the frequency of the a. c. electric field on the limiting current of the zinc ion in the presence of the surface active material. Curve 0 is obtained in the absence of the surface active material. Curves 2, 4, 6, 8 and 10 correspond to the concentration of methyl cellulose as great as 0.002, 0.004, 0.006, 0.008 and 0.01%, respectively. Curves 2′ and 10′ correspond to the concentration of gelatine as great as 0.002 and 0.01%, respectively. The maximum point of curve 10′ appears at about 200 c. p. s. $(Zn^{2+})=1\times10^{-3}$ F. Refer the illustration given in Fig. 1 to the other experimental conditions.

*surface active material.*—The dependence of the limiting current of the zinc ion to the frequency of the vibration was investigated in the presence of gelatine or methyl cellulose of various concentrations. The result is illustrated in Fig. 4. Under the vibration of the frequency less than 20 c. p. s., the mercury droplet is shaken off by the violent vibration in the absence of the surface active material, and the effect of the vibration on the limiting current gradually decreases as the frequency of the vibration increases. Thus, the limiting current gives a maximum at about 25 c. p. s. In the presence of the surface active material, the frequency of the vibration, which gives the maximum limiting current, shifts toward higher frequencies as the concentration of the surface active material increases. In connection with this effect, the difference between gelatine and methyl cellulose is noticeable as is pointed out in *2-ii.*

**3. Effect of Vibration on Maximum Wave.**—It was found that the summit potential of the polarographic maximum of the first kind shifts toward more negative potentials by the vibration.

The test solution contained 1 mF mercuric ion in 0.01 F sodium sulfate solution, and the DME with the comparatively short life-time was preferable in order to obtain reproducible data. The effect of the vibration on the maximum wave of the mercuric ion is illustrated in Fig. 5, and the variation of the summit potential with the intensity of the a. c. electric field is given in Table III.

TABLE III. THE VARIATION OF THE SUMMIT POTENTIAL OF THE POLAROGRAPHIC MAXIMUM WITH THE INTENSITY OF THE a. c. ELECTRIC FIELD ($E_1, E_2, E_3$ and $E_4$ represent the potential given in Fig. 5.)

| The intensity of the electric field, V./cm. | $E_1$ | $E_2$ | $E_3$ | $E_4$ |
|---|---|---|---|---|
| | V. vs. S. C. E. | | | |
| 0 | $-0.37_5$ | $-0.44_8$ | $-0.43_5$ | $-0.36_7$ |
| 0.16 | $-0.39_2$ | $-0.48_0$ | $-0.44_2$ | $-0.37_6$ |
| 0.25 | $-0.43_0$ | $-0.50_3$ | $-0.47_7$ | $-0.41_3$ |
| 0.34 | $-0.49_5$ | $-0.56_1$ | $-0.56_5$ | $-0.50_2$ |

(25 c. p. s. square wave, $t=5.5_6$ sec.)

According to the theory[1] previously reported, the velocity of the vibration is a linear function of the intensity of the a. c. electric field. Accordingly, it seems to be probable that the velocity of the vibration pertains to the shift of the summit potential. In this connection, Heyrovsky and Vascautzanu[2] have pointed out the fact that the summit potential is shifted toward more negative potentials by increasing the mercury head. The authors' observation coincides with this

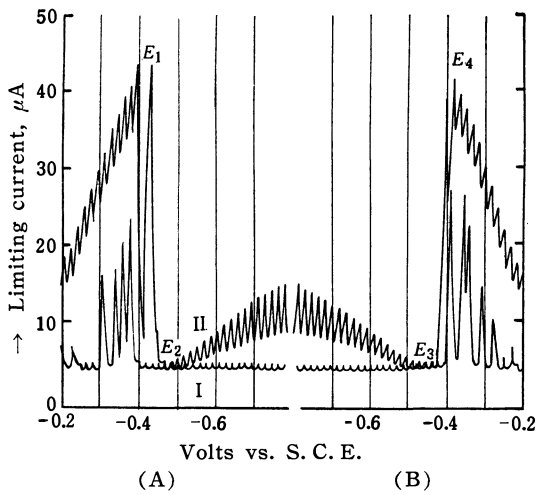

Fig. 5. The effect of the vibration on the summit potential of the maximum wave of $1\times10^{-3}$ F $Hg^{2+}$ in 0.01 F $Na_2SO_4$. The applied voltage is scanned from −0.2 V. to −0.8 V. vs. S. C. E. (A) or from −0.8 V. to −0.2 V. vs. S. C. E. (B). Curves I and II correspond to the cases when the intensity of the applied a. c. electric field is 0 and 0.34 V./cm., respectively. $t=8.0$ sec.

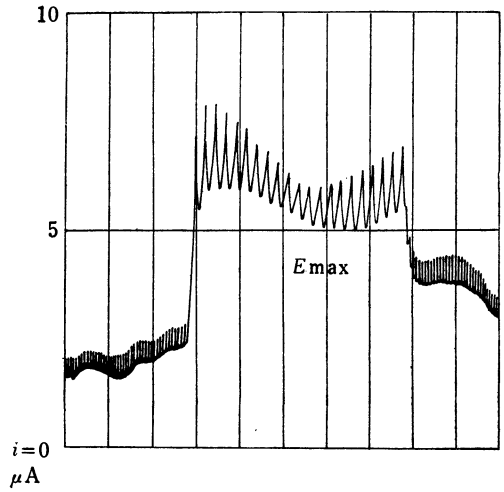

Fig. 6. The current-voltage curve of the mercuric ion under the violent vibration. The voltage starts from 0 V. vs. S. C. E. and each voltage interval corresponds to 0.1 V. $(Hg^{2+})=1\times10^{-4}$ F. The supporting electrolyte=0.1 F KCl. $E=0.38$ V./cm. $t=7$ sec. (open circuit).

effect with respect to the point that the possible change of the $\zeta$-potential due to the movement of the surface of the mercury droplet results in the shift of the summit potential of the maximum.

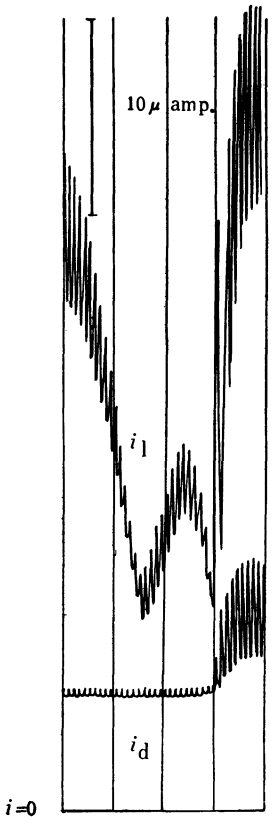

Fig. 7. The "VDME" current-voltage curve of the mercuric ion under the high rate of mercury flow. $i_d$ is the diffusion-controlled current and $i_l$ is the limiting current. $t=5.4_4$ sec. (open circuit). $m=1.34_7$ mg./sec. $(Hg^{2+})=1\times10^{-3}$ F. The supporting electrolyte=0.1 F KCl. The applied voltage starts from $-0.7$ V. vs. S. C. E. and each voltage interval corresponds to 0.1 V.

**4. Anomalous Effect of Vibration on Current-Voltage Curve.** — *4-i. Effect of violent vibration.*—The abrupt change of the limiting current was observed in the current-voltage curve of the mercuric ion under the application of the intense a. c. electric field (cf. Fig. 6). This change is caused by the change of the life-time of the DME. The mercury droplet is attached to the capillary orifice counteracting to the gravity and the vibration, and it is shaken off by the violent vibration caused by the coupled effect of the intense a. c. electric field and the increase of the surface charge density which is a function of the applied potential. Tachi and Okuda[3] have reported a similar phenomenon in the alternating current polarography.

*4-ii. Effect of rapid rate of mercury flow.* —Under the slow rate of the mercury flow, a minimum in the current-voltage curve is observed at the Lippmann-potential by the "VDME" method (cf. **1** and **4**). Under the rapid rate of the mercury flow, however, two minima were observed, the Lippmann-potential lying between them (cf. Fig. 7). It seems to be probable that this effect will be assigned to the variation of the $\zeta$-potential at the mercury-solution interface with the flow of mercury on the surface of the DME.

The authors wish to express their hearty gratitude to Professor Mutsuaki Shinagawa for his valuable advice and encouragement.

# *The Crystal Structure of Phenylarsonic Acid*[1]

By Akira SHIMADA

(Received September 9, 1959)

The chemistry of organoarsenic compounds has an earlier growth than that of others among those of organometallic compounds, and this fact has again attracted much attention of chemists in recent days[2]. However, there are only a few structural studies of the organoarsenic compounds[3-10], and, hence, it may be of interest and importance in this field of chemistry to reveal the spatial configuration and orientation of the molecules in the crystal of phenylarsonic acid, $C_6H_5AsO(OH)_2$, which is one of the fundamental compounds in the organoarsenic compounds. The present work, which provides the first determination of the packing mode of organoarsonic acid, seems of interest also from the standpoint of the hydrogen-bond formation, in comparison with other organic acids.

## Experimental

In a preliminary note, the crystallographic constants were already reported[1]; the crystal of this compound belongs to the orthorhombic system and the space group $D_2^4-P2_12_12_1$ with four chemical units in a unit cell, which has the following dimensions;

$a=10.42\pm0.02$, $b=14.92\pm0.02$, $c=4.70\pm0.02$ Å

The data mentioned above are in fairly good agreement with those recently reported by Bryden[11]. Oscillation and Weissenberg photographs were taken around the principal axes with Cu $K\alpha$ radiation. Intensities were obtained by the multiple-film technique in Weissenberg photographs and were estimated by visual comparison with a calibrated scale. They were corrected by means of the usual Lorentz and polarization factors, while the correction for absorption was evaluated under the assumption that the specimens were cylindrical rods. The absorption effect could not be neglected, especially for $(0\,k\,l)$ and $(h\,0\,l)$ spectra because of the rather high absorption coefficient ($\mu=60.3\,cm^{-1}$) of the crystals and because of their dimensions [cross section with rectangular dimensions: $0.20\times0.25$ mm. for $(h\,k\,0)$, $0.65\times0.40$ mm. for $(0\,k\,l)$, and $0.70\times0.65$ mm. for $(h\,0\,l)$].

## Structure Determination

The structure has been determined by making use of the heavy-atom technique. Thus, the electron density projection $\rho(xy)$, favorable because of the short $c$ axis, were fairly well resolved to reveal the configuration of the molecules, as described in the preliminary note[1]. The electron density projections $\rho(yz)$ and $\rho(xz)$ were easily constructed by the same method, referring to the refined electron density projection $\rho(xy)$. These projections were shown in Figs. 1—3, and the final coordinates are listed in Table I, their refinement being made by the difference syntheses at later stages. In the calculation of structure factors, McWeeny's scattering curves[12] of "valence states" for carbon atom and of $1/3(f^{\parallel}+2f^{\perp})$ for oxygen atom were used, while the scattering curve given by Berghuis et al.[13] was used for arsenic atom. Isotropic temperature factors were estimated to be 3.3 Å$^2$

TABLE I. ATOMIC COORDINATES

| Atom | $x/a$ | $y/b$ | $z/c$ |
|---|---|---|---|
| As | $0.334_4$ | $0.126_5$ | $0.211_2$ |

for all atoms in the case of ($h\,k\,0$) and ($0\,k\,l$), and 4.2 Å$^2$ in the case of ($h\,0\,l$). *R* indices for the final coordinates were 18.0, 14.0 and 15.6%, for ($h\,k\,0$), ($0\,k\,l$) and ($h\,0\,l$), respectively, excluding terms too weak to be observed.

### Description of the Structure

The general nature of the structure is shown in Figs. 1—3, which are *c*, *a* and *b* axis projections for this compound. The aresenic atom is surrounded by a group consisting of three oxygen atoms, $O_1$, $O_2$ and $O_3$ of the arsonic acid and one carbon atom $C_1$ of the benzene ring. The average As–O distance is 1.69 Å, and the As–C distance is 1.90 Å. The disposition of bonds from the arsenic atom appears to be nearly tetrahedral, the angles between the bonds being about 110°. The benzene ring is planer and the averge distance between adjacent carbon atoms is 1.41 Å, individual values ranging from 1.35 to 1.46 Å.

Phenylarsonic acid, which has two active hydrogen atoms, forms two hydrogen bonds, one with a length 2.64 Å from the atom $O_3$ of molecule I to the atom $O_2$ of molecule II, the other with a length 2.49 Å from the atom $O_3$ of molecule I to the atom $O_1$ of molecule I+*c* (molecule displaced by the unit vector *c*). This arrangement of these two types of hydrogen bonds links molecules with each other to form endless chains along the twofold axis perpendicular to the (001) plane. The benzene rings are connected through the arsenic atom to these chains which are held together by the van der Waals force only. The shorter distances between neighboring molecules occur between $O_2$ of one molecule and $C_2$, $O_3$ and $C_3$ of adjacent molecules; these distances are 3.29, 3.39 and 3.40 Å, respectively. Other intermolecular distances exceed 3.71 Å.

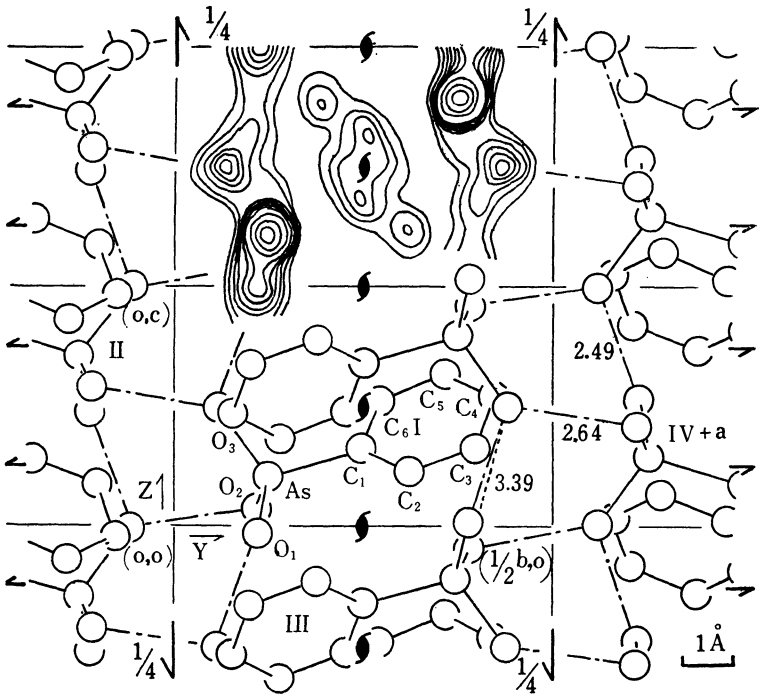

Fig. 2. The structure and the electron-density projection along the *a* axis, with intermolecular distances (Å). Contours at intervals of 2 eÅ$^{-2}$, starting at 4 eÅ$^{-2}$, except at the arsenic atoms, where contours above 16 eÅ$^{-2}$ are at intervals of 10 eÅ$^{-2}$. Dot-dash lines indicate hydrogen bonds.

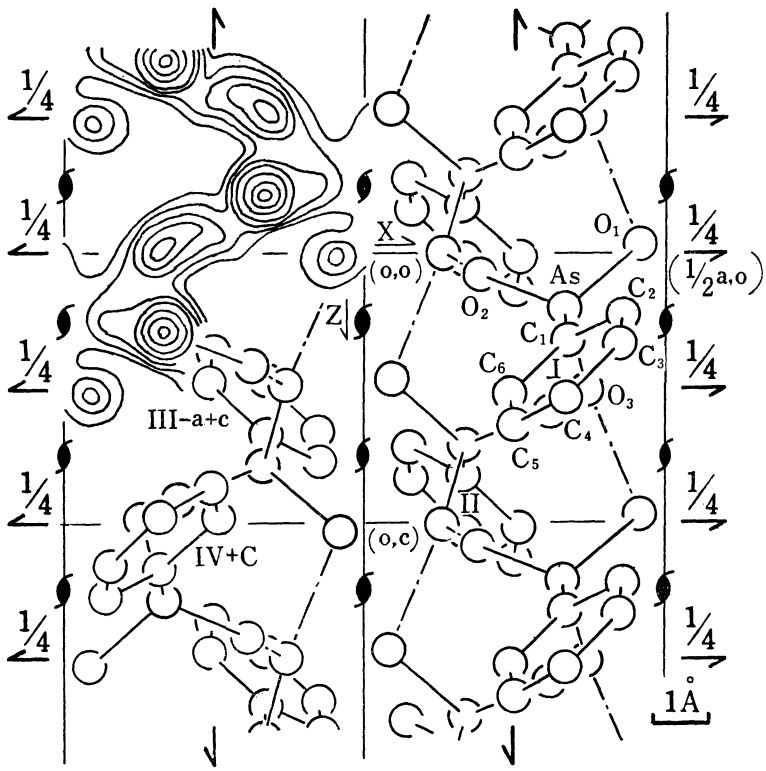

Fig. 3. The structure and the electron-density projection along the *b* axis. Contours at intervals of 3 eÅ$^{-2}$, starting at 5 eÅ$^{-2}$, except at the arsenic atoms, where contours above 11 eÅ$^{-2}$ are at intervals 10 eÅ$^{-2}$. Dot-dash lines indicate hydrogen bonds.

This mode of packing the molecules would explain the cleavages along the planes parallel to the (110) and (100) planes.

The author wishes to express his sincere thanks to Professor I. Nitta and Professor T. Watanabé of Osaka University for their helpful advice, to Professor H. Nakata of Konan University for supplying the specimen, and to other members of this University for their encouragement.

# *On the d Orbital of the Sulfur Atom in Thiophene*

By Kôgorô MAEDA

(Received June 17, 1959)

The idea of *pd* hybridization in thiophene has been used successfully in accounting for the general similarity between thiophenes and their benzene analogues[1-3]. In hybridizing the *p*- and *d*-orbitals on the sulfur atom, the fundamental procedure was that the two hybridized orbitals which conjugate with $2p\pi$ orbitals on the carbon atoms are defined so as to be non-orthogonal to each other. A problem which has to be solved, however, results from adopting the *d* orbitals in bonding; it follows what values should be used for nuclear charge parameters of the *d* orbitals. If the use of the free atom parameter required by Slater's rule[4] for an electron in the *d* orbital is to be retained at all, the orbital becomes too diffuse and weakly bound to participate substantially in bonding. For example, when an electron of an unshared pair on the sulfur atom is considered to be in the *d* state, it bears the value 1 as the effective nuclear charge; this fact gives a small value of overlap integral with the $2p\pi$ orbital on the carbon atom, of the order of 0.1[5] and suggests the level of its energy much higher than the ground state. Under this condition, one might not expect the appreciable participation in bonding to occur through the hybridization, from the point of overlap criterion on bonding[6] and from balancing of energy. The eigenfunction of the electron, however, has its radial function whose maximum lies at 9 atomic units. The orbital, therefore, may be regarded as including the full carbon skeleton of thiophene, so that it would be impossible to avoid the influence of the nuclear charges of neighboring carbon atoms. The charges may distort the orbital, contracting it and allowing its participation in the hybridization, as suggested by Craig and Magnusson[7].

In this paper, the influence of perturbing potentials of the charges will be examined, and the possibility of the participation in the hybridization will be inquired into, following the treatment by Craig and Magnusson, who presented a model to represent *d* electrons in an octahedral molecule, and applied it to the consideration of actual examples.

**Orbital Contraction.**—Let us now consider the system in which a bivalent sulfur atom combines with two carbon atoms at an angle. In this model, a single *d* electron will be supposed to move in the field of the sulfur nucleus of charge $Z_s$, and upon this hydrogen-like atom system will be superposed a perturbation consisting of two positive charges of the carbon atoms of magnitude $Z_c$ at the distance of $\sigma$ atomic units. Furthermore, the central hydrogen-like atom will be considered to be surrounded, not by two hydrogen-like atoms of carbon, but just by point charges of magnitude $Z_c$. The actual potential of perturbation consists of the attraction of the surrounding nuclei minus the

coulomb repulsions of their electrons plus exchange terms; hence the dependence on distance of this composite potential will not follow the $r^{-1}$ law at all closely. The system being thus too complicated, the point charge approximation is employed as approximation in this paper; the charge $Z_c$ will be treated rather as a parameter relevant to making up for the imperfection of the approximation, values plausible in wider range being involved. As for the angle between two C-S bonds, $\theta$, the following three cases will be considered apart from the thiophene in question, from a more general point of view, 90°, 120° and further 180°. For $Z_c=0$, the eigenfunction for $d$ electron is, of course, that of the hydrogen-like atom of charge $Z_s$. As the $d$ electron wave function, two of the usual Slater-type atomic functions are taken up for consideration, as follows:

$$\psi_{xz}=(\sqrt{2}/81\sqrt{\pi})\alpha^{7/2}r^2\exp(-\alpha r/3)\times\sin\vartheta\cos\vartheta\cos\varphi$$

$$\psi_{yz}=(\sqrt{2}/81\sqrt{\pi})\alpha^{7/2}r^2\exp(-\alpha r/3)\times\sin\vartheta\cos\vartheta\sin\varphi$$

where, $\alpha$, as will be mentioned later, is a parameter to be determined with respect to energy. Further, the influence upon $3p$ Slater atomic function will be examined in comparison with the case of the $d$ orbitals.

The potential by the outlying charges may be expanded as a sum in the usual $1/r$ series[8], which reduces to the following expressions for the three cases respectively.

$\theta=90°$:

$$V_{r<\sigma}=-(2Z_c/\sigma)-(Z_c/\sigma)(r/\sigma)\times(\cos\varphi+\sin\varphi)\sin\vartheta-(Z_c/2\sigma)(r/\sigma)^2(3\sin^2\vartheta-2)+\cdots\cdots$$

$$V_{r>\sigma}=-(2Z_c/r)-(Z_c/r)(\sigma/r)\times(\cos\varphi+\sin\varphi)\sin\vartheta-(Z_c/2r)(\sigma/r)^2(3\sin^2\vartheta-2)+\cdots\cdots$$

$\theta=120°$:

$$V_{r<\sigma}=-(2Z_c/\sigma)-(Z_c/\sigma)(r/\sigma)\times\cos(\varphi-\pi/3)\sin\vartheta-(Z_c/2\sigma)(r/\sigma)^2\{(15/4)\cos^2\varphi\sin^2\vartheta+(3\sqrt{3}/2)\sin\varphi\cos\varphi\sin^2\vartheta+(9/4)\sin^2\varphi\sin^2\vartheta-2\}+\cdots\cdots$$

$$V_{r>\sigma}=-(2Z_c/r)-(Z_c/r)(\sigma/r)\times\cos(\varphi-\pi/3)\sin\vartheta-(Z_c/2r)(\sigma/r)^2\times\{(15/4)\cos^2\varphi\sin^2\vartheta+(3\sqrt{3}/2)\sin\varphi\cos\varphi\sin^2\vartheta+(9/4)\sin^2\varphi\sin^2\vartheta-2\}+\cdots\cdots$$

$\theta=180°$:

$$V_{r<\sigma}=-(2Z_c/\sigma)-(Z_c/\sigma)(r/\sigma)^2\times(3\cos^2\varphi\sin^2\vartheta-1)+\cdots\cdots$$

$$V_{r>\sigma}=-(2Z_c/r)-(Z_c/r)(\sigma/r)^2(3\cos^2\varphi\sin^2\vartheta-1)+\cdots\cdots$$

Each expression shows that the perturbing potential has its symmetrical plane bisecting the angle between two C-S bonds, $\theta$. The perturbation energy due to the outlying potential is given by $\int\psi V\psi d\tau$, where $\psi$ and $V$ are both shown above. Hence, after integrating over the angular parts excepting the radial one, it is found that the expressions for $3p_z$ orbitals have the same forms, and that the $3d_{xz}$ and $3d_{yz}$ orbitals are exposed respectively to the same fields of the outlying potentials when $\theta=90°$. Both of these can naturally be expected from their symmetric characters. In integrating with respect to the radial part, the terms higher than 2nd may be neglected because of their small contribution to the potential. Hence, the perturbation energy $E'$ is given by the following, for example, for $3d_{xz}$ when $\theta=180°$;

$$E'=(8Z_c/81^2\times15)\int_0^\sigma\alpha^7r^6\{-2/6-(2/7)\times(r^2/\sigma^3)\}\exp(-2\alpha r/3)dr+(8Z_c/81^2\times15)\int_\sigma^\infty\alpha^7r^5\{-2-(2/7)\times(\sigma^2/r^2)\}\exp(-2\alpha r/3)dr$$
$$=-(2Z_c/\sigma)(2\alpha\sigma/3)^7(1/6)[\{6!(3/2\alpha\sigma)^7-A_6(2\alpha\sigma/3)+A_5(2\alpha\sigma/3)\}+(1/7)\{8!(3/2\alpha\sigma)^9-A_8(2\alpha\sigma/3)+A_3(2\alpha\sigma/3)\}]$$

where

$$A_n(\omega)=\int_1^\infty r^n\exp(-\omega r)dr$$

Hereupon, using the auxiliary function presented by Craig and Magnesson[7],

$$R^p{}_{nn}(\alpha\sigma)=(1/\sigma)(2\alpha\sigma/n)^{2n+1}\{1/(2n)!\}\times\{(2n+p)!(n/2\alpha\sigma)^{2n+p+1}-A_{2n+p}(2\alpha\sigma/n)+A_{2n-p-1}(2\alpha\sigma/n)\}$$

8) H. Eyring, J. Walter and G. E. Kimball, "Quantum Chemistry", John Wiley & Sons, Inc., New York (1944), p. 369.

$$E' = -(2Z_c/\sigma)\{\sigma K^0_{33}(\alpha\sigma) - (1/7)\sigma R^2_{33}(\alpha\sigma)\}$$

For $3d_{yz}$ when $\theta=180°$,

$$E' = -(2Z_c/\sigma)\{\sigma K^0_{33}(\alpha\sigma) - (2/7)\sigma R^2_{33}(\alpha\sigma)\}$$

Similarly, when $\theta=120°$, for $3d_{xz}$

$$E' = -(2Z_c/\sigma)\{\sigma K^0_{33}(\alpha\sigma) - (1/56)\sigma R^2_{33}(\alpha\sigma)\}$$

and also for $3d_{yz}$,

$$E' = -(2Z_c/\sigma)\{\sigma K^0_{33}(\alpha\sigma) - (1/8)\sigma R^2_{33}(\alpha\sigma)\}$$

As mentioned above, the $3d_{xz}$ and the $3d_{yz}$ orbitals have the same potentials of perturbation when $\theta=90°$, and so their energies are given in the same form,

$$E' = -(2Z_c/\sigma)\{\sigma K^0_{33}(\alpha\sigma) - (1/14)\sigma R^2_{33}(\alpha\sigma)\}$$

In the case of the $3p$ orbitals, they have the same energies for three cases of the angle $\theta$ because of their symmetric characters, that is;

$$E' = -(2Z_c/\sigma)\{\sigma R^0_{33}(\alpha\sigma) - (1/5)\sigma R^2_{33}(\alpha\sigma)\}$$

The total energy is the sum of the perturbation energy $E'$ and the unperturbed given by

$$W = (\alpha/3^2)(\alpha/2 - Z_s)$$

for the hydrogen-like orbital of free atom parameter $Z_s$.

The procedure to be performed now is to find the new value of effective nuclear charge for which the total energy is a minimum for given magnitude of $\sigma$, $Z_c$ and $Z_s$, i.e. to minimize the energy with respect to the exponent $\alpha$. The increase in $\alpha$ over $Z_s$ corresponds to a contraction of the orbital and the decrease to an expansion, since Slater radial functions have their maxima at $r_m = n^2/\alpha$. As the value of $Z_s$, the following two are chosen, 1 and 2 for $3d$ orbital, and 5 and 6 for $3p$. The distance $\sigma$ is assigned to three values, 4, 3 and 2 atomic units, the first two come from actual examples containing the sulfur atoms, and the last is taken for the purpose of comparison with the first two. With respect to the value of $Z_c$, it is difficult to determine the straightforwardly equivalent parameter of the outlying potential, because, as mentioned above, the real field is not truly coulombic but much more complicated. Furthermore, there is, in general, a considerable difference between so-called potential- and field-determined nuclear charges on the same atom[9]. Therefore, in this paper, three values are assumed, $Z_c=1$, 2 and 3, which are of course treated as tentative parameters, and the last is introduced from the well-known value of Slater's rule for the $2p$ orbital of carbon. In finding the minimum of the total energy, it is necessary to evaluate the values of $\sigma R^p_{nn}(\alpha\sigma)$, which are tabulated in *Appendix*.

In Tables I and II are given the results. It is shown in these tables that the $3d$ orbitals are largely contracted, while the $3p$ orbitals are little affected by the outlying perturbing charges, and that the contraction is more sensitive to the bond distance $\sigma$ than to the effective charge $Z_c$. The magnitude of the contraction is less for a greater bond distance and for a greater value of $Z_s$. This may be expected for the model employed here. Fig. 1 illustrates the rapid decrease in increment $(\alpha - Z_s)$ with increasing $\sigma$ and

$Z_s$, when $\theta=90°$ (the case of thiophene[10]). The figure also shows that the increment of effective nuclear charge by the perturbation is little altered by $Z_c$ in the range $Z_c=2\sim3$ which are most plausible as the equivalent parameter, $\sigma=3$ and 4 corresponding to the actual molecule containing the sulfur atom.

From these results, it might be inferred in any case that in hybridizing the $d$ orbital on the sulfur atom as in thiophene the effective nuclear charge for the $d$ orbital would not bear the free atom parameter, but it should bear at least a greater value, for example, $\alpha \fallingdotseq 3$ for that in thiophene. Of course, it must be emphasized that this discussion on the effective value for $\alpha$ is by all means tentative under the point charge approximation. Furthermore, the value of $\alpha$ appropriate to the real system should be determined precisely with respect to the whole energy of the molecule. The value obtained through the approximation, however, may be used as the first step of the calculation about the molecular energy.

On the other hand, for the $3p$ orbital, the free atom parameter may be used directly in calculating the molecular energy, because it is little affected by the surrounding nuclei. In general, the contraction of orbital is large only when the orbital with highly screened and loosely bound electrons lies under the perturbation. For the $2p\pi$ orbital of carbon, an argument similar to the case for $3p$ orbital can be applied as follows; the perturbation energy $E'$ for the $2p$ orbital with nuclear charge $Z=3$ is given as

$$E' = -(2Z_c/\sigma)\{\sigma R^0_{22}(\alpha\sigma) - (1/5)\sigma R^2_{22}(\alpha\sigma)\}$$

when $\theta=120°$. Using the values $\sigma R^0_{22}$ and $\sigma R^2_{22}$ (see *Appendix*), the perturbed nuclear charge can be obtained, which is given in Table III for $\sigma=2$, 3 and 4 atomic units. It is seen that the orbital is not altered at all. The free atom parameter for the $2p$ orbital of carbon may be used securely as usual in the molecular energy calculation.

TABLE III. EFFECTIVE NUCLEAR CHARGE $\alpha$ OF $2p_z$ ORBITAL WHEN $\theta=120°$

| $Z$ | $Z_c$ | $\sigma=2$ | $\sigma=3$ | $\sigma=4$ |

| 〃 | 2 | 3.46 | 3.22 | 3.10 |
| 〃 | 3 | 3.64 | 3.33 | 3.14 |

It is of interest to notice that the radial maxima of the $3d$ orbitals contracted lie nearly at the bond distance $\sigma$.

**Overlap Integral.**—The overlap criterion[6] may be used conveniently in discussing the bond formation, because it is generally impracticable to calculate accurately the energy of formation of a bond between two centers, and, as much used and discussed by Mulliken and his collaborators[11], it gives some measure of the concentration of electronic charge between the nuclei. It can be used not only for the discussion of covalent bond, but also can be well applied to that of $\pi$ bonding. An amount of increase in overlap integral means to strengthen the bond to some extent. Further the increase in overlap integral of a $d$ orbital with an orbital on the neighboring atom will be associated by large contribution to the hybridization in which the $d$ orbital participates, because the integral of the hybrid orbital may be written as a sum of those of participating orbitals.

The values of the integral for the contracted and unperturbed $3d\pi$ orbitals with the $2p\pi$ orbitals of carbon are summarized in Table IV, together with those for $3p\pi$ orbitals. In calculating these values, numerical tables given by Jaffé[5] and

* In calculating the overlap integral involving *d* orbital, one must pay some attention to the special symmetric character of the orbital; in this table are given only the values when $\theta=90°$, because both other cases may cause some confusion in the calculation. Cf. Ref. 2.

Mulliken et al.[12] were used. The results show that the values of integral for the contracted 3*d* orbitals are enlarged without exception. Although it does not necessarily signify a very great possibility of bonding by the *d* orbital, it may be said at least that such $d\pi-p\pi$ bonding is likely to be more commom and important than has ever been considered, and that, therefore, the participation of the *d* orbitals in the hybridization is more probable than expected through the direct employment of free atom parameter by Slater's rule. In an actual system such as the sulfur atom in thiophene, the extent to which the *d* orbital participates in bonding will be of the order same as, or less than, that of the 3*p* orbital, despite the greater value of the integral. Because the mixing coefficient of the *d* orbital in the hybridization is not great, and also the balancing of energy is unfavorable; this will be examined in the next section.

**Balancing of Energy.**—Slater's rule seems to be insufficient for the accurate calculation of energy levels of an atom, although it suffices for the discussion of orbital size and overlap of atoms. For example, according to the rule, one has the values 45 and 1.5 eV. for 3*p* and 3*d* orbitals on the sulfur atom, respectively. They are very different from spectroscopic data[13], though these data are not always precisely corresponding to the so-called valence states of the atom. Spectroscopically the ionization energy of the atom is 10.36 eV. and the difference between 3*p* and 3*d* states is about 8.5 eV.

The discussion dealing with the final determining factor in bonding, i.e. the energy, can not be free from some ambiguity, since the general relationships between the overlap and the bond energy, and between the effective nuclear charge and the energy level, are not yet well established. If one should be allowed to assume that the free atom parameters $Z_s=5.45$ and 1 may correspond to the energy values 10.36 and 1.86 eV., respectively, the levels of the contracted *d* orbitals will be settled at about 5 eV. above the ground state. Of course, this estimation is merely tentative. However, it might be said that the level of energy of the *d* orbital will be drawn to some extent near to that of the 3*p* orbital as the result of the contraction by the perturbation, so that the possibility of participation in the hybridization will become greater, setting aside the question of extra promotion energy suggested by Craig and Magnusson[7], who estimated the energy directly by Slater's rule. It is well known that the closer the two energy levels are drawn to each other, the greater the interaction between them[14].

All the discussions above are those under the point charge approximation. It is more or less inevitable that the results obtained in this paper are not so readily available for an accurate discussion of bond formation in the real system. Further, in thiophene, there are two other perturbing charges which are included by the diffuse *d* orbital on the sulfur atom.

Nevertheless, the results will be sufficiently valid for approximate and semiquantitative discussion on the possibility of participation of the *d* orbital in hybridization.

## Summary

The influence of neighboring atoms upon the diffuse *d* orbital on the sulfur atom

and the possibility of the participation in the hybridization were examined. It might be expected that, with respect to the sulfur atom in thiophene, the participation of *d* orbitals in the hybridization would take place to a greater extent than predicted by the direct application of free atom parameter by Slater's rule, owing to the contraction by the perturbation of neighboring carbon atoms.

The author wishes to express his sincere thanks to Dr. S. Nagakura for his kind advice and helpful discussions. Thanks are also due to Dr. K. Saito for his kind inspection and revision of this manuscript.

# *Vapor Phase Oxidation of Alkyl Benzenes*[1]

By Shigeru MORITA

(Received September 7, 1959)

Phthalic anhydride is produced commercially by vapor phase oxidation of naphthalene. By the same process, maleic anhydride is obtained from benzene, anthraquinone from anthracene. Production of benzoic acid from toluene and of phthalic anhydride from *o*-xylene by the oxidation has been studied, but the oxidation of benzene which contains an alkyl group with a longer chain than the methyl group has not been examined.

It has been published that, based on liquid phase oxidation of ethyl benzene, the mechanism of vapor phase oxidation of alkyl benzenes is assumed to be as follows[2]:

R: alkyl group

The author studied the mechanism of vapor phase oxidation of alkyl benzenes and others.

## Experimental

**Apparatus.**—As shown in Fig. 1, a reactor was a steel U tube 18 mm. in diameter, immersed in a molten nitrate bath.

**Catalyst.**—The Catalyst was, throughout the present experiments, a mixture of vanadium pentoxide and molybdenum trioxide on pumice stone, which was prepared from ammonium metavanadate (5 g.), ammonium molybdate (5 g.) and puric stone (100 ml.) by the method described before[3].

**Experimental Conditions.**—The air rate was 150 l./hr. and the feed rate of reactants 1.5 g./hr.; the range of reactor temperatures was 300～500°C and the volume of catalyst was 50 ml. Duration of an experimental run was 3 hr. Substances oxidized are listed in Table I.

**Analysis of Reaction Products.**—Oxidation products, mainly a mixture of phthalic and maleic anhydrides and benzoic acid, after having been dissolved in hot water (and filtered, if necessary,) were dried in vacuo and weighed. Then, using a portion of the dried product, the neutralization equivalent of the whole mixture was ascertained. Another portion of the product was taken, benzoic acid was removed completely by microsublimation apparatus at 65～70°C, and the neutralization equivalent of the remaining product was ascertained. From these values the amounts of phthalic, benzoic, and maleic acids were figured out.

The same procedure was repeated using a known mixture of three acids and the experimental values were found to be within 15% of the theoretical values.

## Results and Discussion

**Vapor Phase Oxidation of Monoalkyl Benzenes.**—Toluene, ethyl benzene, propyl benzenes butyl benzenes, amyl benzenes, hexyl benzenes, and dodecyl benzenes were oxidized under the same conditions. The mole percentage yields of products are listed in Table II.

Table II shows that

1) Ethyl benzene is more easily oxidized

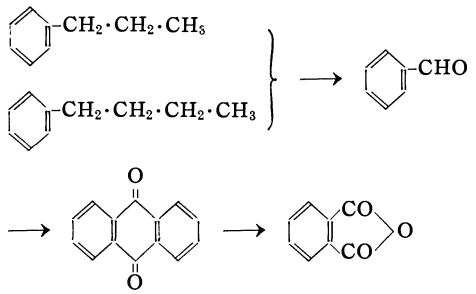
* and 18 mol. % of diphenyl is produced.

than toluene. And benzoic acid and maleic anhydride are obtained from ethyl benzene in the same yields as that from styrene.

2) When the number of carbons in the longest chain of the alkyl group is three or more, for instance, *n*-propyl, *n*-butyl, *sec*-butyl, amyl, hexyl, etc., phthalic anhydride (25~36%), benzoic acid and maleic anhydride are obtained by vapor phase oxidation. When it is two or less, for instance, methyl, ethyl, *i*-propyl, no phthalic anhydride is obtained.

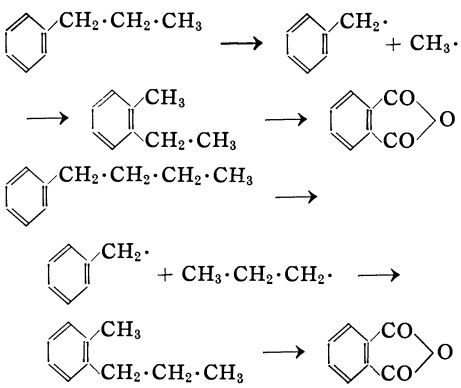
3) The yield of phthalic anhydride obtained from *n*-alkyl benzenes is lower than that from *sec*-alkyl benzenes, and that from *tert*-alkyl benzenes is very small.

4) No benzoic acid is obtained from *tert*-alkyl benzenes by vapor phase oxidation.



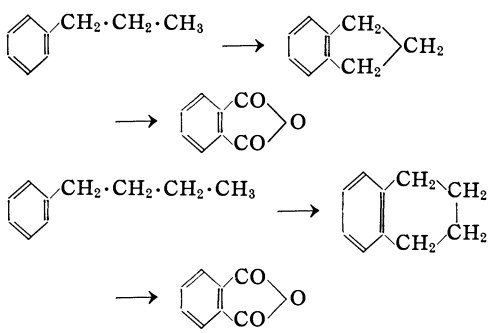
**The Reaction Mechanism of Vapor Phase Oxidation of *n*-Propyl Benzene and *n*-Butyl Benzene.** — *n*-Propyl benzene or *n*-butyl benzene has only one alkyl group. Oxidation of either of these two compounds produces phthalic anhydride in which the benzene ring has two side chains containing carbon atoms. This strange phenomenon, however, can not be explained by the mechanism that has been advocated by Marek, Hahn[2] and others so far.

The range of temperatures of vapor phase oxidation is 350~500°C and a reactant is passed with air through the vanadium pentoxide catalyst zone in vapor phase. Therefore, it is supposed that oxidation, pyrolysis and condensation would occur at the same time.



Concerning the above-mentioned strange reaction the author examined accordingly the following three mechanisms *a*, *b* and *c*.

*Mechanism a.* — *n*-Propyl benzene or *n*-butyl benzene would be oxidized to benzaldehyde. The two molecules of the aldehyde may be condensed to form anthraquinone as Parks[4] observed, and then this would be oxidized to from phthalic anhydride.



4) W. G. Parks et al., *Ind. Eng. Chem.*, **33**, 891 (1941); C. R. Downs, *J. Soc. Chem. Ind.*, **46**, 388, T (1927).

*Mechanism b.* — *n*-Propyl benzene or *n*-butyl benzene would be dissociated to form benzyl and ethyl or propyl radicals, as given in the papers by Szwarc[5], then the alkyl radical would be attached to the ortho position of benzyl radical to form dialkyl benzene[6]. This would be oxidized to phthalic anhydride.

*Mechanism c.*—As already reported by Tonomura[7], Murphy[8] and Nametkin[9], *n*-propyl benzene or *n*-butyl benzene would produce hydrindene or tetralin by cyclization and then this would be oxidized to phthalic anhydride.

The author examimed these mechanisms.

*On mechanism a.*—Oxidation products of *n*-propyl benzene or *n*-butyl benzene contained no anthraquinone, and when the mechanism is true, ethyl benzene would have to produce phthalic anhydride through the same mechanisms. But the experimental results showed that no phthalic anhydride was produced from ethyl benzene. From these facts, it is supposed that this mechanism is not true.

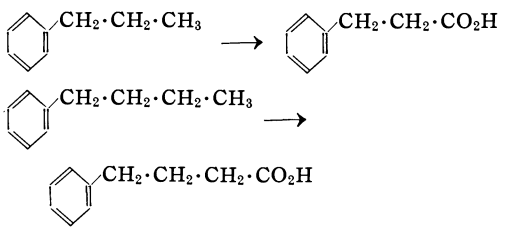
*On mechanism b.*—If this mechanism is correct, ethyl benzene must produce phthalic anhydride by the oxidation. The experiments showed that ethyl benzene did not produce it, and therefore this mechanism is not correct. To ascertain this conclusion, ethyl benzene was oxidized in the vapor phase with air containing vapor of methanol or ethanol, etc., both of which are liable to form a free radical[10], but no phthalic anhydride was obtained.

*On mechanism c.*—*n*-Propyl benzene was passed through the pumice (carrier) bed which contained no vanadium pentoxide under the same conditions as those of the oxidation (temperature, air rate and feed rate). The ultraviolet spectrum of the product showed that it contained styrene but no hydrindene. Moreover, when this product was oxidized in the liquid phase with aqueous solution of potassium permanganate[11], only benzoic acid was found but no phthalic acid. As to *n*-butyl benzene, the spectrum showed the presence of alkenyl benzene (presumably propenyl benzene). Thus the mechanism *c* is incorrect.

With these three mechanisms, the formation of phthalic anhydride from *n*-propyl benzene or *n*-butyl benzene by the oxidation can not be explained.

The author studied the following reactions.

*Mechanism d·1.*—The first carbon atom attacked by oxygen in the alkyl group of *n*-propyl benzene, and *n*-butyl benzene.



Propiophenone $C_6H_5\cdot CO\cdot CH_2\cdot CH_3$, phenyl acetone $C_6H_5\cdot CH_2\cdot CO\cdot CH_3$, hydrocinnamic acid $C_6H_5\cdot CH_2\cdot CH_2\cdot CO_2H$, butyrophenone $C_6H_5\cdot CO\cdot CH_2\cdot CH_2\cdot CH_3$, benzyl ethyl ketone $C_6H_5\cdot CH_2\cdot CO\cdot CH_2CH_3$, benzyl acetone $C_6H_5\cdot CH_2\cdot CH_2\cdot CO\cdot CH_3$ and $\gamma$-phenyl butyric acid $C_6H_5\cdot CH_2\cdot CH_2\cdot CH_2\cdot CO_2H$ were oxidized in vapor phase under the same conditions. The experimental results are given in Table III.

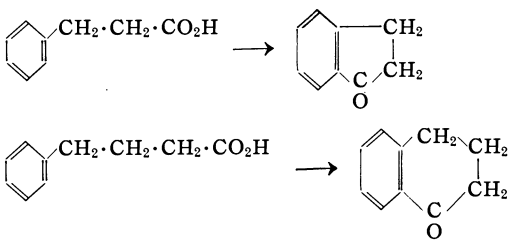
TABLE III. EXPERIMENTAL RESULTS OF VAPOR PHASE OXIDATION OF COMPOUNDS RELATED TO ALKYL BENZENE

| Material | Reaction temp. °C | Products | | |
|---|---|---|---|---|
| | | Phthalic anhydride mol. % | Benzoic acid mol. % | Maleic anhydride mol. % |
| Propiophenone | 300 | 0 | 45 | 39 |
| Propiophenone | 400 | trace | 2 | 49 |
| Phenyl acetone | 400 | trace | 20 | 42 |
| Hydrocinnamic acid | 400 | 20 | 2 | 44 |
| Cinnamic acid | 400 | 15 | 2 | 55 |
| $\alpha$-Hydrindone | 400 | 77 | 0 | 11 |
| Butyrophenone | 300 | trace | 62 | 29 |
| Butyrophenone | 400 | trace | 6 | 42 |
| Benzyl ethyl ketone | 300 | 0 | 18 | 23 |
| Benzyl ethyl ketone | 400 | 0 | 6 | 43 |
| Benzyl acetone | 400 | 18 | 3 | 46 |
| $\gamma$-Phenyl butyric acid | 400 | 30 | trace | 22 |
| Tetralone | 400 | 62 | trace | 12 |

As shown in Table III, propiophenone, butyrophenone, phenyl acetone and benzyl ethyl ketone, of which $C_1$ or $C_2$ contains oxygen atom, produced no phthalic anhydride. While hydrocinnamic acid, benzyl acetone and $\gamma$-phenyl butyric acid whose $C_3$ or $C_4$ has an oxygen atom, produced phthalic anhydride in a yield of 20~30%. From these results, it is concluded that only when the oxidation was initiated at $C_3$ of *n*- propyl benzene or at $C_3$ or $C_4$ of *n*-buthyl benzene, phthalic anhydride was obtained. The waste gas of oxidation of *n*-propyl benzene had a strong odor of hydrocinnamic acid. *n*-Butyl benzene was passed with air through the catalyst bed which contained a very small quantity of vanadium pentoxide, and the presence of $\gamma$-phenyl butyric acid was confirmed by the ultraviolet spectrum of the product.



The mechanism given in *d·1* is different from the already published mechanism where only $C_1$ is oxidized in liquid phase or vapor phase oxidation.

*Mechanism d·2.*—On cyclization of hydrocinnamic acid and $\gamma$-phenyl butyric acid.

Hydrocinnamic acid produces hydrindone by cyclization in the presence of hydrogen fluoride[12], poly-phosphoric acid[13] or 80% phosphoric acid[14] catalyst, and tetralone is obtained from $\gamma$-phenyl butyric acid by the action of concentrated sulfuric acid[15]. However, it has not been reported that the cyclization takes place under conditions of vapor phase oxidation.

The author performed the experiment that a mixture of hydrocinnamic acid or $\gamma$-phenyl butyric acid vapor and air was passed through the bed of catalyst at 400°C which contained a very small quantity of vanadium pentoxide. Among the reaction products hydrindone and tetralone were identified as phenyl hydrazone and 2, 4-dinitrophenylhydrazone, respectively.

This indicates that cyclization took place. To ascertain this results, the reaction product was oxidized by aqueous solution of potassium permanganate, and phthalic acid was obtained.

*Mechanism d·3.*—On vapor phase oxidation of hydrindone and tetralone.

By catalytic air oxidation hydrindone and tetralone gave phthalic anhydride in yields of 77, 62% and maleic anhydride 11, 12%, respectively. From these results (*d·1*, *d·2* and *d·3*), the mechanism through

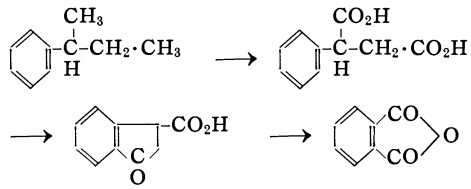
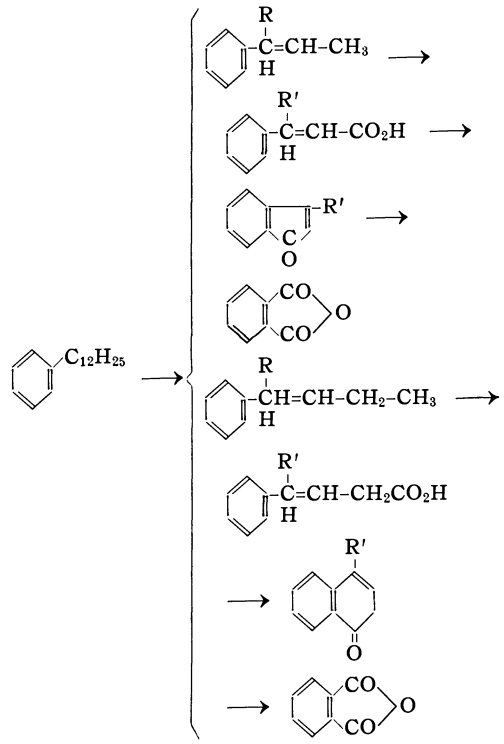
15) K. Krollpfeiffer et al., *Ber.*, **56**, 620 (1922).



which phthalic anhydride is obtained by the oxidation of *n*-propyl benzene and *n*-butyl benzenes, is as follows:

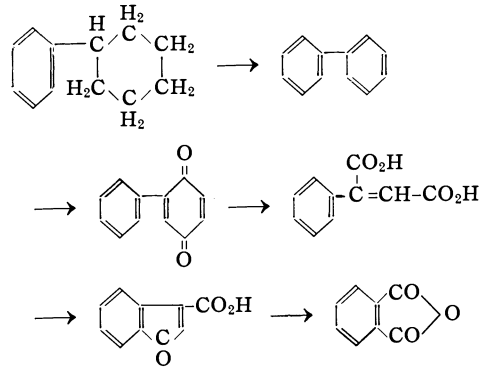
*n*-propyl benzene → hydrocinnamic acid → α-hydrindone → phthalic anhydride



*n*-butyl benzene → γ-phenyl butyric acid → tetralone → phthalic anhydride

*iso*-Propyl benzene and *tert*-butyl benzene gave no phthalic anhydride by the oxidation. They have only two carbon atoms in the longest chain of the alkyl group, and therefore cyclization will be impossible to occur.

The yield of phthalic anhydride from *sec*-butyl benzene was higher than that from *n*-propyl benzene. This will probably be due to the fact that cyclization of hydrocinnamic acid takes place more easily when it has a substituent group than when it has none[16].



**Vapor Phase Oxidation of Amyl Benzenes, Hexyl Benzenes and Dodecyl Benzenes and Others.**—The number of carbons in the longest chain of these alkyl groups is at least 3 or more. For the same reason, phthalic anhydride is obtained by the oxidation of these alkyl benzenes (Table II). The product that was obtained by passing dodecyl benzene through the pumice stone (carrier) zone at 400°C, was separated by distillation into three fractions, boiling at about 162, 182 and 230°C, respectively. These produced benzoic acid by oxidation with aqueous solution of potassium permanganate and were absorbed by 90% sulfuric acid and their ultraviolet spectra were characteristic. These were possibly alkenyl benzene (the number of carbons of the alkenyl group was 4—6). As the result it is apparent that such long-chain alkyl benzene as dodecyl benzene is decomposed by heat into short-chain alkenyl benzenes and then phthalic anhydride is produced by oxidation through the above mentioned mechanism.

Benzoic acid was not produced from *tert*-alkyl benzenes. This is possibly due to dissociation[17] into benzene nucleus and the alkyl group.

It is supposed that phenyl cyclohexane produced phthalic anhydride by oxidation through the following mechanism.

The author is particularly indebted to Professor S. Kimura of Kyoto University, Dr. T. Yoshida, Superintendent of Tobata Chemical Works and Mr. O. Hibino, Manager of the Laboratory Department of the Yawata Chemical Industry Co., Ltd.

# *Fluorine-19 Nuclear Magnetic Shielding in Some Monofluorinated Compounds*

By Kazuo Ito, Kan Inukai and Taro Isobe

(Received July 20, 1959)

The chemical shifts in the proton magnetic resonance spectra of aromatic compounds have been studied by several authors both experimentally[1,2] and theoretically[2-8]. The magnetically non-equivalent nature of protons in these compounds has been essentially interpreted in terms of the interaction between a proton magnetic moment and diamagnetic currents induced on aromatic rings by an external magnetic field. On the other hand, Isobe, Inukai and Ito[9] have shown that the fluorine atoms in fluorobenzene, 1- and 2-fluoronaphthalenes are also magnetically non-equivalent. They have concluded tentatively that the non-equivalent nature of the fluorine atoms can not be attributed to the induced diamagnetic ring current mentioned above but may be attributed to the variation in polarity of the C–F $\sigma$-bonds. As a criterion for predicting such a variation in polarity of C–F bonds, the $\pi$-electron density of McWeeny's sense[10] has been suggested. Recently, however, Fukui and his coworkers[11] have proposed the qualitative assumption that the larger the $\pi$-electron conjugation of a fluorine atom with a neighboring atom or group of atoms and consequently the smaller the $\pi$-electron density on the fluorine atom, the more the fluorine nucleus is magnetically shielded. The $^{19}$F chemical shifts in some aromatic fluoro compounds, including 1- and 2-fluoronaphthalenes, have been interpreted in terms of this assumption, although the variation in polarity of C–F $\sigma$-bonds has also been introduced in order to interpret the $^{19}$F chemical shifts in *p*-nitrofluorobenzene and 1-fluoro-4-nitronaphthalene for which the assumption predicts results contradictory to those of the experiments.

In the present paper the $^{19}$F NMR spectra of 2- and 3-fluoropyridines, 1-fluoropyrene[12] and cyclohexylfluoride are studied and the $^{19}$F chemical shifts in these compounds, together with those in fluorobenzene, 1- and 2-fluoronaphthalenes, are discussed. The spectra of 9-fluoroanthracene and 12-fluorochrysene[12] have also been studied but no signal has been obtained.

## Experimental

**Materials.**—The samples of 1-fluoropyrene and 12-fluorochrysene were kindly provided by Prof. G. M. Badger[13] of the University of Adelaide, South Australia, that of 9-fluoroanthracene by Dr. C. F. H. Allen[14], Eastman Kodak Co., Rochester, U. S. A. and that of cyclohexylfluoride by Dr. K. Okuhara of Government Industrial Research Institute, Nagoya, Japan, to whom the authors are much indebted. The samples of fluorobenzene[15], *m*-nitrofluorobenzene[16], 1- and 2-fluoronaphthalenes[15,17], 2- and 3-fluoropyridines[18] were prepared by the method of the Schiemann reaction. Since no NMR signal was found in 9-fluoroanthracene, the preparation of another sample of the compound was attempted by the general method of Garvey, Halley and Allen[14]. The reaction repeated under the conditions given was followed by some yellowing of the solution but no substance with the melting point specified for 9-fluoroanthracene was obtained.

**Apparatus and Procedure.**—The $^{19}$F NMR spectra were measured with a Varian V-4300-B High Resolution Spectrometer operating at a fixed frequency of 40 Mc./sec. and equipped with a Varian Field Stabilizer. The sample was dissolved in

about the same amount of another fluoro compound, *m*-nitrofluorobenzene in most cases, which provides an internal standard for determining the chemical shift $\delta$ of the sample defined as $\delta = 10^5 \times (H_c - H_r)/H_r$ where $H_c$ is the applied magnetic field for the $^{19}F$ resonance in the sample and $H_r$ is that for the reference. The chemical shift was determined by adjusting that of 1-fluoronaphthalene[9] to +1.32, refered to *m*-nitrofluorobenzene. The value of 1.32 was re-determined for the present work on the basis of the chemical shift of fluorobenzene[19] +0.33, agreeing with the previous one[9].

In the previous work[9], the $\delta$-values obtained from the solutions, 1-fluoronaphthalene+*m*-nitrofluorobenzene, 2-fluoronaphthalene+*m*-nitrofluorobenzene and 1-fluoronaphthalene + 2-fluoronaphthalene, were found to be consistent in themselves. In the present work, the results obtained from the solutions, 2-fluoropyridine+*m*-nitrofluorobenzene, 3-fluoropyridine+*m*-nitrofluorobenzene and 2-fluoropyridine+3-fluoropyridine were, also consistent in themselves. Therefore, the bulk effects[20] for the chemical shifts were assumed to be insignificant in the present experiments.

A 33 mol. per cent solution of 9-fluoroanthracene in *m*-nitrofluorobenzene heated for increasing the solubility gave no signal except that of the solvent which was not greatly deformed compared with that of pure *m*-nitrofluorobenzene. Also no signal was obtained on a solution of 12-fluorochrysene in *m*-nitrofluorobenzene because of its low solubility. Both samples will be examined further.

## Results and Discussion

It is known experimentally[21,22] that the magnetic shielding of an $^{19}F$ nucleus is quite sensitive to the nature of the bond between the fluorine atom in question and the atom to which the fluorine is bound. The simple and direct correlation[23] of $^{19}F$ magnetic shielding in para-substituted fluorobenzenes with the $\pi$-electron densities or Hamett's sigma constants for the para-position in the corresponding non-fluorinated compounds may also be attributed to the dependence of the shielding on the bonding nature of C–F bonds. On the other hand, Saika and Slichter[24] have shown theoretically that the $^{19}F$ magnetic shielding must have a close relation with the nature of the $\sigma$-bond by which the fluorine is bound to another atom. The qualitative extension of their theory suggests readily that a $\pi$-bond character in the bond by which the fluorine in question is bound to another atom would also have a significant effect on $^{19}F$ magnetic shielding. In order to discuss the present results, therefore, it would be necessary to take into account both $\sigma$- and $\pi$-bonding characters of C—F bonds. Since, however, correct estimations of $\sigma$- or $\pi$-bonding characters of C—F bonds in the compounds studied are very difficult, the following three molecular indexes which may serve as measures of $\sigma$- and $\pi$-bonding characters of C–F bonds are taken into account: (1) the $\pi$-electron density $q$ on the ring carbon to which the fluorine in question is bound, (2) the $\pi$-electron "atom charge" density of McWeeny's sense[10] $q'$ on the ring carbon mentioned above, and (3) the $\pi$-electron density $q$ on the carbon atom of a $CH_2^-$ group in a hypothetical molecule in which the fluorine atom of the fluoro compound studied is replaced by a $CH_2^-$ group.

The $\pi$-electron densities on ring carbons may serve as a criterion for predicting chemical differences in these carbons and, consequently, differences in the $\sigma$-bonding nature of C–F bonds. The $\pi$-electron "atom charge" densities may also be usable from the same point of view. The latter, however, may be especially useful in alternant hydrocarbons in which the former fails to interpret chemical differences in ring carbons, being equal to unity on all carbons on the basis of the simple LCAO calculation. It would be worth noting that the $\pi$-electron "atom charge" densities on the 1- and 2-positions of naphthalene show a tendency consistent with the experimental observation[25]. The $\pi$-electron density on the carbon atom of the $CH_2^-$ group in the hypothetical molecule mentioned above may serve as a measure of the $\pi$-conjugation of the fluorine atom substituted at the corresponding position. The smaller the $\pi$-electron density on the $CH^-_2$ group, the greater would be the $\pi$-conjugation of the fluorine atom with the remainder of the molecule.

The $^{19}F$ chemical shifts obtained in the present work are given in Table I, together with those of 1- and 2-fluoronaphthalenes. Three molecular indexes mentioned above are given in Tables II—IV, respectively. The parameters used in these tables for

These parameters would overestimate the electronegative effect of nitrogen (see Refs. 26 and 27), but were used here in order to show an extreme case.
d) Calculated by the method of H. C. Longuet-Higgins, *J. Chem. Phys.*, **18**, 265 (1950).

calculating the indexes of pyridine are their representative values[26,27]. The resonance integral of a C-N bond was assumed to be equal to that of a C-C bond, because small changes in resonance integrals have only negligible effects on the indexes in the tables. The values given in the second and the seventh columns of Table IV were calculated by the use of the mutual atom polarizabilities in a benzyl anion which are shown in Table V.

**Fluorobenzene, 1- and 2-Fluoronaphthalenes, 1-Fluoropyrene and 3-Fluoropyridine.** — The sequence of $\delta$-values for these compounds is, as shown in Table I, fluorobenzene < 2-fluoronaphthalene < 1-fluoropyrene, 1-fluoronaphthalene < 3-fluoropyridine. As seen from Table II, the $\pi$-electron density on the ring carbon to which the fluorine atom is bound fails to explain the

TABLE V. MUTUAL ATOM POLARIZABILITIES IN A BENZYL ANION

| $r-s$[a] | $\pi_{r,s}\times\beta$ |
|---|---|
| 1—1′ | −0.1324 |
| 2—1′ | −0.0716 |
| 3—1′ | −0.0099 |
| 4—1′ | −0.1162 |
| 1′—1′ | 0.4116 |

a) 1′ denotes a $CH_2^-$ group, 1 the carbon atom bonded to the $CH_2^-$ group and 2, 3 and 4 denote the $\alpha$, $\beta$ and $\gamma$ carbon atoms, respectively.

sequence of $\delta$, because the densities in benzene, naphthalene and pyrene are all equal to unity. The $\pi$-conjugation of fluorine atoms, the rough measure of which is seen from Table IV, fails also to interpret the sequence of $\delta$. As far as one restricts the attention only to fluorobenzene, 1- and 2-fluoronaphthalenes, one may find a possible interpretation in terms of the assumption[11] that the greater the $\pi$-electron conjugation of a fluorine atom with a neighboring atom or group of atoms, the greater the value of $\delta$. However, this assumption fails also definitely to interpret the sequence of $\delta$ if one takes into account 1-fluoropyrene and 3-fluoropyridine. On the other hand, the sequence of the $\pi$-electon "atom charge" density (Table III), benzene<2-position of naphthalene < 1-position of naphthalene < 1-position of pyrene < 3-position of pyridine, shows a fairly good parallel tendency with the sequence of $\delta$ mentioned above. Although the parallelism between two sequences is not very good in pyrene, the $\pi$-electron "atom charge" density may be rather satisfactory for interpreting the sequence of $\delta$ compared with other indexes, in the sense that the "atom charge" densities of the 1-position of pyrene and the 1-position of naphthalene are fairly close to each other and that the "atom charge" density of the 3-position of pyridine can be larger than that of the 1-position of naphthalene within the reasonable limits[26,27] of parameters $\delta_N$ and $\delta_{C'}$ (see Table III and footnote e) of Table II). Since the greater the value of $q'$, the more ionic would be the C–F $\sigma$-bond, the increasing tendency of $\delta$ with $q'$ is reasonable[24].

**2-Fluoropyridine.**—This compound has the smallest $\delta$-value. This tendency can be interpreted in terms of any index given in Tables II—IV. However, the $\pi$-electon density would be rather worthless for this case too, because this index is very poor for interpreting the sequence of $\delta$-values as discussed above. The effect of the $\pi$-conjugation of the fluorine atom substituted at the 2-position of pyridine is of interest from the point of view that the $^{35}Cl$ pure quadrupole resonance of 2-chloropyridine[28] has been explained, emphasizing the larger $\pi$-bonding character in the C-halogen bond at the 2-position compared with the $\pi$-bonding characters in those at other positions. The $\pi$-conjugation of the fluorine atom, however, may not be the main cause of the small $\delta$-value of 2-fluoropyridine. Because, if it is so, the $\delta$-value of 1-fluoronaphthalene must also very small contrary to the experiments. Therefore, the $\pi$-electron "atom charge" density and the inductive effect of nitrogen, which has the significant effect on proton NMR spectra of nitrogen heterocycles[29-31], would be responsible for the $^{19}F$ magnetic shielding of 2-fluoropyridine.

**Cyclohexylfluoride.**—This compound has a very great $\delta$-value compared with that of benzene. It is obvious that this difference in $\delta$ is too great to be interpreted in terms of the diamagnetic ring current induced on benzene[2,3]. The assumption of Fukui et al. on the correlation of $\delta$ with the $\pi$-conjugation of the fluorine atom fails also to interpret the $\delta$-value of this compound which is greater than that of fluorobenzene. A possible explanation is that the C–F bond in cyclohexylfluoride is more ionic than that in fluorobenzene. Such an explanation may be rather probable, since it is known that[32] the nature of the $\sigma$-bonding in a C($sp^3$)-Cl bond is more ionic than that in a C($sp^2$)-Cl bond and that[32,33] the ring hydrogens of benzene are more protonic than the hydrogens of C($sp^3$)-H bonds.

In the arguments given above, it has been shown that the $^{19}F$ magnetic shielding of the compounds studied in the present work is correlated most probably with the $\pi$-electron "atom charge" density. Hereupon, it would be worth while to note

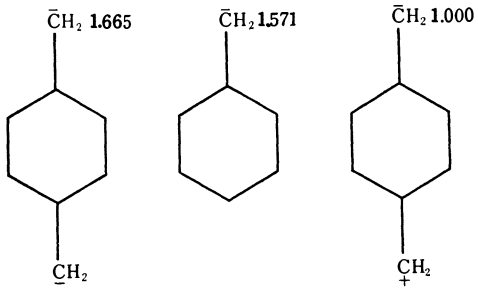

Fig. 2. $\pi$-electron densities in some carbions

that the $^{19}F$ magnetic shielding in substituted fluorobenzenes[23], which has been correlated simply with the $\pi$-electron density $q$, may also be correlated with the $\pi$-electron "atom charge" density $q'$, because $q$ and $q'$ have the parallel tendency as shown in Fig. 1. On the other hand, Fig. 2 predicts that the $\pi$-conjugation of a fluorine atom, which is represented by $CH_2^-$ in the figure, may be reduced by the para-substitution of $-E$ substituents (halogens, OH, $NH_2$, etc.) and is increased by that of $+E$ substituents ($NO_2$, CN, etc.). These predictions suggest that the assumption[11] of Fukui et al. may lead to the contradictory results with the experiments. The pure nuclear quadrupole resonance experiments on para-substituted chlorobenzenes[34] and iodobenzenes[35] have shown that the $\sigma$-bond character of a C–halogen bond is made more ionic by the para-substitution of $-E$ substitution and less ionic by that of $+E$ substituents, whereas the double-bond character of the C–halogen bonds is reduced by the para-substitution of $-E$ substituents and is increased by that of $+E$ substituents. These results support the interpretation of $^{19}F$ magnetic shielding in para-substituted fluorobenzenes in terms of $q'$ or ionicity in C–F bonds, but do not support the interpretation of the same subject in terms of the assumption of Fukui et al. It would also be worth noting that the relative magnetic shielding of $CF_4$ and $CF_3Cl$, which has been one of the important experimental evidences for supporting the assumption of Fukui et al., is not necessarily interpreted merely by their assumption, but is also interpreted by the variation in polarity in C–F bonds as argued in the original paper[36].

**Summary**

The $^{19}F$ NMR spectra of 2- and 3-fluoropyridines, 1-fluoropyrene, cyclohexylfluoride, 9-fluoroanthracene and 12-fluorochrysene were studied. No signal was obtained for the latter two compounds. The magnetic shielding constants obtained were attempted, together with those for fluorobenzene, 1- and 2-fluoronaphthalenes, to be correlated with some molecular indexes. It was found that the $\pi$-electron density in McWeeny's sense ($\pi$-electron "atom charge" density) on the ring carbon atom, to which the fluorine in question is bound, is must probably correlated with the magnetic shielding of the fluorine nucleus. This result suggests that the variation in $^{19}F$ magnetic shielding constants in these compounds may be attributed mainly to the variation in polarity in C–F $\sigma$-bonds. It was noted that such an idea is supported by nuclear quadrupole resonance experiments.

# *Neutron Activation Analysis of Iodine in Silicon*

By Tadashi NOZAKI, Hideo BABA and Hidemaro ARAKI

(Received June 27, 1959)

The determination of trace impurities in silicon is of great importance in the research and industry of the semiconductor material. The neutron activation analysis has played an important role in this field, being used for many kinds of impurity and even in routine work[1]. Among the numerous reports, however, none, as far as listed in the "*Analytical Abstracts* (Society for Analyt. Chem. England)" up to Vol. 6 No. 3 (March, 1959) has dealt with halogens in silicon, though the semiconductor material has been purified through one of its halogen compounds. The present authors determined iodine in silicon purified by the iodide or the chloride method.

Natural iodine consists entirely of $^{127}I$, which is activated by thermal neutrons into $^{128}I$ [$\sigma=6$ barn, $T_{1/2}=25$ min., $\beta$ 2.12 (76%), etc., $\gamma$ 0.45 (17%) etc.]. When more than a few p.p.m. of iodine is present with outany other appreciable amount of impurity that emits $\gamma$-rays or positrons, the $\gamma$-ray spectrometry with a multichannel pulse-height analyzer provides an easy method for quantitative analysis[2]. But when the iodine content is lower, chemical separation becomes necessary, because the photo-peak of $^{128}I$ is masked by the "Bremsung" of $\beta$-rays from $^{31}Si$ ($T_{1/2}=2.62$ hr., $E_{max}=1.48$ MeV.).

The separation method must be checked carefully, because iodine has many oxidation states, which involve complicated behavior of isotopic exchange, and because, molecular iodine as well as hydrogen iodide is volatile. The treatment of silicon with a mixture of hydrofluoric and nitric acid, a suitable process for many cases, cannot be used here. On the other hand, there is an advantageous rule that any kind of iodine oxide, at least in an ordinary concentration, reacts instantaneously and stoichiometrically with an excess of iodide in an acid solution to give molecular iodine. Fusion of the silicon with potassium hydroxide containing potassium iodide as the carrier, followed by treatment with sulfuric acid, and oxidation with sodium nitrite to molecular iodine, provides a method of chemical separation, the last being distilled and converted into silver iodide. Its usefulness was checked by the use of $^{131}I$ produced carrier free in silicon by the neutron irradiation of tellurium diffused in the silicon.

## Experimental

**Sample.**—About 1 g. portion of metallic silicon, prepared by the thermal decomposition of silicon tetraiodide or by the reduction of silicon tetrachloride with zinc was used for each analysis. Details concerning each of the samples are described later.

**Irradiation.**—The sample and reference standard were put side by side in a poly ethylene capsule and irradiated in JRR-1 (Japan Research Reactor 1) under a thermal neutron flux of about $6\times10^{11}$n/cm$^2$·sec. The activity of $^{128}I$ reaches about 80% of its saturation by one hour irradiation.

**Self-shielding Effect.**—Thermal neutrons for which the absorption cross section of natural silicon is only $0.13\pm0.03$ barns, traverse one centimeter in this material, thereby decreasing the flux by only less than 1%. Thus with an ordinary quantity of the sample, the self-shielding effect can legitimately be neglected.

**Chemical Separation of Iodine.**—The irradiated silicon was immediately powdered in a special mortar made of iron. A weighed amount (about 0.8 g.) of the silicon powder was slowly added to potassium hydroxide (about 10 g.) which is maintained just above its melting point, and contained a known quantity (several milligrams) of potassium iodide as the carrier. When the vigorous reaction with the evolution of hydrogen became feeble, the mixture was carefully heated to complete the reaction rapidly. The fused matter was treated with 100 ml. of 5 N sulfuric acid containing a few milligram of sodium chloride and potassium bromide as a hold-back carrier. A solution of sodium nitrite was added to the product, and the liberated iodine distilled into a dilute solution of sodium sulfite. This distillate was treated again with sulfuric acid and sodium nitrite, and the molecular iodine was extracted with xylene, washed with dilute sul-

2) T. Ichimiya et al., *Radioisotopes* (Jap. R. I. Association), 7, 281 (1958).
3) For example, A. C. Wahl, "Radioactivity Applied to Chemistry", John Wiley & Sons, Inc., New York (1951), p. 32.

furic acid and water, and extracted back into an aqueous solution containing a small excess of sodium sulfite, from which silver iodide was precipitated by the addition of acetic acid, silver nitrate and nitric acid. The precipitate was filtered off through a glass filter (No. 3), washed with a very dilute nitric acid, water, ethanol and ether. The entire process required an hour, or, properly operated, slightly less, with a chemical yield of 50 to 70%.

**Radioactivation Standard.**—A weighed crop of potassium iodide in a polyethylene envelope was irradiated together with the silicon, and dissolved into a solution containing a known amount of inactive potassium iodide. A part of this solution was oxidized as above, and the molecular iodine extracted with xylene, washed with an aqueous potassium hydrogen sulfate and water, and similarly converted into silver iodide.

**Counting.**—A simple G-M counter with an end window tube served very conveniently, when the iodine content was more than 0.01 $\mu$g., while a $2\pi$ counter of gas flow type was used for less iodine. By the use of the latter, whose counting efficiency is several times higher than the former, 3/4 or more of the total disintegration could be detected by virtue of the back-scattering of the $\beta$-rays, when the sample was placed on such a heavy metal plate as tin, with negligible loss due to self-absorption. The activity was measured at short time intervals for about 150 min.

**Check on the Chemical Process.**—The chemical process was checked by the use of silicon containing $^{131}$I, which was prepared by the irradiation of silicon doped with tellurium. The following reactions take place,

$$^{130}\mathrm{Te}\ (n,\gamma)\ ^{131}\mathrm{Te} \xrightarrow[25\ \mathrm{min.}]{\beta^-,\gamma} {}^{131}\mathrm{I} \xrightarrow[8.06\ \mathrm{d.}]{\beta^-,\gamma} {}^{131}\mathrm{Xe}\ (\mathrm{stable})$$

or,

$$^{130}\mathrm{Te}\ (n,\gamma)\ ^{131\mathrm{m}}\mathrm{Te} \xrightarrow[30\ \mathrm{hr.}]{} {}^{131}\mathrm{Te} \longrightarrow {}^{131}\mathrm{I} \longrightarrow {}^{131}\mathrm{Xe}.$$

$^{131}$I emits various $\gamma$-rays, among which that of 0.364 MeV. is predominant, and with the irradiated tellurium the area covered by this photo-peak in the $\gamma$-ray spectrum decayed with the half-life of $^{131}$I, while other peaks of lower energies due to other radioactive nuclides of tellurium (mostly of metastable state) survived longer. It would be reasonable to assume that the two radioisotopes, $^{128}$I and $^{131}$I, formed in the silicon, pass the so-called hot atom state and behave similarly throughout the chemical process.

Very pure silicon and a small quantity of metallic tellurium in an evacuated silica ampoule were heated over 1000°C for many hours, to cause the latter to diffuse into the former. The ampoule was kept in the reactor for a week. After several days, the silicon was washed with aqua regia and slightly etched with a mixture of hydrofluoric and nitric acids to remove surface contamination. The activity in the silicon was counted with a scintillation counter with a well-type crystal and a single channel analyzer (the region between 0.32 and 0.41 MeV.). The silicon without tellurium contained but negligible activity. After the same chemical process described above, the activity of $^{131}$I in the silver iodide was measured under the same condition. The chemical yield being taken into account, the separation method was proved satisfactory within a standard error due to counting, which amounted to 3% in this case.

## Results

The results are shown in the table, where I in the column of sample denotes that the silicons were purified by the iodide process, and Cl by the chloride process. The iodide process has been carried out in the Electrical Communication Laboratory in order to obtain semiconductor grade silicon. This method consists of converting a raw silicon into silicon tetraiodide, of purifying the iodide by various techniques, and of thermal decomposition of the iodide with continuous evacuation. The samples I-1 were silicons just after this stage. I-2 was obtained by keeping molten I-1 containing 4.5 p. p. m. of iodine in a silica vessel for an hour under an argon gas flow. I-3 were taken out of the tail of a single crystal made by the cooling method from I-1 containing 1.3 p. p. m. of iodine. The tail end of the crystal contained much more iodine (2.0 p. p. m.) than a part several millimeters above it (0.32 p. p. m.). These silicons were usually of type N. Floating zone refining has also been applied to obtain a material of higher quality. The samples denoted by Cl were silicons of transistor grade prepared by the chloride process in a certain foreign country, and this silicon is now widely used as the transistor material.

| Sample | Number of different samples assayed | Iodine content (p. p. m.) |
|---|---|---|
| I-1 | 3 | 1.3, 4.5, 4.5 |
| I-2 | 1 | 0.35 |
| I-3 | 2 | 2.0, 0.32 |
| Cl | 2 | 0.005, 0.05 |

## Discussion

After the chemical process, the decay curve of the silver iodide is usually straight on a semilog plot in accordance with the theoretical half-life. However, when the iodine content is lower than 0.01 $\mu$g. and the distillation is carried out carelessly, the separated silver iodide is contaminated with radioactive silica. Without the distillation, the precipitate

of silver iodide is by no means free from silica (about 10 $\mu$g. of silicon); without the extraction, about 1 $\mu$g. of silicon enters the precipitate.

When 0.002 $\mu$g. of iodine is present in silicon, it gives an activity of about 100 cpm to the $2\pi$ counter after the chemical treatments, and is enough for quantitative analysis and the measurement of the decay curve. If a reactor with a higher neutron flux were available, less iodine could be determined; however, the problem of decontamination from radioactive silicon would become more important. In such a case, repetition of the distillation would be necessary.

Determination of segregation constant of iodine and analysis of chlorine and bromine, with a slight modification of the method, in silicon are now under planning.

**Summary**

A trace quantity of iodine in silicon was determined by the neutron activation analysis. A chemical separation process, which involves potassium hydroxide fusion with potassium iodide as a carrier, was proved satisfactory by the use of $^{131}I$ produced by the neutron irradiation of tellurium diffused in silicon. By this method, the iodine was converted into silver iodide ready for counting and weighing within an hour, with a yield exceeding 50%. When it is assumed that a counting rate of 100 cpm is enough for accurate detection of activities, the limit of detection is 0.002 $\mu$g. of iodine with a neutron flux of $6\times10^{11}$ n/cm$^2$ sec. and by the use of a $2\pi$ counter.

# *Viscometric Study on Polystyrenesulfonic Acid Solutions*

By Masaaki KATO, Tsurutaro NAKAGAWA and Hideo AKAMATU

(Received August 17, 1959)

Among the physico-chemical properties of polyelectrolytes their flow property makes an important field of study from the viewpoint of polymer science and of electrolyte theory, and many theoretical and experimental investigations on viscosity behavior of various polyelectrolyte solutions have since been reported. Of these, however, comparatively few works have been done on polyelectrolytes of the sulfonic acid type.

It seems, therefore, to be interesting to compare the authors' viscosity data on the polystyrenesulfonic acid, which itself is a strong polymeric acid, with other workers' experimental and theoretical results previously reported, chiefly on sodium salts of polycarboxylic acids or polyquaternary halides.

This paper presents a viscometric study on polystyrenesulfonic acid in various solvents: water, water-dioxane mixed solvent, and aqueous solutions of sodium chloride and some other inorganic salts.

## Part I. Viscosity Behavior of PSA Solution

### Experimental

**Samples.**—For the preparation of polystyrenesulfonic acid, polystyrene pellets manufactured by the American Bakelite Company were used. Its viscosity-average molecular weight is about 180,000 from the viscosity measurement in benzene solution at 25°C.

The main feature of the sulfonation procedure is analogous to that of Neihof[1].

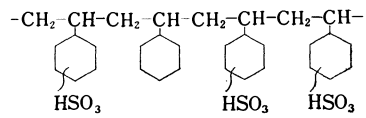
In a 500 cc. conical flask 10 g. of polystyrene pellets and 0.2 g. of silver sulfate as catalyst were taken. To this was added 200 cc. of concentrated sulfuric acid, and the flask was completely corked to exclude moisture and was immersed in a constant temperature bath at 100°C with frequent stirring for 20 hr. By this treatment, polystyrene is completely dissolved in concentrated sulfuric

1) R. Neihof, *J. Phys. Chem.*, 58, 916 (1954).

acid and the content of the flask becomes brown in color and very viscous. The reaction product (i. e. mixture of polystyrenesulfonic acid, sulfuric acid and silver sulfate) is poured into cold distilled water. Then polystyrene sulfonic acid precipitates in the form of a white gummy mass, which is quickly washed with water several times until heat emergence is no longer felt. The precipitate of polystyrenesulfonic acid was then completely dissolved into 500 cc. of distilled water. The large excess of sulfuric acid present could be removed by prolonged dialysis of the aqueous solution using a cellophane membrane. The last trace of remaining sulfuric acid was removed by successive electrodialysis. The presence of sulfuric acid was detected by adding barium chloride solution to the dialyzed polystyrenesulfonic acid solution[2]; a white precipitate which does not dissolve on heating indicates the presence of sulfuric acid. Barium salt of polystyrenesulfonic acid appears also as white precipitate, but it dissolves away on heating. This test was negative after the electrodialysis for three days.

Another sample of polystyrenesulfonic acid was obtained by making the above-mentioned mixture (polystyrene, silver sulfate and conc. sulfuric acid) react in the dark and at the room temperature with frequent stirring for long days, and the following procedure was the same as above-described. The authors will hereafter refer to this as PSA-R and the sample prepared at 100°C as PSA-100.

Determination of the concentration was carried out by completely evaporating the weighed solution to dryness on a steam bath and then drying in an air oven at 110°C until the constant weight was reached.



The degree of sulfonation was determined by the back titration of the PSA solution, to which excess alkali was added, with hydrochloric acid using methyl red as an indicator. The results are:

91% for PSA-100
85% for PSA-R

where 100% is assumed for PSA having one sulfonic acid group on each benzene ring.

A solid sample of the polystyrenesulfonic acid was obtained by freeze-drying of the solution as a white cotton-like material. But throughout the present measurement, PSA as the state of aqueous solution was used.

The polystyrenesulfonic acid, thus prepared, is considered to have the structure shown below.

The degree of sulfonation depends, as was mentioned above, upon the condition of sulfonation.

**Viscometers.**—All our viscosity measurements were carried out at 30°C by using four viscometers of Ostwald type. Their flow time for water (ca. 2 cc.) is about 147, 153, 193 and 254 sec., respectively.

**Effect of Rate of Shear.** — Recently many investigators[3-6] have pointed out the pronounced shear dependence of the observed viscosity of linear chain polyelectrolyte solutions at low ionic strength. But, according to the results of our viscosity measurement with a horizontal capillary viscometer in the range of 80~1400/sec. of velocity gradient, our PSA sample exhibited

only a very slight shear rate effect even in the absence of added electrolytes.

Fig. 1 shows an example* of the shear rate effect. Table I is another example** of viscosity measurement by varying the rate of shear. Here the influence of shear rate is not observed. ($\eta_r$ is relative viscosity, and $q$ is rate of shear.)

It may therefore be accepted that the following data are free from shear-rate dependence to the first approximation. The kinetic energy correction was negligible in all cases studied.

## Results and Discussion

**In Aqueous Solution.**—The viscosity data obtained for the aqueous solutions are shown in Fig. 2, where reduced viscosity

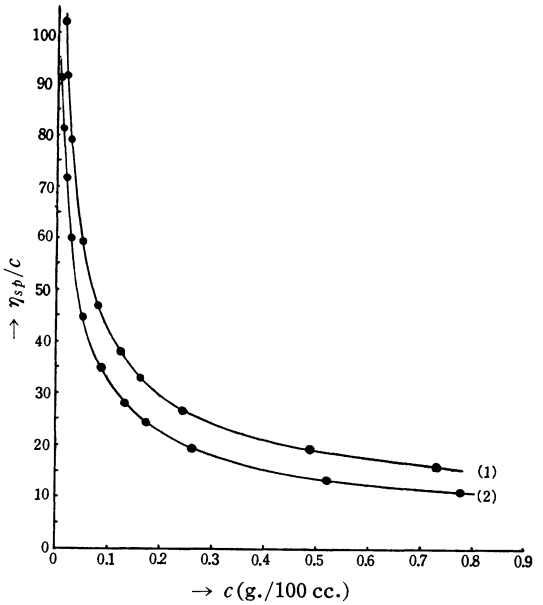

Fig. 2. Reduced viscosity vs. concentration curves.
curve (1) for PSA-100
〃 (2) for PSA-R

$\eta_{sp}/c$ is plotted against concentration $c$ (g./100 cc.). It is noticed that the PSA aqueous solutions have abnormally large $\eta_{sp}/c$ value compared with ordinary non-polar polymer solutions in which $\eta_{sp}/c$ is 2 or 3 at most. $\eta_{sp}/c-c$ plot exhibits a curve strongly concave upward, which is characteristic of polyelectrolyte solutions. In the experimental curves the tendency of decreasing in the low concentration range was not observed.

Considering that the reduced viscosity is a measure of the extention of a polymer coil in solution, the curves show that the size of a polymer becomes larger upon dilution. This phenomenon is generally explained as follows. As the concentration of PSA decreases, the negative net charge on a polyanion increases as a result of increasing dissociation of sulfonic acid groups, and so polymer chains extend more and more, due to the enhanced intramolecular repulsive force between like charges.

The relation between reduced viscosity and concentration of PSA is satisfactorily described by the formula

$$\frac{\eta_{sp}}{c}=\frac{A}{1+B\sqrt{c}} \qquad (1)$$

proposed by Fuoss[7,8]. Here, $A$ and $B$ are empirical constants. $A$ has a meaning of intrinsic viscosity $[\eta]$, and $B$ is a constant dependent on inter-ionic forces. The agreement of the experimental data with Eq. 1 is shown in Fig. 3. The value $A$ is 400 for both PSA samples. The value $B$ is

28 for PSA-100 and
41 for PSA-R

That the two PSA samples of different degrees of sulfonation have the same $A$ value (400) is understandable by recalling that both PSA samples were prepared from the same polystyrene as a starting material and by assuming that no chain scission or cross-link formation through a

sulfone bridge during the course of sulfonation reaction occurred.

**Water-Dioxane Mixed Solvent.** — Viscosity data of PSA-R for water-dioxane mixed solvent of various mixing ratio are shown in Fig. 4.

$\eta_{sp}/c$ vs. $c$ relation in all the solvents studied is well described by Fuoss' Eq. 1 (cf. Fig. 5). The values $A$ and $B$ obtained are summarized in Table II together with the dielectric constant $\varepsilon$ of the solvents. Values of $\varepsilon$ of the mixed solvents are those borrowed from the published data on the $\varepsilon$-mixing ratio relationship by G. Åkerlöf and O. A. Short[9].

From Fig. 4 it is seen that the reduced

viscosity decreases with the decrease of dielectric constant of solvent. This may be explained as follows. The dissociation $-SO_3H \rightarrow -SO_3^- + H^+$ is diminished as $\varepsilon$ decreases, and consequently the negative net charge on a polyanion decreases, so that the polymer coil becomes more contracted in a low $\varepsilon$ solvent than in a solvent of high $\varepsilon$. As the dioxane content in water increases, the Coulombic repulsive force between charged groups becomes stronger due to the decrease of dielectric constant of the medium. This effect to expand a polymer coil, however, may be less dominant than the effect of diminished dissociation of the sulfonic acid group.

Furthermore $B$ vs. $1/\varepsilon^2$ plot is approximated by linear relation (cf. Fig. 6).

The parameter $A$ has the same value 400 in any solvent. This may indicate that PSA molecule has the same size at infinite dilution in any solvent studied here.

solutions of PSA-100 in various concentration of aqueous sodium chloride in the range of 0.000126 to 2.00 N. Reduced viscosity is strongly affected by the presence of sodium chloride and diminished as the sodium chloride content in solution increases. When the sodium chloride concentration is small, the curves exhibit a maximum, which vanishes, however, with the increasing content of sodium chloride and the curves approach those for ordinary non-polar polymers. These behaviors of PSA are characteristic of many other polyelectrolytes. The qualitative explanation was given above. (See, for example, references 10 and 11).

Sodium chloride normality $x$ and PSA normality $c_m$ at the maximum of reduced viscosity are shown in Table III. PSA normality is greater by $10^1$ than sodium chloride normality.

Values of intrinsic viscosity and sodium chloride concentration $x$ (mol./l.) in solution are summarized in Table IV.

$[\eta]$ values for low sodium chloride concentration are unreliable due to difficulty in extrapolating to zero concentration.

The relation between $[\eta]$ and $x$ can be approximately described by the formula

$$[\eta]^{1/3} = a + \frac{b}{\sqrt{x}}$$

presented by Fuoss and Strauss[10] in the range of comparatively high sodium chloride concentration (Fig. 9).

In the Hermans-Overbeek theory[12] the polyion is considered as a sphere in which the separate charges are replaced by a continuous charge distribution, and the small ions are assumed to be governed by the Poisson-Boltzmann equation. Applying the result of the theory to the case in which the polymer coil is free-draining and the added salt concentration is not so low, it is concluded that $[\eta]$ vs. $1/\sqrt{x}$ relation is linear[11]. For the PSA sample a linear relation between $[\eta]$ and $1/\sqrt{x}$ is obtained in the range of concentration above ca. 0.006 N (Fig. 10).

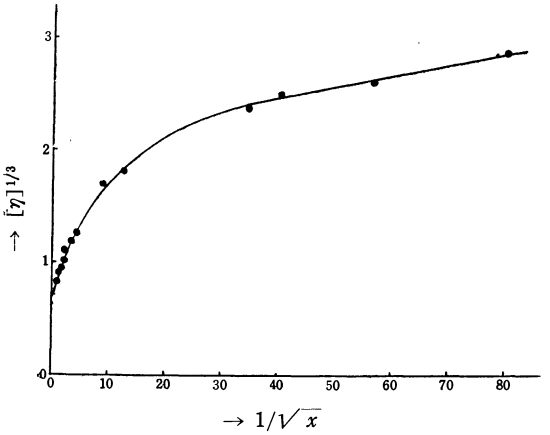

Fig. 9. Effect of salt concentration on the intrinsic viscosity (1).

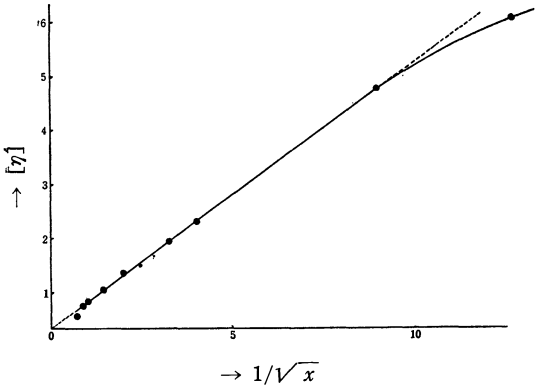

Fig. 10. Effect of salt concentration on the intrinsic viscosity (2).

**In Sodium Bromide and Sodium Sulfate Aqueous Solution.**—In sodium bromide and sodium sulfate aqueous solution the viscosity behavior of PSA-100 is nearly the same as in sodium chloride aqueous solution.

The effect of viscosity depression, i. e. the effect for inducing the contraction of polymer coil is strong in the order NaCl $>$ NaBr $\approx$ $Na_2SO_4$, although the difference is very slight (Table V). No distinct lyotropic effect is observed here.

## Part II. Viscosity Equation for PSA

As was stated in the previous part, PSA behaves like ordinary non-polar polymers in its viscosity character when the concentration of the added salt in the solution is high; here $\eta_{sp}/c$ vs. $c$ relation becomes linear. Hence in this circumstance it is possible to obtain Sakurada-Houwink's viscosity equation for PSA.

In this part it is aimed to prepare various PSA samples of the same charge density and different degrees of polymerization and to obtain the viscosity equation which holds between their degree of polymerization and their intrinsic viscosity in 0.52 N hydrochloric acid and 0.5 N sodium chloride aqueous solution.

For the preparation of PSA samples,

12) J. J. Hermans and J. Th. G. Overbeek, ibid., **67**, 761 (1948).

TABLE VI

| PSA | [η] of PS before sulfonation in benzene soln. at 25°C | P | [η] of PSA in 0.5 N NaCl | [η] of PSA in 0.52 N HCl |
|---|---|---|---|---|
| From Fract. 2 | 1.025 | 2534 | 1.41 | 1.64 |
| 〃 〃 4 | 0.672 | 1421 | 0.84 | 0.89 |
| 〃 〃 5 | 0.544 | 1063 | 0.61 | 0.67 |

polystyrene (average molecular weight= 180,000; American Bakelite Company) was fractionated into several fractions and these were sulfonated under the same condition as was described above.

As the authors have some evidence from the previous experiments (Part I) that neither chain scission nor sulfone bridge formation occurs during the course of sulfonation, the degree of polymerization of the fractionated polystyrenes before and after sulfonation was assumed to be unchanged. The degree of polymerization of the fractionated polystyrenes was determined from the viscosity measurement in benzene solution at 25°C.

## Experimental Results

**Fractionation of Polystyrene.**—30 g. of polystyrene pellets was dissolved into 1.2 l. of methyl ethyl ketone in a 2 l. flask and the solution was filtered with a No. 4 glass filter. At room temperature, methanol was slowly added to the solution with stirring until the solution became turbid and then an additional 6 cc. of methanol was added. The flask was set in a thermostat and the bath temperature was raised up until the solution became clear. Then the bath was gradually cooled to the room temperature with stirring. At the room temperature the mixture was allowed to come to equilibrium, and the precipitate was separated by decantation and then an additional 11 cc. of methanol was added to the solution. This process was repeated six times. The amount of methanol used in each precipitation process was 6, 11, 16, 26, 40 and 150 cc., respectively. Each fraction was redissolved into toluene and reprecipitated by a great excess of methanol and finally dried up to a constant weight in vacuo at 50°C.

**Sulfonation.** — Silver sulfate and concentrated sulfuric acid were added to each fraction in the proportion polystyrene : $Ag_2SO_4$ : conc. $H_2SO_4$=10 : 0.2 : 110 by weight. Each mixture was put into a conical flask, which was compactly sealed to prevent the entrance of moisture. The flask was set in a thermostat at 50°C. The following procedure was the same as described in Part I.

It was expected that PSA's, of the same degree of sulfonation would be obtained, but this was unsuccessful. This may be ascribed to the fact that the texture or structure of the precipitated mass is different for each fraction. (There was no regularity between their reactivity and their molecular weight.) Only the PSA's prepared from Fractions No. 2, 4 and 5 had about the same degree of sulfonation, 85%, so that these PSA's were used for viscosity measurement. The viscosity data obtained are shown in Table VI and Fig. 11.

**Viscosity Equation.**—Molecular weight $M$ of the fractionated polystyrene (before sulfonation) was determined by the viscosity formula by C. Bawn et al.[13]

$$[\eta] = 1.13 \times 10^{-4} \cdot M^{0.73}$$

(in benzene at 25°C, $c$ in g./100 ml.)

which seems to be most reliable.

The relation between $\log[\eta]$ and $\log P$ of PSA is well approximated by a straight line and we obtained the following viscosity equations (cf. Fig. 11).

$$[\eta] = 6.35 \times 10^{-4} \cdot P \quad \text{(in 0.52 N HCl aq.)} \qquad (2)$$

$$[\eta] = 5.75 \times 10^{-4} \cdot P \quad \text{(in 0.50 N NaCl aq.)} \qquad (3)$$

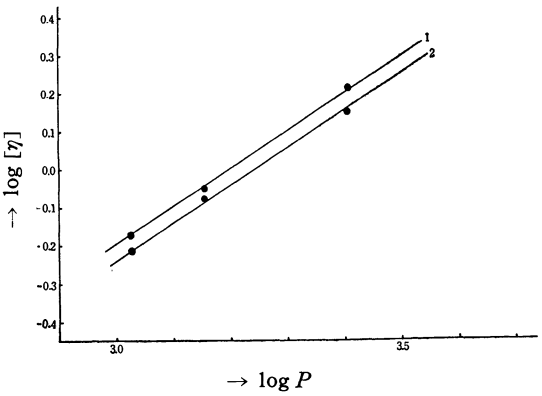

Fig. 11. Intrinsic viscosity vs. polymerization degree relation in salt solution.
1) in 0.52 N HCl
2) in 0.50 N NaCl

13) C. Bawn, R. Freeman and A. Kamaladin, *Trans. Faraday Soc.*, **46**, 1107 (1950).

Here $P$ is the degree of polymerization of PSA. Eq. 2 is for 0.52 N HCl aqueous solution, and Eq. 3 for 0.50 N NaCl aqueous solution.

It is noticeable that $[\eta]$ is directly proportional to the first power of the degree of polymerization.

Calculating the degree of polymerization by Eq. 2 from the viscosity data obtained by Mock and Marshall[14] for vinyltoluene-styrene copolymer sulfonic acid ($P=2036$ by osmotic measurement in methyl ethyl ketone; $[\eta]=1.58$ in 0.54 N HCl at 25°C), $P=2490$ is obtained.

If the authors calculate the degree of polymerization of PSA-R used in the present study ($P=1730$ by viscosity measurement in benzene solution at 25°C before sulfonation; $[\eta]=1.07$ at 25°C in 0.5 N NaCl aq. soln.; degree of sulfonation=85%) by Eq. 3, $P=1860$ is obtained.

Hence Eq. 2 or 3 may be used for calculating roughly the degree of polymerization of highly sulfonated polystyrene-sulfonic acid from its intrinsic viscosity in 0.5 N HCl or 0.5 N NaCl aqueous solution.

The cost of this research has been partly defrayed from the Scientific Research Encouragement Grant from the Ministry of Education, to which the authors' thanks are due.

# *Rapid Colorimetric Determination of Mercury by Tin(II)-Strong Phosphoric Acid Reduction Method*

By Toshiyasu KIBA, Ikuko AKAZA and Osamu KINOSHITA

(Received August 28, 1959)

Tin(II)-strong phosphoric acid, a new powerful decomposing and reducing agent first described by the present authors[1], has been widely employed in this country for the determination of sulfur in various materials; e. g. sulfates[2], sulfide ores[3], iron and steel[4], organic compounds[5], rayon staple fiber, acetylcellulose[6] and proteins[7]. The reagent has also been applied for rapid determination of selenium in various forms. The selenium is reduced by the reagent into gaseous hydrogen selenide, which is absorbed in an alkaline solution, and then the amount is determined colorimetrically[8].

A further attempt was made by the present authors to reduce mercury in various compounds to the metallic state by treating the samples with tin(II)-strong phosphoric acid. The mercury was driven out from the reaction medium by heating and its vapor was carried in a current of carbon dioxide into an absorbing solution containing sulfuric acid and potassium permanganate. The mercury retained in the solution as mercury(II) ions was determined colorimetrically by the usual dithizone method. This new method is very rapid and simple, and moreover, the error caused by the volatillization of mercury during the digestion of the samples by ordinary methods is totally eliminated for the analysis is carried out in a closed system in carbon dioxide.

## Experimental

**Apparatus.**—The apparatus used in this study is shown in Fig. 1. It is composed of two parts, a reaction vessel (A) and an absorbing part (B). The reaction vessel (A) is a round-bottomed flask of hard glass having a glass cap fitted to its top

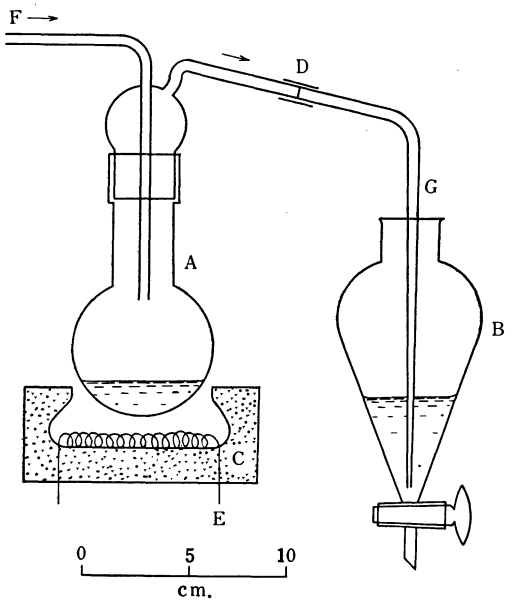

Fig. 1. Apparatus for reduction of mercury compounds and absorption of mercury vapor evolved.

B: A separatory funnel.
C: Electric heater.
D: Short piece of rubber tubing.
E: A. C. electric current regulated by a variable transformer.
F: Carbon dioxide gas introduced into A.
G: Gas-delivery tube.

and provided with an inlet and an outlet tube for the gas. The absorbing part (B) is a separatory funnel of about 100 ml. capacity. A gas delivery tube (C) is connected with a piece of rubber tubing (D) to the outlet arm of the reaction vessel (A) and inserted into the absorbing solution in the separatory funnel. A Kipp's apparatus is employed for the production of carbon dioxide, which is purified by three gas-washing bottles (not shown in Fig. 1) and introduced into the reaction vessel through the inlet arm. The solutions used for the purification of carbon dioxide are described later.

*Photoelectric colorimeter.*—A "Hirama photoelectric colorimeter" with 1 cm. cells was used with a filter of 517 mμ.

**Reagents.**—*Strong phosphoric acid.*—Four hundred grams of commercial ortho phosphoric acid of extra pure grade ($d$=1.7) is placed in a 300 ml. conical beaker, and dehydrated by heating on a 500 W. hot plate until a thermometer dipped in the liquid indicates 300°C. If the heating takes too long the liquid will become turbid and viscous and useless for the purposed in view. During the heating, the water vapor and the mist of phosphoric acid coming off should be rapidly removed from the neighborhood of the liquid surface, through a glass tube, one end of which is held near the surface of the liquid, the other end being connected to a suction pump. This saves much time in the dehydration.

*Tin(II)-strong phosphoric acid.*—Fifty grams of tin(II) chloride dihydrate of extra pure grade is placed in a 300 ml. conical beaker and on it is poured 250 g. of the strong phosphoric acid prepared as described above. The content is heated to 300°C within 30 min. in the manner of the preparation of the strong phosphoric acid. After cooling the tin(II)-strong phosphoric acid thus obtained, a very viscous and possibly slightly turbid liquid is produced, which may be stored in a closed vessel.

*Carbon dioxide.*—Carbon dioxide produced in the Kipp's apparatus is purified by passing through three gas-washing bottles containing, respectively, water, 2% vanadium(II) sulfate solution in 6 N sulfuric acid, 1% potassium permanganate solution in 10% sodium carbonate. This is introduced into the reaction vessel through a glass tube.

*Standard mercuric chloride solution.*—A 1.3539 g. portion of mercuric chloride of pure chemical grade dried in a vacuum desiccator is weighed accurately and dissolved in one liter of distilled water. This solution is used as a stock solution. One milliliter of the solution is diluted to 100 ml. with water before use. One milliliter of this diluted solution contains 10 μg. of mercury. According to Sandell[9] the mercuric ion is usually absorbed on the glass wall of the vessel, especially when the solution is extremely diluted. However, the effect is not noticeable when the diluted solution is employed soon after the preparation.

*Dithizone chloroform solution.*—A 0.001% (w/v) and a 0.005% (w/v) solution are prepared according to Sandell[9], and the former is used for 0 to 20 μg. of mercury and the latter for 0 to 50 μg. of the metal.

*Hydroxylamine hydrochloride solution.*—Twenty grams of hydroxylamine hydrochloride is dissolved in 65 ml. of water, and neutralized with aqueous ammonia using thymol blue as indicator. The solution is transferred into a separatory funnel and 10 ml. of 4% sodium diethyldithiocarbamate solution is added to it and mixed well. After a few minutes, 10 ml. of chloroform is poured into the vessel and the content is shaken vigorously to transfer the metal chelates into the organic layer. After the two layers are disengaged, the chloroform layer is rejected. To the aqueous layer, hydrochloric acid is added drop by drop till the red color of the indicator appears. This solution may be employed for the experiment.

*Potassium permanganate solution.*—A suitable amount of solid potassium permanganate of extra pure grade is dissolved in water and filtered through a glass-sintered crucible to make 0.1, 0.5 and 1 N solution.

*Sulfuric acid.*—Concentrated sulfuric acid of pure grade is diluted with water to a concentration of 10%.

*Acetic acid solution.*—6 N.

9) E. B. Sandell, "Colorimetric Determination of Traces of Metals", 2nd Ed., Interscience Publishers, Inc., New York (1950), pp. 441-452.

*Ferric chloride solution.*—Ferric chloride hexahydrate is dissolved in water to make a solution containing 10 mg. of iron(III) ion per ml.

*Cadmium chloride solution.*—Crystalline cadmium chloride is dissolved in water to make a solution containing 3.5 mg. of cadmium ion per ml.

*Mercuric oxide.*—Mercuric oxide of extra pure grade is used as a powder, and the mercury content was estimated by the ordinary potassium thiocyanate titration method as 97.30% pure.

*Alumina.* — As a diluent of solid samples, powdered alumina of utmost purity for chromatography is used.

*Various samples containing mercury.*—Commercial products, especially water-soluble insecticides and fungicides, are used as the samples of analysis, their mercury content having been determined by other methods.

**Procedure.** — Take an accurately measured sample containing mercury of 0 to 50 $\mu$g.—pipet a solution; weigh a solid—and put it into the reaction vessel (A in Fig. 1). The volume of the vessel should be varied according to the amount of the sample to be analyzed. Pour 5 to 10 ml. of the tin(II)-strong phosphoric acid over the sample. Put into the separatory funnel (B in Fig. 1) 5 ml. of 0.1 N potassium permanganate solution and 5 ml. of 10% sulfuric acid and mix well. Connect all the apparatus as shown in Fig. 1. Pass carbon dioxide very rapidly through the apparatus for two or three minutes to expel the air from the apparatus. The end of the gas-delivery tube (G) should reach the bottom of the separatory funnel. Reduce the flow of gas to a rate of one bubble per second, and heat the bottom of the reaction vessel by passing an electric current through the nichrome wire (E) placed in the diatomaceous block (C). Regulate the voltage of the current by a variable transformer. It is unnecessary to keep the temperature constant but it should be high enough to ensure that the content of the reaction vessel exhibits a white turbidity near the end of the reaction. After about fifteen minutes stop the heating, but continue the passing of the gas about five minutes longer.

Remove the separatory funnel, and pour into it about 15 ml. of 1 N sulfuric acid. To the colored solution add 1 ml. of 20% hydroxylamine hydrochloride solution to reduce the permanganate and, moreover, 2 ml. of 6 N acetic acid to stabilize the dithizonate which will be formed hereafter. Add 5 ml. of chloroform to the aqueous solution in the funnel and shake it vigorously for a while to saturate the aqueous phase with chloroform. After the layers are disengaged by standing the vessel for several minutes, reject the lower chloroform layer from the stem of the funnel. Then, add exactly 10 ml. of 0.05% dithizone-chloroform reagent using a pipet. Shake the vessel vigorously with an electric shaking machine for about two minutes. Allow the vessel to stand for several minutes and then drain the organic layer into an Erlenmyer flask containing unhydrous sodium sulfate as a dehydrant. Set it aside for a while till the water contained in the organic phase is absorbed and the layer becomes clear. Transfer the colored organic phase in a 1 cm. cell and read the absorbancy of the layer in a photoelectric colorimeter with a filter of 517 m$\mu$. A blank test should be conducted with the dithizone-chloroform solution undergoing the same procedure without mercury.

## Results and Discussion

**Recovery of Mercury by This Method.**— Employing an aliquot of the standard mercuric chloride solution, the determination of mercury in the amount between 5 and 50 $\mu$g. was made by carrying out all the procedure described above. Another aliquot of the standard solution was directly treated with dithizone-chloroform reagent and the absorbancy of the organic layer was read as described in the latter part of the procedure, which is similar to the ordinary method for the determination of mercury in solutions. The absorbancies measured on the same amount of mercury by the two methods are tabulated together in Table I, which shows good coincidence

TABLE I. COMPARISON OF THE ABSORBANCIES OF MERCURIC DITHIZONATE FOR THE SAME AMOUNT OF MERCURY

| Amount of Hg $\mu$g./100 ml. $CHCl_3$ | Absorbancy measured | |
|---|---|---|
| | Ordinary direct colorimetry | Via this reduction & evolution method |
| 5 | 0.0928 | 0.0930 |
| 10 | 0.1722 | 0.1716 |
| 15 | 0.2580 | 0.2464 |
| 20 | 0.3172 | 0.3301 |
| 25 | 0.4205 | 0.4200 |
| 30 | 0.4878 | 0.4813 |
| 35 | 0.5695 | 0.5690 |
| 40 | 0.6475 | 0.6420 |
| 45 | 0.7190 | 0.7210 |
| 50 | 0.7975 | 0.7960 |

within the error unavoidable in colorimetry. The calibration curves obtained by the two methods can be represented by the following equations. In case ordinary colorimetry of the dithizone-chloroform phase was used:

$$y = 0.0168 + 0.01569\,x$$

and if colorimetry following this reduction and evolution method was used:

$$y = 0.0156 + 0.01569\,x$$

where $y$ is the absorbancy measured and $x$ the amount of mercury taken in micrograms. The numerical values in the equations were calculated by the method of the least squares from the experimental

data of more than two determinations of the same amount of the metal. In conclusion, it may be pointed out that only a negligible amount of mercury is lost in this reduction and evolution method, and a calibration curve prepared by the ordinary method with a standard solution of mercuric salt can be employed in this method as well.

**Determination of Minute Amounts of Mercuric Oxide.**—A definite amount of mercuric oxide was mixed with a large amount of alumina and the mixture was analyzed by the tin(II)-strong phosphoric acid method. Minute amounts of mercury could be determined by this method as shown in Table II.

TABLE II. DETERMINATION OF MERCURY IN MIXTURE OF MERCURIC OXIDE AND ALUMINA

| Sample taken mg. | Hg content μg. | Hg found μg. |
|---|---|---|
| 15.90 | 30.7 | 30.2 |
| 13.32 | 25.7 | 25.5 |
| 14.59 | 28.2 | 28.3 |
| 14.65 | 28.3 | 28.4 |
| 14.73 | 28.4 | 28.7 |

**Determination of Minute Amounts of Mercury in Solution.**—Because of their volatility, mercury compounds can not be dried or their solutions evaporated without affecting the analytical result. So the co-precipitation method was employed to concentrate the mercuric ion using ferric hydroxide or cadmium sulfide as gathering agent. A suitable volume of a solution containing 20 μg. of mercury as chloride, and a suitable volume of ferric chloride solution containing 10 mg. of iron(III) ion per ml. were placed together in the reaction vessel. Sodium hydroxide solution was added dropwise to complete the ferric hydroxide precipitate, and the mixture was set aside from two hours to overnight till the precipitate settled. The supernatant solution was sucked out by means of a suction pump through a filter stick, a short glass tube containing an asbestos plug near one end, the precipitate being allowed to remain in the reaction vessel. The precipitate caught on the asbestos plug was transferred from the filter stick into the reaction vessel by pushing out the plug with a slender glass rod inserted through the other end of the glass tube. The analysis of mercury caught in the ferric hydroxide precipitate was carried out according to the procedure in which the asbestos plug was completely decomposed by heating with tin(II)-strong phosphoric acid as shown by the clear solution obtained.

Cadmium sulfide can also be employed as the co-precipitant. In this case a suitable volume of a solution containing a minute amount of mercury and of cadmium chloride containing 3.5 mg. of cadmium per ml. were put together in the reaction vessel. The pH of the solution was adjusted to about 1 by adding hydrochloric acid, and then hydrogen sulfide was introduced into the solution to precipitate cadmium sulfide. After the solution was left for several hours to let the precipitate settle, it was filtered by means of the filter stick as described above, and the asbestos plug was transferred to the reaction vessel containing the precipitate. The analysis was then carried out according to the procedure.

Both the ferric hydroxide and the cadmium sulfide co-precipitation method give good recovery of mercury in the solution as shown in Table III. In these cases some problems remain about the reaction of tin(II)-strong phosphoric acid with ferric ions and the metallic sulfides. The ferric ion is reduced to the ferrous by the reagent intended for the reduction of the mercuric ion, and excessive consumption of the reagent occurs if a larger amount of iron(III) ion is present. But when only about ten milligrams of iron(III) is used for the co-precipitation, the amount of the tin(II) ion in the reagent used is far in excess of the need of the iron(III) ion, and the reduction of mercury is not hindered.

TABLE III. RECOVERY OF 20 μg. OF MERCURY BY COPECIPITATION METHOD

Ferric oxide was used as a collector:

| Amount of $Fe^{3+}$ mg. | Hg found μg. | Recovery % |
|---|---|---|
| 10 | 19.9 | 99.5 |
| 20 | 19.2 | 96.0 |
| 30 | 19.7 | 98.5 |
| 30 | 19.7 | 98.5 |

Cadmium sulfide was used as a collector:

| Amount of $Cd^{2+}$ mg. | Hg found μg. | Recovery % |
|---|---|---|
| 3.5 | 19.3 | 96.5 |
| 〃 | 19.5 | 97.5 |
| 〃 | 19.3 | 96.5 |
| 5 | 19.2 | 96.0 |
| 〃 | 18.6 | 93.0 |

When cadmium sulfide is treated with the tin(II)-strong phosphoric acid, gaseous

hydrogen sulfide is evolved at the same time, and the gas is carried with the carbon dioxide into the absorbing solution of potassium permanganate and sulfuric acid. The gas consumes the permanganate and the absorbing power of the solution for mercury vapor is markedly lowered. In this case a large amount of permanganate should be persent in the absorbing solution to oxidize the sulfide in the sample and keep adequate absorbing power for mercury vapor. This applies also to the analysis of mercury in sulfates. The question is what concentration of potassium permanganate should be kept in the absorbing solution for various amounts of sulfur in the sample. Fig. 2 shows the results of experiments

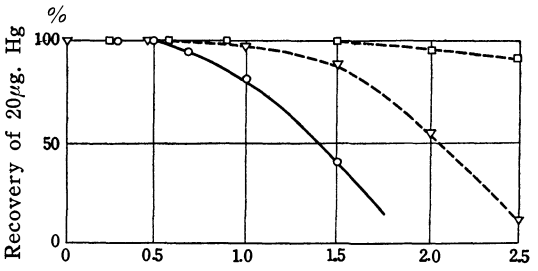

Fig. 2. Dependence of potassium permanganate concentration in the absorbing solution on the recovery of mercury.
Composition of the absorbing solution:
○: 5 ml. 0.1 N $KMnO_4$+5 ml. 10% $H_2SO_4$
▽: 5 ml. 0.5 N $KMnO_4$+5 ml. 10% $H_2SO_4$
□: 5 ml. 1 N $KMnO_4$+5 ml. 10% $H_2SO_4$

to estimate the concentration of permanganate for good recovery of mercury in the presence of various amounts of sulfur as sulfate. When 1 N potassium permanganate solution is used as 1:1 mixture with 10% sulfuric acid, less than 2.0 mg. of sulfur can be allowed to be present in the sample without any hindrance to the determination of 20 μg. of mercury.

**Effect of Chloride for the Analysis.**—The colorimetry of mercury dithizonate is usually dependent on the concentration of the chloride ion in the aqueous solution. In this evolution method, when a sample contains a large amount of chloride, the chloride is given off as hydrogen chloride and absorbed in the absorbing solution. Many papers have been published on the dependence of the accuracy of the dithizone method on the chloride ion concentration, and a suitable pH range for the extraction of mercuric dithizonate by chloroform was reported[10]. However, when the amount of chlorides in the sample is not known, it is very difficult to make the absorbing solution in suitable composition for the colorimetric determination of mercury. In such cases the co-precipitation method is to be preferred.

**Determination of Mercury in Organic Fungicides and Medicines.**—Various methods have already been employed for the determination of mercury in organic compounds, but when the compounds are present mixed with large amounts of other substances or in the form of a solution of extremely low concentration, it is very hard to get an accurate result. Moreover, the decomposition of the compound is usually carried out by strong oxidizing acid with a reflux condenser, through which some of the mercury inevitably escapes during the treatment. If the tin(II)-strong phosphoric acid method is applied for the purpose, the powerful decomposing and reducing power of the reagent acts on the sample instantly, and the mercury vapor is evolved, leaving other interfering metals in the phosphoric acid medium. The procedure of the analysis is the same as in the case of inorganic substances.

**Mercurochrome.** — Crystals of mercurochrome were weighed and dissolved in water to give a solution containing 10 μg. of mercury per ml. Two or three milliliters of the solution was taken in the reaction vessel, and the analysis was carried out according to the procedure. The purity of the sample was estimated by iodometric titration using a large amount of the sample.

**Ethylmercuric Phosphate.**—A substance in tablet form having the trade name "Luberon" (Hokko Chemical Co.) which contains ethylmercuric phosphate among other substances, was employed for the analysis. A 0.4597 g. portion of the sample was dissolved in 1 l. of water, and 2 ml. of the solution was put in a run.

***p*-Toluolsulfonaniline Phenyl Mercury, Ethylmercuric Phosphate and Ethylmercuric Urea.**—A mixture of these compounds, some binding material, some surface active agent and coloring matter, is marketed with the trade name "Fumiron" (Hokko Chemical Co.). A 0.4952 g. portion of the sample was dissolved in 1 l. of water and 2 ml. of the solution was taken for analysis.

**Methoxyethylmercuric Chloride.** — A tablet having the trade name "Usplon" (Japan Special Fungicide Co.) which contains

2.5% of mercury was used as a sample. A 0.4683 g. portion of the sample was dissolved in 1 l. of water and 1 ml. of the solution was taken for analysis.

**Dinaphtholmethane Disulfonic Acid Phenylmercuric Salt.**—This compound is contained in "Mell" (Takeda Pharmaceutical Co.) which is solid in two forms. One is a tablet containing the compound in high concentration, and the other is a powder of lower concentration. A 0.3005 g. portion of the tablet was weighed and dissolved in 1 l. of water, 2 ml. of which was used for analysis. The powder was weighed and placed directly in the reaction vessel.

**Ethylmercury Thiosalicylate.** — A sample dried in a vacuum desiccator containing sulfuric acid was weighed (1.1508 g.) and dissolved in water to a concentration of 1 : 25000. Two milliliters of the solution was pipetted into the reaction vessel and the analysis was carried out.

The data obtained by the above analyses are tabulated together in Table IV. This shows good reproducibility, and a run of the analysis for each sample can be carried out within thirty minutes without any difficulty. Various methods have been proposed by other authors[11-14] for each sample, but some of them are not versatile enough for different substances and the others are very tedious. By the tin(II)-strong phosphoric acid method, analysis can be carried out with inorganic and organic compounds in various forms without any pre-treatments or precaution.

## Summary

A simple and rapid method for the determination of a minute amount of

mercury in organic and inorganic compounds was established. This method uses the powerful decomposing and reducing power of tin(II)-strong phosphoric acid. In this method the sample is heated with the reagent in a round bottomed flask in a current of carbon dioxide. The mercury vapor evolved is carried with the carbon dioxide into an absorbing vessel which is a separatory funnel containing 10 ml. of 0.1 N potassium permanganate solution and 10 ml. of 10% sulfuric acid. The mercury vapor is oxidized again to the mercuric state and the ion is determined colorimetrically by the usual dithizone-chloroform method. After extracting the mercuric dithizonate with chloroform, the absorbancy of the organic layer is measured by a photoelectric colorimeter with a 517 mμ filter. Some organic compounds containing mercury and some inorganic mercuric compounds as mercuric chloride and mercuric oxide were analyzed by this method in extremely low concentrations, and satisfactory results were obtained. This method may be applied to various kinds of samples without special pre-treatments.

A part of the expenses for this study was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

# *Effect of Cupric Ion on Oxidation of Benzene Aqueous Solution by Cobalt-60 Gamma-rays*

By Hiroshi HOTTA and Akira TERAKAWA

(Received July 3, 1959)

The oxidation of benzene aqueous solution by Cobalt-60 gamma-rays has been studied by some investigators[1-4]. The yields of phenol and biphenyl are affected by the presence of some metallic ions[5-7]. The effect of cupric ions will be interpreted in the present paper.

## Experimental

Triply distilled water was saturated with benzene purified by sulfuric acid and then by freezing, by shaking in a separate funnel. Then some solutions were aerated in a gas-wash bottle on covering the solution with benzene. Other inorganic reagents were used without further purification. The concentrations of initial benzene and produced phenol were measured directly by optical density at 253.5 and 270 m$\mu$, respectively.

The solution in a test tube of hard glass (Hario Glass) was irradiated at the Cobalt-60 Irradiation Laboratory of Japan Atomic Energy Research Institute at room temperature (ca. 20°C). The dose, which was measured chemically as mentioned elsewhere[8], was changed not by its irradiation time, but by irradiation for one hour at various positions, namely, at various dose rates. Therefore, the abscissa of Fig. 1 gives the value of the dose in $r$ as well as the value of dose rate in $r$/hr.

## Results

The results of aerated benzene-saturated aqueous solution containing (a) 0.8 N sulfuric acid or (b) nothing are shown in Fig. 1. These curves were linear up to ca. $4\times10^4 r$ for both solutions. The white precipitate, which smelled like biphenyl, was found in the solution irradiated by more than $7\times10^4 r$, and was separated by means of a centrifuge for the measurement of optical density. The corresponding G-value of phenol is listed in Table I with the composition of each solution.

TABLE I. YIELD OF PHENOL

| Name | Solute (in M) | | | | Treatment | G-value | |
|---|---|---|---|---|---|---|---|
| | Cupric sulfate | Cupric chloride | Sulfuric acid | Benzene | | At low dose | At high dose |
| a | 0 | 0 | 0.4 | Saturated | Aerated | 2.63 | 0.33 |
| b | 0 | 0 | 0 | Saturated | Aerated | 2.63 | (0.64)* |
| c | 0.01 | 0 | 0.4 | 0.0115 | Not-aerated | 5.98±1.1 | 0.68±0.03 |
| d | 0 | 0.01 | 0.4 | 0.0132 | Not-aerated | 3.63±0.9 | 0.55±0.14 |
| Burton[1] | 0 | 0 | 0.4 | Saturated | — | (2.64±0.04)** | (0.35±0.02)*** |

* Less reliable; ** Aerated; *** Oxygen-free.

The G-value of solution b) at a high dose was less reliable.

The results of benzene-saturated 0.8 N sulfuric acid solutions containing (c) 0.01 M cupric sulfate or (d) 0.01 M cupric chloride, which were not aerated, are also shown in Fig. 1. These curves were linear up to ca. $6\times10^4$ $r$ for both solutions. These solutions smelled somewhat like biphenyl at a higher does than that corresponding to the break point of the curve. However, nothing was found as precipitate even at the highest dose in spite of the presence of a break point. The corresponding G-value is greater than that in the absence of any cupric ion as listed in Table I.

The earlier result by Burton et al. is listed in the same table for reference[1].

According to the examination of the analytical method by Goodman and Steigman[9], the spectroscopic method without solvent extraction as employed in the present work unavoidably gives a higher G-value of phenol (ca. 29% higher). However, the following discussion might not be proved valueless qualitatively by this uncertainty. Kurien, Phung and Burton indicate that their initial G-value of phenol is very correctly 2.64[2], which is nearly equal to the present value.

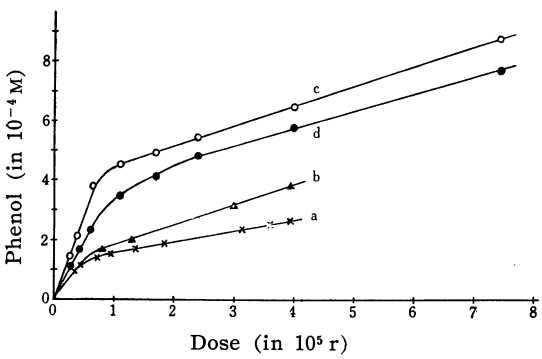

Fig. 1. Oxidation of aqueous benzene solutions. The name of each curve corresponds to the condition in Table. 1.

## Discussion

According to Burton et al.[1,2], phenol and hydrogen peroxide are produced by irradiation of aerated aqueous solution saturated with benzene like the present solutions a) and b). They interpret this fact with the following reactions:

$$H_2O \rightsquigarrow H,\ OH,\ H_2,\ H_2O_2 \qquad (0)$$

$$PhH+OH=Ph+H_2O \qquad (1)$$

$$Ph+O_2=PhO_2 \qquad (2)$$

$$PhO_2+H_2O=PhOH+HO_2 \qquad (3)$$

$$H+O_2=HO_2 \qquad (4)$$

and $$2HO_2=H_2O_2+O_2 \qquad (5)$$

Furthermore, the reactions,

$$Ph+OH=PhOH \qquad (6)$$

$$Ph+Ph=Ph_2 \qquad (7)$$

$$PhH+H=PhH_2 \longrightarrow \text{Polymer} \qquad (8)$$

and $$Ph+H=PhH \qquad (9)$$

must be considered in the oxygen-free or -nearly free solution. Reactions 7 and 8 give some insoluble products. According to Baxendale and Magee[10], the reaction

$$Ph+H_2O_2=PhOH+OH \qquad (10)$$

does not occur. Ph in the above equations denotes phenyl radical ($C_6H_5$).

The above interpretation is based on the assumption that, since the oxygen molecule scavenges all of the phenyl radical as well as H atoms, reactions 7 and 8 are suppressed by oxygen. The yield of phenyl depends not on the concentration of benzene but on that of oxygen. The concentrations at the break point of the curve are supposed to be about $1\times10^{-2}$ M and $1\times10^{-4}$ M for benzene and oxygen, respectively, from the former

9) J. Goodman and J. Steigman, *J. Phys. Chem.*, **62**, 1020 (1958).

10) J. H. Baxendale and J. Magee, *Discussions Faraday Soc.*, **14**, 160 (1953).

and the present experiments[1,11]. In a concentration of oxygen lower than this, phenol radicals are consumed by reactions 6—9[1,6]. The yield of phenol by the above reactions is at the highest $G_w(OH)=2.92$, which is the G-value of the OH radical induced from water. In fact, the experimental G-value supports this restriction, and indicates the partial re-hydrogenation of the phenyl radical to benzene by reaction 9, since the value is smaller than $G_w(OH)$.

In the presence of a cupric ion, the yield of phenol is larger than $G_w(OH)$, and no insoluble product is yielded even at the highest dose. The large yield of phenol can be interpreted by the following reactions,

$$Cu^{2+}+H=Cu^{+}+H^{+} \quad (11)$$

and then

$$Cu^{+}+H_2O_2=Cu^{2+}+OH^{-}+OH \quad (12)$$

The highest yield of phenol from this interpretation is $G_w(OH)+G(H_2O_2)=2.92+2.84=5.76$, where $G(H_2O_2)$ denotes the G-value of hydrogen peroxide by reaction 5 as well as reaction 0 and is estimated from datum by Phung and Burton[1]. Of course, a part of OH radicals may be consumed by the reaction

$$Cu^{+}+OH=Cu^{2+}+OH^{-} \quad (13)$$

This highest G-value is nearly equal to the present observed value of solution c) in Table I. The rate constant of reaction 11 is quantitatively confirmed to be great in the experiment of aqueous ferrous-cupric solution[8].

The concentration of benzene is not necessarily slight at the break point, and benzene should scavenge almost all of the OH radical by reaction 1 even after the break point as well as in the initial stage. Therefore, since the yield of phenyl radical is independent of oxygen, the fate of phenyl radicals, which are not dimerized to biphenyl by reaction 7 in virtue of the presence of the cupric ion, must be considered beside reaction 9. Moreover, reaction 11 suppresses reaction 9. Although reaction 11 suppresses also reaction 8, it is independent of phenyl radical. When the negative phenyl ion, $Ph^{-}$, is assumed to be a more stable form than phenyl radical, the promotion of re-hydrogenation to benzene without dimerization due to the cupric ion can be interpreted by the reactions,

$$Ph+Cu^{+}=Ph^{-}+Cu^{2+} \quad (14)$$

and then

$$Ph^{-}+H^{+}=PhH \quad (15)$$

through reaction 11. An analogous reaction is assumed for ferrous ion by Baxendale and Magee[10]. If almost all of the radical induced from water is scavenged by reactions 1 and 11 in the present condition, reactions 14 and 15 enable them to understand why no precipitate is found even at the highest dose in the presence of a cupric ion. The decomposition of phenol is slight according to Kurien, Phung and Burton[2]. There was no difference for the characteristics of absorption curve between 200~300 mμ for the solution through the whole range of dose.

Next, the effect of a chloride ion on the yield of phenol is noticed for solution d). A chloride ion is usually considered to react with OH radical in an acidic aqueous solution[12] as

$$Cl^{-}+H^{+}+OH=Cl+H_2O \quad (16)$$

and then

$$Cl+H_2O_2=Cl^{-}+H^{+}+HO_2 \quad (17)$$

or

$$Cl+H=Cl^{-}+H^{+} \quad (18)$$

Since reaction 16 competes with reaction 1, the yield of phenol is reduced. The reaction between phenyl and chloride radicals is ignored. The detailed study of the effect of chloride ions on the radiolysis of aqueous solution will be given in a later paper[8].

Since the present experiment is not exhaustive, the detailed study will follow.

## Summary

The effect of a cupric ion on the radiolysis of benzene aqueous solution can be interpreted by the following reactions of a cuprous ion produced in reaction $Cu^{2+}+H=Cu^{+}+H^{+}$. That is, the larger yield of phenol than $G_w(OH)$ in the presence of oxygen is due to the increment of OH radical by reaction $Cu^{+}+H_2O_2=Cu^{2+}+OH^{-}+OH$, and no precipitation in the absence of oxygen is due to re-hydrogenation by reactions $Ph+Cu^{+}=Ph^{-}+Cu^{2+}$ and $Ph^{-}+H^{+}=PhH$, respectively.

# *The Molecular Cross-sectional Areas for the Determination of Specific Surface Areas of Solids. II. Titania and Silica*

By Kumasaburo KODERA and Yoshito ONISHI

(Received August 5, 1959)

As for the determination of the specific surface areas of solids by the B.E.T. method[1], it is generally experienced that the values obtained by different adsorbate gases do not always coincide among themselves. In the preceding paper[2], specific surface areas of carbon blacks were estimated by means of the B.E.T. method using several gases, and by comparing them with those from electron microscopy, the molecular cross-sectional areas of the gases which would give the consistent surface areas with different gases and also with those from electron microscopy were determined. In this paper, similar studies with titania and silica as adsorbents will be mentioned.

## Experimental Method and Results

A series of ten commercial titania samples and five silica samples listed in column 2 of Table I were used. Nitrogen, argon, oxygen, carbon dioxide and *n*-butane were chosen as adsorbate gases, and the adsorption isotherms were measured as in the preceding paper. B.E.T. plots obtained from the isotherms are classified in four types from I to IV as shown in the preceding paper, in which, curves I and III are similar in form excepting that the former has a longer linear portion that the latter, curve II is a normal form with a length of linear portion being intermediate between I and III, and curve IV has a special form with shortest linear part. In Table I, types of isotherms are listed together with the appearance of the hysteresis in the measured pressure range, where "?" shows that the existence of hysteresis is not clear because the desorption isotherm was not measured in these cases. Estimated specific surface areas from the isotherms using the molecular cross-sectional areas[3] listed in column 4 of Table V, i.e. the values calculated from the densities of liquid state, are shown in Table II. Values under $S_{N_2}/S$ in the table are ratios between the surface areas estimated by nitrogen and by other gases. Surface areas* calculated from $d_3 = K\sum nd^3/\sum nd^2$ determined by electron microscopy by Suito and Arakawa[4] are also listed in the table**. It should be noted that in the calculation an equation $S = 6/d_3\rho$ was used. This can be applied only for spherical or cubic particles. In this equation, $S$ represents the specific surface area and $\rho$ the specific gravity of the sample. Values of $\rho$ used were 3.9 for anatase, 4.2 for rutile and 2.0 for silica.

In order to study the effect of the degree of crystallization or other surface states of the sample, surface areas of ten titania samples specially prepared under different conditions were measured by nitrogen, argon, oxygen and carbon dioxide, and the results are given in Table III. These samples were prepared by Kennedy's method[5], namely, titanium dioxide precipitated by hydrolysis of titanium tetrachloride was dried for five hr. at 100°C and then heated at different temperatures under the current of various gases***.

## Discussion

From Table I, it is seen that the isotherms to which the B.E.T. equation can be applied most satisfactorily are those obtained by argon and oxygen, and then those by nitrogen and carbon dioxide; but for *n*-butane, about half of the isotherms are of special types. As in the case of carbon black in the preceding paper, the isotherms of nitrogen and argon generally show no hysteresis, whereas by other gases, hystereses of isotherms are seen in nearly half of the cases.

As are shown in Table II, the average values of $S_{N_2}/S$ for argon at two temperatures are 1.26 and 1.25 and their standard deviations are small. For oxygen, the deviation is also small despite the rather great value for the carbon black but those for *n*-butane and carbon dioxide are great. In these the ratios in parentheses were excluded from the average. This

anomaly for carbon dioxide has been observed also for the carbon black. From the comparison with the preceding paper, it is seen that the ratio in Table II is 7~11% greater than those for carbon black; therefore, the discrepancy between surface areas by nitrogen and those by other gases increased further.

With the titanias prepared under various conditions shown in Table III, nitrogen, argon, and oxygen give surface areas parallel to each other, i.e. the area ratios $S_{N_2}/S$ are nearly constant, and equal to the values in Table II. This fact suggests that these gases give reliable areas despite the difference in the surface state of the samples. For carbon dioxide, however, ratios vary considerably, and in a few cases give values smaller than 1. Such deviations of ratios by carbon dioxide have been observed also for samples of carbon black, silica and other solids in our laboratory. It seems, therefore, that the adsorptions of carbon dioxide change considerably by some slight change in the surface state of the solid, thus, it is concluded that this gas is not suitable for use in the B.E.T. method.

For the reason mentioned above and for the same reason as in the preceding paper, argon may be taken as the standard gas. To determine the molecular cross-sectional areas of the standard gas and of the other gases, the specific surface areas estimated by the B.E.T. method, were compared with those from electron microscopy, the

method independent of the former. The results are shown in Tables IVa and IVb, where figures represent ratios of surface areas estimated by the B.E.T. method and by electron microscopy. In the table, values of Ti-2 were excluded from the average, because it contained needle-like parallel piped particles. Since only a few samples of silica have been measured and the values in the table scatter rather badly, they were used only to verify those with the titanias. These scattered values for the silicas may be explained by the fact that they consist of far smaller particles than the titanias, so that the measurement of the particle diameters on an electron micrograph would yield more series errors. The values shown in the lowest part of Table IVa are obtained by dividing the molecular cross-sections from the liquid densities (column 4, Table V) by respective average ratios in the table. These values should give the consistent surface areas with those from electron microscopy. Since the molecular cross-sections of argon at −196°C thus obtained agree fairly well with both van der Waals' constant and that from liquid density, the value 13.8 Å² from the liquid density was employed as the standard as in the preceding paper. Molecular cross-sections for the other gases are calculated from this value and the values of $S_{N_2}/S$ in Table II, and are shown in column 6 of Table V. From Table IVb it is seen that these values might be applied for silica as well. Since these values, except for that for nitrogen, agree very well with those for the carbon black, average values for both adsorbents can be used for both solids and are shown in the last column. It is seen that these values agree very well with those in Table IV. Agreement with those from the liquid densities also are fairly good, and the value for oxygen agrees with van der Waals' constant. The value for nitrogen, 12.9 Å², however, is considerably smaller than that for the carbon black, 14.2 Å², and deviation from the widely used value, 16.2 Å², from the liquid density is even greater. This deviation amounts to 26% and will be discussed below.

Beebe[6], Arnold[7], Corrin[8], and Pickering et al.[9] determined the molecular cross-sections of several gases for use in the surface area measurement by the B.E.T. method. In their studies, anatase used by Harkins and Jura[10] and determined to

have the specific surface area of 13.8 $m^2/g$.**** by their absolute method was chosen as a standard solid of the known surface area. They measured adsorption isotherms on this sample by several adsorbates, and calculated $V_m$ by the B.E.T. equation. Dividing 13.8 $m^2$ by $V_m$ they determined the cross-sectional area of adsorbate gas molecule. Areas thus obtained for various adsorbate gases are shown in Table VI together with the respective ratios to the areas from the liquid densities. These cross-sections have been proved by the above authors to give consistent surface areas for various solids examined, which include carbon black, rouge, rutile, etc. As are shown in column 5, the ratio of nitrogen is naturally 1, but all other values are greater than 1, i.e. from 1.20 to 1.43. From these ratios it is clear that, except for carbon dioxide and one of kryptons, the deviations of 26% for nitrogen mentioned above will nearly compensate deviations indicated by the ratios in the table, if 12.9 $Å^2$ were used for the cross-section of nitrogen. Moreover, ratios of the cross-sections of argon at two temperatures and carbon dioxide to that of nitrogen are 1.04, 1.12, and 1.50, respectively, by Pickering et al.[9], and 1.07, 1.12, and 1.58, respectively, by the present study. This fact also shows the agreement of the relative molecular cross-sections between both cases. Alexander et al.[11] measured surface area of six silica samples by the B.E.T. method, and determined their mean volume surface diameters ($d_3$) from electron microscopy. The ratios of the specific surface areas by nitrogen adsorption given in Table II in their paper and those calculated from $d_3$ in the same table give 1.27 on an average. Therefore, if the areas by electron microscopy are correct, the cross-section of nitrogen must be larger by 27% and agrees with the present study again.

From those discussed above the relative values of the molecular cross-sections estimated by the present authors are in fair agreement with those by the others, but from comparison with electron microscopy 16.2 $Å^2$ for nitrogen at −196°C seems to be too great and better agreement might be attained by choosing argon as a standard and giving 13.8 $Å^2$ for its cross-section at −196°C.

The specific surface areas of all the samples calculated by the cross-sections shown in column 8, Table V, are shown in Table VIII. The average value for each sample together with that from electron microscopy are also listed. In general, the surface areas from the different gases and from electron microscopy are in fair agreement with each other, except for a few cases which are shown in parentheses under carbon dioxide and excluded from the average. Especially for samples of titania, the agreement is satisfactory. Anomalous results obtained by carbon dioxide in certain cases may be explained by some difference in the surface state as in the case of the carbon black. Anomalous ratios in Table III for carbon dioxide are also explained similarly as was discussed above.

**** The same sample gave 13.9 $m^2/g.$ by the B. E. T. method using nitrogen as the adsorbate and by assuming 16.2 $Å^2$ for its molecular cross-section.

11) G. B. Alexander and R. K. Iler, *J. Phys. Chem.*, **57**, 932 (1953).

## Conclusion

For the estimation of the specific surface areas of titania and silica, argon, nitrogen, and oxygen are suitable for adsorbate gases and *n*-butane may also be available, but carbon dioxide must be used carefully as it gives unreliable results in some cases. The molecular cross-sectional areas given in Table V, column 6, are in fair agreement with those obtained for the carbon black except for that of nitrogen. The discrepancy by nitrogen would need further investigation, but for other gases, average values shown in column 8 may be expected to give consistent surface areas for many kinds of solids by different gases.

# *The Molecular Structure of Hexachlorobenzene by Electron Diffraction*

By Takahide SAITO

(Received July 20, 1959)

An early electron diffraction investigation of the structure of haxachlorobenzene by the usual visual method was reported by Brockway and Palmer[1], observing the scattering in a range of $q$* less than 60 and using the trial and error method, led to the conclusion that the molecule has the planar configuration as a whole. In contrast with their opinion, Bastianssen and Hassel[2] re-investigated the molecule by the sector method and reported that the non-planar structure, illustrated in Fig. 1, is supported on the basis of interpretation of the peaks in the radial distribution curve, but they did not apply the trial and error method to their investigations. The above contradictory results are compared in Table 1, containing the distances of the principal atomic pairs**. Although it is generally recognized that the sector method is superior to the visual method, it is not perfectly meaningless to re-investigate the molecule by the visual method and the trial and error process, if it is possible to obtain the photographs with rings extending to higher scattering angle, that is, if it is possible to observe the rings of larger $q$ values than the previous reports.

## Experimental

The apparatus of electron diffraction is the same as that in the previous reports[3] and the diffraction can be easily observed over the broad range of $q$. The electron wavelength, about 0.055 Å, was calibrated with gold foil diffraction.

The sample was prepared by Holleman's method[4], m. p. 227°C. Measurements of the photographs were carried out by the usual visual method.

TABLE I. A COMPARISON OF TWO REPORTS

| Investigater | $\theta$ | C-Cl | C'-Cl | C''-Cl | Cl-Cl | Cl'-Cl |
|---|---|---|---|---|---|---|
| Brockway, Palmer | 0 | 1.70 | 2.69 | 4.00 | 3.11 | 5.39 |
| Bastianssen, Hassel | 12 | 1.72 | 2.68 | 3.99 | 3.15 | 5.39 |

The unit of interatomic distance is Å.

$\theta$ is the angle between the direction of C-Cl and the benzene plane.

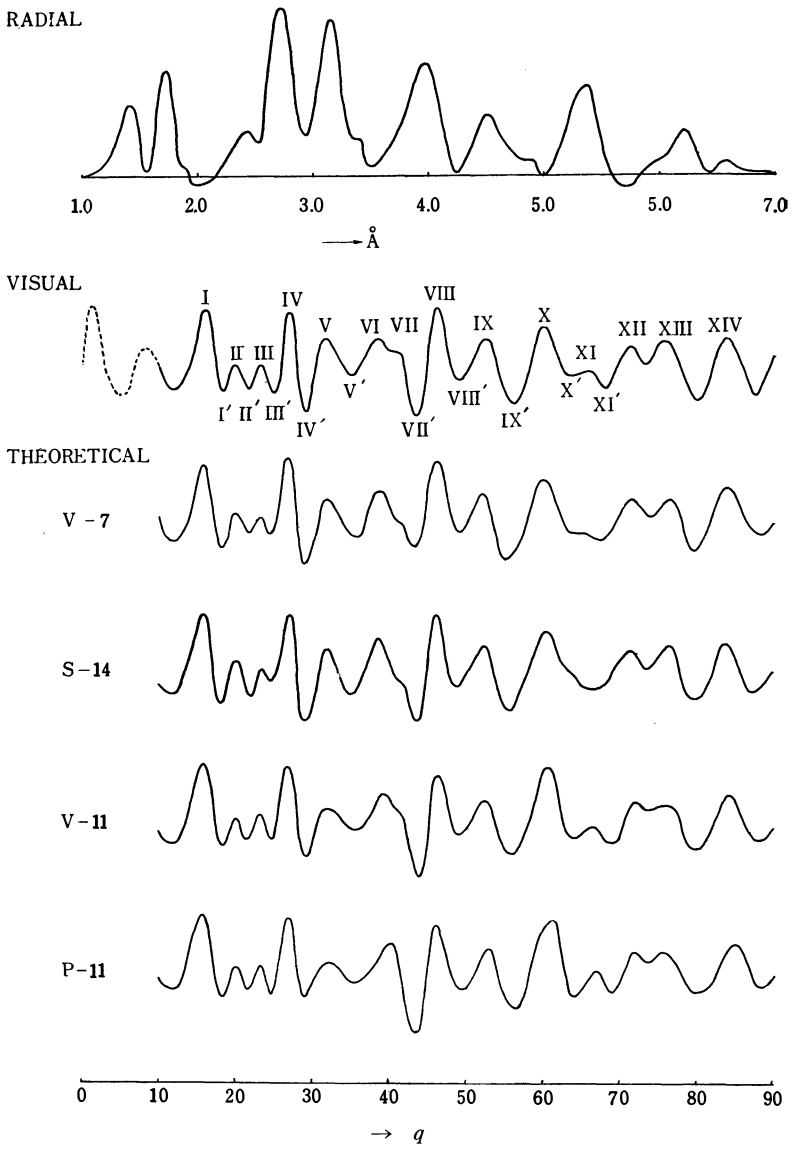

Fig. 2. The radial distribution curve, visual curve and various theoretical curves.

### Procedure and Results

The experimental visual curve is shown in Fig. 2: fourteen maxima and ten minima have been observed in the range of $q$ from 15 to 95. From the visual intensity curve, the radial distribution curve has been calculated according to the equation[5]

$$rD(r)=\sum_{q=1}^{q_{max}} I(q)\exp(-aq^2)\sin(\pi qr/10)$$

$$\exp(-aq^2{}_{max})=0.1$$

$$q=(10/\pi)s \qquad s=(4\pi/\lambda)\sin(\theta/2)$$

in which $\theta$ is the scattering angle and $a$ is a constant. The radial curve shows remaining ghosts, but has clearly six principal peaks at 1.40, 1.72, 2.70, 3.99, 3.15 and 5.36 Å. They correspond to the interatomic distances of C-C, C-Cl, C′-Cl, C″-Cl, Cl-Cl and Cl′-Cl, respectively.

Theoretical intensity curve for the molecular models have been calculated by the use of the equation[5]

$$I(q)=\sum_i\sum_j (Z_iZ_j/r_{ij})\exp(-a_{ij}q^2)\sin(\pi qr_{ij}/10)$$

$$a_{ij}=(\pi^2/200)l^2{}_{ij}$$

where $l_{ij}$ is the mean amplitude of the atomic distance $r_{ij}$. The coefficients of thermal vibration, $a_{ij}$, roughly estimated in reference to the calculated aliphatic data[6-8] is introduced into each model, for $q>30$. The values of coefficients are shown in Table II. The theoretical curves were

values of parameters to those of the interatomic distances from the radial distribution curve.

The values of principal parameters of models are shown in Table III. No distinct differences in the theoretical curves to contribute to any decisive choice can be observed, and the observable, relatively small, difference are as follows: (1) the relative shapes and positions of max. V—VII; (2) the relationships of max. VI and min. XI. The theoretical curves of the non-planar models show the good agreements rather than the curves of the plane models in the shapes of the above respects and in the values of $q_{calc}/q_{obs}$ and of interatomic distances.

## Summary

The non-planar structure of hexachlorobenzene is fairly suitable rather than the planar structure and the values of principal interatomic distances are

C-Cl=1.72±0.01 Å

C'-Cl=2.69±0.02 Å

Cl-Cl=3.15±0.02 Å

They are in agreement with Hassel's data.

The author thinks that the re-investigation of the molecular structure of hexachlorobenzene by the precise sector method is necessary.

The author has great pleasure in acknowledging his debts of gratutude to Professor A. Kotera and Professor K. Suzuki for their continued encouragement and advice, and to Dr. M. Igarashi and Dr. H. Sekine for their kind discussions and to Dr. K. Kuchitsu for his kindness in the calculations. A part of the cost of this research has been defrayed from the Scientific Research Encouragement Grant from the Ministry of Education, to which the author's thanks are due.

# *Studies on Thixotropy. I*. On the Thixotropic Gelation Process*

By Takehiko WATANABE

(Received August 10, 1959)

A number of studies concerning thixotropy, have been carried out by various kinds of methods. Taking as an example the bentonite-water system, which may be regarded as a typical thixotropic system, the studies have been made by the analysis of flow curve[1-9], the measurement of time required for gelation[10-14], and by both the rate constant of thixotropic gelation and the maximum gel strength (maximum yield value) developed as a consequence of completion of gel formation[15-18].

The third method may be said to be the one by which the process of gel formation can be actually followed and expressed in proper terms. The author et al.[16] have also made studies on bentonite (Gumma Bentonite) and some other clays, employing a method of the same kind and found that the thixotropic gel formation of clays generally proceeds in two first order processes which take place successively. Later, as phenomena similar to the above, in the case of the surface film of high polymer, Tachibana et al.[19] found that the thixotropic recovery of the surface elasticity or the surface pressure proceeds also in two steps.

In the present experiments, the author has also made studies on other thixotropic systems than bentonite, e.g. vanadium pentoxide sol, graphite suspension, etc., and found that in any system, in which the form of dispersed particles is plate- or rod-like, the thixotropic gelation generally proceeds in two steps. The conditions, under which the thixotropic gel formation proceeds thus in two steps, are examined and discussed.

## Experimental

**Materials.** — *Bentonite.* — Gumma Bentonite; a product from Gumma Prefecture, which was a finely ground powder, was used. A 10% aqueous suspension of the bentonite was let stand for 5 days and after the removal of the larger sized particles by sedimentation, the suspension (concn. about 5%) was collected and concentrated on a water bath at about 60°C.

Yamagata Bentonite: a 3% aqueous suspension of an original soil from Yamagata Prefecture which was eventually let stand for 5 years after preparation was used. The upper part of the suspension was first filtered by cotton wool and the filtrate (concn. about 1%) was concentrated.

Volclay (Wyoming Bentonite): after sedimentation of a 7% aqueous suspension of the powdery product for 5 days, its upper part (concn. about 3%) was taken and concentrated.

Tixoton: a product of the firm "Deutsche Bentonit" was used as an aqueous suspension.

The order of the capacity of swelling of the above four bentonites is as follows.

Yamagata Bentonite>Volclay>Tixoton>Gumma Bentonite.

The X-ray spectrographic analysis showed that Yamagata Bentonite contained no appreciable impurity, while Volclay contained small amounts of impurity which may be $\alpha$-quartz and $\alpha$-crystobalite, and Tixoton a small amounts of $\alpha$-quartz and Gumma Bentonite a relatively large amount of $\alpha$-crystobalite compared with the other three.

*Kaolin.*—Three kinds of products from Tochigi Prefecture (Kampaku mine), Korea and Hongkong, respectively, were used as aqueous suspensions.

*Sericite.* — The original powdery product from Niigata Prefecture was sieved through 250 mesh and used as an aqueous suspension.

*Vanadium pentoxide.* An aqueous sol was prepared according to Biltz's method, and the heat treatment of the sol was carried out at 96°C for 10 hr. as suggested by Sato[20]. Afterwards the sol was let stand for one month.

*Graphite.* — Flaky powder was used as an aqueous suspension.

In the case of experiments with the suspension in the electrolyte solution, the electrolyte solution was added to the above aqueous suspension until its requisite concentration was attained.

*Organophilic Bentonite.*—Gumma Bentonite was converted into an organophilic bentonite by cation-exchange reaction using oleyl-picolinium chloride or lauryl-picolinium chloride as cation active agent. A dried powdery product was obtained and used as a benzene suspension.

**Apparatus and Procedure.** — The measurement of yield value of the above mentioned suspensions was carried out using Du Noüy torsion balance. The length and diameter of the torsion wire are 40 and 0.025 cm., respectively. A small glass sphere (diameter about 0.7 cm.) is hung from the hook of the apparatus with a thin palladium wire (diameter 0.1 mm.). The force which causes the glass sphere to move upward, is given by twisting the torsion wire and is read on the dial scale.

In kinetic studies, measurements should be carried out at constant temperature. In the present experiments, however, all the measurements were made at room temperature, since the characteristics of the observed phenomena and also the maximum yield value are only slightly influenced by the change of temperature in the neighborhood of room temperature.

Experiments have been made as follows. The suspension is taken into a test tube (inner diameter 2.1 cm.) and thoroughly shaken or stirred. Then the glass sphere is immersed into the suspension about 3 cm. below the meniscus. Then, force is added until the glass sphere begins to show a minute upward movement (about 1/60 mm.). The preceding procedure should be performed within 30 sec. after stopping the stirring. The moment at which the above procedure was done, is regarded as the starting point of the experiment. Then, at 5 min. intervals, the force is superimposingly added in the same manner as stated above. In this experiment, the yield value (unit, dyn./cm$^2$) is expressed with the value obtained by dividing the force with the equatorial cross-section of the glass sphere. The yield value is taken versus the value obtained in the same manner as the above only with the dispersion medium. To observe the upward movement of the glass sphere, a small mirror was attached to the top of the hook and its movement was observed under twenty times enlargement using a lamp and scale. In the course of the application of the additional force, no upward movement of the glass sphere is observed until the total amount of the force has exceeded a certain amount. The force with which the upward movement of the glass sphere of about 1/60 mm. (i.e. that of 0.3 mm. on the scale) is brought about, is used to evaluate the yield value. It was observed that if the excess of force which caused the upward movement was removed immediately after the movement had been induced, the glass sphere returned to the position before the movement. Therefore, it may be said that the experiment has been carried out under the condition where the deformation applied to the suspension is within elastic limit.

With some of the samples used, experiments were also made using the torsion wire of 15 cm. besides one of 40 cm. In these cases, sensibility to detect a minute deformation was poor so that the amount of the added force became inevitably about two times greater than the case of 40 cm. Therefore, after the cessation of the additional increase of the force at the point where the upward movement of 0.3 mm. on the scale had been observed, a further gradual upward movement of 0.3~0.5 mm. was followed during the ensuing interval of about one minute. This movement may be a visco-elastic flow accompanied with the deformation over elastic limit induced by the force above stated.

## Results

Experiments have been made with the various kinds of suspensions stated above. In Fig. 1 the yield value is plotted versus

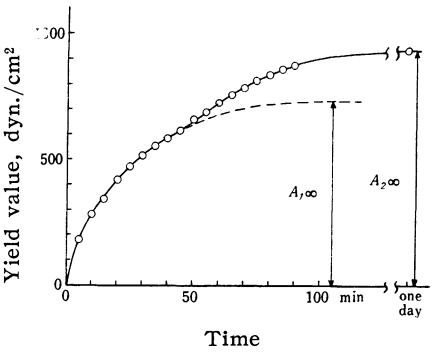

Fig. 1. The process of thixotropic gel formation (result obtained with 3.4% Yamagata Bentonite aqueous suspension).

the setting time. The curve shows that the increase of yield value with time proceeds in two processes which take place successively. The first process starts to develop immediately after the cessation of stirring or shaking. The second one reveals itself successively after some development of the first.

The increase of the yield value varies according to the first order kinetics for each separate process. These may be expressed as follows:

20) K. Sato, "Symposium on Colloid Science (Kōshitsu-gaku Ronsō", Kawade Shobō, Tokyo (1943), p. 93.

$$k_1 = \ln \frac{A_{1\infty}}{A_{1\infty} - A_t} \cdot \frac{1}{t}$$

$$k_2 = \ln \frac{A_{2\infty}}{A_{2\infty} - A_t} \cdot \frac{1}{t}$$

where $A_t$ is the yield value at time $t$ and $A_{1\infty}$ is the maximum yield value of the first process which is obtained from the curve as shown in Fig. 1. $A_{2\infty}$ is the maximum yield value of the second process. $k_1$ and $k_2$ are the rate constants for the first and the second processes, respectively. Similar plots such as that shown in Fig. 1 were generally obtained with the system where the dispersed particles have plate- or rod-like forms. In Table I the systems in which the increase of the yield value proceeds in two steps are collected. In the system to which an electrolyte was added, the two step process was detected, when no marked coagulation of the dispersed particles was observed. On the other hand, in the case where marked coagulation was observed, for example, Gumma Bentonite in 0.01 M $FeCl_3$, the process of the thixotropic gel formation was completed in a single step. The same phenomenon was also observed with the thixotropic sol of ferric oxide in 0.1 M NaCl.

TABLE I. THE SYSTEMS IN WHICH THE THIXOTROPIC GEL FORMATION PROCEEDS IN TWO STEPS

| Dispersed particles | Medium* |
|---|---|
| Gumma Bentonite | Water, 0.1 M NaCl, 0.4 M NaCl, 0.1 M LiCl |
| Yamagata Bentonite | Water |
| Volclay | Water, 0.1 M NaCl, 0.01 M $FeCl_3$, 0.005 M $Th(NO_3)_4$ |
| Tixoton | Water, 0.1 M NaCl, 0.01 M $FeCl_3$, 0.005 M $Th(NO_3)_4$ |

| 40 | 3 | 690 | 4 | 910 |
| 15 | 6 | 1500 | 3 | 2100 |

Yamagata Bentonite aqueous suspension are shown in Table IV. The difference of the value of $k_2$ between the two cases is small but that of $k_1$ is cosiderable. The latter may be due to the following conditions. In the case of 15 cm. wire, the visco-elastic flow has been observed in each measurement as stated above, and consequently the thixotropic gel formation proceeds under small shearing motions which facilitate the formation of the gel structure, i.e. the phenomenon of rheopexy has been observed. In the case of 40 cm. wire such an experimental condition was not established so that the phenomenon of rheopexy was not observed.

## Discussion

In the first place, let us consider the bentonite suspension. As a structure of thixotropic gel, it is adopted in such a network structure that plate-like particles link with each other in a short distance at the junction point. Furthermore as a model of structure, the 'house of cards' structure which was proposed by Hofmann[12] and whose existence in a xerogel was proved by Weiss et al.[21], is recommended.

In the present experiments, it was observed that the dependence on the concentration of $A_{1\infty}$ was different from that of $A_{2\infty}$. This fact can not be explained with the assumption that the yield value of the gel is determined by all the particles in the structure. Therefore, it must be assumed that the particular group of particles contributes to the yield value of the gel. Such a particular particle group which plays the part of a mechanical unit to the yield value, is named 'structural unit' (abbr. S. U.). Further, the particle group which acts as S. U. is classified into two types, i. e. one is the particle group forming linear ribbon and another is that of cross-linkage.

In the structure, the particles are linked at such small distances at any junction point that the steric hindrance caused by the interaction of linking particles must be taken into consideration. In these circumstances, the steric conditions such as freedom of rotation or flexibility around the junction point, may be the same as each other, in any particle group, so far as the co-operation between particles is concerned.

Considering the steric conditions, the association of plate-like particles may be classified into three types as follows.

P-1 association : Two adjacent particles are linked with each other at one point.

P-2 association : Two adjacent particles are linked at two or more points belonging to one straight line.

P-3 association : Two adjacent particles are linked at three or more points so that they are associated with surface-to-surface linkage.

By the third type of association a voluminous structure can not be expected to be formed, so that the discussions are undertaken leaving the third type out of consideration.

Next, it may be assumed that the magnitude of the cohesive force at junction points of S. U., remains constant in a given system unless the range of concentration studied is great. Therefore, as a first approximation, it may be assumed that the contribution to the yield value of each of the same kind of particle group, i. e. the strength of ($b$) the corresponding S. U. is constant, and the yield value ($A$) of any system will be determined by the number ($N_s$) of the S. U. in unit volume as follows :

$$A = bN_s \qquad (1)$$

In this case, the evaluation of the value of $N_s$ is necessary. At first, probability of permanent junction between adjacent particles (abbr. probability of junction) will be considered. The probability of junction where a given particle in a gel is linked to an adjacent one with P-1 association, will be determined by the number of free dispersed particles in unit volume ($N_p$) which may exist when the gel is transformed to sol by stirring etc. In other words, the probability of junction will vary as the concentration of the dispersed particles ($C$). Generally, the probability of junction between a particle and

21) A. Weiss, R. Fahn and U. Hofmann, *Naturwissenschaften*, **39**, 351 (1952); *Ber. deut. keram. Ges.*, **30**, 21 (1953).

its adjacent $l$ particles with P-1 association will vary as $C^l$, where $l \ll N_p$ and $l$ is a positive integer.

The probability of junction will be evaluated in the case of P-2 association. In this case, the above probability will be determined by the following two probabilities. The one is that of orientation of the particle in sol state to the position where the particle can be linked with P-2 association to a given particle. The other is that of formation of junction between particles. The two probabilities will be proportional to $N_p$, i. e. $C$. Therefore, the discussed probability of junction should vary as $C \times C = C^2$. Generally, the probability of junction between a particle and its adjacent $m$ particles in the same manner as stated above will vary as $C^{2m}$, where $m$ is a positive integer.

Let us consider the linear ribbons which act as S. U. The linear ribbons are formed from the aligned particles and in order to act as S. U. they must also be linked to two or more other linear ribbons. In general the linear ribbons are not formed from exactly equal numbers of particles. However, in the present case, the cohesive force between particles is considered to remain constant, so that the yield value may be determined by the number of junction points between particles in unit volume of the gel. The assumptions are made on the way whereby the linear ribbons are formed, i. e. how many particles are separately linked with what type of association to any one particle. And the relations between the yield value and the concentration in the case where the assumed linear ribbons act as S. U., are derived on the basis of the knowledge on the probability of junction above stated. The results are shown in Table V.

The consideration will be given to the cross-linkage. Cross-linkage is a particle group which plays the part of junction between the linear ribbons in structure. When it contributes to the yield value as S. U., it may be expected that one of the particles forming cross-linkage, could not move in accordance with the deformation of the gel under the applied force, but would behave as if it were restricted at a fixed position. Therefore, the characteristics of the cross-linkage are determined by two factors. One of them is the number of effective linear ribbons linked to the above fixed particle and the other is the type of association between particles forming the cross-linkage. In addition, it may be assumed that the degrees of steric hindrance of the junction points between the particles forming a cross-linkage must be the same as each other and further they must be the same as, or higher than, that of forming the linear ribbons participating in the cross-linkage. According to the above considerations, the relations between the yield value and the concentration of the gel are derived from the knowledge of the probability of junction and shown in Table VI. In this table the necessary type of association of the particles forming linear ribbons is also listed.

Considering the process of development of gel structure which is applicable for the two cases of Yamagata Bentonite and Volclay, it must be assumed that S. U. in

TABLE V. THE RELATION BETWEEN THE YIELD VALUE ($A$) AND THE CONCENTRATION ($C$) OF THE GEL IN WHICH THE LINEAR RIBBON ACTS AS STRUCTURAL UNIT

| Nomenclature of structural unit | Mode of formation of linear ribbon | Relations between $A$ and $C$ |
|---|---|---|
| L-1 | P-1 association $l=1$ | $A \propto C$ |
| L-2 | $l=2$ | $A \propto C^2$ |
| L-3 | $l=3$ | $A \propto C^3$ |
| L-4 | P-2 association $m=1$ | $A \propto C^2$ |
| L-5 | $m=2$ | $A \propto C^4$ |

TABLE VI. THE RELATION BETWEEN THE YIELD VALUE ($A$) AND THE CONCENTRATION ($C$) OF THE GEL IN WHICH THE CROSS-LINKAGE ACTS AS STRUCTURAL UNIT

| Nomenclature of structural unit | Mode of formation of cross-linkage | Relations between $A$ and $C$ | Necessary type of association of linear ribbon |
|---|---|---|---|
| M-1 | P-1 association $l=2$ | $A \propto C^2$ | P-1 |
| M-2 | $l=3$ | $A \propto C^3$ | P-1 |
| M-3 | $l=4$ | $A \propto C^4$ | P-1 |
| M-4 | P-2 association $m=1$ | $A \propto C^2$ | P-1 |
| M-5 | $m=2$ | $A \propto C^4$ | P-1, P-2 |

the first step of gel formation is cross-linkage and that of the second is linear ribbon. Therefore, in the case of Yamagata Bentonite having $A_{1\infty} \propto C^2$ and $A_{2\infty} \propto C$, the S. U. for the first step is M-1 or M-4 in Table VI and that of the second is L-1 in Table V, since the linear ribbons of this sample must be formed from the particles linked together by P-1 association. Also in the case of Volclay, the linear ribbons are formed by P-2 association, and the S. U. of the first step is M-5 and that of the second is L-4, since this sample shows the relation, $A_{1\infty} \propto C^4$ and $A_{2\infty} \propto C^2$.

According to the above considerations, it may be explained that the thixotropic gel formation of bentonite will proceed as follows. During the first step, some of the dispersed particles align to form linear ribbons, and the latter further cross-link with neighboring ones to develop into a loose gel structure. In the second step, many particles or linear ribbons having no part in the formation of the first loose gel structure, begin to participate in structure to complete a rigid gel structure. On the other hand, in the first step, the increase of yield value is proportional to the increase in number of cross-linkage and the latter will be accelerated under small shearing motions so that the phenomenon of rheopexy will markedly appear. In the second step, both the increase in number of cross-linkage and that of linear ribbons participating in the formation of the cross-linkage, will simultaneously occur and these will lead to the increase of continuity of the linear ribbons in the gel structure so that the linear ribbons will come to act as S. U. Therefore, though the cross-linkage acting as S. U. in the first step, does not decrease in number nor disappear, its contribution to the yield value as S. U. gradually diminishes in the second step. Moreover, the rheopectic phenomenon can not be observed distinctly in the second step, since the rate of increase of yield value of this step is not determined by the rate of increase of the cross-linkage as in the case of the first step.

In the case of vanadium pentoxide sol, the experimental facts may be explained as follows. It is not necessary to make such a distinction between P-1 and P-2 association as in the case of bentonite, since the vanadium pentoxide particle has a thin rod-like form. It may be assumed that the particle group which acts as S. U. both in the first and in the second step, is the particle group forming cross-linkage. During the first step, a loose gel structure may be developed, in which the dispersed particles are linearly associated and a relatively small number of cross-linkage or entanglement can be seen between the linear chains of particles, and in the second step, it reaches another structure, i. e. a rigid gel structure which may be due to the appreciable increase of cross-linkage between chains. The difference in structure between the loose and rigid one is due to the variance in number of linear chains participating in the formation of the cross-linkage which acts as S. U. The number of linear chains linked to the fixed particle of the cross-linkage is two in the former structure and is three in the latter one, since this sample shows the relation, $A_{1\infty} \propto C^2$ and $A_{2\infty} \propto C^3$. In the course where the rigid gel structure is developed from the loose one, cross-linkage which contributes to the yield value proportional to $C^2$ is transformed to the cross-linkage proportional to $C^3$, according to the increase in number of linear chains linked to form the cross-linkage.

## Summary

(1) In this system, in which the form of dispersed particles is plate- or rod-like, the thixotropic gelation generally proceeds in two steps.

(2) During the first step of thixotropic gel formation, a loose gel structure may be developed and a rigid gel structure in the second step.

(3) In the case of bentonite, the structural unit which contributes to the yield value of the gel in the first step is cross-linkage and that of the second is linear ribbon.

(4) In the case of vanadium pentoxide, the structural unit is cross-linkage both in the first and in the second step.

The author would like to express his gratitude to Professor Sôzaburo Ono for his kind guidance and discussion throughout this work and to Mr. Yoshiyuki Takasaki for his kind assistance in the experiment.

# *A Simple Method for the Preparation of Crystalline D-Mannose*

By Toshihito FUJITA and Tetsuo SATŌ

(Received August 18, 1959)

In the recent studies on the reaction of carbohydrates with boric acid, the present authors have required a large quantity of crystalline D-mannose. This is usually obtained by the hydrolysis of polysaccharides, such as mannan and glucomannan[1].

A better source of the sugar are the corms of *Amorphophallus* konjac, which contain mannose as glucomannan and are commercially available as "Konjac Flour". According to the previous methods[2] for the preparation of the sugar from this source, D-mannose is isolated in the form of its crystalline phenylhydrazone, purified as easily crystallizable methyl-*a*-D-mannoside, and then the glycoside is hydrolyzed to free sugar. This phenylhydrazone method is quite expensive, and not suitable for preparation on a large scale.

The phenylhydrazone method is based on the unusual low solubility in water of mannose phenylhydrazone. *N*-phenylmannosylamine, like the hydrazone, is insoluble and easily crystallized from an aqueous solution[3]. Moreover, the *N*-glycoside is very easily hydrolyzed under neutral conditions in the presence of formaldehyde or benzaldehyde. The authors have used *N*-phenyl-D-mannosylamine in isolating D-mannose from "Konjac Flour" and made certain improvements for the preparatory purpose of D-mannose.

The "Konjac Flour" has been hydrolyzed with concentrated or with dilute acid solution. The best results bave been obtained by refluxing it in 1 N acid solution. From the acid hydrolysate D-mannose has been isolated as crystalline *N*-phenylmannosylamine, and the *N*-mannoside has been readily hydrolyzed to free sugar in the usual manner[4]. The yield of sugar from this method is nearly equal to that of the phenylhydrazone method.

## Experimental

**Preparation of *N*-Phenyl-D-mannosylamine.**—*Procedure-A.*—One hundred grams of "Konjac Flour" was mixed with 60 ml. of cold 75% sulfuric acid under cooling, allowed to stand overnight at room temperature and then added to 1 liter of water. The diluted solution was refluxed for 6 hr. The solution was neutralized with barium carbonate to pH 4~5 and the precipitate was filtered off. The filtrate was decolorized with active charcoal and concentrated to 100 ml. in vacuo. Aniline (16 ml.) in 100 ml. of ethanol was added to it. The mixture was kept overnight in a refrigerator. The crystals formed were collected and recrystallized from 50% ethanol. Yield 24 g., m.p. 180~181°C. It was identified with an authentic sample[3].

*Procedure-B.*—"Konjac Flour" (100 g.) was suspended in 1 liter of 1 N sulfuric acid and the mixture was boiled for 10 hr. under refluxing. The dark brown solution was neutralized to pH 4~5 with barium carbonate. The *N*-mannoside was obtained as described above. Yield, 33 g.

**Isolation of D-Mannose from *N*-Phenyl-D-mannosylamine.**—Fifty grams of *N*-phenyl-D-mannosylamine was dissolved in water at 60~70°C and 35% formaldehyde (25 ml.) was added to it. A white precipitate was soon deposited. The mixture was allowed to stand for 24 hr. at room temperature. The white resinous substance was removed and the filtrate was evaporated to a thick sirup. The colorless sirup was dissolved in methanol and *n*-propanol (1 : 1) and seeded with *a*-D-mannose. The crystals were separated and recrystallized from ethanol or acetic acid. Yield, 30 g. (85%), m.p. 130~131°C. $[\alpha]_D^{30}$: 28.4° →+13.3° (*c* 3.9, in water).

Found: C, 40.18; H, 6.84. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.71%.

# *The Crystal Structure of trans-*[*Cr* $en_2Cl_2$]*Cl·HCl·*$2H_2O$

By Shun'ichiro Ooi, Yoshimichi Komiyama and Hisao Kuroya

(Received September 22, 1959)

The crystal structures of the two cobalt(III)-complexes, which are of the type *trans*-[Co $en_2X_2$]$X\cdot HX\cdot 2H_2O$ (X=Cl, Br)[1], were determined by Saito, Kuroya and their collaborators during the past several years[2,3]. In connection with this, it seems really interesting and important to investigate the crystal structures of the chromium(III)-analogues, which have a great resemblance to the cobalt(III)-complexes in various respects; particularly, it may be very instructive to examine what discrepancies can be found between the bond lengths M–N and M–X in these compounds, where M denotes a central metallic ion and N a nitrogen atom of the coordinated ethylenediamine molecule.

The present authors took up the *trans*-dichloro-bis-ethylenediamine-chromium(III) chloride hydrochloride dihydrate, *trans*-[Cr $en_2Cl_2$]$Cl\cdot HCl\cdot 2H_2O$, in the first place, and made an attempt to analyze the crystal structure of this compound by means of X-rays. This paper is to report the results obtained.

## Experimental

The crystal of [Cr $en_2Cl_2$]$Cl\cdot HCl\cdot 2H_2O$ was prepared by the method of Pfeiffer et al.[4] The crystals are bluish-green tablets and show marked dichroism like the crystals of [Co $en_2Cl_2$]-$Cl\cdot HCl\cdot 2H_2O$. From oscillation and Weissenberg photographs the unit cell dimensions were found to be:

$$a=10.97,\quad b=7.88,\quad c=9.12\ \text{Å},\quad \beta=111.5°.$$

The space group was determined to be No. 14 $P2_{1/c}$ from the systematic extinctions of reflections. The unit cell contains two formula units ($\rho_{calcd}=1.59$, $\rho_{obs}=1.54$ g./cm$^3$). The photographs were taken with Cu$K\alpha$ radiation using multiple film technique. All intensities were estimated visually by comparison with standard scales. The usual correction factors were applied by means of a chart given by Cochran and relative $|F_o|$ values were obtained.

## Structure Determination

The structure determination was carried out using $(h\,k\,0)$ and $(h\,0\,l)$ reflections from Weissenberg data. It was observed that the intensity of each reflection is similar to the corresponding one of the cobalt-analogue at low-angle reflections. This had been expected from the dichroism mentioned above and the crystallographic data, and the outline of the crystal structure was determined without difficulty.

At the stage of refinement, the method of successive difference syntheses was employed. The atomic coordinates obtained are shown in Table I. These parameters gave the reliability index $R=\sum||F_o|-|F_c||/\sum|F_o|$ of 0.131 and 0.121 for $(h\,k\,0)$ and $(h\,0\,l)$ respectively, excluding (100) reflection which could not be observed with full certainty. Calculated and observed structure factors are listed in Table II. In the calculation of structure factors, atomic scattering factors listed in the International Table (1935) were used. Overall temperature factors of the form exp $[-B(\sin\theta/\lambda)^2]$, where $B=2.7$ Å$^2$, were applied in the final calculation of structure factors. Final electron density projections on (010) and (001) are shown in Figs. 1 and 2.

1) N. Fogel and S. D. Christian reported in *J. Am. Chem. Soc.*, **80**, 2356 (1958) that the dichloro-complex should be given a composition formula [Co $en_2Cl_2$]Cl·$HCl\cdot 6H_2O$ instead of [Co $en_2Cl_2$]$\cdot Cl\cdot HCl\cdot 2H_2O$. However, no other formula than the latter can give any satisfactory agreement between the measured and calculated values of density, and furthermore, between $|F_o|$ and $|F_c|$, i. e., the observed and calculated intensities of X-ray diffraction.

## Results

The crystal structure determined is isomorphous with $[Co\ en_2Cl_2]Cl\cdot HCl\cdot 2H_2O$ and consists of the following elements: $[Cr\ en_2Cl_2]^+$, $Cl^-$ and $[H_2O\cdots H\cdots H_2O]^+$. The configuration of the complex is as follows. Two enantiomorphous ethylenediamine molecules, taking *gauche* form, are coordinated to a chromium atom with their four nitrogen atoms. The arrangement of nitrogen atoms around the chromium atom is square coplanar. On a line approximately perpendicular to the plane are two chlorine atoms and these are coordinated to the central metal atom. The calculated bond lengths and angles are shown in Table III. The interatomic distance O···O of $[H_2O\cdots H\cdots H_2O]^+$ was found to be 2.56 Å.

A trial was made for the estimation of some coordinate standard deviations by

TABLE IV. ESTIMATED COORDINATE STANDARD DEVIATIONS (VALUES IN ANGSTROM UNITS)

| | Cl | N(1) | N(2) |
|---|---|---|---|
| $\sigma(X^*)$ | 0.013** | 0.022 | 0.039 |
| $\sigma(y)$ | 0.010 | 0.054 | 0.032 |
| $\sigma(z)$ | 0.012 | —*** | —*** |

* $X$ is the axis normal to the $yz$-plane.
** 0.013 was estimated from the data for $(h\,0\,l)$, 0.012 from those for $(h\,k\,0)$.
*** $\sigma(z)$ for N(1) and N(2) could not be estimated because of the required tedious calculation**** due to mutual overlaps of atomic peaks (see Fig. 1).
**** D.W.J. Cruickshank, *Acta Cryst.*, 5, 511 (1952).

the method of Cruickshank[5], and the results are listed in Table IV. Regarding the bond lengths of chromium to nitrogen atoms, 2.11 and 2.13 Å are found for Cr-N(1) and Cr-N(2), respectively. These values are greater than the corresponding ones in the cobalt-analogue by ca. 0.1 Å. On this value, then, "significance tests"[3] were tried. At a rough approximation with $\sigma(z)$ of N(1) and N(2) ignored, the standard deviations of bond lengths $\sigma(l)$'s could be calculated from the data given in Table IV.

$$\sigma(\text{Cr-N(1)})=0.049, \quad \sigma(\text{Cr-N(2)})=0.037\ \text{Å}.$$

Similar treatments on the data of cobalt-analogues gave

$$\text{N(1)}: \sigma(X)=0.068, \quad \sigma(y)=0.084\ \text{Å},$$

and $$\text{N(2)}: \sigma(X)=0.100, \quad \sigma(y)=0.108\ \text{Å},$$

from which were obtained the values:

$$\sigma(\text{Co-N(1)})=0.080, \quad \sigma(\text{Co-N(2)})=0.099\ \text{Å}.$$

The values of $|l_1-l_2|/\{\sigma(l_1)^2+\sigma(l_2)^2\}^{1/2}$ were estimated to be 1.4 for Cr-N(1) and Co-N(1), and 1.2 for Cr-N(2) and Co-N(2), where $l_1$ and $l_2$ are bond lengths of Cr-N and Co-N, respectively. According to the levels given by Cruickshank, these values indicate that the difference between $l_1$ and $l_2$ is not significant.

The bond length found for Cr-Cl(1) is 2.33 Å which is the same as that found in the cobalt-analogue, and the estimated $\sigma$(Cr-Cl(1)) is 0.012 Å. The cell dimensions of cobalt-analogue are

$$a=10.68, \quad b=7.89, \quad c=9.09\ \text{Å}, \quad \beta=110.4°,$$

and $a$ is shorter than that of the present crystal by ca. 0.3 Å which is apparently beyond the experimental error while no remarkable discrepancies can be found between the values of $b$'s, $c$'s and $\beta$'s, respectively, of the two paired coordination compounds of Cr(III) and Co(III).

Thus, it has been evidenced that the substitution of metal causes the deformation of the unit cell. It is probably not unduly bold to consider that the effect of a metal substitution takes place first of all in the nearest neighbor of the metal. However, since the accuracy is not high enough as can be seen above, the authors' opinion is that it is going too far to give a definite conclusion to this problem.

The present authors wish to express their sincere thanks to Professor Y. Saito for his kind advice and encouragement throughout this work. Part of the cost of this investigation was defrayed from the Fund for Scientific Resarch Expenditure of the Ministry of Education, to which the authors' thanks are also due.

# *Catalytic Activity for Methanol Synthesis of Zinc Oxide-Chromium Oxide-Copper Oxide Catalysts and its Structural Dependency*

By Yoshisada OGINO, Masaaki OBA and Hiroshi UCHIDA

(Received September 19, 1959)

Because of their higher catalytic activity for methanol synthesis than that of zinc oxide-chromium oxide catalysts, three component catalysts, consisting of oxides of zinc, chromium, and copper, are in industrial use in this country. A few papers[1-3] have already appeared dealing with the catalysts. However, only the papers by Natta and Ivanov described the catalysts from a structural view point, and dependency of catalytic activity upon catalyst structures has remained unclarified as yet. The present study attempts to assemble a number of experimental data in this respect, and to approach complete understanding of the promoting action of copper oxide in the three component catalysts.

In this paper a preparative procedure somewhat different from the usual ones is proposed. The major part of the determinations on catalyst structures as well as on catalytic activity are made on the catalysts prepared by the procedure.

## Experimental

Preparations of a series of zinc oxide-chromium oxide-copper oxide catalysts of varying chemical compositions were made by a procedure somewhat different from the usual ones: namely, a commercial zinc oxide powder was kneaded with a chromic acid solution, in which an appropriate amount of cupric oxide had been dissolved, into a paste, which was allowed to dry at room temperature. The resulting cake was crushed, and screened to 2 to 2.5 mm. granules. Another catalyst, denoted by catalyst R, manufactured by a usual procedure was also prepared. According to the procedure, a mixture of powders of zinc oxide and copper oxide was kneaded with a chromic acid solution into a paste, which was then treated similarly to finished catalyst granules.

Chemical compositions of the catalysts used in this study are listed in Table I. Because of rather poor solubility of copper oxide in a chromic acid solution, a catalyst of Cu/Zn ratio in excess of 0.25 could not be obtained.

Catalytic activity for the methanol synthesis was determined according to the same procedure as described in the previous paper[4]. Among the by-products of the synthesis, formaldehyde was determined by a chemical analysis, while water and higher alcohols were determined by means of a gas chromatography.

Catalyst bed density was determined on the catalyst after the synthesis as follows: an amount of the catalyst granules was placed in a graduated cylinder, which was vibrated by hand till no more reduction in volume of the catalyst bed was observed. The density is given by the value of catalyst weight (g.) divided by volume (cc.) at the end of the vibration.

Specific surface area of the catalyst was determined from nitrogen adsorption data plotted according to the BET theory. In addition, volumes were measured by the water- and the mercury-displacement method[5], from values of which true and bulk densities, and pore volume could be evaluated.

Some of the catalysts, the raw as well as the reduced ones, were subjected to an X-ray study by means of a Geiger-counter spectrometer using filtered $K_\alpha$ ray.

## Results

**Catalytic Activity for Methanol Synthesis.** — Some of the results are exemplified in Fig. 1 which, for the sake of comparison, includes the authors' previous results[6] on a zinc oxide-chromium oxide catalyst. Besides the well-known fact that an addition of copper oxide is very effective in improving the catalytic activity of a zinc oxide-chromium oxide catalyst, the figure reveals that a zinc oxide-chromium oxide-copper oxide catalyst exists in either one of two states, A or B, of different activities. State-A appears immediately after reduction of the raw catalyst at temperatures lower than 280°C, and it is not until the reduced catalyst is heated above this temperature that catalytic activity is decreased to a lower level. Being heated beyond 280°C, the catalyst suffers a rapid activity decline until a steady state, state-B, is established. There is little tendency to further decrease in activity, even though the catalyst in state-B heated as high as 360°C.

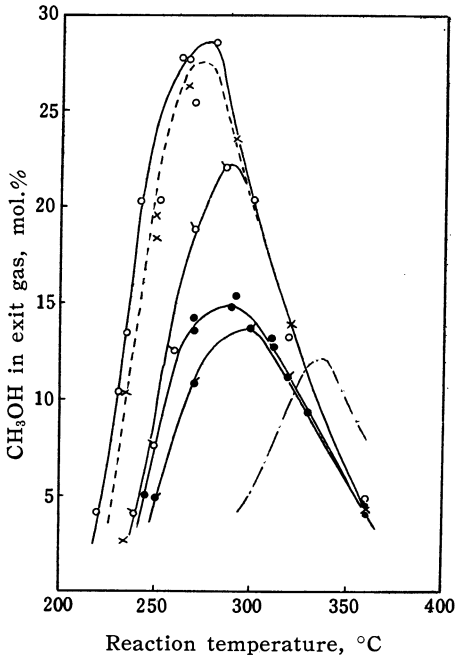

Fig. 1. Methanol concentration as a function of reaction temperature at 150 kg./cm² and S. V. of 1.10⁴.

6) Y. Ogino, M. Oba and H. Uchida, This Bulletin, 32, 284 (1959).

Fig. 1 also indicates that after slow oxidation at low temperatures the catalyst in state-B recovers the activity to such a level that it is approximate to the initial activity in state-A (catalyst in state-A′). Being compared with catalyst No. 6, catalyst R of the same chemical composition as, but of a different manufacturing procedure from, catalyst No. 6 gives a considerably lower activity.

It is more desirable to express catalytic activity in terms of the rate constant of the synthesis than the methanol concentration in the exist gas. The reason for this is the difficulties of arranging experiments at a constant space velocity (based on catalyst bed volume after the synthesis), since the catalyst bed volume is apt to shrink, during the synthesis, in an extent that can not exactly be predicted before the synthesis. Usually the extents of shrinkage are in the range of 15 to 25% of the original bed volume of the raw catalyst. The rate constant can be calculated from a methanol concentration by the aid of the rate equation proposed by the present authors[4].

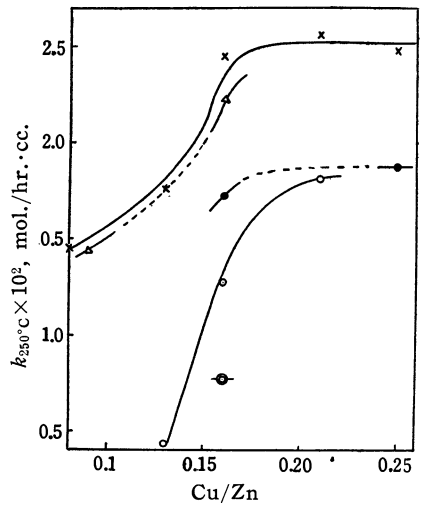

Fig. 2. Catalytic activity as a function of Cu/Zn ratio.
×, Cr/Zn=0.49, △, Cr/Zn=0.89,
●, Cr/Zn=0.65, ○, Cr/Zn=0.55,
◎, cat. R.

The activity thus defined is plotted as a function of chemical composition of the catalysts in Fig. 2. Regarding a series of catalysts of Cr/Zn ratio of 0.49 with varying Cu/Zn ratios, curves in the figure show a rapid initial increase in activity with increasing Cu/Zn ratio, followed by a portion with a smaller slope, and finally

no further increase in the range of Cu/Zn ratios higher than 0.17, while with a series of catalysts with the fixed Cu/Zn ratio of 0.16 and with varying Cr/Zn ratios they show a maximum activity appearing at the Cr/Zn ratio of 0.49.

By-products, such as water and isobutanol, are extremely small in amount (less than 0.7%) in the products at temperatures lower than 270°C, and it makes little difference, whether the catalyst is in state-A or state-B. At higher temperatures the amounts become greater, e. g. attaining to contents of 10% water and 1.4% isobutanol in the product at 360°C. There have been found no alcohols other than isobutanol. Very small quantities of formaldehyde (less than 0.1%) have always been found in the products of the present study.

**Catalyst Bed Density.** — The catalyst bed density after the synthesis is plotted against the chemical composition of the catalyst in Fig. 3, in which it may be seen that the bed density rises with Cr/Zn ratio up to the high value of 1.47 for a catalyst of an appropriate composition. In contrast to this, catalysts of the usual manufacturing procedures, such as catalyst R and a pelleted catalyst in an industrial use, give lower bed densities of 0.808 and 1.15, respectively.

Naturally the catalyst bed density parallels the bulk density of catalyst granules. It is not because the true density

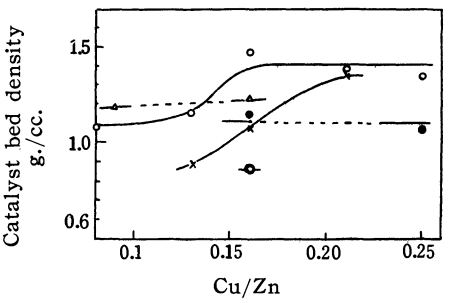

Fig. 3. Catalyst bed density as a function of Cu/Zn.

×, Cr/Zn=0.55, ●, Cr/Zn=0.65,
◎, cat. R.

of catalyst granules is high, but because the pore volume in the granules is extremely small, that the present catalyst gives a high value of the bulk density (refer to Table III). As shown in the table, the bulk density of a raw catalyst can not be correlated directly to that of a reduced one, since the raw one contains an appreciable indefinite quantity of crystallization water.

**Specific Surface Area.** — Specific surface areas of the raw and the reduced catalysts are summarized in Table II. The table discloses that the specific surface area is enlarged remarkably by reduction of the raw catalyst to state-A, and further, but in less degree, by subsequent reduction to

state-B. The present catalysts give much higher surface areas than the zinc oxide-chromium oxide catalysts in the authors' previous paper.

A high extent of specific surface area once obtained on a catalyst in state-B is diminished, by slow oxidation of state-B to state-A, to a smaller area which is approximate to the former area of the catalyst in state-A, with simultaneous recovery of the activity.

**Loss and Gain of Oxygen with Reduction and Oxidation of Catalyst.**—The different states of a catalyst, state-A, −B, and −A′, appeared to be related to different oxygen contents of the catalyst. In this respect, changes in weight of catalyst No. 6 with repeated reduction and oxidation have been pursued in some detail. The results are given in Fig. 4, in which changes in

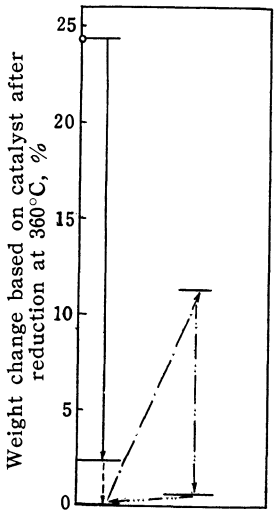

Fig. 4. Changes in weight of catalyst with reduction and oxidation.
○, raw catalyst, ——, reduction at 250°C, ------, reduction at 360°C, —·—·, oxidation at room temperature, —··—··, reduction at 250°C, ——···——, reduction at 360°C.

weight are expressed in per cent increase based on the catalyst weight in state-B. By reduction of the raw catalyst at 250°C, decrease in weight takes place to a remarkable extent, the major part of which is presumably due to release of crystallisation water from the raw catalyst. Subsequent reduction from state-A to state-B accompanies the further decrease in weight, whose major part may probably be due to loss of oxygen[7]. After slow oxidation of the resulting catalyst in dry air at room temperature, gradual take-up of oxygen takes place till it, after a week, attains to as great an amount as 11.3% weight increase. The major part of the oxygen can readily be liberated by reduction at 250°C, and state-A′ is established. On the other hand, it should be emphasized that the gradual oxygen take-up is also observed for zinc oxide-chromium oxide catalysts, though it is of a much smaller amount, e. g. 2.4% increase for a catalyst of Cr/Zn ratio of 0.5.

**Catalyst Structure Revealed by X-ray Diffraction Patterns.** — Among the catalysts, catalysts No. 6 and R were subjected to an X-ray examination. Both of the raw catalysts gave diffraction lines due to zinchydroxychromates I$\beta$ and II$\beta$, with no signs of oxides of copper. With catalyst No. 6 the latter hydroxychromate develops to greater crystallites than the former one, whereas with catalyst R the situation is the opposite. In this respect the authors' previous paper reported that a catalyst of Cr/Zn ratio of 0.49, with no copper, consisted of zinchydroxychromate I$\beta$ alone, and that zinchydroxychromate II$\beta$, together with zinchydroxychromate I$\beta$, appeared only in a catalyst of the smaller ratio. In the present catalysts of high Cr/Zn ratios, zinchydroxychromate II$\beta$ may gradually appear, because the part of chromic acid is consumed by the preferential combination with copper oxide to produce copper chromate. However, no evidence of either copper chromate or cupric chromite has been found in the diffraction diagram, even after the sintering of the catalyst at 600°C[8]. The results also show that in the manufacturing of the present catalysts chromic acid tends to combine with copper oxide more readily than it does in that of catalyst R.

After the synthesis, catalysts No. 6 and R gave no diffraction lines other than the diffused ones due to cuprous oxide[9]. This does not necessarily indicate that the crystallite, such as those of oxides of zinc and chromium or those of zinc chromite, are completely absent in the catalyst

7) The decreases are in the range of 1~3.5% for individual catalyst of the present series. No definite relationship between the extent of decrease and chemical composition has been found.

8) Refer to Stroupe's paper: J. D. Stroupe, *J. Am. Chem. Soc.*, 71, 589 (1949).

9) The crystallites of cuprous oxide may perhaps be produced, during the taking of the diagram, by reoxidation of copper crystallites produced by reduction, though necessary care, such as the leaching of the specimen in methanol, has been taken.

granules, but that the crystallites are too finely dispersed to be detected by an X-ray examination. The diffration lines of cuprous oxide remain essentially unchaned, whether the catalysts are in state-A or state-B. From the diffusivity of the diffraction lines, a rough calculation of the width of cuprous oxide crystallites was made by the aid of Scherrer's formula. The width has proved to be about 50 Å.

## Discussion

**Catalytic Activity and Catalyst Bed Density.**—Fig. 5. presents the relationship between the catalytic activity and the catalyst bed

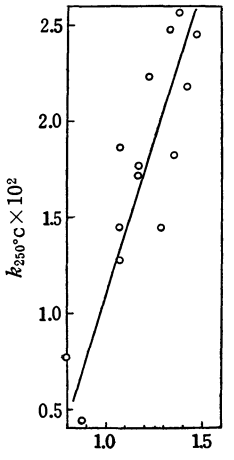

Fig. 5. Relationship between catalytic activity and catalyst bed density.

density, and an approximate proportionality has been found existing between them. The present catalyst owes the fact that it has such a high catalytic activity mainly to the high catalyst bed density. The high catalyst bed density is characteristic of the catalysts made by the present procedure.

**Specific Surface Area and Specific Catalytic Activity.**—With the present catalysts, hardly any relationship between catalytic activity and the extent of the specific surface area has been found. On the other hand, specific activity, namely, activity expressed per unit surface area, tends to increase slowly with copper content throughout the range of the present study (refer to Fig. 6). The tendency, however, is only a minor factor influencing the catalytic activity which is considered on the basis of unit volume of the catalyst bed or unit mass of the catalyst granules. Catalyst R gives a very low specific activity.

**Activation Energy and Frequency Factor of Synthesis.**—Arrhenius' plots are linear with slopes corresponding to an activation energy of 16.6 kcal./mol. for individual catalysts in state-A, and another one of 21.9 kcal./mol. for individual ones in state-B, respectively. Present values of the activation energy are much lower than those of zinc oxide (34.6 kcal./mol.) and zinc oxide-chromium oxide catalysts (e. g. 27.4 kcal./mol. for a catalyst of the Cr/Zn ratio of 0.5).

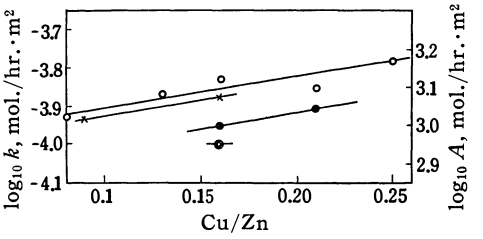

Fig. 6. Specific catalytic activity or frequency factor per unit surface area as a function of Cu/Zn.
○, Cr/Zn=0.49, ×, Cr/Zn=0.39,
●, Cr/Zn=0.55, ◎, cat. R.

By the choice of an adequate scale for the ordinate, the same straight line as cited in Fig. 6 can reveal the relationship between the frequency factor based on unit surface area and the Cu/Zn ratio, since the catalysts give a constant activation energy independently of the varying Cu/Zn ratios[10]. In contrast to the present catalysts, the zinc oxide-chromium oxide catalysts usually showed much higher values of the frequency factor per unit surface area (e. g. $0.5^{-2}$ mol./hr.·m² for the catalyst of Cr/Zn ratio of 0.5). This enables the authors to expect a steep rise of the frequency factor with decreasing Cu/Zn ratios in a range of the extremely low ratios, when the above mentioned straight line relationship is also taken into account. No experimental data, however, are available to demonstrate the expectation as yet.

The catalyst always changes its state from A to B with simultaneous increase of both the activation energy and the frequency factor per unit surface area.

**State-A and State-B of Catalyst.**—It is not because of the sintering of the catalyst granules that a decrease in catalytic

10) From the results, a premise is possible that all active centers are alike, appearing more frequently on the catalyst surface with increasing copper content.

activity appears with the change of the catalyst state from state-A to B, but it is because of a decrease in specific catalytic activity per unit catalyst surface. This is apparent from the rather larger specific surface area for the catalyst in state-B. At first sight, the sintering of copper crystallites, as revealed by the appearance of the diffraction lines due to cuprous oxide in the diagram, seemed to have a great influence upon the specific catalytic activity. This, however, can not be true, because the same diffraction lines appear in the diagram of the catalyst in state-A' of an activity approximate to state-A.

Among structural factors of the catalyst here investigated, only the oxygen content of catalysts seems to have an influence upon the specific catalytic activity. Oxygen of this kind is remarkably increased in amount by an addition of copper oxide. It is increased to such an extent that it is much greater than that estimated to be produced by the reduction of cupric oxide to copper. The oxygen may thus come partly from copper oxide, but also from some other kinds of oxides of high oxidation stage at which the oxygen is rather loosely bound, namely, oxide of chromium. In this respect, the X-ray diffraction diagram has revealed that, by an addition of copper oxide, crystallites of chromium oxide or zinc chromite become more finely dispersed in the catalyst. Chromium oxide in extremely fine dispersion is reasonably expected to be capable of being oxidized more readily to high valency states (refer to the papers of Selwood[11] and others[12,13]).

## Summary

A preparative procedure in which copper oxide is introduced into the catalyst by a different way from the usual ones has presented the catalyst of high catalytic activity for the methanol synthesis. The catalyst owes its high catalytic activity to three structural factors, namely, a high catalyst bed density, a larger extent of specific surface area, and a great amount of oxygen loosely bond in catalyst oxides, among which the first factor plays the most important role. The last is effective in improving the specific catalytic activity based on unit surface area, and is in a close relation to the two states, A and B, of different catalytic activities.

The authors of this paper wish to thank Mr. S. Kato of Tokyo Institute of Technology for taking X-ray diagrams.

# *On The Mechanism of the Extraction of Uranyl Nitrate by TBP* (Partition Study)*

By Keiji NAITO

(Received July 23, 1959)

The TBP (tri-*n*-butyl phosphate) extraction has been extensively employed for the uranium refining and the reprocessing of reactor spent fuel. A number of researches on this subject have appeared[1], and the mechanism of the uranium extraction by TBP was already proposed by Moore[2] as follows:

$$UO_2^{2+}(aq.) + 2NO_3^-(aq.) + 2TBP(org.) \rightleftarrows UO_2(NO_3)_2(TBP)_2(org.) \quad (1)$$

The more rigorous analysis for the mechanism of TBP extraction was made by McKay et al.[3-5] and the mechanism of uranium extraction was confirmed as Eq. 1 proposed by Moore.

* This study was presented at the 1st Symposium on Atomic Energy, Tokyo, January 13, 1957, and the 1st Symposium on Radiochemistry, Tokyo, December 21, 1957.

1) For example, R. I. Smith, TID-3502.

2) R. L. Moore, AECD-3196 (1951).

3) K. Alcock et al., *Trans. Faraday Soc.*, **52**, 39 (1956).

4) T. V. Healy and H. A. C. McKay, ibid., **52**, 633 (1956).

5) E. Hesford and H. A. C. McKay, ibid., **54**, 573 (1958).

The extraction of the nitric acid by TBP was also observed by Moore[2] and the following mechanism was proposed,

$$HNO_3(aq.) + TBP(org.) \rightleftarrows HNO_3 \cdot TBP(org.) \quad (2)$$

The formation of the complex $HNO_3 \cdot TBP$ was supported by McKay et al.[3] and the behavior of uranium on the TBP extraction from a nitric acid solution was concluded as a result of the competition of uranium and nitric acid[4].

The object of the present work is to propose a method of analysis to confirm the formation of a complex and to apply this analysis to the extractions of uranyl nitrate and nitric acid with TBP. The discussion for the extraction behavior of uranium from nitric acid solution by TBP is the second object of this work and thirdly the thermochemical functions for this kind of complex formation are to be determined.

## Experimental

**Reagents.**—The reagents used in these experiments are as follows:

*A) TBP.*—The TBP (tri-*n*-butyl phosphate) was used after vacuum distillation.

*B) Uranyl nitrate.*—Uranyl nitrate was obtained from British Drug Houses Ltd. and was used after recrystallization.

*C) Diluents.*—As diluents, carbontetrachloride and kerosene were used. Boiling point range of kerosene used in the experiments is 190~260°C, specific gravity (15/4°C) is 0.8094.

**Equipment and Method.**—The Measurements of the distribution equilibrium were always made at constant temperature using a thermostated water bath. The separatory funnels were specially designed in order to be easily dipped into the water bath. The method for the measurement of distribution coefficients was the following. The necessary volumes of both aqueous and organic phases were put into a separatory funnel, which was dipped in the water bath. After the temperature had reached equilibrium, shaking of about one minute was repeated at intervals of fifteen or twenty minutes. Both phases were separated rapidly after an equilibrium time of about three or four hours. A centrifuge was used in the case where the separation was difficult. The distribution coefficients of both uranium and nitric acid were obtained by analyzing both in the aqueous phase.

The methods of analysis are the following. For uranium, the alkaline peroxide method[6] was adopted and a Hitachi EPU-2 spectrophotometer was used for the determination (at $\lambda = 400\ m\mu$). For nitric acid, the uranium peroxide precipitation method[7] was taken.

**Notation.**—$C_M$ and $C'_M$ denote the equilibrium concentrations of a species M in aqueous and organic phases respectively. $Kd(M)$ denotes the distribution coefficient of the species M ($=C'_M/C_M$). $a_M$ is the activity of the species M in aqueous phase or organic phase, and $f_M$ is its activity coefficient.

## Results and Discussion

**Distribution Equilibrium.**—Prior to a discussion about the extraction mechanism, a general survey of distribution equilibrium of uranium between the aqueous and TBP phase was made. The results of the measurement can be summarized briefly as the following.

(a) In case nitric acid is added, the distribution coefficient of uranium is constant when the uranium concentration is low and the nitric acid concentration is kept constant, on the other hand, when nitric acid is absent, a constant distribution coefficient can not be obtained.

(b) The uranium concentration in organic phase increases with the uranium concentration in aqueous phase and reaches a constant which corresponds to the uranium concentration of $UO_2(NO_3)_2 \cdot (TBP)_2$ in organic phase as pointed out by Moore[2].

(c) The distribution coefficients of uranium increases with the nitric acid concentration in aqueous phase and reaches a maximum value, and then decreases gradually. Fig. 1 shows the influence of nitric acid concentration upon the distribution coefficient of uranium at various uranium concentrations.

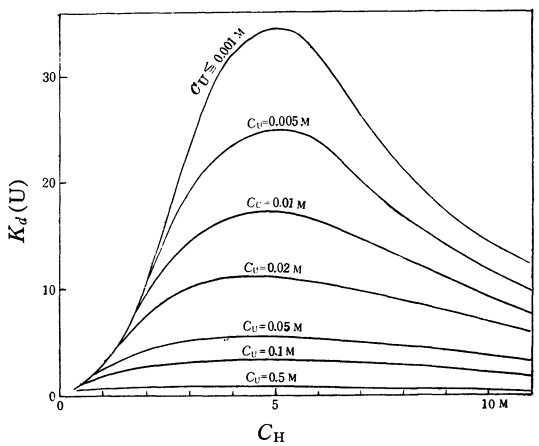

Fig. 1. Influence of nitric acid concentration upon the distribution coefficient of uranium at various concentrations.

6) C. J. Rodden and J. C. Warf, "Analytical Chemistry of the Manhattan Project", (National Nuclear Energy Series VIII-1(1950)).

7) R. E. Connik, MDDC-1245 (1945).

(d) The distribution coefficient of uranium is nearly proportional to the square of the TBP concentration in the organic phase when the concentrations of uranium and nitric acid are low and the nitrate concentration is held constant.

(e) The distribution coefficient of uranium decreases with the increase of temperature.

(f) The distribution coefficient of nitric acid coexisting with uranium decreases gradually with the increase of the uranium concentration in aqueous phase, but in the case where the nitric acid concentration is low the distribution coefficient of uranium reaches a maximum value and then decreases gradually.

(g) The influence of the nitric acid concentration in the aqueous phase on the distribution coefficient of nitric acid is markable when the uranium concentration is low. However, this influence becomes smaller with the increase of the uranium concentration in aqueous phase, and finally the distribution coefficient of nitric acid becomes nearly constant against the concentration of nitric acid in aqueous phase when the uranium concentration is higher than 0.1 M (Fig. 2).

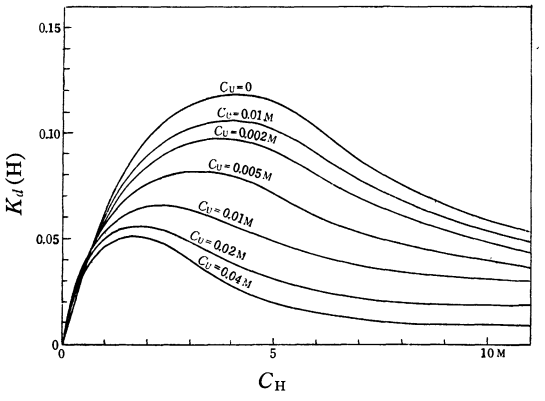

Fig. 2. The distribution coefficient of nitric acid coexisting with uranium.

From the above-mentioned distribution equilibrium of uranium, several pieces of information about the mechanism of the extraction of uranium can be obtained.

Facts b) and d) indicate that formation of the uranium complex with TBP in organic phase is likely. Therefore, it is possible to expect the following complex formation reaction considering the salting-out effect of nitrates on the extraction of uranium,

$$\mu UO_2^{2+}(aq.) + 2\mu NO_3^-(aq.) + \nu TBP(org.) \rightleftarrows [UO_2(NO_3)_2]_\mu(TBP)_\nu(org.) \quad (3)$$

where $\mu$ and $\nu$ are positive integers. The determination of $\mu$ and $\nu$ will be discussed later.

It is estimated from fact e) that this reaction should be an exothermic reaction.

Facts c) and f) also suggest that nitric acid is extracted together with uranium by TBP and both of these extraction reactions take place competitively.

**Method of Analysis for an Extraction Mechanism.**—Although there are several types of mechanisms by which a solute in aqueous phase can be extracted by organic solvent, one is the " mass-action " reaction between the solute ions and the organic solvent molecules as shown by Eq. 3.

This kind of extraction mechanism such as Eq. 3 is written as the following general expression,

$$\mu M^{n+}(aq.) + (n/m)\mu X^{m-}(aq.) + \nu S(org.) \rightleftarrows (MX_{n/m})_\mu S_\nu(org.) \quad (4)$$

where

$M_mX_n$=inorganic solute ($M^{n+}$=cation, $X^{m-}$=anion)

S=organic solvent (extractant)

$\mu$ and $\nu$=positive integers.

The purpose of the analysis is to obtain the value of $\mu$ and $\nu$ respectively without contradiction. The equilibrium constant ($K$) for Eq. 4 is given as

$$K=(a_{complex})/(a_M)^\mu(a_X)^{(n/m)\mu}(a_S)^\nu, \quad (5)$$

where $a$ is the activity in aqueous phase or in organic phase and $a=fC$.

When the concentration of the solute is low, the ratio of the number of bonded solvent molecules to that of free solvent molecules is very small, so that Eq. 5 becomes

$$K=(f_{complex})(C_{complex})/(f_MC_M)^\mu(a_X)^{(n/m)\mu}(a_S^0)^\nu \quad (6)$$

where $a_S^0$ is the activity of the extractant solvent which corresponds to the initial concentration of extractant solvent in organic phase. In Eq. 6, $f_{complex}$ is determined by the concentration of solvent in organic phase so that both $f_{complex}$ and $a_S^0$ are constant at constant concentration of solvent.

If it is assumed that all M ions in organic phase are related to the formation of the complex, the following relation is obtained :

$$C_{complex}=C_M'/\mu \quad (7)$$

Then from Eqs. 6 and 7, considering the relation: $C_{complex}/C_M=Kd(M)$

$$Kd(M)=\text{const.}\ (f_M{}^{\mu}/f_{complex})\cdot (C_M)^{\mu-1}(a_X)^{(n/m)\mu}(a_S{}^0)^{\nu} \quad (8)$$

From Eq. 8, the integers in Eq. 4 are determined experimentally as follows.

*(1) Determination of* $\mu$.—In the case where the salting-out agent is absent, the activity $a_X$ can be replaced with the concentration $C_X$, and $f_M$ becomes unity, and $C_X$ is determined uniquely by $C_M$ as $(n/m)C_M$. When the distribution coefficient of M is measured at constant solvent concentration, $f_{complex}$ and $a_S{}^0$ are constant, as has been stated, so that Eq. 8 becomes

$$Kd(M)\cong\text{const.}\ (C_M)^{(1+n/m)\mu-1} \quad (9)$$

Thus by plotting $\log Kd(M)$ against $\log C_M$ the slope of the line indicates the value of $(1+n/m)\mu-1$, from which $\mu$ can be determined.

In the case where the salting-out agent exists, $C_X$ is determined by both $C_M$ and the concentration of the salting-out agent. If one adds a large amount of salting-out agent compared with $C_M$ (which is low), both $C_X$ and the ionic strength of the aqueous solution are mainly determined by the concentrationof the salting-out agent. Thus, when the distribution coefficient of M is measured at constant solvent concentration keeping the concentration of salting-out agent constant, Eq. 8 becomes

$$Kd(M)\cong\text{const.}\ (C_M)^{\mu-1} \quad (10)$$

because $f_M$ and $a_X$ are constant at costant ionic strength of the aqueous phase and $f_{complex}$ and $a_S{}^0$ are constant at constant solvent concentration. Thus, by plotting $\log Kd(M)$ against $\log C_M$ one can determine $\mu$ from the slope of the line.

*(2) Determination of* $\nu$.—When the distribution coefficient of M is measured, keeping the aqueous phase concentration of M constant, and also keeping the concentration of the salting-out agent constant (if the salting-out agent exists), Eq. 8 becomes

$$Kd(M)\cong\text{const.}\ ((f_S{}^0)^{\nu}/f_{complex})(C_S{}^0)^{\nu} \quad (11)$$

where $f_S{}^0$ is the activity coefficient for $C_S{}^0$. Unfortunately both $f_S{}^0$ and $f_{complex}$ are the function of the solvent concentration $C_S{}^0$, and the determination of these activity coefficints for various solvent concentrations is not easy. However, if the measurement is made at low solvent concentration, the slope which is obtained by plotting $\log Kd(M)$ against $\log C_S{}^0$ roughly indicates the value of $\nu$, because the deviation from the ideal solution becomes smaller according to the dilution of the solution.

The above-mentioned method is applicable to any reaction of the type of Eq. 4; however, it should be noticed that this method stands upon the assumption that all M ions in organic phase are combined with the solvent molecules. If this assumption does not exist, the method of analysis will become more complicated. On the other hand, when one can determine the integers $\mu$ and $\nu$ without contradiction under this assumption, one recognizes the validity of this assumption. An attention should be given to the case in which the successive complex formation by anion takes place according to the increase of the anion concentration, for example,

$$UO_2{}^{2+}+NO_3{}^- \rightleftarrows UO_2(NO_3)^+,$$

$$UO_2(NO_3)^+ + NO_3{}^- \rightleftarrows UO_2(NO_3)_2$$

Since the above-mentioned method of analysis is adopted for a low concentration region of the solute, this method can be applied without correction in case the salting-out agent is absent. In the case salting-out agent is added, the successive formation of the complex by anion will be expected, but the method is still applicable without correction, because the ionic strength of the solution is kept nearly constant. However, if an anionic complex such as $UO_2(NO_3)_3{}^-$, $UO_2(NO_3)_4{}^{2-}$, etc., is formed, the treatment must be changed.

Although this kind of method of analysis was used at first by Moore[2], the treatment was not rigorous. Eq. 11 was also derived by McKey et al.[5] and $\nu$ was called the solvation number. It is important, however, to confirm the existence of "mass-action" reaction for the solvent extraction process by applying the above-mentioned analysis.

**Mechanisms of the Extraction for Uranium and Nitric Acid.**—*(1) Uranyl nitrate extraction by TBP.*—The integers $\mu$ and $\nu$ in Eq. 3 were determined by applying the abovementioned method in the following way.

$\mu$ is determined easily as $\mu=1$ from fact a) and Eq. 10 in case the salting-out agent exists. However, in case the salting-out agent is absent, no linear relation between $\log Kd(U)$ and $\log C_U$ was observed while a linear relation was expected from Eq. 9. This means that the mechanism of extraction in this case is not consistent with

the mechanism postulated in Eq. 3, and uranyl nitrate must be hydrolyzed, especially in the low concentration region and in the case where no acid exists, so that the mechanism of extraction must change.

$\nu$ was determined as $\nu = 2$ by applying Eq. 11. The linear relation between $\log[Kd(\mathrm{U})/(a_{\mathrm{NO_3}})^2]$ and $\log C^0_{\mathrm{TBP}}$ was observed as $\nu=2$ for the low TBP concentration region.

Accordingly one obtained the same mechanism as that proposed by Moore for uranyl nitrate extraction by TBP. Though the same result was obtained, it should be noticed that the existence of this mechanism was confrimed beyond doubt by this analysis and this mechanism does not exist when the hydrolysis of uranium takes place.

On the extraction of uranium from a nitric acid solution by TBP, it was already observed that nitric acid coexisting with uranium is not only effective as a salting-out agent, also extractable together with uranium by TBP, so that the mechanism of the extraction of nitric acid should also be studied in order to clarify the mechanism of the extraction of the U-$HNO_3$-TBP system.

*(2) Nitric acid extraction by TBP.*—One can expect the reaction of nitric acid with TBP molecules as expected in the case of uranyl nitrate extraction, then

$$\mu H^+(\mathrm{aq.}) + \mu NO_3^-(\mathrm{aq.}) + \nu \mathrm{TBP(org.)} \rightleftarrows (HNO_3)_\mu(\mathrm{TBP})_\nu(\mathrm{org.}) \qquad (12)$$

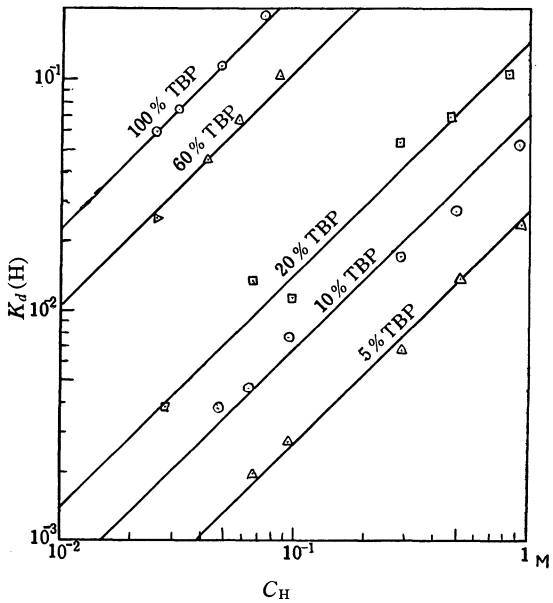

Fig. 3. Determination of $\mu$ in case the salting-out agent is absent.

The integers $\mu$ and $\nu$ in Eq. 12 can be determined as follows.

*(a) Determination of $\mu$.*—In the case where the salting-out agent exists, $\mu$ is determined by Eq. 10. The result of the measurement of $Kd$(H) for dilute nitric acid when sodium nitrate is added as a salting-out agent shows that $Kd$(H) is constant independent of $C_H$ when the concentration of salting-out agent is kept constant. Then, by applying to Eq. 10, $\mu$ is determined as $\mu=1$.

In the case where the salting-out agent is absent, $\mu$ is determined by Eq. 9, Fig. 3 was obtained by plotting $Kd$(H) againts $\log C_H$ at 25°C for TBP-kerosene system. The existence of a linear relation is observed and the slope of this line is 1 independently with TBP concentration. An essentially the same result was obtained when the diluent is carbon tetrachloride. Then, from Eq. 9, $\mu$ is determined again as $\mu=1$.

*(b) Determination of $\nu$.*—The value of $\nu$ is determined by using Eq. 11. Fig. 4 was obtained by plotting $\log Kd$(H) against $\log C^0_{\mathrm{TBP}}$ at 25°C, where the diluent is carbon tetrachloride. In this figure, the lines A and A′ are for the case no

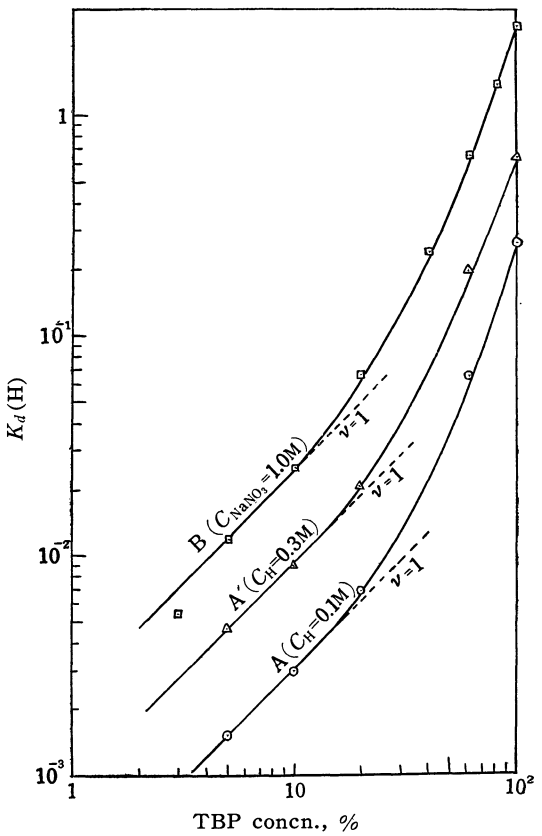

Fig. 4. Determination of $\nu$.

salting-out agent exists and the line B is for the case the salting-out agent exists (1 M $NaNO_3$). It is noteworthy that both A (A′) and B give nearly the same results. For a region where the TBP concentration is low, the linear relations are obtained and slopes are 1 for each case. The essentially the same results are obtained in case the diluent is kerosene. Then, from Eq. 11, $\nu$ is determined as $\nu=1$.

However, in a region where the TBP concentration is higher, the slopes are changing from one to two. It is not clear at the present stage whether this is based upon the change of activity coefficients ($f_S^0/f_{complex}$) in Eq. 11 or the formation of a complex $HNO_3(TBP)_2$.

As a result of above-mentioned analysis for the $HNO_3$–TBP system, the mechanism of the nitric acid extraction by TBP was confirmed as

$$H^+(aq.) + NO_3^-(aq.) + TBP(org.) \rightleftarrows HNO_3 \cdot TBP(org.) \quad (13)$$

On the other hand, Moore proposed Eq. 2 as the mechanism of nitric acid extraction by TBP. This mechanism was derived from the fact that $Kd$(H) is nearly constant, independent of the nitric acid concentration in the case of uranium extraction. However, as shown in fact g) this is true only in case the uranium concentration is higher than about 0.1 M, and his observation was made just in this range ($C_U=0.1\sim0.4$ M). So it is not suitable to discuss the mechanism of nitric acid extraction basing only on this fact. It may be reasonable to interpret this fact as a result of the competition of uranium and nitric acid as will be discussed later.

**Competition of Uranium and Nitric Acid.**—It has been clarified that both uranium and nitric acid are extracted according to the above-mentioned mechanisms. With these mechanisms, the behavior of both uranium and nitric acid during the extraction process should be interpreted as follows.

*(1) Simultaneous partition of uranium and nitric acid.*—In case uranium is extracted from a nitric acid solution by TBP, the distribution equilibria of Eqs. 1 and 13 should be established simultaneously. Then, one obtains the following simultaneous equations,

$$K(U) = [f_{complex}(U)/(f_{\pm}(U))^3] \cdot [Kd(U)/C_{NO_3})^2(a_{TBP})^2] \quad (14)$$

$$K(H) = [f_{complex}(H)/(f_{\pm}(H))^2] \cdot [Kd(H)/(C_{NO_3})(a_{TBP})] \quad (15)$$

where $K$(U) and $K$(H) are the equilibrium constants of uranium for Eq. 1 and of nitric acid for Eq. 13, $f_{\pm}$(U) and $f_{\pm}$(H) are the mean activity coefficients of uranyl nitrate and of nitric acid.

When the concentrations of both uranium and nitric acid are low, if one keeps the ionic strength of solution constant, the activity coefficient in aqueous phase is kept nearly constant, and the activity coeficients of the complex in organic phase are nearly constant because the concentration is very low. In such a case, the following relation is obtained :

$$\log Kd(H) \cong (1/2) \log Kd(U) + \text{const.} \quad (16)$$

This relation was confirmed by Fig. 5

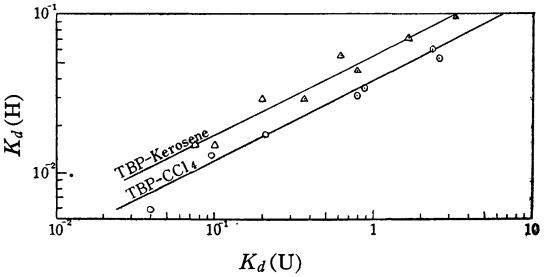

Fig. 5. Existence of simultaneous partition of both uranium and nitric acid.

which was obtained from the measurements under the uranium concentration range : 0.005~0.05 M, and the nitric acid concentration range : 0.1~1 M and at TBP 20%, 25°C. Though this measurement was made at various ionic strengths, the linear relationship is still observed in both the TBP-$CCl_4$ system and the TBP-kerosene system, and the slopes are both 1/2.

By this analysis, it was confirmed that when uranium is extracted from a nitric acid solution by TBP, both the extraction reaction of uranium shown by Eq. 1 and the extraction reaction of nitric acid shown by Eq. 13 take place simultaneously.

*(2) The influence of the nitric acid concentration upon Kd(U).*—In the distribution equilibrium of uranyl nitrate, $Kd$(U) has its maximum value against the change of $C_H$ as shown by fact c). This can be interpreted as a result of the competition of both uranium and nitric acid in the following way.

In the case where the concentration is low, if one replaces the activity by the concentration in order to make the discussion simple, the following simultaneous equations exist approximately,

$$K(U) \cong Kd(U)/C_H^2(C^0_{TBP} - C_H')^2 \quad (17)$$

$$K(\mathrm{H}) \cong C_{\mathrm{H}}'/C_{\mathrm{H}}^2(C^0{}_{\mathrm{TBP}}-C_{\mathrm{H}}') \qquad (18)$$

where $C^0{}_{\mathrm{TBP}}$ represents the initial concentration of TBP in organic phase. From Eqs. 17 and 18 by eliminating $C_{\mathrm{H}}'$,

$$Kd(\mathrm{U}) = K(\mathrm{U})\,[C_{\mathrm{H}}C^0{}_{\mathrm{TBP}}/(1+K(\mathrm{H})C_{\mathrm{H}}^2)]^2 \qquad (19)$$

Eq. 19 gives the relation between $Kd$(U) and $C_{\mathrm{H}}$ in a region where the uranium concentration is low. It can easily be shown from Eq. 19 that $Kd$(U) increases with the increase of $C_{\mathrm{H}}$, reaches a maximum value, then decreases gradually. Furthermore, the maximum value of $Kd$(U) is obtained from Eq. 19 as $K(\mathrm{U})\,(C^0{}_{\mathrm{TBP}})^2/4K(\mathrm{H})$ at $C_{\mathrm{H}}=1/\sqrt{K(\mathrm{H})}$. If one takes $K(\mathrm{U})=27$, $K(\mathrm{H})=0.08$ as the values of equilibrium constants respectively at 25°C, TBP 20% (these values were obtained tentatively as the equilibrium constants), one obtains as the calculated values: $Kd(\mathrm{U})_{\max}=45$ at $C_{\mathrm{H}}=3.5$ M. These correspond to the following experimental values: $Kd(\mathrm{U})_{\max}=34$ at $C_{\mathrm{H}}=5$ M. Considering that this calculation was made using the concentration instead of the activity, the agreement seems to be fairly good.

In case the uranium concentration is higher, although the calculation becomes more complicated, one can obtain a similar result.

Accordingly, it was confirmed that fact c) is interpreted as the result of the competition of both uranium and nitric acid as was pointed out by Moore[2] and McKay[4,8]. From this point of view, facts f) and g) are also interpreted as the result of the competition of both.

*(3) Nitric acid and sodium nitrate as salting-out agent.* — On the extraction of uranium from a nitric acid solution, it was clarified that both uranium and nitric acid are extracted by TBP competitively. Accordingly, it is interesting to observe the behavior of the extraction of uranium when the salting-out agent which is not extractable by TBP is added.

Sodium nitrate was chosen as one of those agents that are suitable for this purpose. The salting-out effects of both nitric acid and sodium nitrate for diluted uranyl nitrate are shown in Fig. 6 which was made at 25°C, TBP 20% (in the case of sodium nitrate, 0.5 M nitric acid is added in order to prevent the hydrolysis of uranium).

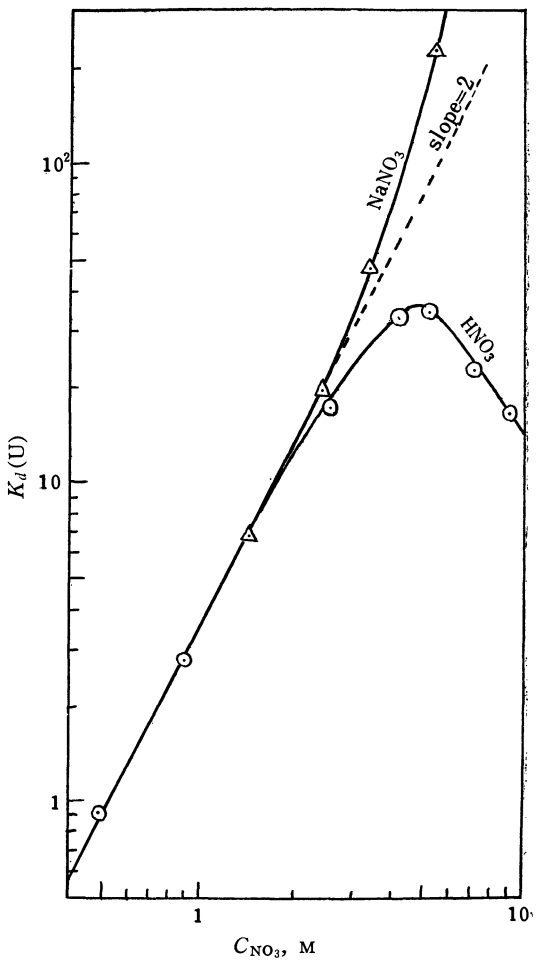

Fig. 6. The salting-out effect of both nitric acid and sodium nitrate for diluted uranyl nitrate.

It is obvious from Fig. 6 that, in the case of nitric acid, $Kd$(U) has the maximum at $C_{NO_3}$ of nearly 5 M; and in the case of sodium nitrate, $Kd$(U) increases monotonously and is nearly proportional to the square of $C_{NO_3}$.

When the salting-out agent is not extracted by TBP and contributes only to the increase of the concentration of $NO_3^-$, one obtains the relation: $Kd(\mathrm{U}) = \text{const.} \times (C_{NO_3})^2$ from Eq. 14 by ignoring the activity coefficient. Then $Kd$(U) is nearly proportional to $(C_{NO_3})^2$. It can also be understood from this analysis that little sodium nitrate is extracted by TBP and is effective only as a salting-out agent for the uranium extraction.

However, it is noteworthy that when the concentration of nitric acid is low, nitric acid is also effective mainly as a salting-out agent. This is observed from

8) H. A. C. McKay, "Int. Conf. Peaceful Uses of Atomic Energy", United Nations, (1955), p./441.

Fig. 6 and is also derived from Eq. 19 as $Kd(U)=\text{const.}(C_H)^2$ by considering $C_H$ is small. This relation just corresponds to the relation $Kd(U)=\text{const.}(C_{NO_3})^2$, therefore, nitric acid is effective mainly as a salting-out agent when its concentration is low.

**Rough Determination of the Thermochemical Functions of the Reaction of Uranyl Nitrate and TBP.**—Although the existence of the complex with TBP such as $UO_2(NO_3)_2(TBP)_2$, $HNO_3 \cdot TBP$ was confirmed, the nature of these complexes remains uncertain. At first the measurement of the thermochemical functions was tried.

$\Delta H^0$, $\Delta F^0$ and $\Delta S^0$ are defined as the enthalpy change, the Gibbs' free energy change and the entropy change respectively for Eq. 1 when the activities of each species of Eq. 1 are unity. These thermodynamical functions are determined roughly by using the distribution coefficient as the following.

*(1) Enthalpy change.* — By applying a thermodynamical relation for the reaction of Eq. 1

$$(\partial \ln K(U)/\partial T)_P = \Delta H^0/\boldsymbol{R}T^2 \qquad (20)$$

The equilibrium constant $K(U)$ is given as Eq. 14. If one keeps both the concentration of salting-out agent and the concentration of TBP constant, the equilibrium constant $K(U)$ becomes

$$K(U)=\text{const.}\,[f_{\text{complex}}/(f_{\pm}(U))^3 \times (f_{TBP})^2]\,Kd(U) \qquad (21)$$

When the concentration is low, the temperature dependence of the activity coefficient is very small, so that one can obtain the following relation from Eqs. 20 and 21

$$(\partial \ln Kd(U)/\partial T)_P \cong \Delta H^0/\boldsymbol{R}T^2 \qquad (22)$$

If one assumes that $\Delta H^0$ is constant for the integration range, from Eq. 22

$$\ln Kd(U) \cong \text{const.} - \Delta H^0/\boldsymbol{R}T \qquad (23)$$

Thus by plotting $\log Kd(U)$ vs. $1/T$ the slope of the line indicates the value $-\Delta H^0/\boldsymbol{R}$, from which $\Delta H^0$ can be obtained.

The measurement of the distribution coefficient of uranium was made at 10, 25 and 50°C, respectively. The concentration of uranium in this measurement is low enough to neglect the temperature dependence of the activity coefficient and to keep the concentration of TBP constant.

The linearity between $\log Kd(U)$ and $1/T$ was observed obviously in both the TBP-$CCl_4$ system and the TBP-kerosene system, and the slopes in both systems were exactly the same. Then, the enthalpy change $\Delta H^0$ was obtained by measuring the slope of the line as

$$\Delta H^0 = -4.3\,\text{kcal.} \quad (10\sim50°C)$$

This value has nearly the same order of the bonding energy of the hydrogen bond, so that it can be estimated that the bond strength or stability of this complex should be of nearly the same order as those of the hydrogen bond.

*(2) Gibbs' free energy change.* — Gibbs' free energy change $\Delta F^0$ for the reaction of Eq. 1 is given as

$$\Delta F^0 = -\boldsymbol{R}T \ln K(U) \qquad (24)$$

The equilibrium constant $K(U)$ is given as Eq. 14 and it is necessary to know the value of the activity coefficient of each species in order to calculate the $Kd(U)$. Unfortunately the activity coefficient of the organic phase is not clear though the activity coefficient of the aqueous phase is available. However, in organic phase, the activity coefficients of each species can be considered as nearly unity so far as the concentration is very low.

It is necessary to make the solution acidic in order to prevent the hydrolysis of uranium, otherwise the mechanism of extraction will change as has been stated already. Therfore, the measurement of the distribution equilibrium of uranium must be made under slightly acidic condition.

The equilibrium constant was calculated by using activity coefficients of uranyl nitrate and nitric acid in aqueous phase and by assuming the activity coefficients of the complex and TBP in organic phase as unity.

The results obtained are the following: $Kd(U)$ are 25.6, 25.2, 21.6 and 20.2 when the initial concentrations of nitric acid are 0.05, 0.1, 0.2 and 0.3 M, respectively. So one can observe that the equilibrium constant of uranium decreases gradually according to the increase of the concentration of nitric acid. This is considered as the result of the extraction of nitric acid into organic phase which causes the deviation of the activity coefficient in organic phase from unity.

Accordingly the following value is obtained as the rough value of $Kd(U)$ at 25°C by extrapolating to the zero nitric acid concentration: $K(U)=27$ (25°C). From this $K(U)$ value, one obtains Gibbs' free energy change of Eq. 1 by using Eq. 24 as

$$\Delta F^0 \cong -2.0 \text{ kcal. } (25°C)$$

This small change of $\Delta F^0$ suggests that uranium can be transferred easily between aqueous and TBP phases by changing the concentration of salting-out agent.

*(3) Entropy change.*—The entropy change $\Delta S^0$ for Eq. 1 is given as

$$\Delta S^0 = (\Delta H^0 - \Delta F^0)/T \qquad (25)$$

If $\Delta H^0 \cong -4.3$ kcal. which was obtained as the average value for 10~50°C is used as the value at 25°C, the entropy change at 25°C is obtained as

$$\Delta S^0 = -7.7 \text{ e. u. } (25°C)$$

## Summary

The method of analysis using the distribution coefficient to confirm the mechanism of extraction was proposed and the formation of the complex $UO_2(NO_3)_2 \cdot (TBP)_2$ and $HNO_3 \cdot TBP$ was confirmed. The extraction behavior of uranium from a nitric acid solution was concluded as a result of the competition of uranium and nitric acid. The thermochemical functions $\Delta H^0$, $\Delta F^0$ and $\Delta S^0$ for the complex formation reaction:

$$UO_2^{+2}(aq.) + 2NO_3^-(aq.) + 2TBP(org.) = UO_2(NO_3)_2(TBP)_2(org.)$$

were determined roughly from the measurement of the distribution coefficient as follows: $\Delta H^0(25°C) \cong -4.3$ kcal., $\Delta F^0(25°C) \cong -2.0$ kcal., $\Delta S^0(\sim 25°C) \cong -7.7$ e.u.

The author would like to express his gratitude to Dr. K. Kimura, Dr. T. Nakai, Dr. K. Oshima and Dr. R. Hara for their invaluable assistance and advice in this work. He also thanks Mr. T. Suzuki for his help during the experiment.

# *The Effect of Metallic Ions on Surface Chemical Phenomena. III. Solubility of Various Metal Dodecyl Sulfates in Water*

By Shigeru MIYAMOTO

(Received August 26, 1959)

In the preceding paper[1] a study was made of the effects of various inorganic electrolytes on the stability and type of emulsions stabilized with sodium dodecyl sulfate. Added polyvalent cations were found to cause phase inversion of the emulsions. These effects can hardly be explained without taking into consideration the properties of corresponding metal dodecyl sulfates formed as the consequence of the reaction of sodium dodecyl sulfate with these cations. In order to understand the nature of the effect of metallic ions in these systems it is, therefore, necessary to investigate fully the properties of various metal dodecyl sulfates, more generally metal alkyl sulfates in aqueous solutions.

Some studies have been reported regarding their properties up to the present. Nishizawa and Tomizuka[2] studied the compositions and crystallographic habits of hexadecyl sulfates of potassium, sodium, ammonium, magnesium and calcium. They also made reference qualitatively to the solubility of these compounds in various solvents. Ueno, Yokoyama and Iwakura[3] found that solubilities of ammonium-, sodium- and potassium dodecyl sulfates and hexadecyl sulfates decrease in this order. They studied also the foam formation, surface tension, interfacial tension at oil-water interface and detergent action of these metal dodecyl sulfates. Yoshizaki and Terashima[4] studied the change of foam volume on aqueous solutions of sodium hexadecyl sulfate with the course of time. Measurement of foam of ammonium-, magnesium- and calcium dodecyl sulfate and hexadecyl sulfate

solutions was made by Nakashima[5]. Lottermoser et al.[6] synthesized metal alkyl sulfates and undertook measurements of conductance, potential, surface tension and interfacial tension of their aqueous solution. These authors gave consideration to the change of dissolved state with the change of concentration of the solution. Further, Giers and Boido[7] measured cloud point, viscosity, pH, contact angle, wetting speed and foaming property of ammonium-, sodium-, potassium-, magnesium-, calcium- and zinc dodecyl sulfates. As regards solubility, sodium dodecyl sulfate, tetradecyl sulfate and hexadecyl sulfate were studied by Hutchinson et al.[8] at various temperatures. On the solubility of metal alkyl sulfates, however, only a few data have been reported. The solubility of calcium dodecyl sulfate was given as 0.03~0.04% at 25°C by Lenher[9], 0.00457 mol./1000 g. $H_2O$ at 50°C by Tartar and Cadle[10] and 0.5 g./l. at 53°C and 1.0~5.0 g./l. at 54°C[11].

In the preceding paper reported by the author[1] values of solubility of sodium-, calcium-, barium-, aluminum-, iron- and thorium dodecyl sulfates were given at 25°C. It seems, however, that further studies are necessary to obtain full knowledge regarding the values of solubility of many other metal dodecyl sulfates. So one has conducted the measurements of solubility of calcium-, strontium-, lead-, barium-, copper, manganese-, magnesium- and cobalt dodecyl sulfates at various temperatures. It is the purpose of the present paper to report the results of the solubility measurement of these metal dodecyl sulfates and to undertake some discussions concerning them.

## Experimental

**Materials.**—Metal dodecyl sulfates were synthesized from pure sodium dodecyl sulfate (abbreviated as SDS) which was synthesized from pure dodecyl alcohol and a guaranteed reagent of concentric sulfuric acid according to the method described in the papers already reported[1,12]. Pure dodecyl alcohol used was obtained by fractional distillations in vacuo. Synthesized SDS was freed from unsulfated dodecyl alcohol by extraction with ethyl ether for about forty hours in a Soxhlet extractor. The purity of the SDS sample was ascertained from the absence of the minimum in the curve representing surface tension of its aqueous solutions versus its concentration and also from results of elementary analysis of the sample. From these results[1], it was found that the SDS sample was highly pure surface-chemically. Metal dodecyl sulfates were precipitated from SDS aqueous solution by adding concentrated aqueous solutions of magnesium-, calcium-, strontium-, barium-, cupric-, lead-, manganous- and cobaltous chlorides. All these electrolytes had been purified before they were used for the preparation of corresponding metal dodecyl sulfates. The precipitated metal dodecyl sulfates were taken out by filtration by a glass filter and then they were recrystallized further three times except in the case of barium salt which was found to be soluble only in small amount even at high temperatures. Washing with water was carried out fully after every recrystallization. Readily soluble metal dodecyl sulfates were washed with cold water. After purification, they were brought into the air-dried state. Elementary analysis and metal content analysis were conducted on these air-dried samples.

**Method.**—Measurements of solubility were performed as usual by weighing the amounts of solute contained after drying up known weights of the saturated solution at 50°C. It was found that long periods of time were necessary to attain true equilibrium of solubility, so the bottle containing the sample was shaken to accelerate the attainment of equilibrium. The process of attainment of equilibrium is shown in Fig. 1 with magnesium-, calcium-, strontium-, lead- and barium dodecyl sulfates.

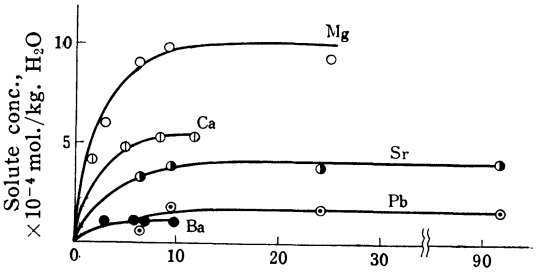

Fig. 1. Attaiment of equilibrium of the solubility in solution of Mg-, Ca-, Sr-, Pb- and Ba dodecyl sulfates in water with the course of stirring time.

## Results

At first, elementary analyses of carbon, hydrogen and metal contents of air-dried metal dodecyl sulfates were carried out.

| 100.0 | — | — | — | $1.66\times10^{-3}$ |

and the results are shown in Table I. From these results the compositions of metal dodecyl sulfates were determined. That is, they were found to have the following formulae. $Ca(DS)_2$, $Sr(DS)_2$, $Ba(DS)_2$, $Pb(DS)_2$, $Mn(DS)_2$, $Mg(DS)_2 \cdot 6H_2O$, $Co(DS)_2 \cdot 6H_2O$ and $Cu(DS)_2 \cdot 4H_2O$, where the abbreviation DS represents the dodecyl sulfate radical.

Values of solubility of these metal dodecyl sulfates were obtained at various temperatures and they are shown in Table II (greater solubility) and Table III (smaller solubility).

It has been well known that soaps have the Krafft point above which their solubilities increase enormously. The Krafft point has also been observed generally with the surface active agents such as sodium alkyl sulfates[8], sodium alkyl sulfonates[13], anisidine sodium sulfonates, alkyl pyridinium halides and alkyl trimethylammonium halides[14]. Metal dodecyl sulfates are considered to be surface active agents also, so they are expected to have a Krafft point. To examine whether they have a Krafft point or not, plots of logarithms of solubility versus reciprocals of temperature were drawn as shown in Fig. 2. In this figure, the intersections of two straight lines are seen, which show the Krafft points. The values of Krafft points thus obtained are shown in Table IV.

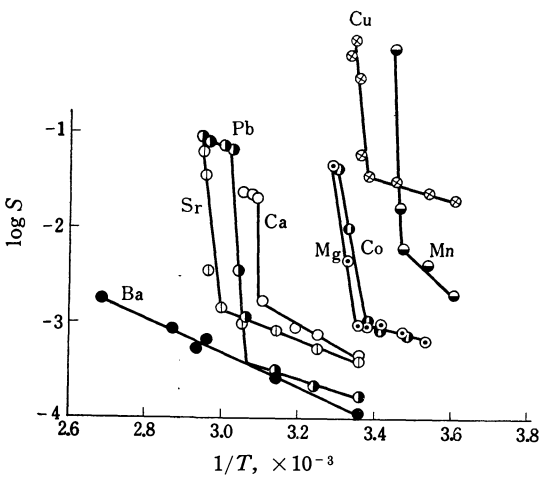

Fig. 2. Relation between the logarithms of solubility of various metal dodecyl sulfates and the reciprocals of absolute temperature.

| $Ca(DS)_2$ | 50 |
| $Pb(DS)_2$ | 53 |
| $Sr(DS)_2$ | 64 |
| $Ba(DS)_2$ | —* |

* Krafft point of $Ba(DS)_2$ was not observed below 100°C.

## Discussion

From the results of the composition of various metal dodecyl sulfates shown in Table I it is confirmed that calcium-, barium, magnesium- and cupric dodecyl sulfates have the same formulae as those already given by Lottermoser et al.[6] It is noted that some of them have crystalline water. All metal dodecyl sulfates examined were found to have the two dodecyl sulfate radicals in their molecules, presumably showing no hydrolysis of the cations contained in them throughout the process of preparation.

The values of solubility of metal dodecyl sulfates examined were found to increase rapidly with the increase of temperature above the respective Krafft point, except for the case of barium dodecyl sulfate as shown in Fig. 2. The Krafft point could be obtained as the intersect of two straight lines in the diagrams of logarithms of solubility versus the reciprocals of temperature. This method of obtaining the Krafft point has been known to be applicable to many surface active substances in general. From their behaviors in solution, metal dodecyl sulfates are considered to be also a group of the surface active substances.

The values of solubility of magnesium-, calcium-, strontium- and barium dodecyl sulfates in water below the respective Krafft point decrease in this order, which is the same order as that of the values of solubility in water of the inorganic metal sulfates having these cations and also the same as the order of increase of ionic radii of these cations. This series of gegenions is also applied to the values of Krafft point of these metal dodecyl sulfates. These correspondences are, however, not to be extended to manganese-, lead-, cobalt- and copper dodecyl sulfates. As a whole, the Krafft points of various metal dodecyl

sulfates seem to become higher as their solubilities decrease. At a temperature above the Krafft point the micelles of a surface active substance may be formed in the aqueous solution as explained by Murray and Hartley[15]. It has been found from the surface tension vs. concentration diagrams that the critical concentration for micelle formation of the solution of metal dodecyl sulfates of divalent cations is almost the same irrespective of the difference in the kind and type of gegenions. (The details of the surface tension measurement will be reported in a separate paper.) A sparingly soluble metal dodecyl sulfate can let its concentration reach the critical concentration for micelle formation at higher temperatures than more soluble metal dodecyl sulfate.

15) R. C. Murray and G. S. Hartley, ibid., **31**, 183 (1935).

**Summary**

Calcium, strontium-, barium-, lead-, manganese-, magnesium-, cobalt- and copper dodecyl sulfates were synthesized and their compositions were determined from the results of their elementary analysis and metal content analysis. Further, the solubility of these metal dodecyl sulfates was measured at various temperatures. From these data, these metal dodecyl sulfates except barium salt were found to have the Krafft points, values of which were shown also.

The author expresses his sincere gratitude to Professor R. Matuura of Kyushu University for his guidance and encouragement.

# *The Effect of Metallic Ions on Surface Chemical Phenomena. IV. Surface Tension Measurement on Aqueous Solutions of Metal Dodecyl Sulfates*

By Shigeru MIYAMOTO

(Received August 26, 1959)

In the preceding paper[1a], the effect of metal ions on the properties of the emulsion stabilized with sodium dodecyl sulfate was investigated and in connection with it the solubility of various metal dodecyl sulfates was studied[1b]. Metal dodecyl sulfates should be formed in many systems containing sodium dodecyl sulfate and metal ions as a result of a reaction of the former with the latter. They were supposed to constitute also a group of surface active substances from the existence of their Krafft points measured by the temperature change of their solubilities in water. To explain the Krafft point, the presence of micelles of the solute has been assumed. It is therefore expected that metal dodecyl sulfates begin to form the micelles at a relatively narrow concentration range, referred to as critical micelle concentration (abbreviated as cmc) as is the case with sodium dodecyl sulfate.

In the present paper, measurements of surface tension were performed to examine how far they lower the surface tension of their aqueous solution and whether or not they would actually show cmc as expected from the Krafft phenomena. Although Lottermoser and Stoll[2] made the surface tension measurements of aqueous solutions of dodecyl sulfates of silver, magnesium, copper, zinc and iron(II), their data were obtained with the samples synthesized from impure sodium dodecyl sulfate as illustrated from the presence of the minimum in the diagram of surface tension of its aqueous solution versus concentration. So it seems to be necessary to undertake measurements with pure samples in order to obtain further knowledge of properties of metal dodecyl sulfates, on which only

a few studies have been made up to the present[3].

## Experimental

Metal dodecyl sulfates were synthesized from pure sodium dodecyl sulfate and then purified as described in the preceding paper[1a,b].

Measurements of surface tension of aqueous solutions of metal dodecyl sulfates were conducted with a Du Noüy's tensiometer at various temperatures kept constant with a water thermostat. The sample solution was contained in a bottle having a narrow neck and this was immersed in the thermostat up to the brim. The solution had been heated to a temperature above the temperature of the measurement of surface tension. In the measurement of surface tension, the ring of the tensiometer was suspended by a thin platinum wire from the bar of the tensiometer and was made to have contact with the surface of the solution prior to the measurement of surface tension. After the attainment of equilibrium of temperature of the solution with that of the thermostat, the measurement was started. At high temperatures, the measurement had to be carried out as rapidly as possible to avoid evaporation of the solvent.

From the data of surface tension, the cmc of each metal dodecyl sulfate solution could be determined and it was compared with the one measured by the dye titration method. The dye titration method was conducted by using pinacyanol chloride and rhodamine 6G and observing the change of their color with the change of the detergent concentration.

## Results and Discussion

The values of surface tension of aqueous solutions of various metal dodecyl sulfates at various temperature are shown graphically in Fig. 1—7 as a function of their concentration. It is seen that every curve represents a kink and no minimum near

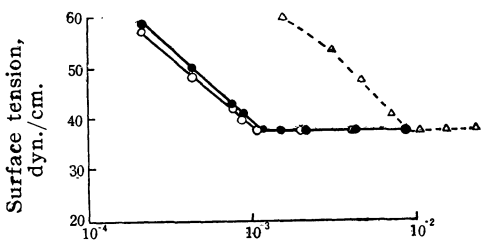

Fig. 1. Relation between surface tension and concentration of magnesium dodecyl sulfate solutions at 40°C (○) and 54°C (●). The dotted line represents the curve obtained with sodium dodecyl sulfate at 54°C.

3) Literatures cited in 1b.

the kink point. The absence of the minimum is considered to show the absence of more surface active impurities than these metal dodecyl sulfates. The value of cmc can be obtained as the concentration at the kink point of every curve. These values of cmc of various metal dodecyl sulfates at various temperatures are shown in Table I. It can be seen from Table I that the temperature dependence of the value of cmc of each

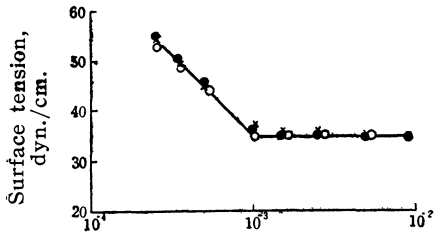

Fig. 5. Relation between surface tension and concentration of manganese dodecyl sulfate. Measurements of surface tension were conducted at 25°C (×), 40°C (○) and 54°C(●).

metal dodecyl sulfate of divalent cation is not so remarkable and also the values of dodecyl sulfates of various cations are almost the same, independent of the kind and type of cations contained in the molecules of these metal dodecyl sulfates.

These metal dodecyl sulfates were found to have their Krafft points as already reported[1b]. It is generally accepted with surfactant solutions that only at the temperatures above the Krafft point the micelles are formed. It seems true for some metal dodecyl sulfates studied in the

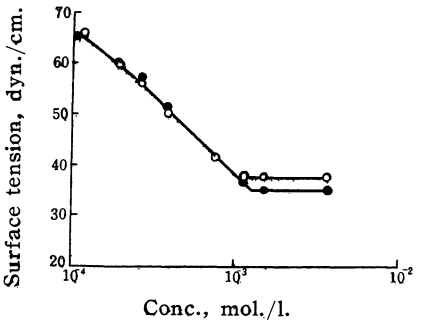

Fig. 7. Relation between surface tension and concentration of cupric dodecyl sulfate. Measurements of surface tension were conducted at 25°C (○) and 40°C (●).

present experiment. For example, calcium dodecyl sulfate was found to show its cmc at 54°C, as illustrated by the kink point of the surface tension-concentration curve (Fig. 2), but at 35°C which is below its Krafft point 50°C, the solution was saturated before its cmc had been reached. Referring to the diagram of Fig. 2 in the preceding paper[1b], it is found that the solubility of magnesium-, calcium-, strontium- and cobalt dodecyl sulfates at each Krafft point is nearly equal to the cmc of each solution which has been determined in the present experiment. In the case of lead salt, however, the solubility at its Krafft point is a little smaller than its cmc, and copper- and manganese salts show considerably larger solubilities than their corresponding value of cmc. It is not clear at the present why these metal dodecyl sulfates show anomalous behaviors. It will be necessary to make measurements of the existence of micelles over a much wider range of temperatures in order to elucidate the relation between the Krafft point and the micelle formation with these metal dodecyl sulfates.

As mentioned above, the dependence of

TABLE I. VALUES OF cmc (mol./l.) OF METAL DODECYL SULFATES AT VARIOUS TEMPERATURES DETERMINED BY SURFACE TENSION MEASUREMENTS

| Subst. | cmc (mol./l.) | | | |
|---|---|---|---|---|

| $Co(DS)_2\cdot6H_2O$ | $8.3\times10^{-4}$ | $9.7\times10^{-4}$ | $1.1\times10^{-3}$ | — |
| $Cu(DS)_2\cdot4H_2O$ | $1.0\times10^{-3}$ | $1.2\times10^{-3}$ | — | — |

the values of cmc of various metal dodecyl sulfates on the kind of divalent cations contained in them is not explicitly found, the cmc being all nearly $1\times10^{-3}$ mol./l. On the contrary, the values of cmc of alkali metal dodecyl sulfates measured by the electrical conductance method have been reported by Meguro et al.[4] to vary with the kind of alkali metal cations; i. e. they reported 7.8, 8.9 and 10.5 millimol./l. as the values of cmc of potassium-, sodium- and lithium dodecyl sulfates, respectively. These authors explained the dependence of cmc on the kind of monovalent cations as being due to the difference in hydration of these monovalent cations. This explanation might be applied also to the case of the metal dodecyl sulfates having the divalent cations examined in this experiment, but actually this effect seems so small that it can hardly be detected in this experiment. Metal dodecyl sulfates having divalent cations show far smaller values of cmc than those of the metal dodecyl sulfates having monovalent cations. This fact shows that the former sulfates have a less hydrophilic nature because of the two hydrocarbon chains for a metal, than the latter ones, and thus they have a tendency to form their micelles in solutions more easily. This may be a reason for the independence of their cmc's on the kind of divalent gegenions.

The value of surface tension of the solution above cmc is nearly constant. It ranges only from 31 to 37 dyn. per cm., depending on the temperature and the kind of metal dodecyl sulfates. In general a salt which is more soluble in water shows a larger value of saturation surface tension.

The cmc of a surface active substance has well been known to be obtained by the dye titration method as well as by the surface tension measurement. To examine the possibility of obtaining the values of cmc of the metal dodecyl sulfates by the dye titration method, measurements were conducted using pinacyanol chloride or rhodamine 6G as the indicator of the dye titration method. It was found that this method can also be applied to metal dodecyl sulfates. The values of cmc of the various metal dodecyl sulfates thus obtained are shown in Table II.

From Table II, the values of cmc obtained by pinacyanol chloride and rhodamine 6G are seen to be in good agreement with each other.

TABLE II. VALUES OF cmc (mol./l.) OF VARIOUS METAL DODECYL SULFATES* AT 40°C OBTAINED BY THE DYE TITRATION METHOD USING PINACYANOL CHLORIDE AND RHODAMINE 6G

| Subst. | cmc (mol./l.) By pinacyanol chloride | cmc (mol./l.) By rhodamine 6G |
|---|---|---|
| NaDS | $6.1\times10^{-3}$ | $6.1\times10^{-3}$ |
| $Mg(DS)_2\cdot6H_2O$ | $1.0\times10^{-3}$ | $1.1\times10^{-3}$ |
| $Ca(DS)_2$ | $1.3\times10^{-3}$ (at 54°C) | — |
| $Mn(DS)_2$ | $1.2\times10^{-3}$ | $1.1\times10^{-3}$ |
| $Co(DS)_2\cdot6H_2O$ | $1.0\times10^{-3}$ | $1.3\times10^{-3}$ |
| $Cu(DS)_2\cdot4H_2O$ | $1.2\times10^{-3}$ | $1.3\times10^{-3}$ |
| $Zn(DS)_2\cdot6H_2O$ | $1.1\times10^{-3}$ | $1.1\times10^{-3}$ |

* Measurements were not performed on strontium- and lead dodecyl sulfates because of their high Krafft points.

Comparing the values obtained by the dye titration method with those shown in Table I, obtained from surface tension measurements, it is found that these two methods of measuring cmc give values approximately coinciding with each other.

As described above, metal dodecyl sulfates with divalent cations are found to lower the surface tension of their solutions exceedingly and have far smaller cmc values than those of the salts of monovalent cations. Relatively soluble salts such as cupric-, manganese-, cobaltous- and magnesium dodecyl sulfates, therefore, may be useful for many purposes based on their strong surface activity.

## Summary

The surface tension of aqueous solutions of various metal dodecyl sulfates with divalent cations was measured at various temperatures with a Du Noüy's tensiometer. The values of surface tension were observed to decrease steeply with the increase of their concentrations up to their cmc's, which are all nearly equal to $1\times10^{-3}$ mol./l. These values of cmc of the metal dodecyl sulfates with divalent cations were found to be practically independent of temperature and the kind of these cations. Further, the dye titration methods were also performed to obtain the values of cmc of these metal dodecyl sulfates using pinacyanol chloride and rhodamine 6G. The values of cmc obtained by these methods were found to coincide with those from the surface tension measurements.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. V. Stilbene*

By Hiroshi SUZUKI

(Received August 15, 1959)

Previously[1] the present author explained successfully the hypsochromic shifts of the conjugation band observed in the ultraviolet absorption spectra of *cis*-stilbene and of some $\alpha$-alkyl- and $\alpha,\alpha'$-dialkylstilbenes as compared with *trans*-stilbene by correlating those with the most probable spatial configurations of the molecules on the basis of the calculations by the simple LCAO molecular orbital method. Thus, he determined by his calculations the relation between the interplaner angle $\theta$ (that is, the angle through which the plane of each phenyl group rotates out of the plane of the central essentially double bond) and the electronic transition energy correspondinng to the conjugation band, and clarified the fact that the perfect coplanarity of the molecular configuration is not prerequisite to an occurrence of conjugation and hence not prerequisite to the appearance of the conjugation band and that the conjugation band is progressively shifted toward shorter wavelengths with increasing $\theta$. He showed also that the value of the interplanar angle of a given compound of the type concerned can satisfactorily be computed from the position of the conjugation band and vice versa. Further, he showed that the earlier interpretations[2,3] of these hypsochromic shifts in terms of " partial chromophores " are to be rejected.

The calculations were carried out on the basis of the assumption that the absorption maximum at about 294 m$\mu$ in the spectrum of *trans*-stilbene in solution was due to the transition in the planar molecule of *trans*-stilbene. According to the X-ray crystal analysis by Robertson and Woodward[4], *trans*-stilbene in the crystalline state has a nearly planar or probably completely planar configuration. Strictly speaking, however, it seems that there is no evidence to indicate that the most probable configuration of *trans*-stilbene in solution is also planar. The observation by Wiegand and Merkel[5] that the absorption curve of *trans*-stilbene in solution is closely similar to that of 2-phenylindene in which one of the phenyl groups of *trans*-stilbene may be considered to be maintained in the coplanar or nearly coplanar position with the central ethylenic bond by the methylene bridge is somewhat interesting in this connection, but it should not be considered as a proof of the planarity of the whole configuration of *trans*-stilbene in solution. As already discussed in the first part[6] of this series, biphenyl is probably non-planar in solution, while it is known to be planar in the crystalline state. In view of this fact, the spectrum of *trans*-stilbene in solution should not be considered without sufficient consideration to be due to the planar molecule.

In this part of the series, the results of measurements of the spectra of *trans*-stilbene in various solvents and in the crystalline state carried out from these considerations are reported, and these spectra as well as the vapor spectrum of *trans*-stilbene are discussed with special emphasis on the relation of the spectra to the spatial configuration of the molecule.

Further, on the basis of the results, the relation between the spectrum and the spatial configuration of *cis*-stilbene is discussed by application of the usual method.

## Spectra of *trans*-Stilbene in Various States

**Solution Spectra of *trans*-Stilbene.**—Data of the spectra of *trans*-stilbene in various solvents measured at room temperature are given in Table I, in which data of the spectrum of *trans*-stilbene at low temperature as well as those of *cis*-stilbene measured by Beale and Roe[7] are also included for comparison. The notation of the absorption bands is according to Beale and Roe. The A-bands are considered to be the conjugation bands. In addition to the bands shown in Table I, the spectrum of *trans*-stilbene in *n*-heptane exhibits a band at about 201.5 mμ ($\varepsilon$=23900), and that in ethanol at about 201.0 mμ ($\varepsilon$=23800). These are termed the C-bands.

The absorption curves of the spectra of the *n*-heptane solution and of the benzene solution of *trans*-stilbene are shown in Fig. 1 as the representatives of the solution spectra of *trans*-stilbene. In Fig. 1 the curve of the spectrum of *cis*-stilbene is also shown for comparison. The spectra of *trans*-stilbene in the other solvents resemble that in *n*-heptane on the whole, although especially the A-α-band in the spectrum in carbon tetrachloride as well as in chloroform is somewhat more diffuse than in the spectra in *n*-heptane and in alcohols.

It is notable that th A-band has a fine structure. The somewhat similar pattern of fine structure is seen also in the B-band. Beale and Roe[7] have concluded that the fine structure originates in the stretching frequency of the ethylenic bond. On the

other hand, in sharp contrast to *trans*-stilbene, *cis*-stilbene as well as $\alpha$- and $\alpha, \alpha'$-substituted stilbenes which will be treated in a later part of this series shows no fine structure. These compounds are considered to be non-planar as will be shown later. Accordingly it would be expected that an appearance of fine structure might be related to the planarity of the molecular configuration or to its rigidity as the hypotheses proposed by Wiegand and Merkel[8] and by Kortüm and Dreesen[9]. However, such a relation has not yet been established.

In comparison with *n*-heptane, methanol exerts almost no, or a very small, hypsochromic effect, and ethanol exerts a small bathochromic effect. The magnitude of the bathochromic shift is considerably greater in chloroform, and is extraordinarily great in carbon tetrachloride as well as in benzene.

The great bathochromic effect of benzene may be especially noteworthy. According to Bayliss[10], a magnitude of wavelength displacement of a band of a nonpolar molecule by a nonpolar solvent is related to the refractivity of the solvent. The refractivity of benzene is slightly greater than that of *n*-heptane. However, it seems that the great bathochromic effect of benzene relative to *n*-heptane can not be attributed wholly to the difference of refractivity alone.

In this connection, it may be noted that the distribution of intensity among the vibrational bands of the A-band varies considerably with the solvent. The ratio of the intensity of the $\beta$-band to that of the $\gamma$-band for each solvent is listed in the last column of Table I. It is seen that the ratio increases in the order *n*-heptane < ethanol ≈ methanol < chloroform ≈ carbon tetrachloride < benzene. It may be noteworthy that while in solvents other than benzene the $\gamma$-band is the most intense maximum of the A-band, in benzene the $\beta$-band is the most intense maximum.

These facts appear to suggest the presence of a special interaction between the $\pi$-orbitals (or $\pi$-electrons) of the solute molecule and those of benzene. This problem will be discussed in somewhat greater detail in a later part of this series.

**Solution Spectra of Some *p*-Substituted *trans*-Stilbenes.** — The special solvent effect of benzene is seen also in the spectra of some *p*-substituted *trans*-stilbenes. The results of measurements of the spectra of *p*-methoxy-*trans*-stilbene and of *p*-nitro-*trans*-stilbene in *n*-heptane as well as in benzene are shown in Table II and Figs. 2 and 3. These spectra, especially those in *n*-heptane, bear a certain similarity in shape to that of *trans*-stilbene, showing similar patterns of fine structure. The magnitudes of the bathochromic displacements of the bands associated with the change of solvent from *n*-heptane to benzene are considerably

great (about 5 mμ) also with these compounds. Furthermore, in the spectra of *p*-methoxy-*trans*-stilbene a marked redistribution of intensity between the β-band and the γ-band occurs, quite similarly to the one observed in the spectra of *trans*-stilbene. It is also noteworthy that the fine structure of the A-band of *p*-nitro-*trans*-stilbene disappears almost completely in the spectrum in benzene.

**Crystal Spectra of *trans*-Stilbene.** — The spectrum of *trans*-stilbene in the crystalline state was measured by the pressed KCl-disk technique. The values of the molecular extinction coefficients were not reproducible and were considerably smaller than th corresponding values in the solution spectra. Thus, the former values varied from about 1/3 to about 1/30 of the latter ones from disk to disk. This fact may be considered to indicate the dependence of the extinction values on the condition of dispersion of the micro-crystals or the sizes of the micro-crystals, in view of the somewhat similar phenomenon observed by Weigl[11] in his study on the absorption spectra of some crystalline cationic dyes. In addition, this lowering of the extinction values may be partly due to the possible loss of the organic substance during grinding and evacuation of the press, as stated by Dale[12]. In spite of this, the reproducibility of the positions of the absorption maxima and inflections was almost completely satisfactory except for the α-band of the A-band. As representatives the results of measurements on the two disks of different thicknesses made from the same mixture (cf. *Experimental*) are shown in Table III and Fig. 4.

The crystal spectra differ considerably in the shape of the absorption curve from the solution spectra. In the crystal spectra the most intense maximum in the fine structure of the A-band is the δ-band, neither the γ-band as in the spectra in *n*-heptane etc., nor the β-band as in the spectrum in benzene. In this connection it may be of interest that in the solution spectrum measured by Beale and Roe[7] at low temperature (−130°C) the β-band is the most intense one, the fine structure being much more sharply resolved.

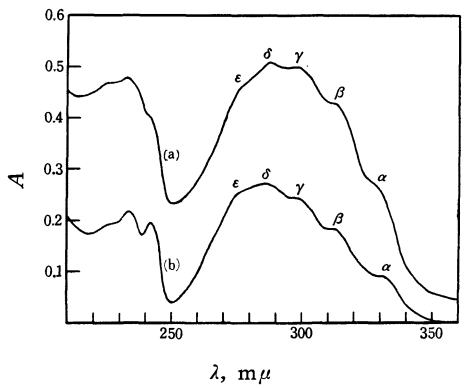

Fig. 4. Crystal spectra of *trans*-stilbene measured by the KCl-disk technique (cf. Table III).

The bands in the crystal spectrum are at longer wavelengths than the corresponding ones in the spectrum in *n*-heptane. The magnitude of the bathochromic shift is about 4.5 m$\mu$ for the $\gamma$-band and about 5.5 or 6 m$\mu$ for the $\beta$-band. These values probably corresponding to the "normal red-shift"[12] of the conjugation band are considerably smaller than those (about 8 m$\mu$ for the $\gamma$-band and about 9 m$\mu$ for the $\beta$-band) anticipated from the regular relation between the magnitude of the shift and the position of the band determined by Dale[12] for rigid molecules. This fact may be considered to indicate that the most probable spatial configuration of *trans*-stilbene in solution does not significantly differ from the one in the crystalline state and hence is planar or nearly planer.

Therefore, in order to infer the most probable spatial configurations of *cis*-stilbene and some related compounds of stilbene in solution by application of our method, the spectrum of *trans*-stilbene in *n*-heptane is taken as the spectrum of the planar reference compound, and the spectra of the *n*-heptane solutions are compared in principle as far as the data are available. In cases of absence of the data of the spectrum of the *n*-heptane solution, the data of the ethanol solution are used. As already mentioned, the spectra of *cis*-stilbene and the stilbene derivatives with substituents at the $\alpha$- and $\alpha'$-positions or at the ortho positions treated in this series all exhibit the structureless conjugation bands in contrast to that of *trans*-stilbene. Therefore, the question arises which maximum of fine structure of the conjugation band in the spectrum of *trans*-stilbene should be taken as the reference for the comparison. In the present treatment the $\gamma$-band at 294.1 m$\mu$ is tentatively chosen as the reference. This band is not only the most intense maximum of fine structure of the conjugation band in the spectrum of the *n*-heptane solution but also probably the central one.

Besides the above mentioned spectra by the pressed KCl-disk technique, the author attempted to measure the crystal spectrum of *trans*-stilbene also on thin films prepared on quartz plates by sublimation of crystals as well as by evaporation of a thin layer of solution, but these attempts were unsuccessful. Thus, the absorption curves obtained were very diffuse and indicated only indistinctly the presence of a band or bands at near 295~335 m$\mu$. This failure of revelation of the conjugation band is probably due to the effect of the orientation of the molecules in the crystals as discussed by Dale[12] in the case of biphenyl.

Pesteil[13] measured the spectrum of *trans*-stilbene on thin crystal plates with polarized light and found a feeble band with two principal maxima at 367 and 387 mμ in addition to the stronger bands below 360 mμ. Jaffé and others[14] have stated that it appears reasonable to assume this feeble band to be the singlet-triplet absorption. Brodin and others[15] measured the spectrum of crystalline *trans*-stilbene at 20°K and found many vibrational frequencies.

**Vapor Spectrum of *trans*-Stilbene.**—According to Kanda[16], the vapor spectrum of *trans*-stilbene prossesses a discontinuous band with nine maxima at the region from 284.4 to 265.6 mμ, of which the most intense maxima are at 284.4 and 283.4 mμ, and a discontinuous band with ten maxima at the region from 244.3 to 233.5 mμ, of which the most intense maximum is at 240.5 mμ. The former band may be considered to be the conjugation band, viz. the A-band, and the latter the B-band. It is noteworthy that the conjugation band in the vapor spectrum is at considerably shorter wavelengths than the corresponding one in the solution spectra as well as the crystal spectrum. This fact probably indicates that the most likely configuration of *trans*-stilbene in the vapor state deviates considerably from the coplanarity, analogously to biphenyl[6].

## Calculation

The relation between the spatial configurations and the electronic absorption spectra of stilbenes can be determined by the following calculations. The procedures of the calculations are the same in principle as the ones described previously[1]. The description is given here in a somewhat more refined form as the basis for the treatments not only in the present part but also in the succeeding parts of this series.

**Determination of the Parameters for the Resonance Integrals as Functions of the Bond Length and the Interplanar Angle.**—The $\pi-\pi$ resonance integral for the central ethylenic bond, namely the $\alpha-\alpha'$ bond, is denoted by $\eta\beta$, and the one for the $\alpha-1$ bond as well as the $\alpha'-1'$ bond by $\rho\beta$. (Symbols $\alpha$ and $\gamma$ in the previous paper were replaced by $\rho$ and $\eta$, respectively). Symbol $\beta$ represents the $\pi-\pi$ resonance integral for the C-C bond in the benzene ring, and $\eta$ and $\rho$ are parameters by which allowances are made for changes of the resonance integrals associated with changes of the bond length and the interplanar angle.

The length of the $\alpha-\alpha'$ bond in *trans*-stilbene was estimated at 1.33±0.04 Å by Robertson and Woodward[4]. The length of the C=C bond in ethylene was recently found to be 1.337 Å[17], and the length of the "double" bonds in butadiene to be 1.337±0.005 Å[18]. Therefore, it may be presumed that the length of the ethylenic "double" bond does not significantly vary with the extent of conjugation. Hence the round value of 1.34 Å is taken as the length of the $\alpha-\alpha'$ bond in *trans*-stilbene as well as the related compounds throughout the present treatment. Consequently, the value of the parameter $\eta$ is estimated at 1.080 from Mulliken's Tables[19] on the basis of the approximate proportionality of the $\pi-\pi$ resonance integral for C-C bond to the $\pi-\pi$ overlap integral.

The parameter $\rho$ can be expressed approximately by the following equation, quite analogously to Eq. 1 in the first part[6] of this series;

$$\rho = S(R,\ 0°)\cos\theta / S(1.39,\ 0°) \qquad (1)$$

where $S(1.39,0°)$ represents the $\pi-\pi$ overlap integral for the C-C bond in the benzene ring and $S(R,\ 0°)$ represents the one in the case where the bond length is $R$ and the interplanar angle is 0°.

According to the result of the X-ray crystal analysis of *trans*-stilbene by Robertson and Woodward[4], two molecules contribute to the asymmetric unit of the crystal, and these molecules have different appearances in the electron density maps. Thus, the length of the "single" bonds joining the phenyl groups to the ethylenic carbon atoms, namely the $\alpha-1$ and $\alpha'-1'$ bonds, and the interplanar angle were estimated at 1.44±0.02 Å and 3°, respectively, for one molecule and at 1.45±0.02 Å and 10°, respectively, for the other. Robertson and Woodward have, however, concluded that the apparent differences are due to the relative orientation of the

molecules and not to any appreciable differences in their shape or dimensions, and that the molecules are nearly planar and may be exactly planar within the limits of experimental error.

Therefore, the values of $\theta$ (the interplanar angle) and of $R$ (the length of the $\alpha-1$ bond) may safely be assumed in the present treatment to be 0° and 1.445 Å, respectively, in the configuration of *trans*-stilbene in the crystalline state and hence in the most probable configuration of the molecule in solution. Accordingly, the relation between $\theta$ and $R$ is assumed as follows, quite analogously to Eq. 4 in Part I[6].

$$\{S(R, 0^\circ)-S(1.54, 0^\circ)\}/\{S(1.445, 0^\circ)-S(1.54, 0^\circ)\}=\cos\theta \quad (2)$$

Then, from Eqs. 1 & 2 and Eq. 3 in Part I, one obtains

$$\rho=\cos\theta\times 0.77108+\cos^2\theta\times(1.54-1.445)\times 1.4458 \quad (3)$$

which is quite analogous to Eq. 7 in Part I. Accordingly, the value of $\rho$ is computed to be 0.9084 when $\theta$ is 0° and $R$ is 1.445 Å. It is evident that the value of $\rho$ becomes smaller with increasing $\theta$ and that it is 0 when $\theta$ is 90°.

**Solution of the Secular Equation for the Determination of the Molecular Orbitals.**— By solving the secular equation for the determination of the molecular orbitals as linear combinations of $2p\pi$ atomic orbitals, one can obtain the values of energies of the molecular orbitals corresponding to the value of the parameter $\rho$. Consequently, the values of the extra-resonance energy (subsequently referred to as *R.E.*), of the coefficients of the $2p\pi$ atomic orbitals in the molecular orbital functions, and of the quantities such as the $\pi$-bond orders corresponding to the molecular configuration prescribed by the value of $\rho$ can also be obtained by the usual procedures.

The stilbene-type conjugated system can be considered as belonging to the symmetry group $D_2$ in the present treatment. Then, the highest occupied $\pi$-orbital ($\pi_1$) belongs to the representation $B_1$, and coincides with the $\varphi_1$ orbital in benzene when $\rho$ is 0. On the other hand, the lowest vacant $\pi$-orbital ($\pi_1^*$) belongs to $B_3$, and coincides with the $\varphi_2$ orbital in benzene when $\rho$ is 0. (The notation for orbitals in benzene is according to Sklar[20].) Transitions from orbitals belonging to $B_1$ to those belonging to $B_3$ are allowed by absorption of light polarized along the direction of the long axis of the molecule. Accordingly, the energy difference between the lowest vacant orbital $\pi_1^*$ and the highest occupied orbital $\pi_1$ (referred to as $\Delta E_A$) is considered to be the transition energy corresponding to the conjugation band (viz. the A-band). The value of $\Delta E_A$ (in $-\beta$) is, of course, twice the absolute value of the enegy (in $-\beta$) of one of the two orbitals.

In addition to the ten orbitals belonging to $B_1$ and $B_3$, whose energies vary with $\rho$ (cf. Fig. 2 in Ref. 1), there are two sets of doubly degenerate orbitals belonging to $A_1$ and $B_2$, whose energies do not vary with $\rho$. These orbitals may be considered as ones localized in the benzene rings. Thus, one ($\varphi$) of the two orbitals belonging to either $A_1$ or $B_2$ has the energy of $+\beta$ and corresponds to the $\varphi_{-1}$ orbital in benzene, while the other orbital ($\varphi^*$) has the energy of $-\beta$ and corresponds to the $\varphi_{-2}$ orbital in benzene. Transitions from the $\pi_1$ orbital ($B_1$) to the $\varphi^*$ orbital belonging to $B_2$ or from the $\varphi$ orbital belonging to $A_1$ to the $\pi_1^*$ orbital ($B_3$) are allowed by absorption of light polarized along the direction of the short-axis of the molecule. These transitions may be considered as corresponding to the B-band, as suggested by Dale[21]. The value of the corresponding transition energy $\Delta E_B(-\beta)$ can evidently be expressed as $1+\Delta E_A(-\beta)/2$.

Transitions between the orbitals belonging to $A_1$ and those belonging to $B_2$ are allowed by absorption of light polarized along the direction of the long-axis of the molecule, and correspond probably to the C-band at about 200 m$\mu$.

The results of the calculations are summarized in Table IV. In this table, $\Delta E_A(-\beta)$ and $R.E.(-\beta)$ are values obtained by ignoring the $\pi-\pi$ overlap integral, and $\Delta E_A(-\gamma)$ and $R.E.(-\gamma)$ are values obtained by taking the overlap integral into account, assuming the value of the overlap integral for the C–C bond in benzene as 0.25. The symbols $p_{\alpha-\alpha'}$ and $p_{\alpha-1}$ represent the $\pi$-bond orders of the $\alpha-\alpha'$ bond and of the $\alpha-1$ as well as the $\alpha'-1'$ bond, respectively.

It is evident that the values of $\Delta E_A$ and hence of $\Delta E_B$ increase with decreasing $\rho$ and agree with the values for benzene when $\rho$ is 0. This means that A-band as well as the B-bond is gradually shifted toward shorter wavelengths as the value

TABLE V

| Stilbene | $\lambda_A$ m$\mu$ | $\nu_A$ cm$^{-1}$ | $\Delta E_A$ $-\beta$ | $\rho$ | $\theta$° | $R$ Å | $R.E.$ $-\beta$ | $p_{\alpha-1}$ | $p_{\alpha-\alpha'}$ |
|---|---|---|---|---|---|---|---|---|---|
| *trans-* | 294.1 | 34002 | 1.1423 | 0.9084 | 0 | 1.445 | 0.704 | 0.384 | 0.8555 |
| *cis-* | 280 | 35714 | 1.247 | 0.787 | 28 | 1.456 | 0.530 | 0.333 | 0.890 |

$\rho$ decreases and therefore as the value of $\theta$ increases, and that these bands will coincide with those of benzene when $\rho$ is 0 and therefore when $\theta$ is 90°.

It appears that there is no simple quantitative relation between $\rho$ and $\Delta E_A$, or between $\Delta E_A$ and $R.E.$ On the other hand, $R.E.(-\beta)$ is almost completely proportional to $\rho^2$ and can approximately be expressed as $0.8473\times\rho^2$. In addition, $p_{\alpha-1}$ is roughly proportional to $\rho$ and can roughly be expressed as $0.425\times\rho$.

**Correlation of the Calculated Transition Energy with the Observed Position of the Conjugation Band.**—The value of $\rho$ when $\theta$ is 0° and $R$ is 1.445 Å is 0.9084, and the corresponding value of $\Delta E_A$ is $1.1423(-\beta)$, which is subsequently referred to as $\Delta E_L$. The value of the wave number corresponding to $\Delta E_L$, namely $\nu_L$, is assumed to be 34002 cm$^{-1}$ (294.1 m$\mu$) which is the wave number of the A-$\gamma$-band in the spectrum of *trans*-stilbene in *n*-heptane, on the basis of the considerations mentioned already.

On the other hand, the value of $\Delta E_A$ when $\rho$ is 0, namely $\Delta E_S$, is $2(-\beta)$, and the corresponding value of the wave number, namely $\nu_S$, is assumed to be 48000 cm$^{-1}$ (208.3 m$\mu$), the center of gravity of singlets of benzene, as usual.

Then, the value of $\Delta E_A$ $(-\beta)$ for a given compound of the stilbene-type is obtained from the observed position ($\nu_A$ in wave number) of the conjugation band by Eq. 8 in the first part[6] of this series. Consequently, the corresponding value of the parameter $\rho$ and then the values of $\theta$, $R.E.$, $p$, etc. can be obtained in turn.

### Spectrum of *cis*-Stilbene

The solution spectrum of *cis*-stilbene (cf. Table I and Fig. 1 and also Refs. 1 and 7) differs considerably from that of the *trans*-isomer. The conjugation band (A-band) in the former is structureless in contrast to the one in the latter, and at a considerably shorter wavelength and of lower intensity than the one in the latter. This hypsochromic shift of the band is explained as being due to the non-planarity of the most probable configuration of *cis*-stilbene. The B-band of *cis*-stilbene is also structureless and at a shorter wavelength than the corresponding band of the *trans*-isomer, while the former is more intense than the latter.

### Application of Calculation and Discussion

Data of the spectrum of the *n*-heptane solution of *cis*-stilbene are not available. Hence, the position of the conjugation band (280 m$\mu$) in the spectrum of the ethanol solution is used as the basis of calculation for *cis*-stilbene, since the solvent effect of ethanol on the position of the band is considered not to differ significantly from

that of *n*-heptane on the analogy of the observation in the case of *trans*-stilbene. The results of application of the calculations to *cis*- and *trans*-stilbenes are shown in Table V.

The value of about 28° for the interplanar angles in *cis*-stilbene is in fairly good agreement with the value of about 25° estimated from the scale model[1].

At these values of the interplanar angles the steric repulsion between the two phenyl groups may be almost completely relieved. The difference between the stabilities of the isomers may be considered as the sum of the difference of extra-resonance (stabilization) energy and the difference of steric repulsion (destabilization) energy. If it is assumed that the difference of steric repulsion energy is small in the most probable configurations of the two isomers, the difference of stability is ascribed mainly to the difference of extra-resonance energy. When the value of $-\beta$ is tentatively assumed as 20 kcal./mol., the extra-resonance energy in *trans*-stilbene is evaluated as 14.07 kcal./mol. and that in the *cis*-isomer as 10.60 kcal./mol. The former value agrees fairly well with the value of 15 kcal./mol.[22] estimated from the heat of formation as well as the value of 12.5 kcal./mol.[23] estimated from the heat of hydrogenation[24], although the estimations of resonance energy, in general, do not seem to be entirely free from ambiguity. The difference between the extra-resonance energies of the two isomers is evaluated as about 3.5 kcal./mol. This value is also in satisfactory agreement with the experimental value of the energy difference between the isomers, 3 kcal./mol., estimated from the equilibrium of the thermal isomerization by Kistiakowsky and Smith[25] and by Taylor and Murray[26].

With a view to explaining the fact that the conjugation band of *cis*-stilbene is at a shorter wavelength and is of lower intensity than the corresponding one of the *trans*-isomer, Braude and other[27] have stated as follows: "Assuming that the wavelength shift of 150 Å from *trans*- to *cis*-stilbene is wholly due to steric hindrance, the differential de-stabilization amounts to about 6 kcal./mol., a value remarkably close to the resonance energy of *trans*-stilbene". That is, it seems that they have attempted to correlate the shift with the resonance energy or/and the steric repulsion energy. However, as already mentioned, there is no direct relation between the resonance energy and the electronic transition energy. And further, as mentioned in the earlier parts[6,28] of this series, there is also no direct relation between the steric repulsion energy and the transition energy. It seems evident that Braude and other's attempt was unsuccessful.

The values of $\Delta E_B(-\beta)$ for *trans*- and *cis*-stilbenes are estimated at 1.571 and 1.624, respectively. From these values the B-bands of these compounds are expected to be at 41001 $cm^{-1}$ (243.9 m$\mu$) and 41864 $cm^{-1}$ (238.9 m$\mu$), respectively, by application of the relation between $\Delta E$ and $\nu$ postulated above originally for the A-band. Considering the approximation used, it may be said that the agreement between these expected positions and the observed positions of the B-bands is nearly perfect.

## Experimental

**Measurements of Spectra.** — All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

The crystal spectra of *trans*-stilbene were measured by the pressed KCl-disk technique described by Dale[12]. The potassium chloride used had been precipitated from water solution with hydrochloric acid to obtain small particle size and dried at 400 to 450°C for about 6 hr., according to Hales and Kynaston[29]. As an example of the procedures of the preparation of the mixtures, that for the disks on which the spectra shown in Fig. 4 as well as Table III were measured will be described below. About 3.5 mg. of pure *trans*-stilbene was thoroughly ground in an agate mortar with about 200 mg. of potassium chloride. About 10.5 mg. of the mixture was then ground with about 350 mg. of potassium chloride, and pressed under vacuum in the usual manner into transparent disks (a radius, 0.65 cm.). The disk (a) weighed 140.4 mg. (the thickness, about 0.532 mm.), and the disk (b) weighed 111.1 mg. (the thickness, about 0.421 mm.).

**Preparations of *p*-Substituted *trans*-Stilbenes.**— *p*-Methoxy-*trans*-stilbene was prepared by the

Meerwein reaction[30] after the procedure of the preparation of *p*-methoxycarbonyl-*trans*-stilbene described by Fuson and Cooke[31]. The diazonium salt of *p*-anisidine was prepared by adding dropwise a solution of 27 g. of sodium nitrite in 45 ml. of water to a mixture of 150 ml. of 25% hydrochloric acid, 46.2 g. of *p*-anisidine, and 150 g. of ice. Throughout this experiment the reaction mixture was well stirred. An ice bath was placed around the reaction flask and 91.8 g. of crystalline sodium acetate was added. A solution of 55.5 g. of cinnamic acid in 450 ml. of acetone was added and the ice bath was removed. Five minutes later a solution of 20.3 g. of cupric chloride in 45 ml. of water was added dropwise and the mixture was stirred for about two hours at room temperature. After removal of a large amount of acetone, the residue was extracted with benzene. The benzene solution was washed in turn with a dilute solution of sodium carbonate, with dilute hydrochloric acid, and with water, and then dried on calcium chloride. After removal of the solvent, about 33 g. of a dark brown solid product was obtained. Treatment of the crude product with activated charcoal and repeated recrystallization from ethanol gave 23 g. of white crystals of *p*-methoxy-*trans*-stilbene, m.p. 136.8~137.5°C; yield, 29.2%.

*p*-Nitro-*trans*-stilbene was prepared from *p*-nitroaniline by the Meerwein reaction, quite analogously to the synthesis of the methoxy-analogue mentioned above. The purified product, yellow crystals, melted at 156~157°C; yield, about 15%.

## Summary

(1) The quantitative relations between the degree of deviation from the coplanarity of the molecular configuration and the ultraviolet absorption spectrum as well as the quantities such as the extra-resonance energy and the $\pi$-bond orders have been determined for the stilbene-type compounds by calculations based on the simple LCAO molecular orbital method.

(2) The ultraviolet absorption spectra of *trans*-stilbene in the crystalline state, in the solution state, and in the vapor state have been discussed in reference to the spatial configurations of the molecule in the various states. The conjugation band in the vapor spectrum is at considerably shorter wavelengths than that in the solution spectra as well as the crystal spectra, a fact which has been considered as probably indicating that the most likely configuration of the molecule in the vapor state deviates considerably from coplanarity. The magnitude of the red-shift of the conjugation band in the crystal spectra measured by the pressed KCl-disk technique relative to the band in the spectrum of the *n*-heptane solution has been found to be smaller than the value anticipated for the rigid molecule. From this fact it has been inferred that the most probable configuration of *trans*-stilbene in solution does not significantly differ from the one in the crystalline state and is planar or nearly planar.

(3) On the basis of the above inference, the calculations have been applied to *cis*- and *trans*-stilbenes, and the interplanar angles in the most probable configuration of *cis*-stilbene have been estimated at about 28° from the position of the conjugation band, in fairly good agreement with the value estimated from the scale model. The results of the calculations have been discussed.

(4) In addition, the solvent effects of various solvents on the spectra of *trans*-stilbene and its *p*-methoxy- and *p*-nitro-derivatives have been discussed with special reference to the effect of benzene which has been found to cause a large bathochromic displacement of the conjugation band and a remarkable redistribution of intensity among the vibrational bands of the conjugation band of each compound.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. VI. Triphenylethylene, Tetraphenylethylene and Tolan*

By Hiroshi SUZUKI

(Received August 15, 1959)

The method developed in the preceding part[1] of this series is applied to triphenylethylene, tetraphenylethylene and tolan, and the relation between the ultraviolet absorption spectra and the spatial configurations of these compounds is discussed.

## Triphenylethylene and Tetraphenylethylene

**Spectra.** — The ultraviolet absorption spectra of tri- and tetraphenylethylene in chloroform were formerly measured by Arends[2]. According to the results, the spectra differ only slightly from the spectrum of *trans*-stilbene. Jones[3] explained this spectral similarity as follows. "The three phenyl groups of triphenylethylene and the four phenyl groups of tetraphenyl ethylene can not be accommodated in a strainless planar structure; the strain can be eased either by a small rotation of all of the phenyl groups along their 1, 4-axes, or by a larger displacement of one of the phenyl groups of triphenylethylene or two of the *trans*-related phenyl groups of tetraphenylethylene, leaving two remaining *trans*-phenyl groups in the plane of the ethylenic bond. This second hypothesis leaves the molecule of tetraphenylethylene with a *trans*-stilbene chromophoric system together with two *insulated* phenyl groups, the absorption of which is too feeble to affect the spectrum".

The spectra of these compounds in *n*-heptane and in benzene have been newly measured by the present author. The results are shown in Table I and Fig. 1, in which the spectra of *trans*-stilbene[1] are included for comparison.

The A-band (conjugation band) of triphenylethylene as well as that of tetraphenylethylene has no distinct fine structure in contrast to that of *trans*-stilbene. The B-band, on the other hand, of triphenylethylene has a pattern of fine

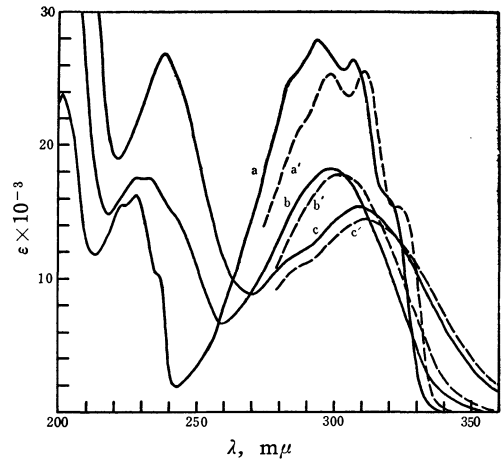

Fig. 1. Ultraviolet absorption spectra of *trans*-stilbene (a, in *n*-heptane; a', in benzene), triphenylethylene (b, in *n*-heptane; *b'*, in benzene), and tetraphenylethylene (c, in *n*-heptane; *c'*, in benzene) (cf. Table I).

structure closely similar to that of *trans*-stilbene.

Assuming that the maxima of the A-bands in the spectra of tri- and tetraphenylethylene in *n*-heptane are to be compared with the most intense maximum, viz. the $\gamma$-band, of fine structure of the A-band of *trans*-stilbene in the same solvent, the position of the maximum of the conjugation band is progressively shifted toward longer wavelengths as the number of phenyl groups in a molecule increases. The B-band is also shifted toward longer wavelengths in the same sequence. On the other hand, while the molecular extinction coefficient of the A-band decreases in the sequence, that of the B-band as well as that of the C-band increases markedly in the sequence.

**Calculation and Discussion.** — When it is assumed that triphenylethylene as well as tetraphenylethylene has a configuration in which the two *trans*-related phenyl groups are coplanar with the plane of the ethylenic bond according to Jones' second

hypothesis, it is evident that calculations quite similar to the one for stilbene described in the preceding part of this series can be applied to these compounds.

Alternatively, when it is assumed that in tetraphenylethylene all of the phenyl groups are rotated out of the plane of the ethylenic bond to the same extent as each other according to Jones' first hypothesis, the secular equation for the determination of the molecular orbitals as linear combinations of $2p\pi$ atomic orbitals is factorized into one equation identical in form with the one for stilbene and two equations for benzene, when $\rho'$ is $1/\sqrt{2}\times\rho$, $\rho'\beta$ representing the $\pi-\pi$ resonance integral for each bond connecting a phenyl group to a ethylenic carbon atom.

Similarly, when it is assumed that $\rho'$ is equal to $1/\sqrt{2}\times\rho$ also in triphenylethylene, in which the $\pi-\pi$ exchange integral for each of the bonds connecting two phenyl groups to the same ethylenic carbon atom and that for the bond connecting the other phenyl group to the other ethylenic carbon atom are denoted by $\rho'\beta$ and $\rho\beta$, respectively, the secular equation for this molecule can be factorized into an equation identical in form with the one for stilbene and the equation for benzene.

Therefore, whichever the configurations may be, the calculation based on the same equation as the one for stilbene can be applied to these compounds. Thus, after the procedure described in the preceding part of this series, the values of $\rho$ can be computed from the observed positions of the A-bands.

Since the A-bands of these compounds

are at longer wavelengths than the A-$\gamma$-band of *trans*-stilbene as the reference, the values of $\rho$ for the former compounds should be larger than that for the latter. If the models according to Jones' second hypothesis are chosen, the large values of $\rho$ for tri- and tetraphenylethylene relative to the value for *trans*-stilbene must be explained only by the assumption that the lengths of the bonds linking the coplanar *trans*-related phenyl groups to the ethylenic carbon atoms in tri- and tetraphenylethylene were shorter than the corresponding one in *trans*-stilbene, since the most probable configuration of *trans*-stilbene is considered to be already planar. This is undoubtedly implausible.

The inference that Jones' second hypothesis is implausible seems to be supported also by the following consideration. Thus, as is seen in Table I and Fig. 1, the molecular extinction coefficient of the A-band decreases markedly in the order *trans*-stilbene > triphenylethylene > tetraphenylethylene. If there were any *trans*-stilbene chromophore in these compounds, all these compounds would show the almost identical molecular extinction coefficient at least approximately.

Now, when the alternative models according to Jones' first hypothesis are assumed for the most probable configurations of tri- and tetraphenylethylene, the values of $\rho'$ are obtained from the values of $\rho$, and then, from the values of $\rho'$ the values of $\theta$, $R$ and $p_{\alpha-1}$ can be obtained by the procedure analogous to the one for stilbene in the preceding part of this series. The results of calculations are shown in Table II, in which those for *trans*-stilbene are included for comparison. (The symbols have the same significance as in the preceding part.)

The fact that the calculated value of $\theta$ in triphenylethylene is apparently greater than that in tetraphenylethylene is, needless to say, due to the probably unreal starting assumption that one of the phenyl groups in triphenylethylene is coplanar with the plane of the ethylenic bond. The most probable configuration of triphenylethylene is presumed to be the one in which all of the phenyl groups are rotated out of the plane of the ethylenic bond to certain extents. Therefore, no reliance is to be placed on the values of $\theta$, $R$ and $p_{\alpha-1}$ for this compound, while the values of $R.E.$, $p_{\alpha-\alpha'}$ and $\Delta E_B$ can probably be considered as rough approximations.

The above mentioned calculations are based on the assumption that the maxima of the A-bands of tri- and tetraphenylethylene are to be compared with the $\gamma$-band in the A-band of *trans*-stilbene. However, as is seen in Table I and Fig. 1, while the maxima in the spectra of tri- and tetraphenylethylene in benzene are considered to correspond to the maxima in *n*-heptane, the most intense maximum in the spectrum of *trans*-stilbene in benzene is the $\beta$-band and not the $\gamma$-band as in *n*-heptane. Accordingly the possibility that the $\beta$-band instead of the $\gamma$-band is to be taken as the reference can not perhaps be ruled out. In Table II, the results of the calculations carried out by taking the $\beta$-band as the reference are also shown, being denoted by symbol $\beta$, in addition to those mentioned already, which are denoted by symbol $\gamma$. However, in view of the correlations of these results with some properties of the compounds, results $\gamma$ seems more adequate, and hence subsequently the results of the calculations refer solely to results $\gamma$.

The B-bands are probably due to the allowed transitions from the highest occupied orbitals to the vacant orbitals with the energy of $-\beta$, or from the occupied orbitals with the energy of $+\beta$ to the lowest vacant orbitals, similarly to the case of stilbene. The C-bands are probably due to the allowed transitions from the orbitals with the energy of $+\beta$ to the orbitals with the energy of $-\beta$.

The B-band as well as the C-band increases the intensity in the order *trans*-stilbene < triphenylethylene < tetraphenylethylene, with an increasing number of benzene nuclei. It is interesting that the ratio of the molecular extinction coefficients of the C-bands of these compounds are roughly 1:2:3, in accordance with the ratio of the numbers of the orbitals which are considered to participate in these transitions.

In addition, it is of interest that the magnitude of the red-shift of the conjugation band associated with the change of solvent from *n*-heptane to benzene is appreciably smaller in the cases of tri- and tetraphenylethylene than in the case of *trans*-stilbene as well as some para-substituted *trans*-stilbenes which are presumed to be planar. If the presumption in the preceding part of this series that the shift is due to the special interaction between the $\pi$-orbitals of benzene and

those of the solute molecule is correct, this fact may be related to the nonplanarity of the configurations of tri- and tetraphenylethylene. This subject will be discussed more fully in a later part of this series.

**Correlations between the Spatial Configurations and Some Properties of the Compounds.**—The melting point of tetraphenylethylene is 223~224°C, and is considerably lower than that of its positional isomer, *p,p'*-diphenyl-*trans*-stilbene (about 300°C). In addition, the solubilities of the former compound in usual organic solvents are much greater than those of the latter. These facts are probably due to the nonplanarity of the configuration of tetraphenylethylene. The melting point of triphenylethylene is 68~69°C and markedly lower than that of its positional isomer, *p*-phenyl-*trans*-stilbene (about 220°C), and even than that of *trans*-stilbene (125°C). This fact is probably due to the nonplanarity and the unsymmetrical nature of the configuration of triphenylethylene.

According to Everard and others[4], the exaltation of the molecular refraction ($E[R]_D$) of *trans*-stilbene is +6.6, and that of triphenylethylene is about the same as, or only 0.1 at most less than, that of *trans*-stilbene. This fact may be considered to indicate that the extent of conjugation in triphenylethylene is almost equal to that in *trans*-stilbene, almost in complete accordance with the present conclusion deduced from the ultraviolet absorption spectra.

Next, the relations between the spatial configurations and the reactivities of these compounds will be discussed. In general, steric effects in reactions of olefinic compounds may be divided into the two main types: the steric hindrance to the approach of the reagent to the reaction site and the steric hindrance to resonance. The former may be illustrated by the fact that the rate of bromination of neopentylethylene is smaller than that of *t*-butylethylene[5]. That is, the steric effect of this type retards the reactions in most cases.

Tetraphenylethylene does not add bromine[6,7]. This is probably due to the steric effect of the first type mentioned above. That is, it seems that the phenyl groups rotated out of the plane of the central ethylenic bond inhibit the approach of the reagent to the bond.

According to Leavitt and others[8], the "methyl affinity" is 205 for *trans*-stilbene, 85 for triphenylethylene, and less than 25 for tetraphenylethylene. The "methyl affinity" is considered as a measure of reactivity of compounds to the methyl radical, although it is not clear which atoms of the compounds are attacked. The order of the "methyl affinity" mentioned above appears to be well explained in terms of the steric effect of the first type.

The reaction of olefins with perbenzoic acid in nonpolar solvents gives excellent yields of the corresponding epoxides. It has been presumed that in this reaction perbenzoic acid acts as a "double-bond reagent". According to Lynch and Pausacker[9], the reactivity of the series of phenyl-substituted ethylenes toward perbenzoic acid follows the double-bond orders of the olefinic links calculated by Coulson and Jacobs[10] (i.e. styrene>*trans*-stilbene > triphenylethylene> tetraphenylethylene). However, the calculations by Coulson and Jacobs are unacceptable because they are based on unreal planar molecular models even in the cases of tri- and tetraphenylethylene.

In spite of this, the sequence of the $\pi$-bond orders calculated by Coulson and Jacobs agrees qualitatively with the sequence of the $\pi$-bond orders as well as that of the extra-resonance energies (i.e. the bond localization energies of the ethylenic bonds) calculated here by taking the spatial configurations into account. (The $\pi$-bond orders of the ethylenic bonds calculated by Coulson and Jacobs are: *trans*-stilbene, 0.820; triphenylethylene, 0.752; tetraphenylethylene, 0.685. On the other hand, those calculated by the present author are 0.8555, 0.845 and 0.820, respectively.) Therefore, the sequence of the bond order and hence the sequence of the bond localization energy are presumed to determine at least partly the sequence of the reactivity. However, judging from the fact that the differences of the bond order and of the bond localization energy among these compounds are small, the steric effect of the first type may also be a contributory factor to the reactivity. This subject will be discussed in somewhat

| $\delta$ | (275.8) | +3.1 | 0.288 | 1960 | (218.5) | +1.3 | 0.264 | 1790 |
| $\varepsilon$ | 268.0 | +2.7 | 0.259 | 1760 | | | | |

Wavelengths in parentheses denote inflections.

$\Delta\lambda$ denotes the magnitude of the wavelength displacement (in m$\mu$) of each band relative to the corresponding band in the spectrum in *n*-heptane.

$A$ denotes the absorbance (optical density).

greater detail in the succeeding part of this series.

In the reactions discussed so far, the reactivity decreases in the order *trans*-stilbene > triphenylethylene > tetraphenylethylene. This order coincides not only with the order in which the steric hindrance to the approach of the reagent to the ethylenic bond increases, but also with the order in which the $\pi$-bond order decreases and hence the bond localization energy increases. Both the factors, steric and electronic, will contribute to the reactivity in the same direction.

On the other hand, in the polarographic reduction the effect of conjugation operates in the opposite direction. Thus, the reduction takes place more easily with an increasing extent of conjugation, and the isolated double bond is not reducible. Maccoll[11] has found that there exists a linear relationship between the reduction potential and the energy required to place one or two electrons in the lowest vacant orbital of the molecule, that is, the energy (in $-\beta$) of the lowest vacant orbital, which is evidently half of $\Delta E_A(-\beta)$ in the present treatment. That is, the reduction potential should be related directly to the transition energy corresponding to the conjugation band. According to Laitinen and Wawzonek[12], in the series of phenylated ethylenes the ease of electro-reduction increases with increasing substitution in the order styrene < 1,1-diphenylethylene < *trans*-stilbene < triphenylethylene < tetraphenylethylene. The mean value of the reduction potential $E$ (in V.) is $-2.1425$ for *trans*-stilbene, $-2.1155$ for triphenylethylene, and $-2.046$ for tetraphenylethylene. On the other hand, the energies of the lowest vacant orbitals (in $-\beta$) of these compounds are calculated to be 0.5712, 0.5558 and 0.5219, respectively. There exists a linear relationship between the reduction potential and the energy of the lowest vacant orbital at least in so far as these compounds are concerned. Tolan has a slightly more negative reduction potential ($-2.195$ V.) than *trans*-stilbene. This fact corresponds only qualitatively to the fact that the conjugation band of tolan is at shorter wavelengths than that of *trans*-stilbene as will be shown in the succeeding section (the energy of the lowest vacant orbital of tolan is calculated to be $-0.635\ \beta$).

*trans*-Stilbene forms a colored complex with 1,3,5-trinitrobenzene. According to the qualitative study by Ley and Rinke[13], when an aromatic compound is mixed with 1,3,5-trinitrobenzene in chloroform (both concentrations, 0.02 mol./l.), the solution colors as follows: *trans*-stilbene, intense yellow; triphenylethylene, yellow; tetraphenylethylene, very feeble yellow; (tetraphenylethane, colorless). The extent of coloration is considered to indicate

qualitatively the extent of the complex formation. Thus, the extent of the complex formation decreases with an increasing number of phenyl groups in the series of phenylated ethylenes, and accordingly may be related to the spatial configurations of these compounds.

## Tolan

**Spectra.** — The ultraviolet absorption spectra of tolan (diphenylacetylene) are shown in Table III and Fig. 2. The spectra exhibit the conjugation band with well-resolved fine structure at considerably shorter wavelengths than the conjugation band of *trans*-stilbene. The spectrum of tolan in the crystalline state measured

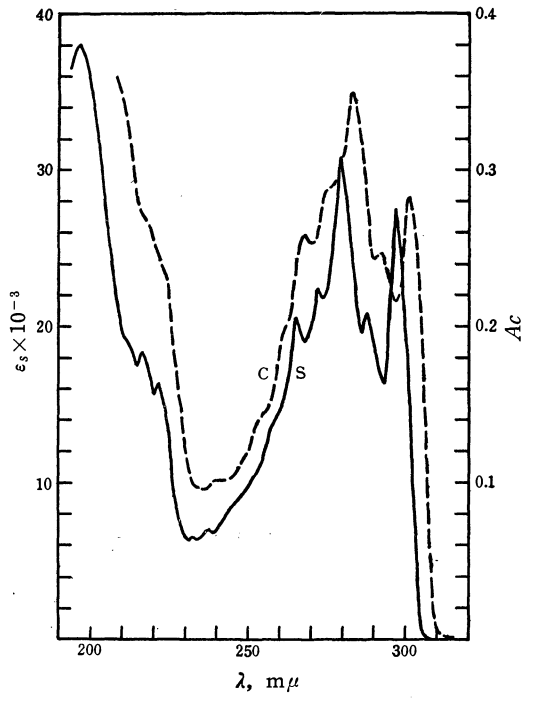

Fig. 2. Ultraviolet absorption spectra of tolan in solution in *n*-heptane (S) and in the crystalline state (the pressed KCl-disk) (C). Note separate ordinates for solution and crystals (cf. Table III).

by the pressed KCl-disk technique resembles the solution spectrum on the whole.

The red-shift of each band associated with the change of the state from the *n*-heptane solution to the crystalline state is seen to increase with almost complete regularity with the wavelength of the band from about 1.3 mμ at 217.2 mμ to about 4.4 mμ at 297.2 mμ, although these shifts are considerably smaller than the values determined by Dale[14] for naphthalene and anthracene (about 2 mμ at 220 mμ to 8 mμ at 300 mμ).

As seen already in the case of *trans*-stilbene in the preceding part of this series, also in the case of tolan, the apparent molecular extinction coefficients in the KCl-disk spectrum are much smaller than the corresponding molecular extinction coefficients in the solution spectrum, the former ones being only about 1/13 of the latter ones.

**Calculation.** — The notation used is as follows: the carbon atoms of the central triple bond, $\alpha$ and $\alpha'$; the carbon atoms attached to $\alpha$ and $\alpha'$, 1 and 1'; the $2p\pi$ atomic orbitals at 1 and 1', $\phi_1$ and $\phi_{1'}$; the two $\pi$-bonds in the triple bond, $(\alpha-\alpha')_x$ and $(\alpha-\alpha')_z$; the corresponding $2p\pi$ atomic orbitals, $\phi_x$, $\phi_{x'}$, $\phi_z$, and $\phi_{z'}$; the $\pi-\pi$ resonance integral for each of $(\alpha-\alpha')_x$ and $(\alpha-\alpha')_z$, $\eta\beta$; the $\pi-\pi$ resonance integral between $\phi_1$ and $\phi_x$ as well as that between $\phi_{1'}$ and $\phi_{x'}$, $\rho_x\beta$; that between $\phi_1$ and $\phi_z$ as well as that between $\phi_{1'}$ and $\phi_{z'}$, $\rho_z\beta$.

The secular equation for the determination of the molecular orbitals of tolan as linear combinations of the $2p\pi$ atomic orbitals can be factorized into the stilbene-type equation and the equation for an isolated $\pi$-bond, either when one of the parameters $\rho_x$ and $\rho_z$ is zero and the other is replaced by $\rho$, or when the parameters are equal to each other and both are replaced by $1/\sqrt{2}\times\rho$. The former requirement means that the two phenyl groups are in conjugation solely with one of the two $\pi$-bonds in the triple bond, leaving the other insulated. The alternative requirement means, needless to say, that the axes of $\phi_1$ and $\phi_{1'}$ form an angle of 45° with the axes of $\phi_x$ and $\phi_{x'}$ as well as the axes of $\phi_z$ and $\phi_{z'}$.

According to the X-ray crystal analysis by Robertson and Woodward[15], tolan in the crystalline state has a planar configuration in which the lengths of the $\alpha-\alpha'$ bond and of the $\alpha-1$ as well as the $\alpha'-1'$ bond are 1.19±0.02 and 1.40±0.02 Å, respectively. The most probable configuration in solution is thought not to differ significantly from the configuration in the crystalline state, in view of the close similarity of the spectra in the two states. From the values of the bond lengths the values of the parameters $\eta$ and $\rho$ are

14) J. Dale, *Acta Chem. Scand.*, **11**, 650 (1957). See also Ref. 1 and Part I of this series: This Bulletin, **32**, 1340 (1959).

15) J. M. Robertson and I. Woodward, *Proc. Roy. Soc.* (*London*), **A164**, 436 (1938).

calculated to be 1.378 and 0.983, respectively, by the usual procedure based on the proportionality between the $\pi-\pi$ resonance integral and the $\pi-\pi$ overlap integral. By solving the secular equation, the following values are obtained: $\Delta E_A(-\beta)$, 1.270; $\Delta E_A(-\gamma)$, 1.303; *R. E.* $(-\beta)$, 0.732; *R. E.* $(-\gamma)$, 0.221; $p_{\alpha-\alpha'}$, 1.868; $p_{\alpha-1}=p_{\alpha'-1'}$, 0.372; $\Delta E_B(-\beta)$, 1.635. (The symbols have the same significance as in the preceding part of this series.)

Whereas the length of the $\alpha-1$ "single" bond in tolan is shorter than the length of the corresponding "single" bond (1.44± 0.02 or 1.45±0.02 Å) in *trans*-stilbene, the $\pi$-bond order of the former is smaller than that of the latter (0.384). This fact is perhaps attributed to the difference of the hybridization of the $\sigma$-orbital at the $\alpha$ carbon atom in these two compounds (tolan, $sp$; stilbene, $sp^2$). Berthier and Pullman[16] reported somewhat different values for the $\pi$-bond orders of these compounds (tolan: $\alpha-\alpha'$, 1.909; $\alpha-1$, 0.307; *trans*-stilbene: $\alpha-\alpha'$, 0.879; $\alpha-1$, 0.352), but the relationship among the values is similar.

By using the linear relation between $\Delta E_A$ and $\nu_A$ postulated for the stilbene-type compounds in the precending part of this series (the longer-wavelength-side reference is the $\gamma$-band in the spectrum of *trans*-stilbene in *n*-heptane and the shorter-wavelength-side reference is the center of gravity of singlets of benzene), the wave number $\nu_A$ corresponding to the value of $\Delta E_A(-\beta)$ for tolan is calculated to be 36086 $cm^{-1}$ (277.1 m$\mu$). This is in good agreement with the observed position (279.9 m$\mu$) of the $\gamma$-band of tolan in *n*-heptane, which is the most intense maximum of fine structure of the conjugation band. In addition, when the $\alpha$-band or the $\beta$-band in the spectrum of *trans*-stilbene in *n*-heptane is taken as the longer-wavelength-side reference, the value of $\nu_A$ is computed to be 33702 $cm^{-1}$ (296.7 m$\mu$) or 34879 $cm^{-1}$ (286.7 m$\mu$), correspondingly, in agreement with the observed positions of the $\alpha$-band (297.2 m$\mu$) and the $\beta$-band (288.5 m$\mu$) in the spectrum of tolan in *n*-heptane. The good agreement between the calculated wavelengths and the observed ones of the bands seems to justify the postulation of the linear relation between $\Delta E_A$ and $\nu_A$.

16) G. Berthier and B. Pullman, *Compt. rend.*, **228**, 397 (1949).

## Experimental

**Measurements of Spectra.**—All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

The crystal spectrum of tolan was measured by the pressed KCl-disk technique quite analogously to the case of *trans*-stilbene in the preceding part of this series. About 3 mg. of tolan was thoroughly ground with about 200 mg. of potassium chloride and then about 10 mg. of the mixture was ground with about 350 mg. of potassium chloride and pressed. The disk used weighed 84.7 mg. (the thickness, about 0.321 mm.).

**Materials.**—Triphenylethylene was prepared by dehydration of 1,1,2-triphenylethanol obtained by the reaction of benzophenone with benzyl magnesium chloride[17]. From 27.3 g. (0.15 mol.) of benzophenone, 24.3 g. (0.095 mol.) of triphenylethylene, white crystals melting at 68~69°C, were obtained after recrystallization from 95% ethanol (63.3% of the theoretical amount).

Tetraphenylethylene was prepared by heating diphenyldichloromethane (benzophenone dichloride) with powdered copper in anhydrous benzene[18]. Diphenyldichloromethane was prepared from benzophenone and phosphorus pentachloride[19]. From 9.1 g. (0.05 mol.) of benzophenone, 4.7 g. (0.014 mol., 56.5% of the theoretical amount) of tetraphenylethylene, almost colorless crystals melting at 223~224°C, were obtained after recrystallization from a 1 : 1 by volume mixture of absolute ethanol and benzene.

Tolan was prepared, according to the directions of Schlenk and Bergmann[20], by oxidizing benzil dihydrazone with mercuric oxide. Benzil was prepared by oxidation of benzoin with nitric acid[21]. The yield of pure tolan, colorless crystals melting at 62°C, from 47 g. (0.219 mol.) of benzil was 16.4 g. (0.092 mol., 42% of the theoretical amount) after repeated recrystallization from ethanol.

## Summary

The most probable configuration of triphenylethylene as well as that of tetraphenylethylene has been inferred to be the one in which all of the phenyl groups are rotated out of the plane of the ethylenic bond, on the basis of the analysis of the ultraviolet absorption spectra by application of the method based on the simple LCAO molecular orbital method described in the preceding part of this series. Some physical and chemical properties of these compounds have been

discussed with reference to the spatial configurations.

The method has been applied also to tolan (diphenylacetylene), and it has been shown that the calculated wavelengths of the bands agree fairly well with the observed ones.

In addition, it has been shown that the spectrum of tolan in the crystalline state measured by the pressed KCl-disk technique resembles the spectrum of the solution in *n*-heptane on the whole, and that the red-shift of each band associated with the change of the state from the *n*-heptane solution to the crystalline state increases with almost complete regularity with the wavelength of the band from about 1.3 mμ at 217.2 mμ to about 4.4 mμ at 297.2 mμ, the shifts observed here being appreciably smaller than the analogous shifts observed by Dale in the spectra of naphthalene and anthracene.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. VII. α-Substituted and α,α'-Disubstituted Stilbenes*

By Hiroshi SUZUKI

(Received August 15, 1959)

The method developed in Part V[1] of this series is applied to α- and α,α'-substituted stilbenes, some of which were preliminarily treated in an earlier paper[2], and the relations between the ultraviolet absorption spectra and the spatial configurations of these compounds are discussed. Further, the relations between the spatial configurations and some physical and chemical properties of these compounds are discussed in detail with special reference to α,α'-dimethylstilbene.

**Ultraviolet Absorption Spectra.**—The ultraviolet absorption spectra of α-alkyl- and α,α'-dialkylstilbenes in ethanol were reported previously[2]. The spectra of some of these compounds as well as α,α'-dihalostilbenes in *n*-heptane have newly been measured. These are shown in Figs. 1 and 2. In Table I, the data of the spectra are summarized.

The spectra of the alkylated stilbenes in *n*-heptane do not differ significantly from the corresponding spectra in ethanol. Thus, the following generalizations, some of which were not explicitly stated in the earlier paper, can be deduced. (1) The conjugation band is shifted toward shorter wavelengths and is reduced in intensity with increasing number and increasing size of substituents at the ethylenic

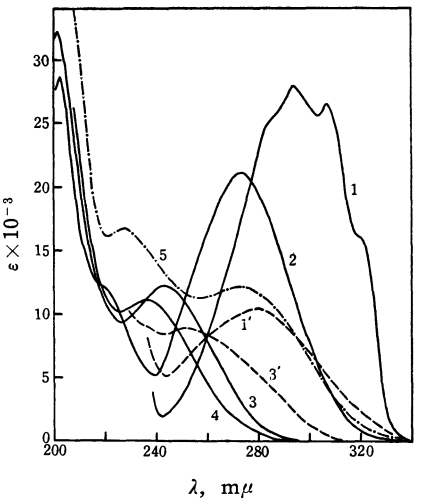

Fig. 1. Ultraviolet absorption spectra of stilbenes in *n*-heptane: 1, *trans*-stilbene; 1', *cis*-stilbene (in ethanol); 2, *trans*-α-methylstilbene; 3, *trans*-α,α'-dimethylstilbene; 3', *cis*-α,α'-dimethylstilbene; 4, *trans*-α,α'-diethylstilbene; 5, methyltriphenylethylene.

carbon atoms in each of the *trans* and the *cis* series. (2) The conjugation band of a *trans* isomer is invariably more intense than that of the corresponding *cis* isomer. (3) With stilbene as well as α-methylstilbene, the conjugation band of the *trans* isomer is at longer wavelengths than that of the *cis* isomer. On the other hand, with α,α'-dimethyl- as well as α,α'-diethylstilbene, the conjugation band of the *trans* isomer is at shorter wavelengths than that of the *cis* isomer. (4) The conjugation bands of these stilbene derivatives have, similarly to that of *cis*-stilbene, no fine structure, in contrast to that of *trans*-stilbene.

Also with *trans*-α,α'-dihalostilbenes, the conjugation band is structureless, and is shifted toward shorter wavelengths as the substituents become larger. *trans*-α,α'-Diiodostilbene in *n*-heptane dissociates

gradually into tolan and iodine, and consequently the absorption due to tolan is detected in the spectrum (cf. Fig. 2 with Fig. 2 in the preceding part[3] of this series). The inflection at near 220.5 mμ probably indicates the vestigial conjugation band of *trans*-α, α'-diiodostilbene.

**Application of Calculation.**—In the application of the method developed in Part V of this series to these stilbene derivatives, the data of the spectra of *n*-heptane solutions newly measured are used. For the compounds, the spectra of which in *n*-heptane have not yet been measured, the data of the spectra of ethanol solutions are used, since the positions of the bands may be considered not to vary significantly in either of the solvents (cf. Table I and also Parts I[4] and V of this series).

The effects of the substituents upon the spectra must include not only the steric hypsochromic effect due to the steric interferences between the substituents and the phenyl groups but also the electronic (probably bathochromic) effect of the substituents (cf. Part II[5] of this series). However, in view of the fact that the substituents in the compounds treated here are at the positions of cross-conjugation to the conjugated system of the stilbene skeleton, this possible electronic effect is considered to be probably very small compared with the steric hypsochromic effect, especially in the cases of the alkyl substituents, and therefore, is ignored in the present treatment.

In the cases of the halogen substituents, the electronic effect of the lone pair electrons of the halogen atoms may be relatively large campared with the electronic (probably hyperconjugation) effect of the alkyl substituents, and perhaps it should not be ignored. Nevertheless, the possible electronic effect of all the substituents is ignored, for simplification, in the present treatment. That is, it is assumed that the position of the conjugation band is determined solely by the spatial configuration of the stilbene skeleton.

The results of the calculations are shown in Table II. The notation used here is the same as in Part V of this series.

In α-methylstilbene as well as α-methyl-α'-ethylstilbene, the positions of the two phenyl groups are not equivalent, and therefore, their angles of twist must differ from each other. In spite of this, the results for these compounds, obtained on the basis of the assumption that the angles of twist of the two phenyl groups are equal, are also shown for comparison.

It is to be noted that the calculated values of the angle of twist $\theta$ (interplanar angle) in Table II are possibly rather smaller than the actual values because of the neglect of the electronic effect of the substituents mentioned above. In addition, when the β-band instead of the γ-band of *trans*-stilbene is taken as the "longer-wavelength-side reference", the calculated values of $\theta$ will evidently become greater than those in Table II.

## Discussion

As will be expected, Table II shows that the calculated interplanar angle becomes larger with the increasing number and size of substituents. It is of interest that the change of the substituents from methyl groups to ethyl groups affects only rather slightly the position of the conjugation band and consequently the interplanar angle. A somewhat similar phenomenon has been seen in the comparison between *o*-methyl- and *o*-ethylbiphenyl[5]. On the

4) H. Suzuki, ibid., **32**, 1340 (1959).
5) H. Suzuki, ibid., **32**, 1350 (1959).

other hand, the replacement of the methyl group in β-methylcinnamic acid by an ethyl group has a greater steric consequence. According to Takahasi[6], the wavelengths (mμ) of the conjugation bands and the molecular extinction coefficients (in parentheses) of the bands of cinnamic acid and its β-alkyl derivatives in 94% ethanol are as follows: cinnamic acid, 273 (22000); β-methylcinnamic acid, 260 (15000); β-ethylcinnamic acid, 244 (10000).

The conjugation band of methyltriphenylethylene (1, 1, 2-triphenylpropene) is at a considerably shorter wavelength than that of triphenylethylene (cf. the preceding part of this series) and coincides in position almost completely with that of *trans*-α-methylstilbene. From this fact, it would be inferred that the most probable configuration of methyltriphenylethylene might be the one in which the phenyl group at the *trans*-position to the methyl group was completely rotated out of the plane of the ethylenic bond, or in other words, was insulated, leaving the two remaining *trans*-related phenyl groups in the configuration analogous to the most probable configuration of *trans*-α-methylstilbene. However, the fact that the intensity of the conjugation band of methyltriphenylethylene is much smaller than that of *trans*-α-methylstilbene suggests that this inference is unlikely. This situation is very similar to that observed in the comparison between the spectra of triphenylethylene and of *trans*-stilbene[3].

As mentioned already, it is especially noteworthy that the conjugation band of *trans*-α, α'-dimethylstilbene as well as its diethyl a analogue is at a shorter wavelength than that of the *cis* isomer, contrary to the generally accepted view that *trans* isomers of conjugated compounds should exhibit the conjugation bands at longer wavelengths than the corresponding *cis* isomers. A similar phenomenon has been observed by Nagai and Simamura[7] with some *p*, *p*'-disubstituted α, α'-dimethylstilbenes. These facts are considered to indicate that with these compounds the *trans* isomers are less conjugated than the corresponding *cis* isomers. In fact, as is seen in Table II, the calculated interplanar angles in the *trans* isomers of α, α'-dimethylstilbene and its diethyl analogue are larger than those of the corresponding *cis* isomers, and the calculated extra-resonance energies of the *trans* isomers are smaller than those of the *cis* isomers. This conclusion deduced here from the absorption spectra seems to be supported by some pieces of information on the properties of these compounds such as the reactivities, the nuclear magnetic resonance spectra, and the exaltations of molecular refraction. Accordingly, the relations between the spatial configurations and some physical and chemical properties of the stilbenes will be discussed in a later section with special emphasis on those for *trans*- and *cis*-α, α'-dimethylstilbenes.

**Correlation of the Calculated Interplanar Angles with the Values Estimated from Scale Models.**—That the calculated interplanar angle (58°) for *trans*-α, α'-dimethylstilbene agrees fairly well with the value estimated from scale models has been described in the earlier paper[2]. Thus, according as one assumes a twisted structure for this compound in which the ortho hydrogen atom of each phenyl group just touches the methyl group attached to the same ethylenic carbon atom as the phenyl group or a structure in which that hydrogen atom just touches the other methyl group, the interplanar angle is estimated at 60° or 56°, in good agreement with the calculated value.

For *trans*-α, α'-dibromostilbene, the interplanar angle is estimated at 48° or 51.5° from analogous models in which the interference radius of a bromine atom is 1.95 Å[8] (van der Waals radius) and the length of a C-Br bond is 1.91 Å[8] (the length of an Alkyl-Br bond). The actual length of the C-Br bond may be shortened more or less from the above normal value by interaction between the bromine atom and the ethylenic bond[9]. When the possible shortening of the bond is taken into account, the interplanar angle estimated from models will become slightly larger. The agreement of the calculated value (54.5°) of the interplanar angle with the value estimated from scale models is not so good as in the case of the dimethyl analogue; still it may be said to be fairly good.

6) M. Takahasi, ibid., 31, 756 (1958).
7) Y. Nagai and O. Simamura, presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958.
8) L. Pauling, "The Nature of the Chemical Bond", Cornell University Press, Ithaca, N. Y. (1940).
9) (a) H. de Laszlo, *Proc. Roy. Soc.* (*London*), **A146**, 690 (1934). (b) J. A. C. Hagill, I. E. Coop and L. E. Sutton, *Trans. Faraday Soc.*, **34**, 1518 (1938).

For the dichloro analogue, the interplanar angle is estimated at 43° or 48° from the analogous medels in which the interference radius of a chlorine atom is 1.80 Å[8] (van der Waals radius) and the length of a C–Cl bond is 1.77 Å[8] (the length of a normal Alkyl-Cl bond). The agreement of the calculated interplanar angle (39°) with the value estimated from models is worse than in the cases of the dimethyl and the dibromo analogues. The discrepancy is probably due mainly to the effect of the interaction of the lone pair electrons of the chlorine atoms with the ethylenic bond on the position of the conjugation band, which has been ignored in the present calculations. The interaction may affect not only the estimation of the interplanar angle from scale models by the contraction of the C–Cl bond (the length of the C–Cl bond in chloroethylene, for example, is 1.69 Å[10]), but also may exert a bathochromic effect on the conjugation band. Thus, if it were not for this effect, this compound would exhibit the conjugation band at a shorter wavelength than the observed position, and consequently the calculated interplanar angle would become larger than the value in Table II.

**Correlation of Some Properties with the Spatial Configurations.** — *Exaltation of molecular refraction.*—As Mulliken[11] stated for the case of alkylstyrenes, the exaltation of molecular refraction can be considered as a measure of the extent of conjugation. Some relevant data selected from the data by Auwers[12,13] are shown in Table III.

The exaltation is markedly greater in *trans*-stilbene than in the *cis* isomer. On the other hand, in contrast to the case of stilbene, the exaltation is, though slightly, smaller in *trans*-$\alpha,\alpha'$-dimethylstilbene than in the *cis* isomer. This reversal is similar to what happens to the electronic absorption spectra.

*Nuclear magnetic resonance.* — Curtin and others[14] measured the proton magnetic resonance spectra of stilbene, azobenzene, and diphenylcycloalkanes, and found that the positions of the aromatic proton resonance and those of the $\alpha$-protons provide a new method of assignment of configuration of such compounds.

According to the results of the measurements by them, the $\alpha$-hydrogens of *cis*-stilbene give rise to resonance at a higher magnetic field than those of the *trans* isomer, indicating that the $\alpha$-hydrogens of the *cis* isomer are more shielded than those of the *trans* isomer.

Recently, we measured the proton magnetic resonances of *trans*- and *cis*-$\alpha,\alpha'$-dimethylstilbenes and related compounds[15]. A relevant part of the results are shown in Table IV, together with the data by

TABLE III

Curtin and others for *trans*- and *cis*-stilbenes.

In contrast to the $\alpha$-hydrogens of *trans*- and *cis*-stilbenes, the hydrogens of the $\alpha$-methyl groups of *cis*-$\alpha,\alpha'$-dimethylstilbene and of the $\alpha$-ethyl groups of *cis*-$\alpha,\alpha'$-diethylstilbene give rise to resonance at lower fields than the corresponding hydrogens of the *trans* isomers. That is, the hydrogens are less shielded in the *cis* isomers than in the corresponding *trans* isomers.

Katayama calculated the magnetic fields due to the circulating $\pi$-electrons' currents for these compounds by making an allowance for the spatial configurations, and found that the calculated differences of the magnetic fields for the *trans* isomers and for the *cis* isomers are smaller than the observed ones. Accordingly, the observed differences may be partly due to the differences of the $\pi$-electron densities at carbon atoms and of the electron densities at the hydrogen atoms concerned, which is, in turn, probably due to the differences of the extent of conjugation as well as hyperconjugation. That is, it appears that the conjugation in the $\pi$-electron systems affects the chemical shift of the nuclear magnetic resonance. At any rate, it is of interest that the observations on the proton resonance mentioned above are considered to correspond to the fact that the sequence of the positions of the conjugation bands of *trans* and *cis* isomers in the case of stilbene is reversed in the cases of $\alpha,\alpha'$-dimethyl- and $\alpha,\alpha'$-diethylstilbene.

*Thermal isomerization.* — As mentioned already in Part V of this series, *trans*-stilbene is thermodynamically much more stable than the *cis* isomer. Thus, according to Taylor and Murray[16], the equilibrium mixture of the *cis-trans* thermal isomerization at 200°C consists of 96% of the *trans* isomer and 4% of the *cis* isomer. In addition, according to Kistiakowsky and Smith[17], the equilibrium mixture at 320~340°C contains 92~94% of the *trans* isomer. The heat of the thermal *cis-trans* isomerization ($-\Delta H$) is about 3 kcal./mol. (In addition, the heat of isomerization at 25°C has been estimated at $7.0 \pm 0.4$ kcal./mol. for *p*-nitrostilbene and at $4.6 \pm 0.3$ kcal./mol. for *p,p'*-dinitrostilbene from the heats of combustion[18]. Also with these compounds, the *trans* isomers are, of course, much more stable than the *cis* isomers.)

The difference of stability between the isomers is by far smaller in the case of $\alpha,\alpha'$-dimethylstilbene than in the case of stilbene. Thus, according to the previous study by Simamura and the present author[2,19], the equilibrium mixture yielded by heating either *trans*- or *cis*-$\alpha,\alpha'$-dimethylstilbene with a little concentrated sulfuric acid for 20 hr. at 210°C contained the *trans* and the *cis* isomers in the ratio of the amounts 55 : 45 or 60 : 40.

The fact that the *trans* isomer is still, though slightly, also more stable in this case than the *cis* isomer would appear, at first sight, to be rather surprising, being contrary to the anticipation from the absorption spectra. As discussed already in the previous paper[2], however, this fact is understandable if one considers that the steric repulsion between the two methyl groups in the *cis* isomer, which can not be reduced by the rotation of the phenyl groups, is also an important contributory factor to the stability besides the resonance stabilization.

According to Taylor and Murray[16], the equilibrium mixture of the *cis-trans* isomerization of $\alpha,\alpha'$-dichlorostilbene at 220~230°C contains 75% of the *cis* isomer. The large stability of the *cis* isomer relative to the *trans* isomer may be partly due to the attractive (London) force between the chlorine atoms in the *cis* isomer as Taylor and Murray stated, and may be partly due to the fact that the difference of the resonance stabilization energy between the two isomers is considered, on the analogy of the case of $\alpha,\alpha'$-dimethylstilbene, to be not so great as in the case of stilbene, the resonance being considerably suppressed in both isomers by the steric factors.

*Reaction with bromine.*—As seen in Tables IV and V in Part V of this series and Table II in the present paper, the extra-resonance energy *R.E.*, i.e. the bond localization energy of the central ethylenic bond, decreases and the $\pi$-bond order of the ethylenic bond $p_{\alpha-\alpha'}$ increases, with decreasing $\rho$, and hence with the increasing interplanar angle. In Table V, the calculated values of *R.E.* and $p_{\alpha-\alpha'}$ for

| 8 | (Unconjugated olefin) | 0 | 0 | 1 |

*trans*- and *cis*-stilbenes and some related compounds are summarized. The variation of the bond localization energy as well as of the $\pi$-bond order of the ethylenic bond should affect the rates of the reactions of these compounds with the "double-bond reagents"[20]. Thus, the decrease in the bond localization energy as well as the increase in the $\pi$-bond order should facilitate such reactions. This effect is subsequently referred to as the bond localization effect.

On the other hand, the substituents themselves or the phenyl groups rotated out of the plane of the ethylenic bond owing to steric necessities may hinder the approach of the reagent to the reaction site in such reactions. This effect, being purely steric in nature, is referred to as the steric (hindrance) effect in a narrow sense. This effect should, of course, retard such reactions. For example, the fact that $\alpha$-*t*-butylstilbene does not add bromine[21] in contrast to $\alpha$-methyl[19] and $\alpha$-ethyl analogues[22] which add bromine is probably due to this effect.

In addition to the effects mentioned above, the substituents may, of course, exert an electronic effect (e.g. the inductive, mesomeric, or hyperconjugation effect) on the reactions. Therefore, in consideration of the reactions of these stilbene-type compounds, all the effects of the above three types are to be taken into account.

Simamura and the present author found in the earlier study[19] on the action of bromine on stilbenes that *trans*-$\alpha$-methyl stilbene adds bromine much faster than *trans*-stilbene. The extreme slowness of the reaction of *trans*-stilbene with bromine is partly due to the retarding effect of atmospheric oxygen, and when a little catechol is added, the rate increases appreciably. On the other hand, the fastness of the reaction of *trans*-$\alpha$-methylstilbene is ascribed partly to the accelerating effect of a little hydrogen bromide formed as a by-product by substitution, which starts the chain addition reaction of bromine by producing, in co-operation with oxygen, bromine atoms, and this effect is considered to be also suppressed by catechol. However, even when a little catechol is added, the rate of the reaction of *trans*-$\alpha$-methylstilbene with bromine is still much greater than that of *trans*-stilbene[23]. This difference of the rates may be partly due to the electron-donating effect of the methyl group, partly to the unsymmetrical nature of the electronic state of the ethylenic bond in methylstilbene, and partly (perhaps mainly) to the bond localization effect due to the nonplanarity of the configuration of methylstilbene.

The $\pi$-bond order of the ethylenic bond in *trans*-$\alpha,\alpha'$-dimethylstilbene is greater than that in methylstilbene, so that dimethylstilbene would be expected to add bromine more rapidly than methylstilbene. In fact, however, the action of bromine on dimethylstilbene leads to the facile substitution at the methyl groups rather than the addition at the ethylenic bond[19]. This fact seems to be attributable to the steric effect in a narrow sense or the unstability of dimethylstilbene dibromide as the possible intermediate due to the steric strain in the molecule caused by the crowding of bulky groups.

Methyltriphenylethylene does not add bromine, but is substituted at the methyl group only slowly[19]. The absence of the addition is probably due to the steric hindrance effect in a narrow sense.

*Reaction with hydrogen bromide and oxygen.* —It was reported previously that the steric effect plays a predominant role in the

| 6 | *cis*-$\alpha,\alpha'$-Dimethylstilbene | 219.5 | 10.8 | 20.0 | 30.5 | 26) |
| 7 | *trans*-$\alpha,\alpha'$-Dimethylstilbene | 228 | 11.0 | 20.0 | 29.8 | 26) |
| 8 | Cyclohexene | 263.5 | 12.7 | 19.95 | 24.0 | 25) |

The values of $k$ (in $mol^{-1}$ l. $sec^{-1}$) are those at 30°C. The values of $\Delta F^\ddagger$ (in kcal. $mol^{-1}$) and of $\Delta S^\ddagger$ (in cal. $deg^{-1}$ $mol^{-1}$) are those calculated from the rates at 30°C. The values of $\Delta H^\ddagger$ are in kcal. $mol^{-1}$.

reactions of stilbene and stilbene derivatives with hydrogen bromide and oxygen[24]. The conclusions are summarized as follows.

(1) *trans*-Stilbene and *trans*-$\alpha$-methylstilbene can produce bromine atoms by the combined action of hydrogen bromide and oxygen, and thus can initiate chain reactions, the former yielding mainly its dibromide, and the latter yielding its dibromide along with $\omega$-bromoacetophenone and benzoic acid as the final products.

(2) On the other hand, both *trans*- and *cis*-$\alpha,\alpha'$-dimethylstilbenes as well as *trans*-$\alpha,\alpha'$-diethylstilbene undergo no such reaction in the absence of a catalyst, because they are unable by themselves to produce bromine atoms from hydrogen bromide and oxygen, probably owing to the steric effect which hinders the approach of hydrogen bromide and oxygen to the ethylenic bond. However, once bromine atoms have been produced from hydrogen bromide and a peroxidic initiator, they are active enough to attack the ethylenic bonds of these stilbene derivatives, producing radicals as chain carriers, and resulting in the oxidative cleavage of the double bonds.

(3) Further, methyltriphenylethylene and $\alpha,\alpha'$-bisbromomethylstilbene (1,4-dibromo-2,3-diphenyl-2-butene) appear not to react with hydrogen bromide and oxygen even in the presence of a peroxidic catalyst. That is, the steric hindrance is so great in these compounds that they are not only incapable of such initiation, but also unsusceptible even to the action of bromine atoms, or, if a bromine atom adds to the double bond, unable to propagate the chain reactions efficiently.

24) H. Suzuki, O. Simamura and T. Ichihashi, This Bulletin, **27**, 235 (1954).

*Reaction with perbenzoic acid (epoxidation).*—The reaction of olefins with perbenzoic acid gives excellent yields of the corresponding epoxides. It has been presumed that perbenzoic acid acts as a double-bond reagent, i. e. that the reaction involves attack on the olefinic bond and not on one of the constituting carbon atoms[25]. The correlation of the reactivities of *trans*-stilbene, triphenylethylene and tetraphenylethylene to perbenzoic acid with the $\pi$-bond orders as well as the bond localization energies of the ethylenic bonds of these compounds was briefly discussed already in the preceding part[3] of this series. The discussion will be extended here to other stilbene derivatives.

The relevant data selected from the results of the kinetic studies by Lynch & Pausacker[25] and by Simamura, Fukuyama & Nagai[26] are shown in Table VI.

While *cis*-stilbene is epoxidized much more rapidly than the *trans* isomer, *cis*-$\alpha,\alpha'$-dimethylstilbene is epoxidized slightly more slowly than the *trans* isomer, in accordance with the expectration from the calculated bond localization energies. The difference in the reaction rate among the compounds may, of course, depend not only on the difference of the bond localization energy, but also on the steric effect in a narrow sense (that is, the degree of unfavorableness of the steric situation to the approach of the reagent, or the magnitude of the steric strain in the transition state), and also on the electronic

26) The author is indebted to Professor O. Simamura, Dr. M. Fukuyama and Mr. Y. Nagai for communicating with him and allowing him to quote these results in advance of publication. They were presented first by them at the Symposium on the Organic Reaction Mechanism held under the auspices of the Chemical Society of Japan, Fukuoka, October, 1958.

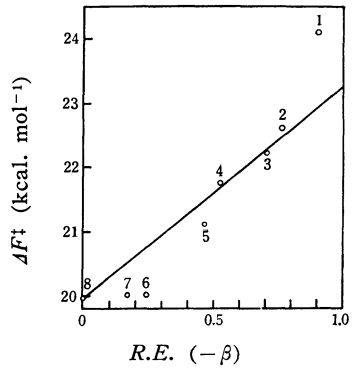

Fig. 3. Relation between the free energy of activation for the reaction of olefins with perbenzoic acid and the bond localization energy. Olefins are represented by the entry numbers in Table V as well as in Table VI.

effect of the substituents (e. g. the electron-donating effect of methyl groups). In spite of this, the sequence of the free energy of activation ($\Delta F^{\ddagger}$) shown in Table VI agrees completely with the sequence of the calculated bond localization energy (*R.E.*) shown in Table V. This fact is seen more clearly in Fig. 3, which shows the values of *R.E.* and $\Delta F^{\ddagger}$ for each compound plotted against one another and numbered according to the entry number in Table VI.

Considering the discrepancy between the experimental value of $\Delta H^{\ddagger}$ for *trans*-stilbene determined by Lynch and Pausacker and that by Simamura and others, it may be somewhat doubtful to compare the data of the different sources. On the other hand, it may also be doubtful to place much reliance on the absolute magnitude of the individual calculated bond localization energy. However, Fig. 3 appears to lead to the following discussions.

The points for *trans*-$\alpha$-methylstilbene and especially for *trans*- and *cis*-$\alpha,\alpha'$-dimethylstilbenes are deviated down from the straight correlation line drawn nearly through the points for cyclohexene, *cis*- and *trans*-stilbenes. That is, the values of $\Delta F^{\ddagger}$ for these methylated stilbenes are smaller than those anticipated from the values of *R.E.* on the basis of the correlation line. These vertical deviations may be considered to indicate the facilitation of the reaction by the hyperconjugation effect or the electron-donating effect of the methyl groups. The steric interference with the approach of the reagent may also exist to some extent in these methylated stilbenes. This interference seems to be revealed by the large absolute values of the entropy of activation for these compounds as compared with *trans*-stilbene.

Tetraphenylethylene and triphenylethylene have greater free energies of activation than anticipated from the calculated bond localization energies on the basis of the correlation line. This fact appears to suggest that the low reactivities of these compounds as compared with *trans*-stilbene are not only due to the larger bond localization energies but also partly to the steric effect in a narrow sense caused by the greater crowding of phenyl groups or by the nonplanarity of the configurations of these compounds. However, in view of the fact that the values of the entropy of activation for these compounds are nearly equal to that for *trans*-stilbene, this possibility may be questionable. Perhaps, the so-called electron-withdrawing effect of the phenyl group relative to the hydrogen atom may be a contributory factor.

Simamura and others measured also the rates of the reaction of many 4,4'-disubstituted $\alpha,\alpha'$-dimethylstilbenes with perbenzoic acid, and found that there exists a linear relation between the logarithms of the rate constants and the sum of the values of Hammett's substituent constant for the 4- and 4'-substituents for each of the *trans* and the *cis* series. According to them, the proportionality constant (Hammett's reaction constant $\rho$) for the *cis* isomers is $-0.88$ at 30°C, $-0.90$ at 20°C, and $-0.93$ at 10°C, and, on the other hand, the value for the *trans* isomers is $-0.80$ at 30°C, $-0.83$ at 20°C, and $-0.86$ at 10°C, meaning that the effect of the 4- and 4'-substituents on the reaction rate constant is stronger in the *cis* series than in the *trans* series. This fact coincides with the present conclusion that the *cis* isomer of $\alpha,\alpha'$-dimethylstilbene is more conjugated than the *trans* isomer. The above mentioned values of Hammett's reaction constant for 4,4'-disubstituted dimethylstilbenes are appreciably smaller than those for 4-substituted *trans*-stilbenes (about $-1.07\sim1.16$, estimated from the data by Lynch and Pausacker). This fact may be correlated with the fact that *trans*-stilbene is more conjugated than *trans*- and *cis*-dimethylstilbenes.

## Experimental

All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

The alkylstilbenes were prepared as reported previously[2,19].

*trans*-$\alpha,\alpha'$-Dichlorostilbene was prepared by the addition of chlorine to tolan. To a solution of 10 g. of tolan in 100 cc. of acetic acid, 140 cc. of a 0.4 mol./l. solution of chlorine in acetic acid was added. The reaction mixture was left to stand for about a month, and then poured into water. The crystalline deposits were collected, pressed on a porous plate to remove some adhering oily matter, and repeatedly recrystallized from ethanol. The substance was obtained in colorless crystals melting at 138.5~139.8°C; yield, 2.4 g. (17.2% of the theoretical amount).

*trans*-$\alpha,\alpha'$-Dibromostilbene was prepared by the addition of bromine to tolan. To a solution of 3.4 g. of tolan in 70 cc. of ether, about 2 cc. (in exess) of bromine was added dropwise. The crystalline deposits were collected and washed twice with ether. The substance was obtained in colorless prisms melting at 205~206°C; yield, 5.1 g. (79% of the theoretical amount).

*trans*-$\alpha,\alpha'$-Diiodostilbene was prepared by the addition of iodine to tolan. To a solution of 356 mg. ($2\times10^{-3}$ mol.) of tolan in 10 cc. of acetic acid, a solution of 508 mg. ($2\times10^{-3}$ mol.) of iodine in 22.5 cc. of acetic acid was added and the reaction mixture was left to stand for about a month. The crystalline deposits were collected and carefully recrystallized from acetic acid. The substance was obtained in colorless, bright prisms hardly soluble in most organic solvents and decomposing at about 199°C with the evolution of iodine vapor; yield, 744 mg. (86% of the theoretical amount).

## Summary

The ultraviolet absorption spectra of some $\alpha$- and $\alpha,\alpha'$-substituted stilbenes have been analyzed, and the most probable spatial configurations of these compounds have been inferred from the spectra by application of the calculation method described in the earlier part of this series.

It is especially noteworthy that with $\alpha,\alpha'$-dimethylstilbene as well as its diethyl analogue the *trans* isomer shows the conjugation band at a shorter wavelength than the *cis* isomer, contrary to the generally accepted view that *trans* isomers of conjugated compounds should exhibit the conjugation bands at a longer wavelength than the corresponding *cis* isomers. This fact is considered to indicate that with these compounds the *trans* isomers are less conjugated than the corresponding *cis* isomers, and that the angle of twist of the "single" bond (interplanar angle) is larger in the *trans* isomers than in the corresponding *cis* isomers. This has been confirmed by the results of the calculations. Further, this is supported also by some pieces of information on the properties of these compounds, such as the reactivities, the exaltation of molecular refraction, and the nuclear magnetic resonance. With special emphasis on this respect, the correlation of some physical and chemical properties of these compounds with the spatial configurations of the molecules has been discussed in detail.

The author desires to thank Professor Osamu Simamura and Professor Kengo Shiomi, for reading the manuscript and for valuable advice, and Dr. Makoto Takahasi for encouragement throughout this study.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. VIII. Stilbene Derivatives with Methyl Groups on the Benzene Nuclei*

By Hiroshi SUZUKI

(Received August 15, 1959)

The method developed in Part V[1] of this series is applied to some stilbene derivatives with methyl groups on the benzene nuclei. With such compounds, the electronic bathochromic effect of the methyl groups on the benzene nuclei should not be ignored. Accordingly, an allowance for this effect is made, analogously to the case of *o*-alkyl- and *o*,*o*'-dialkylbiphenyls in Part II[2] of this series, by choice of the references for correlation between the calculated transition energy $\Delta E_A$ and the observed wave number $\nu_A$ of the conjugation band.

**4-Methyl- and 4, 4'-Dimethyl-*trans*-stilbene.**—In order to determine the longer-wavelength-side reference, the ultraviolet absorption spectra of 4-methyl- and 4, 4'-dimethyl-*trans*-stilbene in *n*-heptane were measured. The results are shown in Table I and Fig. 1. The spectra resemble the spectrum of *trans*-stilbene, on the whole showing fine structures (cf. Table I and Fig. 1 in Part V). The introduction of a methyl group into a para-position of *trans*-stilbene causes the red-shift of about 4.2 m$\mu$ of the maxima of the conjugation band, and the introduction of the second methyl group into the other para-position results in a further red-shift of about 3 m$\mu$.

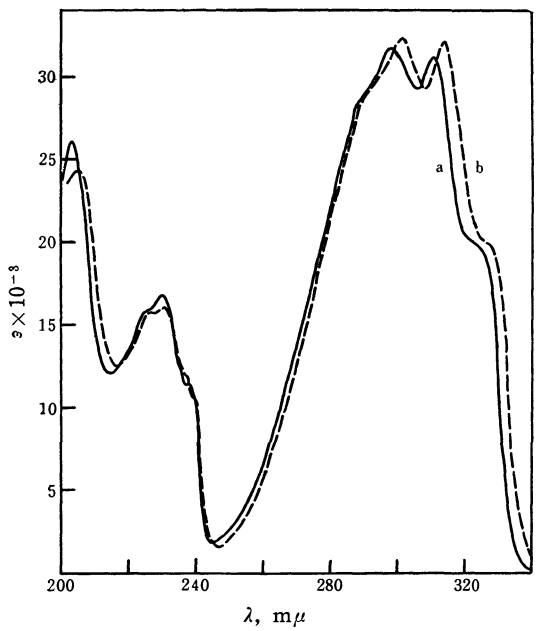

Fig. 1. Ultraviolet absorption spectra (in *n*-heptane): a ——, 4-methyl-*trans*-stilbene; b ------, 4, 4'-dimethyl-*trans*-stilbene.

**4,4',$\alpha$,$\alpha$'-Tetramethylstilbene.**—According to Nagai and Simamura[3], the spectrum of *trans*-4, 4', $\alpha$, $\alpha$'-tetramethylstilbene shows the absorption maximum at 245 m$\mu$ ($\varepsilon$= 15000), and that of the *cis* isomer shows the maximum at 258 m$\mu$ ($\varepsilon$=10000). These maxima are considered as the conjugation bands. Thus, with these compounds, similarly to $\alpha$, $\alpha$'-dimethylstilbene[4], the conjugation band of the *cis* isomer is at a longer wavelength and of lower intensity than that of the *trans* isomer.

In application of our method to these compounds, the possible bathochromic effect of the $\alpha$- and $\alpha$'-methyl groups is provisionally ignored for the same reasons as in the preceding part[4] of this series, and then, in order to make allowance for the bathochromic effect of the *p*- and *p*'-methyl groups, *trans*-4, 4'-dimethylstilbene is taken as the longer-wavelength-side reference compound. That is, the value of $\nu_L$ [wave number corresponding to the calculated transition energy for planar *trans*-stilbene, $\Delta E_L$, 1.1423 ($-\beta$)] is assumed in this case to be 33190 cm$^{-1}$ (301.3 m$\mu$, the $\gamma$-band of *trans*-4, 4'-dimethylstilbene). On the other hand, as the shorter-wavelength-side reference, the value for toluene corresponding to the center of gravity of singlets of benzene is taken. That is, the value of $\nu_S$ [wave number corresponding to the value of $\Delta E_A$ when $\rho$ is 0, $\Delta E_S$,

TABLE I. ABSORPTION MAXIMA OF METHYLATED STILBENES (IN *n*-HEPTANE)

| Compound | A-band | | B-band | | C-band | |
|---|---|---|---|---|---|---|
| | λ, mμ | ε | λ, mμ | ε | λ, mμ | ε |
| 4-Methylstilbene | α (324.5) | 19800 | (238.0) | 11450 | 203.3 | 26100 |
| | β 311.2 | 31200 | △230.2 | 16800 | | |
| | γ △298.3 | 31800 | (225.0) | 15800 | | |
| | δ (292.0) | 29550 | | | | |
| 4,4'-Dimethylstilbene | α (327.5) | 19900 | (239.5) | 10550 | 204.8 | 24350 |
| | β 314.2 | 32100 | (237.0) | 11980 | | |
| | γ △301.3 | 32400 | △230.7 | 16100 | | |
| | δ (293.5) | 29950 | 225.9 | 15730 | | |
| 2,4,6-Trimethylstilbene | 282.7 | 19200 | | | 208.5 | 29600 |
| | | | | | 201.5 | 29700 |
| 2,4,6,2',4',6'-Hexamethylstilbene | 262.7 | 16000 | | | 214.0 | 35700 |

Wavelengths in parentheses denote inflections.
Symbol △ denotes the most intense maximum of fine structure.

TABLE II. RESULTS OF CALCULATION

| Compound | $\lambda_A$ mμ | $\Delta E_A$ $-\beta$ | ρ | θ° | R Å | R. E. $-\beta$ | $p_{\alpha-\alpha'}$ |
|---|---|---|---|---|---|---|---|
| *trans*-Stilbene | 294.1 | 1.1423 | 0.9084 | 0 | 1.445 | 0.704 | 0.856 |
| *trans*-4,4',α,α'-Tetramethylstilbene | 245 | 1.620 | 0.404 | 61 | 1.494 | 0.140 | 0.970 |
| *cis*-4,4',α,α'-Tetramethylstilbene | 258 | 1.491 | 0.530 | 51.7 | 1.481 | 0.242 | 0.948 |
| *trans*-2,4,6,2',4',6'-Hexamethylstilbene | 262.7 | 1.523 | 0.498 | 54.3 | 1.485 | 0.212 | 0.954 |

$2(-\beta)$] is assumed to be 46882 $cm^{-1}$ (213.3 mμ) (cf. Table II in Part II).

On the basis of the above references, calculation by the usual method has been carried out. The results are shown in Table II, in which the notation is the same as in Part V of this series. The calculated values of the interplanar angle θ (the angle of twist of each "single" bond) for *trans*- and *cis*-4,4',α,α'-tetramethylstilbenes agree fairly well with the values for *trans*- and *cis*-α,α'-dimethylstilbenes (58° and 51.5°), respectively (cf. Table II in the preceding part of this series).

**2,4,6-Trimethyl- and 2,4,6,2',4',6'-Hexamethyl-*trans*-stilbene.**—The ultraviolet absorption spectra of 2,4,6-trimethyl-*trans*-stilbene (*trans*-1-mesityl-2-phenylethylene) and 2,4,6,2'4',6'-hexamethyl-*trans*-stilbene (*trans*-1,2-dimesitylethylene) measured in *n*-heptane are shown in Table I and Fig. 2. A comparison of these spectra with the spectrum of *trans*-stilbene[1] reveals that the conjugation band shifts progressively toward shorter wavelengths and reduces the intensity with the increasing number of methyl substituents. This fact is undoubtedly due to the steric interferences

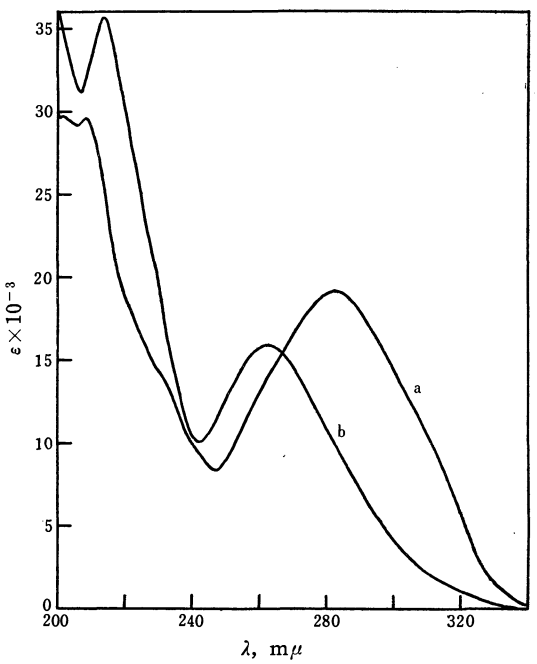

Fig. 2. Ultraviolet absorption spectra (in *n*-heptane): a, 2,4,6-trimethyl-*trans*-stilbene; b, 2,4,6,2',4',6'-hexamethyl-*trans*-stilbene.

of the substituents which prevent the molecule from assuming a planar configuration. It is noteworthy that the conjugation bands of these substituted stilbenes have, similarly to those of *cis*-stilbene[1] and $\alpha$-substituted stilbenes[4], no fine structure, in contrast to that of *trans*-stilbene.

Now, it is assumed that the mean value of the magnitude of the red-shift of the conjugation band caused by substitution of a methyl group at the *o*- or *p*-position of *trans*-stilbene is 3 m$\mu$, and that the effect of methyl substitution is additive analogously to the case of methylbenzenes[5]. Then if the configuration of dimesitylethylene were planar, this compound whould show the conjugation band at a longer wavelength than that of *trans*-stilbene by about 18 m$\mu$ (3×6 m$\mu$). That is, the conjugation band of the hypothetical planar molecule of this compound would be at about 312 m$\mu$ (294+18 m$\mu$). Accordingly, the value of $\nu_L$ is assumed in this case to be 32051 cm$^{-1}$ (312 m$\mu$).

On the other hand, as the shorter-wavelength-side reference compound, mesitylene is taken. While the approximate center of the low-intensity band of benzene in the region between 230 and 270 m$\mu$ is at 255 m$\mu$, the corresponding one of mesitylene is at 266 m$\mu$[6]. In addition, while the 0-0 band of benzene is at 262.54 m$\mu$, that of mesitylene is at 274.06 m$\mu$[5]. That is, the band of mesitylene is at longer wavelengths by about 11 or 11.5 m$\mu$ than that of benzene. On the analogy of the case of toluene as well as ethylbenzene (cf. Table II in Part II), it may be considered that the other bands of mesitylene are probably at longer wavelengths by about 11 or 11.5 m$\mu$ than the corresponding bands of benzene. Accordingly, the value for mesitylene corresponding to the center of gravity of singlets of benzene (48000 cm$^{-1}$, 208.3 m$\mu$) is presumed to be 45600 cm$^{-1}$ (219.3 m$\mu$ = 208.3+11 m$\mu$). Therefore, the value of $\nu_S$ for treatment of dimesitylethylene is assumed to be 45600 cm$^{-1}$.

The results of calculation carried out by the usual procedure on the basis of the above references are shown in Table II. From scale models, it is inferred that the interplanar angle in *trans*-dimesitylethylene should be approximately equal to that in *trans*-$\alpha,\alpha'$-dimethylstilbene. The value calculated here is slightly smaller than that for dimethylstilbene; still it may be said that the agreement is fairly good.

2,4,6-Trimethylstilbene is unsymmetrical, so that the two interplanar angles should be different, and therefore, the resonance integral for the Mes-C bond and that for the Ph-C bond should be different from one another. Therefore, the present method can not be applied to this compound. However, it must be sure that this compound is nonplanar, since the conjugation band is at a considerably shorter wavelength than that of *trans*-stilbene. On the basis of the above assumption that the red-shift caused by a *p*- or *o*-methyl group is about 3 m$\mu$, it is presumed that the conjugation band of this compound would be at about 273.7 m$\mu$ (282.7−9 m$\mu$) if it were not for the red-shift by the electronic effect of the methyl groups. It is of interest that this presumed position coincides almost completely with the observed position of the conjugation band of *trans*-$\alpha$-methylstilbene (273.5 m$\mu$)[4]. It may, therefore, be presumed that the value of the extra-resonance energy *R. E.* of mesitylphenylethylene is approximately equal to that of $\alpha$-methylstilbene [0.457 $(-\beta)$][4] and hence is smaller than that of *trans*-stilbene. This presumption seems to be supported by the following fact. According to Everard and others[7], the exaltation of molecular refraction of *trans*-stilbene is +6.6, and that of 2,4,6-trimethylstilbene is smaller by 1.3 than that of *trans*-stilbene. This fact is considered to indicate that the extent of conjugation is smaller in trimethylstilbene than in stilbene.

Everard and Sutton[8] have found with 4-dimethylaminostilbenes a similar depression of the exaltation caused by *o*-substituents attributable to steric inhibition of resonance. According to them, the exaltation of 4-dimethylaminostilbene is 7.5, and, on the other hand, the values for its 2,2'-dimethyl- and 2',4',6'-trimethyl-derivatives are 3.3 and 1.6, respectively (the values of the exaltation are expressed relative to that of *trans*-stilbene). The value for the 2'-chloro-derivative is much the same as that for the parent compound, indicating that there is negligible inhibition of conjugation in the chloro-compound in contrast to the methyl compounds.

4-Dimethylaminostilbene and related compounds have been studied by several

workers in England, probably in connection with the carcinogenic activity. Haddow and others[9] have found that the derivatives of 4-dimethylaminostilbene with methyl groups at two *o*-positions in a benzene nucleus are biologically ineffective probably because of the non-planarity of the molecular configurations of these compounds. Beale and Roe[10] have found that the oscillator strength of the longest wavelength band (conjugation band) of *trans*-stilbene as well as 4-dimethylaminostilbene is markedly lowered by substitution of methyl groups at the *o*-positions. Thus, in the 2'-position a methyl group causes a decrement of 0.04 in *f*-value, and successive introductions of further methyl groups into the *o*-positions cause larger decrements in *f* of magnitude varying with the position of substitution. This effect has been attributed to the steric hindrance to planarity of the molecular configuration.

Regarding the reactions of the *o*-methyl substituted stilbenes, only a few data are available. According to the present author's preliminary study[11], the rate of bromination of 2, 4, 6-trimethylstilbene in carbon tetrachloride is markedly greater than that of trans-stilbene, even when a little catechol is added to suppress the retarding effect of atmospheric oxygen[4]. The high reactivity of trimethylstilbene as compared with stilbene is probably partly due to the larger $\pi$-bond order of the ethylenic bond or the lower bond localization energy in trimethylstilbene relative to stilbene.

On the other hand, according to Fuson and others[12], the reactivity to potassium permanganate falls in the order *trans*-stilbene > 2, 4, 6-trimethylstilbene > 2, 4, 6, 2', 4', 6'-hexamethylstilbene. Thus, when 0.1 cc. of a 2% solution of potassium permanganate in water is added to a solution of 0.05 g. of the stilbene in 4 cc. of acetone, the time required for discharging the permanganate color is as follows: *trans*-stilbene, less than one minute; trimethylstilbene, four and one-half hours; hexamethylstilbene, 60 hr. In the methylated stilbenes, there should be a considerably large steric hindrance to the approach of the reagent to the ethylenic bond due to the mesityl or phenyl groups rotated out of the plane of the ethylenic bond. The order of the reactivity can be considered to be in conformity with the magnitude of the steric hindrance.

## Experimental

All the spectra were measured with a Cary recording spectrophotometer Model 14 M-50.

*p*-Methylstilbene was prepared by the Meerwein reaction, quite analogously to the synthesis of *p*-methoxystilbene described in Part V of this series. From 53.5 g. of *p*-toluidine, 25.8 g. of the purified product, colorless crystals melting at 121~122°C, was obtained after repeated recrystallization from ethanol (26.5% of the theoretical amount).

*p,p'*-Dimethylstilbene was prepared by reduction of *p,p'*-dimethylbenzoin (*p*-toluoin), quite analogously to the synthesis of *trans*-stilbene from benzoin described in Organic Syntheses[13]. From about 15 g. of *p*-toluoin, the purified product, colorless crystals melting at 177~178°C, was obtained after repeated recrystallization from ethanol; yield, 4.7 g. (32% of the theoretical amount).

Found: C, 92.34; H, 7.86. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74%.

*p*-Toluoin was prepared by the benzoin condensation of *p*-tolualdehyde. To a solution of 82.7 g. of *p*-tolualdehyde in 165 ml. of ethanol, a solution of 18 g. of potassium cyanide in 120 ml. of water was added. The reaction mixture was refluxed for about two hours, and then left to stand for about a month in a refrigerator. The crystalline deposits contaminated with a considerably large amount of orange-colored oily matter were collected and pressed on a porous plate to remove the adhering oily matter. After recrystallization from ethanol, *p*-toluoin was obtained in colorless crystals melting at 87~88°C; yield, 15 g. (18.1% of the theoretical amount).

*p*-Tolualdehyde was prepared according to the method described in Organic Syntheses[14].

2, 4, 6-Trimethylstilbene was prepared, after the procedure described by Fuson and others[12], by dehydration of 1-mesityl-2-phenylethanol prepared by the Grignard reaction of mesitaldehyde with benzyl magnesium chloride. The product was purified by repeated recrystallization from ethanol, and obtained in colorless crystals melting at 56.5~57.5°C.

Mesitaldehyde was prepared, according to the method described in Organic Syntheses[15], by the action of hydrogen chloride on mesitylene in tetrachloroethane in presence of anhydrous aluminum chloride and zinc cyanide.

13) L. I. Smith (Editor-in-Chief), "Organic Syntheses", Vol. 23, John Wiley & Sons, Inc., New York (1943), p. 86.
14) F. C. Whitmore (Editor-in-Chief), ibid., Vol. XII (1932), p. 81.
15) L. I. Smith (Editor-in-Chief), ibid., Vol. 23 (1943), p. 57.

Mesitylene was prepared according to the method described in Organic Syntheses[16].

2,4,6,2',4',6'-Hexamethylstilbene was prepared, according to the method described by Fuson and Best[17], by heating thiomesitaldehyde with copper powder. To a solution of 8.5 g. of mesitaldehyde in 80 ml. of anhydrous ethanol cooled by a freezing mixture, hydrogen chloride was passed for 50 min., and then hydrogen chloride and hydrogen sulfide were passed for one and a third hours at $-5\sim+5$°C. The reaction mixture was left to stand for about two hours. The white deposits were collected and washed repeatedly with anhydrous ethanol. Thus, after being dried in a desiccator, the crude thiomesitaldehyde was obtained as white, apparently amorphous, powder; yield, 4.3 g. About 4.2 g. of the crude thiomesitaldehyde was mixed thoroughly with 3.6 g. of copper powder, and heated for about one hour over an oil bath at 220~230°C. The copper powder turned black. Repeated extraction with hot ligroin afforded, after removal of the solvent, the crude dimesitylethylene. After repeated recrystallization from ethanol and treatment with activated charcoal, the substance was obtained in colorless fine needles melting at 131~132°C; yield, 1.85 g.

The preparation of this compound by dehydration of 1,2-dimesitylethanol was reported by Fuson and others[12]. However, an attempt by the present author to prepare 1,2-dimesitylethanol, according to the directions of Fuson and others, by the Grignard reaction of mesitaldehyde with 2,4,6-trimethylbenzyl magnesium chloride was unsuccessful. 2,4,6-Trimethylbenzyl chloride was prepared from mesitylene according to the directions of Vavon and Bolle[18].

The author desires to thank Professor Kengo Shiomi for reading the manuscript and for advice.

# *Relations between Electronic Absorption Spectra and Spatial Configurations of Conjugated Systems. IX. p-Phenylstilbene, p,p'-Diphenylstilbene, and their Related Compounds*

By Hiroshi SUZUKI

(Received September 21, 1959)

In this part of the series, the results of the measurements of the ultraviolet absorption spectra of *p*-phenylstilbene (1-phenyl-2-*p*-biphenylylethylene), 1-phenyl-2-(2-fluorenyl)-ethylene, *p,p'*-diphenylstilbene (1,2-di-*p*-biphenylylethylene), and its *a,a'*-dimethyl derivative (2,3-di-*p*-biphenylyl-2-butene) are reported, and the calculations based on the simple LCAO molecular orbital method analogous to those for stilbene and related compounds described in the earlier parts[1-4] of this series are applied to these spectra.

In addition, the red-shifts of the conjugation bands observed with these compounds as well as stilbene and related compounds when the solvent is changed from *n*-heptane to benzene are summarized, and the correlation of these shifts with the spatial configurations of the molecules is discussed.

## *p*-Phenylstilbene and 1-Phenyl-2-(2-fluorenyl)-ethylene

The spectra of these compounds (both are probably *trans*) in solutions in benzene and in *n*-heptane are shown in Fig. 1, and the data of the absorption maxima are recorded in Table I. The notation of the bands is analogous to the one in the earlier parts of this series. Thus, the A-band denotes the conjugation band.

These spectra are somewhat similar in shape to that of *trans*-stilbene (cf. Fig. 1 in Part V[1] of this series). The fine

TABLE I. ABSORPTION MAXIMA

| Compound | In benzene | | In *n*-heptane | | | |
|---|---|---|---|---|---|---|
| | A-band | | A-band | | B- & C-bands | |
| | λ, mμ | ε | λ, mμ | ε | λ, mμ | ε |
| *p-Phenylstilbene* | | | | | | |
| | [(343.5)] | 22200 | [(338)] | 23200 | 225.5 | 13100 |
| | △327.8 | 35500 | △322.5 | 36000 | | |
| | (317.4) | 32900 | (311.5) | 33200 | 200.3 | 31900 |
| *1-Phenyl-2-(2-fluorenyl)-ethylene* | | | | | | |
| | 356.5 | 28450 | 351.2 | 29100 | 258.9 | 2170 |
| | △341.5 | 42900 | △335.8 | 43100 | 230.0 | 15230 |
| | [(330.5)] | 37000 | [(327.5)] | 37200 | 223.7 | 15420 |
| | [(321)] | 30800 | (318.5) | 32450 | 210.0 | 26950 |
| | [(307)] | 19430 | [(303.5)] | 21000 | 204.5 | 27800 |
| *p, p'-Diphenylstilbene* | | | | | | |
| | [(362)] | 31300 | [(357)] | 0.126* | [(243)] | 0.042* |
| | △343.0 | 49900 | △337.4 | 0.214* | (220.5) | 0.078* |
| | (332.5) | 46200 | (327.5) | 0.199* | (201.8) | 0.254* |
| *p, p'-Diphenyl-α, α'-dimethylstilbene* | | | | | | |
| | 276.2 | 29000 | 273.3 | 0.838* | 203 | 1.826* |

Symbol △ denotes the most intense maximum of fine structure. Wavelengths in parentheses denote inflections, and those in double parentheses denote very indistinct inflections.
Symbol * denotes the intensity in absorbance.

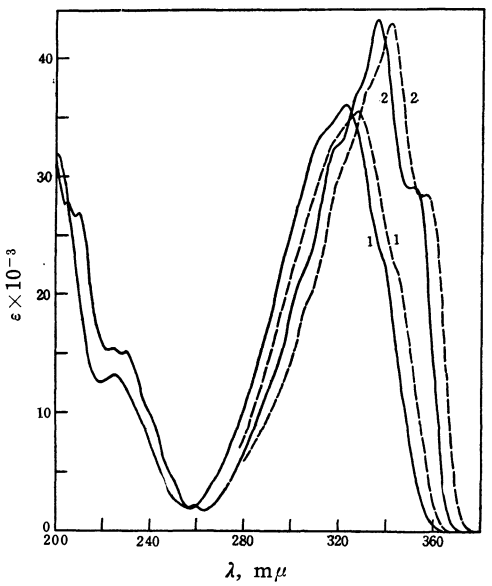

Fig. 1. Ultraviolet absorption spectra: 1, *p*-phenylstilbene; 2, 1-phenyl-2-(2-fluorenyl)-ethylene: ——, in *n*-heptane; ----, in benzene.

structure of the conjugation band of *p*-phenylstilbene is, however, more blurred than that of stilbene. The pattern of the fine structure of the conjugation band of the fluorenyl compound may be said to resemble that of fluorene (cf. Fig. 1 in Part III[5] of this series).

5) H. Suzuki, ibid., 32 1357 (1959).

The maximum of the conjugation band of *p*-phenylstilbene is at a longer wavelength by about 28.4 mμ relative to the most intense maximum (the γ-band) of fine structure of the conjugation band of stilbene, in accordance with the expectation from the length of the conjugated system. The most intense maximum of fine structure of the conjugation band of the fluorenyl compound is at a still longer wavelength by about 13.3 mμ than that of the biphenylyl compound, a fact which may be considered to correspond to the fact that the most intense maximum of fine structure of the conjugation band of fluorene is at a longer wavelength by about 14.5 mμ than the maximum of the conjugation band of biphenyl[5].

Now, the calculation method analogous to the one used so far in this series is applied to these compounds. In the calculation the data of the spectra in *n*-heptane are used as before. The resonance integral for the ethylenic bond is denoted by $\eta\beta$, and as the value of $\eta$ the value of 1.080, corresponding to the bond length 1.34 Å, is taken. The resonance integral for the bonds connecting the benzene rings to the ethylenic carbon atoms is denoted by $\rho\beta$, and as the value of $\rho$, the value of 0.908, corresponding to the bond length 1.445 Å, is tentatively taken as in the case of *trans*-stilbene[1]. The resonance integral for the bond

between the two benzene rings in the biphenyl part is denoted by $\mu\beta$.

When as the value of the variable $\mu$ the corresponding value for fluorene 1.060 is used, the electronic transition energy $\Delta E_A$ (the energy difference between the lowest vacant orbital and the highest occupied orbital) is calculated to be 1.018 $(-\beta)$, by the usual procedure of the simple LCAO molecular orbital method. This calculated value of the transition energy, which is referred to as $\Delta E_L$, is considered to correspond to the wave number of the most intense maximum of the conjugation band of the fluorenyl compound, 29780 $cm^{-1}$ (335.8 m$\mu$), which is referred to as $\nu_L$.

On the other hand, when $\mu$ is zero, the value of $\Delta E_A$ is 1.142 $(-\beta)$, which corresponds conceivably to the wave number of the $\gamma$-band of *trans*-stilbene, 34002 $cm^{-1}$ (294.1 m$\mu$)[1]. These values of the calculated and the corresponding observed transition energies are referred to as $\Delta E_S$ and $\nu_S$, respectively.

On the basis of the above determination of the longer-wavelength-side and the shorter-wavelength-side references, the value of $\Delta E_A$ corresponding to the wave number of the maximum of the conjugation band of the biphenylyl compound, 31008 $cm^{-1}$ (322.5 m$\mu$), is calculated to be 1.054 $(-\beta)$, and the corresponding value of $\mu$ is calculated to be 0.877. This calculated value of $\mu$ is slightly greater than the corresponding value for biphenyl in solution obtained in Part I[6] of this series. This fact would appear to suggest that the length of the bond concerned is shortened and the angle of twist of the bond is decreased in the biphenylyl compound compared with those in biphenyl in solution, owing to the increase in the extent of conjugation. However, it should not be so asserted, since it may be doubtful whether much reliance can be placed on these numerical values, because of the many assumptions made for simplification in the calculation and especially of the peculiar nature of the parameter $\mu$ for fluorene.

### *p,p'*-Diphenylstilbene and its *α,α'*-Dimethyl Derivative

The spectra of these compounds (both are probably the *trans* isomers) in solutions in benzene and in *n*-heptane are shown in Fig. 2, and the data of the absorption maxima are summarized in

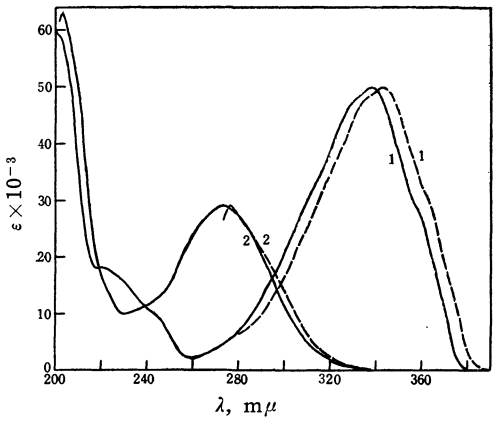

Fig. 2. Ultraviolet absorption spectra: 1, *p,p'*-diphenylstilbene; 2, *p,p'*-diphenyl-*α,α'*-dimethylstilbene: ——, in *n*-heptane; ----, in benzene.

Table I. The solubilities of these compounds in *n*-heptane are so low that the concentrations of the solutions in *n*-heptane and hence the molecular extinction coefficients of the spectra could not be determined. Accordingly, in Table I the intensities of the absorption bands of these compounds in *n*-heptane are represented in absorbance (the solution of the parent compound used is an almost saturated solution, and the solution of the dimethyl derivative is a solution of very roughly quarter the concentration of the saturated solution ; the cell path length is 1 cm.). In Fig. 2, the extinction of the main band of each compound in *n*-heptane has been arbitrarily set to be equal to its extinction in benzene. From these data, it is evident that the solubility of the *α,α'*-dimethyl compound is considerably higher than that of the parent compound. In addition, the melting point of the dimethyl compound (about 240~245°C) is considerably lower than that of the parent compound (about 303~305°C). These facts are very similar to those observed in the comparison between *trans*-stilbene and its *α,α'*-dimethyl derivative[3].

The fine structure of the conjugation band of the diphenylstilbene is further more blurred when compared with that of the phenylstilbene, and the maximum of the former is shifted further toward the longer wavelength than that of the latter. On the other hand, the conjugation band of the dimethyl derivative is almost structureless, and is at a considerably shorter wavelength and of lower intensity than that of the parent compound. This situation is also very similar to that

6) H. Suzuki, ibid., **32**, 1340 (1959).

observed in the comparison between *trans*-stilbene and its $\alpha,\alpha'$-dimethyl derivative[3], and is undoubtedly explained in terms of the steric effect of the methyl substituents.

Similarly to the treatment in the preceding section, the resonance integral for the ethylenic bond is denoted by $\eta\beta$, and the value of $\eta$ is assumed to be 1.080. The resonance integral for the "single" bond between the two benzene rings in each biphenyl part is denoted by $\mu\beta$, and the value of $\mu$ is assumed to be 0.780, being equal to the corresponding value for biphenyl in solution[6]. (This choice of the value is not conclusive, but it is believed that a small change of this value does not alter significantly the final result of the present calculation). The resonance integral for each "single" bond in the stilbene part of the molecule is denoted by $\rho\beta$, in which $\rho$ is the variable in the present calculation.

When as the value of $\rho$ the corresponding value for planar *trans*-stilbene, 0.9084, is taken, the energy of the allowed transition from the highest occupied orbital to the lowest vacant orbital, $\Delta E_A$, is calculated to be 1.0181 $(-\beta)$. This value is $\Delta E_L$ in the present treatment, and is considered to correspond to the wave number of the maximum of the conjugation band of *p,p'*-diphenylstilbene, 29638 $cm^{-1}$ (337.4 m$\mu$). This compound should be more conjugated than *trans*-stilbene as well as biphenyl, and consequently, the lengths of the "single" bonds, the angles of twist of the bonds, and hence the values of $\rho$ and $\mu$ are possibly different from the corresponding ones in *trans*-stilbene and in biphenyl. In spite of this, since it is believed that small changes of the values of $\rho$ and $\mu$ will not significantly alter the final result, on the analogy of the calculation for terphenyls described in Part IV[7] of this series, the calculation is carried out on the basis of the above assumptions.

When $\rho$ is zero, the value of $\Delta E_A$ is 1.523 $(-\beta)$. This value is $\Delta E_S$ in the present calculation, and corresponds to the wave number of the maximum of the conjugation band of biphenyl in *n*-heptane, 40486 $cm^{-1}$ (247.0 m$\mu$)[6].

On the basis of the above references, from the wave numer of the conjugation band of the $\alpha,\alpha'$-dimethyl derivative in *n*-heptane, 36590 $cm^{-1}$ (273.3 m$\mu$), the corresponding value of $\Delta E_A$ is calculated to be 1.342 $(-\beta)$, and then the following corresponding values are obtained by the usual procedure: $\rho$, 0.461; $\theta$, 57°; $R$, 1.488 Å. The calculated value of the interplanar angle $\theta$ between the benzene ring and the ethylenic bond, 57°, for this compound coincides almost completely with the value for *trans*-$\alpha,\alpha'$-dimethylstilbene, 58°[3].

In this connection, it was planned originally to apply a similar method also to 1,2-di-(2-fluorenyl)-ethylene and its 1,2-dimethyl derivative. However, the attempts to prepare these compounds regrettably resulted in failure.

Lastly in this section, the spectra of ketazines may be briefly referred to. Compounds which are probably *p*-biphenylyl methyl ketazine and 2-fluorenyl methyl ketazine were obtained as by-products in the processes of preparation, or in attempts at preparation, of the corresponding dimethylstilbenes, as will be described in the experimental part. The spectra of these ketazines are shown in Fig. 3. These compounds are only very slightly soluble in *n*-heptane, so that the concentrations of the solutions used could not be determined. Consequently, the intensities of absorption are expressed in absorbance (for very roughly saturated solutions; the cell path length, 1 cm.).

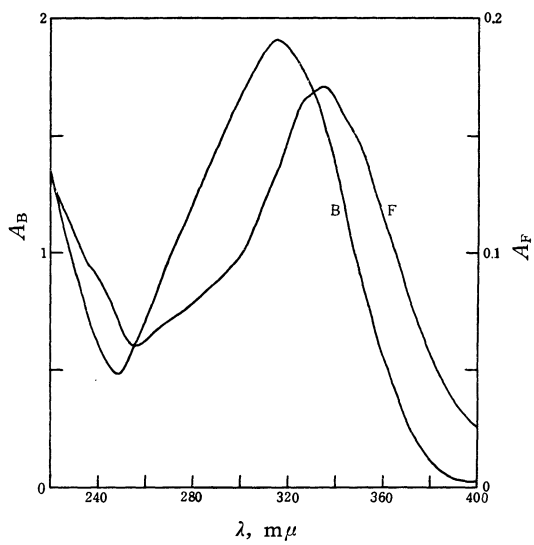

Fig. 3. Ultraviolet absorption spectra: B, *p*-biphenylyl methyl ketazine; F, 2-fluorenyl methyl ketazine. Note separate ordinates for the compounds.

Also in this case, the absorption maximum of the fluorenyl compound (335 m$\mu$) is at a longer wavelength than that of the

7) H. Suzuki, ibid., **33**, 109 (1960).

TABLE II. THE SOLVENT EFFECT OF BENZENE ON THE ULTRAVIOLET ABSORPTION SPECTRA. —The red-shifts of the conjugation bands associated with the change of the solvent from *n*-heptane to benzene.

| Compound | Absorption max. (in *n*-heptane) | | $\Delta\lambda$ mμ | $\Delta\nu$ $cm^{-1}$ | Molecular configuration |
|---|---|---|---|---|---|
| | λ, mμ | ε | | | |
| *p*-Nitrostilbene | 345.0 | 23820 | +5.5 | −455 | planar |
| *p, p'*-Diphenylstilbene | 337.4 | 49900[b)] | +5.6 | −483 | planar |
| 1-Phenyl-2-(2-fluorenyl)-ethylene | 335.8 | 43100 | +5.7 | −497 | planar |
| *p*-Phenylstilbene | 322.5 | 36000 | +5.3 | −502 | planar |
| Tetraphenylethylene | 308.7 | 15300 | +2.5 | −260 | nonplanar |
| *p*-Methoxystilbene | 302.7 | 28950 | +5.0 | −537 | planar |
| Triphenylethylene | 298.5 | 18220 | +3.3 | −366 | nonplanar |
| *trans*-Stilbene | 294.1 | 27950 | +4.7 | −535 | planar |
| *p, p'*-Diphenyl-α, α'-dimethylstilbene | 273.3 | 29000[b)] | +2.9 | −384 | nonplanar |

The values of ε denoted by symbol b represent the values for benzene solutions.

corresponding biphenylyl compound (315 mμ). If these compounds were planar, they would be expected to show the conjugation bands at considerably longer wavelengths than *p,p'*-diphenylstilbene. In fact, however, it is not so. This fact is considered to indicate that these ketazines are conceivably nonplanar.

### Correlation of Solvent Effects of Benzene with Spatial Configurations of Aromatic Solute Molecules

It was previously reported that the conjugation bands of *trans*-stilbene and some related componds are shifted toward considerably longer wavelengths when the solvent is changed from *n*-heptane to benzene[1,2]. A similar phenomenon is observed also with the compounds treated in the present paper. In Table II, the data of the red-shifts observed hitherto are summarized, in which symbols $\Delta\lambda$ and $\Delta\nu$ denote the magnitude of the displacement of the band in wavelength (mμ) and that in wave number, respectively, associated with the change of the solvent from *n*-heptane to benzene. In this table, solely the data on the most intense maximum of the conjugation band of each compound are assembled, the data on the inflections or vestigial bands being excluded.

It is to be noted here that whether or not the apparent absorption maximum of *p,p'*-diphenyl-α, α'-dimethylstilbene in benzene at 276.2 mμ is the true maximum may be somewhat doubtful, because the apparent maximum is so near the shorter-wavelength-side limit (about 270 mμ) of the range in which the measurement of the spectra by using benzene as the solvent is possible. If it is not so, the intrinsic absorption maximum of this compound must be at a shorter wavelength than the apparent maximum. Accordingly, the value of $\Delta\lambda$ for this compound listed in Table II may be considered rather as the upper limit.

Because of inevitable uncertainty in determination of the positions of the absorption maxima, the numerical values of $\Delta\lambda$ as well as $\Delta\nu$ may not be decisive. With such a reservation, however, it seems that the following generalization can be drawn from Table II: whereas the red-shifts for the planar molecules are about 5 mμ, the red-shifts for the probably nonplanar molecules are about 3 mμ and considerably smaller than the values for the planar molecules.

According to Bayliss[8], the magnitude (in $cm^{-1}$) of the red-shift of an absorption band of a nonpolar solute by a nonpolar solvent depends directly on the oscillator strength of the band, inversely on the frequency of the band, therefore, directly on the wavelength of the band, and is related to the refractive index *n* of the solvent at the frequency concerned, depending directly on $(n^2-1)/(2n^2+1)$. Thus, the band is shifted toward lower frequencies and therefore toward longer wavelengths with the increasing refractivity of the solvent.

The refractive index of benzene is greater than that of *n*-heptane. It seems, however, that the great bathochromic effect of benzene relative to *n*-heptane observed here can not be attributed wholly to the difference of refractivity. For

8) N. S. Bayliss, *J. Chem. Phys.*, 18, 292 (1950).

example, by the use of Eq. 12 in Bayliss' paper, the magnitude of the red-shift of the conjugation band of *trans*-stilbene associated with the change of solvent from *n*-heptane to benzene is roughly calculated to be only about 60 $cm^{-1}$. This calculated value is by far smaller than the observed value.

In general, the intensity of the conjugation band of a non-planar compound is considerably smaller than that of the corresponding planar compound. Hence it would be expected that the difference of the magnitude of the red-shift between the planar compounds and the nonplanar compounds might be rather related to the difference of the intensity of the band. This is, however, unlikely, in view of the fact that the conjugation band of *p,p'*-diphenyl-$\alpha,\alpha'$-dimethylstilbene, which is undoubtedly nonplanar, shows a relatively small red-shift in spite of considerably high intensity. Further, as will be evidently seen in Table II, there is no regular relation between the magnitudes of the red-shifts and the wavelengths of the bands.

Therefore, it seems most natural after all to correlate the magnitude of the red-shift with the spatial configuration of the solute molecule, and this correlation seems to suggest, as already mentioned in Part V[1], the presence of a special interaction between the $\pi$-orbitals (or $\pi$-electrons) of the solute molecule and those of benzene.

## Experimental

**Measurements of Spectra.**—The ultraviolet absorption spectra of the olefins were measured with a Cary recording spectrophotometer Model 14 M-50. The spectra of the ketazines were measured with a Beckman type spectrophotometer.

***p*-Phenylstilbene.** — This compound was prepared by the Meerwein reaction. The diazonium salt of *p*-aminobiphenyl was prepared by adding dropwise with stirring a solution of 27 g. of sodium nitrite in 45 ml. of water to a mixture of 300 ml. of 25% hydrochloric acid, 63.4 g. of *p*-aminobiphenyl, and 300 g. of ice. An ice bath was placed around the reaction flask and 235 g. of crystalline sodium acetate was added. A solution of 55.5 g. of cinnamic acid in 900 ml. of acetone was added and the ice bath was removed. Five minutes later a solution of 40.6 g. of cupric chloride in 90 ml. of water was dropwise added and the mixture was stirred for about three hours at room temperature. After being left to stand overnight, the copious green precipitate was collected on a filter and dissolved in a large amount of benzene. The benzene solution was washed in turn with a dilute solution of sodium carbonate, with water, with dilute hydrochloric acid, and then with water, dried on calcium chloride, and treated with activated charcoal. On concentrating the solution by evaporation, pale orange-yellow crystals separated. The crystals were repeatedly recrystallized from benzene. Thus, about 34.5 g. of *p*-phenylstilbene, colorless crystals melting at 220.0~220.5°C, was obtained (about 36% of the theoretical amount). A solution of this compound in benzene shows violet fluorescence.

*p*-Aminobiphenyl was prepared after the procedure described by Schlenk[9] by reducing *p*-nitrobiphenyl in ethanol with stannous chloride and concentrated hydrochloric acid. From 77 g. of *p*-nitrobiphenyl, 64.5 g. of *p*-aminobiphenyl, pale brown-yellow leaflets melting at 53~55°C, was obtained after recrystallization from ethanol (98.6% of the theoretical amount).

*p*-Nitrobiphenyl was prepared, according to the directions of Maki and his coworker[10], by nitration of biphenyl in acetic acid. From 154.2 g. of biphenyl, 91 g. of *p*-nitrobiphenyl, pale yellow needles melting at 114.5~115.3°C, was obtained after recrystallization from ethanol.

**1-Phenyl-2-(2-fluorenyl)-ethylene.** — This compound was prepared by the Meerwein reaction, quite analogously to the preparation of *p*-methoxystilbene described in Part V[1] of this series. From 22.8 g. of 2-aminofluorene, 5.1 g. of the product was obtained after a series of purification processes by treatment with activated charcoal and by repeated recrystallization from benzene; colorless needles melting at 219.5~221.0°C (15.1% of the theoretical amount).

Found: C, 94.04; H, 6.17. Calcd. for $C_{21}H_{16}$: C, 93.99; H, 6.01%.

2-Aminofluorene was prepared by the method described in Organic Syntheses[11], by reducing 2-nitrofluorene in ethanol with zinc dust together with calcium chloride. From 106.3 g. of 2-nitrofluorene, 66.3 g. of 2-aminofluorene, orange-brown needles melting at 125~126.5°C, was obtained (72.7% of the theoretical amount).

2-Nitrofluorene was prepared according to the directions described in Organic Syntheses[11] by nitration of fluorene. From 120 g. of fluorene, 108 g. of the probably somewhat crude product, yellow needles melting at 151~154°C, was obtained (about 71% of the theoretical amount).

***p,p'*-Diphenylstilbene.**—This compound was prepared, after the procedures of preparation of some symmetrical diarylethylenes described by Wood and his coworkers[12] and also the procedures of preparation of 1,2-dimesitylethylene described by Fuson and Best[13], by heating polythio-*p*-phenylbenzaldehyde with copper powder.

9) W. Schlenk, *Ann.*, **368**, 303 (1909).
10) T. Maki and K. Obayashi, *J. Chem. Soc., Japan, Ind. Chem. Sec. (Kogyo Kagaku Zasshi)*, **54**, 375 (1951).
11) W. H. Carothers (Editor-in-Chief), "Organic Syntheses", Vol. XIII, John Wiley & Sons, Inc., New York (1933) p. 74.
12) J. H. Wood, J. A. Bacon, A. W. Meibohm, W. H. Throckmorton and G. P. Turner, *J. Am. Chem. Soc.*, **63**, 1334 (1941).
13) R. C. Fuson and C. E. Best, ibid., **67**, 155 (1945).

A solution of 9.1 g. of *p*-phenylbenzaldehyde in 340 ml. of absolute ethanol was saturated with dry hydrogen chloride. Hydrogen chloride and hydrogen sulfide were then passed into the solution for two and one-half hours at −3∼0°C. The almost white (or pale pink) powder produced in this way was isolated, washed several times with absolute ethanol, and dried in a vacuum desiccator; m. p. 80∼88°C; yield, 9 g. A mixture of 9 g. of the crude thioaldehyde and 26 g. of copper-bronze powder was heated for thirty minutes in a small flask by means of a sand bath at 260∼310°C. The copper powders turned black, and white crystals separated on the surface of the mixture. After cooling, the ethylenic compound was repeatedly extracted with large quantities of boiling xylene. The xylene solution was concentrated to bring about crystallization. Repeated recrystallization from xylene and treatment with activated charcoal gave 0.7 g. of pure *p,p'*-diphenylstilbene, colorless thin plates melting at 301.5∼304.5°C (8.4% of the theoretical amount from the aldehyde). This compound proved to be only slightly soluble in benzene and in xylene, and hardly soluble at all in *n*-heptane and in ethanol. A dilute solution in xylene, benzene, as well as *n*-heptane shows intense violet fluorescence.

Found: C, 94.02; H, 6.28. Calcd. for $C_{26}H_{20}$: C, 93.94; H, 6.06%.

The preparation of *p*-phenylbenzaldehyde, white thin plates melting at 60∼61°C, will be reported in the succeeding part of this series.

The author attempted also to prepare *p,p'*-diphenylstilbene by reducing *p,p'*-diphenylbenzoin with zinc amalgam and hydrochloric acid after the procedures to prepare *trans*-stilbene from benzoin described in Organic Syntheses[14], and also by the method analogous to the one to prepare *trans*-stilbene described by Fieser[15], which involves three steps: replacement of the hydroxyl group of benzoin by chlorine (with thionyl chloride), reduction of the carbonyl group with sodium borohydride to give the chlorohydrin, and elimination of the elements of hypochlorous acid with zinc and acetic acid. These attempts resulted in failure. Thus, by either method, solely an unidentified product, colorless thin plates melting at 227.0∼227.5°C, was obtained in good yield. The ultraviolet absorption spectrum of this compound in *n*-heptane shows a structureless band with the maximum at 275 mμ.

*p,p'*-Diphenylbenzoin was prepared, according to the directions of Gomberg and Natta[16], by the benzoin condensation of *p*-phenylbenzaldehyde. From 42.5 g. of *p*-phenylbenzaldehyde, 25.9 g. of the product purified by repeated recrystallization from xylene and by treatment with activated charcoal, almost colorless or faint yellow crystals melting at 166∼169.5°C, was obtained (61% of the theoretical amount). As a by-product, about 2 g. of *p*-phenylbenzoic acid, colorless needles melting at 219.5∼222°C, was obtained.

***p,p'*-Diphenyl-*α,α'*-dimethylstilbene.**—This compound was prepared from *p*-phenylacetophenone (*p*-biphenylyl methyl ketone) after the Vargha Kovács' method[17]. A mixture of 10 g. of *p*-phenylacetophenone, 100 ml. of isopropyl alcohol, and 25 g. of 80% hydrazine hydrate was refluxed for about 30 hr. A thick white precipitate of the hydrazone was collected and dried in a vacuum desiccator. The hydrazone proved to be soluble with difficulty in petroleum ether. To a solution of the crude hydrazone in about 500 ml. of benzene, 18.1 g. of yellow mercuric oxide was added, and the mixture was stirred for about 9 hr. at room temperature. After filtration, into the pale red-orange solution sulfur dioxide was passed for thirty minutes. After removal of the solvent, the yellow residual solid was extracted with petroleum ether (b.p. 80∼100°C). Repeated recrystallization of the residue from xylene gave 5.8 g. of a compound, yellow, bright, thin plates melting at 274.5°C, which is probably *p*-biphenylyl methyl ketazine. On the other hand, the petroleum ether extract solution was filtered through a chromatographic column of alumina, and then concentrated to bring about crystallization. Fractional recrystallization of the crystals from petroleum ether gave very small quantities of colorless prisms melting at 240∼245°C and small quantities of pale yellow needles melting at about 260∼290°C. Although both the quantities were far too small for complete identification, the former compound (the colorless prisms) is considered probably to be the desired compound. On the other hand, the ultraviolet absorption spectrum of the latter in *n*-heptane shows a band with maxima at 289 and 313.5 mμ, and the spectrum in benzene shows a structureless band at 300 mμ.

The poorness of the yield of the desired compound in the above experiment is considered to originate in imperfection of the oxidation of the hydrazone. The author attempted to oxidize the hydrazone by using lead dioxide instead of mercuric oxide, and also by using petroleum ether as solvent (suspension). However, these attempts resulted in failure, the only isolated product in each experiment being the ketazine.

The author attempted to prepare this dimethyl compound also after the procedures described by Cline and his coworkers[18] to prepare *α,α'*-dimethylstilbene by heating trithioacetophenone with Raney nickel in xylene in an atmosphere of nitrogen. From 6.3 g. of *p*-phenylacetophenone, about 4 g. of the corresponding thio compound, pale grayish yellow powder, was obtained after the procedures of the preparation of trithioacetophenone described by Baumann and Fromm[19].

However, the final product obtained by heating the thio compound with Raney nickel was yellow, bright crystals melting at 328.5~330.0°C and soluble with difficulty in usual organic solvents. The ultraviolet absorption spectrum of this product in benzene showed a structureless band with the maximum at 354 mμ.

The preparation of *p*-phenylacetophenone, m.p. 119~121.5°C, will be described in the succeeding part of this series.

**Unsuccessful Attempts to Prepare 1,2-Di-(2-fluorenyl)-ethylene.** — Preparation of this compound by heating polythio-2-formylfluorene with copper powder after the preparation of *p,p'*-diphenylstilbene described above was attempted. However, the only product isolated was pale yellow needles melting at 289~290.5°C, whose spectrum in *n*-heptane resembles the spectum of 2-formylfluorene as well as that of 2-acetylfluorene (cf. the succeeding part of this series), showing a band with well-resolved fine structure, the most intense maximum of which is at about 310.5 mμ. This product is probably not the desired compound, as was revealed by the spectrum.

The preparation of 2-formylfluorene, faint yellow needles melting at 85.5~86.5°C, will be described in the succeeding part of this series.

**Unsuccessful Attempts to Prepare 2,3-Di-(2-fluorenyl)-2-butene.** — Preparation of this compound by the Vargha and Kovács' method analogously to the preparation of 2,3-di-*p*-biphenylyl-2-butene (*p,p'*-diphenyl-α,α'-dimethylstilbene) described above was attempted. However, the attempts to oxidize the hydrazone of 2-fluorenyl methyl ketone (2-acetylfluorene) with mercuric oxide and with lead dioxide were unsuccessful, and the only isolated product was an orange-yellow crystalline compound melting at 301~302°C, which is considered to be 2-fluorenyl methyl ketazine.

The preparation of 2-acetylfluorene, colorless crystals melting at 127.5~128°C, will be described in the succeeding part of this series.

The author desires to thank Professor Kengo Shiomi for reading the manuscript and for advice, and Dr. Makoto Takahasi for his interest and encouragement. The micro-analyses were carried out by Mr. Shozo Masuda.

# *The Formation Constants of Metal Acetate Complexes. II. Polarographic Determination of the Formation Constants of Acetatocopper(II), Acetatolead(II) and Acetatozinc(II) Complexes*

By Nobuyuki TANAKA and Kiyoko KATO*

(Received September 18, 1959)

In the previous paper[1], a new method for the determination of the formation constants of metal acetate complexes and its application to the study of acetatonickel(II) complexes were presented. The method is based on the polarographic measurement of the sum of the equilibrium concentrations of hydrated metal ions and metal acetate complexes in the presence of an appropriate auxiliary complex-forming substance. Although it has advantages over the conventional methods, its application to other metal acetate complexes seems to be difficult.

In this paper are presented the procedure and the results of the determination of the formation constants of acetatocopper(II), acetatolead(II) and acetatozinc(II) complexes. The procedure is applicable when the formation constants of certain metal acetate complexes are known and can be used as standards.

## Theoretical

Let us consider the acetate buffer solution which contains two different metal ions, $M^{m+}$ and $M'^{m'+}$, and ethylenediaminetetraacetate (EDTA) ions. There exist the following equilibria:

$$M^{m+} + M'Y^{(m'-4)+} \rightleftarrows MY^{(m-4)+} + M'^{m'+} \quad (1)$$

$$MY^{(m-4)+} + H^{+} \rightleftarrows MHY^{(m-3)+} \quad (2)$$

* Present address: The Women's Department, Tokyo College of Pharmacy, 31, Uenosakuragi-cho, Taito-ku, Tokyo.

1) N. Tanaka and K. Kato, This Bulletin, **32**, 516 (1959).

$$M'Y^{(m'-4)+} + H^+ \rightleftarrows M'HY^{(m'-3)+} \quad (3)$$

$$M^{m+} + nOAc^- \rightleftarrows M(OAc)_n^{(m-n)+} \quad (4)$$

$$M'^{m'+} + n'OAc^- \rightleftarrows M'(OAc)_{n'}^{(m'-n')+} \quad (5)$$

where $Y^{4-}$ means a completely dissociated EDTA anion. The overall substitution reaction between $M^{m+}$ and $M'Y^{(m'-4)+}$ in the acetate buffer solution, therefore, may be represented as

$$\left\{\begin{matrix} M^{m+} \\ \uparrow\downarrow \\ M(OAc)_n^{(m-n)+} \end{matrix}\right\} + \left\{\begin{matrix} M'Y^{(m'-4)+} \\ \uparrow\downarrow \\ M'HY^{(m'-3)+} \end{matrix}\right\} \rightleftarrows \left\{\begin{matrix} M'^{m'+} \\ \uparrow\downarrow \\ M'(OAc)_{n'}^{(m'-n')+} \end{matrix}\right\} + \left\{\begin{matrix} MY^{(m-4)+} \\ \uparrow\downarrow \\ MHY^{(m-3)+} \end{matrix}\right\} \quad (6)$$

In the polarographic measurement, the diffusion current of metal ions obtained in acetate media corresponds to the sum of the diffusion current of the hydrated metal ions and that of the acetato complexes[1]. Consequently, the concentrations that can be determined polarographically are $[M^{m+}]_{app}$ and $[M'^{m'+}]_{app}$ given by the equations

$$[M^{m+}]_{app} = [M^{m+}] + \sum_1^n [M(OAc)_n^{(m-n)+}] \quad (7)$$

and

$$[M'^{m'+}]_{app} = [M'^{m'+}] + \sum_1^{n'} [M'(OAc)_{n'}^{(m'-n')+}] \quad (8)$$

respectively.

The total concentrations of metals and EDTA, $[M]_t$, $[M']_t$ and $[EDTA]_t$, in the solution are given in terms of the concentrations of the ionic and molecular species present:

$$[M]_t = [M^{m+}]_{app} + [MY^{(m-4)+}] + [MHY^{(m-3)+}] \quad (9)$$

$$[M']_t = [M'^{m'+}]_{app} + [M'Y^{(m'-4)+}] + [M'HY^{(m'-3)+}] \quad (10)$$

$$[EDTA]_t = [EDTA]_f + [MY^{(m-4)+}] + [MHY^{(m-3)+}] + [M'Y^{(m'-4)+}] + [M'HY^{(m'-3)+}] \quad (11)$$

where $[EDTA]_f$ represents the concentration of the uncomplexed EDTA. Under the condition that $[M]_t + [M']_t > [EDTA]_t$, $[EDTA]_f$ is negligibly small as compared with the concentrations of other species in the solution.

From the polarographic measurement of either $[M^{m+}]_{app}$ or $[M'^{m'+}]_{app}$, the equilibrium constant of Eq. 6

$$K^{M'}_{M,\,app} = \frac{[M'^{m'+}]_{app}\{[MY^{(m-4)+}] + [MHY^{(m-3)+}]\}}{[M^{m+}]_{app}\{[M'Y^{(m'-4)+}] + [M'HY^{(m'-3)+}]\}} \quad (12)$$

is obtained with the relations given by Eqs. 9 to 11, provided that the values of $[M]_t$, $[M']_t$, and $[EDTA]_t$ are known. The constant $K^M_{M',\,app}$ may be called the apparent equilibrium constant of the substitution reaction in question. On the other hand, the equilibrium constant of the substitution reaction given by Eq. 1 is expressed as

$$K^M_{M'} = \frac{[M'^{m'+}]\,[MY^{(m-4)+}]}{[M^{m+}]\,[M'Y^{(m'-4)+}]} \quad (13)$$

Introducing Eqs. 7, 8 and 13 into Eq. 12, $K^M_{M',\,app}$ is rewritten as

$$K^M_{M',\,app} = K^M_{M'} \frac{\beta}{\beta'} \frac{1 + \sum_1^{n'} K_{M'(OAc)_{n'}} [OAc^-]^{n'}}{1 + \sum_1^{n} K_{M(OAc)_n} [OAc^-]^n} \quad (14)$$

$$\beta = 1 + K^H_{MHY}[H^+]$$

$$\beta' = 1 + K^H_{M'HY}[H^+]$$

where $K_{M(OAc)_n}$ and $K_{M'(OAc)_{n'}}$ represent the overall formation constants of $M(OAc)_n^{(m-n)+}$ and $M'(OAc)_{n'}^{(m'-n')+}$, respectively, and $K^H_{MHY}$ and $K^H_{M'HY}$, the equilibrium constants of the reactions of Eqs. 2 and 3, respectively.

If the formation constants of acetato complexes of one of the metals are known, those of the other can be determined with Eq. 14 by the measurement of $K^M_{M',\,app}$ at various acetate concentrations. When the values of $K_{M(OAc)_n}$ are known, Eq. 14 is conveniently arranged as

$$F_0 \equiv K^M_{M',\,app}\left\{1 + \sum_1^n K_{M(OAc)_n}[OAc^-]^n\right\} = K^M_{M'}\frac{\beta}{\beta'}\left\{1 + \sum_1^{n'} K_{M'(OAc)_{n'}}[OAc^-]^{n'}\right\} \quad (15)$$

From the extrapolation of the plot of $F_0$ vs. $[OAc^-]$ to zero acetate concentration, $\frac{\beta}{\beta'}K^M_{M'}$ is obtained. Then, the functions $F_1, F_2, \cdots, F_{n'}$ are defined, which are written as follows:

$$F_1 \equiv \frac{F_0 - \frac{\beta}{\beta'}K^M_{M'}}{\frac{\beta}{\beta'}K^M_{M'}[OAc^-]} = K_{M'OAc} + K_{M'(OAc)_2}[OAc^-] + \cdots\cdots \quad (16)$$

$$F_2 \equiv \frac{F_1 - K_{M'OAc}}{[OAc^-]} = K_{M'(OAc)_2} + K_{M'(OAc)_3}[OAc^-] + \cdots\cdots \quad (17)$$

.....

$$F_{n'} \equiv \frac{F_{n'-1} - K_{M'(OAc)_{n'-1}}}{[OAc^-]} = K_{M'(OAc)_{n'}} \quad (18)$$

$F_1$ is plotted against $[OAc^-]$ and the value of $K_{M'OAc}$ is determined by extrapolating the plot to zero acetate concentration. Further treatment leads to the determination of $K_{M'(OAc)_{n'}}$, if higher acetato complexes are present in the solution.

When the formation constants of $M'(OAc)_{n'}^{(m'-n')+}$ are known, similar relations are derived:

$$F_0' \equiv \frac{1 + \sum_1^{n'} K_{M'(OAc)_{n'}} [OAc^-]^{n'}}{K^M_{M',app}} = \frac{\beta'}{\beta K^M_{M'}} \left\{ 1 + \sum_1^{n} K_{M(OAc)_n} [OAc^-]^n \right\} \quad (15')$$

$$F_1' \equiv \frac{F_0' - \frac{\beta'}{\beta K^M_{M'}}}{\frac{\beta'}{\beta K^M_{M'}} [OAc^-]} = K_{MOAc} + K_{M(OAc)_2} [OAc^-] + \cdots\cdots \quad (16')$$

$$F_2' \equiv \frac{F_1' - K_{MOAc}}{[OAc^-]} = K_{M(OAc)_2} + K_{M(OAc)_3} [OAc^-] + \cdots\cdots \quad (17')$$

The values of $K_{M(OAc)_n}$ can be determined by the same procedure as for those of $K_{M'(OAc)n'}$.

## Experimental

**Reagent.** — Standard solutions of copper(II) nitrate and zinc nitrate were prepared by dissolving known amounts of pure copper and zinc metals, respectively, in a reagent-grade nitric acid. A standard solution of nickel nitrate was the same as used in the previous study[1]. The solution of disodium ethylenediaminetetraacetate was standardized against the standard solution of copper(II) nitrate by amperometric titration[2]. A standard solution of lead nitrate was prepared by dissolving an appropriate quantity of reagent-grade lead nitrate. Its concentration was determined amperometrically with the standardized EDTA solution[2]. For buffers and supporting electrolytes, guaranteed reagents were used without further purification.

**Apparatus and Procedure.** — The polarograph and the dropping mercury electrode used were the same as those described in the previous paper[1]. The dropping mercury electrode had an $m$ value of 1.27 mg./sec. and a drop time $\tau$ of 3.69 sec. in an air-free 0.1 M potassium chloride solution at 25°C with open circuit. The measurements of the diffusion currents of copper(II) in acetate buffer solutions were carried out with the following three reaction mixtures:

(a) copper(II)-nickel(II)-EDTA
(b) copper(II)-lead(II)-EDTA
(c) copper(II)-zinc(II)-EDTA

The measurements were made at 15, 25 and 35°C in acetate buffers of pH 4.7±0.1 in which the acetate concentrations were varied from 0.01 M to 0.2 M. The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.01% in concentration.

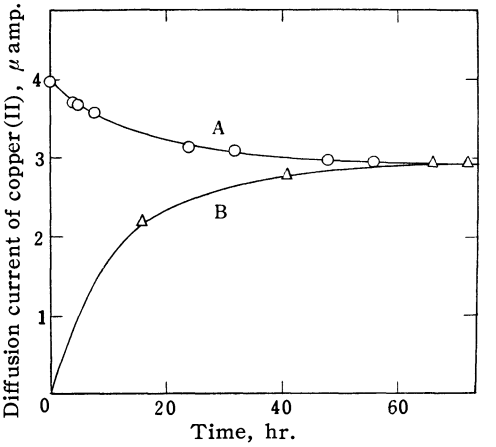

Fig. 1. Relation between the diffusion current of copper(II) and time in the forward (curve A) and the reverse (curve B) reactions of the substitution reaction $Cu^{2+} + NiY^{2-} \rightleftarrows CuY^{2-} + Ni^{2+}$, measured in acetate buffer solutions of pH 4.7 at 15°C. Total concentrations are: $[Cu]_t = 1.00 \times 10^{-3}$ M; $[Ni]_t = 1.50 \times 10^{-3}$ M; $[EDTA]_t = 1.00 \times 10^{-3}$ M.

The substitution reactions involving the EDTA complexes are not always completed instantaneously. The rates of these reactions vary widely according to the system investigated. In systems (b) and (c), the reactions are nearly completed within a few minutes under the experimental conditions. The reaction mixtures, therefore, were subjected to the measurement approximately 3 hours after the preparation. On the other hand, it has often been stated that the exchange or substitution reactions involving the nickel-EDTA complexes proceed at a relatively slow rate[3-7]. This was confirmed also in this study by the fact that the reaction mixtures of system (a) reach the equilibrium extremely slowly. One of the examples is given in Fig. 1, where the change of the polarographic diffusion current of copper(II) in the reaction mixture is plotted against

the time for the forward and reverse reactions. Fig. 1 shows that the reaction equilibrates approximately 60 hours after the initiation of the reaction. In system (a), therefore, all measurements were made about 3 days after the solutions had been prepared.

## Results

The apparent diffusion current constants of copper(II) were determined by measuring the diffusion current at various acetate concentrations. The values of $[Cu^{2+}]_{app}$ were calculated with the aid of those apparent diffusion current constants from the diffusion currents obtained with the reaction mixtures of systems (a), (b) and (c). Then, the apparent equilibrium constants $K^{M}_{M',app}$ given by Eq. 12 were calculated, with which $F_0$, $F_1$……$F_{n'}$ (or $F_0'$, $F_1'$……$F_{n'}$) were successively obtained. The results obtained for systems (a), (b) and (c) are given below. The values of $\beta/\beta'$ (or $\beta'/\beta$) in Eq. 14 were calculated with the equilibrium constants $K^{H}_{MHY}$ and $K^{H}_{M'HY}$ given by Schwarzenbach et al.[5], with the result that they are approximately unity for all three systems at pH of the present experiments.

**Copper(II) - Nickel(II) - EDTA System.** — In the solution containing acetate up to 0.2 M in concentration, nickel(II) forms only a monoacetato complex, its formation constant $K_{NiOAc}$ at ionic strength 0.2 being 2.6, 2.6 and 2.4 at 15, 25 and 35°C, respectively[1]. With the aid of these values, the formation constants of acetatocopper(II) complexes were obtained by determining the values for $K^{Cu}_{Ni,app}$ at various acetate concentrations. The $K^{Cu}_{Ni,app}$ is given by the equation

$$K^{Cu}_{Ni,app}=\frac{[Ni^{2+}]_{app}[CuY^{2-}]}{[Cu^{2+}]_{app}[NiY^{2-}]}$$

$F_0'$ and $F_1'$ given by Eqs. 15′ and 16′ respectively were calculated and plotted against the acetate ion concentration. These plots for 25°C are shown in Fig. 2, in which the $F_1'$ plot gives a straight line. This fact clearly indicates that no appreciable amount of complexes with three acetates or more co-ordinated is present in the solution under the experimental conditions. From the $F_1'$ plot the formation constants of mono- and diacetatocopper(II) complexes, $K_{CuOAc}$ and $K_{Cu(OAc)_2}$, were determined, the former being determined by the intercept at zero acetate concentration and the latter, by the slope.

Similar relations were also found at 15 and 35°C. The formation constants obtained at various temperatures are given in Table I.

**Copper(II)-Lead(II)-EDTA System.** — The formation constants of acetatolead(II) complexes were determined by the measurement of $K^{Cu}_{Pb,app}$ at various acetate concentrations with the aid of the formation constants of $CuOAc^+$ and $Cu(OAc)_2$ obtained in this study, where $K^{Cu}_{Pb,app}$ is given by the equation

$$K^{Cu}_{Pb,app}=\frac{[Pb^{2+}]_{app}[CuY^{2-}]}{[Cu^{2+}]_{app}[PbY^{2-}]}$$

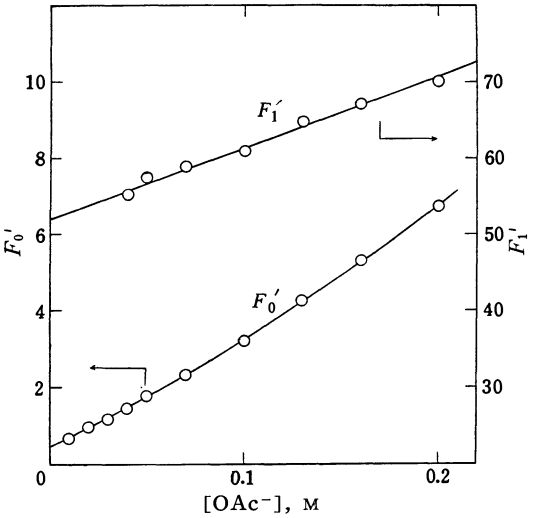

Fig. 2. $F_0'$ (Eq. 15′) and $F_1'$ (Eq. 16′) as a function of the acetate ion concentration in copper(II)-nickel(II)-EDTA system at 25°C.

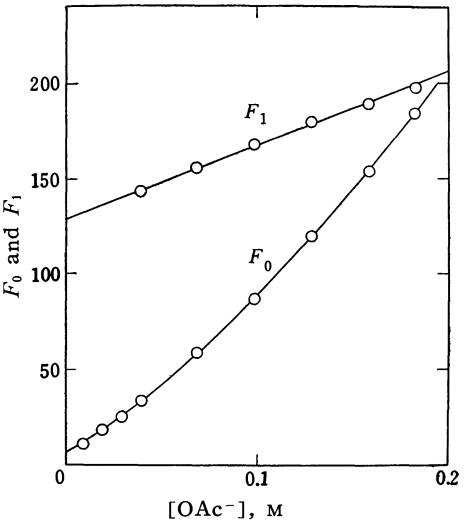

Fig. 3. $F_0$ (Eq. 15) and $F_1$ (Eq. 16) as a function of the acetate ion concentration in copper(II)-lead(II)-EDTA system at 25°C.

In this case $F_0$ and $F_1$ given by Eqs. 15 and 16 were calculated and plotted instead of $F_0'$ and $F_1'$. In Fig. 3 these plots for 25°C are shown, where the $F_1$ plot gives a straight line indicating that $PbOAc^+$ and $Pb(OAc)_2$ are appreciable species of acetatolead(II) complexes present in the solution. Similar plots were obtained at 15 and 35°C. The formation constants of $PbOAc^+$ and $Pb(OAc)_2$ were determined. These are given in Table I.

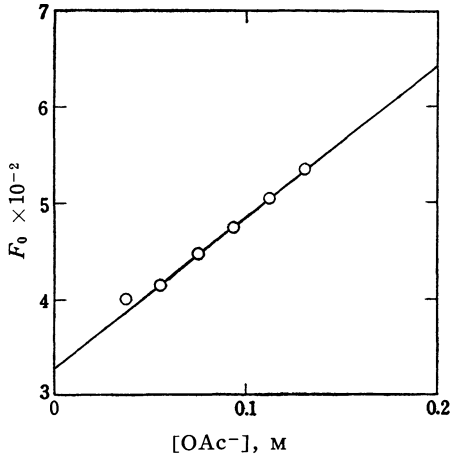

Fig. 4. $F_0$ (Eq. 15) as a function of the acetate ion concentration in copper(II)-zinc(II)-EDTA system at 25°C.

**Copper(II) - Zinc(II) - EDTA System.** — The formation constants of acetatozinc(II) complexes were determined with the same procedure as for the acetatolead(II) complexes. $K^{Cu}_{Zn,\,app}$ which is given by the equation

$$K^{Cu}_{Zn,\,app} = \frac{[Zn^{2+}]_{app}\,[CuY^{2-}]}{[Cu^{2+}]_{app}\,[ZnY^{2-}]}$$

was determined at various acetate concentrations. In this case it was found that

the $F_0$ plot gave a straight line, which is shown in Fig. 4. This fact led to the conclusion that at acetate concentration up to 0.2 M, $ZnOAc^+$ is the only species which exists in the solution at an appreciable concentration. Similar relations were obtained also at 15 and 35°C. The formation constants of $ZnOAc^+$ are listed in Table I.

## Discussion

The formation constants of the acetato complexes of copper(II), lead(II) and zinc(II) have been determined by various researchers. Some of them are given in Table II. These are compared with the formation constants given in Table I.

Recently, Yasuda and Yamasaki[18] studied the complex formation of some carboxylic acids by the pH titration method. They compared the stabilities of the complexes of bivalent metal ions and found that the order of Pb > Cu > Zn, Cd > Ni is valid for the complexes which contain co-ordinating groups such as benzoate, phthalate and succinate. The magnitude of the first formation constants of acetato complexes of nickel(II), copper(II), lead(II) and zinc(II) determined by the present authors are in accordance with the above order. This fact supports the validity of the rule proposed by Yasuda and Yamasaki.

The equilibria of the substitution reaction represented by Eq. 1 have been studied. The equilibrium constants so far obtained, however, are considered to be not $K^M_{M'}$, but $K^M_{M',app}$, because they were determined in the acetate media but not corrected for the effect of acetate ions on the equilibria. In the present paper, the values of $K^M_{M'}$ given in Eq. 13 were determined by the extrapolation of the $F_0$ (or $F_0'$) plot to zero acetate concentration. In Table III, the values of $K^M_{M'}$ for the three substitution reactions obtained in this study are summarized together with those obtained by Schwarzenbach et al.[5] for the same reactions. Schwarzenbach and his co-workers studied these equilibria at 20°C in the solution of ionic strength 0.1 with $8\times10^{-3}$ M sodium acetate. The effect of acetato complex formation can be corrected with the relation given by Eq. 14. The original values given by Schwarzenbach et al. were converted to the $K^M_{M'}$ values using the formation constants $K_{M(OAc)_n}$ and $K_{M'(OAc)_{n'}}$ determined in this study. The resulting constants are also given in Table III, which are in satisfactory agreement with the $K^M_{M'}$ values observed experimentally in this study. This fact proves clearly the validity of the procedure and the results presented in this paper.

## Summary

A new procedure for the determination of the formation constants of metal acetate complexes was developed. The procedure is

17) J. Kielland, *J. Am. Chem. Soc.*, **59**, 1675 (1937).
18) M. Yasuda and K. Yamasaki, presented at the Symposium on Metal Complexes, Tokyo, November, 1958.

based on the polarographic measurements of the sum of the equilibrium concentrations of the hydrated metal ions and the metal acetate complexes in the presence of an appropriate auxiliary complex-forming substance and of the reference metal ions of which the formation constants of acetate complexes are known.

The procedure was applied to the study of acetatocopper(II), acetatolead(II) and acetatozinc(II) complexes, EDTA being used as an auxiliary complex-forming substance. The overall formation constants $K_{M(OAc)_n}$ ($n=1$ and 2) for these metal acetate complexes were determined at an ionic strength of 0.2 at 15, 25 and 35°C.

The authors thank the Ministry of Education for the financial support granted for this research.

# SHORT COMMUNICATIONS

## *Confirmation of the Catalytic Deuteration of Methyl Groups of p-Xylene by the Use of the Infrared and NMR Methods*

By Kozo Hirota, Hazime Kusumoto and Tomiko Ueda

(Received November 11, 1959)

It has been considered generally that the catalytic isotopic exchange reaction of hydrogen atoms with deuterium oxide occurs much more difficultly at paraffinoid hydrocarbons than at benzenoid hydrocarbons. However, as reported already[1] the exchange reaction of *p*-xylene catalyzed by nickel powders occurs also at the hydrogen atoms of the methyl groups, judging from the mass-spectrometric and infrared data of the products. In order to confirm such an expected result, the same samples were analyzed by the NMR apparatus of high resolution type (Varian V-4300 B). The conclusion was the same as already obtained. However, it was found that the proton signal of the methyl groups splitted into three or five components. Such a splitting may be not only interesting as a sure evidence of the above conclusions, but also would be noteworthy as a rare case where spin-spin coupling between H and D nuclei attached to the same carbon atom was observed. Although the similar splitting phenomenon has been reported by some researchers[2], the NMR results also will be presented here preliminarily in connection with the essential point of the research.

Nickel powders were prepared by decomposing nickel formate, oxidizing with air at 300°C and reducing at 400°C with hydrogen for 8 hr. Exchange reaction was carried out in a sealed glass tube, which contained a known amount of pure *p*-xylene and deuterium oxide (99.7% $D_2O$) as well as nickel catalyst. During the reaction, the tube was kept in a thermostat without shaking. After the definite time the reaction was stopped, and the *p*-xylene was separated from both heavy water and catalyst.

As an example of the experiment the most deuterated run, (No. 5), in which the reactants *p*-xylene and $D_2O$, were 0.4792 g. and 0.4864 g., respectively, and which were carried out for 150 hr. at 100°C will be referred. The numbers of deuterium ($d_i$) atoms in *p*-xylene molecules, determined by the mass-spectrometer, were as follows (%):

$$d_0=0.2,\ d_1=2.0,\ d_2=9.0,\ d_3=23.5,\ d_4=32.6,$$
$$d_5=24.7,\ d_6=7.9,\ d_7=0.1,\ d_8=d_9=d_{10}=0.0.$$

2) (a) M. Karplus, D. H. Anderson, T. C. T. Farrer and H. S. Gutowsky, *J. Chem. Phys.*, **27**, 597 (1957); M. Karplus and D. H. Anderson, ibid., **30**, 6 (1957). (b) J. N. Schoolery, *Svensk. Kem. Tidskr.*, **69**, 185 (1957). (c) G. V. D. Tiers, *J. Chem. Phys.*, **29**, 963 (1958).

By the infrared method, three bands could be observed at the region of the C–D stretching bands, i. e. 2187, 2118 and 2047 $cm^{-1}$ (broad). They can be ascribed to the bands of deuterated methyl groups, because in the case when the exchange reaction had been carried out by use of $D_2SO_4$ in order to deuterate the hydrogen atoms at the benzene ring[3], one C–D band appeared at 2254 $cm^{-1}$. This conclusion is not contradictory to the mass-spectrometric data, because *p*-xylene molecules highly deuterated more than six were negligibly small. Therefore it may be concluded that the exchange reaction proceeded practically at the six hydrogen atoms of the methyl groups (cf. Fig. 1).

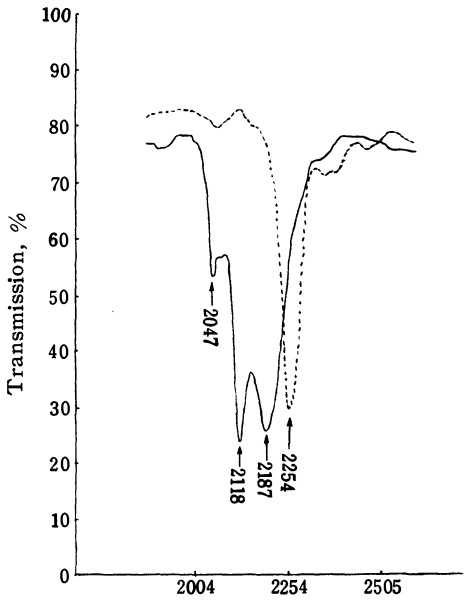

Fig. 1. Infrared absorption spectra of the deuterated samples.
——: Ni catalyst (deuterated degree= 39%)
------: $H_2SO_4$ catalyst (deuterated degree =23%)[3]

By the NMR measurements relative intensity ratio of the proton signals of the methyl and ring groups in the original *p*-xylene should be expected to be 3 : 2 in singlet. This ratio would be expected to change as the deuteration proceeded. Actually the sample in medium process changed it, and moreover the methyl group spectrum had a structure which could be considered as superposed singlet and triplet components. These structures may be assigned to spectra from protons in $CH_3$ groups and those in $CH_2D$ groups, respectively. Though exact measurements were hard, the relative intensity ratio of the ring protons and the methyl ones ($CH_3$ and $CH_2D$) seemed to be almost the same. There was observed no appreciable change in the line shape of the ring protons. It may be difficult to decide whether the ring protons also were exchanged or not. However, the obtained results would suggest that the exchange reaction proceeded easily at the methyl groups. The other features of this spectrum was slight shift of the proton signals of $CH_2D$ to higher field as reported by Tiers[2]. Unfortunately a strong signal from $CH_3$ groups prevented exact measurements of this kind, but the distorted line shape and the slight hump on the central strong component suggested this fact. This tendency was observed more clearly with the more deuterated sample (No. 5). The large sharp central line of the triplet disappeared, and a very weak quintet if compared with the singlet of the ring protons which remained still sharp and strong was observed on the methyl protons. This would suggest at least that the deuteration had proceeded more easily at the two methyl groups than at the ring groups. The observed quintet was very weak and distorted considerably. The observed $J_{H-D}$ was about 2 c. p. s. The distortion might be caused by superimposed structures like singlet, triplet and quintet being slightly shifted each other. These features of NMR measurements confirmed clearly that the deuteration by this method would occur easily at the methyl groups and that the deuteration may take place step by step at the two methyl groups; i. e., roughly speaking, according to the scheme, $CH_3 \rightarrow CH_2D \rightarrow CHD_2 \rightarrow CD_3$.

The authors express their sincere thanks to Professor J. Itoh who gave them valuable suggestions on the NMR spectra.

## *Cyclopentadienyl Cobalt Cyclooctatetraene*

By Akira NAKAMURA and Nobue HAGIHARA

(Received February 4, 1960)

The present authors have previously reported the synthesis of cyclooctatetraene iron tricarbonyl and related compounds[1]. In continuation of the present study, the authors now wish to report a new synthesis of cyclopentadienyl cobalt cyclooctatetraene. Cyclopentadienyl cobalt dicarbonyl was heated at reflux in an excess of cyclooctatetraene under nitrogen for 6 hr. After removal of the unreacted starting materials, brown crystals were obtained by sublimation at 80°C under reduced pressure in 7% yield. These crystals were purified by recrystallization from petroleum ether and by sublimation. The purified sample had a m. p. of 81~82°C. Found: C, 68.32; H, 5.66; mol. wt. (Rast), 256. Calcd. for $C_{13}H_{13}Co$: C, 68.42; H, 5.74%, mol. wt., 228.

(I)

The elemental analysis apparently conformed to the structure, $(C_5H_5)Co(C_8H_8)$, cyclopentadienyl cobalt cyclooctatetraene (I). The same compound (I) could be obtained by irradiation of a mixture of cyclopentadienyl cobalt dicarbonyl and cyclooctatetraene with ultraviolet light under nitrogen for many hours.

I was soluble in common organic solvents and was stable in air. It was also soluble in cold concentrated sulfuric acid and in warm concentrated hydrochloric acid. The solution of I in carbon tetrachloride was decomposed by bromine and by iodine to give green and black precipitates, respectively. I reacted with cyclopentadienyl cobalt dicarbonyl in refluxing dioxane to give dark brown crystals, m.p. >300°C (with decomposition). I readily absorbed 2 mol. of hydrogen in the presence of Raney nickel catalyst at room temperature under ordinary pressure. Orange crystals, m.p. 102°C, were isolated from the hydrogenation mixture by sublimation in a reduced pressure at 80°C. These products of the reaction of I with bromine, iodine, hydrogen, cyclopentadienyl cobalt dicarbonyl and other reagents are now being studied in this laboratory and the results will be reported at a later date.

Three distinct proton resonance peaks were found at 82, 123 and 159 c. p. s, (ratio of the areas; 4.1 : 5 : 4.1), respectively, on the low field side from the proton resonance of cyclohexane. The result of this nuclear magnetic resonance study indicates that three different kinds of protons are present in I in a ratio of 4 : 5 : 4.

The infrared spectrum of I (in Nujol) showed a strong band at 1637 $cm^{-1}$ due to C=C stretching similar to the corresponding 1635 $cm^{-1}$ band of cyclooctatetraene. In the ultraviolet region it had an absorption maximum at 245 m$\mu$ ($\log \varepsilon$ : 4.32, in 95 % alcohol).

These spectral and NMR data together with the chemical reactivity of I are essentially different from those of cyclooctatetraene iron tricarbonyl[1-3]. The double bonds in I which are presumably not used in $\pi$-bonding with the cobalt show usual properties of olefinic double bonds as described above. In contrast to this fact all four double bonds of the cyclooctatetraene moiety in cyclooctatetraene iron tricarbonyl do not show the usual properties of double bonds and they were thought to be affected by $\pi$-complex formation[3]. Accordingly the cyclooctatetraene moiety in I should be different from that of cyclooctatetraene iron tricarbonyl in its spacial and electronic structures. From the above evidences the authors propose the structure shown in the figure for I.

## *The Use of Recoil Fission Rare Gas for the Study of the Change in Crystal Structure*

By Seishi YAJIMA, Sumio ICHIBA, Yuichiro KAMEMOTO and Koreyuki SHIBA

(Received February 5, 1960)

Hahn[1] first investigated the emanation method which used radioactive inert gases $^{222}Rn(T_{1/2}=3.83\ d.)$, $^{220}Rn(T_{1/2}=54.5\ sec.)$ and $^{219}Rn(T_{1/2}=3.92\ sec.)$ as tracers. Since then, crystal structure changes and decomposition reactions were studied by this method[2]. In this method a parent of the radon nuclides is usually incorporated into a solid by coprecipitation with the solid or by deposition on the solid and the correlation between the escaped radioactive inert gas and crystal structure changes was studied.

In the present work, the radioactive fission product rare gases are used in place of radioactive radon nuclides. Uranium dioxide powder (particle size $\sim 0.2\ \mu$) is mixed with the solid powder to be examined, and the mixture is irradiated with thermal neutrons. When the weight ratio of uranium dioxide to the solid is 1 : 30, the fission recoil energy enables about 90% of the fission products to be caught by the surrounding solid powder. The captured fission product rare gases will behave in a similar manner as radon mentioned above, and they will be easily detected because of the relatively high fission-yield of radioactive xenon and krypton.

$\gamma$-Hematite or $\alpha$-hematite and uranium dioxide powder of which the weight ratio is 30 : 1 were mixed and the mixture 500 mg. was irradiated for a total nvt of $\sim 3.5 \times 10^{15}$ thermal neutrons per $cm^2$ in an experimental hole of the JRR-1 reactor. After one-day cooling, the sample was placed in a quartz boat in a quarz tube which was connected with a phosphorus pentoxide drying tube, a dry ice trap (for radioactive iodine), a spiral counting cell inserted into an NaI scintillation crystal well of a $\gamma$-ray spectrometer and a flow rate meter, in the order mentioned. Pure helium gas was passed over the sample at a flow rate of 70 ml./min., and the sample was heated by a furnace surrounding the quartz tube at a rate of 5°C per minute. The radioactive xenon escaping from hematite was carried by helium and the radioactivity was measured by the $\gamma$-ray spectrometer which was previously adjusted to detect 250 keV. $\gamma$-ray of xenon-135 only. The plots of the radioactivity of xenon-135 escaped from $\gamma$-hematite and $\alpha$-hematite versus temperature are shown in Figs. 1 and 2, respectively.

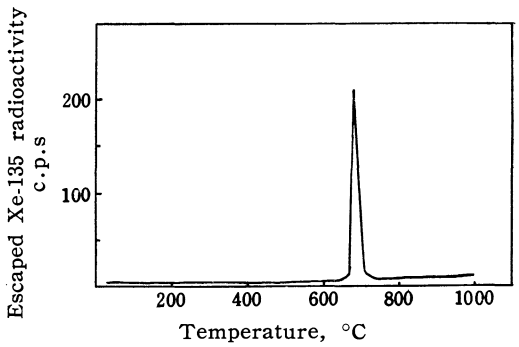

Fig. 1. Heating curve of $\gamma$-hematite. Heating rate, 5°C/min.

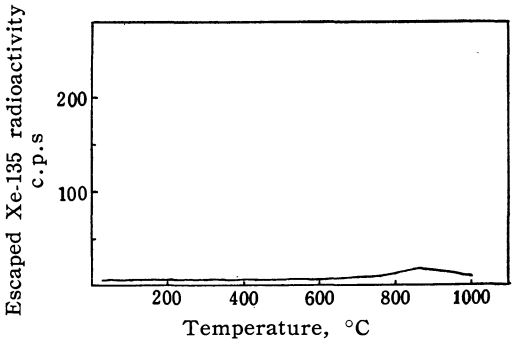

Fig. 2. Heating curve of $\alpha$-hematite. Heating rate, 5°C/min.

The peak at 680°C of $\gamma$-hematite is considered to be related with the crystal change of $\gamma$-hematite to $\alpha$-hematite. An X-ray diffraction method has shown that $\gamma$-hematite changes to $\alpha$-hematite when the former is heated above the temperature at which a peak appears. In the case of $\alpha$-hematite, the peak was not observed, because the crystal structure change is irreversible.

The previous data on the temperature of crystal structure change of $\gamma$-hematite to $\alpha$-hematite are not in good agreement with the present result. The observed peak by the present method may shift with the heating rate, and the temperature

of crystal structure change may be dependent on the preparation method and on impurities in $\gamma$-hematite.

The emanation method by the use of radioactive fission product rare gases will be applicable to many solids, even metals, because the samples can be prepared without chemical treatment, which are prerequisite to the radon emanation method.

## *Intramolecular Interaction between Hydroxyl Group and π-Electrons. IX*[1]*. The Energy of the Interaction in Benzyldimethylcarbinol*

By Michinori Ōki and Hiizu Iwamura

(Received February 8, 1960)

The determination of the energy of the intramolecular interaction between hydroxyl group and π-electrons in this laboratory has so far been confined to the phenolic series[1,2]. In a preceding paper[1], it was referred that alcohols having internal interaction show rather complicated O-H stretching absorption bands ($\nu_{O-H}$) consisting of two free $\nu_{O-H}$ corresponding to rotational isomers about the $C_\alpha$-O bond and an interacting $\nu_{O-H}$, and that the present technique[3] of separating the apparent curve into three Lorentz function type curves leaves some ambiguity and makes the evaluation of the energy inaccurate. However, current studies[4] on the effect of molecular conformations on the intramolecular interaction between the alcoholic hydroxyl group and π-electrons have shown that, in order to make more detailed discussions, the strength of the interaction should be expressed quantitatively. To overcome the aforementioned difficulty the authors took advantage of the observation that the rotational isomers of tertiary alcohols can not be distinguished by the present dispersion of the spectrometer[5], and expected that, unlike 2-phenylethanol, the free $\nu_{O-H}$ of benzyldimethylcarbinol would be single[5] and that the apparent $\nu_{O-H}$ curve could be exactly separated into a free and an interacting $\nu_{O-H}$ by the usual method of Ramsay[6]. This expectation proved to be the case and the energy of the interaction was determined by measuring the temperature variation of the absorption as described previously[1]. The least square method was adopted to determine the six parameters; $a_1$, $b_1$, $\nu_1$, $a_2$, $b_2$ and $\nu_2$, in the Lorentz function;

$$D(\nu)=\frac{a_1}{(\nu-\nu_1)^2+b_1^2}+\frac{a_2}{(\nu-\nu_2)^2+b_2^2}$$

The data are summarized in Table I.

Table I. The effect of temperature on the $\nu_{O-H}$ absorption of benzyldimethylcarbinol

| $1/T\times10^3$ | $\nu_{O-H}$ | $\nu$ | $a$ | $b$ | $\ln(A_1/A_2)$ |
|---|---|---|---|---|---|
| 3.37 | 1 | 3593.5 | 16.13 | 8.14 | −0.292 |
| | 2 | 3614.9 | 25.11 | 9.46 | |
| 3.25 | 1 | 3594.3 | 18.46 | 8.97 | −0.268 |
| | 2 | 3615.9 | 26.24 | 9.76 | |
| 3.16 | 1 | 3594.9 | 17.23 | 9.11 | −0.340 |
| | 2 | 3616.0 | 25.93 | 9.76 | |
| 3.04 | 1 | 3595.4 | 17.22 | 9.28 | −0.349 |
| | 2 | 3615.7 | 25.67 | 9.76 | |

| | 2 | 3617.4 | 24.95 | 9.67 | |

The energy difference ($-\Delta H$) was found to be 0.54±0.13 kcal./mol. This is far less than that of ordinary hydrogen bondings which range from 2.3 to 7 kcal./mol.[7] The energy value is not consistent with those estimated by Goldman and Crisler[8] and by Schleyer and coworkers[9], but is in good agreement with some conformational observations accumulated in this laboratory[10] for β-tetralol, cyclohexen-3-ol and ergosterol. Namely, these compounds only exhibit the free hydroxyl band and

9) While the present work was in progress, P. von Schleyer and his coworkers [*Tetrahedron Letters*, No. 14, (1959), p. 1] alluded that the energy of the intramolecular interaction in 2-phenylethanol was estimated to be about 1.4 kcal./mol. through temperature variation.
10) M. Ōki, H. Iwamura and T. Onoda, unpublished work.

lack the interacting $\nu_{O-H}$. These molecules could have been able to possess an internal interaction if the hydroxyl groups were oriented axially, while the axial conformation is known to be less stable than the equatorial conformation by about one kcal./mol.[11] Thus, if the energy of interaction were more than or at least nearly equal to one kcal./mol., the interaction should have been certainly permitted to exist to some extent. Therefore, the energy of the interaction in these cases must be fairly smaller than one kcal./mol. A full discussion will be given in the near future.

## *NMR Study of α, β-Unsaturated Fatty Acids*

By Shizuo FUJIWARA, Hiroshi SHIMIZU*, Yoji ARATA* and Sachio AKAHORI**

(Received February 10, 1960)

The NMR spectra of six sorts of α, β-unsaturated acids were measured by the 27 Mc. high-resolution spectrometer constructed in this laboratory. The acids used in this experiment were crotonic acid (I), isocrotonic acid (II), methacrylic acid (III), β-methylcrotonic acid (IV), angelic acid (V) and tiglic acid (VI). Among these, II and III were studied in pure liquids and others as saturated solutions in carbon tetrachloride at 25°C. The observed and calculated spectra are shown in Fig. 1,[1] and the approximate values of chemical shifts and spin coupling constants derived from observed spectra are given in Table I, where the spin coupling constants between H and H, and between H and $CH_3$ are about the same as in ethylenic compounds[1]. From the spectra of I and II, it will be concluded that the α-proton signal appears at the field higher than the β-proton, and that the β-proton *trans* to the carboxyl group is about 1 p.p.m. higher than the *cis* proton. The observed chemical shift between gem protons in methacrylic acid is 0.62 p.p.m., which is considerably larger than that between gem protons in the simple ethylenic compounds with the values of 0.1~0.2 p.p.m.[1] This fact seems to be consistent with the conclusion mentioned above on the chemical shifts for the β-protons of crotonic and isocrotonic acids. The magnitudes of the chemical shifts between the two methyl groups attached to the same carbon atom are not so large as the values between the gem protons.

An interesting solvent effect was observed in the system of β-methylcrotonic acid and benzene; where as the acid was diluted by benzene, the chemical shift between gem methyl groups was observed to increase, and the dilution shift at zero concentration was about 0.45 p.p.m. As reported by Shimizu[2,3] and Fujiwara[2], the active methyl group of saturated fatty

acid, such as acetic acid shows the high field shift as the result of $\pi$ complex formation with benzene molecule. The *trans* methyl group which is relatively unaffected from a steric point of view will tend to form $\pi$ complex more easily than the *cis* methyl group and, hence, to show the dilution shift. The fact that the $CH_3$-$CH_3$ shift was increased by the dilution will be explained if the methyl group whose signal appeared at the field higher than the other is more shifted toward a high field. Thus, it is suggested from these considerations that the signal at the higher field may be assigned to the *trans* methyl group and the one at the lower field to the *cis* group. This conclusion may seem contrary to the expectation that the active methyl usually resonates at the field lower than the inactive one owing to the less density of the electronic cloud around it. As these unsaturated molecules have planar structures, however, the magnitude of the paramagnetic effect due to the carbonyl group at the *cis* position will exceed that of the paramagnetic effect at the *trans* position whose effect is mainly caused by inductive force of the carbonyl group.

More refined values of chemical shifts and spin coupling constants will be reported in the near future[4] by H. Shimizu, Y. Arata and S. Fujiwara concerning the general discussion of the analyses of the complex NMR spectra.

## *Remarks on the Mechanism of Ammonia Synthesis*

By Kenzi TAMARU

(Received February 8, 1960)

The importance of adsorption measurements during surface catalysis has recently been emphasized[1] and the adsorption measurements during ammonia synthesis on a doubly promoted iron catalyst has been carried out in a closed circulating system. The apparatus was almost the same with that schematically illustrated in a previous paper[1]. The reaction vessel is 12 cm. in length and 3.5 cm. in internal diameter. The circulation pump has a circulation rate between 4.5 and 8.0 l. (stp) per hour depending upon the pressure,

1) K. Tamaru, This Bulletin, **31**, 666 (1958); *Trans. Faraday Soc.*, **55**, 824, 1191 (1959); *Nature*, **183**, 319 (1959).

reaction temperature and composition of the reaction mixture. The reaction usually proceeded in such a way that the ammonia produced was collected in a trap cooled with liquid oxygen. The composition of the circulating mixture of nitrogen and hydrogen was determined with a thermal conductivity cell connected to the circulating system. The amount of ammonia trapped was determined by releasing it into a space between two stopcocks at room temperature. The amounts of the gases adsorbed on the catalyst surface were estimated from the amount of reactants introduced, the pressure and the composition of the circulating gas, and amount of ammonia trapped. Due allowance was made for the analytical samples removed from the apparatus. The promoted iron catalyst employed was obtained from the Government Industrial Research Institute, Tokyo, and contains 5% $Al_2O_3$ and 1% $K_2O$. The catalyst (198 g.) was powdered to smaller than 20 mesh and was reduced at 500°C for about 1000 hr. in a hydrogen flow of about 36 l. per hour at about atmospheric pressure, water vapor being removed by means of dry ice or liquid oxygen traps in the reaction system. Before each run the catalyst was evacuated for a few hours, treated with circulating hydrogen for 15 hr. in the system, with the traps maintained at liquid oxygen temperature, and then degassed for one hour. All these operations were carried out at 500°C.

TABLE I

| Flow rate l. (stp)/hr. | Relative reaction rate |
|---|---|
| 11.23 | 1.00 |
| 5.58 | 0.95 |
| 10.18 | 1.00 |
| 4.98 | 1.06 |
| 12.27 | 1.00 |
| 5.56 | 0.89 |
| 7.70 | 1.00 |
| 3.37 | 0.98 |
| 7.39 | 1.00 |
| 2.98 | 0.95 |

Typical results for the experiments at 180°C are shown in Fig. 1 which illustrates experiments in which the ammonia trap was not cooled during the first 21 hr. The reaction rate was measured at a variety of circulation rates including alternately slow and fast rates at 250°C, and the results are shown in Table I, where the total pressure of the circulating reactant was between 22.61 and 11.36 cmHg and the nitrogen content was 28~38%. It is shown in the table that the reaction rate is not very sensitive to the circulation rate in the region in which adsorption was studied. It would appear that in the present studies the circulation rate is so high compared to the reaction rate that the partial pressure of the ammonia produced in the reaction vessel is very small.

According to Scholten and Zwietering[2], the rate of chemisorption of nitrogen on a singly promoted iron catalyst is proportional to the pressure. Hence, if allowance is made for the difference in nitrogen pressure, the results of Fig. 1 show that the rate of adsorption of nitrogen *in the absence of hydrogen* almost corresponds to the rate of ammonia synthesis reported by Emmett and coworkers[3]. This is one reason why they consider nitrogen adsorption to be the rate-determining step in the synthesis. However, as is brought out in Fig. 1, hydrogen causes a marked acceleration in the rate of adsorption of nitrogen. This conclusion is in accordance with the

2) J. J. F. Scholten and P. Zwietering, *Trans. Faraday Soc.*, **53**, 1363 (1957).
3) P. H. Emmett and S. Brunauer, *J. Am. Chem. Soc.*, **56**, 35 (1934); S. Brunauer, K. S. Love and R. G. Keenan, ibid., **64**, 751 (1942).

observations of Joris & Taylor, and Kummer & Emmett[4], that isotopic exchange of nitrogen is accelerated by hydrogen.

As shown in Fig. 1, the removal of ammonia from an equilibrated mixture of nitrogen, hydrogen and ammonia has little effect on the adsorption of either hydrogen or nitrogen. Suppose, for example, that all the nitrogen on the catalyst surface takes part in the reaction, then, if all the ammonia in the equilibrated mixture is removed, the adsorbed nitrogen should be rapidly consumed to form ammonia if nitrogen chemisorption is slow compared to all the other surface reaction, including hydrogen adsorption and that ammonia in the reacting gas is negligible. In actual experiments it may be unrealistic to neglect the ammonia pressure completely, but it is to be expected that if all the gaseous ammonia is trapped out the amount of adsorbed nitrogen should fall by an amount corresponding to the distance from equilibrium. But no sign of this tendency could be detected. Consequently, it seems unlikely, as far as one limits his own discussion to the behavior on the whole surface, that the nitrogen chemisorption only is rate determining, though commonly so accepted at present time[5].

# *Polymerization of Styrene with the Ziegler-Natta Catalysts in the Presence of Molecular Hydrogen**

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Yutaka UTSUHARA**

(Received December 22, 1959)

It appears very important matter to have measures of controlling the molecular weight of isotactic polystyrenes in the polymerization with the Ziegler-Natta catalysts. Isotactic polystyrenes hitherto obtained in this laboratory according to the usual way[1] had the molecular weight of the order of several millions. In the course of this study, polymers having lower molecular weight was needed for the study of solution properties.

Among various factors affecting on molecular weight, such as the concentration of monomer, that of catalysts, and that of transfer agents, molecular hydrogen was chosen in the present work as one of the possible transfer agents, which had been known to be effective for controlling the molecular weight of polyethylene[2].

Recently, Natta has revealed in a paper the effectiveness of molecular hydrogen as controlling agents of molecular weight of polypropylene[3].

It has been found in the present work that isotactic polystyrenes of the low molecular weight could actually be obtained in the presence of hydrogen, although in addition to this there has been found another reaction which is competitive to the polymerization reaction, i.e. hydrogenation of styrene to ethylbenzene.

Polymerizations were carried out in an stainless steel autoclave of 200 ml. capacity. After the autoclave was flashed with nitrogen, $TiCl_3$ (3.0 g., the product of Stauffer Chemical Co.) washed with *n*-heptane was poured in with 30 ml. of *n*-heptane, and $AlEt_3$ (0.6 to 0.7 g.) was injected into the bottom of the autoclave

from an injection syringe, and then styrene that was placed in a glass bottle was set in the autoclave. Dry hydrogen was charged to the desired pressure, the temperature was raised to 70°C, and then the shaking was commenced to make styrene contact with the catalyst suspension. Isotactic polymer was purified by the usual extraction procedure with methyl ethyl ketone.

It was found that both yields of total polymer and isotactic fraction in total polymer decreased markedly with increasing hydrogen pressure under the condition otherwise unaltered. As expected, however, intrinsic viscosities of isotactic fractions in toluene at 70°C also decreased as illustrated in Fig. 1.

$H_2$ pressure, kg./cm² in gauge

Fig. 1. Variation of intrinsic viscosities of isotactic polystyrenes with hydrogen pressure.
○: Polymerization time, 5 hr.
×: Polymerization time, 21 hr.
●: Polymerization for 5 hr. under a nitrogen atmosphere.

It was also found that the decreasing yields of polymer with increasing hydrogen pressure was mainly attributable to the occurrance of the competitive reaction, i. e. hydrogenation of styrene catalysed by the Ziegler catalyst. In one run, where styrene (9.1 g., 0.087 mol.) was heated with the catalytic system ($AlEt_3$, 0.71 g.; $TiCl_3$, 3 g.) at the constant hydrogen pressure of 8.9 kg./cm², 0.068 mol. of hydrogen was absorbed and gave a product, in which 3.7 g. of ethyl benzene was identified together with 0.474 g. of a pasty polymer and 0.499 g. of a solid polymer.

A modified catalyst system, $AlEt_3$-$Ti(OBu\text{-}n)_4$, produced no appreciable amount of polymer, but smoothly catalyzed the hydrogenation of styrene. Styrene alone, styrene and $AlEt_3$, and styrene and $TiCl_3$ did not show any absorption of hydrogen at the similar conditions.

From the above results, the observed decrease of molecular weight of isotactic polystyrenes with increasing hydrogen pressure may be considered to be due to following two reasons: the first is the effect of hydrogen as a chain transfer agent. Hydrogen probably cleaves a growing carbon-metal bond giving a metal-hydrogen bond and a saturated dead polymer, and the former would be still capable of initiating a new polymer chain. The second is the early lowering of monomer concentration due to the consumption of monomer by the hydrogenation reaction. Dependence of molecular weight on monomer concentration had been definitely demonstrated in the polymerization of propylene with the Natta catalysts[4] and hence the similar feature might be held in this case.

Propylene and butene-1 did not suffer such a hydrogenation reaction and the molecular weights of their polymers were found to be effectively controlled by the hydrogen pressure.

# *Crystalline Adducts of Dicyclohexylamine with Di- and Triols*

By Masazumi NAKAGAWA and Takashi AKAGAMI*

(Received August 6, 1959)

It has been reported briefly in the literatures that dicyclohexylamine forms crystalline addition compounds with hydroxy compounds such as water[1], ethanol[1], cyclohexanols[2] and cyclohexanediols[2]. An accidental observation of the formation of a white precipitate by mixing dicyclohexylamine with ethylene glycol urged the present authors to a more detailed study on the adducts.

When an acetone solution of dicyclohexylamine was mixed with some di- or tri-hydroxy compounds in the same solvent, immediate precipitation of very fine silky needles accompanied by an evolution of heat was observed. The crystals thus obtained could be easily recrystallized from acetone to give a pure adduct. The melting points, the analytical data of nitrogen and the composition of the adducts with various glycols are summarized in Table I.

It is to be noted that in spite of the remarkable change in the structure of glycols, the composition of the adducts with glycols was always in a ratio of 1 : 2. These results are inconsistent with those of Winans[2] who reported the composition of the adducts with diols is 1 : 1 so far as he studied**.

The properties of the adducts with several kind of triols are listed in Table II together with its analytical data.

In these cases the molar ratio of the triol against the amine was found to be 1 : 3 excepting the case of glycerol in which it was found to be 2 : 3.

These adducts are readily soluble in common organic solvents and are especially easily recrystallized from acetone. The adducts are decomposed into the components by the addition of water. The most striking property of the

** Winans prepared the adducts using petroleum ether or ether as solvent.

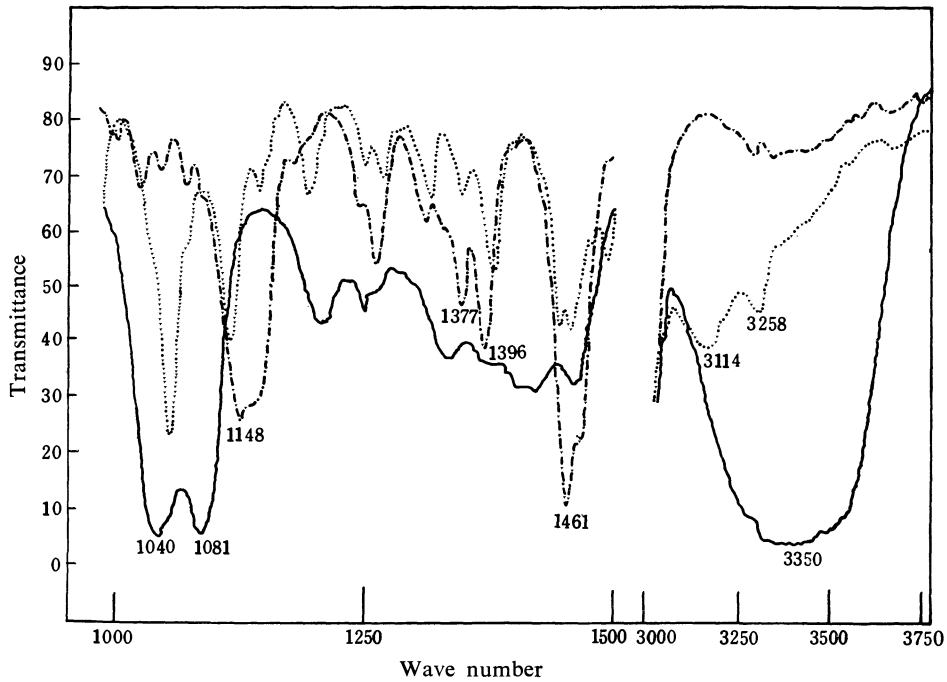

Fig. 1. The I. R. spectra of dicyclohexylamine (·-·-·), ethylene glycol (——) and the adduct with ethylene glycol (····).

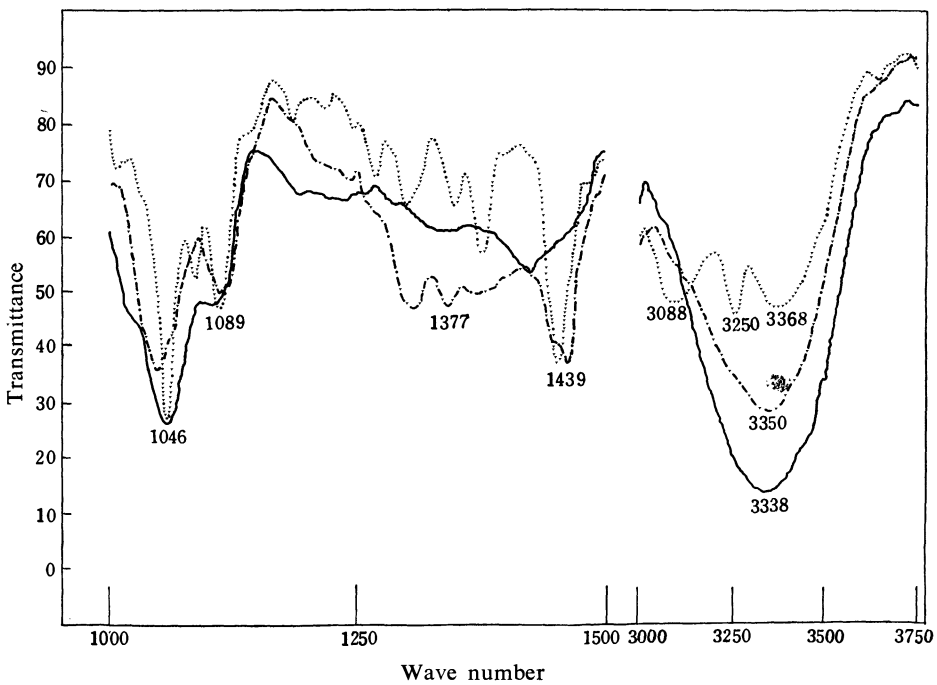

Fig. 2. The I. R. spectra of 1, 2, 4-butanetriol (——), the adduct with 1, 2, 4-butanetriol (····) and the adduct with glycerol (·-·-·).

adducts with diols is its tendency to sublime. When a crystalline adduct with a diol placed in an evacuated sealed tube is heated below its melting point, a rapid growth of beautiful silky needles on the cold wall of the tube can be observed.

The tendency of sublimation is characteristic of the adducts with glycols and can not be seen with the adducts with triols.

The existence of intermolecular polymeric association due to hydrogen bond in hydroxy compounds is well known, and the presence of this type of hydrogen bonds in ethylene glycol and in 1, 2, 4-butanetriol was revealed by the presence of a very broad absorption at 3350 and 3338 $cm^{-1}$ in the infrared spectra of these alcohols as illustrated in Figs. 1 and 2. The diol and the triol also show a broad and strong absorption in the range of 1300~1440 $cm^{-1}$ presumably arising from deformation of the associated hydroxy group or the streching of C–O of the associated hydroxy group. Also the infrared spectrum of dicyclohexylamine shows a broad absorption in the region of 3100~3500 $cm^{-1}$ indicating the presence of associated N–H group. On the other hand, the infrared spectrum of the adduct with ethylene glycol showed two absorption peaks at 3114 and 3258 $cm^{-1}$ instead of the broad absorption band of the glycol at 3350 $cm^{-1}$ (Fig. 1).

Remarkable change in absorption was also observed in the range of 1300~1440 $cm^{-1}$. The broad absorption in the spectrum of ethylene glycol in this region disappeared in the spectrum of the adduct.

These spectroscopic evidences indicate that the formation of amine-glycol adduct is attributed to the formation of new strong intermolecular O—H···N hydrogen bonds destroying the original polymeric intermolecular hydrogen bonds which exist in ethylene glycol and in dicyclohexylamine. These arguments are consistent with the fact that the amine-diol adducts are easy to sublime. The formation of such a type of an "addition compound" in solution has been pointed out by several investigators[3]. The absorption band at ca. 3326 $cm^{-1}$ in the infrared spectrum of the system of alcohol-amine-solvent was attributed to the formation of an amine-alcohol complex by Baker et al.[3c]

The situations are somewhat different in the cases of the adducts with triols. As illustrated in Fig. 2, the infrared spectrum of 1, 2, 4-butanetriol clearly indicates the presence of polymeric intermolecular hydrogen bonds in the triol. However, the infrared spectrum of the adduct with the triol exhibits three absorptions in the range of 3000~3400 $cm^{-1}$ (3368, 3250 and 3088 $cm^{-1}$). Also the adduct with glycerol shows a broad and intense absorption at 3350 $cm^{-1}$ (Fig. 2). These broad absorptions at 3368 or 3350 $cm^{-1}$ seem to indicate the presence of remaining intermolecular polymeric hydrogen bonds in these amine-triol adducts. It is reasonable to conclude that some part of hydrogen bonds is used to associate the amine-triol adduct with each other, giving them the nature of non-sublimation.

Another point of interest in the physical property of the adducts is the oscillation of the melting points. As illustrated in Fig. 3,

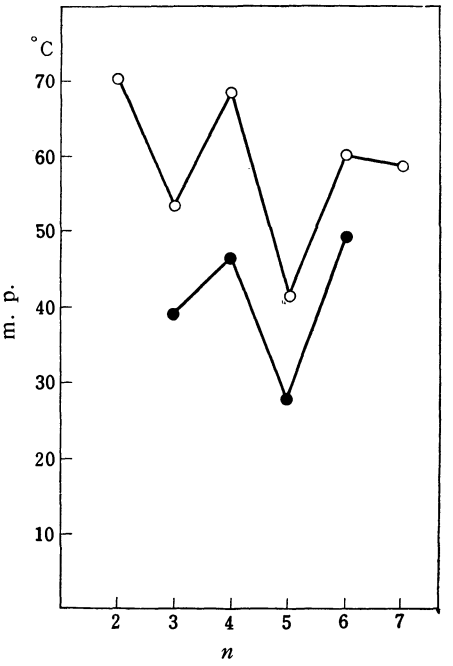

Fig. 3. The melting points of the adducts with $\alpha,\omega$-diols and $\alpha, \beta, \omega$-triols.

B. Isothermal distillation method in acetone solution.

isothermal distillation methods. The results summarized in Table III indicate the dissociation of the adduct in the solution. These results present no evidence on the nature of dissociation, but the calculated degree of dissociation is tabulated in Table III assuming the following types of dissociation.

$$\text{Diol}\begin{cases}(\text{amine})_2(\text{diol}) \overset{\alpha_1}{\rightleftarrows} (\text{amine})(\text{diol})+(\text{amine}) \\ \text{or} \\ (\text{amine})_2(\text{diol}) \overset{\alpha_2}{\rightleftarrows} 2(\text{amine})+(\text{diol})\end{cases}$$

$$\text{Triol}\begin{cases}(\text{amine})_3(\text{triol}) \overset{\alpha_3}{\rightleftarrows} (\text{amine})(\text{triol})+2(\text{amine}) \\ \text{or} \\ (\text{amine})_3(\text{triol}) \overset{\alpha_4}{\rightleftarrows} 3(\text{amine})+(\text{triol})\end{cases}$$

As stated above, the formation of crystalline adduct with dicyclohexylamine is quite general for primary or secondary diols and triols, but it was found that the tertiary glycols such as 2,4-dimethyl-2,4-butanediol and 1,1',4,4'-tetraphenyl-1,4-butynediol give no crystalline adducts. 2-Amino-ethanol, 1,8-terpin and (−)-menthol also gave no crystalline product even at the temperature in a refrigerator. The last two examples are remarkable as structurally related cyclohexanol itself gave a well defined adduct of m. p. 56~57°C with the composition of 1 : 1 (N, found : 4.87 ; calcd. for 1 : 1-adduct : 4.98%). These findings seem to suggest that the formation of crystalline adduct is influenced by the steric environment around the hydroxyl group.

## Experimental***

**Preparation of the Adducts.**—A mixture of diol (1 mol.) and acetone (equal volume) was added to a solution of dicyclohexylamine (2 mol.) in acetone (equal volume). The mixture was kept for several hours in a refrigerator to complete the crystallization. The crystals formed were filtered and recrystallized from acetone. The molar ratio 1 : 3 (triol : amine) was used in the cases of the preparation of the adducts with triols.

Sublimation under reduced pressure was found as an excellent method of purification of the adducts with diols.

**Measurement of the Infrared Spectra.**—The spectrometer used was a Hilger H 800. The spectra of the hydroxy compounds and the amines were measured by the method of liquid film. The spectra of the adducts were measured employing KBr-disk method.

**Determination of the Molecular Weight.**—*(1) Cryoscopic method.*

a) Adduct with ethylene glycol : 0.01385 g.

# *Interaction of Surface Active Agent with Amylose*

By Toshio TAKAGI and Toshizo ISEMURA

(Received August 17, 1959)

In the previous papers, one of the authors have reported the interaction of surface active agents with non-ionizable polymers[1] as well as with proteins[2,3]. It was found that the aspect of the interaction of surface active agents with non-ionizable polymers is entirely different from that of the interaction of surface active agents with proteins. Accidently, the authors have found that there is another way of the interaction of the surface active agent with polymer. Actually, they wished to examine the inactivation of Taka-amylase A by surface active agent using amylose as a substrate. As a matter of fact, it was found that amylose is precipitated by sodium dodecyl sulfate (SDS) even in a concentration as low as 0.007% from 0.05% amylose solution in 0.05 M sodium chloride. Accordingly, the cause of this precipitation of amylose was investigated thoroughly.

The precipitate was examined by the X-ray diffraction method and compared with the amorphous amylose precipitated by ethanol. A complex might be formed between amylose and SDS. It was interesting to examine whether such a complex might be formed even in a dissolved state under proper condition. So the possibility was examined from the two standpoints of view as will be described below. The effect of SDS on the coloration of amylose-iodine complex was investigated spectrophotometrically. As the viscosity of polymer solution is a function of the configuration assumed by the dissolved polymer molecules, the solution of amylose containing SDS was studied also by viscosity measurement. From all these experimental findings, the authors have concluded that the precipitation of amylose by the surface active agent should be due to the formation of an adduct between amylose and the surface active agent. The details of the present investigations and inferences based on them will be described hereafter.

## Experimental

**Amylose.**—Amylose was prepared from potato starch by Schoch's butanol precipitating method[4] and was recrystallized three times. The purified amylose was dehydrated by methanol and then dried over calcium chloride in vacuo.

**Amylopectin.** — Amylopectin was precipitated by adding a large amount of methanol to the supernatant separated from amylose prepared by Schoch's method. The precipitate was suspended in methanol for some time to remove butanol and then dried over calcium chloride in vacuo.

**Sodium Dodecyl Sulfate.**—Sodium dodecyl sulfate was prepared by Dreger's method[5] and was recrystallized three times from aqueous butanol.

**X-ray Diffraction Measurement.** — The sample for X-ray diffraction study was prepared as will be described below. One gram of amylose was dissolved in 10 ml. of 1 N sodium hydroxide and kept in a refrigerator overnight to dissolve the amylose completely, and then diluted to about 50 ml. The solution was neutralized with 1 N hydrochloric acid and diluted with distilled water just up to 100 ml. A precipitate was formed by adding 25 ml. of 0.5% SDS solution to the amylose solution and the solution was stood overnight. The precipitate was gathered by centrifugation and dried over calcium chloride in vacuo. On the other hand, amylose was precipitated by adding excess ethanol to the amylose solution prepared just in the same way without the addition of SDS and after washing the precipitate with ether, it was dried over calcium chloride in vacuo. The amylose thus prepared was used as a reference sample without SDS for X-ray diffraction study.

X-ray diffraction patterns were taken by the powder method using "Norelco" recording X-ray diffractometer (Cu-$K_\alpha$ line was used).

**Measurement of Absorption Spectrum of Amylose-iodine Complex.**—Five milliliters of 0.1% solution of amylose which was prepared by Fuwa's method[6] was diluted to about 200 ml. with distilled water, to which the necessary volume of SDS solution was added to assure a desired final concentration and shaken thoroughly. After bringing out the color by the addition of 5 ml. of 0.2% iodine solution (containing 2% potassium iodide), the solution was diluted just up to 250 ml. After standing for about 30 min., the absorption spectra of the solutions were measured by a Hitachi spectrophotometer model EPU-2 or by a Beckman recording spectrophotometer model DK-2.

**Measurement of Viscosity.**—One gram of amylose was suspended in 10 ml. of 1 N sodium hydroxide, was kept in a refrigerator for 2 days and then was diluted with distilled water just up to 100 ml. This solution was diluted with 0.1 N sodium

hydroxide to obtain the solution of various concentrations in respect to amylose. Each solution was mixed with an equal volume of SDS solution of various concentrations. The solutions of various compositions were heated on a water bath at 60~80°C for about 30 min. and kept for 3 hr. in a thermostat at 30±0.05°C. Then, the viscosity of amylose solutions was measured by a viscosimeter of the Ostwald type in the same thermostat.

Viscosity of the amylopectin solutions was measured just in the same manner.

## Results

**Effect of SDS on the X-ray Diffraction Pattern of Amylose.**—The X-ray diffraction pattern of amylose precipitated by SDS is shown in Fig. 1a, while that for amylose precipitated by ethanol in Fig. 1b. In the pattern for the former, two distinct diffraction peaks were found at $2\theta=13$ and 20° ($\theta$=incident angle) which might be attributed to the helical structure of amylose[7-9], whereas in the pattern for the latter, only a broad peak was found which suggests an amorphous structure of amylose.

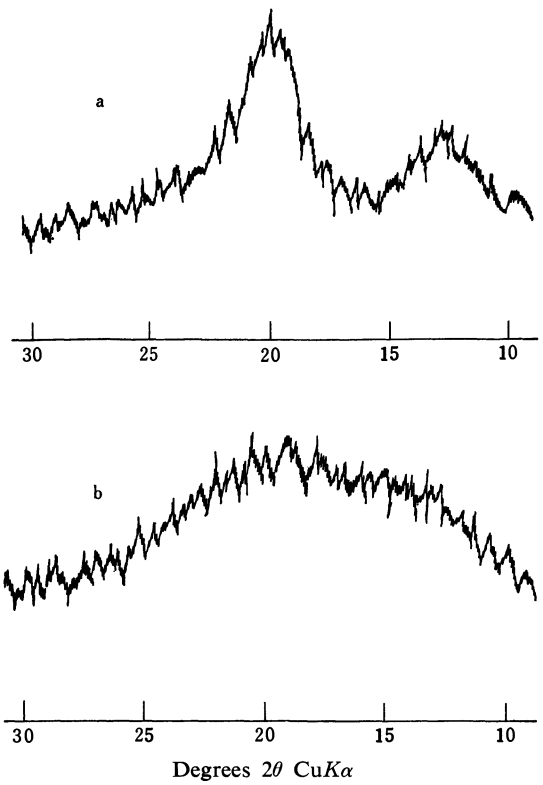

Fig. 1. X-ray diffractometer traces of SDS-treated and non-treated specimens of amylose.
a, precipitated by the addition of SDS.
b, precipitated by the addition of ethanol.

**Effect of SDS on the Coloration of Amylose-iodine Complex.**—If a helical complex is formed between amylose and SDS even in a dissolved state, it is expected that the coloration of amylose-iodine complex may be considerably affected in the presence of SDS. When an aqueous iodine solution was added to the amylose solution to which SDS was added previously, the solution appears at first light yellow assuming the color of $I_3^-$ ion. Then the blue coloration of amylose-iodine complex comes out gradually. It needs about 30 min. to attain the steady coloration. All curves of

8) F. F. Mikus, R. M. Hixon and R. E. Rundle, ibid., **68**, 1115 (1946).
9) R. E. Rundle, ibid., **69**, 1769 (1947).

absorption spectra in Fig. 2 were measured after this steady state was attained. With the increase in the amount of added SDS, the absorption maximum shifts to a shorter wavelength side and the absorption decreases. If one examines the effect of the concentration of SDS by measuring the absorption at 590 mμ over a wide range of the concentration, the effect of SDS increases with the concentration up to $4\times10^{-3}$ M, beyond which the change of the absorption spectra was not found as shown in Fig. 3. The concentration of SDS corresponds nearly to the critical micelle concentration of this surface active agent.

**Effect of SDS on the Viscosity of Amylose Solution.**—As is well known, the viscosity of polymer solution is a function of polymer configuration in solution. So the viscosity of an amylose solution might be profoundly affected by the addition of a small amount of SDS, if amylose changes its configuration from a random coil to a helical structure. The viscosity of amylose solution was measured in the presence of SDS in alkaline solution which is known as a good solvent for amylose and compared with that of amylose solution in the absence of SDS. As shown in Fig. 4., the effect of SDS on the viscosity of amylose solution is very remarkable. On the other hand, amylopectin which can not assume a helical structure because of its branched structure is expected to be scarcely affected by the addition of SDS. The experiment verifies that this is the case, as shown in Fig. 5.

## Discussion

As one of the authors have already reported[1], some surface active agents interact with some polymers causing oriented adsorption on the polymer molecules, often making insoluble polymers soluble. On the other hand, proteins interact with an ionic surface active agent at their ionic sites of the opposite sign[10]. Surface active agents precipitate proteins having opposite electric net charge, changing hydrophilic sites by covering with hydrocarbon chains. However, in the presence of excess surface active agents, surfactant ions are built up on the hydrocarbon tails of surfactant previously combined with protein molecules. Thus, the hydrophobic protein molecules which have been separated from the solution are turned to be hydrophilic again.

In the case of the interaction of amylose with an ionic surface active agent, the ion-ion interaction as in the case of proteins does not occur because of the lack of ionic sites. The oriented adsorption of surfactant ions as in the case of polyvinyl alcohol, as previously reported[1], might be excluded. Also, the dipole-ion interaction between hydroxyl groups of amylose and SDS ions as suggested by Fava and Eyring[11] in the case of adsorption of SDS on cellulose will be refused for the following reasons. In the present case, only an ion of SDS is sufficient to precipitate about 12 glucose residues in amylose. Moreover, it was found in the previous investigation[1] that the interaction of SDS with polyvinyl alcohol which has many hydroxyl groups in a molecule like amylose showed no sign of the insolubilization of the polymer. Further, the insolubilization of amylose can not be ascribed to the adsorption of SDS extending the hydrocarbon tails toward water as in the case of proteins, because of the

10) F. W. Putnam, *Advances in Protein Chem.*, **4**, 83 (1948).
11) A. Fava and H. Eyring, *J. Phys. Chem.*, **60**, 890 (1956).

lack of ionic sites as mentioned above. The precipitation of amylose is also caused by a cationic surface active agent such as cetylbenzyldimethyl amine bromide as well as SDS. On the other hand, the large excess of SDS, even as high as 12% in total concentration does not cause the redissolution of the precipitate. It is also to be noticed that no precipitate was formed by SDS with amylopectin which has a number of branched chains in the molecule.

According to X-ray diffraction study, the amylose precipitate formed by the interaction with SDS gave two distinct peaks at $2\theta=13$ and 20° as shown in Fig. 1a. Rundle and his collaborators[7] concluded from their studies on amylose-iodine complex by X-ray diffraction that amylose forms an adduct with iodine, where amylose assumes a helical structure in which six glucose residues make a turn and iodine molecules lie along the axis of helix, which gives two distinct peaks in X-ray diffraction pattern at $2\theta=13$ and 20°.

Later, they found that amylose forms similar adducts with some higher alcohols and normal fatty acids of moderate chain length[8,9]. As these two diffraction peaks are characteristic of the helical structure of amylose, the amylose precipitate formed by the addition of SDS should be an adduct of amylose including SDS ions in its helical structure. Although the mixture of amylose solution must be heated with higher fatty acid or alcohol at about 70°C and then cooled to obtain the adduct, only the addition of SDS to amylose solution at room temperature is enough in the present case. This difference might originate from the fact that SDS is much more soluble than higher fatty acid or alcohol.

There is another evidence for the formation of the adduct having a helical structure between amylose and surfactant. It is well known that when iodine was added to amylose solution, intensive blue color appears instantaneously. Now it is generally accepted that this characteristic coloration of amylose solution by iodine is caused by the change of an electronic state of iodine molecules lying along the axis of helix of the amylose-iodine complex[12]. The change of the electronic state should be caused by the large polarity of amylose in a helical structure due to the orientation of a large number of hydroxyl groups in glucose residues in a similar direction. As mentioned above, when iodine solution was added to amylose solution containing SDS, the blue color of amylose-iodine complex appears gradually instead of instantaneous coloration as in the case without SDS. It may be expected that it needs some time to exchange SDS ions with iodine in a helix of amylose.

As the authors have mentioned above, the absorption maximum shifts to shorter wavelength-side and absorption decreases with the concentration of SDS. The decrease in absorption is remarkable at the longer wavelength-side. Rundle et al.[13] studied the effect of the molecular weight of amylose on the coloration of amylose with iodine. They found that with the decrease in the molecular weight or the chain length of amylose, the absorption maximum shifts to the shorter wavelength side and the absorption decreases. This change of absorption is remarkable at the longer wavelength side. As iodine competes with SDS in intruding into a helix of amylose, the linear array of iodine molecules which intervened between SDS ions might become shorter with the increase of SDS concentration. The increase of SDS concentration might be assumed to have the same effect as the decrease of the chain length of the amylose molecule forming a helical complex with iodine. Parallel changes in the shift of absorption maximum and the decrease in absorption in both cases mentioned above might be explained in terms of the chain length concerning one continuous unit of the amylose-iodine-complex.

No more change was found in the absorption spectra of amylose-iodine complex, when the concentration of SDS exceeds about $4\times10^{-3}$ M. This concentration almost exactly corresponds to the critical micelle concentration of this surfactant, so that this fact suggests that only the SDS ions are concerned with the formation of the helical complex.

According to the study of the absorption spectra mentioned above, amylose seems to assume a helical configuration in the presence of SDS even in a dissolved state. Viscosity measurments, as well known, give some insights into the configuration of polymer molecules in solution. As shown in Fig. 4., when the reduced viscosity $\eta_{sp}/c$ of amylose solution in the absence of SDS was plotted against amylose concentration, the same linear relation was obtained as in the case of a typical non-electrolytic polymers. However, if SDS is present in the solution, $\eta_{sp}/c$ decreases rapidly with the decrease in amylose concentration and converges to a definite value independent of the concentration of SDS in the low concentration of amylose. The larger the ratio of SDS to amylose is, the larger is the concentration of amylose from which the reduced viscosity begins to decrease. Accordingly, the ratio of SDS to amylose is evidently an important factor to the decrease of the reduced viscosity.

12) R. S. Stein and R. E. Rundle, *J. Chem. Phys.*, **16**, 195 (1948).

13) R. R. Baldwin. R. S. Bear and R. E. Rundle, *J. Am. Chem. Soc.*, **66**, 111 (1949).

In the case of amylopectin, the linear relation between $\eta_{sp}/c$ and $c$ was retained even in the presence of SDS. The line moves parallel, a little downward. Since the intrinsic viscosity of the polymers should be an indication of their volume in the dissolved state, the decrease in the reduced viscosity of amylose suggests the decrease in the effective volume of amylose when SDS was added to the solution. The cause of the decrease in viscosity should be attributed to the formation of a helical complex between amylose and SDS. Owing to the mutual compensation of the polarity of hydroxyl groups in the helical complex, the hydration of amylose might be decreased. This might be one of the reasons why the viscosity of amylose-surfactant-complex decreased.

The minor decrease in viscosity found with amylopectin in the presence of SDS might be caused by the contamination of a small amount of amylose, since the decrease of viscosity is almost the same with the solution containing 0.01% SDS and that containing 0.02% SDS.

In conclusion, it was found experimentally that there are at least three different ways of interaction between surface active agents and polymer, namely, (1) only by van der Waals' force, (2) by electrovalent bonding only or together with van der Waals' force, and (3) by a special combination found in the case of adduct formation. In the case of the interaction of a surface active agent with non-ionizable polymers such as polyvinyl formal or polyvinyl acetate[1], cooperative force between chains of surfactant is very significant. Accordingly, hydrophilic and lypophilic properties of surfactant must be appropriately balanced in this case. The cationic detergent shows poor interaction with polymers, probably because of its stronger hydrophility than that of the anionic detergent.

The electrovalent bonding of the surfactant with polymer is of course encountered with the polymers such as proteins which have ionic sites in the molecules[10]. The surface active agents which can act on the polymers should have the charge of the opposite sign to the polymer. After forming the envelope of the surface active agent of the thickness of a molecule, more layers of surface active agents can be built up on it by van der Waals' force.

The third class of interaction such as these encountered in the case of amylose and surface active agents, some specific steric conditions must be fulfilled. In this case, whether the surface active agent is anion or cation is out of the question. However, non-ionic detergents were found to have scarce interaction with the polymers throughout all these three types of interactions[14].

## Summary

It was found that a specific precipitate is formed when some ionic surface active agents are added to amylose solution and it was confirmed by X-ray diffraction study that this phenomenon is due to the formation of the helical complex between amylose and a surface active agent.

It is also inferred that the same complex is formed even in the dissolved state from the study on the effect of the surface active agent on the viscosity of amylose solution and on the absorption spectrum of amylose-iodine complex.

The authors express their hearty thanks to Dr. S. Hizukuri of the Institute of Scientific and Industrial Research, Osaka Universiy for his valuable advice and cooperation in the X-ray diffraction measurements.

# *Oxidation of Ferrous Ions in the Aqueous Ferrous-Cupric System. I. Effect of Cobalt-60 Gamma-Rays*

By Hiroshi HOTTA, Akira TERAKAWA and Shinichi ŌNO

(Received August 27, 1959)

An irradiation facility with a 10 kilocurie Co-60 gamma-ray source has been in operation at Japan Atomic Energy Research Institute since 1958[1]. Although the characteristics of the source, especially the distribution of radiation intensity around the hollow cylindrical source had to be measured for the public use of this facility, a chemical dosimeter for high dose, which was to be used as the standard, was not studied in Japan. The dose rate inside the present source is about $2\times10^6$ *r*/hr.

For this purpose, the properties of various aqueous solutions were examined to find a suitable chemical dosimeter for high doses. In general, a chemical dosimeter must have certain properties, namely, linearity, reliability, stability, easy standardization and so on[2]. It is concluded from the present experiments that a chemical dosimeter for high doses must have the following properties in addition to the above ones.

The first conclusion is that the oxygen-dependent reaction is not preferable, owing to the restriction of oxygen solubility like ferrous or benzene aqueous solution[3,4]. That is, all components of the system must have great solubility, which determines the upper limit of the appriciable dose. Moreover, the product to be measured should have no secondary reaction such as re-redox reaction and decomposition. Re-redox reactions are considered even for ferric[5] and cerous[6] ions, respectively. Since the temperature of solutions irradiated at a high dose rate is apt to be raised owing to the absorption of radiation energy, it is desirable for the *G*-value to be independent of temperature[7].

It is difficult to find an ideal system having all the above properties. The ceric dosimeter is usually recommended for this purpose, but demands the most careful distillation of water. Moreover, the reagent contains some rare earths occasionally. The ferrous-cupric dosimeter[8] is another one used for high doses. This dosimeter can easily be made from pure and cheap reagents, but this matter is not being so exhaustively studied at present. Therefore, the authors studied the aqueous ferrous-cupric system in detail, and give the results of some discussions concerning it in the present paper.

## Experimental

Triply distilled water was used as usual, but chemical reagents of special grade were used without further purification. The aqueous solutions were irradiated in a test tube of hard glass (Hario Glass) by a 10 kilocurie Co-60 gamma-ray source at the Irradiation Laboratory of Japan Atomic Energy Research Institute at room temperature (ca. 25°C). The solutions were saturated with either oxygen or nitrogen, and sometimes irradiated without any treatment, which is called hereafter the non-treated solution. The concentration of oxygen in distilled water, which was treated similarly with the solution, was measured at 25°C by the Winkler method[9] as listed in Table I. The solubility of oxygen in water is $1.2\times10^{-3}$ M in the handbook[10].

In the present experiment, as mentioned previously[4], the dose was changed not by the irradiation time, but by irradiation for one hour at

TABLE I. INITIAL CONCENTRATIONS OF OXYGEN AND FERRIC ION AT 25°C IN $10^{-3}$ M

| Treatment | Oxygen in water | Ferric ion in ferrous-cupric system | | |
|---|---|---|---|---|
| | | (0)* | ($10^{-3}$)* | ($10^{-2}$)* |
| $N_2$-saturated | 0.019 | 0.2 | 0.2 | 0.2 |
| Non-treated | 0.37 | 0.2 | 1.3 | 1.6 |
| $O_2$-saturated | 1.2 | 0.2 | 2.1 | 2.3 |

| i | 0.04 | 0.01 | 0.4 | $N_2$-saturated | 2.34±0.08 | |

various positions, namely, various dose rates. Therefore, the abscissa of all figures gives a value of the dose in $r$ as well as a value of the dose rate in $r$/hr. The deviation of the observed values from the curve is partially due to the uncertainty of the absolute dose rate at a respective position, for samples were not irradiated at a fixed position as is usually done. The absolute dose rate was determined by the ceric dosimeter, which was corrected up to about $1.4\times10^5 r$ by the oxygen-saturated ferrous dosimeter.

The amount of ferric ion was measured by optical density at 304 m$\mu$ ($\varepsilon$=2205 at 25°C). It should be noticed that the ferrous ion was fairly oxidized due to the addition of cupric ions in the presence of oxygen without irradiation as listed in Table I, in which the mean initial concentration of ferric ions in the irradiated solutions is shown[11].

## Results

**Ferrous Solutions.**—The result of aqueous 0.04 M ferrous ammonium sulfate solution containing 0.8 N sulfuric acid and 0.001 M sodium chloride for a) oxygen-saturated, b) non-treated and c) nitrogen-saturated cases are shown in Fig. 1. Their $G$-value is listed with the composition of the solution in Table II. 0.001 M sodium chloride was added as a stabilizer as usual.

**Ferrous-cupric Solutions.** — The results of aqueous 0.04 M ferrous ammonium sulfate solution containing 0.8 N sulfuric acid and 0.001 M cupric sulfate for the above three treatments, d), e) and f), are shown in Fig. 2. Moreover, the results of the similar solution containing 0.01 M cupric sulfate for the same three treatments, g), h) and i), are shown in Fig. 3. Their $G$-value is also listed with the composition of the solution in Table II. The data below about $4\times10^4 r$ were unreliable.

The present results indicate that the non-treated solution is useful as a chemical dosimeter for high doses with good accuracy at

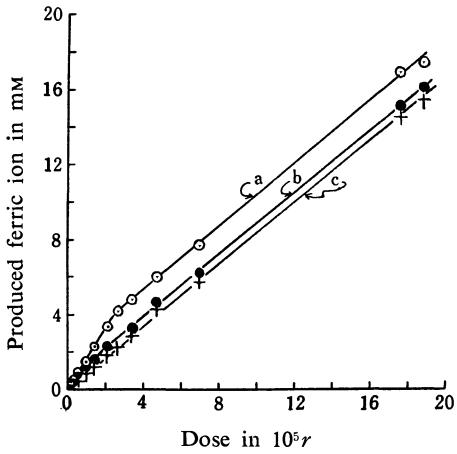

Fig. 1. The oxidation of ferrous ion in 0.04 M ferrous sulfate acidic aqueous solution for (a) oxygen-saturated, (b) non-treated and (c) nitrogen-saturated cases.

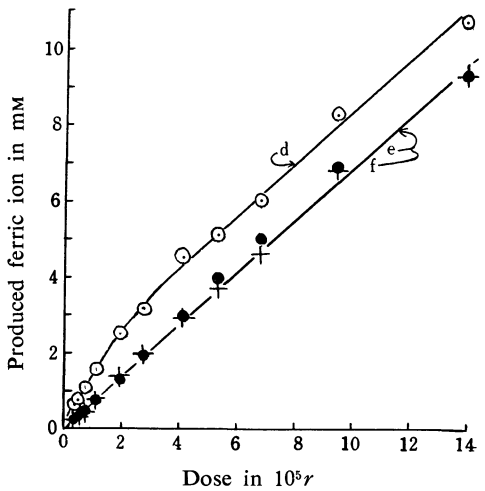

Fig. 2. The oxidation of ferrous ion in 0.04 M ferrous sulfate-0.001 M cupric sulfate acidic aqueous solution for (d) oxygen-saturated (⊙), (e) non-treated (●) and (f) nitrogen-saturated (+) cases.

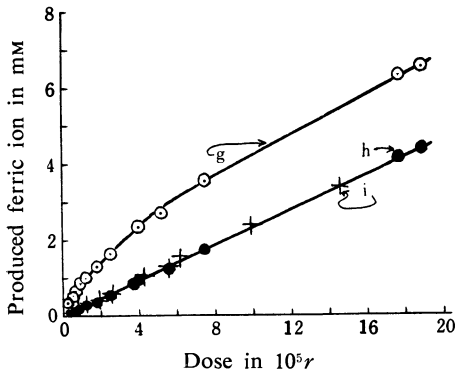

Fig. 3. The oxidation of ferrous ion in 0.04 M ferrous sulfate-0.01 M cupric sulfate acidic aqueous solution for (g) oxygen-saturated (⊙), (h) non-treated (●) and (i) nitrogen-saturated (+) cases.

least up to $2\times10^6 r$ from $4\times10^4 r$. However, the $G$-value is dependent on the composition of the solution[12].

## Discussion

For the primary chemical effects of ionizing radiation on aqueous system,

$$H_2O \rightsquigarrow H_2,\ H_2O_2,\ H \text{ and } OH \qquad (0)$$

the yield of the above products per eV., namely, their $G$-value by Co-60 gamma-rays in the 0.8 N sulfuric acid aqueous system is considered to be $G(H_2)=0.39$, $G(H_2O_2)=0.78$, $G(H)=3.70$ and $G(OH)=2.92$, respectively[13]. The $G$-value of the following reactions, which is shown in parentheses at the right of each equation, is estimated from the above values. The suffix of $G$ denotes the order of reactions included in the $G$-value. For example, $G_{2,1}$ means the total $G$-value of reaction 2 and reaction 1.

The action of OH and $H_2O_2$ in ferrous solution is

$$Fe^{2+}+OH=Fe^{3+}+OH^- \qquad (G_1=2.92) \qquad (1)$$

and

$$Fe^{2+}+H_2O_2=Fe^{3+}+OH^-+OH \qquad (G_{2,1}=2\times0.78) \qquad (2)$$

However, the action of the H atom is very different according to the condition as follows.

**Yield of Ferric Ion in the Absence of Oxygen.**—In the absence of oxygen, the action of the H atom in the acidic solution is

$$H+H^+=H_2^+ \qquad (G_3=3.70) \qquad (3)$$

and then

$$Fe^{2+}+H_2^+=Fe^3+H_2 \qquad (G_4=3.70) \qquad (4)$$

Therefore, the total yield of ferric ion in the absence of oxygen is equal to $G_1+G_{2,1}+G_4=8.18$, as usual. In fact, the observed values at high dose for solutions a), b) and c) in Table I are in good agreement with this value.

In the presence of cupric ion, it reduces the yield of ferric ion by the reaction

$$Cu^2+H=Cu^++H^+ \qquad (5)$$

and then

$$Fe^3+Cu^+=Fe^{2+}+Cu^{2+} \qquad (G_5=G_6) \qquad (6)$$

Reaction 5 competes with reaction 4 within $G_4+G_5=3.70$. Even if the cuprous ion reacts with OH or $H_2O_2$ in addition to reaction 6, the effect of these reactions on the yield of the ferric ion is equivalent to reaction 6. Therefore, these effect are represented by $G_6$.

According to the above interpretation, the $G_5$ for solutions f) and i) are 0.85 and 2.9, respectively. On the assumption that

$$G_4/G_5=k_4K_3(H^+)(Fe^{2+})/k_5(Cu^{2+}) \qquad (i)$$

as pointed out by Hart[12], where $k$, $K$ and parentheses denote rate constant, equilibrium constant and concentration, respectively, the ratios obtained, $k_4K_3(H^+)/k_5$ are 0.084 and 0.069 for solutions f) and i), respectively. If $K_3$ is assumed to be 100 l./mol. according to Hart[12], the ratio, $k_4/k_5$ is estimated to be about $10^{-3}$. It is confirmed from this value that the cupric ion is very reactive for the H atom in comparison with the ferrous ion.

**Yield of Ferric Ions in the Presence of Oxygen.**—In the presence of oxygen, the action of H atom in the acidic solution is

$$H+O_2=HO_2 \qquad (7)$$

$$Fe^{2+}+HO_2=Fe^{3+}+HO_2^- \qquad (8)$$

and then

$$HO_2^-+H^+=H_2O_2 \qquad (G_{7,8,9,2,1}=3\times3.70) \qquad (9)$$

Therefore, the total yield of ferric ions in the presence of oxygen is equal to $G_1+G_{2,1}+G_{7,8,9,2,1}=15.58$, as usual.

In the ferrous and cupric solution, reaction 8 competes with reaction 5 and the reaction

$$Cu^{2+}+HO_2=Cu^++H^++O_2 \qquad (10)$$

and the rate of the consumption of oxygen by reaction 8 is expressed by the equation

$$G(-O_2)_8=G(H)\times\frac{1}{1+\dfrac{k_5(Cu^{2+})}{k_7(O_2)}}\times\frac{1}{1+\dfrac{k_{10}(Cu^{2+})}{k_8(Fe^{2+})}} \qquad (ii)$$

as pointed out by Hart[12]. Therefore, the circumstance of these reactions is complicated.

On the other hand, if $\Delta G$ is considered to be the difference between the observed $G$-value, $G^\circ$, and the ideal one, $G^i$, obtained on the

12) E. J. Hart, *Radiation Research*, 2, 33 (1955).
13) A. O. Allen, 1st Intern. Conf. Peaceful Uses of Atomic Energy", Vol. 7, Geneva, (1956), p. 514.

assumption that cupric ion scavenges all H atoms, it is expressed as

$$\Delta G = G^\circ - G^1 = 4G_8 \qquad \text{(iii)}$$

and

$$G^1 = G_1 + G_{2,1} - G_{5+10} = 0.78$$

Therefore, the consumption of oxygen against the dose in solutions d) and g) is estimated from Eq. iii as shown in Fig. 4. The respective $G$-value of the elementary reactions at the initial stage for both solutions is obtained from the initial slope in Fig. 4 as listed in Table III.

Table III. Yield of elementary reactions at the initial stage for oxygen-saturated ferrous-cupric solutions

| Run | Cupric ion | $G_8$ | $G_{5+10}$ | $G^\circ$ |
|---|---|---|---|---|
| d | $10^{-3}$ M | 3.34 | 0.34 | 14.22 |
| g | $10^{-2}$ M | 2.64 | 1.06 | 11.34 |

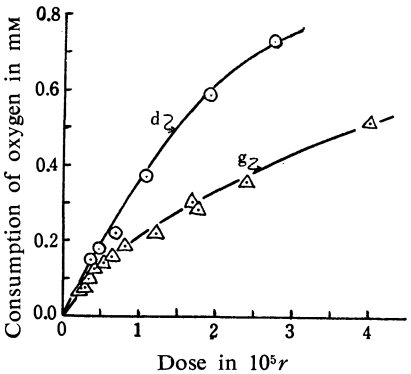

Fig. 4. The consumption of oxygen in oxygen-saturated 0.04 M ferrous sulfate acidic aqueous solution containing (d) 0.001 M and (g) 0.01 M cupric sulfate.

The linearity of the curve at the initial stage in Fig. 4 indicates that the ratios, $k_5(Cu^{2+})/k_7(O_2)$ and $k_{10}(Cu^{2+})/k_8(Fe^{2+})$ should be constant at this stage in Eq. ii, that is,

$$\frac{k_{10}}{k_8} = \frac{G_{10}(Fe^{2+})}{G_8(Cu^{2+})} \qquad \text{(iv)}$$

When the contribution of reaction 5 is assumed to be comparatively slight, $G_{10} \approx G_{5+10}$, in solution d), in which the concentration of cupric ions is low, the ratio, $k_{10}/k_8$ is estimated to be smaller than 4 from Eq. iv on using the values in Table III. According to Hart[12], the ratio, $k_{10}/k_8$ is about 50 for the aqueous solution of $10^{-3}$ M ferrous sulfate and 0.01 N sulfuric acid containing cupric ions between $10^{-6}$ M and $10^{-3}$ M. The disagreement between them may be the pH of the solution.

From the present experiment, $10^{-3}$ M cupric ion is sufficient to suppress the effect of oxygen dissolved naturally. However, it can not be concluded directly from this fact that oxygen is not concerned with the reaction in solution e). It is because the concentration of $HO_2$ radical should be sufficient for a ferrous ion to react with this radical from the result of solution b), and the $G$-value of reaction 10 is not so great as to suppress reaction 8 even in solution d) as listed in Table III. Therefore, it can not be understood why there is no difference between solutions e) and f) in spite of the above condition. However, if the cupric ion scavenges $HO_2^-$ ion by the reaction

$$Cu^{2+} + HO_2^- = Cu^+ + HO_2 \qquad (11)$$

and then $HO_2$ radical or $H_2O_2$ molecule by reaction 9 reacts with ferrous and cupric ions as mentioned already, the effect of oxygen, namely, the difference between reactions 4 and 8 can be actually disregarded. The initial concentration of oxygen in solution e), supposed from Table I, is smaller than the concentration of oxygen at the bend point of solution a), supposed from Fig. 1 and Table I.

## Summary

The oxidation of ferrous ion in ferrous-cupric acidic aqueous solution by Co-60 gamma-rays was studied in order to find a good chemical dosimeter for high doses. Consequently, it is found that the non-treated solution containing the $10^{-3}$ M cupric ion is useful for this purpose, for this amount of cupric ions is sufficient to suppress the effect of oxygen, and that the $G$-value of the ferrous-cupric system is dependent on the composition of the solution. The suppression can be explained by the scavenging of the $HO_2^-$ ion by cupric ions. Furthermore, some discussions regarding the system are given in the present paper.

# *Vibrational Spectra of Methyltrimethoxysilane*

By Toshio TANAKA

(Received August 26, 1959)

The group frequency assignments have already been given for the infrared spectra of methyltrimethoxysilane and its higher homologues in the rock salt region[1]. This paper contains the Raman spectrum of methyltrimethoxysilane, the assignment of the observed frequencies and the calculation of the frequencies and the modes of the skeletal vibration. In the calculation a methyl group was regarded as one particle.

The normal coordinate treatment was carried out by the Wilson *FG* matrix method[2] with a Urey-Bradley potential function. The normal vibration has not yet been calculated for any $YM(XZ)_3$ type molecule.

## Experimental

**Material.**—The preparation and the physical constants of methyltrimethoxysilane used in the present work have already been reported elsewhere[3].

**Raman Spectrum.**—The Raman spectrum has been obtained by a Yūki-gōsei Raman spectrograph. The observed frequencies are shown in Table II together with the infrared and the calculated frequencies.

## Normal Coordinate Treatment

For the convenience of the calculation, it has been assumed that the molecule belongs to the point group $C_{3v}$ and has the structure shown in Fig. 1, in which a C–Si–O–C plane and an O–Si–O plane including the same Si–O bond are assumed to have an interplaner angle of 120°. According to the group theory, this molecule has twelve skeletal vibrations, five of $a_1$, one of $a_2$ and six of $e$ species. One of the six skeletal vibrations of the species $e$ is the torsional oscillation of the (Si–)$OCH_3$ group*. All vibrations except the $a_2$ torsional mode are active both in infrared and Raman spectra.

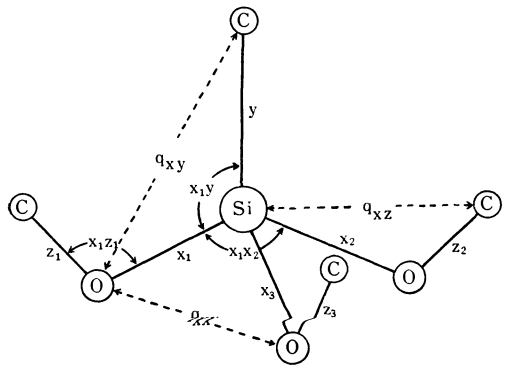

Fig. 1. Internal coordinates of the skeletal of methyltrimethoxysilane.

From the internal coordinates (Fig. 1), the following orthonormal symmetry coordinates have been found:

for the $a_1$ vibrations,

$$R_1=\Delta(z_1+z_2+z_3)/\sqrt{3}$$
$$R_2=\Delta y$$
$$R_3=\Delta(x_1+x_2+x_3)/\sqrt{3}$$
$$R_4=\Delta(x_1x_2+x_1x_3+x_2x_3-x_1y-x_2y-x_3y)/\sqrt{6}$$
$$R_5=\Delta(x_1z_1+x_2z_2+x_3z_3)/\sqrt{3}$$

and for the $e$ vibrations,

$$R_{7a}=\Delta(2z_1-z_2-z_3)/\sqrt{6}$$
$$R_{8a}=\Delta(2x_1-x_2-x_3)/\sqrt{6}$$
$$R_{10a}=\Delta(2x_1z_1-x_2z_2-x_3z_3)/\sqrt{6}$$
$$R_{11a}=\Delta(2x_1x_2-x_1x_3-x_2x_3)/\sqrt{6}$$
$$R_{12a}=\Delta(2x_1y-x_2y-x_3y)/\sqrt{6}$$

The numbering of these symmetry coordinates corresponds to the numbering of the fundamentals in Table II.

From the coefficients of the symmetry coordinates and the potential constants in a Urey-Bradley force field[4], the $F$ matrix elements are obtained as follow:

for the $a_1$ vibrations,

$$F_{11}=K_z+s_{zx}{}^2F_{xz}+t_{zx}{}^2F_{xz}'$$
$$F_{13}=s_{xz}s_{zx}F_{xz}-t_{xz}t_{zx}F_{xz}'$$
$$F_{15}=(s_{zx}t_{xz}F_{xz}+s_{xz}t_{zx}F_{xz}')x$$

$$F_{711}=F_{712}=F_{1011}=F_{1012}=0$$

where the following abbreviations have been adopted:

$$s_{xx}=4x/3q_{xx} \qquad t_{xx}=\sqrt{8}x/3q_{xx}$$
$$s_{xy}=(3x+y)/3q_{xy} \qquad t_{xy}=\sqrt{8}y/3q_{xy}$$
$$s_{yx}=(3y+x)/3q_{xy} \qquad t_{yx}=\sqrt{8}x/3q_{xy}$$
$$s_{xz}=(x-z\cos\theta)/q_{xz} \qquad t_{xz}=z\cos\theta/q_{xz}$$
$$s_{zx}=(z-x\cos\theta)/q_{xz} \qquad t_{zx}=x\cos\theta/q_{xz},$$

and the symbols used for the equilibrium values of the interatomic distances and of the interbond angles are $x$=Si-O, $y$=Si-C, $z$=O-C, $q_{xx}$=O···O, $q_{xy}$=O···C, $q_{xz}$=Si···C and $\theta=\angle$SiOC.

The $G$ matrix elements are obtained by the use of the table of Decius[5] and the method of Crawford[6]. Using the notations $\rho_x$, $\rho_y$ and $\rho_z$ for the reciprocals of Si-O, Si-C and O-C bond lengths, and $\mu_{Si}$, $\mu_O$ and $\mu_C$ for the reciprocals of the masses of silicon and oxygen atoms and methyl group, respectively, the following $G$ matrix elements have been obtained:

for the $a_1$ vibrations,

$$G_{11}=\mu_O+\mu_C$$
$$G_{13}=\mu_O\cos\theta$$
$$G_{14}=-\sqrt{2}\rho_x\mu_O\sin\theta$$
$$G_{15}=-\rho_x\mu_O\sin\theta$$
$$G_{22}=\mu_{Si}+\mu_C$$
$$G_{23}=-\mu_{Si}/\sqrt{3}$$
$$G_{24}=4\rho_x\mu_{Si}/\sqrt{3}$$
$$G_{25}=\sqrt{8/3}\rho_x\mu_{Si}$$
$$G_{33}=\mu_{Si}/3+\mu_O$$
$$G_{34}=-4\rho_x\mu_{Si}/3$$
$$G_{35}=-\sqrt{8}\rho_x\mu_{Si}/3-\rho_z\mu_O\sin\theta$$
$$G_{44}=2\rho_x^2(8\mu_{Si}/3+\mu_O)$$
$$G_{45}=8\sqrt{2}\rho_x^2\mu_{Si}/3+\sqrt{2}\rho_x(\rho_x-\rho_z\cos\theta)\mu_O$$
$$G_{55}=8\rho_x^2\mu_{Si}/3+\rho_z^2\mu_C+(\rho_x^2+\rho_z^2-2\rho_x\rho_z\cos\theta)\mu_O$$
$$G_{12}=0$$

and for the $e$ vibrations,

$$G_{77}=\mu_O+\mu_C$$
$$G_{78}=\mu_O\cos\theta$$
$$G_{710}=-\rho_x\mu_O\sin\theta$$
$$G_{711}=-\rho_x\mu_O\sin\theta/4$$
$$G_{712}=\rho_x\mu_O\sin\theta$$
$$G_{88}=4\mu_{Si}/3+\mu_O$$
$$G_{810}=\sqrt{2}\rho_x\mu_{Si}/3-\rho_z\mu_O\sin\theta$$
$$G_{811}=-\sqrt{8}\rho_x\mu_{Si}/3$$
$$G_{812}=-\sqrt{2}(\rho_x/3+\rho_y)\mu_{Si}$$
$$G_{1010}=\rho_x^2\mu_{Si}/6+\rho_z^2\mu_C+(\rho_x^2+\rho_z^2-2\rho_x\rho_z\cos\theta)\mu_O$$
$$G_{1011}=-\rho_x^2\mu_{Si}/3+\rho_x(\rho_x-\rho_z\cos\theta)\mu_O/4$$
$$G_{1012}=-\rho_x(\rho_x+3\rho_y)\mu_{Si}/6-\rho_x(\rho_x-\rho_z\cos\theta)\mu_O$$

$$G_{1111}=\rho_x^2(8\mu_{Si}/3+5\mu_O/2)$$
$$G_{1112}=\rho_x(\rho_x/3+\rho_y)\mu_{Si}-\rho_x^2\mu_O/4$$
$$G_{1212}=(\rho_x+3\rho_y)^2\mu_{Si}/6+\rho_x^2\mu_O+3\rho_y^2\mu_C/2$$

The geometrical and the potential constants used in the calculation are listed in Table I. As an aid in determining these potential constants, excepting $H_{xz}$ and $F_{xz}$, the results in the previous investigations on tetramethylsilane[7], methoxychlorosilanes[8] and diethylether[9] have been used. However, somewhat lower and higher values for $K_x$ and $K_z$, compared with the corresponding values in methoxychlorosilanes and diethylether, respectively, have been adopted, to obtain better agreement between the observed and the calculated frequencies. The value of $K_z$ adopted here is rather close to that previously obtained in dichloromethylether[10]. The mean value of $H(CH_3\text{–}Si\text{–}CH_3)$ in $Si(CH_3)_4$[7] and $H_{xx}$ in this paper, and that of $F(CH_3\cdots CH_3)$ and $F_{xx}$ have been used as $H_{xy}$ and $F_{xy}$, respectively. The value of $\kappa$ has been derived by means of the proportional allotment from the intramolecular tension of silicon tetrahedron in $Si(CH_3)_4$[7] and that in $Si(OCH_3)_4$[8]. The values of $H_{xz}$ and $F_{xz}$ have been selected so as to give good agreement between the calculated and observed ones. Finally, the value of $F'$ has been assumed to be equal to $-F/10$ by the usual way.

### Assignment of Observed Frequencies

From the $F$ and $G$ matrix elements given above, the fundamental frequencies have been calculated by the use of the molecular and the potential constants listed in Table I, and the results are shown in Table II, together with the observed wave numbers of the Raman and the infrared bands. The skeletal vibrations have been assigned by the calculation of the potential energy distribution in the symmetry coordinates, and also the hydrogen vibrations have been tentatively assigned.

The $L$ matrices and the distribution of potential energy in symmetry coordinates have been calculated for the skeletal normal modes; the results are shown in Table III and IV, respectively.

The calculated frequencies of the skeletal vibrations are in good agreement with their corresponding observed values, except for the Raman line at 425 $cm^{-1}$. This line may be classified as the (Si-)$OCH_3$ torsional oscillation of $e$ species. As shown in Table IV some of

the symmetry coordinates of totally symmetric species are related to several normal modes to a considerable extent; the $R_2$ and $R_3$ coordinates to both modes of $\nu_2$ and $\nu_3$, and the $R_4$ and $R_5$ coordinates to both modes of $\nu_4$ and $\nu_5$. Especially, in the latter case, the symmetrical deformation of the $CSiO_3$ group and that of the SiOC groups have their equal share in the potential energy of the $\nu_4$ normal mode, and also of the $\nu_5$ mode.

The author wishes to express his sincere thanks to Professor T. Watase of this University, and Dr. H. Murata and Dr. K. Shimizu of Osaka Municipal Technical Research Institute for much valuable discussion.

# 5, 6-Epoxy-cholestane

By Fumikazu MUKAWA

(Received September 22, 1959)

Ruzicka et al.[1] have first obtained 5, 6β-epoxy-5β-cholestane (II), m.p. 53°C, as a by-product of the reaction of cholest-5-ene (I) and peroxyacid. Recently Shoppee et al.[2] have reported that the melting point of 5, 6β-epoxy-5β-cholestane (II) obtained by the above method was 55°C. Henbest and Wrigly[3] have prepared II, m. p. 58°C, $[\alpha]_D$ −9°, by the reduction of 5-bromo-5α-cholestan-6-one with lithium aluminum hydride, while Hallsworth and Henbest[4] have reported that the same epoxycholestane (II) prepared from 5, 6β-diacetoxy-5α-cholestane by the method which was adopted in the preparation of 5, 6β-epoxy-5β-cholestane 3β-ol from 3β, 5, 6β-triacetoxy-5α-cholestane[5] melted at 80°C and showed $[\alpha]_D$ +8°.

Mori and the present author[6] have investigated the addition reaction of hypochlorous acid (isocyanuric chloride-acetic acid) to 3-substituted-$\Delta^5$-steroids and found that the products were 5α-chloro-6β-hydroxy derivatives which have been converted by base to 5β, 6β-epoxides. In the same manner I was expected to be converted to II. However the intermediate 5-chloro-6β-hydroxy-5α-cholestane (III) was not produced but 5, 6β-dichloro-5α-cholestane and oily substance were obtained.

Then, the author has turned to another route to obtain II. Thus, reduction of 5, 6β-epoxy-5β-cholestan-3β-yl halide ($I_a$, halogen=Cl; $I_b$, halogen=Br) with lithium in liquid ammonia or zinc-copper alloy in ethanol has lead to II, m.p. 79°C, $[\alpha]_D$ +80° in 70% yield. The structure of II assigned was confirmed in the following way. Reduction of II with hydroiodic acid (55%) in acetone gave I, and reduction with lithium aluminum hydride in ether gave cholestan-6β-ol. Treatment of II with 1 N sulfuric acid in acetone gave 5, 6β-dihydroxy-5α-cholestane.

It was interesting to notice that the oxide ring at $C_5$~$C_6$ was indifferent to the lithium-ammonia reducing system. By the similar reduction 5, 6α-epoxy-5α-cholestan-3β-yl halide ($IV_a$, halogen=Cl; $IV_b$, halogen=Br) yielded 5,6α-epoxy-5α-cholestan (V), m.p. 76°C, $[\alpha]_D$ −39.9°, which showed no melting point depression upon admixture with an authentic specimen.

It has been reported[7,8] that the reaction of the halohydrins of the steroid series with zinc dust and acetic acid yielded the unsaturated steroids, but 6β-halo (chloro and bromo)-5α-cholestan-3β, 5-diol-3-monoester was exceptional. Thus, the latter was converted into the *trans*-triol 3, 6-diester and $\Delta^5$-derivative was not produced at all. It seems to be noteworthy that in the case of 6β-chloro-5α-cholestan-5-ol (VI), 6β-acetoxy-5α-cholestan-5-ol was obtained being accompanied by a small amount of I[9]. III was converted into I with zinc dust and acetic acid or lithium in liquid ammonia. I was also obtained by the reduction of VI with lithium in liquid ammonia.

## Experimental**

**Attempted Hypochlorous Acid Addition on Cholest-5-ene (I).**—To a mixture consisting of 0.5 g. of I, 0.2 g. of isocyanuric chloride and 15 ml. of acetone were added five drops of 30% aqueous acetic acid. The whole was refluxed for five minutes. After cooling to room temperature, the mixture was poured with stirring into 10% aqueous sodium carbonate, and then extracted with ether. The extract was washed with water and dried over magnesium sulfate. After removal of the solvent, the residue was recrystallized from methanol to yield 0.18 g. of needles, m.p. 120~121°C. The compound did not depress the melting point on admixture with the authentic sample of 5, 6β-dichloro-5α-cholestane. The filtrate was left to stand in a refrigerator for one month. However, only a gum was obtained.

**5, 6β-Epoxy-5β-cholestane (II).**—*i) From 5, 6β-epoxy-5β-cholestan-3β-yl chloride ($I_a$).*—To a well stirred mixture of 50 mg. of lithium and 30 ml. of liquid ammonia, 0.3 g. of $I_a$ in 40 ml. of dry ether was added. After thirty minutes, the excess of

* All melting points are uncorrected.

lithium was destroyed by acetone. After two hours at room temperature, addition of water, extraction of ether and crystallization of the crude product from ethanol afforded II, m.p. 70~73°C, raised by crystallization from ethanol-*n*-hexane to 79°C, $[\alpha]_D$ +8°. It exhibited no absorption of hydroxyl band in the infrared spectrum.

Found: C, 83.85; H, 11.20. Calcd. for $C_{27}H_{46}O$: C, 83.87; H, 11.99%

A mixture of 0.3 g. of $I_a$, 0.2 g. of zinc-copper alloy and 20 ml. of alcohol was heated under reflux for 3 hr. But in this case only starting material was recovered.

*ii) From 5,6β-epoxy-5β-cholestan-3β-yl bromide*[10] *($I_b$).*—To a well stirred mixture of 50 mg. of lithium and 30 ml. of liquid ammonia, 0.3 g. of $I_b$ in 40 ml. of dry ether was added. There were obtained needles which melted at 79°C and did not depress the mixed melting point with the authentic 5,6β-epoxy-5β-cholestane (II). The infrared spectra of the two compounds were identical.

In another rum with 0.5 g. of $I_b$, 0.2 g. of zinc-copper alloy and 30 ml. of ethanol were heated under reflux for 3 hr. There were obtained 0.3 g. of needles with a melting point 78~79°C. There did not depress the mixed melting points with an authentic sample.

**Structure of 5,6β-Epoxy-5β-cholestane (II).**—The product obtained as described above was shown to be 5,6-β-epoxy-5β-cholestane (II) by the following series of reactions.

i) A solution of II (0.2 g.) in acetone (5 ml.) was treated with two drops of hydroiodic acid (55%). After being kept to stand at room temperature (21°C) for 24 hr., the solution was poured into water and was extracted with ether. The extract was washed with sodium thiosulfate solution (5%) and water, dried and evaporated. Crystallization of the residue from alcohol gave 0.1 g. of I, m.p. 90~91°C and mixed m.p. with the authentic specimen showed no depression.

ii) II (0.5 g.) dissolved in anhydrous ether (80 ml.) was added dropwise to lithium aluminum hydride (0.1 g.) in ether for 20 min. at room temperature (20°C) and then refluxed for 5 hr. Chromatography of the product over florisil and elution with ether-methanol gave 5α-cholestan-6β-ol, m.p. 81°C (plates from alcohol), undepressed in m.p. on admixture with the authentic specimen.

iii) A mixture of II (0.3 g.), two drops of sulfuric acid (10%) and 50 ml. of methanol was heated under reflux. After two hours, addition of water, extraction with ether and crystallization of the crude product from alcohol afforded 5α-cholestan-5,6β-diol, m.p. 60~73°C, raised by recrystallization from alcohol to 125°C, undepressed on admixture with the authentic sample.

**5,6α-Epoxy-5α-cholestan-3β-yl Bromide ($IV_b$).**—Cholesteryl bromide (0.5 g.) was added to a cold solution of perbenzoic acid (1.3 equiv.) in 20 ml. of chloroform, the reaction mixture briefly stirred and then allowed to stand at room temperature (18°C) for 48 hr. before pouring into a solution of sodium carbonate. The organic phase was separated, washed with water to neutrality, dried and evaporated. The product crystallized from alcohol to afford $IV_b$, m.p. 87~89°C, $[\alpha]_D = -21.2°$.

Found: C, 68.90; H, 9.70. Calcd. for $C_{27}H_{45}OBr$: C, 69.74; H, 9.75.

**5,6α-Epoxy-5α-cholestane (V).**—The procedure of II was followed. The product was recrystallized from methanol, yielded V, m.p. 76°C, $[\alpha]_D$ −39.9°. It was identified by mixed melting points with the authentic sample.

**5-Chloro-5α-cholestan-6β-ol (III).**—A solution of the epoxy-cholestan II (0.2 g.) in alcohol-free chloroform (2 ml.) was treated with a saturated solution of anhydrous hydrogen chloride in alcohol-free chloroform (10 ml.). After standing at 0°C for 4.5 hr., the solution was evaporated to dryness. The residue was recrystallized from aetone-water to give III, yield, 0.12 g., m.p. 121~123°C, $[\alpha]_D = -12°$.[11]

Found: C, 76.51; H, 11.45. Calcd. for $C_{27}H_{47}OCl$; C, 76.10; H, 11.29%.

*i) With zinc dust.*—A mixture of 0.1 g. of III, 0.2 g. of zinc dust, and 5 ml. of acetic acid was heated under reflux for 3 hr. The solids were filtered off and water was added to produce faint turbidity. The crystals were then crystallized from chloroform-methanol and melted at 91°C. The compound did not depress the melting point with the authentic sample of cholest-5-ene (I).

*ii) With lithium in liquid ammonia.*—The chlorohydrin (III) (0.3 g.) in dry ether was added with vigorous stirring to a solution of lithium (50 mg.) in liquid ammonia (50 ml.). After 30 min., excess lithium was destroyed by acetone. The reaction mixture was then diluted with ether and the ether solution was washed with cold hydrochloric acid solution (1%). Finally the solution was washed with water, dried sodium sulfate and the solvent removed. Crystallization of the product from methanol afforded I, yield, 0.2 g., m.p. 90~91°C, undepressed on admixture with the authentic sample.

**Reduction of 6β-Chloro-5α-cholestan-5-ol (VI).**—*i) With zinc dust.*—A mixture of 1 g. of VI, 0.5 g. of zinc dust and 50 ml. of acetic acid was heated under reflux for 1.5 hr. The solids were filtered off and diluted with water. The product was extracted with ether. The ether solution washed with sodium bicarbonate solution (5%) and then with water, dried, and evaporated. The residue was chromatographed on 20 g. of neutral alumina, the petroleum ether elute yielding, after crystallization from chloroform-methanol, 0.1 g. of I, undepressed on admixture with the authentic sample. Chromatography gave in the ether-methanol (1:1) fractions, 0.4 g. of 6β-acetoxy-5α-cholestan-5-ol, m.p. 80~82°C, $[\alpha]_D = -20°$, the melting point being raised by recrystallization from methanol to 108°C.

Found: C, 77.90; H, 11.00. Calcd. for $C_{29}H_{50}O_3$: C, 77.97; H, 11.28%.

*ii) With lithium in liquid ammonia.*—Reduction of 0.3 g. of VI with lithium in liquid ammonia under conditions described for the 5-chloro-isomer afforded 0.1 g. of I. It was identified by mixed melting point with the authentic sample.

# *Detection of Chromatogram by Swelling of Adsorbent*

By Akira HAYAKAWA and Kōji TANAKA

(Received September 17, 1959)

In the field of adsorption chromatography the column chromatography was devised for the first time by Tswett[1] about fifty years ago. Afterwards, in 1950, the chromatostrip as the modifier was introduced by Kirchner et al.[2] and more recently the larger strip called chromatoplate was used by Reitsema[3]. In these methods the adsorbent was sealed with a glass wall or hardened with a binder.

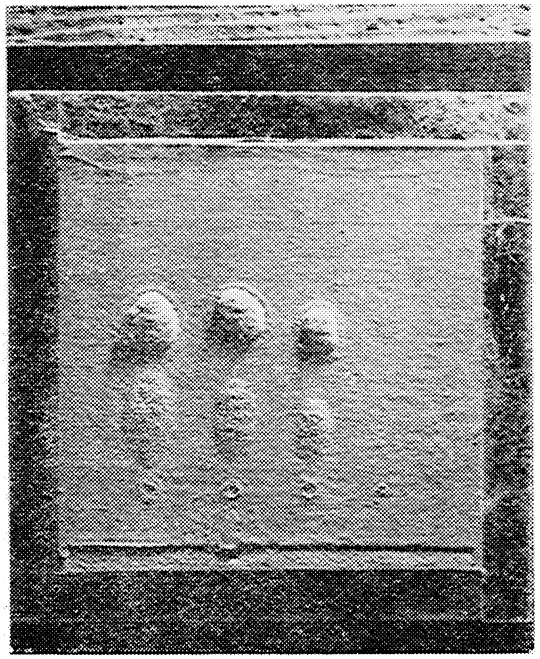

Fig. 1. Swelling of adsorbent by water vapor.
Developer: 10% ethylacetate in *n*-hexane
Adsorbent: Silica gel (about 200 mesh)
Sample : Benzaldehyde
The amount of sample is 15, 10, 5 and 1 drops from left to right, respectively.

Simplifying the operation of the above-mentioned chromatoplate, the authors used the adsorbent alone sprinkled on a glass plate without a binder. As an adsorbent was used silica gel of about 200 mesh. It was sprinkled on the glass plate in constant thickness (2 mm.) and the surface was smoothed with a glass rod. The commercially available pure benzaldehyde was used as a sample. It was developed by 10% ethylacetate in hexane and dried in air to remove the developer.

The present authors happened to discover that the adsorbent of the part of the spot made by benzaldehyde was upheaved by swelling when the plate prepared by the above-described process was left in an enclosed case of high humidity. In order to confirm this phenomenon, the authors left another plate prepared in quite the same way in the sealed case of 100% relative humidity and over a long time observed the change expected to be brought about on it. After 2 to 3 hr. an umbrella-shaped swelling of the adsorbent began to occur at the place of

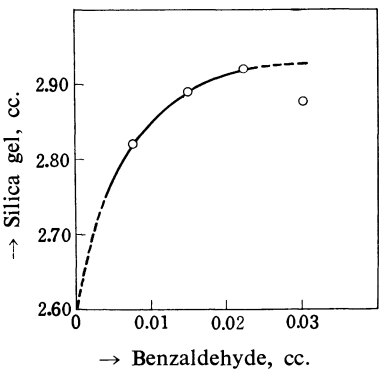

Fig. 2. The apparent volume of silica gel as a function of the amount of benzaldehyde added to 1 g. of silica gel.

1) M. Tswett, *Ber. deut. botan. Ges.*, 24, 384 (1906).
2) J. G. Kirchner and G. J. Keller, *J. Am. Chem. Soc.*, 72, 1867 (1950).
3) R. H. Reitsema, *Anal. Chem.*, 26, 960 (1954).

$R_f$ about 0.5. After one day that of oval shape began to arise at $R_f$ about 0.22 and after three days the rising of ring shape was found around the first one. The second swelling and the third one seem to be caused by derivatives of benzaldehyde or its oxidation products. In either case it is considered that polar groups in these compounds act on polar groups of silica gel and consequently the swelling by water vapor takes place. The condition of the plate after four days is shown in Fig. 1. The amount of the sample dropped on silica gel was 15, 10, 5 and 1 drops from left to right, respectively. In a drip of one drop hardly any upheaval is observed.

Fig. 2 was obtained by plotting the apparent volume of silica gel as a function of the amount of benzaldehyde added to 1 g of silica gel. As is seen in the figure the apparent volume of silica gel increased with the increasing amount of benzal dehyde until it came to 0.025 cc.

The swelling phenomenon was scarcely noted when the relative humidity in the enclosed case was decreased to below 40 or 50%.

So far the expression of the spot of chromatography has been two dimensional or superficial. But the use of the swelling phenomenon above described will make the three dimensional observation possible.

# *Structure of Namakochrome. I**

By Toshihiko MUKAI**

(Received September 16, 1959)

In a previous paper[1] of this series the isolation of namakochrome, which would be a new derivative of the polyhydroxynaphthoquinones, from *Polycheira rufescens* was reported.

*Polycheira rufescens* (in Japanese, Murasaki-kuruma-namako) is a sort of tiny sea cucumber, its body being dark purple in color. A crowd of the animals may be frequently found in the stony tidal zone. As preliminary examination assigned the purple coloration of the sea cucumber to a chromoprotein, some methods to isolate the prosthetic group of the protein had been undertaken, and namakochrome was obtained.

Twenty-eight thousand of the sea cucumbers were collected for material at a sea coast near the Amakusa Marine Laboratory, the Faculty of Science, Kyushu University. These animals were dipped into a dilute aqueous solution of acetic acid. The chromoprotein dissolved easily in the aqueous acid to give a red solution. To the red extract, diluted aqueous solution of sodium hydroxide was added till the color of the extract changed to dark purple. After the resulting opaque solution was allowed to stand overnight, a pale yellow supernatant liquid was decanted off and the remaining purple pasty precipitates were collected***. The precipitates were treated with concentrated hydrochloric acid, followed by extraction with ether. Two and thirty-six hundredths grams of crude, orange red pigment of the prosthetic group were obtained. Repeated recrystallization from glacial acetic acid afforded pure namakochrome, a pigment of crimson prisms, m. p. 218°C.

Namakochrome contains only three elements, namely, carbon, hydrogen and oxygen. Its molecular weight determination (by the micro-Rast method with camphorquinone) and elementary analysis yield the result which is in agreement with the molecular formula $C_{11}H_8O_8$. The ultraviolet (ethanol) and infrared (Nujol) absorption spectra are shown in Figs. 1 and 2, respectively. On heating, a greater part of namakochrome sublimes, leaving some carbonized matter. This pigment is easily soluble in solvents of high polarity. It is soluble in mineral acids, to which it is very stable; even in hot concentrated sulfuric acid a red color of the solution lasts for a considerably long time. It is unstable to the solution of weak alkali. With sodium bicarbonate solution it gives a light yellow color, changing gradually to colorless. On the other hand, it dissolves easily in

*** The same precipitates could be obtained by the addition of methanol instead of aqueous sodium hydroxide, but this caused only imperfect precipitation, and its supernatant liquid still remained deep red.

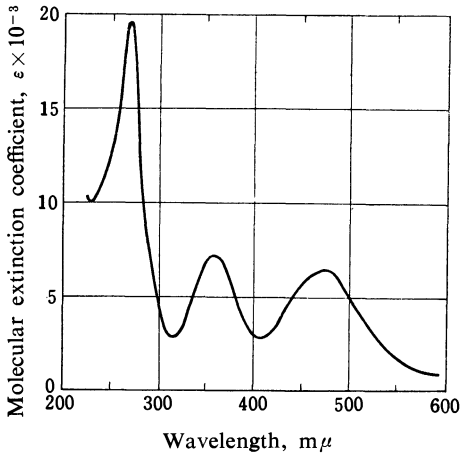

Fig. 1. Absorption curve of namakochrome: solvent, ethanol.

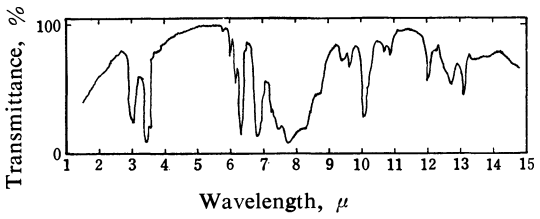

Fig. 2. Infrared spectrum of namakochrome.

dilute solution of strong alkali with orange red color, while with its more concentrated aqueous solution, it forms immediately purplish black salt, which is sparingly soluble in it. With heavy metals also, it gives the difficultly soluble black salts with purple luster. Namakochrome reduces silver nitrate, and gives a dark purple color with ferric chloride. It gives a purple precipitation with neutral lead acetate, a reddish purple precipitation with basic lead acetate, and a dark orange-yellow color with magnesium acetate. On adding zinc dust to a solution of namakochrome in an acetic anhydride pyridine mixture, an original red color soon changes to yellow, then the solution gradually turns colorless, and at last returns to yellow****. This yellow solution becomes red when warmed with concentrated sulfuric acid.

Now, the above-mentioned properties and the molecular formula would suggest that namakochrome is a derivative of polyhydroxynaphthoquinones. To obtain information on the basic structure of the molecular skeleton, zinc dust distillation of namakochrome was carried out, and naphthalene was isolated in a relatively good yield.

Brockmann[2] found that when most of quinone derivatives were hydrogenated in the presence of palladium catalyst on barium sulfate, in aqueous alkaline solution, only the quinone-system prevailed over the other reducible groups in the same molecule. He extended this selective hydrogenation method to a determination of a molecular weight of Actinorhodin, a new hydroxyquinone derivative, isolated from *Streptomyces coeli* color. This method was applied to catalytic hydrogenation of namakochrome, and the result showed that namakochrome shoud have a quinone-system in the molecule, as it absorbed one molecular equivalent of hydrogen. On coming in contact with the air, the resulting pale brown solution changed its color to original red.

In the presence of concentrated sulfuric acid as a catalyst, namakochrome reacts with acetic anhydride to yield a lemon yellow acetyl derivative, m. p. 158~163°C. The acetyl derivative is labile to alkali. When its ethereal solution is brought into contact with aqueous sodium bicarbonate solution even for a short time, decomposition of the acetate occurs and the original material, namakochrome, is isolated. In contrast with namakochrome, the acetate is easily soluble in benzene, sparingly soluble in cold ethanol, and recrystallization from ethanol is very easy. The analytical data[3] obtained for the acetate is in accordance with the formula, $C_{11}H_3O_8(COCH_3)_5$. The infrared absorption spectrum of the acetate is shown in Fig. 3.

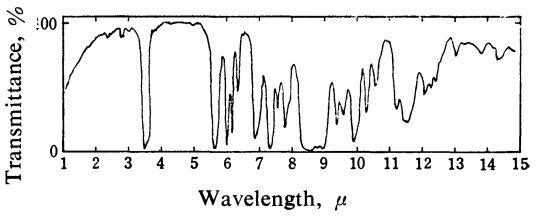

Fig. 3. Infrared spectrum of penta-acetyl namakochrome.

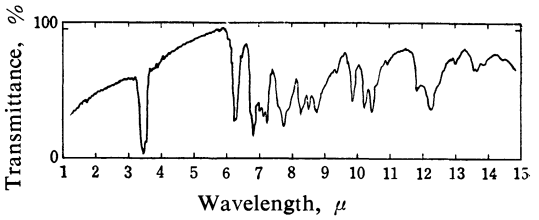

Fig. 4. Infrared spectrum of trimethyl ether of namakochrome.

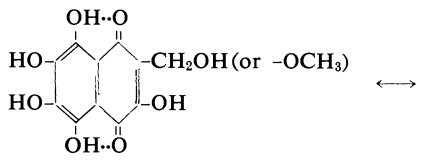
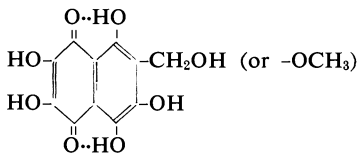


**** There must be a leuco-acetyl derivative of namakochrome in the resulting yellow solution, but no crystalline product is obtained as yet.

2) H. Brockmann et al., *Ber.*, **88**, 781 (1955).



3) In the estimation of acetyl groups of the acetate, 5 N NaOH was emloyed as a saponifying agent. Namakochrome was also treated under the same saponifying condition, because there remained doubt whether this agent degrades namakochrome to acidic volatile substances. It was shown that under these conditions namakochrome which was liberated from the acetate by the saponification, did not suffer an undesirable change.

Since the formation of the acetate evidently shows many hydroxyl groups to be present in the namakochrome molecule, namakochrome was strongly methylated by the Kuroda's method[4]. The resulting ether is of brownish red long needles, melting at 185~187°C. Analysis of the ether yields results which are in accordance with the formula $C_{11}H_5O_5(OCH_3)_3$. The infrared absorption spectrum of the ether is shown in Fig. 4. In the trimethyl ether, two of the hydroxyl groups at the $\alpha$-positions of naphthalene nucleus would, as usual, not be methylated and remain free. Furthermore, the following properties of the ether indicated that the positions of the three methylated hydroxyl groups would be located in 3-, 6- and 7-positions of the naphthalene nucleus. Such properties were of the color reactions, which were introduced by Kuroda[5], and were taken up in the work of Kuhn[6] on the structure of Echinochrome A. That is, namakochrome trimethyl ether, like naphthazarin and $\beta$-alkyl naphthazarin, dissolved in an aqueous solution of sodium hydroxide to give a purplish blue color[7], and did not dissolve in an aqueous solution of sodium bicarbonate. On the contrary, the color reaction and the precipitation reaction of namakochrome itself, already described, could be recognized it as the analogue of naphthopurpurin or $\beta$-alkyl naphthopurpurin.

Although, there is not, as yet, the clue given to the nature of one of the eight oxygen atoms in the namakochrome molecule, this oxygen atom should form a group together with the other remaining one carbon atom and three hydrogen atoms. The unascertained group would, therefore, be either a hydroxymethyl or a methoxyl group, which should locate at the $\beta$-position of the naphthalene nucleus. Namakochrome may be, anyhow, a new derivative of the naphthoquinones, possessing the following structure (I ↔ II).

## Experimental

**Distillation of Namakochrome with Zinc Dust.**—Essentially the method of Ochiai and Tsuda[8] was followed for the distillation of namakochrome with zinc dust. Namely, one end of a glass tube (9 mm. in diameter and about 50 mm. in length) was drawn to a capillary about 2 mm. in diameter. A plug of clean asbestos was inserted at the point where the capillary began. Zinc dust was introduced into the tube so that it covered a length of about 10 mm. from the plug, and a mixture of namakochrome and zinc dust was introduced into the tube to fill a length of about 10 mm. of the tube. Zinc dust was last placed in the tube, which was then sealed at the open end. The mixture of 370 mg. of namakochrome and 7 g. of zinc dust was treated with seventeen of the above-mentioned apparatus. The tube containing the materials was heated from the open side to the closed side with continuous rotation, and was finally heated red hot. The distillates were three separate fractions. The first distillate was a waxy substance having a blue fluorescence near the asbestos plug. At a short distance, there was found the second distillate, colorless liquid over which the third colorless leaflets and white solid was lapped. The portions of the crystals and the solid were cut into sections (about 10 mm.) and packed at a sealed end of a glass tube (about 15 mm. in diameter). The other end of the tube had been drawn out to form a capillary, whose length and inside diameter were 70 mm. and 1.5~2 mm., respectively. Then the apparatus was emptied to about 20 mmHg from the open end of the capillary, which was then sealed off. The portion of the larger tube was horizontally inserted in an aluminum block maintained at 95°C, and a wet filter paper condenser was attached at a half of the capillary portion from its closed end. The part of the capillary where the colorless oil separated perfectly, was cut off, and the remainder portions of the capillary were handled again in the same manner as described. Repeated operations afforded the solid which is slightly contaminated with the oil. The solid was then purified by crystallization from ethanol. About 4 mg. of crystals, m. p. 80°C, were obtained. This was naphthalene, whose melting point was unaffected by admixture with an authentic sample.

**Catalytic Hydrogenation.**—In 4 ml. of 1 N sodium hydroxide, 7.65 mg. of namakochrome were hydrogenated in the presence of about 50 mg. of palladium on barium sulfate catalyst.

Found: 1.02 mol. of hydrogen.

**Penta-acetyl Namakochrome.**—One drop of concentrated sulfuric acid was, at room temperature, added to a suspension of namakochrome (50 mg.) in acetic anhydride (1.5 g.), to give a lemon yellow solution. After setting aside for two hours at room temperature, the resulting solution was poured into

7) When the trimethyl ether was catalytically hydrogenated by the Brockmann's method described above, the purplish-blue color caused by the alkali rapidly changed into nearly colorless and again backed to purplish-blue on exposure to air. At this time the trimethyl ether absorbed one molecular equivalent of hydrogen.

8) E. Ochiai and K. Tsuda, "Yuki Biryo Shyoryo Teiryo Bunsekiho", Nanzando, Tokyo (1940), p. 300.

ice water and extracted with benzene. The yellow extracts were concentrated to a small volume under the reduced pressure. The concentrate was filtered through a calcium carbonate column (3×16 cm.). Evaporation of the effluent under reduced pressure, and recrystallization of the resulting yellow residue from ethanol gave penta-acetyl namakochrome as lemon yellow needles (50 mg.), m. p. 158~163°C.

Found: C, 52.68; H, 3.93; AcO, 45.40. Calcd. for $C_{21}H_{18}O_{13}$: C, 52.73; H, 3.79; AcO, 44.99%.

**Trimethyl Ether of Namakochrome.**—A solution of diazomethane (prepared from 5 g. of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) in ether (40 ml.) was added dropwise to crystalline namakochrome (300 mg.) spread on a large evaporating dish. When the violence of the reaction abated, and evaporation of the ether slowed, the solvent remaining in the evaporating dish was removed. Addition of the diazomethane solution was then continued. After the addition of the whole ethereal solution of diazomethane, the remaining solvent was evaporated as before. The resulting residue was dissolved in benzene, and filtered through a calcium carbonate column. The red effluent was evaporated to dryness under reduced pressure, and there remained brownish red, fine, long, needles, which, by recrystallization from a mixture of ethanol and benzene, gave trimethyl ether (279 mg.), m. p. 185~187°C.

Found: C, 54.17; H, 4.72. Calcd. for $C_{14}H_{14}O_8$: C, 54.20; H, 4.55%.

The author wishes to express his thanks to Professor Dr. Tokuichi Tsumaki under whose guidance this investigation has been carried out. The expenses of the work were partially covered by the Scientific Research Grant of the Ministry of Education.

# *Some Characteristics of Zinc Oxide Phosphor*

By Keiji MAEDA

(Received August 31, 1959)

Zinc oxide is well known as a typical oxide semiconductor and many investigations have been made concerning it. Its characteristics are quite complex compared with those of other materials. It may be said that this complexity is due to the divalency of the constituting ions and the difficulty of preparing prefect crystals. Moreover, since zinc oxide is not a purely ionic crystal, one must take into account the homopolar nature of the binding. Although important progress has been made by the recent studies on the single crystal, there remain many ambiguities. A review of the present status has been given by Heiland, Mollwo and Stöckman[1].

On the other hand, zinc oxide has been used for many practical purposes, for instance, as a catalyst and photocatalyst for a series of chemical reactions, and as a phosphor with very fast decay time. In addition, it may play an important role in future in the "Electrofax" process of photographic duplication in which the photoconductivity of zinc oxide is utilized. These applications depend in a direct way on the electronic processes in zinc oxide. As a phosphor, zinc oxide has never been a subject of such extensive investigations as have been made on other similar materials, i.e. zinc and cadmium sulfides. In this report, several characteristics of zinc oxide phosphors will be described.

1) G. Heiland, E. Mollwo and F. Stöckman, "Solid State Physics", Vol. 8, Academic Press, New York (1959), p. 193.

## Experimental and Results

**Sample Preparation.** — The samples were prepared by firing pure zinc oxide at several temperatures from 950 to 1200°C in an atmosphere of air, forming gas, hydrogen or oxygen for various durations. In some samples, many kinds of impurities were intentionally added before firing. Only the phosphors fired in reducing atmosphere give bright green luminescence. The phosphors fired in air emit yellowish green luminescence and those fired in an oxidizing atmosphere dark orange luminescence. Except in the case of a phosphor containing lead as an activator, effects of added impurities on the luminescence spectrum do not appear clearly. Neither chlorine nor bromine functions as a coactivator. A firing in hydrogen atmosphere at 1000°C for 3 min. produced a phosphor emitting intense luminescence. Because of the strong intensity of the green luminescence, one will be concerned with it in the experiments described below.

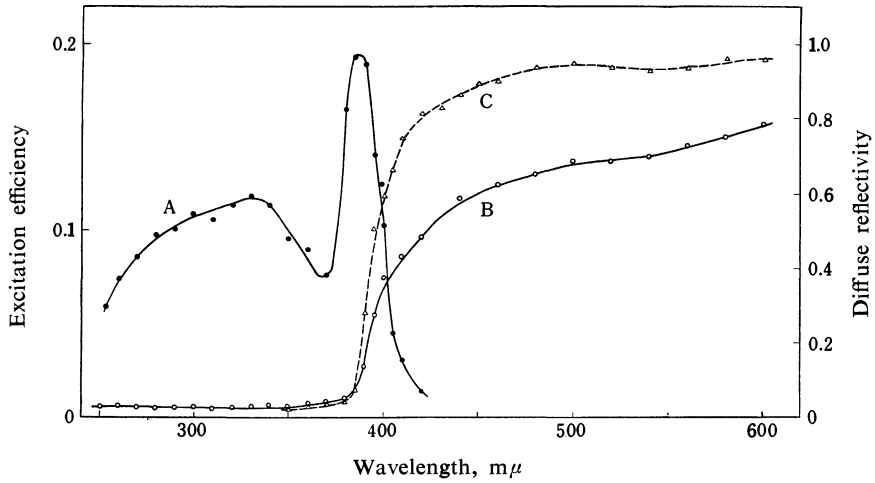

Fig. 1. Excitation and reflectivity spectra of zinc oxide.

A: Excitation efficiency of zinc oxide fired under reducing conditions.
B: Diffuse reflectivity of the same sample as A.
C: Diffuse reflectivity of zinc oxide fired under oxidizing conditions.

**Luminescence Spectrum.**—The luminescence spectrum was measured at both room and liquid air temperatures. The peak of the green luminescence is located at about 5050 Å and does not shift with temperature, but the spectral width decreases with decreasing temperature. This is in agreement with the published data[2].

**Reflection and Excitation Spectra.**—The reflection and excitation spectra were measured with the apparatus made in this laboratory[3]. As examples, some results are shown in Fig. 1. Here, the value of excitation efficiency is defined as the ratio of the number of luminescence photons to that of the incident exciting photons.

The absorption edge of zinc oxide is about 3900 Å at room temperature. The sample fired in an oxidizing atmosphere has a steep rise in reflectivity and a slight absorption at longer wavelengths. On the other hand, for the sample fired in a reducing atmosphere the rise in reflectivity is gradual and a notable absorption extends over the whole wavelength region measured. For the sample fired in stronger reducing condition, a larger absorption results.

There is a remarkable peak in excitation spectrum at the position of the absorption edge. The peak value of the excitation efficiency depends on the sample and amounted to 0.31 in the most efficient phosphor. It has no apparent correlation with the increment in absorption. The excitation decreases with decreasing wavelength of excitation and there are some structures. A similar behavior of excitation spectrum has been reported for zinc sulfide[4] and cadmium sulfide[5].

**Temperature Dependence of Luminescence Intensity.**—The temperature dependence of luminescence intensity was measured under excitation with both 2537 and 3650 Å radiation. As shown in Fig. 2, the characteristics are similar for the

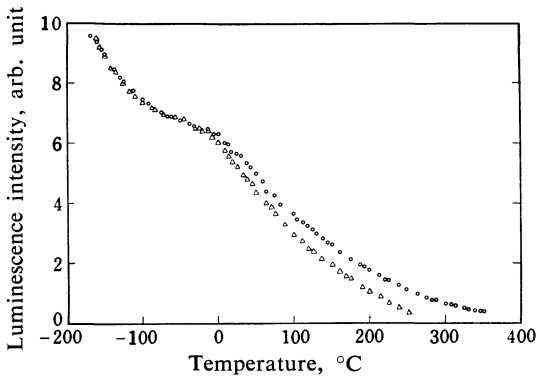

Fig. 2. Temperature dependence of luminescence intensity under 3650 Å excitation (○) and under 2537 Å excitation (△).

two sorts of exciting radiation. The intensity decreases with increasing temperature and the curves have an interesting shape in the neighborhood of 0°C. The author's results are different from those reported by Gobrecht et al.[6]

**Decay of Luminescences.**—The decay of luminescence was measured with an oscilloscope

2) F. J. Studer and L. Gaus, "Soild Luminescent Materials", John Wiley & Sons, Inc., New York (1948), p. 258.
3) Y. Uehara, I. Masuda and Y. Kobuke, to be published.

5) C. C. Klick, ibid., **89**, 274 (1953).
6) H. Gobrecht, D. Hahn and K. Scheffler, *Z. Physik*, **139**, 365 (1954).

Tektronix Model 513D under pulse excitation of cathode ray and care was taken not to distort the fast signal. The luminescence decays very fast and exponentially with time constant of 0.4 $\mu$ sec., which is about an order of magnitude smaller than that reported by Gobrecht et at.[6]

After interruption of photoexcitation it was found a phosphorescence of very weak intensity but with long persistence. This phosphorescence is excited more strongly by 2537 than by 3650 Å radiation. The decay is neither simple monomolecular nor bimolecular type but is represented approximately by $t^{-n}$ for a period of time between 1 and 20 min. following the interruption of excitation. Here $n$ has the value $0.9\pm0.1$ depending on the sample and the condition of excitation. The phosphorescence intensity at one minute after interruption of excitation is smaller by more than three orders of magnitude than the steady state intensity under excitation.

**Atmosphere Dependence of Luminescence Intensity.**—It was found that the luminescence intensity under photoexcitation becomes stronger when the ambient atmosphere of the phosphor is evacuated with a rotary vacuum pump. Fig. 3 illustrates the change of luminescence intensity with time for the processes, excitation on, pumping start, admission of air and excitation off. Average values on several measurements are shown in Table I for the following quantities; the ratio of the luminescence intensity increase $\Delta I$ due to evacuation to the steady state luminescence intensity $I$, in air and the rise time $T_r$ and the decay time $T_d$ of the processes. It was ascertained that $\Delta I/I$ is larger for the weak excitation than for the strong excitation; that is, the proportionality between excitation and luminescence intensities is not satisfied. Here, the intensity ratio of strong to weak excitation is roughly 10. $T_r$ is probably determined by the speed of the evacuating system, and $T_d$ is in dependent on the exciting condition. It could not be detected the slow variation of luminescence intensity compared with $T_r$ and $T_d$ within the experimental accuracy. The light

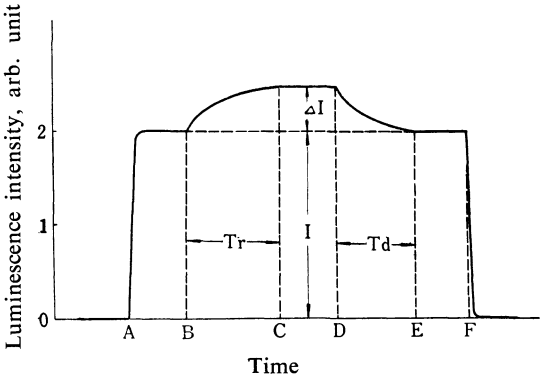

Fig. 3. Variation of luminescence intensity with ambient atmosphere.

A : Excitation on, B : pumping start, C : steady state luminescence intensity in vacuo, D : admission of air, E : steady state luminescence intensity in air and F : excitation off.

TABLE I

| Excitation | $\Delta I/I$ | $T_r$ | $T_d$ |
|---|---|---|---|
| Strong 2537 Å | 0.14 | 1.7 min. | 50 sec. |
| Weak 2537 | 0.18 | 1.8 | 54 |
| Strong 3650 | 0.10 | 1.6 | 62 |
| Weak 3650 | 0.17 | 1.3 | 44 |

intensity reflected from magnesia smoke placed at the same position as the phosphor is independent of the condition of evacuation. Therefore, the variation of luminescence intensity described above can not be attributed to any other causes than the phosphor itself.

Then the author investigated the relationship between the luminescence intensity and the ambient pressure under various kinds of simple atomospheres, such as hydrogen, oxygen, dry air, and mixed vapor of water and ethanol. Of these atmospheres, hydrogen, oxygen or dry air, when passed through a liquid air trap, exhibits no recognizable effect on luminescence intensity. On the other hand, water or ethanol vapor decreases the luminescence intensity

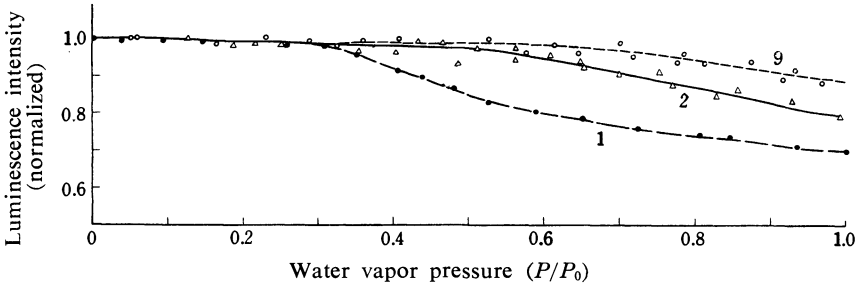

Fig. 4. Dependence of luminescence intensity on water vapor pressure for various exciting intensities (at 30°C). Relative exciting intensity is indicated in the figure and $P_0$ is the saturated vapor pressure.

considerably. Although the results are not always reproduced quantitatively, some of them are shown in Fig. 4 for three excitation intensities. From this figure it is seen that the luminescence intensity suffers quenching for the pressure $P$ which is not so small compared with the saturated vapor pressure $P_0$. In the process of these measurements, photoadsorption or photodesorption of the vapor which gives an effect to luminescence intensity did not occur to a measurable extent.

**Surface Potential.**—It was expected that a change in the surface potential of the phosphor might be accompanied with the variation of the luminescence intensity under the ambient atmosphere. The author measured it by the well known Kelvin method using gold as a reference electrode. When dry or wet air is admitted, the surface potential of zinc oxide becomes more positive compared with that in vacuo.

**X-ray Diffraction.**—From the precise measurements of the lattice constants, it is concluded that the lattice constants are independent of the conditions of preparation within an experimental error. The numerical values are in complete agreement with those reported by Bunn[7].

## Discussion

The green luminescence of zinc oxide is characteristic of phosphors fired under reducing conditions, and it has been reported[8] that a stoichiometric excess of zinc is detected by a chemical analysis from a sample prepared in this way. Although there would be many kinds of lattice defects in the green-emitting zinc oxide, interstitial zinc atoms and oxygen vacancies are considered to be the dominant defects. It is customarily said that the interstitial zinc atom is the luminescence center for the green luminescence. However, according to Mollwo[9], the green luminescence is quenched when the crystal is heated in zinc vapor below 1000°C and zinc atoms diffuse in it. On the contrary, Riehl and Ortman[10] have attributed the green luminescence center to the oxygen vacancy. The energies necessary for formation and migration of the oxygen vacancy would be greater than those of the interstitial zinc atom, since the binding between oxygen and zinc should be broken for the former processes. This consideration agrees with the various conditions for the preparation of the green-emitting phosphor. For example, the efficient phosphor should be fired at higher temperatures than those necessary for the introduction of interstitial zinc atoms.

The oxygen vacancy would be able to accomodate two electrons since it has two effective positive charges in the ionic model of zinc oxide. The same conclusion can be drawn from the covalent model. The first electron would be bound tightly in the vacancy but the second loosely. To be effective as the luminescence center, it would be necessary for the vacancy to have a specific charge. The quenching of green luminescence when the electric conductivity becomes great, for example, by the introduction of excess of zinc as cited above, might be explained by this model.

The ultraviolet emission, which is known to appear in zinc oxide fired under oxidizing conditions, is not observed for these samples. Although Kröger and Meyer[11] attributed this emission to exciton recombination, still more investigations are necessary to arrive at a definite conclusion.

The author has tried an analysis of the one-dimentional configurational coordinate curves[12] based on the experimental result that the peak position of the luminescence spectrum is independent of temperature. From this analysis one may expect an absorption band by the luminescence center in the long wavelength side of the absorption edge. Although an absorption in the expected wavelength region increases as a result of the firing under reducing conditions, one can not observe the excitation of luminescence by this absorption. In additon, the intensity of this absorption does not have any apparent connection with the luminescence efficiency of the phosphor. Therefore, it is considered that this absorption is probably caused by a change of the crystal lattice due to the presence of interstitial zinc atoms.

The decay of luminescence is exponential and the time constant is smaller by one order of magnitude than the reported value. It is considered[1] that the luminescence is emitted by the recombination of electrons at the luminescence center. If it is assumed that the density of the free electron is greater than that of the emptied luminescence center during excitation, the exponential decay and the dependence of time constant upon the sample can be understood.

It might be expected that the temperature dependence of luminescence intensity is different for the two sorts of excitation, i.e. 2537 and 3650 Å radiation, because the author found the structure in the excitation spectrum and the position of the absorption edge shifts toward longer wavelengths with increasing temperature at the

rate of about $10^{-3}$ eV./deg[13]. However, the result is not in accord with the expectation. This suggests that the excitation spectrum changes its shape with temperature. From the temperature dependence shown in Fig. 2, one expects not a single but two kinds of activation energy for the nonradiative de-excitation. In the usual way, one obtains the activation energies of the order of 0.01 and 0.2 eV. by fitting the calculated curve with the observed. However, it is not clear to what process these activation energies correspond.

The slow phosphorescence decay indicates the existence of various metastable states. Considering the *n*-type conductivity of the phosphor, these states are probably deep hole traps.

The effect of atmosphere on the luminescence intensity has been reported only for a case of oxygen on cadmium sulfide[14]. In this case, the photoconductivity of cadmium sulfide is also reduced by the oxygen ambient. It is known that the photoconductivity of zinc oxide is decreased to a large extent by the adsorption of oxygen[16]. However, one found a quenching of luminescence intensity due to molecules having the hydroxyl group but not due to oxygen. Therefore, the above phenomenon seems to have a mechanism of quenching different from that found in cadmium sulfide. As stated in the preceding section, the surface potential of zinc oxide becomes positive when either dry or wet air is admitted relative to that in vacuo. Therefore, the change in the surface potential is not a cause of the luminescence quenching. The adsorbed molecule probably has an effect to accelerate nonradiative recombination of electrons and holes at the surface. Since the absorption constant in the fundamental absorption region is of the order of $10^5$ cm$^{-1}$ [16], electron-hole pairs are created by light absorption to a depth greater than that of a range influenced by surface conditions. Therefore, the amount of quenching is relatively small.

## Summary

Zinc oxide phosphors were prepared under various conditions. From measurements on the characteristics of the green luminescence of the phosphors fired in reducing atmosphere, the following features were observed. (1) In the excitation spectrum, there is a sharp peak at the position of the absorption edge and a gradual decrease toward shorter wavelengths with some structures. The observed maximum value of excitation efficiency is 0.31. (2) The luminescence intensity decreases with increasing temperature. The plot of intensity against temperature has an unusual shape in the neighborhood of 0°C. (3) The decay of luminescence is exponential and the time constant, 0.4 $\mu$ sec., is smaller than that previously reported by an order of magnitude. Long persistent phosphorescence is observed indicating the presence of deep hole traps. (4) The luminescence intensity decreases in a gaseous ambient of molecules having the hydroxyl group.

Standing on the present experimental results, discussions have been undertaken on the luminescence center as well as on the theoretical explanation of the observed characteristics.

The author wishes to express his sincere thanks to Dr. Y. Uehara for his suggestion of this problem, to Mr. Y. Kobuke for the preparation of the samples and to Mr. Y. Hukao for the use of his X-ray apparatus.

# *Twofold Wagner-Meerwein Type Rearrangement of 2,3-Disubstituted Indoles*

By Masao NAKAZAKI

(Received August 31, 1959)

Among various interesting reactions of indoles, little attention has been paid to Fischer's rearrangement, which is as old as the discovery of indole itself. In 1888, Fischer and Schmidt[1] reported the conversion of 3-phenylindole (Ia) into 2-phenylindole (IIa) when heated with zinc chloride. Recently, Clemo and Seaton[2] demonstrated the same type of migration of substituents from 3-position to 2-position of indoles on 3-(2-pyridylmethyl) indole (Ib), 3-benzylindole (Ic) and skatole (Id), using aluminum chloride instead of zinc chloride.

Ia R=$C_6H_5$ IIa R=$C_6H_5$
b R=2-pyridylmethyl b R=2-pyridylmethyl
c R=$CH_2C_6H_5$ c R=$CH_2C_6H_5$
d R=$CH_3$ d R=$CH_3$

Fig. 1

These researchers, however, did not dare to inquire into the possible exchange reaction of substituents between 2- and 3-position of 2,3-disubstituted indoles. This paper is concerned with the demonstration of such possibility.

As a simple representative of 2,3-disubstituted indoles, the reaction of 2-methyl-3-phenylindole (III) with aluminum chloride was initially investigated.

2-Methyl-3-phenylindole (III) was prepared from phenylacetone phenylhydrazone by Fischer's method employing zinc chloride[3] or borontrifluoride[4] as catalyst, but the melting point (78~79°C) was inconsistent with the reported melting point (59~60°C) by Trenkler[3] or Ockenden and Schofield[4]. Because of such a great discrepancy of the melting points, an attempt was made to determine the structure of the indole (m. p. 78~79°C) by ozonolysis.

The melting point of *o*-acetoaminobenzophenone (IVa) obtained by ozonolysis of the indole (m. p. 78~79°C) was found 86~88°C in our hands, but Ockenden and Schofield[4] reported it as 71~73°C. There have been disputes about the melting point of IVa: von Auwers and Meyerburg[5] reported that their sample prepared by the acetylation of *o*-aminobenzophenone showed m. p. 72°C, but from the mother liquor there were obtained other crystals melting at 88.5~89°C, although the latter were the only crystals obtained in the repetitions of their experiment by themselves[6] and by others[7].

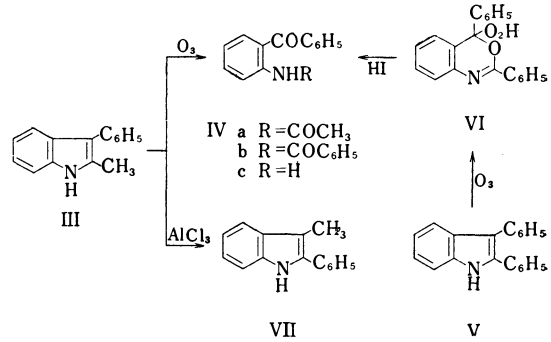

Fig. 2

To secure an authentic sample of *o*-acetoaminobenzophenone for comparison, IVa was synthesized by the process which involved the ozonolysis of 2,3-diphenylindole (V). Although Ockenden and Schofield[4] reported that 2,3-diphenylindole was converted into *o*-benzaminobenzophenone (IVb) (m. p. 85~86°C, 56% yield) when ozone was passed into a solution of V in ethyl acetate at 0°C, our result was found to be another contradiction with their finding.

In our hands, the ozonide VI[8] (m. p. 152

2) G. R. Clemo and J. C. Seaton, *J. Chem. Soc.* **1954**, 2582. An excellent review about the rearrangement reactions of indoles and indolenines are to be found in P. L. Julian, E. W. Meyer and H. C. Pring, "The Chemistry of Indoles" in R. Elderfield. "Heterocyclic Compounds", Vol. 3, John Wiley & Sons, Inc., New York (1952), p. 1.

3) B. Trenkler, *Ann.*, **248**, 111 (1888).

4) D. W. Ockenden and K. Schofield, *J. Chem. Soc.*, **1953**, 612.

5) K. von Auwers and V. Meyerburg, *Ber.*, **24**, 2384 (1891).

6) K. von Auwers, ibid., **29**, 1263 (1896).

7) A. Bishler and D. Barad, ibid., **25**, 3081 (1892); R. Camps, *Arch. Pharm.*, **237**, 683 (1899).

8) The stable ozonides of indole derivatives were first observed by G. Mentzer, D. Molho and Y. Berguer, *Bull. soc. chim.*, 555 (1950). For details see the exhaustive studies by Witkop on the ozonide of phenylskatole. B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.*, **74**, 3855 (1952); B. Witkop, J. B. Patrick and H. M. Kissman, *Chem. Ber.* **85**, 949 (1952). Remembering that 2-aryl indoles usually afford stable ozonides, it seems rather surprising that Ockenden and Schofield[4] obtained *o*-benzaminobenzophenone (IVb) directly from V. The stable ozonide from 2-(dibenzylmethyl)-3-benzylindole which does not possess the 2-aryl group was reported by M. Nakazaki and K. Tanno, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77**, 952 (1956).

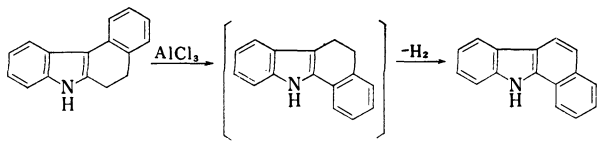

Fig. 3

~154°C, decomp.) of 2, 3-diphenylindole was the only compound isolated following their procedure (in ethyl acetate) or in the ozonolysis in acetic acid. The ozonide VI showed typical reactions of ozonide, and reductive hydrolysis[9] with hydroiodic acid in acetic acid converted it into benzoic acid and *o*-aminobenzophenone (IVc) which was acetylated with acetic anhydride to give *o*-acetoaminobenzophenone (m. p. 86~88°C) which was found identical with IV from 2-methyl-3-phenylindole by mixed melting point determination and comparison of their infrared absorption spectra. Thus being established the structure, 2-methyl-3-phenylindole(III) was subjected to rearrangement by heating with aluminum chloride at 220~240°C for 20 min. The product obtained was found to be identical with 2-phenyl-3-methylindole[10] (VII).

5, 6-Dihydro-7-benzo [*c*] carbazole[11] (VIII) was the next indole derivative tried to demonstrate the analogous rearrangement reaction.

The tetrahydrocarbazole derivative VIII, which was provided from the phenylhydrazone of β-tetralone was heated at 220~240°C for 20 min. with aluminum chloride to give rise to 11-benzo [*a*] carbazole(X), apparently resulted by the dehydrogenation of the intermediate 5, 6-dihydro-11-benzo [*a*] carbazole (IX) with aluminum chloride.

Mechanistically, these rearrangements[12] can be explained by twofold Wager-Meerwein type rearrangement initiated by the electrophilic attack by the Lewis acid (A in Fig. 4.) on the 3-position of indoles (Fig. 4), and the equilibria XI ⇄ XII ⇄ XIII ⇄ XIV are completly parallel to the one to be found in rearrangement of indolenines[13] and Plancher's rearrangement of indolenium compounds[14].

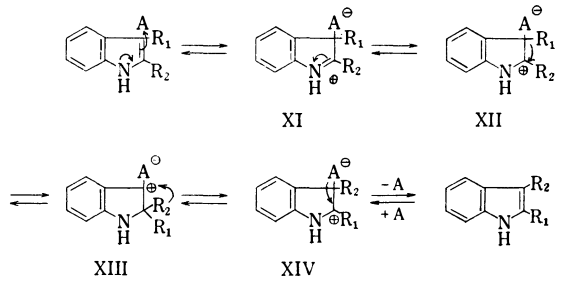

Fig. 4

The *Spiro* type intermediate XV, analogous to the one postulated by Woodward[14] in the dienone-phenol rearrangement, would be the intermediate in the case of 5, 6-dihydro-7-benzo [*c*] carbazole.

Inspection of the ultraviolet spectra (Figs. 6, 7 and 8) and π-electron density in the indole

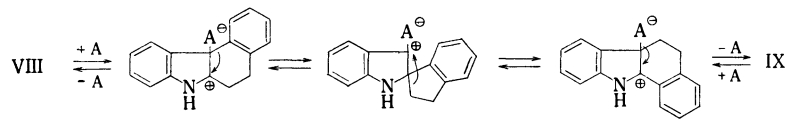

Fig. 5

9) The reductive hydrolysis of the stable ozonide with hydrobromic acid in acetic acid was carried out on the ozonide of 2-(dibenzylmethyl)-3-benzylindole. M. Nakazaki and K. Tanno, Ref. 8.

10) The structure of 2-phenyl-3-methylindole was established by ozonolysis. B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.*, **74**, 3861 (1952); cf. B. Witkop, J. B. Patrick and H. M. Kissman, *Chem. Ber.*, **85**, 949 (1952).

11) Dehydrogenation by heating with 5% palladium-charcoal at 250~260°C converted VIII into the known 7-benzo[*c*] carbazole, m. p. 135~136°C.

12) In Bishler's indole synthesis applied on α-bromo-β-phenylpropiophenone, there was found the formation of two isomeric indoles, i. e. 2-phenyl-3-benzylindole and 2-benzyl-3-phenylindole. [P. L. Julian, E. W. Meyer, A. Magnani and W. Cole, *J. Am. Chem. Soc.*, 67, 1203 (1945); P. L. Julian and J. Pikl, ibid., **55**, 2105 (1953)]. But from a mechanistical standpoint which was worked out recently by Wygand and Richter[*Chem. Ber.*, **88**, 499 (1955)], it is highly improbable to assume the mutual interconversion of these two indoles under the reaction condition *after* they are formed.

13) See the author's papers on Plancher's rearrangement which follow.

14) R. B. Woodward and T. Singh, *J. Am. Chem. Soc.*, 72, 494 (1950). For the dienone-phenol rearrangements of the compounds possessing *spiro* structure, see R. T. Arnold, J. B. Buckley and R. M. Dodson, ibid., 72 3553 (1950); E. N. Marvell and A. O. Geiszler, ibid., **74**, 1259 (1952). Also it is noteworthy to compare the smooth conversion of VIII into X with the dienone-phenol rearrangement of 2-keto-4a-methyl-2, 4a, 5, 6-tetrahydrobenzo[*c*] phenathrene in which the transformation which requires a *spiro* intermediate is inhibited. C. Djerassi and T. T. Grossnickle, *J. Am. Chem., Soc.*, 76, 1741 (1954).

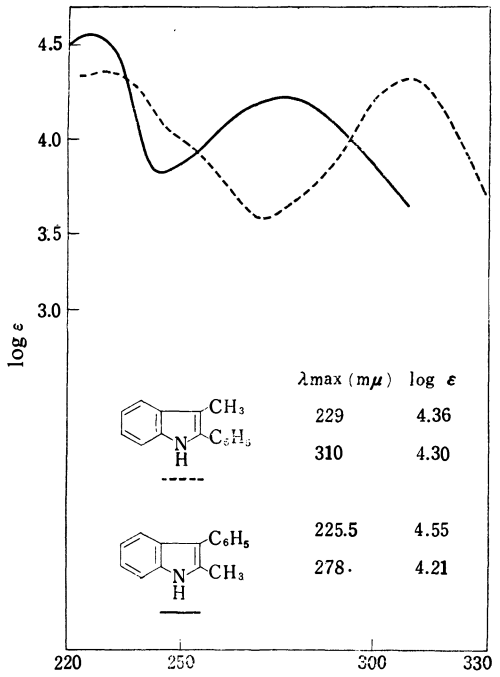

Fig. 6

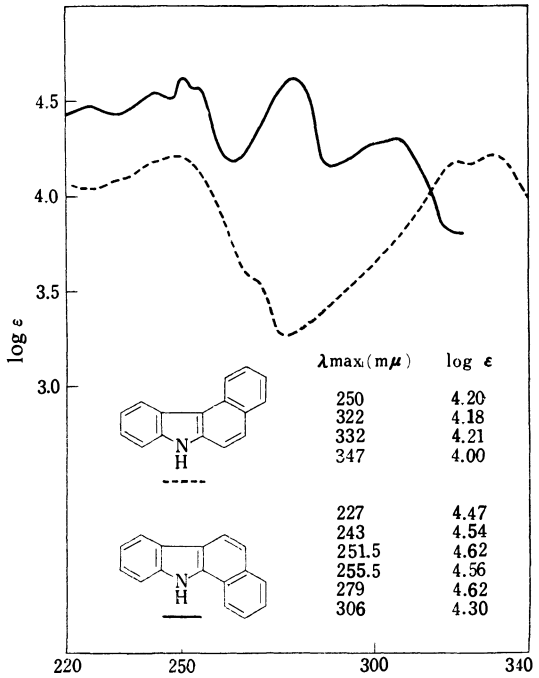

Fig. 8

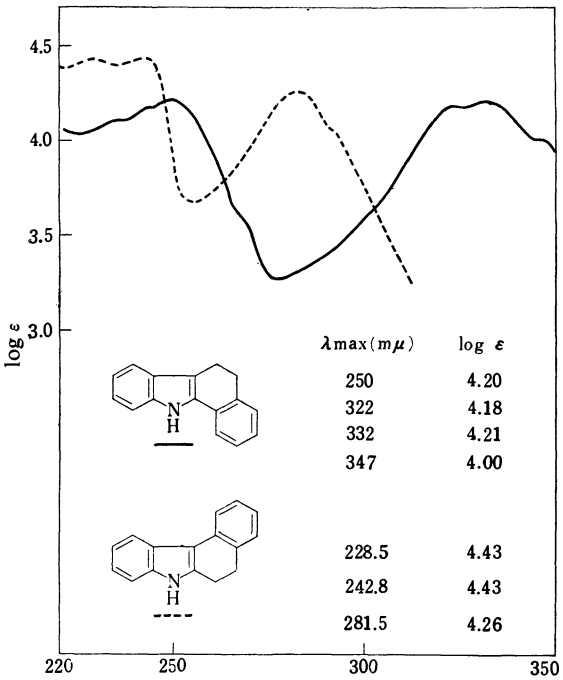

Fig. 7

nucleus[15] (1.059 at 2-position, 1.066 at 3-position) suggest that the driving force of these rearrangement reactions could be sought in the mesomeric stabilization of the products (VII, IX and X) by the phenyl group at 2-position rather than at 3-position.

The same reasoning could be applied to interprete Fischer's rearrangement[1] (migration of hydrogen anion), and the hyperconjugation effect[16] would be the stabilization factor in the case of the rearrangements of the indoles studied by Clemo and Seaton[2].

## Experimental[17]

**2-Methyl-3-phenylindole (III).**—*By borontrifluoride etherate method*[4].—To a solution of 7.0 g. of phenylacetone phenylhydrazone (m. p. 82~83°C) in 70 cc. of acetic acid, 5.1 g. borontrifluoride etherate was added, and the mixture was refluxed on an oil bath for 3 hr. The color of the solution changed from yellow to brown→green→brown. Water was added into the reaction mixture and was extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave a viscous brown

16) The formation of *spiro*-(cyclopentane-1, 3'-*pseudo*-2'-methyl-indole) instead of 11-methyltetrahydrocarbazole nine from *spiro*-(cyclopentane-1, 2'-*pseudo*indoxyl) by the action of methyl/magnesium iodide could be interpreted on the same reason. B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.* 75, 2572 (1953).

17) All melting points are not corrected. All ultraviolet spectra were measured by an EPS-2 Hitachi autorecording spectrophotometer and infrared spectra on a Perkin Elmer Model 12C. The analyses were performed in the Microanalytical Laboratory of the Institute of Polytechnics, Osaka City University.

liquid which was distilled in vacuo to afford a pale yellow liquid, b. p. 196~200°C/3 mmHg, 6.2 g. (57.5% yield). The distilate solidified gradually and was recrystallized from petroleum ether (b. p. 60°C) to give crystals, m. p. 78~79°C (literature[3,4]: 59~60°C).

Found: C, 86.77; H, 6.54. Calcd. for $C_{15}H_{13}N$: C, 86.99; H, 6.32%.

U.V. spectrum[18]: $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 225.5 (4.55), 278 (4.21). $\lambda_{min}$ 245.5 m$\mu$ (log 3.82) in methanol (Fig. 6). I.R. spectrum: 2.95 $\mu$.

The picrate was recrystallized from ethanol to give brown needles, m. p. 139~140°C (literature[3,4]: 141~142°C).

Found: C, 57.42; H, 3.84; N, 12.25. Calcd. for $C_{21}H_{16}O_7N_4$: C, 57.80; H, 3.70; N, 12.84%.

*By zinc chloride method.*—Following Trenkler's procedure[3], III was obtained in a yield of 34.6%, m. p. 78~79°C.

**Ozonolysis of 2-Methyl-3-phenylindole (III)**[4]. —To a mixture of 0.7 g. of 2-methyl-3-phenylindole and 35 cc. of acetic acid, a stream of ozone (approximately 5%) was passed for 45 min. at room temperature, during which time the color of the solution was observed to change from yellow to red and then pale yellow again. After water was added, the solution was extracted with ether thrice and the combined ethereal extract was washed with water followed by 5% sodium carbonate solution and saturated sodium chloride solution. Removal of the solvent yielded a viscous residue which could be brought to crystallization by trituration. The crystals were collected and recrystallized from petroleum ether to give crystals melting at 70~72°C (0.291 g.). The melting point was raised to 86~88°C by further recrystallization from water-ethanol.

Found: C, 75.20; H, 5.78. Calcd. for $C_{15}H_{13}O_2N$: C, 75.30; H, 5.48%.

**Stable Ozonide of 2, 3-Diphenylindole VI.** — *In acetic acid solution.*—A stream of ozone (approximately 5%) was passed into a mixture of 1.4 g. of 2,3-diphenylindole (V) and 40 cc. of acetic acid for 1 hr. at room temperature. Completion of the reaction was estimated by the usual color change of the reaction mixture: yellow→red→yellow. Water was added to the reaction mixture to precipitate crystals which were collected and washed with water.

Recrystallization from water-ethanol and ethanol gave colorless crystals (0.47 g.) which darkened in color at 140°C and decomposed at 152~153°C. On the addition of solid potassium iodide to a solution of VI in acetic acid, the formation of iodine was observed.

*In ethyl acetate solution*[4]. — Into a mixture of 2.7 g. of 2,3-diphenylindole and 75 cc. of ethyl acetate, a stream of ozone (approximately 5%) was passed for 1.5 hr. at 0°C. The color of the solution changed from yellow to brown and then to yellow again. After the excess of ozone was blown out by a stream of nitrogen, the solvent was removed in vacuo to give a viscous residue which crystallized by trituration with ethanol.

The crude ozonide (decomp. 148°C) weighed 1.5 g., and was recrystallized from ethanol to afford crystals which decomposed at 152°C.

Found: C, 75.37; H, 5.12; N, 4.54. Calcd. for $C_{20}H_{15}O_3N$: C, 75.69; H, 4.72; N, 4.41%.

**Reductive Hydrolysis of the Ozonide VI.** — A mixture of 1.50 g. of the ozonide VI, 30 cc. of acetic acid and 10 cc. of constant boiling hydroiodic acid solution was refluxed for 5 hr. After water was added, the reaction mixture was extracted with ether, to separate basic and acidic fractions.

*Acidic fraction.*—The ether layer was washed with sodium thiosulfate solution to discharge the color of iodine, and was extracted with 2 N sodium hydroxide solution. The alkaline solution was acidified with 2 N hydrochloric acid solution to precipitate benzoic acid, 0.381 g. Recrystallization from water gave crystals which melted at 120~121°C, alone and admixed with an authentic specimen of benzoic acid.

*Basic fraction.*—The aqueous layer was washed with ether, and was made basic with 2 N sodium hydroxide solution to precipitate *o*-aminobenzophenone (IVc). Extraction with ether afforded 0.81 g. of golden yellow crystals, m. p. 101~104.5°C, which was recrystallized from ethanol-water to give yellow prisms, m. p. 103~105°C (literature[5-7]: 105~106°C).

Found: C, 78.88; H, 5.68. Calcd. for $C_{13}H_{11}ON$: C, 79.16; H, 5.62%.

***o*-Acetoaminobenzophenone (IVa)**.—After a mixture of 0.287 g. of *o*-aminobenzophenone (IVc) and 3 cc. of acetic anhydride was heated on a water bath for 2 hr., water was added to the reaction mixture and was allowed to stand overnight. The precipitate was collected (0.270 g., m. p. 70~75°C) and was recrystallized from ethanol-water to give crystals melting at 86~88°C, alone and admixed with *o*-acetoaminobenzophenone (m. p. 86~88°C) obtained by the ozonolysis of 2-methyl-3-phenylindole (III) mentioned above. The identity was further comfirmed by the comparison of their infrared spectra.

**Rearrangement of 2-Methyl-3-phenylindole (III)**. —A mixture of 0.8 g. of 2-methyl-3-phenylindole, 0.8 g. of aluminum chloride and 0.1 g. of sodium chloride was heated at 220°C for 15 min. and at 220~240°C for 5 min. After water was added to the resulted brown solid mass, the mixture was extracted with ether and the ether extract was washed with water and dried over anhydrous potassium carbonate. After the removal of the solvent, the residue was distilled in vacuo to afford 0.482 g. of a viscous oil, b. p. 194~195°C/2 mmHg., which crystallized on standing. Recrystallization from ethanol-water gave crystals, m. p. 89~90°C, which were found identical with 2-phenyl-3-methylindole[19] by mixed melting point determination and the comparison of infrared

18) Ultraviolet spectrum of phenylskatole: $\lambda_{max}$(log$\varepsilon$), 229 m$\mu$ (4.36), 310 m$\mu$ (4.30), $\lambda_{min}$271.5 m$\mu$ (3.58) in ethanol (Fig. 6). Cf. R. Huisgen and I. Ugi, *Ann.*, **610**, 57 (1957); B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.*, **74**, 3855 (1952).

19) Prepared from propiophenonephenylhydrazone. Fischer's method employing zinc chloride was found to give better yield than the polyphosphoric acid method and borontrifluoride method. [H. M. Kissman, D. W. Farnsworth and B. Witkop, *J. Am. Chem. Soc.*, **74**, 3948 (1952); B. Witkop and J. B. Patrick, ibid, **74**. 3858 (1952)].

spectrum with an authentic specimen. Also, the picrate, m. p. 144~145°C (from ethanol) was prepared to confirm their identity.

**5, 6-Dihydro-11-benzo[*a*]carbazole (IX)**[20]. — 5, 6-Dihydro-11-benzo[*a*]-carbazole was synthesized following the procedure of Organic Syntheses, **30**, 90 (1950), m. p. 163~164°C (from methanol).

U. V. specrum. $\lambda_{max}$ (log $\varepsilon$), 250 m$\mu$ (4.20), 332 m$\mu$ (4.21); $\lambda_{min}$ (log $\varepsilon$), 227 m$\mu$ (4.04), 276 m$\mu$ (3.26) in ethanol (Fig. 7).

The picrate was recrystallized from ethanol to give black needles, m. p. 153~154°C.

Found: N, 12.79. Calcd. for $C_{22}H_{16}O_7N_4$: N, 12.50%.

**11-Benzo[*a*]carbazole (X)**[20].—A mixture of 0.5 g. of 5, 6-dihydro-11-benzo[*a*]carbazole and 0.1 g. of 5% palladium-charcoal was heated at 250~260°C for 20 min. 11-Benzo[*a*]carbazole which resulted was recrystallized from benzene to yield crystals melting at 227~229°C. (literature[21]: 225°C).

U.V. spectrum[21]: $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 227 (4.47), 243 (4.54), 251 (4.62), 279 (4.62), 306 (4.30). $\lambda_{min}$ m$\mu$ (log $\varepsilon$), 234 (4.42), 248.5 (4.51), 263 (4.18), 289 (4.17) in ethanol (Fig. 8).

**5,6-Dihydro-7-benzo[*c*]carbazole (VIII)**[20].—Considerable generation of heat was observed when 15 cc. of acetic acid was added to a mixture of 2.9 g. of $\beta$-tetralone[22] and 2.2 g. of phenylhydrazine, and the reaction mixture was refluxed for 1 hr. After being kept at room temperature overnight, the crystals precipitated were filtered and washed with methanol. Recrystallization from methanol gave 2.4 g. of crystals, m. p. 102~103°C.

Found: C, 87.91; H, 6.15; N, 6.31. Calcd. for $C_{16}H_{13}N$: C, 87.64; H, 5.98; N, 6.39%.

U.V. spectrum: $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 228.5 (4.43), 281.5 (4.26); $\lambda_{min}$ 253.5 m$\mu$ (log $\varepsilon$ 3.68) in ethanol (Fig. 7).

The picrate was recrystallized from ethanol to give black needles, m. p. 129~132°C.

Found: C, 59.11; H, 3.76; N, 12.82. Calcd. for $C_{22}H_{16}O_7N_4$: C, 58.93; H, 3.60; N, 12.50%.

**7-Benzo[*c*]carbazole**[20].—A mixture of 0.5 g. of 5, 6-dihydro-7-benzo[*c*]carbazole and 0.1 g. of 5% palladium-charcoal was heated at 250~260°C for 30 min. The reaction mixture was extracted with boiling benzene. After the solvent was removed, the residue was recrystallized from benzene-ligroin to give 0.27 g. of crystals, m. p. 135~136°C (literature[23]: 135°C). U.V. spectrum: $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 265 (4.69), 285.5 (4.02), 326 (4.09), $\lambda_{min}$ m$\mu$ (log $\varepsilon$), 237 (4.21), 282 (3.86), 295 (3.45) in ethanol (Fig. 8).

**Rearrangement of 5, 6-dihydro-7-benzo[c]carbazole (VIII)**.—A mixture of 1.0 g. of VIII, 1 g. of aluminum chloride and 0.1 g. of sodium chloride was heated at 220°C for 10 min. and at 220~240°C for 5 min. Water was added to the reaction mixture and extracted with ether. The yellow ethereal solution, which exhibited green fluorescence, was washed with water followed with sodium bicarbonate solution and was dried over anhydrous magnesium sulfate. Distillation of the solvent gave a residue which was recrystallized from carbon tetrachloride to give 0.206 g. of crystals, m. p. 210°C. Recrystallization from benzene improved the melting point to 227~228°C which was undepressed when admixed with an authentic specimen of 11-benzo[*c*]carbazole. The identity was further confirmed by the comparison of their infrared spectra which could be overlapped in every detail.

The author is very grateful to Dr. Itaru Mita for his generous supply of phenylacetone. He also feels indebted to Mr. Satosi Kamei for his technical assistance; to Mr. Sachihiko Isoe who kindly measured the ultraviolet absorption spectra.

# *Mechanism of Plancher's Rearrangement. I. Twofold Wagner-Meerwein Type Rearrangement of Indolenines*

By Masao NAKAZAKI, Koji YAMAMOTO and Kikuo YAMAGAMI

(Received August 31, 1959)

Although, Plancher's rearrangement, which was described as early as 1898, has been much discussed[1], it is unfortunate that there are found many misunderstandings about the scope of this rearrangement, because of lack of definitive studies. In 1898, Plancher[2] obtained a indolenium iodide, m. p. 237°C, from 2-ethyl-3-methylindole (I) and 2-methyl-3-ethylindole (II) by heating with methyliodide at 120°C.

He assigned the structure of 1, 2, 3-trimethyl-3-ethylindolenium iodide (III) to the indolenium iodide, on a non-confirmative chemical base, but whatever structure it has, migration of the subsituents has to be assumed, in order to explain the formation of the same indolenium iodide, m. p. 237°C, from both I and II.

Another type of rearrangement was established when Plancher[3] obtained two indolenium iodides, m. p. 186° and 232°C, from 2-isopropyl-3-methylindole (IV) by heating with methyliodide at 85~90°C for 2 days.

He posturated the formation of the two intermediate indolenines VII and VIII which would give corresponding indolenium iodides V and VI with methyliodide. Although the structure of the indolenium iodides (V or VI) remained unestablished, the conversion of the indolenium iodide, m. p. 186°C, into the isomeric indolenium iodide, m. p. 232°C, was achieved by heating at 180~190°C for 10 min. From these and other experiments, Plancher could draw the following conclusion[4]: 1) The indolenium iodide with the lower melting point can be converted into the isomeric indolenium iodide with the higher melting point. 2) The heavier substituent migrates to the $\beta$-position. However, his conclusion 2) can be hardly justified without further strenuous studies, since the structures of these indolenium iodides were only presumed on nothing but some analogies, except on one occasion; i.e. 1,2,3-trimethyl-3-phenylindolenium iodide (X). By heating 2-phenylindole (IX) with methyliodide at 120°C, Plancher[5] obtained an indolenium iodide, m. p. 226~227°C, which

Fig. 6.

he thought to be 1, 2, 3-trimethyl-3-phenylindolenium iodide (X) as the result of rearrangement involving an exchange of methyl with phenyl group. But the structure of this indolenium iodide was left to be determined by chemical means until Boyd-Barrett[6] (1932) repeated Plancher's experiment and oxidized the product with alkaline potassium permanganate (via the intermediate XI) to form 1, 3-dimethyl-3-phenyloxyindole (XII), the nitro derivative of which was found to be identical with the one obtained by the umambiguous synthetic route.

The mechanism of the rearrangement of indolenium compounds proposed by Plancher[7] is illustrated in Fig. 4. According to this mechanism, the formation of iodobenzene and its subsequent reaction with 1,2,3-trimethylindole to secure 1, 2, 3-trimethyl-3-phenylindolenium iodide (X), though it is highly improbable, is an inevitable consequence to explain the formation of X from 2-phenylindole. Julian[8] pointed out another conceivable route from IX to X, assuming that 3, 3-dimethyl-2-phenylindolenine (XVI) is the intermediate and that rearrangement involving an exchange of methyl with the phenyl group takes place at this point (Fig. 5, route A).

This Julian's alternative postulated the migration of the substituents of indolenine which has not been demonstrated in any indolenine with umambiguous constitution[9], and it is unfortunate

7) G. Plancher, *Atti, accad. Lincei*, (5), **11**, 183 (1902); *Chem.-Zentr.*, **1902**, I, 1322.

8) See Ref. 1, p. 106.

9) M. Garry, *Ann. chim.*, **17**, 5 (1942); *Chem. Abstr.*, **36**, 6875 (1942), obtained two indolenines; 3,3-diphenyl-2-methylindolenine, m. p. 145°C, picrate, m. p. 210°C, and isomeric indolenine presumingly 2, 3-diphenyl-3-methylindolenine, m. p. 108°C, picrate, m. p. 155°C, from 1-anilino-1-phenylethylketone by heating with aniline and aniline hydrochloride at 160~165°C, but unfortunately she did not mention their possible interconversion. According to Julian's description, "she apparently assumed, and let it to the reader to assume, that the shifts involved in her synthesis took place *before* cyclization to the indolenines". But the recent study of the mechanism of Bishler's indole synthesis seems to suggest that the skeleton change of the anilinoketone would not occur *during* or *before* the cyclization. [F. Weygand and E. Richter, *Chem. Ber.*, **88**, 499 (1955).]. From the present achievement, it is safely assumed that the first formed 3, 3-diphenyl-2-methylindolenine rearranges to give 2, 3-diphenyl-3-methylindolenine under the reaction condition.

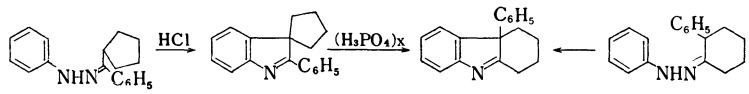

Fig. 7.

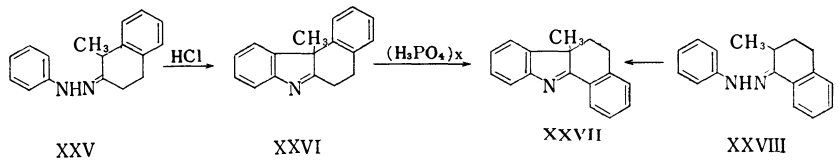

Fig. 8.

that sometimes Plancher's rearrangement was understood as this sort of rearrangement of indolenines only to cause many confusions[10].

This paper is concerned with demonstration of this migration of substituents of indolenines to elucidate the mechanism of Plancher's rearrangement. In order to obtain 2, 3-dimethyl-3-phenylindolenine (XVII), Fisher-Brunner's method was applied on 3-phenylbutane-2-one (XIX) under various conditions using zinc chloride, alcoholic hydrogen chloride and boron-trifluoride etherate as catalyst.

Even under very mild condition (with alcoholic hydrogen chloride at 0°C), all attempts failed only to afford 3, 3-dimethyl-2-phenylindolenine (XVI)[11], apparently resulting from the intermediate indolenine XVII by rearrangement reaction involving an exchange of the phenyl with the methyl group.

The view that 3-phenylbutane-2-one would rearrange to isobutyrophenone and then its phenylhydrazone (XX) would cyclize to XVI seems untenable, since the fact that the entirely reversed process is predominant in acidic condition was firmly established recently[12].

Also it is hard to find any reasonable sequence which would explain a possible migration of substituents in the cyclization steps of Fischer-Brunner's synthesis, which has a common feature with Fischer's indole synthesis extensively studied by Carlin et al.[13] At any rate, route A (Fig. 5) which assumes hypothetical rearrangement XVI → XVII has to be abandoned[14].

Although this is the first case, in which a rearranged indolenine is obtained in Fischer-Brunner's indolenine synthesis, the first example of the rearrangement of an indolenine to the other indolenine, both with established structures, was encountered in the isomerization of XXII to XXIII.

*Spiro*-(cyclopentane-1, 3'-*pseudo*-2'-phenylindole)[15] (XXII) ($\lambda_{max}$ 310 m$\mu$)[16] which was synthesized from cyclopentylphenylketone phenylhydrazone (XXI) by Fischer-Brunner's synthesis by saturating its alcoholic solution with dry hydrogen chloride, was found to convert, when heated with polyphosphoric acid[17], into 11-phenylcarbazolenine (XXIII) which in turn was prepared from 2-phenylcyclohexanone phenylhydrazone (XXIV).

Another interesting rearrangement was demonstrated when 11b-methyl-5, 6-dihydro-11b-benzo-[*c*]carbazole[18] (XXVI) which could be prepared from $\alpha$-methyl-$\beta$-tetralone phenylhydrazone (XXV), was heated with polyphosphoric acid

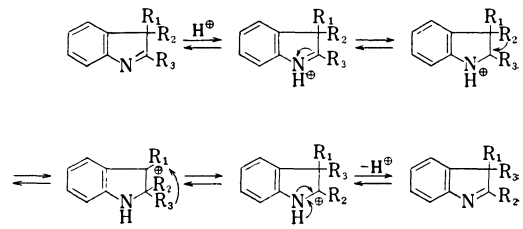

Fig. 9.

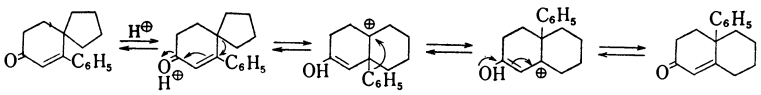
10) For example, B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.*, **73**, 1358 (1951), discussed the rearrangement of indolenine as Plancher's rearrangement.

11) An attempt was made to prepare 2, 3-dimethyl-3-phenylindolenine (XVII) by alkylation of 2-methyl-3-phenylindole with sodium amide and methyliodide in liquid ammonia only to afford 1, 2-dimethyl-3-phenylindole. Also another attempt to obtain the indolenine XVII by Grignard synthesis from 2-methyl-3-phenylindole was found fruitless.

12) S. Barton and C. R. Portor, *J. Chem. Soc.*, **1956**, 2483.

13) R. B. Carlin, W. D. Henley and D. P. Carlson, *J. Am. Chem. Soc.*, **79**, 5712, (1957); and also his preceeding papers on the same subject.



14) The fact that the rearrangement actually takes place by route B (Fig. 5) was established by our experiment which follows. To avoid unnecessary confusion, the term of "Plancher's rearrangement" should be used to indicate solely the *rearrangement of indolenium compounds* such as illustrated XVIII→X (Fig. 5).

15) For the nomenclature of *spiro* compounds, see *Chem. Abstr.*, **39**, 5885, 5888 (1945).

16) U. V. spectrum of 3, 3-dimethyl-2-phenylindolenine: $\lambda_{max}$ 306 m$\mu$ (log $\varepsilon$ 4.177). B. Witkop, J. B. Patrick and H. M. Kissman, *Chem. Ber.*, **85**, 953 (1952).

17) When indolenine synthesis using polyphosphoric acid was applied on cyclopentylphenylketone-phenylhydrazone, 11-phenyltetrahydrocarbazolenine was formed directly.

18) According to the nomenclature of A. M. Patterson and L. T. Capell, "The Ring Index", Reinhold Publishing Corp., New York (1940), p. 331.

Fig. 10.

at 180°C for 5 min. The rearranged indolenine was found to be identical with 6a-methyl-5, 6-dihydro-6a-benzo[*a*]carbazole[18] (XXVII) provided from β-methyl-α-tetralone phenylhydrazone (XXVIII) by usual method.

The mechanism of the migration of the substituents of indolenines can be readily explained by twofold Wagner-Meerwein type rearrangement initiated by the attack of a proton on the nitrogen atom of the indolenine nucleus as formulated in Fig. 9[19-21].

Since undoubtedly all steps are in equilibrium, the thermodynamical stability of the products would be the predominant factor to determine the direction of the migration, and it would be safely assumed that mesomeric stabilization of the phenyl group is responsible in the case of XVII → XVI and XXVI → XXVII. The seemingly contradictory attitude of XXII toward acid can be reasoned when the inspection of its Stuart's model reveals that a considerable steric repulsion is observed between the phenyl group and the hydrogens of 3, 4-position of cyclopentyl group of XXII, i. e. this is the case where steric effects suppress mesomeric stabilization of the phenyl group[22].

Harmonious with this result is the smooth transformation[23] of 6-phenyl-*spiro*(4, 5)decen-6-one-8 (XXIX) to 10-phenyl-2-keto-$\Delta^{1,9}$-octahydronaphthalene (XXX) by heating with polyphosphoric acid.

## Experimental[24]

**3-Phenylbutane-2-one.**—A mixture of 16.3 g. of methyliodide and 30 cc. of absolute ether was added dropwise to a mixture of 6.4 g. of magnesium and 30 cc. of absolute ether at room temperature. To the chilled Grignard solution, a mixture of 24.5 g. of α-methyl benzylcyanide[25] and 30 cc. of ether was added, and the reaction mixture was kept at room temperature for 4 hr. The Grignard complex was destroyed by the addition of diluted sulfuric acid and extracted with ether. The ethereal extract was washed with 5% sodium carbonate solution and water and dried over anhydrous sodium sulfate. Removal of the solvent afforded an oil which was distilled in vacuo to give 21.2 g. of 3-phenylbutane-2-one, b. p. 107~115°C/20 mmHg[26].

**3, 3-Dimethyl-2-phenylindolenine (XVI) from 3-Phenylbutane-2-one Phenylhydrazone.**—*By zinc chloride method*[27].—A mixture of 11.8 g. of 3-phenylbutane-2-one and 8.6 g. of phenylhydrazine was heated on a water bath for 40 min. The mixture became turbid and the separation of water drops was observed. Then the mixture was extracted with ether and dried over anhydrous sodium sulfate. After the solvent was evaporated completely, the residue was dissolved in 160 cc. of absolute ethanol and 80 g. of zinc chloride was added. The mixture was refluxed for 20 hr. and the alcohol was removed. The residue was made basic by the addition of concentrated ammonia solution to precipitate basic material. This was extracted with ether, and the ether extract was washed with water and dried over anhydrous potassium carbonate. Removal of the solvent afforded a residue which was distilled in vacuo to give 2.3 g. of a pale yellow liquid, b. p. 110~139°C/2 mmHg.

Found: C, 86.05; H, 7.27; N, 6.77. Calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.83; N, 6.33%.

The picrate was recrystallized to yield crystals, m. p. 170~172°C, which was found identical with the picrate of 3, 3-dimethyl-2-phenylindolenine, m. p. 167~168°C, prepared from an authentic 3, 3-dimethyl-2-phenylindolenine[28] (XVI), by mixed melting point determination.

19) An intermediate possessing *spiro* structure is to be assumed in the case of XXVI→XXVII, and it seems noteworthy to compare with the dienone-phenol rearrangement of 2-keto-4a-methyl-2, 4a, 5, 6-tetrahydrobenzo[*c*]phenathrene in which the transformation which requires a *spiro* intermediate is inhibited. C. Djerassi and T. T. Grossnickel, *J. Am. Chem. Soc.*, 76, 1741 (1954). See also Ref. 14 in the preceeding paper on the rearrangement of 2, 3-disubstituted indoles.

20) A novel cleavage reaction of benzyl and *t*-butyl group is recently reported when $R_1$ (Fig. 9) is benzyl and *tirt*-butyl, and the same sort of cleavage reaction was demonstrated on 11-benzyltetrahydrocarbazolenine and 11-*tirt*-butyltetrahydrocarbazolenine. M. Nakazaki, S. Isoe and K. Tanno, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 76, 1262 (1955).

21) The mechanism of Brunner-Robinson-Suginome's rearrangement (conversion of 3, 3-dimethylindolenine into 2, 3-dimethylindole) is the special case where $R_3$ is a hydrogen atom. K. Brunner, *Monatsh.*, 17, 255 (1896); R. Robinson and H. Suginome, *J. Chem. Soc.*, 1932, 298.

22) B. Witkop and J. B. Patrick, *J. Am. Chem. Soc.*, 73, 1558 (1951), tried the rearrangement of 11-methyltetrahydorocarbazolenine in a hope to get *spiro*-(cyclopentane-1′, 3-*pseudo*-2′-methylindole) but in vain. This can be attributed to the stability of 11-methyltetrahydrocarbazolenine in respect of the steric effect as well as the small migration aptitude of the methyl group.

23) M. Nakazaki and S. Isoe, unpublished experiment.

24) All the melting points are uncorrected values. All ultraviolet spectra were measured with an EPS-2 Hitachi selfrecording spectrophotometer and infrared spectra on a Perkin Elmer Model 12C. The analyses were performed in the Microanalytical Laboratory of the Institute of Polytechnics, Osaka City University.

25) B. p. 106~112°C/11 mmHg or 71~79°C/2 mmHg. Prepared following the procedure of H. M. Crawford, *J. Am. Chem. Soc.*, 56, 140 (1934).

26) W. D. Kumler, L. A. Strait and E. L. Alpen, *J. Am. Chem. Soc.*, 72, 1463 (1950).

27) Following Leuch's procedure to synthesize 3, 3-dimethyl-2-phenylindolenine from isobutyrophenone phenylhydrazone. H. Leuchs, A. Heller and A. Hoffman, *Ber.*, 62, 877, (1929).

28) B. p. 178~182°C/9 mmHg. Picrate, m. p. 167~168°C. Prepared by polyphosphoric acid method. H. M. Kissman, D. W. Farnsworth and B. Witkop, *J. Am. Chem. Soc.*, 74, 3948 (1952).

*By borontrifluoride etherate method*[29].—To a mixture of 2.7 g. of 3-phenylbutane-2-one phenylhydrazone[30] and 30 cc. of acetic acid, 2.1 g. of borontrifluoride etherate was added and refluxed for 3 hr. After the solvent was removed in vacuo, the residue was dissolved in ether and basic material was extracted with 2 N hydrochloric acid solution. To the cooled acidic solution, 2 N sodium hydroxide solution was added to liberate the basic substance, and extracted with ether. After the ethereal solution was washed with water and dried over anhydrous potassium carbonate, the solvent was removed. The residue was distilled in vacuo to give a pale yellow oil, 1.2 g., b. p. 145~155°C/2 mmHg. The picrate, m. p. 168~169°C was prepared to be found identical with the picrate of 3,3-dimethyl-2-phenylindolenine (XVI) by mixed melting point determination.

*Synthesis with hydrochloric acid in ethanol.*—A solution of 2 g. of 3-phenylbutane-2-one phenylhydrazone[30] in 40 cc. of absolute ethanol was chilled in an ice bath and was saturated with dried hydrogen chloride. After being allowed to stand at room temperature for 2 days (15°C), the solvent was removed in vacuo (below 40°C). Water was added to the residue and extracted with ether. The aqueous layer was made basic by the addition of 2 N sodium hydroxide solution and extracted with ether. The ethereal extract was washed with water and dried over anhydrous potassium carbonate. After removal of the solvent, the residue was distilled to afford a liquid, b. p. 135~145°C/1.5 mmHg, infrared spectrum of which could overlap in every detail on that of 3,3-dimethyl-2-phenylindolenine. The identity was further confirmed by the mixed melting point determination of their picrates.

**1,2-Dimethyl-3-phenylindole.**—To a suspension of sodium amide prepared from 200 cc. of liquid ammonia and 0.78 g. of sodium, 5 g. of 2-methyl-3-phenylindole[31] was added with 10 cc. of ether. After a mixture of 3.4 g. of methyliodide and 10 cc. of ether was added dropwise in a period of 20 min., the reaction mixture was allowed to stand at room temperature overnight to evaporate the liquid ammonia. After 200 cc. of water was added, the mixture was extracted with ether. The ethereal extract was washed with 2 N hydrochloric acid to remove basic material (very small amount, discarded). After this has been washed with 5% sodium carbonate solution and water, the ether extract was dried over anhydrous sodium sulfate. Removal of the solvent gave crystals (4 g.), which were recrystallized from ethanol. m. p. 111~112.5°C.

Found: C, 87.38; H, 7.03; N, 6.33. Calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.38; N, 6.33%.

The picrate was recrystallized from ethanol to give brown black needles, m. p. 199~201°C.

Found: N, 12.40. Calcd. for $C_{22}H_{18}O_7N_4$: N, 12.44%.

***Spiro*-(cyclopentane-1,3'-*pseudo*-2'-phenylindole) (XXII).**—A mixture of 5 g. of cyclopentylphenylketone[32] and 3.4 g. of phenylhydrazine was heated on a water bath for 1 hr. and the water generated was removed by azeotropic distillation with benzene. After the benzene was removed completely in vacuo, the residue was dissolved in 60 cc. of absolute ethanol and the chilled solution was saturated with dry hydrogen chloride. Then 100 cc. of water was added to the semisolid mass, and washed with ether. The aqueous layer was made basic by the addition of 2 N sodium hydroxide solution, and extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. After the solvent was evaporated, the residue was distilled at reduced pressure to give 4.9 g. of a pale yellow liquid, b. p. 164~167°C/1 mmHg. U. V. spectrum: $\lambda_{max}$ mμ (log ε), 239 (4.28), 247 (4.23), 310 (4.28). $\lambda_{min}$ 258 mμ (log ε 3.89) in ethanol (Fig. 11).

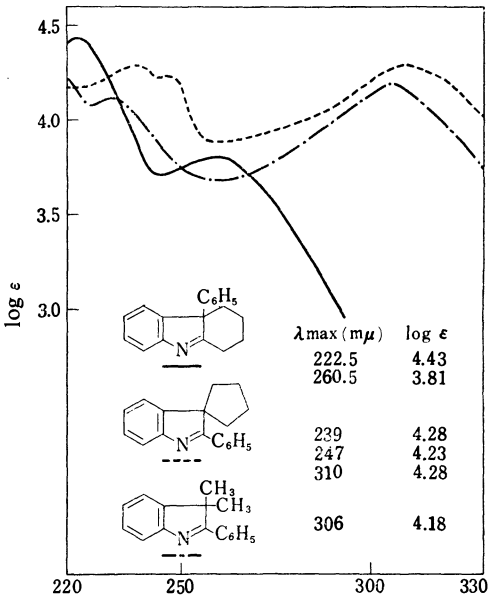

Fig. 11.

Found: C, 87.11; H, 7.21; N, 6.16. Calcd. for $C_{18}H_{17}N$: C, 87.41; H, 6.93; N, 5.55%.

The picrate was recrystallized from ethanol to give yellow crystals, m. p. 175°C.

Found: C, 61.18; H, 4.35; N, 11.74. Calcd. for $C_{24}H_{20}O_7N_4$: C, 60.50; H, 4.23; N, 11.76%.

**11-Phenyltetrahydrocarbazolenine (XXIII).**—*From 2-phenylcyclohexanone phenylhydrazone (XXIV).*—A mixture of 10 g. of 2-phenylcyclohexanone[33] and 7.3 g. of phenylhydrazine was

29) This attempt seems to be the first instance where borontrifluoride etherate was successfully employed for sythesis of indolenine, whereas this reagent has been frequently used for Fisher's indole synthesis. H. R. Snyder and C. W. Smith, ibid., **65**, 2454 (1943).

30) B. p. 160~170°C/2 mmHg; m. p. 76~78.5°C (from ethanol-water). Found: N, 11.83. Calcd. for $C_{16}H_{18}N_2$: N, 11.76%.

33) B. p. 140~146°C/10 mmHg (60% yield). Prepared following Newman's procedure. M. S. Newman and M. D. Frabman, *J. Am. Chem. Soc.*, **69**, 1550 (1944).

heated on a water bath for 1 hr. The water generated was removed by azeotropic distillation with benzene, and the benzene was removed by distillation in vacuo of a water pump. The residue was dissolved in 100 cc. of absolute ethanol, and saturated with dry hydrogen chloride. A considerable amount of ammonium chloride was observed to precipitate. After the reaction mixture was allowed to stand at room temperature for 10 hr., the solvent was removed in vacuo (below 40~45°C). The residue was dissolved in 250 cc. of water and washed with ether, and the aqueous layer was made basic by the addition of 2 N sodium hydroxide solution and extracted with ether. After the ethereal extract was washed with water and dried over anhydrous potassium carbonate, the solvent was removed to give crystals, which were recrystallized from ethanol-water, m. p. 126~127°C. I. R. spectrum: 6.3 $\mu$. U. V. spectrum: $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 222.5(4.42), 260.5(3.81), $\lambda_{min}$ 245 m$\mu$ (3.72) in ethanol (Fig. 11).

Found: C, 87.47; H, 7.02; N, 5.69. Calcd. for $C_{15}H_{17}N$: C, 87.41; H, 6.93; N, 5.66%.

The picrate was recrystallized from ethanol to give yellow prisms, m. p. 182~183°C.

Found: C, 60.48; H, 4.44; N, 11.78. Calcd. for $C_{24}H_{20}O_7N_4$: C, 60.50; H, 4.23; N, 11.76%.

*From cyclopentylphenylketone phenylhydrazone (XXI).*—To 29 g. of polyphosphoric acid, a mixture of 15 g. of cyclopentylphenylketone[32] and 9.8 g. of phenylhydrazine was added. The temperature of the reaction mixture rose spontaneously up to 150°C, and the reaction mixture was kept at this temperature for 10 min. in an oil bath. The viscous mass was dissolved in water and washed with ether. The acidic aqueous layer was made basic by the addition of 2 N sodium hydroxide solution, and was extracted with ether. After the ether extract was washed with water and dried over anhydrous sodium sulfate, the ether was distilled off. The residue was recrystallized from ethanol-water to give needles, m. p. 122~124°C (7.7 g.) which was proved identical with 11-phenyltetrahydrocarbazolenine (XXIII) prepared from 2-phenylcyclohexanone phenylhydrazone (XXIV).

*From rearrangement of spiro-(cyclopentane-1,3'-pseudo-2'-phenylindole) (XXII).*—A mixture of 1.4 g. of indolenine XXII and 7 g. of polyphosphoric acid was heated at 155°C for 10 min. in an oil bath. The reaction mixture was dissolved in water by warming on a water bath. The acidic aqueous layer was made basic by the addition of 2 N sodium hydroxide solution to precipitate needles (1.0 g.), which were collected and recrystallized from ethanol-water to give m. p. 124°C. The mixed melting point with 11-phenyltetrahydrocarbazolenine was 124°C.

**11b-Methyl-5, 6-dihydro-11b-benzo[*c*]carbazole (XXVI).**—A mixture of 8.1 g. of $\alpha$-methyl-$\beta$-tetralone[34] and 5.5 g. of phenylhydrazine was heated on a water bath for 2 hr., and the generated water was removed by azeotropic distillation with benzene. After the solvent was removed in vacuo, the residue was dissolved in 70 cc. of absolute ethanol, and was saturated with dry hydrogen chloride. After being allowed to stand at 5°C overnight, the reaction mixture was poured into 350 cc. of ice water and washed with ether. The aqueous layer was made basic and was extracted with ether. The ether extract was washed with water and dried over anhydrous potassium carbonate. Removal of the solvent gave a viscous liquid, which was distilled in vacuo to afford 4.1 g. of a viscous pale yellow liquid, b. p. 159~163°C/1 mmHg. I. R. spectrum: 6.3 $\mu$. U. V. spectrum: $\lambda_{max}$ 248 m$\mu$ (log $\varepsilon$ 4.02) in ethanol (Fig. 12).

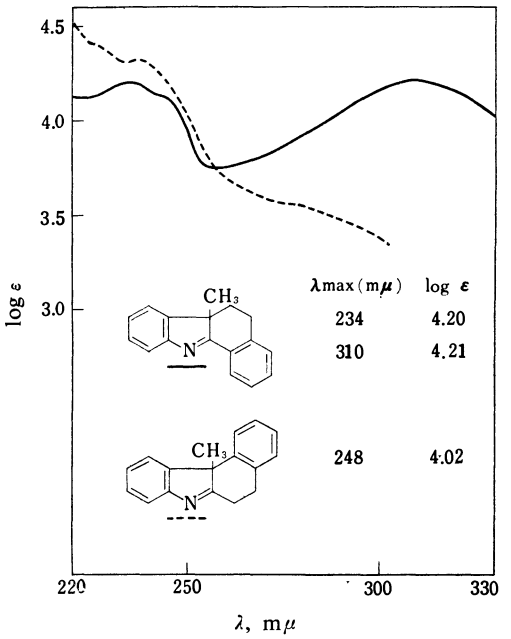

Fig. 12.

Found: C, 86.31; H, 6.83; N, 6.06. Calcd. for $C_{17}H_{15}N$: C, 87.51; H, 6.48; N, 6.00%.

The picrate was recrystallized from ethanol to give yellow prisms, m. p. 167~167.5°C.

Found: C, 59.91; H, 4.03; N, 12.31. Calcd. for $C_{25}H_{18}O_7N_4$: C, 59.74; H, 3.92; N, 12.12%.

**6a-Methyl-5, 6-dihydro-6a-benzo[*a*]carbazole (XXVII).**—When 30 g. of polyphosphoric acid was added to a mixture of 5.2 g. of $\beta$-methyl-$\alpha$-tetralone[35] and 3.6 g. of phenylhydrazine, a considerable generation of heat was observed to cause the reaction temperature to rise to 165°C. After this rather violent reaction subsided, 200 cc. of water was added to dissolve the viscous reaction mass. The acidic aqueous solution was washed with ether, and was made basic to precipitate an oil, which was extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave brown viscous residue which was distilled to give 3.4 g. of a pale yellow oil, b. p. 160~164°C/2 mmHg. I. R. spectrum:

34) B. p. 137~142°C/10 mmHg. Prepared following the procedure of J. English and G. Cavaglieri, *J. Am. Chem. Soc.*, 65, 1085 (1943).

35) B. p. 116~120°C/2 mmHg. Prepared following the procedure of W. E. Bachmann and D. G. Thomas, ibid., 63, 598 (1941).

6.5 $\mu$. U. V. spectrum : $\lambda_{max}$ m$\mu$ (log $\varepsilon$), 234(4.20), 310(4.21). $\lambda_{min}$ 256 m$\mu$ (log $\varepsilon$ 3.76) in ethanol (Fig. 12).

Found : C, 86.41 ; H, 6.69 ; N, 6.11. Calcd. for $C_{17}H_{15}N$ : C, 87.51 ; H, 6.48 ; N, 6.00%.

The picrate was recrystallized from ethanol to give yellow prisms, m. p. 169~170°C. The mixed melting point with the picrate of 11b-methyl-5,6-dihydro-11b-benzo[*c*]carbazole (m. p. 167~167.5°C) was 156~159°C.

Found : C, 59.62 ; H, 4.12 ; N, 12.54. Calcd. for $C_{23}H_{18}O_7N_4$ : C, 59.74 ; H, 3.92 ; N, 12.12%.

*From rearrangement of 11b-methyl-5,6-dihydro-11b-benzo[c]carbazole (XXVI)*—A mixture of 0.4 g. of the indolenine XXVI and 2 g. of polyphosphoric acid was heated at 180°C for 15 min. in an oil bath. After water was added, the aqueous solution was freed from a small amount of unsoluble resinous material by filtration.

The solution was made basic with 2 N sodium hydroxide solution, and the turbid mixture was extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After the ether wae removed, the residue was converted into picrate, without further purification, by the addition of ethanolic picric acid. The picrate was recrystallized from ethanol to give yellow prisms, m. p. 166~167°C, which was proved identical with the picrate of 6a-methyl-5,6-dihydro-6a-benzo[*a*]carbazole (m. p. 169~170°C) by mixed melting point determination.

The authors are very grateful to Mr. Muneo Sato for his technical assistance and to Mr. Sachihiko Isoe who kindly measured the ultraviolet absorption spectra.

# *Mechanism of Plancher's Rearrangement. II*[1]. *Twofold Wagner-Meerwein Type Rearrangement of Indolenium Compounds*

By Masao NAKAZAKI

(Received August 31, 1959)

A novel conversion, by heating at 180~190°C, of an indolenium iodide, m.p. 186°C into an isomeric indolenium iodide, m.p. 232°C, both were obtained by the interaction of 2-isopropyl-3-methylindole and methyliodide was first described by Plancher[2], although the structures of these indolenium iodides were left unsettled.

But on only one occasion was the structure of the rearranged indolenium iodide established: Boyd-Barrett[3] oxidized the indolenium iodide III, obtained from 2-phenylindole (I) by heating with methyliodide at 120°C, to 1, 3-dimethyl-2-phenyloxyindole, and thus confirmed the structure of the rearranged indolenium III proposed by Plancher[4].

Plancher[2] explained the formation of 1, 2, 3-trimethyl-3-phenylindolenium iodide (III) from 2-phenylindole (I) by the sequence of reactions: decomposition of the first formed 1, 3, 3-trimethyl-2-phenylindolenium iodide (II) into iodobenzene and 1, 2, 3-trimethylindole and a recombination of which together with iodobenzene to form III.

It is obvious that such mechanism is hardly tenable, and Julian[5] suggested another mechanism which assumed that 3, 3-dimethyl-2-phenylindolenine is the first intermediate and its rearrangement involving an exchange of the phenyl with the methyl group would give 2, 3-dimethyl-3-phenylindolenine. But the fact that the conversion of 3, 3-dimethyl-2-phenylindolenine into 2,3-dimethyl-2-phenylindolenine, which would give III with methyliodide, however, was proved just opposite to the case[6], leaving only one possible mechanism remaining, i.e. the conversion of the intermediate 1, 3, 3-trimethyl-2-phenylindolenium iodide (II) into III, by a twofold Wagner-Meerwein type rearrangement formulated in Fig. 1. To testify this possibility, Leuch's experiment[7] was repeated in order to obtain 1, 3, 3-trimethyl-2-phenylindolenium iodide (II) from 3, 3-dimethyl-2-phenylindolenine and methyliodide.

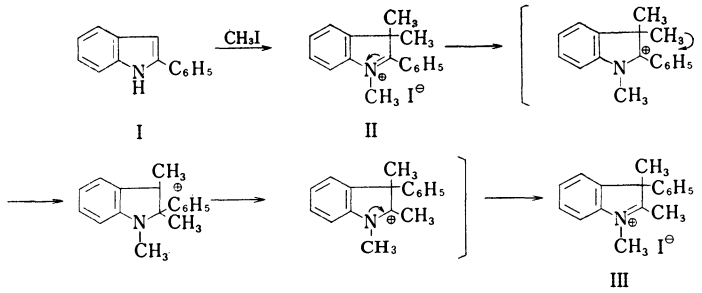

Fig. 1.

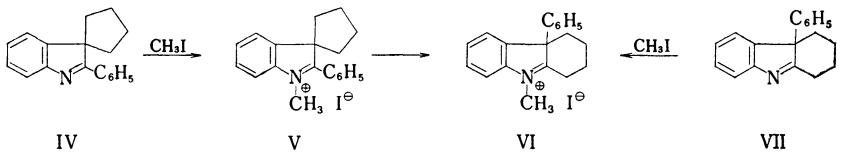

Fig. 2.

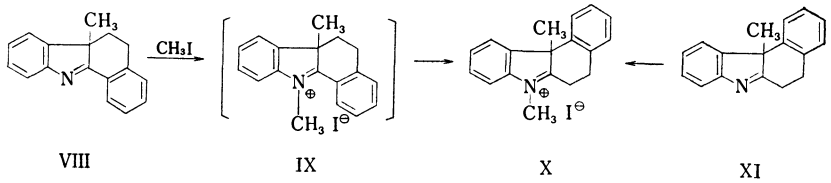

Fig. 3.

When a solution of 3, 3-dimethyl-2-phenylindolenine and methyliodide in methanol was heated at 100°C for 4 hr., there were obtained, in contrary to expectation, colorless prisms, m.p. 226~227°C[8], beside Leuch's indolenium iodide, yellow needles, m.p. 203°C, in about the same amount. Since the indolenium iodide with m.p. 226~227°C was proved to be 1, 2, 3-trimethyl-3-phenylindolenium iodide (III) by Boyd -Barrett's degradative experiment[3], the isomeric yellow indolenium iodide, m. p. 203°C which was a sole product Leuchs could isolate, was to be assigned the structure of 1, 3, 3-trimethyl-2-phenylindolenium iodide (II). These structure assignments were further confirmed by their ultraviolet absorption spectra, which show clearly a bathochromic shift (III, $\lambda_{max}$ 276 m$\mu$ and II, $\lambda_{max}$ 297 m$\mu$) due to conjugation with the phenyl group (Fig. 5).

The conversion of II to III was realised when a methanolic solution of II was heated in a sealed tube at 120~150°C for 1/2 hr., and this is the first case where indolenium compound was rearranged into the isomeric indolenium compound both with known constitutions, exchanging substituents between 2- and 3-position of the indolenium nucleus. Another smooth isomerization was established when *spiro*-(cyclopentane-1, 3'-*pseudo*-2'-phenylindole) methoiodide (V), prepared from the corresponding indolenine IV, with methyliodide, was heated in methanolic solution at 160°C for 3 hr. in a sealed tube to give 11-phenyltetrahydrocarbazolenine methoiodide (VI), which could be prepared from 11-phenyltetrahydrocarbazolenin (VII) and methyliodide.

Although it was unsuccessful to obtain the methoiodide of 6a-methyl-5, 6-dihydro-6a-benzo-[*a*] carbazole (IX) in crystalline form, it could be isomerized by heating its methanolic solution at 150°C for 5 hr. to the isomeric 11b-methyl-5, 6-dihydro-11b-benzo [*c*] carbazole methoiodide (X) provided from the corresponding indolenine XI with methyliodide. The mechanism of these rearrangements of indolenium iodides can be sought in the twofold Wagner-Meerwein type rearrangement[9] illustrated in Fig. 4.

Situated between two substituents at 1- and 3-position of indolenium compounds the substituents at 2-position suffer a considerable steric repulsion from both sides and the most bulky group ($R_3$) would tend to migrate to 2-position,

8) In the repetition of Plancher's experimet, Boyd-Barrett (Ref. 3) obtained a yellow indolenium iodide, m. p. 196°C as a minor product. Apparently this is the intermediate 1, 3, 3-trimethyl-2-phenylindolenium iodide (II), but any structural study as well as its possible rearrangement III was not tried.

9) Twofold Wagner-Meerwein type rearrangement was also demonstrated in indolenines (ref. 6) and 2, 3-disubstituted indoles M. Nakazaki, This Bulletin, 33, 461 (1960) A *spiro* type intermediate has to be assumed in the case of the rearrangement IX→X.

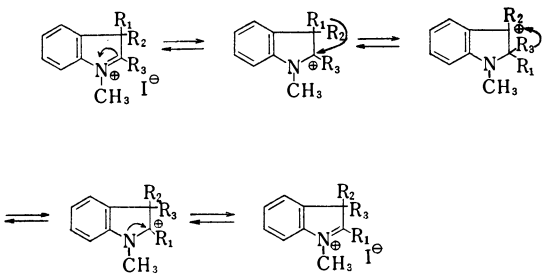

Fig. 4.

compelling the least bulky group ($R_1$) to 2-position (Fig. 4).

This steric effect would be strong enough[10] so as to compensate for the mesomeric stabilization effect of the phenyl group conjugated with the indolenium nucleus.

## Experimental[11]

**1, 3, 3-Trimethyl-2-phenylindolenium Iodide (II) and 1, 2, 3-Trimethyl-3-phenylindolenium Iodide (III).**—A mixture of 12.7 g. of 3, 3-dimethyl-2-phenylindolenine[12], 24.2 g. of methyliodide and 77 cc. of methanol was heated at 100°C. for 4 hr. in a sealed tube. After the solvent was removed on a water bath, the residue was recrystallized from methanol-ethyl acetate. From the more soluble fraction yellow needles were obtained and recrystallization from water (aqueous solution was colorless, whereas the methanolic solution was yellow) gave 3.6 g. of yellow needles, m. p. 202~203°C. (literature[7]: 203°C). Ultraviolet spectrum of 1, 3, 3-trimethyl-2-phenylindolenium iodide: $\lambda_{max}$ 297 m$\mu$ (log $\varepsilon$ 3.97) in methanol (Fig. 5).

Found: C, 56.24; H, 5.07. Calcd. for $C_{17}H_{18}NI$: C, 56.21; H, 4.99%.

From the less soluble fraction, there were obtained colorless prisms which were recrystallized from methanol, m.p. 226~227°C (literature[3]: 227°C). This iodide is rather sensitive to air and gradually changes to pink in color. U. V. spectrum of 1, 2, 3-trimethyl-3-phenylindolenium iodide: $\lambda_{max}$ 276 m$\mu$ (log $\varepsilon$ 3.84) in methanol (Fig. 5).

Found: C, 56.73; H, 5.37. Calcd. for $C_{17}H_{18}NI$: C, 56.21; H, 4.99%.

**Rearrangement of 1,3,3-Trimethyl-2-phenylindolenium Iodide (II).**—The indolenium iodide II (0.5 g.) was dissolved in 6 cc. of methanol and heated at 120~150°C for 3 hr., and then at 180°C for 1/2 hr. in a sealed tube. The original yellow color of the reaction mixture changed to violet-red. After removal of the solvent, the residue was dissolved in a small amount of methanol, and ethyl acetate was added to precipitate prisms (m.p. 222~224°C) with faint pink color, which was recrystallized from methanol to raise the melting point to 224~226°C. This was found identical with 1, 2, 3-trimethyl-3-phenylindolenium iodide (III) by mixed melting point determination and the comparison of infrared spectra.

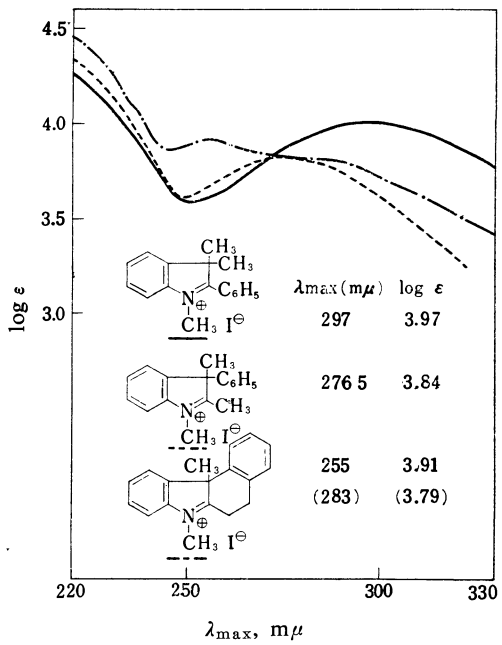

Fig. 5.

***Spiro*-(cyclopentane-1, 3'-*pseudo*-2'-phenylindole)**

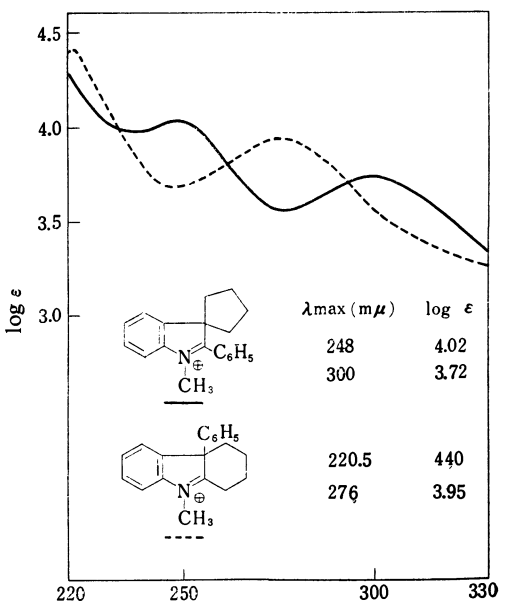

Fig. 6.

10) Even in the indolenine IV, without the repulsion from the substituent at 1-position, the steric strain is sufficient enough to be responsible for the smooth rearrangement of the isomeric indolenine VII (Ref. 6).

11) All the melting points are uncorrected values. All ultraviolet spectra were measured with an EPS-2 Hitachi autorecording spectrophotometer and infrared spectra on a Perkin Elmer Model 12C. The analyses were performed in the Microanalytical Laboratory of the Institute of Ploytechnics, Osaka City University.

12) B. p. 178~179°C/9 mmHg. Picrate, m. p. 167~168°C. Prepared following Witkop's procedure. [H. M. Kissman, D. W. Farnworth and B. Witkop, *J. Am. Chem. Soc.*, 74, 3948 (1952)].

**Methoiodide (V).**—A mixture of 1 g. of *spiro*-(cyclopentane-1, 3'-*pseudo*-2'-phenylindole)[13], 1.0 g. of methyliodide and 10 cc. of methanol was heated at 100°C for 2 hr. in a sealed tube. After the solvent was removed from the dark green reaction mixture, the residue was recrystallized from ethanol to give yellow needles (0.55 g.), m.p. 186.5~188°C. U. V. spectrum: $\lambda_{max}$ m$\mu$(log $\varepsilon$), 248(4.02), 300 (3.72) in ethanol (Fig. 6).

Found: C, 58.51; H, 5.36; N, 3.59. Calcd. for $C_{19}H_{20}N$ I: C, 58.70; H, 5.18; N, 3.60%.

**11-Phenyltetrahydrocarbazolenine Methoiodide (VI).**—A mixture of 1.0 g. of phenyltetrahydrocarbazolenine[14] 1.0 g of methyliodide and 10 cc. of methanol was heated at 100°C. for 3 hr. in a sealed tube. After removal of the solvent, the green residue was dissolved in methanol and decolorized with sulfur dioxide.

Then small amount of water was added to precipitate needles, which were recrystallized from water to give colorless needles, m.p. 116~118°C (decomp.). U. V. spectrum: $\lambda_{max}$ m$\mu$(log $\varepsilon$), 220.5 (4.40), 276(3.95) in ethanol (Fig. 6).

Found: C, 56.26; H, 5.60; N, 3.67. Calcd. for $C_{19}H_{20}NI \cdot H_2O$: C, 56.03; H, 5.45; N, 3.44%.

**Rearrangement of *Spiro*-(cyclopentane-1, 3'-*pseudo*-2'-phenylindole) Methoiodide (V).**—A mixture of 0.4 g. of the indolenium iodide V and 6 cc. of methanol was heated at 160°C for 3 hr. and at 200°C for 15 min. in a sealed tube. After removal of the solvent, the green residue was extracted with boiling water. The aqueous solution was treated with Norit and was concentrated to give colorless needles which were recrystallized from water., m.p. 116~118°C. This was found identical with the 11-phenyltetrahydrocarbazolenine methoiodide (m.p. 116~117°C) by mixed melting point determination (m.p. 116~118°C).

**11b-Methyl-5, 6-dihydro-11b-benzo[*c*]carbazole (X).**—A mixture of 0.2 g. of the indolenine XI[15], 0.4 g. of methyliodide and 4 cc. of methanol was heated at 100°C. for 3 hr. in a sealed tube. After removal of the solvent, a small amount of ether was added to the residue and was allowed to stand with occasional trituration. The crystals precipitated were collected and recrystallized from ethanol to give m.p. 202~204°C. U. V. spectrum: $\lambda_{max}$ 255 m$\mu$(log $\varepsilon$ 3.91) with a plateau at 283 m$\mu$ (3.79) in ethanol (Fig. 5).

Found: C, 57.81; H, 5.18; N, 4.20. Calcd. for $C_{18}H_{15}NI$: C, 57.61; H, 4.83 N, 3.73%.

**Rearrangement of 6a-Methyl-5, 6-dihydro-6a-benzo[$\alpha$]carbazole Methoiodide (IX).**—A mixture of 0.5 g. of the indolenine VIII[16], 1.0 g. of methyliodide and 4 cc. of methanol was heated at 100°C for 3 hr. in a sealed tube. After the solvent was removed at reduced pressure, the residue was washed with ether. After various fruitless attempts to crystallize, the viscous residue was dissolved in 6 cc. of methanol and heated at 150°C for 5 hr. in a sealed tube. The solvent was evaporated and a small amount of ether was added to the residue and triturated. The crystals were collected, and recrystallized from ethanol to give crystals melting at 202~204°C, which was found identical with the indolenium iodide X by mixed melting point determination and the comparison of their infrared spectra.

The author is very grateful to Messrs. Keiji Inui, Koji Yamamoto, Muneo Sato and Kikuo Yamagami for their assistance to prepare various starting materials. He also feels indebted to Mr. Sachihiko Isao for measurement of ultraviolet absorption spectra.

# *Theory on the Small Angle Scattering of Light to Determine the Shape, Size and Orientation of High Polymer Molecules in Flow**

By Masayuki NAKAGAKI

(Received October 6, 1959)

As for the small angle scattering of light by high polymer moleculces in a solution at rest, the Zimm plot, that is a double extrapolation method devised by Zimm[1], has been used widely. On the other hand, a theory regarding the deformation of high polymer molecules in flow and on the light scattering by the deformed molecules has been developed by Peterlin, Heller and Nakagaki[2]. On the basis of this theory, it will be shown in the present paper that the Zimm plot can be used for the quantitative determination of the shape, size and orientation of high polymer molecules in flow, and that the photographic pattern of the small angle scattering can be used to determine the orientation of the molecules in flow.

### Initial Slope of the Zimm Plot

The equation of light scattering derived by Debye[3] on the basis of fluctuation theory, and generalized by Zimm[4] is,

$$Kc/R_u(\vec{s}) = 1/MP(\vec{s}) + 2A_2c \tag{1}$$

where $K$ is a constant, $R_u(\vec{s})$ is reduced scattering intensity, $P(\vec{s})$ is interference factor, and $c$, $M$ and $A_2$ are concentration, molecular weight and the second virial coefficient of the polymer. The constant $K$ is given by

$$K = (2\pi^2\mu_1^2/N_0\lambda_0^4)(\mathrm{d}\mu_{12}/\mathrm{d}c)^2 \tag{2}$$

where $\mu_1$ is the refractive index of solvent, $N_0$ is the Avogadro number, $\lambda_0$ is wavelength of light in vacuo and $\mu_{12}$ is refractive index of solution. The reduced scattering intensity $R_u(\vec{s})$ is

$$R_u(\vec{s}) = (I_u(\vec{s})/I_0)/(1+\cos^2\theta) \tag{3}$$

where $I_0$ is the intensity of the unpolarized incident light, $I_u(s)$ is the intensity of light scattered in the direction designated by $\vec{s}$, and $\theta$ is the scattering angle. The scattering vector $\vec{s}$ is given by

$$\vec{s} = \vec{s'} - \vec{s_0} \tag{4}$$

where $\vec{s_0}$ and $\vec{s'}$ are unit vectors in the direction of the incident beam and scattered beam, respectively; and its absolute value, $s$, is

$$s = |\vec{s}| = 2\sin(\theta/2) \tag{5}$$

Here the scattering angle $\theta$ is the angle between $\vec{s_0}$ and $\vec{s'}$.

In the so called Zimm plot, $(Kc/R_u)$ is taken as ordinate and $\sin^2(\theta/2)+kc$ is taken as abscissa, where $k$ is a constant chosen arbitrarily. Therefore, the curve on the Zimm plot for the values extraporated to infinitely dilute concentration gives

$$[Kc/R_u(\vec{s})]_0 = 1/MP(\vec{s}) \tag{6}$$

as a function of $\sigma$ defined by

$$\sigma = \sin^2(\theta/2) \tag{6a}$$

On the other hand, the theoretical expression for the interference factor of streaming polymer molecules derived by Peterlin, Heller and Nakagaki[2] is,

$$P(\vec{s}) = 2\int_0^1 (1-u)\exp[-X(u+\zeta u^2)]\,\mathrm{d}u \tag{7}$$

where

$$X = (8\pi^2/3\lambda^2)R^2\sin^2(\theta/2)\cdot\xi \tag{8}$$

and

$$\zeta = (2/3)\beta^2 \tag{9}$$

Here $\lambda$ is the wavelength of light in the medium, $R$ is the root-mean-square of the end-to-end distance of the polymer molecule at rest, and

$$\xi = \{1+[\beta^2+\beta(1+\beta^2)^{1/2}\cos 2\phi] \times\cos^2(\theta/2)\}/(1+2\beta^2/3) \tag{10}$$

Here $\beta$ is a quantity proportional to the velocity gradient $q$ defined by

$$\beta = (\pi a/6kT)\eta ZR^2q = (M/N_0kT)[\eta]\eta q \tag{11}$$

where $a$ is the hydrodynamic radius of segments, $k$ is the Boltzmann constant, $T$ is the absolute temperature, $\eta$ is the viscosity, $Z$ is the number of segments in a molecule, $M$ is the molecular weight and $[\eta]$ is the intrinsic viscosity. The angle $\phi$ is concerned with the direction of observation as defined in Ref. 2 and will be described later (See Fig. 2).

---

* Presented before the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959.

1) B. H. Zimm, *J. Chem. Phys.*, **16**, 1099 (1948).
2) A. Peterlin, W. Heller and M. Nakagaki, ibid., **28**, 470 (1958).
3) P. Debye, *J. Appl. Phys.*, **15**, 338 (1944).
4) B. H. Zimm, *J. Chem. Phys.*, **16**, 1093 (1948).

The value of $[Kc/R_u(0)]_0$, that is the height of the ordinate at which the Zimm plot for infinite dilution intersects and the value of the initial slope of this Zimm plot are obtained by expanding $[Kc/R_u(\vec{s})]_0$ of Eq. 6 as a power series of $\sigma$ of Eq. 6a. These values are:

$$[Kc/R_u(0)]_0 = 1/M \tag{12}$$

and

$$\begin{aligned}(\text{Initial slope}) &= [Kc/R_u(0)]_0 \times (8\pi^2R^2/9\lambda^2) \\ &\times [1+\beta^2+\beta(1+\beta^2)^{1/2}\cos 2\phi] \\ &\times (1+\beta^2/3)/(1+2\beta^2/3)\end{aligned} \tag{13}$$

If a parameter $g$ defined by

$$g = (9\lambda^2/8\pi^2)\ (\text{Initial slope})/[Kc/R_u(0)]_0 \tag{14}$$

is used, the value is

$$\begin{aligned}g &= R^2[1+\beta^2+\beta(1+\beta^2)^{1/2}\cos 2\phi] \\ &\times (1+\beta^2/3)/(1+2\beta^2/3)\end{aligned} \tag{15}$$

Thus, the value of the ordinate at which the Zimm plot intersects is constant irrespective of whether the solution is streaming or not. From this value, the molecular weight may be determined on the basis of Eq. 12. On the other hand, the value of $g$ depends on the velocity gradient or $\beta$. The value of $g$ in the case of the solution at rest, designated by $g_0$, is obtained from Eq. 15 with $\beta=0$. The value is

$$g_0 = R^2 \tag{16}$$

Therefore, it is equal to the mean square end-to-end distance. The value of $g$ for streaming solution depends on the direction of observation or $\phi$ as well as the velocity gradient or $\beta$.

At first, the observation plane is fixed and the variation of $g$ with velocity gradient (or $\beta$) is considered. Since the angle $\phi$ is also a function of $\beta$, angle $\omega$ is used instead (see Fig. 2). The angle $\omega$ is the angle between the direction of flow and the plane of observation, and is related to $\phi$ by the equation:

$$\omega = \phi + 90° - \chi \tag{17}$$

where $\chi$ is the extinction angle varying with $\beta$ according to

$$\beta = -\cot 2\chi \tag{18}$$

Then, Eq. 15 is rewritten to

$$\begin{aligned}g/g_0 &= (1+\beta^2+\beta\sin 2\omega+\beta^2\cos 2\omega) \\ &\times (1+\beta^2/3)/(1+2\beta^2/3)\end{aligned} \tag{19}$$

The variation of $g/g_0$ due to $\beta$ for several values of $\omega$ are shown in Fig. 1 with solid curves. Then, at a constant value of $\beta$, the maximum and minimum value of $g/g_0$ are calculated. The results are:

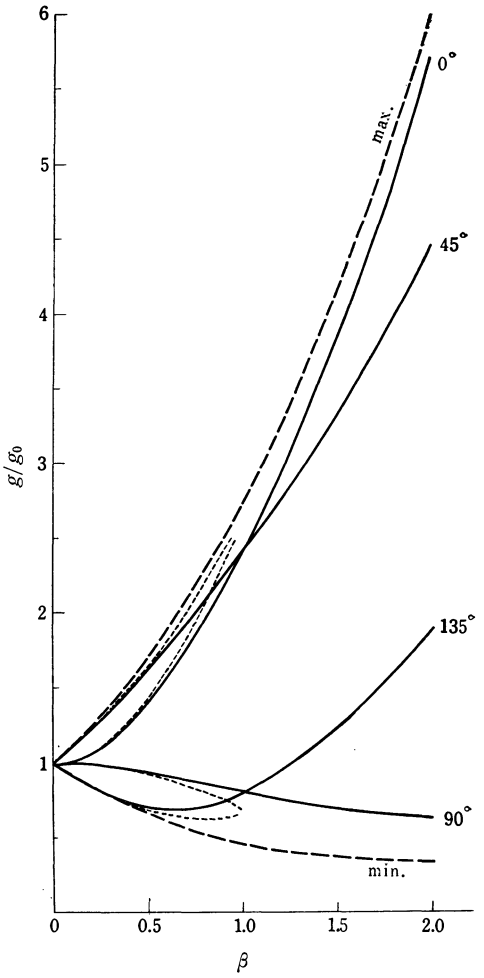

Fig. 1. The relationship between $g/g_0$ and $\beta$.

$$\left.\begin{aligned}g_{max}/g_0 &= [1+\beta^2+\beta(1+\beta^2)^{1/2}] \\ &\times (1+\beta^2/3)/(1+2\beta^2/3) \\ &\text{at}\quad \phi = 0°,\ 180° \\ g_{min}/g_0 &= [1+\beta^2-\beta(1+\beta^2)^{1/2}] \\ &\times (1+\beta^2/3)/(1+2\beta^2/3) \\ &\text{at}\quad \phi = \pm 90°\end{aligned}\right\} \tag{20}$$

These values are shown in Fig. 1 with broken lines.

It may be instructive to estimate here the order of magnitude of $\beta$. If $[\eta]=100$, $\eta=1$ c.p.s., $M=3\times10^5$ and $q=1\times10^4$ sec$^{-1}$, the value of $\beta$ calculated by Eq. 11 is 0.12. Therefore, the usual value of $\beta$ seems to be smaller than unity. If $\beta \ll 1$, Eq. 19 is reduced to

$$g/g_0 \fallingdotseq 1+\beta\sin 2\omega+\beta^2(2/3+\cos 2\omega) \tag{21}$$

The error committed by this approximate equation is less than 5% as far as $\beta \lesssim 0.7$. The values calculated by this equation are shown in Fig. 1 with dotted curves.

As already mentioned, the quantity $\beta$ is proportional to the velocity gradient $q$. When a concentric cylinder apparatus is used, $\beta$ is, therefore, proportional to the rate of rotation $\Omega(\sec^{-1})$, that is

$$\beta = k_1 q = k_2 \Omega \tag{22}$$

with

$$k_2 = k_1(2\pi\rho/d) \tag{23}$$

where $\rho$ is the radius of the rotating cylinder, $d$ is the width of the gap of the concentric cylinder, and the value of $k_1$ is readily obtained from Eq. 11. Thus, there are three methods to determine the value of $k_2$ (or $k_1$). The first is to calculate the value of $k_1$ by Eq. 11. The second is to measure the extinction angle $\chi$ by a streaming double refraction measurement in order to obtain the value of $\beta$ on the basis of Eq. 18. The values of $\beta$ for various values of $q$ or $\Omega$ will give the value of $k_1$ or $k_2$ by Eq. 22. The third and the most direct method for the present experiment is to use the equation derived from Eq. 21, that is:

$$(g/g_0 - 1)/\Omega = A + B\Omega \tag{24}$$

where

$$\left.\begin{aligned} A &= k_2 \sin 2\omega \\ B &= k_2^2(2/3 + \cos 2\omega) \end{aligned}\right\} \tag{25}$$

From the value of $A$ or $B$ determined experimentally, the value of $k_2$ will be obtained.

## A Method for Measurement of the Semi-Major and Minor Axes of Flexible High Polymer Molecules

The extension of high polymer molecules in solution is expressed by the probability distribution of end-to-end distance, that is the probability $\psi$ per unit volume to find one end of the high polymer molecule in a volume element when the other end is fixed at the origin. In the case of freely flexible high polymer molecules, it is well known that the function $\psi$ is Gaussian:

$$\left.\begin{aligned} \psi &= (\mu/\pi)^{3/2} \exp(-\mu r^2) \\ \mu &= 3/2R^2 \end{aligned}\right\} \tag{26}$$

where $r$ is the distance to the volume element from the origin and $R$ is the root mean square end-to-end distance. On the other hand, it is often assumed that the distribution of segments around the center of gravity of the molecule is also Gaussian. The probability $W$ to find a segment in a unit volume of a volume element is then:

$$\left.\begin{aligned} W &= Z(\mu^*/\pi)^{3/2} \exp(-\mu^* r^2) \\ \mu^* &= 6\mu \end{aligned}\right\} \tag{27}$$

where $Z$ is the number of segments in one molecule, and $r$ in this case is the distance between the volume element and the center of gravity. The relation between $\mu^*$ and $\mu$ shown in Eq. 27 is based on the fact established by Debye[5] that the root mean square distance $S$ of a segment from the center of gravity of the molecule is

$$S = R/\sqrt{6} \tag{28}$$

On the other hand, Debye and Bueche[6] concluded from the study of intrinsic viscosity that the radius $R_s$ of a high polymer molecule considered as a sphere should be

$$R_s = \sqrt{5/18}\, R \tag{29}$$

Now, by assuming that the distribution of segments is homogeneous in a sphere of radius $R_s$ the root mean square distance of a segment from the center of gravity of the molecule is readily calculated and the result is

$$S = \sqrt{3/5}\, R_s \tag{30}$$

This result together with Eq. 29 yields a relation exactly the same as that of Eq. 28, the latter being obtained originally on the basis of the Gaussian distribution formulated in Eq. 27.

On the basis of these facts, one may say that the shape of a high polymer molecule in a solution at rest is a sphere with the radius of $R_s$. Then the value of $W$ at the surface of the sphere ($W_s$) relative to the value of $W$ at the center of gravity of the molecule ($W_0$) is,

$$W_s/W_0 = \exp(-5/2) = 0.082 \tag{31}$$

Therefore, to assume a high polymer molecule as a sphere of radius $R_s$ corresponds to the assumption that the surface of the molecule is defined by the points at which $W_s/W_0 = 0.082$ in the Gaussian distribution.

Now, considering high polymer molecules in a streaming solution, Peterlin, Heller and

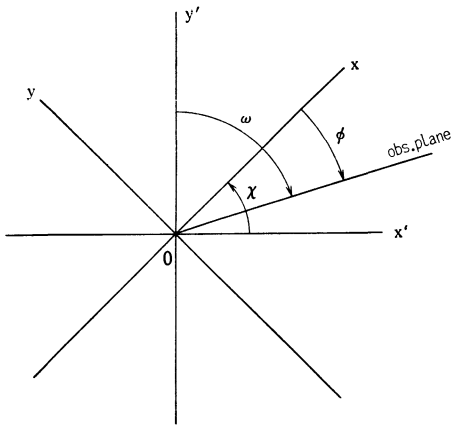

Fig. 2. The coordinate system and angles used.

5) P. Debye, ibid., **14**, 636 (1946).
6) P. Debye and A. M. Bueche, ibid., **16**, 573 (1948).

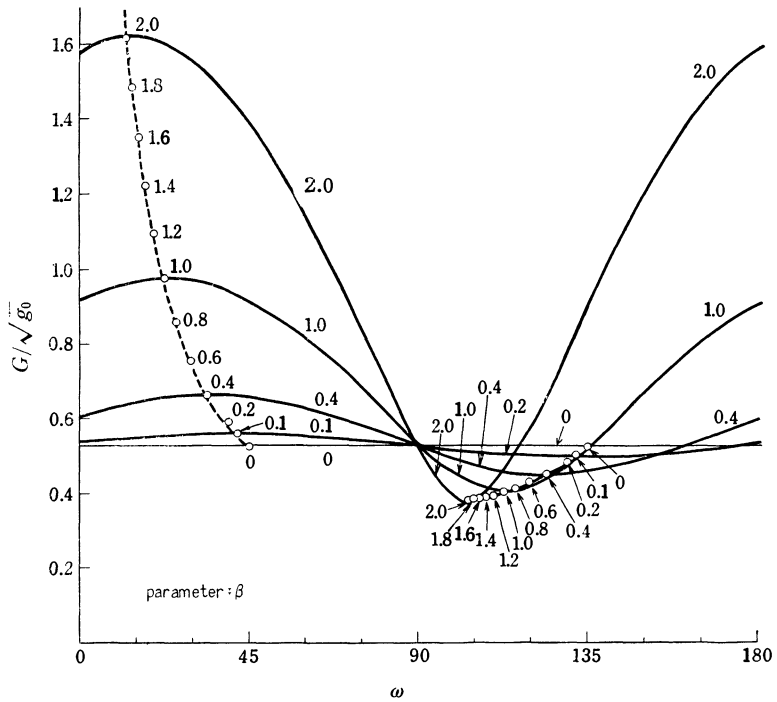

Fig. 3. The relationship between $G/\sqrt{g_0}$ and $\omega$. Parameter: $\beta$.

Nakagaki[2] gave the probability distribution of end-to-end distance by the equation:

$$\psi=\frac{1}{abc}\left(\frac{\mu}{\pi}\right)^{3/2}\times\exp\{-\mu[(x/a)^2+(y/b)^2+(z/c)^2]\} \quad (32)$$

where

$$\left.\begin{aligned} a^2&=\sqrt{1+\beta^2}(\sqrt{1+\beta^2}+\beta)\\ b^2&=\sqrt{1+\beta^2}(\sqrt{1+\beta^2}-\beta)\\ c^2&=1\end{aligned}\right\} \quad (33)$$

Here, the coordinate system $x, y, z$ is that obtained by rotating the coordinate system $x'$, $y'$, $z$ by the angle $\chi$ around the $z$-axis, as shown in Fig. 2, $x'$ and $y'$ being the direction of velocity gradient and velocity, respectively. Eq. 32 is reduced to the usual Gaussian distribution (Eq. 26) when $\beta=0$.

The distribution of segments around the center of gravity of the molecule may then be assumed to be

$$W=\frac{Z}{abc}\left(\frac{\mu^*}{\pi}\right)^{3/2}\times\exp\{-\mu^*[(x/a)^2+(y/b)^2+(z/c)^2]\} \quad (34)$$

with $\mu^*=6\mu$, in analogy to Eq. 27. By the assumption that the surface of the molecule is defined by the points at which $W_s/W_0=\exp(-5/2)$, the molecule should be an ellipsoid expressed by the equation:

$$\mu^*[(x/a)^2+(y/b)^2+(z/c)^2]=5/2 \quad (35)$$

the semi-axes of the ellipsoid $R_a$, $R_b$, and $R_c$ being in the direction of the coordinate axes $x$, $y$ and $z$, respectively, and the values being[7]

$$\left.\begin{aligned} R_a&=\sqrt{5/18}\,aR\\ R_b&=\sqrt{5/18}\,bR\\ R_c&=\sqrt{5/18}\,cR\end{aligned}\right\} \quad (36)$$

When $\beta=0$,

$$R_a=R_b=R_c=R_s \quad (37)$$

since $a=b=c=1$.

In order to determine the values of $R_a$, $R_b$, and $R_c$ experimentally, a quantity $G$ defined by

$$G=\sqrt{(5/18)g(1+2\beta^2/3)/(1+\beta^2/3)} \quad (38)$$

is introduced. Here $g$ is obtainable experimentally from the measurement of the initial slope by using Eq. 14, and $\beta$ is obtainable experimentally by Eq. 22 as a quantity proportional to the rate of rotation $\Omega$. Therefore, the quantity $G$ is a measurable quantity. The theoretical expression for $G$ may be obtained by using Eq. 15 and the result is:

$$G=\sqrt{5/18}\,R\sqrt{1+\beta^2+\beta\sqrt{1+\beta^2}\cos 2\phi} \quad (39)$$

Thus, $G$ as a function of the direction of observation plane, $\omega$, has one maximum and one

7) The quantity $R$ is the root mean square end-to-end distance at rest. The value in flow is $\langle r^2\rangle=R^2(1+2\beta^2/3)$.

minimum in the range $\omega=0\sim180°$. The maximum of $G$ occurs at $\phi=0$, that is, $\omega=90°-\chi$ or the direction of $x$-axis. The maximum value of $G$ is

$$G_{max}=R_a \quad \text{at} \quad \omega_{max}=90°-\chi \tag{40}$$

On the other hand, the minimum value of $G$ occurs at $\phi=90°$, that is the direction of $y$-axis, at which,

$$G_{min}=R_b \quad \text{at} \quad \omega_{min}=180°-\chi \tag{41}$$

The value of $\chi$ can be predetermined theoretically by Eq. 18. Thus, the major and minor semi-axes of the ellipsoidal molecule, $R_a$ and $R_b$, are obtained experimentally from the values of $G_{max}$ and $G_{min}$, and the direction of the major and minor axes of the molecule coinside with $\omega_{max}$ and $\omega_{min}$. The value of $R_c$ is equal to the value of $G$ for $\beta=0$, that is the value for the solution at rest:

$$G_0=R_c \tag{42}$$

The values of $G/\sqrt{g_0}$ are shown in Fig. 3, where $g_0$ is the value of $g$ for the solution at rest. $G_{max}$ and $G_{min}$ are shown by open circles. The numerical values of $G_{max}/\sqrt{g_0}$ and $G_{min}/\sqrt{g_0}$ are shown in Table I for perfectly flexible molecules.

## Expectation from Photographic Study of Small Angle Scattering

The shape of the pattern to be obtained by photographing the small angle scattering from a streaming solution will be discussed here. Let the distance from the specimen (a streaming solution) to the photographic plate be $D$, and the coordinate of one point $P$ on the plate be $(x', y')$. Here the origin of the coordinate system is placed on the point where the primary beam hit the plate, the $x'$-axis being parallel to the direction of the velocity gradient, $\vec{q}$, and the $y'$-axis being parallel to the direction of flow, $\vec{v}$, and the direction of the primary beam being perpendicular to the plate.

Since the small angle scattering only is considered here, $\theta \ll 1$ or $r/D \ll 1$. Therefore,

$$\left.\begin{aligned}\sin(\theta/2) &\fallingdotseq r/2D \\ \cos\theta &\fallingdotseq 1-r^2/2D^2\end{aligned}\right\} \tag{43}$$

The intensity $I_u$ of light per unit solid angle scattered to the direction SP in Fig. 4 is

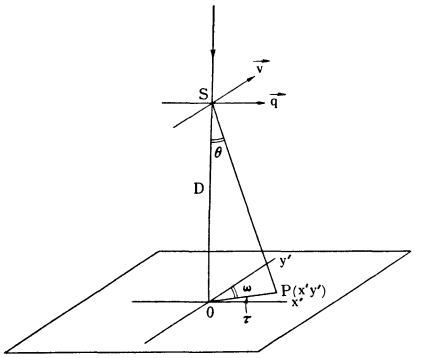

Fig. 4. Illustration of coordinate systems and angles.

$$I_u=I_0(1+\cos^2\theta)\,R_u \tag{44}$$

where $I_0$ is the intensity of the unpolarized incident light, and $R_u$ is the reduced scattering intensity as defined by Eq. 3. Then, the intensity, $I_u'$ of scattered light per unit area on the plate is

$$I_u'=I_u\cos\theta/(D^2+r^2) \tag{45}$$

Now, using Eq. 6 for sufficiently dilute solution, expanding the interference factor $P$ in a power series of $r/D$ and using Eq. 43,

$$I_u'=(2I_0KcM/D^2)\,[1-(r^2/2D^2)\{4+E \times(1+\beta^2+\beta\sqrt{1+\beta^2}\cos 2\phi)\}] \tag{46}$$

where

$$E=(4\pi^2R^2/9\lambda^2)\,(1+\beta^2/3)/(1+2\beta^2/3) \tag{47}$$

The contrast to be obtained on the photographic plate is probably not very great, although it will be the greater, the greater the value of $R/\lambda$ is. Let us, however, expect that the contrast can be emphasized sufficiently by using adequate photographic technique. Here, the shape of the pattern obtained by connecting the points of equal blackness on the plate is discussed. Since $I_u'$ is constant for these points, the value of $h$ defined by

$$h=1-(D^2/2KcM)\,(I_u'/I_0) \tag{48}$$

is constant. Now changing the coordinate system from $(x', y')$ to $(x, y)$ shown in Fig. 2,

$$x^2/\{2D^2h/[4+E(1+\beta^2+\beta\sqrt{1+\beta^2})\} +y^2/\{2D^2h/[4+E(1+\beta^2-\beta\sqrt{1+\beta^2})]\}=1 \tag{49}$$

is obtained from Eqs. 46 and 48. Therefore, the shape of the pattern to be obtained on the plate is an ellipse. The direction of the major axis of the ellipse is parallel to the direction of the minor axis of the molecule ($y$-direction) and the direction of the minor axis of the pattern is parallel to the direction of the major axis of the molecule ($x$-direction). Thus, the orientation of the flexible high polymer molecules in flow can be determined by photographing the small angle scattering of light.

## Summary

Small angle scattering of light by streaming flexible high polymer molecules is studied theoretically. It is concluded that the position at which the Zimm plot for infinite dilution cuts the ordinate does not change with the velocity gradient and is equal to $1/M$. The initial slope of the Zimm plot, however, varies with the velocity gradient as well as the direction of the observation plane. The quantity $g$ proportional to the initial slope varies with the rate of rotation $\Omega$ of a concentric cylinder apparatus according to the approximation equation:

$$(g/g_0-1)/\Omega=A+B\Omega$$

where $g_0$ is the value of $g$ at $\beta=0$, and $A$ and $B$ are parameters depending upon the direction of observation.

Now, when a quantity $G$:

$$G=\sqrt{(5/18)\ g\ (1+2\beta^2/3)/(1+\beta^2/3)}$$

(where $\beta$ is a quantity proportional to the velocity gradient, the proportionality constant being obtained from the value of $A$ or $B$) is measured, the value of $G_{max}$ is equal to the length of the semi-major axis of the molecule, the observation plane for this $G_{max}$ being parallel to the direction of the major axis of the molecule, while the value of $G_{min}$ is equal to the length of the semi-minor axis of the molecule, the observation plane for this value being parallel to the direction of the minor axis of the molecule.

The pattern to be obtained by photographing the small angle scattering from a streaming solution of high polymer is discussed. The pattern is expected to be an ellipse, the orientation of the pattern is expected to be rotated by exactly 90° from the orientation of the molecule.

# *Absorption Spectra of Metallic Complexes with Aromatic Molecules*

By Shoichiro YAMADA, Hiroshi YAMAZAKI[1], Hiroaki NISHIKAWA and Ryutaro TSUCHIDA

(Received September 30, 1959)

Ever since the first preparation of bis-(benzene)-chromium[2] and confirmation with X-rays of the sandwish structure of this compound[3], a number of metallic complexes with aromatic molecules have been synthesized. The study of these compounds is thought to be interesting because of the peculiar bonding involved in the compounds which may be quite similar to that in the ferrocene-type compounds. Many articles have been presented concerning various properties of the compounds, but there have been very few reports available which discuss their absorption spectra in relation to the bonding[4].

In the present work, the authors have determined quantitatively absorption spectra of some chromium compounds containing aromatic molecules and discussed the results of the measurements in relation to the bonding involved in the metal-arenes in general.

## Experimental

**Materials.** — Bis-(benzene)-chromium(I) iodide was prepared in yellow crystals from bis-(benzene)-chromium(0), which was obtained according to the method of Fischer[2]. Dichroism of the compound was reported in the earlier paper[4].

Bis-(toluene)-chromium(I) iodide was prepared

2) E. O. Fischer and W. Hafner, *Z. Naturforsch.*, **10b**, 665 (1955).

3) E. Weiss and E. O. Fischer, *Z. anorg. u. allgem. Chem.*, **286**, 142 (1956).

4) S. Yamada, H. Nakamura and R. Tsuchida, This Bulletin, **30**, 647 (1957).

by the method of Fischer and Seus[5] from bis-(toluene)-chromium(0). The yellow, prismatic crystals of the compound show a straight extinction and a slight but definite dichroism on the well-developed prism face.

Monobenzene-chromium tricarbonyl was prepared in yellow, plate-like crystals by the method of Fischer and Öfel[6] from chromium hexacarbonyl and bis-(benzene)-chromium(0) in a sealed tube. The crystals show a slight dichroism on the face, on which the dichroism measurement was carried out.

Chromium hexacarbonyl was prepared in colorless crystals according to the method of Natta et al.[7]

**Measurements.** — Dichroism in the visible and ultraviolet regions of $Cr(C_6H_6)(CO)_3$ was determined on the above-mentioned face with Tsuchida and Kobayashi's microscopic method[8] using polarized light.

Ultraviolet absorption spectra in solution were determined with a Beckman DU spectrophotometer.

Infrared spectra of the compounds in Nujol mulls and in potassium bromide discs were determined in the rock salt region with a Hilger H800 infrared spectrophotometer.

The notations in the present paper are the same as those used in the former papers of this series.

## Results and Discussion

**Ultraviolet Absorption Spectra of Metal Carbonyls.** — Absorption spectra of chromium hexacarbonyl in various solvents have been determined in the present work, and are shown in Fig. 1. The present measurement indicates that there is a very weak absorption band at about $50\times10^{13}$ $sec^{-1}$, which was not reported by the previous investigators[9]. The weak absorption band of this sort, which is observed in the absorption spectra of $Cr(C_6H_6)(CO)_3$, $[Cr(C_6H_6)_2]^+$ and $[Cr(C_6H_5CH_3)_2]^+$, may belong to a "spin-forbidden absorption band" and is discussed in the later part of the present paper.

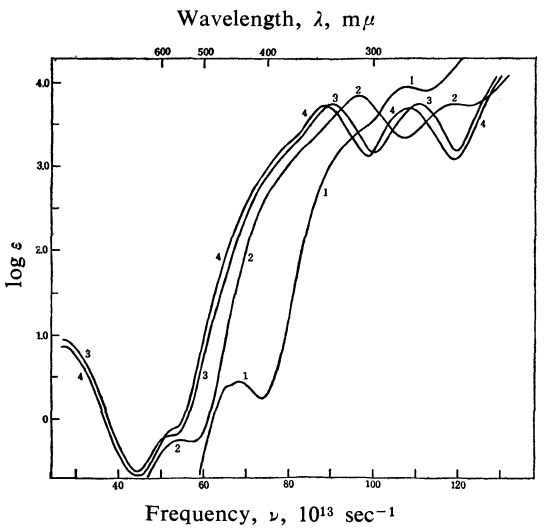

Fig. 1. Ultraviolet absorption spectra: 1, $Cr(CO)_6$ in methanol; 2, $Cr(C_6H_6)(CO)_3$ in methanol; 3, $Cr(C_6H_6)_2I$ in water; 4, $Cr(C_6H_5CH_3)_2I$ in water.

Milazzo and Scheibe[9] believed that most of the intense absorption bands of $Cr(CO)_6$ in the shorter wavelength, excepting the first inflation which they regarded as due to the carbonyl molecule itself, might be due to the decomposition products formed by photo-dissociation from the original molecule. Their conclusion was based upon the absence of a fine structure in the absorption curve. In the opinion of the present authors, however, the absence of a fine structure alone seems to be insufficient for such a conclusion. Such a flat absorption curve may be ascribed rather to the extraordinary nature of the ligand or, in other words, of the metal-to-ligand bond. Flat absorption curves similar to the spectrum of chromium hexacarbonyl are often exhibited; for example, by complexes of transition elements with ligands such as cyanide, isonitriles, ethylene, dimethylglyoxime and so forth.

Generally speaking, absorption spectra of carbonyls of transition elements may be regarded as a superposition of "ligand field absorption bands", due mainly to the metal under the field of the CO molecules, and absorption bands due to the electronic transitions which are closely related with the CO-groups under the field of the metal atom with which they are linked. Thus, the inflation at about $92\times10^{13}$ $sec^{-1}$ of $Cr(CO)_6$, which is found in Fig. 1, may be regarded as corresponding to a "ligand field band", and the absorption bands in shorter wavelength may be due to the electronic transitions closely related with the CO-groups under the field of the central metal. Absorption bands of the latter type, however, can not be ascribed to the CO-groups alone, since the present measurement shows that the absorption bands of $Cr(CO)_6$ undergo a slight "red shift" on changing a solvent from a less polar to a more polar one, whereas the carbonyl-group in ketones, for example, suffers a "blue shift"[10]. The authors are inclined to assume that the bands may most probably be due to electronic transitions from a level related principally with

the metal to excited levels of the CO-groups in the metallic complex.

In connection with the chromium hexacarbonyl, it seems to be interesting to discuss here about the absorption spectrum of $Co_2(CO)_8$. Hieber et al.[11] reported the absorption spectrum of the compound in solution, only pointing out that the binuclear complex showed an absorption spectrum different from that of the corresponding mononuclear complexes. The spectra of the compound in the gaseous and solution states were later determined and discussed in combination with the infrared spectrum, the bibridged structure being regarded as most probable[12]. On re-examination of the ultraviolet spectra reported by the former investigators, it is readily recognized that $Co_2(CO)_8$ exhibits absorption in the wavelength region much longer than the corresponding mononuclear $[Co(CO)_4]^-$ ion. It is known from data so far obtained that the absorption spectrum of bibridged complexes without special interaction between the two metal atoms may be regarded as a superposition of the two mononuclear complexes of which the binuclear complex is assumed to be composed. Thus, the absorption spectrum of the bibridged, binuclear complex is known to show no greatly bathochromic displacement from the spectrum of the corresponding mononuclear complexes. This may be recognized; for example, in comparing absorption spectra of dicobalt-$\mu$, $\mu'$-diol, diplatinum-$\mu$, $\mu'$-dichloro, dipalladium-$\mu$, $\mu'$-dichloro and dichromium-$\mu$,-$\mu'$-diol complexes with the spectra of the corresponding mononuclear complexes[13]. The displacement of the absorption spectrum of $Co_2(CO)_8$ from that of $[Co(CO)_4]^-$ seems to be too great for an ordinary type of binuclear complex without special interaction. Thus, the appearance of the absorption in the enormously long wavelength region may be taken as evidence for the assumption of the direct interaction between the cobalt atoms in the $Co_2(CO)_8$.

**Ultraviolet Absorption Spectra of Bis-(benzene)- and Bis-(toluene)-chromium(I) Iodide.**— Ultraviolet absorption spectra of bis-(benzene)- and bis-(toluene)-chromium(I) iodide, which have been determined in the present work, are shown in Fig. 2 and Table I. The absorption spectrum of $[Cr(C_6H_6)_2]I$ in solution was formerly reported by the present authors, but the measurement has been extended to the longer wavelength region in the present work.

It is seen in Fig. 2 and Table I that the absorption spectrum of $[Cr(C_6H_5CH_3)_2]I$ bears

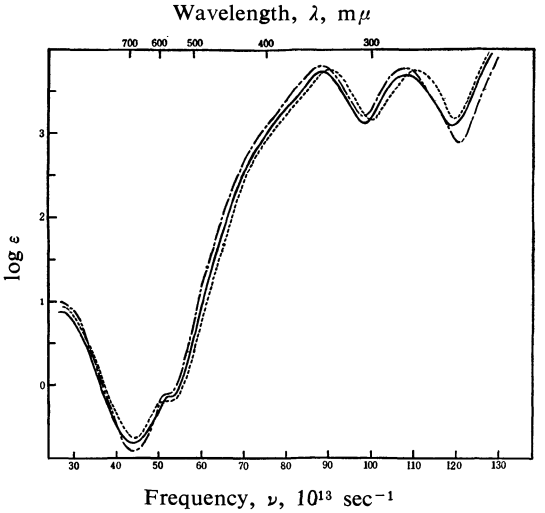

Fig. 2. Ultraviolet absorption spectra: ——, $Cr(C_6H_5CH_3)_2I$ in water; – – –, $Cr(C_6H_5CH_3)_2I$ in ethanol; ------, $Cr(C_6H_6)_2I$ in water.

a close resemblance to the spectrum of $[Cr(C_6H_6)_2]I$. Thus, between the two curves there is only a very slight difference in the wavelength and the intensity of the band maxima. In addition, the solvent effect on absorption bands is also the same for the two compounds, as seen in Table I. It may safely be concluded that the $[Cr(C_6H_5CH_3)_2]^+$ ion has the same structure and bonding as the $[Cr(C_6H_6)_2]^+$ ion. Both the complex ions may most probably have the sandwich structure.

Free benzene and toluene are known to show a characteristic band at about 260 m$\mu$ with a fine structure. On the contrary, both the $[Cr(C_6H_6)_2]^+$ and the $[Cr(C_6H_5CH_3)_2]^+$ ion are found to show no absorption bands of the above sort. The absorption bands of the chromium(I)-complexes in the corresponding wavelength region are much more intense than the band of benzene or toluene, and do not show such a fine structure as is observed in the spectra of the aromatic molecules themselves. Moreover, Bands II and III of the chromium(I)-complexes undergo a slight "blue shift", whereas the absorption band of the benzene ring with a fine structure undergoes a slight "red shift". These facts seem to show that the electronic state of the benzene rings in the chromium(I)-complexes is quite different from that of a benzene ring in the free benzene derivatives. The dichroism of the $[Cr(C_6H_6)_2]^+$ ion also seems to be consistent with this assumption[4]. If the aromaticity of the benzene rings in the chromium(I)-complex were comparatively remarkable, a dichroism similar to the benzene rings would be observed, just as in ordinary benzene derivatives. Since a dichroism of this

c) Taken from H. H. Zeiss and M. Tsutsui, *J. Am. Chem. Soc.*, **79**, 3062 (1957).

d) Taken from Ref. 5, in which the solvent is not given. In the curve there is observed inflation at about $116\times10^{13}$ $sec^{-1}$ (log $\varepsilon$ 4.3).

sort or a band with a fine structure characteristic of the free benzene derivatives is not observed, the electronic state of the benzene rings in this chromium(I)-complex seems to be comparatively far apart from the state of the free benzene molecule. It is most likely, as is shown in the later part of this paper, that the $\pi$-electrons on the benzene rings are attracted to a considerable extent toward the central chromium ion to form firm linkage with it.

The present measurement also indicates that both $[Cr(C_6H_6)_2]I$ and $[Cr(C_6H_5CH_3)_2]I$ exhibit an absorption band (Band I′) in the near-infrared region. Since it is known that neither free benzene, toluene nor iodide ion in solution has any absorption bands of this sort, Band I′ in the infrared region can be ascribed to the $[Cr(C_6H_6)_2]^+$ and $[Cr(C_6H_5CH_3)_2]^+$ ion. Band I′ may be characteristic of the chromium(I)-complexes, since the present measurement indicates that $Cr(C_6H_6)(CO)_3$ or $Cr(CO)_6$ has no absorption bands in the corresponding wavelength region.

It is known that, when a metal ion having an unfilled *d*-electron shell forms a complex-group with ligands, a few absorption bands of moderate intensity, rather characteristic of the metal ion, must generally appear in the visible or near-ultraviolet region. In terms of the "ligand field theory", these absorption bands, Bands I and I′, may be ascribed to electronic transitions between the energy levels which are produced by splitting the lowest levels of the free metal ion under the field of the ligands. The chromium(I) ion with a $3d^5$ configuration has an $^2F_2$ level as its lowest level in the very strong ligand field[14]. Therefore, a few ligand field bands should appear corresponding to electronic transitions from the lowest level to the upper levels of the metal with the same multiplicity which might be regarded, in approximation, as produced by splitting from the original $^2I$ of the free chromium(I) ion under the very strong ligand field[14]. Band I′ in the near-infrared region and the inflation at about 76 to $78\times10^{13}$ $sec^{-1}$ (Band I( of $[Cr(C_6H_6)_2]^+$ and $[Cr(C_6H_5CH_3)_2]^+$ seem to belong to this sort of absorption bands.

The appearance of the ligand field bands, rather characteristic of the metal in ordinary metallic coordination compounds, seems to show

14) Y. Tanabe and S. Sugano, *J. Phys. Soc. Japan*, **9**, 766 (1954).

that *the linkage between chromium and the aromatic molecules in the chromium-complexes discussed here is rather similar, at least essentially, to the linkage in complexes of transition elements of a Werner-type, so that the π-electrons on the benzene rings in these compounds are withdrawn to a considerable extent toward the central chromium.*

Bands II and III may be different in their origin from the ligand field bands, judging from their intensity, which seems to be rather too great for the ligand field bands. The two bands seem to be due most probably to electronic transitions closely related with the benzene rings, but may not be regarded as belonging to those bands that are quite identical in their origin to the typical absorption band of free benzene, since Bands II and III show a slight but definite "blue shift" when the solvent is changed from a less polar to a more polar one, whereas the band of free benzene rings is known to show a slight "red shift". It may be assumed that Bands II and III are due to electronic transitions from the orbital principally related with the central metal ion to the excited levels of the benzene rings in the complexes. The fact that the difference $\nu_{III}-\nu_{II}$ is nearly constant for the $[Cr(C_6H_6)_2]^+$ and the $[Cr(C_6H_5CH_3)_2]^+$ ion may be consistent with the assumption presented in this paper about the origin of these absorption bands. The assumption also is borne out by the observation in the present work that the value $\nu_{III}-\nu_{II}$ for $[Cr(C_6H_6)_2]^+$ and $[Cr(C_6H_5CH_3)_2]^+$ is nearly equal to the value for $Cr(C_6H_6)(CO)_3$. This will be reported in the next paragraph of the present paper.

**Ultraviolet Absorption Spectra of Monobenzene-chromium(0) Tricarbonyl.** — Ultraviolet absorption spectra of $Cr(C_6H_6)(CO)_3$ have been determined and are shown in Fig. 3 and Table I. Since the chromium(0) atom in $Cr(C_6H_6)(CO)_3$ with a $3d^6$ configuration has $^1A_1$ as its lowest level in the case of very strong ligand field, the chromium(0)-complexes are expected to show a few ligand field bands which are due to electronic transitions from the $^1A_1$ level to the upper levels of the metal atom with the same multiplicity. In fact, the present measurement indicates that no absorption bands of this sort are apparently observed in the absorption curve of $Cr(C_6H_6)(CO)_3$ in solution. In the opinion of the present authors, the ligand field bands of the compound are situated possibly in the comparatively short wavelength region and seem to be covered partly under the more intense absorption bands. The inflation at about $80\times10^{13}$ sec$^{-1}$ in the curve of the solution most probably represents a ligand field band superposed by more intense absorption bands. A distinct maximum corresponding to the ligand field band is recognized at about the same wavelength in the absorption curve of the crystal, as seen in Fig. 3.

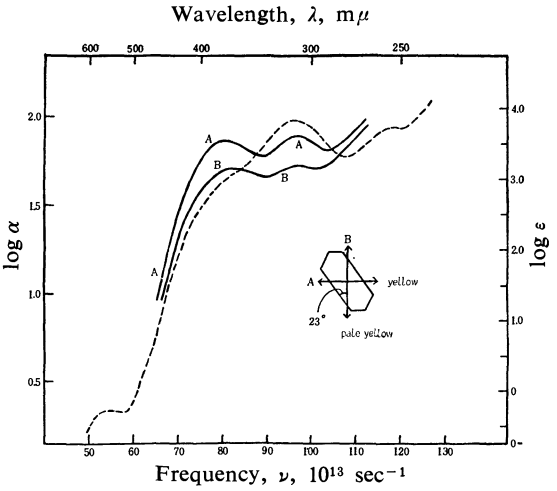

Fig. 3. Ultraviolet absorption spectra of $Cr(C_6H_6)(CO)_3$ in the crystalline state (——) and in methanol (------).

The ultraviolet absorption curve of $Cr(C_6H_6)(CO)_3$ bears a resemblance to that of the $[Cr(C_6H_6)_2]^+$ or the $[Cr(C_6H_5CH_3)_2]^+$ ion excepting that the absorption band in the infrared region, which is observed in the latter complexes, is absent in the former. Thus, the absorption bands at about 86 and $111\times10^{13}$ sec$^{-1}$ of $Cr(C_6H_6)(CO)_3$ in solution apparently correspond to Bands II and III of the $[Cr(C_6H_6)_2]^+$ or the $[Cr(C_6H_5CH_3)_2]^+$ ion, and are regarded as due to the electronic transitions from a level closely related with the central metal to two excited levels of the benzene rings in combination with the metal. It is found that *the difference $\nu_{III}-\nu_{II}$ is almost constant for $[Cr(C_6H_6)_2]I$, $[Cr(C_6H_5CH_3)_2]I$ and $Cr(C_6H_6)(CO)_3$*, it being in agreement with the present assumption about the origin of Bands II and III. The fact that $Cr(C_6H_6)(CO)_3$ shows absorption bands corresponding closely to those of $[Cr(C_6H_6)_2]I$, in spite of the oxidation state of chromium in the former compound which is different from the oxidation state in the latter, seems to indicate that *the linkage of chromium with the aromatic molecule is essentially alike in the above three compounds.* In fact, a recent study with X-rays[15] indicates that a molecule of $Cr(C_6H_6)(CO)_3$ has a structure similar to that of the $[Cr(C_6H_6)_2]^+$ ion having possibly the sandwich structure, the benzene ring in the molecule being parallel to the plane in which the three oxygen atoms are contained.

On the other hand, the absorption spectrum of

15) P. Corradini and G. Allegra, *J. Am. Chem. Soc.*, 81, 2271 (1959).

$Cr(C_6H_6)(CO)_3$ is found to be quite different from the spectrum of $Cr(CO)_6$. Thus, the absorption bands in the ultraviolet region, which are rather characteristic of the metal carbonyls such as $Cr(CO)_6$ and may be due to the electronic transitions closely related with the excited levels of the CO molecules, are missing in $Cr(C_6H_6)(CO)_3$. This fact seems to show that *the linkage of chromium with the CO molecules in* $Cr(C_6H_6)(CO)_3$ *may be different in its nature from the corresponding linkage in* $Cr(CO)_6$. In connection with this, it may be worth noting that mixed carbonyls of wolfram and iron with some isonitriles show

absorption spectra similar to those of $W(CO)_6$ and $Fe(CO)_5$, respectively. The linkage of the metal with the CO molecules in these mixed carbonyls is found to be rather similar to the linkage in the corresponding metal carbonyls.

As seen in Table II, comparison of a CO stretching frequency of $Cr(C_6H_6)(CO)_3$ with the corresponding values of its related compounds gives the following order: free CO > $Cr(CO)_6$ > $Cr(C_6H_6)(CO)_3$. Since the stronger linkage between the carbon and the chromium atom would loosen the linkage between the carbon and the oxygen atom more greatly, the above frequency shift seems to show, at least qualitatively, that *the metal-to-carbon bond in* $Cr(C_6H_6)(CO)_3$ *may be stronger than the corresponding bond in* $Cr(CO)_6$.

As seen in Table III, comparison of a skeletal C–C vibration of a benzene nucleus gives the following order: free $C_6H_6$ > $Cr(C_6H_6)(CO)_3$ > $[Cr(C_6H_6)_2]^+$. Since the displacement of the skeletal C–C vibration from the vibration of free $C_6H_6$ is less in $Cr(C_6H_6)(CO)_3$ than in $[Cr(C_6H_6)_2]^+$, *the linkage of the chromium atom with the benzene molecule may be stronger in the latter than in the former.*

The conclusion that the linkage between the chromium and the carbon of CO is stronger in $Cr(C_6H_6)(CO)_3$ than in $Cr(CO)_6$ is found to be in accordance with the fact that the Cr-C(in CO) distance is shorter in $Cr(C_6H_6)(CO)_3$[15] than in $Cr(CO)_6$[16]. It may also be worth noting that the Cr-C(in $C_6H_6$) distance is longer in $Cr(C_6H_6)(CO)_3$ than in the neutral molecule of $Cr(C_6H_6)_2$[17].

**Dichroism of Monobenzene-chromium Tricarbonyl.**—The results of the dichroism measurement are shown in Fig. 3. A preliminary report on the crystal structure of $Cr(C_6H_6)(CO)_3$ has recently been published, but the more detailed description of the crystal structure is not available. Comparison of the absorption spectra of $Cr(C_6H_6)(CO)_3$ with the spectra of $[Cr(C_6H_6)_2]I$, however, has enabled one to derive the main characteristics of the component absorptions of the former as referred to the principal axes of the molecule. Actually the molecules are not arranged in the crystal with their corresponding molecular axes completely parallel to each other. However, the dichroism of the crystal, as determined in the present work, may be thought to represent the main features of the component absorptions of the molecule.

The absorption band at about $80\times10^{13}$ $sec^{-1}$ of the crystal probably corresponds to the inflation at about the same frequency in the absorption curve of the compound in solution. This band may be regarded as corresponding to the absorption band at about $70\times10^{13}$ $sec^{-1}$ of $[Cr(C_6H_6)_2]I$ in the crystalline state, and may be assigned to one of ligand field bands. It is to be noted that Band II is found to be much weaker in the crystalline state than in solution, as was also found to be the case with $[Cr(C_6H_6)_2]I$.

16) L. O. Brockway, R. V. G. Ewens and M. W. Lister, *Trans. Faraday Soc.*, **34**, 1350 (1938).
17) E. Weiss and E. O. Fischer, *Z. anorg. u. allgem. Chem.*, **286**, 142 (1956).
18) The Z-direction refers to the threefold axis of the molecule of $Cr(C_6H_6)(CO)_3$.

The dichroism for Bands I and II of $Cr(C_6H_6)(CO)_3$ is found to be quite similar to that of $[Cr(C_6H_6)_2]I$ on suitable assumption of the crystal structure. Thus, if it is assumed that A- and B- absorptions in Fig. 3 represent, respectively, the main features characteristic of Z- and X, Y-absorption of the complex-molecule[18], the dichroism of $Cr(C_6H_6)(CO)_3$ seems to be coincident with the dichroism of $[Cr(C_6H_6)_2]^+$. The following relationship may be derived on the dichroism of $[Cr(C_6H_6)_2]I$ and $Cr(C_6H_6)(CO)_3$.

*Z-absorption is stronger than X, Y-absorption for Bands I and II.*

The absorption spectra and the dichroism of these compounds are evidently different from those of free benzene rings. If much aromaticity were kept in the benzene rings within the chromium-complexes, a dichroism similar to the dichroism of the free benzene rings would be observed, just as in most benzene derivatives. Since the dichroism characteristic of the free benzene rings or a band with a fine structure is not observed, the electronic state of the benzene rings in these compounds seems to be far from the state of the free benzene molecule.

The observation that Z-absorption is stronger than X, or Y-absorption for Bands I and II seems to be in good agreement with the concept that *the $\pi$-electrons on the benzene rings in $Cr(C_6H_6)(CO)_3$ are strongly withdrawn toward the chromium atom to form linkage with it.*

A similar type of dichroism was formerly reported with bis-(cyclopentadienyl)-iron(II) and cobalt(III) complexes, where Z-absorption is stronger than X- and Y-absorptions of the complexes for the two absorption bands in the long wavelength region[19]. This relationship also was taken as evidence that the $\pi$-electrons on the pentagonal rings are withdrawn considerably toward the metal atom to form firm bonds with it.

**Weak Absorption Bands in the Long Wavelength Region.**—The present measurement indicates that $Cr(CO)_6$, $[Cr(C_6H_6)_2]^+$ and $[Cr(C_6H_5CH_3)_2]^+$ all display a very weak band system in the long wavelength side. A part in the shorter wavelength region of the weak band is covered by much stronger absorption bands. It is theoretically known that the electronic transitions between levels with different multiplicities are strictly forbidden, appearing in most cases as very weak absorption bands. Thus, chromium(III)-complexes are known to display a spin-forbidden band with very small intensity to the long wavelength side of the ligand field absorption band[20]. In a similar way, the very weak absorption band systems of $Cr(CO)_6$ or $[Cr(C_6H_6)_2]^+$ may most probably correspond to the spin-forbidden bands which are due principally to chromium(0) or chromium(I). The spin-forbidden bands may tentatively be assigned to electronic transitions from the ground state $^1A_1$ to $^3F_1$ and $^3F_2$ in the case of chromium(0), and to transitions from the ground state $^2F_2$ to $^4F_1$ and $^4F_2$ in the case of chromium(I).

The solvent effect upon this type of the weak absorption bands has been examined, and is shown in Table IV. It is found that the band undergoes a slight "red shift" with the compounds examined here.

TABLE IV. SPIN-FORBIDDEN ABSORPTION BANDS

| Compounds | Solvent | $\nu$ | log $\varepsilon$ |
|---|---|---|---|
| $[Cr(C_6H_6)_2]I$ | water | 52 | $\bar{1}.80$ |
| $[Cr(C_6H_5CH_3)_2]I$ | water | 52.5 | $\bar{1}.90$ |
| | ethanol | 53 | $\bar{1}.90$ |
| $Cr(C_6H_6)(CO)_3$ | methanol | 53-4 | $\bar{1}.8$ |
| | ethanol | 55-6 | — |
| $Cr(CO)_6$ | methanol | 67.5 | 0.47 |
| | ethanol | 68.5 | 0.45 |

$\nu$: $10^{13}$ $sec^{-1}$

The present measurement also indicates that the spin-forbidden bands are displaced to the shorter wavelength region, as the ligand field bands are displaced to the same direction in the following series: $[Cr(C_6H_6)_2]^+$, $Cr(C_6H_6)(CO)_3$, $Cr(CO)_6$.
