# *Syntheses of Peptides Related to the N-Terminal Structure of Corticotropin. I. Synthesis of Ser-Tyr-Ser-Met Sequence*

By Ken INOUYE and Hideo OTSUKA

(Received May 31, 1960)

The hypophyseal polypeptide hormones, the corticotropin and melanocyte-stimulating hormone (MSH), have a common amino acid sequence within their structures[1,2].

By Harris and Lerner[1,3] it has been shown that hog $\alpha$-MSH is an *N*-acetyltridecapeptide amide and its amino acid sequence, Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Try-Gly-Lys-Pro-Val, is identical with that occurring in the first tridecapeptide portion of corticotropin. This evidence affords a chemical basis for the intrinsic MSH activity[4,5] of corticotropin.

Considerably large fragments can be enzymatically or chemically removed from the carboxyl end of the molecule of corticotropin without loss of its biological activity[6]. While it has been reported that periodate oxidation of the *N*-terminal serine of corticotropin[7] or the cleavage of peptide bonds in the *N*-terminal Ser-Tyr-Ser segment of the molecule[6] results in complete depression of its ACTH activity, at the same time significant increase in the melanocyte expanding activity is observed[7].

The further detailed relationship between the two biological activities and the chemical structure must await the synthetic studies of active polypeptides.

Synthesis of *N*-terminal twenty sequence of corticotropin was done by Boissonnas et al. and the product exhibited a positive though limited ACTH activity[8]. Guttmann and Boissonnas[9] have recently synthesized the complete structure of $\alpha$-MSH and the synthetic hormone has been shown to possess the same properties as those of the natural hog $\alpha$-MSH. Hofmann et al. have reported that the blocked tridecapeptide amide, Cbz-Ser-Tyr-Ser-Met-Glu($NH_2$)-His-Phe-Arg-Try-Gly-($\varepsilon$-Tos)-Lys-Pro-Val-$NH_2$, has $0.8\times10^8$ MSH units per gram[10] and the replacement of the carbobenzoxy group with an acetyl group results in some twenty-five fold increase in its activity[11]. The substituted polypeptide sequence of $\beta$-MSH has also been synthesized by Schwyzer et al.[12]

Here we wish to write concerning a part of our studies of synthetic peptides corresponding to the amino acid sequence common to corticotropin and $\alpha$-MSH. The synthesis of Ser-Tyr-Ser-Met sequence will be described.

In the syntheses of serine-containing peptides we used *O*-benzylserine[13,14] as a starting material in place of serine to avoid unexpected side reactions which may be caused by the presence of the free hydroxyl group of the latter.

Carbobenzoxy-*O*-benzylseryltyrosine and -*O*-benzylserylmethionine methyl esters were obtained in good yields as compared with the corresponding serylpeptide derivatives[15,16], though as for the method of coupling, the anhydride procedure was different from the procedures used by the others.

The advantageous effect of *O*-benzylserine is much more remarkable in saponification of the peptide esters with alkali. It has been reported that the saponification of carbobenzoxyseryltyrosine methyl[16] or ethyl[15] ester gave only a 50 per cent yield of the desired product and the yield of carbobenzoxyserylmethionine was also significantly low (67%)[15]. However, we could derive carbobenzoxy-*O*-benzylseryltyrosine and -*O*-benzylserylmethionine and formyl-*O*-benzylserylmethionine in very high yields (near 90%) from the preceding methyl esters. The peptide bonds adjacent to the serine residues in corticotropin are sensitive to any alkali treatment[6] and Guttmann and

Boissonnas[16] have, moreover, shown the fact that the saponification of serine peptide esters is accompanied by the cleavage of peptide bond at the carboxyl side of serine residue. However, we could not observe such a fact in regard to the *O*-benzylserine peptides.

On removal of carbobenzoxy and *O*-benzyl groups from carbobenzoxy-*O*-benzylserylmethionine methyl ester by hydrobromic acid/acetic acid or catalytic hydrogenation we failed to obtain the desired dipeptide ester, presumably because of the instability of the thioether bond. Sheehan and Yang[17] have shown that a formyl group, which is easily removed by mild acid solvolysis, can be used on peptide syntheses as an amino protecting function in conjugation with the carbodiimide procedure without racemization of the products. Following this procedure, formyl-*O*-benzylserine and methionine methyl ester were coupled with *N*, *N'*-dicyclohexylcarbodiimide (DCCI) to give formyl-*O*-benzylserylmethionine methyl ester which could be deformylated to *O*-benzylserylmethionine methyl ester without any difficulties.

Coupling of carbobenzoxy-*O*-benzylseryltyrosine with *O*-benzylserylmethionine methyl ester by DCCI yielded almost quantitatively the acyltetrapeptide ester, carbobenzoxy-*O*-benzylseryltyrosyl-*O*-benzylserylmethionine methyl ester in crystalline form.

## Experimental

All amino acids used are of L-configuration. The melting point was determined in a capillary tube in a sulfuric acid bath and not corrected.

**O-Benzylserine Methyl Ester Hydrochloride.**—To 20 ml. of anhydrous methanol previously cooled below −10°C, was added dropwise 1.33 ml. (0.0184 mol.) of thionylchloride and then 3 g. (0.0154 mol.) of *O*-benzylserine was introduced[13,14]. The mixture was stirred for 1.5 hr. at room temperature and then allowed to stand overnight. The resulting clear solution was evaporated under reduced pressure. The residue was crystallized from acetone-ether to give 3.44 g. (91%). Recrystallization from methanol-ether yielded needles, m. p. 141.5~142°C with decomposition.

Found: N, 5.86; Cl, 14.41. Calcd. for $C_{11}H_{16}O_3 \cdot NCl$: N, 5.69; Cl, 14.43%.

***N*-Formyl-*O*-benzylserine.**—This was prepared after the usual procedure for optically active formylamino acids of Sheehan and Yang[17]. 1.95 g. of *O*-benzylserine was formylated and the product was recrystallized from water to give 1.77 g., m. p. 137.5~138.5°C, $[\alpha]_D^{26} = +52.9 \pm 1°$ (*c* 2.613 in ethanol).

Found: C, 59.31; H, 6.03; N, 6.39. Calcd. for $C_{11}H_{13}O_4N$: C, 59.3; H, 5.88; N, 6.29%.

***N*-Carbobenzoxy-*O*-benzylseryltyrosine Methyl Ester.**—To a solution of 8.23 g. (0.025 mol.) of *N*-carbobenzoxy-*O*-benzylserine[18] (m. p. 100.5~101°C, $[\alpha]_D^{22} = +12.0 \pm 2°$ (*c* 2.448 in acetic acid)) in 75 ml. of tetrahydrofuran/dioxane (1 : 4) were added 6.56 ml. (0.0275 mol.) of tri-*n*-butylamine and 2.63 ml. (0.0275 mol.) of ethylchloroformate at −5°C. After 15 min. a solution of tyrosine methyl ester (prepared from 6.37 g. (0.0275 mol.) of the hydrochloride[19] and 4.23 ml. (0.030 mol.) of triethylamine) in 8 ml. water and 32 ml. dioxane was introduced. The reaction mixture was stirred at room temperature for 4 hr. and evaporated under reduced pressure. The residue dissolved in 150 ml. of ethyl acetate was successively washed with 1N hydrochloric acid, water, 5% sodium bicarbonate and water and dried over sodium sulfate. The solution was evaporated to a syrupy residue which was crystallized from methanol-ethyl acetate-petroleum ether, 12.3 g. (97.2%), m.p. 108~111.5°C. Recrystallization from ethyl acetate-petroleum ether yielded 10.2 g. (80.6%), m. p. 112~114.5°C, $[\alpha]_D^{19} = +14.6 \pm 2°$ (*c* 3.068 in 99% ethanol). (lit.[18] m. p. 111~112°C, $[\alpha]_D^{15} = +15.5°$ (*c* 2.84 in 99% ethanol).

Found: C, 66.32; H, 6.13; N, 5.41. Calcd. for $C_{28}H_{39}O_7N_2$: C, 66.3; H, 5.97; N, 5.53%.

***N*-Carbobenzoxy-*O*-benzylseryltyrosine.**—2.533 g. (0.005 mol.) of *N*-carbobenzoxy-*O*-benzylseryltyrosine methyl ester was saponified in 12.5 ml. of methanol with 5.0 ml. (0.01 mol.) of 2N Sodium hydroxide at room temperature for one hour, yielding 2.34 g. (95.0%). Recrystallization from ethyl acetate-petroleum ether gave 2.20 g. (89.5%), m. p. 158.5~159.5°C, $[\alpha]_D^{23} = +39.4 \pm 1°$ (*c* 2.086 in ethanol).

Found: C, 65.38; H, 5.88; N, 5.72. Calcd. for $C_{27}H_{28}O_7N_2$: C, 65.6; H, 5.74; N, 5.70%.

***N*-Carbobenzoxy-*O*-benzylserylmethionine Methyl Ester.**—4.12 g. (0.0125 mol.) of *N*-carbobenzoxy-*O*-benzylserine and methionine methyl ester (prepared from 2.80 g. (0.014 mol.) of the hydrochloride) were coupled in a tetrahydrofuran/dioxane solution almost exactly as in the case of *N*-carbobenzoxy-*O*-benzylseryltyrosine methyl ester. Yield 5.1 g. (86%), m. p. 69.0~70.5°C. Recrystallization for analysis from ethyl acetate-petroleum ether gave a sample with m. p. 69.5~71°C.

Found: C, 60.56; H, 6.48; N, 5.76. Calcd. for $C_{24}H_{30}O_6N_2S$: C, 60.8; H, 6.38; N, 5.91%.

***N*-Carbobenzoxy-*O*-benzylserylmethionine.**—3.56 g. (0.0075 mol.) of *N*-carbobenzoxy-*O*-benzylserylmethionine methyl ester was saponified in 18 ml. of methanol with 4.2 ml. of 2N sodium hydroxide at room temperature for 30 min. The product was recrystallized from ethyl acetate-ether to yield 3.17 g. (92%), m. p. 152~152.5°C.

Found: N, 5.95; S, 7.00. Calcd. for $C_{23}H_{28}O_6 \cdot N_2S$: N, 6.09; S, 6.97%.

***N*-Formyl-*O*-benzylserylmethionine Methyl Ester.**—To a suspension of 6.59 g. (0.033 mol.) of methionine methyl ester hydrochloride in 50 ml. of ether was added 20 ml. of ice-cold 50% potassium carbonate. The mixture was shaken at 0°C until the solid disappeared. The ether layer which separated was dried over sodium sulfate at 0°C and concentrated

in vacuo to an oil. This oily residue was dissolved in 50 ml. of methylene chloride and the solution was mixed with a suspension of 6.69 g. (0.03 mol.) of *N*-formyl-*O*-benzylserine in 50 ml. of methylene chloride. To the resulting clear solution was added at 0°C 6.20 g. (0.03 mol.) of dicyclohexylcarbodiimide dissolved in 15 ml. of methylene chloride. The reaction mixture was stirred at room temperature for 5 hr. and then refrigerated. The separated dicyclohexylurea was collected by filtration, yielding 6.45 g. (95.8%). The filtrate was cooled in ice, washed with ice-cold 1 N hydrochloric acid, ice-water, 5% sodium bicarbonate and finally with water and dried over sodium sulfate. The concentration of the solution gave a syrupy residue which was crystallized from tetrahydrofuran-ether to yield colored needles, 7.55 g., m. p. 73~76°C. An additional 1.0 g. of crystal was obtained from the mother liquor. Total yield, 8.55 g. (77.4%). These crops, reddish orange in color, were combined and dissolved in ethyl acetate and chromatographed on 125 g. of aluminum oxide. Elution with the same solvent gave colorless fractions which were combined and concentrated in vacuo. Crystallization of the resulting syrup from ethyl acetate ether yielded colorless and odorless needles, 7.025 g. (63.5%), m. p. 78.5~79.5°C, $[\alpha]_D^{25} = -23.2 \pm 1°$ (*c* 2.08 in methanol).

Found: C, 55.84; H, 6.84; N, 7.42; S, 8.69. Calcd. for $C_{17}H_{24}O_5N_2S$: C, 55.5; H, 6.57; N, 7.61; S, 8.70%.

***N*-Formyl-*O*-benzylserylmethionine.** — 1.54 g. (0.0042 mol.) of *N*-formyl-*O*-benzylserylmethionine methyl ester was saponified in 11 ml. of dioxane with an equivalent amount of 1 N sodium hydroxide at room temperature for one hour. The resulting solution was diluted with ice-water to 30 ml. and neutralized with ice-cold 1 N hydrochloric acid to a separate crystalline precipitate, 1.30 g. (87.8%), m. p. 161~162°C. Recrystallization from ethanol-water gave 1.19 g. of needles, m. p. 163°C, $[\alpha]_D^{16} = -8.8 \pm 2°$ (*c* 2.095 in methanol).

Found: C, 54.49; H, 6.41; N, 7.96; S, 9.13. Calcd. for $C_{16}H_{22}O_5N_2S$: C, 54.20; H, 6.24; N, 7.88; S, 9.03%.

***O*-Benzylserylmethionine Methyl Ester.**—4.42 g. (0.012 mol.) of formyl-*O*-benzylserylmethionine methyl ester was dissolved in 40 ml. of *N*-methanolic hydrochloric acid and stored at room temperature overnight. After most of the methanol had been removed in vacuo the resulting colored syrup was dissolved in 40 ml. of water and washed several times with ethyl acetate. The colorless aqueous solution was concentrated in vacuo to a small volume and mixed with 15 ml. of 50% potassium carbonate and 40 ml. of ether at 0°C. The ether layer was separated and the alkaline phase was twice extracted with ether. The combined ether solution was dried over sodium sulfate at 0°C and concentrated to give a colorless and clear oil, 3.95 g. (97%). A sample was chromatographed on paper in the system of *n*-butanol-acetic acid-water (2 : 1 : 2) and only one spot positive to both ninhydrin and $PtI_6^{2-}$ reagent[20] was detected.

***N*-Carbobenzoxy-*O*-benzylseryltyrosyl-*O*-benzylserylmethionine Methyl Ester.**—4.925 g. (0.01 mol.) of *N*-carbobenzoxy-*O*-benzylseryltyrosine and 3.95 g. of *O*-benzylserylmethionine methyl ester were dissolved in 80 ml. of methylene chloride. To this birefringent solution was added 2.063 g. (0.01 mol.) of dicyclohexylcarbodiimide in 20 ml. of methylene chloride at 0°C and the reaction mixture was stirred at room temperature. The birefringence of flow almost completely disappeared in about 10 min. as the crystalline dicyclohexylurea separated. After the stirring had been continued for 3 hr. the mixture was stored at room temperature overnight to turn into a semi-solid state. It was returned to a solution by gentle warming at the boiling point and the insoluble urea was filtered off. The filtrate was concentrated to dryness in vacuo and the resulting solid was recrystallized from ethyl acetate-ether to yield 8.03 g. (98.7%), m. p. 163~167°C. Repeated recrystallization from methylene chloride-ether afforded 7.00 g. (86%), m. p. 166~169°C. A sample for analyses was further recrystallized from methanol to needles, m. p. 171~173°C, $[\alpha]_D^{20} = -12.9 \pm 0.1°$ (*c* 1.986 in methanol), $[\alpha]_D^{26} = -16.1 \pm 1°$ (*c* 2.008 in dimethylformamide).

Found: C, 63.54; H, 6.34; N, 6.95; S. 3.87. Calcd. for $C_{43}H_{50}O_{10}N_4S$: C, 63.5; H, 6.19; N, 6.88; S, 3.84%.

## Summary

1. Carbobenzoxy-*O*-benzylseryltyrosyl-*O*-benzylserylmethionine methyl ester, which has the *N*-terminal tetrapeptide sequence of corticotropin and $\alpha$-MSH, has been synthesized.

2. It has been shown that the *O*-benzylseryl peptide bond is very stable to an alkali treatment.

3. Syntheses of the relating serine peptide derivatives have been described.

The authors are indebted to Mr. Makoto Kanayama for valuable technical assistance.

# *Syntheses of Peptides Related to the N-Terminal Structure of Corticotropin. II. Synthesis of Gly-Lys-Pro-Val Sequence*

By Ken INOUYE and Hideo OTSUKA

(Received June 27, 1960)

The sequence, Gly-Lys-Pro-Val is found at positions 10 to 13 in corticotropin and α-MSH[1]. Boissonnas et al.[2,3] synthesized this sequence in the form of tritylglycyl-ε-carbobenzoxylysylprolylvaline methyl ester from the preceding intermediates, tritylglycyl-ε-carbobenzoxylysine (methyl ester) and (carbobenzoxy-)prolylvaline methyl ester, none of which have yet been obtained in any crystalline states.

In connection with our synthetic studies on the *N*-terminal structure of corticotropin we have now obtained this tetrapeptide sequence in another form, formylglycyl-ε-carbobenzoxylysylprolylvaline benzyl ester.

Formylglycine and ε-carbobenzoxylysine methyl ester were coupled in methylene chloride by the use of *N, N'*-dicyclohexylcarbodiimide to give formylglycyl-ε-carbobenzoxylysine methyl ester which was converted by saponification into formylglycyl-ε-carbobenzoxylysine. Both of these dipeptide derivatives were obtained in good yields and in crystalline states. When the coupling was done in dimethylformamide solution the yield of the desired product was less than 30 per cent and in addition a side product, formylglycyl-*N, N'*-dicyclohexylurea was isolated. The mixed acid anhydride procedure also notably lowered the yield and purity of the product.

Carbobenzoxypropoline was condensed with valine benzyl ester by the mixed anhydride method to carbobenzoxyprolylvaline benzyl ester which was easily crystallized. This was then decarbobenzoxylated with hydrogen bromide in glacial acetic acid and the resulting ester hydrobromide was treated with potassium carbonate to the free base.

Coupling of formylglycyl-ε-carbobenzoxylysine with prolylvaline benzyl ester by *N, N'*-dicyclohexylcarbodiimide yielded the tetrapeptide, formylglycyl-ε-carbobenzoxylysylprolylvaline benzyl ester as an amorphous solid. This product was negative to the ninhydrin test and after deformylation with *N*-methanolic hydrochloric acid gave only one spot on the paperchromatogram sprayed with ninhydrin. The complete acid hydrolysate was subjected to the quantitative amino acid analysis and was shown to be composed of glycine, lysine proline and valine in the molar ratio as expected.

## Experimental

All amino acids used are of L-configuration. The melting point was determined in a capillary tube in a sulfuric acid bath and not corrected.

**Formylglycine.**—This was prepared after the usual procedure for DL-formylamino acids of Sheehan and Yang[4]. 3.75 g. of glycine was formylated and the product was recrystallized from water to give 4.20 g. (81.6%), m. p. 149°C with decomposition.

Found: C, 35.12; H, 4.99; N, 13.35. Calcd. for $C_3H_5O_3N$: C, 35.0; H, 4.89; N, 13.6%.

**Formylglycyl-ε-carbobenzoxylysine Methyl Ester.**—To a suspension of 9.10 g. (0.0275 mol.) of ε-carbobenzoxylysine methyl ester hydrochloride[5] in ether was added 23 ml. of ice-cold 50% potassium carbonate. The mixture was shaken and the organic layer separated was dried over sodium sulfate at 0°C. After removal of the solvent in vacuo the oily residue was dissolved in 115 ml. of methylene chloride and 2.58 g. (0.025 mol.) of formylglycine was added. As soon as most of the formylglycine had dissolved, 5.16 g. (0.025 mol.) of *N, N'*-dicyclohexylcarbodiimide in 25 ml. of methylene chloride was quickly added. The mixture was stirred for five hours and allowed to stand overnight at room temperature and refrigerated. The separated dicyclohexylurea was collected by filtration, yielding 5.45 g. (97.2%). The filtrate was cooled at 0°C, washed successively with ice-cold 1 N hydrochloric acid, water, 5% sodium bicarbonate and water and dried over sodium sulfate. Evaporation of the solvent in vacuo gave a clear syrup which was crystallized from methylene chloride-ether. Yield 8.93 g. (94.3 %). This was recrystallized from ethyl acetate-ether to give 8.40 g. (88.7%), m. p. 76~78°C, $[\alpha]_D^{24} = -10.3 \pm 2°$ (*c* 2.901 in methanol).

Found: C, 57.02; H, 6.81; N, 10.89. Calcd. for $C_{18}H_{25}O_6N_3$: C, 57.1; H, 6.60; N, 11.0%.

When dimethylformamide was used as a solvent for this coupling reaction there was obtained, in

addition to the desired peptide (in a 30% yield), a side product, formylglycyl-*N*,*N'*-dicyclohexylurea, m. p. 164.5~165.5°C.

Found: C, 62.46; H, 8.97; N, 13.69. Calcd. for $C_{16}H_{27}O_3N_3$: C, 62.2; H, 8.81; N, 13.6%.

**Formylglycyl-ε-carbobenzoxylysine.**—To a solution of 3.79 g. (0.01 mol.) of formylglycyl-ε-carbobenzoxylysine methyl ester in 27.5 ml. of dioxane was added 11 ml. of 1 N sodium hydroxide and the mixture was stirred at room temperature for one hour. After removal of a slight amount of insoluble precipitates the solution was diluted with water to about 80 ml., neutralized with 11 ml. of ice-cold 1 N hydrochloric acid and concentrated to about 25 ml. under reduced pressure. The concentrate was stored at 0°C overnight to complete the separation of crystals, 3.47 g. (95.1%). Recrystallization from water gave 3.28 g. (89.8%), m. p. 144~146°C, $[\alpha]_D^{24} = +13.1 \pm 0.2°$ (*c* 1.358 in methanol).

Found: C, 56.27; H, 6.33; N, 11.56. Calcd. for $C_{17}H_{23}O_6N_3$: C, 56.0; H, 6.35; N, 11.5%.

**Carbobenzoxyproline**[6]. — 4.6 g. (0.04 mol.) of proline was carbobenzoxylated with 8 g. of benzylchloroformate in 30 ml. of 2 N sodium hydroxide at 0°C. When the reaction was over the solution was washed with ether to remove an excess of benzylchloroformate and acidified. The product was taken up into ethyl acetate and the extract was shaken with 5% sodium bicarbonate. The aqueous solution was acidified and reextracted with ethyl acetate. The organic extract was dried over sodium sulfate and concentrated in vacuo to a syrup which was crystallized from carbon tetrachloride-petroleum ether (1 : 2) to give 9.47 g. (95.3%), m. p. 75~78°C. Recrystallization from the same solvent afforded 9.30 g., m. p. 76~78°C, $[\alpha]_D^{29} = -57.7 \pm 2°$ (*c* 0.975 in glacial acetic acid) (in lit.[6], m. p. 76~77°C, $[\alpha]_D^{20} = -61.7°$ (*c* 5.3 in glacial acetic acid).

Found: C, 62.98; H, 6.05; N, 5.89. Calcd. for $C_{13}H_{15}O_4N$: C, 62.75; H, 6.08; N, 5.63%.

**Valine Benzyl Ester Hydrochloride.**—A mixture of 4 g. of valine and 10 g. of *p*-toluenesulfonic acid monohydrate in 40 ml. of benzyl alcohol was stirred on an oil bath at 100°C (internal temperature). To this solution were added 40 ml. portions of carbon tetrachloride at one hour intervals and distilled out from a side-arm. After 8 hr. the remaining carbon tetrachloride was completely removed under reduced pressure and the crude ester *p*-toluenesulfonate was precipitated with the addition of ether, 10.0 g., m. p. 157~159°C. 10.0 g. of the crystal obtained above was suspended in 150 ml. of ether and mixed with 40 ml. of ice-cold 50% potassium carbonate. The insoluble precipitate was filtered off and the ether layer was dried over sodium sulfate at 0°C. Dry hydrogen chloride gas was bubbled into this ether solution to separate the desired ester hydrochloride, 6.3 g., m. p. 137~139.5°C. Recrystallization from chloroform-ether afforded 6.1 g., m. p. 139~141°C, $[\alpha]_D^{29} = -12.7 \pm 4°$ (*c* 0.495 in 0.1 N hydrochloric acid).

Found: N, 5.76; Cl, 14.50. Calcd. for $C_{12}H_{18}O_2NCl$: N, 5.75; Cl, 14.60%.

6) A. Berger, J. Kurtz and E. Katchalski, *J. Am. Chem. Soc.*, **76**, 5552 (1954).

**Carbobenzoxyprolylvaline Benzyl Ester.**—To a mixture of 2.49 g. (0.01 mol.) of carbobenzoxyproline and 2.39 ml. (0.01 mol.) of tri-*n*-butylamine in 10 ml. of tetrahydrofuran was added 0.96 ml. (0.01 mol.) of ethylchloroformate at −10°C. After 15 min. a solution of 2.44 g. (0.01 mol.) of valine benzyl ester hydrochloride and 2.39 ml. (0.01 mol.) of tri-*n*-butylamine in 10 ml. of tetrahydrofuran was introduced and the reaction mixture was then stirred at room temperature for 5 hr. and concentrated under reduced pressure. The syrupy residue was dissolved in 35 ml. of ethyl acetate, successively washed with 1 N hydrochloric acid, 15% sodium chloride, 5% sodium bicarbonate, and with 15% sodium chloride, and dried over sodium sulfate. The ethyl acetate solution was concentrated to about 10 ml. in vacuo and to this was added petroleum ether to separate an oily precipitate which was soon crystallized in needles, 4.0 g. (91.3%), m. p. 87~91°C. Recrystallization from the same solvent gave thin needles, m. p. 91~92°C, $[\alpha]_D^{29} = -78.6 \pm 1°$ (*c* 1.749 in methanol).

Found: C, 68.40; H, 6.96; N, 6.37. Calcd. for $C_{25}H_{30}O_5N_2$: C, 68.4; H, 6.90; N, 6.39%.

**Prolylvaline Benzyl Ester.**—2.63 g. (0.006 mol.) of carbobenzoxyprolylvaline benzyl ester was dissolved in 15 ml. of 21.2% (w/w) hydromromic acid/glacial acetic acid and the mixture was allowed to stand at room temperature for 50 min. at the end of which time about 80 ml. of anhydrous ether was added. The supernatant was decanted and an oily residue was dissolved in 10 ml. of water and washed twice with ether. A small aliquot of this aqueous solution was chromatographed on paper in the system of *n*-butanol-acetic acid-water (4 : 1 : 2) and there were detected two components which gave yellow spots with ninhydrin. The minor component with the lower $R_f$ value is possibly due to prolylvaline, and it may be found that the benzyl ester is cleaved to some extent under the conditions used, but no other side reactions take place.

The aqueous solution of the crude ester hydrobromide was then concentrated to a small volume in vacuo and shaken with 20 ml. of ether and 10 ml. of 50% potassium carbonate at −10°C. The aqueous phase was extracted with additional ether. The combined ether extract was dried over sodium sulfate at 0°C and evaporated in vacuo to an oil, 1.47 g. which was directly used for the following coupling reaction.

**Formylglycyl-ε-carbobenzoxylysylprolylvaline Benzyl Ester.**—The prolylvaline benzyl ester obtained above was dissolved in 30 ml. of methylene chloride and 1.28 g. (0.0035 mol.) of formylglycyl-ε-carbobenzoxylysine was adedd. The mixture was stirred at 0°C to give a homogeneous but somewhat cloudy solution in 15 min. To this solution was then added 0.723 g. (0.0035 mol.) of *N*,*N'*-dicyclohexylcarbodiimide and the reaction mixture was stirred at room temperature for five hours and allowed to stand overnight at 4°C. Separated dicyclohexylurea was removed by filtration, 0.739 g. (94.3%) and the filtrate was concentrated in vacuo. A syrupy residue was dissolved in ethyl acetate and washed with ice-cold 1 N hydrochloric acid, water, 5% sodium bicarbonate and finally with water and

dried over sodium sulfate. Concentration of the ethyl acetate solution in vacuo gave a foamy residue which was dried over phosphorus pentoxide at room temperature in high vacuum to afford 2.22 g. (97.5%) as colorless powder, $[\alpha]_D^{18} = -62.2 \pm 0.1°$ (*c* 2.505 in methanol).

Found: C, 62.13; H, 7.43; N, 10.54. Calcd. for $C_{34}H_{45}O_8N_5$: C, 62.7; H, 6.97; N, 10.7%.

This product gave a negative ninhydrin test and after treatment with 1N methanolic hydrochloric acid for 16 hr. only one spot[7] was visible on a paper-chromatogram which was developed in *n*-butanol-acetic acid-water (4 : 1 : 2) and sprayed with ninhydrin.

A sample of the tetrapeptide derivative was hydrolyzed with 6N hydrochloric acid at 100°C for 20 hr. and the hydrolysate was subjected to quantitative amino acid analysis by the method of Levy[8]. It was found that the product had a composition of Gly/Lys/Pro/Val in a molar ratio of 1.0/1.1/0.9/1.1.

7) The color of this spot changed with time from yellow to purple. Such a phenomenon has often been observed in glycylpeptides (K. Narita, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **75**, 487 (1954)).

## Summary

Formylglycyl-ε-carbobenzoxylysylprolylvaline benzyl ester, which has a sequence occurring in corticotropin and α-MSH, has been synthesized.

The authors are indebted to Mr. Makoto Kanayama for valuable technical assistance.

# *Calculation on the Electronic States of the Acrolein Molecule by the Semi-Empirical Molecular Orbital Method*

By Kōzō Inuzuka

(Received May 31, 1960)

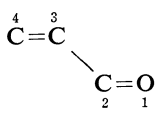
It is known that the semi-empirical molecular orbital method proposed by Pariser and Parr[1] gives good agreement with observation for the $\pi-\pi^*$ transitions of conjugated hydrocarbons and heteromolecules. Anno et al.[2-4] used the Pariser-Parr method to calculate the electronic state energies of some molecules containing C=O and N atoms, obtaining reasonably good agreement between calculated and observed values. Eastwood and Snow[5] have carried out a detailed vibrational analysis for the $n-\pi^*$ absorption spectrum of acrolein, while the experiment in vacuum ultraviolet region was done by Walsh[6]. In a previous paper[7] we were not certain whether or not the very weak band at 24647 $cm^{-1}$ in acrolein spectrum was due to a singlet-triplet transition. In order to get some information about the electronic state energies of the acrolein molecule, we calculated the electronic states of acrolein by the Pariser-Parr method which is expected also to yield successful results for the electronic state energies of some molecules exhibiting $n-\pi^*$ transitions.

## Calculation and Results

The calculation of the electronic state energies of acrolein was done with the semi-empirical method proposed by the previous authors[1-3]. The $\pi$-MO's take in this paper are

$$\phi_1=1/2(\chi_1^O+\chi_2^C+\chi_3^C+\chi_4^C)$$
$$\phi_2=1/2(\chi_1^O+\chi_2^C-\chi_3^C-\chi_4^C)$$
$$\phi_3=1/2(\chi_1^O-\chi_2^C-\chi_3^C+\chi_4^C)$$
$$\phi_4=1/2(\chi_1^O-\chi_2^C+\chi_3^C-\chi_4^C)$$

where $\chi_1^O$, $\chi_2^C$, $\chi_3^C$ and $\chi_4^C$ are $2p\pi$AO's of the oxygen and carbon atoms.



In addition to the above orbitals the acrolein molecule has a nonbonding orbital which can approximately be represented as follows:

$$\phi_n=\chi_n^O$$

$\chi_n^O$ being the $2p\pi$AO of the oxygen atom, the nodal plane of which is perpendicular to the

7) K. Inuzuka, This Bulletin, **33**, 678 (1960).

molecular plane and contains the CO axis. The electron diffraction study of the acrolein molecule in the ground electronic state[8] shows that it is planar, having the following bond lengths and bond angles

$r_{12}=1.21\pm0.02$ Å
$r_{23}=1.46\pm0.03$ Å
$r_{34}=1.36\pm0.02$ Å
$\angle\gamma_{123}=\angle\gamma_{234}=120\pm3°$

Since the molecule belongs to the point group Cs, all the transition are symmetry-allowed. The energy integrals which appear in this calculation were evaluated according to the equation derived by Roothaan[9] and by Anno et al.[2] for the case of $r>2.80$ Å and of $r<2.80$ Å, respectively. We used Kon's formula[10] for the conculation of core integral $\beta_{CO}$ between carbon and oxygen atoms, and the Pariser-Parr formula for $\beta_{CC}$ between carbon and carbon atoms. For the evaluation of core integrals the Coulomb penetration integrals between next-neighboring neutral atoms were taken into consideration, and since we restricted the calculation of energy state up to 10 eV., singly and doubly excited electronic configurations[11] were taken in the calculation of energies for the excited electronic state. Since it is known that the calculation of energy state in $\pi-\pi^*$ transition usually results in a good agreement with the observed value without configuration interaction[12], we did not include the configuration interaction. On the other hand, as for $n-\pi^*$ transition the configuration interaction was taken into account but all the configurations more than 10 eV. higher than the ground configuration were neglected. Even for the configurations considered, we imposed the condition to reduce the order of the C. I. matrix: $(H_{ij}/H_{ii}-H_{jj})^2>1/10$, where $H_{ij}$ is the interaction matrix element between the configurations i and j. Neglected configurations within the 10 eV. energy range were taken into account by the second order perturbation theory. Calculated energy values are shown in Table I. From this result it is seen that in acrolein the $(n, \pi^*)$ triplet state is the lowest excited electronic state.

TABLE I. TRANSITION ENERGIES OF $n-\pi^*$ AND $\pi-\pi^*$ TRANSITIONS OF ACROLEIN MOLECULE

| Orbital jump | Electronic transition | Transition energy no C.I. eV. | Transition energy including C.I. eV. | Experimental eV. |
|---|---|---|---|---|
| $n-\pi_3$ | $^3A'\leftarrow{}^1A''$ | 5.55 | 2.85 | |
| $n-\pi_3$ | $^1A'\leftarrow{}^1A''$ | 5.98 | 3.85 | 3.71 |
| $n-\pi_4$ | $^3A'\leftarrow{}^1A''$ | 7.23 | 6.00 | |
| $n-\pi_4$ | $^1A'\leftarrow{}^1A''$ | 7.66 | 6.53 | |
| $\pi_2, n-\pi_3$, $\pi_3$ | $^3A'\leftarrow{}^1A''$ | 10.68 | 7.86 | |
| $\pi_2, n-\pi_3$, $\pi_3$ | $^1A'\leftarrow{}^1A''$ | 11.11 | 8.36 | |
| $\pi_2-\pi_3$ | $^3A'\leftarrow{}^1A'$ | 4.17 | | |
| $\pi_2-\pi_3$ | $^1A'\leftarrow{}^1A'$ | 6.08 | | 5.96 |
| $\pi_2-\pi_4$, $\pi_1-\pi_3$ | $^3A'\leftarrow{}^1A'$ | 5.85 | | |
| $\pi_2-\pi_4$, $\pi_2-\pi_3$ | $^1A'\leftarrow{}^1A'$ | 7.76 | | |
| $\pi_1-\pi_4$ | $^3A'\leftarrow{}^1A'$ | 7.53 | | |
| $\pi_1-\pi_4$ | $^1A'\leftarrow{}^1A'$ | 9.44 | | |

## Discussion

Acrolein in *n*-hexane solution has three absorption maxima in the 1800~4000 Å region, $\lambda$'s$_{max}$ 2078 Å (5.96 eV., $\log\varepsilon_{max}=3.89$), 3345 Å (3.71 eV., $\log\varepsilon_{max}=1.13$) and 4020 Å (3.08 eV., $\log\varepsilon_{max}=\bar{1}.13$). The last two absorption bands are assigned to the $n-\pi^*$ transition from the solvent effect. The first absorption band has the extinction coefficient of 7700, showing that this transition may be regarded as an allowed one. It is assigned to a $\pi-\pi^*$ transition from the red-shift in the solvent effect.

From these observations the absorption bands at 5.96 and 3.71 eV., may be assigned to the $^1A'\leftarrow{}^1A'$ and $^1A'\leftarrow{}^1A''$ transitions, respectively. In Table I they correspond to the calculated 6.07 eV. $(\pi, \pi^*)$ and 3.85 eV. $(n, \pi^*)$ transitions. The third absorption band may correspond to the lowest calculated singlet-triplet transition 2.85 eV. To account for this small discrepancy we tried to obtain the phosphorescence spectrum of acrolein in cyclohexane and ethyl alcohol solutions at liquid air temperature, but failed. The *n*-hexane solution of acrolein

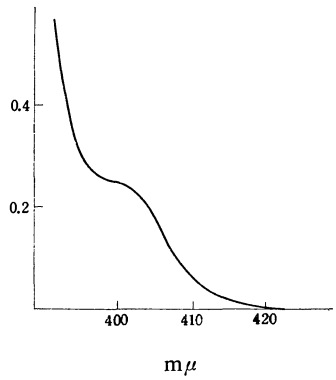

Fig. 1. Absorption band of acrolein in *n*-hexane solution (1.71 mol./l.) at 10°C.

has an absorption maximum at 4020 Å ($\varepsilon = 0.136, f = 1.16 \times 10^{-7}$) as shown in Fig. 1. These values of $\varepsilon$ and $f$ are somewhat greater than those usually given for a singlet-triplet absorption. According to Kasha[13] it may be expected to have increased intensity in ethyl iodide solution because of the spin-orbit coupling. However, we could not observe any increase of the absorption, due to the overlapping of an intense absorption of the iodine molecule which exists in the solution. On the other hand, this band in ethyl alcohol solution showed a remarkable decrease of intensity at dry ice temperature compared with that at 10°C. Hence, we assigned this 4000 Å band as a hot band. Fig. 2 shows the temperature dependence of this band in ethyl alcohol solution. This weak band lies at 1226 $cm^{-1}$ on the red side of the 0−0 band in vapor state.

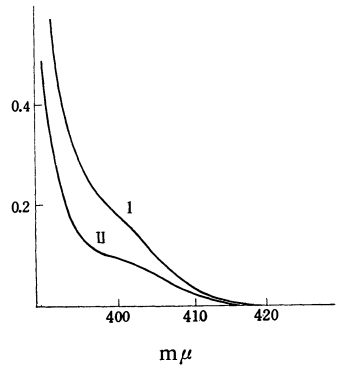

Fig. 2. The effect of temperature on the absorption band of acrolein in ethyl alcohol solution (0.956 mol./l.), curve I at 10°C, curve II at dry ice temperature.

The corresponding frequency could not be found in the infrared and Raman spectra[14], and we could not decide the vibrational mode of this band.

## Summary

It was found that the semi-empirical method proposed by Pariser and Parr can be applied to the $n-\pi^*$ transition as well as the $\pi-\pi^*$ transition in acrolein. In acrolein the $(n, \pi^*)$ triplet state is the lowest state. A weak band in the red side of the 0−0 band is a hot band and it is not the $n-\pi^*$ singlet-triplet transition band. The $n-\pi^*$ triplet band anticipated from calculation could not be found.

The author expresses his sincere thanks to Professor S. Imanishi and Dr. Y. Kanda for their kind encouragement throughout this work. He is also indebted to Dr. M. Ito and Mr. A. Sadō for their kind guidance, and also to Mr. R. Shimada for obtaining the phosphorescence spectrum of acrolein.

# *Studies on D-Glucosamine Derivatives. VI. α-1-C-Phenyl-2-acetamido-2-deoxy-D-glucopyranoside and its Derivatives**

By Juji YOSHIMURA

(Received June 16, 1960)

The glucosylation of hydrocarbons with a carbohydrate moiety in which the pyranose ring is preserved has been accomplished by using glycosyl halides in two familiar organic reactions, i. g. the Friedel-Crafts and the Grignard reactions. Both approaches were originated by Hurd and Bonner[1] and extended by them[2]. Since then the glycosylation of organometallics has been applied to a variety of carbohydrates[3] and Grignard reagents[3-8] as well as

to organocadmium[9] and organoalkali[10] compounds. In earlier works of this series, the glycosylation of D-glucosamine was examined by the Friedel-Crafts[11] and Grignard reactions[12], and crystalline β-1-*C*-substituted-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranosides (R; Me, Et, *n*-Pr, *n*-Bu, phenyl, benzyl) were obtained in the latter case. These crystalline substances were designated as β-anomers on the basis of their low rotations, and their pyranose ring systems were confirmed by periodate oxidation. The present investigation centers about the α-1-*C*-phenyl-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranoside (II), produced as a by-product of the crystalline β-anomer when acetobromo-D-glucosamine hydrobromide reacts with phenylmagnesium bromide.

For the isolation of II from the crystallization mother liquors of the β-anomer, an attempt was first made to fractionate the sirupy materials obtained by concentration of the mother liquors using a magnesol-celite column. The existence of II was, however, scarcely deduced from the rotation of an effluent, though α- and β-pentaacetyl-D-glucosamine, and the β-anomer were separated in pure crystalline form. Secondly, the sirupy materials were de-*O*-acetylated by treatment with sodium in methanol and chromatographed on the same column. As is shown in Fig. 1, α-1-*C*-phenyl-2-acetamido-2-deoxy-D-glucopyranoside (I), m.p. 113~114°C, $[\alpha]_D^{24}$ 75.3°, was successfully isolated from the β-anomer and *N*-acetyl-D-glucosamine.

The proportions of the β-anomer to the α one, listed in Table II[13], are shown about ten to one in two cases. This is also ture for D-glucose derivatives[13].

On acetylation of I with acetic anhydride and pyridine, II was obtained as a thick sirup. Although all attempts to induce crystallization of this sirupy material failed, the values of elementary analysis were consistent with the theoretical values.

Nitration of II with a mixture of concentrated sulfuric and nitric acid affords again a sirupy material. However, the crystalline α-1-*C*-(*p*-nitrophenyl)-2-acetamido-2-deoxy-D-glucopyranoside (III) was obtained from it, by treating it with sodium methylate and afterwards by fractionation using a magnesol-celite column. The position of the nitro group of III was deduced from its ultraviolet absorption spectrum[14] as shown in Fig. 2.

For purposes of comparison with the compounds to be reported later, the β-anomer of III (V) was also prepared from β-1-*C*-(*p*-nitrophenyl)-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranoside[14] by deacetylation.

Compound III was converted into sirupy *N*-dichloroacetyl derivative (IV) by treating with *N*-hydrochloric acid and methyl dichloroacetate in turn. The conformation at the position of *C*-1 and 2 of IV is very similar to that of chloramphenicol (VI), but IV showed no antibiotic activities.

Having several available anomeric glycosyl

TABLE II. YIELDS AND RATIO OF PRODUCTS

| Starting material g. | | Crude yield g. (%) | Acetylderivative of the β-anomer, g. | Residual syrup, g. (β, α) | Ratio of β to α |
|---|---|---|---|---|---|
| Acetobromo-D-glucosamine | | 2.9 | | 0.5 | |
| hydrobromide | (5.0) | (64.0) | 2.1 | (0.2, 0.18) | 12.8 |
| 〃 | (45.0) | 24.1 | | 11.0 | |
| | | (59.3) | 12.6 | (3.69, 1.65) | 9.9 |
| α-Acetochloro-D-glucose[13] | | 19.5 | | 4.2 | |
| | (27.4) | (63.6) | 15.0 | (1.98, 1.58) | 10.7 |

similar to that of the corresponding glucosyl derivatives of D-glucose[13], and behave almost normally.

It is interesting to compare the values $A_{ph}$ and $A_{pho}$ for 1-*C*-phenyl derivatives and phenyl glycosides, substances differing only in the presence or absence of an oxygen atom at *C*-1.

The $A_{pho}$ value is seen to be higher than the $A_{ph}$ by a factor of about two to four.

Apparently, the conjugation with the aromatic nucleus of the unshared electrons on the glycosidic oxygen in the phenyl glycosides produces a considerably higher partial rotatory contribution of the *A*-portion of the molecule than is the case when the aromatic nucleus alone is present.

The substitution of the *p*-nitro group in the aromatic nucleus of 1-*C*-phenyl derivative, however, leads to an anomalously high *A* value which is analogous to that of phenyl glucosides[16].

## Experimental

**Reaction of Acetobromo-D-glucosamine Hydrobromide with Phenylmagnesium Bromide.** — The reaction was performed in the manner described previously[12], using a ninefold increase (45 g.) in the quantities of starting material. The crude product was isolated, after acetylation, as a thick brown sirup in about 60% yield. It was crystallized from a minimum of 2-propanol, yielding β-1-*C*-phenyl-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranoside. The mother liqors were concentrated to dryness, leaving a sirup which contains the α-anomer.

In Table II are tabulated two results of such preparations.

**α-1-*C*-Phenyl-2-acetamido-2-deoxy-D-glucopyranoside (I).**—The entire residual sirup from the second run in Table II was deacetylated with sodium in methanol. Evaporation of methanol affords 7.2 g. of sirupy materials. A part of the sirup (2.5 g.) was dissolved in 10 ml. of benzene-ethanol (10 : 1 mixture) and insoluble *N*-acetyl-D-glucosamine (0.29 g.) was filtered off. The filtrate was chromatographed at room temperature on a column packed with 25 g. of magnesol-celite (5 : 1 mixture). The solvents used for elution were benzene and ethanol of successively increasing concentrations in benzene. The effluents were examined as to the weight of elutes and their rotation. As is shown in Fig. 1, 0.98 g. of the β-anomer, 0.51 g. of the α-anomer and 0.51 g. of crystalline *N*-acetyl-D-glucosamine were obtained. The α and β anomers were again chromatographed, and 0.395 g. and 0.88 g. of pure crystals were obtained respectively. The α-anomer had m. p. 113~114°C, $[\alpha]_D^{24}$ 75.3° (*c* 0.65, chloroform).

Found: C, 59.93; H, 7.02; N, 4.63. Calcd. for $C_{14}H_{19}O_5N$(281.3): C, 59.77; H, 6.81; N, 4.98%.

**α-1-*C*-Phenyl-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranoside (II).**—Compound I (200 mg.) was acetylated with acetic anhydride (10 ml.) and pyridine (5 ml.) at 25°C for one day. Processing in the usual manner gave 290 mg. of a clear sirup. $[\alpha]_D^{25}$ 68.5° (*c* 0.69, ethanol).

Found: C, 58.36; H, 6.45; N, 3.34. Calcd. for $C_{20}H_{25}O_8N$(407.4): C, 58.69; H, 6.18; N, 3.44%.

**α-1-*C*-(*p*-Nitrophenyl)-2-acetamido-2-deoxy-D-glucopyranoside (III).**—A sirupy material of II (1.5 g.) was dissolved in a mixture of 7 ml. of concentrated sulfuric acid (sp. gr. 1.8) and 7 ml. of concentrated nitric acid (sp. gr. 1.38) on cooling with ice-salt bath. After 30 min. the reaction mixture was left to stand for 1 hr. at 0°C, and for 15 min. at room temperature. About 20 ml. of dry chloroform were added and the mixture was poured gradually into ice-water including an excess amount (about 20 g.) of sodium carbonate. The chloroform layer was separated from the water layer, and the latter was extracted with chloroform in the usual manner. Evaporation of the solvent afforded about 1.5 g. of a pale yellow sirup. A small grain of sodium was added to the solution of this sirup and 15 ml. of methanol, and was left to stand for 3 hr. at room temperature. The methanol solution was diluted with 10 ml. of water and treated with 15 ml. of cation-exchanger (IRA 120) and concentrated in vacuo to dryness. The residual sirup was chromatographed on 10 g. of magnesol-celite column (5 : 1 mixture) in a manner similar to that of I shown in Fig. 1. The fractions eluted with benzene-ethanol mixtures the ratios of which were five to one and two to one were crystallized. Yield 200 mg., m. p. 170~171°C, $[\alpha]_D^{22}$ 97.5° (*c* 1.0, methanol).

Found: C, 51.18; H, 5.23; N, 8.25. Calcd. for $C_{14}H_{18}O_7N_2$(326.3): C, 51.53; H, 5.56; N, 8.59%.

**α-1-*C*-(*p*-Nitrophenyl)-2-dichloroacetamido-2-deoxy-D-glucopyranoside (IV).**—A mixture of 1.3 g. of III, 10 ml. of 2 N hydrochloric acid and 10 ml. of

16) W. W. Pigman, *J. Research Natl. Bur. Standards*, 33, 129 (1944).

ethanol was refluxed 3 hr. on a steam bath. The reaction mixture was concentrated in vacuo, and the residual sirup (ca. 1 g.) was neutralized with about 0.072 g. of sodium in methanol. The solution was filtered and concentrated in vacuo, and the residual sirup was refluxed in 8 ml. of *n*-butanol and 3 ml. of methyl dichloroacetate for 5 hr. The precipitate (a small amount) was filtered off, and the filtrate was concentrated to a thick sirup. An attempt was made to fractionate this on a magnesol-celite column, but no crystalline material could be obtained. The main fraction was about 0.8 g., $[\alpha]_D^{23}$ 60.0° (*c* 0.9, methanol).

Found: C, 42.88; H, 4.25; N, 7.34; Cl, 17.32. Calcd. for $C_{14}H_{16}O_7N_2Cl_2$ (395.2): C, 42.52; H, 4.08; N, 7.09; Cl, 17.94%.

**β-1-*C*-(*p*-Nitrophenyl)-2-acetamido-2-deoxy-D-glucopyranoside (V).**—β-1-*C*-(*p*-Nitrophenyl)-2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-D-glucopyranoside (0.5 g.) was deacetylated with sodium in methanol. Processing in the usual manner gave 0.3 g. of crystals. m. p. 269~271°C, $[\alpha]_D^{27}$ −21.0° (*c* 0.8, ethanol).

Found: C, 51.33; H, 5.47; N, 8.52. Calcd. for $C_{14}H_{18}O_7N_2$ (326.3): C, 51.53; H, 5.56; N, 8.59%.

**Summary**

The sirup obtained as a by-product with β-1-*C*-phenyl-2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-D-glucopyranoside by the action of phenylmagnesium bromide on acetobromo-D-glucosamine hydrobromide has been deacetylated and chromatographed to yield the α-anomer. Several α-derivatives have been described, among which, α-1-*C*-(*p*-nitrophenyl)-2-dichloroacetamido-2-deoxy-D-glucopyranoside which is a chloramphenicol derivative showed no antibiotic activities. The application of Hudson's rules of isorotation to the anomeric compounds in this series is discussed.

The author would like to express his gratitude to Professor T. Sato for his encouragement in carrying out this study. He also thanks Mr. H. Ono for his help during the experiment.

# *Studies on Lactone Formation in Vapor Phase. I. Synthesis of γ-Butyrolactone*

By Shinzaburo OKA

(Received June 1, 1960)

Dehydrogenation of aliphatic glycols to the corresponding lactones with a copper catalyst was originated by Reppe[1,2] and later investigated by several investigators[3-5]. The reaction was generally carried out in the following two ways: (1) Heating glycol and a small amount of copper chromite under continuous stirring at 200~250°C until hydrogen evolution ceased, (2) passing glycol with hydrogen over reduced copper supported on silica gel or pumice at the same temperature.

In Germany, γ-butyrolactone had been manufactured from 1,4-butanediol by the second method, and Copenhaver[6] has described its outline in "Acetylene and Carbon Monoxide Chemistry". The yield of γ-butyrolactone (90%) was satisfactory but its space time yield was very small (about 0.015).

In order to find a more active catalyst for the vapor phase catalytic dehydrogenation of 1,4-butanediol to γ-butyrolactone, the activities of reduced copper supported on various carriers, the effects of the catalyst composition, and the reaction conditions have been examined.

## Experimental

**Catalyst.**—The catalyst consisting of 20% copper and 80% zinc oxide was prepared as follows.

An aqueous solution 300 ml. containing 51 g. of cupric nitrate trihydrate was slowly added to 300 ml. of water in which 109 g. of zinc carbonate was suspended with stirring. Stirring was continued until the deposition of basic copper carbonate on zinc carbonate with evolution of carbon dioxide had ceased. The material was then washed three times with one liter of water, filtered and dried at 70°C. The final decomposition to copper oxide was carried out in a porcelain dish with frequent stirring and cautious heating at 300°C until the color of the

catalyst turned from light blue into dark brown.

When magnesium oxide was used as carrier, the catalyst was prepared similarly. In the case of alumina, copper hydroxide and aluminum hydroxide were coprecipitated with ammonia from the solution of copper nitrate and aluminum nitrate. In the case of silica gel, the catalyst was prepared from copper nitrate and sodium silicate by the usual manner. These catalysts were put in tablets, 8 mm. in diameter and 2 mm. in thickness. About 70 ml. of the tablets was used in each experiment.

**Apparatus and Procedure.** — The apparatus used is shown in Fig. 1. The dehydrogenation tube

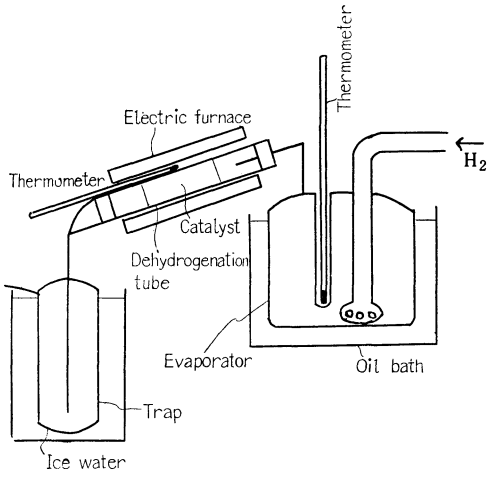

Fig. 1. Apparatus.

(60 cm.×15 mm.) was made from silica and heated in a furnace. Activation of the catalyst was carried out at 220°C in a stream of hydrogen until reduction was completed. The sample was passed in with a steady current of hydrogen. The evaporator containing 1,4-butanediol ($n_D^{25}$ 1.4452, $d_4^{25}$ 1.0130) was immersed in an oil bath and the feed speed of the sample was adjusted by regulating the temperature of the oil bath and rate of hydrogen. The evaporator was weighed before and after a run to determine the weight of material used. The reaction products were collected in a trap cooled by ice water, weighed and fractionated under a reduced pressure. $\gamma$-Butyrolactone (b. p. 98~100°C/25 mmHg) was easily fractionated from unreacted 1,4-butanediol (b. p. 142°C/25 mmHg). $\gamma$-Butyrolactone was a colorless liquid of $n_D^{25}$ 1.4350, $d_4^{25}$ 1.1264 and gave a hydrazide melting at 92°C.

Found : C, 40.92 ; H, 8.79. Calcd. for $C_4H_{10}O_2N_2$ : C, 40.66 ; H, 8.53%.

## Results and Discussion

Typical results for four carriers are tabulated in Table I.

The catalyst 70 ml. containing 20% copper was used. The reaction temperature was maintained at 230~240°C and the reaction time was one hour. The velocity of hydrogen passed with sample was 20 l. per hour. The yields of $\gamma$-butyrolactone were based upon the amount of butanediol consumed. With any carriers used, the conversion was very good. In the case of alumina, the yield was decreased owing to dehydration of butanediol to tetrahydrofuran. Magnesium oxide or zinc oxide was a superior carrier in respect to the yield

* Space velocity, ** Liquid space velocity, *** Space time yield.

and undesirable side reaction. These catalysts were prepared by the new method described in the experimental part.

Effects of the catalyst composition, relative ratio of copper to magnesium oxide and to zinc oxide, are shown in Tables II and III, respectively. The reaction conditions were the same as those in Table I. The suitable contents of copper were about 10~20%. The higher contents of copper did not improve the yield and conversion. Effects of the reaction temperature in the case of 20% copper-zinc oxide is shown in Table IV. The reaction time and the hydrogen velocity were the same as those of the above experiments. The conversion increased with the elevation of the reaction temperature and $\gamma$-butyrolactone was obtained in a good yield at 210~260°C. At above 280°C the product decreased owing to undesirable decompositions.

Finally, in use of the same catalyst as the above, effects of space velocity of hydrogen and liquid space velocity of butanediol on yield, space time yield and conversion were examined at 230~240°C and the results were summarized in Table V.

The yield was hardly affected with varying velocity of hydrogen and butanediol, but the long contact with the catalyst lowered the yield to some extents. With increase of liquid space velocity from 0.17 to 0.58, the space time yield increased from 0.14 to 0.41, but the conversion decreased from 97% to 77%.

No final information was yet available as to the life of the catalyst, but its activity hardly decreased after several hours.

## Summary

Vapor phase catalytic dehydrogenation of 1, 4-butanediol to $\gamma$-butyrolactone with reduced copper supported on various carriers was studied. It was found that copper supported on zinc oxide or magnesium oxide was a superior catalyst. In the case of a catalyst consisting of 20% copper and 80% zinc oxide, the yield and space time yield of $\gamma$-butyrolactone were 95% and 0.28 at 230~240°C, respectively.

The author wishes to thank Professor S. Kunichika of Kyoto University, for valuable advices and criticism.

# *Studies on Leucomycin. IV. Isolation of Mycaminose from the Acid Hydrolysate*

By Tetzuo WATANABE

(Received July 6, 1960)

Recent studies in this laboratory have demonstrated that the leucomycin complex produced by Streptomyces kitasatoensis Hata[1-3], can be resolved into six basic antibiotics by elution chromatography[4] or by counter current distribution[5]. The present paper will describe the presence of a mycaminose residue[6] as the basic moiety in each leucomycin component. Leucomycin A1 ($C_{46}H_{81}NO_{17}$, m. p. 135~138°C), the main component of this antibiotics complex, possessed a $pK_a'$ of 7.1 and did not reduce Fehling's solution. It gave no color with carbohydrate reagents such as anthrone under the usual conditions[7]. Upon hydrolysis with 2 N hydrochloric acid at 100C°, however, there was produced an appreciable amount of reducing sugars which became colored with sulfuric acid-anthrone reagent[8], together with some humic substances. By the elution chromatography of the hydrolysate from a column of Dowex-50 of H-phase with 2 N hydrochloric acid, the anthrone reaction-positive components were separated into three fractions, as shown in Fig. 1. The first fraction possessed no nitrogen, while the second fraction (IIa) contained a basic sugar, which was crystallized as a hydrochloride ($C_8H_{17}NO_4 \cdot HCl$, m. p., 114~116°C) from the alcoholic solution by the addition of ether.

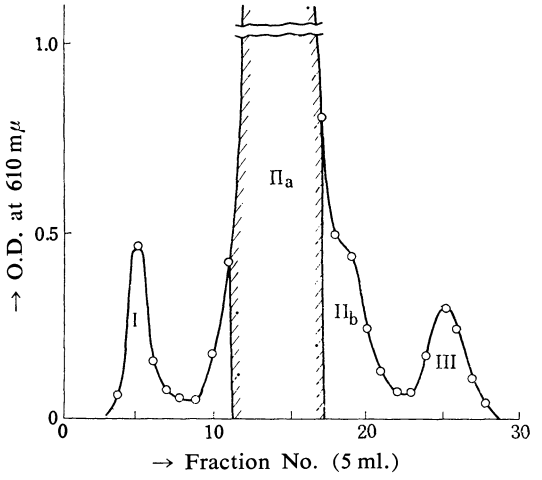

Fig. 1. Elution chromatogram of sugar components derived from leucomycin A1 with hydrochloric acid. The acid hydrolysate corresponding to 20 g. of leucomycin, was eluted from a column of Dowex-50 (H-phase) of 1×30 cm. with 2 N hydrochloric acid. The concentration of sugar was determined photocolorimetrically with sulfuric acid-anthrone reagent[8].

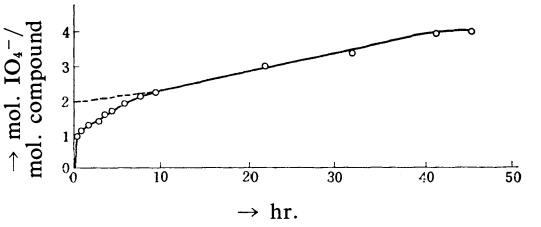
This basic sugar rapidly consumed one mole of slight alkaline iodine at room temperature, indicating that it was an aldose[9].

The aldose possessed one *C*-methyl group and showed a characteristic iodoform reaction, too. By the action of 3 N sodium hydroxide at 50°C, the basic group of this aldose was easily split as dimethylamine, which was identified as 2, 4-dinitro-*N*-dimethyl aniline after coupling with 1-fluoro-2, 4-dinitrobenzene[10]. These results seemed to indicate that the basic sugar isolated from leucomycin A1 was an aldomethylpentose having a dimethylamino group.

As shown in Fig. 2, the dimethylamino-aldomethylpentose consumed 4 mol. of periodate in aqueous solution at room temperature : one



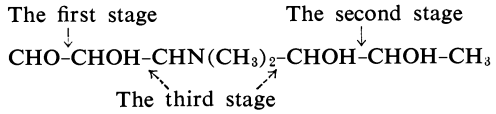


Fig. 2. Periodate consumption by the basic sugar isolated from leucomycin A1.

mole very rapidly, one mole with moderate speed, and the additional two moles very slowly. During the initial stage of the oxidation, formic acid was produced at a rate approximating one mole per mole of periodate consumed: while the formation of acetaldehyde which was identified as the 2,4-dinitrophenylhydrazone and assayed photocolorimetrically with *p*-hydroxydiphenyl[11], was observed mainly during the second stage of oxidation. During the final stage of the oxidation, there was observed the formation of dimethylamine and an increase of the amount of formic acid with the increase of periodate consumption. No formation of formaldehyde was confirmed with the use of chromotropic acid[12]. These results suggested that the basic sugar possessed the following structure.

As already described in the present paper, the dimethyl amino group of this sugar was rather easily split as dimethylamine under the action of alkali. Fig. 3 illustrates the velocity of liberation. As a control, was used $C_7$-dimethylamino aldose, which had been derived from the original $C_8$-sugar with the action of one mole of periodate (presumably possessing methyltetrose structure[6,9]; see Fig. 2). A marked difference observed between the stabilities of both dimethylamino sugars in alkaline solution, seemed not to be inconsistent with the structure presumed above; thus the original $C_8$-sugar possessed the dimethylamino group at the $\beta$-position, while the oxidation product possessed it at the $\alpha$-position from the aldehyde group, respectively. As to the steric configuration of the 3,6-deoxy-3-dimethyl amino aldohexose isolated from leucomycin A1, the present author had no experimental data. The physical constants of this sugar, however, were very close to those reported on a 3,6-deoxy-3-dimethylaminoaldohexose, mycaminose which had been previously obtained from the acid hydrolysate of magnamycin and the infrared absorption spectra of both sugars were essentially the same, as shown in Fig. 4. These results indicated that mycaminose was a basic moiety of leucomycin A1.

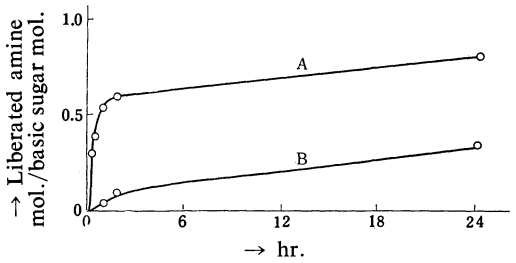

Fig. 3. Liberation of dimethylamine from dimethylamino sugar under the action of 3 N sodium hydroxide at 50°C.
A: CHO-CHOH-CHN$(CH_3)_2$-CHOH-CHOH-$CH_3$ from leucomycin A1.
B: CHO-CHN$(CH_3)_2$-CHOH-CHOH-$CH_3$ derived from A with the action of one mole of periodate.
The amount of dimethylamine was determined spectrophotometrically, after the coupling with 1-fluoro-2,4-dinitrobenzene.

It should be emphasized here that p$K_a'$ value of mycaminose (8.1) was somewhat higher than that of intact leucomycin A1 (7.1). Such a difference between their p$K_a'$ values may suggest that the hydroxyl group adjacent to the dimethylamino group of mycaminose residue in intact leucomycin A1, was blocked with other groups in the same way as magnamycin[13]. The p$K_a'$ of leucomycin, magnamycin, and their related compounds are listed in Table I.

Other components of leucomycin, A2 ($C_{65}H_{111}NO_{22}$, m. p., 142~144°C), B1 ($C_{35}H_{59}NO_{13}$,

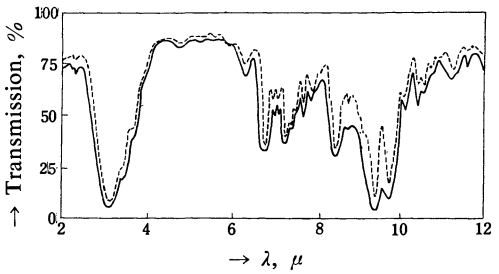

Fig. 4. Infrared absorption spectra of the basic sugars from leucomycin A1 and from magnamycin.

TABLE I. p$K_a'$ OF LEUCOMYCIN, MAGNAMYCIN AND THE RELATED COMPOUNDS

| | Leucomycin A1, A2 | Leucomycin B1, B2, B3, B4 | Magnamycin |
|---|---|---|---|
| Intact antibiotics | 7.1 | 6.6~6.8 | 7.0 |
| Basic sugar obtained with 6 N HCl hydrolysis | | 8.1 | 8.1 |
| A basic moiety obtained with methanolysis | 8.1* | 7.8* | 8.3 |

13) R. B. Woodward, *Angew. Chem.*, **68**, 13 (1956).

m. p., 214.5～216.5°C), B2 ($C_{38}H_{65}NO_{16}$, m. p., 214～216°C), B3 ($C_{34}H_{53}NO_{13}$, m. p., 216～217°C), B4 ($C_{38}H_{59}NO_{16}$, m. p., 221～223.8°C), also gave a basic sugar which was absorbed on a column of Dowex-50 of H-phase, on their acid hydrolysis. Although the isolation of the basic sugar in preparative scale was impossible, due to the limited amounts of these minor antibiotics, the paper chromatographic $R_f$ values was just the same as that of mycaminose and differed from that of desosamine which had been reported as another basic moiety of macrolides[14,15].

## Experimental

**Leucomycin.**—The leucomycin complex used in this experiment, was a commerical bulk, Lot No. 9LM-44, which was kindly offered from the Research Institute, Toyo Jozo Co. Ltd. Leucomycin components, A1, A2, B1, B2, B3 and B4, were isolated from the complex by the previous fractionation with benzene, followed by the further minute resolution with the use of counter current distribution technique, as already reported by the present author[5].

**Isolation of Basic Sugar from the Acid Hydrolysate of Leucomycin A1.**—Twenty grams of leucomycin A1 (m. p. 135～138°C, Found: C, 60.99; H, 8.72; N, 1.52. Calcd. for $C_{46}H_{81}NO_{17}$: C, 60.13; H, 8.75; N, 1.54%.) were disolved into 300 ml. of 2 N hydrochloric acid, and the solution was heated at 100°C for 3 hr. The dark brown solution so produced, after repeated washing with chloroform (five times, 30 ml. each) to remove humic substances, was concentrated to syrup under reduced pressure. The residue, dissolved in 10 ml. of water, was added to a column of Dowex-50 (H-phase, 150～200 mesh) of 1×30 cm. As soon as the applied sample solution had been allowed to flow into the column, elutions with 50 ml. of water, then with 2 N hydrochloric acid were initiated. Throughout these procedures, the rate of flow was maintained to be 10±2 ml. per hour. The concentration of sugar in the effluent, which had been collected in 5 ml. fractions by means of an automatic fraction collector, was determined spectrophotometrically with sulfuric acid-anthrone reagent, as follows. A half millilitre of the solution to be analyzed was mixed with 2 ml. of 2 per cent anthrone in concentrated sulfuric acid, and the mixture was heated for 15 min. in boiling water bath. The optical density of the resulting blue color was measured at 610 mμ.

The combined fractions, corresponding to the second main peak component (from No. 11 to No. 16; see Fig. 1), were concentrated to dryness under reduced pressure. The crystalline residues were dissolved into a minute amount of ethyl-alcohol and recrystallized out by the addition of ether. m. p. 114～116°C $[\alpha]_D^{25}$ +30° (*c* 1 in water 24 hr.) Yield 2.8 g.

Found: C, 42.18; H, 8.09; N, 5.94. Calcd. for $C_8H_{17}NO_4 \cdot HCl$: C, 42.19; H, 7.81; N, 5.59%.

**Periodate Oxidation of the Basic Sugar Isolated from Leucomycin A1.**—The oxidation was achieved in 0.1 per cent acetic acid at 25°C, with the uses of 3～7 mM of basic sugar hydrochloride and of 25～30 mM sodium metaperiodate, and an aliquot of the reaction mixture was pipetted out after a definite period, for the following analysis. The periodate consumption was determined, after the addition of potassium iodide by the titration with thiosulfate, and the amounts of acetaldehyde and of formaldehyde were determined spectrophotometrically with *p*-hydroxybiphenyl-[11] and chromotropic acid-[12] reagents, according to the method described in the cited reference, respectively. The amount of formic acid was assayed by the alkali-titration, on the oxidation mixture in aqueous solution instead of 0.1 per cent acetic acid solution. Acetaldehyde, formic acid, and dimethylamine produced by the periodate oxidation, were identified as the 2,4-dinitrophenylhydrazone (m. p. 160～161°C), *p*-bromophenacyl ester (m. p. 100～101°C) and dinitrophenyl derivative (m. p. 78°C), respectively.

**Alkali Degradation of the Basic Sugar from Leucomycin A1.**—Four hundred milligrams of the basic sugar hydrochloride was dissolved into 25 ml. of 3 N sodium hydroxide at 45°C. A 5 ml. portion of the solution, after a definite period, was immediately cooled and neutralized, and dinitrophenylated with 1-fluoro-2, 4-dinitrobenzene according to the method of Sanger[10].

The dinitrophenylation mixture, was directly added to a column of Amberlite IRC-50 of H-phase (100～150 mesh, 1×20 cm.)[16] and the column was washed with water. The unreacted reagent and 2,4-dinitrophenol, a main by-product, were removed in the filtrate and the washing. 2, 4-Dinitro-*N*-dimethylaniline derived from dimethylamine, was then eluted from the column with a mixture of acetone and water (1 ; 1 *V/V*) and the amount was determined by the spectrophotometry at 380 mμ. The absorption spectrum of the effluent was essentially the same as that of the authentic specimen in a wavelength range between 250 to 450 mμ.

As a control, a reaction mixture derived from the basic sugar with the equimolecular amount of sodium periodate (see Fig. 2) was used.

**Other Analysis of the Basic Sugar Isolated from Leucomycin.**—Aldose-reaction with alkaline iodine[9] 2-deoxyaldose reaction with perchloric acid-vanilline reagent[17], dinitrophenylation with 1-fluoro-2,4-dinitrobenzene for the detection of primary and secondary amino groups[10], were achieved under the conditions reported in the references cited, respectively.

Paper-chromatographic analysis was performed by the usual ascending method, with the uses of isopropanol-pyridine-acetic acid-water (8 : 8 : 1 : 4 *V/V*), *n*-butanol-pyridine-water (6 : 4 : 5 *V/V*) and collidine-pyridine-water (2 : 1 : 1 *V/V*) as the solvent

# *Polyaddition Reaction of Diphenylsilane to Diallyl Carboxylate*

By Kuniharu KOJIMA

(Received June 21, 1960)

The monofunctional addition reaction of phenylsilane or methyl diethoxysilane to allyl acetate was first studied by Speier and coworkers[1,2], and 3-(phenylsilyl) propyl acetate and 3-(diethoxy methylsilyl)propyl acetate were prepared by this method under the influence of *tert*-butyl hydroperoxide. The addition reaction of trichlorosilane and methyl dichlorosilane to allyl acetate was also studied under the influence of platinum catalyst[3].

As an example of the bifunctional addition reaction, we have reported in the previous short communication, the polyaddition reaction of diphenylsilane to diallyl phthalate[4].

In the present work we have tried to extend the reaction in order to obtain larger molecules which might have more interesting properties. Some experiments using diallyl phthalate and diphenylsilane at various reaction conditions (reaction temperature, catalyst concentration and monomer concentration) are summarized in Tables II—VI.

The new method of polymer synthesis was further extented to the polyaddition reaction of diphenylsilane and the following diallyl carboxylate : diallyl oxalate, malonate, succinate, adipate, sebacate, phthalate, isophthalate and terephthalate.

## Experimental

**Materials.**—*Diphenylsilane.* — Diphenylsilane was prepared from diphenyldichlorosilane and lithium aluminum hydride by ordinary method[5]. Three hundred and four grams (1.2 mol.) of diphenyldichlorosilane was added to 25 g. (0.68 mol.) of lithium aluminum hydride in 300 ml. of anhydrous ether. The solution was refluxed for several hours and hydrolyzed with 260 ml. of dilute hydrochloric acid. The ethereal layer was distilled to give 215 g. of diphenylsilane b. p. 109°C/7 mmHg, $n_D^{20}$ 1.5799, $d_4^{20}$ 0.9970.

*Diallyl Phthalate.* — The commercial product was distilled under reduced pressure before use. The portion boiling at 155°C/6 mmHg, $n_D^{20}$ 1.5205, $d_4^{20}$ 1.1205, was used in the polyaddition reaction.

*Other Diallyl Carboxylates.* — Diallyl carboxylates were prepared by the method described previously[6]. Their physical properties were listed in Table I.

TABLE I. PHYSICAL PROPERTIES OF DIALLYL CARBOXYLATES

| Diallyl carboxylates | B. p. °C/mmHg | $n_D^{20}$ | $d_4^{20}$ |
|---|---|---|---|
| Oxalate | 104～106/15 | 1.4470 | 1.0890 |
| Malonate | 115/4 | 1.4480 | 1.0643 |
| Succinate | 112～113/8 | 1.4514 | 1.0559 |
| Adipate | 136～138/8 | 1.4539 | 1.0226 |
| Sebacate | 181～183/9 | 1.4564 | 0.9788 |
| Phthalate | 155/6 | 1.5205 | 1.1205 |
| Isophthalate | 163/8 | 1.5250 | 1.1213 |
| Terephthalate | 166～167/8 | — | — |

*Catalyst.* — Prepared by dissolving 0.518 g. of commercial $H_2PtCl_6 \cdot 6H_2O$ ($10^{-3}$ mol.) in 100 ml. *tert*-butyl alcohol.

**Polyaddition Reaction.**—To the equimolar mixture of diphenylsilane, and to diallyl carboxylate in a glass tube was added a constant amount of chloroplatinic acid solution. The tube was then sealed in a nitrogen atmosphere, and heated for several hours in a dry oven of constant temperature. The reaction product was dissolved in 100 ml. of acetone, and filtered. To the filtrate 30 ml. of water was added and reprecipitated. The precipitates were separated by decantation and dried in a vaccum desiccator at 50°C for 7 days until it reached constant weight.

**Determination of Molecular Weight.**—The molecular weight was calculated from the freezing point depression in benzene.

**Determination of Inherent Viscosity.**—One fifth of a gram of solvent free polymer was dissolved in 50 ml. of benzene and the viscosity was determined by an Ostwald type viscosimeter at 25°C.

## Results and Discussion

The preliminary experiment for determing conditions which favor formation of polyaddition products were carried out using diphenylsilane and diallyl phthalate.

**Temperature Dependence.**—Polymerization of diphenylsilane with diallyl phthalate was carried out at various temperatures. The results are given in Tables II, III and IV.

The largest polymer was prepared at 120°C, 48 hr. and 0.1 ml. catalyst. The degree of polymerization increased as the conversion became higher. Higher reaction temperature also seemed to increase the degree of polymerization. It became clear that the addition

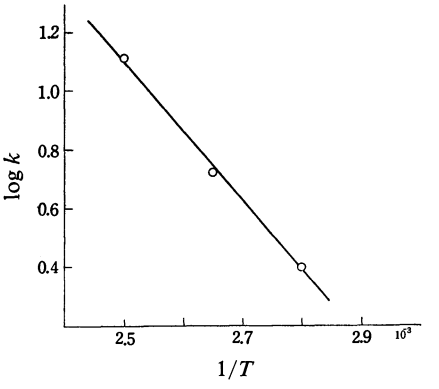

Fig. 3. Correlation of $\log k$ with $1/T$.

reaction was of second order at the initial stage (Figs. 1 and 2), and the $k$ values were $k_{80}=2.5$, $k_{100}=5.2$ and $k_{120}=13.2\times10^{-8}$ g./sec. mol. When the logarithm of the initial rates of polymerization was plotted against reciprocals of temperatures ($1/T$), a good straight line was obtained (Fig. 3). The over-all activation energy calculated from the slope in

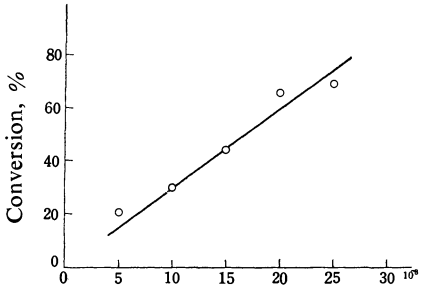

Fig. 3 was found to be 12 kcal./mol. for this reaction.

**Effect of the Catalyst Concentration.** — The data for the effect of the catalyst concentration is given in Table V, and the dependence of the initial rate of polymerization upon the concentration of catalyst are shown in Fig. 4.

TABLE V. EFFECTS OF CATALYST CONCENTRATION IN ADDITION REACTION OF DIPHENYLSILANE WITH DIALLYL PHTHALATE

| Catalyst conc. mol./ml. | Conversion % | Mol. wt. | $[\eta]$ |
|---|---|---|---|
| $5\times10^{-3}$ | 21.2 | 758 | 0.6 |
| 10 | 29.7 | 836 | 0.6 |
| 15 | 44.9 | 746 | 0.6 |

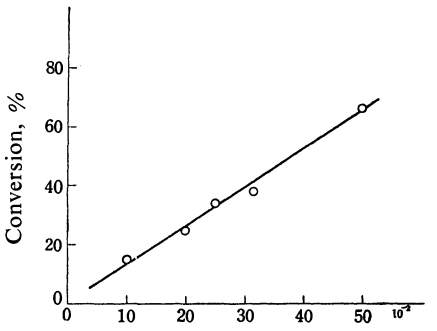
| 25 | 68.6 | 773 | 0.6 |

Diphenylsilane 4.519 g., diallyl phthalate 6.041 g. were used and were heated at 110°C., 6 hr.

Catalyst concentration, mol./ml.

Fig. 4. Effect of catalyst concentration.



It is evident that the initial rate of polymerization is proportional to the concentration of chloroplatinic acid solution. The molecular weight of the polymer, however, is almost independent of the concentration of the catalyst.

**Effect of Initial Monomer Concentration.** — The relationship between initial rate of polymerization and the concentration of diphenylsilane-diallyl phthalate mixture in toluene

TABLE VI. EFFECTS OF INITIAL MONOMER CONCENTRATION IN ADDITION REACTION OF DIPHENYLSILANE WITH DIALLYL PHTHALATE

| Monomer conc. g./ml. | Conversion % | Mol. wt. | $[\eta]$ |
|---|---|---|---|
| $50\times10^{-2}$ | 66.3 | 870 | 0.6 |
| 33 | 36.7 | 627 | 0.6 |
| 25 | 33.5 | 597 | 0.5 |
| 20 | 24.6 | 545 | 0.5 |
| 10 | 15.5 | 463 | 0.5 |

Diphenylsilane 4.519 g., diallyl phthalate 6.041 g. and catalyst $20\times10^{-3}$ mol./ml. were used and were heated at 110°C, 24 hr.

Monomer concentration, g./ml.

Fig. 5. Effect of initial monomer concentration.

was studied at 110°C. The data for the rate of diminution of monomer concentration are given in Table VI and Fig. 5.

It is clear that the initial rate is proportional to the concentration of diphenylsilane—diallyl phthalate mixture.

The above result indicates that the over-all rate of polyaddition reaction, $k_p$ of diphenylsilane with diallyl phthalate is proportional to the initial monomer concentration (M) and to the catalyst concentration (C).

$$k_p \propto (M)(C)$$

The molecular weight of the polymer is proportional to the initial monomer concentration, but independent of the catalyst concentration.

**Polyaddition Reaction of Diphenylsilane to Diallyl Carboxylates.** — Similar experiments of diphenylsilane to diallyl oxalate, malonate, succinate, adipate, sebacate, phthalate, isophthalate, and terephthalate were carried out. The results obtained are shown in Table VII.

TABLE VII. ADDITION REACTION OF DIPHENYLSILANE WITH DIALLYL CARBOXYLATES

| Diallyl carboxylate | Conversion % | Mol. wt. | $[\eta]$ | Si Calc. % | Si Found % |
|---|---|---|---|---|---|
| Oxalate | 27.5 | 650 | 0.6 | 7.93 | 8.64 |
| Malonate | 59.5 | 990 | 0.6 | 7.62 | 7.36 |
| Succinate | 64.9 | 1080 | 0.6 | 7.34 | 7.38 |
| Adipate | 55.8 | 1120 | 0.6 | 6.84 | 7.58 |
| Sebacate | 76.3 | 1170 | 0.6 | 6.02 | 5.45 |
| Phthalate | 73.6 | 1860 | 0.7 | 6.52 | 6.24 |
| Isophthalate | 66.5 | — | — | 6.52 | 6.49 |
| Terephthalate | 53.0 | — | — | 6.52 | 6.35 |

Diallyl carboxylate 0.02 mol. and diphenylsilane 0.02 mol. were used and were heated at 110°C, 50 hr.

Addition products were viscous oily liquids, but the adducts of diphenylsilane to diallyl phthalate and isophthalate and terephthalate

were light yellow, glassy solid, and were useful as adhesives. Their softening temperatures were ca. 108°, 120°and >200°C.

## Summary

The polyaddition reaction of diphenylsilane to diallyl phthalate was studied. The reaction was found to be of the second order at the initial stage. The over-all rate is proportional to the initial monomer and catalyst concentration. The over-all activation energy calculated for this reaction was found to be 12 kcal./mol. at 80~120°C.

By a similar method following polyesters have been prepared from diphenylsilane and diallyl carboxylates: Polydiphenylsilylene 3, 3′-bis(trimethylene)oxalate, malonate, succinate, adipate, sebacate, phthalate, isophthalate and terephthalate. Their molecular weight and inherent viscosity were determined and properties have been described.

The author is much indebted to Professor Yoshio Iwakura for his many useful suggestions and to Mr. Niro Tarumi for his help in the experiments. Appreciation is also expressed to Shin-etu Chem. Co. for their kindness in supplying the diphenyldichlorosilane.

# *Absorption Spectra of Unstable Colored Intermediates from Picryl Chloride by the Action of Sodium Hydroxide*

By Takehiro ABE

(Received July 9, 1960)

In a previous paper[1], it was reported that on treatment of an aqueous solution of picryl chloride with a drop of aqueous solution of sodium hydroxide, a red solution was instantaneously formed and in a few minutes changed into a yellow solution which showed a spectrum closely resembling a spectrum of picric acid. At room temperature the red color faded away so fast that its spectrum could not be measured. It has, however, been found that the red solution containing a small quantity of ethanol is relatively stable. An attempt has, therefore, been made to measure the spectrum of the red solution prepared by adding a sodium hydroxide solution to an aqueous picryl chloride solution containing a small quantity of ethanol, together with spectra of colored solutions of picryl chloride in ethanol and in acetone in the presence of sodium hydroxide. These spectra have been compared to investigate a solvent effect on them.

## Experimental

Picryl chloride of Tokyo Kasei Co. guaranteed grade was recrystallized twice from methanol-water; m. p. 82.5°C (lit. 83°C). Commercial pure picric acid was recrystallized three times from water; m. p. 122.6°C (lit. 122.5°C). Commercial guaranteed ethanol and acetone were fractionally distilled after usual treatments. The spectra of the solutions were measured with a Hitachi EPU-2 spectrophotometer at room temperature. Path length of absorption celles was 1 cm.

## Results and Discussion

**Absorption Spectra of the Red-Colored Solution in Water Containing a Small Quantity of Ethanol.** — The orange aqueous solution of picryl chloride was made by pipetting 1 cc. of an aqueous sodium hydroxide solution and 5 cc. of ethanol into 1 cc. of a paleyellow ethanolic solution of picryl chloride and diluting the solution with water to 25 cc. The orange solution changed into a paleyellow solution by addition of a dilute aqueous solution of hydrochloric acid immediately after the preparation. When it was allowed to stand at room temperature, the orange solution changed gradually into a yellow solution. The spectra of the orange solution are shown in Fig. 1. Picryl chloride in water, in ethanol and in acetone dose not show an absorption maximum in a range of wavelengths from 300 mμ to 600 mμ[1]. The orange solution gives absorption bands at about 360, 416 and 490 mμ immediately after the preparation, but an only intense absorption band at about 397 mμ when the solution is allowed to stand at room temperature for more than six hours.

1) T. Abe, This Bulletin, 32, 339 (1959).

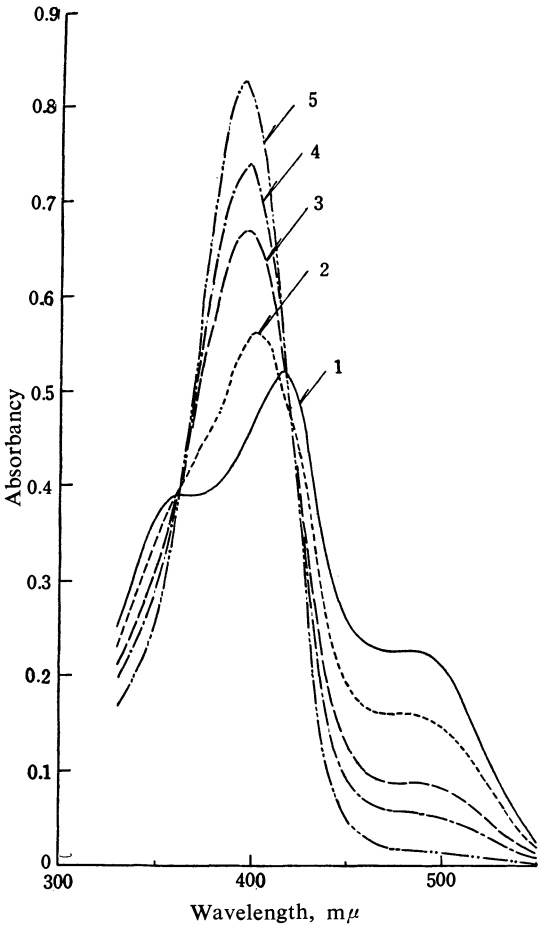

Fig. 1. Absorption spectra of picryl chloride ($3.15\times10^{-5}$ mol.) in water containing ethanol (24% by volume) in the presence of sodium hydroxide (0.377 N) at room temperature.
1 immediately after the preparation,
2 after 2.5 hr.,
3 after 6 hr.,
4 after 9 hr.,
5 after 20 hr.

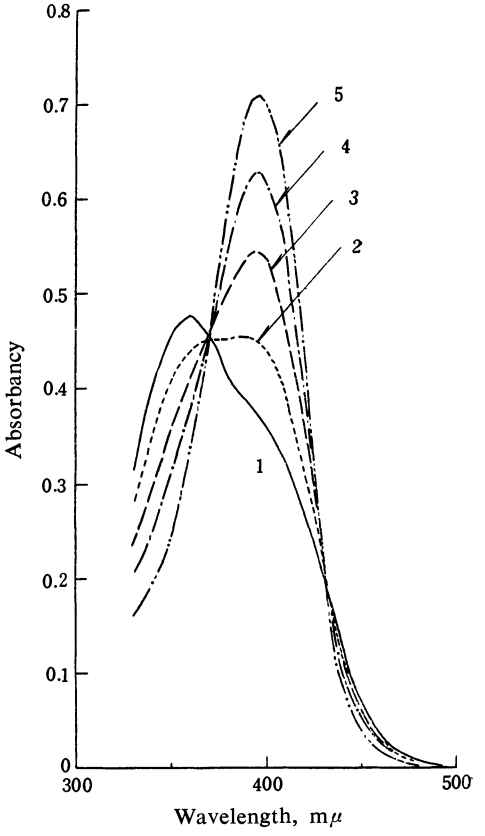

Fig. 2. Absorption spectra of picric acid ($3.12\times10^{-5}$ mol.) in water containing ethanol (24% by volume) in the presence of sodium hydroxide (0.377 N) at room temperature.
1 immediately after the preparation,
2 after 2 hr.,
3 after 5 hr.,
4 after 9 hr.,
5 after 20 hr.

Spectra of a solution of picric acid under the same condition in which the orange aqueous solution of picryl chloride was prepared, are indicated in Fig. 2. The solution of picric acid shows absorption bands at about 360 and 400 mμ, due to picrate anion, immediately after the preparation. However, when it is allowed to stand for many hours, the solution gives a 396 mμ band similar to the absorption curves 3-5 in Fig. 1. On addition of an aqueous hydrochloric acid solution, the 396 mμ band of the solution of picric acid disappears, as indicated in Fig. 3. Neither a spectrum of an aqueous picric acid solution ($3.12\times10^{-5}$ mol.) only in the presence of sodium hydroxide of 0.377 N nor a spectrum of an aqueous picric acid solution ($3.12\times10^{-5}$ mol.) containing only 24% ethanol by volume changed at all, although the solutions were allowed to stand at room temperature for more than ten hours. The intense 396 mμ bands in Fig. 2 closely resemble those of aqueous concentrated sodium hydroxide solutions of picric acid[2]. Both of the latter also disappeared when hydrochloric acid was added to the solutions. Accordingly, the 396 mμ bands in Fig. 2 may be due to a complex between picric acid and sodium hydroxide.

From the above results, the 397 mμ band of the solution in Fig. 1 can be considered to be due to picric acid produced from picryl chloride, in water containing both ethanol and sodium hydroxide. The 360 mμ band of the absorption curve 1 in Fig. 1 appears to be

2) T. Abe, *Nature*. **187**, 234 (1960).

1 water,
2 hydrochloric acid.

due to picric acid that changes later into the complex giving the 397 mμ band. Therefore, the 416 and 490 mμ bands of the curve 1 in Fig. 1 can be considered to be due to an labile intermediate that appears in the process of the substitution reaction of picryl chloride (I) to picric acid (III). This intermediate may be expected to be the same addition product II of Meisenheimer's type as presented for many colored products of polynitrobenzene derivatives with alkalies[1-15].

The absorption curve 1 at 416 and 490 mμ in Fig. 1 closely resembles those of red aqueous solutions of 1, 3, 5-trinitrobenzene, 2, 4, 6-trinitrotoluene and tetryl in the presence of sodium hydroxide[1,7]. The intense 416 mμ band lies at the wavelength close to that of

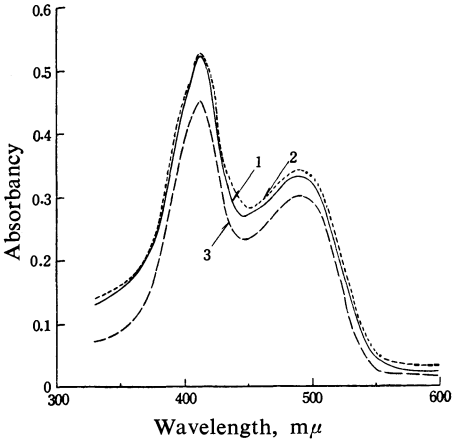

Fig. 4. Absorption spectra of picryl chloride ($1.77\times10^{-5}$ mol.) in ethanol (containing 4% water by volume) in the presence of sodium hydroxide ($4.16\times10^{-2}$ N) at room temperature.
1 immediately after the preparation,
2 after 2 hr.,
3 after 20 hr.

the maximum for an aqueous solution of a red complex obtained from an acetone solution of picryl chloride in the presence of ammonia water[6].

**Absorption Spectra of the Red-Colored Solution in Ethanol.**—The orange ethanolic solution of picryl chloride was made by pipetting 1 cc. of an aqueous sodium hydroxide solution into an ethanolic picryl chloride solution and diluting the solution to 25 cc. As indicated in Fig. 4, the orange ethanolic solution shows two absorption maxima at about 412 and 490 mμ close to those of the bands for the orange aqueous solution of picryl chloride. Yellow crystals began to precipitate from the orange ethanolic solution allowed to stand at room temperature for two hours. As shown in Fig. 4, the part of the solution gives the absorption maxima at the same wavelengths.

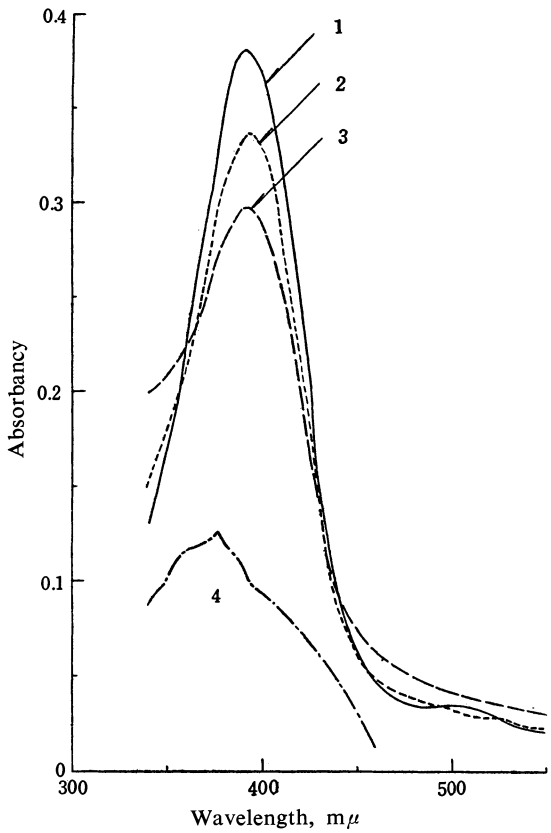

Fig. 6. Absorption spectra of picric acid ($1.81\times10^{-5}$ mol.) in acetone (containing 4% water by volume) in the presence of sodium hydroxide ($4.16\times10^{-2}$ N) at room temperature.
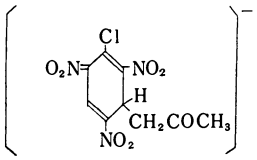
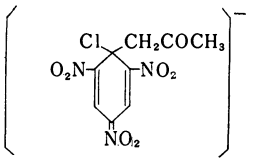
1 immediately after the preparation,
2 after 1 hr.,
3 after 3 hr.,
4 a solution of picric acid ($1.81\times10^{-5}$ mol.) in acetone.



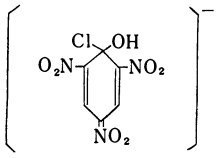
It was reported by Farmer[8] that on treatment of picryl chloride with methanolic potash, Meisenheimer's anion of [Picryl chloride·$OCH_3$]$^-$ was produced. It was reported by Nagakura and Oosawa[15] that when methoxide ion was added to a methanolic solution of chloro-dinitrobenzene, a red color appeared immediately and soon disappeared, and that chloro-dinitrobenzene was almost completely converted into dinitroanisole. The visible absorption curves in Fig. 4 would be due to Meisenheimer's product II. These absorption curves do not resemble that (showing an intense absorption band at about 425 mμ) of an ethanolic solution of the red complex obtained from the acetone solution of picryl chloride in the presence of ammonia water[6].

**Absorption Spectra of the Red-Colored Solution in Acetone.**—The reddishorange solution of picryl chloride in acetone was made by pipetting 1 cc. of an aqueous sodium hydroxide solution into an acetone solution of picryl chloride and diluting the solution to 25 cc. As indicated in Fig. 5, the reddishorange solution gives two absorption maximum bands at longer wavelengths of about 450 and 515 mμ, as compared with the orange aqueous solution in Fig. 1 and the orange ethanolic solution in Fig. 4. When allowed to stand, the reddishorange solution gradually changed into a decolorized solution giving a band at about 390 mμ. About three hours after the preparation the reddishorange solution became turbid. The spectra of the solution could not, therefore, be measured after that time.

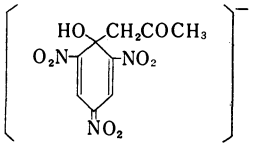


Spectra of a solution of picric acid under the same condition as when the reddishorange solution was prepared, are indicated in Fig. 6. The solution of picric acid showed an intence band at about 390 mμ immediately after the

preparation and also became turbid after about three hours. Absorbancy of the 390 mμ band decreases as the solution is allowed to stand.



Kimura[11] reported that picryl chloride in a mixture of acetone and methanol (50% by volume) gave an intense 450 mμ band and weak 520~530 mμ ones, and stated that the following four products were responsible for the color, where the product IV was predominant.



IV

V

VI

VII

The color reactions of trinitrobenzene derivatives with alkalies, however, occur instantaneously at room temperature even in the absence of acetone[1-9,13-15]. The absorption curve 1 in Fig. 5 closely resembles that of 1 in Fig. 1. In addition, the 360 mμ band of the absorption curve 3 in Fig. 5 seems to be due to picric acid produced in comparison with the absorption curves 1-3 in Fig. 6. Accordingly, the curve 1 in Fig. 5 would be due to the product II described above.

The curve (1) in Fig. 5 closely resembles that of a red solution prepared by adding a drop of aqueous sodium hydroxide solution to 1, 3, 5-trinitrobenzene in acetone[16].

## Summary

The red solution prepared by adding sodium hydroxide to an aqueous picryl chloride solution containing a small quantity of ethanol, was relatively stable even at room temperature. The red solution showing the two bands at about 416 and 490 mμ, changed into the yellow solution showing the band similar to that of picric acid under the same condition. Accordingly, the 416 and 490 mμ bands may be due to the intermediate of Meisenheimer's type in the process of the substitution reaction of picryl chloride to picric acid.

In the presence of sodium hydroxide, picryl chloride in ethanol as well as in acetone finally gave the absorption bands analogous to that of picric acid in water containing ethanol. The red solutions in ethanol and in acetone, therefore, would be due to the same intermediate.

The author is particularly indebted to Professor Yōkan Nomura for helpful discussions.

# *Vinyl Polymerization XLVII*. Polymerization of Acenaphthylene with Ziegler-Type Catalysts*

By Minoru IMOTO and Isamu SOEMATSU

(Received July 22, 1960)

Recently it was patented by Baxter et al.[1] that indene and acenaphthylene were polymerized in the presence of catalysts containing a titanium, vanadium or molybdenum halide in conjunction with a lithium alkyl, lithium aluminum hydride or lithium aluminum tetraalkyl. Partially crystalline homopolymers as well as copolymers of these polymers with ethylene, propylene or 1-hexadecene were described in the patent examples.

Before the patent was published, a kinetic study on polymerization of acenaphthylene in the presence of catalyst of $Ti(OBu)_4$-$AlEt_3$ or $Ti(OBu)_4$-$LiAlH_4$ was undertaken by the present authors. In this paper, the results obtained are described. In literature, polymerization of vinyl monomer with $Ti(OBu)_4$-$AlEt_3$ is found[2]. However, the system of $Ti(OBu)_4$-$LiAlH_4$ was little investigated.

## Experimental

**Materials.**—Aluminum triethyl was obtained from Mitsui Petroleum Co. It was specified to contain 25.87% Al and 74.10% $C_2H_5$. The material was used without further purification. The lithium aluminum hydride was of commercial grade. *n*-Butyl titanate was prepared by the descriptions in literature[3]; b. p. 189~189.1°C (16 mmHg), Ti 13.82% (as $Ti(OC_4H_9)_4$, 14.07%). Acenaphthylene was obtained from acenaphthene by its dehyrogenation; m. p. 92~93°C, b. p., 106~107°C/3 mmHg. *n*-Heptane and toluene, pure grade, was purified as usual.

## Results

**Polymerization of Acenaphthylene with $AlEt_3$-$Ti(OC_4H_9)_4$.**—*Procedure.*—Freshly distilled *n*-heptane was added to a 200 ml. three-necked flask with a mercury seal stirrer, an inlet tube for nitrogen and monomer, and a thermometer. The system was flushed with dry nitrogen. A solution of $(BuO)_4Ti$ in heptane and then a solution of $AlEt_3$ in heptane were added under vigorous stirring. Color appeared immediately, varying from light red to deep green. No precipitate was formed. After 10 min. stirring, the monomer solution was introduced dropwise.

The polymerization system was poured into a large excess of methanol and the precipitate was repeatedly purified by reprecipitation from benzene solution with methanol. The polymer thus obtained contained no trace of ash.

*Effects of Al/Ti Molar Ratio on Conversion of Monomer and on* $[\eta]$ *of Polymer.*—Keeping

3) F. Bischoft and H. Adkins, *J. Am. Chem. Soc.*, **46**, 256 (1946).

the quantity of $AlEt_3$ constant at 0.376 g, the quantity of tetrabutyl titanate was varied. 5.00 g. of acenaphthylene was taken. The total volume was 100 ml.

Polymerization was carried out for 10 hr. The results obtained were illustrated in Figs. 1 and 2.

A maximum of conversion appeared at the molar ratio of Al/Ti of 2 : 1.

*Estimation of Activation Energy.* — The concentrations of aluminum triethyl and acenaphthylene were 0.376 g. and 5.00 g. in 100 ml. of the reacting solution. The molar ratio of Al/Ti was kept constant at 2 : 1. The conversions were shown in Fig. 3.

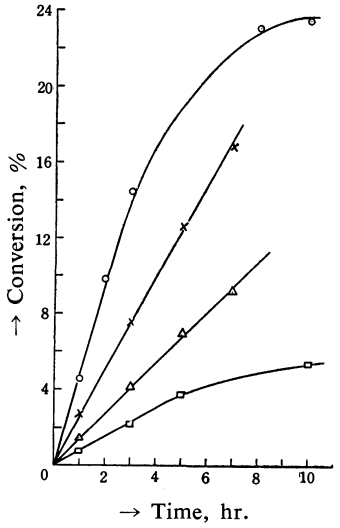

Fig. 3. Conversion of monomer vs. polymerization time.

From the slopes of the conversion curves, the initial rates of polymerisation were computed as Table I.

Table I. Rates of polymerization

| | $Rp$(mol./l. sec.) |
|---|---|
| 50±0.05°C | $0.723\times10^{-6}$ |
| 60 | 1.300 |
| 70 | 2.438 |
| 80 | 4.775 |

From Table I the activation energy for the polymerization of acenaphthylene with $AlEt_3$-$Ti(OC_4H_9)_4$ was computed as 14.3 kcal./mol. (c. f. Fig. 4).

Using collodion film, molecular weight of a polymer was measured by the method of osmotic pressure, as shown in Table II. Intrinsic viscosity was also measured in benzene ($c$=g./100 ml.).

Even if polyacenaphthylene had the small value of $[\eta]$, its molecular weight measured

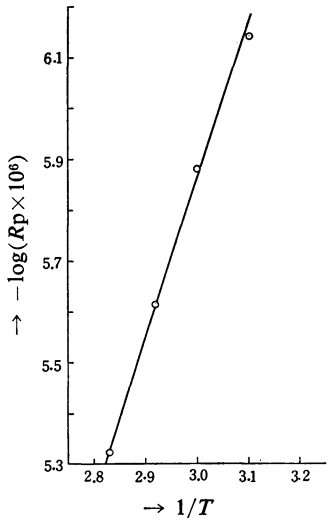

Fig. 4. Estimation of activation energy.

Table II.

| Polymer | Mol. wt. | $[\eta]^{30°}_{Benzene}$ | Literature |
|---|---|---|---|
| Al/Ti=3 : 1 80°C, 10 hr. | 108000 | 0.035 | This paper |
| $BF_3Et_2O$ (60°C) | 125000 | 0.040 | Imoto, Takemoto[4] |

by the method of osmotic pressure was very great. As Table II shows, this characteristic figure coincided with the result obtained in the previous paper[4].

**Polymerization of Acenaphthylene with $LiAlH_4$-$Ti(OC_4H_9)_4$.** — In a tube, 0.0671 g. of $LiAlH_4$, 1.00 g. of acenaphthylene and various quantities of $Ti(OC_4H_9)_4$ in 10 ml. of toluene were sealed. The tubes were heated at 100± 1°C for 2 hr. and then treated as described above. The results were illustrated in Fig. 5.

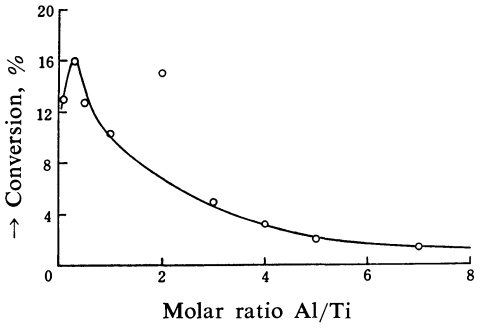

Fig. 5. Conversion of monomer vs. molar ratio of Al/Ti.

The initial rates of polymerization at several reaction temperatures were measured from the conversion curves, as shown in Fig. 6.

4) M. Imoto and K. Takemoto, *J. Polymer Sci.*, **15**, 271 (1955). (The value of $[\eta]$ was not described.)

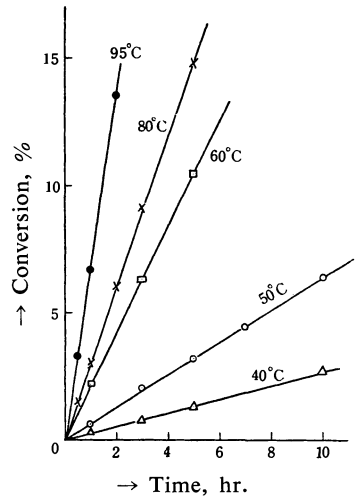

Fig. 6. Conversions of monomer at various temperatures vs. polymerization time.

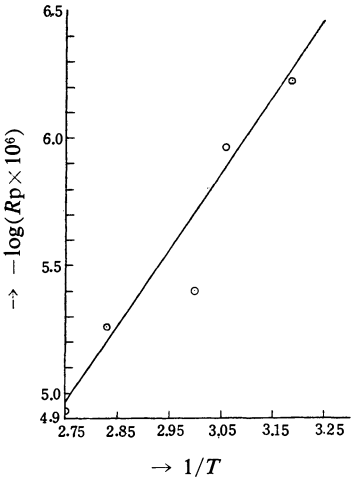

Fig. 7. Estimation of activation energy.

TABLE III. THE INITIAL RATES

| Temp. | $[Rp]_0$ |
|---|---|
| 40±0.05°C | $0.603\times10^{-6}$ mol./l. sec. |
| 50 | 1.15 |
| 60 | 3.99 |
| 80 | 5.55 |
| 95 | 12.2 |

These observations were made in the condition as follows: $LiAlH_4$ 0.25 g., acenaphthylene 1.00 g., toluene 10 ml. and the molar ratio of Al/Ti 2:1. The computed values of the initial rates are tabulated in Table III.

From the values of $[Rp]_0$ in Table III, the apparent activation energy was estimated at about 13 kcal./mol., as in Fig. 7.

After ten hours polymerization, five kinds of polymers were obtained. As to these polymers, the intrinsic viscosities were measured in benzene at 30±0.1°C and the apparent softening points were observed in sealed tubes. The results were shown in Table IV.

TABLE IV. $[\eta]$ AND SOFTENING POINTS

| Temp. | $[\eta]$ | Soften. pt. |
|---|---|---|
| 40°C | 0.0259 | 303°C |
| 50 | 0.0260 | 305 |

**Polymerization of Styrene and Methyl Methacrylate with $LiAlH_4$-$Ti(OB_4H_9)_4$.**—The procedure for polymerization was the same as that described above. 0.0256 g. of $LiAlH_4$ and 0.5 mol. equivalents of $Ti(OB_4H_9)_4$, i.e., the Al/Ti molar ratio 2:1, were used as catalyst. The temperature was 80±1°C and the duration of reaction was 20 hr. The results obtained in toluene were shown in Table V.

TABLE V.

| | Methyl metacrylate g. | Styrene g. | Acenaphthylene, g. | Yield g. |
|---|---|---|---|---|
| Copolymerization | 1.980 | — | 1.000 | 1.1235 |
| | — | 2.040 | 1.000 | 0.1065 |
| Polymerization | 1.980 | — | — | 0.3360 |
| | — | 2.040 | — | 0.6980 |

## Summary

Polymerization of acenaphthylene was studied kinetically in heptane or toluene in the presence of titanium butanate-aluminum triethyl or titanium butanate-lithium aluminum hydride at 40~95°C. Activation energy was computed as 14.3 and about 13 kcal./mol.

Molecular weight of the polymer obtained was 125000, while $[\eta]^{30°}_{\text{Benzene}}$ was only 0.035 ($c$=g./100 ml.).

# *Studies on the Mucilage of the Root of "Tororo-aoi" (Abelmoschus manihot, MEDIC). III. On the Mechanism of the Characteristic Colloidal Nature of the Mucilage*

By Saburo INOKAWA

(Received April 28, 1960)

In the previous paper[1] it has been shown that in the freshly purified mucilage there exists a network structure built by a very strong interaction between the mucin molecular chains, and that an irreversible marked loss of the interaction occurs by heat treatment although the change in average molecular weight measured by osmotic pressure is small[2]. The present investigation was undertaken in order to explain the mechanism of the network structure in the fresh mucilage and its breaking by heat treatment. Details are shown as follows.

## Experimental

**1) Material.**—Roots of "*Tororo-aoi*" were stored in 0.5% formalin.

**2) Crude Mucilage, Purified Mucin, and Purified Mucilage.**—These preparations were similar to those described in the previous paper[3].

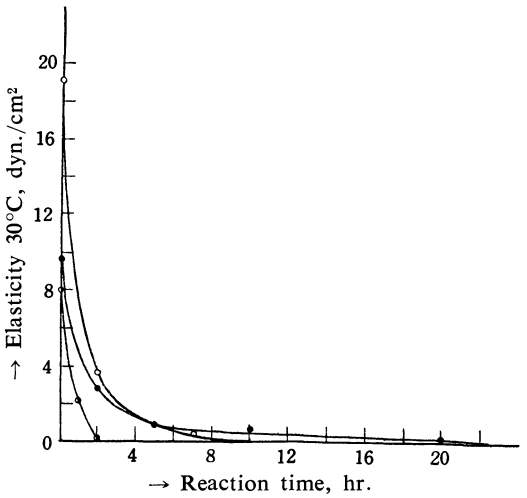

Fig. 1. Effect of addition of $H_2O_2$, $H_2SO_4$, or $H_2O_2$–$H_2SO_4$ on the elasticity of the purified mucilage.
Concentration of mucilage: 0.53%
○, $H_2O_2$ (0.12%)
●, $H_2SO_4$ (9.8%)
◑, $H_2O_2$–$H_2SO_4$ (0.06% : 9.8%)

**3) Elasticity and Intrinsic Viscosity.**—These determinations were the same as those described in the previous paper[3].

**4) Action of Hydrogen Peroxide on the Mucilage.**—The elasticity changes (at 15°C) in the purified mucilage in the presence of hydrogen peroxide, sulfuric acid, or the mixture of both, are shown in Fig. 1.

Acetone was added into the mucilage to precipitate the mucin, just when the elasticity could hardly be observed in the above experiments. The mucin thus obtained was washed with acetone, dried up in vacuo and redissolved in water. In the experiment using sulfuric acid, the redissolved mucilage was neutralized with a dilute sodium hydroxide solution. Table I gives the results of measurement of intrinsic viscosity of the redissolved mucilage.

TABLE I. INTRINSIC VISCOSITY OF THE PURIFIED MUCILAGE JUST WHEN THE ELASTICITY COULD HARDLY BE OBSERVED BY ADDITION OF HYDROGEN PEROXIDE, SULFURIC ACID, OR BOTH

| Treatment by | Intrinsic viscosity l./g. | | | | Mean value l./g. |
|---|---|---|---|---|---|
| $H_2O_2$ | 1.7 | 1.2 | 1.8 | 1.6 | 1.6 |
| $H_2SO_4$ | 0.47 | 0.55 | 0.58 | 0.50 | 0.53 |
| $H_2O_2$–$H_2SO_4$ | 1.8 | 1.7 | 1.4 | 1.7 | 1.7 |
| Heating at 80°C for 2 hr. | 1.5 | 1.6 | 1.4 | 1.4 | 1.5 |

The intrinsic viscosity of the mucilage treated with hydrogen peroxide or hydrogen peroxide-sulfuric acid is about the same as that of the heated mucilage. However, that of the mucilage treated with sulfuric acid is 0.52, and is considerably smaller than the above-mentioned values.

**5) Effect of Oxygen in the Air upon the Mucilage and the Mucin.**—a) The purified mucins, one in nitrogen atmosphere and the other in the air, were

TABLE II. EFFECT OF OXYGEN UPON THE INTRINSIC VISCOSITY LOSS OF THE PURIFIED MUCIN BY HEAT TREATMENT

| Heated in | Intrinsic viscosity, l./g. | |
|---|---|---|
| | Before heating | After heating at 80°C for 120 min. |
| $N_2$ atmosphere | 2.86 | 2.77 |
| Air | 2.86 | 1.83 |

1) S. Inokawa, This Bulletin, **33**, 1476 (1960).
2) S. Inokawa, R. Goto and I. Morimoto, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagagu Zasshi*), **81**, 783 (1960).
3) S. Inokawa, This Bulletin, **33**, 1472 (1960).

TABLE III. EFFECT OF OXYGEN UPON THE INTRINSIC VISCOSITY LOSS OF THE PURIFIED MUCILAGE BY HEAT TREATMENT

| Condition | Method | Intrinsic viscosity, l./g. | | |
|---|---|---|---|---|
| | | Before heating | After heating 80°C, 90 min. | After heating 80°C, 150 min. |
| Oxygen-free mucilage | High vacuum | 2.64 | 2.23 | 2.10 |
| | $N_2$-blowing | 2.55 | 2.20 | 2.08 |
| Air-containing mucilage | | 2.80 | 1.47 | 1.38 |

heated at 80°C for 120 min. by the high vacuum method described in the previous paper[4]. Both the heated mucins were dissolved in water and the viscosity was measured. As shown in Table II the intrinsic viscosity of the mucin heated in nitrogen atmosphere does not decrease practically. b) The purified oxygen-free mucilage prepared by the high vacuum method[4] was heated at 80°C and the intrinsic viscosity was measured. As shown in Table III the intrinsic viscosity loss of the purified oxygen-free mucilarge by heating is much smaller than that of the usual air-containing mucilage.

For the purpose of obtaining oxygen-free mucilage more simply, oxygen-free nitrogen[5] was blown for 10 hr. into the purified mucilage in the glass tube shown in Fig. 2, and then the glass tube was sealed off first at A and next at B. The viscosity loss of the obtained oxygen-free mucilage by heating was similar to that of oxygen-free mucilage prepared by the high vacuum method as shown in Table III. Then, the effect of oxygen upon the elasticity loss of the purified mucilage by heating was examined

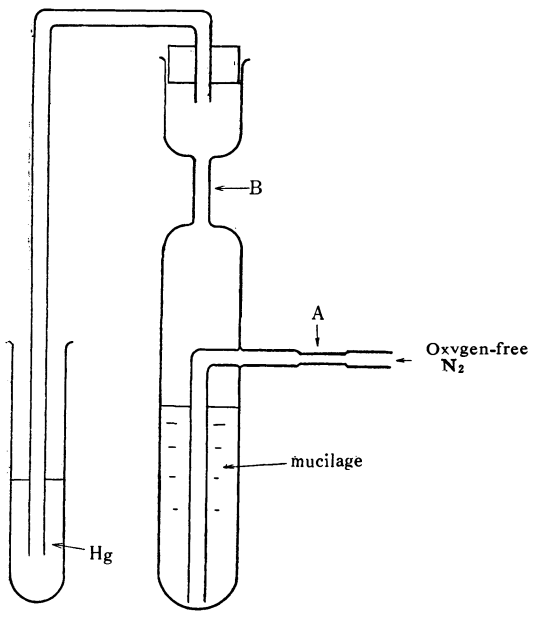

Fig. 2. Apparatus for the blowing method.

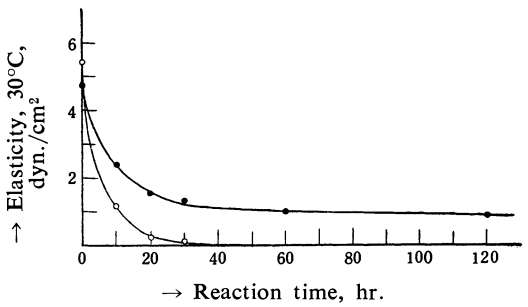

Fig. 3. Effect of oxygen on the elasticity fall of the purified mucilage by heating.
Concentration of mucilage: 0.31%.
○, air-containing mucilage
●, oxygen-free mucilage

by this nitrogen-blowing method. The elasticity loss of nitrogen-blowing mucilage by heating as shown in Fig. 3 is much smaller than that of the air-containing mucilage.

**6) Muddy Matter Produced by Heating.**—It has been reported[1], from the observation of sedimentation diagrams of the heated purified mucilage in an ultracentrifuge that there was something which sedimented rapidly in the initial few minutes. A precipitate[6] (ca. 1.1 wt. % of mucin), which was dispersed easily by irradiation of ultrasonic wave, was obtained from the purified mucilage heated at 95°C for 16 hr. The dispersed precipitate was mounted on a specimen holder for electron microscopy with a formvar supporting-film and dried.

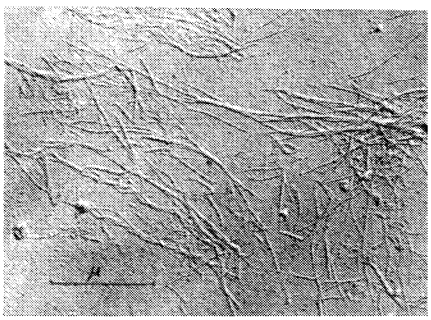

Fig. 4. Electron micrograph of the precipitate produced by heating the purified mucilage.
(dispersed by ultrasonic wave)
(Cr-shadowing)

4) S. Inokawa, R. Goto and E. Fujimoto, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **81**, 678 (1960).

5) By blowing of carbon dioxide instead of nitrogen, similar results were obtained.

6) This precipitate did not show reactions of starch.

After chromium-shadowing the specimen was observed by an electron microscope of the type Akashi TRS-50 B, showing a fine fiber-like picture as shown in Fig. 4. The nitrogen content of the precipitate was 1.9%. After hydrolysis of the precipitate in 2 N hydrochloric acid at 100°C for 22 hr. in a sealed tube, the hydrolyzed solution was diluted with water, filtered, passed through a cation-exchange resin Amberlite IR-112, evaporated, and dried, in vacuo. From the residue only glucose was detected by paper chromatography using the solvent system: ethyl acetate: pyridine: water (12 : 5 : 4).

**7) Effect of Potassium Thiocyanate, Sodium Lauryl Sulfate, Guanidine Hydrochloride, and Dichloro acetic Acid on the Elasticity of the Purified Mucilage.**—Fig. 5 shows the elasticity curves plotted against concentrations of four sorts of reagents. It is observed that the elasticity is practically uninfluenced by the addition of these reagents[7].

**8) Periodate Oxidation of the Mucilage.**—The mucilage (0.448 g.) was dissolved in water (in 500 ml. bottle), and sodium periodate solution (0.2 M, 10 ml.) was added, followed by water to the requisite volume. Formic acid was yielded, and uptake of periodate of the solution followed. The results are tabulated in Table IV. It is clear that 1 M of formic acid was produced by consuming 2 M of periodate.

## Discussion

It is said that the mucin of "*Tororo-aoi*" is a polysaccharide consisting of rhamnose and galacturonic acid linked in straight chains[10] and the molecular weight is very high, that is, the value is 150000~200000[2]. The relative amounts of the components vary, depending on the source. However, it is shown from the results of periodate-oxidation (experiment 8) that the mucin molecule has branched chains. Thus, it seems to be plausible that the mucin molecule is a long chain polysaccharide with many short branched chains. Also, it has been shown that in the fresh purified mucilage there exists a network structure like a gel[1]. Considering that the elasticity is little changed by the electrolysis[3] or the addition of sodium chloride[3], the network structure may not be built by intermolecular ionic bonds of the mucin. Moreover, the elasticity is little influenced by the addition of potassium thiocyanate, sodium lauryl sulfate, guanidine hydrochloride, and dichloroacetic acid (experiment 7). Therefore the network structure may not be built by hydrogen bonds between mucin molecules. Also, the agitation of mucilage causes an irreversible diminution of the elasticity[3]. From the consideration of these experimental results, it seems to be most reasonable to suppose that the network structure is built by interlocking or entanglement of mucin molecules.

By heating, the elasticity of the purified mucilage diminishes and at the same time muddy matters consisting of fibrous glucosans and proteins were produced (experiment 6) but the molecular weight change is slight[2]. These experimental results mentioned above would lead to the conclusion that the mucin molecules are entangled between short branched chains of the mucin molecules, fibrous glucosans and proteins. On heating, the entanglement is broken by oxidation (experiment 5).

## Summary

1) The colloidal characteristics of the mucilage from "*Tororo-aoi*" such as the elasticity, spinnability, and so on are caused by the network built by interlocking between short branched chains of the mucin molecules, fibrous glucosans and proteins.

7) It seems to be reasonable that a little loss in elasticity by the addition of dichloroacetic acid was caused by a change of pH in the mucilage because the elasticity loss was identical with the case in which acetic acid or oxalic acid was added.

8) P. F. Fleury and J. Lange, *J. pharm. Chim.*, [8], **17**, 107, 196 (1933).

9) The value of G mol. was assumed to be 161, which is the mean value of molecular weight of rhamnose and galacturonic acid.

10) S. Machida and N. Uchino, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **74**, 183 (1953).

2) The remarkable change of the colloidal nature by heating is caused by breaking down the interlocking by oxidation.

Finally the writer wishes to express his hearty thanks to Professor R. Goto, Kyoto University, for his invaluable advice and encouragement throughout this work. He is also indebted to Professor E. Suito and Dr. K. Takiyama of Kyoto University for their help in the preparation of the electron micrographs, and further to Mr. A. Sera, Mr. A Takatsuki, Mr. I. Morimoto and Mr. E. Fujimoto for their kind co-operation in this research. It is a pleasure to thank Koshin Kogyo Co. for the generous supply of roots of "*Tororo-aoi*".

# *Hydrogenation and Hydrogenolysis. V*[1]*. Rhodium-Platinum Oxide as a Catalyst for the Hydrogenation of Organic Compounds*[2]

By Shigeo NISHIMURA

(Received July 26, 1960)

In previous papers[1,2], it was reported that rhodium-platinum oxide, prepared by fusion of the mixture of rhodium chloride and chloroplatinic acid or ammonium chloroplatinate in a ratio of 3 : 1 by the weights of the metals with sodium nitrate exactly in the same way as in the preparation of Adams platinum oxide, can be reduced with hydrogen to the metal form under ordinary conditions and also that the resulting rhodium-platinum black is an excellent catalyst retaining the nature of pure rhodium catalysts and is substantially superior to Adams platinum oxide both in activity and in selectivity in the hydrogenation of various aromatic compounds. The present paper describes the use of the rhodium-platinum oxide as a catalyst and also the comparisons with platinum oxide and with palladous oxide in the hydrogenation of various organic compounds under ordinary conditions.

## Experimental

**Materials.** — The oxide catalysts were prepared according to the procedures described in the preceding paper[1]. Glacial acetic acid of Wakō Pure Chemical Industries G. R. grade was used without further purification. Commercial 95% ethanol was used after distillation. All the substrates were carefully purified before use by recrystallization or by distillation.

**Hydrogenation.**—Hydrogenation was carried out under atmospheric pressure and at room temperature (24~26°C). After the oxide was reduced to metal, the substance was added with a small amount of solvent, and the mixture was shaken with hydrogen at about 350~400 oscillations per minute.

## Results and Discussion

**Catalytic Reduction, where the C-O Linkage is Liable to Hydrogenolysis.** — As already reported in previous papers[1,2], the compounds, which have C-O linkages susceptible to hydrogenolysis, are less hydrogenolyzed and much more rapidly hydrogenated in acetic acid with rhodium-platinum oxide than with platinum oxide[3]. Further results are shown in Tables I and II, and also the hydrogenation of acetophenone in Table III and furfuryl alcohol in Table IV. If less hydrogenolysis is desired, it is preferable to use ethanol with a small amount of acetic acid as the solvent, as shown in the hydrogenation of benzyl methyl ether[4]. Benzyl acetate is almost completely hydrogenolyzed even under these conditions. The addition of a slight amount of hydrochloric acid increases the hydrogenolysis as shown in the hydrogenation of hydroquinone with platinum oxide[5].

Aliphatic and alicyclic ketones are also less hydrogenolyzed and much more rapidly hydrogenated with rhodium-platinum oxide than with platinum oxide in acetic acid (Table II).

TABLE II. CATALYTIC REDUCTION OF ALIPHATIC AND ALICYCLIC KETONES

| Compound, g. | Solvent, ml. | Catalyst, g. | Hydrogen uptake mol./mol. | Time for hydrogenation min. |
|---|---|---|---|---|
| Diethyl ketone, 0.861 | AcOH, 20 | Rh-Pt oxide, 0.05 | 1.01 | 140 |
| 〃 | 〃 | Pt oxide, 〃 | 1.01 | 150 |
| Cyclohexanone, 0.981 | 〃 | Rh-Pt oxide, 〃 | 1.03 | 7 |
| 〃 | EtOH, 20 | Pt oxide, 〃 | 1.00 | 80 |
| 〃 | AcOH, 20 | 〃 〃 | 1.27 | 30 |
| 〃 | AcOH, 20+ 3 N HCl, 0.1 | 〃 〃 | 1.31 | 24 |
| Cyclopentanone, 0.841 | AcOH, 20 | Rh-Pt oxide, 〃 | 1.08 | 40 |
| 〃 | 〃 | Pt oxide, 〃 | 1.56 | 200 |
| Ethyl acetoacetate, 1.302 | 〃 | Rh-Pt oxide, 〃 | 1.11 | 15 |
| 〃 | 〃 | Pt oxide, 〃 | 1.56 | 300 |

In neutral ethanolic solution these ketones are hydrogenated quantitatively with platinum oxide to the corresponding alcohols with the absorption of just one mole of hydrogen, and the addition of hydrochloric acid increases hydrogenolysis, though only to a small extent, as shown in the hydrogenation of cyclohexanone. As is well known, palladous oxide is practically ineffective for the hydrogenation of these ketones. Details of the hydrogenation and hydrogenolysis of aliphatic and alicyclic ketones will be published later.

**Catalytic Reduction of Acetophenone (Table III).**—Acetophenone is reduced with rhodium-platinum oxide to cyclohexylmethylcarbinol quantitatively in ethanol and almost quantitatively in acetic acid. The hydrogenation is especially rapid in the latter solvent accompanied only by a slight hydrogenolysis (6%). With platinum oxide, in ethanol as the solvent, one mole of hydrogen is absorbed rather rapidly and further reduction occurs only very slowly, and in acetic acid as the solvent, as much as 84% is hydrogenolyzed to give ethylcyclohexane as indicated by the hydrogen uptake. Both platinum oxide and palladous oxide show the greatest activity for the reduction to ethylbenzene in the presence of acetic acid with

TABLE III. CATALYTIC REDUCTION OF ACETOPHENONE

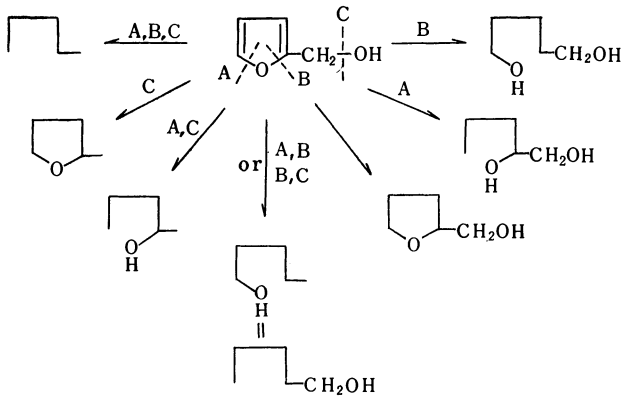

Fig. 1. Catalytic reduction of furfuryl alcohol.

added hydrochloric acid, while the reduction proceeds only very slowly with rhodium-platinum oxide in the same medium. As is well known, palladium is a catalyst preferred for the selective reduction of the side chain because of its low activity for the hydrogenation of the benzene nucleus. Like platinum and palladium catalysts, deactivated rhodium-platinum is also reactivated by shaking with air, and this process is very effective in the hydrogenation of a larger amount of a substrate.

**Catalytic Reduction of Furfuryl Alcohol (Table IV).**—The complete hydrogenation of furfuryl alcohol under mild conditions is generally expected to give the seven compounds as the result of various competitive reactions between the hydrogenation of the double bonds and the hydrogenolysis of the three C–O linkages indicated by A, B and C, as illustrated in Fig. 1. The kinds and amounts of the products largely depend on the nature of the catalyst and the solvent used. Both rhodium-platinum oxide and palladous oxide give tetrahydrofurfuryl alcohol quantitatively in acetic acid as well as in ethanol with the absorption of two moles of hydrogen. The reduction proceeds most rapidly with rhodium-platinum oxide in acetic acid. With platinum oxide the reduction could not be completed in ethanol because of the decreasing rate of the hydrogenation. But in acetic acid the reduction proceeds smoothly to completion

TABLE IV. CATALYTIC REDUCTION OF FURFURYL ALCOHOL

TABLE V. PRODUCTS OF CATALYTIC REDUCTION OF FURFURYL ALCOHOL WITH PLATINUM OXIDE IN ETHANOL (OR TETRAHYDROFURFURYL ALCOHOL) WITH HYDROCHLORIC ACID

| Product | Yield, % | B. p., °C | $n_D^{20}$ |
|---|---|---|---|
| Pentane* | 0.8 | 35 | |
| 2-Methyltetrahydrofuran* | 14.8 | 75～84 | 1.4031 |
| 2-Pentanol | 5.5 | 120～123 | 1.4047 |
| 1-Pentanol | 11.6 | 137～139 | 1.4096 |
| Tetrahydrofurfuryl alcohol | 20.6 | 173～177 | 1.4505 |
| 1,2-Pentanediol | 13.3 | 110～113/21 mmHg | 1.4402 |
| 1,5-Pentanediol | 3.3 | 138～142/21 mmHg | 1.4499 |

* These compounds were isolated with the use of tetrahydrofurfuryl alcohol as the solvent.

with an extensive hydrogenolysis as indicated by the absorption of 2.86 mol. of hydrogen[6]. On the other hand, in the presence of hydrochloric acid and ethanol (or tetrahydrofurfuryl alcohol), all the seven compounds were obtained with absorption of 3.11 mol. of hydrogen as shown in Table V[7]. The portion of hydrogenolysis increases further in the presence of acetic acid and hydrochloric acid. With palladous oxide, even in the presence of hydrochloric acid, no hydrogenolysis occurs before the saturation of the double bonds.

**Catalytic Reductions of Other Aromatic and Heterocyclic Compounds (Table VI).**—Rhodium-platinum oxide is as effective for the hydrogenation of pyridine and quinoline as for aromatic compounds, and substantially more active than platinum oxide also in these hydrogenations. The rhodium-platinum catalyst is also the most active of the three oxides in the hydrogenation of the double bond of the side chain as shown in the hydrogenation of ethyl cinnamate (Table VI) and cinnamyl alcohol (Ref. 1). Palladous oxide is more active in these hydrogenations than platinum oxide.

**Catalytic Reduction of Nitrobenzene (Table VII).**—Rhodium-platinum oxide is also the most active catalyst in the hydrogenation of nitrobenzene to aniline. Contrary to platinum oxide and palladous oxide, rhodium-platinum oxide is more active in acetic acid than in ethanol. The subsequent hydrogenation of the benzene nucleus proceeds rather slowly both with rhodium-platinum oxide and with platinum oxide in acetic acid. Palladous oxide is almost entirely ineffective for the hydrogenation.

The present results with those reported previously show that the rhodium-platinum (3 : 1) oxide is a substantially more active catalyst than platinum oxide and palladous oxide in the hydrogenation of various organic compounds under ordinary conditions[8], and especially effective where it is desired to avoid hydrogenolysis. Decrease of the platinum in the rhodium-platinum oxide depresses the hydrogenolysis further, but only to a small extent. On

6) H. A. Smith and J. F. Fuzek, *J. Am. Chem. Soc.*, **71**, 415 (1949), report that 1, 2-pentanediol was obtained almost quantitatively under similar conditions.

7) W. E. Kaufmann and R. Adams, *J. Am. Chem. Soc.*, **45**, 3029 (1923), reported that 1-pentanol, 1, 2- and 1, 5-pentanediols and tetrahydrofurfuryl alcohol were obtained with platinum oxide in the presence of ethanol and a small amount of ferrous chloride with the absorption of 2.5 mol. of hydrogen. Their results show that only the C-O linkages A and B were hydrogenolyzed under these conditions.

8) The metal content of rhodium-platinum (3 : 1) oxide is only 65% of its weight. The value is considerably smaller than those of platinum oxide (80%) and palladous oxide (87%). Therefore, the activity of the rhodium-platinum oxide is much greater when compared in a unit weight of the metal.

TABLE VI. CATALYTIC REDUCTIONS OF OTHER AROMATIC AND HETEROCYCLIC COMPOUNDS

the other hand, the decrease of platinum causes the following disadvantages: (a) It takes a longer time for the reduction of the oxide to the metal. (b) The recovery of the catalyst becomes more difficult, because the residue insoluble in aqua regia increases with the decrease of the platinum[9]. For the reasons mentioned above, the present author chooses the proportion 3 : 1 of the two metals in the rhodium-platinum oxide as satisfactory for most hydrogenations and convenient for practical use. The fact that the rhodium-platinum oxide is not identical with a mere mixture of rhodium oxide and platinum oxide, the former being reduced with hydrogen much more rapidly and uniformly than the latter, was further confirmed by an X-ray diffraction of these oxides. The peak of rhodium oxide at $2\theta=28°$ (Cu-$K_\alpha$ radiation) disappers completely and most of other peaks of the oxide are greatly deformed in the pattern of rhodium-platinum (3 : 1) oxide, while the peak of rhodium oxide at 28° and the peak of platinum oxide at 33.3° are clearly detected in the pattern of a mechanical mixture of rhodium oxide and platinum oxide in a ratio of 3 : 1 by the weights of the metals.

The author wishes to express his hearty thanks to Professor Yoshiyuki Urushibara for his valuable suggestions and encouragement. The author is also indebted to Dr. Hiroshi Takahashi for the measurement of the X-ray diffraction and to the Ministry of Education for a Grant-in-Aid for Scientific Research.

9) This insoluble residue can be dissolved, e. g., by heating with hydrobromic acid and bromine at 100°C in a sealed tube ("Gmelins Handbuch der Anorganischen Chemie", Vol. 64, Verlag Chemie, G. m. b. H., Berlin (1938), p. 43.).

# *Molecular Orbital Theory of Reactivity in Non-Alternant Hydrocarbons*

By Kenichi FUKUI, Teijiro YONEZAWA and Chikayoshi NAGATA

(Received July 11, 1960)

In the past decades there have been proposed not a few theoretical indexes for explaining chemical reactivity of a conjugated system. These are such as $\pi$-electron density[1], self-polarizability[2], free valence[3], localization energy[4], Dewar's approximate localization energy[5], frontier electron density[6], super-delocalizability[7], and so forth[8,9]. These quantities were derived from entirely different physical grounds. Nevertheless, predictions of the position of chemical attack by these quantities agreed well with known experimental results. This remarkable fact has attracted the attention of theoretical chemists, and several authors have attempted to interrelate these quantities[3,5,10-12]. The mathematical relations underlying these quantities in alternant hydrocarbons and hetero-alternant molecules have been clarified by the present authors[13] and Baba[14]. That is, as far as some conditions are satisfied, theoretical indexes in static, localization, and frontier electron methods were found to be entirely parallel. If this were so, good coincidence between the indexes and experiments does not always mean that each one of these indexes is the true reflection of the process of reaction. Rather, a possibility might exist that some of them are not qualified as the "good" index in the most general sense and the coincidence of such quantities with experimental facts may due mainly to the existing mathematical relations.

In this connection we should compare the theoretical prediction of an index with experimental data with regard to the compounds in which no such mathematical interrelation as found in alternant hydrocarbons exists. This will serve as testing the availability of theories and finding out the theory closest to the true mechanism of reaction. For this purpose the most suitable material may be non-alternant hydrocarbons in which less intimate relations than in alternant molecules are expected between these theoretical indexes.

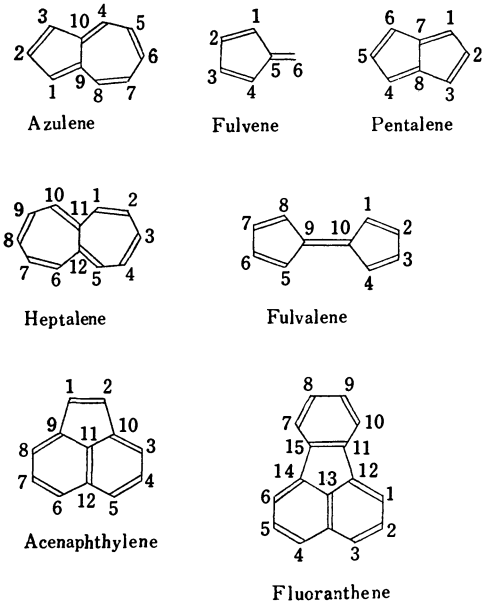

Fig. 1. Structure and numbering of non-alternant hydrocarbons.

In the present paper frontier electron density and superdelocalizability for several non-alternant hydrocarbons were calculated. The structure and numbering of these hydrocarbons are shown in Fig. 1. The calculated values of frontier electron density and superdelocalizability were compared with known experimental results, together with other theoretical indexes.

## Results and Discussion

Theoretical indexes of non-alternant hydrocarbons were compared with experiments for three cases of reactions, that is, for electrophilic, radical and nucleophilic reactions, respectively.

**Reaction with an Electrophilic Reagent.**—In Table I, the values of localization energy, frontier electron density and superdelocalizability for an electrophilic attack and the value of $\pi$-electron density were listed and compared with known experimental results. The values corresponding to the predicted position of attack are specified by italic letters. Experiments were once carried out for azulene, acenaphthylene and fluoranthene. As is seen in Table I, all indexes predict the same position as the most reactive for azulene and for acenaphthylene in accordance with experiments[15,16]. For fluoranthene, however, the situation is different. That is, the experiments showed that the bromination reaction occurred at two positions giving 3, 8-dibromo fluoranthene[17,18]. The prediction of frontier

electron theory agreed well with this fact because the values of frontier electron density and superdelocalizability at 3 and 8 positions are larger than the other positions. On the other hand, the total $\pi$-electron density method (the static method) predict 8 and 2 positions as the most susceptible to an electophilic attack, and localization method 3 and 7 positions. Other compounds such as fulvene, pentalene, heptalene and fulvalene have never been synthesized and accordingly no available experimental data have hitherto been obtained. The prediction of all indexes agreed entirely with each other in these compounds.

**Reaction for a Radical Reagent.**—In Table II, localization energy, frontier electron density and superdelocalizability for radical attack and the values of free valence were shown in comparison with known experimental data. For azulene the experiments showed that radical reagents attack position 1[19]. As is clearly seen in Table II, the values of frontier electron density and superdelocalizability explain the experimental fact well, whereas other indexes such as free valence and localization energy predict that position 4 will be the most reactive. Some doubts have been pointed out in connection with the reliability of the free valence as a chemical reactivity index[5,20]. Not a few cases appeared in which this index failed to explain the experiments; for example, in phenanthrene and 2-pentene[21]. On the other hand, localization energy has proved to be a good index in the case of alternant hydrocarbons. It may be of theoretical interest to observe in non-alternant hydrocarbons the inability of localization energy to explain the experimental results of, for example, the electrophilic reaction of fluoranthene and radical attack of azulene stated above.

Acenaphthylene has been found to make a colorless dimer, and it has been suggested that the mechanism of formation is not a simple "collisional" one, but depends on the existence of van der Waals complexes and Crawford and Coulson considered that the formation of these complexes is probably facilitated by the presence of a high free valence at the reacting carbon atoms. They calculated the free valence in this molecule and found that the values of 5, 6 positions are larger than that of 1, 2 positions[20]. On the other hand, experiments showed that the dimer has the following structure indicating that the 1, 2 positions have greater reactivity than 5, 6 positions[20,22].

Hence, the free valence, as is stated by Crawford and Coulson[20], is not a sufficient guide to reactivity. Frontier electron method and localization method both predict that the 1, 2 positions will be more reactive than 5, 6 positions. This result coincides with the experiment although there may remain some questions as to the applicability of the reactivity indexes to such a dimer-forming reaction.

For other compounds such as fulvene, pentalene, heptalene, fulvalene and fluoranthene there are no available data. The prediction of the most reactive position of these molecules by theoretical indexes agreed entirely with each other.

**Reaction for a Nucleophilic Reagent.**—Braun and Manz heated fluoranthene and CuCN for 6 hr. at 260°C and got 3-CN derivative[23]. The nature of this reaction has not been determined. The reaction may be nucleophilic or otherwise radical in nature. Provided that the reaction proceeds in radical mechanism the theories agree with the experiment because free valence, localization energy, frontier electron density and superdelocalizability all predict position 3 as the most reactive, as is seen in Table II. On the other hand if the reagent attacks the substrate molecule as a nucleophilic reagent, the $\pi$-electron density method fails to predict the correct position as is shown in Table III, whereas the localization and frontier electron methods both succeed also in this case.

For other molecules no experiment seems to have been carried out and all indexes predict the same position as the most reactive center except for acenaphthylene and fulvalene. Some experimental information may be looked for in relation to acenaphthylene; position 5 is predicted by the localization method and the frontier electron method, and position 3 by $\pi$-electron density method. In the case of fulvalene, disagreement of predictions by the localization method and the static method has been pointed out by Brown[12] in connection with the "chemical non-crossing rule"; that is, the former predict position 1, whereas the latter, position 2. The frontier electron density and the superdelocalizability predict position 2 as the most reactive center toward nucleophilic reagents in agreement with the static method.

As was stated above, the static method fails to explain the experimental results of fluoranthene with regard to the electrophilic attack and the radical reaction of azulene and acenaphthylene. The localization method also could not correctly predict the position of attack in the case of electrophilic reaction of fluoranthene and radical reaction of azulene. On the other hand, the predictions by the frontier electron method were entirely consistent with experiments for all molecules so far tested.

Since no ambiguous parameter has been used in the calculations stated above, such a comparison of availability of various theoretical indexes may be of significance in the sense that it may be able to afford us a clue to search for the "true" feature of substitution process in conjugated molecules.

# *The Formation and the Reactions of 3α-Chloro-5, 6β-epoxy-5β-cholestane**

By Michio SHIOTA, Taeko OGIHARA** and Yumi WATANABE***

(Received July 26, 1960)

The present paper describes a study on the configuration of the epoxide derived from 3α-chlorocholest-5-ene[1] by oxidation with monoperphthalic acid and also on the reaction of the epoxide with boron trifluoride-ether complex.

Oxidation of 3α-chlorocholest-5-ene with monoperphthalic acid gave an epoxide. The epoxide could not be reduced with lithium aluminum hydride in the usual way, but it was catalytically reduced with platinum oxide to afford, besides other products, 5β-cholestane (II) and 5β-cholestan-6β-ol (IIIa). The formation of the 5β-cholestane derivatives is of interest, and this reduction is analogous to the catalytic reduction of 5, 6β-epoxy-5β-cholestan-3α-ol[2]. The reductive cleavage of the

3α-chlorocholest-5-ene oxide with lithium-ethylamine[3] was also effected to give 5α-cholestan-6-β-ol (IVa) as the major product, along with an unsaturated material. In both of the above reductions, no 5α-cholestan-5-ol (V) was found in the products. On the basis of these observations, it was concluded that the epoxide is 3α-chloro-5,6β-epoxy-5β-cholestane

(I). An isomeric α-oxide was not obtained by the peracid oxidation of 3α-chlorocholest-5-ene.

The reaction of the epoxide with boron trifluoride-ether complex was investigated to complement the study by Henbest[4,5]. This lacks the reaction of a 3α-substituted 5,6β-epoxide with the reagent.

On treatment with boron trifluoride-ether complex, the epoxide was easily isomerized to 3α-chloro-5α-cholestan-6-one (VI) in a 35% yield. A "non-polar" oil[6] (13%) and an unsaturated substance (36%) were also produced. The yield of the 6-ketone was considerably lower than in the case of 3α-acetoxy-5,6α-epoxy-5α-cholestane[5]. It is probably because the resulting 6-ketone is a 5α-cholestane derivative (cis migration of $C_6$-hydrogen[4]) with 3α-chlorine and the 3-axial substituent decreases the yield of the 6-ketone. Since 5β-cholestane-3,6-dione was not transformed into 5α-cholestane-3,6-dione under the same condition, 3α-chloro-5α-cholestan-6-one was formed directly from 3α-chloro-5,6β-epoxy-5β-cholestane and, therefore, the above assignment of a β-configuration to the epoxide is further confirmed.

The formation of a diaxial fluorohydrin (5α-fluoro,6β-hydroxy) (VII) was probably discouraged because 1,3-diaxial interaction between 3α-chlorine and 5α-fluorine was involved.

6) An oily substance which was not adsorbed on alumina.

## Experimental****

**3α-Chloro-5,6β-epoxy-5β-cholestane (I).**—A mixture of 200 mg. of 3α-chlorocholest-5-ene and 2 equivalents of monoperphthalic acid in 10 ml. of dry ether was allowed to stand at room temperature overnight. The solution was washed with 5% aqueous sodium hydroxide and then with water to neutral reaction. Removal of the solvent from the dried (sodium sulfate) solution afforded a colorless crystalline residue. Recrystallization from methanol gave 120 mg. of 3α-chloro-5,6β-epoxy-5β-cholestane in needles, m. p. 98~99°C. Filtration through alumina, followed by recrystallization from methanol, raised the m. p. to 101.5~103°C. $[\alpha]_D^{16}$ −7° (*c* 2.65, chloroform).

Found: C, 77.06; H, 10.92. Calcd. for $C_{27}H_{45}ClO$: C, 77.01; H, 10.77%.

**Reductive Cleavage of the Epoxide I.**—*Catalytic Reduction.*—A mixture of 150 mg. of I and 20 mg. of Adams platinum oxide in 10 ml. of acetic acid was agitated with hydrogen at room temperature. In 1.5 hr. the hydrogen uptake was complete (2 mol.). The catalyst was removed by filteration and the solvent was evaporated under reduced pressure. The colorless oily residue was acetylated in the usual way and the product was chromatographed on 4.5 g. of alumina. Fractions eluted with petroleum ether gave oily residues (108 mg. in total), some of which were crystallized from methanol to give 3 mg. of 5β-cholestane (II), m. p. 63~65°C (recrystallized from methanol) and 20 mg. of 5β-cholestan-6β-ol acetate[7] (IIIb), m. p. 108~108.5°C (recrystallized three times from methanol; the yield of the crude product was 46 mg.). These compounds were identified by the mixed melting point test with authentic samples. Further elution of the column with benzene-petroleum ether (1:9) afforded a small amount of a halogen-containing substance in needles, m. p. 117~124°C, which was not further investigated. The oily residues from other fractions failed to crystallize, and 5α-cholestan-5-ol was not isolated from them.

*Reduction with Lithium-Ethylamine.*—A solution of 150 mg. of I in 4.3 g. of ethylamine was treated with 100 mg. of lithium at room temperature. A deep blue color appeared after 20 min., and persisted during 40 min. The reaction product was isolated according to the procedure of Benkeser[8] to give 137 mg. of a pale yellow oily product, which gave a yellow color with tetranitromethane and showed a negative Beilstein test. The oil (81 mg.) was acetylated in the usual way and the resulting yellow oil (80.5 mg.) was treated with monoperphthalic acid, and the resulting epoxide was subjected to hydrolytic cleavage with phosphomolybdic acid[9]. An oily product (75.4 mg.), which did not give a yellow color with tetranitromethane, was chromatographed on 2.1 g. of alumina, and from the fractions

**** All melting points were not corrected.

8) R. A. Benkeser, R. E. Robinson, D. M. Sauve and O. H. Thomas, *J. Am. Chem. Soc.*, **77**, 3230 (1955).
9) By this procedure, the unsaturated material was converted into a 1,2-*trans*-glycol (M. Sawai, presented at the 10th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1957).

eluted with petroleum ether, 43.9 mg. of an oily residue was obtained. This was crystallized from methanol to give 34 mg. of 5α-cholestan-6β-ol acetate[10] (IVb) in needles, m. p. and mixed m. p. 74~75°C. The amount of the unsaturated material in the above reduction products was estimated by catalytic reduction. From the amount of hydrogen uptake, it was inferred that the unsaturated material amounted to about 30% of the total.

*Attempted Reduction with Lithium Aluminum Hydride.* — I was treated with lithium aluminum hydride at the boiling point of ether in the usual way, but the reduction was not effected. An attempt to effect the reduction at the boiling point of benzene was also unsuccessful.

**Reaction of I with Boron Trifluoride-Ether Complex.** — Freshly distilled boron trifluoride-ether complex (4 drops) was added to a solution of 200 mg. of I in 20 ml. of dry benzene. After 4 min. at room temperature, the solution was treated with aqueous sodium bicarbonate, and washed with water. Removal of the solvent from the dried (sodium sulfate) solution afforded a semi-solid residue, which was crystallized from acetone to give 3α-chloro-5α-cholestan-6-one (VI), m. p. 178~180°C. Under the same condition, 5β-cholestane-3,6-dione was not converted into 5α-cholestane-3,6-dione.

The chromatography of the above semi-solid residue (200 mg.) afforded 26.9 mg. of a "non-polar" oil, 69 mg. of 3α-chlorocholestan-6-one, and 73.2 mg. of an oily material. The oily substance gave an intense yellow color with tetranitromethane and showed a positive Beilstein test and hydroxyl infrared absorption. Since it was readily acetylated in the usual way, and the 3α-chlorine in 3α-chlorocholest-5-ene and in 3α-chloro-5α-cholestan-6-one was not eliminated with boron trifluoride-ether complex to give unsaturated compounds, it is probable that the oily material consisted mainly of 3α-chlorocholest-4-en-6β-ol (VIII).

# *Studies on Pyridotropolones. VI*[1]. *Rearrangement Reactions of Brominated 8-Isopropyl-pyrido[3, 2-d]tropolones to 7-Isopropyl-6-quinolinols*

By Kameji YAMANE

(Received July 13, 1960)

Previously the author[2] reported that nitroso-, amino-, quinoxalo- and oxazolo-compounds were obtained from 2-methyl-8-isopropyl-pyrido[3, 2-*d*]tropolone. The present work was carried out for the purpose of elucidating the chemical reactivity of pyrido[3, 2-*d*]tropolone, and the rearrangement reactions of brominated 8-isopropyl-pyrido[3, 2-*d*]tropolones to 7-isopropyl-6-quinolinols were studied.

Bromination of 2-methyl-8-isopropyl-pyrido-[3, 2-*d*]tropolone (Ia) with 1 molar equivalent of NBS gave 5-bromo-compound IIa. IIa showed brownish yellow coloration in benzene layer with ferric chloride solution. Heating IIa in 2 N potassium hydroxide solution afforded pale yellow (nearly colorless) needles, m. p. 229.5~230°C (IIIa), 2-methyl-8-isopropyl-pyrido-[3, 2-*d*]-tropolone (Ia) and a red oily matter. IIIa gave no Beilstein test, whose analytical values agreed with formula $C_{13}H_{15}ON$. Its ultraviolet absorption spectrum (Fig. 1) closely resembled that of 6-quinolinol[3]. The infrared spectrum of IIIa exhibited several absorption bands (2980 $cm^{-1}$ for CH stretching vibrations, 1530, 1568, 1607 and 1630 $cm^{-1}$ for C=C and C=N streching vibrations, and 1245 $cm^{-1}$ for phenolic OH deformations). Furthermore, the compound IIIa readily underwent some typical electrophilic substitution reactions. Namely, IIIa was readily brominated in acetic acid solution to form a monobromo compound

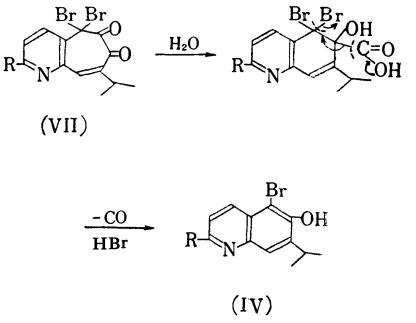
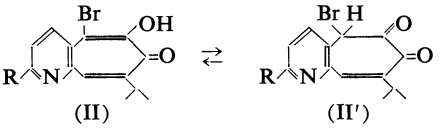
3 : Dibromo-compound VIIb (in methanol)



(IVa). Nitrosation of IIIa in acetic acid solution gave nitroso compound Va. The compound IIIa coupled with diazotized *p*-toluidine in alkaline solution to yield an azo compound VIa. From these facts shown above, IIIa was assumed to be 2-methyl-7-isopropyl-6-quinolinol.

Bromination of 2-methyl-8-isopropyl-pyrido-[3, 2-*d*] tropolone gave dibromo compound as yellow rhombic prisms, m. p. 129~130°C (VIIa). The analytical values of this compound agreed with formula $C_{14}H_{13}O_2NBr_2$, and its ultraviolet absorption spectrum (Fig. 2) differed from that of 2-methyl-5-bromo-8-isopropyl-pyrido [3, 2-*d*] tropolone (IIa). Moreover, the infrared spectrum of VIIa exhibited two bands at 1742 and 1684 $cm^{-1}$ due to the carbonyl group, and no bands in the hydroxyl region. The compound VIIa was unstable against water, acid, alkali and alcohols. In fact when heated with water, it dissolved gradually under foaming and gave 2-methyl-5-bromo-7-isopropyl-6-quinolinol (IVa) which was obtained by bromination of IIIa described above. Heating VIIa with 1 N hydrochloric acid also gave IVa in good yield. VIIa, however, gave 2-methyl-5-bromo-8-isopropyl-pyrido [3, 2-*d*] tropolone (IIa) when it was heated with 2 N potassium hydroxide solution. These facts indicated that the dibromo compound VIIa possessed the structure shown as *o*-diketone formula (VIIa).

8-Isopropyl-pyrido [3, 2-*d*] tropolone (Ib)[4] showed almost the similar reactions as in the case of Ia. Namely, Ib was readily brominated with NBS to form 5-bromo-compound (IIb) and dibromo compound (VIIb). Heating IIb in 2 N potassium hydroxide solution afforded 7-isopropyl-6-quinolinol (IIIb). IIIb afforded bromo compound (IVb), nitroso compound (Vb) and *p*-tolylazo-compound (VIb). Furthermore VIIb was rearranged to 5-bromo-7-isopropyl-6-quinolinol (IVb) when treated with water or 1 N hydrochloric acid, and or 2 N potassium hydroxide solution.



It is thought that the mechanism of this interesting rearrangement of VII to 5-bromo-7-isopropyl-6-quinolinols (IV) goes on first through benzilic acid rearrangement, followed by decarboxylation and dehydrobromination as follows:

In the case of the rearrangement reaction of 5-bromo-8-isopropyl-pyrido [3, 2-*d*] tropolones (II) to 7-isopropyl-6-quinolinols (III) with potassium hydroxide solution, it is thought

4) K. Yamane, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 509 (1960).

that II undergoes rearrangement in like manner as VII via its tautomeric structure II'.

(II) (II')

## Experimental

**2-Methyl-5-bromo-8-isopropyl-pyrido[3,2-*d*]tropolone (IIa).**—A mixture of 0.2 g. of 2-methyl-8-isopropyl-pyrido[3,2-*d*]-tropolone (Ia) and 0.18 g. of NBS in 4 cc. of carbon tetrachloride was refluxed for 2 hr. After cooling, succinimide and the solvent were removed and the residue was recrystallized from ethanol to give 0.25 g. of yellow needles, m. p. 145~145.5°C.

Found: C, 54.37; H, 4.65; N, 4.84. Calcd. for $C_{14}H_{14}O_2NBr$: C, 54.54; H, 4.58; N, 4.55%.

**5-Bromo-8-isopropyl-pyrido[3,2-*d*]tropolone (IIb).**—A mixture of 0.7 g. of 8-isopropyl-pyrido-[3,2-*d*]tropolone (Ib) and 0.64 g. of NBS in 40 cc. of carbon tetrachloride was refluxed for 2 hr. After cooling, succinimide and the solvent were removed and the residue was recrystallized from ethanol to give 0.72 g. of yellow needles, m. p. 155.5~156°C.

Found: C, 53.22; H, 4.02; N, 4.92. Calcd. for $C_{13}H_{12}O_2NBr$: C, 53.07; H, 4.11; N, 4.76%.

**2-Methyl-7-isopropyl-6-quinolinol (IIIa).—a)** A solution of 1 g. of IIa in 3 cc. of 2 N potassium hydroxide solution was heated for 2 hr. on a water bath. After cooling, 10 cc. of water was added and acidified with 1 N hydrochloric acid to deposite dark brown precipitates. The precipitates were collected and sublimated, yielding yellow sublimates, which were recrystallized from ethanol in pale yellow needles, m. p. 127~128°C, about 0.1 g. These did not depress by admixture with 2 methyl-8-isopropyl-pyrido[3,2-*d*]tropolone (Ia). The mother liquor of the dark brown precipitates was evaporated on a water bath to dryness and the residue was extracted with acetone. Acetone extracts were purified by passing through an alumina column to give about 30 mg. of crystals. Recrystallization from alcohol gave pale yellow (nearly colorless) needles, m. p. 229.5~230°C.

Found: C, 77.32; H, 7.19; N, 6.84. Calcd. for $C_{13}H_{15}ON$: C, 77.58; H, 7.51; N, 6.96%.

**b)** A solution of 0.4 g. of IIa in 3 cc. of 2 N potassium hydroxide solution was heated on a water bath for 2 hr. After cooling, the solution was slightly acidified with acetic acid to deposit brown precipitates (20 mg., m. p. 240°C). The filtrate of the precipitates was evaporated on a water bath to dryness and the residue was sublimated to give 130 mg. of pink prisms. Recrystallization from alcohol gave red needles, m. p. 228~229°C, undepressed by admixture with IIIa. Furthermore, the red needles were dissolved in acetone and purified by passing through an alumina column to give pale yellow (nearly colorless) needles, m. p. 229~230°C.

**7-Isopropyl-6-quinolinol (IIIb).**—A solution of 0.4 g. of IIb in 2.3 cc. of 2 N potassium hydroxide solution was heated on a water bath and acidified with 2 N hydrochloric acid to deposite pale brown precipitates. The precipitates were recrystallized from methanol to give yellow needles, m. p. 160~161°C, undepressed by admixture with Ib. Mother liquor of the pale brown precipitates was evaporated on a water bath to dryness and the residue was extracted with acetone. Acetone extracts were purified by passing through an alumina column to give colorless plates, m. p. 193°C. Yield 90 mg.

Found: C, 76.67; H, 6.85; N, 7.46. Calcd. for $C_{12}H_{13}ON$: C, 76.97; H, 7.00; N, 7.48%.

*Picrate*, yellow plates, m. p. 229~230°C (decomp.) from methanol.

Found: N, 13.43. Calcd. for $C_{18}H_{16}O_8N_4$: N, 13.46%.

**2-Methyl-5-bromo-7-isopropyl-6-quinolinol (IVa).**—To a solution of 0.13 g. of IIIa in 2 cc. of acetic acid, a solution of 0.1 g. of bromine in 0.5 cc. of the same solvent was added dropwise with stirring. When the addition had been nearly completed some yellow crystals were deposited. After removal of the crystals, water was added and neutralized with ammonia to give precipitates, which were recrystallized from dilute alcohol in pale yellow (nearly colorless) needles, m. p. 129~130°C.

Found: C, 55.84; H, 4.79; N, 4.92. Calcd. for $C_{13}H_{14}ONBr$: C, 55.72 H, 5.04; N, 5.00%.

**5-Bromo-7-isopropyl-6-quinolinol (IVb).**—To a solution of 20 mg. of IIIb in 0.5 cc. of acetic acid, 20 mg. of bromine dissolved in 0.5 cc. of the same solvent was added dropwise with stirring. After standing for 2 hr., water was added and neutralized with ammonia to give colorless precipitates, which were recrystallized from acetone in pale yellow needles, m. p. 128~129°C. Yield about 25 mg.

Found: C, 54.04; H, 4.26; N, 5.24. Calcd. for $C_{12}H_{12}ONBr$: C, 54.15; H, 4.55; N, 5.26%.

**2-Methyl-5-nitroso-7-isopropyl-6-quinolinol (Va).**—To a solution of 0.15 g. of IIIa in 1 cc. of acetic acid, a solution of 0.08 g. of sodium nitrite in a small amount of water was added dropwise. The yellow crystals that separated out were collected by filtration and washed with water. Yield 0.15 g. Recrystallization from methanol yielded yellow prisms, m. p. 181°C (decomp.).

Found: C, 67.76; H, 5.72; N, 11.59. Calcd. for $C_{13}H_{14}O_2N_2$: C, 67.81; H, 6.13; N, 12.17%.

**5-Nitroso-7-isopropyl-6-quinolinol (Vb).**—To a solution of 41 mg. of IIIb in 1 cc. of acetic acid, 23 mg. of sodium nitrite in a small amount of water was added dropwise. The yellow crystals that separated out were collected by filtration and washed with water. Recrystallization from methanol yielded bright yellow scales, m. p. 156°C (decomp.). Yield about 45 mg.

Found: C, 66.66; H, 5.76; N, 13.02. Calcd. for $C_{12}H_{12}O_2N_2$: C, 66.65; H, 5.59; N, 12.96%.

**2-Methyl-5-(*p*-tolylazo)-7-isopropyl-6-quinolinol (VIa).**—To a cold solution of 45 mg. of *p*-toluidine in 2 cc. of 3 N hydrochloric acid, a solution of 42 mg. of sodium nitrite in 0.5 cc. of water was dropped, and the resultant cold diazonium solution was added dropwise to the cold solution of 80 mg. of IIIa in 10 cc. of 2 N-potassium hydroxide solution. The red precipitates thereby formed were collected by filtration. These were recrystallized from methanol

in orange red needles, m. p. 109.5~110°C. Yield 90 mg.

Found: C, 75.46; H, 6.35; N, 13.57. Calcd. for $C_{20}H_{21}ON_3$: C, 75.21; H, 6.63; N, 13.16%.

**5-(*p*-Tolyl-azo)-7-isopropyl-6-quinolinol (VIb).**—A cold solution of diazonium salt prepared from 35 mg. of *p*-toluidine, 1 cc. of 3 N hydrochloric acid and 55 mg. of sodium nitrite was added dropwise to a solution of 60 mg. of IIIb in 2 cc. of 2 N sodium hydroxide solution. The reddish brown precipitates which formed were recrystallized from methanol in red needles, m. p. 122~123°C. Yield 50 mg.

Found: C, 74.62; H, 6.02; N, 13.92. Calcd. for $C_{19}H_{19}ON_3$: C, 74.73; H, 6.27; N, 13.76%.

**Bromination of 2-Methyl-8-isopropyl-pyrido[3, 2-*d*]tropolone (Ia) with 2 Molar Equivalents of NBS. (Dibromo-Compound VIIa).**—A mixture of 1.43 g. of Ia and 2.21 g. of NBS in 30 cc. of carbon tetrachloride was refluxed on a water bath for 2 hr. After cooling, succinimide and the solvent were removed, the residue was recrystallized from carbon tetrachloride to give 1.16 g. of yellow rhombic prisms, m. p. 129~130°C.

Found: C, 43.37; H, 3.56; N, 3.56. Calcd. for $C_{14}H_{13}O_2NBr_2$: C, 43.44; H, 3.39; N, 3.62%.

**Bromination of 8-Isopropyl-pyrido[3, 2-*d*]tropolone (Ib) with 2 Molar Equivalents of NBS. (Dibromo-Compound VIIb).**—A mixture of 1.72 g. of Ib and 2.85 g. of NBS in 100 cc. of carbon tetrachloride was refluxed on a water bath for 2 hr. After cooling, succinimide and the solvent were removed, and the residue was recrystallized from chloroform or carbon tetrachloride to give 2.21 g. of dibromo compound VIIb in yellow polyhedrones, m. p. 142~143°C.

Found: C, 42.09; H, 2.90; N, 3.69. Calcd. for $C_{13}H_{11}O_2NBr_2$: C, 41.85; H, 2.97; N, 3.76%.

**Rearrangement Reaction of Dibromo Compound VIIa to 2-Methyl-5-bromo-7-isopropyl-6-quinolinol (IVa).—a) By Water.**—When a mixture of 0.39 g. of dibromo compound VIIa and 3 cc. of water was heated on a water bath, VIIa slowly dissolved under foaming. The mixture was further heated for 2 hr. After removal of a small amount of brownish yellow resinous matter which appeared during the heating, the solution gradually deposited orange needles (hydrochloride of IVa) on standing. The needles were dissolved in 6 cc. of hot water and neutralized with 2 N potassium hydroxide solution to give precipitates, which were recrystallized from dilute alcohol in pale yellow (nearly colorless) needles, m. p. 129~130°C. Yield, 0.1 g. No depression in m. p. was observed on admixture of 2-methyl-5-bromo-7-isopropyl-6-quinolinol (IVa) which was obtained by bromination of IIIa described above.

**b) By 1 N Hydrochloric Acid.**—A mixture of 0.39 g. of VIIa and 3 cc. of 1 N hydrochloric acid solution was heated on a water bath for 30 min. On cooling, 0.31 g. of yellow crystals, m. p. 223~224°C (decomp.) were obtained. The crystals were dissolved in 5 cc. of hot water and neutralized with a 2 N potassium hydroxide solution to give colorless precipitates, which were recrystallized from dilute methanol in pale yellow (nearly colorless) needles, m. p. 129~130°C. Yield, 0.13 g. The needles were undepressed on admixture with IVa.

**Reaction of Dibromo Compound VIIa with 2 N Potassium Hydroxide Solution.**—When 0.16 g. of VIIa was mixed with 0.68 cc. of 2 N potassium hydroxide solution, an exothermic reaction began immediately to give a dark greenish yellow solution. After being heated for 20 min., the solution was slightly acidified with acetic acid to give yellow precipitates, which were recrystallized from alcohol in yellow prisms, m. p. 145~146°C, undepressed by admixture with 2-methyl-5-bromo-8-isopropyl-pyrido-[3,2-*d*]tropolone (IIa). Yield, about 0.04 g.

**Rearrangement Reaction of Dibromo Compound VIIb to 5-Bromo-7-isopropyl-6-quinolinol (IVb).—a) By Water.**—A mixture of 0.37 g. of VIIb and 1 cc. of water was heated on a water bath for 2 hr. After cooling, a small amount of water was added and neutralized with 2 N potassium hydroxide solution to deposit brown precipitates. Recrystallization from acetone yielded 0.17 g. of colorless needles, m. p. 128.5~129°C. No depression in m. p. was observed on admixture with the authentic sample of IVb which was obtained by bromination of IIIb described above.

**b) By 1 N Hydrochloric Acid.**—A mixture of 0.37 g. of VIIb and 3 cc. of 1 N hydrochloric acid solution was heated on a water bath for 1 hr. After cooling, the resultant red solution was neutralized with a 2N potassium hydroxide solution to give precipitates, which were recrystallized from acetone in colorless needles, m. p. 127~128°C. Yield 0.2 g. The needles also were undepressed on admixture with the authentic sample of IVb.

**c) By 1 N Potassium Hydroxide Solution.**—A mixture of 0.3 g. of VIIb and 3 cc. of 1 N potassium hydroxide solution was heated on a water bath for 10 min. After cooling, the mixture was neutralized with acetic acid to give brown precipitates, which were recrystallized from acetone in pale yellow needles, m. p. 129°C. The mother liquor was evaporated on a water bath to dryness and the residue was extracted repeatedly with acetone. The extracts were purified by passing through an alumina column. After removal of the solvent, the residue was crystallized from a dilute acetone to yield another crop of yellow needles, m. p. 129°C. Total yield 43 mg. These were found to be identical with IVb by mixed fusion.

The author takes this opportunity to express his sincere gratitude to Professor T. Nozoe (Tohoku University) and Professor A. Yokoo for their guidance and encouragement. Thanks are also due to Assistant Professor J. Iwasa for measurements of infrared spectra. The author is also grateful to Mrs. K. Kodaira, Mr. S. Azumi and Miss A. Iwanaga (Nozoe laboratory) for measurements of ultraviolet spectra and for carrying out micro analyses, and to Mr. Y. Shimoyama for his cooperation in these experiments.

# *Partition Equilibria of 2-Methyl 5-Ethyl Pyridine in the Systems of Benzene-Water and Chloroform-Water*

By Tokio KATO and Yasugoro TSUNODA

(Received February 27, 1960)

It is well known that 2-methyl 5-ethyl pyridine (M. E. P.) is prepared through the condensation of paraldehyde with aqueous ammonia[1], where benzene and chloroform are used to extract M. E. P. from the reaction product[2,3].

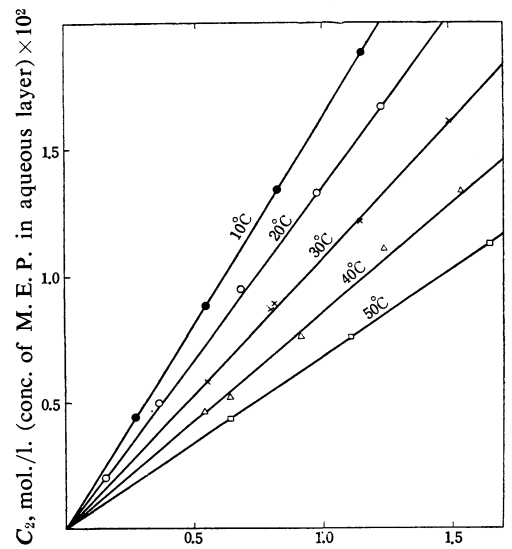
This paper presents a brief discussion on the partition equilibria of M. E. P. in the above-mentioned systems.

## Experimental

A thermostat adjusted to ±0.1°C, and conical flasks of 300 cc. with tight stoppers were used. M. E. P. was prepared by catalytic condensation of paraldehyde with aqueous ammonia[1]. The crude M. E. P. was rectified for several times; b. p. 74°C/20 mmHg, $n_D^{20}$, 1.4966.

Benzene and chloroform were rectified, and their boiling points were 80~81°C and 61~62°C respectively. Several solutions, being varied in concentration of M. E. P. (less than 3.0 mol./l.) in benzene and chloroform (50 cc.) were prepared in the flasks. Distilled water (150 cc.) was added to each of them, and they were settled for a certain time after being subjected to vigorous shaking every 5~6 min.

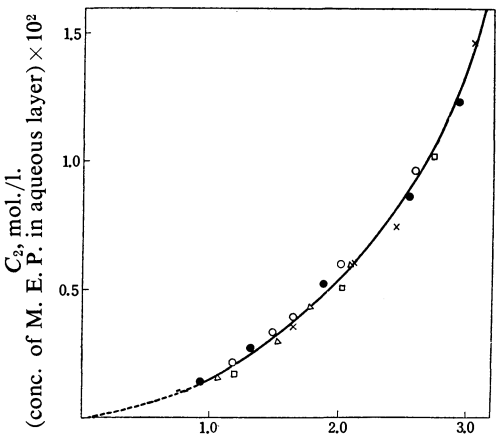
Each group of five samples was brought side by side in the thermostat for 2 hr. at 10, 20, 30, 40 and 50°C, and used for analysis.



The concentration of M. E. P. was easily determined by titration with N/2 HCl, where methyl orange was used as an indicator.

Volumes of samples employed for analysis were 5 cc. for benzene and chloroform layer and 100 cc. for the aqueous layer, where the former was titrated in the mixed solvent (100 cc.) of isopropyl benzene and ethylene glycol.

## Results and Discussion



In Fig. 1 (2), $C_1$ and $C_2$ are the concentrations of M. E. P. in benzene (chloroform) and aqueous layers and both of them were calculated from volumes of consumed N/2 HCl (cc.), while titrating volumes were corrected by blank tests.

In the system of benzene-water, the constancy of $K(C_2/C_1)$ with the change of $C_1$ or $C_2$ at each temperature is confirmed, and the linear relation between $\log K$ and $1/T$ ($T$: absolute temperature, °K) shown in Fig. 3 suggests that it satisfies the following thermodynamic formula.

$C_1$, mol./l. (conc. of M. E. P. in benzene layer)

Fig. 1. Equilibrium concentrations of M. E. P. in benzene and water.

$C_1$, mol./l. (conc. of M. E. P. in chloroform layer)

Fig. 2. Equilibrium concentrations of M. E. P. in chloroform and water.

1) U. S. Pat., 2,615,022 (1952).
2) U. S. Pat., 2,703,804 (1955).
3) U. S. Pat., 2,769,007 (1956).

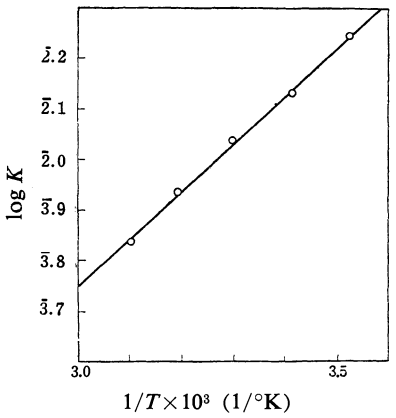

Fig. 3. Equilibrium constant $K$ (benzene-water).

$$\ln K_2/K_1 = -Q/R(1/T_1 - 1/T_2)$$

where $R$ is gas constant, and $Q$ the heat of transference of 1 mol. M. E. P. from benzene to water under equilibrium state.

Thus $Q$ was determined to be 4.3 kcal./mol. Therefore the equilibrium constant $K$ of M. E. P. between benzene and water satisfies the following formula

$$K = 7.7_6 \times 10^{-6}\, e^{2.19 \times 10^3/T}$$

In the system of chloroform-water, the parabolic relation between $C_1$ and $C_2$ was found (Fig. 2) and the constancy of $K$ ($\sqrt{C_2}/C_1$) at each temperature was confirmed, as shown in Fig. 4.

This means that the molecular weight of M. E. P. in chloroform is half of that in water

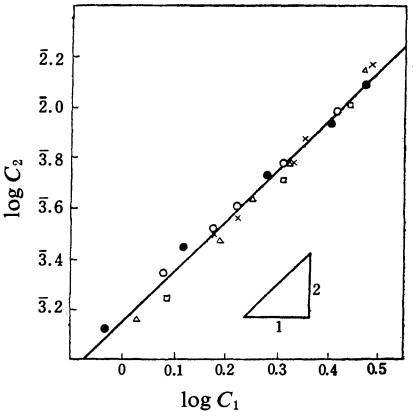

Fig. 4. Linear relation of $\sqrt{C_2}$ to $C_1$ (chloroform-water).

—×— 30 〃

or benzene, so the molecules of M. E. P. in latter solvents seem to associate with each other. Furthermore, the values of $K$ in each temperature are uniformly equal to $3.7 \times 10^{-2}$, and their changes with temperatures (10～50°C) are negligibly small.

The authors are grateful to Dr. H. Sobue, Professor of the Tokyo University and Dr. A. Tomita, chief of the Laboratory Institute, for their valuable advice.

# *On the Reaction of Aromatic Dinitriles and Formaldehyde*

By Toshihisa TACHIKAWA

(Received June 20, 1960)

The nitrile group is known to be hydrolysed to acid amide according to the following mechanism,

$$R\text{-}C{\equiv}N \xrightarrow{HCl} R\text{-}\underset{\displaystyle Cl}{\underset{|}{C}}{=}NH$$

$$R\text{-}\underset{\displaystyle Cl}{\underset{|}{C}}{=}NH \xrightarrow{H_2O} R\text{-}\underset{\displaystyle OH}{\underset{|}{C}}{=}NH + HCl$$

$$R\text{-}\underset{\displaystyle OH}{\underset{|}{C}}{=}NH \longrightarrow R\text{-}CONH_2$$

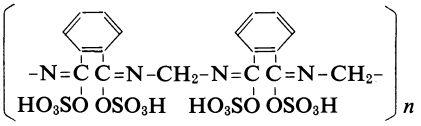
the reaction being caused by the polar structure of nitrile group. Therefore it is possible to synthesize the compounds having amide linkage by the reaction between nitrile compounds and the compounds which form carbonium cation readily. If the compounds having two nitrile radicals in a molecule are used as the starting material, it is possible to synthesize macromolecules having amide linkages.

Magat[1] and Ritter[2] have studied such

1) E. E. Magat, *J. Am. Chem. Soc.*, **73**, 1028, 1367 (1951).
2) J. J, Ritter, ibid., **70**, 4045 (1948).

reactions. Magat synthesized the polyamide known as 1, 6-nylon having the following structure by reacting adiponitrile and formaldehyde in concentrated sulfuric acid at normal temperature

$$n\,CN(CH_2)_4CN + n\,CH_2O \rightarrow CN\text{-}(CH_2)_4\text{-}\left[\text{-}CONHCH_2NHCO(CH_2)_4\cdot CONHCH_2NHCO(CH_2)_4\right]_n\text{-}CN$$



It is reported that this compound had the following properties: m. p. 225°C, mol. wt., 10,000~20,000 (by the osmotic pressure method) and the intrinsic viscosity $[\eta_{sp}/c] = 0.7 \sim 1.3$ (solvent: *m*-cresol). Magat also reported that this compound had good solvent resistance and fiber-forming ability. In his study on the dinitriles, aliphatic dinitriles have been used, but aromatic dinitriles have not been studied. However, it is probable that a new characteristic polyamide having a benzene nucleus and -CONH- linkage will be obtained by the reaction of the aromatic dinitrile and the formaldehyde.

In the present paper the reaction of aromatic dinitriles such as ortho-, iso-, tere-phthalonitrile and *p*-xylylene cyanide, with the formaldehyde has been investigated by means of Magat's method and as a result the author has been able to synthesize a new polyamide having benzene nucleus and -CONH- linkages.

The condensation polymers having -CONH- linkages in the molecule are obtained from all the above dinitriles except orthophthalonitrile. Condensation polymer from terephthalonitrile and formaldehyde has the largest intrinsic viscosity.

## Results and Discussion

In the reaction of aromatic dinitriles and formaldehyde in concentrated sulfuric acid, the effect of the substituted position of two nitrile groups is shown in Table I. In the case of orthophthalonitrile, it does not react with formaldehyde. This is believed to be due to the steric hindrance of the neighboring two nitrile groups in the intermediate polymer in the sulfuric acid.

In the case of terephthalonitrile on the other hand, it reacts easily with formaldehyde without the effect of steric hindrance and the product which has the highest condensation polymerization degree is formed. Further, *p*-xylylene cyanide with difficulty causes condensation polymerization reaction with formaldehyde. This is believed to be due to the high reactivity of the methylene hydrogen between the nitrile groups and the benzene nucleus of *p*-xylylene cyanide, which easily causes the side reaction with formaldehyde.

The infrared absorption spectra of the isophthalonitrile and the terephthalonitrile condensation polymer is shown in Fig. 1.

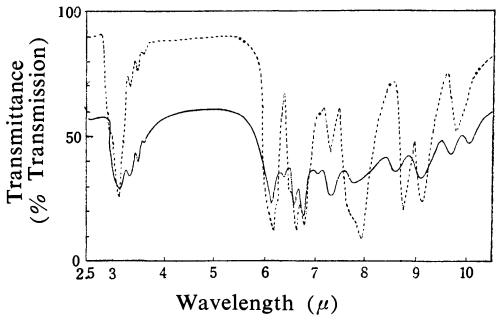


Fig. 1. Infrared spectra
—— Isophthalonitrile+$(HCHO)_n$ polymer
---- Terephthalonitrile+$(HCHO)_n$ polymer

As shown in Fig. 1, a C≡N stretching vibration at 4.5 $\mu$ disappears and an N-H stretching vibration at 3.05, 3.30, 3.45 $\mu$, an N-H deformation vibration at 6.6 $\mu$ and a C=O stretching vibration at 6.1 $\mu$ appears as in 6,6-nylon. Furthermore, a $-CH_2-$ deformation vibration at 6.75 $\mu$ is observed. So it is now clear that both of these polymers have -CONH $-CH_2-NHCO-$ linkages, as expected. The result of elementary analysis indicated that these polymers have the following structures;

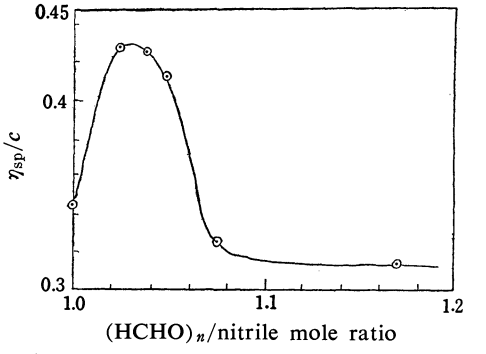
| Adding the mixture of terephthalonitrile and paraformaldehyde into the sulfuric acid. | 0.428 |

From these findings, it is understood that the aromatic dinitrile compounds are also capable of forming polyamide as in the case of aliphatic dinitrile compounds.

As benzene rings and -NHCO- linkages are arranged alternately in such polyamide, the crystallization will be accelerated by the intermolecular hydrogen bonds between -CONH- groups and the molecules will be oriented easily. The insolubility of these condensation polymers in almost all organic solvents as shown in Table II and the higher decomposition point above 300°C without melting or softening may be attributed to this crystalline structure.

In concentrated sulfuric acid, aromatic dinitrile is easily hydrolysed into acid amide and formaldehyde forms carbonium cation and becomes very reactive. Therefore, it is believed that the molar ratio between these two reagents



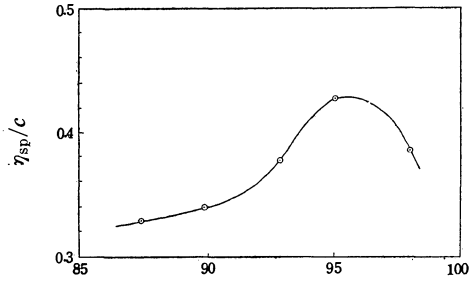


Fig. 2. Effect of the molar ratio of formaldehyde to terephthalonitrile.

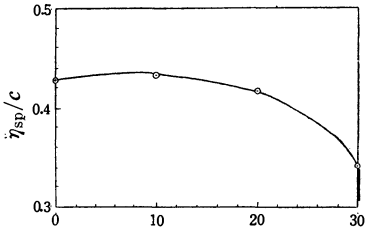
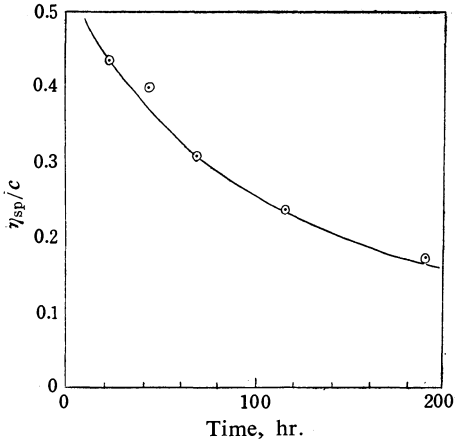
greatly influences the condensation polymerization reaction in sulfuric acid. As shown in Fig. 2 and Table III, the product which has the highest condensation polymerization degree is obtained when the equimolecular mixture of terephthalonitrile and formaldehyde is added into sulfuric acid.



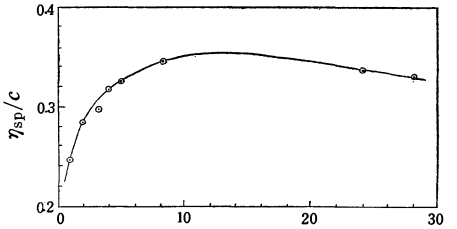
When terephthalonitrile is added into the sulfuric acid solution of formaldehyde and when the molar ratio of formaldehyde to terephthalonitrile is large, formaldehyde is always in excess to the dinitrile in the reaction

solution. In this condition the side reaction with activated formaldehyde becomes so predominant that the condensation polymerization reaction is impeded and consequently the intrinsic viscosity of the reaction product becomes low. Similarly when formaldehyde is added into the sulfuric acid solution of terephthalonitrile and the molar ratio is small, the intrinsic viscosity of the reaction product becomes low. It is considered that this fact is due to the hydrolysis of terephthalonitrile into terephthalamide. It is probably for the same reason that the condensation polymerization product of great intrinsic viscosity can not be obtained when the concentration of sulfuric acid is lower than 95% and the reaction temperature is higher, as shown in Figs. 3 and 4.



Concentration of sulfuric acid, %

Fig. 3. Effect of concentration of sulfuric acid.



Reaction temperature, °C

Fig. 4. Effect of reaction temperature.

Time, hr.

Fig. 5. Degradation by sulfuric acid.

Time, hr.

Fig. 6. Effect of reaction time.

The condensation polymer from terephthalonitrile and formaldehyde rapidly degrades in the presence of sulfuric acid at room temperature as shown in Fig. 5. This behavior is somewhat unexpected since the condensation polymer itself is prepared in the concentrated sulfuric acid. Although the mechanism of degradation is not clear, -CONH- linkage may be hydrolysed by acid. As it is probable that the condensation polymerization reaction is accompanied by a simultaneous degradation reaction, the degree of condensation polymerization of the product becomes lower when the reaction time is longer, as shown in Fig. 6.

On the other hand no condensation polymer can be obtained by reacting terephthalamide with formaldehyde under the same reaction conditions as in the case of the terephthalonitrile. Thus it is clear that the mechanism of this reaction is not considered as the formation of acid amide by the hydrolysis of nitrile group in sulfuric acid followed by the methylol condensation as in urea resins, but is considered as follows.

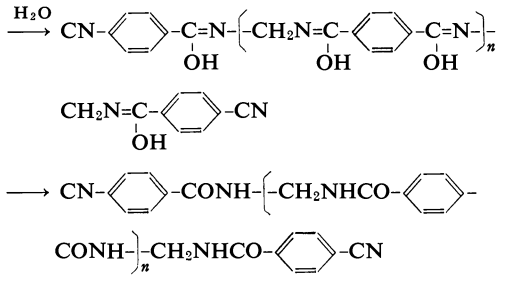
$$CH_2O + H_2SO_4 \rightarrow CH_2OH^+ + HSO_4^-$$

$$CN\text{-}C_6H_4\text{-}CN + CH_2OH^+ + HSO_4^- \rightarrow CN\text{-}C_6H_4\text{-}C(OSO_3H)=N\cdot CH_2OH$$

(I)

$$I + H_2SO_4 \rightarrow CN\text{-}C_6H_4\text{-}C(OSO_3H)=N\cdot CH_2^+ + HSO_4^- + H_2O$$

(II)



$$II + HSO_4^- + CN\text{-}C_6H_4\text{-}CN \rightarrow CN\text{-}C_6H_4\text{-}C(OSO_3H)=N\cdot CH_2\cdot N=C(OSO_3H)\text{-}C_6H_4\text{-}CN$$

$$\vdots$$

$$CN\text{-}C_6H_4\text{-}C(OSO_3H)=N\text{-}\left[\text{-}CH_2N=C(OSO_3H)\text{-}C_6H_4\text{-}C(OSO_3H)=N\text{-}\right]_n\text{-}CH_2N=C(OSO_3H)\text{-}C_6H_4\text{-}CN$$

TABLE IV. ELEMENTARY ANALYSIS

| Dinitrile | Found | | | Calcd. | | | |
|---|---|---|---|---|---|---|---|
| | C | H | N | C | H | N | |
| Isophthalonitrile | 58.6 | 4.7 | 15.5 | 61.4 | 4.6 | 15.9 | for $(C_9H_8N_2O_2)_n$ |
| Terephthalonitrile | 58.9 | 4.7 | 16.6 | 61.4 | 4.6 | 15.9 | for $(C_9H_8N_2O_2)_n$ |
| *p*-Xylylene cyanide | 62.3 | 6.0 | 13.0 | 64.7 | 5.9 | 13.7 | for $(C_{11}H_{12}N_2O_2)_n$ |

## Experimental

**Synthesis of Orthophthalonitrile.** — Phthalamide was prepared from phthalic anhydride and aqueous ammonia by the standard method, and then phthalamide (68 g.) was dehydrated to phthalonitrile with acetic anhydride (425 g.) in chlorobenzene (88 g.) by the known method[3]. Yield 26.5 g. (50% of theoretical yield). After recrystallizing from water, a colorless crystal was obtained, m. p. 141~142°C.

**Sntheysis of Isophthalonitrile.** — Isophthalyl chloride was prepared from isophthalic acid and thionyl chloride, and transformed to isophthalamide with aqueous ammonia. Isophthalamide (32.8 g.) and phosphorus pentachloride (41.6 g.) were mixed in chlorobenzene (200 g.) and the mixture was heated gradually. It was heated for an hour at 98°C. until a homogeneous solution was obtained. After pouring the solution into ice water, 20 g. of crude isophthalonitrile was obtained with 78% yield. The crude material was recrystallized from water. The pure material melted at 160.5°C.

**Synthesis of Terephthalonitrile.**—Terephthalyl chloride was prepared from terephthalic acid and phosphorus pentachloride and transformed to terephthalamide with aqueous ammonia and then terephthalamide was dehydrated to terephthalonitrile with phosphorus pentachloride in chlorobenzene, using the same methods as in the case of the isophthalonitrile. The crude terephthalonitrile was recrystallized from benzene to needle crystals, m. p. 221.5~222.0°C.

**Synthesis of *p*-Xylylene Cyanide.**—A solution of potassium cyanide (13 g.) in 25 g. of water was added dropwise into a solution of *p*-xylene bromide (13 g.) in 200 cc. of ethanol at 80°C and the mixture was heated under reflux for three hours. After the reaction was completed, ethanol was distilled off and the residue was poured into ice water and filtered. The precipitate was recrystallized from ethanol and hot water to get pure *p*-xylylene cyanide (4.7 g.), m. p. 96~97.5°C.

3) E. Koike; *J. Chem. Soc. Japan. Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **57**, 925 (1954).

**Condensation Polymerization of Aromatic Dinitriles and Formaldehyde.**—A mixture of paraformaldehyde and dinitriles was added in small portions with stirring at a constant temperature into sulfuric acid which was placed in a 100 cc. three-necked flask equipped with thermometer and stirrer. External cooling was necessary to maintain the constant temperature at 0°C because the reaction was exothermic. After the exothermic reaction was over, the mixture began to thicken gradually. The stirring was continued for two hours after the nitrile was added, to complete the reaction. The reaction product was poured into ice water with stirring to precipitate the condensation polymer. The precipitate was washed with water and the remaining acid was removed by washing with sodium bicarbonate solution (1%), then it was dried at 60°C until it was posssible to get constant weight under reduced pressure. The result of the elementary analysis is shown in Table IV.

**Infrared Absorption Spectrum.**—A specimen film of the condensation polymer of isophthalonitrile was prepared by evaporating the *m*-cresol solution of the polymer under reduced pressure. The specimen film of the condensation polymer of terephthalonitrile was prepared by squeezing the viscous reaction product between the two glass plates followed by washing the thin layer of polymer with water. The clear thin film thus obtained was dried under reduced pressure. The infrared absorption spectra were observed on these films using a Perkin-Elmer Model 21 spectrophotometer.

**Intrinsic Viscosity.**—Four hundred milligrams of the condensation polymer was added into 1000 cc. of 85% sulfuric acid and dissolved completely. This was left at 11~12°C for 24 hr. with shaking. The specific viscosity was measured on this solution by using Ostwald's viscosimeter at 30°C and the intrinsic viscosity was calculated.

**The Reaction of Terephthalamide and Formaldehyde.**—A mixture of terephthalamide (8.2 g.) and paraformaldehyde (1.5 g.) was added into concentrated sulfuric acid (98%, 75 g.) with stirring at 20°C. Although the stirring was continued for two hours after addition, the viscosity of the reaction mixture did not increase. When the reaction mixture was poured into the ice water, white precipitates (8.0 g.) were obtained.

Found: C, 58.41; H, 4.99; N, 17.10. Calcd. for $C_8H_8N_2O_2$: C, 58.53; H, 4.91; N, 17.07%

## Summary

1. Like aliphatic dinitriles, polyamide having benzene nucleus and -CONH- linkages was synthesized by condensation polymerization reaction of aromatic dinitriles and formaldehyde in concentrated sulfuric acid.

2. The condensation polymer obtained from terephthalonitrile had the greatest intrinsic viscosity among ortho-, iso-, tere-phthalonitrile and *p*-xylylene cyanide. A product of the highest condensation polymerization degree was obtained, by adding the 1.025 : 1 molar mixture of paraformaldehyde and terephthalonitrile in small portions into ten molar amounts of 95% sulfuric acid at 0°C and then stirring for ten hours at the same temperature.

3. These condensation polymers were insoluble in almost all organic solvents and had no melting and softening point. They decomposed above 300°C.

The author wishes to express his sincere thanks to Professor Ryozo Goto of Kyoto University for his kind advice, and also to Mr. Murataro Nakashima, President of Kunoshima Chemical Co., for his permission to publish this paper.

# *Ultraviolet Spectra of N-Heterocyclic Systems. I. The Anions of Uracils**

By Koji NAKANISHI, Noboru SUZUKI and Futaba YAMAZAKI

(Received July 26, 1960)

The keto-enol equilibria of uracil and its anions have been studied in order to clarify the nature of the tautomerism encountered in the complicated derivatives of a natural product[1,2]. Moreover, besides being of interest because of its relation to nucleic acids, uracil contains two potentially dissociable protons, and accordingly it was felt that this simple molecule might provide a convenient means for more complex systems. The keto-enol equilibria of various monohydroxy *N*-heterocyclic bases have already been studied extensively by means of infrared, ultraviolet, and Raman spectroscopy, and other methods[3]. The studies with dihydroxy compounds are much more limited, and although the phenomena have indeed been investigated with uracil, especially by Shugar and Fox[4], the tautomeric equilibrium constants $K_T$ were not taken into consideration.

Six tautomeric forms are conceivable for uracil. However, the following evidence shows that it exists predominantly in the diketo form I (Plate 1) in solution as well as in the solid state. The solid infrared spectrum of uracil (Table I) in the double bond stretching region is very similar to 1, 3-dimethyluracil (VIII) which has a fixed structure; 1-methyluracil (IV) and 3-methyluracil (VI), for which three tautomeric forms are possible, respectively, also show very similar absorptions. The dioxane solution spectra of uracil, 1-methyluracil, and 3-methyluracil are also quite similar to 1, 3-dimethyluracil. Hence, it is easily seen that all four compounds can be represented by the diketo forms both in dioxane and in the solid state. It is well-known that among the possible tautomers, the more polar forms are favored in the solid state and in solutions of high dielectric constants. The fact that the tautomers present in dioxane, a solvent of low dielectric constant (2.101 at 25°C)[5], and in the solid state, are the diketo forms (I, IV, VI) suggests that the same diketo forms are also predominant

in water, a solvent of higher dielectric constant[6]. This was supported by measuring the ultraviolet spectra in dioxane-water mixtures. Isosbestic points, suggestive of an equilibrium mixture, were absent, and in all cases the only trend observed was a slight red shift in going from 100 percent dioxane to water (pH 6.86, Table II, intermediate dioxane concentrations are omitted); it is well-known that in neutral uncharged molecules the $\pi-\pi^*$ bands are shifted towards the red as the dielectric constant of the solvent is increased.

The ultraviolet spectra are recorded in Figs. 1—3. In going from the neutral to the anionoid

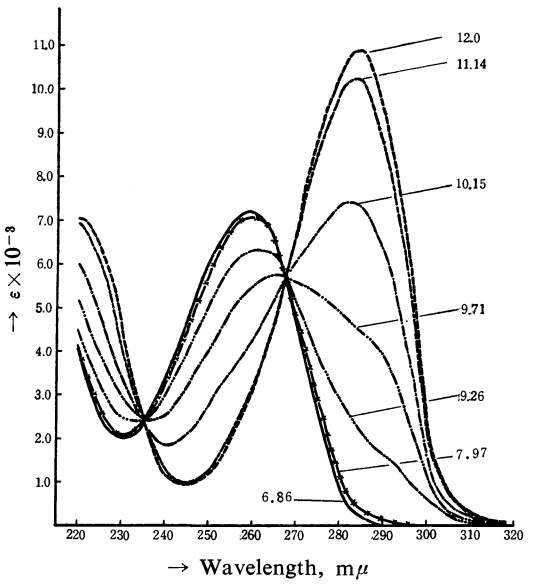

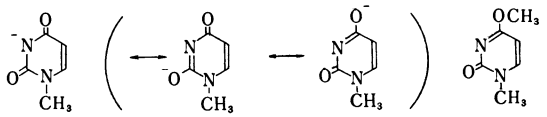

Fig. 3. Ultraviolet spectra of 3-methyluracil at various pH (numbers beside curves).

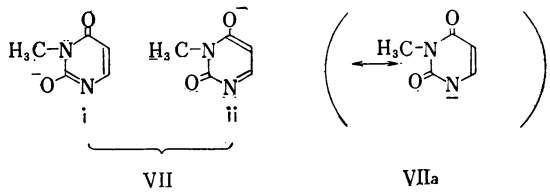

species in the case of 1-methyluracil, the peak intensity is lowered, but the wavelength is almost unaffected (Fig. 2 and Table II). This rules out the contribution of canonical structures such as Va or Vb; because of a more extended conjugated system, Va and Vb should show absorption at much longer wavelengths than the original species. For example, 1-methyl-4-methoxy-2-pyrimidone (IX) (cf., Experimental), which contains the O=C–N=C–$OCH_3$ system, already absorbs at 275 mμ, and accordingly Va and Vb containing the O=C–N=

V Va Vb IX

275 mμ
(ε 5,890)
at pH 6.86

C–$O^-$ system would be expected to show absorption at a still longer wavelength. Localization of the negative charge on the nitrogen atom has recently been suggested for the anion of 2-hydroxypyridine[8]. The cause for this localization is probably due to the fact that the intrinsic stability of the two carbonyl bonds outweigh the stabilization gained by an extended conjugation. Similar trends, i. e., lowering of peak intensity and constancy or slight blue shift of band position, are encountered upon anion formation in other 1-substituted uracils (Table II, nos. 4—6) and various uridine phosphates[9] such as uridine-5′-diphosphate (262 mμ, ε 10,000 vs. 261 mμ, 7,900), and uridine-5′-triphosphate (262 mμ, ε 10,000 vs. 261 mμ, 8,100). The anion of 3-methyluracil, on the other hand, shows a considerable red shift and increases in peak intensity. This behavior can be accounted for by canonical structures VII-i or VII-ii[10] but not by VIIa; in VII a conjugated system more extended than Va or Vb is present, and this probably compensates for the carbonyl bond energy.

i ii VII VIIa

The anion of uracil (Fig. 1) has its peak at 286 mμ (ε 6,010) with a broad hump around 260 mμ (ε ca. 4,000). The peak undoubtedly corresponds to the 284 mμ (ε 10,890) peak of VII; if wing correction (Fig. 4) is carried out by subtracting the curve of 3-methyluracil anion multiplied by 6,010/10,890, a peak is revealed at 258 mμ (ε 2,490). This peak is due to the anion II, the equivalent of V (266 mμ). Thus, the following empirical rule is apparent

7) H. McConnell, *J. Chem. Phys.*, **20**, 700 (1952).
8) E. Spinner, *J. Chem. Soc.*, **1960**, 1232.

10) At present, no conclusion can be drawn as regards the relative weights of contributions of structures VII-i and VII-ii.

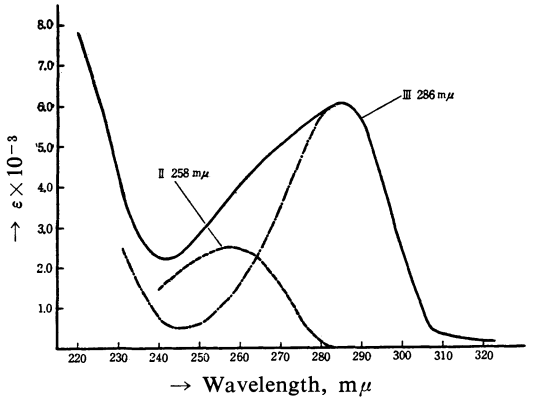

Fig. 4. Ultraviolet absorptions of uracil anions at pH 12.0.

in the ultraviolet spectra of uracils (Plate 1, see also Table II): (1) Alkylation at N-1 results in a red shift of ca. 8 mμ (I vs. IV, II vs. V). (2) Deprotonation at N-1 similarly results in a red shift of ca. 26 mμ (I vs. III, VI vs. VII). (3) Alkylation at N-3 results in a slight blue shift of 1~2 mμ (I vs. VI, III vs. VII). (4) Deprotonation at N-3 similarly results in a slight blue shift of ca. 2 mμ (IV vs. V, I vs. II). It is interesting to note that this simple calculation is also applicable to the disubstituted 1,3-dimethyluracil (VIII): calculated $\lambda_{max}$ 266~267 mμ; observed 267 mμ. The ultraviolet absorption curves of thymine

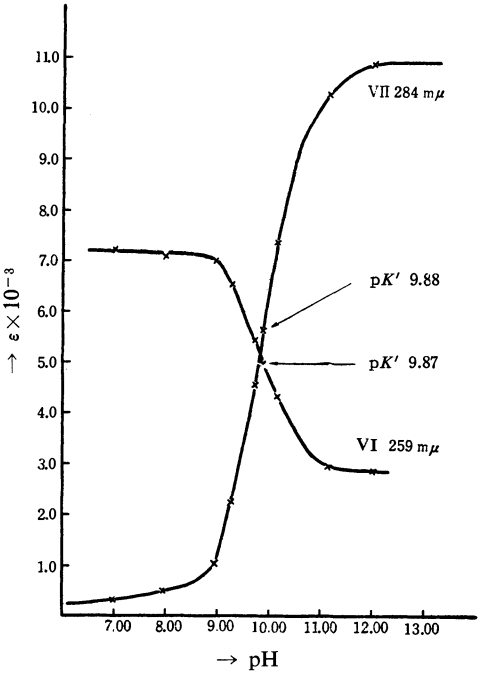

Fig. 5. 3-Methyluracil; variation of peak intensities with pH.

(5-methyluracil) and thymidine[4] show that this general trend is apparent in this series also.

The p$K$ of uracil (p$K_U$), 1-methyluracil (p$K_C$), and 3-methyluracil (p$K_D$) were obtained by spectroscopic measurement of the p$K'$ from the curves at pH 6.86, 9.71 and 12.0 (Figs. 1—3), and correction to thermodynamic p$K$ values (Table II). The p$K'$ values were also obtained by graphical plotting of extinction coefficients versus pH as shown in Fig. 5 for 3-methyluracil; the results are identical with the calculated values and, therefore, are omitted for other samples. The extinction coefficients for the anions II and III, which cannot be obtained experimentally, were calculated as follows:

$$\varepsilon_{III}/\varepsilon_I = \varepsilon_{VII}/\varepsilon_{VI}$$

hence, $\varepsilon_{III} = 8100 \times 10890/7210 = 12200$

and the percentage of III present in the uracil anion is

$$\text{III (percentage)} = 6010/12200 \times 100 = 49$$

Accordingly, the ratio of II to III, $K_T$, is 51/49=1.0.

Similarly,

$$\varepsilon_{II}/\varepsilon_I = \varepsilon_V/\varepsilon_{IV}$$

hence, $\varepsilon_{II} = 8100 \times 6880/9570 = 5820$

The percentage of II may be estimated from the intensity of the 258 mμ peak (Fig. 4):

$$\text{II (percentage)} = (2490/5820) \times 100 = 43$$

hence, $K_T = \text{II}/\text{III} = 43/57 = 0.8$

The agreement with the ratio 1.0 calculated from the 286 mμ peak is not quite satisfactory, but the 1.0 value is probably more correct because no wing correction is necessary.

If $K_A$ and $K_B$ are the individual dissociation constants leading from I to II and III, respectively (Plate 1), it can be readily shown[11] that

$$K_u = K_A + K_B \quad \text{and} \quad K_T = \text{II}/\text{III} = K_A/K_B$$

Substitution of $K_T = 1.0$ gives $pK_A = pK_B = 9.81$.

Occasionally[11,12], $K_T$ is calculated by assuming that $K_C$ or $K_D$ is approximately equal to $K_A$ or $K_B$, respectively, since substitution of a methyl group for a hydrogen atom would have a minor effect. However, the above results show that the approximation is not so satisfactory. Since the ultraviolet spectra of the other compounds listed in Table II and of the uridine phosphates[9] closely resemble those of the uracils treated in the present paper, the tautomeric behavior can be handled in an identical manner.

## Experimental

**Materials.**—1-Methyluracil[13] was prepared from uracil through 2,4-dichloropyrimidine, 2,4-dimethoxypyrimidine and 1-methyl-4-methoxy-2-pyrimidone (hydrolysis). The structure of the product as 1-methyluracil has been confirmed by Brown et al.[14].

3-Methyluracil[15] was prepared from ethyl ethoxy methylenemalonate[16] through 3-methyl-5-carbethoxyuracil and 3-methyl-5-carboxyuracil(decarboxylation). Product confirmed by Brown et al.[14]

1,3-Dimethyluracil[17] was prepared by methylation of uracil with dimethyl sulfate.

**Spectral Measurements.** — The infrared spectra were recorded with a Koken model 301 spectrophotometer. The ultraviolet spectra were recorded with a Hitachi model EP-1 spectrophotometer; a pair of 1 cm. quartz cells with stoppers was used and the cell temperature was maintained at 25±1°C. The error in absorbancy is ±0.002.

**Measurement of p*K*.**—All pH measurements were carried out at 25±1C° with a Horiba model P pH meter equipped with extension glass and calomel electrodes; the meter was calibrated with a standard Horiba buffer solution of pH 6.86 at 25°C($KH_2PO_4$+$Na_2HPO_4$). The following buffers were used for the pH indicated: pH 7.97, $KH_2PO_4$+$Na_2HPO_4$; pH 8.95, 9.26, 9.71 and 10.15, $Na_2CO_3$+$NaHCO_3$; pH 11.14 and 12.0 (uncorrected), $Na_2HPO_4$+NaOH. The ionic strength of the solutions was 0.1. The apparent p$K'$ was calculated from:

$$pK' = pH - \log (\varepsilon_{HX} - \varepsilon_{obs})/(\varepsilon_{obs} - \varepsilon_X)$$

where $\varepsilon_{HX}$ and $\varepsilon_X$ are the molecular extinction coefficients ($\varepsilon$) measured in pH 6.86 and pH 12.0 buffer solutions, respectively, and $\varepsilon_{obs}$ is the $\varepsilon$ measured in an intermediate pH solution where the pH was chosen so that the value of $(\varepsilon_{HX}-\varepsilon_{obs})/(\varepsilon_{obs}-\varepsilon_X)$ was near unity, i. e., pH 9.71. The wavelength chosen was 260 m$\mu$ and 285 m$\mu$ for uracil, 265 m$\mu$ for 1-methyluracil, and 259 m$\mu$ and 284 m$\mu$ for 3-methyluracil.

The p$K'$ was also obtained graphically as shown in Fig. 5. These apparent constants were corrected to the thermodynamic scale with the aid of the Debye-Hückel relationship,

$$pK = pK' + \log f_{HX} - \log f_X \quad (1)$$

$$\log f_X = -0.509(\sqrt{I}/1+\sqrt{I}) \text{ (at 25°C)}$$

where $f$ and $I$ represent the activity coefficient and the ionic strength. Since for neutral molecules $f_{HX}$ is approximately unity, the correction becomes

$$pK = pK' - \log f_X = pK' + 0.12$$

## Summary

In aqueous solutions uracil exists predominantly in the diketo form, whereas in alkaline solutions it exists as an approximately 1 : 1 mixture of two deprotonated forms. The two deprotonated anions show ultraviolet absorptions similar to the anions of 1-methyluracil and 3-methyluracil, and the main contributing canonical structures which give rise to the general absorption feature of the anions are discussed. The peak shifts accompanying N-alkylation or deprotonation may be summarized in a simple empirical rule. Individual ionization constants have also been estimated.

The results of uracil can be extended to thymine, uridine, thymidine, and their phosphates. The pesent method can probably be extended to other systems containing two dissociable protons.

The authors are indebted to Professor F. Egami, the University of Tokyo, for his initial suggestion of the problem and interests. Part of the expenses have been covered by the Grant in Aid for Fundamental Scientific Research, Ministry of Education.

# *Secondary Electron Emission from Copper-Beryllium (4%) Surface by Bombardment of Various Positive Ions*

By Toshio SUGIURA and Teruo HAYAKAWA

(Received July 4, 1960)

According to the development of the mass spectrometric investigations, the necessities for the measurements of the minute ion intensity are rapidly increasing. The secondary electron multiplier has now widely been used as an excellent ion detector for the measurements of ionization potentials and the microanalysis of many isotopes. Many reports on the secondary electron emission from the metal surfaces by the bombardment of high energy ions were already published. But unfortunately, some results of them disagree with each other[1,2], and these discrepancies might be caused by the different surface conditions of the ion targets for the secondary electron emission.

Recently, Hagstrum[3-6] has reported the many important results of the Auger ejection process of secondary electrons from the atomically clean surfaces of transition metals by the bombardment of the noble gas ions, and he suggested that the existence of the adsorbed layer causes the remarkable influence on the mechanism of the secondary electron ejection. But the target surfaces are not always atomically clean under the ordinary operating conditions, and the influence of the adsorbed layer seems considerably complicated since the semiconductor surfaces are usually used for obtaining the large electron yield.

The characteristics necessary for the secondary electron multiplier are the large electron yield per impinged ion or electron and the excellent stability for the electron yield under the usual operating conditions. The electron yield mainly depends upon the following factors:

(1) the mass, energy, electronic charge and configuration of the incident particle;

(2) the chemical and physical properties of the metal surface; and

(3) the angle with which the incident particle strikes the metal surface.

The present investigation was undertaken in order to find the optimum condition of the preparation of the sensitive and stable surface of the copper-beryllium target suitable for the secondary electron multiplier. This paper reports the main results of the following studies:

(1) the dependency of the electron yield of the non-activated and activated target surfaces upon the kinetic energy of various noble gas and hydrocarbon ions;

(2) the determination of the surface structures of the ion targets by means of electron diffraction analysis; and

(3) the influence of the temperature of treatment upon the electron yield and the stability of the target surfaces.

## Experimental

**Mass Analyser and Ion Targets.** — The present experiments were performed by a mass spectrometer self-constructed in our laboratory. This mass spectrometer is a single focusing 90° sector type and the radius of curvature of the ion path is 135 mm., and the ion source of the usual electron bombardment type was installed in this instrument. In the present experiments two kinds of simple detectors were used. The constructions of the target assembly of them are schematically shown in Figs. 1a and 1b.

In Fig. 1a, $T_1$ indicates the ion target, $C_1$ the collecting plate of secondary electrons, $S_1$ the enclosing cage of the detector, and $E_1$ the collector slit. The other detector shown in Fig. 1b was constructed in order to measure the electron yield of the copper-beryllium surface by the bombardment of secondary electrons. But in the present experiments this detector shown in Fig. 1b was also used for the measurements of the electron yield by the bombardment of various positive ions. In Fig. 1b, $T_2$ indicates the ion traget, D and $C_2$ the collecting plates of sencondary electrons, $S_2$ the enclosing cage of the detector, $E_2$ the collector slit.

The geometries of the ion tragets ($T_1$ and $T_2$) and the collecting plate of secondary electrons (D) are similar to those of the electron multiplier of the Nier type[7]. The width of the collector slit was fixed to 2 mm., while the width of the exit slit of

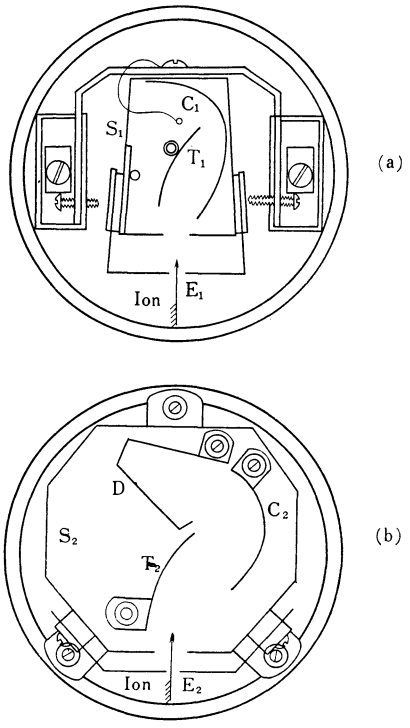

Fig. 1. Schematic diagrams of the ion collectors of the mass spectrometer. $T_1$(a) and $T_2$(b) are the ion targets, $C_1$ (a) and D(b) are the electron collectors, $C_2$(b) is Cu-Be dynode, $S_1$(a) and $S_2$(b) are the enclosing cages, and $E_1$(a) and $E_2$(b) are the collector slits.

the ion source is 0.2 mm. The ion targets were formed from the copper-beryllium plates* of 0.16 mm. in thickness, and the collecting plates of secondary electrons, the enclosing cages and the collector slits were all shaped from the molybdenum plates of 0.15 mm. in thickness.

For the measurements of the ion currents the collector slit ($E_1$ or $E_2$) and the ion target ($T_1$ or $T_2$) were kept to the earth potential and the electron suppressor voltage of $-20$ V. was supplied to all collecting plates ($C_1$ and $S_1$ in Fig. 1a; D, $C_2$ and $S_2$ in Fig. 1b). On the other hand, for the measurements of the secondary electron currents the collecting plates of secondary electrons were all kept to the earth potential and the potential of $-270$ V. was supplied to the ion target. It has been experimentally confirmed that these two types of detectors show the same value in the electron yield under the same experimental conditions.

A UX-54 tube was used as the primary tube of the d. c. amplifier, and the output currents were recorded by two galvanometers that have different sensitivities. The end vacuum under the ordinary experimental conditions was somewhat better than $1\times10^{-6}$ mm Hg.

**Treatment of Ion Targets.** — The non-activated targets were treated in the following manner. After being tempered, the alloy plates were mechanically polished with the fine emery papers of No. 0000 to 0005. After that the ion targets were formed and then electropolished in the polishing solution** for about one minute.

The treatment of activation of the ion targets was carried out in a quartz tube (25 mm. in outer diameter and 300 mm. in length) which was connected by the water-cooled taper joint to the vacuum system, the reservoir of purified oxygen and a McLeod gauge. The quartz tube was heated in an electric furnace and the temperature was measured by a copper-constantan thermocouple enclosed in this quartz tube. The electropolished targets were put into the quartz tube and evacuated to lower than $5\times10^{-6}$ mmHg at about 800°C for three hours. After the evacuation the temperature was lowered to each required temperature (i. e. 350, 420, or 480°C), and then the known quantity of oxygen was introduced into the quartz tube. The initial pressure of oxygen for each treatment was about $2\times10^{-2}$ mmHg, and the pressure decrease in each time was measured by a McLeod gauge.

The results are shown in Fig. 2. As seen in

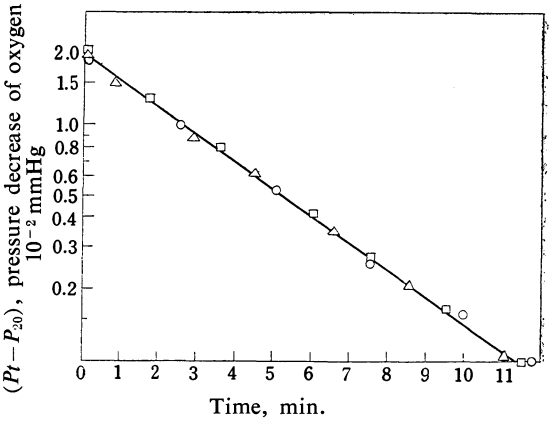

Fig. 2. Rate of the pressure decrease of the oxygen, by the treatment of the Cu-Be at the various temperatures: □; 350°C, △; 420°C and ○; 480°C.

Fig. 2, the present results indicate that the initial rate of the pressure decrease is independent of the temperature of treatment. After the treatment of 20 min. the quartz tube was evacuated and gradually cooled to the room temperature, and then the targets were taken out and mounted in the ion collector of the mass spectrometer.

**Determination of Surface Structure.** — The surface structure of the non-activated and activated ion targets was analysed by means of a commercial Hitachi E. D. C. type electron diffraction apparatus.

**Gaseous Materials.** — Oxygen was prepared by the thermal decomposition of potassium permanganate, and purified by passing through the trap

* The copper-beryllium plates of 0.16 mm. in thickness were prepared from a copper-beryllium(4%) alloy rod of the Beryllico Co., U. S. A.

** The electropolishing solution was prepared by mixing four volumes of phosphoric acid, four volumes of glycerin and three volumes of water.

cooled by liquid nitrogen. Spectroscopically pure argon and neon of the Teikoku Oxygen Co. were used without any further purification. The mass spectrometric analyses of these gaseous samples revealed that the total impurities were less than 0.005 per cent in volume. The research grade ethylene and ethane of the Philips Petroleum Co. were used in the present experiments, and the purity was also checked by means of the mass spectrometer.

## Results

**Surface Structure of Copper-Beryllium Targets.** — The surface structures of the copper-beryllium targets examined by the electron diffraction apparatus are summarized in Tables I and II. The main results of the analysed interplanar distances for the three kinds of ion targets — i. e. (a) tempered at about 800°C and mechanically polished, (b) tempered, mechanically polished, and then electropolished, and (c) tempered, mechanically polished, electropolished, and then bombarded by various positive ions for five hours — are listed in Table I together with that of Cu, $Cu_2O$ and CuO by X-ray diffraction analysis[8] for the sake of comparison. As seen in Table I, the oxide films of copper (mainly $Cu_2O$) are partially left on the mechanically polished surface (a). The electropolished surface (b) shows that the mechanically polished surface was re-oxidized by electropolishing, while the surface bombarded by various positive ions (c) indicates that the electropolished surface was partially reduced during the prolonged bombardments of various positive ions.

The interplanar distances analysed for the activated surfaces treated at various temperatures are summarized in Table II together with the X-ray diffraction data[8] of BeO and CuO. As seen in Table II, the difference in the surface structure between each temperature of the treatment is not clear, but the diffraction patterns peculiar to BeO are clearly observed for all specimens. This fact may be interpreted to mean that beryllium ions (or atoms) in the alloy rapidly migrate through the lattice and arrive at the surface at these temperatures of the treatment, and that since they easily react with oxygen and are fixed as beryllium oxide the concentration of this compound in the neighborhood of the alloy surface will be considerably increased by the treatments of activation.

**Dependency of Electron Yield upon Ion Kinetic Energy.**—In Figs. 3 and 4, the electron yield for the non-activated and activated (treated at 420°C) target surfaces is plotted as a function of the kinetic energy of singly- and doubly-charged argon ions and the five different ions from ethylene, respectively. The variation of the electron yield with the kinetic energy of the parent and fragment ions from ethane for the activated target surface treated at 420°C is shown in Fig. 5. Fig. 6. shows

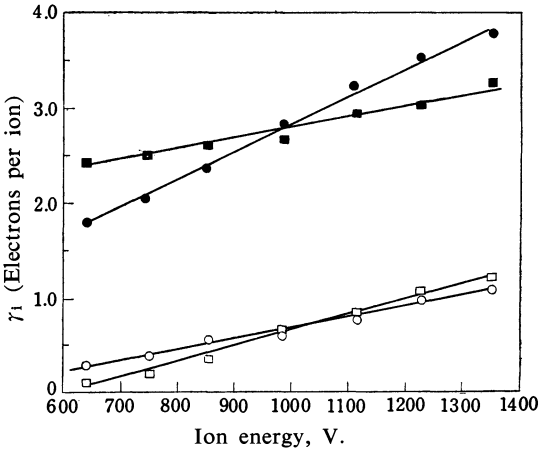

Fig. 3. Plot of experimental data giving electron yield $\gamma_i$, as a function of ion kinetic energy for $A^+$(● activated, and ○ non-activated) and $A^{2+}$(■ activated and □ non-activated) on 420°C activated and non-activated Cu-Be targets.

bombardments of the various positive ions mentioned above for five hours. On the other hand, no measurable decrease in the electron yield for the activated target surface treated at 420°C was obtained within the limit of the experimental errors by the prolonged bombardments of various ions for ten hours.

## Discussion

As seen in Figs. 3 and 4, the electron yield of the activated surface treated at 420°C for the argon ions or the various ions of ethylene is considerably larger and more stable than that of the non-activated surface. Moreover, as seen in Figs. 3—6 (excepting the results obtained for the activated surface at 480°C in Fig. 6), the increment of the electron yield for each activated surface with the kinetic energy of various ions in the range 600 to 1000 V. is very small, while that for the non-activated surface in the same energy range is considerably large. The typical results shown in Fig. 6 indicate that the electron yield and the increment of it with the kinetic energy of ions are greatly influenced by the temperature of the treatment. It is worth while to notice that the electron yield curve of the singly-charged neon ions for the target surface activated at 480°C is markedly different from those activated at 350 and 420°C.

These characteristics in the electron yield of the activated target surfaces might be correlated with the structure and the concentration of beryllium oxide formed in the neighborhood of the target surface. But unfortunately, the present results of the electron diffraction analyses shown in Tables I and II can not elucidate the fine structures of the oxide layers, and the more detailed measurements of the surface structure are necessary in order to discuss the correlation mentioned above.

The detailed experiments and theoretical treatise on the mechanism of the electron ejection by the impacts of various noble gas ions from both atomically clean surfaces of molybdenum and tungsten and the surfaces of tungsten covered by various foreign gases have been reported by Hagstrum[5,6]. From his results it has been suggested that the probability of the electron ejection in a non-Auger process may begin at low ion energies when a monolayer is present on the target surface and that even for the atomically clean surface there is strong evidence of a non-Auger process setting in at energies above 400 eV. with the singly-charged helium ions.

The present results shown in Figs. 3—6 indicate that the electron yield for the activated surface of copper-beryllium by various noble gas and hydrocarbon ions is only slightly influenced by the kinetic energy of ions, while for the non-activated target surface there is a marked increase in the electron yield with the increase in the ion kinetic energy. But since we must recall that under the present experimental conditions the considerable part of the target surface might be covered by the residual gases, it seems unreasonable to simply correlate the mechanism of the electron ejection from the activated and non-activated surfaces to the Auger and a non-Auger processes, respectively.

Hagstrum[3] also reported that when the electron ejection from the target surface is mainly dominated by the Auger neutralization process the electron yield is proportional to the value of the ionization potential minus twice the work functions of the target surface. The present results of the electron yield for the target surface activated at 420°C and the literature values[9] of the ionization potentials are summarized in Table III. When we assume that the electron ejection from the activated target surface of copper-beryllium simply obeys the Auger neutralization process and that the work function was unchanged throughout the

9) G. C. Eltenton, *J. Chem. Phys.*, 15, 455 (1947).

measurements, it is reasonable to expect that the electron yield is proportional to the ionization potential. Table III indicates that the present results are somewhat complicated and do not simply satisfy the proportionality mentioned above.

Since the present experimental conditions are considerably complicated, it is necessary to continue more detailed experiments on the dependency of the electron yield upon the ion energy and energy distribution of secondary electrons both for the activated and non-activated target surfaces which are atomically clean and covered by foreign gases in order to discuss the mechanism of the electron ejection process.

## Summary

The secondary electron emission from the non-activated and activated surfaces of copper-beryllium (4%) by the impacts of various noble gas and hydrocarbon ions was studied together with the determination of the surface structure by the electron diffraction analysis. The main results obtained are as follows.

(1) The considerably thick layer of beryllium oxide is formed in the neighborhood of the target surface activated by oxygen at the temperature range of 350 to 480°C.

(2) The oxide films of copper are formed on the target surface by electropolishing, but these oxides easily undergo reduction by the prolonged ion bombardments.

(3) The optimum temperature of activation for the electron yield seems to be about 420°C, and the electron yield for the activated target surface treated at 350 or 420°C is only slightly dependent upon the ion kinetic energy.

(4) No measurable decrease in the electron yield for the activated surface treated at 420°C was obtained by the prolonged bombardments of various positive ions for ten hours, while the electron yield for the non-activated surface decrease about 20 per cent by the prolonged bombardments of ions for five hours.

(5) Under the present experimental conditions, the mechanism of the electron ejection process seems to be considerably complicated and it is difficult to deduce any definite conclusion for the electron ejection process.

The authors wish to express their sincere thanks to Professor N. Sasaki of Koyto University, Professor T. Chitani of Tokyo Metropolitan University, Professor O. Toyama of the University of Osaka Prefecture and Professor K. Ogata of Osaka University for their kind encouragement and discussions. The authors' thanks are also due to Mr. A. Iwata of the Central Research Laboratory of Hitachi Factory who kindly offered the copper-beryllium (4%) alloy and to Mr. M. Mera for his kind helpfulness in the course of the electron diffraction analysis.

The expense has been defrayed in part from a grant given by the Ministry of Education to which the authors thanks are due.

# *Inorganic Extraction Studies on the System between Bis(2-ethyl hexyl)-orthophosphoric Acid and Hydrochloric Acid. II*

By Kan KIMURA

(Received July 25, 1960)

In the previous paper[1], was reported the influence of acid concentration on the solvent extraction of about fifty elements in the system of 50 percent bis(2-ethyl hexyl) orthophosphoric acid (HDEHP)-aqueous hydrochloric acid. As is well known in solvent extraction studies[2], the distribution ratio, $K_d$, is much affected by the solvent concentration in a way similar to that by the acid concentration.

Accordingly, a study on the influence of solvent concentration in organic phase is very important for the purpose of determining the suitable concentration for a given separation procedure. Besides that, the relationship

2) G. H. Morrison and H. Freiser, "Solvent Extraction in Analytical Chemistry", John Wiley & Sons Inc., New York (1957), p. 52.

between $K_d$ values of a given ion and solvent concentrations gives some suggestions on the chemistry of the extraction.

Along this line, have been published many studies[3-5] on the chemical mechanisms of thenoyltrifluoroacetone extraction or the chemical composition of the thenoyltrifluoroacetates. Concerning HDEHP extraction, the solvent dependence of the distribution ratios was already studied for lanthanide elements[6-8], uranium[8-9], iron and a few other chemical elements[8]. However, no comprehensive study on the extraction from a given mineral acid solution has been reported. In the present paper, the influence of solvent concentration is presented, discussing the extraction carried out from hydrochloric acid solution of a given acidity containing each of about fifty elements.

## Experimental

**Sources of Materials.** — The bis(2-ethyl hexyl)-orthophosphoric acid received from Virginia Chemicals Co. was purified and checked on its purity as reported in the previous study[1]. The work reported here was carried out using HDEHP diluted with toluene of guaranteed reagent grade.

Radioisotopes used were the same as those which were reported previously[1] except for the following: The nuclides 19day $^{86}$Rb and 40day $^{103}$Ru were imported and used as received. The radioactive tracers of neodymium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium and lutetium contributed for counting were mainly 11.3day $^{147}$Nd, 47 hr. $^{153}$Sm, 9.2hr. $^{152}$Eu, 18.0hr. $^{159}$Gd, 73day $^{160}$Tb, 2.32hr. $^{165}$Dy, 9.4day $^{169}$Er, 129day $^{170}$Tm and 6.8day $^{177}$Lu, respectively[10]. These were prepared by the neutron irradiation of highly-purified oxides in JRR-1. In the cases of gadolinium and erbium, the radioactivities caused by the radioactive daughters (6.75day $^{161}$Tb and 680day $^{171}$Tm) of simultaneously yielded short half-lived nuclides (3.73 min. $^{161}$Gd and 7.5hr. $^{171}$Er) were corrected from the total activities of gadolinium and erbium by the results of their decay measurements, respectively. The nuclide 27.4day $^{233}$Pa was obtained as a by-product of uranium-233 processings[11].

The radiochemical purity of these nuclides was checked by their half-lives, $\gamma$-ray spectra, and/or $\beta$-ray absorption curves with aluminum foils.

**Determination of Distribution Ratios.**—The distribution ratio, $K_d$, of a given nuclide was radiometrically determined. The details and some remarks of the method written about in the previous report[1] were also adopted in the present study. Most of the data in this experiment were obtained after shaking the two layers for three minutes.

Although the HDEHP concentration in the organic layer was varied usually in the range from 0.5 to 50 volume percent, it was extended to 0.01 volume percent in some cases. The extraction with barren toluene containing no HDEHP was also checked. On the other hand the acidity in the aqueous layer was kept constant in a series of extractions of a given element.

## Results and Discussion

The results are summarised in Fig. 1 as a series of graphs of $\log K_d$ vs. log (% HDEHP) where $K_d$ is the distribution ratio and % HDEHP the concentration of HDEHP in volume percentage.

As reported previously[1], $K_d$ values for each cation usually depend on inverse power of hydrogen ion concentration, and furthermore $K_d$ values for mono-, di-, tri-, and tetra-valent cation decrease with the following general sequence; $M^{4+} > M^{3+} > M^{2+} > M^{+}$. Meanwhile, $K_d$ values for the ion ready to form an anion are usually low. Therefore, it is desired that the acidity should be changed according to the valence of the ion concerned.

Although the acidity of aqueous phase was kept constant at 0.5 N for most of the elements, it was 0.05 N for the alkali and alkaline earth elements, 0.3 N for the rare earth elements, and 0.1 N or 2 N for some other elements. In some cases, the extractions of ion from the solutions of two different acidities were undertaken. The Arabic numeral in each graph shows the acidity taken.

Fig. 1 was compiled from some published and unpublished results. Data for lead and bismuth were taken from the observation of Ishimori[12]. Data for yttrium, promethium, thulium and americium were taken from the work of Peppard et al[6]. The $K_d$ values for selected lanthanide cation(III) in HDEHP-hydrochloric acid system are inverse third power dependent on the hydrogen ion concentration of the aqueous phase. Therefore, $K_d$ values for yttrium, promethium, thulium and americium were obtained correcting Peppard's value (at 0.552 M, 0.146 M, 0.552 M, and 0.275 M, respectively) for 0.3 N hydrochloric acid solution.

As is seen in Fig. 1, the $K_d$ values for each

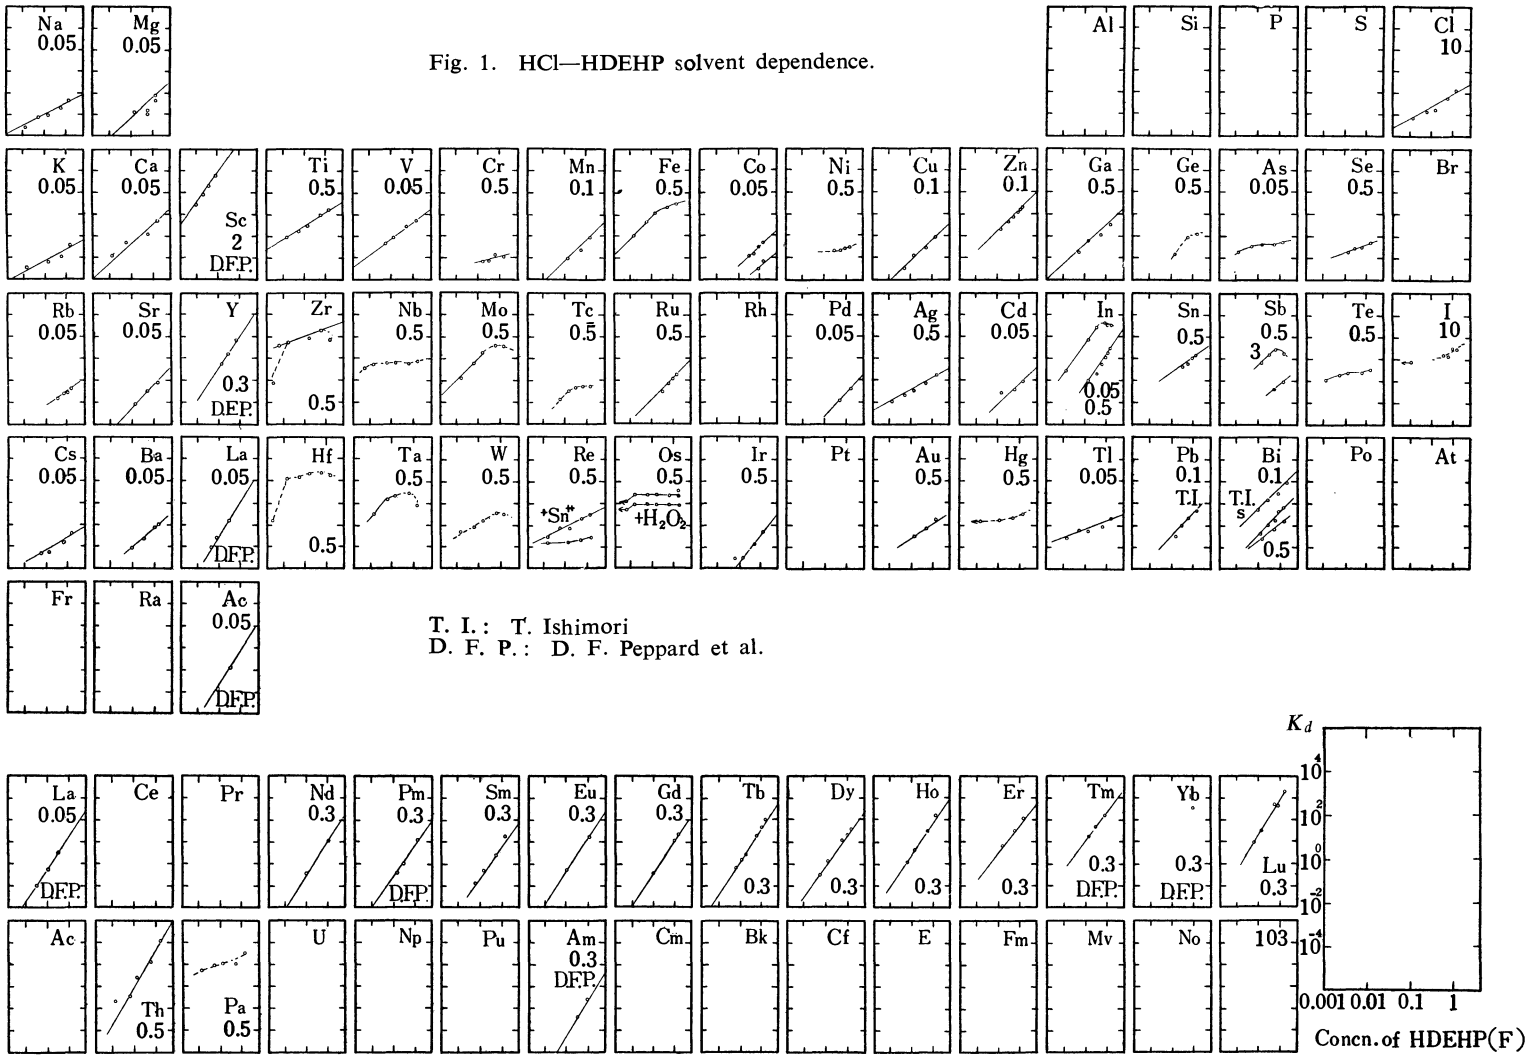

Fig. 1. HCl—HDEHP solvent dependence.

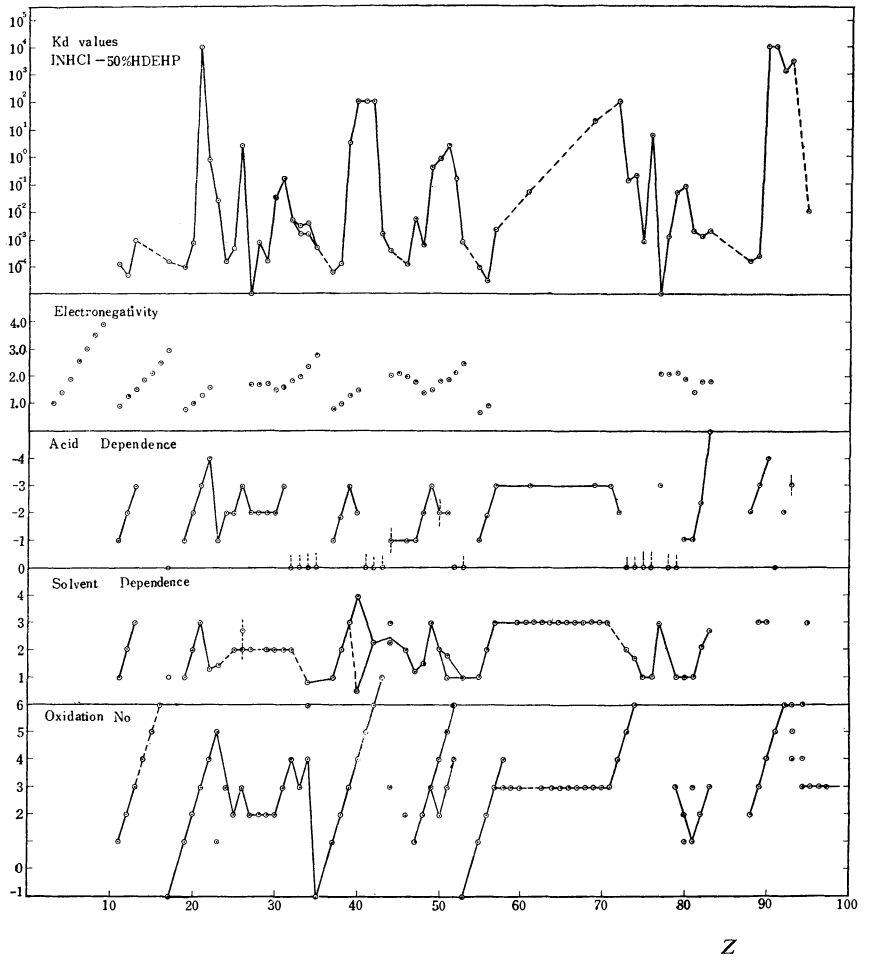

Fig. 2. $Z$ dependences.

of almost all the elements increase as the concentration of HDEHP in the toluene phase increases. A similar relationship is observed generally in many solvent extraction systems.

The $K_d$ values for alkali metals, alkaline earth metals and lanthanide elements show the first, second and third power dependence on the HDEHP concentration in the toluene phase, respectively. A similar relationship holds for some other elements: silver and thallium(I) indicate the first power solvent dependence, manganese, cobalt, copper, zinc and cadmium the second dependence, and indium indicates the third. The $K_d$ values for iron and gallium follow the second power solvent dependence and those for thorium the third dependence.

The $K_d$ values for zirconium remain nearly constant in almost the whole range of the solvent concentration. Although the strange behavior of zirconium is not clearly explained, it might be caused by both the hydrolysis of zirconium ion and its high $K_d$ values. Scadden and Ballou[13] reported that only zirconium and indium are completely extracted with 0.06 M dibutylphosphoric acid (HDBP) for 1 M nitric, hydrochloric, or perchloric acid; and Ishimori et al[14] reported that only zirconium is extracted with dilute tributyl phosphate (1%. toluene diluent) from 8 M hydrochloric acid solution of the fission products. Furthermore, White[15] reported that zirconium is completely extractable from 1 M hydrochloric acid solution with 0.1 M trioctylphosphine oxide and partially extractable with 0.1 M tris-2-ethylhexyl phosphine oxide. This high extractability of zirconium with many alkyl phosphorous reagents is noteworthy as compared with the very low solubility of zirconium phosphate in mineral acids. Hafnium, niobium and protactinium resemble zirconium in the solvent dependence of their $K_d$ values.

The $K_d$ values for osmium are relatively high and kept nearly constant. Besides that, osmium can be extracted with pure toluene fairly well, giving the $K_d$ value of 1.31. This $K_d$ value is as low as about one tenth of the $K_d$ values for toluene containing HDEHP. The $K_d$ value is shown with open circles attached with arrow in Fig. 1. The addition of hydrogen peroxide to the tracer solution makes all the $K_d$ values for osmium low, keeping the shape of the curve unchanged. This would be explained as a partial reduction of the readily extractable species of osmium. Thus, the relatively high $K_d$ values for osmium might be explained assuming the extraction of a neutral molecule such as osmium tetroxide. Futhermore, the higher $K_d$ values with the HDEHP toluene solution might indicate that HDEHP promotes the extraction to some extent.

The $K_d$ value for mercury with pure toluene is also high. It appears as if the extraction of mercury is partially based on the extraction of a neutral molecule such as $HgCl_2$, which is slightly ionized in the low concentration region of chloride.

In the case of iodine, the $K_d$ values for the acid range up to 5 N were very low[15]. However, the slightly high $K_d$ value is obtained at 10 N. Similarly the $K_d$ value for pure toluene at 10 N hydrochloric acid remains high. It may be based on the oxidation of tracer quantity of iodide ion with the micro-amount of chlorine. Scadden and Ballou[13] reported that the neutral iodine molecule, $I_2$, showed a high extractability with dibutyl phosphate.

The different slopes of solvent dependence curve for bismuth are obtained varying the acid concentration of aqueous phase. Because it is known that bismuth forms a series of chloride complexes in hydrochloric acid solution[16], and that the ratios among these chloride complexes vary with the chloride concentration, it may be natural that the slope is changed according to the acid concentration.

On the other hand, the slopes of the $K_d$ curves for indium and rare earth elements are not dependent on the acid concentration. For instanse, the $K_d$ values for thulium follow the third power solvent dependence both at 0.552 M[6] and at 0.3 N hydrochloric acid. Concerning the $K_d$ values for indium, a similar relationship also holds at 0.5 N and 0.05 N hydrochloric acid. The $K_d$ values for cobalt are very low, but similar results are obtained at 0.5 N and 0.05 N, using a larger amount of radioactive cobalt-60.

The slopes of the solvent dependence and of the acid dependence and the oxidation number are plotted against the atomic number, $Z$, in Fig. 2. The graph of the "best values of electronegativity"[17] vs. $Z$ and that of the $K_d$ values between 50% HDEHP and 1 N hydrochloric acid vs. $Z$ are attached to Fig. 2. The values of electronegativity of cobalt, nickel, ruthenium, rhodium, palladium, iridium and platinum are taken from Haïsinsky's data[18].

As mentioned above, the solvent dependence is studied at one of the several definite acidities. Accordingly the data of the solvent dependence may not be suitable for detailed discussion, because the formation of chloro-complexes differs both with the acidity and with the element. However, the data may be applicable to general discussion. The vertical dotted lines indicate that the slope could not be clearly obtained. Almost all of the elements showed the slope defined as "the second type" in the previous paper indicate the slope of zero in the graph of the acid dependence vs. $Z$.

As is seen in Fig. 2, the slopes and the oxidation numbers vary regularly in Na-Mg-(Al), K-Ca-Sc, Rb-Sr-Y, and Cs-Ba-La, showing the increasing lines with increasing $Z$. Although the Fr-Ra-Ac-line is not studied, it may follow the similar relationship. Concerning the Ib-IIb-IIIb group of the periodic table, only the Ag-Cd-In line is satisfied with this increasing relation. On the other hand, the Cr-Zn line or La-Lu line is nearly horizontal. The curves indicate some complicated relationships for the ranges of the IVb-Vb-VIb group and of the platinum group in the periodic table.

Fig. 2 shows that the relation among the slopes of the dependences and the oxidation number is roughly divided into two types.

The first type is characteristic in the fact that the relation which the slope of the solvent dependence has equals that of the acid dependence and further that the oxidation number does so also. Scandium, yttrium, or lanthanum are satisfied with this relationship. This tendency is generally observed in the solvent extraction system where chelation plays an important role:

$$M^{m+}{}_{(aq.)} + mHR_{(org.)} \rightleftarrows MR_{m(org.)} + mH^{+}{}_{(aq.)} \quad (1)$$

In Eq. 1, the distributio ration of M is given:

$$K_d = K[HR]^{m}{}_{(org.)}[H^{+}]^{-m}{}_{(aq.)} \quad (2)$$

Baes and Peppard[6,7] assumed the following

16) L. S. Newman and D. N. Hume, *J. Am. Chem. Soc.*, 79, 4576 (1957).

17) H. O. Pritchard and H. A. Skinner, *Chem. Revs.* 55, 767 (1955).

18) M. Haïsinsky, *J. Phys.* 7, 7 (1946); *J. Chim. Phys.* 46, 298 (1949).

equilibrium for the reaction between uranium(VI) or lanthanide elements in perchloric acid solution and HDEHP, considering that the HDEHP molecule is essentially completely dimerized in the toluene phase:

$$M^{m+}_{(aq.)} + m(HDEHP)_{2\,(org.)} \rightleftarrows MH_m(DEHP)_{2m\,(org.)} + mH^+_{(aq.)} \quad (3)$$

where the $K_d$ value of M is given as:

$$K_d = K[(HDEHP)_{2\,(org.)}]^m [H]^{-m}_{(aq.)} \quad (4)$$

It is assumed that the alkali metal cation(I) and the alkaline earth metal cations(II) follow Eq. 3, showing the first and second power solvent dependence and the inverse first and second power acid dependence, respectively. Because manganese(II), cobalt(II), copper(II), zinc(II), silver(I), cadmium(II), indium(III) and thallium(I) also show the relationship of equal figures, it seems that they are also satisfied with Eq. 3.

$K_d$ values of iron(III) are approximately second-power dependent on the HDEHP concentration for 0.5~0.05% HDEHP in the organic phase and are inverse third-power dependent on the acid concentration in the aqueous phase. Thus, iron belongs to a modified first type. Blake et al.[8] postulate the following equilibrium for the partition of ferric iron:

$$Fe^{3+} + 2(HDEHP)_2 + HOH \rightleftarrows Fe(OH)H_2(DEHP)_4 + 3H^+ \quad (5)$$

Besides that, Peppard and Ferraro[19] mentioned that the solvent extraction of thorium is approximately third-power dependent on the HDEHP concentration and inverse forth-power dependent on the HDEHP concentration and inverse forth-power dependent on the acid concentration, and that these tentative dependencies are consistent with either or both of the following equilibria:

$$M^{4+}_{(aq.)} + 3H_2DEHP_{2\,(org.)} \rightleftarrows MDEHP_2(HDEHP_2)_{2\,(org.)} + 4H^+_{(aq.)} \quad (6)$$

and

$$M^{4+}_{(aq.)} + 3H_2DEHP_{2\,(org.)} + HOH \rightleftarrows M(OH)(HDEHP_2)_{3\,(org.)} + 4H^+_{(aq.)} \quad (7)$$

It seems that the solvent extraction of gallium also follows similar equilibria, showing the second-power solvent dependence and the inverse third-power acid dependence. A similar relationship also holds for the extraction of titanium.

On the other hand, the second type is characteristic both in the acid dependence with the slope of zero defined as "the second type"[1] and in the solvent dependence with the slope of one or more. These tendencies are commonly seen in the solvent extraction, in which the ion association plays an important role[20] such as TBP extraction of uranyl ion[21].

Chlorine, selenium, molybdenum, tungsten and gold, which form anions easily and have a relatively high value of electronegativity, are typical for the second type. Accordingly, it appears that the solvent extraction of these elements is based on partition as is found in the extraction with TBP. As for the electonegativity, it is noticed that the more extractable element generally has a value between 1.0 and 2.0.

Thanks are due to Dr. Tomitaro Ishimori for his guidance and suggestions, to Dr. Kenjiro Kimura and Dr. Toshio Nagai for their encouragement, and also to Mr. Ikuo Suzuki for his assistance.

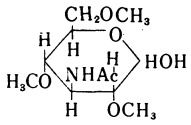
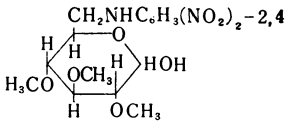
# *Studies on Antibiotics and Related Substances. XI. Methylated Amino-sugar Moieties from Methylated Kanamycin*[1]



By Sumio UMEZAWA and Yukio ITŌ

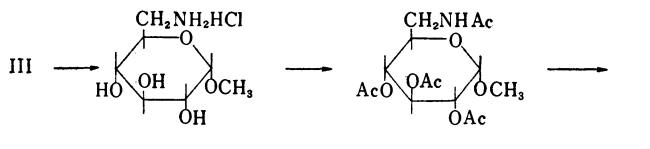
(Received July 25, 1960)



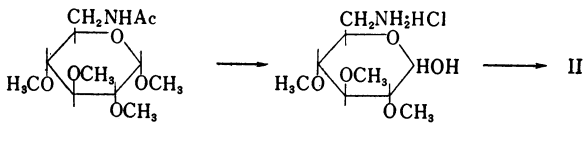
In a previous paper[2] we described the fact that 1,3-diamino-4,6-dihydroxy-5-methoxycyclohexane was isolated from the hydrolyzate of exhaustively methylated *N*-acetyl kanamycin. It was therefore concluded that both of the two aminohexose moieties in kanamycin are directly joined to deoxystreptamine through 4- and 6-hydroxyl groups by glucosidic linkages, the structure of kanamycin[3] being established. Subsequently, attempts have been made to isolate amino-sugar moieties from the same hydrolyzate. The present paper is concerned with the isolation of methylated derivatives of 3-amino-3-deoxy glucose and 6-amino-6-deoxyglucose.

Separation of 1,3-diamino-4,6-dihydroxy-5-methoxycyclohexane from acid-hydrolyzate was accomplished as described in a previous paper[2]. The residue from the mother liquor was chromatographed on a column of cellulose powder with butanol–ethanol–water (4 : 1 : 5). Repetition of the chromatography resulted in the isolation of 3-acetamido-3-deoxy-2,4,6-tri-*O*-methyl-D-glucose (I). The new derivative was converted into a methyl glucoside, which has been identified with the synthetic specimen prepared from D-glucose by the route of Peat and Wiggins[4].

On the other hand, an aqueous solution of



I



II

the above-mentioned residue from the mother liquor was passed through a column of Amberlite IRC-50 ($Na^+$ form) to remove *N*-acetylated amino-sugar moieties and developed with dilute hydrochloric acid. The combined residues from the early fractions were subjected to a cellulose powder chromatography to give fractions which showed a single ninhydrin-positive spot and positive Tollens and aniline phthalate reaction. The product was chromatographically identical with the synthetic specimen of 6-amino-6-deoxy-2,3,4-tri-*O*-methyl-D-glucose hydrochloride, the synthesis of which is mentioned below. The product could not be caused to crystallize. However, condensation with 2,4-dinitrofluorobenzene afforded yellow needles of 6-(2,4-dinitrophenylamino)-6-deoxy-2,3,4-tri-*O*-methyl-D-glucose (II).

The synthetic specimen of II has been prepared from 6-amino-6-deoxy-3,5-benzylidene-1,2-isopropylidene-D-glucose[5] (III) by the following scheme.

5) B. Helferich and R. Mittag, *Ber.*, **71**, 1588 (1938).

In the course of our synthesis of II, an alternative synthesis of methyl 6-amino-6-deoxy-α-D-glucoside hydrochloride (IV) was performed by Cramer et al.[6] The glucoside prepared by our method has been identified with a sample prepared by the alternative method by the mixed melting point method and infrared absorption spectra.

The mixed melting point determination of the natural and synthetic specimens of II was undepressed and the respective infrared spectra were completely superimposable.

## Experimental

**Isolation of 3-Acetamido-3-deoxy-2, 4, 6-tri-*O*-methyl-D-glucose (I).**—The exhaustively methylated tetra-*N*-acetyl-kanamycin was hydrolyzed with 6 N hydrochloric acid and 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane was separated from the hydrolyzate, details of which were described in a previous paper[1]. The mother liquor was evaporated to dryness. Paperchromatographic studies of the residue (brown syrup) showed ninhydrin-positive spots of $R_f$ 0.54 (violet) 0.41 (violet), 0.31 (orange) 0.23 (violet) and 0.08 (brown) using butanol-ethanol-water (4 : 1 : 5). The residue (9.67 g.) was dissolved in the above-mentioned solvent, chromatographed on a column (3×51 cm.) of cellulose powder and developed with the same solvent. One hundred and fourteen fractions were cut into 10 ml. each, evaporated to dryness, weighed and tested for $R_f$ values. The combined fractions of tube Nos. 27—37 (6.89 g., $R_f$ 0.48, 0.41, 0.36) were again chromatographed in the same manner and the combined fractions of tube Nos. 13-30 were evaporated to yield a crystalline residue (600 mg.). Recrystallization from absolute ethanol afforded needles of m. p. 229~230°C (decomp.), $[\alpha]_D^{15}$+107.1° (*c* 0.98, methanol).

Found: C, 49.89; H, 7.90; N, 5.49; $OCH_3$, 35.20; $COCH_3$, 14.70. Calcd. for $C_{11}H_{21}NO_6$: C, 50.18; H, 8.04; N, 5.32; $OCH_3$, 35.36; $COCH_3$, 16.35%.

The product feebly reduced Fehling's solution and showed a negative ninhydrin reaction. On hydrolysis by refluxing with 6 N hydrochloric acid for 2 hr., the product gave a hydrolyzate which showed a ninhydrin-positive spot of $R_f$ 0.29 (orange). These results indicated that the product was an *N*-acetylated derivative of methylated hexosamine. By refluxing in excess absolute methanol (40 ml.) in the presence of hydrogen chloride (2%), the product (350 mg.) afforded a methyl glucoside (120 mg.) of m. p. 156~157°C, $[\alpha]_D^{15}$+120.7° (*c* 0.41, chloroform), which had nearly the same m. p. with the methyl 3-acetamido-3-deoxy-2, 4, 6-tri-*O*-methyl-α-D-glucoside reported by Peat and Wiggings[4].

Found: C, 51.87; H, 8.10; N, 5.18; $OCH_3$, 44.00. Calcd. for $C_{12}H_{23}NO_6$: C, 51.97; H, 8.36; N, 5.05; $OCH_3$, 44.76%.

The synthetic specimen was therefore prepared from D-glucose by the route of the above authors. The mixed m. p. determination of the natural and synthetic specimen (m. p. 157~158.5°C) was undepressed and the respective infrared spectra were completely superimposable.

**Isolation of 6-Amino-6-deoxy-2, 3, 4-tri-*O*-methyl-D-glucose.**—The residue (4.89 g.) obtained by evaporation of the mother liquor from 1, 3-diamino-4, 6-dihydroxy-5-methoxycyclohexane was dissolved in water (20 ml.) and passed through a column of Amberlite IRC-50 ($Na^+$ form, 80 ml.) to remove *N*-acetylated amino-sugar moieties and developed with 0.5 N hydrochloric acid. Thirty-one fractions of eluate were cut into 20 ml. each, evaporated to dryness and tested for $R_f$ values. Fractions of tube Nos. 4-9 showed ninhydrin-positive spots of $R_f$ 0.44~0.46, 0.23~0.24*. The combined residues (4.54 g.) from the fractions were treated with absolute ethanol (30 ml.) to separate off the sodium chloride and the solution was evaporated to dryness to give a syrup (1.60 g.), which was treated with active charcoal in absolute ethanol (20 ml.). To the filtrate was added absolute ether (30 ml.) to precipitate sodium chloride and the filtrate was evaporated. A solution of the resulting syrup (1.39 g.) in methanol (2 ml.) was passed through a column (2×70 cm.) of cellulose powder and developed with *n*-butanol-acetic acid-water (10 : 2 : 5); fifty-seven fractions were cut into 5.0 ml. each. A residue (0.70 g.) obtained from tube Nos. 35-45 showed a single ninhydrin-positive spot of $R_f$ 0.33~0.38 and gave positive Tollens and aniline phthalate reactions. The combined residue (0.60 g.) obtained was mixed with cellulose powder (1.0 g.) in a small quantity of methanol, placed on a column (2×70 cm.) of cellulose powder, washed with *n*-butanol-ligroin-water (19 : 30 : 1) and developed with *n*-butanol-acetic acid-water (10 : 2 : 5); eighty-nine fractions were cut into 5.0 ml. each. Fractions of tube Nos. 43—55 showed a single ninhydrin-positive spot of $R_f$ 0.40 and were chromatographically identical with the synthetic specimen of 6-amino-6-deoxy-2, 3, 4-tri-*O*-methyl-D-glucose hydrochloride.

The combined residues (170 mg.) obtained from the above fractions were dissolved in an aqueous solution (3.0 ml.) of sodium bicarbonate (100 mg.) and to the solutions was added 2, 4-dinitrofluorobenzene (100 mg.) dissolved in absolute ethanol (2.0 ml.); the solution was stirred at room temperature for 1 hr. to give yellow needles. After standing overnight, the needles (180 mg.) were separated and treated with ether to remove a trace of any insoluble part. The ethereal solution was passed through a column of alumina** (10.0 g.) and eluted with ether-petroleum ether and ether in turn. Evaporation of the combined eluates gave a crystalline residue (92 mg.); recrystallization from absolte methanol afforded a pure sample (72 mg.) of 6-(2, 4-dinitrophenylamino)-6-deoxy-2, 3, 4-tri-*O*-methyl-D-glucose (II), m. p. 97~99°C sintered from 92°C), $\lambda_{max}^{EtOH}$ 261.5 (ε 3833), 348 mμ (ε 8293).

6) F. Cramer, H. Otterbach and H. Springmann, *Chem. Ber.*, **92**, 384 (1959).

* Unless otherweise indicated, the solvent system of *n*-butanol-acetic acid-water (10 : 2 : 5) and Toyo filter paper No. 51 were used.

** Aluminum Oxide, Merck.

Found: C, 46.31; H, 5.20. Calcd. for $C_{15}H_{21}N_3O_9$: C, 46.51; H, 5.46%.

**6-Amino-6-deoxy-D-glucose Hydrochloride (IV).**—6-Amino-6-deoxy-3,5-benzylidene-1,2-isopropylidene-D-glucose[5] (21.0 g.) was hydrolyzed by refluxing with 75% acetic acid (300 ml.) for 3 hr. and followed by treatment with active charcoal (1.0 g.). The filtrate was evaporated to dryness to give a residue (14.1 g.) which reduced Fehling's solution. To the residue (14.0 g.) which was dried over phosphorus pentoxide in a vacuum desiccator were added silver acetate (10.6 g.), acetic anhydride (11.5 g.) and methanol (141 ml.). The mixture was stirred at room temperature for 3 hr. and refluxed on a water bath for an additional 5 min. The reaction mixture was filtered and washed with hot water; the filtrate was acidified with concentrated hydrochloric acid to Thymol blue to precipitate silver salt. The filtrate was evaporated up to give a crude *N*-acetylated product***, which was dried over phosphorus pentoxide in a vacuum desiccator. The product as converted into a methyl glucoside by refluxing with 300 ml. of methanolic hydrochloride (2%) for 10 hr. The hydrolyzate was neutralized with basic lead carbonate (100 g.), filtered, and the filtrate was evaporated up in vacuo to give a dark syrup, which showed a positive ninhydrin reaction, indicating that de-*N*-acetylation occurred as well as the glucoside formation. The dark product was dissolved in methanol (26 ml.) and the solution was passed through a column of alumina (40 g.), washed with 1 N hydrochloric acid, and developed with methanol; early fractions (170 ml.) were combined and evaporated up to give a brown residue (7.88 g.), An aqueous solution (100 ml.) of the residue was passed through a column of Amberlite IRA-410 (base form, 100 ml.) and the early effluent (77 ml.) was treated with active charcoal (2 g.) and followed by evaporation to dryness to give crude methyl 6-amino-6-deoxy-D-glucoside (3.85 g., overall yield 23%). A solution of the crude product in absolute methanol was acidified with hydrogen chloride and evaporated to dryness. Recrystallization of the resulting solid from absolute methanol-ether afforded colorless crystals (1.5 g.) of methyl 6-amino-6-deoxy-α-D-glucoside hydrochloride, m. p. 200°C. (decomp.).

**Methyl 6-Acetamido-6-deoxy-2, 3, 4-tri-*O*-methyl-α-D-glucoside (VI).**—A mixture of methyl 6-amino-6-deoxy-α-D-glucoside hydrochloride (3.9 g.), acetic anhydride (15.5 g.) and pyridine (20.7 g.) was stirred at room temperature for 43 hr. The reaction mixture was added to ice water, stirred for 4.5 hr. and then extracted thrice with chloroform (100 ml.). The combined extracts were washed thrice with 35% potassium bisulfate (50 ml.) to remove the pyridine and further washed with a saturated solution (50 ml.) of sodium bicarbonate and water (90 ml.) in turn. The chloroform solution was dried with calcium chloride and evaporated to dryness. To a vigorously stirred solution of the acetylated product (5.90 g.) in methanol (6.0 ml.) was added a solution of dimethyl sulfate (60 ml.) in carbon tetrachloride (24 ml.) and water (4.0 ml.). During this and the subsequent addition of alkali, the temperature of the reaction was kept at about 40°C. A solution of sodium hydroxide (12.5 N, 60 ml.) was added dropwise over a 25 min. period. Again, dimethyl sulfate (20 ml.) was added and 12.5 N sodium hydroxide solution (80 ml.) was added gradually during one-hour period. The reaction mixture was kept at 75°C for 1 hr. and then heated on a boiling water bath for an additional 30 min. The temperature was lowered to about 40°C and the mixture was extracted with two 250-ml. portions of chloroform. After drying with calcium chloride, the combined extract was evaporated to give a crystalline solid (3.80 g. 96.3%). Recrystallization from ethyl acetate gave colorless needles of methyl 6-acetamido-6-deoxy-2,3,4-tri-*O*-methyl-α-D-glucoside, m. p. 121~121.5°C, $[\alpha]_D^{18}$ +250.8° (*c* 1.03, chloroform).

Found: C, 52.13; H, 8.06; N, 5.10; $OCH_3$, 44.36. Calcd. for $C_{12}H_{23}NO_6$: C, 51.97; H, 8.36; N, 5.05; $OCH_3$, 44.76%.

**6-Amino-6-deoxy-2, 3, 4-tri-*O*-methyl-D-glucose Hydrochloride (VII).**—A solution of VI (1.47 g.) in 3 N hydrochoric acid (30 ml.) was refluxed for 6 hr. and treated with active charcoal (100 mg.); the filtrate was evaporated in vacuo. The residue obtained was dissolved in water (30 ml.) and again the solution was evaporated in vacuo. The residue was dried over phosphorus pentoxide in a vacuum desiccator and crystallized from absolute ethanol-absolute ether; colorless needles (1.70 g., 99.6%). Recrystallization from the same solvent gave a pure sample of 6-amino-6-deoxy-2,3,4-tri-*O*-methyl-D-glucose hydrochloride, m. p. 179~180°C (decomp.), $[\alpha]_D^6$ +27.25° → +65.3° (*c* 1.32, water).

Found: C, 42.27; H, 7.56; N, 5.43; $OCH_3$, 36.37. Calcd. for $C_9H_{20}NO_5Cl$: C, 41.94; H, 7.82; N, 5.43; $OCH_3$, 36.13%.

**6-Deoxy-6-(2, 4-dinitrophenylamino)-2, 3, 4-tri-*O*-methyl-D-glucose.**—Condensation of VII with 2,4-dinitrofluorobenzene was accomplished in the same manner as described in the end of the second clause. The crude product (52%) was washed with ether and dissolved in absolute methanol to remove a trace of any insolube part. The residue from the methanol solution was recrystallized from a small quantity of absolute methanol to give an analytically pure sample of m. p. 97~99°C (sintered at about 90°C), $[\alpha]_D^{11}$ +37.7° (*c* 0.61, methanol); $\lambda_{max}^{EtOH}$ 261.5 (ε 3833), 348 mμ (ε 8393).

Found: C, 46.38; H, 5.24; N, 11.04. Calcd. for $C_{15}H_{21}N_3O_4$: C, 46.51; H, 5.46; N, 10.85%.

## Summary

1) 3-Acetamido-3-deoxy-2,4,6-tri-*O*-methyl-D-glucose (I) and *N*-(2,4-dinitrophenyl) derivative (II) of 6-amino-6-deoxy-2,3,4-tri-*O*-methyl-D-glucose have been isolated from the hydrolyzate of exhaustively methylated *N*-acetyl kanamycin.

2) II has been synthesized from 6-amino-6-deoxy-3,5-benzylidene-1,2-isopropylidene-D-glucose.

*** As direct formation of glucoside from free hexosamine seemed difficult, the glucoside formation was preceded by *N*-acetylation. See T. White, *J. Chem. Soc.*, **1940**, 428.

The authors are indebted to Mr. S. Fukatsu for technical assistance in some of the preparations here described and to Mr. S. Nakada for microanalyses.

# *Spectrophotometric Determination of Beryllium, Copper and Iron with Sodium-2'', 6''-dichloro-4'-hydroxy-3, 3'-dimethylfuchsone-5, 5'-dicarboxylate*

By Yukiteru KATSUBE, Katsuya UESUGI and John H. YOE

(Received May 9, 1960)

Several organic compounds which have the hydroxydimethylfuchsone dicarboxylic acid structure have been used as the reagents for the determination of certain trace metals. Typical of these are eriochrome cyanine R for the colorimetric determination of aluminum[1] and beryllium[2], and chrome azurol S as an indicator for the complexometoric titration of aluminum, copper, iron and zirconium[3-5]. Sodium-2'', 6''-dichloro-4'-hydroxy-3, 3'-dimethylfuchsone-5, 5'-dicarboxylate (pontachrome azure blue B) has been examined spectrophotometrically for the determination of beryllium in an alkaline solution[2], but was not satisfactory because of the overlap of the absorption peak of the reagent with that of its beryllium complex. This paper reports an extensive study of the color reaction between the compound and metallic ions and procedures for its use as a reagent for the spectrophotometric determination of beryllium, copper and iron.

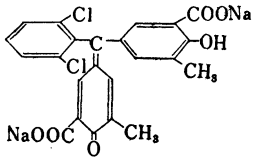

Fig. 1. Sodium-2'', 6''-dichloro-4'-hydroxy-3, 3'-dimethylfuchsone-5, 5'-dicarboxylate.

## Experimental

**Apparatus and Reagent.**—A Shimadzu spectrophotometer model QB-50, with 1.00 cm. glass cells and a Hitachi photoelectric photometer Type-FPW 4 with 1.00 cm. glass cells were used.

Amberlite IRA 410 (50 to 100 mesh) was used in a goose-neck type column (30 cm. in height and 10 mm. in inside diameter).

The reagent solution was prepared by dissolving 0.2 g. of sodium-2'', 6''-dichloro-4'-hydroxy-3, 3'-dimethylfuchsone-5, 5'-dicarboxylate in 100 ml. of 99% ethanol and filtering off the residue.

The standard solution containing 0.1 mg. of beryllium per milliliter was prepared by dissolving beryllium chloride (analytical grade) in distilled water. The standard copper solution containing 0.1 mg. of copper per milliliter was prepared by dissolving pure crystals of $CuSO_4 \cdot 5H_2O$ in distilled water. The standard iron(III) solution was prepared by dissolving crystals of pure $Fe_2(SO_4)_3(NH_4)_2SO_2 \cdot 24H_2O$ in dilute sulfuric acid to give a solution containing 0.1 mg. of iron per milliliter. Five grams of 8-hydroxyquinoline was dissolved in 12 ml. of 17 N acetic acid and diluted to 100 ml. with distilled water.

Concentrated ammonium hydroxide (130 ml.) was neutralized with 120 ml. of glacial acetic acid and diluted to 100 ml. with distilled water to give ammonium acetate solution.

**Determination of Beryllium.**—*Separation of Beryllium.*—Acidify slightly a solution, containing interfering ions such as $Al^{3+}$, $Co^{2+}$, $Cu^{2+}$, $Fe^{2+,3+}$ and $Ni^{2+}$, with dilute acetic acid, and warm it on a steam bath to 60~70°C. Add the oxine-acetic acid solution in 50% excess, and then add the ammonium acetate solution slowly, until precipitation is complete. Let stand for one hour with frequent stirring, filter off the precipitate and wash with dilute acetic acid. Determine the beryllium in the filtrate.

*Procedure of Determination.*—Transfer the solution (not more than 1.5 ml.) containing 2 to 20 p.p.m. of beryllium to a 25 ml. volumetric flask, add about 10 ml. of the acetate-acetic acid buffer solution (pH 5.8) and mix well. Then add 1 ml. of the 0.2% reagent solution, shake well, and make up to the

mark with the buffer solution. After 20 min., measure the absorbance at 570 mμ, using a reagent blank solution (or distilled water) as a reference.

**Determination of Copper and Iron(III).**—*Separation of Copper and Iron.*—Separate copper and iron(III) by the method of Kraus[6], using an anion exchange resin. (Copper and iron do not interfere with each other's determination if the solution is adjusted to pH 7.2 for copper and 3.5 for iron.)

*Procedure of Determination.*—Transfer 1.00 ml. of the neutralized sample solution containing 10 to 100 p.p.m. of copper (or iron) to a 25 ml. volumetric flask containing about 10 ml. of borax-succinic acid buffer solution (pH 7.2 for copper or 3.5 for iron). Then add 2 ml. of the reagent solution, mix thoroughly, and fill up to the mark with the buffer solution. After 20 min., measure the absorbance at 610 mμ, using a reagent blank solution (or distilled water) as a reference.

For all these measurements, a photoelectric photometer equipped with 570 and 610 mμ filters was used.

## Results and Discussion

**Color Reactions.**—Sodium-2'', 6''-dichloro-4'-hydroxy-3, 3'-dimethylfuchsone-5, 5'-dicarboxylate is a red-brown solid, soluble in water and ethanol. It was stable indefinitely in the solid state and for at least one month when dissolved in ethanol. The effect of pH on the reagent solution is shown in Fig. 2. Its color reaction was tested on a spot plate with 52 ions. Some metallic ions in an acid or a neutral medium reacted with it to give the colors shown in Table I. In an ammoniacal solution, only large amounts of calcium, magnesium and nickel ions gave blue solutions.

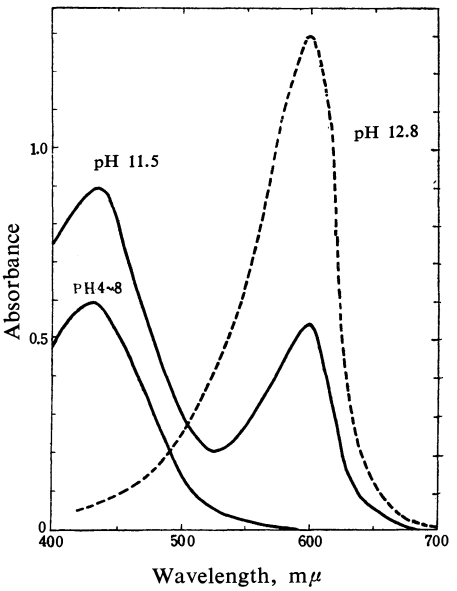

Fig. 2. Effect of pH on the reagent. Reagent: 40 ppm. pH was adjusted by HCl and NaOH solutions.

Seven of the colored complexes were examined spectrophotometrically. The results are summarized in Table II.

**Absorption Spectra.** — *Beryllium Complex.* — Absorption spectra of the reagent solution and

of its beryllium complex solution are shown in Fig. 3. All solutions were adjusted to pH 5.8, using the acetate-acetic acid buffer solution. The beryllium complex had a maximum absorption at 570 mμ. However, the reagent appreciably absorbed light at 570 mμ when its concentration was more than 50 p.p.m.

*Copper and Iron(III) Complex.* — The copper complex in a solution of pH 7.2 had a maximum absorption at 610 mμ; the reagent did not appreciably absorb light at this wavelength when its concentration was less than 100 p.p.m. The iron(III) complex in a solution of pH 3.5 had also a maximum absorption at 610 mμ.

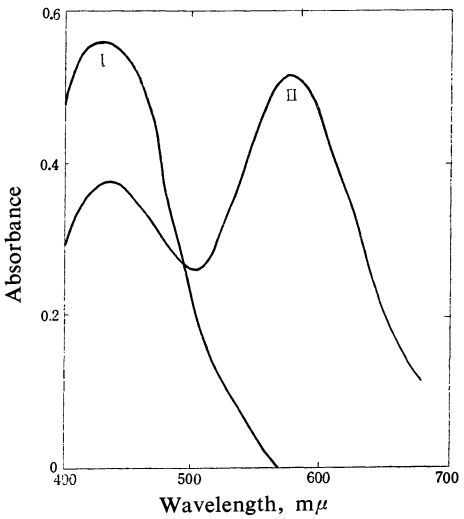

Fig. 3. Absorption spectra.

II: Reagent (30 p.p.m.)+Be(0.1 p.p.m.)
pH: 5.8

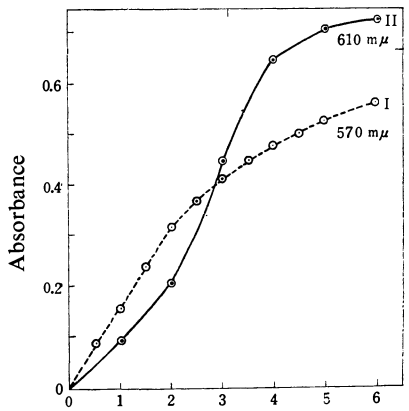

Fig. 4. Application of the mole ratio method.
I: Beryllium complex (pH 5.8)
II: Copper complex (pH 7.2)

**Mole Ratio Studies.**—*Beryllium Complex.*— Application of the mole ratio method[7] showed no sharp break or leveling-off to a constant absorbance for ratios up to as high as one mole of beryllium to six moles of reagent. The results are shown in Fig. 4.

Obviously the colored complex is appreciably dissociated and hence a large excess of the reagent is required to cause the reaction to proceed completion. By the application of the continuous variation method[8], the ratio of beryllium to the reagent was shown to be 1 to 2 (see Fig. 5).

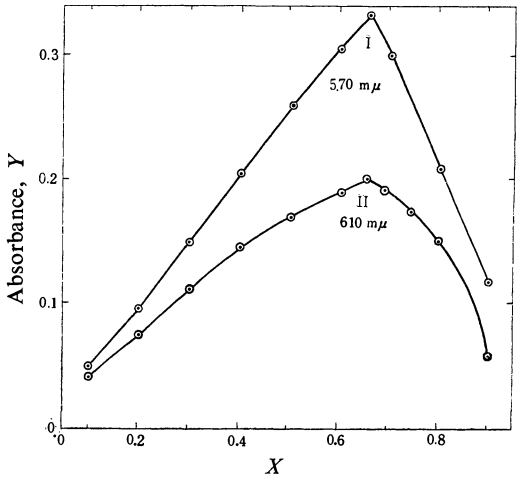

Fig. 5. Application of the method of continuous variation.
I: Be-complex (pH 5.8), II: Cu-complex (pH 7.2).

The best analytical results were obtained when the concentration of unreacted reagent was between 50 and 80 p.p.m.

*Copper and Iron(III) Complexes.*—Mole ratio studies for copper complex solution (pH 7.2) gave results similar to those for beryllium; the copper complex was appreciably dissociated and the ratio of copper to the reagent was 1 to 2 (see Figs. 4 and 5). The iron complex was also studied in a solution of pH 3.5. The ratio of iron to the reagent was 1 to 3.

**Effect of pH.** — Borax-succinic acid buffer and acetate-acetic acid buffer were satisfactory for the determination of beryllium, copper and iron. For an accurate measurement it was necessary to hold the pH fairly constant. The effect of pH on the color intensities of the metal complexes is shown in Fig. 6. The optimum pH range for the determination is listed in Table II.

**Effect of Temperature.**—There was no variation in the absorbance of the color systems

7) J. H. Yoe and A. I. Jones, *Ind. Eng. Chem., Anal. Ed.*, **16**, 111 (1944).

8) W. C. Vosburgh and G. R. Cooper, *J. Am. Chem. Soc.*, **63**, 437 (1941).

over a temperature range of 15 to 30°C Hence, normal temperature changes in the laboratory introduce no error.

**Rate of Color Development.** — At room temperature the color intensities increased during the first 20 min. then remained constant for 40 to 50 min.

**Interfering Ions.**—Color reactions of 52 ions are listed in Table I. The limiting concentrations of seven ions in the determination of beryllium are given in Table III. The concentration of an ion that causes a diviation of 0.01 unit in the absorbance of a solution containing 0.1 p.p.m. of beryllium was taken to be the limiting concentration.

TABLE III. LIMITING CONCENTRATIONS OF INTERFERING IONS FOR DETERMINATION OF BERYLLIUM

| Ion | Added as | Limiting concentration p.p.m. |
|---|---|---|
| $Al^{+3}$ | $K_2SO_4Al_2(SO_4)_3$ | 0.09 |
| $Co^{+2}$ | $Co(NO_3)_2$ | 20.0 |
| $Cr^{+3}$ | $Cr_2(SO_4)_3$ | 3.0 |
| $Cu^{+2}$ | $CuSO_4$ | 0.22 |
| $Fe^{+3}$ | $K_2SO_4Fe_2(SO_4)_3$ | 0.27 |
| $Ni^{+2}$ | $Ni(NO_3)_2$ | 16.4 |
| $UO_2^{+2}$ | $UO_2(NO_3)_2$ | 1.9 |

Several methods were tried to eliminate the interfering ions for the determination of beryllium. The 8-hydroxyquinoline method[9] effected a good separation of beryllium. Interfering ions for the determination of copper and iron, such as $Al^{+3}$, $Be^{+2}$, $Co^{+2}$ and $Cr^{+3}$, were eliminated by the method of Kraus[6].

9) E. B. Sandell, "Colorimetric Determination of Traces of Metals", 3rd Ed., Interscience Publishers, Inc., New York (1959), p. 306.

**Beer's Law.**—As a large excess of the reagent required for the determination of beryllium, was copper and iron, the calibration curves of water blank did not pass through the origin because of the absorption of the reagent solution at 570 or 610 mμ. The use of these curves provided satisfactory results whenever the same concentration of the reagent was used for

standards and unknowns. However, color intensities measured with the reagent solution as a blank obeyed Beer's law better than those with a water blank; Beer's law was obeyed up to about 0.3 p.p.m. of beryllium, about 4.0 p.p.m. of copper and about 3.0 p.p.m. of iron (see Fig. 7). In addition, the absorbances were sufficiently reproducible to permit beryllium to be determined up to 0.4 p.p.m., but for the best precision the concentration range should be 0.05 to 0.3 p.p.m.

TABLE V. DETERMINATION OF COPPER AND IRON

* These values are the averages of three repeated determinations.

**Determination of Beryllium in Solutions Containing Various Ions.** — Beryllium has been determined in three solutions containing various amounts of certain foreign ions, after separation of the latter by oxine precipitation. The results are listed in Table IV.

**Determination of Copper and Iron in Solutions Containing Various Ions.**—Copper and iron(III) have been determined in three solutions, after separation of the foreign ions by the exchange resin. The results are given in Table V.

## Summary

Procedures have been developed for the spectrophotometric determination of trace amounts of beryllium, copper and iron(III) with sodium-2″, 6″-dichloro-4′-hydroxy-3, 3′-dimethylfuchsone-5,5′-dicarboxylate. Certain ions that interfere with the beryllium determination are removed by an oxine precipitation. Ions that interfere with the analysis of copper and iron(III) are removed with an anion exchange resin column.

Accuracy and precision are good. Beer's law is obeyed up to about 0.3 p.p.m. of beryllium, about 4 p.p.m. of copper and about 3 p.p.m. of iron.

# *Electronic Spectra of Substituted Aromatic Hydrocarbons. I. Phenol and Aniline*

BY Hiroaki BABA

(Received July 22, 1960)

Recent advances in both theoretical[1-4] and experimental[5,6] studies have made it possible to understand fully the origin of the electronic spectra of aromatic hydrocarbons. On the other hand, it appears that no satisfactory interpretations have been given to the spectra of substitution products of the aromatics other than benzene. The present series of papers are concerned with systematic analyses of the electronic spectra of substituted aromatic hydrocarbons, especially hydroxyl and amino derivatives.

As to the spectra of monosubstituted benzenes, a number of theoretical investigations have been carried out[7-13]. There remain, however, unsettled problems even concerning

the qualitative assignment of the observed absorption bands. In this paper, a molecular orbital (MO) calculation has been made of the $\pi$-electronic spectra of phenol and aniline. Herein a semiempirical method of calculation is developed, which will be applied also to naphthalene derivatives in the next paper.

## Method of Calculation

The so-called simple LCAO MO theory originally proposed by Hückel is inadequate for dealing with molecules in their excited states. The more rigorous theoretical method, which is based on the correct many-electron Hamiltonian, has been developed to account for the electronic spectra of unsaturated compounds. Although the latter method has been simplified by Pariser and Parr[14] and Pople[2], it seems troublesome to apply it directly to such complex molecules as monosubstituted naphthalenes.

In this calculation an eclectic method is adopted; namely, the simplicity of the Hückel theory is retained, and at the same time it is somewhat modified by reference to the rigorous theoretical method so as to allow for electronic interaction. Thus, MO's are determined by the simple LCAO procedure; configurational wave functions are built up as antisymmetrized products of these MO's, configuration interaction being taken into account.

In the simple LCAO procedure, the energy of an MO is expressed in termes of the resonance integral $\beta[\equiv\beta_{CC}]$. In the present calculation, the evaluation of this integral is made, after the scheme of Goodman and Shull[11], in the following way.

According to the simple LCAO MO theory, the energy required for exciting an electron from an occupied MO $\phi_i$ to an unoccupied MO $\phi_k$ is given by

$$\Delta E=e_k-e_i=(m_k-m_i)\beta \qquad (1)$$

Here, $e_i$ and $e_k$ are the energies of the MO's $\phi_i$ and $\phi_k$, respectively; $e_i=\alpha+m_i\beta$ and $e_k=\alpha+m_k\beta$, where $\alpha[\equiv\alpha_C]$ is the Coulomb integral of a carbon atom.

In the rigorous theory, configurational wave functions are obtained as antisymmetrized products of molecular spin-orbitals. Such wave functions for the lowest energy configuration and for the singlet configuration resulting from the excitation $\phi_i\rightarrow\phi_k$ are denoted by $V_0$ and $V_{ik}$, respectively. The energies associated with these wave functions are

$$E(V_0)=\int V_0^*\mathbf{H}V_0\,d\nu, \quad \text{etc.}$$

where **H** is the complete many-electron Hamiltonian. Deriving an expression for the excitation energy $\Delta E=E(V_{ik})-E(V_0)$ by the self-consistent field method, Mulliken pointed out that the energy quantity which is acceptable as the energy of the excited MO $\phi_k$ is dependent not only upon the MO $\phi_k$, but also upon the MO $\phi_i$ from which the excitation occurs[15]. On the contrary, the orbital energy $e_k$ in Eq. 1 does not depend on $\phi_i$.

In view of this situation, let the resonance integral be regarded as a quantity depending upon both $i$ and $k$, and be designated as $\beta_{i\rightarrow k}$ instead of $\beta$. Then, the following relation may be assumed to hold[16]

$$(m_k-m_i)\beta_{i\rightarrow k}=E(V_{ik})-E(V_0) \qquad (2)$$

If the purely theoretical quantity, $E(V_{ik})-E(V_0)$, is replaced by an appropriate experimental one, $\beta_{i\rightarrow k}$ will immediately be determined, for the values of $m_i$ and $m_k$ can be obtained from the simple MO procedure.

In this study only the singlet transitions will be treated.

## Results of Calculation

**Molecular Orbitals.** — The MO's have been determined by the simple LCAO MO theory with neglect of overlap integrals.

In the parent hydrocarbon, benzene, the following four MO's are responsible for the lower electronic transitions:

$$\phi_2^0=(1/2)(\chi_2+{}_3\chi-\chi_5-\chi_6) \qquad (3a)$$

$$\phi_3^0=(1/\sqrt{12})(2\chi_1+\chi_2-\chi_3-2\chi_4-\chi_5+\chi_6) \qquad (3b)$$

$$\phi_4^0=(1/\sqrt{12})(2\chi_1-\chi_2-\chi_3+2\chi_4-\chi_5-\chi_6) \qquad (3c)$$

$$\phi_5^0=(1/2)(-\chi_2+\chi_3-\chi_5+\chi_6) \qquad (3d)$$

where $\chi_p$ is the $p$th carbon $2p\pi$ atomic orbital; the superscript zeros refer to the parent hydrocarbon; $\phi_2^0$, $\phi_3^0$ and $\phi_4^0$, $\phi_5^0$ are degenerate pairs of MO's, viz., $e_2^0=e_3^0=\alpha+\beta$, $e_4^0=e_5^0=\alpha-\beta$.

In the calculation of the MO's of a monosubstituted benzene, the Coulomb integral $\alpha_X$ of the substituent X is taken as

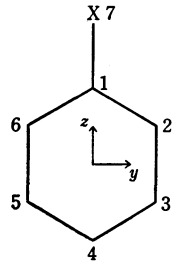

Fig. 1.

14) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 466, 767 (1953).

15) R. S. Mulliken, *J. chim. phys.*, **46**, 497 (1949); R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).

16) A more detailed discussion on this point is given in H. Baba and S. Suzuki, ibid., **32**, 1706 (1960).

$$\alpha x = \alpha + \delta x \beta$$

The MO's and their energies are calculated for various values of the parameter $\delta x$. Let the MO of the monosubstituted benzene corresponding to $\phi_i^0$ of the parent hydrocarbon be designated as $\phi_i$, and suppose that the substituent X is attached to the carbon atom 1, as shown in Fig. 1. Then, the MO's $\phi_2$ and $\phi_5$ of symmetry type $a_2$ are identical with $\phi_0^2$ and $\phi_5^0$, respectively[17]; the MO's $\phi_3$ and $\phi_4$ are of symmetry type $b_1$. The variation of the MO energies with the magnitude of $\delta x$ was reported by Matsen[9].

**Configuration Energies.**—Owing to the high symmetry ($D_{6h}$) of benzene, $V_{24}^0$, $V_{35}^0$ and $V_{25}^0$, $V_{34}^0$ are degenerate pairs of configurations, and the interaction of the configurations of each pair is automatically introduced to give excited states, the characteristics of which are shown in Table I. Referring to this table, one obtains

TABLE I. EXCITED STATES OF BENZENE

| Symmetry $D_{6h}$ | Symmetry $C_{2v}$* | Wave function | Observed excitation energy**, eV. |
|---|---|---|---|
| $B_{2u}$ | $B_2^-$ | $\frac{1}{\sqrt{2}}(V_{24}^0 - V_{35}^0)$ | 4.88 |
| $B_{1u}$ | $A_1^+$ | $\frac{1}{\sqrt{2}}(V_{25}^0 + V_{34}^0)$ | 6.14 |
| $E_{1u}$ | $B_2^+$ | $\frac{1}{\sqrt{2}}(V_{24}^0 + V_{35}^0)$ | 6.74 |
| | $A_1^-$ | $\frac{1}{\sqrt{2}}(V_{25}^0 - V_{34}^0)$ | |

* In this column are given symmetry types for the subgroup $C_{2v}$ of $D_{6h}$. The plus or minus sign refers to the manner in which two configurations combine with each other.

** Taken from Ref. 18.

$$E(V_{24}^0) = E(V_{35}^0) = \frac{1}{2}\{W^0(B_{2u}) + W^0(E_{1u})\}$$
$$= E(V_0^0) + 5.81 \text{ eV}.$$
$$E(V_{25}^0) = E(V_{34}^0) = \frac{1}{2}\{W^0(B_{1u}) + W^0(E_{1u})\}$$
$$= E(V_0^0) + 6.44 \text{ eV}.$$

in which $W^0(B_{2u})$, for instance, represents the energy of the $B_{2u}$ state of the parent hydrocarbon, benzene. Since $m_2^0 = m_3^0 = 1$, $m_4^0 = m_5^0 = -1$, it follows from Eq. 2 that

$$\beta_{2\to4}^0 = \beta_{3\to5}^0 = -2.905 \text{ eV}. = \beta^0(B_2) \quad (4a)$$
$$\beta_{2\to5}^0 = \beta_{3\to4}^0 = -3.22 \text{ eV}. = \beta^0(A_1) \quad (4b)$$

In the monosubstituted benzene, the energies of the $B_2$ configurations, $V_{24}$ and $V_{35}$, are no longer equal to each other; the same is the case with the energies of the $A_1$ configurations, $V_{25}$ and $V_{34}$. In evaluating the energies of these configurations, the assumption is made that

$$\beta_{2\to4} = \beta_{3\to5} = \beta^0(B_2) \quad (5a)$$
$$\beta_{2\to5} = \beta_{3\to4} = \beta^0(A_1) \quad (5b)$$

Then the energies $E(V_{ik})$'s for the configurations $V_{ik}$'s are readily derived on the basis of Eq. 2, since $m_i$ and $m_k$ can be obtained from the simple MO calculation.

**Configuration Interaction.**—The matrix element of the total Hamiltonian **H** between $V_{ik}$ and $V_{jl}$ is, in general, given by

$$\{V_{ik} \mid V_{jl}\} = \int V_{ik}^* \mathbf{H} V_{jl}\, dv$$
$$= 2[ki \mid jl] - [kl \mid ji] \quad (i \neq j,\ k \neq l) \quad (6)$$

with

$$[ij \mid kl] = \int \phi_i^*(1)\phi_k^*(2)(e^2/r_{12})\phi_j(1)\phi_l(2)\,dv \quad (7)$$

The orthonormal MO's determined by the simple MO theory are used for the calculation of the above matrix element. On the assumption of zero differential overlap, the integral $[ij \mid kl]$ may be expressed in terms of integrals over atomic orbitals of the form

$$(pp \mid qq) = \int \chi_p^*(1)\chi_q^*(2)(e^2/r_{12})\chi_p(1)\chi_q(2)\,dv \quad (8)$$

The integrals of this type were evaluated by Pariser and Parr's method[14]. Necessary values of the valence-state ionization potentials and electron affinities for carbon, oxygen and nitrogen atoms were taken from the table of Pritchard and Skinner[19]. The values of the integrals $(11 \mid 11)_{CC}$ and $(11 \mid 22)_{CC}$ were slightly modified in the following manner.

To the approximation adopted in the present calculation, one obtains

$$\{V_{24}^0 \mid V_{35}^0\} = (1/12)\{(11 \mid 11)_{CC} + 3(11 \mid 22)_{CC} - (11 \mid 33)_{CC} - 3(11 \mid 44)_{CC}\}$$
$$= (1/2)\{W^0(E_{1u}) - W^0(B_{2u})\} \quad (9a)$$
$$\{V_{25}^0 \mid V_{34}^0\} = (1/12)\{(11 \mid 11)_{CC} - 9(11 \mid 22)_{CC} + 11(11 \mid 33)_{CC} - 3(11 \mid 44)_{CC}\}$$
$$= (1/2)\{W^0(B_{1u}) - W^0(E_{1u})\} \quad (9b)$$

17) Monosubstituted benzenes belong to symmetry group $C_{2v}$. The group-theoretical notation used in this paper is the same as that of G. Herzberg, "Infrared and Raman Spectra of Polyatomic Molecules", D. Van Nostrand Company, Inc., New York (1945), p. 106. The y and z axes are chosen as in Fig. 1 and the x axis is perpendicular to the molecular plane.

18) H. B. Klevens and J. R. Platt, "Technical Report, Laboratory of Molecular Structure and Spectra. Univ. of Chicago", Part One (1953-1954), p. 145.

19) H. O. Pritchard and H. A. Skinner, *Chem. Revs.*, 55, 745 (1955).

in which the superscript zeros refer, as before, to benzene. Pariser and Parr's method gives $(11 \mid 33)_{cc}=5.470$ eV. and $(11 \mid 44)_{cc}=4.894$ eV. Inserting these values into Eqs. 9a and 9b and using the experimental values, quoted in Table I, for $W^0(B_{2u})$, etc., one may determine those values of $(11 \mid 11)_{cc}$ and $(11 \mid 22)_{cc}$ which simultaneously satisfy Eqs. 9a and 9b. The result is

$$\left.\begin{aligned}(11 \mid 11)_{cc}&=11.212\text{ eV.}\quad(10.84\text{ eV.})\\(11 \mid 22)_{cc}&=\ 6.700\text{ eV.}\quad(7.392\text{ eV.})\end{aligned}\right\} \tag{10}$$

the values obtained by the method of Pariser and Parr being given in parentheses.

The matrix elements $\{V_{24} \mid V_{35}\}$ and $\{V_{25} \mid V_{34}\}$ for the monosubstituted benzene are calculated to be

$$\begin{aligned}&\{V_{24} \mid V_{35}\}\\&=(1/2)(-g_{22}+g_{33})\{(11 \mid 11)_{cc}-(11 \mid 33)_{cc}\}\\&+(3/2)(g_{32}-g_{23})\{(11 \mid 22)_{cc}-(11 \mid 44)_{cc}\}\end{aligned} \tag{11a}$$

$$\begin{aligned}&\{V_{25} \mid V_{34}\}\\&=(-g_{22}+g_{33})\{(1/2)(11 \mid 11)_{cc}-(11 \mid 22)_{cc}\\&+(3/2)(11 \mid 33)_{cc}-(11 \mid 44)_{cc}\}\\&+(1/2)(g_{32}-g_{23})\{(11 \mid 22)_{cc}-(11 \mid 44)_{cc}\}\\&-(g_{11}-g_{44})\{(11 \mid 22)_{cc}-(11 \mid 33)_{cc}\}\\&-g_{77}\{(22 \mid 77)_{cx}-(33 \mid 77)_{cx}\}\end{aligned} \tag{11b}$$

Here $g_{pq}=c_{3p}c_{4q}$, in which $c_{ip}$ is the coefficient of the atomic orbital $\chi_p$ in MO $\phi_i$. The matrix elements have been computed for various values of $\delta_X$, the results being shown in Fig. 2. Actually, the curve for $\{V_{25} \mid V_{34}\}$ was obtained by assuming X to be $NH_2$. It should be noted in this connection that, while $\{V_{24} \mid V_{35}\}$ does not contain any terms associated with the substituent X, $\{V_{25} \mid V_{34}\}$ does contain such terms (see Eq. 11b). Accordingly, a deviation from the above-mentioned curve may occur when X is taken to be OH instead of $NH_2$. An examination on this point, however, revealed that the deviation is so small as to be virtually negligible. Consequently the curve in question can be applied to the case of the hydroxyl substituent as well as to the amino substituent.

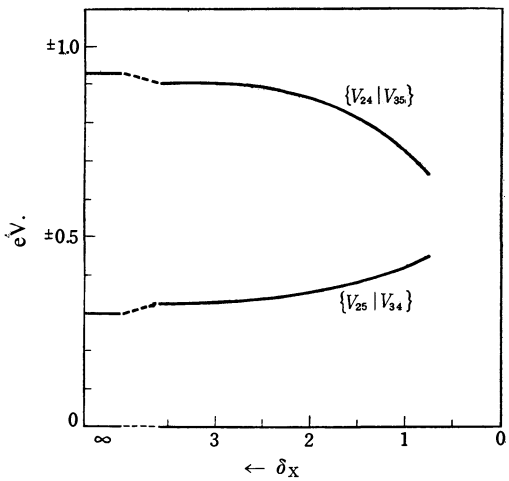

Fig. 2. Relation of the configuration interaction integrals to $\delta_X$. The plus and minus signs on the scale numbers of the ordinate correspond to $\{V_{24} \mid V_{35}\}$ and $\{V_{25} \mid V_{34}\}$, respectively.

**State Energies.**—The interaction between the two $B_2$ configurations, $V_{24}$ and $V_{35}$, gives two $B_2$ states, $B_2^+$ and $B_2^-$. Similarly $A_1^+$ and $A_1^-$ states arise from the interaction of $V_{25}$ and $V_{34}$. The dependencies of the energies of these states upon $\delta_X$ are shown in Fig. 3, together with the observed excitation energies[18,20] for phenol and aniline.

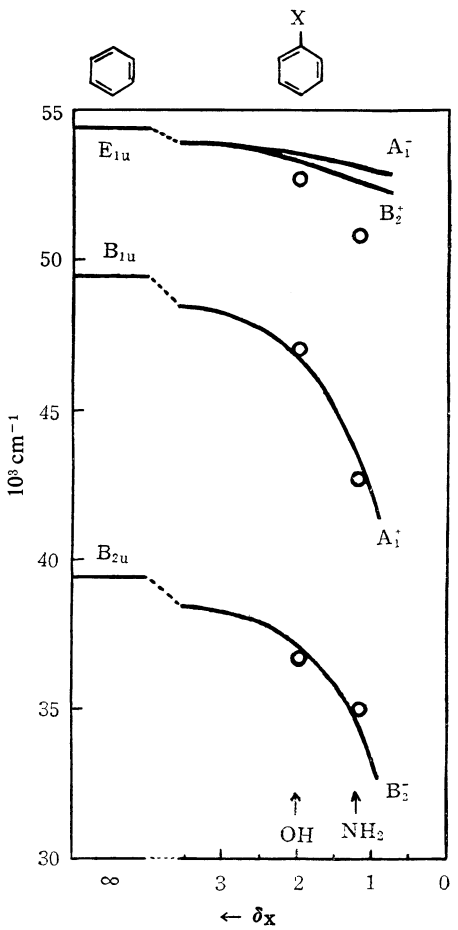

Fig. 3. Relation of the energies of the excited states to $\delta_X$. The observed energies are represented by circles.

20) American Petroleum Institute Research Project 44, Ultraviolet Spectral Data, Serial No. 171.

**Oscillator Strengths.**—The oscillator strengths, $f$, have been calculated by the use of the well-known relation[21]

$$f = 1.085 \times 10^{11} \nu \mathbf{Q}^2 \qquad (12)$$

where $\nu$ is wave number in $cm^{-1}$ and $\mathbf{Q}$ is transition moment in cm. The results are graphed in Fig. 4. The directions of the

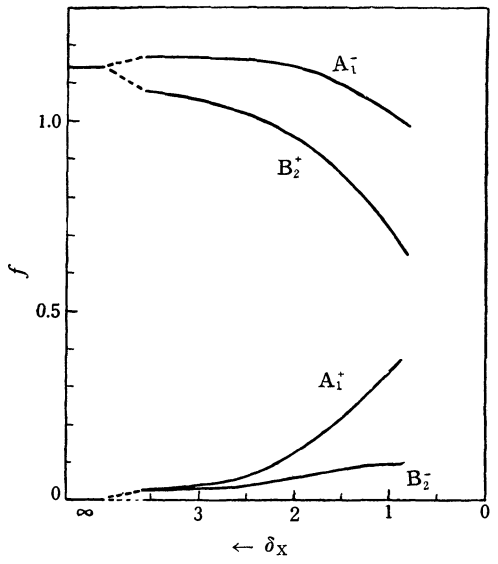

Fig. 4. Relation of $f$ values to $\delta_X$.

transition moments are known from the symmetry types of the excited states concerned. Thus the moments of the transitions to the $B_2^{\pm}$ states are perpendicular to the $C_1$-X axis, while those of the transitions to the $A_1^{\pm}$ states lie along the direction of the $C_1$-X axis.

**Changes of Electron Density Accompanying Electronic Transitions.**—The changes of the $\pi$-electron density at the substituent X, $\Delta q_X$, accompanying the electronic transitions have been calculated as functions of $\delta_X$. The results

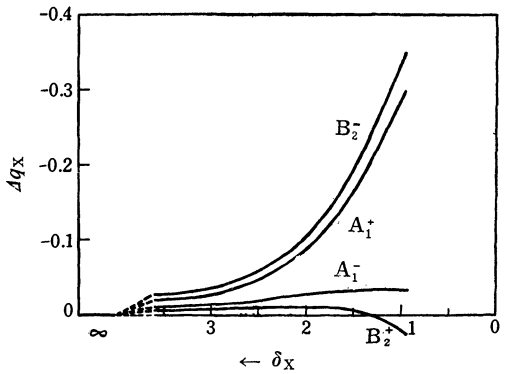

Fig. 5. Relation of $\Delta q_X$ values to $\delta_X$.

21) R. S. Mulliken and C. A. Rieke, *Repts. Progr. Phys.*, **8**, 231 (1941).

are shown in Fig. 5. The calculation of the electron density is based on the definition of Pariser[3].

**Summary of Calculation.**—In the preceding sections several theoretical quantities, e. g., configuration interaction integrals and energies of excited states, have been given as functions of the parameter $\delta_X$ to see the general trend of the substitution effects. However, in order to find the values of these quantities for a particular molecule, one must assign a suitable value to $\delta_X$. In this calculation the values of $\delta_X$ for phenol and aniline have been determined in such a way that the calculated excitation energies might be in best agreement with the observed. This led to the following parameter values (cf. Fig. 3):

$$\text{phenol}, \quad \delta_O = 2.0 \qquad (13a)$$

$$\text{aniline}, \quad \delta_N = 1.2 \qquad (13b)$$

Other theoretical quantities than the excitation energies are also derived by using these parameter values. The calculated results thus obtained for phenol and aniline are summarized in Tables II and III, together with available experimental data.

## Discussion

It is seen from Table III that the degrees of configuration mixing in the wave functions of the excited states are considerably changed upon substitution. As was pointed out by Goodman and Shull[11], this fact is of basic importance in discussing the effect of substitution on the excitation energies and intensities.

In making the assignment of the electronic transitions of the substituted benzenes, particularly of aniline, a problem is raised concerning the nature of the excited state for the transition corresponding to the $A_{1g} \rightarrow B_{1u}$ transition of benzene. Murrell[22] regarded the absorption band at 42700 $cm^{-1}$ in aniline as due to a transition to an electron transfer state characteristic of this molecule. According to the present calculation, the above band is attributed to the transition to the $A_1^+$ state of aniline which corresponds to the $B_{1u}$ state of benzene. As is seen from the data on $\Delta q_N$ of Table III, this transition is accompanied by an electron transfer, but its amount is much smaller than that in the electron transfer transition of Murrell. Moreover, there occurs an electron transfer also in the transition to the $B_2^-$ state, the amount of which is comparable to that in the case of the transition to the $A_1^+$ state. Inspection of the calculated values of $\Delta q_X$ will show that there is no substantial difference between the natures of

** Values for phenol are obtained from the unpublished data of the present author, and those for aniline from the data of Ref. 20.

the 42700 $cm^{-1}$ band of aniline and of the 47000 $cm^{-1}$ band of phenol. Thus, as to the origin of the aniline band, the present interpretation is somewhat different from Murrell's. A further experimental examination is desirable for reaching a final conclusion.

In both phenol and aniline, the calculated energy levels of the $B_2^+$ and $A_1^-$ states are situated close to each other. This suggests that the 52700 $cm^{-1}$ band of phenol, or the 50800 $cm^{-1}$ band of aniline, consists of two absorptions corresponding to the excitations to the $B_2^+$ and $A_1^-$ states.

The calculated values of the oscillator strengths may account for the general feature of the effect of the substitution on the band intensities, but their absolute values are too high. A correction factor of 0.30 was introduced, which is the ratio of $f_{obs}$ to $f_{calcd}$ for the $A_{1g}\rightarrow E_{1u}$ transition in benzene; the corrected values are given in parentheses in Table III.

In making a comparison of the calculated and observed $f$ values, one should keep the following point in mind. Both the $A_{1g}\rightarrow B_{2u}(B_2^-)$ and $A_{1g}\rightarrow B_{1u}(A_1^+)$ transitions in benzene are theoretically forbidden, i.e., $f_{calcd}=0$; whereas $f_{obs}$ values for these transitions were found to be 0.0014 and 0.10, respectively[18]. This discrepancy was shown to be due to the distortion of the ring by unsymmetrical vibrations[23]. A part of the $f_{obs}$ values for the corresponding transitions of the substituted benzenes may come from such a ring distortion effect[24]. This is not taken into consideration in deriving the $f_{calcd}$ values. If allowance is made for the contribution from the ring distortion effect, the $f_{obs}$ values for phenol and aniline are known to be in fairly good agreement with the corrected values of $f_{calcd}$.

The calculation of $\Delta q_X$ provides useful information about the charge distributions in the excited states. It is seen in Table III that all the $\Delta q_X$ values are negative except for that associated with the $B_2^+$ state of aniline, and that the magnitudes of $\Delta q_X$ for the $B_2^-$ and $A_1^+$ states are noticeably greater than those for the $B_2^+$ and $A_1^-$ states. In the ground state of the substituted benzenes under consideration, the substituent has a formal positive charge on account of the migration of the non-bonding pair of electrons into the benzene ring[25]. It will be expected from the calculation that the transitions to the $B_2^-$ and $A_1^+$ states are accompanied by an appreciable increase of the said positive charge. This expectation is consistent with the observation that the absorption bands corresponding to the transitions to the $B_2^-$ and $A_1^+$ states are distinctly shifted to the longer wavelengths by the formation of a hydrogen bond between phenol or aniline and

25) The charge distribution in the ground state of aniline will be shown in the next paper.

a proton-accepting substance, e. g., dioxane[26].

In consideration of the electronegativities of oxygen and nitrogen, the magnitudes of the Coulomb integral parameters $\delta_O$ and $\delta_N$, given in Eqs. 13a and 13b, appear to be reasonable. However in the present treatment no allowance has been made for the inductive effect of the substituent group on the ring carbon atoms, which is to be taken into account in a more precise calculation; further, the resonance integral $\beta_{CX}$ has been assumed to be equal to $\beta_{CC}$. Accordingly, the values of $\delta_O$ and $\delta_N$ should be regarded as effective ones. At any rate, in view of its practical nature, the present method of calculation is expected to be useful for dealing with the spectra of substitution products of complex organic compounds.

26) H. Baba and S. Suzuki, to be published in *J. Chem. Phys.*

**Summary**

The electronic spectra of monosubstituted benzenes are examined from the viewpoint of semi-empirical MO theory. To allow for electronic interaction, the simple LCAO method is refined in the light of purely theoretical procedure, configuration interaction being included. The refined method is particularly convenient for dealing with the spectra of substituted organic compounds.

The origins of the absorption bands for phenol and aniline are clarified on the basis of the calculated excitation energies, oscillator strengths and changes of charge distribution accompanying electronic transitions. The nature of the second excited state of aniline is discussed in detail, in connection with the problem of electron transfer.

# *Electronic Spectra of Substituted Aromatic Hydrocarbons. II. Naphthols and Naphthylamines**

By Hiroaki BABA and Satoshi SUZUKI

(Received July 22, 1960)

The effect of substitutions on the electronic spectrum of a conjugated molecule depends upon the positions at which the substituents are attached to the molecule. With naphthalene, there is a noticeable difference between the spectral changes caused by substitutions at $\alpha$- and $\beta$-positions. Several theoretical studies have been made to account for this interesting phenomenon[1]. The treatments, however, were limited to the framework of the LCAO molecular orbital (MO) theory in its simplest form, because substituted naphthalenes are complex molecules which have only low symmetry or none at all.

In the present study, the ultraviolet absorption spectra of naphthols and naphthylamines have been newly measured, and the effects of hydroxyl and amino substitutions upon the naphthalene spectrum have been examined on the basis of a calculation which was carried out according to the same method as that used in the preceding paper[2] (hereafter referred to as I).

## Experimental

**Materials.**—$\alpha$-Naphthol was recrystallized from ligroin, and $\beta$-naphthol from water and ligroin. Both were further purified by vacuum sublimation; m. p. 93.0~93.5°C and 119.0~119.5°C, respectively. $\alpha$-Naphthylamine and $\beta$-naphthylamine were repeatedly recrystallized from ligroin, and were sublimed in vacuo; m. p. 48.5~49.0°C and 110.0~110.5°C, respectively. Each of the four samples was subjected to vacuum sublimation whenever it was used for a measurement.

Isooctane (2,2,4-trimethylpentane; Enjay Co., Inc., U. S. A.) was carefully purified by distillation and by being passed through a chromatography tube filled with dried silica-gel powder. The isooctane thus purified is transparent down to 200 m$\mu$.

**Measurement of Spectra and Results.**—Ultraviolet absorption spectra were measured at controlled

* Read in part at the Symposium on Electronic States in Molecules, held by the Chem. Soc. Japan, Oct. 1958. (See Abstract of the Meeting, p. 73).

2) H. Baba, This Bulletin, 34, 76 (1961).

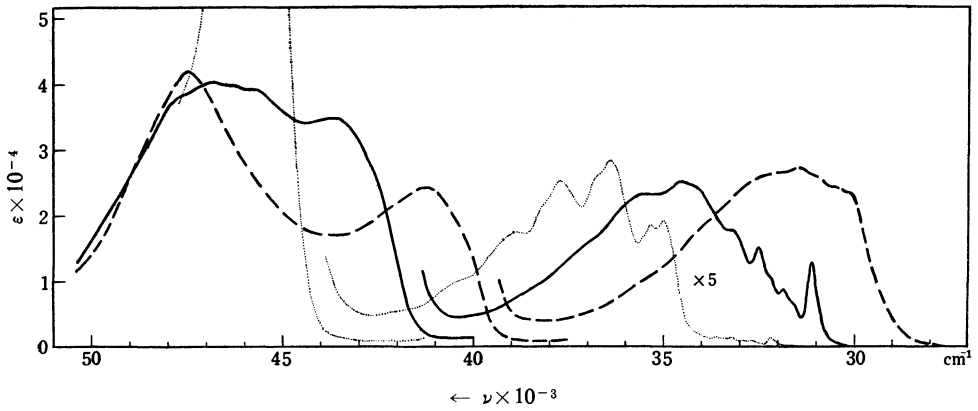

Fig. 1. Ultraviolet absorption spectra of α-naphthol (——), α-naphthylamine (----) and naphthalene (·····) in isooctane.

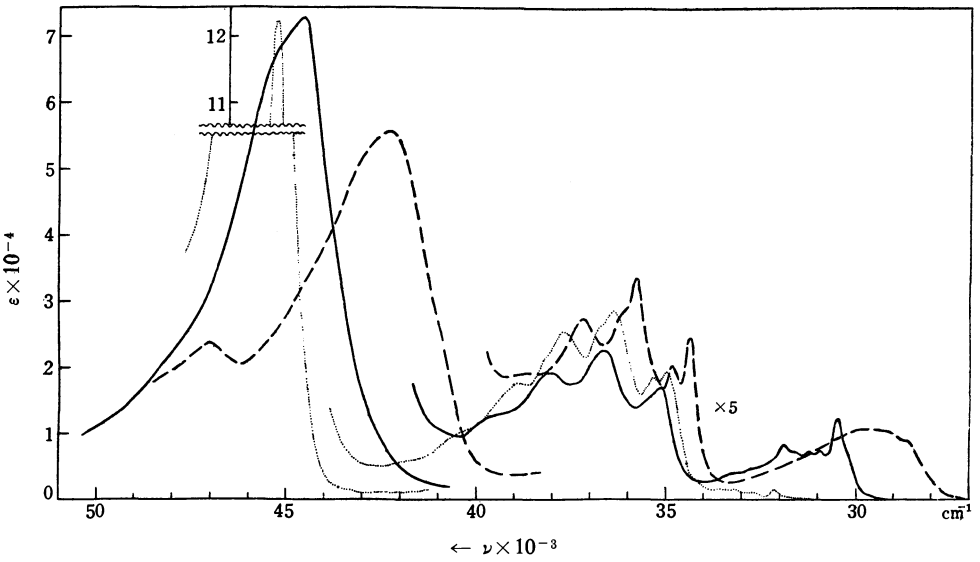

Fig. 2. Ultraviolet absorption spectra of β-naphthol (——), β-naphthylamine (----) and naphthalene (·····) in isooctane.

temperatures with a Hitachi quartz spectrophotometer of type EPU-2A. Attention was paid to the width of the slit so that the effective band width of the exit beam came to be sufficiently narrow as compared with the width of the absorption bands. Silica cells of 10 mm. and 2.5 mm. lengths were used, each of which was fitted with a ground-glass stopper. It was confirmed that Beer's law holds for all the substances in isooctane over the range of concentrations ($10^{-4}$~$10^{-5}$ mol./l.) used in the present measurement.

The absorption spectra of the α- and β-derivatives are shown, respectively, in Figs. 1 and 2. The spectra were observed at 20°C except for that of α-naphthylamine, which was obtained at 17.5°C. In the figures the spectrum of naphthalene[3] is also given for ready comparison.

## Calculation

Calculations have been made for α-, β-naphthols and α-, β-naphthylamines by following the same procedure as in I. Various theoretical quantities are at first presented as functions of the parameter $\delta_X$; and then the values of the quantities for naphthols and naphthylamines are derived by assuming $\delta_O$ and $\delta_N$ to

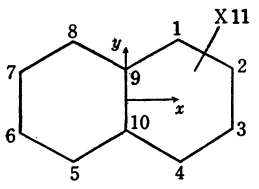

Fig. 3.

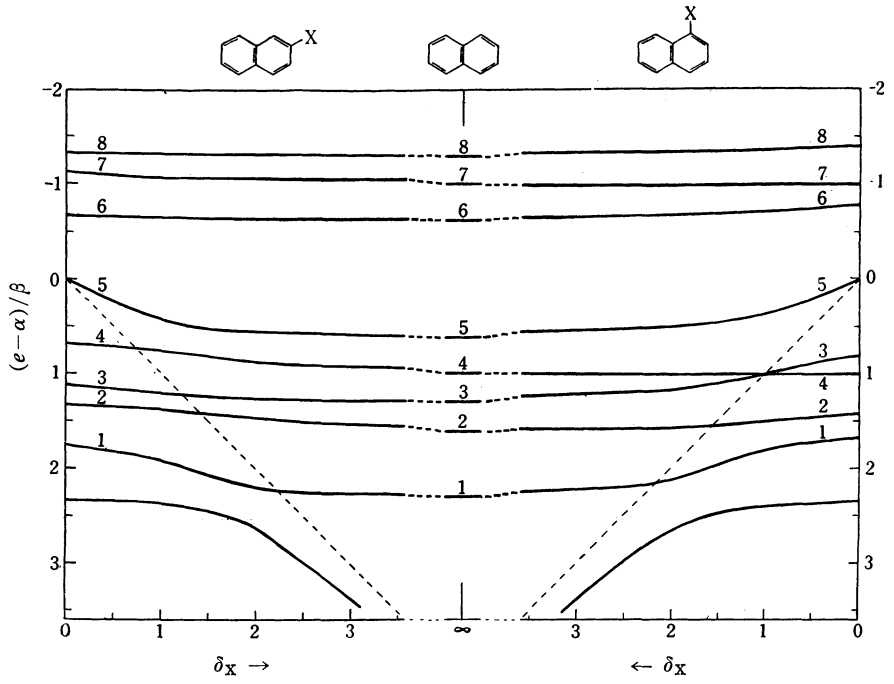

Fig. 4. Relation of MO energies to $\delta_X$.

be equal to the corresponding parameter values determined in I for phenol and aniline. The notation used in this paper is the same as in I.

**Molecular Orbitals.**—The MO's of the parent hydrocarbon, naphthalene, are designated as $\phi_1^0, \phi_2^0, \cdots\cdots$ in the sequence of ascending energy. Among these the following MO's are primarily associated with the lower electronic transitions[4].

$$\phi_4^0 = a(\chi_2+\chi_3+\chi_6+\chi_7) - a(\chi_9+\chi_{10}), \quad e_4^0 = \alpha+\beta \tag{1a}$$

$$\phi_5^0 = b(\chi_1-\chi_4+\chi_5-\chi_8) + c(\chi_2-\chi_3+\chi_6-\chi_7), \quad e_5^0 = \alpha+0.6180\beta \tag{1b}$$

$$\phi_6^0 = b(\chi_1+\chi_4-\chi_5-\chi_8) - c(\chi_2+\chi_3-\chi_6-\chi_7), \quad e_6^0 = \alpha-0.6180\beta \tag{1c}$$

$$\phi_7^0 = -a(\chi_2-\chi_3-\chi_6+\chi_7) + a(\chi_9-\chi_{10}), \quad e_7^0 = \alpha-\beta \tag{1d}$$

where $a=0.4082$, $b=0.4253$, $c=0.2629$; $\chi_p$ is the $p$th atomic orbital (see Fig. 3 for the numbering of the positions); the superscript zeros refer to the parent hydrocarbon.

The energies of the ground-state MO's and of the lower excited MO's for the monosubstituted naphthalenes are plotted against $\delta_X$ in Fig. 4.

**Configuration Interaction.**—With naphthalene, configurations $V_{46}^0$ and $V_{57}^0$ belong to $B_{3u}$, and $V_{47}^0$ and $V_{56}^0$ to $B_{2u}$ species of the symmetry group $D_{2h}$[5]. According to the simple LCAO treatment, the configuration $V_{46}^0$ and $V_{57}^0$ are degenerate, but $V_{47}^0$ and $V_{56}^0$ are not (cf. Eqs. 1a—1d). To a first approximation, interaction is included only between the degenerate configurations, $V_{46}^0$ and $V_{57}^0$[6]. The wave functions thus obtained for the lower excited states of naphthalene are shown in Table I. Using the observed excitation energies, given in Table I, one obtains

Table I. Excited states of naphthalene

| Symmetry | Wave function | Observed excitation energy* (eV.) |
|---|---|---|
| $B_{3u}^-$ | $\frac{1}{\sqrt{2}}(V_{46}^0 - V_{57}^0)$ | 3.99 |
| $B_{2u}$ | $V_{56}^0$ | 4.51 |
| $B_{3u}^+$ | $\frac{1}{\sqrt{2}}(V_{46}^0 + V_{57}^0)$ | 5.62 |

* Taken from Ref. 3.

$$E(V_{46}^0) = E(V_{57}^0) = \frac{1}{2}\{W^0(B_{3u}^-) + W^0(B_{3u}^+)\} = E(V_0^0) + 4.80 \text{ eV}.$$

$$E(V_{56}^0) = E(V_0^0) + 4.51 \text{ eV}.$$

4) R. Pariser, *J. Chem. Phys.*, **24**, 250 (1956).

5) The group-theoretical notation is the same as that used in G. Herzberg, "Infrared and Raman Spectra of Polyatomic Molecules," D. Van Nostrand Company, Inc., New York (1945), p. 108. The x and y axes are chosen as in Fig. 3 and the z axis is perpendicular to the molecular plane.

6) M. J. S. Dewar and H. C. Longuet-Higgins, *Proc. Phys. Soc.* (*London*), **A67**, 795 (1954).

Hence it follows from Eq. 2 of I

$$\beta^0_{4\to6}=\beta^0_{5\to7}=-2.97\text{ eV.}=\beta^0(B_{3u}) \quad (2a)$$

$$\beta^0_{5\to6}=-3.65\text{ eV.} \quad (2b)$$

With the naphthalene derivatives, even the energies of $V_{46}$ and $V_{57}$ are no longer equal. In this calculation, only the interaction is taken into account between those configurations of the derivatives which are degenerate in the parent hydrocarbon. Thus the interaction of $V_{46}$ and $V_{57}$ is included; on the other hand, $V_{56}$ is assumed to represent the wave function for an excited state without mixing with any other configurations. The energies of these configurations are obtained from Eq. 2 of I on the assumption that $\beta_{4\to6}=\beta_{5\to7}=\beta^0(B_{3u})$ and $\beta_{5\to6}=\beta^0_{5\to6}$.

The calculation of the matrix element $\{V_{46}\mid V_{57}\}$ is made in exactly the same way as in I. The integral values used in the present calculation are the same as those used in I. As a result, it follows that

naphthalene, $\{V^0_{46}\mid V^0_{57}\}=0.918$ eV.

$\alpha$-derivative, $\{V_{46}\mid V_{57}\}=0.866$ and 0.782 eV.

$\beta$-derivative, $\{V_{46}\mid V_{57}\}=0.824$ and 0.693 eV.

where the values for each derivative correspond, respectively, to the paramater values $\delta_X=2.0$ and 1.2.

**State Energies.**—The calculated energies of the excited states are shown in Fig. 5 as functions of $\delta_X$; the observed excitation energies of naphthalene, naphthols and naphthylamines are also indicated in the figure. In the parent hydrocarbon, naphthalene, the calculated and observed energies of the $B_{2u}$ state are, of course, in accord with each other. The energies of the $B^-_{3u}$ and $B^+_{3u}$ states are calculated, respectively, to be 3.89 and 5.72 eV., both being in good agreement with the observed excitation energies (see Table I). This may be regarded as a proof that the used integrals are of suitable values.

The monosubstituted naphthalenes have no symmetry, apart from their symmetry with respect to the molecular plane. However, the wave functions or energy levels of the derivatives may be denoted by the analogy of the notation for the corresponding quantities of the parent hydrocarbon. Thus, for example, the lowest excited state of the derivatives will be designated as $(B^-_{3u})$, where the symbol of the symmetry type for the parent hydrocarbon is inclosed in parentheses.

**Oscillator Strengths.** — Oscillator strengths, $f$, are calculated from Eq. 12 of I. Plots of $f_{calc}$ vs. $\delta x$ are given in Fig. 6. It may be noted that $f_{calc}$ values for the transitions to $B^-_{3u}$, $B_{2u}$ and $B^+_{3u}$ states in naphthalene are, respectively, 0, 0.52 and 2.14, corresponding $f_{obs}$ values being 0.002, 0.11 and 1.70[3,7].

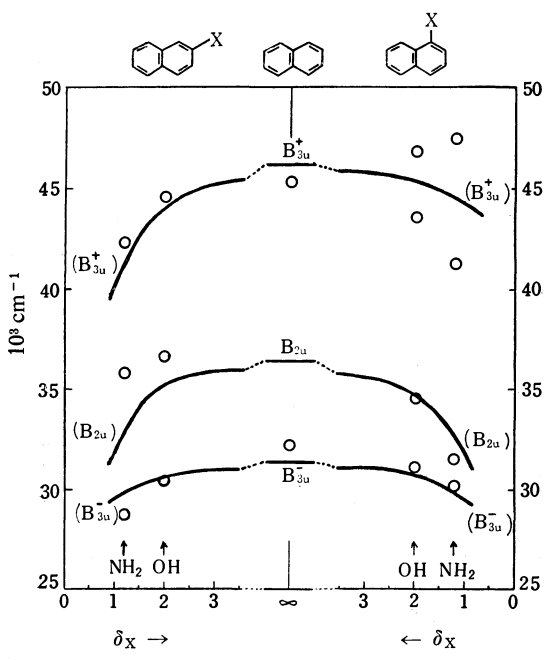

Fig. 5. Relation of the energies of the excited states to $\delta_X$. The observed energies are represented by circles.

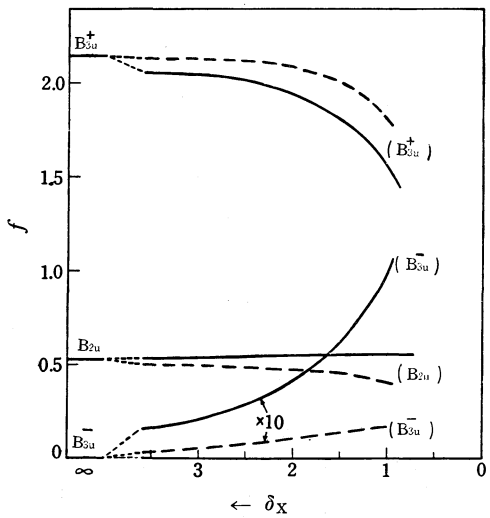

Fig. 6. Relation of $f$ values to $\delta_X$.

* For the details of the determination of the observed $f$ values see Ref. 8.

$\delta_O=2.0$ and $\delta_N=1.2$ were obtained in I. Application of these values to the case of the naphthalene derivatives leads to the results summarized in Table II, where the changes of the $\pi$-electron density, $\Delta q_X$, accompanying the electronic transitions are also given. The observed excitation energies and oscillator strengths are cited in the table.

In connection with the $\Delta q_X$ values it is instructive to know the charge distribution in the ground state. Thus, from the ground-state MO's corresponding to $\delta_X=1.2$, quantities related to the charge distribution in the ground state were derived for naphthylamines. The results are collected in the molecular diagrams of Fig. 7, in which the analogous diagram for aniline is shown for the sake of comparison.

## Discussion

Inspection of Fig. 4 reveals several features of the MO's of the naphthalene derivatives. In the α-derivative, orbital energies $e_4$ and $e_7$ are completely identical with $e_4^0$ and $e_7^0$, respectively, regardless of the value of $\delta_X$; $e_3$ is raised with decreasing magnitude of $\delta_X$, and consequently the sequence of the heights of $e_3$ and $e_4$ is reversed at $\delta_X=1$; $e_5$ is most affected by the α-substitution. In the β-derivative $e_4$ is strongly influenced by the substitution, while $e_3$ remains almost unaltered. When $\delta x$ is large $e_5$ is little changed upon the β-substitution, but it is considerably affected by a substituent with a small magnitude of $\delta_X$, i.e., by a strongly conjugating substituent. The behaviors of the orbital energies in the α- and β-derivatives may, at least in part, be understood in terms of the coefficients of the atomic orbitals in the MO's of the parent hydrocarbon (cf. Eqs. 1a—1d).

Regarding the wave functions of the excited states, it is to be noted that the degrees of configuration mixing in the wave functions of the ($B_{3u}^{\pm}$) states are appreciably changed by the substitutions.

Before proceeding to a discussion of the excitation energies, mention should be made of the spectra shown in Fig. 1. In the spectrum of α-naphthol, several minor peaks are present on the lower frequency side of the 34570 $cm^{-1}$ band. In the light of the spectrum of naphthalene it is reasonable to regard these peaks as showing a fine structure of a definite electronic band which corresponds to the lowest frequency band of the parent hydrocarbon. No analogous band is found, at first sight, in the α-naphthylamine spectrum. However, the 31500 $cm^{-1}$ band of α-naphthylamine exhibits relatively high extinction at the shoulder of 30100 $cm^{-1}$, as compared with the corresponding bands of α-naphthol and naphthalene. In view of this fact, the present authors tentatively assumed that the band in question is hidden under the more intense band of 31500

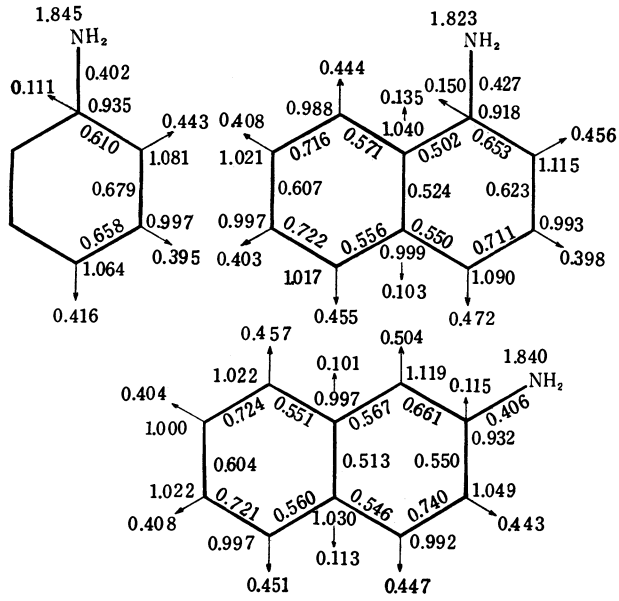

Fig. 7. Molecular diagrams for aniline, $\alpha$-naphthylamine and $\beta$-naphthylamine. The $\pi$-electron density, $\pi$-bond order and free valence are shown in the usual manner for each molecule.

$cm^{-1}$ in the neighborhood of the said shoulder.

$\alpha$-Naphthol has two absorption bands ($\nu_{max}$ =43570 and 46820 $cm^{-1}$) in the higher frequency region, which are not fully separated from each other. It has been observed that, when a hydrogen bond is formed between $\alpha$-naphthol and dioxane, these bands exhibit quite different behaviors: that is, the lower frequency band is displaced to the red and the other to the blue[8]. This observation conclusively indicates that the bands under consideration are due to two distinct electronic transitions.

The calculated excitation energies for the ($B_{3u}^-$) and ($B_{2u}$) states of the $\alpha$-derivatives are in good accord with the observed. A difficulty arises in the fact that two levels are observed near the calculated ($B_{3u}^+$) level of the $\alpha$-derivatives. A tentative explanation for this will be given below.

According to Pariser's calculation for naphthalene, there exists a $B_{1g}^+$ state slightly below the $B_{3u}^+$ state[4]. A plus state in general favors the transition from the ground state[4], but in the case of the $B_{1g}^+$ state the transition is forbidden, because $A_g \rightarrow B_{1g}$ is not allowed by the selection rule. To a first approximation, the $B_{1g}^+$ state is represented by $(1/\sqrt{2})(V_{36}^0 + V_{58}^0)$. As has already been shown, $\phi_3^0$ and $\phi_5^0$ are profoundly influenced by the $\alpha$-substitution, so that the $B_{1g}^+$ state will be subjected to a considerable distortion. It is therefore probable that the $B_{1g}^+$ state comes to be allowed in the $\alpha$-derivatives, and that a fairly strong interaction occurs between the ($B_{3u}^+$) and ($B_{1g}^+$) states to give two mixed states which can be assigned to the observed levels mentioned above. It seems reasonable to conclude that, of the two observed bands in question, the one of higher intensity, i.e., that of higher frequency, primarily corresponds to the ($B_{3u}^+$) state and the other to the ($B_{1g}^+$) state, for the transition to the $B_{3u}^+$ state is allowed even in the parent hydrocarbon.

Next, discussion will be turned to the excitation energies in the $\beta$-derivatives. There is a discrepancy between the calculated and observed energies of the ($B_{2u}$) state. It is generally accepted that the $p$ band of naphthalene, which arises from the $A_g \rightarrow B_{2u}$ transition, is makedly shifted to the red by $\alpha$-substitution, whereas it exhibits almost no shifts due to $\beta$-substitution[1]. The $B_{2u}$ state of naphthalene is approximately represented by $V_{56}^0$. Also, for the coefficients of the atomic orbitals in $\phi_5^0$ and $\phi_6^0$, the relation $b^2 \gg c^2$ is seen to hold. Accordingly, so far as the behaviors of the $p$ band are treated from the viewpoint of the perturbation theory, the calculation will lead to a result which is compatible with the observation. This is substantiated by the

8) H. Baba and S. Suzuki, to be published in *J. Chem. Phys.*

results of Peters' perturbation treatment[1]. However, quite a different situation may be produced for strongly conjugating substituents, to which the perturbation theory fails to apply. In fact, in cases $\delta_X < 2$ the orbital energy $e_5$ is noticeably raised even in the $\beta$-derivatives, and hence the calculated excitation energy for $\phi_5 \rightarrow \phi_6$ becomes considerably smaller than the observed. This discrepancy is the most serious is the most serious difficulty involved in the present calculation.

From the spectra of Figs. 1 and 2, the effect of substitutions on the band intensities may be summarized as follows: the intensity of the transitions to the ($B_{3u}^-$) state is greatly enhanced, while that of the transition to the ($B_{3u}^+$) state is lowered; the transition to the ($B_{2u}$) state is subject to only a slight change in its intensity. These remarks are applicable to each of the $\alpha$- and $\beta$-derivatives. It may be said that the $f_{calc}$ values account, at least qualitatively, for the observed intensity variations due to the substitutions.

One may predict from the calculation of $\Delta q_X$ that all transitions in both the $\alpha$- and $\beta$-derivatives are accompanied by an increase of the positive charge at the substituent, and that the increment of the charge is extremely small as regards the transition to the ($B_{3u}^+$) state of the $\alpha$-derivatives. This prediction has been verified in its essential points by experimental studies of the hydrogen bonding effect on the spectra of naphthols and naphthylamines[8].

By comparing the diagrams of Fig. 7, which are based on the molecular orbital method, with those obtained by the valence bond method[9,10], it is found that the two theoretical methods lead to essentially the same results in respect of both the charge distributions and the bond orders for aniline and the amines. It may be worthy of note that the $\pi$-electron densities at the nitrogen atoms are in the order

aniline> $\beta$-naphthylamine> $\alpha$-naphthylamine

The present calculation is based on the assumption of the transferability of the parameters $\delta_N$ and $\delta_O$ from the benzene derivatives to the naphthalene derivatives. This assumption is seen to be reasonable on the inspection of Table II and Fig. 5.

## Summary

The ultraviolet absorption spectra of $\alpha$-, $\beta$-naphthols and $\alpha$-, $\beta$-naphthylamines have been newly measured down to 200 m$\mu$. On the basis of a calculation which was carried out in the same manner as in the preceding paper, the effect of substitutions at $\alpha$- and $\beta$-positions upon the spectrum of napthalene has been explained and the assignment of the observed absorption bands has been made. It is suggested that, upon substitution at the $\alpha$-position, the $A_u \rightarrow B_{3u}^+$ band of naphthalene splits into two electronic bands because of the interaction of the $B_{3u}^+$ state with a $B_{1g}^+$ state. Molecular diagrams are given for naphthylamines and for aniline.

# *Thermal Decomposition of Potassium Chlorate*

By Shōtarō Tobisawa

(Received June 22, 1960)

The thermal decomposition of potassium chlorate has been investigated mostly by measuring the volume of oxygen gas evolved[1-4]. The present author has studied this reaction from the viewpoint of the loss in weight ($x$), due to oxygen gas released in the progress of the decomposition. The measurement of loss in weight was made at definite intervals of 45 sec. with a thermal balance of automatic recording type. Plots of $dx/dt$ against time ($t$) were obtained accurately.

## Experimental

Commercial guaranteed potassium chlorate was recrystallized four times from water. A single crystal and a polycrystal were selected from the recrystallized samples under a microscope. A powdered sample was obtained by carefully squeezing the recrystallized sample in an agate mortar with a pestle. The detail of the thermal balance was already described in a previous report[5]. This balance was modulated to be able to indicate distinct differences of 0.022 mg. on a recording chart.

## Results

When the temperature of the powdered sample was raised at constant rate, 250°C per hour, it decomposed at 500°C, evolving oxygen gas. Although the measurements were made for the powdered samples of different weights and also at different rates of heating, these samples decomposed at the same temperature of 500°C which was higher than the decomposition temperature obtained by Vitoria[6]. Since the melting point of potassium chlorate has been found to be 352[7] or 356°C[6], it is reasonable to consider that the thermal decomposition of potassium chlorate takes place in liquid state.

The kinetic measurements were made at several temperatures above 500°C. The reactant sample could reach these constant temperatures within five minutes. Fig. 1 shows the plots

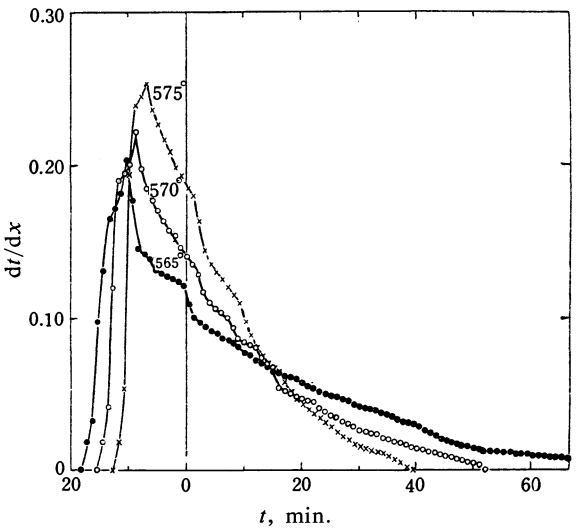

Fig. 1. Plots of $dx/dt$ against time for the powdered samples (12.0 mg. in weight).

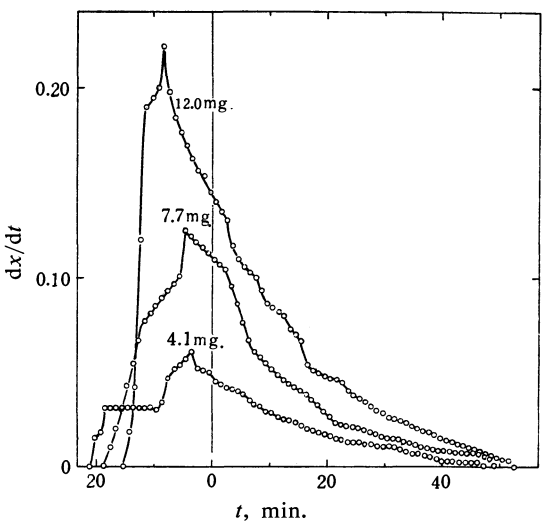

Fig. 2. Plots of $dx/dt$ against time for the powdered samples at 570°C.

of $dx/dt$ against $t$ for the powdered samples of 12.0 mg. at 565, 570 and 575°C, respectively. The time of zero in Fig. 1 was set at the point where half of the weight of the sample was decomposed. In the figure, the acceleratory period is extremly short in comparison with the decay period. From the curves of $dx/dt$

against $t$ at the same temperature in Fig. 2, it is seen that, as the weight of the sample decreases, the acceleratory period becomes long and the shape of the curve of $dx/dt$ against $t$ in the acceleratory period becomes complicated. Fig. 3 shows the plots of $dx/dt$ against $t$ for the single crystal, the polycrystal and the powdered sample, all in the same weight of 4.1 mg. at the same temperature, 570°C. In the figure, the curves of $dx/dt$ against $t$ for the three samples show different shapes in the acceleratory period, while the curves in the decay period show analogous shapes. In each measurement, total losses in weight, due to the exhausted decomposition, agreed with the amount of oxygen calculated from the equation, $2KClO_3=2KCl+3O_2$, within the error of about one per cent.

## Discussion

As shown in Figs. 1, 2 and 3, each curve of $dx/dt$ against $t$ shows a complicated shape, and such complication tends to disappear as the decomposition progresses. It has been reported by Otto et al.[3] that the reaction, $2KClO_3 \rightarrow 2KCl+3O_2$, is a monomolecular reaction. Glasner et al.[4] have also stated that the decomposition at high temperature is of the first order. However, as is evident from Figs 1, 2 and 3, the thermal decomposition of potassium chlorate is so complicated that a rate-equation can not be determined.

In a microscopic study of the sample undergoing the thermal decomposition, zig-zag bubbles of oxygen gas were observed in the liquid. Moreover, by visual observation of a reaction vessel at the end of the experiment, specks which were considered to be owing to the splashing of the liquid, were recognized along the wall. The bubbling of gas causes the splashing of the liquid. On the liquid-phase decomposition of potassium perchlorate, Bircumshaw et al.[8] have stated that the composition of the liquid which consists of perchlorate, chlorate and chloride, will not be constant on account of the spreading of the liquid along the tube, owing to bubbling, and thus variations in the rate of evolution of gas may be expected, depending on how much splashing takes place. On the thermal decomposition of potassium chlorate, it has been known that the reaction system consists of chlorate, chlorite, perchlorate and chloride, and that the chlorate, the chlorite and the perchlorate convert into chloride with the evolution of oxygen gas[9]. The bubbling and splashing under such a complicated condition will take place very irregularly. The complication of the curves of $dx/dt$ against $t$ may, therefore, be associated with the irregularities of the bubbling and splashing. As the decomposition progresses, the bubbling and splashing will become difficult to take place on account of the accumulation of chloride in the liquid. Consequently, the complication of the curves of $dx/dt$ against $t$ may be expected to disappear.

## Summary

The curves of $dx/dt$ against $t$ were obtained with accuracy; in consequence, the complication of the curves appeared, and the complication may be associated with the irregularities of the bubbling and splashing.

# *Infrared Spectra of Troponoid Compounds. II. Absorption Band of O–H Stretching Vibration in Some Tropolones**

By Yusaku IKEGAMI

(Received February 10, 1960)

In the previous report[1], it was shown that the absorption bands assignable to O–H stretching vibration in tropolone (I) appear at around 3210 $cm^{-1}$ in solid and around 3140 $cm^{-1}$ in solution or gaseous state, indicating the characteristic properties in absorbing at a lower wave number in dilute solution or gaseous state than in solid. This fact has been explained[1-3] on the basis of the intermolecular or intramolecular hydrogen bonding in tropolone, but the nature of these bands was not studied in detail. In this paper, the examinations were made on O–H stretching absorption bands of tropolone, by using a calcium fluoride prism, to see how the absorption bands changed with different concentrations and states. The same examinations were also made on 4-isopropyltropolone (hinokitiol) (II) and 3-bromotropolone (III).

## Experimental

Infrared absorption spectra were measured with a Perkin-Elmer model 21 infrared spectrophotometer with a calcium fluoride prism. The solid spectra were obtained by potassium bromide disk or sandwich method, and a cell of 0.109, 0.508, 11.10 or 50.30 mm. thick with potassium chloride windows was used to obtain solution spectra.

## Results and Discussion

Fig. 1 shows the infrared spectra of tropolone in the region of 3600~2600 $cm^{-1}$, measured for solid, liquid and solution in carbon tetrachloride, and shows that there are more absorption bands in this region than had been expected. It also reveals the change in the spectrum accompanying variation of the concentration in solution and of the phase. The two bands in the ranges of 3051~3049 and 3020~3003 $cm^{-1}$ in these spectra correspond to the C–H stretching vibration in the seven-membered ring, which appear with comparative regularity in many of the troponoids[4]. Absorption bands other than these two must be those of O–H stretching vibration in respective states since corresponding bands do not appear in 2-deuteroxytropone[5] and metal tropolonate[4].

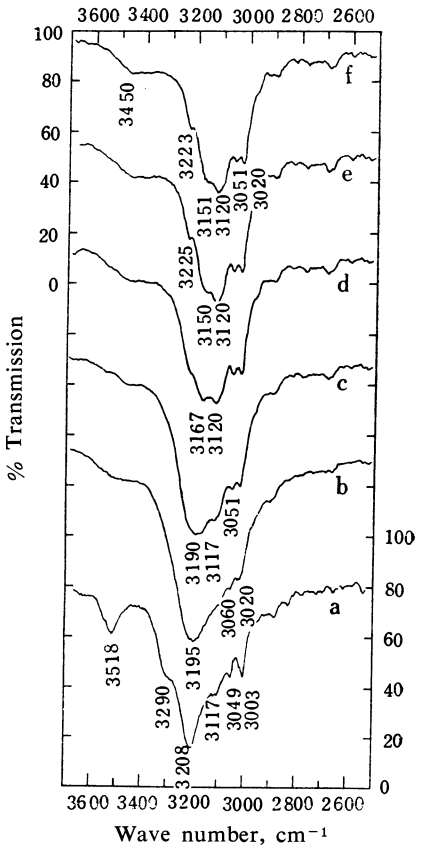

Fig. 1. Infrared spectra of tropolone in the states of solid, liquid and carbon tetrachloride solution (3600~2600 $cm^{-1}$ range): a; solid (crystalline film), b; liquid, c; ca. 1.5 mol./l. in $CCl_4$ (0.109 mm. thickness), d; 0.29 (0.508), e; 0.014 (11.10), f; 0.0029 (50.30).

From the spectra shown in Fig. 1, the following characteristics can be pointed out. a) When measured in the most dilute solution shown in Fig. 1 f, there is no sharp absorption

* A part of this work was presented at the 10th Annual Meeting of the Chemical Society of Japan, April 4, 1957.

5) Y. Ikegami, This Bulletin, **34**, 94 (1961).

and there are bands at 3151 and 3223 $cm^{-1}$ besides the strongest one at 3120 $cm^{-1}$ and a broad band at 3500~3300 $cm^{-1}$. b) The O-H stretching absorption is dependent of the concentration in solution, although it had been reported that the spectrum is independent[2], and the bands at 3151 and 3223 $cm^{-1}$ increase their intensity gradually with increasing concentration, which finally merge into the comparatively broad absorption at 3195 $cm^{-1}$ in liquid. c) The spectrum in solid state exhibits shoulders at 3117 and 3290 $cm^{-1}$, besides the strongest band at 3208 $cm^{-1}$, and a distinct band at 3518 $cm^{-1}$. The spectrum obtained in gaseous state[1] is the same as that of Fig. 1 f.

Such characters of the O-H stretching absorption band in dilute solution are not essentially different from those of chelated hydroxyquinones[6] and enolized $\beta$-diketones[7] possessing a conjugated chelate system, and can be taken as the characteristics indicating tropolone structure. It is seen from Fig. 1 that the absorption bands shift to the higher wave number side as the concentration increases and as the compound transits liquid or solid. On the other hand, the absorption band at 1618 $cm^{-1}$ in solution appears at a wave number 5 $cm^{-1}$ higher than that in solid[1]. This is contrary to the direction of the shift of $\nu_{C=O}$ anticipated from that of $\nu_{O-H}$ in the hydrogen bonding of -O-H···O=C< type, and then the shift of O-H stretching absorption band can not be explained merely by the strength of hydrogen bonding in this type. Considering the fact that the direction of the shift of C=O stretching absorption band in tropolone according to changes in the states agrees with that in tropone[1], it is assumed that the cycloheptatrienone part in tropolones interacts in a manner similar to that in the case of tropone[8] and the intramolecular

hydrogen bonding is weakend by this interaction. Kuratani et al.[2] assumed a dimer form for tropolone in the solid state. However, a wave number 3208 $cm^{-1}$ in tropolone is approximately 700 $cm^{-1}$ higher than that in

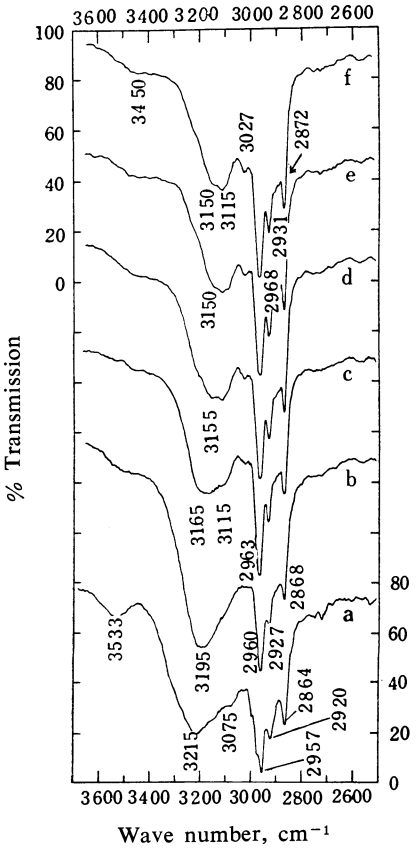

Fig. 2. Infrared spectra of 4-isopropyltropolone in the states of solid, liquid and carbon tetrachloride solution (3600~2600 $cm^{-1}$ range): a; solid (crystalline film), b; liquid, c; ca. 1.2 mol./l. in $CCl_4$ (0.109 mm. thickness), d; 0.29 (0.508), e; 0.014 (11.10), f; 0.0029 (50.30).

6) D. Hadzi and N. Sheppard, *Trans. Faraday Soc.*, **50**, 911 (1954).

7) S. Bratoz, D. Hadzi and G. Rossmy, ibid., **52**, 464 (1956).

8) Unpublished data. Infrared spectra of tropone in the region of 1700~1500 $cm^{-1}$ were measured in the states of vapor, liquid and solutions in various solvents. Two strong absorption bands in this region indicated the following wave-numbers, e. g.

| | | |
|---|---|---|
| vapor | 1651 $cm^{-1}$ | 1613 $cm^{-1}$ |
| in *n*-heptane | 1645 $cm^{-1}$ | 1602 $cm^{-1}$ |
| in acetonitril | 1634 $cm^{-1}$ | 1585 $cm^{-1}$ |
| in ethanol | 1633 $cm^{-1}$ | 1574 $cm^{-1}$ |
| pure liquid | 1634 $cm^{-1}$ | 1580 $cm^{-1}$. |

Also the shape of their bands in liquid tropone is similar to that in such a solvent as acetonitril, differing from it in the vapor state (cf. Ref. 1). From these facts, it is assumed that the tropone in liquid state associates by its polar character of B type as also shown in its large dipole moment (4.17D) (cf. Y. Kurita, S. Seto, T. Nozoe and M. Kubo, This Bulletin, **26**, 272 (1953)).

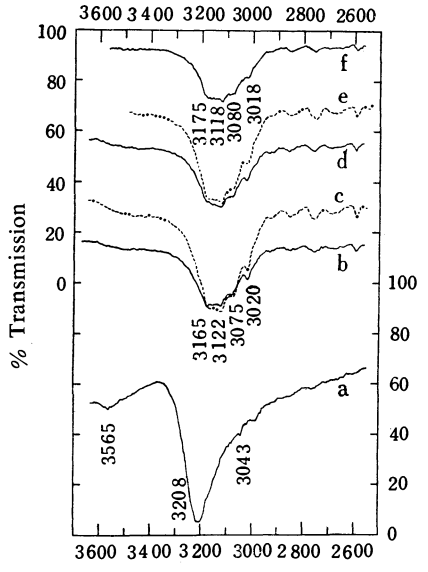

Fig. 3. Infrared spectra of 3-bromotropolone in the states of solid and carbon tetrachloride solution (3600~2600 $cm^{-1}$ range): a; solid (KBr disk), b; 0.1 mol./l. in $CCl_4$ (0.508 mm. thickness), c; 0.01 (11.10), d; 0.005 (11.10), e; 0.002 (50.30), f; 0.001 (50.30).

4-hydroxytropone[9,10] (IV) ($\nu_{O-H}$; 2920 (w.) and 2530 $cm^{-1}$ (v. s., broad)) and 3-hydroxytropone[11], which form a strong intermolecular hydrogen bond in solid and show the higher melting points and less volatilities than those of tropolone. Therefore, even though solid tropolone forms a dimer, it is not easy to explain why the hydrogen bonding in the dimer form is weaker than that in hydroxytropones. In addition, a distinct band at 3518 $cm^{-1}$ in Fig. 1a indicates the existence of unchelated O-H group as Ib type.

The absorption spectra of 4-isopropyltropolone (II) and 3-bromotropolone (III) are respectively indicated in Figs. 2 and 3. The spectra in Fig. 2 are essentially the same, with the exception of the bands due to isopropyl group, as the spectra in Fig. 1. 3-Bromotropolone is sparingly soluble in carbon tetrachloride. Its spectra in higher concentrations have not been measured, but the mode of change in the form of absorption can be learned similarly. It is therefore possible to discuss the absorption of these compounds in the same manner as in the case of tropolone.

The characters of O-H absorption bands above-mentioned will generally be observed in compounds possessing the skeletal structure of tropolone[12], but those forming a strong intermolecular hydrogen bonding such as 4- and 5-hydroxytropolones[13] and those showing extremely low intensity such as 3,7-dibromo- and 3,5,7-tribromo-tropolones[14] do not show the typical O-H absorption band of tropolones.

## Summary

Infrared spectra of tropolone, 4-isopropyltropolone and 3-bromotropolone in the solid, liquid and solution in carbon tetrachloride were measured with a calcium fluoride prism in the region of 3600~2600 $cm^{-1}$. The absorptions of O-H stretching vibration in these compounds in dilute solution are strongest at around 3120 $cm^{-1}$ with numerous branches, and these bands shift gradually to the higher wave number side with 100~88 $cm^{-1}$, as the concentration increases and the compound transits to the liquid or solid state. This character was explained by the assumption that the tropolone skeleton has a stable chelate system and that the intermolecular action increases with the increase of concentration. In the solid state, a distinct band corresponding to the O-H group of Ib type was also observed at around 3540 $cm^{-1}$.

The author deserves to express his deep gratitude to Professor Susumu Kinumaki and Assistant Professor Koyo Aida for their unfailing guidance during the course of this work, and to Professor Tetsuo Nozoe and members of his laboratory for the donation of valuable samples.

# *Infrared Spectra of Troponoid Compounds. III. Tropolone and 2-Deuteroxytropone**

By Yusaku IKEGAMI

(Received February 10, 1960)

Absorption of O–H stretching vibration of tropolone (I) in solid, liquid and carbon tetrachloride solution was described in the preceding paper[1]. In the present paper the spectra of tropolone, chiefly in finger-print region, will be described. Infrared spectra of tropolone have been reported earlier by Koch[2], Kuratani[3], Kinumaki[4] and others, and its Raman spectrum by Imanishi and Ito[5], but only a few vibrations, such as those of C=O, C=C and C–H out-of-plane, have been assigned in the finger-print region. In order to clarify the absorption bands originating in C–O–H group in the spectrum of tropolone, an infrared spectrum of 2-deuteroxytropone (II) was measured and compared with that of I. On heating I with heavy water, a compound III, in which the deuterium atom had entered the seven-membered ring, was obtained and brief mention will be made of this compound. Further, some considerations were given to the spectrum of I in the finger-print region.

## Results and Discussion

**Comparison of the Infrared Spectra of 2-Deuteroxytropone and Tropolone.**—2-Deuteroxytropone (II) was obtained by recrystallization of tropolone (I) from heavy water. The infrared spectra of I and II in carbon tetrachloride and carbon disulfide solutions are shown in Fig. 1, a and b. The presence of an absorption due to hydroxyl compound can not be denied in the spectrum of Fig. 1b but most of it is in the spectrum of II.

In the spectral curve of Fig. 1b, the O–H stretching absorption around 3150 $cm^{-1}$ in 1a has shown drastic decrease of its intensity and a new absorption originating in the O–D bond has appeared at around 2400 $cm^{-1}$. This band has two peaks at 2400 and 2342 $cm^{-1}$ and the shape of this band is similar to that of tropolone in which the O–H stretching absorption is not sharp even in the state of dilute solution. The ratio of the wave numbers of $\nu_{O-H}$ and $\nu_{O-D}$ is indicated in Table I together with values obtained in 3-bromo- and 3-methyl-tropolones. These values are in good agreement with the values (1.33~1.34) obtained by Keussler et al.[6] on deuteration of phenols

TABLE I. $\nu_{O-H}/\nu_{O-D}$ VALUES FOR SOME TROPOLONES

possessing a conjugated chelate structure as tropolone.

In the region of 1700~650 $cm^{-1}$ : — In this region, the absorption band at 1618 $cm^{-1}$ in I shifts to the lower wave number side by 6 $cm^{-1}$ in II, and a certain amount of difference is observed between I and II below 1500 $cm^{-1}$. New bands have appeared at 1406, 1230, 1095, 970 and 932 $cm^{-1}$ in the spectrum of Fig. 1b. On the other hand, the absorption bands at 1490, 1444, 1251, 953 and 726 $cm^{-1}$ in I do not appear in II, and the intensity of the absorption at 1267 $cm^{-1}$ is weaker. These bands in Fig. 1a are considered to have some relation, either directly or comparatively closely, to the vibration of the C–O–H group.

Identification of absorption bands originating in the C–O–H group by conversion of hydroxyl to deuteroxyl compound has been reported already by Hadzi, Mecke and others in carboxylic acids[7], chelated hydroxyquinones[8], enolized β-diketones[9,10] and phenols[11]. These results point out that the distribution of absorption bands which shift by deuteration and their interpretation vary according to the shape of a molecule, even in the same C–O–H group. In the case of tropolone, a storng absorption band at 1490 $cm^{-1}$ disappeared and a new band appeared at 1095 $cm^{-1}$ (1086 $cm^{-1}$ in solid) by deuteration, and these wave numbers are close to those which were assigned to the O–H and O–D deformation vibrations in enolized β-diketones (around 1435 and 1090 $cm^{-1}$ respectively)[9]. Moreover, the other band which can be assigned to the O–D deformation vibration appeared at

932 $cm^{-1}$ (896 $cm^{-1}$ in solid) by deuteration, while the band at 1267 $cm^{-1}$ weakened. These wave numbers are close to those of chelated hydroxyanthraquinones, in which two bands characteristic to the deuteroxyl group had been recognized at around 980 and 930 $cm^{-1}$ [8]. Anyway, these facts indicate that the bands at 1490 and 1267 $cm^{-1}$ in tropolone originate in the C–O–H group, although the definite assignments of these bands are indistinct.

It is clear that the bands at 1490 and 1267 $cm^{-1}$ in Fig. 1a are related to the vibration of the C–O–H group, not only because these bands shift by deuteration but because 2-halotropones, which have no C–O–H group, do not have strong absorptions this wavenumber region[12]. The fact that the absorption at around 1267 $cm^{-1}$ in tropolone has the character of O–H deformation is also understandable by comparing the spectra in solid, liquid, solution and gaseous states. The spectra in these states in the region of 1450～1050 $cm^{-1}$ are shown in Fig. 2, and the spectra of 4-isopropyltropolone, for the comparison with those, are also shown in Fig. 3. From the spectra in Fig. 3, it is clear that the broad absorption

Wave number, $cm^{-1}$

Fig. 5. Infrared spectrum of deuterated tropolone (III) in carbon disulfide (ca. 8%) (900～650 $cm^{-1}$ range).

at 1188 $cm^{-1}$ in solid has shifted to the higher wave number side, merging in the position at around 1265 $cm^{-1}$ in other states. In the same manner, the broad absorption in the region of 1208～1100 $cm^{-1}$ in solid tropolone (Fig. 2a) shifts to the higher wave number side in other states and is assumed to correspond to the strong absorption at 1265 $cm^{-1}$ in the gaseous. The direction of such a shift of absorptions according to changes in the state agrees with the direction of the shift of $\delta_{O-H}$ anticipated from that of $\nu_{O-H}$ as stated in the preceding report[1].

The absorption bands which shift by deuteration are recognized at 1444, 1251 and 953 $cm^{-1}$, but these bands have also disappeared in the compound III, as will be described below. In these bands, the absorption at 1251 $cm^{-1}$ is assumed to correspond to that at 1230 $cm^{-1}$ in Fig. 1b, from their similar shape.

In the region of 800～700 $cm^{-1}$, there are three strong absorption bands in the state of solution. Of these, the band at around 720 $cm^{-1}$ was assigned by Koch[2] and Kuratani et al.[3] to the out-of-plane vibration of hydrogen atoms in the seven-membered ring. On the other hand, Imanishi and Ito[5,13] assigned the Raman line at 743 $cm^{-1}$ to the breathing vibration of the seven-membered ring. Moreover, the following considerations are possible

12) Y. Ikegami, unpublished data.

13) S. Imanishi and M. Ito, *J. Chem. Phys.*, **24**, 1272 (1956).

from the spectra indicated in Fig. 1. The comparatively broad absorption at 726 $cm^{-1}$ in I is no longer visible in II and, therefore it can be assigned to the out-of-plane deformation vibration of C–O–H expected in this region. Analogous absorption bands have been recognized in carboxylic acids[7], chelated β-diketones[9] and hydroxyquinones[8]. This is also understandable since a broad absorption is seen in this region in tropolones in general but not in tropones[12]. The absorption at 767 $cm^{-1}$ can be assigned to the C–H out-of-plane deformation vibration as the majority of 1,2-disubstituted troponoids show strong absorption in this region[12] and because this absorption band has disappeared in deuterated tropolone (III), as shown in Fig. 5. Aside from such considerations in solution, the spectra in other states show a marked difference in shape, as shown in Fig. 4, and this fact indicates that such absorptions are easily affected by intermolecular action.

**On Deuterated Tropolone.** — Deuterated tropolone was obtained by heating a mixture of I and heavy water in a sealed tube at 150°C for a few hours. The compound III, obtained

e) The region of 650~400 $cm^{-1}$ was measured by using KBr prism only in solid (KBr disk).

by treating I twice with 99.78% heavy water for 5 hr., melted at 50°C, alone and in admixture with I. The ultraviolet spectrum of III is also very similar to that of I but their infrared spectra are very different. The absorption bands of III appeared at 3180, 1616, 1556, 1472, 1227 (in carbon tetrachloride) and 729 $cm^{-1}$ (in carbon disulfide), all corresponding to those in Fig. 1a with similar shape. The absorption of C–H stretching vibration in I has become indistinct and appears as a weak band of C–D stretching vibration at 2266 $cm^{-1}$ in III. Further, the strong absorptions at 1444, 1251 and 767 $cm^{-1}$ in I have all disappeared and appear at around 1370, 1084 and 810 $cm^{-1}$ in III (partly shown in Fig. 5), also indicating that these bands are closely related to the C–H bond in the seven-membered ring in I. However, there is not sufficient evidence to determine the position and number of deuteration.

**Considerations Regarding Vibrational Spectrum of Tropolone.**—The infrared absorption bands of tropolone, wave numbers of Raman lines reported by Imanishi[5], and their assignments are summarized in Table II. These assignments were chiefly based on the considerations of the foregoing deuteration and previously reported data[2-5]. Further, the weak absorptions at 1355 and 789 $cm^{-1}$ were assumed to correspond respectively to the overtone, $2\times675$ $cm^{-1}$, and combination tone, $357+436$ $cm^{-1}$. The spectrum of tropylium cation[14], which has the most fundamental form among tropoids, was compared with that of tropolone and bands corresponding well were recognized in the lower wave number region. The vibration due to the seven-membered ring in the cation should not differ greatly from that of tropolone. It is expected to indicate similar wave numbers. Therefore, the absorptions at 675 and 433 $cm^{-1}$ and Raman line at 357 $cm^{-1}$ can be assigned to the ring deformation vibration. The few medium intensity bands observed clearly in the region of 1300~1200 $cm^{-1}$, which are characteristics of tropoids, may be assigned to the C–H deformation vibration of the seven-membered ring.

## Experimental

**Materials.** — Recrystallization of tropolone (I), m. p. 50~51°C, was repeated several times from a mixed solvent of dioxane, dehydrated by metallic sodium, and 99.78% heavy water or from heavy water alone and 2-deuteroxytropone (II) was obtained as colorless needles, m. p. 51°C. Admixture of II and I showed no depression of the melting point. II easily reverted to I by the presence of a slight amount of moisture. Corresponding deuteroxyl compounds were also obtained by the same procedure from 3-bromotropolone, m. p. 108°C, and 3-methyltropolone, m. p. 50°C.

A mixture of 100 mg. of I and ca. 2 ml. of heavy water was heated in a sealed tube at 150°C for 5 hr. This procedure was repeated twice with fresh heavy water each time. The product purified by sublimation and recrystallization to colorless prisms (III), m. p. 50°C alone and in admixture with I.

U. V. $\lambda_{max}^{cyclohexane}$: 226, 239, 247 (sh.), 308 (sh.), 322, 355 and 374 m$\mu$[15].

**Infrared Absorption Spectra.**—All infrared spectra were measured by a Perkin-Elmer model 21 infrared spectrophotometer equipped with a sodium chloride prism. The solid spectra were obtained by the potassium bromide disk method and solution spectra in carbon tetrachloride, purified several times by dehydration with phosphorus pentoxide, or carbon disulfide.

## Summary

In order to find infrared absorption of tropolone, especially the absorption that can be assigned to the C–O–H group, the spectrum of 2-deuteroxytropone was measured and there were discussions chiefly on absorptions in the finger-print region. The absorption bands at around 3150, 1490, 1267 and 726 $cm^{-1}$ were assigned to the vibration of C–O–H group. In this connection, some mention was made on deuterated tropolone and considerations were made on the assignment of vibrational spectra of tropolone, as summarized in Table II.

The author expresses his deep gratitude to Professor Susumu Kinumaki and Assistant Professor Koyo Aida, both of this institute, for their valuable guidance throughout the course of this work.

# *The Dehydration Reactions by Means of Esters of Phosphoric Acid*

By Teruaki MUKAIYAMA and Tsujiaki HATA

(Received July 9, 1960)

Dehydration reactions of primary nitroparaffins and aldoximes by means of organic reagents, such as isocyanates, carbodiimides, ketene acetals and vinylogs, have been described in preceding papers[1-3]. In the present study, dehydration reactions using esters of phosphoric acid have been investigated in order to extend the scope of dehydrating reagents.

In general, the dehydrating reagents can be classified in three classes according to their abilities of dehydration: The first class involves well known strong dehydrating reagents, such as sulfuric acid and phosphorus pentoxide, which remove the hydrogen atom and the oxygen atom at the ratio of 2:1 irrespective of the structures of the compounds to be dehydrated. The second class involves very weak dehydrating reagents, such as calcium chloride and sodium sulfate, which can not remove a water molecule other than that included in the form of water, such as the water of crystallization or adhering water. The third class involves organic dehydrating reagents, such as carboxylic acid anhydrides, carboxylic acid chlorides, isocyanates, carbodiimides and vinylogs, which show that moderate dehydrating abilities and selective intramolecular or intermolecular dehydration of organic compounds are affected with these reagents.

These three classes of dehydrating reagents can be modified by strengthening or weakening their respective dehydrating abilities. For example, it is possible to weaken the strong dehydrating ability of sulfuric acid or phosphorus pentoxide till it is moderate. Recently, it was reported[4] that polyphosphoric acid which is considered to be a mixture of hydrates of phosphorus pentoxide is a very useful dehydrating reagent under moderate conditions.

Esters of phosphoric acid used as dehydrating reagents in the present study are prepared by the reaction of phosphorus pentoxide with alcohols instead of phosphoric acid in the preparation of polyphosphoric acid:

$$n\ P_2O_5 + m\ ROH \rightarrow P{-}R\ (n{-}m),$$

where P—R($n$—$m$) denotes an ester of phosphoric acid prepared by the reaction of $n$ mol. of phosphorus pentoxide with $m$ mol. of alcohol ROH. In general, the molar ratio of phosphorus pentoxide to monohydric alcohols is favorable when it is more than 1/3.

Esters of phosphoric acid are prepared very readily by adding alcohols to phosphorus pentoxide with vigorous agitation. In the preparation of these esters, it is desirable to make the reaction mixture as homogeneous as possible. For this purposes the addition of a pre-formed ester of phosphoric acid to phosphorus pentoxide in advance is favorable, just as shown in the preparation of polyphosphoric acid by the reaction of phosphorus pentoxide with phosphoric acid instead of water.

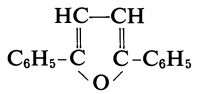
Monohydric alcohols, such as methyl, ethyl, *n*-propyl, isopropyl and *tert*-butyl alcohols, and also dihydric alcohol, and ethylene glycol, react with phosphorus pentoxide to give viscous esters of phosphoric acid, except in the case of *tert*-butyl alcohol. This does not form a homogeneous ester with phosphorus pentoxide, but the product separates into two layers, probably because of the branched structure of the alcohol. The esters of phosphoric acid thus formed, except that from *tert*-butyl alcohol, show nearly the same reactions. As an example of the dehydration reactions, the dehydrations using P—Et (2—5) prepared from 2 mol. of phosphorus pentoxide and 5 mol. of ethyl alcohol are described.

The reactions of benzaldoxime and heptanaldoxime with P—Et (2—5) give corresponding nitriles in quantitative yields without any accompanying side reactions:

$$RCH{=}NOH + P{-}Et\ (2{-}5) \rightarrow RC{\equiv}N$$

On the other hand, it was reported that the same dehydration reaction of an aldoxime could scarcely be observed with polyphosphoric acid and an acid amide formed by the Beckmann rearrangement of the aldoxime was mainly obtained because of the strong acid character of polyphosphoric acid. The yield of benzonitrile is maximum when benzaldoxime reacts with P—Et (2—5) for 15 min. and then it decreases with the time of heating as shown in Table I.

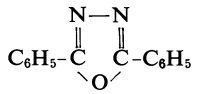
The dehydration of cyclohexanol to cyclohexene results by a simple treatment with



1) T. Mukaiyama and T. Hoshino, *J. Am. Chem. Soc.*, **82**, 5339 (1960).
2) T. Mukaiyama and T. Hata, This Bulletin, **33**, 1382 (1960).
3) T. Mukaiyama and T. Hata, ibid., **33**, 1712 (1960).
4) F. D. Popp and W. E. McEwen, *Chem. Revs.*, **58**, 321 (1958).

esters of phosphoric acid in a yield higher than when other dehydrating reagents, such as a catalytic amount of phosphoric acid, are used[5].

$$C_6H_{11}OH + P—Et\ (2—5) \rightarrow C_6H_{10}$$



The reaction of dibenzoylethane with P—Et (3—4) gives 2, 5-diphenylfuran in a nearly quantitative yield:

$$C_6H_5COCH_2CH_2COC_6H_5 + P—Et\ (3—4) \rightarrow$$

Similarly, the reaction of dibenzoylhydrazine with P—Et (2—5) gives 2, 5-diphenyl-1, 3, 4-oxadiazole in a good yield:

$$C_6H_5CONHNHCOC_6H_5 + P—Et\ (2—5) \rightarrow$$

The results of the dehydrations of benzaldoxime and cyclohexanol with the other esters are listed in Tables I and II. It should be noted that the reactivities of the five esters are nearly the same irrespective of their nature, except the ester of *tert*-butyl alcohol. It is also noted that the yield increases as the molar ratio of phosphorus pentoxide to alcohols increases and the maximum yield is obtained when benzaldoxime reacts with P—Et (3—4). P—Et (3—4), being a highly viscous liquid, is made to react more smoothly with benzaldoxime in a separate layer of a benzene solution.

Moreover, the esters of phosphoric acid possess several obvious advantages over polyphosphoric acid: 1) Since esters of phosphoric acid are less acidic than polyphosphoric acid, side reactions other than dehydration do not take place as shown in the dehydration of benzaldoxime. 2) In contrast to polyphosphoric acid, esters of phosphoric acid are soluble in organic solvents, such as chloroform, and reactions of organic compounds are conducted in homogeneous systems. 3) By the change of the molar ratio of phosphorus pentoxide to alcohols, the dehydrating ability of the esters is properly controlled.

The dehydrations by means of esters of phosphoric acid are considered to proceed through the bond fission of the pyrophosphate linkage by an attack of compounds containing a hydroxyl group to form 2 mol. of phosphates, and it is established that tetraethyl pyrophosphate reacts with benzaldoxime to give benzonitrile in a 76% yield along with 2 mol. of diethyl phosphate (95% yield).

$$(EtO)_2POOPO(OEt)_2 + C_6H_5CH{=}NOH \rightarrow 2(EtO)_2POOH + C_6H_5C{\equiv}N$$

Dehydrations of aldoximes, cyclohexanol, dibenzoylethane and dibenzoylhydrazine are well conducted with esters of phosphoric acid and also mostly with polyphosphoric acid, but dehydration of an acid amide with these reagents does not succeed and, when benzamide reacts with P—Et (2—5), ethyl benzoate is obtained in an 18% yield instead of the dehydrated product, benzonitrile, probably because of a replacement reaction of the alkoxyl group of the esters with the amino group of the acid amide.

$$C_6H_5CONH_2 + P—Et\ (2—5) \rightarrow C_6H_5COOEt$$

Since esters of phosphoric acid contain alkoxyl groups and form a carboxylic ester by the reaction with an acid amide, polyphosphonic acid is prepared from phosphorus pentoxide and benzenephosphonic acid.

$$C_6H_5PO(OH)_2 + P_2O_5 \rightarrow \text{polyphosphonic acid}$$

When benzamide reacts with the polyphosphonic acid, the dehydrated product, benzonitrile, is obtained, as expected, in a 60% yield.

## Experimental

**Preparation of Esters of Phosphoric Acid [P—R(*n*—*m*)].**—To *n* mol. of phosphorus pentoxide was added *m* mol. of a monohydric alcohol or *m*/2 mol. of a dihydric alcohol dropwise with continuous stirring. When unchanged phosphorus pentoxide remained in a viscous ester, the whole was further heated on a boiling water bath until phosphorus pentoxide was completely dissolved. In general, the resulting esters, P—R (*n*—*m*), are viscous homogeneous liquids, but the ester from *tert*-butyl alcohol separated into two layers. P—Me (*n*—*m*)

TABLE I. THE REACTIONS OF α-BENZALDOXIME WITH VARIOUS ALKYL ESTERS OF PHOSPHORIC ACID, P—R (*n*—*m*), AT 100°C

| P—R (*n*—*m*) | Reaction time, min. | Benzonitrile, yield % |
|---|---|---|
| P—Et (2—5) | 5 | 60 |
| | 15 | 92 |
| | 60 | 70 |
| | 120 | 48 |
| P—Et (1—3) | 15 | 48 |
| P—Et (2—5) | 15 | 92 |
| P—Et (1—2) | 15 | 92 |
| P—Et (3—4) | 15 | 98 |
| P—Me (2—5) | 15 | 68 |
| P—*n*Pr (2—5) | 15 | 90 |
| P—iso Pr (2—5) | 15 | 92 |
| P—*t*Bu (2—5) | 15 | 53 |
| P—EG (3—4) | 15 | 87 |

5) L. F. Fieser, "Experiments in Organic Chemistry", D. C. Heath & Co., Boston (1955), p. 61.

and P—EG (*n*—*m*), prepared by the reactions of phosphorus pentoxide with methyl alcohol and ethylene glycol, respectively, were dark brown liquids, but they showed similar reactions to the other esters.

**Reactions of α-Benzaldoxime with Esters of Phosphoric Acid.**—A solution of α-benzaldoxime (5.0 g., 0.05 mol.) in 10 ml. dry benzene was added to 7.5 g. of P—Et (3—4) and the mixture was heated at 90°C with continuous stirring for 15 min. After removal of benzene, 4.2 g. (98% of the theoretical) of benzonitrile, b. p. 65~66°C (8 mmHg), was obtained. The results of the dehydration of α-benzaldoxime with P—R (*n*—*m*) are summarized in Table I.

**Reaction of Heptanaldoxime with P—Et (3—4).**—A solution of heptanaldoxime (2.6 g., 0.02 mol.) in 10 ml. dry benzene was added to 25 g. of P—Et (3—4). The mixture was heated on a boiling water bath for 30 min. with continuous stirring. After removal of benzene, 1.8 g. (80%) of heptanenitrile, b. p. 71~73°C (20 mmHg), was obtained.

**Reactions of Cyclohexanol with Esters of Phosphoric Acid.**—Cyclohexanol (6.0 g., 0.06 mol.) was added to 8.0 g. of P—Et (2—5) and the mixture was heated at 90°C with continuous stirring for 2 hr. 4.5 g., (92%) of cyclohexene, b. p. 47°C (200 mmHg), was obtained. The results of the dehydration of cyclohexanol with P—R (*n*—*m*) are summarized in Table II.

**Reaction of Dibenzoylethane with P—Et (3—4).**—Dibenzoylethane (1.0 g., 0.004 mol.) was added to P—Et (3—4) (5.0 g.) and the mixture was heated at 100°C with continuous stirring until the viscous mixture became brownish yellow in color. Then the mixture was poured into 150 ml. of ice water with vigorous stirring and the precipitate was collected by filtration. It was recrystallized from 95% ethanol and 0.86 g. (93%) of 2,5-diphenylfuran, m. p. 88~90°C, was obtained.

Table II. The reactions of cyclohexanol with various alkyl esters of phosphoric acid at 100°C

| P—R (*n*—*m*) | Reaction time, hr. | Cyclohexene, yield, % |
|---|---|---|
| P—Et (2—5) | 1.0 | 68 |
| | 1.5 | 92 |
| | 2.0 | 88 |
| | 3.0 | 93 |
| P—Me (2—5) | 2.0 | 88 |
| P—*n*Pr (2—5) | 2.0 | 99 |
| P—iso Pr (2—5) | 2.0 | 99 |
| P—*t*Bu (2—5) | 2.0 | 52 |

**Reaction of Dibenzoylhydrazine with P—Et (3—4).**—A solution of 1.0 g. (0.004 mol.) of dibenzoylhydrazine in 10 ml. dimethylformamide was added to 10 g. of P—Et (3—4). Then, the mixture was heated at 100°C for 2 hr. and poured into 200 ml. of ice water with vigorous stirring. The precipitate was collected by filtration and recrystallized from benzene to give 0.6 g. (65%) of 2,5-diphenyl-1,3,4-oxadiazole, m. p. 136°C.

**Reaction of α-Benzaldoxime with Tetraethyl Pyrophosphate.**—A mixture of tetraethyl pyrophosphate (2.9 g., 0.01 mol.) and α-benzaldoxime (1.21 g., 0.01 mol.) was heated at 95°C for 14 hr. and 0.78 g. (76%) of benzonitrile, b. p. 42~44°C (2 mmHg), and 2.92 g. (95%) of diethyl phosphate, b. p. 120~123°C (0.02 mmHg), were obtained.

**Reaction of Benzamide with Polyphosphonic Acid.**—To fused benzenephosphonic acid (2.0 g., 0.013 mol.) was added phosphorus pentoxide (3.0 g., 0.021 mol.) little by little with stirring during a period of 20 min. To the viscous polyphosphonic acid thus prepared was added benzamide (1.0 g., 0.008 mol.) with continuous stirring. After heating the mixture for 30 min. at 130°C, it was cooled at room temperature. Then it was dissolved in 20 ml. of water and extracted twice with 20 ml. of chloroform. The chloroform layers were combined and distilled under reduced pressure to give 0.5 g. (60%) of benzonitrile, b. p. 87~89°C (25 mmHg).

The authors wish to express their hearty thanks to Miss Hiroko Takahashi for her help throughout the course of this experiment. Thanks are also due to Mr. Asaji Kondo for the microanalyses.

# *Oxidizing Action of Hydroperoxides. V. On the Oxidation of Ketones*

By Kazuhiro MARUYAMA

(Received June 14, 1960)

In the previous paper of this series[1], it has been reported that hydroperoxides have a strong oxidizing action cooperating with alkali hydroxides. For example, alkylbenzenes are oxidized to the corresponding alcohols, ketones and carboxylic acids. Further, alkyl aryl ketones are split very smoothly to benzoic acid derivatives and alcohols,—but diaryl ketones are not cleft by these oxidizing agents[2]. Furthermore, in order to obtain more extensive knowledge of the reaction, the same kinds of reactions were examined on some ketones; isopropyl phenyl ketone, cyclohexyl phenyl ketone *p*-chloroacetophenone, desoxybenzoin, phenyl *p*-chlorobenzyl ketone, benzoin, benzil, $\alpha$-tetralon, 3-pentanone, 3-heptanone and cyclohexanone were examined. All these reactions were performed in nonaqueous solvent and the examined ketones were also cleft smoothly with the one exception of cyclohexanone. An outstanding difference between this cleavage reaction mechanism and the Baeyer-Villiger mechanism is that any C–C linkage between carbonyl carbon and aromatic carbon in alkyl aryl ketones, is never attacked.

## Experimental

**Reagents.**—The reagents cited in Table I were synthesized by the Friedel-Crafts reaction.

Benzoin was prepared by condensation of benzaldehyde, m. p. 137°C; semicarbazone, m. p. 206°C. Benzil was prepared by nitric acid oxidation of benzoin, m. p. 95°C. $\alpha$-Tetralon was synthesized from tetralin after Thompson's method, checked by Shriner and Poland[3], b. p. 107°C/2 mmHg, $n_D^{15}$, 1.5640; semicarbazone, m. p. 217°C. 3-Pentanone and 3-heptanone, the commercially available guaranteed grade reagent was used without further purification. *tert*-Butylhydroperoxide was snythesized by the action of 30% hydrogen peroxide on *tert*-butanol according to Milas and Surgenor's method[4] and purified by fractional distillation under reduced pressure. B. p. 36°C/19 mmHg, $n_D^{27}$ : 1.3967. Cyclohexanone, the commercially available guaranteed grade reagent was treated with potassium permanganate and was purified by distillation. b. p. 157°C, Semicarbazone, m. p. 155°C.

**Reaction Procedure.**—The reaction apparatus and the treatments of reaction mixture are quite the same as that described in the previous paper[2]. With the exception of the case with benzil and $\alpha$-tetralon the experiment was conducted as following.

The weighed ketone was dissolved in purified monochlorobenzene (150 cc.). Carbonate free powdered potassium hydroxide was added to the mixture after the air in the reaction vessel was completely exchanged with dry pure nitrogen. As soon as the temperature of the reaction mixture reached 70°C, *tert*-butylhydroperoxide was added. The temperature raising of about 10°C was observed. After six hours, the reaction mixture was extracted with 100 g. of water three times. The water extract was acidified with 2 N-sulphric acid and the precipitated benzoic acid derivative was collected and weighed. The filtrate was neutralized with conc. ammonia

| 11. Cyclohexanone 9.8 g. (0.1 mol.) | *tert*-Butylhydroperoxide 5.4 g. (0.06 mol.) | almost completely recovered | No reaction (oxygen, *tert*-butanol, methanol) |

* In this case, the solution of benzoin suspended with potassium hydroxide was deeply colored violet before the addition of hydroperoxide. As the peroxide was dropped, however, the violet color disappeared.

** In this reaction, potassium hydroxide was added in the mixture of benzil and hydroperoxide in order to avoid the so-called "benzilic acid rearrangement." By this precaution, the rearrangement was in practice avoided.

*** In this case, benzene was used as a solvent and its solution of $\alpha$-tetralon and hydroperoxide were dropped to suspension of potassium hydroxide in benzene. However, a large quantity of resinous product was not avoided.

and was concentrated to 10 cc. and subjected to a paper chromatographic analysis.

The obtained experimental results are shown in Table II.

**Benzoic Acid.**—In the reaction 1, 2, 4, 5, 6 and 7 benzoic acid was obtained by the acidifying of the water extraction of the reaction mixture. The crude products were recrystallized from the water-alcohol mixture. The acid was identified by the mixed melting point method and paper chromatography.

**Isopropanol.** — In reaction 1, isopropanol was collected in a trap cooled by ice-salt mixture. This was identified as its phenylurethan derivative (from ligroin m. p. 88°C) and also verified by gas chromatography.

Found: C, 66.98; H, 7.22. Calcd. for $C_{10}H_{13}\cdot NO_2$: C, 67.02; H, 7.31%.

**Adipic Acid.**—In reaction 2, the acid was found in the solid acid of reaction products and in the concentrated part of the filtrate. Adipic acid was identified by paper chromatography ($R_f$ 0.22, solvent: 5% ammonia 1 vol.+isopropanol 4 vol., temp. 15~20°C). Another acid ($R_f$ 0.44) was found on the paper chromatogram accompanying benzoic acid and adipic acid. But, this acid could not be identified.

***p*-Chlorobenzoic Acid.**—In reaction 3, acid was obtained by the acidifying of the water extract of the reaction mixture, and was identified as *p*-chlorobenzoic acid by the mixed melting point method and paper chromatography (m. p. 243°C).

Found: C, 53.77; H, 3.11. Calcd. for $C_7H_5O_2Cl$: C, 53.69; H, 3.21%.

In reaction 5, *p*-chlorobenzoic acid was obtained by the acidifing of the water extract of the reaction mixture accompanying benzoic acid, and was easily separated from benzoic acid by crystallization from hot water. The obtained crude acid was recrystallized from the water-alcohol mixture, m. p. 242~243°C and was identified by the mixed melting point method and paper chromatography.

**Benzilic Acid.**—In reaction 7, a trace of benzilic acid was found in the acid products, and was detected paperchromatographically and identified by comparison with a known sample.

***o*-Carboxyhydrocinnamic Acid.** — In reaction 8, the acid was obtained as the main reaction product. The water extract of the reaction mixture was acidified and the obtained precipitation was recrystallized from hot water. *o*-Carboxyhydrocinnamic acid is slightly soluble in hot water and separated from insoluble acid. Repeated recrystallization resulted in the paperchromatographically pure product, and was identified by the mixed melting point method and paper chromatography ($R_f$ 0.21 solvent: 5% ammonia 1 vol. isopropanol 4 Vol., room temp.) m. p. 166~167°C.

Found: C, 62.14; H, 5.30. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%.

***o*-Carboxycinnamic Acid.** — In reaction 8, this acid was obtained as a product insoluble in hot water, but soluble in hot alcohol, m. p. 173~174°C and was identified by the mixed melting point method and paper chromatography.

**Phthalonic Acid.**—In reaction 8, phthalonic acid was obtained as the benzene soluble part of acid products, m. p. 150~151°C and was identified by the mixed melting point method and on a paper chromatogram by comparison with a known sample.

**Methanol and *tert*-Butanol.**—These products were collected in a trap cooled by ice-salt, and analyzed gaschromatographically. *tert*-Butanol was separated as its phenylurethan, m. p. 136°C.

Found: C, 68.86; H, 7.93. Calcd. for $C_{11}H_{15}\cdot NO_2$: C, 68.40; H, 7.80%.

***n*-Valeric Acid, *n*-Butyric Acid, Propionic Acid and Acetic Acid.**—These acids were detected by paper chromatography and their total acid contents were determined by titration.

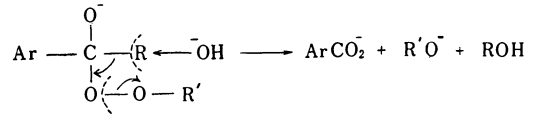
## Discussion

It was discussed in the previous paper[1], almost all of the examined ketones, there being only one exception, are subjected to a cleavage reaction by *tert*-butylhydroperoxide. These reactions are summarized in the next equations.

i) Aromatic ketone

$$\mathrm{Ar\text{-}CO\text{-}R} \xrightarrow[\mathrm{KOH}]{t\text{-BuOOH}} \mathrm{ArCOOH + ROH} \qquad (1)$$

R=alkyl

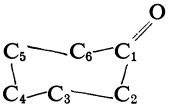


ii) Aromatic $\alpha,\beta$-diketone

$$\mathrm{ArCO\cdot COAr'} \xrightarrow[\mathrm{KOH}]{t\text{-BuOOH}} \mathrm{ArCOOH + Ar'COOH} \qquad (2)$$

iii) Aliphatic ketone

$$\mathrm{RCOR'} \rightarrow \begin{cases}\mathrm{RCOOH + R'OH}\\ \mathrm{R'COOH + ROH}\end{cases} \qquad (3)$$



From results of Table II, it could be confirmed that in general, an alkyl aryl ketone can be cleft to benzoic acid derivative and alcohol by hydroperoxide cooperating with alkali hydroxide. The hydroperoxide was reduced to alcohol — e. g. *tert*-butylhydroperoxide → *tert*-butanol. Furthermore, aromatic $\alpha,\beta$-diketone was also cleft by the same oxidizing reagent to benzoic acid derivatives. It was a outstanding difference from the cleavage of aromatic ketones by peracids according to Baeyer-Villiger reaction that phenolic product was not found in the oxidation products. This difference, of course, is ascribed to the different reaction mechanism, for this kind of reactions are performed in alkaline medium. As it was briefly discussed in the previous paper, the reason of the absence of phenolic product may be due to a difficulty of formation of phenyl cation (or of $S_N2$-type reaction at nucleus carbon) at the moment of scission from the complex [I], which is consisted of ketone and hydroperoxide.

[I] (4)

The same kind of cleavage reaction occurred even in the aliphatic ketones, but in this case, the two linkages on both sides of carbonyl carbon have a chance of scission. The chance of scission, however is determined by the stability of the alkyl group as a cation*.

For cyclohexanone, which is only one exception to the cleavage reaction, it may be guessed that the complex can not be formed. This is because, in the alkaline medium the attack of the hydroperoxide anion to the positively polarized carbonyl carbon atom will be most easily performed on the opposite side of the negatively polarized oxygen atom and the steric hindrance which will be caused by the axial hydrogens on $C_2$, $C_6$, $C_3$ and $C_5$ and by the $C_3$, $C_4$ and $C_5$ carbon atom, against the attack of the hydroperoxide anion makes the formation of complex [I] impossible.

The author is indebted to Professor Ryozo Goto for discussion and encouragement throughout this investigation.

# *Oxidizing Action of Hydroperoxides. VI. On the Oxidation of Ketones*

By Kazuhiro MARUYAMA

(Received June 20, 1960)

In the previous work[1], it was reported that hydroperoxides acted as a strong oxidizing agent in the presence of alkali hydroxide, and especially a vigorous reaction occurred with alkyl aryl ketone and resulted in a cleavage of C–C linkage between the carbonyl carbon and the alkyl carbon. The mechanism of this reaction must be different from the "Baeyer-Villiger" mechanism, because alkyl aryl ketone does not produce any phenolic products and diaryl ketone affords none of its reaction products.

From this point of view, the following three points were examined:

i) In the first place, it must be decided that the cleavage reaction of ketone with hydroperoxide can proceed by way of an intermediate complex, in which the hydroperoxide anion will be added to the carbonyl carbon atom of the ketone. And, if not, an active oxygen atom isolated from the hydroperoxide anion will be responsible for the cleavage reaction. In order to examine these points, a method of competitive reaction was employed; that is, with the selection of acetophenone-1-$^{14}$C (carbonyl $^{14}$C) as a standard ketone, the reactivity among methyl derivatives of acetophenone, substituted on the methyl group, was compared.

ii) The influence of *p*-substituent to acetophenone towards the reactivity was confirmed.

iii) The progression of cleavage reaction was traced for some ketones — acetophenone, ethyl phenyl ketone and isopropyl phenyl ketone.

## Experimental

**Reagent.** — Ketones used as reagents are all synthesized, as can be seen from the following tabulation.

Acetophenone-1-$^{14}$C was prepared from benzene and acetyl-1-$^{14}$C chloride. Acetyl-1-$^{14}$C chloride was synthesized from sodium acetate-1-$^{14}$C according to Anker's method.[2] The obtained acetophenone-1-$^{14}$C has b. p. 196~199°C (yield 75%). *tert*-Butyl-hydroperoxide was prepared from *tert*-butanol and

2) H. S. Anker, *J. Biol. Chem.*, **176**, 1333 (1948).

30% hydrogen peroxide according to Milas's method[3], b. p. 36°C/19 mmHg, $n_D^{27}$ 1.3967.

**Reaction Procedure.** — *1) Competitive Reaction with Acetophenone-1-$^{14}$C.*—A three-necked 200cc. flask, equipped with a thermometer, a dropping funnel and a reflux condenser was placed in a thermostat, controlled to (70±1°C). A mixture of 0.01 mol. of acetophenone-1-$^{14}$C and 0.01 mol. of testing ketone, dissolved together in 50 g. of monochlorobenzene, was charged in the flask and the contents were agitated vigorously with a magnetic stirrer. When the temperature of the contents became constant, 0.062 mol. of finely powdered pure potassium hydroxide* was added and 0.06 mol. of *tert*-butylhydroperoxide, dissolved in 10 g. of monochlorobenzene, was dropped through a dropping funnel within three minutes. After one hour, the reaction was finished. The contents were cooled with ice, added with 50 cc. of ether and extracted with 20 cc. of water three times. The water extract was collected and acidified with 6N hydrochloric acid, and then precipitated benzoic acid was collected and purified. A hundred milligrams of the obtained benzoic acid was used for the counting** of the activity in each reaction.

*2) Comparison of Reactivity of p-Substituted Acetophenone.*—The same reaction apparatus as that described above was employed. A mixture of 0.02 mol. of ketone, 0.062 mol. of finely powdered pure potassium hydroxide dissolved in 50 g. of monochlorobenzene and a solution of 0.06 mol. of *tert*-butylhydroperoxide dissolved in 10 g. of monochlorobenzene was caused to react in the reaction vessel. After one hour, the reaction was ceased, the mixture was immediately cooled with ice, added with 50 cc. of ether, and extracted three times with 20 cc. of water each. The water extract was acidified with 14 cc. of 6N hydrochloric acid and extracted three times with 20 cc. of ether each. The ether extract was washed with 5 cc. of water three times, and then the ether extract was added with pure ethanol till the total volume became just 100 cc., and titrated with 0.054 N sodium hydroxide solution. Thus the obtained benzoic acid was determined.

*3) Measurement of Progression of Cleavage Reaction.*—In these reactions, 0.042 mol. of ketone, 0.056 mol. of *tert*-butylhydroperoxide and 0.056 mol. of finely powdered pure potassium hydroxide were used and reaction procedures were the same as in 2. The reaction mixture was not completely homogeneous, hence a pipetting-out method could not be used, and so the total reaction mixture was used for analysis after the definite time of reaction had elapsed. Therefore, to determine the cleavage velocity of a ketone, five reactions under the same conditions should be performed. In this method, the accuracy of the measurements was fairly good (see Fig. 2).

## Results and Discussion

**Competitive Reaction with Acetophenone-1-$^{14}$C.** —The results are given in Table II. A relative reactivity derived from counting the amount of the benzoic acid obtained in each reaction is cited in column 4.

TABLE II. COMPETITIVE REACTION WITH ACETOPHENONE-1-$^{14}$C

| | Ketone | Counting number*) (c. p. m.) | Reactivity |
|---|---|---|---|
| 1. | $C_6H_5\cdot C(=O)\cdot CH_3$ | 1000±19 | 1 |
| 2. | $C_6H_5\cdot C(=O)\cdot CH_2CH_3$ | 514±15 | 2.9 |
| 3. | $C_6H_5\cdot C(=O)\cdot CH_2C_6H_4Cl(p)$ | 860±19 | 1.3 |
| 4. | $C_6H_5\cdot C(=O)\cdot CH(CH_3)_2$ | 707±19 | 1.8 |
| 5. | $C_6H_5\cdot C(=O)\cdot CH(CH_2{-}CH_2{-}CH_2{-}CH_2)$ | 1706±27 | 0.2 |
| 6. | $C_6H_5\cdot C(=O)\cdot C(CH_3)_3$ | 1111±19 | 0.8 |

*) A hundred milligrams of the obtained benzoic acid was used for the counting of the activity in every reaction.

Conditions of reactions: Temp. 70°C, reaction time 1 hr.

{acetophenone-1-$^{14}$C 0.01 mol. + ketone 0.01 mol.; *tert*-butyl hydroperoxide 0.06 mol.; powdered potassium hydroxide 0.062 mol.} dissolved in 60 g. of monochlorobenzene.

| 6. | $p$-$Br\cdot C_6H_4\cdot C(=O)\cdot CH_3$ | -Br | 212.4 |

Conditions of reactions: Temp. 70°C, reaction time 1 hr.
{ketone 0.02 mol., *tert*-butylhydroperoxide 0.06 mol., powdered potassium hydroxide 0.062 mol.} dissolved in 60 g. of monochlorobenzene.

From the above results, it may be seen that the successive methyl substitution on the methyl group of acetophenone produces a ketone which has the maximum reactivity upon *tert*-butylhydroperoxide in the series of acetophenone derivatives; that is, the relative reactivities of acetophenone, ethyl phenyl ketone, isopropyl phenyl ketone and *tert*-butyl phenyl ketone were about 1 : 3 : 2 : 1. On the other hand, the reactivity of *p*-chlorobenzyl phenyl ketone is one third of that of ethyl phenyl ketone. The same result is also seen in the comparison between isopropyl phenyl ketone and cyclohexyl phenyl ketone. The latter is about one tenth of the former in its reactivity. Moreover, *tert*-butyl phenyl ketone is even more reactive upon *tert*-butylhydroperoxide than cyclohexyl phenyl ketone is.

These results obtained above would lead to the conclusion that the steric effect of the alkyl group and the effect of the stability of the alkyl group as its cation are conversely responsible for the reactivity of alkyl phenyl ketone, that is, the size of the alkyl group obviously increases in the following order, $CH_3 < CH_2CH_3 < CH(CH_3)_2 < C(CH_3)_3$ and so the more bulky the alkyl group is, the larger is the steric hindrance of alkyl groups against the attack of *tert*-butylhydroperoxide on the carbonyl group (F-strain). On the other hand, the stability of the alkyl group as a cation is in the following order $CH_3 < CH_2CH_3 < CH(CH_3)_2 < C(CH_3)_3$. If the alkyl group of an alkyl aryl ketone is cleft as a cation*, the same order of the relative reactivity may be expected. Then, based on these considerations, it seems reasonable to suppose that the appearance of maximum reactivity in ethyl phenyl ketone depends upon the overlap of the conversely acting two effects.

**Comparison of Reactivity of *p*-Substituted Acetophenones.**—Relative reactivities of *p*-substituted acetophenones are given in Table III and their relation to Hammett's $\sigma_p$ value is shown in Fig. 1. From the results obtained, it can be deduced that the more electron attractive the substituent of an acetophenone, the

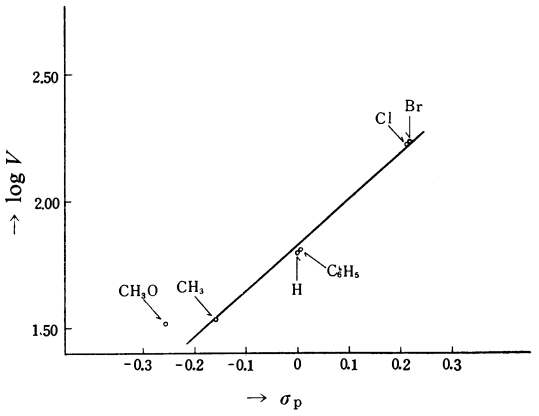

Fig. 1. The relation between $\sigma_p$ value and reactivity of *p*-substituted acetophenones.

* This is also supported from the following facts: i) alcohol derived from the alkyl group was confirmed as a reaction product and ii) diaryl ketones could not be cleft by these reagents.

more reactive is the acetophenone derivative. Furthermore, Hammett's plot of log $V$ to $\sigma_p$ gives straight line (see Fig. 1). It may be deduced that, in general, an electron attractive substituent on the phenyl group raises the reactivity of acetophenone derivatives for *tert*-butylhydroperoxide.

**Measurement of Progression of Cleavage.**—In order to study the progression of reaction and to elucidate its mechanism, the cleavage reaction of acetophenone, ethyl phenyl ketone and isopropyl phenyl ketone was examined. From the results obtained, the following may be written (see Fig. 2).

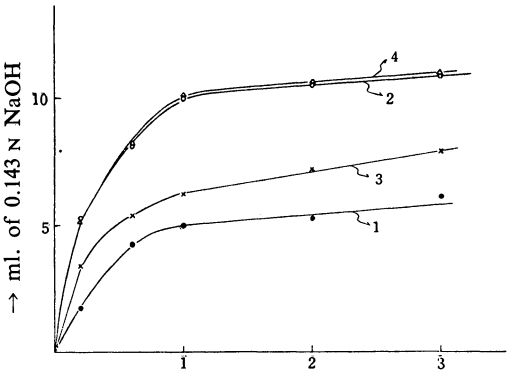

Fig. 2. Progression curve of reaction derived from titration curve of produced benzoic acid.

(1) $C_6H_5COCH_3$ 0.042 mol.
(2) $C_6H_5COC_2H_5$ 0.042 mol.
(3) $C_6H_5COCH\langle^{CH_3}_{CH_3}$ 0.042 mol.
(4) $\{^{C_6H_5COC_2H_5}_{As_2O_3}$ 0.042 mol. / 0.0005 mol.

Conditions of reactions: Temp. 70°C
{ketone 0.042 mol. / *tert*-butylhydroperoxide 0.056 mol. / powdered potassium hydroxide 0.056 mol.} dissolved in 60 g. of monochlorobenzene.

i) There is no induction period for any reaction.

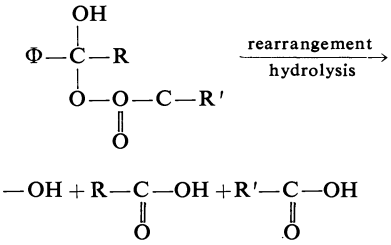
ii) The addition of arsenious acid to the reaction mixture has no effect.

iii) The reproducibility of these reactions is fairly good.

From the above three points, it might be possible to obtain the conclusion that the cleavage of ketones with hydroperoxides in the presence of alkali hydroxide is not a chain reaction.

**Reaction Mechanism.**—On the examination of reaction mechanism, the followings should be born in mind:

i) Alkyl aryl ketone is cleft with hydroperoxide cooperating with alkali hydroxide and produces benzoic acid derivative and alcohol derived from the alkyl group of ketone.



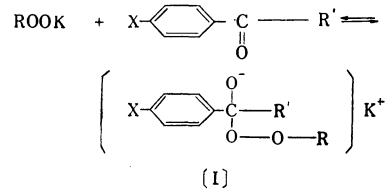
ii) Diaryl ketone (e. g. benzophenone, *p*-nitrobenzophenone and fluorenone) can not be cleft with this oxidizing reagent.

iii) In the series of methyl substituted derivatives of acetophenone having the substituent on the methyl group, a maximum reactivity is observed in ethyl phenyl ketone.

iv) In *p*-substituted derivatives of acetophenone, the more electron attractive the *p*-substituent is, the larger is the reactivity upon hydroperoxide.

v) These reactions have no induction period, and arsenious acid which is known as an inhibitor of the chain reaction has no effect.

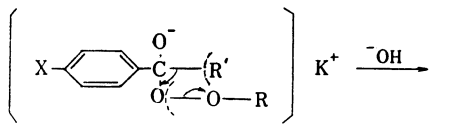
In view of i) — iii), this cleavage reaction of ketone should be different from the "Baeyer-Villiger" reaction, which is a cleavage reaction of ketone by peracid, for the cleavage of ketone according to "Baeyer-Villiger" mechanism is of a rearrangement of carbanion to oxygen cation.

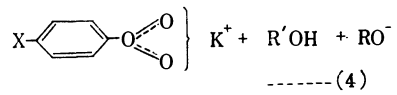


(1)

If this reaction, which is an oxidizing action of hydroperoxide cooperating with alkali hydroxide upon ketone, is supposed to follow the same mechanism as that of B. V., phenolic derivative and fatty acid must be produced, but, in fact, only benzoic acid derivative and fatty alcohol are obtained and so the C–C linkage between carbonyl carbon and phenyl carbon is not cleft. In order to explain these results conveniently, the following reaction mechanism seems very probable.

This mechanism implies that the hydroperoxide, first produces its potassium salt, and then this salt attacks carbonyl carbon and gives a complex (I), which is cleft by hydroxide anion to acid and alcohol. Reaction 3 should be a reversible reaction and the position of equilibrium would probably be settled under

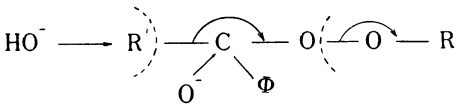




(2)

(3)

(I)



-------(4)

-------(5)

the influence of the size of alkyl group. F-Strain of alkyl group against the attack of hydroperoxide anion on the carbonyl carbon may act as a factor inhibiting the formation of complex [I]. On the other hand, the back-side attack of hydroxide anion on the alkyl group may play an important role* (Eq. 4) for the cleavage of complex I. The same equilibrium as in Eq. 3 may exist in the case of diaryl ketone, but the succeeding back-side attack of hydroxide anion would not act effectively, so that diaryl ketones could not be cleft. However, the cleavage reaction may be started by the scission of R'-cation from complex I, and a promoting action of $HO^-$ anion for this, too, may act and at the same time the scission of $RO^-$ anion may take place concertedly with the above process, that is:

As the result of this cleavage reaction, benzoic acid derivatives, R'OH and ROH are produced. According to this mechanism, it is quite possible that a maximum reactivity observed in ethyl phenyl ketone (discussion 3) is caused by a result of two counter-acting effects which are effects of R' cation and steric hindrance for the back-side attack of $HO^-$ anion. Moreover, the increase of of F-strain, caused by the increase in size of the alkyl group, for the formation of complex I (Eq. 3) may contribute to the decrease of reactivity. On the other hand, the promoting action of an electron attracting substituent on the phenyl group can be explained as follows; that is, the increase of stability of the *p*-substituted benzoate anion by an electron attracting substituent may cause an increase of driving force for the cleavage reaction of the complex [I].

Contrary to the above mechanism, i) the possibility of contribution of radicals for the cleavage reaction of the complex [I], ii) the possibility of contribution of enol-type of ketone this cleavage reaction, and iii) the possibility of contribution of atomic oxygen isolated completely from $ROO^-$ may be doubted. However, i) diaryl ketones can not be cleft and phenolic derivatives are not produced in any cleavage reaction, ii) *tert*-butyl phenyl ketone is cleft almost easily as acetophenone, and iii) when formaldehyde, acetaldehyde, propionaldehyde, acetone and methyl ethyl ketone are selected as carbonyl compounds, the decomposition velocity of hydroperoxide is strikingly different according to the structure of carbonyl compounds[5]. For example, *tert*-butylhydroperoxide did not decompose in the reaction with acetone (at 30°C), but the same hydroperoxide was decomposed in the reaction with methyl ethyl ketone under the same condition. If the isolated oxygen atom acts as an oxidizing agent, there must be no such phenomena.

The author is indebted to Professor Ryozo Goto for discussion and encouragement throughout this investigation.

* In fact, it was confirmed that an increase of hydroxide anion, in homogeneous alkaline solution, accelerates the cleavage of the complex, which is inferred from the decomposition velocity of hydroperoxide, in the case of methyl ethyl ketone. The decomposition velocity of hydroperoxide was studied on the next two reaction mixtures;

A: methyl ethyl ketone 0.05 mol., *tert*-butylhydroperoxide 0.028 mol. and potassium hydroxide 0.03 mol. are all dissolved in 250 ml. of water.

B: methyl ethyl ketone 0.05 mol., *tert*-butylhydroperoxide 0.028 mol. and potassium hydroxide 0.06 mol. are all dissolved in 250 ml. of water.

The decomposition velocity of the hydroperoxide was in A: 0.30 mol./1 hr., in B: 0.40 mol./1 hr. at 35.0°C and in A: 0.49 mol./1 hr., in B: 0.60 mol./1 hr. at 40.2°C (unpublished work).

# *Rates of Solvolysis of Di-p-toluenesulfoxycyclohexanes*

By Nobuo MORI

(Received May 23, 1960)

In the previous paper[1] it was reported that *trans*-1,3-di-*p*-toluenesulfoxycyclohexane, in which one of two toluenesulfoxyl groups was axial and the other equatorial in stable form, was solvolyzed more rapidly than the cis form, in which two toluenesulfoxyl groups were equatorial in stable form, in agreement with the general rule as described below. However, it was unexpectedly observed that solvolysis of *trans*-4-hydroxy- or -acetoxy-cyclohexyl *p*-tosylate in which two substituents were equatorial proceeded at a rate twice as fast as that of the corresponding cis isomer in which one of two substituents was axial and the other equatorial[2]. In connection with the unexpected result mentioned above it was desirable to study further the configuration and the reactivity of the 4-substituted cyclohexyl *p*-tosylates.

In the present work, also in relation to the problem mentioned above, the solvolysis of 1,2- and 1,4-di-*p*-toluenesulfoxycyclohexanes (described as ditosylates in this paper) has been made.

## Experimental

**Samples.** — *cis*- and *trans*-Cyclohexane-1,2- and -1,4-diols used as starting materials were those which were previously prepared[2,3]. Each of them was treated in pyridine at 0 to 5°C with two equivalent quantities of *p*-toluenesulfonyl chloride according to the conventional method, and the resulting ditosylate was recrystallized from a mixture of benzene and ligroin. The ditosylates obtained in this way had respectively the following melting points.

| Position of tosyl groups | M. p. (reported m. p.), °C |
|---|---|
| *cis*-1,2 | 129～130 (128.5～129.5[4]) |
| *trans*-1,2 | 109～110 (109[4]) |
| *cis*-1,4 | 98～98.5 (98～99[5]) |
| *trans*-1,4 | 159 (159°[5]) |

**Procedure for Rate Measurements.**—Solvolysis rates were measured at 99.8°C in ethanol (98.5% by weight), in methanol (99.5% by weight) and in acetic acid containing a slight excess of acetic anhydride, by the usual ampoule technique[1,2]. Concentrations (all given at room temperature) of ditosylates were in the range from 0.005 to 0.01 mol./l., since they are less soluble in these solvents, especially in alcohol. Solvolysis of 1,4-ditosylates was performed in 0.01 mol./l. in acetic acid and also in 0.005 mol./l. in methanol since the solubility of the compounds in ethanol was very small, and that of 1,2-ditosylates was performed in ethanol. The reactions were followed by titrating at intervals for the sulfonic acid liberated or the alkali consumed during the solvolysis. Titrations in acetic acid were carried out with a 0.05 N solution of anhydrous sodium acetate or *p*-toluenesulfonic acid in acetic acid using bromophenol blue as indicator. In methanol and ethanol, a 0.05 N aqueous solution of sodium hydroxide or hydrogen chloride was used as a standard solution for titration with phenolphthalein as indicator. Rate constants were calculated from the formula:

$$k_1 = (1/t)\ln\{a/(a-x)\}$$

in which $a$ was the initial concentration of ditosylate and $x$ was the concentration of sulfonic acid liberated at time $t$.

## Results and Discussion

The solvolysis of the di-tosylates will proceed substantially in two steps as described below, and therefore a real solvolysis rate constant for each of them is not shown by the averaged value of the rate constants calculated from the formula. In fact, a calculated rate constant increased gradually during the alcoholysis and the acetolysis, and decreased gradually during the alcoholysis in the presence of a small amount of sodium alcoholate, in agreement with the behavior of 3-methylcyclohexyl *p*-tosylate and 1,3-di-*p*-toluenesulfoxycyclohexanes previously reported[1]. But, in all cases, since the differences between the rate constants and the averaged rate constant in the solvolysis were within 5%, the solvolysis could be approximately expressed as the first order reaction. Table I lists the data for a run with *cis*-1,4-ditosylate in acetic acid. It is seen that, though the first order rate constant increases gradually during the solvolysis, it is approximately constant.

The mean rate constants of the acetolysis of the 1,4-ditosylates were not substantially changed by the addition of a small quantity

| | | Mean 0.280 |

of anhydrous sodium acetate, and therefore the acetolysis is predominantly of the unimolecular type. On the other hand, since the mean rate constants of the alcoholysis were decreased by the addition of sodium alcoholate, and under this condition the rate constant decreased during the solvolysis as described above, a part of the alkaline alcoholysis consists of the bimolecular displacement and elimination reactions based on a back-side attack on carbon and hydrogen coincident with the departure of the toluenesulfoxyl group. The rate constants and the relative rates for the isomeric di-tosylates are summarized in Tables II and III.

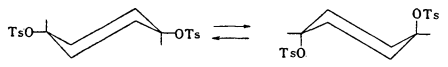
c, not contained alkali.
d, contained sodium acetate in 0.023 mol/l.

**Mechanism of Solvolysis.**—The solvolysis of the ditosylates proceeds substantially in two steps where in the first step three monotosylates are produced and in the second step they are converted into final products. For example, in the case of *trans*-1,4-ditosylate, the process is illustrated by the following formula:



where $H^+A^-$ is the solvent and Ts is the tosyl group.

In the present work, it has been observed that a calculated rate constant increased gradually during the neutral alcoholysis and the acetolysis. The increase in the rate constants is probably due to the fact that the reaction rate in the second step is higher than that in the first step, as explained for the similar behavior of 1,3-di-*p*-toluenesulfoxycyclohexanes[1]. This suggestion is supported for example by the experimental facts that the acetolysis rate of *trans*-4-acetoxycyclohexyl *p*-tosylate is 1.7 times that of the *trans*-1,4-ditosylate and 3.4 times that of the *cis*-1,4-ditosylate, and that 2-acetoxycyclohexyl *p*-tosylates[6] and 2-hydroxycyclohexyl *p*-brosylates[3] are rapidly solvolyzed, but 1,2-ditosylates are not acetolyzed.

**Relative Rate $k_{cis}/k_{trans}$.**—The relation between conformation and reactivity in a rigid cyclohexane system is very important. An axial group is sterically more strained and therefore, in general, more ionizable or easier to depart than an equatorial group. In the labile cyclohexane system, the trans form of cyclohexyl *p*-tosylate with a group such as the acetoxyl group[6] at the $\beta$-position is solvolyzed more rapidly than the cis isomer, but *trans*-2-substituted cyclohexyl *p*-tosylates and *p*-brosylates with a group such as *p*-bromobenzenesulfoxyl[6], nitroxyl[7], and hydroxyl[3] group are solvolyzed at a slightly faster or slower rate than the corresponding cis forms. *trans*-3-Alkyl[8],

6) S. Winstein, E. Grunwald and L. L. Ingraham, *J. Am. Chem. Soc.*, **70**, 821 (1948).
7) S. J. Cristol and B. Franzus, ibid., **79**, 2488 (1957).
8) S. Winstein and H. J. Holmess, ibid., **77**, 5562 (1955).

hydroxy[1], acetoxy[1] or methoxycarbonyl[9] cyclohexyl *p*-tosylate is solvolyzed more rapidly than the corresponding cis from. Further, *cis*-4-alkylcyclohexyl *p*-tosylate is solvolyzed more rapidly than the trans form[8]. The *trans*-1, 4-ditosylate has the two possible chair conformations as follows:

trans (e, e) trans (a, a)

The trans (e, e) is more stable than the trans (a, a). On the other hand, the cis form has only one chair conformation as follows:

cis (e, a) cis (a, e)

where Ts is the toluenesulfonyl group.

Similarly, also in the case of the 1, 2-ditosylates, the cis form has two chair conformations and the trans form only one. From those facts it is expected that the solvolysis rates of the *cis*-1, 2- and 1, 4-ditosylates are higher than that of the corresponding trans forms.

In the present work, the 1, 2-ditosylates were not solvolyzed in acetic acid after being heated for 20 hr. at 100°C, as reported by Criegee[4]. They were, however, sowewhat ethanolyzed and especially solvolyzed more rapidly in the presence of sodium alcoholate and the relative rate $k_{cis}/k_{trans}$ was 5.6 (see Table II). Winstein[6] reported that the relative rate of acetolysis (75°C) of 1, 2-dibromobenzenesulfoxycyclohexanes was 1.1, although the rate constants of those brosylates were very low. Those facts are in agreement with the expectation described above.

In the solvolysis of the 1, 4-ditosylates, the trans form was solvolyzed in acetic acid unexpectedly at a rate 2.2 times faster than the cis form. Also, a similar result was obtained in the acetolysis of 1, 4-dibromobenezenesulfoxycyclohexanes[10] and the ratio of $k_{cis}$ to $k_{trans}$ was 0.78. Those facts are substantially similar to the results previously obtained in the solvolysis of 4-hydroxy- and 4-acetoxycyclohexyl tosylates[2], and are not explained by the rule as described above. Up to the present, the author can not give reasons for the fact that the trans form was acetolyzed more rapidly than the cis form. However, the methanolysis of the ditosylates, especially in the presence of alkali, proceeded more rapidly than their acetolysis and the cis form was methanolyzed more rapidly than the trans form. Thus, the ratio of $k_{cis}$ to $k_{trans}$ was 0.9 in methanol without alkali, 1.1 in methanol with NaOMe in 0.013 mol./l. and 1.6 in methanol with NaOMe in 0.02 mol./l.

**Solvent and Alkali Effects.**—In general, in unimolecular reaction solvation with solvent is very important, and the solvolysis rate in acetic acid is higher than that in ethanol. Further, such an enhancement in the rate in going from ethanol to acetic acid is nicely shown in the case of unsubstituted and substituted cyclohexyl tosylates. For example, the ratio of $k_{EtOH}$ to $k_{AcOH}$ for the cis form (with a-tosyl group) of 4-*tert*-butylcyclohexyl tosylate is 0.87 and that for the trans form (with e-tosyl group) 0.72[8]. On the other hand, primary alkyl tosylates, which are sensitive to a nucleophilic attack, are more reactive in ethanol than in acetic acid, such as those shown by the solvent-rate sequences[11] (EtOH : AcOH) for MeOTs, EtOTs and *iso*-BuOTs respectively to be 80 : 1, 39 : 1 and 6.2 : 1 at 75°C.

Furthermore, a carbon atom having an a-tosyl group is more easily attacked by a nucleophilic agent than that having an e-tosyl group, and the bimolecular reaction[12] of *cis*-*tert*-butylcyclohexyl tosylate with phenolate ion proceeds more rapidly than that of the trans form.

In the present work, however, the ditosylates were solvolyzed more rapidly in alcohol, especially in the presence of alkali, than in acetic acid and the solvolysis rate of the cis forms with the a-tosyl group was enhanced more than that of the trans forms without such a group, in going from acetic acid to alcohol containing alkali. Therefore, the alcoholysis and the alkaline alcoholysis of the di-tosylates probably involve bimolecular nucleophilic attack on carbon or hydrogen in the rate-determining step, similar to the primary alkyl tosylates, but in contrast to the general cyclohexyl tosylates.

## Summary

Rates of solvolysis of *cis*- and *trans*-1, 2- and -1, 4-di-*p*-toluenesulfoxycyclohexanes were measured at 99.8°C in methanol or in acetic acid. In all cases, the solvolysis was approximately of first order.

Mean rate constants of the solvolysis increased in going from acetic acid to alcohol, and were enhanced by the addition of a small

amount of alkali, in agreement with the behavior in solvolysis of primary alkyl tosylates.

The 1, 2-isomers were not solvolyzed in acetic acid in 20 hr., and in ethanol containing EtONa in 0.02 mol./l., the ratio of $k_{cis}$ to $k_{trans}$ was 5.6.

In the case of the 1, 4-isomers, the ratio was ca. 0.5 in acetic acid, 0.9 in methanol without alkali, 1.1 in methanol with MeONa in 0.013 mol./l. and 1.6 in methanol with MeONa in 0.02 mol./l.

The author wishes to express his hearty thanks to Professor Y. Tsuzuki for his advice.

# *Phase Relationship in System $3CaO \cdot P_2O_5$-MgO-$SiO_2$*

By Toshiyuki SATA

(Received July 6, 1960)

The author already presented in 1958 the result of a study on system $3CaO \cdot P_2O_5$–MgO·$SiO_2$–$SiO_2$ in this Bulletin[1]. This is a partial system at high silica portion in the three-component system $3CaO \cdot P_2O_5$–MgO–$SiO_2$. The present report concerns a basic portion in the system $3CaO \cdot P_2O_5$–MgO–$SiO_2$, and its phase relationships are important for the study of a composition of fused phosphate fertilizer[2] and a corrosion problem of magnesia-containing basic refractories against the molten fertilizer. This report consists of four parts; system $3CaO \cdot P_2O_5$–MgO, system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$, system $3CaO \cdot P_2O_5$–MgO–$2MgO \cdot SiO_2$, and the synthesis of these to system $3CaO \cdot P_2O_5$–MgO–$SiO_2$. Phase equilibria studies in these systems have never been published in any paper.

## Experimental

Tricalcium phosphate ($3CaO \cdot P_2O_5$), forsterite ($2MgO \cdot SiO_2$), and magnesia (MgO) were used as raw materials. The first was prepared by the reaction of calcium carbonate with phosphoric acid at 1350°C as mentioned in the previous paper[1]. The second was prepared by calcining the stoichiometric mixture of magnesia and silica constituents at 1300°C. The magnesia and silica fired from 1200 to 1300°C were used as raw materials respectively. After weighing, the batches were thoroughly mixed in an agate mortar with some methyl alcohol until they became dry. They were heated in a platinum crucible or in a platinum envelope above their melting points. Then they were rapidly cooled in air or water. For batches having the melting point above 1600°C, perfect glassification was impossible. These mixing, heating, and quenching processes were repeated once more.

The silicon carbide resister furnace with an inner diameter of 25 mm. was used for this study. The sample in a platinum envelope (8×8 mm.) was suspended by a platinum wire (0.5 mm. in diameter, 200 mm. in length) at the center of the furnace tube, and quenched together with the wire in water after holding for some minutes at constant temperature (±1°C). For measuring the temperature, two kinds of thermocouples (Pt-PtRh 10% and PtRh 5%-PtRh 20%) were used. These were calibrated with the melting point of silver, copper, diopside, and palladium.

The quenched samples were powdered and examined by a polarizing microscope and by an X-ray diffractometer. Pure silicon metal was used as a standard material in X-ray examination, its accuracy being ±0.003 Å

## Results and Discussion

**System $3CaO \cdot P_2O_5$–MgO.** — In the first place, specimens slowly cooled from 1650°C were examined in their microstructure. The specimen containing 3.20% of MgO consisted of a primary crystal part of $\beta$-tricalcium phosphate and an eutectic part which is a turbid phase containing periclase spots surrounded by tricalcium phosphate matrix. The specimen containing 5.28% of MgO revealed the eutectic structure only. The specimen containing 7.98% of MgO consisted of the eutectic part and large periclase grains. The softening temperatures of small cones of these three compositions were measured on platinum plates in the usual way. It was found that their temperatures decreased in order of contents of MgO ranging from 1620 to 1530°C.

TABLE I. QUENCHING DATA IN THE SYSTEM $3CaO \cdot P_2O_5$–MgO

| No. | Composition | | | Holding | | Phases present |
|---|---|---|---|---|---|---|
| | $C_3P$ wt. % | MgO | MgO mol. % | temp. °C | time min. | |
| 193 | 99 | 1.0 | 7.2 | 1470 | 60 | $\beta$-$C_3P$, $\alpha$-$C_3P$ |
| 19 | 98.58 | 1.42 | 10.0 | 1450 | 60 | $\beta$-$C_3P$ |
| 20 | 96.8 | 3.2 | 20.0 | 1568 | 15 | $\beta$-$C_3P$, small $\alpha$-$C_3P$, periclase, glass |
| | | | | 1450 | 60 | $\beta$-$C_3P$, periclase |
| 21 | 94.7 | 5.3 | 30.0 | 1568 | 15 | $\beta$-$C_3P$, periclase |
| 22 | 92.1 | 7.9 | 40.0 | 1568 | 15 | $\beta$-$C_3P$, periclase |
| | | | | 1555 | 10 | 〃 |
| | | | | 1524 | 10 | 〃 |

The subsequent quenching runs, as listed in Table I, indicated that the specimen containing 3.20% of MgO, quenched from 1568°C, consisted of tricalcium phosphate ($\beta$ and small amount of $\alpha$), periclase, and glass. It is estimated from these results that this $3CaO \cdot P_2O_5$–MgO system is a binary one and its eutectic occurred at a composition of 4～7% of MgO and at a temperature near 1570±20°C, as shown in Fig. 1.

It is noted from Fig. 2, in which some X-ray diffraction lines of $\beta$-tricalcium phosphate quenched from 1450°C are plotted, that 15±3 mol. % of MgO is apparently dissolved into $\beta$-tricalcium phosphate as a solid solution. Another fact is that the transition temperature of $\beta$-$\alpha$ modification is considerably elevated nearly to 1550°C with increasing magnesia contents. These facts concerning tricalcium phosphate are difficult to discuss further without direct examination by a high-temperature X-ray technique. There is a new presentation of super $\alpha$-$3CaO \cdot P_2O_5$ phase by Nurse et al.[3]

the softening points of this system. But the phase relationships of this system have not been presented.

Results of the quenching runs of this two-component system are summarized in Table II, from which a preliminary phase diagram of this system was obtained as shown in Fig. 3. Nagelschmidtite[6] (which was identified by a hexagonal X-ray pattern similar to that in $3CaO \cdot P_2O_5$–$2CaO \cdot SiO_2$ system) appeared over a wide range of this system above a temperature of 1350°C, and was crystallized primarily in the composition range of $3CaO \cdot P_2O_5$ side.

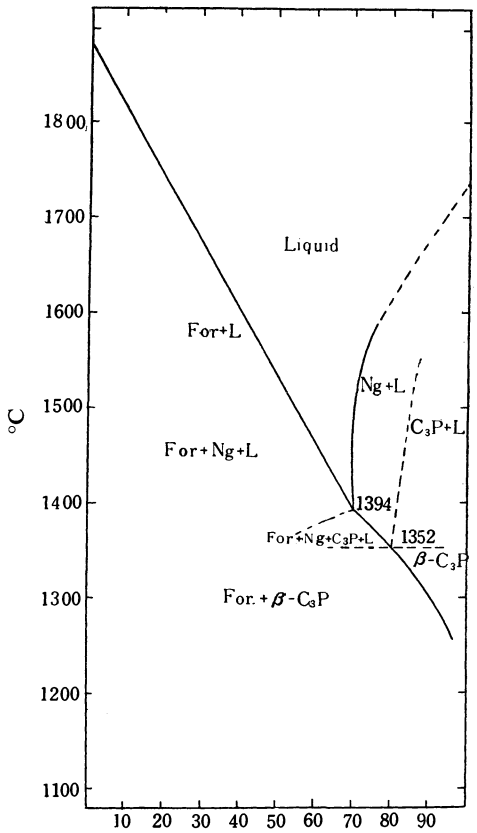

Fig. 3. The system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$.

The liquidus line falls very steeply to a temperature minimum at 1394°C and a composition of 70% $3CaO \cdot P_2O_5$ and 30% $2MgO \cdot SiO_2$. Below this temperature 1394°C, the secondary crystallization temperature of forsterite from nagelschmidtite and liquid decreases. Below 1352°C, nagelschmidtite and liquid disappeared, and forsterite and β-tricalcium phosphate phase only appeared. The meaning of this disappearance temperature 1352°C is not clear now. β-Tricalcium phosphate seems to contain magnesia component, judging from the fact that the crystallization temperature of forsterite from β-tricalcium phosphate phase descends with increasing contents of $3CaO \cdot P_2O_5$, and *d*-spacings of β-tricalcium phosphates in their X-ray patterns decrease till the content of 15 mol. % (7.4 weight %) of $2MgO \cdot SiO_2$ is attained, as shown in Fig. 4. Below about 1200°C, this two-component system is a binary one consisting of forsterite and β-tricalcium phosphate.

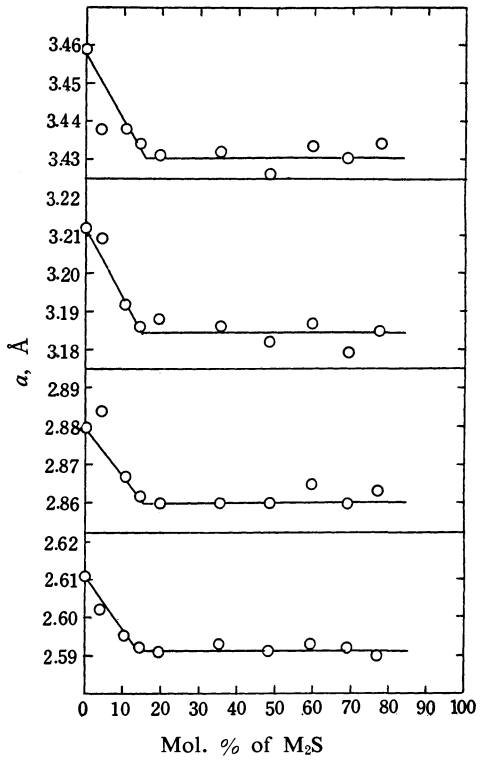

Fig. 4. The change in spacings of β-tricalcium phosphate in the system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$.

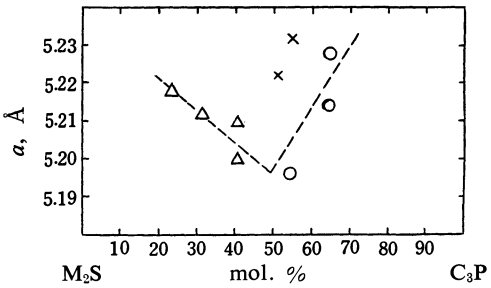

Fig. 5. The change in lattice constants of nagelschmidtite in the system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$ at 1370~1490°C.

× Ng.+β-$C_3P$+L

6) G. Nagelschmidt, *J. Chem. Soc.*, 1937, 865.

When the lattice constants $a$ of hexagonal negelschmidtite are calculated from their (110) peak and plotted against molar compositions, a valley-type change are obtained, whose bottom may occur at the composition of temperature minimum of liquidus as shown in Fig. 5.

From the results mentioned above, this system was found to be complex, owing to the formation of nagelschmidtite above 1350°C, below which it is considered to be binary.

**System $3CaO \cdot P_2O_5$ – MgO – $2MgO \cdot SiO_2$.** — Although all of the specimens of this system slow-cooled to room temperature consisted of $\beta$-tricalcium phosphate, periclase, and forsterite, the primary crystal in the area of high content of $3CaO \cdot P_2O_5$ was nagelschmidtite, being the same as that mentioned in the system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$. But it was found by the preliminary quenching test that a ternary eutectic among their three components seems to be present. This paragraph described results of quenching experiments made to decide the position of a three-component eutectic.

The twelve compositions, which are expected to locate near the eutectic, were taken on the two tie lines connecting No. 24 ($60C_3P$–40M) with No. 72 ($75C_3P$–$25M_2S$) and No. 74 ($67.5C_3P$–$32.5M_2S$) along the $C_3P$–$M_2S$ join, as represented in Fig. 6. Results obtained are listed in Table III, from which a eutectic position was graphically decided to locate at the composition of 70% $3CaO \cdot P_2O_5$, 21% MgO and 9% $SiO_2$, and at 1362±5°C.

This eutectic temperature is close to the transition point between nagelschmidtite and $\beta$-tricalcium phosphate. It was, however, found that $\beta$-tricalcium phosphate was present at this eutectic temperature. The primary field of nagelschmidtite was approximately estimated as a dotted boundary from the previous results of the investigation in the systems $C_3P$–MS and $C_3P$–$M_2S$. The facts that a small amount of periclase was present even in the specimens quenched above liquidus temperatures of all compositions, and that nagelschmidtite was present even in the primary field of periclase or forsterite above eutectic

temperature, were neglected in drawing this phase diagram at the step of this study, Detailed studies of the system containing nagelschmidtite will be made in future, because of the interesting scope of nagelschmidtite structure (super $\alpha$-tricalcium phosphate by Nurse or its solid solution containing MgO and $SiO_2$).

**System $3CaO \cdot P_2O_5$–MgO–$SiO_2$.** — The preliminary phase diagram, as shown in Fig. 6, was obtained from the results of previous paragraphs and the separate report of the system $3CaO \cdot P_2O_5$–$MgO \cdot SiO_2$–$SiO_2$[1]. The probable boundary curve between the phosphate and the forsterite fields in the $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$–$MgO \cdot SiO_2$ triangle was drawn from the results without a cooling experiment.

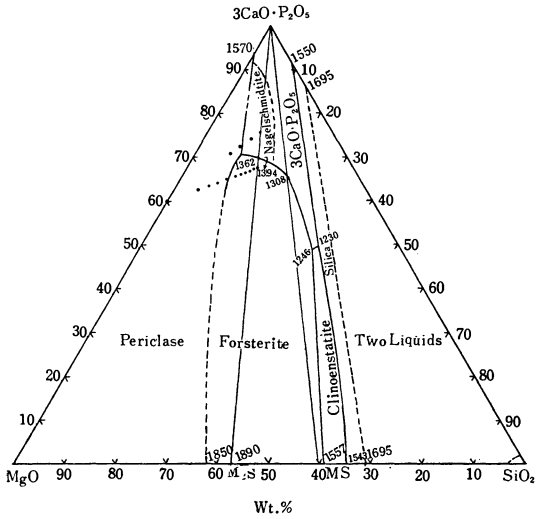

Fig. 6. The system $3CaO \cdot P_2O_5$–MgO–$SiO_2$.

## Summary

The phase relationship in the system $3CaO \cdot P_2O_5$–MgO–$SiO_2$ was investigated by a cooling experiment in the usual manner. The system $3CaO \cdot P_2O_5$–MgO, a side of this triangle, is a simple binary one, its eutectic being located at the composition of 4~7% by weight of magnesia and 1570±20°C. The system $3CaO \cdot P_2O_5$–$2MgO \cdot SiO_2$ is not binary over the temperature of about 1350°C, below which it is considered as binary. Above 1350°C, nagelschmidtite is formed over the whole composition range and crystallized primarily from liquid at a high $3CaO \cdot P_2O_5$ portion. The minimum liquidus temperature is 1394°C, which is located at the composition of 70% $C_3P$ and 30% $M_2S$. The system $3CaO \cdot P_2O_5$–MgO–$2MgO \cdot SiO_2$ was considered to be complex owing to the presence of nagelschmidtite, but the eutectic among their three components is located at the composition of 70% $3CaO \cdot P_2O_5$, 21% MgO, and 9% $SiO_2$, and 1362±5°C.

From the results described above and from those of the author's previous reports, the preliminary phase diagram of the system $3CaO \cdot P_2O_5$–MgO–$SiO_2$ was constructed. In this diagram the problem that nagelschmidtite is formed in the composition range which is rich in $3CaO \cdot P_2O_5$ was not mentioned in detail. In addition to this, it was found by X-ray examination that $\beta$-tricalcium phosphate may be apparently stabilized at a higher temperature than $\beta$-$\alpha$ transition point, and has the appearance of dissolving magnesia component.

The author acknowledges the constant help and encouragement given by Professor R. Kiyoura, Tokyo Institute of Technology. This work was conducted as a part of a program to investigate the corrosion problems of various refractory bricks in the manufacture of fused phosphate fertilizer.

# *Interactions of Surface Active Agents with Congo Red*

By Makoto HAYASHI

(Received April 11, 1960)

Interactions between various surface active agents and many substances such as protein, dyes and polymers have been studied for contribution to the elucidation of fundamental properties of surface active agents to or extend their applications[1-4]. It has been reported that some dyes such as azo, thiazine or triphenylmethane dyes were changed in their spectra with the addition of various substances such as agar, chondroitin sulfate, nucleic acid or albumin[5-9]. The similar effects of surface active agents, though the greater part of these are ionic ones, on the spectral changes of some dyes have also been studied in recent years[10-15]. In the case of non-ionic detergents, a complex formation has been predicted between dyes and detergents[12,15], but details are not known.

In this paper, the metachromatic effects of a non-ionic surface active agent, Tween 80 and a cationic one, cetyl pyridinium chloride on the absorption spectrum of Congo Red solution are reported.

## Experimental

**Reagents.**—The Congo Red used in this experiment was purified by salting out with sodium acetate and recrystallizing several times from water. Tween 80 (Atlas Powder Co.) was dissolved in water to about 5%, ionic impurities were removed by means of ion-exchange resins (Amberlite IR-120, IRA-400), then evaporated and dried in vacuo at about 50°C. Other reagents were recrystallized from water before use.

**Absorption Spectra.**—The absorption spectra of the solutions were measured with a Beckman type spectrophotometer using a 1 cm. glass absorption cell.

**Procedures.**—The procedure used in the preparation of the dye solutions to be measured was as follows: 1 ml. of the Congo Red stock solution ($2.34\times10^{-3}$ mol./l.) was measured in a 100 ml. volumetric flask. Then 1 ml. of the concentrated buffer solution was pipetted in and an appropriate amount of 4.9% Tween 80 solution was added to the flask to obtain the desired pH and detergent concentrations. The entire contents of the flask were then diluted to 100 ml. and stirred sufficiently. It was left to stand for about 30 min. after the preparation in order to secure an equilibrium (it had been confirmed that 30 min. was sufficient for the equilibrium), then the spectrum was measured using an aliquot part of the solution. Another part of solution was used to determine the pH of the solution. In the experiments of cetyl pyridinium chloride, the sample solutions prepared were centrifuged and then the supernatant solutions were used to measure the spectra.

## Results

Fig. 1 represents the absorption spectra of Congo Red solution of $2.34\times10^{-5}$ mol./l. in the presence of various amounts of Tween 80 at the fixed pH of 3.4. The spectrum varies gradually with the addition of Tween 80 and the new absorption peak appears at about 510 m$\mu$. This peak increases in height with increasing concentration of Tween 80 and it becomes constant above the Tween 80 concentration of 0.309%. The isosbestic point is clearly observed among these spectra, which may suggest that there is a definite molecular constitution of the product. An isosbestic point of this kind was also observed in other reports[3,13,15] which studied the interaction between some dyes such as Methyl Orange, Benzopurpurine 4B and Erythrosine and non-ionic or cationic detergents.

Fig. 2 shows the results measured at pH 4.3. As a whole the spectra are similar to those in Fig. 1, but the spectral change occurs with the addition of a smaller amount of Tween 80 than in the case of that at pH 3.4. The wavelength of the absorption peak of the product is the same in both cases.

Fig. 3 shows the change of the absorbance at the absorption peak with the concentration

of Tween 80 at three values of pH of the dye solution.

The identical effects of Tween 80 are also observed in either the neutral or basic medium, the results being shown in Figs. 4 and 5. In these cases the absorbance at 510 mμ became constant with the addition of a very small amount of the detergent and their spectral changes were not remarkable as compared with that in the acidic medium.

When cetyl pyridinium chloride (c. p. c.) is added to the Congo Red solution at pH 4.2, a spectral shift occurs and indicates the presence of an interaction product between c. p. c. and Congo Red, as shown in Fig. 6. In this case, Congo Red is dispersed by a small quantity of c. p. c., and has an absorption peak at about 660 mμ. When the concentration of the detergent increases, a new peak appears at 460 mμ which may be assigned to the interaction product between Congo Red and c. p. c. This peak increases in height with increasing

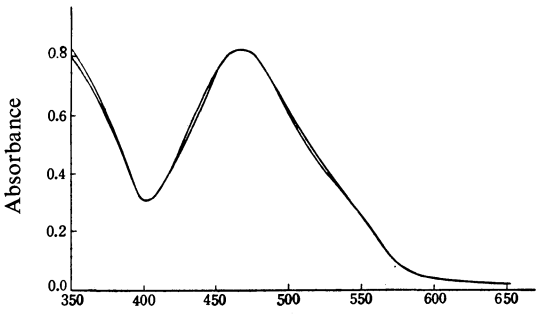

Fig. 10. Effect of the addition of cetyl pyridinium chloride at pH 1.45; concentration of Congo Red, $2.88\times10^{-5}$ mol./l; concentration of cetyl pyridinium chloride, 7.3 and $14.5\times10^{-5}$ mol./l.

concentration of c. p. c. The interaction products are precipitated in the presence of a certain amount of the detergent and then dispersed again with further increase of the concentration of c. p. c. The same effect of c. p. c. is observed in the neutral medium as shown in Fig. 7. In either case the interaction products are completely precipitated in the concentration range where the mole ratio of Congo Red to c. p. c. is about 1/2 and begins to be dispersed with further increase of c. p. c. concentration as shown in Fig. 8. Figs. 9 and 10 show that the same interaction product is also formed in the more acidic medium.

## Discussion

The absorption peak at 510 mμ, as seen from Figs. 1, 2, 4 and 5, is considered to indicate that Congo Red and Tween 80 make a definite molecular compound irrespective of the pH of the solution. The results of Fig. 3 show that the hydrogen ion in the medium plays an important role in the equilibrium of the interaction between Congo Red and Tween 80. Either the acid or the base form of Congo Red is similarly varied in its spectrum and well dispersed by the addition of a sufficient amount of Tween 80. However, the amount of detergent required to show just sufficient change increases with lowering the pH of the medium. Although in acidic Congo Red solutions containing insufficient Tween 80 (below 0.309% of Tween 80 concentration at pH 3.4), precipitates appear by aging (about 24 hr. after preparation), in the systems containing sufficient detergent, no precipitation occurs. This is probably due to a kind of solubilization, but the precise mechanism is not known at the present.

In view of these results, it may be considered as follows: in an acidic medium, an acid form of Congo Red is equilibrated to a base form as in the following formula,

$$R\begin{matrix}NH_2\\NH_2\end{matrix} + 2H^+ \rightleftharpoons R\begin{matrix}NH_3^+\\NH_3^+\end{matrix} \qquad (1)$$

It is possible to assume the following equilibrium process for the spectral change,

$$R\begin{matrix}NH_2\\NH_2\end{matrix} + 2\,\text{Tween 80} \rightleftharpoons R\begin{matrix}NH_2-\text{Tween 80}\\NH_2-\text{Tween 80}\end{matrix} \qquad (2)$$

In this expression $R\begin{matrix}NH_2\\NH_2\end{matrix}$, $R\begin{matrix}NH_3^+\\NH_3^+\end{matrix}$ and $R\begin{matrix}NH_2-\text{Tween 80}\\NH_2-\text{Tween 80}\end{matrix}$ represent the base form of Congo Red, the acid one and the interaction product respectively.

The effect of pH (Fig. 3) may be interpreted qualitatively by these assumptions as follows. When the pH of the medium is lowered, the concentration of the base form decreases according to the formulation 1, which results in an increase of the amount of Tween 80 required to give a definite absorbance. In either neutral or basic medium, the same processes are probably considered to occur from the results of Figs. 4 and 5. In these cases, however, the concentrations of the base form become so great that the process is mainly represented by the formulation 2 and the same effect is produced with a smaller amount of Tween 80 than that in the acidic medium.

Thus, the amino groups of Congo Red molecule are considered to be blocked with Tween 80 and the products are well dispersed, since the aggregation of Congo Red molecules is prevented by the attachement of Tween 80. It has been observed that the adsorption of Congo Red for filter paper or cotton (which is considered to have a negative surface), was reduced remarkably by the addition of Tween 80, which may also be interpreted by a similar process.

In the case of cetyl pyridinium chloride, the wavelength of the new peak is 460 mμ, the position of which is not affected by the medium pH as shown in Figs. 6 and 7.

When the concentration of the detergent is $4.2\times10^{-5}$ mol./l., at which the mole ratio of Congo Red to detergent is 1/2, the products are most hydrophobic and precipitated. They have a trend to be dispersed both sides of this ratio. In the lower concentrations of the detergent, in which the mole ratio is below about 1/1, neither precipitation nor metachromatic color is oberved. In the higher concentrations above the mole ratio of about 1/4, the products are well dispersed. The dispersion in the latter case is not considered to be due always to solubilization[11], since the system being dispersed with sufficient c. p. c. produces no precipitation even by means of dilution.

From these facts, it is considered that Congo Red is bound at the anionic loci, sulfonates, with c. p. c. by ionic force. It is probable that the products whose sulfonates are blocked become hydrophobic, but with further c. p. c. they will become hydrophilic again owing to the adsorption of the excess of c. p. c. with the hydrophilic groups towards water.

## Summary

The spectral changes of Congo Red solution with the addition of Tween 80 and cetyl pyridinium chloride were measured at various pH.

The wavelength of the absorption peak of

the interaction product between Congo Red and Tween 80 is 510 mμ in the acidic medium as well as those in the neutral and the basic ones, from which it is considered that they produce a molecular compound of a definite constitution irrespective of the medium pH. However, since the amount of Tween 80 required to show the same effect in spectra increases with lowering pH, it is considered that only a base form of Congo Red is probably active and binds with Tween 80 at the amino groups.

The solutions of Congo Red containing sufficient cetyl pyridinium chloride have an absorption peak at 460 mμ. The product is completely precipitated as the ratio of Congo Red to cetyl pyridinium chloride is 1/2 and dispersed in both sides of this ratio, which depends little on the medium pH. This is considered to show that cetyl pyridinium chloride binds with Congo Red at the sulfonate groups, the product becomes most hydrophobic as two sulfonates in a molecule are blocked and hydrophilic with an excess of the detergent.

In conclusion, the author wishes to express his sincere thanks to Professor R. Matsuura of Kyushu University for his kind guidance and encouragement during this experiment, and also to Dr. H. Kimizuka of Kyushu University for his supply of the cationic detergent and discussion concerning this work.

# *Studies on the Chemical Forms of the Recoil Products in Some Neutron-Irradiated Phosphorus Compounds*

By Kenji YOSHIHARA and Tetsuyoshi YOKOSHIMA

(Received July 22, 1960)

The Szilard-Chalmers effect in the neutron-irradiated phosphorus compounds is rather complicated. This phenomenon was studied by several authors, but some important problems seem to be still left without any clear solution. In 1940, Libby[1] studied the Szilard-Chalmers effect in phosphate and phosphite, and found that phosphite is formed in neutron-irradiated phosphate. The retention of phosphate was about 50%. Thomas et al.[2] studied similar effects. In 1951, Fiskell[3] discovered some formation of hypophosphite in neutron-irradiated phosphate.

Fiskell et al.[4] continued further investigation on the Szilard-Chalmers effect of calcium phosphates, and found that pyro- and meta-phosphate are formed besides hypophosphate. Aten et al[5]. also investigated the formation of the polyatomic species in several neutron-irradiated phosphorus compounds, and demonstrated the presence of pyrophosphate in the recoil products. In the papers mentioned above the precipitation method was used for the analysis of the irradiated phosphorus compounds, and therefore exact determination of the complicated products was difficult.

Recently, the technique of paperelectrophoresis has been developed and has been applied successfully to the separation of many components in the complicated system. Sellers et al.[6] studied the chemical form of the recoil products in various phosphorus compounds by this method. Sato et al.[7] further investigated the question in the same way. These authors[6,7] reported that the principal component in each case was the parent species, and besides this principal component several components appeared in the chromatogram in small percentages. They argued that neutron-irradiation of various phosphates does not bring about extensive disruption of the P-O bonds or the P-O-P linkage.

Although paper electrophoresis is an excellent method for the separation and the determination of various phosphorus compounds, it

should be limited to the analysis of the species which are stable to the electric current and to the heat liberated on the paper for several hours. Therefore we felt it would be necessary to compare the results with those by ordinary paper chromatography. We were particularly interested in the formation of polyatomic species which might be produced by the heat liberated in the neighborhood of the recoil atom. Sato et al.[7] detected a component presumably corresponding to pyrophosphate in neutron-irradiated phosphate, but they did not show the percentage of this component. Aten et al.[5] showed that an appreciable fraction of pyrophosphate is formed from phosphate. However, the formation of higher polyphosphates than pyrophosphate might occur, but this has not been shown so far. Thus we studied the chemical form of the recoil products in the neutron-irradiated phosphorus compounds by paper chromatography, and found several new facts.

## Experimental

**Target Materials.**—The target materials used in this work are as follows: $H_3PO_4$; $NaH_2PO_4$, $NaH_2PO_4 \cdot H_2O$, $NaH_2PO_4 \cdot 2H_2O$, $NH_4H_2PO_4$, $KH_2PO_4$, $Na_2HPO_4$, $Na_2HPO_4 \cdot 12H_2O$, $(NH_4)_2HPO_4$; $Na_3PO_4$, $Na_3PO_4 \cdot 12H_2O$, $Zn_3(PO_4)_2$; $Na_4P_2O_7$, $Na_4P_2O_7 \cdot 10H_2O$; $Na_2HPO_3 \cdot 5H_2O$.

These substances are guaranteed reagents of the Kanto Chemical Co. or of the Wako Pure Chemical Ind. Before the experiment the purity of each substance was tested by means of radioactivation analysis; the sample was dissolved in water (zinc phosphate was dissolved in dilute hydrochloric acid), and one drop of the solution was put on the filter paper for chromatography; this was developed with *n*-butanol which had been shaken with the same volume of 2 N nitric acid; the filter paper was dried and irradiated in a nuclear reactor; after appropriate cooling time, the radioautogram of the filter paper was prepared. Each test gave no impure component.

**Irradiation.**—Solid targets were irradiated in the Irradiation Hole No. 3, 12 or 15 in the nuclear reactor JRR-1 (homogeneous solution type). Hole No. 16 was used for short irradiation of solid targets. Liquid targets were irradiated in Hole No. 6. The standard thermal neutron flux in each hole is given as follows[8].

| | |
|---|---|
| No. 3. | $0.48 \times 10^{12}$ n/cm$^2$/sec. |
| 6. | 0.40 〃 |
| 12. | 0.38 〃 |
| 15. | 0.22 〃 |
| 16. | 0.51 〃 |

These values were given at the operation of 40 kW. per hour. In the whole period of this work the reactor was operated at 40 kW. per hour. It is desirable to irradiate the sample in the same position of the same hole, but this could not be realized for all cases. Presumably the variation of neutron flux in these experiments will not bring about any difference in the results. In Hole No. 16 (the nearest from the reactor core) the contribution of fast neutrons to the total radioactivation was tested by the cadmium foil absorption method. The result showed that about 5% of the radioactivity was produced by fast neutrons (residual 95% by slow and thermal neutrons). In the other holes contribution of neutrons to the total radioactivation will be smaller. Perhaps the contribution of fast neutrons will not greatly affect the results in all the experiments. Except in the case of short irradiation, the targets were usually irradiated for 5 hr. a day, and for successive three days a week. The irradiation temperature did not exceed about 50°C in any of the experiments.

**Analysis.**—*Paper chromatography.*—The irradiated target was dissolved in water, and one drop of the solution was put on the starting point of the filter paper, Tôyô No. 53 (2 cm × 40 cm). Other sorts of filter paper such as Tôyô No. 50, 51, 51A, 52 and 54 were tested, but No. 53 gave the best results. Several developing solvents were tested, and the best results were obtained by the use of *n*-butanol which had been shaken with the same volume of 2 N nitric acid. Development was made by the one-dimensional ascending method for about 15 hr., the travelling distance being 23~27 cm.

*Detection of Radioactive Zones.* — After development the filter paper was dried well and the radioautogram was taken on Fuji X-ray film. For the determination of the components on the chromatogram, the paper was cut in sections of 0.5 cm. width, and the radioactivity was measured by a proportional counter (Radiation Counter Laboratories, Inc.; an end-window type; flow gas, methane; counting efficiency about 30%,). When other radionuclides such as $^{24}$Na and $^{42}$K were produced, decay curves were investigated to distinguish them from $^{32}$P.

**Miscellaneous.**—Experiments on the time-dependency of $^{32}$P were carried out at room temperature (about 20°C) in air (under atmospheric pressure). Enrichment of $^{32}$P was roughly examined by the coloration test on the chromatogram obtained. A solution of ammonium molybdate was sprayed on the filter paper. In the cases of phosphate, pyrophosphate and higher polyphosphates a yellow color appeared, and in the cases of phosphite and hypophosphite a pale blue color appeared after the filter paper was heated. Thus amounts of the phosphorus compounds were roughly estimated.

## Result

There were small changes in $R_f$ values according to the experimental condition, but they did not exceed 0.02. In Fig. 1, chromatograms of several species are shown. The $R_f$ values of phosphate, phosphite* and pyrophosphate

8) K. Takahashi, M. Imai and Y. Kato, *JAERI-1004* (1958).

* The $R_f$ value of hypophosphite is nearly the same as that of phosphite and they could not be distinguished from each other. The sum of these fractions are shown in the tables.

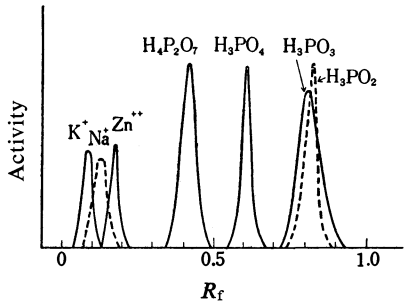

Fig. 1. $R_f$ values of some phosphorus compounds.

were referred to in each experiment. In some cases an unknown species was developed at an $R_f$ value of 0.95~1.0. This was usually observed as a very small spot. In almost all the experiments, spots appeared at the $R_f$ value of 0.05~0.4. Usually these were not clear but diffused and trailing. Sometimes two or three spots appeared in these parts. On the other hand, when a disodium hydrogen phosphate sample was heated and dehydrated into pyrophosphate and higher polyphosphate, this sample always showed the spots at the $R_f$ value of 0.05~0.4 besides a spot of pyrophosphate. Moreover, trimetaphosphate and hexametaphosphate were developed at the $R_f$ value of 0.05~0.1. Therefore the spots at the $R_f$ value of 0.05~0.4 were considered to be due to higher polyphosphates. In some experiments a spot appeared at the starting point of the chromatogram. This small fraction seems to be due to elementary phosphorus as was suggested by previous authors[6,7]. Oxidation of phosphorus might occur because the targets were irradiated in air. In the tables the sum of the percentages of the fractions is not always 100%, because the fractions of the tailing part of each spot, of the spot at the starting point, and of the spot at the $R_f$ value of 0.95~1.0 are omitted. Errors shown in the tables include not only counting errors but errors based on incomplete separation of the spots.

The enrichment of $^{32}P$ was examined by the coloration already mentioned. Except for the target compound the chemical species which appeared in the chromatogram were not detected by the test. Comparing it with the radioactivity data in the tables, this result shows that the chemical species other than the target compound are enriched by the Szilard-Chalmers effect.

The test for radioactive gases such as phosphine and diphosphine was omitted in this work. As shown in Sellers's work[6] these were present only in a very small percentage.

**Phosphoric Acid.** — Liquid phosphoric acid was irradiated in Hole No. 6 (neutron flux: $0.40\times10^{12}$n/cm$^2$/sec.) in JRR-1 for 5 hr. The results are shown in Table I. Small changes in the distribution are observed with the time elapsed. Most of $^{32}P$ atoms are present as phosphoric acid, and small portions are present as phosphorous and pyrophosphoric acids. Phosphorous acid and pyrophosphoric acid seem to change slowly into phosphoric acid. Besides these, higher polyphosphates fractions were detected.

**Potassium Dihydrogen Phosphate.**—The target was irradiated in Hole No. 15 (neutron flux: $0.22\times10^{12}$n/cm$^2$/sec.) in JRR-1 for 15 hr. The results are shown in Table II.

were not completely separated. Phosphate and phosphite fractions did not show remarkable change with standing time.

**Ammonium Dihydrogen Phosphate.** — Two samples were tested. Sample I was irradiated in Hole No. 16 (neutron flux: $0.51 \times 10^{12}$n/cm$^2$/sec.) for 1 hr. and Sample II was irradiated, in Hole No. 12 (neutron flux: $0.38 \times 10^{12}$n/cm$^2$/sec.) for 15 hr. The results are shown in Table III. The sum of the fractions of phosphate and phosphite in Table III is almost constant, 61~62%, and the sum of pyrophosphate and higher polyphosphates is 37~38% except for the result after 17 days for Sample II.

**Sodium Dihydrogen Phosphates.** — Hydrous and anhydrous salts were tested. The results were markedly different from each other.

i) *$NaH_2PO_4 \cdot 2H_2O$.*—The target was irradiated in the Hole No. 12 (neutron flux: 0.38 $10^{12}$n/cm$^2$/sec.) for 15 hr. The results are tabulated in Table IV. The data show some irregularities especially in the fractions of pyrophosphate and higher polyphosphates, but time dependency of the distribution seems to be small. The experiment was not done immediately after irradiation because of the formation of $^{24}Na$ (half-life: 15.0 hr.).

ii) *$NaH_2PO_4 \cdot H_2O$.*—The target was irradiated in Hole No. 15 (neutron flux: $0.22 \times 10^{12}$n/cm$^2$/sec.) for 15 hr. The result shown in Table V are similar to those for $NaH_2PO_4 \cdot 2H_2O$.

iii) *$NaH_2PO_4$.*—The anhydrous salt was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$ n/cm$^2$/sec.) for 5 hr. The results shown in Table VI are different from those for the hydrous salts. The difference is as follows. 1) The retention for the anhydrous salt is smaller than those for the hydrous salts. 2) The sum of the pyrophosphate and higher polyphosphate fractions for the anhydrous salt is larger than those for the hydrous salts. 3) The phosphite fraction for the anhydrous salt is larger than that for the hydrous salts.

**Diammonium Hydrogen Phosphate.**—The target was irradiated in Hole No. 12 (neutron flux: $0.38 \times 10^{12}$n/cm$^2$/sec.) for 15 hr. The results are shown in Table VII.

The sum does not attain to 100% because of the presence of tailing between the spots of pyro- and orthophosphate. The time dependency of distribution seems to be small. Three peaks appear in the fractions of polyphosphates.

**Disodium Hydrogen Phosphates.** — Both hydrous and anhydrous salts were tested.

i) *$Na_2HPO_4 \cdot 12H_2O$.*—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results shown in Table VIII are different from the data for $Na_2HPO_4 \cdot 2H_2O$ and $Na_2HPO_4 \cdot 5H_2O$ in Aten's experiments[5]. Phosphite or hypophosphite can not be detected in Table VIII, while a large percentage of phosphite (or hypophosphite) appeared for $Na_2HPO_4 \cdot 2H_2O$ and $Na_2HPO_4 \cdot 5H_2O$ in Aten's work. In the table, the percentage of phosphate slowly increases with standing time while the percentage of pyrophosphate slowly decreases. Apparently, this is likely to be hydrolysis of pyrophosphate in to phosphate.

ii) *$Na_2HPO_4$.*—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results are listed in Table IX. These are somewhat different from those in Aten's[5] and Sellers's work[6].

The distribution shows similar tendencies as those for $NaH_2PO_4$ (Table VI). These results are markedly different from those for the hydrous salt. 1) The retention for the anhydrous salt is smaller than that for the hydrous salt. 2) Fraction of pyrophosphate and higher polyphosphates in the anhydrous salt is larger than that in the hydrous salt. 3) An appreciable fraction of phosphite appears in the anhydrous salt, while it does not appear in the hydrous salts.

**Trisodium Phosphates.**—Both hydrous and anhydrous salts were tested.

i) *$Na_3PO_4 \cdot 12H_2O$.*—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results are listed in Table X.

Fractions of phosphate and phosphite show remarkable changes with standing time. In Fig. 2, these changes are shown. Phosphite is slowly converted into phosphate.

ii) *$Na_3PO_4$.*—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results are shown in Table XI.

Changes of fractions of phosphate and phosphate are shown in Fig. 3. The difference between the results of the hydrous and of the anhydrous salts is as follows. 1) Time dependency is remarkable in the hydrous salt, while it is scarcely ever observed in the anhydrous salt. 2) Retention in the hydrous salt is greater than that in the anhydrous salt. 3) Fractions of pyrophosphate and higher polyphosphates for the anhydrous salts are larger than that those in the hydrous salt.

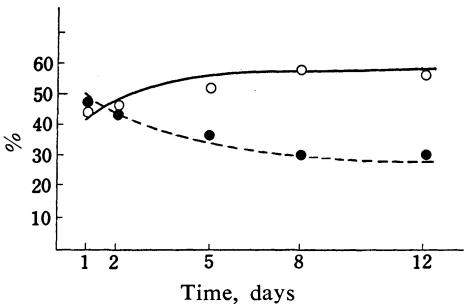

Fig. 2. Variation of percentages of $^{32}$P components in $Na_3PO_4 \cdot 12H_2O$. (The phosphate content in % is shown by the solid line and the phosphite (+hypophosphite) content in % is shown by the broken line).

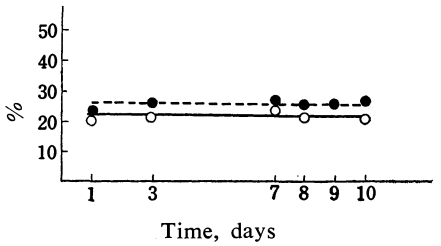

Fig. 3. Variation of percentages of $^{32}$P components in $Na_3PO_4$. (The phosphate content in % is shown by solid line and the phosphite (+hypophosphite) content in shown by the broken line).

**Zinc Phosphate.**—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results are shown in Table XII. The results were similar to those for $Na_3PO_4$ (anhydrous).

**Sodium Phosphite** ($Na_2HPO_3 \cdot 5H_2O$). — The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$n/cm$^2$/sec.) for 5 hr. The results are tabulated in Table XIII.

TABLE XI. SZILARD-CHALMER EFFECT IN $Na_3PO_4$

TABLE XIV. SZILARD-CHALMERS EFFECT IN $Na_4P_2O_7 \cdot 10H_2O$

| Chemical forms of $^{32}P$ | Time elapsed after irradiation (days) | | | | |
|---|---|---|---|---|---|
| | 2 | 5 | 12 | 15 | 22 |
| | % | % | % | % | % |
| Phosphate | 47.9±2.4 | 44.2±2.2 | 51.4±2.5 | 53.9±2.7 | 50.2±2.5 |
| Phosphite (+hypophosphite) | — | — | — | — | — |
| Pyrophosphate | 45.3±2.3 | 43.4±2.2 | 35.5±1.8 | 34.5±1.8 | 38.1±1.9 |
| Higher polyposphates | 7.1±0.5 | 12.1±0.9 | 12.8±0.9 | 11.0±0.8 | 11.6±0.8 |

TABLE XV. SZILARD-CHALMERS EFFECT IN $Na_4P_2O_7$

| Chemical forms of $^{32}P$ | Time elapsed after irradiation (days) |
|---|---|
| | 4 |
| | % |
| Phosphate | 9.4±1.6 |
| Phosphite (+hypophosphite) | 24.8±0.9 |
| Pyrophosphate | 36.2±4.2 |
| Higher polyphosphates | 26.5±2.3 |

Several components also appear in the chromatogram, but the major component is the parent substance. Pyrophosphate and higher polyphosphates are detected in appreciable quantities. Changes by standing time are not great.

**Sodium Pyrophosphates.**—Both hydrous and anhydrous salts were tested.

i) *$Na_4P_2O_7 \cdot 10H_2O$.*—The target was irradiated in Hole No. 3 (neutron flux: $0.48 \times 10^{12}$ n/cm$^2$/sec.) for 5 hr. The results are listed in Table XIV.

The distribution slightly changed by standing time.

ii) *$Na_4P_2O_7$.*—The anhydrous salt was irradiated in Hole No. 12 (neutron flux: $0.38 \times 10^{12}$ n/cm$^2$/sec.) for 15 hr. The result is shown in Table XV.

There are great differences between the results of the hydrous and of the anhydrous salt. 1) The phosphate fraction in the anhydrous salt is much smaller than that in the hydrous salt. 2) The phosphite fraction is not detected for the hydrous salt, while it is more than 20% for the anhydrous salt.

## Discussion

On the study on the Szilard-Chalmers effect, the exchange reaction between the separated atoms and parent substance is an important factor. If this exchange reaction occurred rapidly, we could not observe the Szilard-Chalmers effect. Several exchange reactions of phosphorus acids have been investigated so far. No isotopic exchange of phosphorus was

detected in the systems: $H_3PO_4+H_3PO_2$[9,10], $H_3PO_4+H_3PO_3$[10,11], $H_3PO_4+(HPO_3)_3$[12], $(NaPO_3)_3+(NaPO_3)_6$ and $(NaPO_3)_3$[13], $NaH_2PO_4+(NaPO_3)_6$[13]. Therefore, the effect of the exchange reaction between the parent substance and the daughter species can be ignored in the present paper. The phosphite fraction seems to become larger in the order of the targets of phosphoric acid, primary, secondary and tertiary phosphate. But this is not applicable to the hydrous salts.

Ammonium chromate[14] and iodate[15] show a much lower retention value in the Szilard-Chalmers effect than other alkali chromates and iodates do. Namely, the yield of the reduced form for the ammonium salts is much higher than that for other alkali salts. Therefore, Harbottle et al.[16] suggested that the ammonium ion may act as a reducing agent in the hot zone. However, in the present case the yield of the reduced forms for ammonium phosphates is not markedly higher than that for the corresponding alkali phosphates. Perhaps the ammonium ion does not act as a reducing agent to phosphate in the hot zone. This may be attributed to the difference in oxidation potential of phosphate and chromate or iodate to their reduced forms.

Remarkable differences are present between the Szilard-Chalmers effects of anhydrous and hydrous phosphates. Retention in the Szilard-Chalmers effect of the hydrous salt is generally greater than that of the anhydrous salt. In the cases of $NaH_2PO_4\cdot 2H_2O$, $NaH_2PO_4\cdot H_2O$ and $Na_2HPO_4\cdot 12H_2O$, the fraction of phosphite (or hypophosphite) is smaller than that in the anhydrous salts. Similar effects are observed in the cases of hydrous and anhydrous sodium pyrophosphates. The water molecule seems to act as an oxidizing agent for these salts. However, in the case of $Na_3PO_4\cdot 12H_2O$, the fraction of phosphite (+hypophosphite) is larger than that for the anhydrous salt. This seems to be inconsistent with the fact that the water molecule apparently acts as an oxidizing agent in the former cases, but the reason is not yet clear. Usually phosphite (or hypophosphite) changes slowly into phosphate by standing in the case of the hydrous salt, while it scarcely changes in the case of the anhydrous salt. This time dependency may be attributable to the formation of any oxidizing agent in the presence of the water molecule. Phosphite (or hypophoshite) may react slowly with this oxidizing agent and change into phosphate. Fractions of pyrophosphate and higher polyphosphates are smaller for the hydrous salt than those of the anhydrous salt. This fact may be interpreted by the dilution effect (or any other hindrance effect) of the water molecule on the condensation of phosphate in the solid state.

Formation of pyrophosphate and higher polyphosphates occurs in all phosphorus acids and their salts which have been tested. The presence of higher polyphosphates has not been pointed out clear by so far. The condensation reaction of phosphate to condensed polyphosphates usually occurs at a high temperature. For example, orthophosphoric acid is converted into pyrophosphoric acid by heating at 250°C. Therefore, the experiments may suggest that the high temperature reactions play important roles in the present cases. Really, at the event of the recoil a large amount of heat is liberated, and it is expected that the neighbor of the recoil atom is raised up to a high temperature[17]. According to the calculation based on the theory of Hatbottle et al.[17], the hot zone in an ionic crystal includes about 1000 atoms at 1000°K, and about 2000 atoms at 500°K, provided that the recoil energy is about 300 eV.

The spot at the $R_f$ value of 0.09 appears only in the primary phosphates. This is likely to correspond to polymetaphosphate. This may be produced by the following reaction:

$$nMH_2PO_4 \rightarrow (MPO_3)_n + nH_2O.$$

In the cases of the molecular and ionic crystals which are unstable to heat, the mechanism of the thermal reaction in the hot-zone is likely to be very important. This localized thermal reaction or high temperature reaction may be necessary to explain some complicated phenomena in the Szilard-Chalmers effect.

The authors wish to express their hearty thanks to Dr. Kenjiro Kimura, the Director of this Institute, for his encouragement.

# *Natural Furan Derivatives. V*[1]. *The Number of Double Bonds in Obacunone*

By Takashi TOKOROYAMA, Tadao KAMIKAWA and Takashi KUBOTA

(Received July 21, 1960)

Obacunone ($C_{26}H_{30}O_7$) is known as the bitter principle contained in the plants of the *Rutaceae* family, together with limonin[2] and nomilin[3]. It has been studied by many investigators[3-6] since the beginning of this century. Casimirolid, isolated from *Casimiroa edulis* Lave et Lex, was recently proved to be identical with obacunone[7-10].

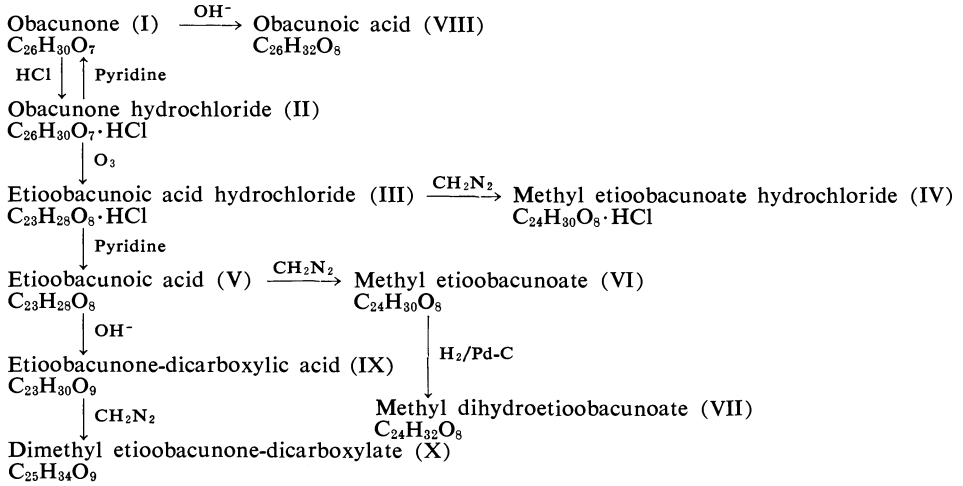
Studies made to date have revealed the presence of one ketone group and two lactone groups, one being opened reversibly and the other being an $\alpha,\beta$-unsaturated lactone group which suffers irreversible fission. Of the remaining two oxygen atoms, one has been proved by Kubota and Tokoroyama[11] to be present in $\beta$-substituted furan ring and the other is considered to be present as an oxide bond from its inert nature.

Dean and Geissman[6] concluded from spectroscopic studies on obacunone and nomilin (acetoxydihydroobacunone with an acetoxyl group in the $\beta$-position of the unsaturated lactone group in obacunone)[3] and from the complicated behavior of these two compounds toward catalytic reduction* that obacunone had another double bond besides the three in the furan ring and the $\alpha,\beta$-unsaturated lactone group, and that it is a monocarbocyclic compound. The present paper presents evidences that obacunone possesses only three double bonds.

Obacunone (I) easily undergoes the addition of one mole of hydrogen chloride to form obacunone hydrochloride (II)[6]. Since this compound does not show the characteristics of an $\alpha,\beta$-unsaturated lactone and easily regenerates obacunone on being heated with pyridine, it is clear that the addition of hydrogen chloride has taken place at the double bond in the $\alpha,\beta$-unsaturated lactone group[6].

Ozonolysis of obacunone hydrochloride at room temperature affords an acid, $C_{23}H_{28}O_8\cdot HCl$, by losing three carbon atoms. The acid has been named etioobacunoic acid hydrochloride (III) which is characterized as its methyl ester (IV), $C_{24}H_{30}O_8\cdot HCl$. III and IV do not show infrared absorption characteristics of the furan ring at 3.18, 6.66 and 11.42 $\mu$[12]. Treatment of III with pyridine results in dehydrochlorination and a dilactone-carboxylic acid, etioobacunoic acid (V), $C_{23}H_{28}O_8$, is formed. Etioobacunoic acid shows the absorption of a double bond conjugated with a carboxyl group at 6.18 $\mu$ and an absorption maximum at 214.5 m$\mu$ ($\varepsilon$ 11,500) indicating that the $\alpha,\beta$-unsaturated lactone system has been regenrated as in the case of the conversion of obacunone hydrochloride to obacunone. It follows, therefore, that the change of obacunone to etioobacunoic acid may be indicated as follows:

$$(C_{22}H_{27}O_6)\text{-}\underset{\diagdown O \diagup}{\overset{\|}{\square}}\overset{\|}{\square} \rightarrow (C_{22}H_{27}O_6)\text{-}CO_2H$$



I V

Hydrolysis of obacunone results in the irreversible fission of the unsaturated lactone ring and an unsaturated hydroxy acid, obacunoic acid (VIII), is formed[5]. Mild hydrolysis of etioobacunoic acid (V) also gives an unsaturated hydroxy-dicarboxylic acid $C_{23}H_{30}O_9$, which has been named etioobacunone-dicarboxylic acid (IX) and shows absorptions at 2.96 (hydroxyl) and 6.18 $\mu$ (conjugated double bond). Careful methylation of IX with diazomethane affords a dimethyl ester (X) corresponding to methyl obacunoate[5].

Methyl etioobacunoate hydrochloride (IV) gives no coloration with tetranitromethane.

Also its ultraviolet absorptions are weak in intensity, being end absorptions at 207 m$\mu$ ($\varepsilon$ 520) and at 210 m$\mu$ ($\varepsilon$ 400). If acid III should retain a double bond of poor reactivity with ozone and with tetranitromethane and thus a double bond of a tetrasubstituted ethylene, compound IV should show an absorption maximum of strong intensity of several thousands in $\varepsilon$ at around 205 m$\mu$[13]. Catalytic reduction of methyl etioobacunoate (VI) results in absorption of one mole of hydrogen to form methyl dihydroetioobacunoate (VII), which does not color with tetranitromethane and shows an end absorption of low intensity at 205 m$\mu$ ($\varepsilon$ 850). Consequently, it follows that IV and VII are completely saturated and therefore it is concluded that obacunone possesses three double bonds, two in the furan ring and one in the $\alpha,\beta$-unsaturated lactone group, and that it possesses a bicarbocyclic ring.

## Experimental

**Etioobacunoic Acid Hydrochloride (III).**— Obacunone hydrochloride (2.0 g.), which was prepared according to the method of Dean and Geissman[6], was dissolved in methylene chloride (50 ml.) and ozonized until the solution was saturated with ozone. The mixture was poured into water (50 ml.) and allowed to stand for several days with occasional swirling. The separated crystals were filtered and recrystallized from acetone-water as needles (1.1 g.), m. p. 238~240°C (decomp.). Infrared absorption (Nujol): 3.6~4.1 (carboxylic group), 5.74 (lactone goups), 5.96~6.00 $\mu$ (ketone and carboxylic groups).

Found: C, 58.61; H, 6.43. Calcd. for $C_{23}H_{29}O_8Cl$: C, 58.91; H, 6.23%.

**Methyl Etioobacunoate Hydrochloride (IV).**— A solution of etioobacunoic acid hydrochloride in acetone was methylated with an ether solution of diazomethane. Repeated recrystallization of the product from acetone-water gave needles, m. p. 202°C (decomp.). Infrared absorption (Nujol): 5.74 ~5.77 (lactone and ester groups), 5.83 $\mu$ (ketone group).

Found: C, 59.53; H, 6.61. Calcd. for $C_{24}H_{31}O_8Cl$: C, 59.68; H, 6.47%.

**Etioobacunoic Acid (V).** — Etioobacunoic acid hydrochlorid (150 mg.) was dissolved in pyridine (2 ml.) and the solution refluxed for 1 hr. After removal of the solvent under reduced pressure, the residue was dissolved in water and the solution was acidified with dilute sulfuric acid. Recrystallization of the resulting precipitates (132 mg.) from acetone-water gave needles, m. p. 236°C (decomp.). Infrared absorption (Nujol): 3.3~4.1 (carboxylic group), 5.74 (lactone groups), 6.00~6.05 (carboxylic group, ketone and $\alpha,\beta$-unsaturated lactone group), 6.18 $\mu$ (conjugated double bond).

Found: C, 63.76; H, 6.80. Calcd. for $C_{23}H_{28}O_8$: C, 63.88; H, 6.53%.

Neutralization equivalent: 423 (Calcd. value 432.5). Saponification equivalent: 150 (Calcd. value: 144.2).

**Methyl Etioobacunoate (VI).** — A solution of etioobacunoic acid in a mixture of acetone and methanol was methylated with an excess of diazomethane in ether. Recrystallization of the product from acetone-water gave needles, m. p. 275~277°C, in a practically quantitative yield. Infrared absorption (Nujol): 5.69 (lactone group), 5.75 (ester group), 5.89~5.92 $\mu$ (ketone and $\alpha,\beta$-unsaturated lactone groups).

Found: C, 64.52; H, 6.67. Calcd. for $C_{24}H_{30}O_8$: C, 64.56; H, 6.77%.

**Methyl Dihydroetioobacunoate (VII).** — Methyl etioobacunoate (500 mg.) dissolved in a mixture of ethyl acetate (25 ml.) and dioxane (10 ml.) was shaken with hydrogen at 31°C in the presence of 10% palladium-charcoal (100 mg.). Absorption of 1 mol. (31 ml.) of hydrogen was completeted in $4\frac{1}{8}$ hr. After filtration of the catalyst, the solvent was evaporated under reduced pressure. Recrystallization of the residue from acetone-water or from ethanol gave prisms, m. p. 236~237°C. Infrared

13) P. Blauden, H. B. Henbest and G. W. Wood, *J. Chem. Soc.*, **1952**, 2737.

absorption (Nujol): 5.72~5.88 $\mu$ (lactones, ester and ketone groups). Ultraviolet absorption: $\lambda_{205}^{EtOH}$, $\varepsilon$ 850; $\lambda_{210}^{EtOH}$, $\varepsilon$ 525.

Found: C, 63.81; H, 7.50. Calcd. for $C_{24}H_{32}O_8$: C, 64.27; H, 7.19%.

Saponification equivalent: 146 (Calcd. value: 149).

The dihydroester (VII) was also obtained by the hydrogenation of methyl etioobacunoate in the presence of palladium-alumina[14] in dioxane.

**Etioobacunone-Dicarboxylic Acid (IX).** — Etioobacunoic acid (2 g.) was dissolved in 1 N potassium hydroxide (20 ml.) and the solution heated below 80°C for 1 hr. After cooling the solution was acidified with 1 N hydrochloric acid (Congo Red). The separated crystals were collected and recrystallized twice from dilute methanol as needles (0.9 g.), m. p. 192~193°C (decomp.). Infrared absorption (Nujol): 2.97 (hydroxyl group), 3.07 (hydroxyl group), 5.74 (lactone group), 5.84 (ketone and carboxylic groups), 6.18 $\mu$ (conjugated double bonds). Ultraviolet absorption: $\lambda_{205}^{EtOH}$ $\varepsilon$ 5,500; $\lambda_{210}^{EtOH}$, $\varepsilon$ 5,500.

Found: C, 61.24; H, 6.89. Calcd. for $C_{23}H_{30}O_9$: C, 61.32; H, 6.71%.

**Dimethyl Etioobacunone-dicarboxylate (X).**—To a solution of etioobacunone-dicarboxylic acid (IX) in methanol was added an ethereal solution of diazomethane in an amount less than the theoretical. Immediately after the addition of diazomethane, the solvent evaporated under reduced pressure. The residue was dissolved in chloroform and the solution was shaken with aqueous bicarbonate to remove an acidic material. The chloroform layer was washed with water, dried and evaporated. Recrystallization of the residue from acetone-water, then from ethanol, gave needles, m. p. 177~178°C. Infrared absorption (Nujol): 2.81 (hydroxyl group), 5.73 (lactone and ester groups), 5.82 ($\alpha,\beta$-unsaturated ester group), 5.88 (ketone group), 6.15 $\mu$ (conjugated double bond).

Found: C, 62.61; H, 7.43. Calcd. for $C_{25}H_{34}O_9$: C, 62.75; H, 7.16%.

## Summary

Obacunone has only three double bonds in total, two in its furan ring and one in its $\alpha,\beta$-unsaturated lactone group and, therefore, it possesses a bicarbocyclic ring.

# *The Use of Radioactive Fission Product Rare Gases for the Study of the Change in Crystal Structure*

By Seishi YAJIMA, Sumio ICHIBA, Yuichiro KAMEMOTO and Koreyuki SHIBA

(Received July 14, 1960)

In our previous paper[1], the possible correlation between released fission rare gas which was captured in a sample of hematite by its recoil energy and the crystal structure change was reported, and the use of radioactive fission product rare gas for the emanation method in place of radon was proposed. In our present work, the experiment was carried out more extensively using the high temperature X-ray diffraction method to confirm the correlation. The usefullness of this emanation method using radioactive fission rare gas in place of radon for the studies in the field of physical chemistry is also discussed.

## Experimental

**Usable Nuclides in Fission Product Rare Gases for the Emanation Method.**—A major fraction of Uranium-235 thermal fission products consist of gaseous materials and the sum of independent and primary cumulative yields of all gaseous fission products, including iodine, bromine, xenon and krypton, amount to 52.3%. Of this value 55.3%, or a yield of 28.9%, is attributed to xenon and krypton.

Referring to a table of isotopes[2], krypton-85m, xenon-135 and xenon-133 have considerably long half-lives and large fission yields. To investigate the interference of the precursor and the radioactivity of the other nuclides, the changes of the radioactivity of the krypton-85m, xenon-135 and xenon-133 after two hours' irradiation with time are measured and these changes are plotted in Fig. 1. In these experiments, a closed polyethylene sheet containing 20 mg. of uranium dioxide was irradiated

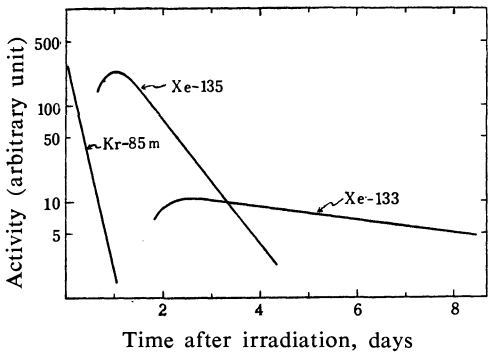

Fig. 1. Change of the radioactivities of the fission product krypton and xenon with time after two hour irradiation.

by thermal neutrons (flux,$\sim 5\times 10^{11}$ n/cm$^2$ sec.) for two hours. The sample is placed in a small flask after each cooling period and the sheet is broken, and the uranium dioxide is dissolved in concentrated nitric acid. Helium is made to flow through the flask, a trap is cooled by dry ice (for iodine) and a charcoal trap is cooled by liquid nitrogen (for xenon and krypton) during treatments and for ten minutes after the uranium has been dissolved. The radioactivities of the krypton and xenon trapped in charcol are measured by a multi-channel gamma ray spectrometer. Their gamma-ray spectra are shown in Fig. 2. The cooling periods to minimize the interference of precursor and radioactitvity of the other nuclides are found to be 1.5 and 4 days for xenon-135 and xenon-133, respectively. The use of one of these nuclides depends on the nature of the sample and the function of the measuring instrument, and the cooling period is therefore determined by the nuclide thus selected.

**Preparation of the Heating Curve and X-ray Diffraction Measurement.** — In the emanation method, the samples containing radioactive rare gases were heated at a constant rate and the radioactivity of the escaping rare gases was measured (heating curves), or the samples were heated at various temperatures and kept at these temperatures while the changes in escaped radioactivity with time were followed (isothermal curves). In the present

TABLE I. THE HEMATITE SAMPLES AND THEIR PREPARATION METHODS

| Sample No. | Chemical form | Preparation method |
|---|---|---|
| 1 | $\alpha$-$Fe_2O_3$ | Dehydration of $\alpha$-FeO·OH at 250°C |
| 2 | $\alpha$-$Fe_2O_3$ | Dehydration of $\alpha$-FeO·OH at 300°C |
| 3 | $\alpha$-$Fe_2O_3$ | Thermal decomposition of $FeSO_4\cdot 7H_2O$ at 780°C |
| 4 | $\gamma$-$Fe_2O_3$ | Oxidation of $Fe_3O_4$ at 250°C |
| 5 | $\gamma$-$Fe_2O_3$ | Pure $\gamma$-$Fe_2O_3$ |

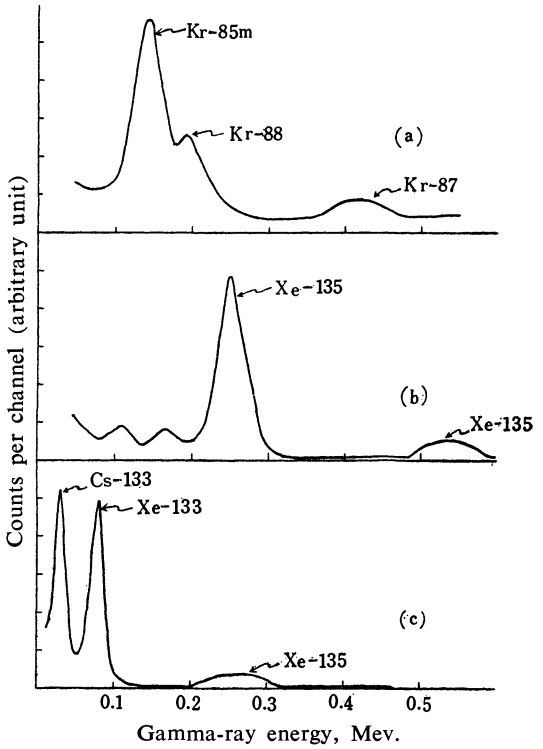

Fig. 2. Gamma-ray spectra of the fission product rare gases.
(a) 2 hr. irradiation and 8 hr. cooling.

work, the crystal structure change of $\gamma$-hematite to $\alpha$-hematite is studied by the heating curve. An X-ray diffraction method is also employed to identify the crystal structures. The samples of hematites to be examined are shown in Table I.

Two hundred milligrams of thin film of formvar, in a small size, containing uranium dioxide of which the weight ratio to formvar is 1 : 5 was mixed with 500 mg. of hematite and irradiated by thermal neutron flux $\sim 5\times 10^{11}$ n/cm$^2$ sec. for 2 hr. in an experimental hole of JRR-1 reactor. Then the fission recoil energy enables the fission products to be caught by the surrounding solid powder through the film[4-6]. After 1.5 days' cooling ethyl alcohol was added to the sample and the solid powder retaining fission products was separated by a wire gauze and filter paper and was dried. The solid powder was placed in a quartz boat in a quartz tube which was connected to a phosphorus pentoxide drying tube, a dry ice trap for radioactive iodine, a counting cell inserted into an NaI scintillation crystal well of a $\gamma$-ray spectrometer and a flow rate meter, in the order mentioned. The schematic diagram of the apparatus is shown in Fig. 3. Solid powder was heated by a furnace at a rate 5°C/min. in a current of argon (100 ml. per min.). The radioactive xenon-135 escaping from hematite was carried by argon and the radioactivity was measured with the scintillation counter. Plots of the radioactivity of xenon-135 escaped from the sample versus temperature are shown in Fig. 4.

The correlations between the observed peaks in the heating curves and the crystal structure changes were studied by the high temperature X-ray diffraction method at temperatures below and over the temperatures where the peaks appear. $\gamma$-Hematite samples (Nos. 4 and 5) were investigated by the continuous recording method, by the use of the peaks (220) of $\gamma$-hematite and (104) of $\alpha$-hematite. The charts are shown in Figs. 5 and 6.

## Results and Discussion

The peaks in the heating curves of Nos. 1 and 2 samples are considered to be related to the dehydration of FeO·OH, although the X-ray diffraction chart shows that the No. 2 sample is in $\alpha$-hematite form at room temperature. In the heating curve of No. 3 sample, no sharp peak is observed because no change

4) R. Wolfgang, *J. Inorg. Nucl. Chem.*, **2**, 180 (1956).
5) R. Henry and C. Herczeg, UNESCO/NS/RIC/14 (1957).
6) T. Nakai and S. Yajima, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **79**, 1267 (1958).

in structure takes place. The slow ascendant of the curve probably shows that the xenon trapped in the dislocation of the crystal is released. The samples of Nos. 4 and 5 are identified to be $\gamma$-hematite at room temperature by the X-ray diffraction method but their heating curves of Fig. 4 are considerably different from each other. The charts of the continuous recording method of Figs. 5 and 6 show that peaks at 680°C and 530°C are the temperatures of the crystal structure change of $\gamma$-hematite of samples Nos. 4 and 5 to $\alpha$-hematite, respectively. The difference of their crystal structures might be investigated in detail by other methods, e. g., electron diffraction method.

The heating curves of the emanation method will suggest the temperature at which the crystal-structure change, dehydration and decomposition occur and also the detailed difference of the crystal structure for which the X-ray diffraction method does not give sufficient informaton. The heating curves may also suggest the possible existence of the dislocation of the crystal.

On the basis of the following reasons, the proposed method will promise a future development in various fields of the study.

1) This method will be applicable to many solids because the samples are prepared without chemical treatments.

(2) Different radioactive rare gases can be used at the same time. For example, prior to the reaction, if different nuclides of radioactive rare gas were retained in the reactants, the more detailed knowledge of the reaction between solids would be obtained.

3) When most of the rare gas is released at the first peak, it is possible to investigate the emanation at the higher temperature above the peak by means of the decay products of the precursor.

The radiation damage of the crystal will be negligible because the radioactivity of the fission rare gases is detected very sensitively and the sample does not require so much irradiation, as radiation damage occurs. The fission products captured in the solid will be also negligible as impurities.

The proposed method will be useful for the studies of crystal-structure change, reaction between solids and other problems of physical chemistry when the X-ray diffraction method and electron diffraction method are employed at the same time.

The authors wish to thank Professor S. Kachi of Kyoto Uuiversity for invaluable suggestions to this work and also for providing the hematite samples.

# SHORT COMMUNICATIONS

## *Rapid Separation of Nuclides in Fission Products and their Determinations by Focussing Chromatographic Method*

By Mutsuaki SHINAGAWA, Yoshiyuki KISO and Akira OYOSHI

(Received October 14, 1960)

Although many procedures such as ion exchange, extraction, paper chromatographic and precipitation methods etc. have been applied to the separation of nuclides in fission products, the present focussing chromatographic method has been proved to be more rapid and convenient for their determinations comparing with other methods mentioned above.

The apparatus and its manipulation were the same as in previous paper[1]. As the complexing agent of cathodic solution, 0.1 M citric, oxalic, malonic, malic, maleic, lactic, succinic and tartaric acid, 0.05 M sodium triphosphate, 0.01 M EDTA and NTA were used and hydrochloric acid was used as cathodic solution in the present experiment.

The separation of several kinds of nuclide in fission products (imported from U. S. A.) were possible in a few minutes by the adjustment of pH value between both solutions of hydrochloric acid and complexing agent under suitable conditions of initial dipped width of sample solution (1~3 cm.) and applied voltage (750~1000 V./20 cm. of strip length). The autoradiographic method was used to decide the position of separated lines. Identification of nuclides was carried out by measuring their half-lives and energies.

Autoradiogram exemplified in Fig. 1, shows the situation of separation obtained by hydrochloric acid-citric acid system. Fig. 2 shows the general view of the separated patterns obtained with several complexing agents.

Separated lines of $^{137}Cs$ and $^{95}Zr$ in fission products were formed with the complexing agent without mutual contaminations. Quantitative determinations of $^{137}Cs$ and $^{95}Zr$ proved

to be effective by measuring $\gamma$-activity of their separated lines cut from the paper strip. The mean deviation rate of reproducibility of radioactivity obtained and recovery were found within $\pm 5\%$ and $95 \pm 5\%$ respectively, from the result of blank test using the standard sample solution prepared by mixing with known amounts of $^{95}Zr$ ($^{95}Nb$), $^{144}Ce$ ($^{144}Pr$), $^{90}Sr$ ($^{90}Y$) and $^{106}Ru$ ($^{106}Rh$). Even when the closeness or overlapping of separated lines of $^{90}Y$ and $^{144}Ce$, or $^{90}Sr$ and $^{106}Ru$, the determinations of $^{144}Ce$ and $^{106}Ru$ by $\gamma$ counting were feasible with an accuracy of the same order as $^{137}Cs$ and $^{95}Zr$, because $^{90}Y$ and $^{90}Sr$ have no $\gamma$-activity.

The proposed method is considered to be a new rapid and simple method for analysis of product; i.e. fall-out analysis, burn-up determination of nuclear fuels, etc.

## *On the Constitution of Sulfo-Aluminous Clinker*

By Nobue FUKUDA

(Received October 26, 1960)

According to Lafuma[1], sulfo-aluminous clinker is produced by burning the mixture of gypsum, bauxite, and calcium carbonate, and is used as an expansive agent for the manufacture of expansive cement.

He succeeded in identifying the minerals, free anhydrous calcium sulfate, calcium aluminates particularly $5CaO \cdot 3Al_2O_3$, and $\gamma$ $2CaO \cdot SiO_2$ in the clinker, but he could not confirm the ternary compound, calcium-sulfo-aluminate.

In the course of previous studies[2] on the system $CaO$-$Al_2O_3$-$CaSO_4$, the author could conclusively establish the existence of a ternary compound of the composition $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ which gave the X-ray diffraction data as shown in Table I.

With the opinion that this ternary compound may be expected to exist in sulfo-aluminous clinker the author has carried out the following experiments.

1) Heating the mixture of bauxite, lime, and gypsum for 30 min. at 1350°C the clinker was prepared, which was similar in appearance as described by Lafuma.

2) A series of sulfo-aluminous clinkers with the mole ratios of $Al_2O_3/SO_3$, 8.2, 6.0, 3.5, 2.0 and 0.8, respectively, were prepared by heating the batches containing different amounts of gypsum under the same conditions as above.

The samples 1 and 2 were identified by the determination of their chemical composition, X-ray diffraction patterns (powder method), and quantitative X-ray analysis using standard substances.

The X-ray data and chemical composition of sample 1, and the chemical composition of sample 2 are given in Tables II, III and IV.

The results are summarized as follows:

a) The existence of $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ as the main constituent in sulfo-alminous clinker has definitely been established.

b) The amount of this ternary compound in clinkers estimated from the content of $Al_2O_3$ or $CaSO_4$ determined by the chemical

analysis is in fairly good agreement with the results of direct measurements by quantitative X-ray analysis. The author, furthermore, has found that the amount of this compound is in equivalent with $Al_2O_3$-content when $Al_2O_3/SO_3 < 3$, and with $CaSO_4$-content when $Al_2O_3/ > SO_3 > 3$.

c) As for the other constituents the existence of free anhydrous calcium sulfate was distinctly observed, while that of $\beta$ $2CaO \cdot SiO_2$ was not so clear.

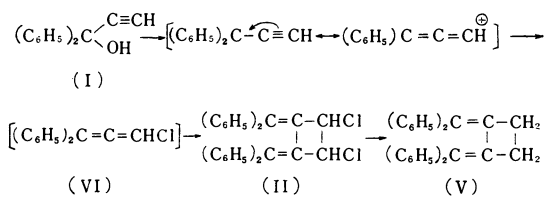
## *Einwirkung von Thionylchlorid auf Diaryläthinylcarbinolen*

Von Tsuneyuki NAGASE



(Eingegangen am 22. Oktober, 1960)

Diphenyläthinylcarbinol (I) ergab bei der Einwirkung von Thionylchlorid in Äther-Pyridin-Lösung bei Zimmertemperatur ein gelbes nadelförmiges Produkt vom Schmp. 188 ~189°C (II) (UV. $\lambda_{Max}^{EtOH}$ m$\mu$ ($\varepsilon$) : 262(24,300), 372(18,100)) von der Zusammensetzung $C_{30}H_{22}\cdot Cl_2$ (Ber. C, 79.47; H, 4.89; Cl, 15.64; Mol. Gew., 453.4. Gef. C, 79.04; H, 4.92; Cl, 15.62%; Mol. Gew. (Rast), 435) mit der Ausbeute von ca. 40 proz. der Theorie. In seinem IR-Spektrum ist ein C–H Band von der Acetylenbindung bei 3300 $cm^{-1}$ verschwunden und bei 1950 $cm^{-1}$ ist nur eine schwache Bande bemerkbar, die scheinbar nicht der Allenbindung, sondern dem substituierten Benzolring zu zuschreiben ist. Seine 2 Chloratome sind durch die Acetoxylgruppe ersetzbar, wenn man II in Eisessig-Lösung mit wasserfreiem Kaliumacetat unter Rückfluss erhitzt. Das entstandene Diacetat (III) ($C_{34}H_{28}O_4$-Ber. C, 81.57; H, 5.64; Mol. Gew. 500. Gef. C, 80.95; H, 5.70%; Mol. Gew., 494. UV. $\lambda_{Max}^{EtOH}$ m$\mu$ ($\varepsilon$): 261(30,000), 363(20,000). IR. $\nu$ $cm^{-1}$ (in Nujol) : 1745 (Acetat)) bildet schwachgelbe Nadeln vom Schmp. 222°C und ergab beim Verseifen mit Salzsäure kein Produkt, das sich zu dem Brady'schen Reagens positiv verhält, sodaß die Enolacetat-Gruppe in ihm nicht vorhanden ist. Durch Ozon-Abbau von II konnte man ca. 1.6 Mol. Benzophenon erfassen und nebenbei eine chlorhaltige $\gamma$-Dicarbonsäure isolieren, die in das entsprechende Pyrrol übergeführt und durch die Ehrlich'sche Probe des letzteren bestätigt wurde. Diese Daten zeigen, daß II höchstwahrscheinlich einen Bisdiphenylmethylencyclobutan-Ring enthält.

II widersteht der Reduktion mit $LiAlH_4$, man konnte es jedoch durch katalytische Reduktion mit Pd-Kohle in methanolischer Kali-Lösung in das entsprechende entchlorierte Tetrahydroderivat (IV) als farblose Nadeln vom Schmp. 153~154°C ($C_{30}H_{28}$-Ber. C, 92.73; H, 7.27. Gef. C, 92.57; H, 7.23%) überführen. Andererseits ergab II beim Erhitzen mit frisch bereitetem Raney-Nickel W-7 in Tetrahydrofuran-Lösung das entsprechende entchlorierte Produkt (V) ($C_{30}H_{24}$-Ber. C, 93.70; H, 6.30. Gef. C, 93.31; H, 6.48) als schwachgelbe Nadeln vom Schmp. 180~181°C (UV. $\lambda_{Max}^{Dioxan}$ m$\mu$ ($\varepsilon$): 257(34,000), 352(28,000)), das mit der Beschreibung von 1,2-Bisdiphenylmethylencyclobutan[1] sehr ähnlich war. So wurde das letztere ausgehend von Adipinsäure über *trans*-Cyclobutandicarbonsäure[2] nach Alberman und Kipping[1] hergestellt und seine Identität mit V wurde durch eine Mischprobe sowie direkten Vergleich der IR-Spektren tatsächlich festgestellt. Die Konstitution von II ist dementsprechend 3,4-Dichlor-1,2-bisdiphenylmethylencyclobutan.

Die Entstehung von II aus I kann man nur in der Weise erklären, daß das zuerst durch eine anionotrope Umlagerung entstandene 1,1-Diphenyl-3-chlorallen (VI) dimerisiert hat. Zu bemerken ist dabei, daß in der Mutterlauge von II keine Allenverbindung IR-spektrographisch nachweisbar war.

(I)

(VI) (II) (V)

Es ist daher merkwürdig, daß Hennion und seine Forschungsgruppe[3] bei analoger Reaktion von 9-Äthinyl-9-fluorenol (VII) mit Thionylchlorid 9-Chlorvinylidenfluoren (VIII) erhielten. So wurde VII aufs neue nach der Beschreibung von Hennion et al. in wasserfreier Äther-Lösung bei Gegenwart von wasserfreiem Pyridin mit Thionylchlorid behandelt und gelbe Nadeln vom Schmp. 223~224°C (u. Zers.) IX in einer Ausbeute von 71.5 proz. erhalten, die mit der literarischen Angabe[3] gut übereinstimmten. Dasselbe Produkt wurde auch durch Einwirkung von konz. Salzsäure auf VII in einer Ausbeute von 74 proz. erhalten. Die Zusammensetzung von IX stimmte jedoch nicht mit VIII ($C_{15}H_9Cl$) sondern mit $C_{30}H_{18}Cl_2$ (Ber. C, 80.18; H, 4.03; Cl, 15.78; Mol. Gew., 449.4. Gef. C, 79.92; H, 4.25; Cl, 15.78%; Mol. Gew. (Rast) 428) überein. Ferner im Gegensatz zur literarischen Angabe wurde im IR-Spektrum von IX keine scharfe Bande einer Allenbindung bei 1950 $cm^{-1}$ bemerkt, obwohl bei 2000~1650 $cm^{-1}$ Banden von einem substituierten Benzolring vorhanden waren. Außerdem ist das UV-Spektrum von IX (UV. $\lambda_{Max}^{CHCl_3}$ m$\mu$ ($\varepsilon$): 276(54,000), 375(30,000)) mit demjenigen von II sehr ähnlich und durch Ozon-Abbau von IX konnte man neben ca. 1.4 Mol. Fluorenon eine $\gamma$-Dicarbonsäure isolieren, wie bei dem Abbau von II. Diese Daten zeigen, daß IX kein 9-Chlorvinylidenfluoren sondern 3,4-Dichlor-1,2-bisfluorenylidencyclobutan ist, und daß die Reaktion von VII mit Thionylchlorid ganz analog wie beim I verläuft. Zur weiteren Bestätigung wurde IX mit Pd-Kohle katalytisch reduziert, wobei man kein 9-Äthylfluoren vom Schmp. 108°C, sondern ein halogenfreies Kristall vom Schmp. 167~168°C (X) ($C_{30}H_{24}$-Ber. C, 93.71; H, 6.29. Gef. C, 93.13; H, 6.06%.) unter 4 Mol. Wasserstoff-Aufnahme erhalten konnte.

# *Mechanism of the Recoil Phenomena in Hexamminecobalt(III) Chloride*

By Nagao IKEDA, Kenji YOSHIHARA and Shigeru YAMAGISHI

(Received August 18, 1960)

In the previous paper[1], we studied the heterogeneous extraction of recoil atoms in neutron-irradiated hexamminecobalt(III) nitrate target, and observed the anomalously high extraction yield with this compound. In the present paper, we studied the recoil effects in hexamminecobalt(III) chloride and found the following two interesting facts. 1) The recoil effects in hexamminecobalt(III) chloride involve more complicated processes than the simple replacement process. 2) A small percentage of the activity produced in the target is found in the form of chloropentamminecobalt(III) chloride as the result of recoil effect, and its radiochemical yield decreases on keeping it to stand even at room temperature; the rate determining step in this process is not diffusion, which has been usually considered to be responsible to the thermal annealing process of the recoil atom[2], but a chemical reaction.

Purified hexamminecobalt(III) chloride was subjected to neutron irradiation in the reactor, JRR-1 (neutron flux: $6\times10^{11}$ n/cm$^2$/sec.) for 10 min., and was dissolved in water in about

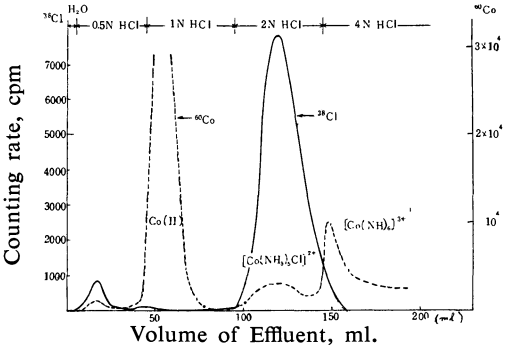

Fig. 1. Elution curve for recoil products in neutron-irradiated hexamminecobalt(III) chloride.

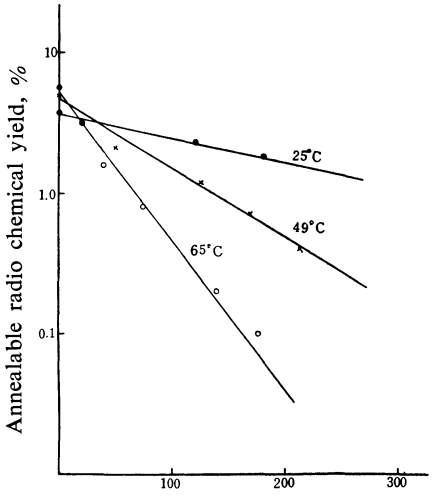

Fig. 2. Decrease of radiochemical yield of $[Co(NH_3)_5Cl^*]$ by standing irradiated hexamminecobalt(III) chloride at various temperatures.

30 min. after irradiation. The solution was passed through a cation-exchange resin column (Diaion SK #1, HR-form, 100~200 mesh, 1 cm. $\phi \times 4$ cm.). After being washed with a small quantity of water, the resin bed was eluted with hydrochloric acid of various concentrations. By the use of a pulse-height analyzoer, the $\gamma$-rays of $^{38}Cl$ and $^{60}Co$ in the eluted fractions were measured separately. The elution curve is shown in Fig. 1. The solid line shows the elution curve for $^{38}Cl$ activity and the dotted one shows that for $^{60}Co$ activity. The formation of $[Co(NH_3)_5Cl^*]^{2+}$ might be interpreted as simple replacement of $NH_3$ by $^{38}Cl$ recoil atom, but the formation of $[Co^*(NH_3)_5Cl]^{2+}$ can not be understood by this concept. Moreover, such a simple replacement can not explain the appearance of a peak at the earlier stage of the elution curve; a peak due to an unknown species containing both cobalt and chlorine atoms which might be a cobalt ammine complex, such as $[Co(NH_3)_4Cl_2]^+$.

The radiochemical yield of $[Co(NH_3)_5Cl^*]^{2+}$ was accurately measured after being separated from the luteo-salt. It was about 7% immediately after irradiation, but this value decreased on keeping the sample to stand in the solid state. At various temperatures, the relation between the standing time and the radiochemical yield of $[Co(NH_3)_5Cl^*]^{2+}$ was observed. The annealing curves for the earlier stage are shown in Fig. 2. The curves correspond to those of the first-order reaction. An apparent activation energy of 8.6 kcal. was obtained for this decreasing process of $[Co(NH_3)_5Cl^*] \cdot Cl_2$. Mori and Tsuchiya[3] studied the thermal decomposition of $[Co(NH_3)_6]Cl_3$ and reported the heat of formation $\Delta H = 9.6$ kcal./mol. and the activation energy $E_h = 18.0$ kcal./mol. for the reaction,

$$[Co(NH_3)_6]Cl_3 \rightleftarrows [Co(NH_3)_5Cl]Cl_2 + NH_3$$
(solid) (solid) (gas)

In the back-reaction, therefore, the activation energy $E_p = E_h - \Delta H = 8.4$ kcal./mol. is obtained. This value is very close to that obtained in this experiment. So that, one possible explanation of the annealing reaction observed by the present authors may be given by considering the back-reaction of the above-mentioned system provided that the quantity of ammonia is much larger compared with that of $[Co(NH_3)_5Cl]Cl_2$.

These results would lead us to the following model. In the neighborhood of the recoil atom, the chemical bonds of the molecules are broken and local fragmentation occurs. Unstable intermediate systems are formed. These are immediately rearranged into a group of several chemical species in the cooling step. However, some unbalances are still present in these systems, and slow changes occur by thermal annealing.

Details are to be reported in the full paper.

# *Solvent Shift of Methyl Proton Nuclear Magnetic Resonance*

By Naoya NAKAGAWA and Shizuo FUJIWARA

(Received June 27, 1960)

The solvent effect of high resolution proton magnetic resonance has been investigated by many workers[1-3], recently. We also reported that the HCN, $-C\equiv CH$, and $-CH_3$ protons show quite large solvent shifts[4]. In this paper, we will show the results of the investigations for methyl protons in various compounds.

Chemical shifts of the NMR spectra of methyl protons in a number of organic compounds dissolved in solvents such as benzene, pyridine, dioxane, and carbon tetrachloride were measured by the internal reference method. Each sample consists of solute, solvent, and cyclohexane as the internal reference, with a molar ratio of 1 : 9 : 0.25, and is sealed in a glass tube of 3.5 mm. O. D. The apparatus of the NMR measurement is the one constructed by one of the authors (S. F.), and is operated at 27 Mc. The details of this set-up were reported elsewhere[5]. The chemical shifts of the methyl protons of the samples were measured on the recorded charts as the separations from cyclohexane by taking the separation between toluene $CH_3$ and cyclohexane as 0.75 p.p.m. This value of the reference was determined by the side-band technique[6].

* Values for the compounds with asterisks are for 17°C.

The results of measurements are summarized as shown in Table I. In meta- and para-substituted toluenes, the solvent shifts of the methyl protons, $\Delta\delta$, which are defined as the difference between the chemical shifts in any two solutions of different solvents, are linearly correlated with Hammett's sigma values as shown in Fig. 1. If we assume that the solvent shift of cyclohexane is constant, and if this is also the case with respect to the samples listed in the same column of Table II, the observed values of $\Delta\delta$ will mainly refer to the solvent shifts of the methyl protons.

In the results of Tables I and II, we notice that the magnitudes of the solvent shifts of the methyl protons are increased with the acidity of the methyl protons of the solute molecule. For example, the $\Delta\delta$ value of *p*-nitrotoluene for the benzene-$CCl_4$ system is 0.57 p.p.m. and that of *p*-toluidine is 0.02 p.p.m. This result coincides with the behavior of the solute parameter $x_1$ of the medium effect defined by Bothner-By[7].

According to the results of the measurements, we can conclude that the chemical shift of methyl proton in acetic acid is a linear function of the mole fraction solute (Fig. 2), as in the cases of nitromethane and of acetonitrile[5]. In acetic anhydride, or in acetone, the linear relation is not obtained with the simple mole fraction of the solute, but a fine linearity is obtained by taking the corrected mole fraction as abscissa, where one methyl group of the solute is taken into account as one solute molecule (cf. Figs. 2 and 3). In the cases of acetophenone and *m*-nitrotoluene, similar corrections are also necessary, and we have used the corrected mole fractions as shown in Figs. 3 and 4, where the number of the phenyl groups of the solute has been taken into account for the calculation as well as the solvent benzene.

In the case of *o*-toluidine, the chemical shifts of the methyl protons linearly depend on the simple mole fraction of the solvent (cf. Fig. 4) and, moreover, the magnitudes of the solvent shifts are anomalously large (cf. Table II). Similar results are observed with *o*-cresole.

# *Syntheses of Benzo[b]tropothiazine and its Derivatives*

By Tetsuo NOZOE, Toyonobu ASAO and Kazuko TAKAHASHI

(Received July 22, 1960)

The preparation of oxime and arylhydrazones of quinoxalotropone (I) by the condensation of 5-nitroso- or 5-arylazo-tropolones and *o*-phenylenediamine was reported earlier in this laboratory[1]. A parent compound II, named benzo[b]tropazine, was obtained also by condensation of 2-halo- or 2-methoxy-tropone, or 3-carboxy-tropolone and *o*-phenylenediamine[2]. In the present series of this work, several compounds having a new ring system IV containing sulfur and nitrogen atoms were synthesized and examinations were made on their properties.

A mixture of 2-halotropone (III) and *o*-aminothiophenol in methanol was allowed to stand at room temperature and red plates IV, m. p. 87°C, $C_{13}H_9NS$, were obtained. IV is stable to heating with alkali or hydrochloric acid, is easily soluble in various organic solvents and in dilute acid to form a deep red solution, and easily gives some molecular compounds such as picrate. The ultraviolet absorption spectrum of IV (Fig. 1) in hydrochloric acid solution shows a shift to a longer wavelength region compared with that in methanol.

Attempted catalytic hydrogenation of IV in

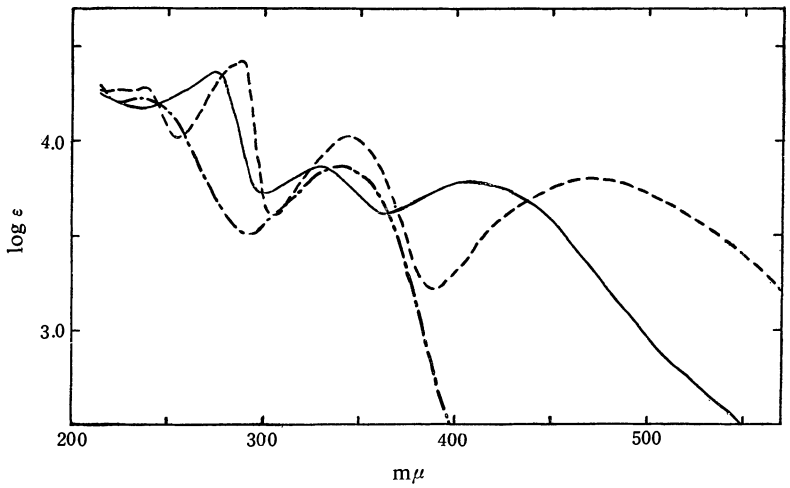
2) T. Nozoe, Y. Kitahara, K. Takase and M. Sasaki, *Proc. Japan Acad.*, **32**, 349 (1956).



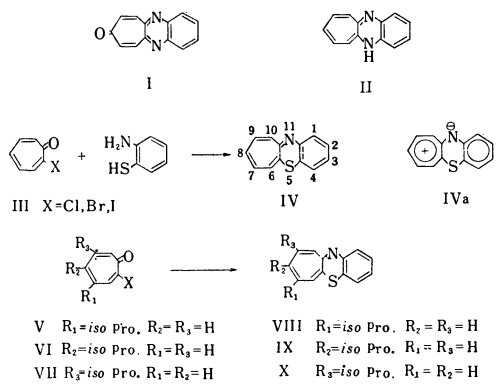


Fig. 1. Ultraviolet absorption spectra.
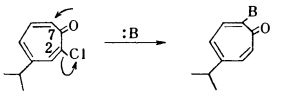
—·—· II (in methanol), —— IV (in methanol), ---- IV (in 0.1 N HCl).

the presence of palladium-carbon or Adams catalyst was unsuccessful with no hydrogen uptake and the complete recovery of the

original compound IV. The reaction of IV with methyl iodide did not give methiodide, but gave hydroiodide of IV. Hydrobromide of IV was also formed by treatment of IV with hydrobromic acid.



From these properties, the course of preparation, and the analytical values of IV and its several derivatives, the structure of IV could be proved to be cyclohepta[b]benzo-[e]-1,4-thiazine, for which the name of benzo[b]-tropothiazine is proposed.

It is interesting to compare compound IV with compound II. The latter compound II forms colorless prisms with poor solubility, and is unstable toward acids, reducible with palladium-carbon to 2,3-pentamethylene-quinoxaline. Also the ultraviolet spectrum of compound II is quite different from that of compound IV as shown in Fig. 1. These results would indicate that IV is stabilized by the resonance between IV and IVa.

Three kinds of isopropyl-2-halotropones (V, VI and VII)[3,4] were also reacted with *o*-aminothiophenol, easily affording 7-, 8- and 9-isopropylbenzo[b]tropothiazines (VIII, IX and X) as red oils. These isopropyl compounds have properties similar to those of the compound IV. In view of the fact that the abnormal nucleophilic substitution, which is frequently observed in troponoid chemistry*, does not occur in the reaction of 2-halotropone derivatives and methylmercaptane[5], it is considered that the same normal substitution occurs in the reaction of 2-halotropone derivatives and *o*-aminothiophenol; therefore it is assumed that the structure of VIII-X is correct.

2-Bromo-7-methoxytropone (XI)[6] gave a red oil XII, $C_{14}H_{11}ONS$, by the condensation with *o*-aminothiophenol. The compound XII, like IV, is soluble in dilute acid and gives molecular compounds such as picrate. Hydrolysis of XII with hydrochloric acid gave red needles XIII, m.p. 169°C, which were identical with a compound obtained by the reaction of 3-bromo-2-methoxytropone (XIV)[6]

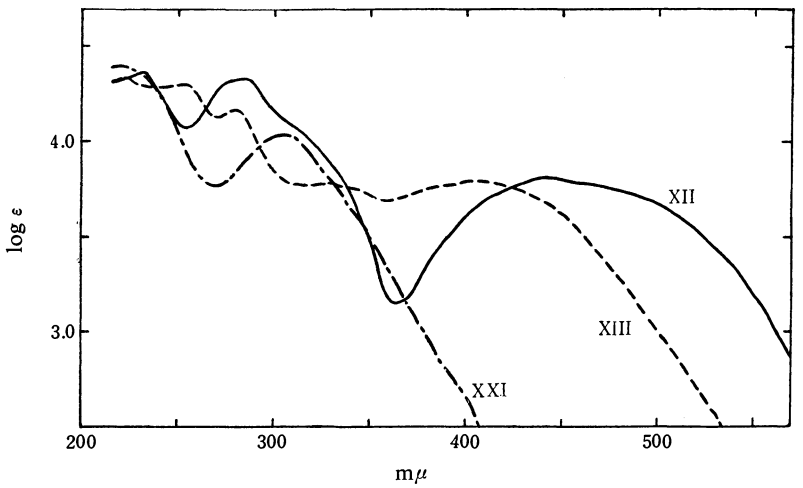

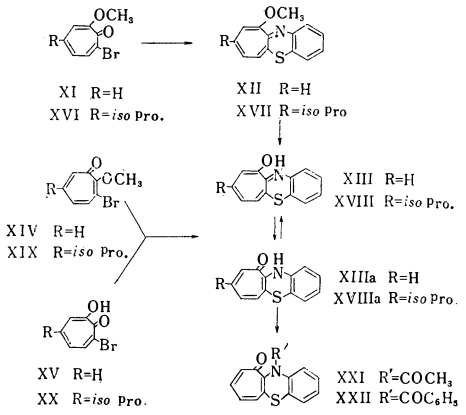

Fig. 2. Ultraviolet absorption spectra of XII, XIII and XXI in methanol.

and *o*-aminothiophenol. XIII was also obtained from 2-bromotropolone (XV) in good yield. From these results, it is assumed that the structure of XII is 10-methoxybenzo [b] tropothiazine and of XIII is 10-hydroxybenzo [b] - tropothiazine.

Attempted substitution of methoxyl in XII with amino or substituted amino group was not successful. The original compound XII was recovered unchanged.

2-Bromo-5-isopropyl-7-methoxytropone (XVI)[7] gave 7-isopropyl-10-methoxybenzo [b] tropothiazine (XVII) by the reaction with *o*-aminothiophenol. Hydrolysis of XVII with hydrochloric acid afforded 7-isopropyl-10-hydroxybenzo [b] - tropothiazine (XVIII). This was also obtained by the reaction of 3-bromo-6-isopropyl-2-methoxytropone (XIX)[7] or 7-bromohinokitiol (3-bromo-6-isopropyltropolone) (XX) with *o*-aminothiophenol. XIII and XVIII do not dissolve in dilute acids. XIII does not give molecular compounds such as picrate, but XVIII gives them.

It is considered that compounds XIII and XVIII could exist in two tautomeric forms respectively, i. e. 10-hydroxy derivatives of benzo [b] tropothiazine (XIII and XVIII) and benzothiazinotropone derivatives (XIIIa and XVIIIa). Information on this problem comes from the following data: 1) The ultraviolet spectrum of XII is similar to IV rather than to XIII as shown in Fig. 2. 2) The infrared spectrum of XIII shows $\nu_{NH}$ at 3218 $cm^{-1}$ and $\nu_{C=O}$ at 1607 $cm^{-1}$ (small peak). 3) XIII did not react with diazomethane, but gave yellow acetate XXI with acetic anhydride and orange benzoate XXII with benzoyl chloride in poor yield. The hydrolysis of these acyl derivatives converts them into XIII. $\nu_{C=O}$ at 1673 $cm^{-1}$ in infrared spectrum of XXI indicates that XXI is *N*-acetyl derivative. Remarkable shifts to a shorter wavelength region in the ultraviolet spectra of XXI and XXII (Fig. 2) seem to indicate that a conjugation of seven membered ring and benzene nucleus in XIII is broken by the introduction of the acyl group in the *N*-atom, as an additional reason for the decrease of the coplanarity of these nuclei is also considered.

From consideration of the above results, it seems reasonable to conclude that XIII would exist not as 10-hydroxybenzo [b] tropothiazine, but as its keto form, benzo-1, 4-thiazino [3,2-b] - tropone (XIIIa). XVIII would be named 8 - isopropylbenzo - 1, 4 - thiazino [3, 2-b] tropone (XVIIIa).

It is supposed that *N*-alkylation of the compound XII is possible as in the case of phenothiazine, but the attempted alkylations were not actually successful. Further experiments in this field will be reported in near future.

## Experimental**

**Benzo[b]tropothiazine (IV).** — A solution of 2 g. of 2-chlorotropone and 2 g. of *o*-aminothiophenol in 20 ml. of methanol was allowed to stand at room temperature for 3 hr. The solvent was distilled off and 100 ml. of water added to the residue, and the insoluble portion was filtered off. The filtrate was extracted with two 10 ml. portions of benzene. The mother liquor left after benzene extraction was adjusted to make it slightly alkaline with sodium carbonate solution, then was extracted with five 10 ml. portions of benzene. The latter benzene extract was dried over sodium sulfate and the benzene was distilled off, affording 2.4 g. of deep red crystals. Recrystallization of the crude crystals from petroleum (b. p. 60～70°C) gave 2.2 g. of IV as red plates, m. p. 86～87°C.

The reaction of 2-bromo- or 2-iodo-tropone with *o*-aminothiophenol gave the same compound IV.

Found: C, 74.05; H, 4.20; N, 6.61. Calcd. for $C_{13}H_9NS$: C, 73.92; H, 4.30; N, 6.63%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 275 (4.37), 330 (3.86), 405 (3.79). $\lambda_{max}^{0.1N\ HCl}$ mμ (log ε): 224 (4.27), 238 (4.28), 289 (4.44), 343 (4.02), 470 (3.81).

*Picrate;* dark brown needles, m. p. 188～189°C (decomp.).

Found: C, 52.74; H, 3.42; N, 11.23%.

**9-Isopropylbenzo[b]tropothiazine (X).** — X as red oil was obtained from 2-halo-6-isopropyltropone (VII) and *o*-aminothiophenol.

*Picrate;* violet plates, m. p. 198～199°C (decomp.).

Found: C, 54.39; H, 3.27; N, 11.64%.

*Styphnate;* violet prisms, m. p. 191～192°C (decomp.).

Found: C, 53.19; H, 3.77; N, 10.97%.

**10-Methoxybenzo[b]tropothiazine (XII).** — A solution of 215 mg. of 2-bromo-7-methoxytropone (XI) and 130 mg. of *o*-aminothiophenol in 3 ml. of methanol was warmed for twenty minutes. After allowing it to stand at room temperature for 10 min., the solvent was distilled off, and 20 ml. of water was added and extracted with two 5 ml. portions of benzene. The water layer left after the benzene extraction was adjusted to slightly alkaline with sodium carbonate and was extracted with benzene. The latter benzene extract was dried over sodium sulfate and the solvent was removed, affording 150 mg. of XII as red oil, and was purified by chromatogram, using an alumina.

$\lambda_{max}^{MeOH}$ mμ (log ε): 222 (4.33), 253 (4.28), 280 (4.15), 328 (3.78), 408～410 (3.78).

*Picrate;* dark brown needles, m. p. 184～185°C.

Found: C, 51.01; H, 2.83; N, 11.76. Calcd. for $C_{21}H_{14}O_8N_4S$: C, 51.07; H, 3.00; N, 11.91%.

*Styphnate;* dark brown needles, m. p. 173～174°C.

Found: C, 49.55; H, 2.78; N, 11.25. Calcd. for $C_{21}H_{14}O_9N_4S$: C, 49.39; H, 2.90; N, 11.52%.

**Benzo-1,4-thiazino[3,2-b]tropone (XIII).** — a) A solution of 3 g. of 3-bromotropolone (XV) and 2 g. of *o*-aminothiophenol in 20 ml. of methanol was refluxed for 2 hr. The red needles which separated out by cooling thoroughly were collected by filtration and recrystallization from ethanol or acetic acid, giving 2.6 g. of XIII as red needles, m. p. 168～169°C.

Found: C, 68.84; H, 3.76; N, 6.11. Calcd. for $C_{13}H_9ONS$: C, 68.72; H, 3.99; N, 6.17%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 233 (4.36), 285 (4.33), 440 (3.82). $\lambda_{max}^{0.1N\ HCl}$ mμ (log ε): 230 (4.37), 285 (4.35), 450 (3.81).

b) After allowing a solution of 215 mg. of 3-bromo-2-methoxytropone (XIV) and 130 mg. of *o*-aminothiophenol in 2 ml. of a methanol to stand under cooling, 220 mg. of XIII was obtained.

c) A solution of 50 mg. of XII in 3 ml. of 2 N hydrochloric acid was refluxed for 5 hr., and the crystals which separated out were recrystallized from ethanol, affording 30 mg. of XIII.

**10-Methoxy-8-isopropylbenzo[b]tropothiazine (XVII).** — A solution of 520 mg. of 2-methoxy-4-isopropyl-7-bromotropone (XVI) and 250 mg. of *o*-aminothiophenol in 2 ml. of methanol was refluxed for thirty minutes. The solvent was distilled off and 7 ml. of water was added to the residue and the solution was extracted with benzene. The mother liquor left after the benzene extraction was adjusted to slightly alkaline with sodium carbonate and was extracted with benzene. The latter benzene extract was dried and the removal of the solvent left 270 mg. of red oil. The oil was crystallized with methanol and the recrystallization from methanol gave XVII as orange prisms, m. p. 123～124°C.

---

** All the melting points were uncorrected. The microanalyses were carried out by Mr. S. Azumi and Miss A. Iwanaga, and I. R. spectra were measured with Perkin-Elmer Model 112 by the member of Professor Kinumaki's laboratory, Research Institute, Chemistry of Non-Aqueous Solution, Tohoku Univ., to whom the authors' sincere acknowledgements are hereby extended.

Found: C, 71.70; H, 5.84; N, 4.93, Caled. for $C_{17}H_{17}ONS$: C, 72.06; H, 6.05; N, 4.94%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.41), 255 (4.24 sh), 280 (4.14 sh), 333 (3.74), 408~410 (3.78).

*Picrate;* brown needles, m.p. 160~161°C.

Found: C, 53.99; H, 3.93; N, 10.85. Calcd. for $C_{23}H_{20}O_8N_4S$: C, 53.91; H, 3.93; N, 10.93%.

**8-Isopropylbenzo-1, 4-thiazino[3, 2-b] tropone (XVIII).** — a) A solution of 500 mg. of 7-bromohinokitiol (3-bromo-6-isopropyltropolone) (XX) and 250 mg. of *o*-aminothiophenol in 3 ml. of methanol was refluxed for an hour, the solvent was distilled off and 20 ml. of water was added to the residue, and then extracted six times with 3 ml. each of benzene. The benzene solution was dried over sodium sulfate, passed through an alumina column, and 440 mg. of oily substance was obtained after removal of the solvent from the effluent. The oil crystallized with cyclohexane and the recrystallization from cyclohexane afforded XVIII as red needles, m. p. 94~95°C.

Found: C, 71.01; H, 5.50; N, 5.27. Calcd. for $C_{16}H_{15}ONS$: C, 71.36; H, 5.61; N, 5.20%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 237 (4.31), 277 (4.23), 430 (3.65).

*Picrate;* brownish violet plates, m.p. 141~142°C.

Found: C, 53.70; H, 3.98; N, 11.19. Calcd. for $C_{22}H_{18}O_8N_4S$: C, 53.01; H, 3.64; N, 11.24%.

*Styphnate;* brownish violet plates, m. p. 170~171°C.

Found: C, 51.47; H, 3.47; N, 10.39. Calcd. for $C_{22}H_{18}O_9N_4S$: C, 51.36; H, 3.53; N, 10.89%.

b) A solution of 260 mg. of 2-methoxy-3-bromo-6-isopropyltropone (XIX) and 130 mg. of *o*-aminothiophenol in 3 ml. of methanol was allowed to stand for an hour. 300 mg. of red crystals was obtained after treatment using the same method as (a). These crystals showed no depression of melting point on admixture with a specimen obtained in (a).

c) After refluxing a solution of 50 mg. of XVII in 3 ml. of 2 N hydrochloric acid for 5 hr., the solution was extracted with benzene and the benzene extract was passed through an alumina column, affording 30 mg. of red needles, m. p. 92~93°C. The crystals showed no depression of melting point on admixture with XVIII.

**Acetate (XXI) of XIII.** — One hundred mg. of XIII were dissolved in 0.5 ml. of acetic anhydride, to which one drop of concentrated sulfuric acid was added, and then the mixture was allowed to stand at room temperature. After removing the acetic anhydride, the residue was dissolved in benzene and the benzene solution was passed through an alumina layer. The first elution gave unreacted XIII, but the second effluent afforded yellow prisms. Recrystallization of the latter crystals from methanol gave XXI as yellow prisms, m.p. 169.5~170.5°C.

Found: C, 66.62; H, 3.71; N, 5.36. Calcd. for $C_{15}H_{11}O_2NS$: C, 66.91; H, 4.12; N, 5.20%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 220 (4.39), 303 (4.04).

**Benzoate (XXII) of XIII.** — To a solution of 100 mg. of XIII in 1 ml. of pyridine, 0.2 ml. of benzoylchloride was added and heated for 20 min. The crystals separated out by adding water were dissolved into benzene and the insoluble portion was recrystallized from methanol, affording XXII as orange prisms, m. p. 193~194°C.

Found: C, 72.39; H, 3.71; N, 4.38. Calcd. for $C_{20}H_{13}O_2NS$: C, 72.50; H, 3.96; N, 4.23%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 220 (4.49), 308 (4.01).

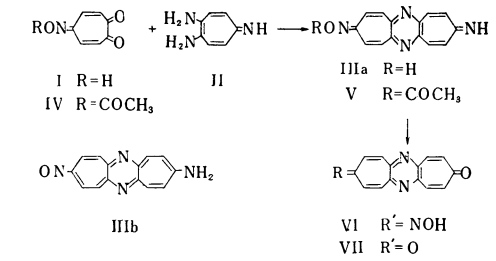
# *On Pyrazino[d, d']ditropone and its Derivatives*

By Toyonobu Asao

(Received July 22, 1960)

It is already known that 2, 5-diaminotroponimine reacts with formic acid and nitrous acid forming 1, 3-diazaazulene or 1,2,3-triazaazulene derivatives respectively[1,2].



If one considers the facile condensation of 5-nitrosotropolone with 1, 2-diamine to form a troponeoxime with the heterocyclic system[3-6], it is expected that the formation of a new 7-6-7 hetrocyclic system in which N-atoms are located in a six-membered ring by application of 2, 5-diaminotroponimine, will make a tautomer of 4,5-diaminotroponimine.

An account of the attempt to synthesize such a 7-6-7 membered ring system is reported herein.

Heating of 5-nitrosotropolone (I)[7] in methanol afforded brown crystals, m. p. over 300°C, $C_{14}H_{11}ON_4Cl$, very easily with dihydrochloride of 2, 5-diaminotroponimine (II)[1]. Neutralization of the aqueous solution of these crystals with sodium hydrogencarbonate gave brown powder III, m. p. over 300°C, $C_{14}H_{10}ON_4$, indicating the former crystals to be monohydrochloride of III. III is insoluble in various organic solvents and recrystallized with difficulty. Ultraviolet spectra of III in acidic and alkaline media show a little shift to longer wavelength region compared with that in methanol.

The structural confirmation of III came from alkaline permanganate oxidation, in which pyrazine tetracarboxylic acid dihydrate, m. p. 205°C[8], was obtained. Its tetramethyl ester obtained by the reaction with diazomethane showed no depression of melting point on admixture with authentic tetramethyl pyrazinetetracarboxylate, m. p. 182°C, obtained by methylation of pyrazinetetracarboxylic acid, the latter being synthesized by oxidation of quinoxalotroponeoxime[3]. Therefore, together with its analytical value and the following reactions, it is clear that III is pyrazino [d, d'] - ditroponemonoiminemonooxime.

Attempted acetylation of III with acetic anhydride led to the formation of a black substance. However, acetate V was obtained by the reaction of acetate IV[3] of 5-nitrosotropolone with II.

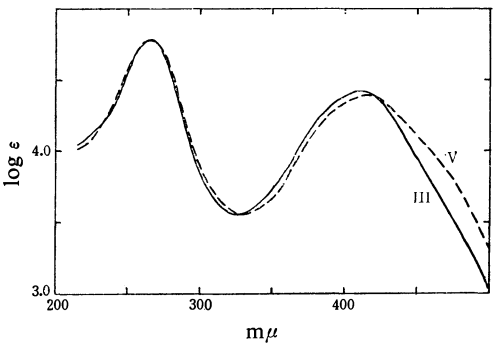


Fig. 1. Ultraviolet absorption spectra of III and V in methanol.

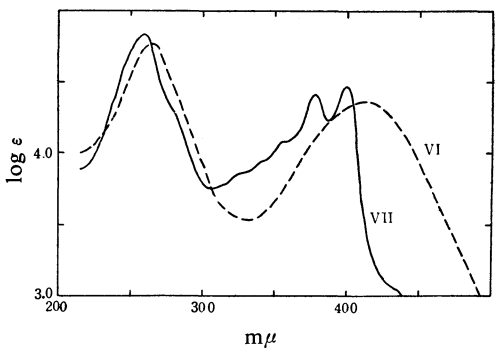

Fig. 2. Ultraviolet absorption spectra of VI and VII in methanol.

8) F. D. Chattaway and W. G. Humphrey, *J. Chem. Soc.*, **1929**, 645.

From the similarity of the ultraviolet spectra of III and V shown in Fig. 1, compound III is assumed to have the structure IIIa rather than its tautomeric form IIIb.

Although III and V are easily soluble in aqueous alkali, acidification of these solutions with acetic acid afforded not the original substance but the same needles VI, m. p. 266°C, $C_{14}H_9O_2N_3$, from both III and V. The infrared spectrum of VI shows peaks at 3250 (O-H), at 1627 (C=O) and at 1585 $cm^{-1}$ (C=C). VI gives carbonyl derivatives such as oxime and 2, 4-dinitrophenylhydrazone. These results indicate VI to be pyrazino[d, d'] ditroponemonoxime, which is produced by hydrolysis of the acetyl group and or imino group in V or III.

The reaction of benzoate[3] of 5-nitrosotropolone and II afforded dark brown crystals. Although these crystals were unstable for further purification, VI was obtained by treatment of these crystals with alkaline.

Heating of III or VI in formic acid in the presence of copper carbonate[5,9] gave pyrazino-[d, d'] ditropone (VII), peaks of infrared spectrum at 1635 (C=O) and at 1598 $cm^{-1}$ (C=C), in poor yield. The ultraviolet spectrum of VII (Fig. 2) exhibits the characteristic fine structure compared with III and VI. This kind of fine structure has been observed in the case of quinoxalotropone or pyrazinotropone[5,6]. While being stable to acid, VII is unstable to alkali and gradually turns to brown in alkaline solution.

## Experimental*

**Pyrazino[d, d']ditroponemonoiminemonoxime (III.)**—A solution of 900 mg. of I and 1.1 g. of dihydrochloride of II dissolved in 40 ml. of methanol was refluxed for twenty minutes and brownish orange crystals separated out. After cooling, 1.3 g. of the crystals, m. p. over 300°C, were obtained by filtration. These crystals are positive to the halogen test and are insoluble in various organic solvents. Recrystallization of the crystals was carried out from a large amount of dilute hydrochloric acid.

Found: C, 58.55; H, 3.66; N, 18.93. Calcd. for $C_{14}H_{10}ON_4 \cdot HCl$: C, 58.64; H, 3.88; N, 19.54%.

Neutralization of these crystals dissolved in a large amount of water with aqueous sodium hydrogencarbonate gave brown powder III, m. p. over 300°C. Attempted recrystallization of III from various solvents was in vain.

Found: C, 66.98; H, 4.10; N, 22.10. Calcd. for $C_{14}H_{10}ON_4$: C, 67.19; H, 4.03; N, 22.39%.

*Picrate;* red needles, m. p. over 300°C, turn to black from about 225°C.

Found: C, 50.21; H, 3.00; N, 20.50. Calcd. for $C_{20}H_{13}O_8N_7$: C, 50.11; H, 2.73; N, 20.45%.

**Oxidation of III.**—To a solution of 500 mg. of III and 400 mg. of potassium hydroxide dissolved in 40 ml. of water, a solution of 5g. of potassium permanganate dissolved in 250 ml. of water was added at 80°C in a period of 6 hr. The excess of potassium permanganate was killed by a few drops of methanol and the resulting manganese dioxide was filtered. Manganese dioxide was washed with hot water thoroughly, and the combined solution of filtrate and washing was concentrated to about 15 ml., and was acidified with dilute hydrochloric acid affording colorless crystals, 230 mg. Recrystallization of the crystals from hydrochloric acid gave pyrazinetetracarboxylic acid as colorless plates, m. p. 205°C (decomp.).

Found: C, 32.72; H, 2.43; N, 9.81. Calcd. for $C_8H_4O_8N_2 \cdot 2H_2O$: C, 32.89; H, 2.76; N, 9.59%.

By the methylation reaction of 10 mg. of pyrazinetetracarboxylic acid with diazomethane, colorless needles, m. p. 181~182°C (from methanol-benzene) were obtained. This ester showed no depression of melting point on admixture with tetramethyl pyrazinetetracarboxylate obtained by another route.

Found: C, 46.32; H, 3.84; N, 8.92. Calcd. for $C_{12}H_{12}O_8N_2$: C, 46.16; H, 3.87; N, 8.97%.

**Acetate V.**—A solution of 200 mg. of acetate IV of 5-nitrosotropolone and 200mg. of dihydrochloride of II dissolved in 5 ml. of methanol was refluxed for 10 min., affording 300 mg. of red needles, which turn to black from around 250°C.

Found: C, 58.27; H, 3.77; N, 17.81. Calcd. for $C_{16}H_{12}O_2N_4 \cdot HCl$: C, 58.44; H, 3.98; N, 17.04%.

Neutralization of aqueous solution of the above crystals gave acetate V of III as brown powder, m. p. over 300°C.

Found: C, 65.60; H, 3.99; N, 19.07. Calcd. for $C_{16}H_{12}O_2N_4$: C, 65.75; H, 4.14; N, 19.17%.

**Pyrazino[d, d']ditroponemonoxime (VI).**—A solution of 100 mg. of hydrochloride of III dissolved in 1.5 ml. of 3 N sodium hydroxide solution was heated gently for 3 min. Ammonia gas evolved during this time. After allowing the solution to stand for 30 min. at room temperature, it was acidified with a few drops of acetic acid. Orange crystals, 70 mg., precipitated out were recrystallized from pyridine yielding, orange needles, m. p. 266°C (carbonize).

Found: C, 66.95; H, 3.77; N, 17.16. Calcd. for $C_{14}H_9O_2N_3$: C, 66.92; H, 3.61; N, 16.73%.

*Oxime;* red fine crystals (from pyridine), m. p. over 300°C.

Found: C, 63.79; H, 3.84; N, 20.62. Calcd. for $C_{14}H_{10}O_2N_4$: C, 63.15; H, 3.79; N, 21.04%.

*2, 4-Dinitrophenylhydrazone;* violet crystals, carbonize at about 265°C.

Found: C, 55.31; H, 3.24; N, 22.88. Calcd. for $C_{20}H_{13}O_5N_7$: C, 55.68; H, 3.04; N, 22.77%.

**Pyrazino[d, d']ditropone (VII).**—a) A mixture of 150 mg. of hydrochloride of III and 150 mg. of copper carbonate in 4.5 ml. of 80% formic acid was

9) R. Robinson, *Nature*, 173, 541 (1954).

* All the melting points were uncorrected. The microanalyses were carried out by Messrs. S. Oyama, S. Azumi and Miss A. Iwanaga, and I. R. spectra were measured with Perkin-Elmer Model 112 by a member of Professor Kinumaki's laboratory, Research Institute, Chemistry of Non-Aqueous Solution, Tohoku Univ., to whom the author's sincere acknowledgements are hereby extended.

heated at 80°C for 70 hr. The resulting brown precipitates were filtered affording 30 mg. of VI. By neutralization of the filtrate, 20 mg. of precipitates were obtained. Recrystallization from pyridine gave VII as gold-colored needles, m. p. 244~245°C (decomp.).

Found: C, 71.14; H, 3.43; N, 12.38. Calcd. for $C_{14}H_8O_2N_2$: C, 71.18; H, 3.41; N, 11.86%.

b) Three hundred milligrams of VI were heated at 75°C for 120 hr. with 300 mg. of copper carbonate and 10 ml. of 80% formic acid. After cooling, 150 mg. of undissolved VI was obtained. Neutralization of the filtrate with sodium hydrogencarbonate afforded 70 mg. of solid. Recrystallization from pyridine gave gold-colored needles VII, m. p. 244~245°C (decomp.).

The author takes this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe for his kind guidance throughout these experiments, as well as to Assistant Professor Toshio Mukai and Dr. Sho Ito for their kind advice and suggestions.

# *The Mechanical Behavior of Swollen Polystyrene, Poly-p-chlorostyrene and their Copolymers in Benzene. II. Stress Relaxation under Constant Strain*

By Kazuyoshi OGINO

(Received May 2, 1960)

In the previous paper[1], the stress relaxation of swollen polymethylacrylate gels in several organic solvents was studied, and it was shown that the smaller the volume fraction of polymer is, the greater degree of relaxation, and the higher temperature dependency of stress relaxation are observed.

In this paper, the stress relaxation of gel swollen in benzene is studied as a function of intermolecular force which is controlled by changing the content of substituted chlorine atoms in the chain molecules[2].

When a viscoelastic body is strained quickly to a definite extent and kept at this state, the relaxation of stress is observed.

Tobolsky et al. have shown[3] that the relaxation curves at different temperatures can be superposed upon each other when plotted as the reduced stress, $g$, against the logarithmic time, and that a change in temperature corresponds to a shift of the curve along the logarithmic time scale. (In the present experiment, the stress is arbitrarily reduced to 20°C, and is denoted by $g_{20}$.)

The existence of this superposition principle of relaxation curves at different temperatures indicates that the relaxation curves for the same polymer at different temperatures are identical if plotted as the reduced stress vs. the logarithm of $(Kt)$ where $K$ is a function of temperature. Or we can express the reduced stress $g_{20}$, for example, as a function of $Kt$[3]; i. e.,

$$g_{20} \equiv g_{20}(Kt)$$

It is found that the temperature dependence on $K$ may be expressed by Arrhenius's equation[3]

$$K = A \exp.\ (-H/RT)$$

The apparent activation energy $H$ can therefore be calculated by plotting the logarithm of the time factor $K$ against the reciprocal of absolute temperature.

## Experimental

**Samples.**—About 4 cc. of styrene (for sample A), *p*-chlorostyrene (for sample D) or their mixtures (for samples B and C) which contains one drop (about 2 mg.) of divinylbenzene and about 10 mg. of benzoyl peroxide was polymerized thermally in bulk in a sealed glass tube. They were swollen in

benzene to the equilibrium state. Benzene was purified by shaking several times with concentrated sulfuric acid, and with distilled water, and was then dried over calcium chloride and redistilled.

Volumes of *p*-chlorostyrene and styrene monomer before polymerization are shown in Table I.

**Apparatus.** — The apparatus used to observe the change of stress with time is the same as was described in the previous paper[1], and is shown in Fig. 1; a definite strain (11.2%) is given to the specimen (A) and the stress, measured by the vertical component of the chain length, is recorded on a rotating drum. The chain corresponding to and following the decaying stress at each time is controlled by a balancing motor (E) which is connected to a relay (F) through an amplifier circuit (G).

## Results and Discussion

The experimental curves of the reduced stress against logarithmic time for each polymer are shown in Figs. 2, 3, 4 and 5.

The apparent activation energy for the relaxation obtained by plotting the logarithm of the time factor $K$ against the reciprocal temperature is also shown in each figure.

If these curves at different temperatures are superposed with each other by suitable translations along the logarithmic time axis, the master curves shown in Fig. 6 are obtained.

Four parameters in the mechanical model[1]

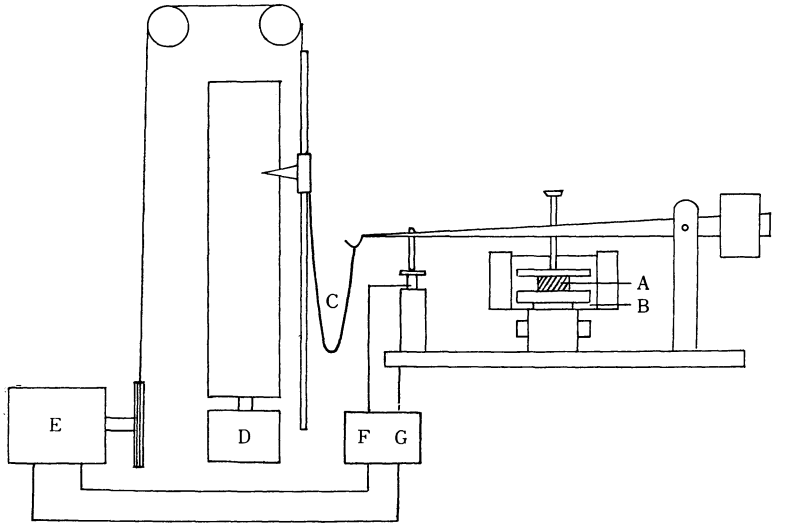

Fig. 1. Chainomatic balance.

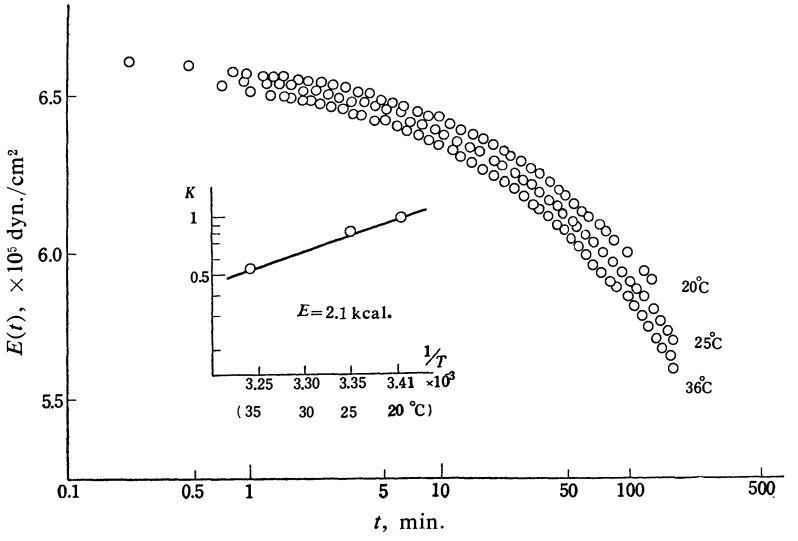

Fig. 2. Stress relaxation curves for sample A, $E$=2.1 kcal.

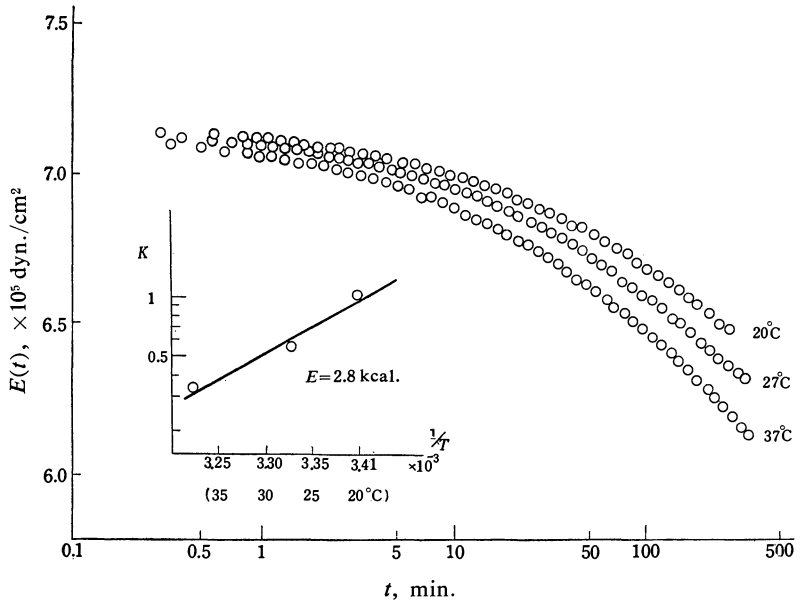

Fig. 3. Stress relaxation curves for sample B, $E$=2.8 kcal.

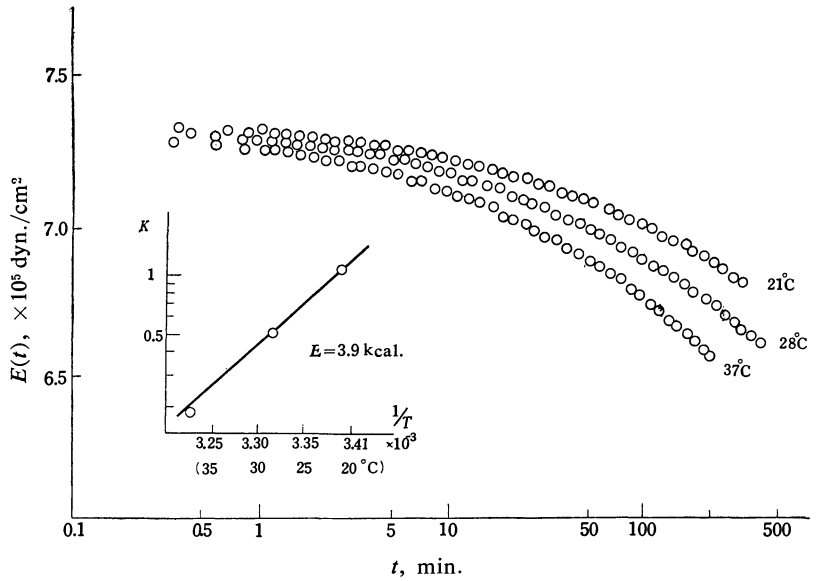

Fig. 4. Stress relaxation curves for sample C, $E$=3.9 kcal.

to express the curves of Fig. 6 are listed in Table II.

As these gels are cross-linked chemically by divinylbenzene, we can expect that the stress relaxation in the present case arises mainly from the breakage or slippage of some weak bonds such as entanglements or other secondary bonds present between junction points.

The value of $G_1$, in Table II, increases with the increase of chlorine content. Considering that these gels have nearly equal values of $v_r$, volume fraction of polymer at swelling equilibrium[4], the fact that the initial Young's modulus $G_1$ increases with the increase of chlorine content leads to the assumption that the stronger interaction force between chain molecules appears by the presence of chlorine atoms.

As each parameter in the four-element model for the chlorine rich gel, especially $\eta_2$ or $\eta_3$, is large, we can assume that the contribution of chlorine atoms to the relaxation or viscous

property is, primarily, a decisive factor.

When we express these mechanical properties by this four-element model, the value of the retardation time $\eta_2/G_2$ can be expected to have a comparable value to the observation time scale, and values of these parameters in Table II can be considered to be reasonable from this point.

Hatfield and Rathmann assumed[5] that for swollen gels viscous flow or molecular slippage is brought about by chemical rupture of primary bonds. For the fact that $\eta_2/G_2$ in Table II has the order of about 10° sec., the author assumed that the retardation time of this order

5) M. R. Hatfield and G. B. Bathmann, *J. Appl. Phys.*, 25, 1082 (1951).

may correspond to the slippage of some secondary bonds in polymeric substances.

The values of $\eta_3$ in the four-element model for the other polymeric substances are much smaller than that of this gel (about $10^7$ poises is expected in the usual case). This parameter may be considered to correspond to a process of a longer retardation time. It will be possible to consider that for swollen gels most of the secondary bonds are set free by solvation, and that the number of bonds which are to slip off or to be liberated per unit time under constant strain are much fewer than those in the dry and undiluted states. The apparent rate of flow will therefore be smaller, and the viscosity will then be much greater ($10^{12}$ poises).

The apparent activation energy for relaxation process is also great when the chlorine content increases. The great activation energy means great temperature dependence. As the contribution of energy term to the elasticity or the value of $\mu$, polymer-solvent interaction parameter[4], increases with the increase of chlorine content[2], we can presume that the cause of the great temperature dependence may be the fact that the breaking of some secondary bonds are favored because the solvent-polymer contacts increase, or that these bonds come to be slipped off more easily as temperature rises. In the case of polystyrene gel, on the other hand, there may be no residual secondary bonds to be released by temperature rise.

These facts can be interpreted by considering the appearance of the interaction force by the introduction of chlorine atoms, as was mentioned here and in the previous paper[2].

In this discussion, the author considered that the nature of the solvent itself has no influence upon the relaxation phenomena of swollen gels, as it may not be affected by the different content of chlorine atoms in the swollen gels.

# *The Chemical Reaction in Silent Electric Discharge. I*

By Kihei MORINAGA and Momotaro SUZUKI

(Received June 16, 1960)

In a series of reports[1-3], it was proposed that in regard to the chemical processes in silent electric discharge, more significance should be put on the high frequency pulse current which accompanies the discharge, rather than on the basic current, usually 50 c/s, which sustains the whole discharge process.

In the present work some electrical, as well as geometrical conditions contributing significantly to the ozone formation process, were studied in more detail. This seems to have been helpful in realizing the actual feature of the reaction.

## Experimental

The discharge tube used was of the Siemens type with two concentric glass cylinders which served as dielectric electrodes. The whole length and diameter of the discharge tube was 35 cm. and 4 cm. respectively. The outer surface of the outer cylinder was patched with tin foil and the inner tube was filled with brine. The area covered by the foil patches varied from 50 to 200 $cm^2$ for the purpose of having the desired electrode area. To change the gap distance, several ozonizers of the same type with different gap distance of 1~3 mm. were used. The electrical system was a usual circuit. The current of 50 c/s city source was sent through a voltage regulator to a leakage transformer where the voltage was stepped up to the required value. The discharge current was side circuited by a cathode ray oscillograph (Toshiba ST-1651) for the observation of basic 50 c/s, as well as the high frequency pulse current.

The whole system of the circuit is shown diagrammatically in Fig. 1. A series of shots of each oscillogram were taken using the single sweep system. The time constant of the oscillogram circuit was $5.4\times10^{-6}$ sec.

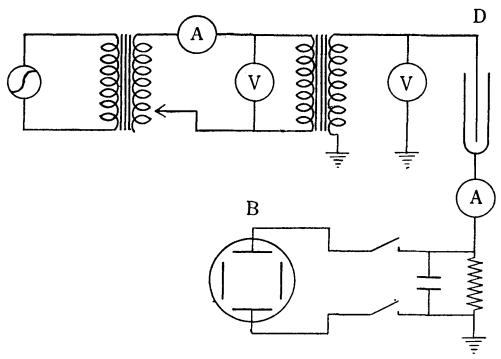

Fig. 1. The circuit system.
D, ozonizer; B, oscillograph

The sum of the height of each pulse current which appears as hairs on the base current diagram in an oscillogram, is due to the total electricity carried through the electric discharge during a cycle of base current which is simply noted here as pulse current[2]. The value of the sum in every run is an arithmetic mean of several successive shots of the oscillogram.

To obtain the yield of ozone in each run the leading glass tube distance from the discharge tube to the ozone absorption bulb was shortened as much as possible. The gas mixture submitted to the discharge was led through the neutral potassium iodide solution in the absorption bulb which was later analyzed by the usual known process. The oxygen, which served as a reactant, was taken from a cylinder and used after drying with calcium chloride.

## Results

Variation in ozone concentration in the oxygen gas after leaving the discharge vessel with apparent residence time $\tau$, is shown in Fig. 2. The ozone concentration increases at first linearly as the time of residence increases, until finally it reaches a saturation value. At a saturation state the rates of the ozone formation and of the ozone destruction by any of the chemical entities existing there have equal values. This leads to the stationary ozone concentration in the exit gas.

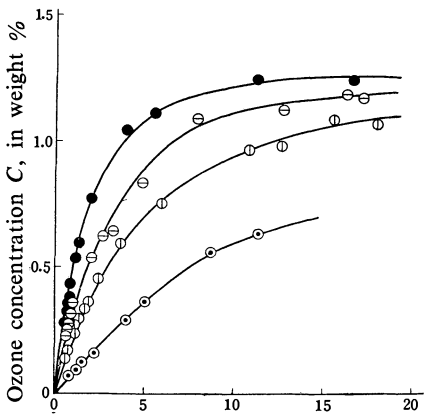

Fig. 2. The relation between the ozone concentration $C$ and the residence time $\tau$. Gap distance 2 mm. electrode area 100 cm².
● Pulse current 184~199 μamp.
⊖ 148~155 μamp.
⊕ 87~92 μamp.
⊙ 28~30 μamp.

The rate value of ozone formation $Y$ (mg./sec.) at $\tau=0$ where presumably hardly any destruction reaction takes place is referred to further in the results. This consideration will simplify the discussion to some extent, because the reaction, in that case, will be restricted simply to the formation of ozone.

The numerical value of the pulse current is obtainable from the comparison of the sum of length of a certain pulse current with an adequate standard current. In Fig. 3, the value of $Y$ (mg./sec. at $\tau=0$) is plotted against the pulse current in $\mu$amp. which was obtained through the above procedure. These curves manifest themselves again as a group of straight lines of which the inclination depends solely upon the physical conditions under which the experiments were carried out.

The dependence of ozone yield per unit pulse current $Y_I$ (mg./sec. $\mu$amp.) on $A/d$, where $A$ (cm²) is the area of the electrode,

■ Area 50 cm². Gap 3 mm.

and $d$ (mm.) is the gap distance between electrodes, is shown in Fig. 4. $Y_I$ values increase linearly with $A/d$, no matter how the individual value of $A$ or $d$ varies respectively, nor does it depend upon the total value of the current through the discharge vessel. The inclination of the straight lines has the value of $7.0\times10^{-7}$ (mg./sec. $\mu$amp. cm.).

In Figs. 5, 6 and 7, ozone concentration (weight %) at steady state was plotted against pulse current. It will be seen from the figures that the ozone concentration is the highest at a certain optimum value of electrode area, and above or under this value the ozone concentration becomes lower.

## Discussion

The behavior of the diagram which manifests itself in Fig. 4 seems to require some explanation from the chemical as well as the electrical viewpoint.

To begin with, under the experimental conditions during which the measurements were made, Paschen's law is applicable with virtual validity[4]. Then, as the pressure throughout the measurements is atmospheric and therefore constant, the sparking potential $E_s$, which initiates each individual small discharge at certain points on the electrode surface, depends solely on the gap distance $d$[2]. Further, $E_s$ should increase proportionally with $d$ within our experimental conditions[2].

With increasing $E_s$, the leaving of electrons from the electrode surface will be more difficult where on the oscillogram the hairs will shift to the upper part of the basic wave form and its placement will be more dense. Keeping ones sight on a certain definite number of electrons from the electrode, and taking into consideration the fact that the spots are distributed fairly uniformly and that the number of electrons issuing from each spot are virtually equal[2], the number of spots from which the individual small discharge starts will accordingly be less and the decrease of the number of spots in a unit area shows that the spots are located more sporadically. Or in our experimental conditions the greater the gap distance is, the greater the sparking potential, the less the number of spots in a unit area where the individual small discharge starts and finally the more the number of electrons which leave each spot, so long as one definite number of electrons which come into reactions are dealt with.

Now electrons leaving the electrode will collide with surrounding chemical molecules initiating some chemical change which leads to a chemical reaction.

Collisions which would cause some chemical reaction would seem to prevail as long the electrons travel along the spark gap distance. But actually the electrons, just after leaving the electrode, only then have sufficient energy to provoke a chemical effect such as dissociation. With the first collision, electron energy is virtually lost. Normally, the electron would regain energy in the electrical field; but, because of the very short mean free path, which is in the order of $10^{-6}$ cm. at atmospheric pressure[5], the electrons can not acquire sufficient energy to be able to react further chemically. Thus, further collisions between electron and molecule will hardly contribute to the initiation of the ozone formation. Accordingly, after the first collision, the distance traveled by the electron through gap distance may be disregarded in this discussion.

As far the change of Townsend's first coefficient $\alpha$ in relation to the gap distance; $\alpha/P$ is known to be the function of $X/P$ where $X$ is field strength. In this experiment the pressure is constant, $\alpha$ therefore, depends solely on $X$. As $X=E_s/d$ and $E_s$ increases proportionally with $d$, the $X$ value is independent of $d$. Thus the behavior of $\alpha$ along with change of $d$ can likely be neglected in this present case.

In Fig. 4 $Y_I$ is shown to be proportional to the electrode area $A$ and inversely proportional to the gap distance $d$. The increase of $A$, keeping the total electron number constant, leads to the increase of the total spot number in a whole discharge tube, because the increase

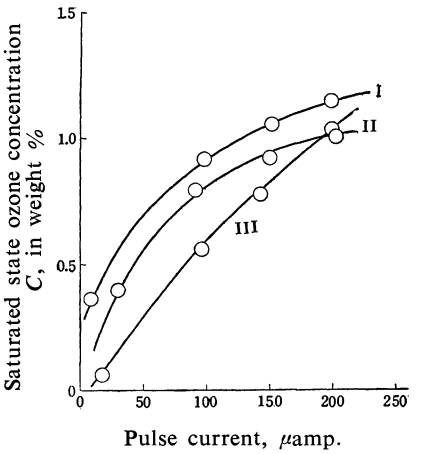

Fig. 7. Saturation ozone concentration against pulse current (Gap distance 3 mm.).
I Electrode area $A=100\,cm^2$; II $A=200\,cm^2$; III $A=50\,cm^2$

of the discharge area implies that the spots come to be distributed more sporadically and more chances are offered for the generation of more new spots. This corresponds to the effect of decreasing gap distance as just stated above. It might be conceivable if $Y_1$ be inversely proportional to $d$; then it should be proportional to $A$.

A tentative explanation of this phenomena is proposed as follows: In the experiment the average value of the pulse current is about 100 μamp., and the number of hairs on the half wave of 50 c/s base current from city source, in an oscillogram, is virtually 30~50. The number of spots involved in a hair, i. e. in one shot of pulse current, is about $10\sim10^{2}$ [2], thus the number of electrons ejected from a spot has the order of $10^{10}$. On the other hand, the area of each spot is $10^{-2}\sim10^{-4}\,cm^2$ [2], and the number of molecules just in front of this area is about $10^{10}$ or a little less, which means that the above number of gas molecules has almost the same number or a little fewer than those of ejected electrons from a spot.

Now the velocity of electrons, just after they leave the electrode, is estimated at $10^{8}\sim10^{9}$ cm./sec.[6] which features, because of the virtually instantaneous time of travel up to the first collision, that the electron beam from each spot might seem to suffer hardly any appreciable conical diversion and hit the molecule target covering almost the same dimension as the spot area.

In this pattern of collision, the more sporadically the spots are located, the more packed is the ejected stream electrons, which lead to the increase of the ineffective collision. The rate of the ineffectiveness will essentially be regarded to be linear to the rate of congestion of the electron stream. Thus the effective collision number for a definite number of electrons of $Y_1$ is proportional to the number of spots, or in other words, to the electrode area and the reciprocal of the gap distance.

The postulate appears qualitatively to make sense, but from the quantitative point of view further and more detailed investigation may be required.

**Summary**

1. The ozone yield $Y$ from oxygen gas in the silent electric discharge in a Siemens ozonizer is proportional to the pulse current which was measured from an oscillogram where $Y$ is referred to $\tau=0$ value. The proportionality is valid independent of the gap distance $d$ between electrodes and the effective area $A$ of electrodes.

2. The above ozone yield $Y_1$ which is referred to $\tau=0$ and further to unit pulse current is proportional to $A/d$.

3. The reason of the above relationship is briefly discussed.

# *Dehydrogenation of Secondary Alcohols with Reduced Copper. III*[1]. *Catalytic Dehydrogenation of Isopropyl Alcohol (Part 1)**

By Kazuaki KAWAMOTO**

(Received July 16, 1960)

Although there are a large number of patents and are latively small number of reports concerning the vapor phase dehydrogenation of isopropyl alcohol to acetone, the majority deal with the use of copper in some form as the catalysts. Sabatier[2] found that reduced copper heated at 200~300°C is a suitable catalyst for the dehydrogenation of alcohols to aldehydes or ketones with no side reaction, and he showed that isopropyl alcohol, in the presence of reduced copper, is dehydrogenated to acetone slowly at 150°C, and rapidly and smoothly in the whole range of temperatures between 250°C and 430°C without the formation of a large amount of propylene. This method was improved by Bouveault[3], Armstrong[4] and Palmer[5]. A remarkable addition to the knowledge of the contact action of reduced copper was made by Komatsu[6], who found that reduced copper has the property of promoting not only the dehydrogenation but also dehydration of alcohols and that isopropyl alcohol is transformed into acetone and propylene by exposure to high temperature (300°C). Platonow et al.[7] found that in the presence of copper dehydrogenation of isopropyl alcohol at 300°C furnishes 53.2% of the theoretical yield of acetone. Moreover, Katsuno[8] reported the synthesis of acetone from isopropyl alcohol, using copper-active-carbon or copper-kieselguhr as a catalyst. Dunbar and Arnold[9] also used a copper-chromium-oxide catalyst with considerable success in the dehydrogenation of isopropyl alcohol.

The reduced copper is little used at present for the industrial synthesis of ketones from alcohols. However, copper is considered as the most important component in the majority of widely used mixed catalysts. Therefore, the behavior of the reduced copper catalyst will be of special interest for the interpretation of the mechanism of catalysis with mixed copper catalysts.

Earlier, Frolich et al.[10] found that the copper catalyst prepared by precipitation with sodium hydroxide is more active in the decomposition of methanol than that precipitated with ammonia, and Fischer and Meyer[11] studied the influence of the precipitants on the

nickel-thoria-kieselguhr catalyst, which is used as a catalyst for the Fischer-Tropsch synthesis. For this catalyst potassium carbonate was the best precipitant and the preparation using sodium hydroxide or potassium hydroxide was virtually inactive. Further, Niwa and Yamaguchi[12] reported that the activity of the copper catalyst prepared with sodium hydroxide is greater than that treated with ammonium carbonate.

As no comparative study of the action of reduced copper catalysts prepared with a number of precipitants upon secondary alcohols has been reported, the present work has been undertaken to discover how the reaction temperature and the precipitant influence the activity and the behavior of the catalysts, and furthermore to find the most suitable condition and the most suitable catalyst for the preparation of acetone from isopropyl alcohol. Experiments were carried out at several temperatures between 185°C and 325°C, and five different precipitants, i. e. sodium hydroxide, potassium hydroxide, potassium carbonate, sodium bicarbonate and potassium bicarbonate, were used.

## Experimental

**Purification of Isopropyl Alcohol and Acetone.**—The isopropyl alcohol used in this research was purified, after being dried with anhydrous potassium carbonate, by fractionation through a Widmer column: b. p. 82~82.5°C, $n_D^{25}$ 1.3753, $d_4^{25}$ 0.7811. Acetone was also purified in an analogous manner: b. p. 56.2~56.3°C, $n_D^{25}$ 1.3564, $d_4^{25}$ 0.7844.

**Preparation of Catalysts.**—Komatsu and Kurata[13] previously found that the reduced copper catalysts derived from copper sulfate and copper nitrate act to promote both dehydrogenation and dehydration of *l*-menthol. The degree of dehydration, however, was smaller with the catalyst prepared from copper nitrate than with that from copper sulfate under the same conditions. Consequently, the present author used copper nitrate as the starting material to prepare the dehydrogenation catalyst. Copper nitrate was prepared from electrolytic copper and nitric acid, and was purified by recrystallization. The catalysts are classified into Cu I, II, III, IV and V, as shown in Table I. These catalysts were prepared similarly except for the species and amount of the precipitant. For example, Cu I was prepared as follows: A solution of 30 g. of cupric nitrate hexahydrate in 900 ml. of distilled water was kept at 90°C. A sodium hydroxide solution, prepared from 300 ml. of distilled water and 15 g. of sodium hydroxide, was brought to the same temperature and added rapidly to the stirred copper nitrate solution. After the mixture was stirred at this temperature for 30 min., the precipitate was washed by decantation with a copious amount of warm water (at 70°C), collected on a glass filter, dried in an electric oven at 105°C for 10 hr., powdered in an agate mortar and finally stored in a stoppered bottle. It has been reported[14] that the occluded or absorbed impurities (mainly anions) in the preparation of reduced copper influence the activity. Accordingly, to minimize the inclusion of such impurities dilute solutions were used for precipitation and the resulting precipitates were then washed well with distilled water by decantation. The chemicals used were of the purest reagent grade and all vessels were washed with nitric acid and rinsed with distilled water.

TABLE I. PREPARATION OF CATALYSTS

| Catalyst | Precipitant | Amount of precipitant g. | Distilled water ml. | Color of catalyst |
|---|---|---|---|---|
| Cu I | NaOH | 15 | 300 | black |
| Cu II | KOH | 24 | 500 | black |
| Cu III | $K_2CO_3$ | 25 | 500 | dark brown |
| Cu IV | $NaHCO_3$ | 30 | 300 | yellowish green |
| Cu V | $KHCO_3$ | 40 | 400 | yellowish green |

**Apparatus.**—The apparatus, illustrated diagrammatically in Fig. 1, is designed to measure the ratio of dehydrogenation and dehydration by the catalysts. Hydrogen coming from the reservoir (A) was passed through a tube (C) containing heated copper gauze to remove the oxygen present in the hydrogen by converting it into water, and then through a bottle (D) containing a 30% sodium hydroxide solution

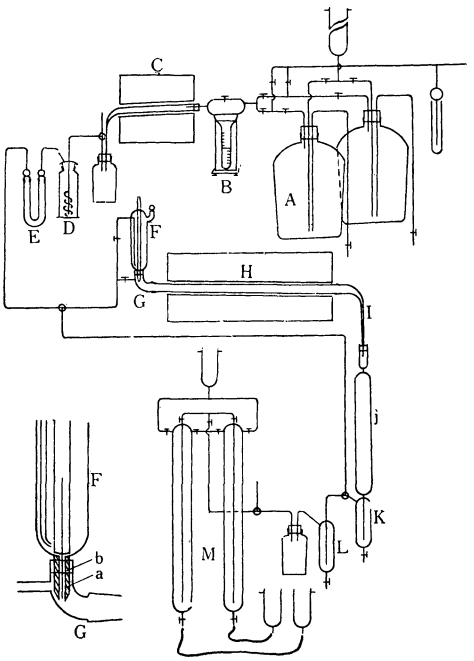

Fig. 1. Apparatus.

and a solid sodium hydroxide tube (E). The hydrogen flow was measured by passing it through a calibrated flowmeter (B). The reaction tube (H) was a hard glass tube of 1 m. length and 18 mm. inside diameter, and was set in a combustion furnace and in this tube 10 g. of the catalyst to be used was spread in a length of approximately 70 cm. This tube was inclined at an angle of about 5° to insure proper drainage of the liquid product and the temperature was measured by a thermometer at a position of 30 cm. from the exit end of the catalyst bed. A rate of flow of the sample can be kept approximately constant by varying the extent of the insertion of the tungsten wire (a) into the capillary (b) (Fig. 1), and connecting the funnel (F) with a receiver (K) to keep the pressure equal. The sample is vaporized through a vaporizer (G) before reaching the catalyst. This vaporizer was made of a hard glass tube filled with glass wool and heated to a desired temperature by a heater. The reaction tube was connected with a condenser (J) by means of an adapter (I). The liquid product condensed was collected in a receiver (K) and uncondensed vapor was absorbed in water in a bottle (L). Noncondensable gas was collected in a gas-holder (M).

**Procedure.**—The catalyst was placed in the reaction tube and the apparatus was tested for gas-tightness. After the tube was filled with hydrogen, the furnace was heated to the reduction temperature, and was kept at this temperature for the period of reduction. Care was taken during the reduction to avoid the overheating of the catalyst as the reaction is exothermic, and the reduction temperature was always below 185°C. The standard flow rate of hydrogen (measured at room temperature) was 750~900 ml. per hour. The reduction was continued until the color of the catalyst changed from black or yellowish green to reddish purple and then the hydrogen supply was stopped and the resulting catalyst was heated to the operating temperature. Experiments were performed at 185, 250, 305 and 325°C under the ordinary pressure, and in the case of the copper catalyst precipitated with sodium hydroxide, further experiments were carried out at 220°C and 280°C, and during the run which lasted for several hours, the temperature was maintained within about ±5°C of the desired temperature. A definite weight of the alcohol or acetone was supplied from the dropping funnel (F) at the predetermined rate. The vapor coming out from the reaction tube was condensed by passing through a condenser cooled with ice water and the escaped gas from the condenser was passed into ice-cooled distilled water (50 ml.) to catch condensable products completely. The noncondensable gas which came out of the receiver (L) was collected in a gas-holder and its volume was measured from time to time. At the end of the run, the weight of liquid products collected in the receiver, that absorbed by water in the bottle, and the volume of noncondensable gas in the gas-holder were measured. The condensed product and the water solution in the bottle were combined. If an oily product

* Calculated from the volume of the gaseous product collected in each experiment on the assumption that original isopropyl alcohol is transformed completely into gases such as hydrogen or propylene.

was formed, this was separated from the water layer and washed with a known volume (20 ml.) of distilled water. If the oily product was not formed, the aqueous solution was analyzed by the method described below.

**Analysis of the Products.**—The aqueous solution was recognized to consist of acetone and unchanged isopropyl alcohol by the preparation of the 2,4-dinitrophenylhydrazone and the phenylurethan, respectively, and the content of the acetone was determined by the hydroxylamine method[15]. The reliability of this analytical method was checked by titrating a known sample of acetone and the result was found to be correct within experimental errors. The oily product, which was obtained in some of the experiments, was dried with anhydrous sodium sulfate and then fractionally distilled through a Widmer column. Isobutyl methyl ketone was present in a fraction that showed the properties: b. p. 110~125°C, $n_D^{25}$ 1.3963, $d_4^{25}$ 0.7908, and a semicarbazone, m. p. 133~133.5°C and a 2,4-dinitrophenylhydrazone, m. p. 93.5~94°C were obtained and showed no depression of the melting points when mixed with the known derivatives of isobutyl methyl ketone. Diisobutyl ketone was found mainly in a fraction as follows: b. p. 160~170°C, $n_D^{25}$ 1.4115, $d_4^{25}$ 0.8012, and it was identified on the basis of the preparation of the 2,4-dinitrophenylhydrazone, m. p. 92~92.5°C and the semicarbazone, m. p. 122~122.5°C which were shown to be the corresponding derivatives of diisobutyl ketone by the mixed melting point determination. The formation of unsaturated and hydroxy ketones such as mesityl oxide, phorone and diacetone alcohol, was not detected in the oily product.

## Results and Discussion

The influence of the precipitants and reaction temperatures on the activity and the selectivity of the copper catalysts is summarized in Table II. Experiments were controlled so as to regulate the reducing condition of the precipitate* with hydrogen as far as possible and further to maintain the constancy of the velocity of the isopropyl alcohol passing over the catalyst. To find the difference in the reaction products on varying the reaction temperature and the optimum temperature for dehydrogenation, the catalytic reaction was performed at 185, 250, 305 and 325°C. Since isopropyl alcohol was not changed in the absence of the catalysts over the range (185~325°C) of temperatures, the changes shown in Table II do not involve the simple pyrolysis of isopropyl alcohol. The yield of acetone shown in Table II does not necessarily represent the maximum yield but is an average of three or four experiments under the constant operating condition. However the fluctuation in the yields of acetone and of the oily product obtained by the repeated experiments was less than 1 per cent, and thus within the limit of experimental error in the determination of acetone.

**Influence of the Reaction Temperatures on the Dehydrogenating Activity of Reduced Copper.**—The dehydrogenating activity of the various copper catalysts depends upon the temperature at which the reaction is carried out. Using a copper catalyst, the equilibrium constant for the reaction of isopropyl alcohol to form acetone and hydrogen has been measured[16]. Though the results obtained by various workers show little agreement, it is accepted that the equilibrium transfers to the direction of dehydrogenation at the reaction temperature above 220°C. Consequently, at low temperatures the copper catalyst has a poor activity for dehydrogenation. In the present research all catalysts act to promote dehydrogenation of isopropyl alcohol at high temperatures, and at the highest reaction temperature (325°C) the dehydrogenation of isopropyl alcohol to acetone is the highest.

**Influence of the Precipitants on the Dehydrogenating Activity of Reduced Copper.**—As shown in Table II, the dehydrogenating activity of the copper catalysts varies considerably with the sort of precipitants, and the catalyst prepared by the treatment with potassium bicarbonate showed the largest activity. On the contrary, the catalyst prepared with sodium hydroxide showed the smallest activity. The dehydrogenating activity of the copper catalysts prepared with various precipitants is in the following order: $KHCO_3 > NaHCO_3 > K_2CO_3 > KOH > NaOH$.

The author presumed that the catalysts prepared with alkali bicarbonates possess a capillary or a porous structure on account of the evolution of carbon dioxide at precipitation or the hydrogen treatment, and this is one of the reasons for the large dehydrogenating activity of the catalysts.

**The Relation between the Amount of Gas Evolved and that of Acetone Produced.**—When the oily product was not formed, the difference between the theoretical yield of acetone and the percentage of conversion was a few per cent. Therefore, the dehydration of isopropyl alcohol to propylene seems to occur little at temperatures below 325°C. Accordingly, the dehydration is not an important factor from the viewpoint of dehydrogenation. When the

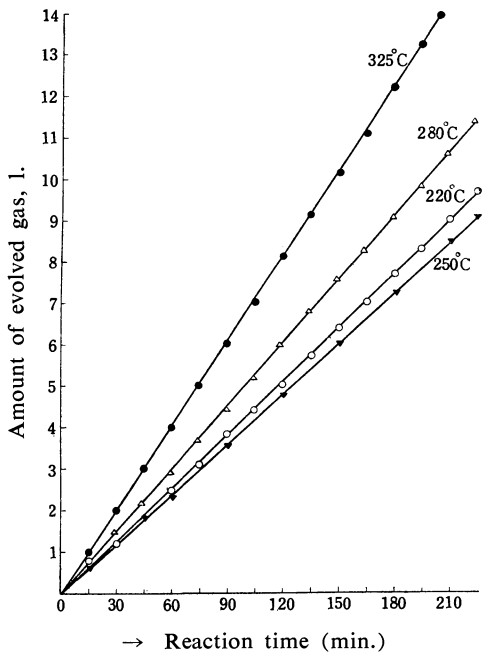
* Copper compound prepared from copper nitrate by "precipitant".

16) G. S. Parks and H. M. Huffman, "Free Energies of Some Organic Compounds", Reinhold Pub. Corp., New York (1932), p. 22; H. J. Kolb and R. L. Burwell, Jr., *J. Am. Chem. Soc.*, **67**, 1084 (1945); A. H. Cubberley and M. B. Mueller, ibid., **68**, 1149 (1946).

oily product was not formed, a proportional relation was found between the amount of the gas evolved and that of acetone produced, namely the greater the amount of the evolved gas, the greater the amount of acetone. This is reasonably accounted for by considering that both the gas and acetone result from the dehydrogenation of isopropyl alcohol. Also the amount of the gas collected increased proportionally with the temperature rise.

**The Relation between the Amount of Gas Evolved and the Reaction Time.**—A test was made by the following method to see whether the catalytic activity is kept constant during the whole reaction time or not. The amount of gas evolved (Table II) was measured at intervals of 15~20 min. and the volumes of the evolved gas reduced to the normal state were plotted against the reaction time in Fig. 2. Since the evolution of the gas is constant during the reaction time as seen in Fig. 2, it is concluded that the sustained activity of the catalyst holds over the period of the operation. Thus the constancy of the activity of the catalyst can be detected by inspecting the amount of the gas evolved.



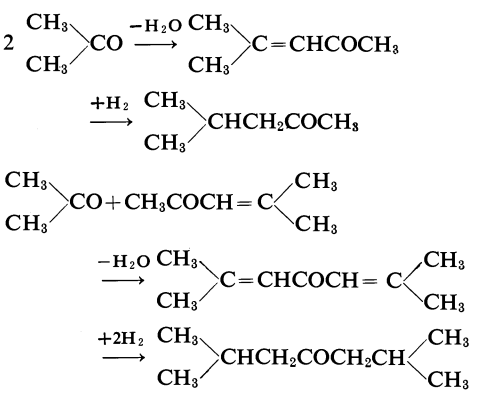


Fig. 2. The amount of evolved gas as a function of the reaction time for various temperatures (precipitant: NaOH)

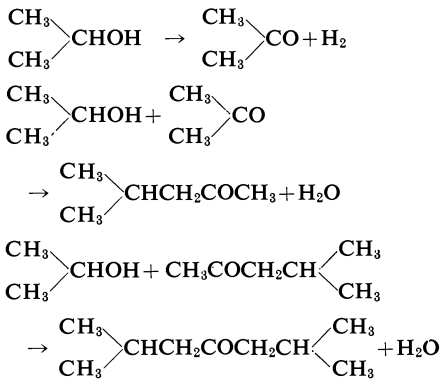
**Two Types of Reduced Copper Catalysts.**—It was found that there are two distinct types of reduced copper catalysts. One of them catalyzes the decomposition of isopropyl alcohol to acetone and hydrogen; that is, promotes dehydrogenation. Cu IV and Cu V belong to this type. The other type catalyzes the conversion of isopropyl alcohol into isobutyl methyl ketone and diisobutyl ketone together with acetone and hydrogen, that is, promotes both dehydrogenation and condensation. Cu I, Cu II and Cu III belong to this type. Further, there is a distinct difference in color before reduction between these two types of catalysts. As shown in Table I, the precipitates prepared with sodium hydroxide, potassium hydroxide, and potassium carbonate are black or dark brown in color. On the contrary, those prepared with potassium bicarbonate and sodium bicarbonate have a yellowish green color. Cu I and Cu II were nearly equal in the activity for the production of both the oily product and acetone, and Cu III has a relatively poor activity for the formation of the oily product. Also Cu IV and Cu V were entirely inactive to the production of the oily product. There is thus a marked difference of activity between the copper catalysts prepared with alkali hydroxides and those prepared with alkali bicarbonates with respect to the relative amount of acetone formed. Cu I and Cu II are especially convenient for preparing isobutyl methyl ketone and diisobutyl ketone. The new synthetic process of these ketones, which consists in passing isopropyl alcohol over Cu I or Cu II under the atmospheric pressure at 220~250°C, is now proposed as one which has not yet been observed with a copper catalyst alone.

**Mechanism of the Condensation Reaction.**—Lassieur[17] found that a mixture of acetone and hydrogen, when it is passed over reduced nickel at 200~300°C, yields mesityl oxide, isobutyl methyl ketone, phorone and diisobutyl ketone. Concerning the mechanism of this reaction he showed that acetone undergoes condensation to give mesityl oxide and phorone, and these unsaturated ketones are then reduced by hydrogen.



17) M. A. Lassieur, *Compt. rend.*, **156**, 795 (1913).

On the other hand, Ipatieff and Haensel[18] found that in the presence of a copper-alumina or a copper-zinc-oxide-alumina catalyst, a mixture of isopropyl alcohol and acetone is converted into isobutyl methyl ketone and diisobutyl ketone, and that in the absence of isopropyl alcohol, acetone reacts to give only small amounts of mesityl oxide and phorone, and they reported that isobutyl methyl ketone is obtained by a regular ketonic condensation of acetone to diacetone alcohol and then a hydrogen disproportionation between isopropyl alcohol and diacetone alcohol.

$$2\ CH_3COCH_3 \rightleftarrows (CH_3)_2COHCH_2COCH_3$$

$$(CH_3)_2COHCH_2COCH_3+CH_3CHOHCH_3 \rightarrow (CH_3)_2CHCH_2COCH_3+CH_3COCH_3+H_2O$$

In the present research, isobutyl methyl ketone and diisobutyl ketone were obtained from isopropyl alcohol with the copper catalyst prepared with sodium hydroxide or potassium hydroxide, but the formation of mesityl oxide, diacetone alcohol and phorone was not observed. Further, it was confirmed that, when the catalytic reaction is carried out with acetone alone under a condition similar to that in the experiment with isopropyl alcohol, acetone is not changed. It is generally recognized that hydrogen atoms of a methyl group adjacent to a carbonyl group are reactive. From these considerations, the formation of the reaction products obtained by the present author can be illustrated by the following schemes:

Further, the following results have been obtained by the present author: (1) Alicyclic alcohols (cyclohexanol and *l*-menthol) do not undergo alcohol-ketone condensation under a condition similar to that employed for isopropyl alcohol[1], consequently giving no higher ketones. (2) When *sec*-butyl alcohol is passed over reduced copper, 5-methyl-3-heptanone together with ethyl methyl ketone is formed.* From these results it seems that the condensation reaction takes place when three hydrogen atoms are attached to the alpha carbon atom of a carbonyl group, but is not favored when only two hydrogen atoms are attached. The alcohols which on dehydrogenation can yield ketones containing a methyl group adjacent to the carbonyl group can condense with the ketones produced.

Up to the present, isobutyl methyl ketone has been prepared by the following method: Acetone is first condensed in the presence of bases to give diacetone alcohol, and this diacetone alcohol is dehydrated by heating with an acid such as sulfuric acid to give mesityl oxide, and then the mesityl oxide thus formed is hydrogenated in the presence of a copper catalyst to give isobutyl methyl ketone. It is of interest that isobutyl methyl ketone can be prepared in one step by passing isopropyl alcohol over reduced copper as described above.

## Summary

In order to determine whether the dehydrogenating activity of reduced copper is affected by the species of precipitants in the preparation, the dehydrogenation of isopropyl alcohol to acetone was studied by using five different precipitants, i. e. sodium hydroxide, potassium hydroxide, potassium carbonate, sodium bicarbonate and potassium bicarbonate. The dehydrogenation was the highest with no side reaction at 305~325°C, especially when potassium bicarbonate was used as precipitant.

When the copper catalysts, prepared with sodium hydroxide, potassium hydroxide and potassium carbonate, were used, condensation together with dehydrogenation occurred. The formation of higher ketones is explained by the assumption of intermolecular dehydration between acetone and original isopropyl alcohol.

The author wishes to express his hearty thanks to Professor T. Matsuura for his kind guidance and valuable suggestions throughout this work.

# *Studies on Tritium Labeled Compounds. II.*[1] *Preparation of Tritium Labeled Stearic Acid*

By Yoshishige SATO, Teruhiko MESHI and Tadao TAKAHASHI

(Received May 19, 1960)

In an attempt to prepare $^3$H-labeled stearic acid as a biochemical tracer, we have carried out three different methods; chemical method, electric discharge method and recoil tritium labeling method. Wolfgang, Pratt and Rowland[2] investigated the labeling of organic compounds by a electric discharge in tritium in 0.05 mmHg region on the assumption that accelerated tritium ions will be active transients required for labeling. Dorfman and Wilzbach[3] have recently conducted investigations on the labeling method by means of electric discharge in a 10 mmHg region. We have also studied the labeling method by electric discharge in tritium-hydrogen in 100 mmHg region[1].

Wolfgang and Rowland[4] have developed a $^3$H-labeling method of organic compounds. According to their reports, the compound to be labeled is mixed with lithium salt and the mixture is irradiated by slow neutrons in a reactor. A considerable fraction of the energetic tritium produced in the $^6Li(n, \alpha)T$ reaction will replace bound hydrogen in the molecules of stopping medium to form a radioactive form of the original hydrogenous molecule.

We have made investigations on the recoil tritium labeling method using a mixture of stearic acid and lithium carbonate in a reactor of the Japan Atomic Research Laboratory (JRR-1).

## Experimental and Results

**Chemical Method.**—*Reduction of Ethyl Linoleate*[5]. —154 mg. of ethyl linoleate, 5 mg. of platinum oxide catalyst and 2 ml. of ethyl acetate are mixed together in a reaction vessel connected with a vacuum apparatus. Then in the apparatus, H$^3$-labeled ethyl stearate was prepared by catalytic hydrogenation of ethyl linoleate with $^3$H-H gas liberated by electrolysis of $^3$HHO. After about 20 min., 23 ml. (theoretical: 22.4 ml.) of $^3$H-H was absorbed and the uptake of $^3$H-H has ceased. The catalyst was removed by filtration and after the solvent was evaporated, $^3$H-labeled ethyl stearate was hydrolyzed by heating under reflux for three hours with potassium hydroxide-methanol solution. The solution was acidified with 10 N-hydrochloric acid, cooled and filtered. Then, deposited $^3$H-stearic acid was extracted with ether. The yield of $^3$H-stearic acid was 90% on the basis of ethyl linoleate, with a specific activity of 0.9 $\mu$c/mg.

*Exchange Method in the Presence of Catalyst.* — In an attempt to prepare $^3$H-stearic acid, exchange method for deuterium labeling of fatty acid developed by Heyninger, Rittenberg and Schoenheimer[6] was employed. In a glass tube, 20 mg. of $PtO_2$ suspended in 1 ml. of ethyl alcohol was reduced in a hydrogen stream. After alcohol was distilled, 200 mg. of stearic acid, 5 mg. of potassium hydroxide and 0.4 ml. of $^3$HHO (50 mc./ml.) were added. The mixture was frozen, the tube was sealed and then heated at 135°C for a week. After the period of reaction, the tube was opened and connected with a vacuum apparatus, and the liquid was distilled in vacuo. The dried residue was dissolved in potassium hydroxide-ethyl alcohol solution and filtered, and the filtrate was acidified with hydrochloric acid. The deposited $^3$H-stearic acid was recrystallized from ether. The yield of $^3$H-stearic acid was 90% on the basis of stearic acid, with a specific activity of 6.2 $\mu$c/mg.

**Electric Discharge Method.** — Discharge was carried out in a sample cell of approximately 20 ml., with tungsten electrodes (15 mm. apart). A sample to be labeled was placed on the bottom of the glass cell. Discharge was normally run from 20 sec. to 180 sec. in $^3$H-H mixture gas under a constant pressure of 100 mm Hg. The following is the procedure: A quantity of approximately 20 mg. was placed on the bottom of a glass cell and the cell was degassed. After the degassing was completed, $^3$H-H gas liberated by electrolysis of tritiated water (30 mc./ml.) was introduced into the cell and the discharge was made to run. In running of the discharge, the electrodes were over-heated. The electrodes were cooled by stopping the discharge. The cell was again degassed and air was introduced into the cell.

The stearic acid was then assayed for tritium in a gas-flow counter. The following table summarize the results.

Table I shows activity levels obtained for stearic acid subjected to the discharge technique. The

Chart I

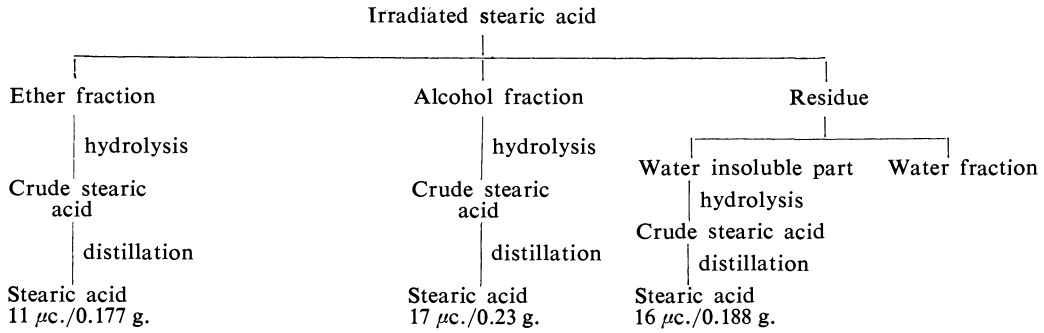

TABLE I. LABELING BY ELECTRIC DISCHARGE IN $^3$H-H GAS

| $^3$H-H Pressure, mm Hg | Discharge Time, sec. | Activity, μc./g. |
|---|---|---|
| 100 | 20 | 1.9 |
| 100 | 40 | 5.7 |
| 100 | 60 | 8.6 |
| 100 | 120 | 23.6 |
| 100 | 180 | 91.6 |

tritium content of the product increases approximately with the discharge time.

**Recoil Tritium Labeling Method.** — A mixture of 2 g. stearic acid and 1 g. lithium carbonate was irradiated with thermal neutrons for 17 hr. at a flux $2.5\times10^{11}$ n/cm$^2$ sec. The irradiated product was first extracted with anhydrous ether, and then with anhydrous ethyl alcohol. Infrared spectra of the ether fraction, alcohol fraction and the residue are shown in Fig. 1. It was recognized, that ester of fatty acid was produced by irradiation. Hydrolysis of each fraction was carried out by alcoholic potassium hydroxide. The hydrolyzed compounds were identified as stearic acid by infrared spectra, and they all distilled in vacuo (10 mm Hg) at 206~208°C.

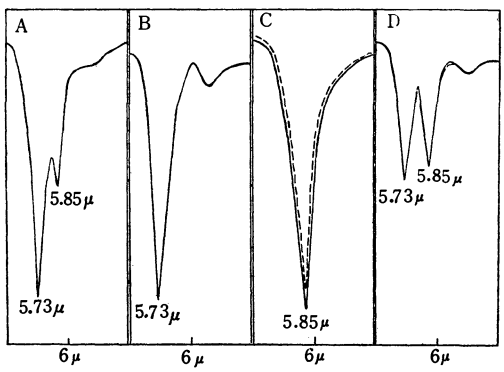

Fig. 1. Infrared absorption spectra of recoil tritiated stearic acid.
A: Residue, B: Alcohol fraction, C: —— Authentic stearic acid, ---- Hydrolyzed specimens of A, B and D, D: Ether fraction.

The stearic acid was assayed for tritium by means of a gas-flow counter. Chart I represents the experimental treatments described above.

The total yield of radio active stearic acid was about 0.6 g. (about 30%). Activity ($A$) of recoil tritium atoms produced by irradiation was calculated on the basis of the following equation.

$$A=\sigma Nf(1-e^{-0.693/t})$$

$\sigma$: Cross section 945 barn, $N$: Number of Li atom, $f$: Neutron flux, $T$: Half-life, $t$: Irradiation time.

When a mixture of stearic acid and lithium carbonate was irradiated by a $2.5\times10^{11}$ neutron flux, value of $A$ was 832 μc. The tritium content of the obtained stearic acid was therefore about 5% of the theoretical value.

**Radioactivity Measurement of Tritium Labeled Stearic Acid.** — Tritium activity was counted according to the Jackson and Lampe's method.[7] A windowless gas flow counter was used for radioassay of $^3$H-stearic acid. The self-absorption characteristics of tritium labeled stearic acid samples are given in Fig. 2.

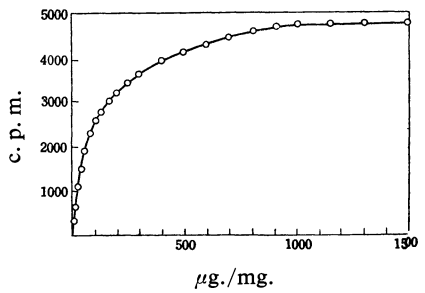

Fig. 2. Self-absorption curve of $^3$H-stearic acid.

These curves indicate that self-absorption is negligible up to sample weights of about 20 μg. per sq. cm.

7) F. L. Jackson and H. W. Lampe, *Anal. Chem.*, **28**, 1735 (1956).

## Discussion

By using tritium gas with higher specific activity than in above chemical process, it is easy to get a much higher specific activity. A higher specific activity can also be obtained using the discharge method when the discharge time is made prolonged and the tritium gas is of a higher specific activity. Tritium labeling in a reactor, on the other hand, is less usable, since this method gives rise to high destruction and lower specific activity. From the infrared absorption spectra of each fraction of irradiated products, it was recognized that the irradiated products contain fatty acid ester, because a 5.73 $\mu$ band of these products was identical with the carboxyl band of ethyl stearate.

## Summary

Chemical reduction method, exchange method, electric discharge method and recoil tritium labeling method were applied for preparing tritium labeled stearic acid. As the result of the recoil tritium labeling, the irradiated stearic acid was found to contain high destruction products which are mainly composed of esters of fatty acid.

# *Studies on Tritium Labeled Compounds. IV*. Preparation of Tritium Labeled Alanine by Means of Electric Discharge*

By Yoshishige SATO and Tadao TAKAHASHI

(Received July 4, 1960)

On the assumption that accelerated-tritium ions are the active transients required for labeling, Wolfgang, Pratt and Rowland[1] studied methods for preparing tritium labeled organic compounds using the electric discharge method. On the other hand, Dorfman and Wilzbach[2] investigated the labeling method under electric discharge in a 10 mmHg pressure region and reported that the labeling would be expected to occur as a result of the primary process of ionization, excitation and dissociation of tritium molecules in the gas phase. We recently reported[3] that the labeling would be produced in the same mechanism as that reported by Dorfman and Wilzbach. In this work, we carried out tritium labeling under electric discharge by employing $\alpha$-hydroximinopropionic acid as the sample and obtained DL-alanine of a high specific activity.

## Experimental and Results

About 50 mg. of $\alpha$-hydroximinopropionic acid was placed in the bottom of a glass cell which has two electrodes of tungsten as shown in Fig. 1. The cell was attached to a vacuum line and degassed. $^3$H-H gas, which was liberated by electrolysis of tritiated water (130 mc./ml.), was introduced into the cell and electric discharge (8000 V.) was struck at 40 mmHg for 10 min.

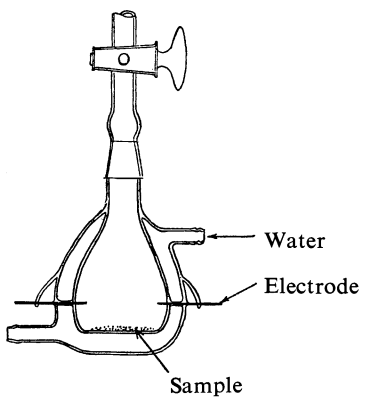

Fig. 1. Discharge cell.

During the discharge, the electrodes were overheated. In order to avoid over-heating, the electrodes were cooled by passing of cold water around the outside of the cell and by stopping further discharge. After the discharge the cell was degassed and air was introduced into the cell. As it was presumed that tritium labeled alanine was produced by this method, the discharged sample was extracted with ether. Almost all $\alpha$-hydroximinopropionic

2) L. M. Dorfman and K. E. Wilzbach, *J. Phys. Chem.*, 63, 799 (1959).

acid being soluble in ether, was removed from the discharged sample by filtration. The amount of residue was about 5 mg. and was assayed for tritium in a gas flow counter. Its specific activity was 0.66 $\mu$c./mg.; on the other hand, the specific activity of ether soluble part was 0.71 $\mu$c./mg.

Paper chromatography of the residue, using *n*-butanol-acetic acid-water (4 : 1 : 1) as developing solvent, was performed. Owing to the low energy of the $\beta$-rays from tritium, the radioactivity from tritium could not be measured directly on the paper chromatogram. The paper was cut into pieces, and the active products were extracted with water. Water was evaporated in stainless steel dishes, and the activity of the extracted products was measured in a gas flow counter. Fig. 2 shows the results of the paper chromatogram and the radioactivity. As a comparison, parallel runs were made with ordinary DL-alanine and $\alpha$-hydroximinopropionic acid.

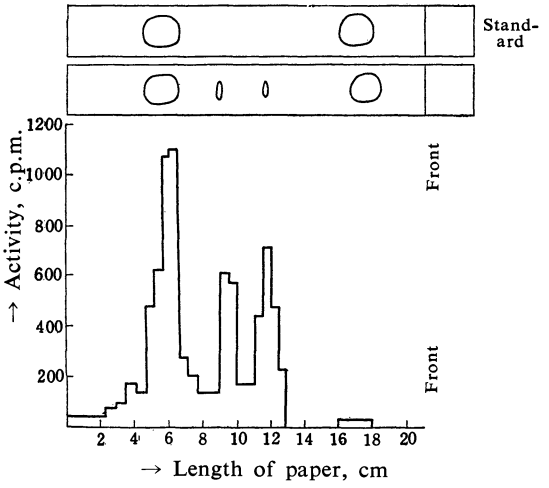

Fig. 2. Paper chromatography and the radioactivity of ether insoluble part. For comparison spots obtained with pure DL-alanine and $\alpha$-Hydroximinopropionic acid are shown.

Four hundred $\mu$g. of ether insoluble part of sample was employed as a sample of paper chromatography. DL-Alanine, the unidentified product A and B and, $\alpha$-hydroximinopropionic acid were obtained in the amounts and with activity values as shown in Table I.

TABLE I. SPECIFIC ACTIVITY OF THE PRODUCTS SEPARATED BY PAPER CHROMATOGRAPHY

| Compound | Activity c. p. m. | Amount $\mu$g. | Sp. act. $\mu$c./mg. | $R_f$ |
|---|---|---|---|---|
| DL-Alanine | 15600 | 20* | 4.4 | 0.28 |
| Unidentified product A | 4600 | 2* | 12.9 | 0.36 |
| B | 6450 | 2* | 17.2 | 0.45 |
| $\alpha$-Hydroximinopropionic acid | 100 | 350** | 0.0016 | 0.80 |

* Determination by spraying with ninhydrin.
** Determination by spraying with Bromophenyl Blue.

## Discussion

In the previous reports[3], it was reported that specific activity of tritium labeled DL-alanine obtained by means of electric discharge was only about 0.02 $\mu$c./mg. when DL-alanine was used as the sample. However, in this paper, tritium labeled DL-alanine with specific activity of 4.4 $\mu$c./mg. was obtained by using $\alpha$-hydroximinopropionic acid as the sample. A higher specific activity can be expected by using carrier free tritium gas.

## Summary

To obtain tritium labeled alanine of a high specific activity by means of electric discharge, $\alpha$-hydroximinopropionic acid was employed in place of alanine. After electric discharge, tritium labeled $\alpha$-hydroximinopropionic acid was removed by ether extraction and the residue was chromatographed. Tritium labeled alanine was obtained with a specific activity of 4.4 $\mu$c./mg. which was two hundred times as great as that obtained by the use of alanine.

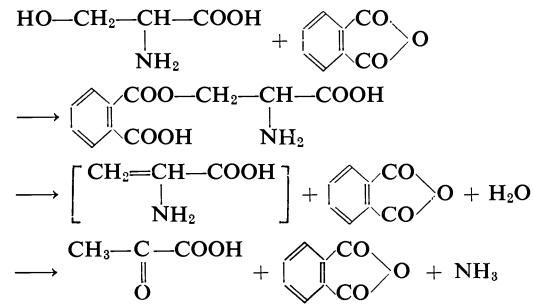
# *Studies on Dehydroalanine Derivatives. IV. Synthesis of N-Phthaloyl-Dehydroalanine by Thermal Decomposition of Cysteine and Serine in the Presence of Phthalic Anhydride*

By Shumpei SAKAKIBARA



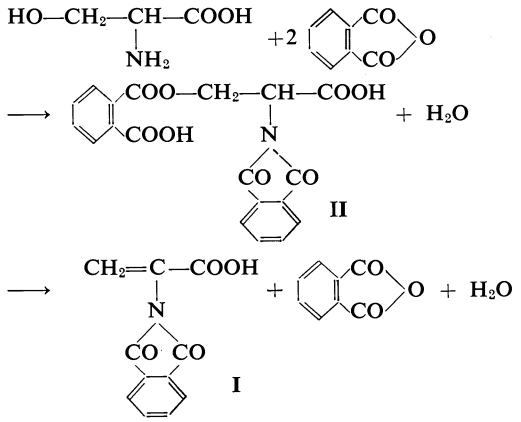
(Received July 13, 1960)

Bergmann et al.[1] reported, that in alkaline solution, serine- or cysteine- diketopiperazine (or peptide) was converted to dehydroalanine-diketopiperazine (or peptide). Weygand and Rinno[2] pointed out that *N*-trifluoroacetyl-serine was converted into *N*-trifluoroacetyl dehydroalanine, when it was distilled under high vacuum. In the present investigation, the thermal decomposition of cysteine and of serine in the presence of phthalic anhydride were studied.

Usually $\alpha$-amino acids are easily *N*-phthaloylated when heated with phthalic anhydride at 180°C for about half an hour[3]. However, cystine has not yet been tested owing to its poor solubility and reactivity. On the contrary, cysteine and serine were both very unstable to heat, and their *N*-phthaloyl derivatives have not been separated from the respective reaction mixtures after the thermal treatment. When a mixture of cysteine and phthalic anhydride was heated at or above 150°C, formation of hydrogen sulfide was detected by its characteristic odor and by using the lead acetate paper test. The thermal decomposition of cysteine at about 180°C was, however, not so great that its complete decomposition might not be expected within a short time. It was found experimentally that an equimolar amount of yellow mercuric oxide greatly accelerated the desulfhydration reaction and the reagent was rapidly converted into mercuric sulfide at 180°C. After purification of the reaction mixture, *N*-phthaloyl dehydroalanine (I) was obtained as colorless prisms (m. p. 171°C). Use of more than twice the molar equivalent of phthalic anhydride resulted in a better yield, because during the reaction, water is formed and the excess phthalic anhydride may compensate for the partial rehydrolysis of the newly-formed phthaloylimino groups.

When a mixture of serine and phthalic anhydride was heated at 180°C, vigorous evolution of water was observed, and the mixture changed to a dark brown syrup within a short time. At the same time, the formation of pyruvic acid was detected by its order. The purification of the reaction product was very difficult and the yield of substance I was poor. Perhaps part of the serine might have been converted into its *O*-phthalic acid monoester, which was then decomposed to pyruvic acid and ammonia at high temperature before the *N*-phthaloylation reaction occurred. Therefore it was necessary to establish conditions

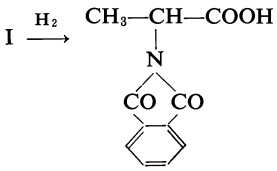
in which the *N*-phthaloylation of serine was complete before such a dehydration reaction could occur. Sheehan et al. have shown[4] that usual amino acids could be *N*-phthaloylated in



1) M. Bergmann and A. Miekeley, *Ann.*, **458**, 40 (1927); B. H. Nicolet, *J. Am. Chem. Soc.*, **53**, 3066 (1931); B. H. Nicolet, *J. Biol. Chem.*, **140**, 685 (1941).

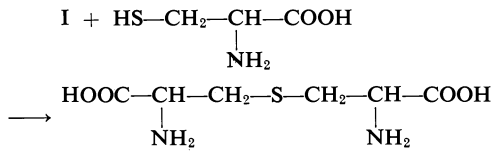
2) F. Weygand and H. Rinno, *Chem. Ber.*, **92**, 517 (1959).

3) J. H. Billman and W. F. Harting, *J. Am. Chem. Soc.*, **70**, 1473 (1948).



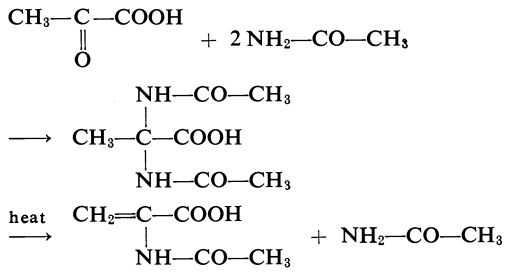
4) J. C. Sheehan, M. Goodman and G. P. Hess, ibid., **78**, 1367 (1956).

a gentle reaction in boiling dioxane. However, they did not mention such a reaction for serine. When serine and an equimolar amount of phthalic anhydride were boiled in dioxane for about five hours, a part of the serine remained in suspension, but twice the molar amount of phthalic anhydride readily solubilized the remaining serine in dioxane. Perhaps *O*, *N*-diphthaloylated serine (II) is formed under these conditions.



After the solvent had been distilled off, the residual syrup was heated gently in an oil bath at 200°C for about one hour under reduced pressure, and as in the case of cysteine, *N*-phthaloyl dehydroalanine (I) was obtained from the reaction mixture. The melting points of substance I from cysteine and serine were the same (m. p. 171°C), and no depression of the melting point was observed, when equal amounts of product I from cysteine and from serine were mixed. However, the yield of substance I from serine was inferior to that from cysteine. When substance I was recrystallized from dimethylformamide, crystals were obtained which melted at 84~88°C and contained one mole of dimethylformamide as crystallization solvent. Since the dimethylformamide complex was readily crystallizable, this procedure was suitable for purification of the product.

Hydrogenation of substance I gave rise to *N*-phthaloyl-DL-alanine, and lanthionine could also be formed from substance I by an addition reaction with L-cysteine under the conditions described by Schöberl[5].



5) A. Schöberl, *Chem Ber.*, **80**, 379 (1947).

The properties of substance I all supported structure I.

Bergmann[6] first prepared *N*-acetyl dehydroalanine from pyruvic acid and acetamide as follows:

Many investigators utilized this procedure for preparing other *N*-acyl-dehydroalanine derivatives[7]. However, an attempt in the present work to prepare substance I by this procedure failed, because of the poor reactivity of phthalimide with pyruvic acid.

Substance I can polymerize to a vinylidene-type poly-$\alpha$-phthalimino acrylic acid, which may be converted into poly-$\alpha$-amino acrylic acid by hydrazinolysis.

## Experimental

***N*-Phthaloyl Dehydroalanine (I) from Cysteine.** —A mixture of freshly prepared cysteine (12 g.) and phthalic anhydride (37 g.) was placed in a round bottomed flask (300 ml.) fitted with a distillation adaptor. The flask was heated in an oil bath at 180°C (for about 20 min.) until a clear syrup was obtained, and then the water formed was distilled off under vacuum, using a water pump for about 10 min. more. An intimate mixture of yellow mercuric oxide (20 g.) and phthalic anhydride (22 g.) was added to the reaction mixture in one portion and then the flask was kept under vacuum for about 10~15 min. at 180~190°C. After being cooled to 50~60°C, the reaction mixture was extracted with hot ethyl acetate (300 ml.). The black precipitate was centrifuged off, and extracted three times with 40 ml. each of ethyl acetate. The combined extracts were concentrated to dryness under reduced pressure. The excess phthalic anhydride was separated by sublimation at 140°C in vacuo. The residue was dissolved in ethyl acetate (about 50 ml.) and the resinous products were precipitated by adding ether (about 150~200 ml.). The precipitates were centrifuged off and the supernatant was concentrated to dryness. The

6) M. Bergmann and K. Grafe, *Z. Phys. Chem.*, **187**, 187 (1930).

7) Cf. S. Sakakibara, This Bulletin, **32**, 13 (1959).

residue was recrystallized from toluene (about 30 ml.) to yield light-brown prisms (15 g.), which melt at 150~165°C. The small amount of phthalic anhydride remaining was sublimed out at 140°C in vacuo, and the remaining crystals were recrystallized from ethyl acetate after treatment with a small amount of active charcoal. The yield of slightly colored prisms with a melting point of 164~167°C was 60% (13.2 g.).

For final purification, the product was recrystallized from dimethyl formamide. The dimethyl formamide-complex (plates) formed melted at 84~88°C.

Found: C, 58.70; H, 4.98; N, 9.11. Calcd. for $C_{11}H_7O_4N \cdot C_3H_7ON$: C, 58.00; H, 4.84; N, 9.65%.

The complex was dried at 120°C in vacuo for about 3 hr. and recrystallized from ethyl acetate to yield colorless prisms with m. p. 169~171°C. The over-all yield was about 50~55%.

Found: C, 60.80; H, 3.17; N, 6.37. Calcd. for $C_{11}H_7O_4N$: C, 60.82; H, 3.24; N, 6.46%.

**I from Serine.**—A mixture of DL-serine (10.5 g.) and phthalic anhydride (37 g.) in dioxane (100 ml.) was refluxed until a clear solution was obtained (for about 5 hr.). The solution was concentrated to dryness in a flask, as shown in Fig. 1, under

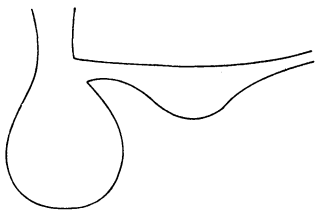


Fig. 1.

reduced pressure, and the residue was heated to 190~200°C under reduced pressure for about 20 min., during which time about 22 g. of phthalic anhydride distilled over. The residue was dissolved in ethyl acetate (50 ml.) and resinous products were precipitated by adding ether (150~200 ml.). The precipitates were centrifuged off, and the supernatant was concentrated to dryness. The residue was heated at 190~200°C for about 20 min. in vacuo and then the same procedures for separating the resinous products formed were repeated. The residue obtained was recrystallized from toluene (30 ml.) to yield light-brown prisms (9 g.) which melted at 150~160°C. The crystals were recrystallized from butanol-toluene (1 : 1) and then from dimethylformamide. The dimethylformamide complex (8.5 g., m. p. 82~88°C) was dried at 120°C in vacuo for about 3 hr. and recrystallized from ethyl acetate to yield colorless prisms (5 g.) with m. p. 169~171°C. The yield was 23%. The product was identified exactly with that obtained from cysteine by the mixed melting point test.

***N*-Phthaloyl DL-Alanine (II).**—A solution of I (1 g.) in ethanol (30 ml.) was hydrogenated in the presence of silk-palladium catalyst[8] (150 mg.) in an autoclave. The initial hydrogen pressure was 60 atm. The mixture was heated at 40°C for about 3 hr. and then at 70°C for additional 3 hr. After the reaction, the mixture was cooled to room temperature, and the catalyst was filtered off. The filtrate concentrated to dryness under reduced pressure. The residue was recrystallized from water-ethanol, and prisms with m. p. 159~161°C (650 mg.) and with m. p. 157~160°C (280 mg.) were obtained; the total yield was 93%. No depression of the melting point was observed, when the substance with m. p. 159~161°C was mixed with an authentic sample with m. p. 161~161.5°C. The infrared absorption spectrum of the product was also exactly the same as that of an authentic sample.

**Lanthionine (III).**—Substance I (3.3 g.) and L-cysteine hydrochloride (1.6 g.) were dissolved in aqueous N sodium hydroxide (24 ml.), and the solution was heated at 50°C for 1 hr. and then at 80°C for 2 hr. in an atmosphere of hydrogen. Concentrated hydrochloric acid (30 ml.) was added to the reaction mixture and the solution was boiled for about 6 hr. After colling to room temperature, the phthalic acid formed was filtered off, and the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in water, and recrystallized by neutralizing the solution with aqueous ammonia. After being kept overnight in a refrigerator, the crystals were filtered off and recrystallized from 6 N hydrochloric acid and aqueous ammonia as described above. The crystals formed were filtered off, washed with water, and alcohol, and dried; wt. 1.8 g., the yield was 86% (calcd. from cysteine).

Found: C, 34.18; H, 6.02; N, 13.44; S, 15.39. Calcd. for $C_6H_{12}O_4N_2S$: C, 34.61; H, 5.81; N, 13.45; S, 15.40%.

## Summary

*N*-Phthaloyl dehydroalanine (I) was synthesized by heating cysteine or serine in the presence of phthalic anhydride. Yellow mercuric oxide greatly accelerated the desulfhydration reaction. The yield of I from serine was inferior to that from cysteine. *N*-Phthaloyl-DL-alanine and lanthionine were derived from I.

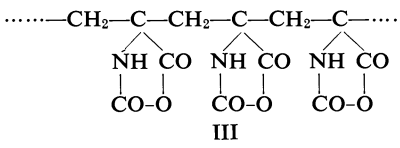
# *Studies on Dehydroalanine Derivatives. V. Radical Polymerization of N-Carboxy-dehydroalanine Anhydride and of N-Phthaloyl-dehydroalanine. Synthesis of a New Amphoteric Polymer*

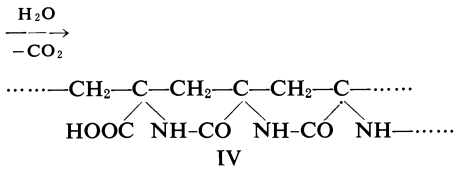
By Shumpei SAKAKIBARA

(Received July 13, 1960)

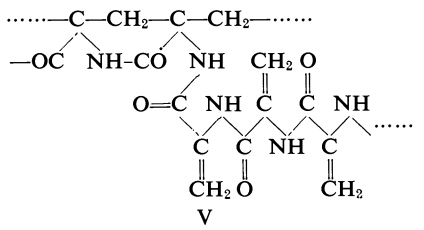
Dehydroalanine derivatives such as *N*-carboxy-dehydroalanine anhydride (I)[1] and *N*-phthaloyl-dehydroalanine (II)[2] are considered as vinylidene derivatives. In the present communication, radical homo-polymerization and co-polymerization of compounds I and II are described.



As reported previously[3], compound I is readily polymerized to poly-dehydroalanine in pyridine at 100°C with the evolution of carbon dioxide. The polymer obtained is dark brown because of the presence of conjugated double bonds. On the other hand, it was found in this study, that, when this same compound I was heated at 50°C in a dry inert solvent such as ethyl acetate or acetone in the presence of a radical initiator, the solution changed to an opaque jelly within 2 hr. Since, no evolution of carbon dioxide was observed during the polymerization reaction, it was considered that active *N*-carboxy anhydride groups were still present in the polymer obtained. This suggestion was supported by the fact that, when the polymer obtained was dissolved in aqueous ammonia, the solution rapidly turned into a clear gel. Perhaps intermolecular cross-linkages are formed in the solution due to a secondary polymerization reaction of the remaining *N*-carboxy anhydride groups.



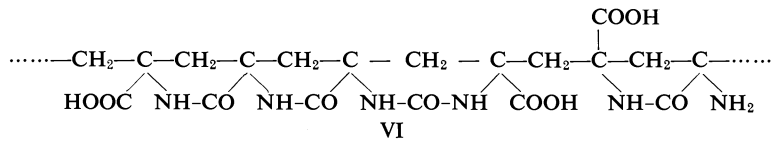
I III



However, separation of analytically pure poly-*N*-carboxy-$\alpha$-amino acrylic acid anhydride (III) from the reaction mixture was unsuccessful because of the partial hydrolysis and secondary polymerization of the *N*-carboxy anhydride groups during the course of the purification of this compound. Actually, due to air humidity or impurities in the solvents used, analytical data of the polymers obtained from different experiments were between the theoretical values for formula III and those for the completely decarboxylated formula IV. Moreover, it was found that the nitrogen content of the compound gradually increased during storage over phosphorous pentoxide in a desiccator at room temperature. Since the *N*-carboxy anhydride groups should be in juxtaposition in polymer III, they may readily polymerize forming the poly-lactam IV.

III

IV



V

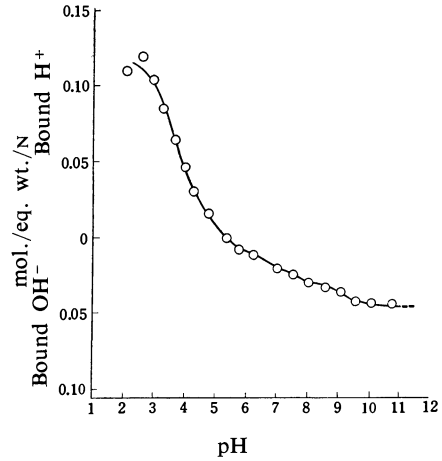
Structure V could scarcely be considered because polymerization of *N*-carboxy-dehydroalanine anhydride I to poly-dehydroalanine is very slow as described previously[3]. This is also supported by the color; that is, the polymer obtained was white, not dark brown like poly-dehydroalanine.

Polymer III was soluble in aqueous alkaline solution accompanied with decarboxylation reaction, but not in inert solvents. When the polymer was hydrolyzed with aqueous N potassium hydroxide at 100°C, the greater part of the hydrolyzed polymer was precipitated on acidification of the medium. As shown from

1) S. Sakakibara, This Bulletin, **32**, 13 (1959).
2) S. Sakakibara, ibid., **34**, 171 (1961).
3) S. Sakakibara, ibid., **32**, 814 (1959).

the pH-titration curve of the hydrolyzed polymer (Fig. 1), there were few amino groups and these were far exceeded by the number of carboxyl groups. Perhaps this is due to ureide formation as well as lactam formation, as described below (formula VI).

VI



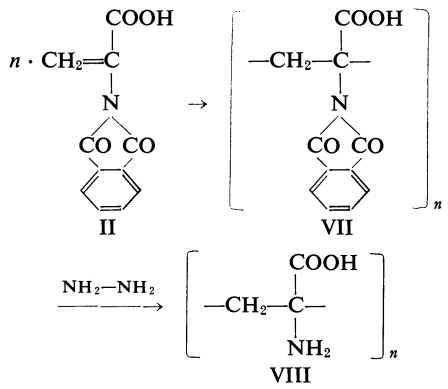


Fig. 1. pH-Titration curve of compound VI.

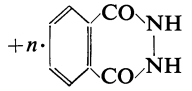


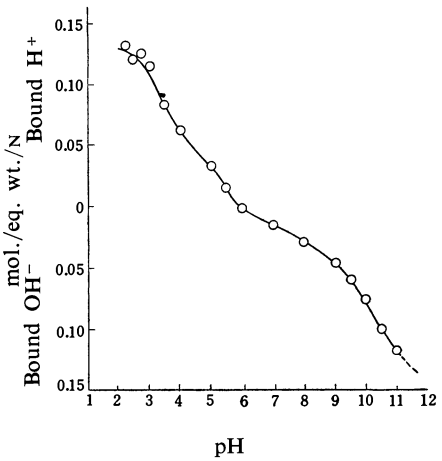
Frank[4] and Smets et al.[5] indicated that the equilibrium between a five-membered cyclic lactam and its open amino acid, in a polymer chain, tends to the former. Such a ureide-ring may be more stable against hydrolysis than a lactam.

Radical polymerizability of $\alpha$-phthalimido acrylic acid (II) was rather weak. When the monomer was heated in methanol at 60°C for about 200 hr. in the presence of azobisisobutylonitrile, a polymer(VII) was separated as a methanol-insoluble oil. The polymer was finally obtained as white powder, and it was soluble in dimethylformamide, and in hot acetic acid.

II VII VIII

4) H. P. Frank, *J. Polymer Sci.*, **12**, 570 (1954).

After hydrazinolysis, poly-$\alpha$-amino acrylic acid (VIII) was obtained in poor yield. To molecular weight of the starting polymer may not have been very high. The poly-$\alpha$-amino acrylic acid obtained was soluble in water. However, elementary analysis and pH-titration (Fig. 2) indicated that the content of ionizable groups was lower, than the calculated values, for the same reason as explained above.



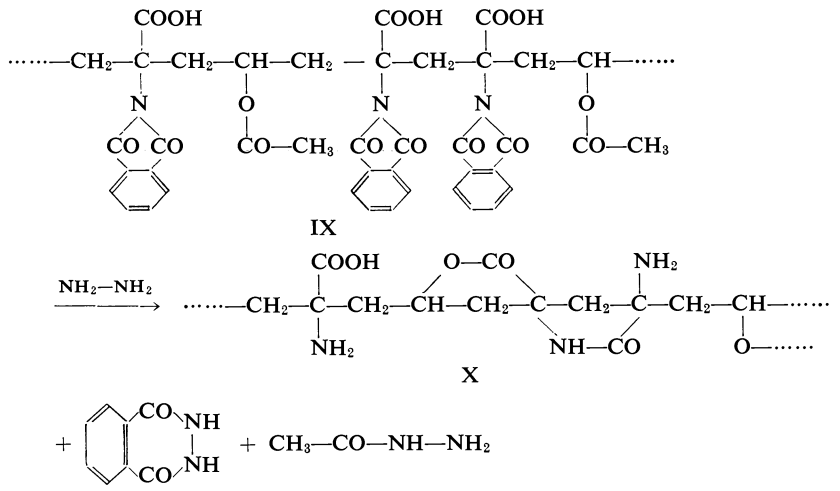


Fig. 2. pH-Titration curve of compound VIII.

Copolymerization of monomer II with vinyl acetate (V. Ac.) in methanol gave a gelatinous precipitate (IX-a). From the mother liquor, a second fraction (IX-b) was precipitated on addition of ether. Elementary analysis indicated that polymer IX-a was about 8 : 5-co-polymer (II : V. Ac.) and polymer IX-b was about 1 : 5-co-polymer (II : V. Ac.). The former was only soluble in dimethyl formamide, but the latter was soluble in pyridine, glacial acetic acid, dimethyl formamide, *m*-cresol, chloroform, hot ethanol, a mixture of methanol and acetone, and of ethyl acetate and acetone. Polymer IX-b was sparingly soluble in methanol, ethyl acetate and acetone, and insoluble in

5) M. Vrancken and G. Smets, ibid., **14**, 521 (1954); A. Conix, N. V. Mortsel and G. Smets, ibid., **15**, 221 (1955).

benzene, toluene and water. After hydrazinolysis of these copolymers, water soluble polyampholytes (X) were obtained. The pH-titration curves of these copolymers (Figs. 3 and 4) were of a typical polyampholyte-type, the structure of which was assumed to be as follows:

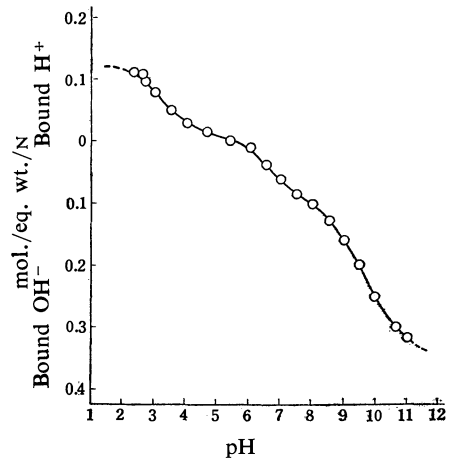

Fig. 3. pH-Titration curve of compound X-a.

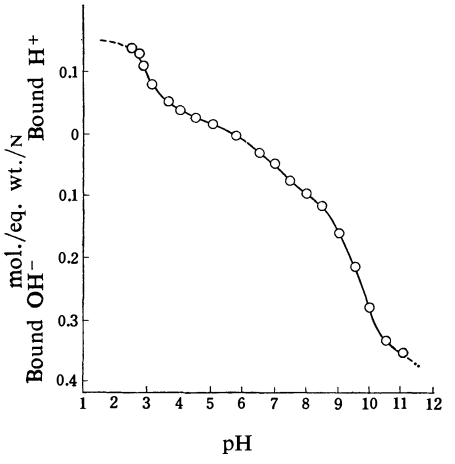

Fig. 4. pH-Titration curve of compound X-b.

If the sequence of co-monomer-segments was at random, five-membered lactam formation, as in poly-$\alpha$-amino acrylic acid, should not occur. As shown in Figs. 3 and 4 however, the number of ionizable groups was about 30% of the theoretical value. The values increased inversely with the number of amino acid segments. In this cases, the number of amino groups was greater than that of carboxyl groups. Perhaps, amino acid segments may have been localized in the molecule. Moreover, partial intramolecular lactone formation may have occurred.

If copolymerization of small amounts of compounds I or II with vinyl monomers such as acrylonitrile were possible, these would improve the affinity for dyeing of the parent polymers. Moreover, these would be useful as key-substances for preparing graft-copolymer of vinyl- and amino acid-polymers.

## Experimental*1

**Polymerization of I to III.**—A solution of I (2 g.) and azobisisobutylonitrile (0.1 g.) in purified ethyl acetate (20 ml.) was heated at 50°C in a sealed tube for about 4 hr. The opaque jelly formed, was crushed up finely and became powdery on addition of dry ether. The powder formed III was collected centrifugally, washed with ether and dried over phosphorus pentoxide in a desiccator; colored gradually above 180°C, sintered at about 250°C, yield 40% (0.8 g.).

Found*2: C, 44.5; H, 4.9; N, 15.8. Found*3:

*1 All melting points were determined by using capillary tubes in a Kanechlole-bath, maximum temperature of which was 300°C.

*2 Analyzed immediately after preparation.

*3 Analyzed after storing the same sample for 10 days in a desiccator over phosphorus pentoxide.

C, 46.9; H, 5.07; N, 16.9. Found*4 : C, 46.5; H, 4.1; N, 16.5. Calcd. for $C_4H_3O_3N$ (III): C, 42.5; H, 2.6; N, 12.4%. Calcd. for $C_3H_3ON$ (IV): C, 52.2; H, 4.35; N, 20.3%.

**Formation of VI from III.**—The polymer obtained above (0.5 g.) was dissolved in aqueous N potassium hydroxide (20 ml.) and the solution was heated in a sealed tube at 105°C for about 20 hr. The hydrolyzate was dialyzed against distilled water for 2 days and then lyophilized. White spongy material (0.4 g.) was obtained, which was soluble in water at above pH 6. For analysis, this materials was dissolved in distilled water, and reprecipitated by adding hydrochloric acid. The precipitates formed were washed with water, ethanol and, ether and dried; colored gradually above 250°C without melting.

Found: C, 49.1; H, 5.1; N, 17.3. Calcd. for $C_3H_3ON$-0.1·$CO_2$-0.2·$H_2O$ (VI): C, 48.5; H, 4.4; N, 18.2%; equiv. wt./N=77.0.

**Polymerization of II to VII.**—A solution of II (4 g.) and azobisisobutylonitrile (0.6 g.) in methanol (10 ml.) was heated in a sealed tube at 60°C for about 200 hr. The polymer formed (VII) precipitated on addition of ether and washed with methanol and ether, and dried; sintered at 250°C and melted at 270°C, yield 55% (2.2 g.).

Found: C, 60.3; H, 4.2; N, 6.8. Calcd. for $C_{11}H_7O_4N$ (VII): C, 60.8; H, 3.2; N, 6.4%.

**Hydrazinolysis of VII.**—The polymer VII (1.5 g.) was dissolved in hydrazine hydrate (15 ml.) and the solution was boiled for about 3 hr. The hydrazinolyzate was concentrated to drynes and the residue was redissolved in aqueous 0.1 N potassium hydroxide (5 ml.) and the phtaloyl hydrazide formed, precipitated on addition of enough acetic acid to reduce the pH to 5. The white precipitate formed was centrifuged off, and washed with water; 1.0 g. of phthaloyl hydrazide was recovered. The supernatant was concentrated to 5 ml. and poured into ethanol (about 100 ml.) to precipitate polymer VIII, which was centrifuged off, washed with ethanol, and dried in vacuo at room temperature; slightly brown powder (80 mg.) which colored gradually above 250°C.

Found: C, 43.9; H, 4.5; N, 17.5. Calcd. for $C_3H_3ON$-0.7·$H_2O$: C, 44.1; H, 5.4; N, 17.2%; equiv. wt./N=81.6.

**Copolymerization of II with Vinyl Acetate.**—A mixture of II (5 g.), vinyl acetate (20 g.) and azobisisobutylonitrile (0.5 g.) in methanol (20 ml.) was heated in a sealed tube at 60°C for about 100 hr. The gelatinous precipitates formed were centrifuged off, washed with methanol, and powdered from dimethyl formamide and ether (IX-a); m. p. 220~230°C, wt. 4.0 g.

Found: C, 56.9; H, 5.2; N, 5.0. Calcd. for $C_{11}H_7O_4N$-0.625·$C_4H_6O_2$-$H_2O$ (IX-a): C, 56.1; H, 4.5; N, 4.9%; eq. wt./N=289.

From the methanolic mother liquor, polymer IX-b was precipitated by addition of ether. It was centrifuged off, washed with ether and dried; sintered at 160~170°C and melted at 200°C, wt. 4.6 g.

Found: C, 56.6; H, 6.3; N, 2.2. Calcd. for $C_{11}H_7O_4N$-4.8·$C_4H_6O_2$-0.67·$H_2O$ (IX-b): C, 56.5; H, 5.8; N, 2.2%; equiv.wt./N=642.

**Hydrazinolysis of IX-a and IX-b.**—The polymer IX-a (3 g.) was dissolved in hydrazine hydrate (50 ml.) and the solution was boiled for about 3 hr. The hydrazinolyzate was concentrated to dryness, and the residue was redissolved in aqueous N potassium hydroxide (5 ml.) and the phthaloyl hydrazide formed precipitated on additon of acetic acid. The white precipitates were centrifuged off, and washed with water; about 1.6 g. of phthaloyl hydrazide was recovered. The supernatant and the washings were combined and after adding a few drops of N potassium hydroxide, the solution was dialyzed against distilled water for about 2 days. The dialyzed solution was lyophilized to yield a spongy material X-a; colored gradually above 250°C, wt. 0. 5 g.

Found: C, 48.5; H, 7.6; N, 13.5. Calcd. for $C_3H_3ON$-0.625·$C_2H_4O$-0.5·$H_2O$: C, 48.5; H, 6.2; N, 13.3%; equiv.wt./N=105.5.

The polymer IX-b (4 g.) was similarly treated with hydrazine hydrate (50 ml.) as described above, and material X-b) (1.1 g.) was obtained as a white spongy material; m. p. 200~210°C.

Found: C, 51.2; H, 8.1; N, 6.0. Calcd. for $C_3H_3ON$-3.5·$C_2H_4O$-0.67·$H_2O$ (X-b): C, 51.1; H, 7.8; N, 6.0%; equiv.wt./N=235.

**pH-Titrations.**—Each polyampholyte (VI, VIII, X-a or X-b) was weighed (50~150 mg.) and dissolved in 0.1 N potassium chloride (20.00 ml.) containing 0.30 ml. of 1.00 N potassium hydroxide. The solution was titrated with 1.00 N hydrochloric acid using an Agla micrometer-syringe under stirring in an atmosphere of nitrogen. Determination of pH-values was carried out by using a Beckman, GS pH-meter. The curves shown in Figs. 1, 2, 3 and 4 were obtained by Parke and Davis's method[6].

## Summary

Homopolymers of *N*-carboxy-dehydroalanine anhydride (I) and of *N*-phthaloyl-dehydroalanine (II), and copolymers of II with vinyl acetate were synthesized. Hydrolysis or hydrazinolysis was carried out to obtain polymers containing $\alpha$-amino acid structures. Actual structures of these polymers were discussed.

The author wishes to express his thanks to Professor Shiro Akabori and Professor Shunsuke Murahashi for their valuable advice and encouragement.

# *The Acid Product Obtained in the Synthesis of 2-Phenyltropone Derivatives from 2-Phenylsuberone*[1]

By Tadashi MUROI*

(Received February 20, 1960)

Previously Nozoe, Kitahara and others[2] reported that in the direct bromination-dehydrobromonation of suberone, a considerable amount of an acid product was sometimes obtained besides the 2,4,7-tribromotropone, and thereafter confirmed the structure of this acid product to be 2,4,7-tribromo-5-hydroxytropone[3].

The present author also reported[4] previously that by the application of 4~5 molar equivalents of bromine on 2-phenylsuberone (I), 4-bromo-and 4,7-dibromo-2-phenyltropone (II and III) were obtained in a good yield and that these products were occasionally accompanied by a considerable amount of an acid substance (A), assumed to be a mixture of bromo-derivatives of 4-hydroxy-2-phenyltropone (IV). This paper describes the details of A and the four methyl ethers derived from A.

(I) (II): $X_1$=Br, $X_2$=$X_3$=H
(III): $X_1$=$X_3$=Br, $X_2$=H
(IV): $X_1$=OH, $X_2$=$X_3$=H

Scheme I

The yield of A was found to increase remarkably, when somewhat impure I, or a solvent containing a trace of water was used, i.e. when fairly prolonged heating had to be applied in order to complete the reaction. Compound A separated as yellow needles or pale yellow scales of decomp. point ca. 200°C, and was sparingly soluble in chloroform, alcohol and acetic acid, and insoluble in benzene, ether and water. It gave no coloration with ferric chloride characteristic of tropolone or enol. It gave, however, a sparingly soluble yellow sodium salt when treated with sodium hydroxide or sodium carbonate solution. When treated with diazomethane, A afforded four kinds of methyl ethers; pale yellow needles (V), m.p. 173~174°C, yellow needles (VI), m.p. 131~132°C, yellow prisms (VII), m.p. 74~75°C, and pale yellow plates (VIII), m.p. 112~113°C. Their formation ratio was not constant but, in general, V and VI were always obtained in a better yield than VII or VIII and some times the yield of VII and VIII was so small that they can not be isolated.

Both V and VII had the molecular formula of $C_{14}H_{11}O_2Br$ and were obtained chiefly from the sparingly soluble portion of A in alcohol. On the other hand VI and VIII analyzed for $C_{14}H_{10}O_2Br_2$ and were obtained from the comparatively soluble portion of A.

Previously, Kitahara and others reported[5] that 2,4,7-tribromo-5-hydroxytropone (IXa) gave two kinds of methyl ethers and predicted from this fact that IXa existed as an equilibrium mixture of IXa and its tautomeric isomer, i.e. 2,4,6-tribromo-5-hydroxytropone (IXb).

(IXa) (IXb)

Scheme II

Acid hydrolysis of V gave yellow needles (X), $C_{13}H_9O_2Br$ m.p. ca. 210°C (decomp.), treatment of which with diazomethane afforded V and VII, with the former predominating. This fact indicates that X exists in a tautomeric mixture (Xa and Xb) and that V and VII are the respective methyl ethers of Xa and Xb.

When refluxed with sodium methoxide in absolute methanol, VII underwent aromatization, and the successive hydrolysis of its product yield pale yellow crystals (XI), m.p. 98~103°C. When treated with concentrated sulfuric acid, XI was converted to give yellow scales (XII), m.p. 93~94°C, which was proved to be 3-methoxyfluorenone[6] by mixed fusion with the authentic sample. It is, therefore, clear

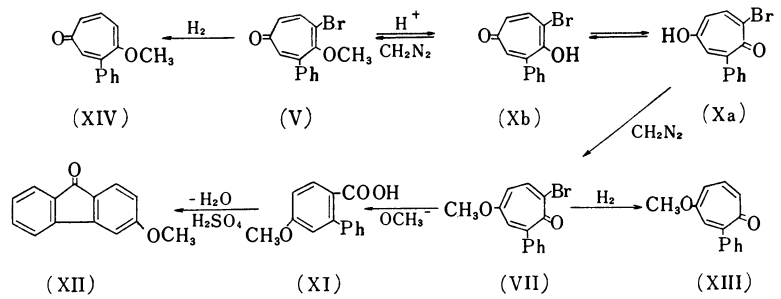
2) T. Nozoe, Y. Kitahara, T. Ando, S. Masamune and H. Abe, *Sci. Repts. Tohoku Univ., Ser.* I, **36**, 166 (1952).

3) T. Nozoe, Y. Kitahara and H. Abe, *Proc. Japan Acad.*, **29**, 347 (1953).



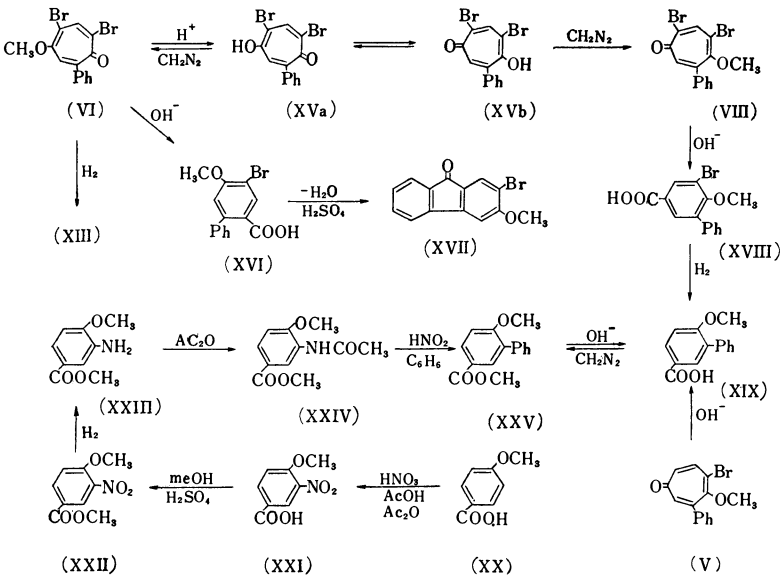
4) T. Muroi, This Bulletin, **33**, 1166 (1960).

5) Y. Kitahara, J. Shin and T. Toda, Presented at the Local Meeting of Tohoku District of the Chemical Society of Japan, Yamagata, Oct. 6, 1955.

6) F. Ullmann and H. Bleier, *Ber.*, **35**, 4272 (1902).

that XI is 4-methoxy-2-phenyl-benzoic acid and VII is 7-bromo-4-methoxy-2-phenyltropone, and X is a tautomeric mixture of 7-bromo-4-hydroxy-2-phenyltropone (Xa) and 5-bromo-4-hydroxy-3-phenyltropone (Xb).

Catalytic debromination of VII and V in the presence of palladium-carbon gave 4-methoxy-2-phenyltropone (XIII), m. p. 93~94°C, and 4-methoxy-3-phenyltropone (XIV), m. p. 75~76°C, respectively.



Scheme III

Acid hydrolysis of VI afforded pale yellow needles (XV), $C_{13}H_8O_2Br_2$ m. p. ca. 200°C (decomp.) which when treated with diazomethane, gave a mixture of VIII and VI. Catalytic debromination of VI gave XIII in a good yield. These facts indicate that XV also exists in a equilibrium mixture of two tautomeric forms (XVa and XVb) as in the case of IX and X, and moreover, that VI and VIII are respective methyl ethers of XVa and XVb.

When heated with alkali in alcohol, VI easily underwent aromatization to give colorless needles (XVI) m. p. 168~169°C, accompanied by a small amount of XV. When treated with concentrated sulfuric acid, XVI afforded yellow scales (XVII) m. p. 235~237°C, which was assumed to be monobromo-derivatives of XII. It follows therefore that one of the bromine atoms of VI occupies its C-7 position.

It was also found that VIII underwent aromatization very easily with alkali to give colorless needles (XVIII), m. p. 187~188°C, in a good yield. Catalytic debromination of XVIII gave colorless needles (XIX), m. p. 208~210°C. The structure of XIX is proved to be 4-methoxy-3-phenylbenzoic acid by the synthetic method shown in scheme IV.

These facts indicate, that VI and VIII are 5, 7-dibromo-4-methoxy-2-phenyltropone and 5, 7-dibromo-4-methoxy-3-phenyltropone, respectively, and XV is 5, 7-dibromo-4-hydroxy-2-phenyltropone as shown in the Scheme IV.

Scheme IV

From the fact mentioned above, the acid substance(A) is clarified to be a mixture of 7-bromo- and 5,7-dibromo-4-hydroxy-2-phenyltropone (Xa and XVa) and their respective tautomeric isomers. As the reaction of bromine on I is fairly complicated as reported previously[4], the mechanism of the formation of A can not be discussed at this stage. It is, however, assumed that A is derived through II or III by their hydroxylation or successive bromination during the reaction.

When treated with alkali, V was easily converted to give XIX in a good yield with the elimination of bromine at the C-5 position. Similar reaction was reported previously[7] by the present author, and this reaction is considered to be very interesting from the viewpoint that, in the rearrangement reaction of troponoid compound, the elimination of the substituents other than in C-2 (i. e. C-7) position has not been observed so far[8].

The synthesis and some reactions of IV and its bromoderivatives will be reported in the next paper.

## Experimentals[9]

**Formation of Acid Substance (A) from 2-Phenylsuberone(I).**—i) To a mixture of 4.7 g. of I, (b. p. 110~111°C/0.3~0.4 mmHg, $n_D^{25}$: 1.5390) 7.5 cc. of acetic acid and 1 cc. of water, a solution of 20 g. of bromine dissolved in 3.5 cc. of acetic acid was added dropwise over a period of 2 hr. at 50~80°C. The whole was heated on a water bath for about 3 hr. until there were no liberations of hydrogen bromide, cooled, and diluted with about 200 cc. of methanol, and yellow crystals (a) thereby separated were collected by filtration. Yield, ca. 4.3 g., m. p. 110~130°C. Crystalline residue, obtained after the evaporation of the solvent under reduced pressure, was digested with water and chloroform to give 0.25 g. of yellow crystals (b), m. p. 200°C (decomp.). The chloroform solution was shaken with 10% sodium carbonate solution and the aqueous layer was acidified with hydrochloric acid to give pale yellow crystals (c), m. p. 195°C (decomp.). Yield, 0.25 g.

The crystals (a) were digested with benzene and the insoluble portion (d), m. p. 195°C (decomp.) was collected by filtration. Yield, 0.85 g. The crystals (b), (c), and (d) were combined and dissolved in sodium carbonate solution. After treated with active carbon, the solution was acidified again and an acid product (A) was obtained as pale yellow crystals, m. p. 195~200°C (decomp.). Yield, 1.3 g.

The benzene soluble parts of (a) gave 2.8 g. of III. Similarly, chromatographic separation of the chloroform solution (aforementioned)[4] through a silica-gel column gave small amounts of III, II and 7-bromo-2-phenyltropone.

ii) To a solution of 4.7 g. of impure I (b. p. 140~149°C/2~3 mmHg, $n_D^{20}$: 1.5339) dissolved in 7.5 cc. of acetic acid, a solution of 16 g. of bromine in 3 cc. of acetic acid was added dropwise at 50~80°C. The whole was heated on a water bath for about 20 hr. till the liberation of hydrogen bromide was ceased. The solvent was evaporated under reduced pressure and the residue was washed with chloroform and water by which 1.8 g. of yellow crystals (a), m. p. 150~180°C (decomp.) were obtained. After the treatment of the chloroform solution with 10% sodium carbonate solution as in the above case, 0.2 g. of pale yellow crystals (b), m. p. ca. 175°C (decomp.) were obtained. The combined crystals (a) and (b) were repeatedly recrystallized from ethanol. Yellow needles ($A_1$) m. p. 207~210°C (decomp.) and pale yellow scales ($A_2$) m. p. 195~198°C (decomp.) were obtained from the sparingly soluble portion and comparatively easily soluble portion in alcohol, respectively.

Further recrystallization did not give pure substances and the analytical values of $A_1$ and $A_2$ were as below:

8) a) S. Seto, *Sci. Repts. Tohoku Univ., Ser.* I., **37**, 377 (1953). b) Y. Kitahara, ibid., **38**, 280 (1954). b) T. Mukai, ibid., **39**, 250 (1956). d) P. L. Pauson, *Chem. Revs*, **55**, 9 (1955).

9) Melting points are uncorrected. The micro analyses and the measurement of U. V. spectra were carried out by Mrs. K. Kodaira of Tohoku University, to whom deep gratitude is hereby expressed.

$A_1$: Found: C, 51.08; H, 2.88. Calcd. for $C_{13}H_9O_2Br$: C, 56.35; H, 3.27%.

$A_2$: Found: C, 44.11; H, 2.33. Calcd. for $C_{13}H_8O_2Br_2$: C, 45.15; H, 2.33%.

The neutral portion, when treated as in i), gave a small amount of the bromo derivatives of 2-phenyltropone whose structures were confirmed by mixed fusion with their authentic samples, respectively.

**Methylation of A.**—i) To a suspension of 1.15 g. of A, m. p. 185~190°C (decomp.) in 10 cc. of ether, ethereal diazomethane was added and the whole was kept standing overnight in a refrigerator. The crystals, m. p. 110~115°C, thereby separated, were collected by filtration and recrystallized from benzene or methanol to give 0.5 g. of VI as yellow needles m. p. 131~132°C.

Found: C, 46.00; H, 2.84. Calcd. for $C_{14}H_{10}O_2Br_2$: C, 45.44; H, 2.74%.

The filtrate was evaporated and the residue, dissolved in a mixture of benzene and petroleum ether, was chromatographed through a silica-gel column. This was eluted successively with benzene-petroleum ether mixture, benzene, and chloroform to give 0.15 g. of VI and 0.05 g. of V.

ii) A mixture of 0.7 g. of $A_1$ and 5 cc. of ether was treated with diazomethane as in i). The raw crystals thereby obtained were recrystallized from benzene or methanol to give 0.2 g. of V, as pale yellow needles, m. p. 173~174°C.

Found: C, 58.53; H, 4.14. Calcd. for $C_{14}H_{11}O_2Br$: C, 58.09; H, 3.81%.

The mother liquor, chromatographed as above, gave 0.1 g. of VI, 0.05 g. of V and a trace of VII as in their respective raw crystals.

iii) A mixture of 0.7 g. of $A_2$ and 5 cc. of ether was treated with diazomethane as above, and 0.3 g. of VI was separated. The chromathographic separation of the mother liquor through a silica-gel column gave 0.03 g. of VII, 0.05. of VI and 0.03 g. of V.

**Acid Hydrolysis of 5-Bromo-4-methoxy-3-phenyltropone (V).**—To a solution of 0.2 g. of V dissolved in 0.6 cc. of concentrated sulfuric acid, 6 cc. of water was added and the mixture was refluxed for 2 hr. After cooling, additional 10 cc. of water was added and the yellow crystals that separated were collected by filtration and washed with hot benzene. Yield 0.23 g. Recrystallization from ethanol gave X as yellow needles, m. p. 210~212°C (decomp.).

Found: C, 56.30; H, 3.40. Calcd. for $C_{13}H_9O_2Br$: C, 56.35; H, 3.27%.

From benzene solution 0.05 g. of V was recovered.

**Acid Hydrolysis of 5, 7-Dibromo-4-methoxy-2-phenyltropone (VI).**—A mixture of 0.37 g. of VI, 2 cc. of concentrated sulfuric acid and 4 cc. of water was refluxed for 30 min. After cooling the whole, the separated crystals were collected by filtration and washed with benzene. Yield 0.32 g. Recrystallization from ethanol gave XV as yellow scales, m. p. 195~198°C. (decomp.).

Found: C, 45.63; H, 2.46. Calcd. for $C_{13}H_8O_2Br_2$: C, 45.15; H, 2.33%.

**Methylation of 7-Bromo-4-hydroxy-2-phenyltropone (X).** — Treatment of X (0.3 g.) with diazomethane in ether followed by the removal of the solvent gave crystalline residue. Recrystallization from benzene gave 0.16 g. of raw crystals of V, m. p. 160~165°C. The mother liquor, after the removal of the solvent, was dissolved in a mixture of benzene and petroleum ether and chromatographed through a silica-gel column. About 0.07 g. of yellow crystals of VII, m. p. 62~65°C and a small amount of V were obtained. Recrystallization of VII from cyclohexane or dilute methanol gave yellow needles, m. p. 73~74°C.

VII: Found: C, 58.09; H, 3.60. Calcd. for $C_{14}H_{11}O_2Br$: C, 58.09; H, 3.81%.

**Methylation of 5,7-Dibromo-4-hydroxy-2-phenyltropone (XV).**—In the usual manner, 0.3 g. of XV was treated with diazomethane in ether. The crystals that separated were recrystallized from benzene or methanol to give 0.18 g. of VI as yellow needles, m. p. 129~130°C and 0.02 g. of VIII as pale yellow plates, m. p. 112~113°C.

VIII: Found: C, 45.51; H, 2.68. Calcd. for $C_{14}H_{10}O_2Br_2$: C, 45.44; H, 2.72%.

Chromatographic separation of the mother liquor through a silica-gel column gave additional 0.03 g. of VIII and a trace of VI.

**Reaction of 7-Bromo-4-methoxy-2-phenyltropone (VII) and Sodium Methoxide.**—To a solution of 0.04 g. of metallic sodium in 4 cc. of absolute methanol, 0.2 g. of VII was added and the solution was refluxed over a period of 20 hr. on an oil bath. After removal of the solvent, 5 cc. of water was added, and the solution was refluxed for an additional period of 3 hr. The solution was shaken with chloroform to remove the neutral portions and the water layer was acidified with dilute sulfuric acid. The acidic product that separated was extracted with chloroform. After removal of the solvent, the crystalline residue was recrystallized from cyclohexane to give 0.03 g. of XI as yellow crystals, m. p. 95~100°C. This was dissolved in 0.5 cc. of concentrated sulfuric acid and heated on a water bath for several min. After cooling, the solution was diluted with water and extracted with benzene. The benzene extract, after being washed with dilute sodium hydroxide solution, was evaporated and the residue was recrystallized from cyclohexane to give yellow needles, m. p. 95~97°C. This was proved to be identical by mixed fusion with the authentic sample of 3-methoxyfluorenone (XI).

**Reaction of 5, 7-Dibromo-4-methoxy-2-phenyltropone (VI) and Alkali.**—A mixture of 0.12 g. of VI, 3 cc. of ethanol and 1 cc. of 2 N sodium hydroxide was refluxed for 30 min. After removal of ethanol, the residue was acidified and extracted with benzene. Benzene extract gave 0.06 g. of pale yellow crystals which were digested, with a small amount of yellowish brown crystals, m. p. 185~193°C (decomp.). This was proved to be XV from its analytical value.

Found: C, 43.88; H, 2.20. Calcd. for $C_{13}H_8O_2Br_2$; C, 45.15; H, 2.33%.

The benzene solution was passed through a short silica-gel column to give 0.03 g. of raw crystals of m. p. 140~155°C. Recrystallization from dilute methanol gave XVI as colorless needles, m. p. 168~169°C.

Found: C, 54.51; H, 3.46. Calcd. for $C_{14}H_{11}O_3Br$: C, 54.75; H, 3.61%.

When XVI was heated with concentrated sulfuric

acid on a water bath for several minutes and then diluted with water, there were obtained yellow crystals of m. p. 235~237°C.

Found: C, 57.52; H, 3.04. Calcd. for $C_{14}H_9O_2Br$; C, 58.16; H, 3.14%.

**Reaction of 5, 7-Dibromo-4-methoxy-3-phenyltropone (VIII) and Alkali.**—A mixture of 0.06 g. of VIII, 3 cc. of methanol and 10 cc. of 2 N sodium hydroxide was refluxed on a water bath for 30 min. After treated as in the case of VII, 0.05 g. of raw crystals of m. p. 175~180°C were obtained. Recrystallization from methanol gave XVIII as colorless needles of m. p. 187~188°C.

Found: C, 55.28; H, 3.60. Calcd. for $C_{14}H_{11}O_3Br$: C, 54.75; H, 3.61%.

Debromination of 0.03 g. of XVIII dissolved in 3 cc. of methanol, in the presence of palladium carbon catalyst and sodium acetate, gave 0.02 g. of colorless crystals m. p. 190~200°C. This was recrystallized from methanol to give colorless needles of m. p. 210~211°C, which was proved to be identical with the authentic sample of XIX obtained from V.

**Reaction of 5-Bromo-4-methoxy-3-phenyltropone (V) and Alkali.**—A mixture of 0.14 g. of V, 2.5 cc. of ethanol and 0.8 cc. of 2 N sodium hydroxide was refluxed for 30 min. After treated as in the above cases, 0.12 g. of pale yellow acidic crystals were obtained. This was digested with hot benzene to give a minute amount of yellow crystals of m. p. 205~208°C (decomp.). Which was proved to be identical with X from its analytical value and ultraviolet spectrum.

Found: C, 56.28; H, 3.34. Calcd. for $C_{13}H_9O_2Br$: C, 56.35; 3.27%.

From the benzene solution, colorless needles of m. p. 207~209°C were obtained. This was proved to be identical with the sample of XIX obtained from 4-methoxybenzoic acid (XX).

Found: C, 73.97; H, 5.04. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

**Reduction of 7-Bromo-4-methoxy-2-phenyltropone (VII).**—Catalytic reduction of 0.11 g. of VII dissolved in 3 cc. of ethanol, in the presence of 0.02 g. of sodium acetate and 0.02 g. of palladium carbon, resulted in absorption of hydrogen at room temperature. After removal of the catalyst by filtration, the filtrate was diluted with water and extracted with benzene. This extract, evaporated under reduced pressure, gave crystalline residue which was recrystallized from cyclohexane to give XIII as pale yellow needles m. p. 91~92°C.

Found: C, 79.63; H, 5.80. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

**Reduction of 5, 7-Dibromo-4-methoxy-2-phenyltropone (VI).**—Catalytic reduction of 0.1 g. of VI, as in the case of VII, gave 0.02 g. of XIII.

**Reduction of 5-Bromo-4-methoxy-3-phenyltropone (V).**—Catalytic reduction of 0.1 g. of V dissolved in 40 cc. of ethanol, in the presence of 0.1 g. of palladium carbon and 0.1 g. of sodium acetate, resulted in absorption of hydrogen at room temperature. After removal of the catalyst and the solvent, the residue was diluted with water and extracted with benzene. This solution, passed through a silica-gel column, gave raw crystals of m. p. 70~74°C. Recrystallization from cyclohexane gave XIV, as pale yellow prisms, m. p. 75~76°C.

Found: C, 78.31; H, 5.81. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

**Synthesis of 4-Methoxy-3-phenylbenzoic Acid (XIX).**—4-Methoxy-3-nitrobenzoic acid (XXI)[10], m. p. 191~192°C, was obtained by the nitration of 4-methoxybenzoic acid (XX) in a mixture of acetic acid and acetic anhydride with concentrated nitric acid.

The methylation of XXI with methanol and concentrated sulfuric acid gave methyl-4-methoxy-3-nitrobenzoate (XXII)[11] m. p. 110~111°C in a good yield. Catalytic reduction of XXII in ethyl acetate in the presence of Raney nickel catalyst (W-5), gave methyl-3-amino-4-methoxy benzoate (XXIII)[12], m. p. 83~85°C.

A solution of 0.7 g. of acetic anhydride and 3 cc. of acetic acid was heated for 30 min. To the cold reaction mixture, nitrous fume generated by the action of concentrated nitric acid to solid sodium nitrate, was passed in for a period of 1 hr. at about 5°C. When diluted with water, the reaction mixture separated a yellow oily product, which was extracted with benzene. After washed with water and dried over anhydrous sodium sulfate, the benzene solution was poured on a mixture of 0.7 g. of anhydrous sodium carbonate and 0.7 g. of anhydrous sodium sulfate. The whole was stirred for a period of 5 hr. and then kept to stand for 2 days. After removal of solid materials, the filtrate was evaporated to give 0.6 g. of an oily product. This was distilled under reduced pressure and about 0.2 g. of yellow crystalline oil was obtained. Recrystallization from ether and methanol gave methyl 4-methoxy-3-phenylbenzoate (XXV) as colorless prisms, m. p. 88~89°C. Hydrolysis of XXV gave XIX as colorless needles of m. p. 115~117°C which was proved to be identical by mixed fusion with the sample obtained from V or VII. Methylation of 0.04 g. of XIX with diazomethane gave about 0.03 g. of XXV.

The author takes this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe of Tohoku University for his guidance and encouragement throughout the course of this work, to Professor Shuichi Seto, Professor Yoshio Kitahara of Tohoku University and to Assistant Professor Katsuo Kikuchi of Yamagata University for their very helpful and kind discussions.

# *A Study on Anion Exchange aud Amine Extraction of Rare Earth Elements in Nitric Acid*

By Fujio ICHIKAWA

(Received April 28, 1960)

The use of amine extraction for uranium, thorium and many other elements has recently been developed by a number of investigators[1-7]. It is reported that the mechanism of amine extraction is similar to that of anion exchange and the former is called commercially liquid anion exchanger. The author previously reported[8] the amine extraction and anion exchange of uranium, protactinium and thorium in nitric, hydrochloric and sulfuric acid. Peppard, Mckay and their coworkers[9-12] reported on the extraction of rare earth nitrates with tri-*n*-butyl phosphate.

In the present paper, the distribution coefficients of rare earth elements between anion exchange resin and nitric acid are compared with those between amine and nitric acid. Based on the resuls from these distribution studies, the mechanism of amine extraction is discussed.

## Experimental

**Materials.**—Dowex 1, X8 (100~200 mesh), converted into nitrate form by nitric acid, is used as an anion exchange resin. Primene JM-T, Amberlite LA-2 and tri-*n*-octyl amine are respectively used as primary, secondary and tertiary amine. Amines are diluted with kerosene, and octyl alcohol is added to this solution to avoid the third phase formation, making phase separation clear. These amine solutions are converted into the nitrate form with 8 N nitric acid, as shown in the following equation.

$$RR'NH + HNO_3 \rightleftarrows RR'NH_2NO_3$$

Promethium-147 is used as a tracer of Pm. Other radioactive tracers of rare earth elements are prepared by neutron irradiation of rare earth oxides in J. R. R.-1 Reactor or by separation from isotopes of alkaline earth elements which are in a state of equilibrium with their daughter nuclides. The irradiated oxides are dissolved in 8 N nitric acid. The $\gamma$-ray spectrograms of these samples are obtained with a single channel pulse height analyzer and the radioactivities of these samples are measured by $\gamma$-ray or $\beta$-ray counting.

Table I shows the radioisotopes used in this experiment and the method for radioactivity measurement.

TABLE I. RADIOISOTOPES OF RARE EARTH ELEMENTS

| Nuclide | Preparation | Counting method |
|---|---|---|
| $^{140}$La | Imported $^{140}$Ba→$^{140}$La, coprecipitation with $Fe(OH)_3$, extraction of Fe by Amberlite LA-1 from 6 N HCl | $\gamma$ |
| $^{141}$Ce | $(n, \gamma)$ | $\gamma$ |
| $^{142}$Pr | $(n, \gamma)$ | $\beta$ |
| $^{147}$Nd | $(n, \gamma)$ | $\gamma$ at 0.092 MeV. of $^{147}$Nd |
| $^{147}$Pm | imported | $\beta$ |
| $^{152}$Eu+$^{154}$Eu | $(n, \gamma)$ | $\gamma$ |
| $^{159}$Gd | $(n, \gamma)$ | $\gamma$ at 0.364 MeV. of $^{159}$Gd |
| $^{160}$Tb | $(n, \gamma)$ | $\gamma$ |
| $^{165}$Dy | $(n, \gamma)$ | $\gamma$ |
| $^{166}$Ho | $(n, \gamma)$ | $\gamma$ |
| $^{170}$Tm | $(n, \gamma)$ | $\gamma$ |
| $^{175}$Yb | $(n, \gamma)$ | $\gamma$ at 0.396 MeV. of $^{175}$Yb |
| $^{176m}$Lu+$^{177}$Lu | $(n, \gamma)$ | $\gamma$ |

Sm and Er are omitted from this experiment because their $\gamma$-ray spectra resemble those of the daughters'.

**Procedure.**—The distribution coefficients in both anion exchange and amine extraction are measured by the batch method. Half a gram of dried resin is immersed in 5 ml. of nitric acid solution of rare earth elements and then shaken for 20 hr. at a constant temperature so that a state of equilibrium is attained. Then the sample is filtered and the activity of 1 ml. of the filtrate is compared with that of a reference solution.

In the case of the amine extraction, 2 ml. of 30% kerosene solution of amine is shaken for 1 min. with 2 ml. of nitric acid solution of rare earth element. Then resulting solution is then centrifuged and two phases are separated. The activity of both organic and aqueous solutions are measured. The distribution coefficient is calculated from the data which are obtained in these experiments.

## Results

Distribution coefficients ($K_d$) of lanthanum, promethium and holmium are measured for the nitric acid solution of various concentrations.

Results are shown in Figs. 1—4. In the concentration range from 1 to 8 N nitric acid, the $K_d$ value of anion exchange increases slowly and then decreases in acidities over 8 N. The distribution coefficients in primary amine extraction increases with the increase in the concentration of nitric acid. As is shown in Fig. 1, the maximum value of $K_d$ decreases with increasing atomic number. In order to confirm this trend, values of $K_d$ for rare earth elements in 8 N nitric acid is determined at 20°C. Fig. 5 shows the result of this experiment. For rare earth elements from lanthanum to gadolinium the $K_d$ value decreases with increasing atomic number. The difference in the $K_d$ value for rare earth elements of higher atomic number is very small and the relation between the $K_d$ value and the atomic number is complicated.

In the case of amine extraction, the $K_d$ values for rare earth elements are very small. Results are shown in Figs. 6—8. $K_d$ decreases slowly from lanthanum to dysprosium in

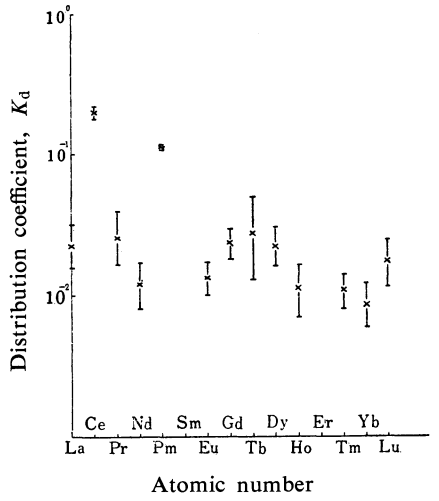

Fig. 8. Distribution coefficients of rare earth elements between 30% tri-*n*-octyl amine and 8 N nitric acid.

primary amine extraction. From holmium to lutetium, the difference in $K_d$ value is very small. This is a tendency similar to that observed in anion exchange. As to the secondary amine extraction, a small decrease in $K_d$ is found. But no significant variation in $K_d$ is observed in tertiary amine extraction.

To compare these results, the extraction of rare earth elements by 100% TBP from 8 N nitric acid solution is studied. Fig. 9 shows the result. $K_d$ value increases with increasing atomic number and this result is very different from those in anion exchange or amine extraction.

## Discussion

Peppard and his coworkers[9,10] found the tendency of the increase in the extractability of rare earth nitrates by TBP with increasing atomic number. Mckay and his coworkers[11,12] reported that this trend is not always found in the subgroup from Gd to Lu. In the present experiment, the extractability of rare earth elements by 100% TBP from 8 N nitric acid solution also increased with increasing atomic number and some difference is found between lower and higher subgroups.

On the contrary, anion exchange study shows

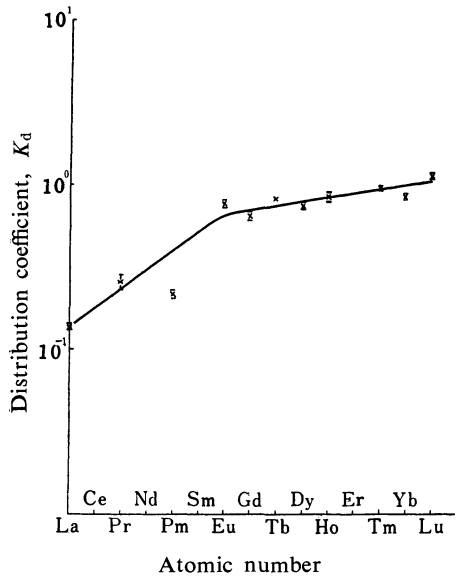

Fig. 9. Distribution coefficients of rare earth elements between 100% TBP and 8 N nitric acid.

decreasing of $K_d$ value with increasing atomic number for rare earth elements of lower subgroup.

The different behavior of these two subgroups is probably due to the ionic radius, electronic structure and other characters. The reverse trend observed in TBP extraction and anion exchange might be due to the different probability of neutral complex formation and anionic complex formation in each circumstance.

From these points of view, the amine extraction behavior of these elements is very interesting. As is shown in Figs. 6—8, the difference in $K_d$ value between rare earth elements of lower and higher atomic number is greater in the case of primary amine extraction than in secondary amine extraction. But, in both cases, decrease in $K_d$ value with increasing atomic number is observed. It is suggested from these facts that the mechanism of amine extraction of rare earth elements resembles more the mechanism of anion exchange than TBP extraction does.

## Summary

The amine extraction of rare earth elements in nitric acid is compared with anion exchange and TBP extraction with respect to the increase or decrease in $K_d$ value with increasing atomic number of rare earth elements.

Concerning the relationship between distribution coefficient and atomic number of rare earth element, a similar trend is observed in anion exchange and amine extraction. The distribution coefficient decreases with increase in the atomic number. In TBP extraction, however, the corresponding value increases with increasing atomic number. It seems that the mechanism of amine extraction for rare earth element is similar to that of anion exchange.

The author expresses his gratitude to Dr. T. Nakai for his encouragement in this work. He also wishes to thank Miss. S. Uruno for assistance with experimental work.

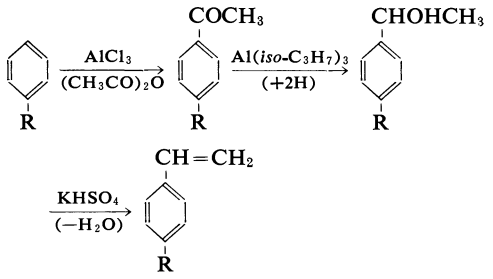
# *Vinyl Polymerization. XLVIII.* Polymerization of Methylstyrenes and the Effect of Dimethylaniline on their Polymerization*

By Minoru IMOTO, Kiichi TAKEMOTO and Yuichi IIKUBO

(Received July 22, 1960)

Previously we have carried out polymerization of styrene and *p*-methylstyrene initiated by the azobisisobutyronitrile (ABIN)-dimethylaniline (DMA) system. Consequently a peculiar effect was observed in the polymerization of *p*-methylstyrene[1]. In this paper, the polymerization of *p*-methylstyrene with the ABIN-DMA system was studied repeatedly, and some different conclusions were obtained. The value of $k_1$ in this system was also measured by the ferric chloride method of Bamford et al.[2]

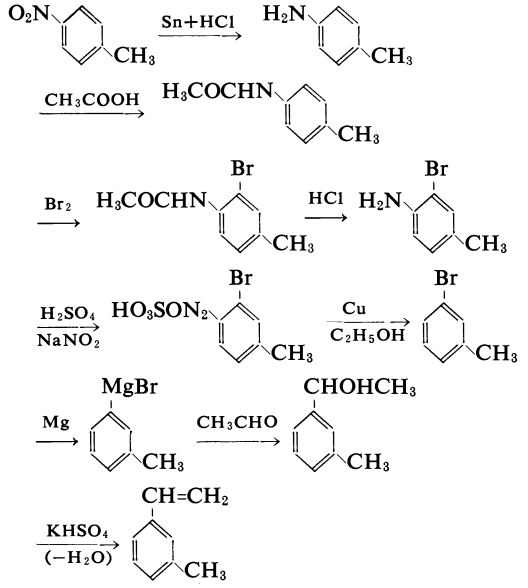
* XLVII of this series: M. Imoto and I. Soematsu, in contribution.



1) M. Imoto and K. Takemoto, *J. Polymer Sci.*, **19**, 205 (1956).

2) J. C. Bamford, A. D. Jenkins and R. Johnston, *Proc. Roy. Soc.*, **A241**, 364 (1957).

As the polymerization of other monomethyl- and dimethylstyrenes has been little investigated, it was interesting to carry out the polymerization of these monomers. The polymerization with ABIN was studied in benzene, and rates of polymerization and intrinsic viscosities were determined.



## Experimental

**Syntheses of Monomers.**—*Syntheses of p-Alkylstyrenes.*—*p*-Methyl-, *p*-ethyl- and *p-tert*-butylstyrene were synthesized from corresponding alkylbenzenes, according to the following sequence of reactions[3]:

(R : $CH_3$, $C_2H_5$, *tert*-$C_4H_9$)

*Synthesis of m-Methylstyrene.*—*m*-Methylstyrene was synthesized from *p*-nitrotoluene as follows[4]:

*Syntheses of Dimethylstyrenes.*—2,4-Dimethyl-, 2,5-dimethyl- and 3,4-dimethylstyrene were synthesized from corresponding xylenes in a manner similar to that used in the case of *p*-alkylstyrenes[5].

The Meerwein-Ponndorf reduction of the substituted acetophenones was found to be unsuccessful in the case of 3,4-dimethyl derivative. By the direct hydrogenation in autoclave, using copper-chromium oxide or Raney nickel as catalyst, 3,4-dimethylphenylcarbinol was obtained with yield of 90%.

*Purification of Monomers.*—All monomers were purified by distillation in vacuo under flushing of nitrogen after drying over calcium chloride. Before use, they were distilled again through a 40 cm. Stedman column. Reflux ratios were 10 : 1∼6 : 1. Physical constants of the monomers were shown in Table I. Infrared spectroscopic analyses were also made for all the monomers to ascertain their structures.

Styrene was purified by distillation in the same manner as the substituted styrenes (b. p. 145°C/760 mmHg).

**Purification of Reagents.**—2,2'-Azobisisobutyronitrile (ABIN) was purified by recrystallization from methanol and dried in vacuo (m. p. 103°C). Dimethylaniline (DMA) was distilled in a nitrogen atmosphere and stored. Before use, it was again distilled under reduced pressure through a Vigreux column (b. p. 68°C/10 mmHg). Benzene was distilled, after thiophene was removed, dried over calcium chloride and again distilled over metallic sodium (b. p. 80°C). Ferric chloride ($FeCl_3 \cdot 6H_2O$), commercial pure grade, was used after crushing. Benzoquinone was synthesized from hydroquinone by oxidation with sodium dichromate and purified by sublimation under reduced pressure twice before use (m. p. 113∼114°C). Nitrogen was purified by washing through alkaline pyrogallol solution and concentrated sulfuric acid and by passing over reduced copper at 550°C.

**Procedures.**—*Measurement of Rate of Polymerization.*—In order to determine the initial rate of polymerization, the dilatometric and usual sealed tube methods were adopted. In some experiments, the dilatometer reported earlier[6] was used. In another case, a dilatometer in a different form was used, the total capacity being about 4.5∼5.5 ml. and the diameter of the capillary tube about 0.3∼0.5 mm.

Polymerization was carried out as described in the previous paper. The polymerization temperature was regulated within ±0.02°C in the case of dilatometry, and ±0.05°C in the case of the sealed tube method.

*Measurement of Intrinsic Viscosity.*—Intrinsic viscosities [$\eta$] of polymers were measured in benzene solution at 30±0.1°C, using Ostwald's viscometer. Assuming that the following equation given by Tobolsky et al.[7] for polystyrene can also be available for substituted polystyrenes, the number-average polymerization degree $\bar{P}_n$ of all polymers was computed.

$$\bar{P}_n = 1770[\eta]^{1.40}$$

*Measurement of Rate of Decomposition of ABIN.*—The rate of decomposition of ABIN was measured, with the volume of nitrogen evolved[8].

TABLE I. PHYSICAL PROPERTIES OF SUBSTITUTED STYRENES

| Styrene | B. p., °C (mmHg) | S. g. | Refractive index |
|---|---|---|---|
| *p*-Methylstyrene | 58 ( 7) | $d_4^{25}=0.890$ | $n^{25}=1.5393$ |
| *p*-Ethylstyrene | 68 (10) | $d_4^{20}=0.9070$ | $n^{25}=1.5349$ |
| *p-tert*-Butylstyrene | 90~92 (10) | $d_4^{23}=0.8739$ | $n^{20}=1.5212$ |
| *m*-Methylstyrene | 90~91 (30) | $d_{25}^{25}=0.9032$ | $n^{24.5}=1.5392$ |
| 2,4-Dimethylstyrene | 90 (25) | $d_{25}^{25}=0.9048$ | $n^{20.5}=1.5425$ |
| 2,5-Dimethylstyrene | 81~83 (23) | $d_{25}^{25}=0.9050$ | $n^{20}=1.5389$ |
| 3,4-Dimethylstyrene | 86~88 (20) | $d_{25}^{25}=0.9200$ | $n^{20}=1.5420$ |

TABLE II. RATES OF POLYMERIZATION AND DEGREES OF POLYMERIZATION FOR SUBSTITUTED STYRENES

| Monomer | Rate of polymerization: Sealed tube method, 50°C (mol./l. sec.) | Rate of polymerization: Dilatometry, 70°C (mol./l. sec.) | Degree of polymerization $\bar{P}_n$ |
|---|---|---|---|
| Styrene | $11.13\times10^{-6}$ | $5.10\times10^{-6}$ | 700 |
| *p*-Methylstyrene | 14.30 | 5.32 | 190 |
| *p*-Ethylstyrene | — | 2.13 | — |
| *p-tert*-Butylstyrene | — | 1.73 | — |
| *m*-Methylstyrene | 4.20 | — | 280 |
| 2,4-Dimethylstyrene | 6.52 | — | 150 |
| 2,5-Dimethylstyrene | 6.86 | — | 300 |
| 3,4-Dimethylstyrene | 10.96 | — | 490 |

* Monomer concentration=3.43 mol./l., ABIN concentration=$1.097\times10^{-2}$ mol./l.
** Monomer concentration=0.455 mol./l., ABIN concentration=$2.50\times10^{-3}$ mol./l.

## Results

**Polymerization of Substituted Styrenes.**—*Polymerization of p-Alkyl- and Dimethylstyrenes.*— Polymerizations of styrene, *p*-methyl-, *p*-ethyl- and *p-tert*-butylstyrene were carried out dilatometrically in benzene at 70°C. The linear time-conversion relationship was obtained for all runs. Polymerization of *m*-methyl-, 2,4-dimethyl-, 2,5-dimethyl and 3,4-dimethylstyrene were also carried out in benzene at 50°C by the sealed tube method. Time-conversion curves were shown in Fig. 1 (including the curves of styrene and *p*-methylstyrene), where the concentrations of monomer and initiator were kept constant at 3.43, and $1.097\times10^{-2}$ mol./l., respectively. The linear time-conversion curves were also obtained. The rate for *p*-methylstyrene was greater than that for styrene. The rates for other monomers were smaller than that for styrene.

[M]=3.43 mol./l.
[ABIN]=$1,097\times10^{-2}$ mol./l.
50°C, in benzene

The values of the rate of polymerization obtained were tabulated in Table II. The table includes also the values of degree of polymerization. The polymers used for the determination of $[\eta]$ were obtained by 4.5 hr. polymerization.

Comparing the values of $\bar{P}_n$ and *Rp* of *p*-methylstyrene with these of styrene, it was assumed that *p*-methylstyrene easily underwent chain transfer reaction. This was because in spite of the larger value of *Rp*, the degree of polymerisation was smaller. In order to study the effect of solvents on reaction, polymerization of *p*-methylstyrene was carried out in acetone or dimethylformamide (DMF) in the same manner as in benzene. As shown in Table III, the rates of polymerization in acetone were nearly the same as that in benzene. But the value obtained in DMF was relatively low. Separation of the polymer from benzene or DMF solution was easy, because the polymer separated granulously when the reaction mixture was poured into an excess of methanol.

TABLE III. OVERALL RATES OF POLYMERIZATION OF *p*-METHYLSTYRENE IN SOME SOLVENTS (DILATOMETRY, 60°C)

| Exp. run | Solvent | Rate of polymerization mol./l. sec. |
|---|---|---|
| 1 | Dimethylformamide | $2.13\times10^{-5}$ |
| 2 | 〃 | 2.08 |
| 3 | Benzene | 2.47 |
| 4 | 〃 | 2.46 |
| 5 | 〃 | 2.56 |
| 6 | Acetone | 2.46 |
| 7 | 〃 | 2.47 |

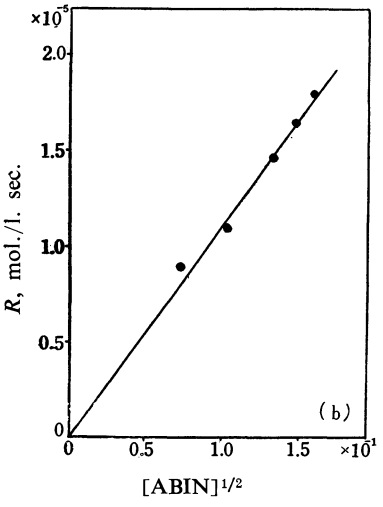

Fig. 2. Polymerization of 3,4-dimethylstyrene initiated by ABIN (sealed tube, in benzene, 50°C).
(a) Relationship of the initial rate of polymerization with the monomer concentration. ([ABIN] = $1.098\times10^{-2}$ mol./l.)
(b) Relationship of the initial rate of polymerization with the initiator concentration. ([M] = 3.49 mol./l.)

However, when acetone was used, a turbid emulsion was obtained and the separation by filtration was much more difficult.

**Rate Equation of Polymerization for Substituted Styrene.**—From the results of 3,4-dimethylstyrene as shown in Fig. 2, the following equation was derived. This was identical with that for styrene.

$$R_0 = k\,[\mathrm{M}]\,[\mathrm{ABIN}]^{1/2}$$

**Determination of Rate Constants for Initiation.**—The rate constants of initiation of the polymerization of styrene and *p*-methylstyrene were determined, according to the $FeCl_3$-method by Bamford et al.[2], using the following equation.

$$\tau = \frac{[FeCl_3\cdot 6H_2O]}{2f\cdot k_d\,[\mathrm{ABIN}]} = \frac{[FeCl_3\cdot 6H_2O]}{2k_i\,[\mathrm{ABIN}]}$$

where $\tau$ is the induction period (in minutes), $f$ the initiator efficiency, and $k_d$ and $k_i$ the rate constants for decomposition of initiator and for initiation, respectively. The measurement of the value of $\tau$ for *p*-methylstyrene was carried out in DMF at 60°C.

In Fig. 3, examples of the time-conversion curve were illustrated. In Fig. 4, the relationship between the induction period and the amount of ferric chloride was shown. In Fig. 5, the relationship between the concentration of ABIN and the reciprocal of induction period was shown. The rate constants of initiation

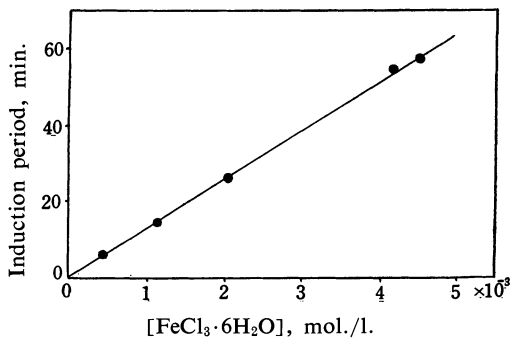

Fig. 4. Relationship between the induction period and the amount of ferric chloride in the polymerization of *p*-methylstyrene (in DMF, 60°C). [M]=2.17 mol./l., [ABIN]=$1.00\times10^{-1}$ mol./l.

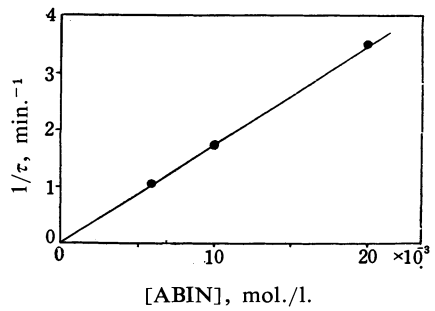

Fig. 5. Relationship between the induction period and the amount of ABIN in the polymerization of *p*-methylstyrene (in DMF, 60°C). [M]=2.17 mol./l., [$FeCl_3\cdot6H_2O$]=$4.46\times10^{-3}$ mol./l.

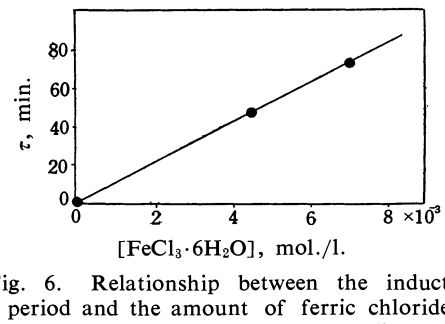

Fig. 6. Relationship between the induction period and the amount of ferric chloride in the polymerization of styrene (in DMF, 60°C). [M]=2.04 mol./l., [ABIN]=$1.00\times10^{-1}$ mol./l.

for the polymerization of *p*-methylstyrene were estimated as follows:

$$k_1=0.67\times10^{-5}\ (\mathrm{sec}^{-1})$$

Similar determination was also made for styrene in DMF at 60°C, and the result obtained was shown in Fig. 6. The value of $k_1$ was as follows:

$$k_1=0.76\times10^{-5}\ (\mathrm{sec}^{-1})$$

This value was in good agreement with the value, $k_1=0.70\times10^{-5}$ ($\mathrm{sec}^{-1}$), obtained by Bamford et al. From the agreement of our value with that by Bamford et al., the value of $k_1$ for *p*-methylstyrene seemed to be reasonable.

As for $k_1$, the value for *p*-methylstyrene was found to be rather smaller than that for styrene. As shown in the former section of this paper, however, the overall rate of the polymerization of *p*-methylstyrene was greater than that of styrene. These results imply that in the sase of *p*-methylstyrene the rate constant for the propagation would be greater than that for styrene, or, that the rate constant of the termination $k_t$ would be smaller. Further work will be done to clarify this point.

**Polymerization of Substituted Styrene in the Presence of Dimethylaniline.—Polymerization of Styrene and *p*-Methylstyrene.**—*a) Polymerization with $Bz_2O_2$-DMA.*—Polymerization of *p*-methylstyrene was carried out dilatometrically at 70°C, using a system of benzoyl peroxide ($Bz_2O_2$)-dimethylaniline (DMA) as initiator. Time-conversion curves were shown in Fig. 7, where the concentrations of monomer and $Bz_2O_2$ were kept constant at 0.455 and $2.50\times10^{-3}$ mol./l., respectively, and the concentration of DMA was varied from 0 to 0.02 mol./l. Fig. 8 shows the results obtained, where the concentration of monomer and DMA were kept constant at 0.455 and $2.50\times10^{-3}$ mol./l., respectively, and the concentration of $Bz_2O_2$ was varied from 0 to 0.085 mol./l. The initial rates of polymerization were determined by the extrapolation method previously reported[5].

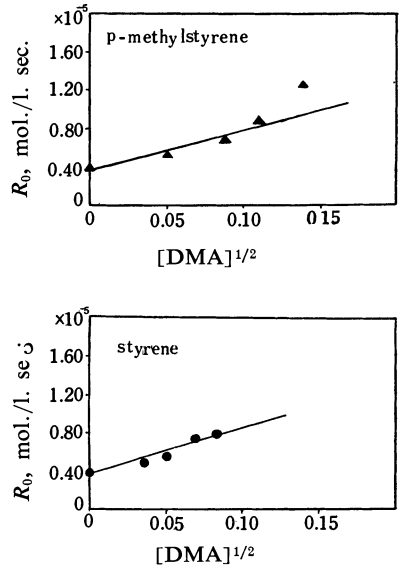

Fig. 7. Polymerization of styrene and *p*-methylstyrene initiated by $Bz_2O_2$ at 70°C (dilatometry).

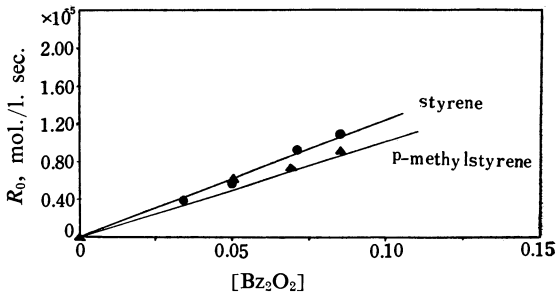

Fig. 8. Polymerization of styrene and *p*-methylstyrene initiated by $Bz_2O_2$ at 70°C (dilatometry).

The polymerization of styrene was carried out in parallel.

It was found that in the polymerization of *p*-methylstyrene, the initial rate of polymerization was also regarded as of 1/2-order with the concentrations of $Bz_2O_2$ and DMA, respectively.

$$R_0 = k'[Bz_2O_2]^{1/2}[DMA]^{1/2}$$

This agrees well with the results reported for the polymerization of several vinyl monomers[9].

*b) Polymerization with ABIN-DMA.*—Polymerizations of styrene and *p*-methylstyrene were carried out dilatometrically at 70°C by the ABIN-DMA system. Keeping the concentrations of monomer and ABIN constant at 0.455 and $2.50\times10^{-3}$ mol./l., respectively, and varying the concentration of DMA from 0 to $2.5\times10^{-2}$ mol./l., the initial rates of polymerization were measured.

Previously, two of the present authors, M. Imoto and K. Takemoto, published a paper on the polymerization of *p*-methylstyrene by ABIN-DMA[1]. There an apparent conclusion was obtained that the initial rate of polymerization increased with the addition of a small

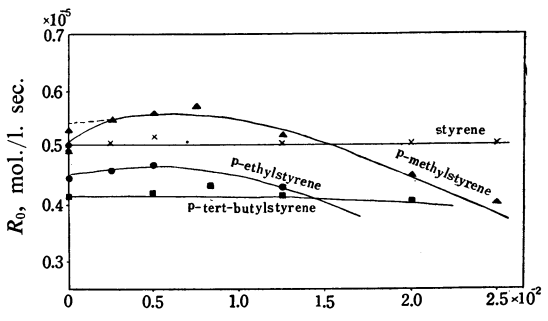

Fig. 9. Polymerization of styrene and *p*-alkylstyrenes initiated by ABIN in the presence of DMF at 70°C.
[M] = 0.455 mol./l.
[ABIN] = $2.50\times10^{-3}$ mol./l.

9) M. Imoto, T. Otsu and T. Ota, *Makromol. Chem.*, **16**, 10 (1955).

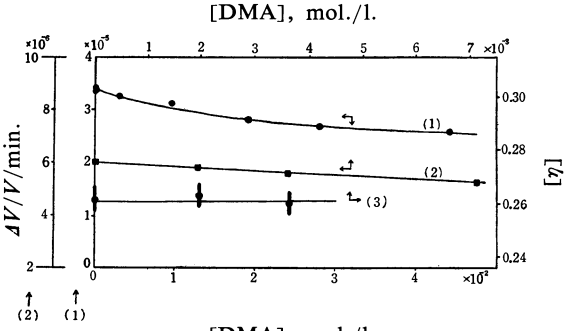

Fig. 10. Relationship of overall rate and intrinsic viscosity with the amount of DMA in the polymerization of *p*-methylstyrene initiated by ABIN at 60°C (in benzene). [M] = 2.17 mol./l., [ABIN], (1) $1.00\times10^{-1}$ mol./l., (2), (3) $2.68\times10^{-3}$ mol./l.

quantity of DMA and then decreased with the increasing quantity of DMA, after passing a maximum value (Fig. 9). It had been assumed that this phenomenon was due to the acceleration of the hyperconjugation effect of the *p*-alkyl group by DMA. For four years the study to ascertain this phenomenon was carried out repeatedly. In many cases, it was observed that no such accelerating effect by DMA existed as shown in Fig. 10.

Granting the dotted line in Fig. 9 to be correct, the former observations coincided with the results obtained in this paper. (As stated above, the rate of polymerization of *p*-methylstyrene was surely greater than that of styrene.) It was now concluded that an accelerating effect by hyperconjugation might be denied, and that the initial rates of polymerization seemed to decrease with DMA as seen from Figs. 9 and 10.

**Polymerization of Dimethylstyrenes and *m*-Methylstyrene.**—We have carried out further

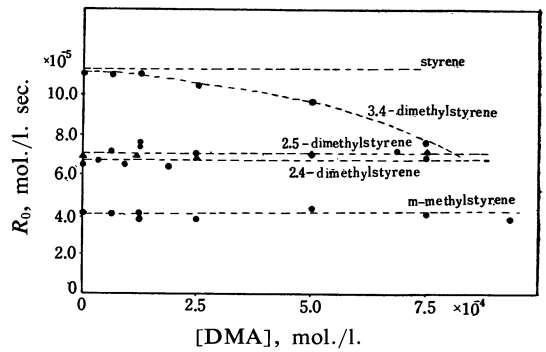

Fig. 11. Polymerization of *m*-methylstyrene and dimethylstyrenes initiated by ABIN in the presence of DMA at 50°C.
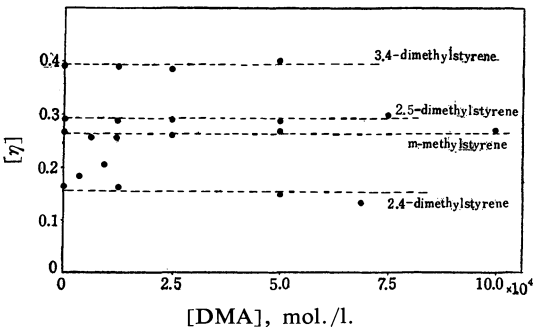
[M] = 3.43 mol./l.
[ABIN] = $1.097\times10^{-2}$ mol./l.

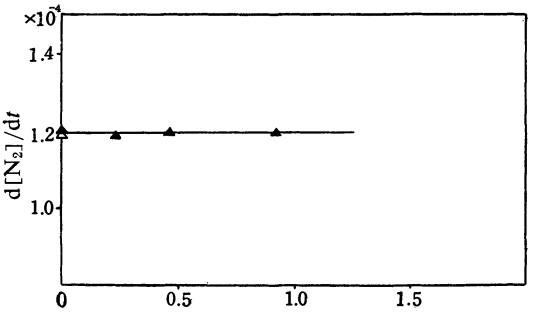
experiments on the polymerization of dimethylstyrenes in order to examine the effect of DMA on the polymerization initiated by ABIN.



Polymerization was carried out by the sealed tube method at 50°C. The concentrations of the monomer and ABIN were kept constant at 3.43 and $1.097\times10^{-2}$ mol./l. respectively, while the concentration of DMA was varied from 0 to $1.0\times10^{-3}$ mol./l. As shown in Fig. 11, in the case of *m*-methylstyrene no effect of DMA on the initial rate was observed as in the case of styrene, while in the case of 2, 4- and 3, 4-dimethylstyrene a slight decrease with DMA was observed.

**Measurement of Intrinsic Viscosity.**—Intrinsic viscosities of the polymers obtained were measured in benzene at 30°C. Figs. 10 and 12 gave the plots of the intrinsic viscosities to the amounts of DMA added in the polymerization. From the results, it was concluded that no effect of DMA on the intrinsic viscosity was present.

**Rate of Decomposition of ABIN in the Presence of DMA and Monomer.**—The rate of decomposition of ABIN was measured at 50°C in benzene in the presence of monomer and DMA, using the apparatus described in the experimental part. The concentration of ABIN was kept constant at $9.84\times10^{-2}$ mol./l.



It was established that the rate of decomposition of ABIN was independent of the concentrations of styrene and DMA as shown in Fig. 13.

**Relationship between DMA and Induction Period.**—(*a*) *In DMF, with Ferric Chloride.*—We have already shown that an induction period was observed in the polymerization of styrene or *p*-methylstyrene in the presence of ferric chloride. We have studied further the effect of DMA on the induction period for the polymerization of *p*-methylstyrene initiated by ABIN in DMF, where the concentrations of ABIN and ferric chloride were kept constant at $1.00\times10^{-1}$ and $3.5\times10^{-3}$ mol./l. respectively, and the concentration of DMA was varied from 0 to 2.4 mol./l. As can be seen from Fig. 14 and Table IV, it was found that no effect of DMA on the induction period was observed.

(*b*) *In Benzene, with p-Benzoquinone.*—It could not be completely denied, that DMF reacted with a free radical. Therefore, it was

considered that DMF was not the most suitable solvent. Thus, in the following runs, benzene was chosen as solvent. However, ferric chloride did not dissolve in benzene. We have studied finally the polymerization of *p*-methylstyrene in the presence of *p*-benzoquinone and DMA in benzene and studied the effect of DMA on the induction period, on the rate of polymerization after induction period and on the intrinsic viscosity of polymers. As can be seen from Fig. 15 and Table V, the induction period was decreased with the amount of DMA, which was somewhat different from the result obtained when the ferric chloride-DMA system was used. The rate of polymerization after the induction period had a tendency to increase,

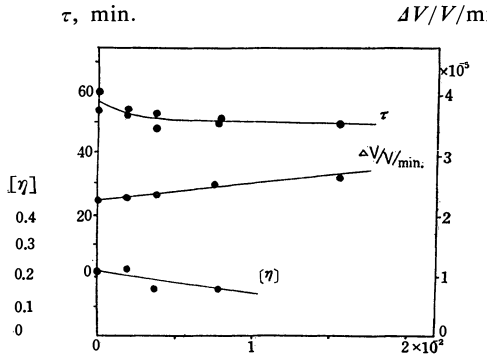

Fig. 15. Relationship of the amount of DMA with induction period, with over-all rate after induction period, and with intrinsic viscosity in the polymerization of *p*-methylstyrene at 60°C (in benzene). [M]=2.17 mol./l., [ABIN]=$7.05\times10^{-2}$mol./l., [*p*-Benzoquinone] =$1.06\times10^{-3}$ mol./l.

TABLE V. INDUCTION PERIOD, AND OVER-ALL POLYMERIZATION RATE AFTER INDUCTION PERIOD IN THE POLYMERIZATION OF *p*-METHYLSTYRENE IN THE PRESENCE OF DMA AT 60°C (IN BENZENE)

| DMA mol./l. | Induction period min. | Volume conversion $\Delta V/V$/min. | Rate$\times10^5$ mol./l./sec. |
|---|---|---|---|
| 0 | 56.0 | — | — |
| $2\times10^{-3}$ | 54.0 | — | — |
| $4\times10^{-3}$ | 49.0 | — | — |
| $8\times10^{-3}$ | 52.0 | — | — |
| 0 | 60.5 | 2.24 | 1.69 |
| $1.8\times10^{-3}$ | 53.5 | 2.27 | 1.71 |
| $3.8\times10^{-3}$ | 54.0 | 2.27 | 1.71 |
| $7.8\times10^{-3}$ | 51.5 | 2.43 | 1.82 |
| $15.6\times10^{-3}$ | 49.5 | 2.60 | 1.95 |

while the intrinsic viscosities decreased with DMA.

Determination of the individual rate constants in the polymerization of *p*-methylstyrene is in progress using the sector method. The results will be reported in near future.

## Summary

1. Solution polymerizations of styrene, *p*-methyl-, *p*-ethyl-, *p*-*tert*-butyl-, *m*-methyl-, 2,4-dimethyl-, 2,5-dimethyl- and 3,4-dimethylstyrene were carried out at 50 and 70°C by ABIN in benzene, and the rates of polymerization and $[\eta]$'s of the polymers were determined. For 3,4-dimethylstyrene, the same equation as for styrene was obtained:

$$R_0=k[\mathrm{M}][\mathrm{ABIN}]^{1/2}$$

2. Rate constants of initiation of the polymerizations of styrene and *p*-methylstyrene were determined, according to the $FeCl_3$-method as follows:

$$k_i=0.67\times10^{-5}\ (\mathrm{sec}^{-1})$$

(for *p*-methylstyrene)

$$k_i=0.76\times10^{-5}\ (\mathrm{sec}^{-1})$$ (for styrene)

3. Polymerizations of styrene and *p*-methylstyrene were carried out at 70°C by the $Bz_2O_2$-DMA system, and the same equation as styrene was derived for *p*-methylstyrene as follows:

$$R_0=k'[Bz_2O_2]^{1/2}[\mathrm{DMA}]^{1/2}$$

4. Polymerizations of styrene, *p*-methyl-, and dimethylstyrenes were carried out at 50 and 70°C by ABIN-DMA system, and the results for the rate of polymerization and the value of $[\eta]$ were discussed. A correction was made for the results previously obtained.

5. The effect of DMA on the induction period for the polymerization of *p*-methylstyrene was studied at 60°C. In the case of polymerization with $FeCl_3$ in DMF, no effect of DMA on the induction period was observed, while in the case of that with *p*-benzoquinone in benzene, the induction period was decreased with the amount of DMA.

# *Visco-elastic Behaviors of Aluminum Soap-Hydrocarbon Systems. I. Aluminum Stearate in Nujol*

By Sukekuni SHIBA

(Received August 6, 1960)

Aluminum soaps dispersed in hydrocarbon oils exhibit many interesting flow properties. Gelling characteristics of aluminum soaps and flow properties of aluminum soap-hydrocarbon systems have been studied by many authors[1-3].

Flow properties have been studied usually for viscous or plastic properties under static conditions. The conception of "elastic fluid" for these systems was adopted first by Goldberg and Sandvik[4], who studied visco-elastic properties (dynamic viscosity and shear modulus) of aluminum soaps gelled in varsol, and found breakdown under steady shear at audio frequency. Garner, Nissan and Wood[5], studying elasto-viscous properties of aluminum stearate in petrol, found the correlation of free energy with the mechanical shearing of the system. Weber and Bauer[6], studying flow properties of aluminum dilaurate-toluene gels, found from the initial elastic axial extension in a capillary that pronounced elastic properties appear abruptly in the gels as the concentration of soap increases, and a concentration of 1% by weight of aluminum dilaurate in toluene is reached.

In the preceding paper[7], flow properties of aluminum soaps in nujol and time effects of flow under shear were studied in static conditions. In the present paper, dynamic visco-elastic behaviors of aluminum stearate dispersed in nujol were studied in a region of low frequency, rangining from $10^0$ to $10^{-3}$ cycles/sec. to examine the correlation of the rheological properties and dispersed states of the soaps.

## Experimental

**Materials.** — Aluminum stearate was prepared from purified stearic acid by a metathetic process as described in the previous paper[7]. Stearic acid, found: m. p., 69.5°C; neutralization equivalent, 281.9. Analysis of the soap showed that the ratio of moles of acid per mole of aluminum was 1.72. Nujol, which was a paraffin-rich saturated hydrocarbon, was used as a vehicle. Physical constants were: $d_4^{25}=0.8429$; $\eta_{25}=0.217$ poise; $n_D^{20}=1.4672$. The purity of the materials was checked by infrared absorption measurements.

**Apparatus.** — A top-drive concentric cylinder rheometer, essentially the same as the apparatus designed by Nakagawa[8], was used. The outer cylinder was fixed in a thermostat; the inner cylinder was suspended coaxially on a torsion wire. The specimen was placed in the annular space between the two cylinders, and a sinusoidal torsional oscillation was applied at the top of the torsion wire. The oscillation of the inner cylinder was detected by a small mirror attached to the inner cylinder, and the oscillation was combined rectangularly with the driving oscillation optically. The resulting Lissajous' figure, which indicates the phase angle and amplitude ratio of the oscillations, was recorded on an oscillographic paper and analysed for visco-elasticity by an approximate method neglecting the inertia of the specimen. Details of the apparatus and analysis were reported elsewhere[9].

**Procedure.**—Aluminum stearate was added to the weighed portions of nujol and the mixture was heated at 110~120°C with stirring for 15 min. The resulting isotropic solution was cooled and kept in a desiccator over phosphorus pentoxide. The specimen thus prepared was aged more than 24 hr. at room temperature. Measurements were carried out under the following conditions:

Temperature; 15~100°C.
Period of oscillation; 2~1,000 sec.
Maximum shear strain; 0.01~0.3.
Soap concentration; up to 1 wt. %.

Experiments were performed avoiding effects of humidity as far as possible.

## Results and Discussion

The systems both in gel and sol states behave always as visco-elastic bodies. A relatively dilute system (sol) shows linear visco-elastic behaviors, whereas a more concentrated system (gel) shows non-linear behaviors as seen in the case of static measurements[7]. In this experiment, the systems were treated as linear visco-elastic bodies, because the shear strain was

small and approximation by linear behaviors was possible.

**Aging.**—It is necessary to examine the effect of aging in order to get reproducible results. Changes in dynamic viscosity $\eta$ and shear modulus $G$ with time are shown in Fig. 1.

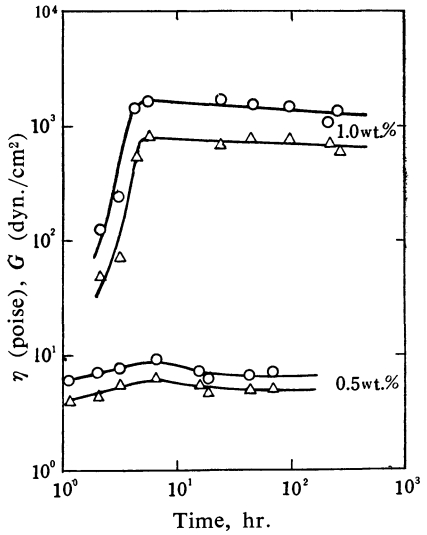

Fig. 1. Change in dynamic viscosity (○) and modulus (△) with time.
25°C, period $T=12$ sec.

Rapid increase in dynamic properties was found in the first stage of aging, then the properties approach constant values after they reach maximum values 4~6 hr. after preparation of the specimen. This result supports the results obtained by viscosity and flow birefringence measurements for benzene and nujol solutions of aluminum soaps[7,10]. However, the change in the properties of a gel was extraordinarily great compared with other cases. This fact indicates that the properties of the system which has not been disturbed by shear were measured in this experiment; whereas in the former reports, a state in which the weak structures formed by aging in the system had been broken, was measured.

**Amplitude Dependence.**—Effects of amplitude of oscillation which are a measure of non-linear behavior, were examined changing the amplitude of the oscillation given at the top of the torsion wire. Results are shown in Fig. 2, where $\gamma_{max}$ is the maximum shear strain at the wall of the internal cylinder expressed as follows;

$$\gamma_{max}=\left[\frac{2Ar_e^2r_i^2}{(r_e^2-r_i^2)r^2}\right]_{r=r_i}=\frac{2Ar_e^2}{r_e^2-r_i^2} \qquad (1)$$

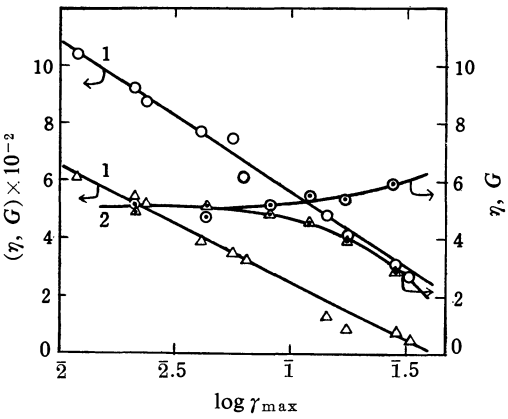

Fig. 2. Amplitude dependence of dynamic viscosity (○) and shear modulus (△), 25°C, period $T=12$ sec, 1. 1.0 wt. %, 2. 0.5 wt. %.

$A$ is the amplitude of the oscillation of the internal cylinder; $r_i$ and $r_e$ are the radii of internal and external cylinders, respectively. The 1 wt. % gel shows marked amplitude dependence; for the 0.5 wt. % sol dependence is found for large values of $\gamma$, but is negligible for usual measurements carried out in the region of $\gamma$ up to 0.1.

As was found from static measurements of viscosity[7], the aluminum soap-hydrocarbon gels undergo shear breakdown. Accordingly, amplitude dependence may be ascribed not only to the non-linearity but also to the shear breakdown of the rheological structures. In the first stage of flow, it requires a certain amount of work to begin deformation against the network structures in the gel, and this work results in the amplitude effect in this experiment. It is not clear, however, whether the effect is due completely to shear strain or to the rate of shear; because the maximum rate of shear changes proportionally to shear strain when other conditions are equal.

Because of this dependence, a series of experiments should be carried out under constant shear strain and shear rate, but the apparatus is not suitable for this purpose. The amplitude was kept as small and constant as possible to avoid these effects.

**Frequency Dependence.**—Frequency dependence of the dynamic rheological properties of the system was examined under various conditions. Fig. 3 shows the shear modulus, dynamic loss, and relaxation spectra of a gel containing 1 wt. % of soap in nujol. The spectra were obtained from shear modulus ($E'$) and dynamic loss ($E''$) by the approximation method[11],

10) J. W. McBain and E. B. Working, *J. Phys. & Colloid Chem.*, **51**, 974 (1947).

11) F. Schwarzl, "Proceedings of the Second International Congress on Rheology" (Edited by V. G. W. Harrison), Butterworths Sci. Pub., London (1954), p. 197.

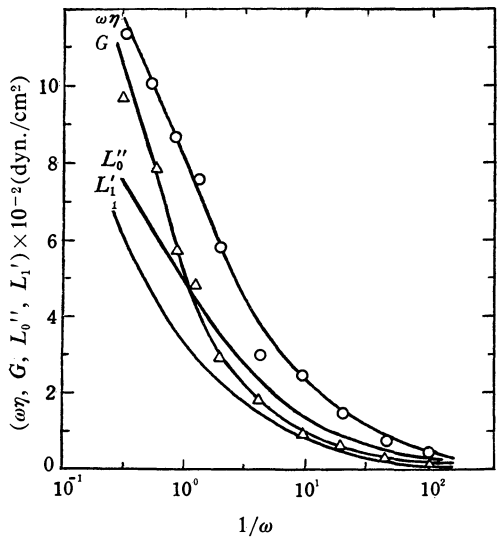

Fig. 3. Frequency dispersion of visco-elasticity and relaxation spectra, 25°C, 1.0 wt%.

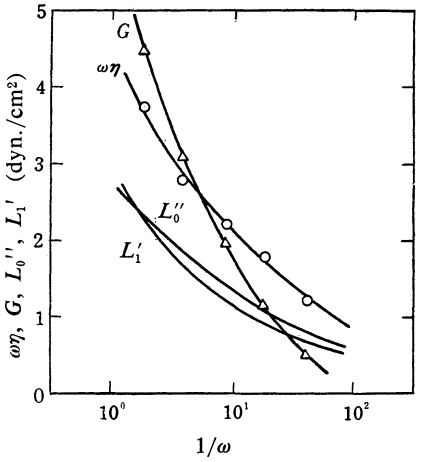

Fig. 4. Frequeny dispersion of visco-elasticity and relaxation spectra, 25°C, 0.5 wt. %.

$$L(t) \simeq L_1'(t) = [\mathrm{d}E'(\omega)/\mathrm{d}\log\omega]_{\omega=1/t} \quad (2)$$

$$L(t) \simeq L_0''(t) = (2/\pi)\,[E''(\omega)]_{\omega=1/t} \quad (3)$$

In these formulae $L$ without index is the exact spectrum, whereas $L$ with index indicates an approximation to the spectrum. The system shows typical visco-elastic properties. Curves of visco-elasticity show marked dispersion; the dynamic shear modulus and dynamic loss increase conspicuously with the increase of frequency. Relaxation spectra obtained from the two approximation methods show similar results. The spectra show a wedge type similar to the spectra found for polyisobutylene. This indicates that the gel resembles the polymer solution or gels in dynamic properties, accordingly the dispersed state of the soap crystallites as well. Fig. 4 shows the dispersion of a sol containing 0.5 wt. % of soap in nujol; similar results are observed in this case, although the visco-elasticity is far smaller than in the case of gel.

Frequency dependence at various temperatures is shown in Figs. 5 and 6. At each temperature, similar dispersion is found. It is possible to express these data by a single curve by the method of reduced variables[12]. The reduced curves for the dynamic shear modulus and dynamic loss are shown in Fig. 7. Good coincidence was found except for the data obtained at 80°C. The results suggest the

TABLE I. SHIFT FACTORS FOR ALUMINUM STEARATE-NUJOL GEL (1 wt. %)

| Temperature (°C) | $\log a_T$ |
|---|---|
| 15 | 0.52 |
| 25 | 0 |
| 40 | −0.53 |
| 60 | −0.97 |
| 80 | −1.38 |

absence of serious changes in rheological structures up to 60°C, that is, the system is thermo-rheologically simple in that temperature region. The shift factors for this transformation to 25°C are summarized in Table I. Change in the reducing factor with temperature is somewhat small compared with the data of usual polymers.

**Concentration Dependence.**—Change in shear modulus and dynamic viscosity with concentration at various temperatures is shown in Fig. 8. Modulus and viscosity show similar curves which are composed of two straight lines, and have a break point near concentration 1 wt. %. Above this point, modulus and viscosity increase abruptly. This point corresponds to the appearance of soft gel, therefore it is considered as the critical concentration for gel formation. Change in temperature has a minor effect both on the type of the curve and on the critical concentration. The critical concentrations of gel formation obtained from the curves at 15, 25 and 40°C are 0.86, 0.82, and 0.86 wt. % respectively. The curves were obtained from a single period of oscillation; however, these types of curves and critical concentrations are expected under various conditions, because the frequency dependence of the systems is similar,

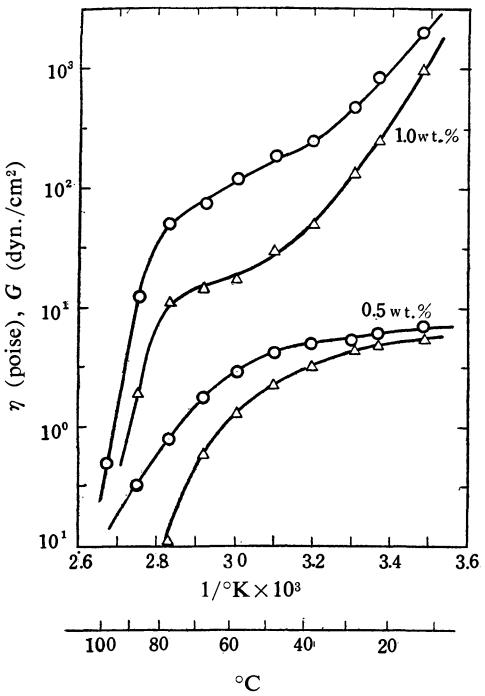

Fig. 9. Temperature dependence of dynamic viscosity (○) and shear modulus (△), period $T=12$ sec.

as shown in Figs. 5 and 6.

Below the critical concentration, the viscosity and elasticity change exponentially with concentration; this region corresponds to the sol in which the soap crystallites are dispersed with secondary interactions. Above the critical

concentration, an extraordinarily sudden increase in visco-elasticity occurs due to the strong network structures in the system, which is stable under a very low rate of shear. This was not observed in a static viscosity measurement carried out under a high rate of shear, owing to the degradation of the structure under shear.

**Effect of Temperature.** — Changes in visco-elasticity with temperature are shown in Fig. 9. Viscosity change of the vehicle is expressed approximately by the Andrade formula ; whereas the system shows complex thermal behaviors. The curves have deflection points near 80°C, which show some phase change in the structure of the systems, the transition from dispersion to isotropic solution. Below this transition temperature, the 1 wt. % gel shows greater temperature effect than the vehicle due to the effect of temperature on the strength of network structures; that is, the gel structures change continuously with temperature. On the other hand, a 0.5 wt. % sol undergoes less temperature effect than the vehicle, which shows that the rheological structures remain unchanged by temperature.

**Summary**

Dynamic visco-elastic behaviors of the aluminum stearate nujol system were studied, using a concentric cylinder type forced oscillation rheometer. The system behaves always as a typical visco-elastic body in a wide range of concentrations and temperatures, and manifests conspicuous amplitude and frequency dependence, which indicates non-linear visco-elastic properties. Wedge type relaxation spectra of the system were obtained, and it was found that the system is thermo-rheologically simple in a confined region of temperatures. The time effect of the specimen and temperature dependence of dynamic properties were examined, and the rheological structures in the system under various conditions were discussed.

The author wishes to express his thanks to Professor H. Akamatu and Dr. T. Nakagawa, both of the University of Tokyo, for their kind advice and encouragement throughout this investigation.

# *Visco-elastic Behaviors of Aluminum Soap-Hydrocarbon Systems. II. Aluminum Soaps in Nujol*

By Sukekuni SHIBA

(Received August 6, 1960)

In the previous paper[1], dynamic behaviors of the aluminum stearate-nujol system were studied, and typical visco-elastic properties of the system were found. In this paper, visco-elastic behaviors of aluminum soaps from various fatty acids and aluminum stearates of different compositions dispersed in nujol were studied.

## Experimental

**Materials.**—Aluminum soaps from various parent fatty acids were prepared from purified fatty acids. The purity of the fatty acids and method of preparation were described in the previous paper[2]. Results of aluminum analysis of the soaps are shown in Table I. Aluminum stearates of different compositions were prepared, varying the amount of excess of sodium hydroxide during the precipitation

of the soaps. Compositions of the aluminum stearates are summarized in Table II.

The vehicle was the same nujol as in the previous work. Infrared absorption measurements showed no free fatty acid for the soaps from various fatty acids, whereas the spectra of aluminum stearates containing more than 2 acid molecules per aluminum showed the presence of free fatty acids.

**Apparatus and Procedure.** — Forced oscillation rheometer and the experimental procedure are the same as in the previous work[1].

## Results and Discussion

Various aluminum soaps dispersed in nujol show thickening properties to some extent, and the system becomes an elastic gel at a high concentration or a viscous sol at lower concentrations. Gelling characteristics of the soaps were examined for varying fatty acids and soap compositions.

**Frequency Dependence.** — The frequency dependency of aluminum palmitate, caprate and caprylate in nujol is shown in Fig. 1. A gel

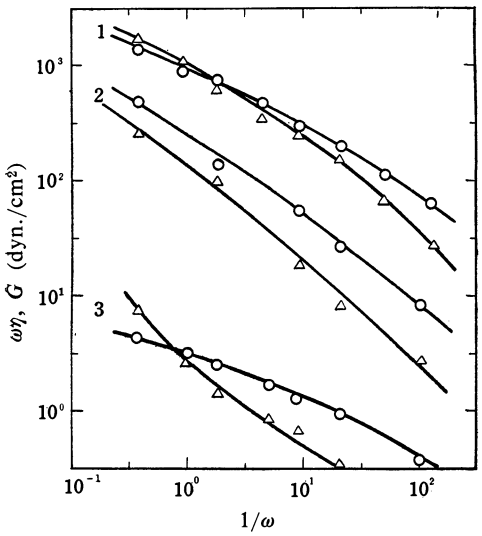

Fig. 1. Frequency dependence of dynamic loss (○) and shear modulus (△), aluminum soaps in nujol at 25°C.
1. Palmitate 1 wt. % 2. Caprate 2 wt. %
3. Caprylate 3 wt. %

containing 1 wt. % of palmitate shows frequency dispersion similar to stearate which indicates wedge type relaxation spectrum. A gel of aluminum caprate (2 wt. %) shows a dispersion which resembles that of palmitate as shown in Fig. 1, despite the higher concentration of the soap. Aluminum myristate and laurate show behaviors similar to palmitate; caprylate scarcely shows the elastic properties. That is to say, the visco-elastic properties of the systems decrease suddenly when the length of the fatty acid molecule decreases below ten carbon atoms.

**Concentration Dependence.** — The concentration dependences of visco-elastic properties for the systems are shown in Figs. 2 and 3.

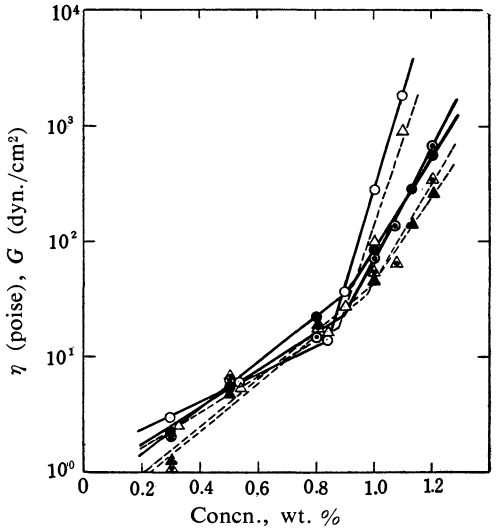

Fig. 2. Concentration dependence of dynamic viscosity (—○—) and shear modulus (--△--), 25°C period $T=12$ sec.
○ Palmitate ● Myristate ⊙ Laurate

Palmitate, myristate and laurate show curves similar to stearate, and each curve consists of two straight lines in the concentration range above and below the break point. The break points correspond to the critical concentrations necessary to form gels, and the two straight lines represent the concentration dependence of visco-elasticity of gels and sols respectively. These curves are expressed by empirical formulae;

$$\log \eta_s = a_s + b_s c, \qquad \log \eta_g = a_g + b_g c \tag{1}$$

$$\log G_s = a_s' + b_s' c, \qquad \log G_g = a_g' + b_g' c \tag{2}$$

where $\eta$ and $G$ are dynamic viscosity (poise) and shear modulus (dyn./cm²), the subscripts s and g mean that the values are referred to the sol and gel states. Changes in critical concentration and constant $b_g$ with soaps are summarized in Table III. The two values represent the gelling capacity of the soaps and the concentration dependence of the rheological properties of the resulting gel. The fatty acid of shorter hydrocarbon chain length gives an indistinct and higher critical concentration and a lower value of $b_g$. When the mole concentrations of the systems are considered, the difference will be larger. This tendency indicates the superiority of soaps from higher fatty acids as thickener. The results for laurate support those of Weber and Bauer[3], who found the appearance of pronounced elastic properties

TABLE III. CRITICAL CONCENTRATION AND CONSTANT $b_g$

| Soap | Crit. conc. wt. % | $b_g$ 1/wt. % |
|---|---|---|
| Stearate* | 0.81 | 10.2 |
| Palmitate | 0.85 | 8.3 |
| Myristate | 0.92 | 4.1 |
| Laurate | 0.91 | 4.9 |
| Caprate | 2.0 | 1.4 |
| Caprylate | — | — |

* Obtained from Ref. 1.

in the gels as the concentration of soap increased over 1 wt. %.

Caprate and caprylate show a somewhat different type of concentration dependence, as shown in Fig. 3. Caprate has a critical concentration near 2 wt. % and visco-elasticity

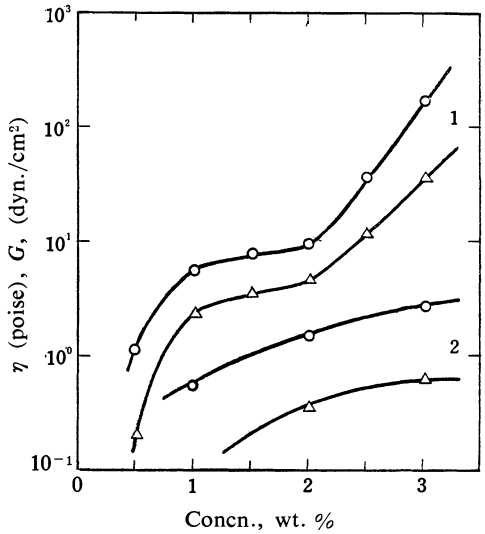

Fig. 3. Concentration dependence of dynamic viscosity (○) and shear modulus (△), 25°C period $T=12$ sec.

1. Caprate 2. Caprylate

decreases rapidly at a concentration below 1 wt. %. Caprylate shows neither conspicuous thickening effect nor gelling property. Thus, the aluminum soaps from fatty acid lower than capric acid, show remarkably different rheological behaviors.

A mixture of the stearate and palmitate shows intermediate concentration dependence of both soaps.

The experiments were carried out under definite conditions, however results similar to the case of stearate[1] are expected under various conditions, due to their relatively similar dependence on frequency and temperature.

3) N. Weber and W. H. Bauer, *J. Phys. Chem.*, **60**, 270 (1956).

**Temperature Dependence.**—Changes in visco-elastic properties of aluminum soap-nujol systems with temperature are shown in Fig. 4. The soaps examined do not show linear relation as described by the Andrade formula. In this temperature region, distinct transition was not

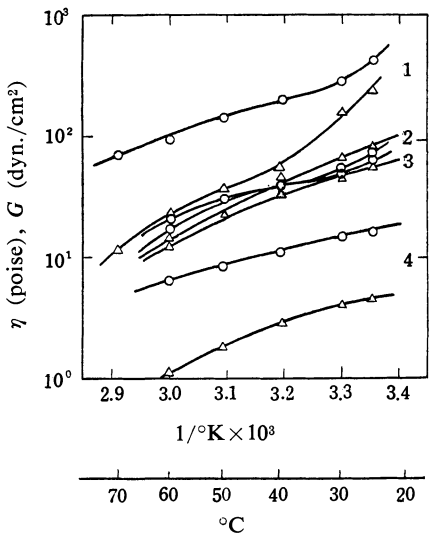

Fig. 4. Temperature dependence of dynamic viscosity (○) and shear modulus (△), aluminum soaps in nujol 1 wt. %, $T=12$ sec.

1. Palmitate 2. Myristate 3. Laurate 4. Caprate

observed; however, the transition from dispersion to solution found for stearate may exist in these cases. The curves show a convex type against temperature. This suggests that gradual transition or structural change occurs over a wide range of temperatures resulting in decrease in rheological properties. Therefore, the apparent activation energies of flow calculated from gradients of the curves are somewhat larger than that of the vehicle, nujol.

**Effect of Soap Composition.** — Aluminum stearate of different compositions that is, the soaps in which a different number of acids combined with the aluminum atom, in nujol were examined. Comparison of the results for 1 wt. % soaps in nujol is made in Fig. 5. An extraordinary difference was found; however, when the conspicuous concentration dependence of the systems as shown in Fig. 2 is considered, it is clear that the results expressed by single point observations on visco-elasticity do not reveal the full aspects of the properties of the soaps. The critical concentration was observed by a simple method: soap solutions of various concentrations were cooled in test tubes and kept still overnight; when the specimen did not flow in a minute after the

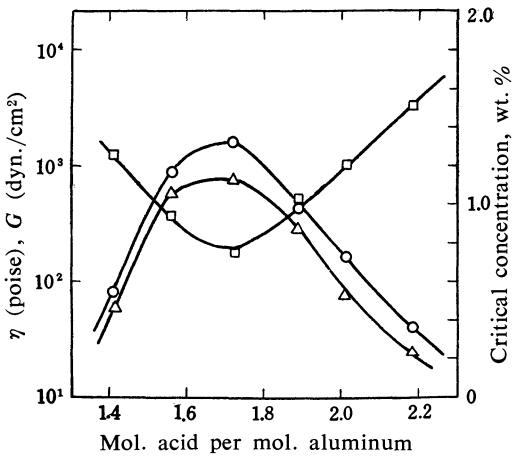

Fig. 5. Visco-elastic properties and critical concentrations of aluminum stearates in nujol at 25°C.

○ $\eta$, △ $G$ for 1 wt. % soaps in nujol, $T$=12 sec., □ critical concentration.

tube was laid down, the specimen was judged to be a gel. The results are also shown in Fig. 5, which shows the maximum effects as thickener near 1.7 mol. acid per aluminum.

**Rheological Structures in the Systems.**—Visco-elastic behaviors of the systems show evidence of strong rheological structures in the systems. The system is essentially a colloidal dispersion of elongated aluminum soap crystallites in hydrocarbon media as ascertained by electron microscope observation[4]. The system containing soaps in more than the critical concentration exhibits typical visco-elastic properties of gels indicating the network structures of soap crystallites by secondary interactions. At lower concentrations the network is incomplete, resulting in a sol with fluidity. At elevated temperatures, e. g. above 80°C, the soaps disperse homogeneously to a transparent solution. Transition from dispersion to solution is expected from conspicuous change in rheological properties.

Static flow properties of the system under constant shear were discussed elsewhere[2]. Network structures suffer a breakdown by shear and result in relatively high fluidity in that case. In this experiment, extraordinarily high values of visco-elasticity were obtained, since the specimen was treated so as not to be affected by shear. The effects of weak secondary interactions which undergo breakdown are recognized as the difference between the two results.

4) D. Evans and J. B. Matthews, *J. Colloid Sci.*, 9, 60 (1954).

## Summary

Dynamic visco-elastic behaviors of aluminum soaps from various fatty acids and aluminum stearates of different compositions in nujol were studied, using a forced oscillation rheometer. The systems behave always as typical visco-elastic bodies in a wide range of concentrations and temperatures. Aluminum palmitate, myristate, and laurate show properties similar to stearate, whereas caprate and caprylate show less effects on rheological properties. Optimum composition of aluminum stearate as thickener was obtained. Rheological structures in the systems were discussed and comparison of the results by static and dynamic measurements was made.

The author wishes to express his thanks to Professor H. Akamatu and Dr. T. Nakagawa, both of the University of Tokyo, for their kind advice and encouragement throughout this investigation.

# *Infrared Studies of the Librations of Water Molecules in the Solid Matrices at 20°K*

By Tatsuo MIYAZAWA

(Received July 28, 1960)

The matrix isolation technique has been applied for the infrared absorption studies in the rocksalt or potassium bromide regions[1-4], however, not in the cesium iodide region so far. In the cesium iodide region (400~190 $cm^{-1}$) librational frequencies of small molecules in the crystalline state as well as internal rotation frequencies and bending frequencies are observed. These intramolecular vibrations are coupled with rotational motions in the vapor phase and quite complicated vibration-rotation bands are observed. In the solid matrices at sufficiently low temperatures, however, translational diffusion as well as rotational diffusion of trapped molecules are generally hindered, and the overall rotational motions are reduced to librational motions. No rotation envelope is apparent, and complicating effects frequently arising from rotational motions in the vapor phase are absent.

In carrying out matrix isolation experiments it is necessary to purify the matrix material carefully since the molar ratio (M/R) of the matrix (M) and the reactive species (R) may be as high as 1000 or more. It is not possible to remove the trace of water in nitrogen gas by simply passing the gas through a liquid nitrogen bath. It was necessary first to measure the spectra of water in the nitrogen matrix at various M/R ratios. Spectroscopic studies of water itself are also interesting in relation with hydrogen bonds and with the effects of matrix solids on the low frequency vibrations.

## Experimental Results

For spectroscopic measurements in the region 400~190 $cm^{-1}$ a Perkin Elmer Model 12C spectrometer was used with the cesium iodide optics[5]. The experimental technique of the matrix isolation method has been described[1]. The infrared spectra of water in the solid nitrogen matrix at 20°K were measured for the molar ratios ($N_2/H_2O$) of 1000, 200, 80 and 40. In each case 55 micromoles of water was dispersed in the matrix over an area of about 2 $cm^2$. The nitrogen gas used in the measurement was purified by being passed over copper at 600°C and then through a liquid nitrogen bath. The observed spectra are shown in Fig. 1. It may be seen that the intensity of the

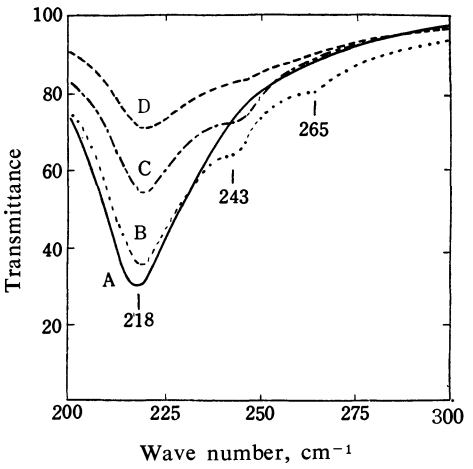

Fig. 1. Infrared spectra of water in the solid nitrogen matrix at 20°K. A: M/R =1000, B: M/R=200, C: M/R=80, D: M/R=40.

band at 218 $cm^{-1}$ increases as M/R is increased from 40 to 1000. The intensity of the band at 243 $cm^{-1}$ increases as M/R is increased from 40 to 80, reaches its maximum for M/R of 80~200 and then decreases as M/R is increased to 1000. The band at 265 $cm^{-1}$ appears to exhibit its intensity maximum for M/R of 200.

In order to measure the effect of isotopic substitution on the water bands, 55 micromoles of heavy water was also suspended in the solid nitrogen matrix for M/R of 200; however, in this case no bands were observed in the region above 190 $cm^{-1}$.

The infrared spectrum of water (55 micromoles, M/R of 200) was also measured in the solid argon matrix at 20°K. Argon gas was

purified by being passed over copper heated to 600°C and then through a dry ice-acetone bath. In this case no bands were observed in the region 400~190 $cm^{-1}$, in contrast with the case of the nitrogen matrix.

## Discussion

Infrared spectra of water in the solid nitrogen matrix have been measured in the region 3500~3000 $cm^{-1}$ by Van Thiel, Becker and Pimentel[2]. Eleven peaks have been observed at various M/R ratios, and the bands at 3725 $cm^{-1}$ and 3627 $cm^{-1}$ have been assigned to the monomeric species, and the other bands have been assigned to the dimeric, trimeric, and polymeric species.

**Assignment of Low Frequencies.** — In the present study in the cesium iodide region three bands were observed at 218, 243 and 265 $cm^{-1}$. The intensity of the band at 218 $cm^{-1}$ is plotted against M/R in Fig. 2, along with the corresponding curve for the 3725 $cm^{-1}$ band. It

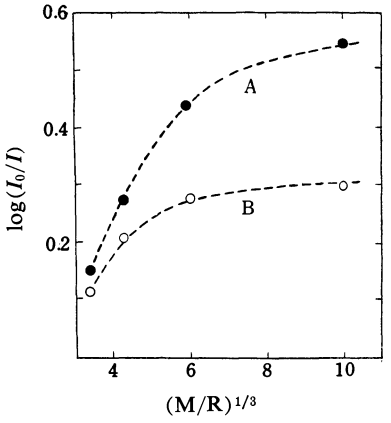

Fig. 2. Peak intensities vs. $(M/R)^{1/3}$.
A: 218 $cm^{-1}$, B: 3725 $cm^{-}$.

may be seen that the intensity of the 218 $cm^{-1}$ band changes in iust the same manner as the intensity of the 3725 $cm^{-1}$ band of the monomeric species. The 218 $cm^{-1}$ band is therefore assigned to the monomeric species. The 243 $cm^{-1}$ band is observed as a shoulder of the 218 $cm^{-1}$ band and its intensity change with M/R appears to correspond most closely with the 3691 $cm^{-1}$ band of the dimeric species[2].

**218 $cm^{-1}$ Band of Monomer.**—All the intramolecular vibrations of the monomeric species have already been observed[2] at 3725, 3627 and 1600 $cm^{-1}$. The 218 $cm^{-1}$ band is, therefore, undoubtedly due to translational or rotational modes in the solid matrix. The translational and rotational motions are restricted in the matrix and become vibrational motions giving rise to vibrational infrared bands.

**Lattice Vibrations of Ice.** — Prior to more detailed discussions of the matrix spectra the infrared bands of crystalline ice due to these translational or rotational vibrations will be briefly reviewed. The infrared bands due to the translational lattice vibrations of water and heavy water (at −190°C) have been observed at 229 and 222 $cm^{-1}$ respectively[6]. The observed frequency ratio ($\nu_{H_2O}/\nu_{D_2O}$) of 1.03 agrees with the theoretical ratio of $1.05=(M_{D_2O}/M_{H_2O})^{1/2}$ for the translational mode. On the other hand the rotational lattice vibrations (librations) of water and heavy water (at −170°C) have been observed at 850 and 630 $cm^{-1}$ respectively[7] and in this case the frequency ratio of 1.35 is much greater than the ratio of 1.03 for the translational mode.

**Three Librations in the Nitrogen Matrix.**— The 218 $cm^{-1}$ band in question disappears on deuteration and the corresponding band of heavy water has not been observed in the region above 190 $cm^{-1}$. The isotopic frequency ratio for this mode is definitely greater than the ratio of 1.05 expected for the translational mode. The 218 $cm^{-1}$ band may thus be assigned to a librational mode of the monomeric species in the nitrogen matrix.

So far we have not specified the types of librations in the matrix. For the monomeric species of water there are three types as shown in Fig. 3; one around the twofold axis (the B axis), one around the axis perpendicular to

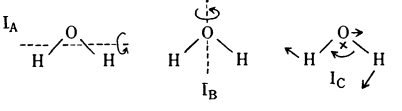

Fig. 3. Librational modes of monomer.

the molecular plane (the C axis), and the last one around the axis of the least moment of inertia (the A axis). The first one will not be infrared active since the B axis is parallel to the dipole moment of the molecule. The other two involve rotations of the molecular dipole moment and will give rise to strong infrared bands.

**Intensity of Libration Bands.**—The infrared intensities of these libration bands may be estimated assuming that the molecules carry out librations about the axes passing through the center of the mass. The moments of inertia about the three axes are

$$I_A = 2m_H r^2 (m_O/M_{H_2O}) \cos^2 \alpha$$

$$I_B = 2m_H r^2 \sin^2 \alpha$$

6) R. Zimmermann and G. C. Pimentel, unpublished.
7) K. B. Harvey and P. A. Giguère, *Can. J. Chem.*, **34**, 798 (1956); N. Ockman, *Advances in Physics*, **7**, 199 (1958); D. F. Hornig, H. F. White and F. P. Reding, *Spectrochim. Acta*, **12**, 338 (1958).

and $I_C = I_A + I_B$

where $m_H$ and $m_O$ are the masses of the hydrogen and oxygen atoms, respectively, $r$ the bond length and $2\alpha$ the interbond angle. Now if the monomeric species is randomly oriented in the matrix the infrared intensities, $D_A$ and $D_C$, of the A and C librations are expressed analogous to the vapor intensities, and

$$D_i \propto |\partial\mu/\partial Q_i|^2 = |\partial\mu/\partial\theta_i|^2 \cdot |\partial\theta_i/\partial Q_i|^2 = \mu^2/I_i$$

where $\mu$ is the dipole moment, $Q_i$ the $i$th normal coordinate, $\theta_i$ the angle of rotation around the $i$th axis, and $I_i$ the corresponding moment of inertia. The intensity ratio of the A and C bands is calculated to be $D_A/D_C = 2.7$ for the $H_2O$ molecule with the bond angle of 105°. The 218 $cm^{-1}$ band of the monomeric species is considered to be primarily due to the A librational mode.

**Librational Frequencies.** — The three librational frequencies may be estimated assuming that the potential energy arises from Cartesian displacements of the hydrogen atoms in the matrix. The potential energy possibly arising from Cartesian displacements of the oxygen atom was not considered in the present treatment. The Cartesian displacements of the hydrogen atoms, $\xi_A$, $\xi_B$ and $\xi_C$, due to the rotations around the three axes are

$$\xi_A = \theta_A (m_O/M_{H_2O}) r \cos\alpha$$

$$\xi_B = \theta_B r \sin\alpha$$

and

$$\xi_C = \theta_C r [\sin^2\alpha + (m_O/M_{H_2O})^2 \cos^2\alpha]^{1/2}$$

Taking into account the potential energies for the two hydrogen atoms, the librational frequencies, $\nu_A$, $\nu_B$ and $\nu_C$, are found to be

$$(2\pi\nu_A)^2 = (K/m_H)(m_O/M_{H_2O})$$

$$(2\pi\nu_B)^2 = (K/m_H)$$

and

$$(2\pi\nu_C)^2 = (K/m_H)\{\tan^2\alpha + (m_O/M_{H_2O})^2\}/\{\tan^2\alpha + (m_O/M_{H_2O})\}$$

whre $K$ is the potential constant. The value of $K$ is calculated to be 0.032 millidyne/A from the $\nu_A$ frequency (218 $cm^{-1}$) of water, and other librational frequencies were calculated to be $\nu_B = 231$ and $\nu_C = 226$ $cm^{-1}$ for $H_2O$ and $\nu_A' = 146$, $\nu_B' = 164$ and $\nu_C' = 157$ $cm^{-1}$ for $D_2O$.

The $\nu_C$ frequency of 226 $cm^{-1}$ is slightly higher than the observed $\nu_A$ frequency of 218 $cm^{-1}$ and the intensity of the $\nu_C$ band is considered to be weaker than the intensity of the $\nu_A$ band as mentioned before. In fact the 218 $cm^{-1}$ band has an ill-defined shoulder on the high frequency side around 230 $cm^{-1}$, in agreement with the result of the present treatment*. The librational frequencies calculated for $D_2O$ are much lower than 190 $cm^{-1}$, again in agreement with the result of the present measurement on $D_2O$.

**243 $cm^{-1}$ Band of the Ring Dimer.** — The structure of the dimeric species of water in the solid nitrogen matrix has been found to be a ring dimer by Van Thiel et al.[2] The ring dimer has a center of symmetry and there will be three infrared active low frequency vibrations as shown in Fig. 4. The $b_u$ vibration

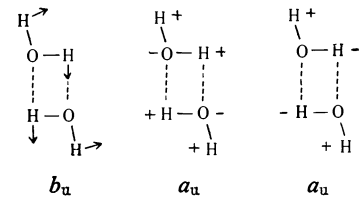

Fig. 4. Infrared active low frequency modes.

involves the stretching of the O···H hydrogen bonds and its frequency will be appreciably higher than the two $a_u$ frequencies involving only the bending of the hydrogen bonds. The observed frequency of 243 $cm^{-1}$ is slightly higher than the monomeric frequency and this is most probably due to either one of the two $a_u$ modes of the ring dimer.

**Libration in the Argon Matrix.** — The librational frequencies of water in the argon matrix have not been observed in the region above 190 $cm^{-1}$. It has been found that the nitrogen and argon matrices have different effects on the monomeric bands of water. Catalano and Milligan have observed seven sharp peaks (1654~1554 $cm^{-1}$) due to the bending vibration in the argon matrix but only one peak at 1600 $cm^{-1}$ in the nitrogen matrix[3]. The observed fine structure in the argon matrix has been ascribed to overall rotations of the monomeric species in the argon matrix**. The rotations may not be unrestricted of course; however, they should be much less restricted in the argon matrix than in the nitrogen matrix. The present observation in the cesium iodide region is in accord with the conclusion drawn by Catalano and Milligan[2].

The author wishes to thank Professor K. S. Pitzer and Professor G. C. Pimentel of the University of California for their interest and

* In crystalline ice the $\nu_A$ and $\nu_C$ librations give rise to a band at 850 $cm^{-1}$ (at −170°C). The two librations, however, have not been resolved from each other[7].

** It is interesting to note that $NH_2$ radical has been found to carry out almost free rotation in the argon matrix[8].

# *Studies on Dehydroalanine Derivatives. III. Formation of Amino Acids from Poly-dehydroalanine*

By Shumpei SAKAKIBARA

(Received July 13, 1960)

In the previous papers of this series[1,2], the synthesis of *N*-carboxy-dehydroalanine anhydride and of poly-dehydroalanine was described. However, the synthesis of analytically pure poly-dehydroalanine was unsuccessful, and it was found that the polymer contained only about 10% dehydroalanyl residues in the molecule[2]. This suggested that the dehydroalanyl groups in the polypeptide chain are very reactive. The present investigation is on the reactivity of dehydroalanyl residues in polypeptide chains. Poly-dehydroalanine was used as test material, and the reagents used for the reaction were potassium carbonate, potassium cyanide, benzyl mercaptane and acetonitrile. The amino acids derived from the poly-dehydroalanine were examined after hydrolysis of the reaction products.

## Experimental

**Meterial.**—Poly-dehydroalanine was prepared from *N*-carboxy-dehydroalanine anhydride[1]. It was polymerized in pyridine as described in the previous paper[2]. The freshly prepared polymer was used in these experiments.

**Reaction Conditions and Detection of Amino Acids Formed.**—The reaction mixtures shown in Table I were hydrolyzed for about 15 hr. at 105°C after addition of concentrated hydrochloric acid (an equal volume to that of the reaction mixture), and then concentrated to dryness. These concentrates were analyzed by Dowex 50 column chromatography using the conditions of Moore and Stein[3] (Fig. 1) and/or by two dimensional paper chromatrgraphy after dinitrophenylation under the improved conditions of Levy[4] (Fig. 2). Amino acids formed were analyzed quantitatively by Levy's method (Table II). The spot corresponding to DNP-aspartic or glutamic acid in Fig. 2 was rechromatographed on paper by descending method using 2.5 M phosphate buffer as solvent, as shown Fig. 4. Since the spot corresponding to DNP-aspartic acid from reaction mixture 3 contained a little DNP-glutamic acid, these two compounds were separated on a buffered celite column using 0.2 M phosphate-citric acid as buffer and chloroform-ether (90 : 10) as developer[5] (Fig. 3). Then, the bands corresponding to DNP-aspartic acid (A) and DNP-glutamic acid (B) were reconfirmed and repurified by paper

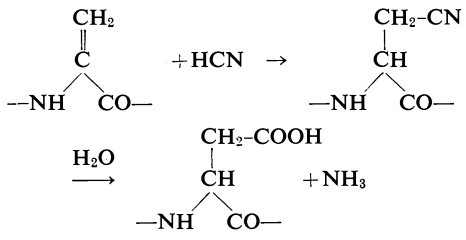
## Results and Discussion

Before hydrolysis, reaction mixtures 1 and 3 were clear light-brown solutions, 2 and 5 were clear light-yellow solutions, and 4 was a stable white emulsion. The hydrochloric acid hydrolyzates of these reaction mixtures contained small amounts of huminic material as mentioned in the previous paper[2]. As can be seen in the chromatograms of each reaction mixture (Figs. 1 and 2), several unknown bands and spots were observed besides bands and spots corresponding to natural-type amino acids such as alanine, glycine, serine, threonine, glutamic acid and aspartic acid. Formation of glycine and serine in each case could be explained by the following scheme.



However, formation of amino acids such as alanine, glutamic acid, aspartic acid and threonine could not be explained. Perhaps, compounds such as carbon dioxide, formaldehyde,

ammonia and hydrochloric acid may react in various complex ways with the dehydroalanyl groups. It was very interesting to find spot 1 in the chromatogram shown in Fig. 2. This might correspond to di- or poly-DNP-derivative of some amino acid. Since the structure has not yet been confirmed, some kinds of basic amino acids or polyamino polycarboxylic acids may be derived from dehydroalanine.

Ultraviolet-radiation of dehydroalanyl groups resulted in the liberation of greater amounts of glycine.

As shown in Figs. 1, 2, 3, 4 and 5, and in Table II, formation of considerable amounts of aspartic acid in reaction mixture 3 was definitely confirmed, and this was explained by the following reactions:

In reaction mixture 5, the liberation of greater amounts of glycine, aspartic acid and glutamic acid was observed. However, the reason of their formation is as yet unknown.

*S*-Benzyl cysteine was clearly detected in reaction mixture 4 (Figs. 2 and 6). It was expected that cystine would have been found in some reaction mixtures containing sodium sulfide and thiosulfate, but this could not be confirmed. Similary, attempts to detect formation of tryptophane and tyrosine residues in the polymer using indol and phenol reagents, were unsuccessful because of the difficulty of detecting small amounts of these amino acids. Nevertheless, it was interesting that many kinds of amino acids were liberated from polydehydroalanine.

A few years ago, Akabori[6,7] proposed a hypothesis on the mechanism of formation of primordial protein. He suggested that initially polyglycine was formed by the polymerization of amino-acetonitrile[8] on the surface of clay. Then, many kinds of side chains were introduced into polyglycine through the reactions of this material with simple substances such as aldehydes or olefines. Subsequently, he confirmed experimentally the formation of serine, threonine[9] and leucine[7] from polyglycine, dispersed on kaolinite, on treatment with formaldehyde, acetoaldehyde and butene-2, respectively. If it is assumed that dehydroalanyl residues are formed from polyglycine during the dehydration reaction with formaldehyde, the formation of residues such as aspartic acid, glutamic acid, alanine and threonine, from polyglycine would be rationally explained. This suggestion is supported by the fact, as shown in the following communication, that *N*-phthaloyl-dehydroalanine can be derived from serine and phthalic anhydride. Furthermore, if experimental confirmation is possible, the formation of amino acids such as cystine, tryptophane and tyrosine could also be explained in a similar way.

## Summary

Reaction of poly-dehydroalanine with various reagents such as potassium carbonate, potassium cyanide, benzyl mercaptane and acetonitrile were studied. In every reaction mixture, alanine, glycine, serine, threonine, glutamic acid, aspartic acid and several unknown amino acids were detected. Ultraviolet-radiation resulted in the liberation of greater amounts of glycine. It was observed that considerable amounts of aspartic acid, *S*-benzyl-cysteine and glutamic acid were formed in reaction mixtures of potassium cyanide, benzyl mercaptane and acetonitrile, respectively.

# *The Beckmann Rearrangement of the Geometrical Isomers of Cyclohexyl Phenyl Ketoxime in Liquid Sulfur Dioxide*[1]

Ritsuro TADA, Yoichi MASUBUCHI and Niichiro TOKURA

(Received May 21, 1960)

In the previous report[1] of this series some effects of reagents on the products of the Beckmann rearrangement have been reported. It is currently accepted[2] that the Beckmann rearrangement is accompanied by exclusive trans migration. However, Some anomalies on the migratory aptitude in this rearrangement have been observed. Recently, Brown, van Gulic and Schmid[3] have reported that when pivalophenoxime was subjected to the Beckmann rearrangement with hydrochloric acid in acetic acid, similar products were obtained either from the *syn*-oxime or from the *anti*-isomer. This phenomena could be accounted for by a preliminary isomerization of the oximes before the rearrangement. On the other hand, Yukawa, Hanabusa and Kin[4] have examined the Beckmann rearrangement of cyclohexyl phenyl ketoximes and found that the migratory aptitude varied according to the reagents applied.

In addition, in the light of the publications hitherto reported[5-7], the geometrical structures of the cyclohexyl phenyl ketoximes are still ambiguous. Contradictory geometrical structures have been assigned to the oximes by Meyer and Scharvin[5,6] and also by Meisenheimer and Theilacher[7]. Moreover, since its first synthesis in 1897 by Meyer and Scharvin[5], the establishment of the geometrical structures mainly depended upon the analysis of the migrated products of the Beckmann rearrangement and the above-mentioned random migratory aptitude was ignored.

It is the purpose of the present writers to carry out the rearrangement in liquid sulfur dioxide of this compound to obtain further information on the geometrical structures of this ketoxime and the migration tendency in the Beckmann rearrangement by subjecting it to a more moderate condition. The isomeric cyclohexyl phenyl ketoximes were prepared and separated by the well-known precedure[5], to give the $\alpha$-oxime, m. p. 156~157°C., and $\beta$-oxime, m. p. 113~114°C, respectively after repeated fractional precipitations from acetic acid solution by the addition of water.

The authentic specimens of the acid amides,

which should be expected to produce by the Beckmann rearrangement from the ketoximes, *N*-cyclohexyl benzamide (III), m. p. 148~149°C (reportedly[8] 146°C) and cyclohexanecarboxyanilide (IV), m. p. 146.5~147°C (reportedly 139°C)[9] respectively, were also prepared for identification of the reaction product and the ultraviolet spectra of the respective amides were compared. Although the melting point of the two compounds were close to each other, the mixed melting point of the two authentic acid amides, III and IV, was depressed to 112 ~116°C.

A preliminary test was performed to confirm the stability of the oximes in liquid sulfur dioxide. In the range of this experimental condition the α-oxime was sufficiently stable whereas the β-oxime isomerized to the α-oxime gradually in liquid sulfur dioxide. Accordingly, special attention was paid to carry out the Beckmann rearrangement of the β-oxime.

Table I. Rearrangement of cyclohexyl phenyl ketoximes in liquid sulfur dioxide

| Reagent | −70±0.2°C, 1 hr. | |
|---|---|---|
| | Product | Rearrangement |
| α-Oxime I | | |
| $SOCl_2$ | III | trans |
| $C_6H_5SO_2Cl$ | I | No |
| Bromine | III | trans |
| HCl | I | No |
| HBr | I | No |
| $SOCl_2$ in ether | I | No |
| β-Oxime II | | |
| $SOCl_2$ | IV | trans |
| $C_6H_5SO_2Cl$ | IV | trans |
| Bromine | IV | trans |
| HCl | I+V | No, deoximation |
| HBr | I+V | No, deoximation |
| $SOCl_2$ in ether | IV | trans |

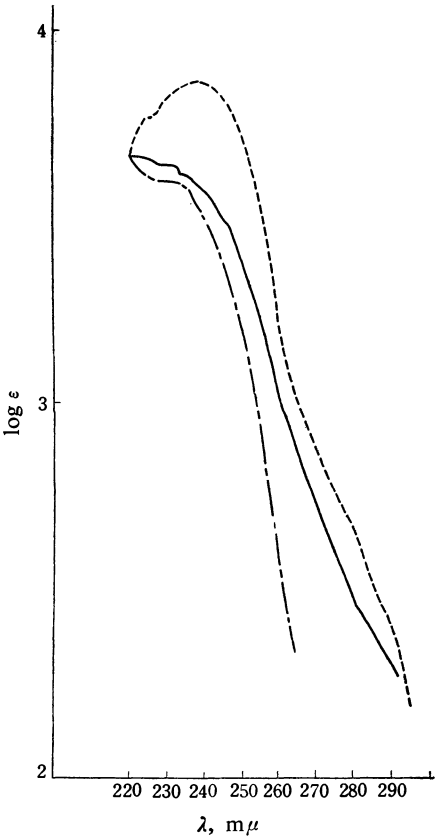

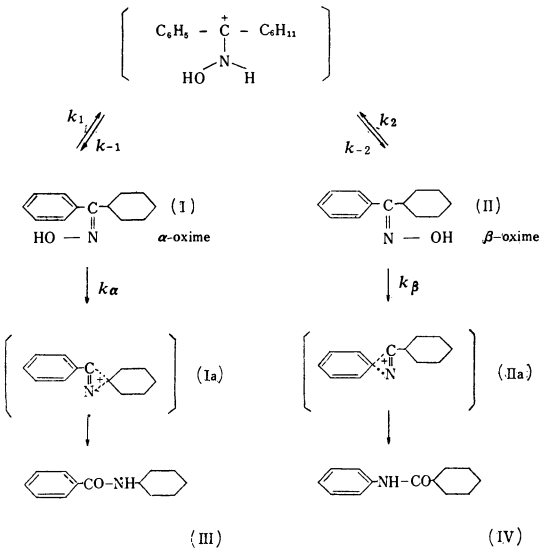

Fig. 5. Ultraviolet spectra of the reaction products from β-oxime II in liquid $SO_2$ at −70°C.
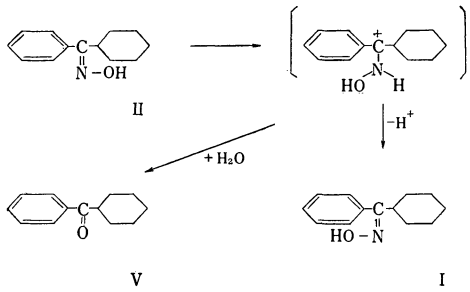
---- HCl —— HBr
—— β-oxime (II)

The Beckmann rearrangement were carried out in liquid sulfur dioxide at −70°C to avoid any undesirable side reaction. The reagents adopted for the rearrangement were thionyl chloride, benzenesulfonyl chloride, bromine and hydrogen halides. The result of the rearrangement is listed in Table I.

When the Beckmann rearrangement was carried out with thionyl chloride at −70°C in liquid sulfur dioxide, neither the α-oxime nor the β-oxime showed the random migratory aptitude, affording only *N*-cyclohexyl benzamide(III) from α-oxime I, and cyclohexanecarboxyanilide (IV) from β-oxime II, respectively. The mixed melting point and the superimposability of the ultraviolet spectra with those of the authentic specimen have proved that the rearrangement was progressing only in one direction, producing a single acid amide of the two.

The similar results were also obtained by other reagents, by which the different migratory aptitudes were not displayed in the rearrangements.

Chart 1.



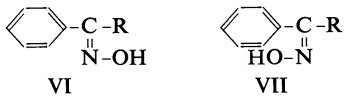
Thus, among a variety of reagents examined, within the range of these experimental conditions, thionyl chloride and bromine were only effective for the rearrangement of the α-oxime,

from which both reagents yielded the compound III exclusively as the result of trans migration.

As for the less stable β-oxime, the rearrangements were effected by thionyl chloride, benzenesulfonyl chloride and bromine to yield the amide IV exclusively, again the trans migration being predominant.

Hydrogen chloride and hydrogen bromide were both ineffective for the rearrangement, recovering the original α-oxime when it was started from the α-oxime or yielding a mixture of cyclohexyl phenyl ketoxime (V) and the α-oxime isomerized when the β-oxime was reacted. It is not surprising that the β-oxime unreacted was transformed to the more stable α-oxime (Chart 1, $k_2 > k_{-2}$ and $k_{-1} > k_1$) and the ketone V was recovered as the result of deoximation in liquid sulfur dioxide (Chart 2).

Chart 2.



The ultraviolet spectra of the respective specimens and the crude products were recorded in methanol solutions and are seen in Fig. 1—5.

The products were obtained in the pure state or in a comparatively pure state. Sometimes the melting points of the crude products (after being washed with water and dried in vacuo) were in a range such as 135~142°C, but the ultraviolet spectra showed no contamination of another amide and were almost superimposable to the authentic acid amide. It is worthy to note that the formation of the ketone V and the possible contamination of the ketone in small quantity would make the quantitative analysis of the β-oxime impossible by ultraviolet spectrometry, because the ultraviolet spectrum of the ketone V was closely resembling that of the β-oxime. (Fig. 1)

It is a plausible conclusion that the more stable α-oxime I is in the *syn*-phenyl structure VII and the less stable β-oxime II is in the *anti*-phenyl structure VI.

When R (alkyl) is methyl[10], the structure of the oxime is principally of the *anti*-phenyl oxime VI,

because the Beckmann rearrangement affords mainly acetanilide, the phenyl groups migrating. Thus the *anti*-phenyl structure VI of the oxime is favored. As the bulkiness of the alkyl group increases, the presence of the *syn*-phenyl structure becomes more favorable[11].

When R is cyclohexyl, the *anti*-structure VII will be predominant because the steric interference between the hydroxyl group and the puckered cyclohexane ring will be more serious than that between the hydroxyl group and the planer phenyl group. Thus, the α-oxime, structure I, viz. *syn*-phenyl VII, is the more stable form, from which the Beckmann rearrangement should give III by the trans migration.

The rearrangement reaction in liquid sulfur dioxide was so rapid that the isomerization of one isomer to the other or the equilibration between the two oximes could not be competitive against the Beckmann rearrangement reaction, ($k_\alpha \gg k_1$, $k_\beta \gg k_2$, Chart 1). Even the labile β-oxime afforded only the trans migrated product IV on the Beckmann rearrangement. On this occasion the elucidation of Brown et al.[3] may again be recalled to account for the discrepancy of our result.

The complication of the result may be increased if the isomerization and the deoximation of the oxime were accompanied competitively with the rearrangement.

Another point of interest is that when the Beckmann rearrangement was carried out at −70°C in ether as the solvent in place of sulfur dioxide with thionyl chloride as the reagent, α-oxime could not be rearranged, whereas β-oxime rearranged to the acid amide IV smoothly with trans migration. The difference of the reactivity in these solvents and oximes may perhaps depend on the different solvations of the two solvents on oximes and the difference of the reactivity of the two oximes.

That the β-oxime II is more reactive than the α-oxime I is satisfactorily explicable by the facility of producing the intermediate azirinum cation[12] (IIa) by phenyl group participation, and the release of the steric hindrance by rearranging.

In conclusion, the assignment of Meisenheimer and Theilacher[7] has been verified for

the geometrical structure of cyclohexyl phenyl ketoximes, the $\alpha$-oxime being of the *syn*-phenyl and the $\beta$ being of the *anti*-structure.

## Experimental

**Material.**—The purification and the manipulation of the liquid sulfur dioxide has already been published elsewhere. Thionyl chloride and benzenesulfonyl chloride were used after one distillation respectively[1]. Bromine was washed with concentrated sulfuric acid and distilled.

**Preparation and Separation of Cyclohexyl Phenyl Ketoxime (I) and (II).**—Essentially the method of Meyerand Scharvin[5] was used and modified slightly. A Grignard reagent from cyclohexyl bromide was reacted with benzaldehyde to obtain the corresponding carbinol, b. p. 130~135°C (5 mmHg), 26%, which was spontaneously oxidized in the air to cyclohexyl phenyl ketone (V), fine crystals, m. p. 57~58°C. The oxidation of the ketone resulted in a mixture of the geometrical isomers in good yield. The oximes were dissolved in acetic acid and fractionally precipitated by adding water gradually to obtain first the $\beta$-oxime, fine crystals, m. p. 113~114°C (II), then the $\alpha$-isomer, fine needles, m. p. 156~157°C (I), respectively. For compound I. Found: N, 6.64. Calcd. for $C_{13}H_{17}ON$: N, 6.89%. For compound II. Found: N, 6.80. Calcd. for $C_{13}H_{17}ON$: N, 6.89%.

***N*-Cyclohexyl Benzamide(III).**—This material was prepared by the known method[8], from cyclohexyl amine and benzoyl chloride in a yield of 82.3%, fine needles, m. p. 148~149°C (methanol). Found: N, 6.51. Calcd. for $C_{13}H_{17}ON$: N, 6.89%.

**Cyclohexanecarboxyanilide (IV).**—Aniline and cyclohexanecarboxylic acid was refluxed for several hours and the resulting mass was twice recrystallized from ethanol[9], long pillars, m. p. 146.5~147°C. Found: N, 6.60. Calcd, for $C_{13}H_{17}ON$: N, 6.89%.

**Mixed Melting Point of III and IV.**—Though the melting points of the two acid amides III and IV, were very close to each other, the mixed melting point of the two materials, III and IV, was depressed to 112~126°C.

**Isomerization of $\alpha$- or $\beta$-Oxime, I or II in Liquid Sulfur Dioxide.**—$\alpha$-Oxime I, (1.0 g.) was dissolved in 300 ml. of liquid sulfur dioxide at $-70 \pm 0.2$°C and allowed to stand for 24 hr. No change of melting point of I, 156~157°C, was seen after the recovery of the material (0.89 g.), which showed no depression of mixed melting point with an authentic specimen. On the contrary, the same treatment on the $\beta$-oxime II was carried out at $-70$°C for 24 hr. and $\alpha$-oxime was obtained as the result of isomerization which was identified by the mixed melting point measurement with the authentic $\alpha$-oxime.

**The Beckmann Rearrangement.**—To a solution of 0.5g. (0.0025 mol.) of the $\alpha$-oxime in 100 ml. of liquid sulfur dioxide, a reagent (0.0025 mol.), e. g. 0.3 g. of thionyl chloride in a small ampoule was added and the vessel was cooled to a definite temperature in a constant temperature bath. After the mixture reacted to the temperature ($-70 \pm 0.2$°C) the vessel was vigorously shaken in order to break the ampoule in the mixture. The mixture was allowed to stand at this temperature for one hour. Then the mixture was filtered and the filtrate was poured into ice-water. The precipitate afforded was collected, washed with water and dried in vacuo. The product was examined as to its melting point and the mixed melting point with the authentic acid amide, and ultraviolet spectrum of the product was compared in methanolic solution.

As the $\beta$-oxime was so unstable in liquid sulfur dioxide that the oxime in a glass ampoule was placed in a mixture of a reagent and sulfur dioxide. The rearrangement by hydrogen chloride or hydrogen bromide was carried out by passing the dry hydrogen halide gas into the reaction mixture at $-70$°C, followed by the crushing of the ampoule of the oxime.

**Ultraviolet Spectra Measurement.**—A Hitachi EPU-2A type spectrophotometer was used. All the measurements were carried out in methanolic solution.

**Results of the Rearrangements.**—*$\alpha$-Oxime by Thionyl Chloride.*—The melting point of the product (0.42 g.) was 142~145°C, the mixed melting point with III being 144~147°C, whereas with IV, the melting point depressed to 112~116°C. The ultraviolet spectrum was superimposable with that of III. (Fig. 2)

*$\beta$-Oxime by Thionyl Chloride.*—The melting point of the product (0.43 g) was 145~146°C. No melting point depression with IV, whereas with III it was depressed. The ultraviolet spectrum was superimposable on that of IV. (Fig. 3)

*$\alpha$-Oxime by Benzenesulfonyl Chloride.*—The product was recovered $\alpha$-oxime (0.46 g), melting point and mixed melting point being 155~157°C.

*$\beta$-Oxime by Benzenesulfonyl Chloride.*—The reaction gave a product (0.44 g.) of meltng point 135~142°C. The mixed melting point with IV was 136~145°C. The ultraviolet spectrum was superimposable on that of IV. (Fig. 3) The wide range of the melting point will mean that the reaction was not complete in one hour.

*$\alpha$-Oxime by Bromine.*—The result in this case was somewhat complicated, as the Beckmann rearrangement of a phenyl ketoxime by bromine was often accompanied by a bromination of the benzene nucleus[13]. The ultraviolet spectrum of the crude product was close to that of III, (Fig. 2), however, the melting point of the product (0.43 g.) was 112~120°C. A fractional crystallization from alcohol yielded two crystals, one melting at 116~120°C and containing bromine (by the Beilstein test), but was a very small quantity for its further identification. The other was the acid amide III, m. p. 145~146°C (0.30 g.) and mixed melting point with III was 146~147°C.

*$\beta$-Oxime by Bromine.*—From the crude product (0.46 g.), the fractional precipitation (from acetic acid solution by adding water), yielded crystals of m. p. 131~139°C, which was negative for the Beilstein test but was not pure enough. However, the ultraviolet spectrum of this material was resembling well that of IV, (Fig. 3).

*$\alpha$-Oxime by Hydrogen Chloride.*—$\alpha$-Oxime (0.47

13) N. Tokura, R. Asami and R. Tada, *J. Am. Chem. Soc.*, **79**, 3135 (1957).

g.), melting point and mixed m. p. 154~157°C was recovered. (Fig. 4)

*β-Oxime by Hydrogen Chloride.*—The ultraviolet spectrum of the product was reproduced in Fig. 5. Two kinds of crystals were separated by fractional precipitation as above mentioned. One, melting point and mixed m. p. 55.56°C (0.40 g.) was the ketone V, 2,4-dinitrophenyl hyrazone, m. p. 198~199.5°C, Found: N, 15.68. Calcd. for $C_{10}H_{20}O_4N_4$: N, 15.21%. The other, (0.12 g.), melting point and mixed m. p. 156~158°C was the α-oxime[1] isomerized from the β-oxime II.

*α-Oxime by Hydrogen Bromide.*—α-Oxime (0.48 g.), melting point and mixed m. p., 155~157°C was recovered.

*β-Oxime by Hydrogen Bromide.*—The ketone V, (0.15 g.), meltng point and mixed m. p. 53~55°C, and the α-oxime (0.23 g.), melting point and mixed m. p. 156~158°C, were separated and identified respectively, as above.

*α-Oxime by Thionyl Chloride in Ether at −70°C.*—The α-oxime (0.33g.) was recovered, melting point and mixed m. p. 155~157°C, (ultraviolet spectrum, Fig. 2).

*β-Oxime by Thionyl Chloride in Ether at −70°C.*—The product (0.43 g.), melting point and mixed m. p. 142~143.5°C was proved to be the IV. The ultraviolet spectrum was superimposable. (Fig. 3)

## Summary

The Beckmann rearrangement of the isomeric cylcohexyl phenyl ketoximes was carried out in liquid sulfur dioxide at low temperature (−70°C) with thionyl chloride, benzenesulfonyl chloride, bromine and hydrogen halides. In liquid sulfur dioxide, the β-oxime was unstable and isomerized slowly to the α-oxime with no reagent. The α-oxime yielded *N*-cyclohexyl benzamide and the β-oxime yielded cyclohexanecarboxyanilide, respectively, by the Beckmann rearrangement in liquid sulfur dioxide. The geometrical structure of the isomers and isomerization between them were discussed. As for the β-oxime, the rate of the rearrangement by far surpassed the rate of the isomerization. The principle of the trans migration in the Beckmann rearrangement has been confirmed within the range of this experiment. The deoximation of the oxime to the parent ketone, cyclohexyl phenyl ketone was observed in the reaction of β-oxime with hydrogen chloride and bromide.

We are indebted to the Befu Chemical Industries Ltd., for the donation of liquid sulfur dioxide. The present authors are also grateful to Professor Y. Yukawa of Osaka University for his courtesy in carrying out this project.

# *On the Reactivity of Various Silicate Minerals toward Acids*

By Hanzo MASE

(Received May 31, 1960)

As for the relative difficulty of dissolution of oxyacids and their salts toward water, a few qualitative rules have been proposed on the standpoint of ionic potential[1]. However, it is not too much to say that no comprehensive treatises on the reactivity of various silicate minerals toward ordinary acids (except hydrofluoric acid) have been reported, although the studies on the individual one have been undertaken by many investigators[2].

Previously, the author pointed out the requirements for the frothing reaction of silicate minerals toward water and concentrated sulfuric acid. Those requirements were summarized as follows: 1) the silicates belonging to either the neso- or the phyllo-silicates are generally reactive; 2) in the phyllosilicates, most of those of the 1 : 1 type (e. g., serpentine) are as a rule reactive, but those of the 2 : 1 type are not at all or only slightly reactive; and 3) the more electropositive the metallic components are, the more reactive the silicates become. But the electropositivity of metals was not discussed in detail.

2) W. Eitel, "The Physical Chemistry of the Silicates", The University of Chicago Press, Chicago, Illinois (1954), p. 965; S. Nagai and Y. Arai, *Gypsum and Lime (Sekko to Sekai)*, **34**, 7 (1958); J. Ando, *J. Chem. Soc. Japan, Ind. Chem. Sec. (Kogyo Kagaku Zasshi)*, **63**, 83 (1960).

In this paper, the author attempted to make this problem clear by using various terms concerning the combining forces between the cations and the silicate ions, and also to explain it energetically from the bonding energies of silicate minerals.

## Results from the Electropositivity of the Constituent Metals

It is well known in the field of crystal chemistry that the bonding force between various cations and silicate ions is related to the polarizing power of the cations or their tendencies to form covalent bonds with oxygen atoms. One may say that a cation with strong polarizing power or a pronounced tendency to make covalent bonds loosens bonds within a silicate ion, thus causing a splitting up of it into free acids. On the contrary, cations with small polarizing power allow strong bonds to form within the silicate ion and do therefore make stable silicate.

This polarizing power of cations is qualitatively or approximately measured with their ionic potentials (e. g., cation charge/cation radius), the ratio of cation charge to the square of cation radius (Goldschmidt's polarizing power), or the field strength around the cations[3], etc. (hereafter referred to as $\phi$, $\phi'$ or F. S., respectively.)

Therefore, the author tried to calculate and to view the above mentioned values of various cations contained in silicate minerals. The results were listed in the following table[4].

| | |
|---|---|
| $\phi$; more than 4 | Ti, Be, Al, Cr, V(III), Zr, Fe(III), Mn(III). |
| 3~4 | Th, Sc. |
| 2~3 | Y, Mg, Ni, Ce, La, Fe(II), Zn, Mn(II). |
| less than 2 | Cu, Ca, Sr, Pb, Ba, Li, Na, K. |
| $\phi'$; more than 6 | Be, Ti, Al, Cr, V(III), Fe(III), Mn(III). |
| 4~6 | Zr, Sc. |
| 2~4 | Th, Mg, Ni, Y, Fe(II), Zn, Mn(II), Ce, La. |
| less than 2 | Cu, Ca, Li, Sr, Pb, Na, Ba, K. |
| F. S.; more than 0.7 | Ti, Th, Al, Cr, Zr, V(III), Fe(III), Be, Mn(III). |
| 0.5~0.7 | Sc, Y. |
| 0.4~0.5 | Ce, La, Mg, Ni, Fe(II), Zn, Mn(II). |
| less than 0.4 | Cu, Ca, Sr, Pb, Ba, Li, Na, K. |

As shown in this table, the polarizing power of the following cations seems to be extremely great, and further the electropositivity of them to be small: e. g., Ti, Be, Al, Cr, V(III), Fe(III), Mn(III), Zr, etc. Thus the existence of these metals may contribute to the decrease of reactivity of silicate minerals. This conclusion is in agreement with the experimental results that kaolinite is not completely decomposed, although serpentine is easily attacked by acids.

As is generally known, all the silicate minerals were now divided into five classes structurally; namely, neso-, soro-, ino-, phyllo-, and tecto-silicate. According to this classification, it was at first in Tables I—V[5] examined whether or not the singularity of the above eight metal ions is applicable to those silicates. In Tables I—V the results of reactions toward acids are made an entry. Most of them are cited from the data of Lange's Handbook[6], Dana's Textbook of Mineralogy[7], and Mellor's Treatise[8]. The parenthesized passage is refered to the author's prediction.

**Nesosilicate Minerals.**—The nesosilicates are termed the silicates having the structures with separated tetrahedra $(SiO_4)^{4-}$ groups, and involve the following minerals listed in Table I.

Generally speaking, the results in Table I seem to indicate that the majority of nesosilicate minerals are able to react with acids, and to be decomposed with the formation of gelatinous silica, except the garnet group and a few particular complex silicate minerals. Also it is confirmed that one of the above eight metallic elements is inevitably contained in these insoluble nesosilicate minerals.

For example, phenacite ($Be_2SiO_4$) is not attacked by acids. This fact is probably due to the existence of Be atoms, which have very large $\phi$, $\phi'$ and F. S. For the same reason, the garnet group minerals, euclase, topaz, zunyite, andalusite, sillimanite, mullite, kyanite, sapphirine, etc. may be not decomposed by acids. Moreover titanosilicate minerals containing Ti atoms are inactive toward acids. Although

(Abbreviations used in Tables I—V.)

a.: acids; abbr.: abbreviation; app.: appendix; conc.: concentrated; decomp.: decomposed (by); gel.: gelatinize; insol.: insoluble (in, or, in acids); misc.: miscellanea; sl.: slightly; sol: soluble (in); undecomp.: undecomposed (by).

(The minerals cited in the appendixes in these tables are unassigned up to the present.)

*1) This value was calculated regarding the compositional formula of olivine as $9Mg_2SiO_4\cdot Fe_2SiO_4$.

*2) These values were calculated regarding $nMg_2SiO_4\cdot Mg(OH, F)_2$ as $nMg_2SiO_4\cdot Mg(OH)_2$.

*3) This value was calculated regarding the chemical formula of johnstrupite as ideally $Ca_3Al(SiO_4)_2(OH)$.

Table II. Reactivity of sorosilicate minerals toward acids

| Minerals | Chemical formula | Reactivity toward acids | Bonding energy (kcal.) |
|---|---|---|---|
| Benitoite | $BaTi(Si_3O_9)$ | Sol. HF | |
| Rhodonite series | | | |
| Rhodonite | $(Mn, Ca)_5Si_5O_{15}$ | Sl. sol. HCl | |
| Pyroxmangite | $(Mn, Ca)_7Si_7O_{21}$ | Insol. a. | |
| Wollastonite group | | | |
| Wollastonite | $Ca_3Si_3O_9$ | Decomp. HCl | |
| Bustamite | $(Ca, Mn)_3Si_3O_9$ | (Decomp. HCl) | |
| Pectolite | $Ca_2NaH(SiO_3)_3$ | Gel. HCl | |
| Alamosite | $PbSiO_3$ | (Gel. $HNO_3$) | |
| Catapleiite series | | | |
| Catapleiite | $Na_2Zr(Si_3O_9)\cdot H_2O$ | Sol. HCl | |
| Eudialyte | $(Na, Ca, Fe)_6ZrSi_6O_{18}(OH, Cl)$ | Gel. HCl | |
| Steenstrupine | $(Ca, Na)_4Mn(Ce, La, Al, Fe(III))_6(Si, Ti)_9O_{27}(OH)_7\cdot 3H_2O$ (?) | Decomp. a. | |
| Tourmaline series | $WX_3Y_6(Z_3O_9)_3(O, OH, F)_4$ | | |
| Dravite | $NaMg_3B_3Al_3(Al_3Si_6O_{27})(OH)_4$ | Undecomp. a. | |
| Uvite | $CaMg_3B_3Al_3(Al_3Si_6O_{27})(O, OH)_4$ | Undecomp. a. | |
| Indigolite | $Na(Al, Fe(II), Li, Mg)_3B_3Al_3(Al_3Si_6O_{27})(O, OH, F)_4$ | Undecomp. a. | |
| Tourmaline | $(Na, Ca)(Mg, Fe(II), Fe(III))_3B_3Al_3(Al_3Si_6O_{27})(O, OH)_4$ | Undecomp. a. | |
| Schorl | $NaFe_3B_3Al_3(Al_3Si_6O_{27})(OH)_4$ | Undecomp. a. | |
| Misc. | | | |
| Dioptase | $Cu_6(Si_6O_{18})\cdot 6H_2O$ | Gel. HCl | |
| Axinite | $(Fe, Mn)Ca_2Al_2(BO_3)(Si_4O_{12})(OH)$ | Undecomp. a. | |
| Beryl | $Al_2Be_3Si_6O_{18}$ | Insol. | |
| Osumilite | $(K, Na, Ca)(Mg, Fe(II))_2(Al, Fe(III), Fe(II))_3(Si, Al)_{12}O_{30}\cdot H_2O$ | (Sl. decomp. a.) | |
| Indialite | $(Mg, Fe)_2Al_3(Si_5, Al)O_{18}$ | (Sl. decomp.) | (31920)*1) |
| Cordierlite | $(Mg, Fe)_2Al_3(Si_5, Al)O_{18}$ | Sl. decomp. a. | (31920)*1) |
| Thalenite group | | | |
| Thalenite | $Y_2Si_2O_7$ | (Insol. a.) | |
| Thortveiteit | $(Sc, Y)_2Si_2O_7$ | Insol. HCl | |
| Cerite | $(Ce, Y, Pr, Nd)_2Si_2O_7\cdot H_2O$ | Gel. HCl | |
| Rowlandite | $(Y, Ce, La)_4Fe(II)(Si_2O_7)_2F_2$ | Gel. HCl | |
| Melilite series | | | |
| Åkermanite | $Ca_2MgSi_2O_7$ | Gel. HCl | 30391 |
| Gehlenite | $Ca_2Al(AlSiO_7)$ | Gel. HCl | 26890 |
| Melilite | $(Ca, Na)_2(Al, Mg)(Si, Al)_2O_7$ | Gel. HCl | |
| Hardystonite | $Ca_2ZnSi_2O_7$ | Gel. HCl | |
| Leucophanite | $(Ca, Na, H)_2BeSi_2O_6(OH, F)$ (?) | Sol. HF | |
| Meliphanite | $(Ca, Na)_2(Be, Al)Si_2O_6F$ | (Insol.) | |
| Barysilite group | | | |
| Barysilite | $Pb_3Si_2O_7$ | Gel. $HNO_3$ | |
| Ganomalite | $Pb_6Ca_4(Si_2O_7)_3(OH)_2$ | Gel. $HNO_3$ | (27383)*2) |
| Nasonite | $Pb_6Ca_4(Si_2O_7)_3Cl_2$ | Gel. $HNO_3$ | |
| Hemimorphite group | | | |
| Hemimorphite | $Zn_4(OH)_2Si_2O_7\cdot H_2O$ | Gel. a. | |
| Clinohedrite | $Ca_2Zn_2Si_2O_7(OH)_2\cdot H_2O$ | Gel. HCl | |
| Bertrandite | $Be_4Si_2O_7(OH)_2$ | Insol. a. | |
| Cuspidine | $Ca_4Si_2O_7(F, OH)_2$ | (Gel. HCl, $HNO_3$) | (28427)*3) |
| Molybdophyllite | $Pb_2Mg_2Si_2O_7(OH)_2$ | (Gel. $HNO_3$) | |
| Murmanite | $NaTiSiO_4(OH)$ (?) | (Insol. a.) | (32,164) (?) |
| (App.) | | | |
| Barylite | $BaBe_2Si_2O_7$ | Insol. | |
| Lawsonite | $CaAl_2Si_2O_7(OH)_2\cdot H_2O$ | Insol. | (31,030) |
| Danburite | $CaB_2Si_2O_8$ | Sl. decomp. HCl | |

TABLE II. (Continued)

| Minerals | Chemical formula | Reactivity toward acids | Bonding energy (kcal.) |
|---|---|---|---|
| Astrophyllite | $(K_2, Na_2, Ca)(Fe, Mn)_4(Ti, Zr)Si_4O_{14}(OH)_2$ | Decomp. HCl | |
| Aenigmanite | $(Na, Ca, K)_4(Fe(II), Mn, Fe(III), Ti, Al)_{13}(Si_2O_7)_6$ (?) | Sl. sol. a. | |
| Vesuvianite | $Ca_{10}Al_4(SiO_4)_5(Si_2O_7)_2 \cdot 2(Mg, Fe)(OH)_2$ | Sl. decomp. HCl | |
| Epidote group | $W_2Y_3(ZO_4)(OH)(Z_2O_7)O$ | | |
| Zoisite | $Ca_2Al_3(SiO_4)(Si_2O_7)O(OH)$ | Insol.*4) | |
| Epidote series | | | |
| Clinozoisite | $Ca_2Al_3(SiO_4)(Si_2O_7)O(OH)$ | Insol. | |
| Epidote | $Ca_2(Al, Fe)_3(SiO_4)(Si_2O_7)O(OH)$ | Sl. decomp. HCl | |
| Piedmontite | $Ca_2(Al, Fe, Mn)_3(SiO_4)(Si_2O_7)O(OH)$ | (Sl. decomp. a.) | |
| Allanite series | | | |
| Allanite | $(Ca, Ce, La, Na)_2(Al, Fe, Mn, Be, Mg)_3(SiO_4)(Si_2O_7)O(OH)$ | Gel. HCl | |
| Nagatelite | $(Ca, Ce)_2(Al, Fe(III), Fe(II))_3[(P, Si)O_4][(P, Si)_2O_7]O(OH)$ | Sol. HCl, $HNO_3$ | |
| Pumpellyite | $Ca_4(Mg, Fe, Mn)(Al, Fe, Ti)_5Si_6O_{23}(OH)_3 \cdot 2H_2O$ | (Sol. HCl ) | |

*1) These values were calculated regarding $(Mg, Fe)_2Al_3(Si_5, Al)O_{18}$ as $Mg_2Al_3(Si_5, Al)O_{18}$.
*2) This value was calculated regarding the chemical formula of ganomalite as $Ca_{10}(Si_2O_7)_3(OH)_2$.
*3) This value was calculated regarding $\cdots\cdots(F, OH)_2$ as $\cdots\cdots(OH)_2$.
*4) The fine powder of zoisite is completely decomposed by boiling hydrochloric acid.

TABLE III. REACTIVITY OF INOSILICATE MINERALS TOWARD ACIDS

| Minerals | Chemical formula | Reactivity toward acids | Bonding energy (kcal.) |
|---|---|---|---|
| Pyroxene group $W(X, Y)(Z_2O_6)$ | W=Ca, Na, K, Mg, Mn. X, Y=Mg, Fe(II), Al, Ti, Li, Mn, Fe(III), Cr, Ni. Z=Si, Al. | | |
| (1) Enstatite series $WXZ_2O_6$ | | | |
| Enstatite | $Mg_2Si_2O_6$ | Insol. HCl | 32344 |
| Hyperthene | $(Mg, Fe)_2Si_2O_6$ | Insol. a. | |
| (2) Pigeonite series | | | |
| Clinoenstatite | $Mg_2Si_2O_6$ | Insol. a. | |
| Pigeonite | $(Ca, Mg)(Mg, Fe)Si_2O_6$ | (Insol. a.) | |
| (3) Diopside series $W(X, Y)Z_2O_6$ | | | |
| Diopside | $CaMgSi_2O_6$ | Insol. a. | 32052 |
| Hedenbergite | $CaFeSi_2O_6$ | Insol. HCl | (32080) |
| Augite | $(Ca, Mg)(Mg, Fe, Al)(Al, Si)_2O_6$ | Insol. a. | 30728 |
| Schefferite | $Ca(Mg, Fe, Mn)Si_2O_6$ | (Insol. a.) | |
| Jeffersonite | $Ca(Mg, Mn, Zn)Si_2O_6$ | (Insol. a.) | |
| (4) Acmite-Jadeite series $WYZ_2O_6$ | | | |
| Acmite | $NaFe(III)Si_2O_6$ | Very sl. sol. a. | |
| Jadeite | $NaAlSi_2O_6$ | Insol. a. | (33848) |
| Aegirite | $(Ca, Na)(Mg, Fe(III), Al)Si_2O_6$ | Insol. a. | |
| Spodumene | $LiAlSi_2O_6$ | Insol. a. | |
| (App.) | | | |
| Margarosanite | $(Pb, Ca, Mn)SiO_3$ | Gel. $HNO_3$ | |
| Babingtonite | $Ca_2Fe(II)Fe(III)Si_5O_{14}(OH)$ | Gel. HCl | |
| Taramellite | $BaFeSi_2O_6(OH)$ | Insol. a. | |
| Hyalotekite | $(Pb, Ca, Ba)_4BSi_6O_{17}(F, OH)$ | Insol. a. | |
| Neptunite | $Na_2FeTiSi_4O_{12}$ | Insol. HF | (33938) |

TABLE III. (Continued)

| Minerals | Chemical formula | Reactivity toward acids | Bonding energy (kcal.) |
|---|---|---|---|
| Calcium metasilicates | | | |
| Inesite | $Ca_2Mn_7H_2Si_{10}O_{30}\cdot 5H_2O$ | (Sol. HCl) | |
| Hillebrandite | $Ca_2SiO_4\cdot H_2O$ | Sol. HCl | (28027)*1) |
| Riversideite | $Ca_5H_2Si_6O_{18}\cdot 2H_2O$ | Sol. HCl | (31285) |
| Copper metasilicates | | | |
| Chrysocolla | $CuSiO_3\cdot nH_2O$ | Decomp. a. | |
| Shattuckite | $8CuSiO_3\cdot 4H_2O$ | (Decomp. a.) | |
| Plancheite | $14CuSiO_3\cdot 4H_2O$ | (Decomp. a.) | |
| The others | | | |
| Carpholite | $MnAl_2Si_2O_6(OH)_4$ | Insol. HCl | |
| Stokesite | $CaSnSi_3O_9\cdot 2H_2O$ | Insol. a. | |
| Searlesite | $NaBSi_2O_6\cdot H_2O$ | Decomp. HCl | |
| Bavenite | $Ca_4AlBe_3HSi_9O_{27}\cdot H_2O$ | (Sl. sol. a.) | |
| Cainosite | $Ca_2(Ce, Y)_2Si_4O_{12}CO_3\cdot 1\sim 2H_2O$ | Sol. HCl | |
| Epididymite | $NaBeSi_3O_7(OH)$ | Very sl. sol. a. | |
| Elpidite | $Na_2(Zr, Ti)Si_6O_{15}\cdot 3H_2O$ | (Sl. sol. a.) | |
| Leucosphenite | $Ba(Na, Ca)_4Ti_3BSi_8O_{27}$ | Decomp. HF | |
| Ussingite | $Na_2Al(Si_3O_8)(OH)$ | Gel. HCl | |
| Amphybole group $(W, X, Y)_{7\sim 8}(Z_4O_{11})_2(O, OH, F)_2$ | | | |
| (1) Anthophyllite series | | | |
| Anthophyllite | $(Mg, Fe)_7Si_8O_{22}(OH)_2$ | Insol. | |
| Gedrite | $(Mg, Fe, Al)_7(Al, Si)_8O_{22}(OH)_2$ | (Insol.) | |
| (2) Cummingtonite series $X_7(Z_4O_{11})_2(OH)_2$ | | | |
| Cummingtonite | $(Mg, Fe)_7Si_8O_{22}(OH)_2$ | (Insol.) | |
| Grunerite | $(Mg, Fe, Mn)_7Si_8O_{22}(OH)_2$ | Insol. a. | |
| Kupfferite | $Mg_7Si_8O_{22}(OH)_2$ | (Insol.) | (32430) |
| (3) Tremolite series | | | |
| Tremolite | $Ca_2Mg_5Si_8O_{22}(OH)_2$ | Insol. | 32284 |
| Actinolite | $Ca_2(Mg, Fe)_5Si_8O_{22}(OH)_2$ | Insol. | |
| (4) Hornblende series $W_6(X, Y)_{10}(Z_4O_{11})_4(O, OH, F)_4$ | | | |
| Edenite | $Ca_4Na_2Mg_{10}Al_2Si_{14}O_{44}(OH, F)_4$ | (Insol.) | (31272)*2) |
| Pargasite | $Ca_4Na_2Mg_9Al_4Si_{13}O_{44}(OH, F)_4$ | (Insol.) | (31088)*3) |
| Hastingsite | $Ca_4Na_2Mg_8Al_6Si_{12}O_{44}(OH, F)_4$ | (Insol.) | (30904)*3) |
| Hornblende | $Ca_4Na_2(Mg, Fe(II))_8(Al, Fe(III), Ti)_6Si_{12}O_{44}(OH, O)_4$ | Insol. a. | |
| Kaersutite | $Ca_4Na(Mg, Fe(II))_7(Al, Fe(III))_6Ti_2Si_{12}O_{46}(OH)_2$ | (Insol.) | |
| Arfvedosonite | $Na_6Mg_8Al_2Si_{16}O_{44}(OH, F)_4$ | Insol. a. | (32538)*2) |
| 〃 | $Ca_2Na_4Fe(II)_7(Al, Fe(III))_6Si_{13}O_{44}(OH)_4$ | Insol. a. | |
| Holmquistite | $CaNaLi_2Mg_6Al_5Si_{15}O_{44}(OH)_2$ | (Insol. a.) | |
| Glaucophane | $Na_4Mg_6Al_4Si_{16}O_{44}(OH, F)_4$ | Insol. a. | (33182)*2) |
| Riebeckite | $Na_6Fe(II)_6Fe(III)_4Si_{16}O_{46}(OH)_2$ | Insol. a. | |
| Narsarsukite | $Na_2(Ti, Fe(III))Si_4(O, OH, F)_{11}$ | Insol. a. | |
| Chrysotile | $(Mg, Fe)_6Si_4O_{11}(OH)_6\cdot H_2O$ | Decomp. $H_2SO_4$ | (29468)*3) |
| (App.) | | | |
| Sepiolite | $Mg_8H_2(Si_4O_{11})_3\cdot 3H_2O$ | Decomp. HCl | (32627) |
| Attapulgite | $Mg_5Si_8O_{20}(OH)_2\cdot 8H_2O$ | (Decomp. a.) | (31076) |

*1) This value was calculated regarding the chemical formula of hillebrandite as $Ca_2SiO_3(OH)_2$.
*2) These values were calculated regarding ……$(OH, F, or, OH, O)_4$ as …… $(OH)_4$.
*3) This value was calculated regarding $(Mg, Fe)_6$…… as $Mg_6$…….

TABLE IV. REACTIVITY OF PHYLLOSILICATE MINERALS TOWARD ACIDS

| Minerals | Chemical formula | Reactivity toward acids | Bonding energy (kcal.) |
|---|---|---|---|
| | Phyllosilicates of aluminum. $Y_pSi_4O_{10}(OH)_{3p-4}\cdot sH_2O$ Y=Al, Fe(III), rarely Cr; $p=2\sim3$; $s=0\sim4$. | | |
| 2 : 1 Type | | | |
| Pyrophyllite | $Al_2Si_4O_{10}(OH)_2$ | Sl. decomp. HCl | 32558 |
| 1 : 1 Type kaolin minerals | $Al_4Si_4O_{10}(OH)_8$ | | |
| Kaolinite | $Al_4Si_4O_{10}(OH)_8$ | Sl. decomp. HCl | |
| Dickite | 〃 | (Sl. decomp. HCl) | 32165 |
| Nacrite | 〃 | (Sl. decomp. HCl) | |
| | Phyllosilicates of iron, magnesium, calcium and manganese. | | |
| 2 : 1 Type | | | |
| Talc | $Mg_3Si_4O_{10}(OH)_2$ | Undecomp. a. | (32516) |
| Minnesotaite | $(Fe(II), Mg)_{5.5}$ $(Si, Al, Fe(III))_8O_{18.5}(OH)_{5.5}$ | (Undecomp. a.) | |

trimerite contains Be, it is dissolved by hydrochloric acid. This fact may be due to the presence of a considerable amount of electropositive Mn(II) and Ca.

Generally, it may safely be assumed that 1) of the above-mentioned requirements and the singularity of the above eight metallic elements hold in the case of nesosilicates.

Furthermore, it is noteworthy that the nesosilicate minerals containing Ca, Sr, Ba and Pb react with difficulty with sulfuric acid, because sulfates of these metals are hardly soluble. Of these metals, lead chloride is soluble with difficulty in water, and so the silicate minerals containing Pb do not react easily with hydrochloric acid at ordinary temperatures.

**Sorosilicate Minerals.**—The results for the solosilicate minerals are listed in Table II. The above inductive rules appear also to be applicable in this case as well as in the case of the nesosilicate minerals. For example, osumilite, indialite, cordierite, the tourmaline and the epidote series minerals may be scarcely attacked by acids, because of the presence of great amounts of Al, and Fe(III); and then for the same reason, schorl probably appears to be undecomposed by acids. In the thalenite group minerals, the fact that thortveiteit is insoluble in acids, in spite of the reactivity of cerite toward acids, is presumably due to the existence of scandium atoms having comparatively large values of $\phi$, $\phi'$ or F. S. Similarly, the fact that bertrandite only in the hemimorphite group is undecomposed by acids appears to be due to the presence of Be. Beryl containing Al and Be is insoluble as shown from the above results. In addition, in the melilite series, leucophanite and meliphanite are slightly decomposed by hydrochloric acid (and perhaps nitric acid) owing to the existence of Be.

From this standpoint, it appears to be deducted that thalenite and rowlandite are probably attacked by acids. Moreover, it is noteworthy that dioptase ($Cu_6Si_6O_{18}\cdot 6H_2O$) having the structure identical with that of beryl[9] is easily decomposed by acids, because $Cu^{2+}$ has remarkably smaller $\phi$, $\phi'$ or F. S. than those of $Be^{2+}$. But the unreactivity of the rhodonite series[10] seems to be impossible to explain from this viewpoint, and appears to indicate the necessity of consideration for their structures, but now no satisfactory explanation has been offered as to this fact.

**Inosilicate Minerals.**—As is generally known, the inosilicate minerals are structurally classified in the pyroxene and the amphybole group. The former consists in structure with infinite single chain $(SiO_5)_\infty^{2-}$ of $(SiO_4)^{4-}$ tetrahedra with common corners, and the latter is characterized by the double chains of the type $(Si_4O_{11})_\infty^{6-}$.

The results are listed in Table III.

From Table III, it would be presumably derived that these inosilicate minerals could not for the most part be decomposed by acids. Taken in connection with their structures, this fact would seem to prove that these silicates are probably constructed by the compact arrangements of metallic ions and $(SiO_3)_\infty^{2-}$ or $(Si_4O_{11})_\infty^{-6}$ ions; in other words, their metal ions are compactly surrounded with the above-cited giant ions. Relating to this structure, it is noteworthy that the inosilicates containing alkali metals, e. g., the acmite-jadeite series and hornblende series, are not decomposed by acids. Therefore, it seems that the structural factor adds a striking effect to the reactivity toward acids in these cases. But the chemical composition of these silicates also has a comparative effect on their reactivity. For example, the inertness of the above-mentioned acmite-jadeite series and epididymite are probably in part due to the existence of Be and Al; and from the same viewpoint, it is presumably best to deduct the inertness of carpholite and bavenite. Furthermore, the fact that sepiolite and attapulgite are easily decomposed by acids would probably be due to the existence of large voids such as caves passing through between chains of $(Si_4O_{11})_\infty^{6-}$ ions[11].

**Phyllosilicate Minerals.** — As stated above, it is confirmed from the Table IV that all the 1 : 1 type phyllosilicate minerals are easily decomposed by acids, except the aluminum ones (e. g., the kaolin minerals) as was expected. On the contrary, in the 2 : 1 type phyllosilicate minerals, the magnesium type (talc) also is unattacked by acids, as well as the aluminum type (pyrophyllite). This seems to be mainly due to its 2 : 1 type structure; namely, all the magnesium ions in talc are compactly sandwiched with the two infinite layerous ions $(Si_2O_5)_\infty^{2-}$. Furthermore, the inertness of the muscovite and lepidolite series appears to be in part due to the above-cited structure and in part to the existence of aluminum. The biotite series contain no aluminum for positive ions, and then these would perhaps be attacked by acids.

**Tectosilicate Minerals.** — Table V seems to indicate that the reactivity of tectosilicate minerals toward acids are scarcely connected

with their chemical compositions. For example, the fact that orthoclase, microclire, and albite are insoluble to acids, and leucite and nepheline are decomposed by acids, cannot be explained from their chemical compositions. Therefore, in this case, it is suggested that their structures have an important effect on their reactivity.

As for their structures, the position and state of metallic ions in their crystal lattices would seem to carry on connection with their reactivity.

### Results from the Bonding Energies

It appears that the bonding energies of the silicate minerals are closely related to their reactivity. Especially the bonding energies of the tectosilicate minerals would seem to be important. As for this problem, Keller[12] made a computation by adding the energies of the bonds between their constituent cations and oxygen, starting with the elements in the gaseous state, on the basis of the data from Huggins and Sun[13].

The author computed the bonding energies of the various silicate minerals by adding the bonding energies of their constituent elements, utilizing data compiled by Huggins and Sun[13], and Keller[12]. Of the valuse in Tables I—V, those in parentheses are computed by the author, and the rest are reprinted from Keller's paper.

It is reasonable to assume that there are some deep relationships between the reactivity and the bonding energies of silicate minerals. Judging from the comparison of these two properties in Tables I—V, the following results were obtained. Generally speaking, the neso-, soro-, ino-, and phyllo-silicate minerals of which bonding energies are less than about 30500 kcal. and the tectosilicate minerals of which these energies are less than about 33500 kcal. seem to be decomposed by acids. The fact that the tectosilicate minerals alone are in particular different from others appears presumably to be relative to the singularity of themselves; namely, this seems to depend primarily upon their ultimately polymerized structures—the three-dimentional frameworks —constructed by complete sharing of all oxygens in all the tetrahedra contained in their structures.

### Summary

In this paper, the author proposed a classified table of metals contained in silicate minerals, and the qualitative and conventional rules in which it appeared possible to predict the reactivity of all the known silicate minerals toward ordinary mineral acids. In the classification and rules, ionic potential, Goldschmidt's polarizing power, and field strength of the metals in the silicate minerals play important roles.

The rules are summarized as follows: 1) the silicate minerals—especially, the neso- and soro-silicate ones composed of the comparative simple ionic crystal lattices—containing the less electropositive metals (e. g., Ti, Be, Al, Cr, V(III), Fe(III), Mn(III), Zr, etc.) are generally unattacked by acids; 2) in the ino-, phyllo-, and tecto-silicate minerals, which contain various polymerized and giant silicate ions, their structures exert a favorable influence upon their reactivity toward acids. Thus, in these minerals, it is necessary for us to take their structural effects into consideration, besides the above rule 1); and 3) the bonding energies of silicate minerals are closely related to their reactivity. In general, the neso-, soro-, ino-, and phyllo-silicate minerals of which bonding energies are less than about 30500 kcal. and the tectosilicate ones of which the energies are less than about 33500 kcal. seem to be decomposed by acids.

# *Studies on Mass Spectra and Appearance Potentials of Acetic Acid and Deuteroacetic Acid $CD_3COOH$*

By Kozo HIROTA, Kazuo NAGOSHI* and Motoyoshi HATADA

(Received June 8, 1960)

Recently the data of mass spectra have often been utilized in the discussion of radiation-induced reactions of organic compounds[1]. On such an occasion it is indispensable to determine the chemical species corresponding to each peak in the spectra by some methods, e. g. by comparing the spectra of the compounds marked by isotopes. For the same purpose, ionization potentials of these compounds are required, if possible. Although the data of this kind have been accumulated to some extent, those of the appearance potentials which are necessary to produce fragment ions do not exist so much yet in spite of their increasing importance. Such being the situation, as a part of our research on radiation chemistry of oxygen-containing compounds, mass spectra of acetic acid and deuteroacetic acid $CD_3COOH$ were measured at several accelerating voltages and temperatures of the ion source on one hand, and also the appearance potentials of parent ions and main fragment ions of these acids on the other hand.

## Experimental

**Materials.**— The purest commercial acetic acid was used without any treatment. Deuteroacetic-$d_3$ acid was synthetized as follows; carbon suboxide $C_3O_2$ obtained by dehydrating commercial malonic acid with phosphorus pentoxide was reacted with deuterium oxide. The deuteromalonic acid thus produced was decomposed thermally into deutero-acetic-$d_3$ acid-d $CD_3COOD$. The deuterium atom of the carboxylic group of this acid was replaced by protium atom, bubbling gaseous hydrogen chloride through the acid. The result of mass spectrometric analysis of the acid thus obtained showed that the amount of $CD_3COOH$ in the deuterated acid was 95.6 atomic per cent, while $CD_2HCOOH$ was the major parts of the impurities, $CH_3COOH$ being negligibly small.

**Apparatus.** — The specifications of the mass spectrometer (Hitachi type RMU-5) are as follows: 90° focusing type, the temperature of the ion source is variable from 120 to 240°C, and electron accelerating voltage is also variable between 0 and 200 V. The standard conditions for gas analysis were as follows: electron accelerating voltage, 82 eV.: ion accelerating voltage, 1500 V., total emission current, 130 $\mu$A ; target current, 35 $\mu$A ; standard temperature of the ion source, 130°C.

## Results

**Mass Spectra.**—Mass spectra of both acids are shown in Table I, where each peak height is per cent of total ion yield. From the table, the peak heights of the ions produced from $CH_3COOH$ are in the order: $m/e=43>45>15>60>29$. The result is concordant with that of some other research[2], but not with that of Kambara[3] who found the ion of $m/e=28$ to be the most abundant followed by the ions of $m/e=43>45>15>14>12$ (cf. Table II). The discrepancy between the two data is too great to be explained by the discrimination peculiar to the respective apparatus. However, larger values of the peaks of $m/e=28$, 14 and 12 of Kambara may be explained by the contamination of carbon monoxide and nitrogen, and this explanation is supported by the fact that the peak at $m/e=28$ in the mass spectrum of

* The peak height of $m/e=43$ is normalized to 100.

$CD_3COOH$ obtained under the same experimental condition is also small. Moreover, the heights of the main peaks of both spectra of $CH_3COOH$ and $CD_3COOH$ can be explained without contradiction, i. e., the peaks at $m/e=43$, 15 and 60 in $CH_3COOH$, corresponding to $CH_3CO^+$, $CH_3^+$ and $CH_3COOH^+$, shift to those at $m/e=46$, 18 and 63 in $CD_3COOH$, corresponding to $CD_3CO^+$, $CD^+$ and $CD_3COOH^+$, while the peak of $COOH^+$ ($m/e=45$) occupies the second height in both spectra. Therefore it may be concluded that our spectra are free from the peaks due to some impurities or thermally decomposed products.

In Fig. 1, the effect of temperature on the mass spectrum of acetic acid is shown over a temperature range 130~230°C, taking the temperature of the ion source as abscissa and the percentage of the peak height as ordinate. It is found that the observed effect is not so large, as to be explained by such a mechanism as that the fragment ions are produced monomolecularly from the parent ions with some activation energies for bond breaking processes. However, considering that the gaseous acetic acid molecules may not be in thermal equilibrium completely with the wall of the ion

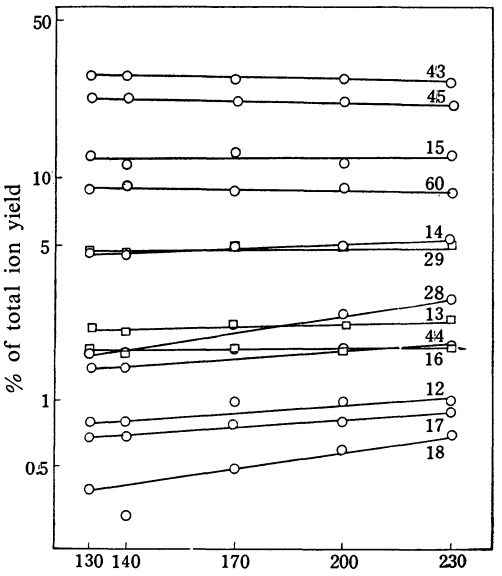

Fig. 1. The effect of ion source temperature on the mass spectrum of acetic acid.

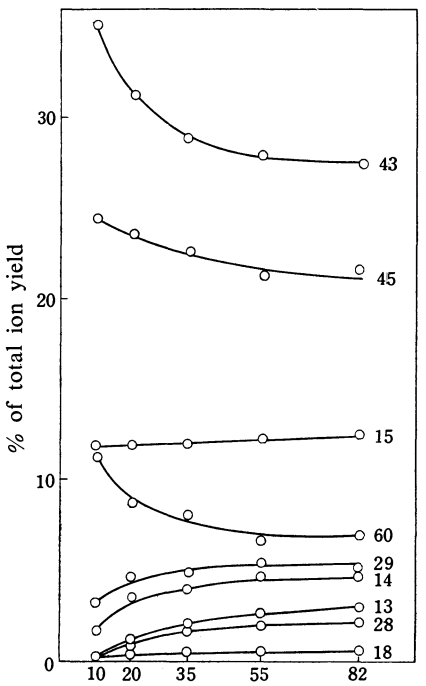

Fig. 2. The effect of electron accelerating voltage on the mass spectrum of acetic acid.

source this result may not be curious. But from this figure, it might be said that the temperature effect has the following tendencies: ions $m/e=15$, 43 and 45 are practically independent on temperature, while others

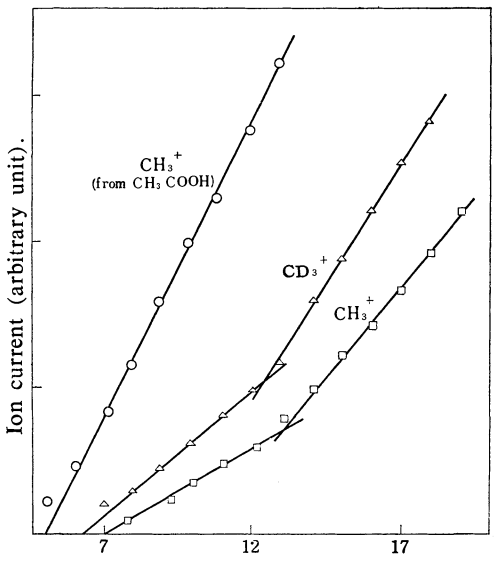

Fig. 3. Ionization efficiency curves of $CH_3^+$, $CD_3^+$ and $COOH^+$ ions.

increase, especially those of $CO_2^+$ ($m/e=44$), $CO^+$ ($m/e=28$) and $H_2O^+$ ($m/e=18$), $HO^+$ ($m/e=17$) and $C^+$ ($m/e=12$), which are the parent and fragment ions from molecules probably produced by the thermal decomposition of acetic acid.

The effect of electron accelerating voltage on the spectrum of acetic acid is shown in Fig. 2, where the voltage is varied from 9 to 82 V., and the sum of each peak height is normalized to 100 at each voltage. It is evident that the main peaks can be classified into three groups, i. e., the first group, $CH_3^+$ ion is practically constant, the second group, $CH_3COOH^+$ ($m/e=60$), $CH_3CO^+$ ($m/e=43$) and $COOH^+$ ($m/e=45$) ions, decreases and the residual third group, $COH^+$ ($m/e=29$) and $CH_2^+$ ($m/e=14$) increases with the increasing electron accelerating voltage. These tendencies may be reasonable if it is assumed, as is done by King and Long[4] on the mass-spectra of formic esters, that most of the ions which belong to the first and the third groups are produced from the ions of the second group. Detailed mechanism of production of $CH_3^+$ will be discussed again.

**Appearance Potential.**—As described above, the ions, $CH_3^+$, $CH_3CO^+$, $COOH^+$ and $CH_3COOH^+$ can be regarded as the main peaks in the spectrum of $CH_3COOH$, because the total contribution of the other ions to the spectrum is below 30%. The appearance potential of the above four ions were measured by the following procedure. The ionization efficiency curve for the ion under investigation was determined up to about 10 V. above the expected value of appearance potential and then the accurate one was determined by extrapolating the linear portion of the curve to the voltage axis. Thus, the obtained value of the ionization potential was calibrated by use of Moore's photo-ionization datum of argon ion, i. e., 15.76 V.[5]

In Fig. 3, the measurements on $CH_3^+$, $CD_3^+$ and $COOH^+$ are plotted against apparent voltage of electron acceleration. The results of these and other ions are summarized in Table III.

TABLE III. APPEARANCE POTENTIALS IN VOLT

| Ions | $CH_3COOH$ | $CD_3COOH$ |
|---|---|---|
| $CH_3COOH^+$ or $CD_3COOH^+$ | $10.7_2$ | $10.7_1$ |
| $CH_3CO^+$ or $CD_3CO^+$ | $12.6_8$ | $12.9_7$ |
| $COOH^+$ | $14.1_5$ | $14.0_8$ |
| $CH_3^+$ or $CD_3^+$ | $16.0_8$ | $15.5_6$ |
| Break point of $CH_3^+$ or $CD_3^+$ curve | 22.3 | 21.5 |

**General discussion.**—In order to confirm the reliability of our data, the appearance potential of the parent ion $CH_3COOH^+$ ($10.7_2$ V.) was compared with those in the literatures. Among the latter values, our appearance potential coincides fairly well with those obtained by the critical slope method of Honig ($10.70^6$ and $10.6_7$[7] V.), but is higher than the value $10.3_3\pm$ 0.03 V. obtained by the method of photo-ionization[8]. Such a situation may be plausible considering the generally accepted fact that the former method as well as our linear extrapolation method gave higher values than the latter.

Thus it has been found that the degree of accuracy of our measurement is sufficient for discussing the appearance potentials of other fragment ions and of other ions produced from $CD_3COOH$. The first point to be discussed will be the fact that the appearance potentials of the parent ions of both acids are $10.7_2$ and $10.7_1$ V.; i. e., they coincide with each other within the experimental errors, while those of the corresponding fragment ions differ definitely from each other.

Secondly, it may be noteworthy that the appearance potential of $CD_3CO^+$ ion is higher by 0.3 V. than that of $CH_3CO^+$ ion. On the other hand, the appearance potentials of $COOH^+$ (from deuterated acid) and $CD_3^+$ ions are lower than those of $COOH^+$ and $CH_3^+$ ions by 0.1 and 0.5 V., respectively. According

8) K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957).

to the results hitherto published, it seems to be a rule that the ionization potential of a molecule increases by deuteration; e. g. 13.04 V. for $CH_4^+$ against 13.21 V. for $CD_4^+$ [9]. Our data, therefore, seem to be an exceptional case. At present, such an anomaly can not be explained easily. The next point to be mentioned may be the breaks of the curves observed in cases of $CH_3^+$ and $CD_3^+$ ions. The breaks occur at about 6 V. higher than the corresponding appearance potentials in both cases.

The occurrence of these breaks might be explained by assuming that above this break point the simultaneous fragmentation process (1b) of the parent ion at two bonds occurs in addition to the single fragmentation process (1a) to form $CH_3^+$ ion:

$$CH_3COOH \rightarrow CH_3^+ + COOH \quad (1a)$$
$$\searrow CH_3^+ + CO_2 + H \quad (1b)$$

However, according to the theoretical result[10] which has been derived by the quasi-equilibrium theory, most of the $CH_3^+$ ions must be produced secondarily, i. e., by the decomposition of highly excited $CH_3CO^+$ ion. This explanation may not be extraordinary, because a similar shape of ionization efficiency curve of $CH_3NO_2$, in which a sharp break point occured about 4.3 V. above the first appearance potential of $NO_2^+$, was explained reasonably by the existence of a bent excited state of $NO_2^+$ [11]. Therefore, the mechanism of producing the $CH_3^+$ ions whose appearance potentials are different is not such as that described by Scheme 1, but both ions are produced by Scheme 2,

$$CH_3COOH \rightarrow CH_3CO^+ + OH$$
$$\rightarrow CH_3^+ + CO + OH \quad (2)$$

The states of the $CH_3^+$ produced below and above the break point in the curve are therefore different.

**Summary**

In order to obtain information on the decomposition process of acetic acid in radiation chemistry, not only mass spectra of both acetic acid and deuteroacetic acid but also appearance potentials of parent and main fragment ions of both acids have been measured.

By studying the effects of ion source temperature and of electron accelerating voltage on the spectra, and by comparing the mass spectra of both acids, it has been possible to identify the chemical species produced by electron impact without ambiguity and also to estimate the process of their production to some extent.

It has been found that, although the appearance potentials of the parent ion of both acids coincide fairly well, those of $CH_3^+$ and $COOH^+$ from $CH_3COOH$ are higher than those of corresponding ions from deuterated acid. The breaks of ionization-efficiency curves have been observed in $CH_3^+$ and $CD_3^+$ ions at about 6 volts higher than the appearance potentials suggesting a possibility of the presence of an excited state of the product ions.

The authors express their sincere thanks to Dr. I. Kanomata of Tokyo Metropolitan University and also to Dr. K. Fueki of Osaka University for their discussions.

# *Theoretical Reactivity Index of Addition in the "Frontier Electron Theory"*

By Kenichi FUKUI, Chikayoshi NAGATA, Teijiro YONEZAWA and Keiji MOROKUMA

(Received August 8, 1960)

It is well known that many polycondensed aromatic hydrocarbons undergo addition such as that of the Diels-Alder type and oxidation with osmium tetroxide: the former is the addition of e. g. quinone or maleic anhydride to the reactive para position and the latter is the addition to the reactive ortho bond.

It is suggested that the frontier electron density and superdelocalizability which have been proved to be good indexes of substitution reaction in conjugated compounds[1-3] will also be applicable to interpreting the reactivity in simultaneous addition reactions stated above, because the substitution and addition seem to be not so greatly different in nature from each other, at least until the activated complex is formed. In substitution reaction, the hydrogen atom of the attacking position and the reagent was considered to form a pseudoatom and the hyperconjugation energy due to the charge transfer between the pseudoatom and the orbital at the attacking position was assumed to make the reaction easy[4]. The situation in the addition reaction can be considered to resemble the substitution reaction in the sense that the delocalization energy due to the charge transfer in the transition state play a dominant role in decreasing the activation energy of the reaction. The circumstances will be clearly seen in the following example: the addition of maleic anhydride to the para position of polycondensed aromatic hydrocarbon, e. g. anthracene is deemed to proceed by a one-step process as follows:

(I) (II) (III)

The charge transfer between the maleic anhydride and the substrate molecule through the orbitals at the ethylenic bond of the former and the para position of the latter will occur in the transition state (II), and the delocalization energy due to the charge transfer is naturally considered a measure of easiness of addition reaction because the activation energy is decreased according as the increase of delocalization energy. In this connection, the frontier electron density and the superdelocalizability which could be derived from the delocalization energy are expected to be a good measure of the addition reaction.

In the present paper, the theoretical index for addition reaction in the frontier electron theory is derived and the index is compared with the rate of reactions hitherto carried out.

## Theoretical Treatment

The secular equation of the $\pi$ part of the transition complex which includes the orbitals of reagent and substrate $\pi$ electron system is written as

$$D(\varepsilon) = \begin{vmatrix} \alpha_h-\varepsilon & 0 & 0 & \gamma & 0 & 0 & \cdots & 0 \\ 0 & \alpha_h-\varepsilon & \gamma & 0 & 0 & 0 & \cdots & 0 \\ 0 & \gamma & a_{11}-\varepsilon & a_{12} & a_{13} & a_{14} & \cdots & a_{1n} \\ \gamma & 0 & a_{21} & a_{22}-\varepsilon & a_{23} & a_{24} & \cdots & a_{2n} \\ 0 & 0 & a_{31} & a_{32} & a_{33}-\varepsilon & a_{34} & \cdots & a_{3n} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & a_{n1} & a_{n2} & \cdots & \cdots & \cdots & a_{nn}-\varepsilon \end{vmatrix}$$

$$= (\alpha_h-\varepsilon)^2\Delta(\varepsilon) - \gamma^2[(\alpha_h-\varepsilon)\{\Delta_{rr}(\varepsilon) + \Delta_{ss}(\varepsilon)\}] + \gamma^4\Delta_{rrss}(\varepsilon) = 0 \qquad (1)$$

where

$$\Delta(\varepsilon) = \begin{vmatrix} a_{11}-\varepsilon & a_{12} & a_{13} & \cdots & a_{1n} \\ a_{21} & a_{22}-\varepsilon & a_{23} & \cdots & a_{2n} \\ a_{31} & a_{32} & a_{33}-\varepsilon & \cdots & a_{3n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ a_{n1} & a_{n2} & \cdots & \cdots & a_{nn}-\varepsilon \end{vmatrix}$$

is the secular determinant for the substrate $\pi$-electron system and $\Delta_{rr}(\varepsilon)$ and $\Delta_{ss}(\varepsilon)$ are the minors of $\Delta(\varepsilon)$ corresponding to the *rr*- and *ss*-elements, and $a_{ii}$ and $a_{ij}(i \neq j)$ are the

Coulomb and the resonance integrals, respectively. For simplicity, the values of these integrals are assumed to be the same as those in an isolated molecule. $\alpha_h$ and $\gamma$ are the Coulomb integral of the reagent*, and the resonance integral between the reagent and the $r$th and the $s$th atom of the substrate molecule at which the reaction takes place, respectively.

When the conjugation between the substrate molecule and reagent is small, i. e., in the case of $0<\gamma\leqq 1$, the perturbed orbital energy of the complex are given by the following formula

$$\varepsilon_j' = \varepsilon_j + \delta\varepsilon_j\gamma^2 + 0(\gamma^4) + \cdots\cdots \quad (2a)$$

$$\alpha_h' = \alpha_h + \delta_h\gamma^2 + 0(\gamma^4) + \cdots\cdots \quad (2b)$$

The values of $\delta\varepsilon_j$ and $\delta\alpha_h$ are easily obtained by the perturbation treatment as

$$\delta\varepsilon_j = \frac{\Delta_{rr}(\varepsilon_j)+\Delta_{ss}(\varepsilon_j)}{(\alpha_h-\varepsilon_j)\Delta'(\varepsilon_j)}\gamma^2 + \cdots\cdots \quad (3)$$

$$\delta\alpha_h = -\frac{\{\Delta_{rr}(\alpha_h)+\Delta_{ss}(\alpha_h)\}}{2\Delta(\alpha_h)} \pm \frac{\sqrt{\{\Delta_{rr}(\alpha_h)-\Delta_{ss}(\alpha_h)\}^2+4\{\Delta_{rs}(\alpha_h)\}^2}}{2\Delta(\alpha_h)} \quad (4)$$

$\varepsilon_j'$ and $\alpha_h'$ are the roots of $D(\varepsilon)=0$ and they correspond to the energy of the molecular orbital of the unperturbed system $\Delta(\varepsilon)$ and the orbitals of the reagent, respectively. We assumed that $\Delta(\varepsilon)=0$ has no multiple roots here, but in the case in which $\Delta(\varepsilon)=0$ has double roots, the final result is not altered.

The delocalization energy $\mathcal{K}_{r+s}$ is derived by treatment analogous to the case of substitution reaction[3]. It is given according as the type of reaction as follows:

for electrophilic reaction,

$$\mathcal{K}_{r+s} \cong 2\sum_{j=1}^{m}\frac{\Delta_{rr}(\varepsilon_j)+\Delta_{ss}(\varepsilon_j)}{(\alpha_h-\varepsilon_j)\Delta'(\varepsilon_j)}\gamma^2 = 2\sum_{j=1}^{m}\frac{(C_r^j)^2+(C_s^j)^2}{\varepsilon_j-\alpha_h}\gamma^2 \quad (5)$$

for radical reaction**,

$$\mathcal{K}_{r+s} \cong \left[-\sum_{j=1}^{m}\frac{\Delta_{rr}(\varepsilon_j)+\Delta_{ss}(\varepsilon_j)}{(\varepsilon_j-\alpha_h)\Delta'(\varepsilon_j)} - \sum_{j=m+1}^{n}\frac{\Delta_{rr}(\varepsilon_j)+\Delta_{ss}(\varepsilon_j)}{(\alpha_h-\varepsilon_j)\Delta'(\varepsilon_j)}\right]\gamma^2$$

$$= \left[\sum_{j=1}^{m}\frac{(C_r^j)^2+(C_s^j)^2}{\varepsilon_j-\alpha_h} + \sum_{j=m+1}^{n}\frac{(C_r^j)^2+(C_s^j)^2}{-(\varepsilon_j-\alpha_h)}\right]\gamma^2 \quad (6)$$

for nucleophilic reaction,

$$\mathcal{K}_{r+s} \cong -2\sum_{j=m+1}^{n}\frac{\Delta_{rr}(\varepsilon_j)+\Delta_{ss}(\varepsilon_j)}{(\alpha_h-\varepsilon_j)\Delta'(\varepsilon_j)}\gamma^2 = 2\sum_{j=m+1}^{n}\frac{(C_r^j)^2+(C_s^j)^2}{-(\varepsilon_j-\alpha_h)}\gamma^2 \quad (7)$$

where $C_r^j$ is the coefficient of the $r$th atomic orbital of $j$th molecular orbital of non-perturbed substrate molecule and the relation $-\Delta_{rr}(\varepsilon_j)/\Delta'(\varepsilon_j)=(C_r^j)^2$ was used in deriving the last terms of the right hand side of the above equations.

When the value of $\alpha_h$ is equal to $\alpha$, the Coulomb integral of carbon atom in benzene, the coefficients of $\gamma^2$ in Eqs. 5, 6 and 7 are nothing but $(S_r+S_s)$ for electrophilic, radical and nucleophilic reactions, respectively. Therefore, the theoretical index for addition reaction at two positions $r$ and $s$ is the sum of the superdelocalizability at $r$ and $s$ positions. It is clearly seen in the expression in Eqs. 5, 6 and 7 that the contribution of the frontier orbital is the greatest, hence as in the case of the treatment of substitution reaction[3], the one term approximation taking into consideration the frontier orbital alone, will be allowed.

It is noted that the present treatment gives the same result regardless whether one considers the reaction as a simultaneous or two-step one. This indescernability is also seen in other treatments such as static and localization methods. Therefore, it is impossible to decide whether the reaction is one-step or not by comparing the theories and experimental results.

The theoretical index derived above is qualified as a good index for predicting the reactivity in simultaneous addition reaction as a result of comparison with the experiment. For instance, the data of the attacking positions in the Diels-Alder reaction are in agreement without an exception with the predicted most reactive position in a molecule (Table I). The relative rate of these compounds in the Diels-Alder reaction has not been measured in one

* In this treatment, the attacking reagent was assumed to be composed of two non-conjugating components. In other words, the reaction was considered to occur with two reagents. The one reagent attacks the $r$ position and the other the $s$ position simultaneously or stepwise. In the case of the addition of maleic anhydride to poly-condensed aromatic hydrocarbons, the reagent as well as the substrate is a conjugated system, and the whole $\pi$ electron system of maleic anhydride should be taken into consideration. In this case, however, the reaction was considered as an addition of two reagents to the substrate separately.

** For a radical reaction twice the second term (the energetically lower term) of Eq. 4 are omitted in deriving Eq. 6. It is because one may conclude that the term has no connection with the simultaneous addition reaction. That is to say, from the configuration interaction's point of view, it originates in the interaction between the initial configuration (initial state of reaction) and the configuration corresponding to one-electron transfer from a component of the reagent to another component. Not involving the charge transfer between the reagent and the substrate molecule but between the two components of reagents, this interaction seems to have no connection with the reaction.

and the same condition. However, considering the experimental data which have been so far reported (cf. references in Table I), one can conclude that the following order of reactivity might exist : hexacene> pentacene> naphthacene >anthracene> 1, 2-benzanthracene> 1, 2, 5, 6-dibenzanthracene> naphthalene, phenanthrene, benzene. This is in excellent accord with the order of magnitude of $S_r+S_s$ of these compounds.

As is seen in Table II, the experimental position of attack of osmium tetroxide to the double bond of some polycondensed aromatic hydrocarbons agree very well with the prediction by the theory. The reactive rate of reaction of these compounds is not determined completely ; however, the experiment by Badger and Reed showed that 1, 2-benzanthracene reacts with osmium tetroxide faster than phenanthrene does[5]. This fact is explained well by our calculated result.

# *Diamagnetic Behavior of Some Aliphatic Molecules in Crystals*

By A. MOOKHERJI, S. N. MOOKHERJI and D. NEOGY

(Received May 18, 1960)

According to Pauling[1] the normal susceptibility in the plane of the aromatic molecules is due to the bound electrons, contributing to the susceptibility equally in all directions, and the electrons which are free to precess only in the plane of the molecule in orbits, provided by the entire molecular ring system, contribute only to the susceptibility along the normal to the molecular plane. When such anisotropic molecules are regularly arranged in crystals, the crystal as a whole will exhibit magnetic anisotropy. Hence anisotropy of the diamagnetic crystals is obviously due to the anisotropy of its constituent molecules.

Krishnan and Banerji[2] and Banerji[3] showed that, if the molecular anisotropy is known, it is possible to obtain much useful information regarding the orientation of the molecules in crystals relative to one another.

In a recent paper (Mookherji et al.)[4] studying the susceptibilities of a few dibasic aliphatic acids and their salts observed that,

a) Unlike the normal aliphatics the maximum diamagnetic susceptibility for the these salts lies normal to the plane of the carboxylic groups.

b) This extra diamagnetism could be attributed to resonance which exists in these molecules.

From X-ray studies and chemical considerations one may be led to think that the carboxylic groups in mono- and dibasic aliphatic acids and their salts can be represented by two or more structures and hence in these molecules resonance will exist. It would be therefore interesting to study the diamagnetic anisotropy of the crystals of the above mentioned acids and their salts and to find whether a similar diamagnetic behaviour like succinic and tartaric acids and their salts could be observed.

## Experimental

Crystals were grown out of aqueous solution at room temperature by slow evaporation. The chemicals used were Merk's extra pure reagent quality prewar variety.

The magnetic anisotropy and the orientation of the crystals in magnetic field were carried out by the well known method of Krishnan and Banerji[2]. The absolute susceptibility in any convenient direction was measured by a modified quartz balance (Bose)[5]. The magnetic field used for the purpose had a constant gradient over a considerable volume by using pole pieces as devised by Dutta Roy[6]. The standard crystal for calibration of this balance was a well developed crystal of naphthalene for which mass susceptibility is accurately known (Banerji)[7].

## Results

The results of measurements are collected in Tables I and II, and are expressed in the usual units i. e. c. g. s. E. M. units. $\chi_3$ is the gram molecular susceptibility along b-crystallographic axis of a monoclinic crystal; the algebraically greater of the two values in the symmetry plane (010) is denoted by $\chi_1$ and the smaller by $\chi_2$; $\phi$ is the angle that $\chi_1$-direction makes with c-crystallographic axis taken positive from c-axis towards a-axis through obtuse $\beta$.

In orthorhombic crystals, the gram molecular susceptibilities along the crystallographic axes a, b and c are represented by $\chi_a$, $\chi_b$ and $\chi_c$, respectively.

## Discussion

**Magnetic Analysis of Molecular Orientation in Crystals.**—We proceed now to discuss the magnetic anisotropy in the light of the orientation of the molecules in the unit cell of the crystal. The crystals are discussed individually.

*Oxalic Acid Dihydrate.* — Complete X-ray studies by Robertson and Woodword[8] revealed that the crystal is monoclinic in the space group $C_{2h}^5$ with two molecules in the unit cell. The molecules are centro symmetric, approximately plane, and are magnetically nearly uniaxial.

Let us represent the axes of symmetry of the two molecules by $Z_1$ and $Z_2$ and the principal susceptibilities of the molecule by $K_\perp$ and $K_\parallel$ in the plane of the molecule and normal to it respectively.

TABLE II. ABSOLUTE SUSCEPTIBILITIES

| Sl. No. | Name of the crystal | Temp. °C | Direction along which suscept. was measured | Volume suscept. | Corresponding $\chi_M$ | Principal gram molecular suscept. | Mean suscept. $\bar{\chi}_m$ | Pascal's value $\bar{\chi}_m$ |
|---|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| 1. | Oxalic acid dihydrate, Monoclinic | 33.00 | Along "b" axis | −0.4214 | −53.1 | $\chi_1=-53.1$<br>$\chi_2=-55.2$<br>$\chi_3=-61.63$ | −56.64 | −60.42 |
| 2. | Ammonium oxalate monohydrate, orthorhombic | 33.00 | Along "b" axis | −0.4257 | −60.4 | $\chi_a=-60.4$<br>$\chi_b=-61.51$<br>$\chi_c=-74.68$ | −65.33 | −68.20 |
| 3. | Potassium oxalate monohydrate, monoclinic | 33.00 | Along "b" axis | −0.3740 | −68.82 | $\chi_1=-68.82$<br>$\chi_2=-70.42$<br>$\chi_3=-78.82$ | −72.68 | −67.20 |
| 4. | Ammonium bi-oxalate monohydrate, orthorhombic | 33.00 | Along "b" axis | −0.3417 | −42.72 | $\chi_a=-42.72$<br>$\chi_b=-31.94$<br>$\chi_c=-33.63$ | −36.09 | −56.83 |
| 5. | Potassium bi-oxalate monohydrate, monoclinic | 33.00 | Along "b" axis | −0.2954 | −43.13 | $\chi_1=-43.13$<br>$\chi_2=-52.13$<br>$\chi_3=-41.93$ | −45.73 | −57.33 |
| 6. | Calcium formate orthorhombic | 33.00 | Along "b" axis | −0.2650 | −34.46 | $\chi_c=-34.46$<br>$\chi_a=-36.182$<br>$\chi_b=-34.895$ | −35.179 | −44.70 |
| 7. | Barium formate orthorhombic | 33.00 | Along "b" axis | −0.2892 | −65.77 | $\chi_c=-65.77$<br>$\chi_b=-67.50$<br>$\chi_a=-66.88$ | −66.71 | −65.40 |
| 8. | Barium acetate trihydrate, monoclinic | 33.00 | Along "b" axis | −0.3772 | −116.7 | $\chi_1=-116.7$<br>$\chi_2=-117.88$<br>$\chi_3=-116.242$ | −116.94 | −128.00 |

Then $\chi_1$ will lie in the direction, normal to the plane containing $Z_1$ and $Z_2$ axes and $\chi_2$ will be the internal bisector of the angle $2\Psi$ between $Z_1$ and $Z_2$ and hence,

$$\left.\begin{aligned}\chi_1&=K_\perp\\ \chi_2&=K_\parallel\cos^2\Psi+K_\perp\sin^2\Psi\\ \chi_3&=K_\parallel\sin^2\Psi+K_\perp\cos^2\Psi\end{aligned}\right\} \quad (1)$$

and $$\bar{\chi}=(\chi_1+\chi_2+\chi_3)/3=\frac{K_\parallel+2K_\perp}{3}$$

substituting the values of $(\chi_1-\chi_2)$ and $(\chi_1-\chi_3)$ in Eq. 1 we have $(K_\perp-K_\parallel)=10.7\times10^{-6}$ and $\Psi=63.5°$, which agrees well with X-ray findings, i. e. 61.9°.

*Ammonium Oxalate Monohydrate.*—Fine structure studies by X-ray methods (Hendricks, and Hendricks and Jefferson[9,10]) reveal that there are two molecules in the unit cell in space group $P_{2_12_12}$ and that the two parts of the COOH group are in planes making an angle of 20° whereas in oxalic acid both parts are in the same plane. The planes containing the oxygens of the oxalate groups are almost parallel to (001) plane. Following Mookherji[11] we can attribute the abnormal diamagnetism to oxygen atoms of the oxalate groups. Hence according to X-ray findings (001) plane should approximately be a plane of magnetic symmetry, whereas normal to this plane we should expect algebraically maximum susceptibility. From Table I we find that in the (001) plane $\Delta\chi=\chi_a-\chi_b=1.1\times10^{-6}$, whereas it is $14.2\times10^{-6}$ in the plane normal to it.

We may therefore conclude that for oxalate molecules, which are in strained condition because of its two parts being in two different planes $\Delta K=K_\perp-K_\parallel=14.0\times10^{-6}$, more by 4 units for the oxalate groups, where both the parts are in the same plane.

*Ammonium Bi-oxalate.*—From Table I it is seen that the two susceptibilities in the (001) plane are nearly equal and numerically less than the third susceptibility by about 10 units, which is almost equal to the value of the oxalate group in oxalic acid dihydrate. Thus we conclude that in this crystal all the oxalate groups are oriented parallel with (001) plane. At present no X-ray data are available to verify the above conclusions.

*Potassium Oxalate Monohydrate.*—Hendricks[9] by X-ray methods found that the crystal is

9) S. B. Hendricks, *Z. Kristallogr.*, **91**, 48 (1935).
10) S. B. Hendricks and M. E. Jefferson, *J. Chem. Phys.*, **4**, 102 (1936).
11) A. Mookherji, *Acta Cryst.*, **10**, 25 (1957).

monoclinic in the space group of $C_{2/c}$ with four molecules in the unit cell; they form a set of two pairs with the two molecular planes in each pair being parallel. If the slight tilt between the two pairs is neglected then the molecules may be taken oriented parallel to the plane (010).

Evidently, $K_{\parallel}=\chi_3$, $K_{\perp}\approx\chi_2\approx\chi_1$

Hence, $1/2[(\chi_1-\chi_3)+(\chi_2-\chi_3)]=K_{\perp}-K_{\parallel}$

Thus it is observed that $(K_{\perp}-K_{\parallel})$ for oxalate group in the crystal is 9.2 as against 10.7 for that in the oxalic acid. This is evidently due to the neglect of the tilt. On calculating the tilt comes out as 15.0° with the (010) plane.

*Potassium Bi-oxalate.* — According to Hendricks[9], the crystal has four molecules in the unit cell and the molecular planes are oriented parallel to (100) plane. Hence $K_{\perp}-K_{\parallel}=10.0\times10^{-6}$, which is almost the same as found with other oxalate groups.

*Calcium Formate.*—It crystallises in the orthorhombic system in the space group $P_{Cab}$ with eight molecules in the unit cell (Nitta and Osaki[12]). If $n$, $m$ and $l$ are the direction cosines of the normal to the formate group, following Banerji[3] we have,

$$l^2-m^2=\frac{\chi_b-\chi_a}{K_{\perp}-K_{\parallel}},\qquad l^2-n^2=\frac{\chi_c-\chi_a}{K_{\perp}-K_{\parallel}}$$

and $l^2+m^2+n^2=1$

In order to calculate $m$, $l$ and $n$ one must know $(K_{\perp}-K_{\parallel})=\Delta K$ for COOH group. This may be estimated as follows:

According to Pauling and Sherman[13] resonance energy in monobasic acids is 1.20 electron volts. Now according to Pauling[14], if one attributes to $\Delta K$ this resonance energy then,

$$\Delta K=\frac{E\times M}{3.22\times\rho}=8.36\times10^{-6}$$

where $E$ is kinetic energy, $M$ the molecular weight and $\rho$ the density. On substituting this value and $(\chi_b-\chi_a)$ and $(\chi_c-\chi_a)$ from Table I we find that the formate groups are inclined at 48.1, 56.0 and 59.8° to a, b and c crystallographic axes respectively.

*Barium Formate.*—The crystal is orthorhombic. The orientation of the formate group is calculated following the same method as in the case of calcium formate, which show that the normal to the formate group is inclined at 54.0° to a-axis 35.8° to b-axis and 38.8° to c-axis.

12) I. Nitta and K. Osaki, *X-Rays*, 5, 37 (1948).
13) L. Pauling and J. Sherman, *J. Chem. Phys.*, 1, 679 (1933).
14) L. Pauling, *Phys. Rev.*, 34, 954 (1929).

**Diamagnetic Anisotropy and Resonance Energy.**—According to Pauling, mono- and dicarboxylic acids and their salts exhibit resonance with two contributing forms and the actual resonance structure is a resonance hybrid intermediate between the contributing forms. Taking into account the empirical values of the polar effect and the dissociation constants of fatty acids Pauling calculated the resonance energy in carboxylic groups. One direct consequence of such resonance is the abnormal diamagnetism normal to the plane of the groups. Therefore it would be very interesting to correlate the measured abnormal diamagnetism with the resonance energy as obtained empirically. As already stated the kinetic energy $E$ of the resonating electron is related to $\Delta K$ by expression

$$E=3.22\times\frac{\Delta K\times\rho}{M}$$

Using the above relation we have calculated the resonance energy for formates, oxalates, succinates and tartrates using $\Delta K$-values which are given in Table III. We have also taken

TABLE III

| Substances | $\Delta K\times10^6$ | Extra resonance energy calculated By Pauling | Extra resonance energy calculated From magnetic values |
|---|---|---|---|
| | Aromatics | | |
| Diphenyl | 118.6 | 86.88 | 84.65 |
| Naphthalene | 114.0 | 74.66 | 82.62 |
| Anthracene | 182.6 | 104.70 | 100.30 |
| Stilbene | 141.6 | 94.26 | 101.00 |
| | Aliphatics | | |
| Succinic acid | 10.7 | 54.86 | 52.00 |
| Tartaric acid | 9.6 | 54.86 | 52.00 |
| Oxalic acid | 10.7 | 54.86 | 53.31 |

some of the $\Delta K$-values for some typical aromatics as determined by Krishnan and Banerji[2] and calculated resonance energy. The agreement between the observed and calculated values is very encouraging.

**Influence of Resonance Energy on Diamagnetism.**—Adopting the conventional structural formulae for oxalates, formates and acetates, we have calculated mean gram molecular susceptibilities $\bar{\chi}_m$ for them on the basis of Pascal's additive law which are given in Table II. On comparing with our measured values of $\bar{\chi}_m$ a lowering is observed. This lowering is well understood if we recall that the resonance occuring in these groups impart on them some amount of double bond character (unsaturated) which lowers $\bar{\chi}_m$. A similar comparison of $\bar{\chi}_m$ deduced on the basis of Pascal's law and those measured by Krishnan and Banerji[2] for a number of aromatic substances

points to the same findings. Matsunaga[15] found with azobenzene the same value as Banerji[3] which is lower than Pascal's value Thus one can safely conclude that resonance lowers diamagnetic values.

The above point of view is further strengthened by our findings that for molten oxalic acid dihydrate $\bar{\chi}_m$ is $-60.89\times10^{-6}$ (100°C) while that for the powder state is $-56.4\times10^{-6}$ (30°C). In molten state the crystal lattice completely breaks down so that the double bond character almost vanishes and hence there is an increment of $\bar{\chi}_m$ approaching Pascal's value.

## Summary

The principal magnetic susceptibilities of single crystals of some aliphatic mono- and di-basic acids and their salts have been measured and the results have been correlated with the fine structure studies of the crystals by X-ray methods. It is observed that the anisotropy per -COOH group is 5 units, which increases by nearly 2 units if two parts of $\begin{matrix}\text{COOH}\\|\\\text{COOH}\end{matrix}$ groups are not in the same plane.

The observed extra diamagnetism normal to the plane of the carboxylic groups, if attributed to resonance, the calculated energy compares very favourably with that deduced by Pauling from a consideration of the heat of formation of molecules and the lowering of the susceptibility from Pascal's value is then well understood.

We take this opportunity to thank the Ministry of Education, Govt. of India for the individual (A. M.) research grants and to U. P. S. R. G. C. for the award of scholarship to one of us (D. N.).

# *The Surface Tension and the Critical Micelle Concentration in Aqueous Solution of β-D-Alkyl Glucosides and their Mixtures*

By Kozo SHINODA, Tokio YAMAGUCHI and Ryohei HORI

(Received August 11, 1960)

There have not been many research works on the pure non-ionic agents[1-3]. Future progress in this field should be assured by the study of pure non-ionic agents. Some colloid chemical properties of a series of pure octyl polyol ethers in aqueous solution have been studied to determine the effect of differences in the hydrophilic group[3]. In the present paper, we have measured the surface tension vs. concentration of octyl, decyl and dodecyl glucosides in order to know the effect of paraffin chain length on the physico-chemical properties of alkyl glucosides. The CMC was determined from the inflexion of the surface tension vs. concentration curve. The surface tension of mixtures of alkyl glucosides solutions and the effect of added salts on the surface tension of octyl glucoside were also measured.

## Experimental

The procedures and purifications of alkyl glucosides were similar[4] as in the case of octyl glucoside[3]. The melting points and specific rotations of β-D-octyl, decyl and dodecyl glucosides were m. p. 63.8~65°C, $[\alpha]_D^{20} = -33.8°$ ($H_2O$); m. p. 135°C, $[\alpha]_D^{25} = -27.8°$ ($H_2O$); m. p. 143.5°C, $[\alpha]_D^{25} = -24.7°$ ($H_2O$), respectively.

The materials were further purified by foam fractionation. The concentration of the solution foam fractionated was chosen slightly below the CMC, because the foam stability and the efficiency of the elimination of highly surface active impurities were optimum in this concentration[5]. Surface

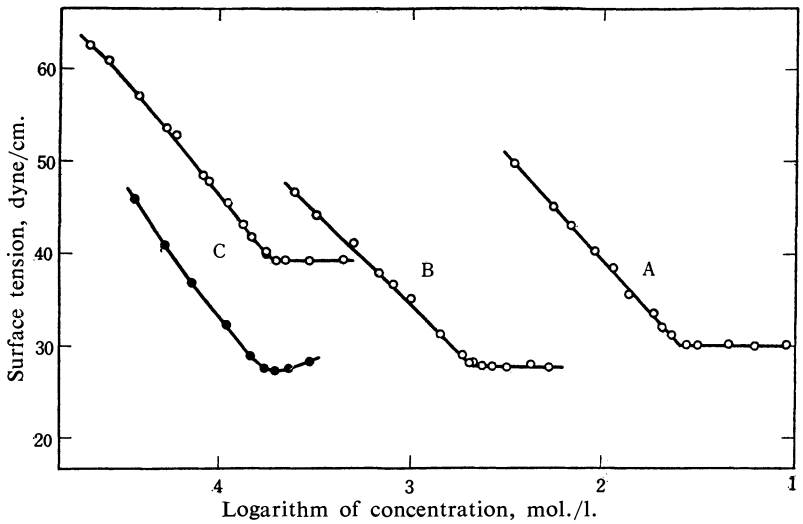

Fig. 1. The surface tension vs. log. concentration curves of β-D-alkyl glucosides at 25°C: A, octyl glucoside; B, decyl glucoside; C, dodecyl glucoside; ●, before foam fractionation.

tension was measured by the drop weight method, with a tip 0.576 cm. in diameter in an air thermostat at 25±0.2°C. The correction of Harkins et al.[6] was applied. There was appreciable change, 2~4 dyne cm. of surface tension, with time durations of 4~20 min. and 10~60 min. for decyl and dodecyl glucosides, respectively.

## Results

The surface tension vs. concentration relations are shown in Fig. 1 and summarized in Tables I, II and III. There was great change in surface tension between foam fractionated unfractionated solution of dodecyl glucoside. However, there was no appreciable change in solutions of octyl and decyl glucosides.

TABLE I. THE SURFACE TENSION IN AQUEOUS SOLUTION OF β-D-OCTYL GLUCOSIDE AT 25°C

| Concentration, mol./l. ×10² | Time per drop in min. | Number of measurements | Surface tension dyne/cm. | Mean variation dyne/cm. |

TABLE II. THE SURFACE TENSION IN AQUEOUS SOLUTION OF β-D-DECYL GLUCOSIDE AT 25°C

| Concentration, mol./l. ×10³ | Time per drop in min. | Number of measurements | Surface tension dyne/cm. | Mean variation dyne/cm. |
|---|---|---|---|---|
| 0.255 | 20 | 2 | 46.7 | 0.1 |
| 0.325 | 15 | 3 | 44.2 | 0.1 |
| 0.513 | 15 | 4 | 41.2 | 0.3 |
| 0.683 | 10 | 4 | 37.8 | 0.1 |
| 0.816 | 10 | 2 | 36.7 | 0.0 |
| 1.025 | 10 | 4 | 35.0 | 0.3 |
| 1.46 | 10 | 2 | 31.2 | 0.2 |
| 1.91 | 5 | 3 | 29.0 | 0.0 |
| 2.06 | 5 | 3 | 28.1 | 0.1 |
| 2.14 | 5 | 2 | 28.3 | 0.0 |
| 2.41 | 5 | 4 | 27.8 | 0.1 |
| 2.67 | 5 | 2 | 27.7 | 0.1 |
| 3.22 | 5 | 3 | 27.7 | 0.1 |
| 4.28 | 5 | 3 | 28.0 | 0.3 |
| 5.35 | 5 | 4 | 27.7 | 0.5 |

The inflexion in the surface tension vs. logarithm of concentration curve was distinct and there was no minimum in foam fractionated solution. The surface tension of mixtures of alkyl glucosides has been measured. The results are summarized in Fig. 2. The surface tension vs. concentration curve showed the minimum in the mixture of octyl-decyl glucosides. The effect of added sodium chloride, calcium chloride and sodium sulfate on the surface tensions of aqueous solution of octyl glucoside has also been measured. The results are shown in Fig. 3.

## Discussion

The CMC was obtained from the inflexions in the curves. As the surface tension remains constant, the activity of solute is constant over the flat portion of the surface tension vs. concentration curve. Because, in Gibbs adsorption isotherm,

$$\left(-\frac{\partial\gamma}{\partial \ln c_2}\right)_T\left(\frac{\partial \ln c_2}{\partial \ln a_2}\right)_T = -RT\Gamma_2 \qquad (1)$$

if $(\partial\gamma/\partial \ln c_2)_T=0$ and $\Gamma_2>0$, then $(\partial \ln a_2/\partial \ln c_2)_T=0$ and therefore $a_2$=const. with concentration.

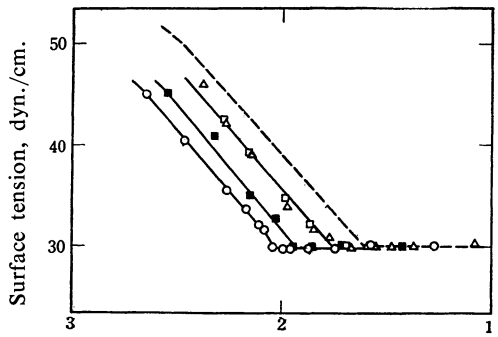

Fig. 3. The effect of added salts on the surface tension of β-D-octyl glucoside at 25°C: △, 0.93 N $CaCl_2$; □, 0.47 N NaCl; ■, 0.93 N NaCl; ○, 0.93 N $Na_2SO_4$.

The fact that the activity vs. concentration remains constant suggests that something similar to a phase separation is occurring in the solution. Namely, the micelle formation begins above the concentration of inflexion and the concentration of single species stays constant.

Table IV gives the CMC, surface excess and residual area per molecule calculated from the data in Tables I, II and III under the assumption that $(\partial \ln a_2/\partial \ln c_2)_T=1$ below the concentration of inflexion point.

Table IV. The CMC, surface excess and residual area of β-D-alkyl glucosides at 25°C

| Substance | CMC mol./l. | Surface excess $10^{-10}$ mol./cm² | Residual area Å² |
|---|---|---|---|
| Octyl glucoside | 0.025 | 3.9 | 42 |
| Decyl glucoside | 0.0022 | 3.5 | 47 |
| Dodecyl glucoside | 0.00019 | 4.6 | 36 |

The CMC of ionic agents was given as a function of hydrocarbon chain length and the concentration of gegenions[7-10],

$$\log \mathrm{CMC} = -\frac{m\omega}{kT} + K_6 \ln C_i + \text{const.} \qquad (2)$$

where $\omega$ is the cohesive energy change per methylene group passing from the bulk of the solution to the micelle, $m$ the number of carbon atoms in hydrocarbon chain, $K_6$ the experimental constant, $C_i$ the concentration of uni-valent gegenions.

As there is no electrical work accompanying

7) A. B. D. Cassie and R. C. Palmer, *Trans. Faraday Soc.*, 37, 156 (1941).
8) H. Lange, *Kolloid-Z.*, 117, 48 (1950).
9) M. E. Hobbs, *J. Phys. & Colloid Chem.*, 55, 675 (1951).
10) K. Shinoda, This Bulletin, 26, 101 (1953).

the formation of micelles of non-ionic agents, the electrical term in Eq. 2 disappears. The change in CMC as a function of the paraffin chain length may be expressed as,

$$\log \mathrm{CMC} = -\frac{m\omega}{kT} + \text{const.} \quad (3)$$

Actually the CMC of octyl, decyl and dodecyl glucosides decreased to 1/3.4 per one additional methylene group. This relation is similar to that of ionic agents under the condition of a definite concentration of gegenions[11] as will be expected from Eq. 2. In a case where no salt is added, the decrease in CMC of ionic agent is much smaller. Lange has found similar results for octyl, decyl and dodecyl polyoxyethylene ether[12].

The CMC's of mixtures of ionic agents have been studied and interpreted rather well[13,14]. As there is no electrical energy involved in micellization of non-ionic agent, the theoretical treatment is far simpler and the CMC is given as a function of the mole composition of the mixture.

$$\sum \mathrm{CMC}_{mi} \cdot x_i = \mathrm{CMC}_{\mathrm{mix}} \quad (4)$$

$$\sum \mathrm{CMC}_{mi} \frac{x_i' \exp(m_i\omega/kT)}{\sum x_i' \exp(m_i\omega/kT)} = \mathrm{CMC}_{\mathrm{mix}} \quad (5)$$

Where $x_i$ is the mole fraction of the $i$th component in the micelle and $x_i'$ the mole fraction of the $i$th component in the bulk of the solution. The comparison between the calculated and observed CMC values is shown in Table V.

Table V

| Substance | Mole fraction of the latter compound | CMC mol./l. | Calcd. CMC mol./l. |
|---|---|---|---|
| Octyl/Decyl glucoside | 0.089 | 0.0125 | 0.013 |
| Octyl/Dodecyl glucoside | 0.0084 | 0.015 | 0.012 |

It seems very interesting to us that the surface tension vs. concentration curve showed the minimum in the mixture of decyl and octyl glucoside, but the mixture of dodecyl octyl glucoside did not show the recognizable minimum as shown in Fig. 2. The existence of the minimum in the former and non-existence in the latter can be explained as being based on the change in composition at the surface. In the mixture of decyl and octyl glucosides, the more surface-active molecule, decyl glucoside, has lower suface tension over the flat portion, as shown in Fig. 1. The mole fraction of decyl glucoside is relatively large at the surface at the minimum, i. e., at the beginning of micelle formation, whereas the fraction of decyl glucoside decreases above the CMC, due to the increase of the micellar species, and the surface tension approaches that of pure octyl glucoside solution. This discussion may hold for the mixture of homologous compounds of non-ionic agents.

The addition of salts to solutions of non-ionic agents has a relatively small effect compared with ionic agents. Moreover, the slope of surface tension vs. logarithm of concentration curve does not change appreciably in contrast with ionic agents[15]. The effect is not electrical and probably rather indirect. Sodium chloride showed a greater effect than calcium chloride depressing the cloud point[16] and increasing relative viscosity and turbidity[17] of non-ionic agents. The same trend was observed in depressing the CMC. Sodium sulfate of the same concentration shows an even greater effect than sodium chloride. The CMC obtained from the inflexions of surface tension vs. concentration curves are summarized in Table VI.

Table VI. The effect of added salts on the CMC determined by surface tension measurements at 25°C

| Substance | Medium | CMC mol./l. |
|---|---|---|
| Octyl glucoside | $H_2O$ | 0.025 |
| 〃 | 0.93 N $CaCl_2$ | 0.017 |
| 〃 | 0.47 N NaCl | 0.017 |
| 〃 | 0.93 N NaCl | 0.012 |
| 〃 | 0.93 N $Na_2SO_4$ | 0.009 |

The salts of the same ionic strengths do not exhibit the same effect. The volume of salts added, including hydration water, may change the effective concentration of agents and the change in solvent property may decrease the hydration and the CMC decreases.

## Summary

The surface tension in aqueous solutions of β-D-alkyl glucoside and their mixtures at 25°C has been measured. The CMC was determined from the inflexions of the curves; octyl glucoside, 0.025 mol./l., decyl glucoside 0.0022 mol./l., dodecyl glucoside, 0.00019 mol./l. The effect of hydrocarbon chain length was explained theoretically. The CMC of mixtures has been also explained by the extension of the theory of ionic agents. The effect of added sodium chloride, calcium chloride and sodium sulfate

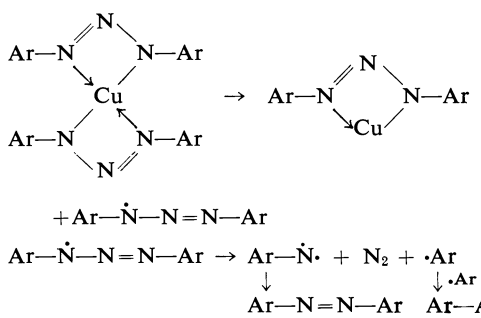
# *Some Copper Complexes of Diazoaminobenzene Derivatives and their Properties**

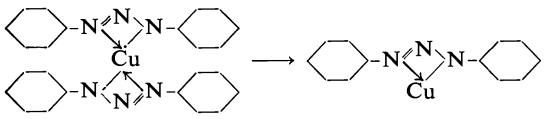
By Hiraku YAMADA, Hiroshi OHTA, Masaru YAMAGUCHI and Tokuichi TSUMAKI



(Received August 13, 1960)

It is well known that the copper(I) complexes of diazoaminobenzene and its derivatives are, in some organic solvents, more stable than the copper(II) complexes. Dwyer et al.[1-6] found that in solution the copper(II) complex of diazoaminobenzene decomposed rapidly into the copper(I) complex by auto-reduction, splitting off the organic fragments. But they did not investigate these fragment. In the present paper are described the synthesis of the copper(II) complexes of diazoaminobenzene derivatives and the isolation and identification of their thermal decomposition products.

As the starting materials for the synthesis of the copper(II) complexes, we chose 4, 4'-dichloro-, 4, 4'-dimethoxy-, 4-chloro-, 4-methoxy- and 4-ethoxydiazoaminobenzenes. The synthesis of their copper(II) complexes was fairly difficult owing to their extreme instability in solution. The synthesis was, therefore, carried out successfully at low temperature, and, in some cases, at temperature as low as possible by cooling with an ethanol-dry ice bath. The complexes were obtained as dark green crystals or powder. In the dry state they are stable, but in solution they become much less stable; and, when heated, they decompose very rapidly into black brown solutions containing tarry substances.



From the tarry substances we could obtain by chromatography on alumina, the copper(I) complexes as yellow to orange-red crystals. From the solution after the separation of the copper(I) complexes a considerable amount of azobenzene derivatives was obtained.

In order to obtain some knowledge concerning the decompositon mechanism, we furthermore investigated the thermal decomposition products of bis(diazoaminobenzene)copper(II) [or bis(1, 3-diphenyltriazenato)copper(II)] and estimated quantitatively nitrogen gas evolved by the thermal decomposition of the copper(II) complexes of diazoaminobenzene derivatives. From bis(diazoaminobenzene)copper(II), only biphenyl, not azobenzene, was obtained. Further it was ascertained that one molecule of nitrogen was evolved per molecule of each of the complexes during the decomposition. It is, therefore, considered most probable that the decomposition of the copper(II) complexes proceeds in the manner shown below.

## Experimental

The following diazoaminobenzene derivatives were synthesized:

4,4'-dichlorodiazoaminobenzene[7],
4,4'-dimethoxydiazoaminobenzene[8],
4,4'-diethoxydiazoaminobenzene[9],
4-chlorodiazoaminobenzene[10],
4-methoxydiazoaminobenzene[11],
and 4-ethoxydiazoaminobenzene[12]

**The Synthesis of the Copper(II) Complexes of Diazoaminobenzene Derivatives.**—*General Remarks*: Since the copper(II) complexes of diazoaminobenzene and its derivatives are very unstable in solution, the synthesis must always be carried out below 0°C.

**Bis(4, 4'-dichlorodiazoaminobenzene)copper(II).**—To a solution of 5 g. of 4,4'-dichlorodiazoaminobenzene in 50 cc. of ethanol is added a solution of 1.8 g. of copper acetate in 100 cc. of the same solvent. The solvent is removed in vacuo, till the precipitate deposits. The precipitate is filtered off and washed with water and then with ethanol. The precipitate is then dissolved in cold acetone and concentrated under reduced pressure at room temperature, when dark green crystals separate out. Dark green plates, which decompose violently at 114°C. Soluble in acetone, ethanol, benzene and chloroform.

Found: C, 48.02; H, 3.02; N, 18.18; Cu, 11.43. Calcd. for $C_{24}H_{16}N_6Cl_4Cu$: C, 48.54; H, 2.72; N, 14.15; Cu, 10.70%.

**Bis(4, 4' - dimethoxydiazoaminobenzene)copper(II).**—To a solution of 5.2 g. of 4,4'-dimethoxydiazoaminobenzene in 100 cc. of ether is added a solution of 1.8 g. of copper acetate in 200 cc. of ethanol, and the mixture is cooled in an ethanol-dry ice bath and stirred well. The color of the solution becomes green. After standing for an hour, the solvent is removed under reduced pressure at room temperature. The precipitate produced is filtered and washed successively with water, ethanol, acetone and ether, and dried. Dark green micro-crystals, which decompose at 200~204°C. Soluble in acetone, ethanol, benzene and chloroform. In solution it is extremely unstable.

Found: C, 58.45; H, 5.08; N, 14.47; Cu, 11.08. Calcd. for $C_{28}H_{28}N_6O_4Cu$: C, 58.37; H, 4.90; N, 14.59; Cu, 11.03%.

**Bis(4, 4'-diethoxydiazoaminobenzene)copper(II).**—To a solution of 5.7 g. of 4,4'-diethoxydiazoaminobenzene in 200 cc. of acetone is added a solution of 1.8 g. of copper acetate in 100 cc. of ethanol, and the mixture is maintained between −10~−20°C for an hour, and after that concentrated under reduced pressure. The precipitate is filtered and washed successively with water, acetone and ether, and dried. Dark green plates, which decompose at 150°C. Soluble in ether, acetone and ethanol.

Found: C, 60.28; H, 6.05; N, 13.20; Cu, 9.92. Calcd. for $C_{32}H_{36}N_6O_4Cu$: C, 60.79; H, 5.74; N, 13.29; Cu, 10.05%.

**Bis(4-chlorodiazoaminobenzene)copper(II).**—To a solution of 4.5 g. of 4-chlorodiazoaminobenzene in 100 cc. of ethanol is added a solution of 1.8 g. of copper acetate in 100 cc. of ethanol, and the mixture is maintained between −10~−20°C for an hour, and then concentrated under reduced pressure at room temperature. The precipitate is filtered, washed successively with water, ethanol, and ether, and dried. Dark green powder, which decomposes at 85~87°C. Soluble in acetone, ethanol and benzene.

Found: C, 57.07; H, 3.84; N, 15.97; Cu, 12.05. Calcd. for $C_{24}H_{18}N_6Cl_2Cu$: C, 54.92; H, 3.46; N, 16.01; Cu, 12.10%.

**Thermal Decomposition of the Copper(II) Complexes of Diazoaminobenzene Derivatives in Solution.**—One per cent solution of each of the copper(II) complexes in acetone, benzene or ether is refluxed on a water-bath. In 15~30 min. the color of the solution changes from green to black-brown, and a tarry precipitate is produced. After 1~3 hr. the decomposition is complete. The tarry precipitate is filtered off from the solution, dissolved in benzene-chloroform-petroleum ether mixture and chromatographed on alumina, when the copper(I) complexes were obtained. The effluent was combined with the filtrate from the tarry precipitate and the combined solution was used for the later operations.

The following copper(I) complexes were obtained.

**4, 4' - Dichlorodiazoaminobenzenecopper(I).**—Yellow needles, which decompose at 242°C explosively. Readily soluble in benzene and chloroform, soluble with difficulty in ether and acetone.

Found: C, 43,47; H, 2.46; N, 12.20; Cu, 19.34. Calcd. for $C_{12}H_8N_3Cl_2Cu$: C, 43.85; H, 2.45; N, 12.78; Cu, 19.33%.

**4, 4' - Dimethoxydiazoaminobenzenecopper(I).**—Orange-red needles, which decompose at 228°C, giving tarry substance. Readily soluble in benzene and chloroform, soluble with difficulty in ether and acetone.

Found: C, 52.95; H, 4.56; N, 13.88; Cu, 19.78. Calcd. for $C_{14}H_{14}N_3O_2Cu$: C, 52.58; H, 4.41; N, 13.14; Cu, 19.87%.

**4, 4'-Diethoxydiazoaminobenzenecopper(I).**—Orange-colored needles, which decompose at 240°C, giving tar. Readily soluble in benzene and ethanol, soluble with difficulty in ether and acetone.

Found: C, 55.59; H, 5.55; N, 12.01; Cu, 18.12. Calcd. for $C_{16}H_{18}N_3O_2Cu$: C, 55.24; H, 5.22; N, 12.08; Cu, 18.26%.

The above-mentioned combined solution was extracted with 1 N hydrochloric acid after the addition of 3~4 times its volume of ether. From this acid extract no identifiable substance was obtained. The remaining ether solution was chromatographed on alumina, using petroleum ether, petroleum benzine and acetone as eluents, when

10) A. Hantzsch et al., ibid., **30**, 1413 (1897).
11) D. Vorländer, ibid., **62**, 2830 (1929).
12) D. Vorländer, ibid., **62**, 2825 (1929).

five fractions were obtained. From the first fraction the following azobenzene derivatives were obtained, and identified by the measurement of the mixed melting point with the authentic samples: 4,4'-dichloroazobenzene, 4,4'-dimethoxyazobenzene, and 4,4'-diethoxyazobenzene. From the fractions following we could not obtain any identifiable substances. We could, further, obtain biphenyl from the decomposition products of bis(diazoaminobenzene)copper(II) in benzene, but in this case we could not notice azobenzene.

**Determination of Nitrogen Gas Evolved during the Decomposition of the Copper(II) Complexes in Solution.**—The solution of 20~25 mg. of the complex in 10 cc. of benzene was heated in an airtight vessel in a stream of carbon dioxide. After removal of benzene vapour through the efficient trap cooled by dry ice, the nitrogen gas evolved was collected on an azotometer. The results are shown below:

| Copper(II) complexes (one mole) | Nitrogen gas evolved (mole) |
|---|---|
| Bis(4, 4'-dichlorodiazoaminobenzene)copper(II) | 0.754 |
| Bis(4, 4'-dimethoxydiazoaminobenzene)copper(II) | 0.952 |
| Bis(4, 4'-diethoxydiazoaminobenzene)copper(II) | 0.836 |
| Bis(4-chlorodiazoaminobenzene)-copper(II) | 0.748 |

The authors wish to express their gratitude to Mr. Michio Shido, Miss Sachiko Indo and Miss Takeko Tahara for the microanalyses.

# *Studies on Heavy-Nitrogen Labeled Compounds. III.*[1] *Preparation of $^{15}N$-Labeled α-Hydroximinopropionic Acid*

By Yoshishige SATO, Teruhiko MESHI and Norio SUGIMOTO

(Received July 16, 1960)

There are a number of methods of preparing $^{15}N$-labeled compounds by using $(^{15}NH_4)_2SO_4$ as a starting substance but there are not many methods which resort to $K^{15}NO_3$. However, the use of $K^{15}NO_3$ as a starting substance will be required, when reactions including diazotization are performed. In 1950, Clusius et al.[2] succeeded in preparing $Na^{15}NO_2$ by the reaction of aqueous solution of sodium hydroxide with a mixture of oxygen and nitric oxide obtained by decomposition of $K^{15}NO_3$. Using $Na^{15}NO_2$ obtained, they prepared potassium azide-$^{15}N$[3], phenyl hydrazine $^{15}N$[2] and diphenyl hydrazine-$^{15}N$[4]. Bothner-By and Friedman[5], in 1951, synthesized 3, 5-dinitrobenzoylazide-3-$^{15}N$ according to the same method as described above.

In this paper synthesis of α-hydroximinopropionic acid-$^{15}N$ was performed by using $K^{15}NO_3$ as a starting substance. For preliminary experiment, $K^{14}NO_3$, $K^{14}NO_2$ and $^{14}NH_2OH \cdot HCl$ were employed for preparing $K^{14}NO_2$, $^{14}NH_2OH \cdot (1/2)H_2SO_4$ and $CH_3C(^{14}NOH)COOH$, respectively. Then, using $K^{15}NO_3$, $CH_3C(^{15}NOH) \cdot COOH$ was prepared without separating the intermediate products: $K^{15}NO_2$ and $^{15}NH_2OH \cdot (1/2)H_2SO_4$.

## Experimental and Results

**Preliminary Experimental by Use of $^{14}N$-Compound.** — *Preparation of $K^{14}NO_2$ from $K^{14}NO_3$.* — In order to reduce $KNO_3$ to $KNO_2$, lead, copper, sodium bisulfite, sodium formate and zinc were used and potassium hydroxide was sometimes employed as an accelerating agent for the reduction in a fused state. The amount of potassium nitrite was measured by the titration with N/10-$KMnO_4$ solution. The data are shown in Table I.

When a mixture of potassium hydroxide with copper, sodium formate or zinc is employed as a reducing agent, a high yield can be obtained as seen from this table.

On the other hand, in the case of the reduction of the aqueous solution, it was found that potassium nitrite was obtained with a greater yield than in the case of the fusion method. The procedure is as follows. Ten milliliter of aqueous solution containing 4 g. of potassium nitrate was

* From literature.

mixed with 30 ml. of 30% aqueous ammonia solution and the mixture was kept below 10°C. Then, 2.6 g. of zinc dust was added in small portions to the mixture. The zinc-oxide was filtered off and the filtrate was concentrated to 3 ml. under vacuo. The yield of potassium nitrite was found to be 85%, when measured by titration with potassium permanganate solution.

**Synthesis of Hydroxylamine Hydrochloride.** — Using potassium nitrite as a starting substance, hydroxylamine hydrochloride was synthesized according to the method of organic syntheses[9]. The aqueous solution of potassium carbonate saturated with sulfur dioxide gas was added to the aqueous solution containing 1.7 g. of potassium nitrite in a vessel, the temperature of which was kept at 0°C. The mixed solution was kept at pH 3 with 7% aqueous solution of sulfurous acid. Two milliliter of acetone was added to it. The acetoxime was hydrolized with concentrated hydrochloride. The yield of hydroxylamine hydrochloride was about 70%.

**Synthesis of α-Hydroximinopropionic Acid.**—In 4 ml. of aqueous solution containing 0.9 g. of pyruvic acid, 0.732 g. of hydroxylamine hydrochloride was added and allowed to stand for one hour. Hydrochloric acid was neutralized by addition of 0.7 g. potassium carbonate powder. After the aqueous solution was neutralized, the solution was concentrated to dryness in vacuo. The solid residue was extracted with 100 ml. of ether, and α-hydroximinopropionic acid was obtained by removing ether. The yield is 85% on the basis of hydroxylamine hydrochloride and about 50% on the basis of potassium nitrate.

**Synthesis of α-Hydroximinopropionic Acid-$^{15}$N.** —α-Hydroximinopropionic acid-$^{15}$N was synthesized by the method described above. The procedure is as follows. Two and a half grams of $K^{15}NO_3$ ($^{15}$N atom % : 88%) was dissolved in an aqueous ammonia solution and kept below 10°C. Zinc powder (1.6 g.) was added for the reduction of $K^{15}NO_3$ to $K^{15}NO_2$. After the deposited zinc oxide was removed by filtration, the solution was concentrated to 10 ml., kept at 0°C and made pH 3 with 7% sulfurous acid. Further 0.4 ml. of concentrated sulfuric acid was added to the solution in order to hydrolize the reaction product and refluxed for five hours. Into the hydrolized solution, 50% aqueous solution containing 1.5 g. pyruvic acid was added and allowed to stand for one hour. Using the powder of potassium carbonate, the liberated sulfuric acid was neutralized and its solution was concentrated to dryness in vacuo. The residue was extracted with 100 ml. of ether. Water in the extracted ether solution was removed by anhydrous sodium sulfate and ether was removed in vacuo to give α-hydroximinopropionic acid-$^{15}$N. The yield is 1.55 g. and 61.5% on the basis of $K^{15}NO_3$.

## Summary

By use of $K^{15}NO_3$ as a starting material, α-hydroximinopropionic acid-$^{15}$N was synthesized in accordance with the following reactions:

$$K^{15}NO_3 \rightarrow K^{15}NO_2 \rightarrow {}^{15}NH_2OH \rightarrow CH_3C(={}^{15}NOH)COOH$$

The above reactions were carried out without separating any intermediate products. The yield of α-hydroximinopropionic acid-$^{15}$N was about 61% on the basis of $K^{15}NO_3$.

# *The Resonance Effect of Amide Group on the Polymerizability of Lactam Derivatives. I. The Infrared Spectrum of N-Methyl Lactams**

By Naoya OGATA

(Received July 7, 1960)

The amide linkage of chain amide molecule tends to take a planar structure owing to the resonance in the molecule[1]. The two configurations of cis and trans forms shown below are possible:

trans form cis form

It it known that the trans form of an amide group is more stable than the cis form and monosubstituted acid amide RCONHR′ takes the trans[1,2] form, while lactams of less than 9 membered rings take the cis form owing to the steric hindrance[3].

It has been reported on the polymerizability of ε-caprolactam that the configuration of the amide group relates to its reactivity[4] and *N*-alkyl-substituted derivatives of the cis amide such as *N*-methyl-ε-caprolactam are too stable to polymerize[5].

The great stability of *N*-alkyl-substituted lactams can not be explained from the difference in the ring strain or in the thermodynamical character[6] caused by the intramolecular rotational isomerism, but it is supposed to be due to the increase of resonance in the amide group[7]. Therefore, the infrared spectra of several chain and cyclic amide compounds have been measured with special interest in the range of 1600~1800 $cm^{-1}$, and the effect of the resonance on the characteristic band of the amide group has been investigated.

## Experimental

The infrared spectra of several amide compounds were measured with a Hitachi model EPI-2 spectrophotometer in the range of 2~15 $\mu$, with a rock salt prism. The cell thickness was 0.01 mm.

The infrared spectra of chloroform solution of *N*-alkyl-substituted chain or cyclic amides were measured in the range of 5.5~6.5 $\mu$ at various concentrations and temperatures. The cell thickness was selected suitably so that the transmittance at the absorption maximum is within the range of 20 ~80%. Although it is desirable to use a nonpolar solvent such as carbon tetrachloride, *N*-methyl lactams do not dissolve in carbon tetrachloride.

## Results

The infrared spectra of several amide compounds are shown in Figs. 1—5. The frequencies of the carbonyl absorption (amide I band) of these compounds are shown in Table I, in which values in parentheses mean the frequencies of shoulders in the amide I band. The absorptions of the chloroform solution of *N*-methyl lactams are shown in Fig. 6. *N, N*-Disubstituted chain amide shows a sharp absorption at 1626 $cm^{-1}$ (Fig. 7), while the amide I band of *N*-methyl lactams splits into

## Discussion

*N*-Methyl-ε-caprolactam is too stable to polymerize at a temperature over 200°C and *N*-methyl-ε-aminocaproic acid transforms easily into *N*-methyl-ε-caprolactam by heating[8].

The rate of hydrolysis[7] of *N*-methyl-ε-caprolactam into *N*-methyl-ε-aminocaproic acid is much slower than that of ε-caprolactam. Since the cyclic structure of *N*-methyl-ε-caprolactam is the same as that of ε-caprolactam, it is supposed that this stability of *N*-methyl-ε-caprolactam is not due to the change in the ring strain, but to the increase of the resonance in the amide group as shown below by the −I effect of the methyl group:

All *N*-monosubstituted acid amides show a strong absorption band usually near 1640 $cm^{-1}$ in the solid state[8,9]. The lower frequencies of the carbonyl absorption of these amides are considered to be due to the resonance with the ionic form. The shifts of the carbonyl absorption towards lower frequencies by the *N*-alkyl substitution, therefore, seem to suggest the increase of the resonance in the amide group.

As stated before, the infrared spectra of *N*-methyl lactams with less than 7 membered rings exhibit a doublet or triplet in the region of the amide I band, and this is not caused by the interaction among molecules or by the solvent effect, since the molar extinction coefficients of these amide I bands in the chloroform solution are hardly influenced by the change of the amide compounds. The changes with temperature of the molar extinction coefficients of these absorption peaks are different from each other, as can be seen from Fig. 6. The elucidation of the cause of this interesting fact requires further investigation. The frequency of the maximum intensity among these doublets or triplets shifts towards lower frequencies with the enlargement of the ring. These bands are now named amide I-a, I-b and I-c in the order of the increasing frequency, respectively. These are shown in Table VI.

The integrated intensity of these split amide I bands was measured as follows: a point by point measurement of $\log(I_0/I)$ was made at intervals of 0.02 μ in the range of 5.5~6.5 μ and these data were plotted against the wavelength and the area under the curve was

8) H. Yumoto, K. Ida and N. Ogata, ibid., 31, 249 (1958).
9) H. K. Hall, Jr. and R. Zbinden, *J. Am. Chem. Soc.*, 80, 6428 (1958).

graphically determined. The true integrated absorption intensities were obtained by the method proposed by Ramsey[10]. The integrated absorption of the amide I band is almost unaltered with the ring size, as shown in Table VII. Therefore, these split absorptions are estimated to be due to the amide group.

## Summary

The infrared spectra of several *N*-methyl lactams and acid amides have been measured in chloroform solution in order to investigate the correlation between the polymerizability of lactams and the frequencies of the carbonyl absorption of the amide group. The observed frequency lowering of the amide I band by *N*-methyl substitution can be related to the increasing contribution of the ionic structure to the resonance in the amide group, and to the low polymerizability. The infrared spectra of *N*-methyl lactams exhibit doublets or triplets in the carbonyl stretching region.

The author wishes to express his sincere gratitude to Dr. H. Kobayashi and Dr. H. Yumoto for their instruction in these studies and for their permission to publish the results. Thanks are also due to Mr. M. Nakata who collaborated with him in experiments.

# *The Resonance Effect of Amide Group on the Polymerizability of Lactam Derivatives. II*. The Basicity of Amide Group of Lactams***

By Naoya OGATA

(Received July 23, 1960)

Th polymerizability of lactams becomes very small by *N*-alkyl substitution[1,2]. *N*-Methyl-ε-caprolactam, for instance, is too stable to polymerize at a temperature above 200°C and *N*-methyl-ε-aminocaproic acid converts easily into *N*-methyl-ε-caprolactam by heating. The increase in the stability of the ring structure by the *N*-alkyl substitution of lactams is explained[3] from the increase of resonance in the amide group as shown below:

If the resonance effect of the amide group increases by *N*-alkyl substitution, it is expected that the basicity of the amide group will decrease. In this connection, an addition reaction of hydrogen chloride with several cyclic or chain amides has been investigated by the measurement of the infrared spectrum.

## Experimental

**Measurement ot the Infrared Spectrum of Addition Products of Hydrogen Chloride and Amide Compounds.**—A chloroform solution of hydrogen chloride of 0.15 mol./l. was prepared by introducing dry hydrogen chloride gas into chloroform. This hydrogen chloride solution was diluted with chloroform to the concentrations of 0.08, 0.04, 0.02 and 0.01 mol./l. and 3.5 cc. of each of the solutions was mixed with 3.5 cc of a chloroform solution of several amide compounds of 0.04 mol./l.

The infrared spectra of the mixtures and the amide solutions were measured by a Hitachi model EPI-2 spectrophotometer with a rock salts prism, using hydrogen chloride-chloroform solution or pure chloroform as reference, respectively.

**Determination of Equilibrium Constant of the Addition Reaction between the Amide Group and Hydrogen Chloride.**—The equilibrium constants of the addition reaction between the amide group and hydrogen chloride were determined for several cyclic or chain amides by the intensity measurement of the carbonyl absorption in the infrared spectra.

The calibration curves for several amide compounds in chloroform were determined by measuring absorbances of the amide I band at 20°C which are shown in Figs. 1 and 2. The calibration curves at

* I, This Bulletin, **34**, 245 (1961).

** Presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

3) N. Ogata, ibid., **32**, 813 (1959).

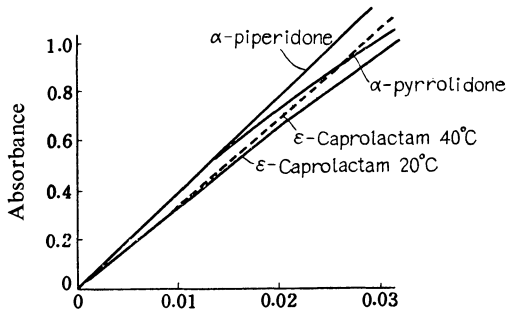

Fig. 1. The calibration curves for several lactams in chloroform solutions.

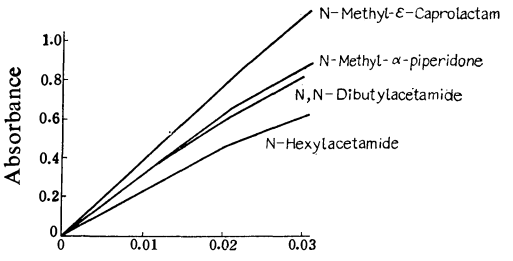

Fig. 2. The calibration curves for several amides in chloroform solutions.

40 and 55°C were almost the same as those at 20°C.

The concentrations of amide [-NHCO-] in chloroform solutions in the presence of hydrogen chloride were determined by these calibration curves. As hydrogen chloride has a tendency to be volatilized with rise of temperature, infrared spectra were measured for the narrow range of 1400~1800 $cm^{-1}$ to avoid the change of concentration. The concentration of hydrogen chloride in chloroform was determined by titrating with N/100 sodium hydroxide.

The equilibrium constant $K$ of the addition reaction between the amide group and hydrogen chloride can be calculated as follows:

$$[\text{-NH}_2^+\text{CO-}] = [\text{-NHCO-}]_0 - [\text{-NHCO-}]_{HCl}$$

$$[H^+] = [HCl] - [\text{-N}^+\text{H}_2\text{CO-}]$$

$[\text{-NHCO-}]_0$: Initial concentration of amide

$[\text{-NHCO-}]_{HCl}$: Concentration of amide in the presence of HCl

$$K = \frac{[\text{-N}^+\text{H}_2\text{CO-}]}{[\text{-NHCO-}][H^+]}$$

## Results

Figs. 3—9 show the spectra, where a solid line represents the spectrum of the chloroform solution of the amide compound in the presence of hydrogen chloride and a dotted line the spectrum of the amide compound only.

In the presence of equal moles of hydrogen chloride and amide, the N—H absorption of cyclic or chain amides in the 3400~3500 $cm^{-1}$ region is replaced by a broad absorption in the 2000~2400 $cm^{-1}$ region and the intensity of the C=O absorption near 1650 $cm^{-1}$ becomes weaker, accompanied by the appearance of a weak absorption in the 1750~1800 $cm^{-1}$ region as shown in Table I.

The whole infrared spectrum of secondary or tertiary chain amide is not much altered in the presence of hydrogen chloride, while that of cyclic amide is altered considerably, accompanying a new absorption in the 1560~1640 $cm^{-1}$ region.

The broad absorption in the 2000~2400 $cm^{-1}$ region which appears in the chloroform solution of the amides in the presence of hydrogen chloride is supposed to be due to the $\rangle N^+H_2$ stretching motion.

The values of $K$ at various concentrations of hydrogen chloride at 20, 40 and 55°C are shown in Table II. Table III shows the mean values of $K$ for several amide compounds. The value of $K$ decreases with the rise of temperature. $K$ for chain amides is considerably smaller than that for cyclic amides. The values of $K$ for cyclic amides increase with the enlargement of the lactam ring and those for tertiary amides are smaller than those for the corresponding secondary amides, especially for lactams.

From the slope of the linear relationship between the logarithm of $K$ and reciprocals of absolute temperatures as shown in Fig. 10, heats of the addition reaction of the amide with hydrogen chloride are obtained. These are shown in Table IV. The heats of the addition reaction for cyclic amides become lower

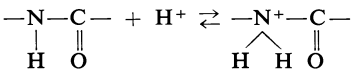
| *N*,*N*-Dibutylacetamide | 4.1 |
| *N*-Hexylacetamide | 2.2 |

with the enlargement of the ring and those for chain amides are generally lower than those for cyclic amides.

## Discussion

The configuration of the amide group takes a planar structure owing to the resonance and two configurations of trans and cis forms are possible. It is known[4-7] that chain amides take the trans form, while cyclic amides of less than 9 membered rings take the cis form.



Although the basicity of the nitrogen atom of the amide becomes very weak by the +E effect of the carbonyl group, the amide group acts as a base, adding a proton[8]. It has been reported[9] that chain amide reacts with hydrogen chloride forming an addition product with 1/2 or 1 mol. of hydrogen chloride to 1 mol. of amide. The structure of the 1/2 mol. salt is proposed[9] as follows:

The intensity of the absorption which appears in lactams near 1800 $cm^{-1}$ in the presence of hydrogen chloride becomes stronger with the enlargement of the lactam ring. This absorption shifts towards 1759 $cm^{-1}$ in the case of *N*-methyl lactams or tertiary amide.

It has been presumed[10] that the higher frequencies of the carbonyl absorption of acid halide, which appears near 1800 $cm^{-1}$, is due to the strong +I effect of the halogen atom. Therefore, it is expected that the absorption near 1800 $cm^{-1}$ in the amide-hydrogen chloride addition product may be the free carbonyl absorption which shifts towards higher frequencies by the increase in the electron affinity of the nitrogen atom of the amide.

It is supposed that a proton adds to the nitrogen atom of the amide group as shown in the following equation, since the N—H absorption disappears and new absorption due to the $\rangle N^+H_2$ and the free C=O stretching motion (near 1800 $cm^{-1}$) appear in the infrared spectrum of the amide hydrogen chloride addition product.

Primary and secondary amides show a strong absorption in the 1600~1500 $cm^{-1}$ region, which is absent from those of cyclic lactams, and this band is refered to generally as the amide II band. The origin of the amid II band is generally supposed to be due to a mixed vibration which can be described as an out-of-phase combination of OCN and NH vibrations. The frequency of the amide II band of secondary amide shifts from 1530 $cm^{-1}$ to 1550 $cm^{-1}$ in the presence of hydrogen chloride, as shown in Fig. 9. This is explained from the increase in the ionic character of the N—H linkage by the addition of a proton.

The addition products of lactams and hydrogen chloride show a sharp absorption in the region of 1570~1640 $cm^{-1}$. This absorption does not appear in *N*-methyl lactams or tertiary chain amides in the presence of hydrogen chloride. It is supposed that this band may be assigned to the N—H deformation vibration. The assignment of this band to the C—N stretching motion is not accepted, since no absorption in the 1570~1640 $cm^{-1}$ region appears in tertiary cyclic or chain amides in the presence of hydrogen chloride.

The equilibrium constants $K$ of the addition reaction of hydrogen chloride and cyclic amide (cis form) are considerably greater than those of chain amide (trans amide). It is supposed that the basicity of the nitrogen atom of the cis amide may increase owing to the decrease of resonance in the amide group. The addition of hydrogen chloride to cyclic amide becomes easier with the enlargement of the ring, as shown by the greater value of $K$ and the lower heat of addition reaction.

The values of $K$ for $N$-methyl lactams are considerably smaller than those for the corresponding lactams and they are almost the same as those for tertiary chain amide. The heat of the addition reaction of hydrogen chloride with amide becomes higher with the $N$-methyl substitution of an amide hydrogen in lactams. This is expected to be due to the fact that the amide group is stabilized by hyperconjugation of methyl group as well as the increase in resonance by the $-I$ effect of methyl group. It is presumed that the small polymerizability of $N$-methyl-substituted lactams is due to the increase of resonance in the amide group.

## Summary

The addition reaction of hydrogen chloride with several cyclic or chain amides has been investigated by the infrared absorption measurement in order to study the correlation between the polymerizability of lactams and the resonance in the amide group. The equilibrium constant $K$ for the addition reaction with cyclic amide (cis form) is 150~180 and it becomes greater with enlargement of the ring size, while $K$ for $N$-methyl lactams is about 30~40. The $K$ value for secondary chain amide (trans form) is 60. The heat of the addition reaction of hydrogen chloride with lactams becomes lower with the enlargement of the lactam ring and also with the $N$-methyl substitution of the amide hydrogen.

The stronger basicity of the cis amide compared with the trans amide may be due to the decrease of resonance in the amide group, and the stabilization of the lactam ring by the $N$-methyl substituion may be ascribed to the increase in resonance by hyperconjugation of the methyl group.

The author wishes to express his sincere gratitude to Dr. H. Kobayashi and Dr. H. Yumoto who instructed him through these studies and permitted him to publish the results. Thanks are also due to Mr. M. Nakata for his collaboration in experiments.

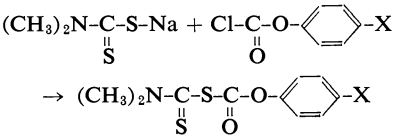
# *Studies on the Thiocarbamoylthiocarbonates. I. Synthesis of Aryl Thiocarbamoyldithiocarbonates*



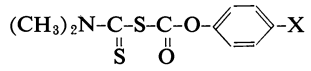
By Aritsune KAJI

(Received July 26, 1960)

*O*-Alkyl *S*-(*N*, *N*-disubstituted-thiocarbamoyl)-thiocarbonates were studied by Cambron[1] and Lo[2]. Lo reported that these alkyl esters, except isopropyl ester, were unstable and decomposed even at room temperature. No report on the aryl esters of this thiocarbonic acid has been given. The present author succeeded in the synthesis of these aryl esters.

## Results and Discussion

Aryl chloroformates reacted with sodium dimethyldithiocarbamate in acetone, giving *O*-aryl *S*-(*N*, *N*-dimethylthiocarbamoyl) thiocarbonates as shown in Table I.



(X: -H, $-CH_3$, -Cl) (1)

But these esters were unstable and decomposed even at room temperature within a few weeks.

Aryl chlorothionoformates reacted with sodium or ammonium dialkyldithiocarbamates, giving various *O*-aryl *S*-(*N*, *N*-dialkylthiocarbamoyl) dithiocarbonates in good yields as

1) A. Cambron, *Can. J. Res.*, **2**, 341 (1930).
2) C. Lo and W. E. Craig, Japanese Pat. 253207 (1958).

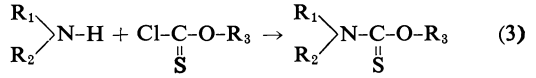
shown in Tables II—V. *O*-Aryl *S*-(*N*-alkyl-*N*-arylthiocarbamoyl) dithiocarbonates and *O*-aryl *S*-(*N*, *N*-diarylthiocarbamoyl) dithiocarbonates were also given by the similar reaction and listed in Table VI. In these reactions, water, methanol, ethanol, acetone and benzene can be used as the reaction medium. These aryl esters of *S*-(*N*, *N*-disubstituted-thiocarbamoyl)-dithiocarbonic acid, isolated as yellow or orange crystals when recrystallized from acetone-ethanol, were stable at room temperature.

*O*-Aryl *S*-(*N*-monosubstituted-thiocarbamoyl)-dithiocarbonates could not be isolated by the reaction between aryl chlorothionoformates and sodium *N*-monoalkyl- or *N*-monoaryl-dithiocarbamates, because of their decomposition during the reaction period.

It was concluded that both of the two hydrogen atoms connected with the nitrogen atom of the thiocarbamoyl group must be substituted to stabilize these dithiocarbonates.



The substituents of the aryl group, as shown in Tables II—VI, did not have such strong effects on the stability of the esters which were kept at a lower temperature than their respective melting points.

Aryl esters of *S*-(*N*, *N*-disubstituted-thiocarbamoyl) dithiocarbonic acid decomposed when heated at the melting points for a long period, giving carbon disulfide and *O*-aryl *N*, *N*-disubstituted thionocarbamate as shown in Table VII.

(2)

These thionocarbamates showed no depression of the melting point on the admixture with *O*-aryl *N*, *N*-disubstituted-thionocarbamates prepared from *N*, *N*-disubstituted-amines and aryl chlorothionoformates.

(3)

## Experimental

**Starting Materials.**—Sodium or ammonium salts of *N*,*N*-disubstituted-dithiocarbamic acid were synthesized by the known methods[3]. Aryl esters of chlorothionoformic acid were prepared as follows: To a solution of 1 mol. of thiophosgen and 1 mol. of phenol in chloroform was added gradually 1 mol. of sodium hydroxide (5% aqueous solution) under vigorous agitation. The temperature was kept at 5~10°C during the reaction period of 30 min. The chloroform layer was washed with water and dried over calcium chloride. The removal of chloroform gave esters which could be used in the following reaction without further purification.

***O*-(3,5-Dimethyl-4-chlorophenyl) *S*-(*N*,*N*-dimethylthiocarbamoyl)dithiocarbonate.**—To a solution of 14.3 g. (0.1 mol.) of sodium dimethyldithiocarbamate in 100 cc. of water was added gradually 23.5 g. (0.1 mol.) of 3,5-dimethyl-4-chlorophenyl chlorothionoformate keeping the temperature at 10~15°C during the reaction period of 2 hr. By the filtration of the reaction mixture, 27.2 g. (yield, 85%) of yellow crystals with m. p. 112~114°C were obtained. Recrystallization from acetone-ethanol gave yellow prisms with m. p. 113~114.5°C.

3) Houben-Weyl, "Methoden der organischen Chemie", 9, Georg Thieme Verlag, Stuttgart (1955), p. 826.

***O*-(4-Chlorophenyl) *S*-(*N*-methyl-*N*-phenylthiocarbamoyl)dithiocarbonate.**—To a solution of 20 g. (0.1 mol.) of ammonium *N*-methyl-*N*-phenyldithiocarbamate in 200 cc. of acetone was added gradually 21 g. (0.1 mol.) of 4-chlorophenyl chlorothionoformate keeping the temperature at 5~10°C during the reaction period of 1 hr. The reaction mixture, poured into 500 cc. of cold water, gave 31 g. (yield, 85%) of yellow precipitates with m. p. 132~134°C. Recrystallization of the preceipitates from acetone-ethanol gave yellow prisms with m. p. 133~134°C.

The other esters shown in Tables II—VI were synthesized in the similar way.

**4-Tolyl *N*,*N*-dimethylthionocarbamate.**—In an oil bath, 0.45 g. of *O*-(4-tolyl) *S*-(*N*,*N*-dimethylthiocarbamoyl)dithiocarbonate was kept at 160°C for 1 hr. After the subsidence of evolution of carbon disulfide, the reaction mixture was cooled to room temperature. Twice repeated recrystallization of the reaction mixture from 0.5 cc. of ethanol, gave 0.2 g. (yield, 62%) of 4-tolyl *N*,*N*-dimethylthionocarbamate with m. p. 95~96°C.

The author wishes to express his sincere thanks to Professor Dr. Ryozo Goto, Kyoto University, for his guidance and encouragement throughout this work.

# *Spectrophotometric Determination of Submicrogram Quantities of Orthophosphate in Natural Waters*

By Ken SUGAWARA and Satoru KANAMORI

(Received August 13, 1960)

In advanced researches of natural waters, need is felt for a method of determining phosphate more sensitive than the current Dénigè's colorimetric method[1] especially when the quantity of the sample is limited. Such a need is partly filled with the radioactivation method[2,3]. However, a nuclear reactor is not easily accessible. Furthermore, irradiation and cooling are time-consuming. This situation initiated the present work.

It is true that there have been made various trials to increase the sensitivity of the determination of phosphate by the use of solvent extraction of phosphomolybdate[4-7] where the yellow complex is extracted with an organic solvent to be directly or after reduction to molybdenum blue subjected to spectrophotometry. These methods, however, are not sufficiently sensitive to determine submicrogram quantities of the compound. The authors' idea was to step up this increased sensitivity. Thus the phosphomolybdate which was once extracted in an *n*-butanol-chloroform mixture is decomposed into the components. Then, the

liberated molybdenum is separated to be spectrophotometrically determined as thiocyanate complex whereby 0.02~1.00 μg. of phosphorus as phosphate in a water sample less than 250 ml. can be determined with an accuracy of an error less than 5%.

## Experimental

**Apparatus.**—Absorbance was measured with a Beckman spectrophotometer model DU by using 10 mm. cells of Pyrex glass.

**Reagents.**—Hydrochloric acid, concentrated.

*n*-Butanol and chloroform, distilled.

*n*-Butanol-chloroform mixture: *n*-Butanol and chloroform are mixed in the proportion of 3 : 7 by volume.

Ammonium molybdate solution, 10%.

Washing solution. Thirty mlliliter of *n*-butanol is dissolved in 500 ml. of 0.5 N nitric acid.

Sodium hydroxide solution, 1N.

Ferrous ammonium sulfate solution: In 100 ml. of 0.2 N sulfuric acid 1 g. of the hexahydrate is dissolved.

Potassium thiocyanate solution, 10%.

Stannous chloride solution: In 100 ml. of 1 N hydrochloric acid 10 g. of the dihydrate is dissolved.

Phosphate standard solution: The stock solution which contains 1 mg. of phosphorus as phosphate per ml. is prepared by dissolving 0.439 g. of dihydrogen potassium phosphate in distilled water and making it up to 100 ml. The addition of a few drops of chloroform keeps the solution from mold growth. The working standard solutions are prepared by properly diluting the stock solution.

**Procedure.** — A sample is properly diluted or evaporated so that 250 ml. contains 0.02~1.0 μg. of phosphorus. After having been filtered, if necessary, this 250 ml. is placed in a 500 ml. separatory funnel. Then, 10 ml. of hydrochloric acid, 15 ml. of *n*-butanol and 10 ml. of the *n*-butanol-chloroform mixture are added. The funnel is shaken for 1 min. to saturate the aqueous phase with the mixed solvent. When two layers clearly separate, the organic layer is drawn out to be replaced by a new addition of 5 ml. of the ammonium molybdate solution and 5 ml. of the mixed solvent. Two minutes shaking follows whereby the phosphomolybdate is formed and extracted into the solvent. The extract is transferred into a 100 ml. funnel. The extraction is repeated by using another 5 ml. of the mixed solvent. The two extracts are combined and shaken for 1 min. with 50 ml. of the washing solution, whereby the uncombined molybdate is completely washed out. The remaining organic layer which contains exclusively phosphomolybdate is transferred into a 50 ml. separatory funnel. After the addition of 10 ml. of 1 N sodium hydroxide solution and 5 ml. of distilled water, the funnel is shaken for 1 min. to strip the phosphomolybdate completely from the oily phase by the aqueous alkali solution. After 15 min. standstill during which the decomposition of the phosphomolybdate into molybdate and phosphate is complete, the organic layer is drawn off. With swirling, 3 ml. of concentrated hydrochloric acid, 1 ml. of ferrous ammonium sulfate solution, 3 ml. of thiocyanate solution and 3 ml. of stannous chloride solution are added successively. An amber color develops immediately. This is extracted with two small portions of the mixed solvent and made up to 5 ml. To the joint extract a few small crystals of stannous chloride are recommended to be added to protect the ferrous iron from oxidation. Otherwise ferric thiocyanate is formed to cause a high blank value because of its red coloration. The quantity of phosphate is determined from the absorbance reading at 475 mμ in reference to the standard curve. The curve has previously been constructed by following the same procedure with the standard solutions at different dilutions.

## Discussion

**Extraction of Phosphomolybdate.** — The extraction must proceed on a condition where following two requirements are satisfied: 1) The extraction must be complete. 2) The possible contaminations of arseno-, germano- and silicomolybdate must be avoided. To this

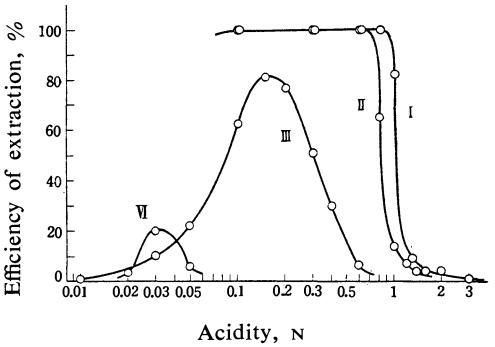

Fig. 1. Effect of the acidity on the extraction of heteromolybdates with *n*-butanol.
I Phosphomolybdate
II Arsenomolybdate
III Germanomolybdate
IV Silicomolybdate

aim an appropriate solvent and the range of acidity where the solvent is most efficiently active were sought. Two sets of 50 ml. of arsenate, germanate and silicate solutions, each containing 10 $\mu$g. of one of the three elements, As, Ge and Si, were prepared and adjusted to various acidities with hydrochloric acid. Then, after the addition of 1 ml. of 10% ammonium molybdate solution, one of the sets was extracted with *n*-butanol, while another set with the *n*-butanol-chloroform mixture. The extracts were processed with 1.0% stannous chloride solution (1 N in hydrochloric acid) to reduce and strip the extracted heteropolyacids which were subjected to spectrophotometry to determine the efficiency of these extractions. As is seen from Figs. 1 and 2, the results point to the fact that the extraction is practically complete in a wider range of acidity from 0.1 to 0.8 N with *n*-butanol as compared with the range from 0.5 to 0.6 N with the mixed solvent. However, in these ranges, separation of phosphate from arsenate, germanate and silicate is not complete with *n*-butanol, while it is nearly complete with the mixed solvent. Thus the *n*-butanol-chloroform mixture is only acceptable as a solvent.

**Standard Curve***.—Standard curves for three different methods are compared in Fig. 3, where the high sensitivity of the authors' method is quite evident.

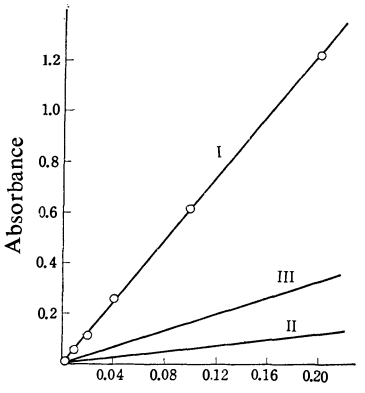

Fig. 3. Standard curves.

I The present method
II Molybdenum blue method (940 m$\mu$)
III Simple phosphomolybdate extraction method (245 m$\mu$)

**Washing of the Extract.**—This treatment is indispensable for removing the contamination of unbound moybdate which otherwise gives a higher apparent value at the final spectrophotometry. To check this point, samples containing 0.50 $\mu$g. of phosphorus and samples with

* Sulfuric acid was used in place of hydrochloric acid for the extraction of phosphomolybdate.

* The molar extinction coefficient of molybdenum thiocyanate under the present experimental condition was determined as $1.55\times10^4$ l. per mol. cm. and the corresponding value of phosphate $1.85\times10^5$ l. per mol. cm. Thus, the atom ratio of phosphorus to molybdenum is calculated to be 1/12 within an experimental error.

no phosphorus were processed according to the procedure in which they were subjected to one to three washings. The results listed in Table I show that the blank value is already nearly zero after one washing. This points to the fact that one washing is sufficient to completely remove free molybdate from the extract. On the other hand, the phosphate value remains constant even after three washings. This shows that there is no risk for the extracted phosphomolybdate to escape through the washing.

**Interference.** — The interference of various ions with the present determination of phosphate was examined with the results listed in Table II.

A) An error of 5% is found only with a concentration of 100 $\mu$g. As/50 ml. for arsenate, with 100 $\mu$g. Ge/50 ml. for germanate, and with 5 mg. Si/50 ml. for silicate. B) $Na^+$, $K^+$, $Mg^{2+}$, $Ca^{2+}$, $Cl^-$, $SO_4^{2-}$ and $NO_3^-$ cause no interference up to a considerable concentration. C) Tungstate and vanadate may be partly extracted in the mixed solvent to cause a considerable interference. However, the concentration of these elements in usual natural waters is too small to consider their interference. The same thing can be said in the case of titanium. In conclusion, the present method of phosphate determination can be safely applied to usual waters with no special consideration of the interference which might be caused by co-existing elements. Examples of the application of the method to several natural waters are listed in Table III.

# *Reduction of Organic Compounds with Urushibara Catalysts under High Pressure. VII*[1]*. Feature of Various Urushibara Catalysts as Revealed in the Reduction of Benzophenone*

By Shinichi TAIRA

(Received August 22, 1960)

In the previous paper[2] of this series, catalytic reductions of ketones under high pressure with Urushibara nickel B were reported. In the present paper, reduction of benzophenone with various Urushibara catalysts under various conditions was investigated.

The preparation of the Urushibara nickel catalyst has been successively modified, and some varieties of this catalyst were reported. Each of these Urushibara nickel catalysts is prepared by digesting precipitated nickel with alkali or acid. In the original preparation[3], nickel was precipitated from nickel chloride solution with zinc dust, and digested with caustic alkali to obtain U-Ni-B. The alternative catalyst U-Ni-A[4] was prepared by digesting the precipitated nickel with acetic acid or propionic acid instead of caustic alkali. The third catalyst U-Ni-BA[1,5] was developed by modifying the preparation of U-Ni-B, using aluminum grains instead of zinc dust for precipitating nickel metal from nickel chloride solution. Each of these Urushibara nickels has been found to have a comparable activity with the Raney nickel for the hydrogenation of various organic compounds.

Now it is expected that metallic cobalt and metallic copper prepared by the same procedure as to obtain the Urushibara nickel may have

5) K. Hata, S. Taira and I. Motoyama, ibid., **31**, 776 (1958).

catalytic activities for hydrogenation. Actually it was already reported[6] that Urushibara cobalt B had a property similar to Raney cobalt and was recognized to be useful for the hydrogenation of nitriles. A similar copper catalyst was also reported[7] to be prepared from copper sulfate solution and zinc dust.

In case of catalytic reduction under high pressure, the reaction velocity may be influenced by various factors, namely, the nature of the groups to be reduced, the purity of substance, the activity and quantity of catalyst, the kind of solvent, the concentration and pH value of solution, the pressure of hydrogen, the temperature of reduction, the efficiency of agitation, etc. The temperature at which the absorption of hydrogen gas begins, or the time or the quantity of catalyst required for the completion of reduction, may be regarded as a measure to determine the activity of the catalyst.

In the present experiments, reduction of benzophenone is selected as an example for determining the activities of Urushibara catalysts prepared by various methods. The time required for reducing the ketone to benzhydrol was compared with each other under a similar condition.

## Experimental

**Apparatus.** — Reductions were carried out in a Sakashita SE-20, electro-magnetically stirring type autoclave having a capacity of 200 ml.

**Materials.** — Benzophenone was prepared from benzoyl chloride and benzene by the Friedel-Crafts reaction[8]. The raw product was submitted to vacuum distillation and then recrystallized twice from ethanol, b. p. 140~141°C/5 mmHg, m. p. 48°C.

**General Procedure for Reduction.**—The catalyst containing 1 g. of nickel, cobalt, or copper was carefully transferred with ethanol into the autoclave. Then air in the autoclave was replaced by hydrogen gas. Most operations were carried out under the following conditions: (1) benzophenone; 12.74 g. (0.07 mol.) (2) ethanol(99%); 110 ml. (3) pH; 9~11 (When Urushibara catalysts A and CA were used, 0.5 ml. of 10% sodium hydroxide solution was added.) (4) agitation; 40~50 strokes per minute (5) temperature; Since a remarkable reduction of carbonyl compounds was found to begin at about 60°C as was reported in the previous paper[2], agitation was started when the temperature in the autoclave was reached at 60°C, and it was kept between 58° and 70°C. (6) Pressures were observed at intervals of five minutes.

After the reduction was finished and the autoclave got cold, hydrogen gas was discharged and the contents were taken out with ethanol. The catalyst was filtered off and washed with ethanol. The major part of the combined solvent was distilled off and the hot residue was poured into 300 ml. of hot water with stirring. The crude benzhydrol was filtered off and dried. It was recrystallized from ligroin into colorless silky needles, m. p. 68~69°C. Yield, 90~95% of the theoretical. It did not depress the m. p. with an authentic sample.

**Preparation of Catalysts.**—The Urushibara nickel B[3], the Urushibara nickel A[4] and the Urushibara nickel BA[1,5] were prepared by the methods described in the references cited. Some new types of Urushibara catalysts were prepared as follows. The procedures described below are the methods for the preparation of the catalysts, each containing 1 g. of catalyst metal.

*(a) Urushibara Nickel B (U-Ni-B) Prepared from Nickel Acetate.*—On a boiling water bath 4.24 g. of nickel acetate ($Ni(CH_3CO_2)_2 \cdot 4H_2O$) is dissolved in 20 ml. of water. This hot solution is added at once with stirring by hand onto a hot mixture of zinc dust (10 g.) and water (10 ml.) placed in a 500 ml. beaker warmed on a boiling water bath. As a vigorous reaction takes place and the reaction mixture swells up, good agitation is required to prevent the contents running over. When the reaction subsides, 200 g. of 10% sodium hydroxide solution is cautiously added with stirring onto the reaction product (precipitated nickel). The temperature of the mixture is kept at about 50~55°C for fifteen minutes with occasional stirring. When solid matter settles down, the upper liquor is decanted. The solid is washed with two 100 ml. portions of hot water, and then with two 50 ml. portions of ethanol. In this way 8.5~10.5 g. of bulky catalyst, containing nickel (about 1 g.), zinc, zinc oxide and a very small amount of alkali, is obtained.

*(b) Urushibara Cobalt B (U-Co-B).* — To a hot mixture (90~100°C) of zinc dust (10 g.) and water (4 ml.) placed in a 100 ml. flask is added at once 10 ml. of hot aqueous solution (90~100°C) containing 4.04 g. of cobalt chloride ($CoCl_2 \cdot 6H_2O$) with vigorous stirring on a boiling water bath. The reaction product (precipitated cobalt) is transferred into a 300 ml. beaker and washed with 200 ml. of hot water. After 160 g. of 10% sodium hydroxide solution is added, the mixture is warmed at about 50~55°C on a water bath for fifteen minutes with occasional stirring. Then the upper liquor is decanted, and the residual solid is washed with two 100 ml. portions of hot water and then with two 50 ml. portions of ethanol. About 6.5~7 g. of catalyst, containing cobalt (about 1 g.), zinc, zinc oxide and a trace of alkali, is obtained.

*(c) Urushibara Nickel CB (U-Ni-CB).*—Ten milliliter of aqueous solution containing 4.04 g. of nickel chloride ($NiCl_2 \cdot 6H_2O$) is added to a mixture of zinc dust (10 g.) and water (4 ml.) placed in a 100 ml. flask. This mixture is stirred at room temperature or under cooling with water or ice until the green color of nickel ion disappears. This process requires about three to four hours. As the major part of the ion exchange reaction proceeds during the initial period, the reaction mixture may be left standing until the green color has disappeared

after stirring for an hour. When the preparation of a large quantity of precipitated nickel is required, the reaction mixture must be cooled with ice to remove the generated heat of the reaction. The slushy precipitated nickel is transferred into a 300 ml. beaker and washed with 200 ml. of cold water. After 160 g. of cold 10% sodium hydroxide solution is added, the mixture is stirred for an hour under cooling with water or ice if necessary. When the major part of solid settles down, the upper liquor is cautiously decanted, and the solid is washed with two 100 ml. portions of cold water and then with two 50 ml. portions of ethanol. About 8~11 g. of bulky catalyst, containing nickel (about 1 g.), zinc, zinc oxide and a very small quantity of alkali, is obtained.

*(d) Urushibara Cobalt CB (U-Co-CB).* — This catalyst is prepared from cobalt chloride by the same procedure as is described above.

*(e) Urushibara Nickel A (U-Ni-A) Prepared from Nickel Acetate.*—Precipitated nickel was prepared by the same procedure as is described in (a). Instead of caustic alkali, 160 ml. of 13% acetic acid is added with stirring onto the precipitated nickel. The mixture is stirred occasionally until the generation of hydrogen gas ceases and a solid comes up to the surface of the solution which is of green color. The solid is collected on a glass filter and washed with 200 ml. of hot water and then with 100 ml. of ethanol. About 0.7 g. of catalyst, containing nickel, small quantities of zinc and zinc oxide, is obtained.

*(f) Urushibara Cobalt A (U-Co-A).* — The precipitated cobalt prepared by the same way as is described in (b) is treated with 160 ml. of 13% acetic acid. The mixture is stirred for about five minutes until the generation of hydrogen gas ceases and a solid comes up to the surface of the solution which is rose-colored. This coloration is necessary to obtain an active catalyst. The solid is collected on a glass filter and washed with 200 ml. of hot water and then with 100 ml. of ethanol. About 1~1.2 g. of catalyst, containing cobalt (about 0.8 g.), small quantities of zinc and zinc oxide, is obtained.

*(g) Urushibara Copper (U-Cu).*—To a hot mixture (90~100°C) of zinc dust (10 g.) and water (5 ml.) placed in a 200 ml. flask is added at once 10 ml. of hot aqueous solution (90~100°C) containing 2.69 g. of cupric chloride ($CuCl_2 \cdot 2H_2O$) with vigorous stirring. The reaction ends at once. The upper liquor is decanted and the solid (precipitated copper) is transferred into a 300 ml. beaker and washed with 200 ml. of hot water. After the precipitated copper is treated with 160 ml. of 13% acetic acid at 70~75°C on a water bath for about thirty minutes, the upper liquor is decanted. The solid is washed with two 100 ml. portions of hot water and then with two 50 ml. portions of ethanol. About 2~2.5 g. of black catalyst, containing copper (about 1 g.) and zinc, is obtained.

*(h) Urushibara Nickel CA (U-Ni-CA).*—The precipitated nickel prepared by the same way as is described in (c) is transferred into a 500 ml. beaker and is carefully treated with 200 ml. of 10% acetic acid under cooling with water. After about five minutes the generation of hydrogen gas subsides and a solid comes up to the surface of the solution, which carries more deep green color than in case of Urushibara nickel A. The solid is collected on a glass filter and washed with 200 ml. of cold water and then with 100 ml. of ethanol. About 0.6~0.8 g. of fine catalyst, containing nickel (0.4~0.5 g.), small quantities of zinc and zinc oxide, is obtained.

*(i) Urushibara Cobalt CA (U-Co-CA).*—This catalyst is prepared from cobalt chloride by the same way as is described above, the volume of 10% acetic acid being modified to 150 ml. for the treatment of the precipitated cobalt.

*(j) Urushibara Copper C (U-Cu-C).*—During ten minutes 30 ml. of cold aqueous solution containing 2.69 g. of cupric chloride is added dropwise to a vigorously stirred mixture of zinc dust (10 g.) and water (10 ml.) placed in a 100 ml. flask under cooling with ice. The precipitated copper is transferred into a 300 ml. beaker and washed with 200 ml. of cold water. After the precipitated copper is treated with 160 ml. of 13% acetic acid for two hours at room temperature, the upper liquor is decanted and the residual solid is washed with two 100 ml. portions of cold water and then with two 50 ml. portions of ethanol. About 3~4 g. of black catalyst, containing copper (about 1 g.) and zinc, is obtained. Urushibara copper catalyst carries a black color before use, and it is changed in red-brown after use for reduction.

In cases of the preparations of the Urushibara catalysts B, the Urushibara copper and the Urushibara copper C, every washing is removed by decantation. In all procedures, distilled water is used for washing, and the solid must be protected from the contact with air as far as possible after the treatment of the precipitated metals with acid or alkali.

## Results and Discussion

The results obtained from the reduction of benzophenone which was purified by a single vacuum distillation are summarized in Tables I and II. A series of experiments shown in Table I were carried out to examine the effect of initial pressure, and to find the difference due to the kind of nickel salt or amount of zinc dust used for preparing the catalyst. The activities of U-Ni-B and U-Co-B were also compared. As seen from Table I, the velocity of reduction was affected only slightly, if any, by the initial pressure within 30~134 kg./cm$^2$. Therefore the effect of the initial pressure was ignored in the following operations. The use of potassium hydroxide solution for digesting the precipitated nickel in place of sodium hydroxide solution gave the similar result (Exp. No. 14). The U-Ni-B contains a large quantities of zinc and zinc oxide aside from nickel metal. To diminish these ingredients the precipitated nickel was prepared with less amount of zinc dust and was treated with much quantities of alkaline solution (Exp. No. 15). As the catalyst thus obtained was less active and the velocity of reduction was depressed in the course of the

TABLE I. REDUCTION OF BENZOPHENONE* WITH U-Ni-B OR U-Co-B

| Exp. No. | Catalyst[a] | pH | Total weight of catalyst g.[b] | Initial press. kg./cm² | Initial temp., °C | React. temp. °C | Time min. |

* Benzophenone, purified by a single vacuum distillation, was used.
a) Each catalyst was prepared so as to contain 1 g. of nickel or cobalt.
b) The figures were obtained by weighing the dried catalysts after use for reduction.
c) The precipitated nickel was treated with 200 g. of 14% potassium hydroxide solution.
d) The precipitated nickel, obtained from nickel chloride solution with 5 g. of zinc dust, was treated with two 150 g. portions of 10% sodium hydroxide solution.
e) The precipitated nickel was prepared from nickel acetate. The other was prepared from nickel chloride.
f) The precipitated nickel was treated with 150 g. of 20% sodium hydroxide solution.

reaction, higher temperature was required to complete the reaction. This may be partly due to the big size of the particles of nickel metal and partly to the contact with an alkali for a long time. Moreover, it must be considered that the zinc and zinc oxide contaminated in the U-Ni-B may act as carrier[9]. For the reduction of benzophenone, purified by a single vacuum distillation, the U-Ni-B prepared from nickel acetate was more effective than the catalyst obtained from nickel chloride (Exp. Nos. 16, 17, 18), but this was not always true, when more carefully purified benzophenone was used. The U-Ni-B prepared from nickel acetate weighs in dry state about 8.5~10.5 g. (for 1 g. of nickel), and is about three times as bulky as the catalyst obtained from nickel chloride. Therefore, it must contain more zinc oxide (cf. micro-photograph, Fig. 1 (d)), which may act as a sort of an effective carrier in the reduction of a less purified substance.

It was already reported[10], that the catalytic reduction of a carbonyl group with Raney nickel was accelerated by a trace of alkali. For the Urushibara nickel catalyst, the effect of an alkali was quantitatively investigated in the reduction of cyclohexanone under ordinary pressure[11]. The results of the reduction of benzophenone in neutral solution with the Urushibara catalyst A and the well washed Urushibara catalyst B are shown in Table II. From these results, it is obvious that the catalytic reduction of a carbonyl group with these catalyst is desirable to operate above pH 8 (S. Nishimura reported that the excess of alkali retarded the reaction[11]).

The results tabulated in Tables III, IV, V and VI were obtained by the use of more carefully purified benzophenone, which was recrystallized twice from ethanol after vacuum distillation. The effect of purification was remarkable when the U-Ni-B was used. The U-Ni-BA was reported to be specially useful in the hydrogenation of aromatic nucleus[1,5], but it was found to be not so particularly effective for the reduction of a carbonyl group (Table III, Exp. Nos. 37, 38). It was revealed by micro-photographs that the size of the particles of the U-Ni-BA catalyst is greater than that of the other Urushibara catalysts* as shown in Fig. 1. Also the X-ray diffraction of the U-Ni-BA gives a different pattern from that of the U-Ni-A. The U-Co-BA was proved to be less active for the reduction of benzophenone, and it required higher temperature and longer time to finish the reduction than the other Urushibara catalysts (Exp. No. 39). As was already described, the U-Ni-A in neutral solution was not suitable for the reduction of a carbonyl group. But an addition of a small amount of alkali promoted remarkably the reduction and such a nickel catalyst gave better results than those obtained with the U-Ni-B (Exp. Nos. 310—313). The reason may be partly supposed to be due to the dispersability of the catalyst.

Benzophenone, purified by a single vacuum distillation and then recrystallized twice from ethanol, was used.

As a solvent 55 ml. of ethanol was used.

a) Each catalyst was prepared so as to contain 1 g. of copper.
b) 0.5 ml. of 10% sodium hydroxide solution was added.
c) The figures were obtained by weighing the dried catalyst after use for reduction.

As the apparent bulk of the U-Ni-A is much smaller than that of the U-Ni-B, the fine particles of the former may be easily dispersed into a solution by the up and down agitation employed in these experiments. However, the U-Ni-A prepared from nickel acetate was less active than the U-Ni-B prepared from the same salt (Exp. No. 314), and the reason is obscure. In alkaline solution the U-Co-A also gave better results than those obtained with the U-Co-B (Exp. Nos. 315, 316).

Reaction temperature, concentration of solution and quantity of catalyst are naturally expected to exert some influences on the rate of reduction. As a catalyst with high activity is not suitable for the purpose of this series of experiments, the U-Ni-A, which was specially prepared to have a lower activity, was used.

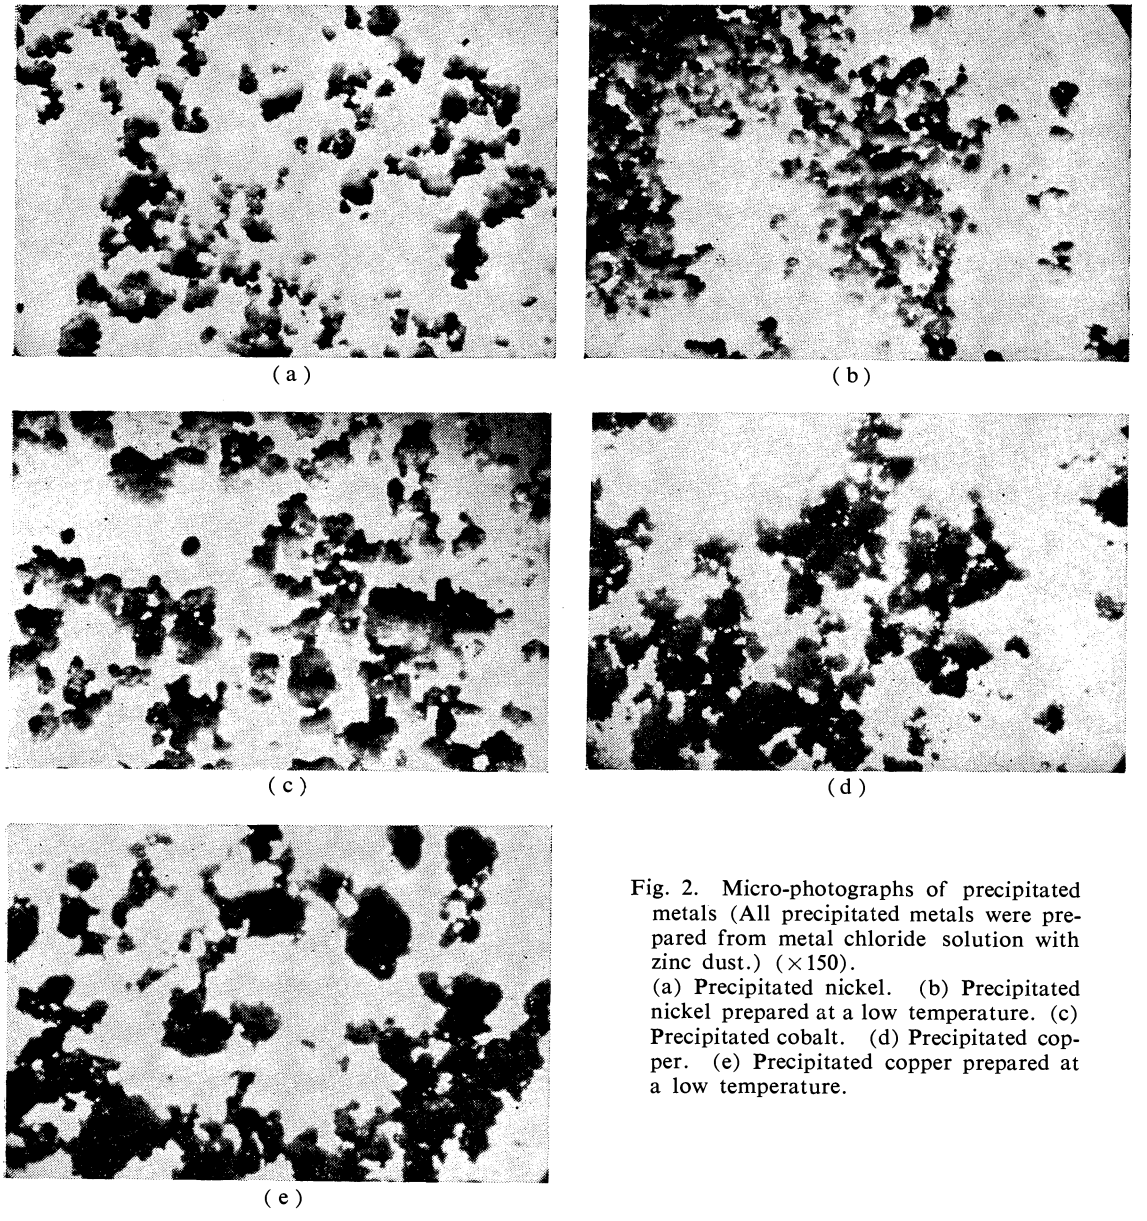

Fig. 2. Micro-photographs of precipitated metals (All precipitated metals were prepared from metal chloride solution with zinc dust.) (×150).
(a) Precipitated nickel. (b) Precipitated nickel prepared at a low temperature. (c) Precipitated cobalt. (d) Precipitated copper. (e) Precipitated copper prepared at a low temperature.

The results are listed in Table IV. To obtain a highly active U-Ni-A, the treatment of the precipitated nickel with diluted acetic acid should be continued until the solution acquires the green color of nickel ion. The U-Ni-A, used for these experiments, was prepared by interrupting the digestion before the solution was colored. The activity of this catalyst was considerably lower than that of the ordinary U-Ni-A. As shown in Table IV, the increment of either the concentration of solution or the amount of catalyst exerts a similar favorable effect on the reduction of benzophenone.

The first step of the preparation of Urushibara catalyst is to obtain precipitated metal by an ion exchange reaction. The so-called precipitated metal may consist of particles of metallic zinc covered with proper metal to be used as a catalyst, admixed with a quantity of zinc dust and zinc compounds. It can be said that the former is a true precipitated metal. Supposing that the size of the particles of a catalyst are decided mainly by those of the precipitated metal, it is necessary to prepare the fine particles of the precipitated metal for making the particles of catalyst to be fine. When a definite weight of zinc dust is used for preparing a definite weight of catalyst, the size of the particles of the precipitated metal may be decided by the size of the particles of

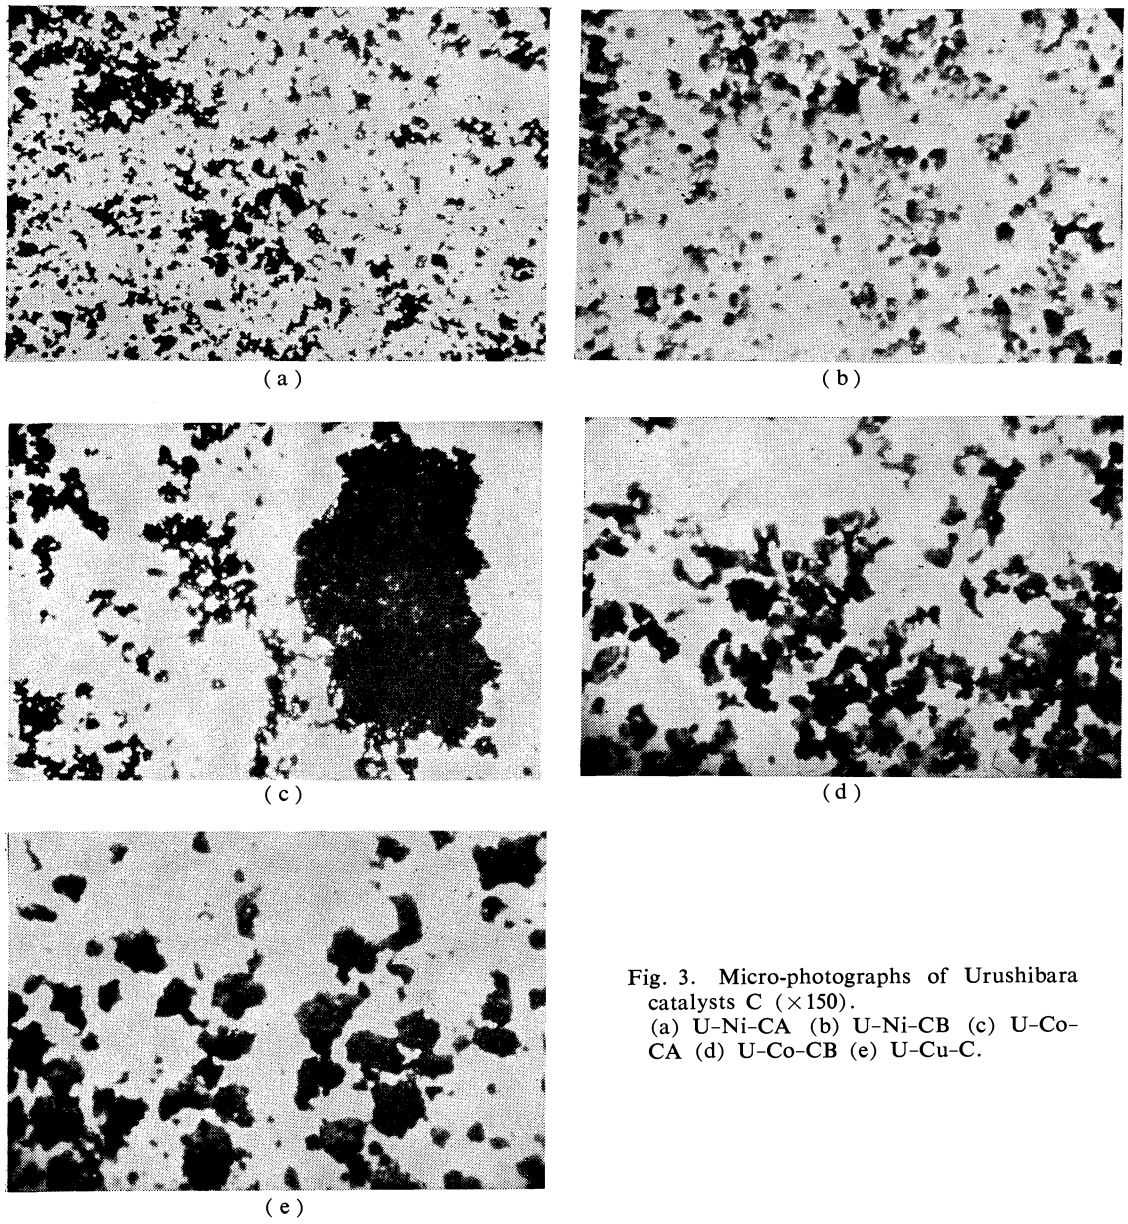

Fig. 3. Micro-photographs of Urushibara catalysts C (×150).
(a) U-Ni-CA (b) U-Ni-CB (c) U-Co-CA (d) U-Co-CB (e) U-Cu-C.

zinc dust and the rate of the ion exchange reaction. The rate of the ion exchange reaction may be affected by several factors, such as the difference of the standard electrode potential between zinc and the metal used to form a catalyst, the fineness of zinc dust, the concentration of the solution of metal chloride, the temperature and the efficiency of agitation when the precipitated metal is prepared. Of the above-mentioned factors, the size of the particles of zinc dust is difficult to change, so far as a commercially available product is used. The difference of the standard electrode potential is almost constant, and the improvement of the efficiency of agitation is limited to some extent. If the concentration of the solution of metal chloride is definite, only the temperature at which the ion exchange reaction is carried out can be freely varied. At a low temperature the ion exchange reaction occurs very slowly, and the influence of the efficiency of agitation can be minimized. Consequently, the metal may uniformly separate out on the surface of the particles of zinc dust and then fine particles of catalyst may be obtained (cf. micro-photographs, shown in Fig. 2).

Urushibara catalysts, thus prepared at a low temperature as described in the experimental part, are temporarily named Urushibara catalysts C and the abbreviations, such as U-Ni-CB,

U-Ni-CA, etc., are used. The results obtained with these catalysts are shown in Table V.

With the U-Ni-CB, better results were obtained than with the U-Ni-B. The dried U-Ni-CB is somewhat heavier in weight and more bulky than the U-Ni-B. The appearance of the U-Ni-CB resembles that of the U-Ni-B prepared from nickel acetate. A microphotograph (Fig. 3) shows that the size of the particles of this catalyst are somewhat smaller than that of the U-Ni-B, and that much zinc oxide remains undissolved. The U-Ni-CA was also proved to be effective, but somewhat longer time was necessary with this catalyst to finish the reduction than with the U-Ni-A. It is partly explained by the fact that the weight of the U-Ni-CA is about a half of that of the U-Ni-A. In the same manner, the U-Co-CB and the U-Co-CA were found to be superior to the corresponding ordinary cobalt catalyst.

To obtain a highly active Urushibara catalyst it has been claimed that the ion exchange reaction to obtain the precipitated metal should be carried out in a short time at a high temperature. Nevertheless, it was proved as mentioned above that the precipitated metal prepared in a long time at a low temperature gives an excellent catalyst. The X-ray diffraction of the U-Ni-CA gives a somewhat different pattern from that of the U-Ni-A, and it will be reported in another paper.

In Table VI the results obtained with copper catalyst are shown. As the precipitated copper does not react with 10% sodium hydroxide solution, only acid is a suitable reagent for treating the precipitated copper. The copper catalyst being considered not so active as a nickel catalyst for catalytic reduction, the condition of reduction was decided in consideration of the results obtained in Table IV. The results shown in Table VI are similar to those obtained with Raney copper[12]. Again, the U-Cu-C gave better results than those obtained with the ordinary U-Cu.

## Summary

High pressure reduction of benzophenone was examined with various Urushibara catalysts under various conditions. The purity of benzophenone, the concentration and pH of a solution, reaction temperature and quantity of the catalyst exerted considerable effects on the rate of reduction. Effective Urushibara catalysts were prepared from the precipitated metals which were obtained from the metal chlorides and zinc dust at a low temperature.

The author wishes to express his gratitude to Professor K. Hata for his helpful suggestions and encouragement throughout this work.

# *Formation of Cyclohexano[c]1, 2, 5-oxadiazole from 1, 2-Cyclohexanedione Dioxime. An Attempted Beckmann Rearrangement with Thionyl Chloride in Liquid Sulfur Dioxide*[1,2]

By Niichiro TOKURA, Ritsuro TADA and Kunio YOKOYAMA

(Received July 20, 1960)

It has already been shown by the present authors[2,3] and also by other writers[4] that the direction of the migratory aptitude in the Beckmann rearrangement was often changed by the circumstances, by the reagents or for other reasons. A transannular rearrangement was observed when 1, 6-cyclodecanedione dioxime was subjected to the rearrangement with thionyl chloride in place of sulfur trioxide in liquid sulfur dioxide[3].

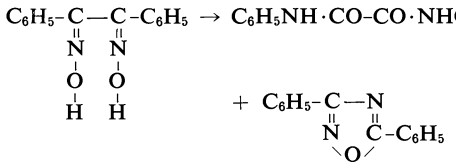
Tada, Masubuchi and Tokura[2] carried out the Beckmann rearrangement of the geometrical isomers of cyclohexyl phenyl ketoximes in liquid sulfur dioxide without any appreciable difference of the migratory aptitude by a variety of reagents at −70°C.

The Beckmann rearrangements of 1,2-diketone dioximes have scarcely been reported at all, but those of 1,2-diketone monoximes have been examined extensively to yield nitriles and carboxylic acid as the result of cleavage[5,6] of the dione monoximes. A number of trials of the Beckmann rearrangement on benzil dioximes have been reported since the turn of the last century[7-9] but the result were subjects of controversy[10] and the presence of geometrical isomers in the dioxime led the direction of the rearrangement to various products, for example, 3,5-diphenyl-1,2,4-oxadiazole, oxanilide and so on, among which the derivation of the 1,2,4-oxadiazole was ascribed to the Beckmann rearrangement of one of the two oximino groups, followed by dehydration. The reagents used were phosphorus pentachloride, phosphorus pentoxide, phosphoryl chloride and sulfuric acid. Of the three isomers, only the $\gamma$-isomer was reported to yield oxanilide, a product of the double Beckmann rearrangement, whereas the $\alpha$- and $\beta$-isomers gave the diphenyl-1,2,4-oxadiazole. Recently, Conley and Mikulski[6] have obtained the same oxadiazole with polyphosphoric acid as the reagent.



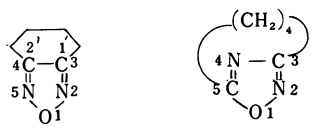


Chart 1.

The present paper describes the experiments which have been undertaken to throw light upon the nature and the migratory tendency of 1,2-cyclohexanedione dioxime in sulfur dioxide. The preparation of the 1,2-cyclohexane dioxime has been reported in a number of papers, of which the method of Belcher, Hoyle and West[11] has been adopted. This method, consisting in the oximation of 2-bromocyclohexanone (Ia), is essentially similar to that of Tokura and Oda[12] which was published earlier in 1943 and uses 2-chlorocyclohexane (Ib) as the starting material. The former method is however more convenient for laboratory work. To our regret, however, neither method was satisfactory enough to be a standard method of preparation owing to the formation of many resinous matters and unavoidable fluctuation in the yields.

1,2-Cyclohexanedione dioxime (II) was obtained in yields of 10~34% as crystals of m.p. 185~186°C (literature[11], 186~187°C), from which it was impossible further to separate the possible isomers by repeated crystallization or by repeated precipitation. Since the various reagents examined on this material have given no symptom of the geometrical isomers which will be reported in the following paper, the problem of the possible isomers was shelved in this project.

In this light of such a consideration, it is interesting to examine the direction of the Beckmann rearrangement, but contrary to expectation, the rearrangement was not caused by thionyl chloride in liquid sulfur dioxide. When thionyl chloride was used as the reagent, a low melting material III, m.p. 26°C, was obtained in a yield of 70% by ether extraction of the residue obtained on evaporation of sulfur dioxide from the reaction mixture. Although the elementary analysis was consistent with the anhydride of the dioxime II, there still remained another possibility of the presence of isomeric matters such as those produced by single and/or double rearrangement followed by dehydration. As cited above, benzil dioxime gave in such a case 3,4-diphenyl-1,2,4-oxadiazole and oxanilide, products of single and double rearrangement, respectively.

If the anhydride was formed by a simple dehydration without rearrangement, the structure must be a 1,2,5-oxadiazole derivative A, and not a 1,2,4-oxadiazole derivative B.

(A) (B)

The I.R. spectrum of III showed the characteristic absorption of a 1,2,5-oxadiazole (furazan)[13] at 1630 and 1588 $cm^{-1}$. This substance was very stable and resisted hydrolysis on refluxing with concentrated hydrochloric acid for 5 hr., with aqueous 25% caustic soda for 6.5 hr., with aqueous 40% sulfuric acid for 7 hr. and

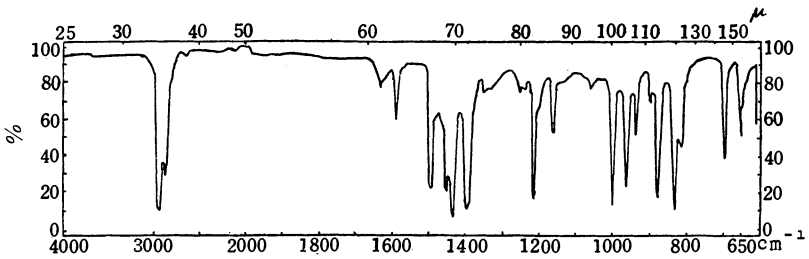

Fig. 1. I. R. spectrum of III.

heating with concentrated sulfuric acid for 5 hr. on a steam bath. Oxidation with chromic anhydride in acetic acid or with ozone in 50% acetic acid and reduction with tin and hydrochloric acid were all ended in the recovery of the starting compound. The compound underwent an oxidation only with potassium permanganate in dilute sulfuric acid to yield a dicarboxylic acid, $C_6H_6O_5N_2$, m. p. 147~148°C (decomp.), which showed no coloration with a nickel salt and is assigned to the structure of IVa. Another possible structure IVb is ruled out because the cleavage of this sort may be more difficult than the cleavage to afford IVa.

The exhaustive oxidation of the compound with the same oxidant gave a dicarboxylc acid, m. p. 178°C (decomp.), 1, 2, 5-oxadiazole-3, 4-dicarboxylic acid (V), (literature[14], m. p. 178°C), the structure being proved as V by elementary analysis and mixed melting point.

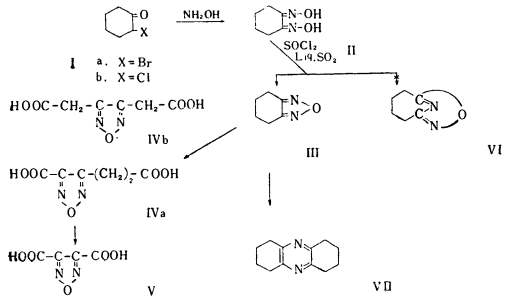

Chart 2.

Another evidence of structure III as the anhydride of the unrearranged dioxime was attained by reduction with sodium in ethanol. The use of lithium aluminum hydride was avoided because of the possible rearrangement[15] by this reagent. The reduction of III gave a basic compound, the analysis and the melting point corresponding to octahydrophenazine, $C_{12}H_{16}N_2$ (VII), m.p. 108~109°C, which was prepared by Wallach[17a], by Baumgarten and Bower[17b] and by Smith[16]. Wallach[17a] prepared the compound VII from II by reduction with zinc and alkali and a structure of decahydrophenazine was assigned, but recently[17b] it was found to be octahydrophenazine.

It was reported as early as in 1886 that 3, 4-diphenyl-1, 2, 5-oxadiazole[18] was synthesized from benzil dioxime by the reaction with potassium ferricyanide. The present authors have deviced a method of synthesis of compound III in a low yield by refluxing II in aqueous 10% sodium hydroxide. The coincidence of the melting point and the mixed melting point, and the I. R. spectra of the two materials confirmed the structure III unequivocally.

Thionyl chloride is one of the most powerful reagents to effect the Beckmann rearrangement. The failure of the rearrangement of II with thionyl chloride in liquid sulfur dioxide in contrast to benzil dioxime suggests some meaning. Benzil dioxime has presumably a coplanar structure favorable for a Beckmann rearrangement at least in one moiety of the molecule, whereas cyclohexanedione dioxime will prefer dehydration rather than a Beckmann rearrangement since it is sterically more restricted than benzil dioxime to build an intermediate azilinium cation[19] (aza-cyclopropenyl cation). In addition, the formation of the intermediate cation of benzil dioxime may be facilitated by the presence of phenyl ring participation in the rearrangement.

Gillis[20] recently reported that a cyclic sulfite derived from tetramethylene glycol and thionyl chloride gave tetrahydrofuran without stopping at the stage of a cyclic sulfone via the Bissinger rearrangement[21]. The formation of the anhydride III may likely proceed through cyclic sulfite IIa and sulfone IIIb (Chart 3).

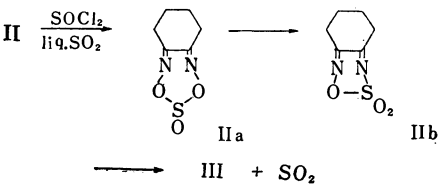

Chart 3.

A variety of products have also been obtained as the results of the attempted Beckmann rearrangement with some other reagents. The results will be reported elsewhere in near future.

## Experimental

**Material.**—Commercial sulfur dioxide was dried with concentrated sulfuric acid and distilled. A commercial thionyl chloride was redistilled.

**Apparatus and General Procedure.** — The procedure and manipulation for the Beckmann rearrangement were essentially the same as described earlier[1,2].

**1,2-Cyclohexanedione Dioxime (II).** — To a refluxed mixture of hydroxylamine hydrochloride (227 g.), sodium acetate (45 g.), methanol (400 ml.) and water (460 ml.) was added 128 g. of 2-bromocyclohexanone (Ia) gradually. After the mixture was refluxed for 45 min., it was condensed and diluted with water. The crystals were recrystallized from water, m. p. 186~187°C. Yield, 31 g. (34%).

Found: N, 19.66. Calcd. for $C_6H_{10}O_2N_2$: N, 19.71%.

**Reaction of II will Thionyl Chloride in Liquid Sulfur Dioxide.** — A mixture of the dioxime II (7.1 g.), thionyl chloride (13.0 g.) and 150 ml. of liquid sulfur dioxide was allowed to stand for an hour at room temperature. The solution was then poured into ice water, sulfur dioxide was evaporated and the residue was extracted with ether. The ether solution was washed with water, dried and condensed to give 5 g. (70%) of colorless crystals III, m. p. 26°C (recrystallized from ethanol), b. p. 99~101.5°C (13 mmHg). The substance was later identified as cyclohexano[c]1,2,5-oxadiazole.

Found: C, 58.19; H, 6.16; N, 22.10. Calcd. for $C_6H_8ON_2$: C, 58.05; H, 6.50; N, 22.57%. Mol. wt. Found: 139.5 (benzene). Calcd.: 124.

I. R. $\nu_{max}^{liq}$ 1588(m) (C=N-), and 2960(s), 2880(s) ($CH_2$=), $cm^{-1}$, U. V. $\lambda_{max}^{MeOH}$ 220 m$\mu$ ($\log \varepsilon = 3.56$). No significant amount of any other material was found in the residual solution after the ether extraction.

**Synthesis of III with Alkali.**—With 20 ml. of 10% aqueous sodium hydroxide, 3 g. of II was refluxed for 1.5 hr. The reaction mixture was extracted with ether. After the distillation of the ether, a small quantity of crystals was obtained as the residue. This was recrystallized from ethanol, m. p. 25.5~26.0°C, b. p. 180~196°C (18 mmHg), 0.3 g. (10%). This material showed no depression of melting point when mixed with III from II and thionyl chloride and gave an I. R. spectrum completely identical with that given by the specimen obtained from II and thionyl chloride.

**Oxidation of III with Potassium Permanganate.** —To 10 ml. of 10% aqueous solution of sulfuric acid was added 1.5 g. of III and the mixture was stirred and heated on a water bath. About 2.0 g. of potassium permanganate was added to the mixture bit by bit till the permanent red color remained. The precipitate of manganese dioxide was dissolved by introducing sulfur dioxide gas, and the mixture was extracted with ether, and the extract was condensed to give 1.3 g. (86.7%) of colorless fine crystals IVa, m. p. 147~148°C (decomp.) (from acetone-ligroin), IVa was soluble in hot water, alkali, alcohol and acetone, but insoluble in benzene.

Structure of 4-ethyl-1,2,5-oxadiazole-3,2'-dicarboxylic acid (IVa) was assigned.

Found: C, 38.08; H, 3.62; N, 14.78. Calcd. for $C_6H_6O_5N_2$: C, 38.72; H, 3.25; N, 15.02%. Acid value, Found: 628. Calcd. for 2-COOH: 617.0. I. R. $\nu_{max}^{KBr}$ 3400~3540 (-OH) and 1695 (>CO) $cm^{-1}$. White precipitates with $Ag^+$ and $Ba^{2+}$ ions. No red coloration with $Ni^{2+}$.

**Exhaustive Oxidation of IVa.** — A mixture of 0.5 g. of IVa, 1.0 g. of potassium permanganate and 10 ml. of 10% sulfuric acid was stirred and warmed for two days on a water bath. The precipitate of manganese dioxide was dissolved by passing sulfur dioxide gas. Extraction of the mixture with ether followed by condensing the ether solution yielded 0.1 g. of fine crystals V, m. p. 178°C (decomp.). (repeated recrystallization from alcohol.)

Found: N, 17.78. Calcd. for $C_4H_2O_5N_2$: N, 17.72%.

V was mixed with an authentic specimen of 1,2,5-oxadiazole-3,4-dicarboxylic acid prepared by the method of Wallach[17a] to show no melting point depression.

**Reduction of III with Sodium and Ethanol.**— To a solution of 2.0 g. of III in 100 ml. of ethanol was added 5 g. of metallic sodium with stirring. The mixture was further refluxed for 1.5 hr. and then a half of the ethanol was evaporated. The residual mixture was acidified with concentrated hydrochloric acid and was extracted with ether. Evaporation of the ether extract gave 0.4 g. of a product which was identified as the starting material III. The residual solution was again made alkaline with soda ash and the mixture was again extracted with ether. Evaporation of the ether extract gave colorless needles VII contaminated with a brown resinous matter. The needles sublimed at 60~80°C (15 mmHg). The needles were repeatedly recrystallized from ethanol to m. p. 108~109°C. Picrate, yellow needles, m. p. 155°C (decomp.).

Base: Found: C, 75.89; H, 8.10; N, 14.46. Calcd. for $C_{12}H_{16}N_2$: C, 76.55; H, 8.57; N, 14.88%. Picrate: Found: N, 16.83. Calcd. for $C_{18}H_{19}N_5O_7$: N, 16.78%.

The material VII was proved to be octahydrophenazine by admixing with an authentic sample prepared by reduction of II by the method of Wallach. No depression of the melting point[17a] was observed.

**Summary**

An attempted Beckmann rearrangement of 1, 2-cyclohexanedione dioxime with thionyl chloride in liquid sulfur dioxide resulted in the formation of cyclohexano [*c*] 1, 2, 5-oxadiazole in 70% yield. The structure of the oxadiazole was established by oxidation, reduction, and synthesis. The reason why the condensation was predominant over the rearrangement was discussed in comparison with the case of benzil dioxime.

The authors are indebted to the Befu Chemical Industries Co., for the donation of liquid sulfur dioxide.

# *A Synthesis of an Octahydrophenanthrene Derivative*[1]

By Takeshi MATSUMOTO and Akira SUZUKI

(Received August 22, 1960)

In the previous paper[2] synthesis of 2-methoxy-5-hydroxy-1-naphthylacetic acid and unsuccessful attempts to prepare therefrom 1, 2, 3, 4-tetrahydro-2-oxo-5-methoxy-1-naphthyl acetate (IIIb) were described. This paper reports a successful synthesis of the acetate IIIb from 5-methoxy-2-tetralone (I) and of a hydrophenanthrene derivative IX, a promising intermediate in the synthesis of certain diterpenoid skeletons, from IIIb.

The monoalkylation of $\beta$-tetralones had been in general difficult to achieve by direct alkylation since they tend to undergo partial or exclusive dialkylation[3]. However, the difficulty was recently overcome by the ingeneous procedure of Stork[4], which is concerned with alkylation of enamine derivatives of ketones with alkyl halides. In this study, the Stork method was adopted. The reaction of 5-methoxy-2-tetralone with pyrrolidine in boiling benzene afforded a previously undescribed enamine II, m. p. 78.5~79.5°C, in almost quantitative yield. II was then alkylated in benzene with ethyl bromoacetate and the intermediary ammonium salt was hydrolysed with water. Ethyl 1, 2, 3, 4-tetrahydro-2-oxo-5-methoxy-1-naphthyl acetate (IIIb), thus obtained in 74% yield, is a viscous liquid, boiling at 150~151°C (0.05 mmHg). Piperidine enamine of the methoxytetralone, on being treated in the same way, afforded a poor yield of IIIb. Hydrolysis of the ester IIIb with aqueous sodium hydroxide gave the acid IIIa, m. p. 172~173°C.

In hope of preparing a tricyclic $\alpha\beta$-unsaturated ketone V, the authors next examined the reaction of IIIb with 1-(*N*, *N*-diethylamino)-butan-3-one methiodide in benzene in the presence of potassium ethoxide. After chromatography on acid alumina, there could be isolated from the reaction mixture a compound $C_{19}H_{24}O_5$, m. p. 134~135°C, as the main product. The infrared spectrum (Fig. 1; nujol mull) of this compound exhibited absorption bands at 3400 (broad; OH), 1700 (six-membered ring ketone) 1735 and 1175 $cm^{-1}$ (ester). The authors supposed at this stage that they had ketol IV in hand. In several instances, the Robinson annelation reaction has been shown[5] to lead to intermediary ketol of type IV, which affords $\alpha\beta$-unsaturated ketone of type V by a $\beta$-elimination process. On treatment with isopropenyl acetate in the presence of *p*-toluenesulfonic acid, the ketol IV afforded an acetate

| 14 and others | | d, e-H | | |

spectrum[6] of the ketol (Fig. 2) showed one sharp maximum at a high applied magnetic field, characteristic of proton resonance for the $-\overset{|}{\underset{|}{C}}-CH_3$ group (203 c. p. s.; standard, benzene). This observation is clearly incompatible with structure IV, and the spectrum is completely accounted for in terms of structure VI (see Table I). A formula such as VIII and Xa would also explain the resonance line at 203 c. p. s., but would not give any explanation for the other lines. The formation of a bridged ketol system similar to VI through the Robinson annelation-reaction was first disclosed only quite recently by Johnson and his coworkers[7].

In order to elucidate the conformation the authors further examined the O-H stretching absorption band of the ketol in the 3300 $cm^{-1}$ region. The spectrum was measured in 0.0046 M[8] tetrachloroethylene solution[9] and as indicated in Fig. 3, was found to exhibit two bands at 3430 and 3590 $cm^{-1}$. The latter band corresponds to the vibration of aliphatic free OH group[10] while the former band may be attributed to OH group bonded to the carbonyl oxygen atom[11]. In structure VIa, in which the cyclohexanone ring takes a boat form, the hydroxyl group, be it either axial or equatorial, is unable to form an intramolecular hydrogen bond[12].

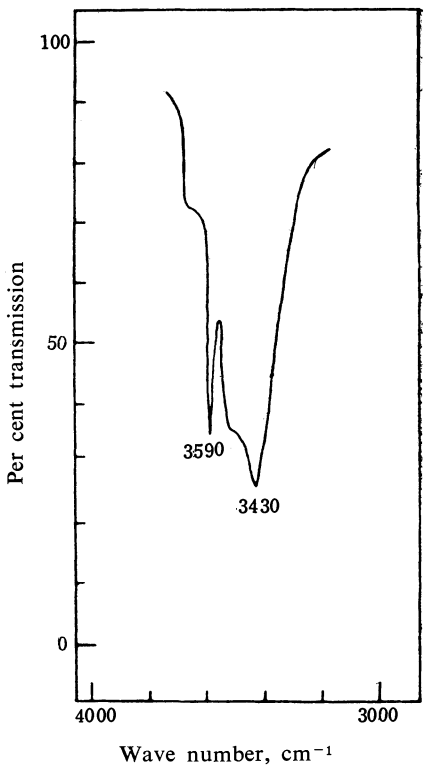

Fig. 3. ν O-H absorption of VI in tetrachloroethylene (0.0046 M).

The conformation VIb with chair cyclohexanone ring and axial OH group is the only one in which the formation of an intramolecular hydrogen bond is possible.

6) The N. M. R. spectra were taken on a Varian 40 MC instrument at the University of Illinois through the courtesy of Drs. Ben Shoulder and Masaji Ohno, to both of whom the authors are pleased to express their sincere thanks.

8) At this dilution the association of the solute molecule is neglegible. N. D. Coggeshall, *J. Chem. Phys.*, **18**, 978 (1958); F. A. Smith and E. C. Creitz, *J. Research Natl. Bur. Standards*, **46**, 145 (1951).

9) The infrared spectrum was taken with a Hilger H 800 infrared spectrophotometer with calcium fluoride optics. The authors wish to express their gratitude to Assistant Professor Sanjuro Matsushita and Miss Hisako Nakato of the Physical Chemistry Laboratory for the infrared spectral measurement. For the absence of interaction between hydroxyl group of solute and π-electrons of tetrachloroethylene, see L. L. Ingraham, J. Corse, G. F. Bailey and F. Stitt, *J. Am. Chem. Soc.*, **74**, 2297 (1952).

10) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen and Co., Ltd., London (1958), p. 96.

11) In general, an intramolecularly bonded OH group exhibits a sharp band. The rather broad absorption band at 3430 $cm^{-1}$ might be caused by the overlapping of the absorption due to intramolecular hydrogen bond between the OH group and the ethoxy carbonyl oxygen atom (see formula VIb) and or by the rotatory isomerism of the hydroxyl group. For the latter effect, see R. Piccolini and S. Winstein, *Tetrahedron Letters*, No. 13, 4 (1959); M. Kahn, N. Lüttke and R. Mecke, *Z. anal. Chem.*, **170**, 106 (1959).

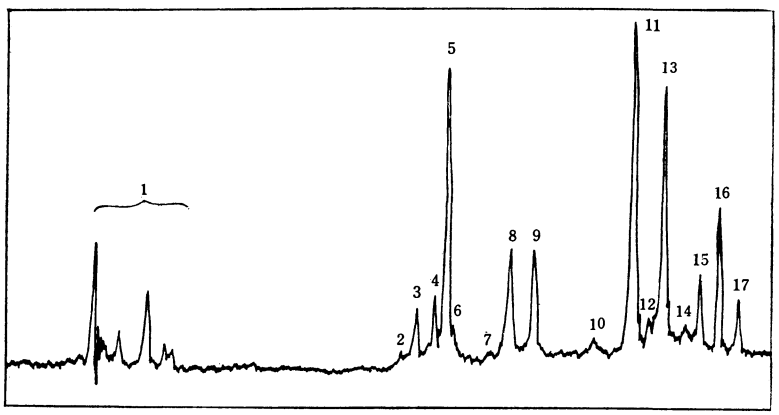

Fig. 5. N. M. R. spectrum of VIII in $CDCl_3$.

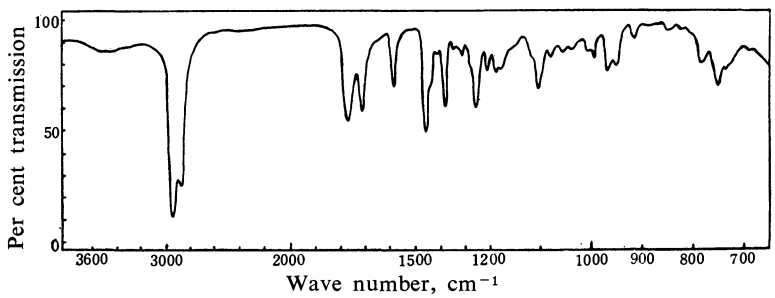

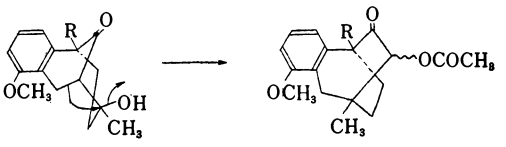

Fig. 6. Infrared spectrum of IX.

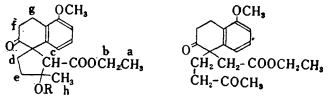
Next, examination was made of the structure of the acetylation product with m. p. 98.5°C (vide supra). The infrared spectrum (Fig. 4) of the acetate showed complete absence of hydroxyl function and presence of the following groups: saturated ester (1730 and 1175 $cm^{-1}$), acetate (1730 and 1230 $cm^{-1}$) and six-membered cyclic ketone (1715 $cm^{-1}$). Therefore a structural formula VII may be considered for this compound. Invalidity of this structure was however concluded from the N. M. R. spectrum, which is depicted in Fig. 5. The paramagnetic shift of the peak due to presence of $CH_3-\overset{|}{C}-$ protons to 190 c. p. s., disappearance of the peak at 151 c. p s. due to $-\overset{|}{C}-CH_2-CO_2$ protons and appearance of a new peak at 138 c. p. s. suggest a fundamental change in the framework of VI. The acetate may then be expressed by VIII, since an attack of proton upon the hydroxyl function of compound VIc would result in the formation of structure VIIIa through the well known 1, 2-shift as follows:

(VIc) (VIIIa)

R=$CH_2-COOCH_2CH_3$



This structure is consistent with the N. M. R. spectrum; the interpretation of the spectrum in terms of formula VIII is summarized in Table II. The structure also explains the stability of the acetate to pyrolitic treatment, since in formula VIII elimination of an element of acetic acid would be impossible. Further, convincing evidences in favor of the formula VIII were provided by positive reactions with triphenyltetrazolium chloride and with the Tollens' reagent. On the basis of these findings the structure of the acetate may be concluded to be VIII[13].

Contrary to the case of acid treatment described above, treatment of VI with dilute aqueous alkali or with sodium ethoxide in ethanol, followed by acidification gave rize to a product $C_{17}H_{18}O_4$, to which a hydrophenanthrene structure IX was assigned on the basis of infrared (Fig. 6) and N. M. R. spectra. Although the product was amorphous and could not be crystallized by chromatography or by any other means, it was regarded homogeneous enough on the basis of the behavior in chromatography and of infrared spectrum. The infrared absorption spectrum showed complete absence of the hydroxyl group and presence of six-membered cyclic ketone (1720 $cm^{-1}$) and $\gamma$-lactone (1770 $cm^{-1}$). The formation of $\gamma$-lactone is impossible from the above mentioned skeletons VI and VIII and is possible only from the structure containing the hydrophenanthrene skeleton IX. The correctness of structure IX is further substantiated by the elemental analysis and by the N. M. R. spectrum. In the spectrum[14], the sharp maximum at high magnetic field characteristic for $-\overset{|}{C}-CH_3$ protons could not be recognized. This type of conversion from skeletons VI to IX by alkaline reagent has been recently described by Johnson and coworkers[7]. The authors were thus able to obtain an intermediate IX which seems to be promising for the synthesis of a certain diterpenoid skeleton.

## Experimental[15]

**Preparation of Pyrrolidine Enamine (II).** — A solution of 4.3 g. (0.0244 mol.) of 5-methoxy-2-tetralone, which was prepared from 2,5-dimethoxynaphthalene by the procedure of Cornforth and Robinson[16], and 3.5 g. (0.0488 mol.) of freshly distilled pyrrolidine in 40 ml. of dry benzene was refluxed on a water bath while water, distilled off as an azeotropic mixture with benzene, was separated with a Dean-Stark type apparatus[17]. The condensation reaction was completed after 3 hr. After removal of the solvent and excess pyrrolidine, the residue afforded a distillation under reduced pressure

13) In the preliminary report[1] a formula Xb was suggested as the structure of the acetate. The formation of the spirocyclic compound was explained through a reverse aldol condensation and a subsequent aldol condensation of an intermediary diketone XI. Peaks at 129 and 138 c. p. s. were interpreted to be attributable to f and g protons, although in general these four protons constitute an ABCD system and a rather simple absorption pattern as in Fig. 5 is not to be expected except in special cases.

(X) (XI)

a. R=H
b. R=COCH3

14) The spectrum was taken on a Varian 40 MC instrument at Tohoku University. The authors are very grateful to Professor Genjiro Hazato and his coworkers for the measurement.

15) All melting and boiling points are uncorrected. Unless otherwise specified, infrared spectra were taken in nujol mull on a Koken model DS-301 infrared spectrophotometer with sodium chloride optics. Ultraviolet spectra were measured in 95% ethanol or methanol solutions by means of a Beckmann model DK-2 spectrophotometer. The authors are indebted to Miss Noriko Fujino for microanalysis.

16) J. W. Cornforth and R. Robinson, *J. Chem. Soc.*, **1949**, 1861.

17) E. W. Dean and D. D. Stark, *Ind. Eng. Chem.*, **12**, 486 (1920); S. Natelson and S. Gottfried, *Org. Syntheses*, **23**, 37 (1943).

5.35 g. (95.5%) of a product, boiling at 159~160°C (0.09 mmHg). The enamine derivative II was a pale yellow viscous liquid, which crystallized on being allowed to stand. Recrystallization from petroleum ether yielded colorless prisms, m. p. 78.5~79.5°C.

$\nu_{max}^{nujol}$ [18] 1610, 1590 and 1565 $cm^{-1}$.

$\lambda_{max}^{MeOH}$ [18] 243 ($\varepsilon$ 13800) and 315 m$\mu$ ($\varepsilon$ 19300).

Found: C, 78.48; H, 8.21. Calcd. for $C_{15}H_{19}ON$: C, 78.56; H, 8.35%.

Piperidine enamine of 5-methoxy-2-tetralone was obtained under the same condition. The condensation of 5 g. (0.0284 mol.) of the tetralone with 5 g. (0.0588 mol.) of the amine in 30 ml. of dry benzene was complete in 3 hr.; yield 4.6 g. (67%), b. p. 135~140°C (0.001 mmHg).

Found: C, 79.16; H, 8.54. Calcd. for $C_{16}H_{21}ON$: C, 78.97; H, 8.70%.

**Ethyl 1,2,3,4-Tetrahydro-2-oxo-5-methoxy-1-naphthyl Acetate (IIIb).**—At room temperature and during 45 min., 3.9 g. of ethyl bromoacetate in 5 ml. of benzene was added to a solution of 5.3 g. of 3,4-dihydro-2-(*N*-pyrrolidyl)-5-methoxy naphthalene (II) in 10 ml. of benzene. After refluxing for 3 hr. on a water bath (ca. 70°C), the solution was cooled to room temperature and 20 ml. of water was added. The whole was vigorously stirred for one hour at room temperature and the organic layer was separated; the water layer was extracted twice with benzene. The combined organic layer was washed with water, dried over anhydrous sodium sulfate and distilled under reduced pressure; b. p. 150~151°C (0.05 mmHg.), colorless viscous liquid, yield 4.5 g. (74%).

$\nu_{max}^{film}$ 1725 (ketonic carbonyl) and 1735 $cm^{-1}$ (ester carbonyl).

Found: C, 68.36; H, 6.59. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

The keto ester IIIb was also prepared from the piperidine enamine derivative by the same procedure. The yield, however, was lower than the above case; there was obtained 2 g. (41%) of IIIb from 4.5 g. of the piperidine enamine and 3.1 g. of ethyl bromoacetate.

**Hydrolysis of the Ethyl Ester IIIb.**—A mixture of 300 mg. of IIIb, 3 ml. of 60% sodium hydroxide and 3 ml. of ethanol was heated on a water bath for one hour. The solution was then diluted with 5 ml. of water, acidified with 6 N hydrochloric acid and extracted with ethyl acetate three times. The combined extracts were washed with water and dried over anhydrous sodium sulfate. Removal of the solvent in vacuo left an oily pale brown residue, from which on trituration with ether, a crystalline material was obtained. For analysis the product was recrystallized from benzene to afford colorless prisms, m. p. 172~173°C.

$\nu_{max}^{nujol}$ 1695 (carboxylic carbonyl) and 1710 $cm^{-1}$ (ketonic carbonyl).

$\lambda_{max}^{MeOH}$ 271 ($\varepsilon$ 2200) and 278 m$\mu$ ($\varepsilon$ 2220).

Found: C, 66.77; H, 6.00. Calcd. for $C_{13}H_{14}O_4$: C, 66.65; H, 6.02%.

18) For the characteristic frequencies of enamine, see G. Opitz, H. Hellmann and H. W. Schubert, *Ann.*, 623, 112 (1959).

**Condensation of IIIb with 1-(*N*, *N*-Diethylamino)-butan-3-one Methiodide.** — Diethylaminobutanone (4.2 g.), prepared according to the Wilds and Shunk method[19] was swirled gently in a 200 ml. flask and cooled with ice during the addition of methyl iodide (4.2 g) in portions for 15 min. The swirling was regulated, so as to obtain crystalline methiodide as an even coating on the walls of the flask. When no more liquid remained, the flask was kept in ice for one hour. A solution of the keto ester IIIb (7 g.) in dry thiophen-free benzene (40 ml.) was added, air was expelled from the flask by dry nitrogen, and a solution of potassium (1.7 g.) in absolute ethanol (25 ml.) was added with ice cooling during 5 min. Swirling was continued until the methiodide had all dissolved (about one hour) and was replaced by a precipitate of potassium iodide. After it had been kept in ice for another hour, the mixture was heated gently for 30 min. An excess of 3 N sulfuric acid was then added and the nitrogen gas was stopped. After addition of enough water (60 ml.) to dissolve the potassium sulfate the benzene layer was separated and the aqueous layer extracted three times with ether. The united extracts were washed with water, cleared with a little sodium sulfate, and concentrated in vacuo to leave 3.5 g. of an oil which was chromatographed through a column of acid-washed alumina[20] (50 g.) packed and washed with benzene. The portions eluted with benzene-chloroform (volume ratio 1 : 1, 450 ml.) and with chloroform only (400 ml.) were viscous oils and gave no crystalline products. The fraction obtained by elution to a total of 450 ml. of ethanol, contained 1.8 g. (20.3%) of a solid, m. p. 124~130°C; recrystallization from ligroin yielded a pure sample of the bridged ring ketol VI as colorless prisms, m. p. 134~135°C.

$\lambda_{max}^{MeOH}$ 271 ($\varepsilon$ 1410) and 278 m$\mu$ ($\varepsilon$ 1310).

Found: C, 68.44; H, 7.10. Calcd. for $C_{19}H_{24}O_5$: C, 68.65; H, 7.28%.

The 2,4-dinitrophenylhydrazone of VI was crystallized from ethanol as orange needles and had m. p. 260°C (decomp.).

Found: C, 58.61; H, 5.43. Calcd. for $C_{25}H_{28}O_8N_4$: C, 58.58; H, 5.51%.

**Acetylation of the Ketol VI.**—A mixture of 300 mg. of VI, 6 mg. of *p*-toluenesulfonic acid and 3 ml. of isopropenyl acetate (Eastman) was heated on a water bath for 4 hr. After the acid was neutralized with a few drops of pyridine, the solution was concentrated in vacuo to leave a pale yellow brown oil, which on trituration with petroleum benzine completely crystallized; yield 300 mg. (89%), m. p. 77~85°C. Upon recrystallization from petroleum benzine, it formed colorless plates, m. p. 97.5~98.5°C.

Found: C, 67.10; H, 6.94. Calcd. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00%.

**Alkali Treatment of the Ketol VI.**—A mixture consisting of 300 mg. of VI, 35 mg. of sodium and 5 ml. of ethanol was refluxed on a water bath for 4 hr. and was then acidified with glacial acetic acid. After removal of most of the ethanol, the residue

19) A. L. Wilds and C. H. Shunk, *J. Am. Chem. Soc.*, 65, 471 (1943).

20) E. Lederer and M. Lederer. "Chromatography", Elsevier Publishing Company, Amsterdam (1954), p. 22.

was diluted with water and extracted with chloroform three times. The united extracts were washed with an aqueous solution saturated with sodium chloride, dried over anhydrous sodium sulfate and then concentrated in vacuo. There remained a pale brown oil which was chromatographed on acid-washed alumina[20] (ca. 30 g.) packed and washed with benzene. One hundred and six fractions were collected as in the following table.

| Fraction No. | Eluant | Residue |
|---|---|---|
| 1— 15 | Benzene-chloroform (1 : 1); 150 ml. | Colorless oil 24 mg. |
| 16— 36 | The same; 200ml. | Nil. |
| 37— 46 | Benzene-chloroform (1 : 2); 100 ml. | Colorless oil 8 mg. |
| 47— 51 | Benzene-chloroform (1 : 2); 100 ml. | Nil. |
| 52— 61 | Benzene-chloroform (1 : 3); 100 ml. | Colorless oil 10 mg. |
| 62— 71 | The same; 100ml. | Pale orange oil 7 mg. |
| 72— 91 | Chloroform, 200 ml. | Nil. |
| 92— 96 | Chloroform-ethanol (1 : 1); 50 ml. | Colorless oil 8 mg. |
| 97—101 | The same; 50 ml. | Colorless oil 120 mg. |
| 102—106 | The same; 50 ml. | Colorless oil 10 mg. |

Treatment of the fractions numbered 97 through 101 with ether-petroleum ether yielded an amorphous product which could not be turned into a crystalline substance by any means. The substance was however submitted to elemental, infrared and N. M. R. analysis.

Found: C, 70.64; H, 6.45. Calcd. for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34%.

Infrared absorption spectrum is reproduced in Fig. 6.

## Summary

Ethyl 1, 2, 3, 4-tetrahydro-2-oxo-5-methoxy-1-naphthyl acetate (IIIb) has been synthesized. Condensation of IIIb with 1-diethylaminobutan-3-one methiodide afforded an anomalous product VI. Treatment of VI with isopropenyl acetate in the presence of *p*-toluenesulfonic acid gave rise to an acetate VIII, while on treatment with alkali and then with acid, a hydrophenanthrene lactone IX was obtained.

# *Über die Kupfer-salze der ω-Aminosäure I. Zur Kenntnis des Kupfer-Glycins*

Von Ken-ichi TOMITA

(Eingegangen am 23. Juli, 1960)

Für die Kristallanalyse der Kupfer-Komplexe von ω-Aminosäuren haben wir den Kupfer-Glycin-Komplex als erste Stufe der Versuchsmaterialien ausgewählt und einige physikalisch-chemischen Versuche mit diesem Material unternommen, weil das Glycin einerseits die einfachste ω-Aminosäure und andererseits die einfachste α-Aminosäure ist.

Wenn das Cu-Ion mit verschiedenen ω-Aminosäuren einen Komplex bildet, ist es strukturchemisch sehr interessant zu sehen welche Rolle das Cu-Ion bei dieser Komplexbildung spielt und welche räumliche Konfiguration die um Cu-Ion koordinierte Gruppe hat. Überdies ist es weit bekannt, daß Kupfersalze der ω-Aminosäuren so häufig Kristallwasser enthält (z. B., daß Kupfer-salze von β-Alanin, Isoserin und γ-Aminobuttersäure jeder für sich sechs, drei und zwei Kristallwassermoleküle haben). Deshalb ist es von Bedeutung für Chemiker zu wissen wie das Kristallwassermolekül auf den Prozess der Kristallbildung und der geometrischen Anordnung der um das Cu-Ion koordinierten Atome wirkt.

Bei der Kristallstrukturbestimmung der ω-Aminosäuren selbst ist es uns auch sehr wichtig festzustellen, ob die "Schwer-atom" Methode in der röntgenographischen Kristallanalyse auch für die Kupfer-salze der ω-Aminosäuren gültig ist.

Neben dieser strukturchemischen Wichtigkeit gibt es auch noch andere biochemischen Gründe, warum wir die Kupfer-salze der ω-Aminosäuren als Versuchsmaterie gewählt haben: die verschiedenen ω-Aminosäuren wurden neuerdings in der Natur entdeckt und ihre physiologisch-chemischen Bedeutungen werden

mit grossem Interesse verfolgt. Ausserdem ist die Funktion der Cu-Ionen in den Tierkörpern sehr wichtig. Einige Beispiele dafür seien hier aufgeführt.

1) In dem Blut der Mollusken und Arthropoden findet sich Hämocyanin, welches aus einem Cu-Ion und dem Porphyrin bestehendes Farbstoffprotein ist.
2) Ferner gibt es unter den Metallproteiden einige Oxydationsenzyme mit einem Cu-Ion, z. B., Tyrosinase, Polyphenoloxydase und Ascorbinsäure-oxydase[1].
3) Wie aus der Bakteriologie bekannt, fördert das Cu-Ion die bakteriziden Wirkungen des N-haltigen Heilmittels, Isonicotinsäure-hydrazid (INH) gegen den Tuberkelbazillus[2].

### Darstellung des Kupfer-Glycins

Wenn man, wie bei der gewöhnlichen Darstellung[3] der Kupfersalze, eine wässerige Lösung von Glycin mit überschüssigem, gereinigtem Kupferhydroxyd im Wasserbad etwa 1 Stunde erhitzt und filtriert, so bekommt man eine tiefblaue Lösung. Um verschiedene Kristallisationen aus dieser Lösung zu erhalten, werden Ammonium-hydroxyd, Kohlensäure oder Methanol addiert; beim nachherigen Einengen des tiefblauen Filtrates scheidet sich daraus der Kupfer-Komplex entweder als tiefblauer, aus langer Nadel bestehender Kristall (Kristall I) oder als hellblauer pulveriger Kristall (Kristall II) ab.

a) Kristall I; tiefblaue, lange Nadel, die sich bei 213°C (unkorr.) zu verkohlen beginnt und sich bei 228°C unter Gasentwicklung zersetzt. Dieser Komplex enthält 1 Molekül Kristallwasser, das bei etwa 120°C nach 32 stündigem Erhitzen entweicht. Die Analyse gibt das folgende Resultat.
Gef. Cu, 28.12; C, 20.01; H, 4.39; N, 12.19; $H_2O$, 7.78. Ber. für $Cu(C_2H_4NO_2)_2+H_2O$(Mol. Gew. 229.54): Cu, 27.68; C, 20.91; H, 4.39; N, 12.19; $H_2O$, 7.84%.

b) Kristall II; hellblauer, pulveriger Kristall, der sich bei 222~225°C unter Gasentwicklung zersetzt. Aus den folgenden Analysendaten geht hervor, dass dieser Komplex 2 Moleküle Kristallwasser enthält, das nach 12 stündigem Erhitzen bei etwa 120°C grösstenteils entweicht. Gef. Cu, 27.67; C, 18.22; H, 4.36; N, 11.81; $H_2O$, 13.99. Ber. für $Cu(C_2H_4NO_2)_2+2H_2O$ (Mol. Gew. 247.54): Cu, 25.66; C, 19.39; H, 4.84; N, 11.31; $H_2O$, 14.54%.

Aus obiger Mikroanalyse bestätigt man dass das Kupfer-Glycin zwei Hydrate, nämlich Mono- und Di-hydrat, hat.

### Differential-thermoanalyse des Kupfer-Glycins

Um die Kristallwassermenge von Kristall I und II auf andere Weise zu bestimmen, wurde die Entwässerungswärme beobachtet, die in einem gewissen Verhältnis zur Kristallwassermenge steht.

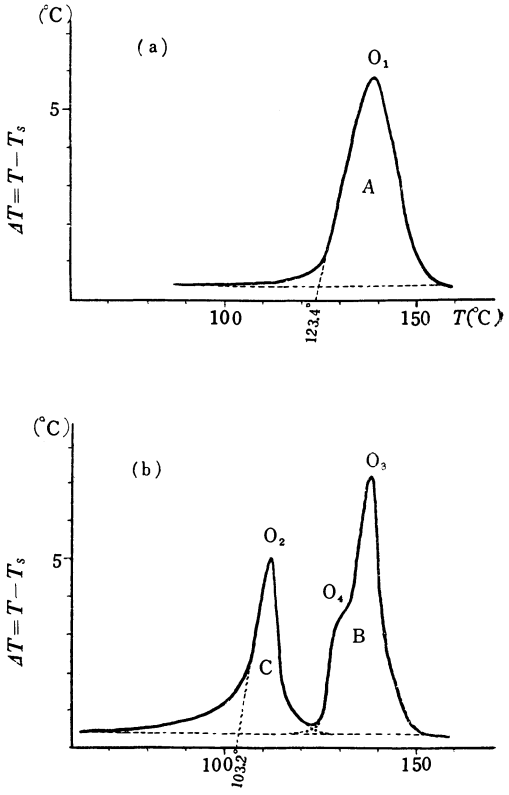

Abb. 1. Differential-thermoanalyse (DTA)-Kurven.
(a) Kupfer-Glycin-Monohydrat (Kristall I)
(b) Kupfer-Glycin-Dihydrat (Kristall II)
$T$: Temperatur von Normalsubstanz ($Al_2O_3$)
$T_s$: Temperatur von Versuchssubstanz.

Das Entweichen des Kristallwassers lässt sich leicht mit Hilfe der Differential-thermoanalyse (DTA) nachweisen und das Resultat wird in Abb. 1 gezeigt. Dabei gebrauchten wir $Al_2O_3$ als Normalsubstanz[4]. Bei dynamischem Erhitzen (z. B., 7.5°C/Min.) setzt die Reaktion für Kristall I bei $T=100$°C ein, durchläuft ein Maximum ($O_1$ in Abb. 1(a)) bei etwa $T=138$°C und klingt dann ab. Dieser endotherme Effekt wird durch die Entwässerung des 1 Molekülkristallwassers verursacht, welche durch die Messung der Verlustmenge von Kristallwasser nach der endothermen Reaktion bestätigt wird (Ber. 7.8%, Gef. 8.2%). Für Kristall II werden drei endotherme Reaktionen beobachtet, wie in Abb. 1(b) gezeigt, indem das erste Maximum

1) B. J. Ralph, *Rev. Pure and Appl. Chem.*, **4**, 85 (1954).
2) E. Sorkin, W. Roth und H. Erlenmeyer, *Helv. Chim. Acta*, **35**, 1736 (1952); J. Cymerman-Craig, G. N. Vaughan und D. Willis, *Nature*, **177**, 480 (1956).
3) E. Abderhalden und E. Schnitzler, *Z. physik. Chem.*, **163**, 96 (1927).
4) Über den automatischen Messungsapparat der Differential-thermoanalyse hat Herr H. Suga von unserem Institut eine baldige Veröffentlichung vorgesehen.

$O_2$ (Temperaturbereich von 80°C bis 120°C) durch die Bildung von Monohydrat (Verlustmenge: Ber. 6.5%, Gef. 7.8%) und das zweite Maximum $O_3$ durch das Entweichen von übrigem 1 Molekül-kristallwasser (Verlustmenge: Ber. 7.8%, Gef. 7.8%) verursacht wird.

Das Verhältnis der Entwässerungswärmemenge zwischen Kristall I und II wird wie dasselbe der Fläche zwischen Null-linie und DTA-Kurve beurteilt: d. h., das Verhältnis der Flächen zwischen A und B (Abb. 1(a) und 1(b)) ist ungefähr 1 : 1, dagegen ist das der Fläche zwischen A und C (Abb. 1(a) und 1(b)) ungefähr 1 : 0.58.

Daraus läßt sich ersehen, daß das erste Kristallwassermolekül von Kristall II leichter entwässert wird als das zweite Kristallwassermolekül von Kristall II. Die zwei Kristallwassermoleküle des Kupfer-Glycin-Dihydrates (Kristall II) unterscheiden sich voneinander durch ihre Verbindungsweise.

Es unterliegt also keinem Zweifel, daß es in Kupfer-Glycin-Komplexen zwei Hydrate gibt, nämlich Mono- und Di-hydrat.

Wie in Abb. 1 ersichtlich ist, ist die Entwässerungstemperatur für Kristall I (Maximum $O_1$) 123.4°C, und für Maximum $O_2$ des Kristall II 103.2°C. Für Maximum $O_3$ des Kristall II

TABELLE I. BEUGUNGSWINKEL UND NETZEBENENABSTÄNDE

| 46 30 | 1,95 | 52 55 | 1,73 | 56 50 | 1,62 |
| 47 20 | 1,92 | 53 30 | 1,71 | 57 25 | 1,60 |
| 47 40 | 1,91 | 54 20 | 1,69 | | |
| 48 40 | 1,87 | 55 55 | 1,64 | | |
| 49 20 | 1,85 | | | | |
| 51 00 | 1,79 | | | | |
| 52 55 | 1,73 | | | | |
| 53 30 | 1,71 | | | | |

können wir aber die genaue Entwässerungstemperatur nicht festlegen, weil es noch ein anderes flaches Maximum $O_4$ zwischen 125°C und 130°C gibt, das vielleicht irgendeine Umwandlung im Kristall anzeigt.

### Röntgenographische Untersuchungen des Kupfer-Glycins nach Debye-Scherrer'scher Pulver-Methode

Von den röntgenographischen Untersuchungen der Kristalle I und II, und ihrer kristallwasserfreien Materie mußten wir uns auf die Debye-Scherrer'sche Pulver-Methode beschränken, weil es sehr schwierig war, einen Einkristall von Kristall II mit geeigneter Grösse zu bekommen. Bei dieser Untersuchung wurde die gewöhnliche zylindrische Kamera (Kameraradius: 50.6 mm) angewandt. Die Versuchsmaterien (Kristalle I und II) wurden

(b) Kupfer-Glycin-Dihydrat

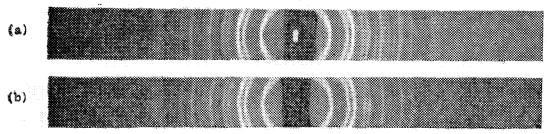

Abb. 3.
(a) Nach Entwässerung des Kristallwassers von Kupfer-Glycin-Monohydrat
(b) Nach Entwässerung des Kristallwassers von Kupfer-Glycin-Dihydrat

in die Glaskapillaren gepackt und nach Debye-Scherrer'scher Methode aufgenommen (Abb. 2). Nach etwa halb-stündigem Erhitzen bei 150°C im Vakuum wurden die Substanzen in diesen Kapillaren entwässert, sofort eingeschlossen und wieder photographiert. Abb. 3 zeigt die Debye-Scherrer'schen Aufnahmen nach Entzug des Kristallwassers.

Bei der Anwendung Norelco Diffraktometers (North American Philips Gesellschaft) wurden auch die Pulver-Diagramme von Kristallen I und II vor und nach Entwässerung erhalten und davon wurden die Beugungswinkel ($2\theta$) und die Netzebenenabstände ($d$) jeder Reflexion festgesetzt (Tabelle I).

Aus den obigen experimentalen Ergebnissen können die folgenden Schlussfolgerungen gezogen werden.

1) Die Kristallstrukturen der Kristalle I und II unterscheiden sich voneinander.
2) Bei der Entweichung des Kristallwassers zeigen die Debye-Scherrer'sche Aufnahmen von Kristallen I und II eine vollkommene Übereinstimmung, d. h., Kristalle I und II haben nach Entzug des Kristallwassers die gleiche Kristallstruktur.
3) Bei der Benutzung von Tabelle I und Hull-Davey-Harrington'schen Kurven[5] wurde vorausgesehen, daß Kristall I vor Entwässerung zu dem rhombischen System gehört, während Kristall II vor Entwässerung und Kristalle I und II nach Entzug des Kristallwassers nicht zu den vier Systemen (isometrischen, tetragonalen, hexagonalen, und rhombischen Systemen) gehören.

### Infrarotspektroskopische Untersuchungen des Kupfer-Glycins

Die Spektren wurden mittels eines Hilger H-800 Doppelstrahlspektrophotometers mit Kochsalz-optik bei Zimmertemperatur (23°C) untersucht. Die in Nujol (Messungsbereich von 650 $cm^{-1}$ bis 2000 $cm^{-1}$) oder Daifloil (Messungsbereich von 1500 $cm^{-1}$ bis 4500 $cm^{-1}$) suspendierten Substanzen von Kristallen I und II wurden benutzt (Abb. 4). Die Wellenzahlen jeder spektralen Lage von Kristallen I und II sind in der ersten und dritten Reihe von Tabelle II wiedergegeben.

Von S. Mizushima et al.[6] wurden infrarotspektroskopische Untersuchungen des Kupfer-

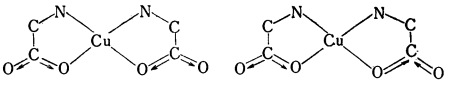
Glycin-Monohydrates und Nickel-Glycin-Dihydrates durchgeführt. Ihre Messergebnisse über das Kupfer-Glycin-Monohydrat stimmen mit unserem Ergebnis des Kristall I überein.

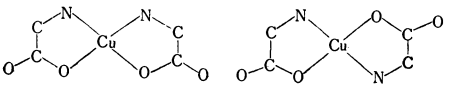


K. Nakamura[7] hat neulich die Isotopenverschiebungen der Infrarotspektren des Kupfer-Glycin-Monohydrates beim Substituieren des Wasserstoffs von Kristallwassermolekül und den $CH_2$- und $NH_2$-Gruppen des Glycinmoleküls durch das Deuterium untersucht und er hat die genauen Zuordnungen über jede Spektren ausgeführt, die in der zweiten Reihe von Tabelle II gezeigt werden.

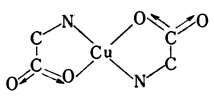
Die Infrarotabsorptionsspektren von Kristall II sind etwas anders als Kristall I (vgl. Abb. 4 und Tabelle II).

Die infrarotspektroskopischen Unterschiede von Kristallen I und II beruhen, im allgemeinen gesagt, auf den Unterschieden der beiden Kristallsysteme, der Symmetrieeigenschaften von beiden Molekülen, der Zahlen des Kristallwassermoleküls, usw.

Ausgegangen nur von dem Unterschied der geometrischen Konfiguration von Molekül, d. h., cis und trans Konfiguration[8], muß sich deutlich dieser Unterschied in dem Band von symmetrischer COO-Valenzschwingung (Bereich : 1300 $\sim$1420 $cm^{-1}$) und in den Bändern von $NH_2$-Schaukelschwingung und COO-Deformationsschwingung (Bereich : 400$\sim$700 $cm^{-1}$, und diese Bänder können mit KBr-optik beobachtet werden) zeigen.

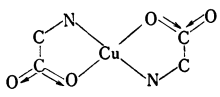


Bei der Benutzung unserer Messergebnisse über das Spektrum der symmetrischen COO-Valenzschwingung können wir den Unterschied der geometrischen Konfiguration von Kristallen I und II betrachten. Wenn das Kupfer-Glycin-Molekül eine cis oder trans Konfiguration hat, so gibt es folgende vier symmetrische COO-Valenzschwingungen :



(I) (II)

7) K. Nakamura, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), (in der Presse).



8) In diesem Fall bedeuten die cis und trans Konfigurationen den folgenden geometrischen Anordnungsunterschied der um zentrales Cu-Atom eben koordinierten N und O von zwei Glycin-Molekülen;

(cis) (trans)

(III)

(IV)

Während dabei (I), (II) und (IV) alle ultrarot-aktiv sind, ist aber (III) ultrarot-inaktiv. Es zeigt, dass der Kristall mit cis Konfiguration zwei symmetrische COO-Valenzschwingungen hat, während der Kristall mit trans Konfiguration nur einen Band hat.

Benutzt man diese Annahme auf Kristall I und II, so zeigt Kristall I zwei Spektren von symmetrischer COO-Valenzschwingung bei 1391 $cm^{-1}$ und 1403 $cm^{-1}$, während bei Kristall II nur ein Spektrum bei 1391 $cm^{-1}$ beobachtet wird. Demnach vermuten wir, dass Kristall I eine cis Konfiguration und Kristall II eine trans Konfiguration hat.

Rosenberg[9] hat schon beobachtet, dass der Unterschied zwischen cis und trans Konfiguration von Metall-Komplexen der verschiedenen Aminosäuren in den Infrarotabsorptionsspektren bei der Temperatur von flüssiger Luft (−170°C) in den Gebieten von 3$\mu$ und 6$\mu$ ($NH_2$-Valenzschwingungsband und antisymmetrischer COO-Valenzschwingungsband) erscheint. Aus unseren Messergebnissen konnten wir aber den Unterschied zwischen cis und trans Konfiguration in dieser Gebieten nicht feststellen, weil unsere Beobachtung nur bei Zimmertemperatur durchgeführt wurde und der gebrauchte Apparat kein genügendes Auflösungsvermögen hat, um die Differenz der Zahl der Spektren und die Verschiebung der Wellenzahl von cis und trans Konfigurationen in diesen breiten Bändern zu bestimmen.

## Schluss

Aus der obigen physikalisch-chemischen Untersuchung können wir die folgenden Schlüsse ziehen:

1) Bei Zimmertemperatur hat das Kupfer-Glycin zwei Hydrate, nämlich Mono- und Di-hydrat. Von diesen beiden ist das Kupfer-Glycin-Dihydrat (Kristall II), worüber bis heute keine Mitteilung erschien, ein neu gefundenes Hydrat.
2) Mit Hilfe der Differential-thermoanalyse findet sich, dass das Kupfer-Glycin-Monohydrat (Kristall I) eine endothermische Reaktion wegen der Entwässerung eines Kristallwassermoleküls zeigt, während die endothermischen Reaktionen des Kupfer-Glycin-Dihydrates (Kristalls II) drei Maxima haben, zwei davon durch die Entwässerungen von zwei Kristallwassermolekülen entstehen, und ein übriges Maximum vielleicht wegen irgendeiner Umwandlung im Kristall vorkommt. Die Entwässerungstemperaturen sind 123.4°C für Kristall I und 103.2°C für erstes Maximum von Kristall II, aber wir können die genauen Entwässerungstemperaturen für die zweite und dritte Maxima von Kristall II wegen der Überlappung der zwei Maxima nicht feststellen. Aus Kristall II wird das erste Kristallwassermolekül leichter entwässert als das zweite Kristallwassermolekül.
3) Das Kristallsystem des Kupfer-Glycin-Monohydrates (Kristalls I) gehört vor Entwässerung zu dem rhombischen System, das Kristallsystem des Kupfer-Glycin-Dihydrates (Kristalls II) ist aber vor Entzug des Kristallwassers noch nicht feststellbar. Nach Entwässerung haben diese beiden Kristalle die gleiche Kristallstruktur miteinander.
4) Von der infrarotspektroskopischen Untersuchung können wir vermuten, dass das Kupfer-Glycin-Monohydrat (Kristall I) eine cis Konfiguration hat, und das Kupfer-Glycin-Dihydrat (Kristall II) eine trans Konfiguration hat.
5) Aus der Tatsache des gleichzeitigen Entstehens zwei verschiedener Kristalle (Kristalle I und II) aus wässeriger Lösung wird vorausgesehen, dass die Differenz der freien Energie beider Hydrate also sehr klein ist und in wässeriger Lösung die zweierlei Komplexmoleküle (mit cis Konfiguration einerseits, und mit trans Konfiguration andererseits) vermutlich existieren.

Es scheint uns, dass die Strukturbestimmung dieser zwei Hydrate nicht nur zur Erweiterung der Kenntnis des geometrischen Verbindungszustandes des Glycin-Moleküls im Kristall, sondern auch zur Kenntnis der Wirkungsarten des Kristallwassermoleküls sehr wünschenswert ist.

Herrn Professor Dr. I. Nitta danke ich herzlichst für mannigfache Anregungen und seine Unterstützung bei der Durchführung dieser Arbeit, insbesondere für seine freundlichen Diskussionen. Mein Dank gilt auch Dr. Y. Sasada für seine hilfreichen Ratschläge bei der Durchführung dieser Arbeit. Zu danken habe ich ferner Dr. H. Suga für seine freundliche Mitwirkung bei Benutzung des Messungsapparates der Differential-thermoanalyse und den Herren T. Shiba, T. Inui und

# *Über die Kupfer-salze der ω-Aminosäure. II. Über die Kristallstruktur des Kupfer-Glycin-Monohydrates*

Von Ken-ichi TOMITA und Isamu NITTA

(Eingegangen am 23 Juli, 1960)

Wie schon in Teil I gesagt[1], hat das Kupfer-Glycin zwei Hydrate, Mono- und Di-hydrat, die sich durch die Kristallstruktur unterscheiden. Während diese beiden Kristallstrukturen durch die röntgenographischen Untersuchungen bestimmt werden können, wurde zunächst das Kupfer-Glycin-Monohydrat (Kristall I in Teil I) als Strukturbestimmungsmaterie genommen, weil ein reiner Einkristall von Kupfer-Glycin-Dihydrat (Kristall II in Teil I) schwer zu bekommen war.

Vor kurzem erschien eine Mitteilung von Stosick[2,3], dass sowohl Nickel-Glycin-Dihydrat als auch Kupfer-*dl*-α-Aminobuttersäure eine plane trans Konfiguration haben. Schon vorher haben wir durch unsere infrarotspektroskopischen Untersuchungen[1] vermutet, daß das Kupfer-Glycin-Monohydrat eine plane cis Kofiguration und das Kupfer-Glycin-Dihydrat eine plane trans Konfiguration hat.

Im Anschluss daran haben wir die Kristallanalyse von Kupfer-Glycin-Monohydrat mit der röntgenographischen Methode unternommen, das Verhalten des Kristallfeldes um das zentrale Metallatom zu untersuchen, deren Ergebnisse im folgenden mitgeteilt werden.

## Experimentelles

Bei der gewöhnlichen Darstellungsmethode, wie schon in Teil I gesagt[1], konnte man der Kristall von Kupfer-Glycin-Monohydrat erhalten; die Grösse der angewandten Kristallnadeln bei der röntgenographischen Untersuchung ist ungefähr 0.2 mm × 0.2 mm × 0.6 mm. Mittelst der Oszillationsmethode, wobei die mit dünner Ni-Folie filtrierte Cu$K_\alpha$-Strahlung ($\lambda_{CuK\alpha}=1.542$ Å) gebraucht wurde, konnten die Gitterkonstanten dieses Kristalls wie folgt ausgemessen werden.

$$a=10.78\pm0.01\text{ Å}$$

$$b=5.208\pm0.004\text{ Å}$$

$$c=13.47\pm0.02\text{ Å}$$

Dabei wurden die genauen Werte der Gitterkonstanten nach der folgenden Methode bestimmt.

Bei der Benutzung des Norelco-Diffraktometers (von North American Philips Gesellschaft geliefert) haben wir zuerst die Beugungswinkel $2\theta_0$ von acht Reflexionen des pulverigen Silikon-Kristalls (normale Materie) beobachtet. Von dem Diagram des Winkels $2\theta_0$ versus $\Delta(2\theta)=2\theta_s-2\theta_0$, wobei Winkel $\theta_s$ den normalen Wert der Reflexion des Silikons (nach der Tabelle von Norelco-Gebrauchsanleitung) zeigt, wurde der Nullpunkt-fehler des Norelco-Diffraktometers mit der Methode der kleinsten Quadrate korrigiert. Zunächst wurden die Bragg-Winkel von acht Reflexionen des Kupfer-Glycin-Monohydrates beobachtet, die in dem Gebiet $10°<2\theta_0<20°$ erschienen, und nach der Berichtigung des Nullpunkt-fehlers, wie oben gesagt, wurden die genauen Werte der Gitterkonstanten mit der Methode der kleinsten Quadrate festgestellt.

Die Dichte dieses Kristalls beträgt nach einer Messung mittels der Schwebemethode (Äthylen-Dibromid/Benzol-Gemisch) bei 15°C 1.998 g/cc. Aus diesem Wert kann man annehmen, daß vier Moleküle von der Formel $Cu(C_2H_4NO_2)_2+H_2O$ in jedem Zellinhalt vorhanden sind (Die röntgenographishe Dichte dieses Kristalls beträgt 2.016 g/cc).

Die Auswertung der Weissenberg- und Sauter-Aufnahmen ergab folgende Auslöschungsgesetze:

($hkl$) in allen Ordnungen vorhanden,
($h00$), ($0k0$) und ($00l$) jeder für sich nur mit $h=2n$, $k=2n$ und $l=2n$ vorhanden.

Diese Auslöschungen kommen nur in der Raumgruppe $D_2^1$-$P2_12_12_1$ vor.

Mittels Äquator-Weissenberg-Aufnahmen um [010], [100] und Schwenkaufnahme um [001] mit Cu$K_\alpha$-Strahlung (Ni-Folie) werden die Intensitäten nach der „multiple-film method" aus vier Filmen im Vergleich zu einer Intensitätsskala geschätzt, und das Verhältnis der relativen Intensitäten von stärkster Reflexion zu schwächster Reflexion war ungefähr 3000 : 1 für ($h0l$) Zone, 1800 : 1 für ($0kl$) Zone, und 120 : 1 für ($hk0$) Zone. Unberücksichtigt

3) A. J. Stosick, ebenda **67**, 362 (1945).

der Absorption und Extinktion wurden die Lorentz-Polarizationsfaktoren und die $(\sin\theta/\lambda)$-Werte für die einzelnen Reflexe mit der gewöhnlichen Weise ermittelt. Die totalen Zahlen der unabhängigen Äquator-Reflexionen, die in der Ausbreitungskugel enthalten sind, sind 190 für [010]-Projektion, 92 für [100]-Projektion und 74 für [001]-Projektion, während die beobachteten Zahlen jeder für sich 170, 75 und 26 sind.

## Strukturbestimmung

Es wurde eine Pattersonprojektion nach [010] gerechnet, die in Abb. 1 wiedergegeben ist. Eine „zugespitzte" („sharpened")[4] Synthese unter Verwendung „unitärer" Atomformamplituden wurde ausgeführt. Berücksichtigt man

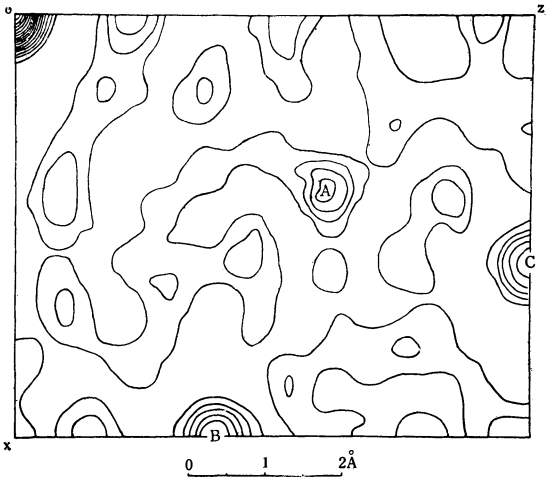

Abb. 1. „Zugespitzte" Pattersonprojektion nach [010].

die Raumgruppe und die Zahl der Formeleinheiten in der Elementarzelle von diesem Kristall, können alle Metallatome (Cu-Atome) eine allgemeine Lage in der Elementarzelle einnehmen. Aus den Maxima A, B und C in der Pattersonprojektion nach [010] kann aber der $x$- und $z$-Parameter des Kupferatoms leicht gefunden werden.

Raumgruppe $D_2^4$-$P2_12_12_1$ hat kein symmetrisches Zentrum im Kristall. Wird für jede Projektion dabei der Anfangspunkt auf der $2_1$-Achse aufgewährt, so steht dieser Anfangspunkt auf symmetrischem Zentrum in Projektion. Dann wurde eine vorläufige Fouriersynthese mit 87 $(h0l)$-Reflexen gerechnet (Abb. 2), und die Vorzeichen jedes Reflexes wurden von der mit Parameterswert des Cu-Atoms gerechneten Strukturfaktoren geführt. (Von den gebrauchten 87 Reflexen veränderten im

4) H. Lipson und W. Cochran, „The Determination of Crystal Structures", G. Bell & Sons, London (1953), S. 170.

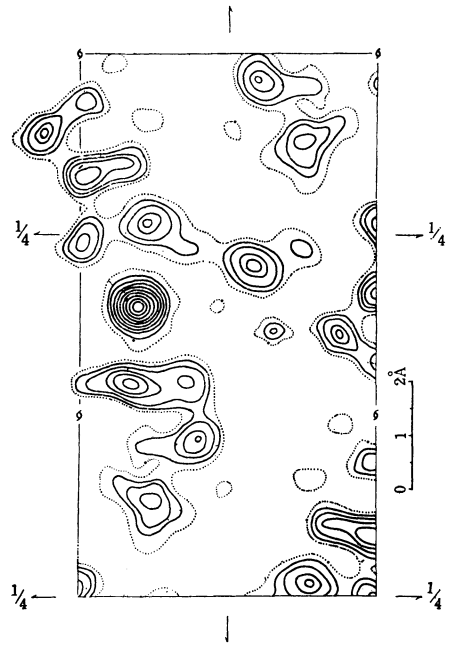

Abb. 2. Erste Fourierprojektion nach [010]. Es wurde die für die Kupferlagen berechneten Vorzeichen eingesetzt (Methode des schweren Atoms).

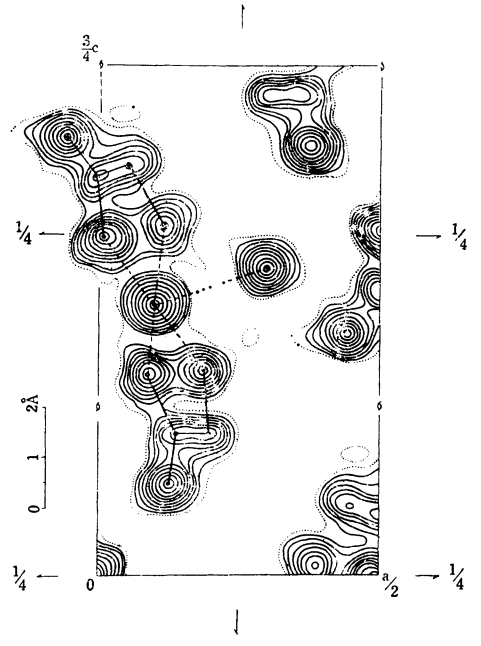

Abb. 3. Elektronendichteprojektion nach [010]. Das punktierte Niveau der Kurven geht durch $2\,e/Å^2$ und die Kurven gleicher Elektronendichte liegen um $1\,e/Å^2$ auseinander, ausgenommen in den Kupfermaxima, wo die Äquidistanz $5\,e/Å^2$ beträgt.

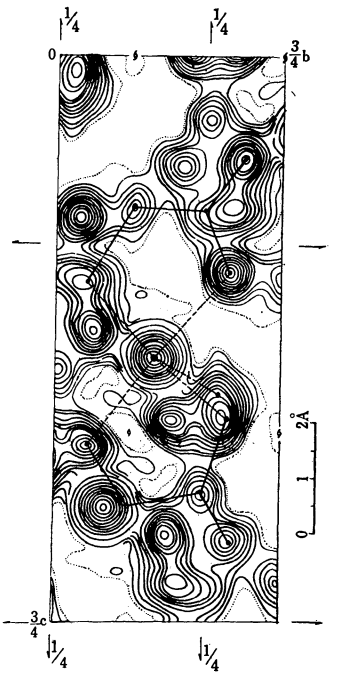

Abb. 4. Elektronendichteprojektion nach [100]. Das punktierte niedrigste Niveau der Kurven liegt bei $3\,e/Å^2$ und die Kurven gleicher Elektronendichte sind in Abständen von $1\,e/Å^2$ gezeichnet, von den Cu-Maxima abgesehen, wo diese Äquidistanz fünfmal grösser ist.

Vergleich zu den endgültigen $F_c$-Werten nur 7 Reflexe die Vorzeichen.)

Zur Berechnung der Strukturamplituden wurde die Atomstreukurve für Cu nach Berghuis et al.[5] gebraucht, die mit der genauen Berechnungsmethode gefunden wurde und im Vergleich zu den Werten von „Internationalen Tabellen„[6] bei weitem die besseren Werte zeigt. Für C, N und O benutzen wir die Atomstreukurven nach McWeeny[7].

Der $y$-Parameterswert des Kupferatoms kann auch mit der Pattersonsynthese nach [100] in gleicher Weise wie mit derselben nach [010] leicht gefunden werden. Die Parameterswerte von anderen leichten Atomen wurden schrittweise mit Fouriersynthese und sukzessiver Näherung („trial-and-error" method) gefunden und verfeinert, wie in Tabelle I gezeigt. Der Abbruchsfehler von Parameterswerten wurde im Vergleich von $F_0$- und $F_c$-Synthesen nach [010] und [100] korrigiert; dabei sind die Zahl und Vorzeichen der Reflexe von $F_0$- und $F_c$-Synthesen selbstverständlich gleich, und die Lagen der Maxima (Atome) von $F_0$- und $F_c$-Synthesen wurden nach Booth-Methode[8] gerechnet. Die letzten absoluten Fourierprojektionen nach [010] und [100] zeigen sich in Abb. 3 und 4, während die letzte absolute Fourierprojektion nach [001] nicht gezeigt wurde. Die isotropischen $B$-Werte nach [010], [100] und [001] betragen jeder für sich 3.0, 2.8 und 2.5. Werden die nicht beobachteten Reflexe berücksichtigt, so beträgt der Zuverlässigkeitsfaktor ($R=\Sigma||F_0|-|F_c||/\Sigma|F_0|$) 0.16 für [010]-Projektion und 0.17 für [100]-Projektion. Für [001]-Projektion wurde $R=0.17$ gerechnet; dabei wurden die aus dem Projektionen nach [010] und [100] gefundenen Parameterswerte und die beobachtbaren Reflexe benutzt. Die mit diesen endgültigen Parameterswerten (Tabelle I) berechneten $F_c$ und die beobachteten $F_0$ sind graphisch in Abb.

TABELLE I. PARAMETER

5 zusammengestellt, wobei sich die $F_c$ auf vier Formeleinheiten in der Elementarzelle beziehen.

Zur Bestätigung der gefundenen Parameter wurde für jedes Atom und jede Bindungslänge noch mittlere Fehler nach Cruickshank[9] wie folgt gerechnet:

$\sigma(x) \fallingdotseq 0.005$ Å, $\sigma(y) \fallingdotseq 0.006$ Å,
$\sigma(z) \fallingdotseq 0.006$ Å für Cu,

$\sigma(x) \fallingdotseq 0.030$ Å, $\sigma(y) \fallingdotseq 0.025$ Å,
$\sigma(z) \fallingdotseq 0.030$ Å für N,

$\sigma(x) \fallingdotseq 0.025$ Å, $\sigma(y) \fallingdotseq 0.027$ Å,
$\sigma(z) \fallingdotseq 0.029$ Å für O,

$\sigma(x) \fallingdotseq 0.034$ Å, $\sigma(y) \fallingdotseq 0.043$ Å,
$\sigma(z) \fallingdotseq 0.043$ Å für C,

für Bindungslänge;

$\sigma(r) \fallingdotseq 0.03$ Å für Cu—N,
$\sigma(r) \fallingdotseq 0.03$ Å für Cu—O,
$\sigma(r) \fallingdotseq 0.06$ Å für N—C,
$\sigma(r) \fallingdotseq 0.06$ Å für C—C,
$\sigma(r) \fallingdotseq 0.05$ Å für C—O,
$\sigma(r) \fallingdotseq 0.04$ Å für O—O,
$\sigma(r) \fallingdotseq 0.04$ Å für N—O.

## Beschreibung der Struktur und Diskussion

Die Projektionen der Atomschwerpunkte nach [010] und [001] sind jeder für sich in Abb. 6 und 7 wiedergegeben. Die interatomaren Abstände und Bindungswinkel werden auch in Abb. 6 und 7 gezeigt.

Wie schon in Abb. 6 und 7 deutlich gezeigt, haben die um das zentrale Metallatom (Cu-Atom) koordinierten vier Atome der zwei Glycin-Molekülen (d. h., $O_1^I$, $O_1^{II}$, $N^I$ und $N^{II}$) in Beziehung auf dem zentralen Metallatom eine plane cis Konfiguration; das Kupfer-Glycin-Monohydrat hat eine andere Kristallstruktur als wie in Nickel-Glycin-Dihydrat, das eine plane trans Konfiguration hat.

Um das zentrale Metallatom wurde ein entstellter Oktaeder mit sechs Atomen, d. h., $O_1^I$, $O_1^{II}$, $N^I$, $N^{II}$, $O_3$ (ein Sauerstoffatom von Kristallwassermolekül) und $O_2^I$ (ein Sauerstoffatom der COO-Gruppe von einem anderen Salz, welches mit $2_1$-Achse zu dem zentralen Metallatom koordiniert wird) gebildet. In diesem entstellten Oktaeder gibt es eine intramolekulare Wasserstoffbindung zwischen $N^{II}$ und $O_3$ und damit wird $O_3$ Atom nach einem Glycin-Molekül (II) mehr oder weniger gezogen.

Von den infrarotspektroskopischen Untersuchungen haben schon Mizushima et al.[10] folgendes geschlossen: das Kupfer-Glycin-Monohydrat (Kristall I) hat wie Nickel-Glycin-Dihydrat eine plane trans Konfiguration, die mit *sp* Hybridisation geradlinig gebildet ist, und die Bindung zwischen COO-Gruppe von zwei Glycin-Molekülen und ein zentrales Metallatom (Cu-Atom) ist wesentlich eine Ionenbindung. Das Resultat unserer röntgenographischen Kristallanalyse stimmt aber nicht gänzlich mit ihrer Schlussfolgerung überein: das Kupfer-Glycin-Monohydrat hat eine um das zentrale Metallatom gebundene plane cis Konfiguration und deshalb können wir die Bindung zwischen der COO-Gruppe und dem zentralen Metallatom mit sp Hybridisation nicht anerkennen. Es scheint uns, dass diese, um das zentrale Metallatom gebildeten Bindungen auf $dsp^2$ oder $d^2sp^3$ Hybridisation beruhen, so daß ein planes Quadrat mit $O_1^I$, $O_1^{II}$, $N^I$ und $N^{II}$ gebildet wird.

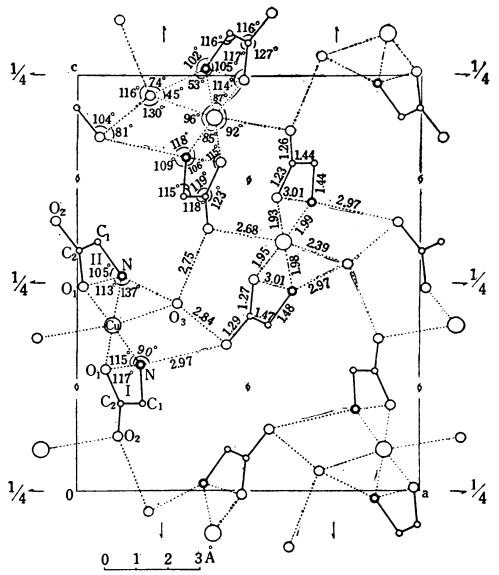

Abb. 6. Schematische Projektion der Atomschwerpunkte nach [010].

Die interatomaren Abstände von Cu—$O_3$ und Cu—$O_2^I$ weichen miteinander über die Grenze von mittlerem Fehler ab: dieser Unterschied wird vielleicht auf den folgenden Ursachen basieren, nämlich auf den Unterschied der molekularen Anordnungsweisen, der Ioneneigenschaften und der Zahlen der Wasserstoffbindung von $O_3$ und $O_2^I$, die jedes Sauerstoffatom ($O_3$ und $O_2^I$) bilden kann.

Wenn die Bildung von Cu—$O_1^I$ (oder Cu—$O_1^{II}$) wesentlich den Ionencharakter hat, soll sich diese Bindungslänge zwischen Cu und $O_1^I$ (oder $O_1^{II}$) im Vergleich zu der Kovalenzbindungslänge ziemlich verändern. Bis heute ist

9) D. W. J. Cruickshank, *Acta Cryst.*, **2**, 65 (1949).

10) D. N. Sen, S. Mizushima, C. Curran und J. V. Quagliano, *J. Am. Chem. Soc.*, **77**, 211 (1955).

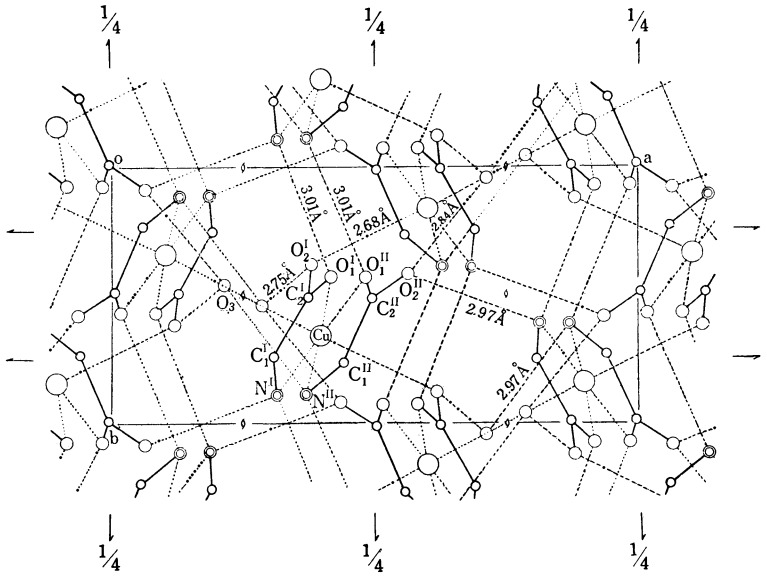

Abb. 7. Schematische Projektion der Atomschwerpunkte nach [001].

das genaue Resultat über den Ionenradius von $Cu^{2+}$-Ion noch nicht veröffentlicht geworden[11], und es ist undenkbar, dass das $Cu^{2+}$-Ion die vollkommende Kugel-Konfiguration hat, wenn sich das $Cu^{2+}$-Ion mit anderen Atomen im Kristall verbindet. Damit ist es unmöglich, den Unterschied zwischen Ionen- und Kovalenzradius über die Bindung von $Cu—O_1^I$ (oder $Cu—O_1^{II}$) zu vergleichen und die Menge des Ionencharakters von $Cu—O_1^I$ (oder $Cu—O_1^{II}$) Bindung zu bestimmen.

Werden auch die Verbindungsweise berücksichtigt, müssen sich die interatomaren Abstände von $Cu—O_1^I$ (oder $Cu—O_1^{II}$) und $Cu—N^I$ (oder $Cu—N^{II}$) sichtbar voneinander verändern, weil das Cu-Atom einerseits mit Stickstoffatom eine Kovalenzbindung oder Koordinationsbindung bildet und andererseits mit Sauerstoffatom von COO-Gruppe zum Teil eine Ionenbindung und zum Teil eine Kovalenzbindung bildet. Wir konnten aber den Unterschied von diesen beiden Bindungslängen nicht erklären, weil der Unterschied von beiden beobachteten Abständen weniger als die Grenze von einem mittlerem Fehler war.

Wie in Abb. 6 und 7 gezeigt, formiert der zentrale Cu-Atom mit $O_2^I$ von einem anderem Molekül die $Cu—O_2^I$-Bindung und das Molekül von Kupfer-Glycin-Monohydrat bildet mit der $2_1$-Operation die unendliche spiralförmige Konfiguration nach der *c*-Achse, wobei zwei N—H···O Wasserstoffbindungen ($N^I—H\cdots O_1^I$ und $N^{II}—H\cdots O_1^{II}$) die Bindungskraft nach der *c*-Richtung verstärken. Die intermolekularen Bindungskräfte nach *a*- und *b*-Richtungen werden mit verschiedenen Wasserstoffbindungen (N—H···O und O—H···O) zusammengesetzt.

Während dem, das Kupfer-Glycin-Monohydrat eine plane cis Konfiguration hat, was von uns festgestellt worden ist, können wir aber noch nicht bestätigen, welche Kristallstruktur das Kupfer-Glycin-Dihydrat hat. Obgleich wir den Schluss gezogen haben, daß das Kupfer-Glycin-Dihydrat (Kristall II von Teil I) der Analogie der Kristallstruktur des Nickel-Glycin-Dihydrates nach und aus dem Resultat der infrarotspektroskopischen Untersuchung von Teil I eine plane trans Konfiguration mit zwei N und zwei O von Glycin-Molekülen hat, kann man aber nicht bestimmen, ob die zwei Kristallwassermoleküle einander mit gleicher Bindungsweise zu dem zentralen Metallatom koordinieren oder nicht. Wie aus DTA-Kurve von Teil I festgestellt, entwässert sich ein Kristallwassermolekül (Maximum $O_2$ in Abb. 1 von Teil I) leichter als ein anderes Kristallwassermolekül (Maximum $O_3$ in Abb. 1 von Teil I), so daß die Bindungsweise von beiden Kristallwassermolekülen nicht gleich ist: d. h., in dem Fall des Kupfer-Glycin-Dihydrates (Kristall II von Teil I) ist es also undenkbar, daß die zwei Kristallwassermoleküle mit der gleichen Bindungsweise koordiniert sind. Aus den Tatsachen, daß die Entwässerungswärme von Maximum $O_1$ (von Kupfer-Glycin-Monohydrat) in DTA-Kurve mit derselben von

11) V. M. Goldschmidt, *Nature*, **157**, 192 (1949).

Maximum $O_3$ (von Kupfer-Glycin-Dihydrat) ungefähr gleich ist und die beiden Entwässerungstemperaturen voneinander ähnlich sind, kann man vermuten, daß das eine Kristallwassermolekül des Kupfer-Glycin-Dihydrates in seiner Bindungsweise dem Kristallwassermolekül des Kupfer-Glycin-Monohydrates ähnlich ist und das ein übriges Kristallwassermolekül des Kupfer-Glycin-Dihydrates mit einer anderen schwächeren Bindungskraft gebunden ist.

In Teil I haben wir schon bestimmt, daß das Kupfer-Glycin-Monohydrat (Kristall I von Teil I) und das Kupfer-Glycin-Dihydrat (Kristall II von Teil I) nach Entweichung des Kristallwassers eine vollkommen gleiche Kristallstruktur zeigt. Die Kristallstrukturen dieses Anhydrates und des Dihydrates sind noch nicht festgestellt. Berücksichtigt man aber das Resultat der DTA-Kurve von Teil I, so kann man vermuten, daß nach Entwässerung von erstem Wassermolekül der Kristall II eine Umwandlung von planer trans Konfiguration nach planer cis Konfiguration beginnt und nach dem Durchgang von Maximum $O_4$ in DTA-Kurve eine plane cis Konfiguration hat, so daß die Kristalle I und II bei dem Zustand von Anhydrat eine gleiche Kristallstruktur haben.

Herrn Professor Dr. T. Watanabe danken wir herzlichst für mannigfache Anregungen bei der Durchführung dieser Arbeit. Sei auch dabei Herrn Dr. Y. Sasada für seinen hilfreichen Rat gedankt.

# SHORT COMMUNICATIONS

## *Electron Spin Resonance and Electronic Absorption Spectra of the Radical Anions of Pyridine and Acridine*

By Keiji KUWATA, Teiichiro OGAWA and Kozo HIROTA

(Received December 20, 1960)

Recently a number of radical anions of aromatic hydrocarbons have been studied[1-3] extensively and their electronic structures have been elucidated to some extent. As for anions of conjugated heterocyclic compounds, however, the phenazine anion was the only one studied hitherto[4]. It seems to be interesting, therefore, to study the electronic structures of anions of heterocyclic compounds, giving special attention to hyperfine interaction between unpaired electron spins and nuclear moments of heteroatoms, and to compare the results with those of aromatic hydrocarbons. In the present communication a study on the anions of pyridine and acridine is reported briefly. The method of preparation of the anions was the same as reported in the previous paper[3]; that

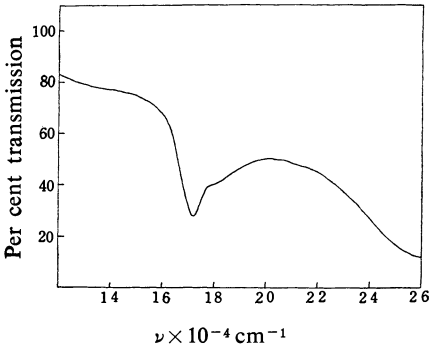

Fig. 2. Absorption spectrum for the THF solution of the adduct of pyridine with sodium.

is to say, all the procedures were carried out in an extremely evacuated system.

On heating pyridine with metallic sodium in tetrahydrofuran solution, a brownish yellow solution was obtained after evolution of a definite amount of gas[5]. This solution exhibited an ESR spectrum of a broad singlet as shown in Fig. 1. On continuing the procedure a red solution was obtained. Its absorption spectrum in the visible region is shown in Fig. 2, and the ESR spectrum obtained in this reaction stage was the same as that obtained in the early stage.

In the case of acridine a red solution of diamagnetic adduct was formed at the early stage of the reaction with sodium. The color of the solution changed to blue on heating it with sodium, and the ESR spectrum of a broad singlet was observed, the *g*-facter and the line width ($H_{msl}$) of which were 2.003 and 13 gauss, respectively.

In the previous investigation on the reaction of pyridine with alkali metals[6], formation of "sodium bipyridyl" was proposed on the basis of the results of chemical analysis of its decomposition product. However, according to our experiment described above, it is highly probable that radical anions of pyridine and also of acridine were formed.

Further studies will be published elsewhere.

The authors wish to express their sincere thanks to Professor M. Nakagawa of Osaka University for his helpful discussions.

## *Selectivity in Radiation-Induced Crosslinking and Scission of Polyvinyl Alcohol (PVA)*

By Yutaka HIRANO and Ayao AMEMIYA

(Received December 17, 1960)

The chemical structure of radiation-induced crosslinking of PVA irradiated in aqueous solution was supposed to be of 1, 2-glycol type and/or $\alpha$-oxy ketone type[1].

We studied the mechanism of scission and/or crosslinking of irradiated PVA. The samples were either dry or swollen with water, when irradiated.

We found a certain selectivity in scission and crosslinking in PVA. The samples were exposed to radiation from a cobalt-60 gamma source in air or in vacuo up to $10^8$ rad. at several temperatures and intensities.

We observed the influence of oxidation by periodic acid ($HIO_4$) upon the limiting viscosity number of irradiated PVA and, in particular, its variation with radiation dose.

In our experiments, the limiting viscosity number of PVA decreased with the increase in radiation dose. As shown in Fig. 1, there is a difference in the results between dry samples and swollen ones.

It should be noted that the limiting viscosity number after oxidation of dry samples is quite independent of radiation dose and agrees with the value of the sample, oxidized but not irradiated. But swollen samples show a different behavior of the limiting viscosity number after oxidation which definitely increases with radiation dose.

These results are inconsistent with the assumption of random scission and crosslinking, on which current theories[2,3] are based.

We are forced to conclude as follows: Only special types of bonds such as of 1, 2-glycol type which exists initially in usual samples[4], can be fractured selectively in either dry or swollen samples. Also, bonds formed by crosslinking in dry samples are definitely of the special types that are susceptible to oxidation by periodic acid. But in swollen samples we have at least two kinds of bonds formed by crosslinking, one susceptible and one not susceptible to oxidation.

## *A Method for Estimation of the Hydration Numbers of Ions in Ion Exchange Resins*

By Hitoshi Ohtaki, Kôzô Gonda and Hidetake Kakihana

(Received December 16, 1960)

A method for estimation of the hydration numbers of ions in ion exchange resins is proposed on the basis of the measurement of the amount of the solvent adsorbed isopiestically on the resin. The sulfonated cation exchange resins, Dowex 50-X4 (4% DVB resin), Diaion SK (8% DVB), Dowex 50-X16 (16% DVB) and Diaion SK-X24 (24% DVB) of sodium form, were used in mesh sizes of 50 to 200. They were dried at 50°C in vacuo. The resins were placed in the small dishes of stainless steel and were contacted with the solvent vapor under the pressure of about 3 mmHg. Ethanol-water and dioxane-water mixtures were used as the solvent systems. The concentrations of the organic solvents were in the range of 0 to 99.6% (v/v). The equilibrium of each isopiestic experiment had been attained in three days in a thermostat at 25 $\pm$0.5°C.

The total amount of solvents adsorbed on the resin was determined gravimetrically. The solvent composition on the resin was determined by the following ways: in the ethanol-water system the solvents adsorbed on the resin were eluted with water and the amount of ethanol in the eluate was measured colorimetrically[1]. In the dioxane-water system, the solvents on the resin were distilled completely

1) B. Lange, "Kolorimetrische Analyse", Verlag Chemie, Weinheim (1956), p. 334.

and the refractive index of the distilled solution was measured.

The distribution coefficient of the solvents, $K_o^w$, is defined as

$$K_o^w = \frac{\bar{m}_w \cdot m_o}{\bar{m}_o \cdot m_w} \quad (1)$$

where $\bar{m}$ and $m$ denote the concentrations of the solvents in the resin and the solution phases, respectively, and subscripts w and o represent water and the organic solvent.

The distribution of the solvents between the resin and the solution phases is thermodynamically given as follows*:

$$\ln \frac{\bar{a}_w \cdot a_o}{\bar{a}_o \cdot a_w} = \frac{\pi}{RT}(\bar{v}_o - \bar{v}_w) \quad (2)$$

where $\bar{a}$ and $a$ denote the activities of the solvents in the resin and the solution phases, respectively, and $\bar{v}$ is the partial molal volume of the solvent in the resin phase. $\pi$ is the swelling pressure of the resin.

It may be considered that the solvent adsorbed on the resin is devided to two different parts: the one I is the solvents solvating to the functional groups (sulfonic acid groups) and their counter ions (sodium ions), another II is the solvents condensed on the exchange sites which become solvophilic by the solvation of the exchange groups. The fact that the resin particles without functional groups do not adsorb the solvent shows that the solvent is not adsorbed on the resin skeleton. We assume that only water molecules can solvate to the ions even in the considerably high concentration of the organic solvent in the solution phase (probably up to about 80%).

From these considerations Eq. 1 may be rewritten as follows:

$$K_o^w = \frac{(\bar{m}_{w_I} + \bar{m}_{w_{II}})}{\bar{m}_{o_{II}}} \cdot \frac{m_o}{m_w} \quad (3)$$

where subscripts I and II denote part I and part II described above.

Being different from the case in which the resin is derectly dipped in the solvents, it is observed that the resin scarcely swells in the equilibrium with the solvent vapor. From this observation, we assume that $\pi$ in Eq. 2 is very small, or

$$\frac{\pi}{RT}(\bar{v}_o - \bar{v}_w) \simeq 0 \quad (4)$$

As the water molecules solvated to the functional groups are fixed and hardly move, the fugacities of the solvents in the resin phase which is equilibrated with the vapor phase may be proportional to the molar fractions of the solvents in part II. It is assumed that the activities of the solvents in the solution phase are proportional to their molar fractions, the following equation is derived from Eqs. 2 and 4:

$$\ln \frac{\bar{a}_{w_{I,II}} \cdot a_o}{\bar{a}_{o_{II}} \cdot a_w} \simeq \ln \frac{\bar{N}_{w_{II}} \cdot N_o}{\bar{N}_{o_{II}} \cdot N_w} = \ln \frac{\bar{m}_{w_{II}} \cdot m_o}{\bar{m}_{o_{II}} \cdot m_w} \simeq 0 \quad (5)$$

where $\bar{N}$ and $N$ denote the molar fractions of the solvents in the resin and the solution phases, respectively, and hence

$$\frac{\bar{m}_{w_{II}}}{\bar{m}_{o_{II}}} \simeq \frac{m_w}{m_o} \quad (6)$$

Applying Eqs. 3 and 6, the hydration number per one functional group and its counter ion (sodium ion), $\bar{H}$, is calculated readily by the following equation:

$$\bar{H} = \frac{(1-m_o)\bar{W}_o}{1000\, E M_w m_o}(K_o^w - 1) \quad (7)$$

where $\bar{W}_o$ is the weight of the organic solvent adsorbed on the resin (gram), $E$ denotes the exchange capacity (meq.) of the resin used, $M_w$ is the molecular weight of water and $m_o$ represents the concentration of the organic solvent given in the scale of weight percentage.

In Fig. 1 the hydration numbers are plotted against the concentrations of ethanol for the variously cross-linked resins. The similar results can be obtained in the dioxane-water system.

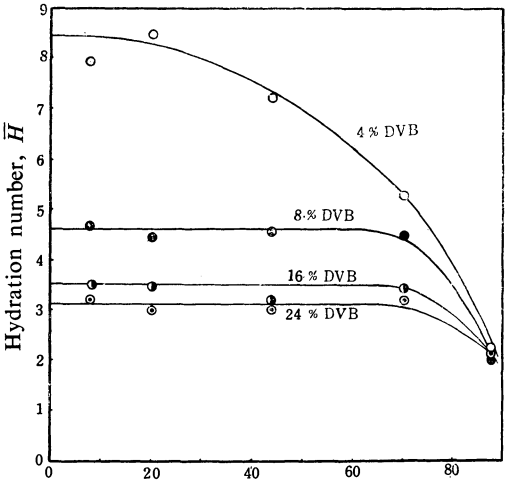

Fig. 1. Hydration number per one functional group and its counter ion (sodium ion) of the cross-linked sulfonic acid resins in the various concentrations of ethanol.

* Cf. H. Kakihana, H. Ohtaki and T. Nomura, *Bull. Tokyo Inst. Tech., Series-B*, No. 1, 1 (1960); H. Kakihana, T. Nomura and H. Ohtaki, ibid., No. 1, 14 (1960).

The numbers extrapolated to zero concentration of the organic solvents may correspond to the hydration numbers of the ions on the ion exchange resins equilibrated with the saturated water vapor. The values of the numbers are listed in Table I. The agreement of the results obtained in the cases of ethanol-water and dioxane-water systems is satisfactory.

TABLE I. HYDRATION NUMBERS, $\bar{H}$, EXTRAPOLATED TO ZERO CONCENTRATION OF THE ORGANIC SOLVENTS

| Resins | Ethanol-water | Dioxane-water | Mean |
|---|---|---|---|
| 4% DVB resin | 8.3 | 8.4 | 8.4 |
| 8% DVB resin | 4.6 | 4.5 | 4.6 |
| 16% DVB resin | 3.5 | 3.7 | 3.6 |
| 24% DVB resin | 3.1 | 3.0 | 3.1 |

## *The Crystal Structure of* $[Cr(NH_3)_6]\,[CuCl_5]$*

By Masayasu MORI, Yoshihiko SAITO** and Tokunosuké WATANABE

(Received December 9, 1960)

Unstable halogen complexes of heavy metals sometimes exist in more than two forms having considerably different chemical constitutions and structures. Thus bromothallates(III) are found with compositions, $KTlBr_4 \cdot 2H_2O$, $Rb \cdot TlBr_4 \cdot H_2O$ and $CsTlBr_4$. These complexes have the octahedral, pyramidal and square configurations[1]. The interatomic distances Tl-Br in these complexes are considerably different from that found in a more stable complex, $[Co(NH_3)_6]\,[TlBr_6]$[2].

Such variety in ionic species is also found in the case of chlorocuprates, but the information seems much less satisfactory. A pentachlorocuprate(II) of hexamminechromium(III), $[Cr(NH_3)_6]\,[CuCl_5]$ has recently been prepared[3]. It occurred to the present authors that the crystal analysis of this compound would give a useful guide to the structural chemistry of chlorocuprates(II).

Weissenberg photographs for the equatorial, the first and fourth layer lines, and oscillation photographs were prepared using Cu$K\alpha$ ($\lambda$= 1.5418 Å) radiation. From these data, it was concluded that the crystals belong to the cubic system, and the systematic reflections were characteristic only for $O_h^8$-Fd3c. The exact reflection angles of several ($hk0$) reflections for Cu$K\alpha_1$ radiation ($\lambda$=1.5405 Å) were determined by means of a GM counter X-ray defractometer which was calibrated with a standard microcrystalline plate of metallic silicon ($a$=5.4301 Å). From these values the unit cube edge was determined to be $a$=22.265 ±0.01 Å. There are 32 formula units in each unit cell, the calculated density being 1.901 g. $cm^{-3}$, in good agreement with the observed value, 1.892 g. $cm^{-3}$. The relative intensities of reflections were visually estimated with a calibrated standard, and the Lorentz and polarization corrections were made using Cochran's chart[4].

There are 32 Cu, 32 Cr, 160 Cl and 192 N atoms in the unit cell. The observed intensities were best accounted for when these atoms are placed in the following equivalent positions:

32 Cu: (b) 1/4, 1/4, 1/4, etc.,
32 Cr: (c) 0, 0, 0, etc.,
64 Cl: (e) $u$, $u$, $u$, ($u$=0.190), etc.,
96 Cl: (g) 1/4, $v$, $-v$, ($v$=0.075), etc.,
192 N: (h) $x$, $y$, $z$, ($x$=0.070, $y$=0.050, $z$=−0.030), etc.

The parameters were obtained by the trial and error method, by comparing the calculated and observed structure factors, $F_c$ and $F_o$ at the each stage. At the final stage, corrections were made for extinction and the anomalous dispersion of copper and chromium atoms. The atomic coordinates given above, combined with the overall temperature factor, $B$=2.5, gave for the equatorial ($hk0$) Weissenberg data a reliability factor, $R$=0.136. The intensities of the unobserved reflections were taken equal to zero in this comparison. For 333 ($hkl$) reflections up to $l$=8 the $R$ value was 0.190 (in this case the unobserved reflections were excluded).

According to the above atomic coordinates, the crystal is composed of octahedral complex ion, $[Cr(NH_3)_6]^{3+}$ and trigonal bipyramidal complex ion, $[CuCl_5]^{3-}$ arranged the sodium chloride type. Because of the symmetry requirement, however, the unit cube edges are twice as much of a simple sodium chloride

* Presented at the Symposium on Coordination Chemistry, Sendai, September 1960.

** Present Address: Institute for Solid State Physics, the University of Tokyo, Shinryudo-cho, Azabu, Minato-ku, Tokyo.

1) T. Watanabe, Y. Saito, R. Shiono and M. Atoji, *Structure Repts.* 11, 393 (1947—8).

arrangement. The threefold axis of the $[CuCl_5]^{3-}$ ion lies on the body diagonal of the cube cell, in accordance with the point symmetry of the Cu position, $D_3$–32. This structure of the $[CuCl_5]^{3-}$ ion is quite a new one, most chlorocomplexes of copper(II) being distorted octahedra. The only exception is the structure of $[CuCl_4]^{2-}$ ion in $Cs_2CuCl_4$ or its bromine analogue, in which case $[CuCl_4]^{2-}$ ion can be taken to be a flattened tetrahedron or a twisted square[5,6].

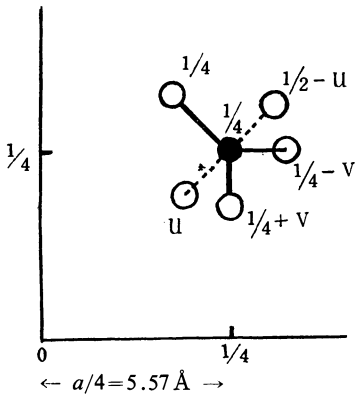

Fig. 1. The structure of $[CuCl_5]^{3-}$ with Cu at 1/4, 1/4, 1/4 (the figure refers to the $z$ coordinate).

The important characteristic of the trigonal bipyramidal structure of $[CuCl_5]^{3-}$ found in the present research is that the distance between the copper atom and the two chlorine atoms on the threefold axis (2.32 Å) is of the same order of magnitude as the distance between the copper atom and the three chlorine atoms at the corner of the triangle (2.35 Å) (Fig. 1). This is in a clear contrast to much greater distances (2.8~3.0 Å) between copper and chlorine atoms on the fourfold or nearly four fold axis found in many distorted octahedral chlorocomplexes.

The authors wish to express their sincere thanks to Dr. Yozo Chatani of Osaka University for the cooperation in preparing Weissenberg photographs.

# *Über die Kupfersalze der ω-Amino-säuren. III. Über die Kristallstruktur von Kupfersalz des β-Alanins*

Von Ken-ichi TOMITA

(Eingegangen am 23. Juli, 1960)

In Teil II[1] wurde die Kristallstruktur des Kupferglycinmonohydrates dargestellt. Als zweite Stufe der Versuchsmaterialien haben wir dasKupfersalz des β-Alanins gewählt und die Kristallstruktur dieses Materials mit Hilfe der röntgenographischen Methode untersucht. Nach der Feststellung dieser Kristallstruktur können wichtige Erkenntnisse, nicht nur über den Koordinationszustand des Cu Atomes, sondern auch über die molekulare Konfiguration des β-Alanins selbst[2], abgeleitet werden.

Wir würden uns auf die Kristallanalyse des Kupfersalzes des Isoserins, das ein Derivat von β-Alanin ist, weiter einlassen, aber diese Kristallstruktur ist so kompliziert, daß wir diese Analyse unterbrechen mussten. Trotzdem fügen wir am Ende dieser Abhandlung die kristallographischen Daten bei, weil diese Substanz sehr wichtig ist.

## Experiment und Resultat

**Darstellungsweise.**—Das gereinigte, überschüssige Kupferhydroxyd wurde mit einer wässerigen Lösung von β-Alanin im Wasserbad etwa 2 Stunden erhitzt und filtriert. Beim nachherigem Einengen des tiefblauen Filtrates scheidet sich das Kupfersalz von β-Alanin als ein papierstreifenförmiger tiefblauer Kristall ab.

Wenn dieser Einkristall in der Atomsphäre liegen gelassen wird, verändert sich die Oberflächenfarbe zu hellblau. Dieses Ausbleichen beweist teilweise Entwässerung des Kristalles.

Die Mikroanalyse gibt folgende Resultate:

$Cu(C_3H_6NO_2)_2+6H_2O$ (Mol. Gew. 347.81)

Ber.: C, 20.72; H, 6.96; N, 8.06; $H_2O$, 31.08; Cu, 18.28. Gef.: C, 21.31; H, 7.02; N, 8.06; $H_2O$, 31.77; Cu, 18.12%.

Mit Hilfe der Schwebemethode (Benzoläthylendibromid Gemisch) ergibt sich ein spezifisches Gewicht von 1.50.

**Gitterkonstante.**—Mittels Rotation- und Weissenberg-Aufnahmen um [100] und [010] mit Cu$K\alpha$-Strahlung wurde die Intensität jeder Reflexion nach der sogenannten "multiple film method" aus vier Filmen im Vergleich zu einer gewöhnlichen Intensitätsskala bestimmt; die Schnittflächeneinheit des gebrauchten Einkristalls ist ungefähr $0.1\times0.2$ mm bei $(0kl)$-Reflexionen und ungefähr $0.8\times1.2$ mm bei $(h0l)$-Reflexionen. Das Verhältnis der relativen Intensitäten von stärkster zu schwächster Reflexion war ungefähr 1500 : 1 für $(0kl)$-Reflexion und 700 : 1 für $(h0l)$-Reflexion.

Wir nahmen keine Notiz von der Absorption, aber auf die Kompensation des primären Extinktioneffekts wurde der genaue $g$-Wert angewandt ($g=6.76\times10^{-4}$), der aus der Formel

$$I_r=I_o/(1-gI_o)$$

gerechnet wurde, wobei $I_o$ die beobachtete Intensität und $I_r$ die reale Intensität zeigt.

Die gesamten unabhängigen Zahlen der Äquator-Reflexionen, welche in der Ausbreitungskugel enthalten sind, sind 182 für [100]-Projektion und 133 für [010]-Projektion, während die beobachteten Zahlen 132 bzw. 125. Für die Bestimmung der Raumgruppe wurden die Auslöschungsgesetze für $(0kl)$, $(1kl)$ und $(h0l)$-Reflexionen benützt.

Die gefundenen Gitterkonstanten sind wie folgt:

$a=5.46$ Å, $b=7.71$ Å, $c=18.11$ Å,
$\beta=92°$ (Monoklinisches System).
Die Zahl der Moleküle pro Elementarzelle; $z=2$.
Raumgruppe: $C_{2h}^5-P2_1/c$.

## Strukturbestimmung und Betrachtung

Die Raumgruppe $C_{2h}^5-P2_1/c$ hat ein symmetrisches Zentrum auf dem Anfangspunkt; wenn das Molekül die allgemeine Lage einnimmt, ist die Zahl der Moleküle in der Elementarzelle vier. Beim Kupfersalz des β-Alanins, beträgt jedoch diese Zahl nur zwei; hierzu muss das Cu-Atom die spezielle Lage in der Elementarzelle, d. h., den Anfangspunkt, einnehmen, und die um das Cu-Atom koordinierten zwei Moleküle des β-Alanins haben daher selbstverständlich eine trans Konfiguration. Unmittelbar darnach wurde eine vorläufige Fouriersynthese um [100] und [010]-Projektionen kalkuliert, wobei die Vorzeichen jeder Reflexion nur mit den Parametern des Cu-Atoms berechneten Strukturfaktoren durchgeführt wurden. Aus den vielen Maxima, die sich in Fourier-projektionen um [100] und [010] zeigen, wurden einige, die gleiche $z$-Parameterwerte haben, gewählt und in Hinsicht auf den Valenzwinkel und die interatomaren Abstände wurden einige weitere schnittweise

1) K. Tomita und I. Nitta, diese Zeitschrift, **34**, 286 (1961).

2) Die Strukturanalyse von β-Alanin wurde schon ungefähr 1948 von Herrn Dr. M. Katayama durchgeführt, aber bis heute ist dieses Resultat noch nicht veröffentlicht worden.

Abb. 3. Graphisches Vergleich der beobachteten und berechneten F-Werte.
(——: $|F_o|$, ------: $|F_c|$)

Fouriersynthesen unternommen. Zur Berechnung der Strukturamplituden wurde die Atomstreukurve für Cu nach Berghuis et al.[3] und für C, N und O nach McWeeny[4] angewandt. In Tabelle I sind die gefundenen Parameterwerte jedes Atoms zusammengestellt. Die letzte Elektronendichteprojektion nach [100] wird in Abb. 1, und nach [010] in Abb. 2 gezeigt, die ein weiteres Maximum G um das zentrale Cu-Atom vorweist; es scheint, daß dieses letztere Maximum von Abbruchs- oder Absorptionseffekt abhängt. In Abb. 3 sind die graphischen Vergleiche der beobachteten und berechneten F-Werte zusammengestellt. Die gefundenen isotropischen Temperaturfaktoren nach [100] und [010] betragen je 3.9 und 2.4, und für die [100]-Projektion wurde ein Zuverlässigkeitsindex $R$ von 0.19 berechnet und für die [010]-Projektion von 0.22, wobei die Kalkulation über alle Reflexionen in der Ausbreitungskugel durchgeführt wurde.

Aus der schematischen Projektion der Atomschwerpunkte (Abb. 4) kann man auch die interatomaren Abstände und Bindungswinkel ersehen. Wie Abb. 4 deutlich zeigt, haben die um das zentrale Cu-Atom koordinierten vier Atome der zwei β-Alanin Moleküle (d. h., $O_1^I$, $O_1^{II}$, $N^I$ und $N^{II}$) in Beziehung zu dem zentralen Metallatom eine plane trans Konfiguration; um das zentrale Metallatom wurde ein ungefähr planes gleichseitiges Viereck mit $O_1^I$, $O_1^{II}$, $N^I$ und $N^{II}$ gebildet und zwei Sauerstoffatome des Kristallwassermoleküls (d. h., $O_3^I$ und

$O_3^{II}$) nehmen zur gleichen Zeit die auf- und abgehenden Spitzen eines Oktaeders ein, das um das Cu-Atom gebildet wurde. Mit den übrigen vier Kristallwassermolekülen wurden die verschiedene Bindungen zwischen jedem Komplexmolekül in Form von Wasserstoffbrücken, d. h., N—H···O oder O—H···O, gebracht.

Es ist auch sehr interessant, die molekulare Struktur von β-Alanin selbst zu erkennen; Die $NH_2$- und COO-Gruppen des β-Alanin Moleküls haben eine sogenannte gauche Konfiguration in Beziehung zu der αC—βC Bindung. (Der Winkel zwischen der durch $C_1^I$, $C_2^I$ und $C_3^I$ und der durch $C_2^I$, $C_3^I$ und $N^I$ gebildeten Ebene ergab ungefähr 70°.) Bis heute wurde das Resultat über die Struktur des β-Alanins noch nicht veröffentlicht[2], aber wenn das Molekül des β-Alanins im Fall von Komplexbildung die gleiche molekulare Form als im freien Zustand beibehält, kann man daraus schliessen, dass es eine gauche Konfiguration hat.

Zum Schluss wird der Vergleich zwischen den verschiedenen interatomaren Abständen im Kupfersalz des β-Alanins mit denjenigen in anderen begleitenden Substanzen dargestellt (Tabelle 2a, 2b und 2c). Beim Kupfersalz der ω-Aminosäuren ist der Cu—O Abstand etwas kürzer als der Cu—N Abstand, während der Cu—O Abstand bei dem Kupfersalze des Prolins im Gegenteil etwas länger als der Cu—N Abstand ist. Wie in Tabelle 2b und 2c deutlich gezeigt wird, sind die O—H···O Abstände zwischen Wassermolekül und Car-

boxylgruppe bei dem Kupfersalz des β-Alanins etwas kürzer als bei dem Kupfersalz des Glycins, aber die ersteren N—H···O Abstände sind etwas länger als die letzteren. Damit kann man vermuten, dass bei Kristallbildung des Kupfersalzes des Glycins die O—H···O und N—H···O Waserstoffbindungen zugleich die grössere Rolle spielen, während bei Kristallbildung von Kupfersalz des β-Alanins grösstenteils nur bei der O—H···O Wasserstoffbindung durchgeführt wird.

### Kristallographische Daten von Kupferisoserintrihydrat

$CuC_3H_5NO_3+3H_2O$ (Mol. Gew. 220.67)

Ber.: C, 16.33; H, 5.02; N, 6.35; $H_2O$, 24.48; Cu, 28.81. Gef.: C, 16.11; H, 4.92; N, 6.49; $H_2O$, 21.91; Cu, 28.50%.

Gitterkonstanten:

$a=7.06$ Å, $b=22.47$ Å, $c=15.77$ Å, $\beta=109°43'$.

Gefundene Dichte:

1.88 g/cc (Schwebemethode).

Die Zahl der Moleküle pro Elementarzelle:

$z=12$.

Raumgruppe: $C_{2h}^5-P2_1/c$ (Monoklinisch).

Bei dieser Raumgruppe ist die Zahl der Moleküle in jeder Elementarzelle vier, wenn das Molekül die allgemeine Lage einnimmt.

Demnach sind in diesem Kristall drei kristallographisch verschiedenartige Moleküle, jeder für sich vier, vorhanden.

Meinem verehrten Lehrer, Herrn Professor Dr. I. Nitta, danke ich herzlich für wertvolle Anregungen und für seine stete Unterstützung bei der Durchführung dieser Arbeit. Dabei sei auch Herrn Dr. Y. Sasada für seine hilfreichen Ratschläge gedankt.

# *Quinones. I. The Syntheses of Acetyl-p-benzoquinone Derivatives and 2-Acetylnaphthoquinone*

By Eturo KUROSAWA

(Received August 8, 1960)

Acetyl-*p*-benzoquinone derivatives are expected to show interesting chemical and biological properties, owing to the presence of an acetyl carbonyl group conjugated to quinone double bond. However, only acetyl-*p*-benzoquinone has been reported in the literature[1].

An attempt was made as described below to synthesize several acetyl-*p*-benzoquinone derivatives, e. g., 2-methyl-5-acetyl-*p*-benzoquinone (acetyltoluquinone), 2, 3-dimethyl-5-acetyl-*p*-benzoquinone (acetyl-*o*-xyloquinone) and 2-acetyl-1, 4-naphthoquinone by the oxidation of corresponding acetylhydroquinone derivatives with silver oxide.

Acetylhydroquinone has been synthesized by several methods: viz., i) by the action of zinc chloride on hydroquinone in glacial acetic acid[2], ii) by the Fries migration of hydroquinone diacetate[3], and iii) by the action of acetyl chloride on hydroquinone dimethyl ether in the presence of aluminum chloride followed by demethylation[1]. But because of the complicated procedures or low yield, these methods did not give good results.

It has been found that these acetylhydroquinone derivatives are obtained in good yield as a result of the action of boron trifluoride on hydroquinone derivatives in glacial acetic acid[4]. Acetylation was carried out by the saturation of boron trifluoride to the suspension of hydroquinone derivatives in excess glacial acetic acid. 2-Acetylhydroquinone (III, $R=R'=H$) was obtained directly by this method from hydroquinone (I, $R=R'=H$) in an almost quantitative yield. But in the cases of 2-methyl- and 2, 3-dimethylhydroquinone and naphthohydroquinone, there were obtained mono- or diacetates of corresponding acetyl derivatives. For example, acetylation of 2-

methylhydroquinone (I, R=H, R'=$CH_3$) afforded pale yellow crystals, then after several recrystallizations from dilute ethanol, colorless crystals were obtained. This material melted at 112°C and exhibited no coloration with ferric chloride in ethanol.

(I) (II) (III) (IV)

After saponification of this diacetate (II, R=H, R'=$CH_3$) with aqueous sodium hydroxide containing a small amount of sodium hydrosulfite, 2-methyl-5-acetylhydroquinone (III, R=H, R'=$CH_3$) was obtained; it melted at 145°C. Similarly, there was obtained 2, 3-dimethyl-5-acetylhydroquinone diacetate (II, R=R'=$CH_3$), m. p. 98°C, which was hydrolyzed to corresponding hydroquinone (III, R=R'=$CH_3$), m. p. 151°C. In the case of acetylation of naphthohydroquinone, 2-acetyl-4-acetoxynaphthol (V, R=$COCH_3$), m. p. 101°C, was obtained and it was hydrolyzed to 2-acetylnaphthohydroquinone (V, R=H).

(V) (VI)

2-Methyl-5-acetylhydroquinone was oxidized quantitatively to 2-methyl-5-acetyl-*p*-benzoquinone (IV, R=H, R'=$CH_3$) by being shaken with silver oxide and anhydrous potassium carbonate in dry benzene. When 2, 3-dimethyl-5-acetylhydroquinone was oxidized under the same conditions, an oily product was obtained. It gave the stimulative odor characteristic to quinone derivative and it was easily reduced to 2, 3-dimethyl-5-acetylhydroquinone by shaking its chloroform solution with aqueous sodium hydrosulfite. In infrared spectrum, this compound showed the band attributed to quinone carbonyl at 1640 $cm^{-1}$ as shown in Fig. 1, but no band in the region of about 3300 $cm^{-1}$. Similarly, 2-acetylnaphthohydroquinone was oxidized to 2-acetyl-1, 4-naphthoquinone (VI), m. p. 83~84°C, in good yield.

2-Acetyl-*p*-benzoquinone and 2-methyl-5-acetyl-*p*-benzoquinone have the bands attributed to quinone carbonyl at 1645 $cm^{-1}$ and 1635 $cm^{-1}$

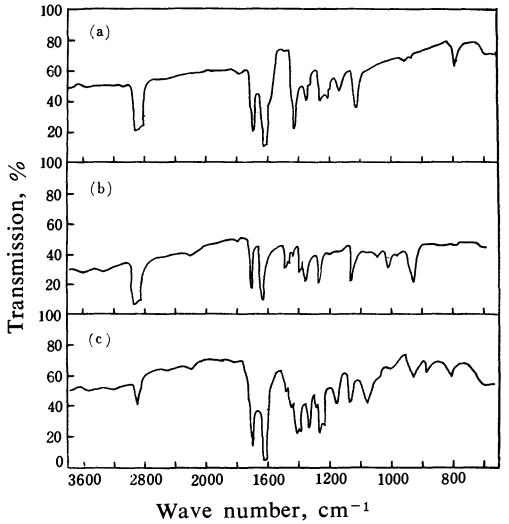

Fig. 1. IR spectra.
(a) Acetylbenzoquinone (Nujol)
(b) Acetyltoluquinone (Nujol)
(c) Acetyl-*o*-xyloquinone (direct)

in infrared spectrum as shown in Fig. 1. Likewise, 2, 3-dimethyl-5-acetyl-*p*-benzoquinone and 2-acetyl-1, 4-naphthoquinone have the bands attributed to quinone carbonyl at 1640 $cm^{-1}$ and 1662 $cm^{-1}$, respectively. In general, it has been reported[5], that *p*-benzoquinone has the band attributed to quinone carbonyl at 1663 $cm^{-1}$; when the substituent is a negative group as chlorine or bromine, the quinone carbonyl band shifts to a higher frequency, and when the substituent is positive, the band shifts to a lower frequency. The position of the absorption maximum can be qualitatively interpreted by the sum of I-effect and M-effect. Contrary to expectation that acetyl-*p*-benzoquinone derivatives would show the band attributed to quinone carbonyl at a higher frequency than that of *p*-benzoquinone, due to the influence of the acetyl carbonyl group, these compounds show the bands at a considerable lower frequency as shown in Fig. 1.

These results indicate the existence of a large M-effect in the molecules of acetyl-*p*-benzoquinone derivatives. For the confirmation of this fact, the author attempted to find the relationship between the frequency of quinone carbonyl in infrared spectrum and the other properties of quinone derivatives. L. J. Bellamy[6] reported the existence of a straight lineal relationship between the sum of electronegativity of substituents of ethylene derivatives and frequency of $CH_2$-deformation ($\delta CH_2$), and between the molecular refractions of

functional derivatives and frequencies of the carbonyl band of carboxylic acids. The author gave attention to the oxidation-reduction potential of quinone derivatives which is one of the important properties of these compounds. It has been suggested that certain quinones, e. g., ubiquinone, play a part in the oxidation-reduction process of living matter[7] and the feature of the reactions is interpreted with the oxidation-reduction potential[8].

The oxidation-reduction potentials and the frequencies of quinone carbonyl bands of some benzoquinone derivatives are listed in Table I. When the oxidation-reduction potentials are plotted against the frequency of quinone carbonyl bands, the resulting curve is a nearly straight line as shown in Fig. 2.

This result indicates that the hypsochromic shift of the quinone carbonyl band resultant from the effect of the substituent linearly depends on the elevation of oxidation-reduction potential of the quinones.

8) Fausto Ramirez, et al., *J. Am. Chem. Soc.* **81**, 4338 (1959).

The author determined the oxidation-reduction potentials of acetylbenzoquinone derivatives by the polarographic method. The buffer solution used was that of Smith et al.[9] The results, given in Table II and Fig. 2, show that these acetyl benzoquinone derivatives have relatively low potentials, but the quinone carbonyl frequencies are slightly higher than the other benzoquinone derivatives as compared with the potentials.

In general, the effect of substituents upon the oxidation-reduction potential has not been interpreted sufficiently, but in this case, the following explanation is possible. When the substituent of benzoquinone derivative gives a fairly large inductive effect in comparison with the M-effect against quinone carbonyl, a straight linear relationship between quinone-carbonyl frequency in the infrared spectrum and oxidation-reduction potential exists as shown in Fig. 2.

In the case of naphthoquinone and anthraquinone, however, relatively high frequencies of quinone carbonyl-bands against the oxidation-reduction potentials were observed as shown in Table III and Fig. 2. This fact is interpreted as due to the influence of the M-effect of an aromatic ring against quinone carbonyl.

Similarly, it is possible that in the cases of acetylbenzoquinone derivatives, deviation from the above linear relationship, as shown in Fig. 2, may be interpreted as due to the fairly large M-effect of the acetyl group against quinone carbonyl in comparison with the inductive effect.

From these results, it is expected that the interesting properties may be gained about acetylquinone derivatives by reason of the low oxidation-reduction potential and the lack of substituent in $\beta$-position toward quinone carbonyl and acetyl carbonyl.

Further investigation concerning the effect of the substituent upon the oxidation-reduction potential and the reactivity of acetylbenzoquinone derivatives is in progress.

## Experimental

**2-Methyl-5-acetylhydroquinone.** — Methylhydroquinone (5 g.) was suspended in glacial acetic acid (30 cc.) and warmed on a water bath. Boron trifluoride was passed into the mixture. The suspension slowly dissolved and a red color appeared. The saturation of boron trifluoride afforded a clear red solution which was heated for further 5 hr. on a water bath. The reaction mixture was then poured into ice water. The crystals thus separated (crude product) were collected by filtration and dried. After repeated recrystallizations from dilute ethanol, colorless needles were obtained, m. p. 112°C. (Found: C, 62.35; H, 5.78%). This material was found to be identical with 2-methyl-5-acetylhydroquinone diacetate[10] by use of the mixed melting point method.

The above crude product was treated with 2 N sodium hydroxide containing a small amount of sodium hydrosulfite for half an hour and then the alkaline solution was neutralized with 2 N hydrochloric acid. The crystals thus obtained were filtered and recrystallized from dilute ethanol. 2-Methyl-5-acetylhydroquinone was obtained as yellow needles, m. p. 145°C. (Found: C, 65.10; H, 6.17%).

**2-Methyl-5-acetylbenzoquinone.** — 2-Methyl-5-acetylhydroquinone (5 g.), anhydrous potassium carbonate (5 g.) and freshly prepared silver oxide (15 g.) were shaken in dry benzene (50 cc.) for 5 min. at 40°C. The reaction mixture was filtered and the solids were shaken with fresh benzene. On evaporation of the combined solution under reduced pressure, orange yellow crystals were obtained. After sublimation in vacuo or recrystallization from carbon disulfide, this substance melted at 79.5°C, yield 94%.

Found: C, 65.90; H, 4.95. Calcd. for $C_9H_8O_3$: C, 65.85; H, 4.88%.

**2, 3-Dimethyl-5-acetylhydroquinone.** — *o*-Xylohydroquinone (5 g.) was suspended in glacial acetic acid (30 cc.) and warmed on a water bath. Boron trifluoride was passed into the mixture. The suspension slowly dissolved and a yellow color appeared. After saturation of boron trifluoride, the reaction mixture was heated for further 5 hr. on a water bath. After the solution was poured into ice water, the resulting crystals (crude product) were collected and dried. After repeated recrystallizations from dilute ethanol, colorless needles were obtained, m. p. 97~98°C. This material exhibited no coloration with ferric chloride in ethanol and gave positive result to the iodoform test; by the mixed melting point method, it was found to be identical with 2,3-dimethyl-5-acetylhydroquinone diacetate (see below).

The above crude product was treated with 2 N alcoholic sodium hydroxide for 5 min. and then the alkaline solution was neutralized with 2 N hydrochloric acid. The crystals thus obtained were recrystallized from dilute ethanol. Yellow needles were obtained, m. p 151°C, yield 5.9 g. (91%).

Found: C, 66.83; H, 6.92. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67%.

This material exhibited green coloration with ferric chloride in ethanol and a positive result to the iodoform test.

**Acetylation of 2,3-Dimethyl-5-acetylhydroquinone.** —2,3-Dimethyl-5-acetylhydroquinone (0.5 g.) was refluxed for 2 hr. in acetic anhydride (2 cc.). The solvent was removed under reduced pressure and the residue was sublimated in vacuo. Diacetate m. p. 97~98°C, was obtained as colorless needles.

Found: C, 63.64; H, 5.94. Calcd. for $C_{14}H_{16}O_5$: C, 63.64; H, 6.06%.

9) L. I. Smith, I. M. Kolthoff, S. Wawzonek and P. M. Ruoff, *J. Am. Chem. Soc.*, **63**, 1018 (1941).

10) R. D. Desai and C. K. Mavani, *Proc. Indian Acad. Sci.*, **29A**, 269 (1949).

**2,4-Dinitrophenylhydrazone of 2,3-Dimethyl-5-acetylhydroquinone.** — 2, 3-Dimethyl-5-acetylhydroquinone and 2,4-dinitrophenylhydrazine reacted in ethanol in the presence of a few drops of concentrated sulfuric acid. Crystals deposited were collected and recrystallized from butanol. Orange red needles were obtained, m. p. 271°C.

Found : C, 53.26 ; H, 4.55. Calcd. for $C_{16}H_{16}O_6N_4$ : C, 53.33 ; H, 4.45%.

**2,3 - Dimethyl - 5 - acetylbenzoquinone.** — 2,3 - Dimethyl-5-acetylhydroquinone (5 g.), anhydrous potassium carbonate (5 g.) and freshly prepared silver oxide (15 g.) were shaken in dry benzene (50 cc.) for 5 min. at 35°C. The reaction mixture was filtered and the solid was shaken with fresh benzene. On evaporation of combined solution under reduced pressure, 2,3-dimethyl-5-acetylbenzoquinone was obtained in yellow brown oily state, yield 92%.

Found : C, 67.52 ; H, 5.68. Calcd. for $C_{10}H_{10}O_3$ : C, 67.41 ; H, 5.62%.

**2 - Acetylnaphthohydroquinone.** — Naphthohydroquinone (5 g.) was suspended in glacial acetic acid (30 cc.) and under water cooling, boron trifluoride was passed into the suspension. Under heat evolution, hydroquinone dissolved slowly and a clear red-brown solution was obtained. After saturation with boron trifluoride the reaction mixture was immediately poured into ice water. The orange red product (crude product) was filtered ; after repeated recrystallizations from dilute ethanol, it melted at 101°C.

Found : C, 68.96 ; H, 5.00. Calcd. for $C_{14}H_{12}O_4$ : C, 68.85 ; H, 4.93%.

In the infrared spectrum, this material has the bands attributed to OH at 3300 $cm^{-1}$ (broad), acetate carbonyl at 1750 $cm^{-1}$ and carbonyl (bonded) at 1630 $cm^{-1}$. It exhibited greenish blue coloration with ferric chloride in ethanol solution and a positive result to the iodoform test.

The above crude product was dissolved in 2 N aqueous sodium hydroxide containing a small amount of sodium hydrosulfite. After 20 min., the insoluble materials were filtered off, the solution was neutralized with 2 N hydrochloric acid and the resulting crystals collected by filtration. After repeated recrystallizations from dilute ethanol, yellow crystals were obtained, m.p. 206～208°C, yield 3.5 g. (56%).

Found : C, 70.92 ; H, 4.96. Calcd. for $C_{12}H_{10}O_3$ : C, 71.29 ; H, 4.96%.

This material exhibited yellow brown coloration with ferric chloride in an ethanol solution and a positive result to the iodoform test. In the infrared spectrum, it has the bands attributed to OH at about 3300 $cm^{-1}$ (bonded) and acetyl carbonyl at 1618 $cm^{-1}$ (bonded.).

**2-Acetylnaphthoquinone**[11]. — 2-Acetylnaphthohydroquinone (1 g.), anhydrous potassium carbonate (1 g.) and freshly prepared silver oxide (3 g.) were shaken in dry benzene at 40°C for 15 min. The reaction mixture was filtered and the solvent was removed under reduced pressure. The residue was recrystallized from light petroleum ; golden yellow needles were obtained, m. p. 83～84°C, yield 0.84 g. (85%). (Found : C, 71.85 ; H, 3.87%).

**Determinations of Oxidation-Reduction Potential by Polargroaphic Method.** — Oxidation-reduction potential measurement was carried out by preparing 0.001 M solution of quinone derivatives in a buffer solution containing 0.1 N sodium acetate and 0.1 N acetic acid in 50% ethanol at pH 5.4. In order to find the standard normal hydrogen electrode the potentials were calculated for pH of zero, using 0.246 V. as the standard potential of the saturated calomel electrode.

The author wishes to thank Professor Tosi Irie of Hokkaido University for his kind guidance throughout this work.

# *Interaction Polarization of the Hydrogen Bonded Complexes. II*

By Ko KIMURA and Ryoichi FUJISHIRO

(Recieved August 22, 1960)

An increase of the molecular polarization due to hydrogen bonding reported by Sutton et al.[1], by Tsubomura[2] and also by the present authors[3] is one of variations of dielectric properties arising from the molecular interaction. Many obstacles are present in the precise determination of the molecular polarizations for the hydrogen bonded complexes from the measurements of dielectric constants, specific volumes and refractive indexes of ternary solutions (proton donors, proton acceptors and inert solvents). The most important point is

1) J. R. Hulett, J. A. Pegg and L. E. Sutton, *J. Chem. Soc.*, **1955**, 3901.
2) H. Tsubomura, This Bulletin, **31**, 435 (1958).
3) K. Kimura and R. Fujishiro, ibid., **32**, 433 (1959).

whether or not Debye's equation holds even approximately in ternary solutions, because the measurements are carried out in such solutions that the interaction between proton donors and proton acceptors can take place. This problem will be discussd elsewhere. In so far as polarization values for the complexes are calculated by the use of Debye's equation, we must devise a way to make the difference as small as possible between the dielectric constant of a pure solvent and that of a ternary solution containing large quantities of a proton acceptor. Otherwise the polarization values obtained from observed dielectric constants and specific volumes are not reliable because of the solvent effect. In order to make the dielectric constants of ternary solutions with high concentrations of proton acceptors as low as possible, it is necessary to use nonpolar proton acceptors such as *p*-dioxane and bipyridyl. For example, it follows that when we want to investigate the polarization value of the phenol + pyridine complex, examination of the phenol + bipyridyl complex instead of the phenol + pyridine complex itself is more reasonable from consideration of the solvent effect.

In the previous paper, the dielectric measurements were carried out for some of the OH···O hydrogen bonded systems by using benzene as an inert solvent, and the analysis was performed based on a model with the covalent character of the hydrogen bonds[4]. This report describes first the results of dielectric measurements for the OH···N hydrogen bonded systems such as benzyl alcohol + bipyridyl, benzyl alcohol + triethylamine, phenol + bipyridyl and phenol + triethylamine by exactly the same procedure as in the previous report, and secondly the correlation between the dielectric data and the infrared spectra.

## Experimental

Materials used in this work were purified by the method described in Weissberger's text-book[5]. Benzene was used as a solvent throughout this work. It was frozen three times after being shaken with concentrated sulfuric acid and with dilute sodium hydroxide, dried over phosphorous pentoxide, and then fractionally distilled through a "Heli-Pack" column. Benzyl alcohol was purified by shaking with aqueous potassium hydroxide solution and extracting with ether, which had been freed from peroxides. The extract was treated with saturated sodium hydrogen sulfite solution and dried over potassium carbonate. After the removal of ether, benzyl alcohol was dried over lime and distilled under reduced pressure. $\alpha,\alpha'$-Bipyridyl (the special grade made by Wako Pure Chemicals Co., Ltd.) was dried in a desiccator and used without further purification. Its melting point was 70. 5°C. The measurements of dielectric constants $\varepsilon$, refractive indexes $n$ and specific volumes $v$ were carried out at 25°C with the apparatus already reported[3].

## Results

The results of the measurements of $\varepsilon$, $n^2$ and $v$ for the four ternary systems i. e., benzyl alcohol + $\alpha,\alpha'$-bipyridyl + benzene, benzyl

alcohol + triethylamine + benzene, phenol + $\alpha,\alpha'$-bipyridyl + benzene and phenol + triethylamine + benzene, are expressed in Table I by formulae relating $\varepsilon$, $n^2$ and $v$ to $w$, respectively, where $w$ represents the weight fraction of the proton donors. The calculation of the molecular polarizations from these experimental data was performed according to the method described in the previous paper[3]. Polarization values $P'$ thus obtained are also shown in Table I, together with those for the corresponding binary systems already reported i. e., benzyl alcohol + benzene and phenol + benzene. $P'$ will contain the polarization for the free proton donor as well as that for the complex. If the fraction of the proton donor existing in the form of the complex in the limit $w\to 0$ is estimated by the use of the formation constant $K$ of the complex, the true polarization value $P_1$ for the complex is determined by both the polarization value $P$ for the free proton donor and $P'$. The formation constants of the complexes tabulated in Table I are either taken from literatures or measured by the present authors. As $K$ for the benzyl alcohol + $\alpha,\alpha'$-bipyridyl complex is expected to be of the same order as that for the ethanol + pyridine complex, we measured the ultraviolet spectra[6] of the latter system by using *n*-heptane as a solvent, and determined $K$ from the variation of the intensity of the $n\to\pi$ electronic transition of pyridine[7] due to the addition of ethanol. $K$ for the benzyl alcohol + triethylamine complex is reported to be about 2.9 l./mol.[8] by the measurement of infrared absorptions. When the content of triethylamine is 9.30 or 29.95 weight per cent, $P_1$ is calculated to be 168.2 cc. or 167.0 cc. The difference 1.2 cc. between these two values is attributable to the solvent effect. On the other hand, one can deduce both $K$ and $P_1$ from $P$'s in two concentrations of triethylamine. The calculated values of $K$ and $P_1$ are 3.2 l./mol. and 166.2 cc., respectively. This result indicates the fact that the reliable association constant can be obtained in the case of the complexes of the small $K$ and large $\Delta P=P_1-P$. As $K$ for the phenol + $\alpha,\alpha'$-bipyridyl complex, we used the formation constant for the phenol + pyridine[9] determined by the measurement of infrared absorptions. The value of $K$ for the phenol + triethylamine complex is reported to be about 83.8 l./mol.[10] by the measurement of ultraviolet absorptions.

If we assume that the distortion polarization does not vary with complex formation and is equal to the molecular refraction $R_D$ at the sodium D line, then we can calculate the permanent dipole moment $\mu_1$ for the proton donor forming the complex. This assumption is not always reasonable, because it is conceivable to ascribe $\Delta P$ to an increase of the atomic polarization. However, we shall carry out tentatively the analysis of experimental data under the assumption that $\Delta P$ arises from the intermolecular charge transfer. The vector subtraction of the dipole moment $\mu$ of the free proton donor from $\mu_1$ gives the increment of the dipole moment due to complex formation. The results of the vector calculations are summarized in Table II.

6) Ultraviolet absorption spectra were measured with a Beckman model DU spectrophotometer.

## Discussion

It is generally believed that the hydrogen bond is not only of the electrostatic, but also of the covalent character. If the hydrogen bond is somewhat of the covalent character, structure III among the following three

(I) $O \cdots H \cdots Y$

(II) $O^- \quad H^+ \cdots Y$

(III) $O^- \cdots H - Y^+$

will play a relatively important role. Then the observed increment of the dipole moment $\vec{\Delta\mu}_T = \vec{\mu}_1 - \vec{\mu}$ is considered to be due to the contribution of structure III in the case of benzyl alcohol + triethylamine, whereas in the phenol + triethylamine system, polarization of $\pi$-electrons of phenol will, to a certain extent, arise owing to the lone pair field of triethylamine. This induced moment will be of the magnitude of 0.16 D, as estimated from the detailed description for the phenol + dioxane system. In systems such as phenol + triethylamine, therefore, the vector subtraction of 0.16 D from $\Delta\mu_T$ gives the average increment of the dipole moment due to the contribution of the structure III. Furthermore, in the case of phenol + bipyridyl, it must be considered that polarization of $\pi$-electrons will be induced in pyridine owing to the proton field of phenol. This calculation is very difficult, and we could not estimate this value. The increase of the dipole moment $\Delta\mu_D$ arising from delocalization in this system, therefore, may be smaller than the tabulated $\Delta\mu_D$ which gives the upper limit.

If we estimate the O···Y distance from the shift of the wave number of the OH stretching vibration[11], the electric moment for structure III is evaluated. Moreover, when we suppose that the ratio of the weight of structure I to that of structure II is the same as in a free state, then we can estimate the contribution of structure III from the increment of the dipole moment. The results thus obtained are shown for all systems in Table II. The large contribution of structure III means the weakening of the OH bond, which is reflected on the decrease of the force constant of the OH bond, and hence leads to a decrease in the wave number of the OH stretching vibration. The wave number shift $\Delta\nu$ of the OH stretching vibration has often been correlated with the strengths of the hydrogen bonds. Therefore, we may expect the correlation of $\Delta\nu$ with the weight of structure III. The observed $\Delta\nu$'s for the OH stretching vibration are given in the last column in Table II. The weight of structure III is plotted against $\Delta\nu$ in Fig 1. The four complexes lie on a straight line except benzyl alcohol + triethylamine and phenol + triethylamine, but the latter two complexes show extraordinarily great values for the weight of structure III in spite of the small $\Delta\nu$. If the spectroscopic results are correct, it seems that there are some questions about the above-mentioned treatment of the dielectric data. This is because it is natural to expect that the weight of structure III varies continuously with $\Delta\nu$. However, it has already been found by Barrow[12] that when pyridine and triethylamine are used as proton acceptors, the latter shows a character considerably different from that of the former. He distinguished acetic acid + pyridine from acetic acid + triethylamine, and called the former and the latter the hydrogen bonded complex and the hydrogen bonded ion pair, respectively. If we accept the idea suggested by Barrow, the hydrogen bonded complex belongs to a different category from the hydrogen bonded ion pair, that is to say, there is a distinct boundary between the former and the latter. The dielectric data suggest this idea, but it seems difficult to understand even qualitatively that benzyl alcohol + triethylamine is of the ion pair character without showing an intermediate character. This point will be discussed elsewhere in near future.

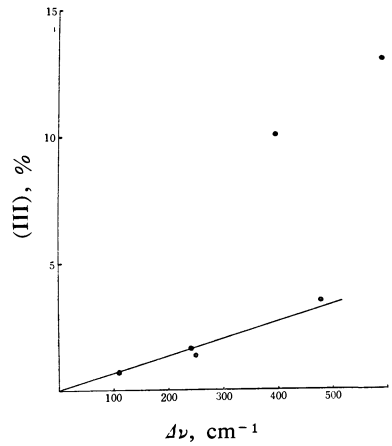

Fig. 1. The correlation of the weight of the structure III with $\Delta\nu$.

## Summary

The dielectric measurements were carried out for benzyl alcohol + $\alpha$, $\alpha'$-bipyridyl, benzyl alcohol + triethylamine, phenol + $\alpha$, $\alpha'$-bipyridyl and phenol + triethylamine by using

11) K. Nakamoto, M. Margoshes and R. E. Rundle, *J. Am. Chem. Soc.*, 77, 6480 (1955).

12) G. M. Barrow, ibid., 78, 5802 (1956).

benzene as a solvent, and the polarization value for each system was calculated. The additional moments due to complex formation were evaluated, as in the previous paper, from both the polarization data and the spectroscopically determined formation constants. Then the weight of structure III was estimated and correlated with the wave number shift $\Delta\nu$ of the OH stretching vibration.

The authors wish to express their thanks to Dr. M. Momotani and Mr. M. Shiro of the Momotani Juntenkan Co., Ltd. for their kind permission to use an infrared spectrometer. The expense of this work has been partly defrayed by a grant from the Ministry of Education.

# *Studies on Antibiotics and Related Substances. XII. Syntheses of 10-Oxo-11-dodecenoic Acid and 11-Oxo-12-tridecenoic Acid, Antitumor Substances*[1]

By Mitsuhiro KINOSHITA and Sumio UMEZAWA

(Received August 18, 1960)

A recent publication[2] from this laboratory described the syntheses and antitumor activities of some methylene derivatives of ketocarboxylic acids, among which the calcium salt of 4-keto-5-hexene-1-carboxylic acid was found to have low toxicity as well as strong activity. The present paper is concerned with an extension of this work and presents the syntheses and antitumor activities of two higher members of even- and odd-numbered carbon acids of the above mentioned series. The syntheses have been worked out as shown in the accompanying chart.

**11-Oxo-12-tridecenoic Acid (IXa).**—Ethyl 9-bromononanoate (II) was prepared from ethyl hydrogen sebacate by the method[3] used for methyl 5-bromovalerate. The bromoester was converted into 13-(dimethylamino)-11-oxotridecanoic acid hydrochloride (Va) by the sequence of acetoacetic ester condensation, decarboxylation and the Mannich reaction. The methyl ester VIa of the Mannich base hydrochloride was converted into its free base and then to the methiodide VIIa. Thermal degradation of the methiodide afforded the desired methylene derivative VIIIa in a yield of 75.5%. Hydrolysis of the ester VIIIa with hydrochloric acid in acetone afforded 11-oxo-12-tridecenoic acid IXa.

The ultraviolet absorptions of VIIIa and IXa in methanol solution showed peaks at 210, 317~318 and 210, 317 mμ, respectively, suggesting the presence of α, β-unsaturated ketone group (Fig. 1), The infrared absorption characteristics of VIIIa and IXa were just as expected,

1) Presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April 1960.
2) M. Kinoshita and S. Umezawa, This Bulletin, 33, 1075 (1960).
3) C. F. H. Allen and C. W. Wilson, "Organic Syntheses," Coll. Vol. 3 (1955), p. 579.

showing the presence of double bond, conjugated carbonyl and carboxyl groups (Fig. 2 and Fig. 3).

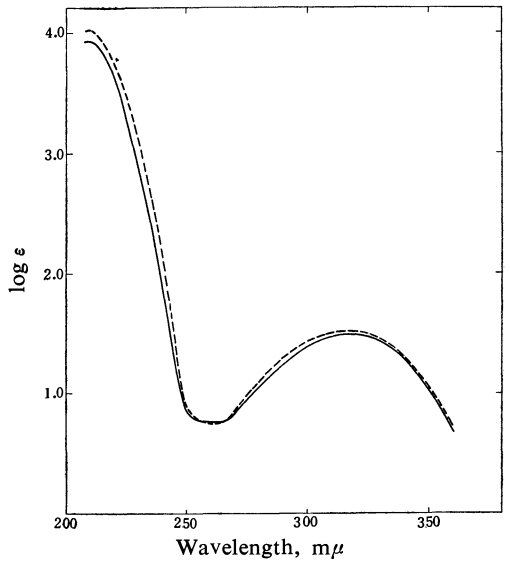

Fig. 1. Ultraviolet absorption spectra of methyl 11-oxo-12-tridecenoate (VIIIa) (----) and 11-oxo-12-tridecenoic acid (IXa) (——) in methanol.

Ozonolysis of the unsaturated keto-acid IXa gave formaldehyde, indicating the presence of a terminal methylene group.

As described above, 11-oxo-12-tridecenoic acid was obtained when the hydrolysis of methyl 11-oxo-12-tridecenoate (VIIIa) with hydrogen chloride in acetone was followed by adjustment of pH to feebly alkaline with a saturated solution of sodium bicarbonate and by removal of acetone at 60~65°C. However, it has been found that 13-chloro-11-oxotridecanoic acid was obtained by a similar procedure except that acetone was removed under cooling at about 5°C. On being treated with an aqueous acetone solution of sodium bicarbonate at 60~65°C, the saturated chloro derivative afforded IXa.

**10-Oxo-11-dodecenoic Acid (IXb).** — 12-(Dimethylamino)-10-oxododecanoic acid hydrochloride(Vb) was prepared from 10-oxo-undecanoic acid which had been described by J. Cason[4]. An analogous sequence of reactions as described above in the synthesis of IXa has been applied to yield the title compound.

Both 11-oxo-12-tridecenoic acid and 10-oxo-11-dodecenoic acid have been found to possess antitumor and antifungal activities. These compounds showed rather higher toxicity in

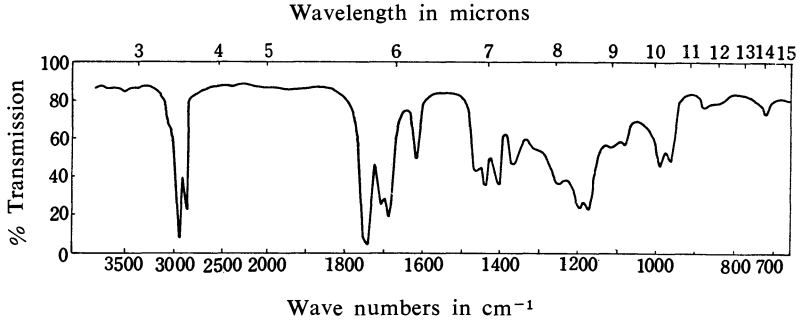

Fig. 2. Infrared absorption spectrum of methyl 11-oxo-12-tridecenoate (VIIIa) (liquid).

comparison with 4-keto-5-hexene-1-carboxylic acid, which was previously reported[2].

## Experimental

**Ethyl 9-Bromononanoate (II).**—This preparation was carried out according to the method used for methyl 5-bromovalerate[3]. Ethyl hydrogen sebacate (139 g.) was dissolved in a solution of potassium hydroxide (40 g.) in water (1.8 l.). A solution of silver nitrate (103 g.) in water (1.2 l.) was added under stirring. The precipitate of ethyl silver sebacate was collected, washed with methanol (400 ml.) and dried in a vacuum desiccator overnight. The silver salt was finely powdered, sieved through a 60-mesh screen and again dried in vacuo at 100°C over phosphorus pentoxide for 15 hr.; yield 183 g. (90%). To a stirred suspension of the dried salt in dry carbon tetrachloride (238 ml.) was added dry bromine (27.2 ml.) over a 45-min. period, and then the mixture was refluxed for 1 hr. on a water bath. The resulting mixture was filtered to remove silver bromide, which was washed with warm carbon tetrachloride (68 ml.). The filtrate was washed with 10% sodium carbonate and dried over sodium sulfate. The filtration followed by the removal of the solvent afforded a crude product of the title compound boiling at 148.5~151.8°C (9.8 mmHg), yield 80.1 g. (50% based upon ethyl hydrogen sebacate). Redistillation of the product gave an analytical sample, b. p. 147.5~148.5°C (8.9 mmHg), $n_D^{20}$ 1.4622.

Found: C, 50.02; H, 8.14; Br, 30.35. Calcd. for $C_{11}H_{21}O_2Br$: C, 49.81; 7.94; Br, 30.19%.

**Ethyl 10-Oxoundecane-1, 9-dicarboxylate (III).**—A solution of sodioacetoacetic ester was prepared from sodium (7.75 g.), absolute ethanol (135 ml.) and ethyl acetoacetate (43.9 g.). Ethyl 9-bromononanoate (II) was added at 40~45°C under stirring in a 45 min. period and then the mixture was refluxed on a water bath for 2 hr. After filtration of sodium bromide, the filtrate was concentrated under reduced pressure. Distillation of the residue gave ethyl 10-oxoundecane-1,9-dicarboxylate, b. p. 173~191°C (5 mmHg), yield 62.3 g. (58.8%). Redistillation gave an analytical sample; b. p. 188.5~191.4°C (1.8 mmHg), $n_D^{20}$ 1.4051.

Found: C, 64.80; H, 9.68. Calcd. for $C_{17}H_{30}O_5$: C, 64.94; H, 9.62%.

**11-Oxododecanoic Acid (IVa).**—A mixture of ethyl 10-oxoundecane-1,9-dicarboxylate (14.6 g.), 35% hydrochloric acid (26.3 ml.) and glacial acetic acid (50 ml.) was refluxed in an oil bath (125~130°C) for 1.5 hr. After cooling, the mixture was extracted with five 40 ml. portions of ether. The extract was evaporated to yield a crude solid of the title compound. Recrystallization from petroleum benzine (45~80°C) gave 82.5 g. (82.5%) of crystals. Repeated recrystallization from the same solvent gave an analytical sample, m. p. 62.8~63.7°C[5].

Found: C, 67.36; H, 10.08. Calcd. for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35%.

5) J. Cason et al. recently reported m. p. 61~61.5°C of this compound which was prepared by an alternative method; see J. Cason and D. J. McLeod, *J. Org. Chem.*, 23, 1499 (1958).

**13-(Dimethylamino)-11-oxotridecanoic Acid Hydrochloride (Va).**—A mixture of 10-oxododecanoic acid (IV) (5.0 g.) and dimethylamine hydrochloride (1.9 g.) was heated at 110~115°C. To a resulting melt was added paraformaldehyde (0.7 g.) and the mixture was stirred at 105°C for 45 min. Evaporation under reduced pressure to remove moisture gave a solid, which was recrystallized from absolute ethanol to afford fine needles of 13-(dimethylamino)-11-oxotridecanoic acid hydrochloride, m. p. 145.0~146.5°C, yield 2.15 g. (31.2%). Repeated recrystallization from the same solvent gave an analytical sample, m. p. 145.5~146.5°C.

Found: C, 58.72; H, 9.70; N, 4.59. Calcd. for $C_{15}H_{30}O_3NCl$: C, 58.54; H, 9.83; N, 4.56%.

**Methyl 13-(Dimethylamino)-11-oxotridecanoate Hydrochloride (VIa).**—A mixture of 13-(dimethylamino)-11-oxotridecanoic acid hydrochloride (Va) (3.85 g.) in absolute methanol (40 ml.) was saturated with dry hydrogen chloride and allowed to stand overnight. Removal of the solvent under reduced pressure afforded the title compound as colorless fine needles, yield 3.85 g. (96.3%). An analytical pure sample was obtained by recrystallization from absolute methanol-ether followed by fractional sublimation under reduced pressure; m. p. 105~107°C.

Found: C, 59.44; H, 9.55; N, 4.28. Calcd. for $C_{16}H_{32}O_3NCl$: C, 59.67; H, 9.95; N, 4.38%.

**Methyl 13-(Dimethylamino)-11-oxotridecanoate Methiodide (VIIa).**—The crude methyl 13-(dimethylamino)-11-oxotridecanoate hydrochloride (2.55 g.) was triturated with water (3 ml.) and 50% aqueous potassium carbonate solution (5.5 ml.). The separated oil was extracted with eight 10 ml. portions of ether. After the extract was dried with fused potassium acetate, the ether was removed by distillation to give the crude crystalline solid of methyl 13-(dimethylamino)-11-oxo-tridecanoate melting at 22.0~23.0°C. Yield, 2.04 g. (90.4%). The product (2.0 g.) was dissolved in a mixture of absolute benzene (8.5 ml.) and absolute acetone (4.3 ml.) and to the solution was added methyl iodide (9.64 ml.) rapidly. The reaction was exothermic and immediately afforded a crystalline methiodide VIIa, which was washed with benzene-acetone (2:1); m. p. 142.5~144.8°C, yield, 3.05 g. (89.8%).

Found: C, 47.99; H, 7.59 N, 3.34. Calcd. for $C_{17}H_{34}O_3NI$: C, 47.79; H, 7.96; N, 3.28%.

**Methyl 11-Oxo-12-tridecenoate (VIIIa).**—A sample of the above methiodide VIIa (3.0 g.) was placed in a small distillation flask and heated at 164°C in an oil bath under highly reduced pressure (0.005 mmHg). The colorless crystals of methyl 11-oxo-12-tridecenoate were obtained in a receiver cooled in a dry ice-methanol bath; 1.27 g. (75.7%). Microdistillation gave an analytical sample; b. p. 85~90°C (bath temperature) (0.002 mmHg), m. p. 7.5~8.5°C.

Found: C, 69.88; H, 10.14. Calcd. for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%.

Maxima in the ultraviolet absorption spectrum were observed in methanol at 210 and 317~318 mμ with ε 10,360 and 32.8, respectively. The infrared absorption spectrum with liquid film showed maxima at 1747 (ester C=O), 1692 (conjugated C=O) and 1618 $cm^{-1}$ (C=C).

**11-Oxo-12-tridecenoic Acid (IXa).** — A solution of methyl-11-oxo-12-tridecenoate (VIIIa) (1.100 g.) in acetone (30 ml.) and 35% hydrochloric acid (5 ml.) was kept at 20°C for 20 hr. The solution was cooled in an ice bath and adjusted to pH 8.2~8.4 with a saturated solution of sodium bicarbonate (35 ml.) and with solid sodium bicarbonate (9 g.). After removal of acetone by distillation at 60~65°C, the solution was shaken with two 10 ml. portions of ether to remove any unreacted ester. The water-layer was adjusted to pH 1.8~2.0 with 3 N hydrochloric acid and extracted with five 10 ml. portions of ethyl acetate. After the extract was dried over sodium sulfate, the ethyl acetate was distilled off under reduced pressure to yield a crude product of 11-oxo-12-tridecenoic acid (IXa), which was crystallized from petroleum benzine (b. p. 45~80°C); yield 588 mg. (57.3%), m. p. 57.5~61.0°C. An analytical sample was prepared by fractional vacuum sublimation, m. p. 61.0~62.0°C. The substance gave a negative iodoform reaction. Maxima in the ultraviolet absorption spectrum were observed at 210 and 317 mμ with ε 8575 and 30.5 in methanol, respectively. The infrared absorption spectrum in Nujol showed maxima at 1700 (C=O) and 1616 $cm^{-1}$ (C=C).

Found: C, 68.58; H, 9.97. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

**Ozonolysis of IXa.**—A solution of IXa (100 mg.) in ethyl acetate (5 ml.) was treated with an approximately 2% (by weight) ozone-oxygen mixture at 0°C at a rate of 500 ml./min. for 2 hr. The resulting solution was mixed with water (5 ml.) and zinc dust (150 mg.) and the mixture was refluxed for 30 min. The reaction mixture was filtered while hot into a solution of methone (150 mg.) in ethanol (5 ml.). Dilution with 10 ml. of water afforded the needles of formaldehyde methone, m. p. 187~189°C; yield 22 mg. (17.1%). Admixing with an authentic specimen of formaldehyde methone showed no change of melting point.

**13-Chloro-11-oxotridecanoic Acid.**—A solution of methyl 11-oxotridecenoate (VIIIa) (1.0 g.) in acetone (30 ml.) and 35% hydrochloric acid (5 ml.) was kept at 20°C for 20 hr. The solution was cooled in an ice-bath and adjusted to pH 8.2~8.4 with a saturated solution of sodium bicarbonate (35 ml.) and with solid sodium bicarbonate (9 g.). After removal of acetone under reduced pressure at 5°C, the resulting solution was shaken with two 10 ml. portions of ether to remove any unchanged ester. The water layer was adjusted to pH 1.8~2.0 with 3 N hydrochloric acid and extracted with five 10 ml. portions of ethyl acetate. After the extract was dried over sodium sulfate, the solvent was distilled off in vacuo. The residue was crystallized from petroleum benzine (b. p. 45~80°C) to afford colorless fine plates of 13-chloro-11-oxotridecanoic acid; yield 639 mg. (58.4%), m. p. 58.5~61.0°C. They were recrystallized twice from petroleum benzine, m. p. 61.0~61.8°C. The substance gave a positive Beilstein's test. Admixing with a sample of IXa showed depression of melting point (m. p. 53.0~59.5°C). Only one maximum in the ultraviolet absorption spectrum was observed in methanol at 280 mμ (ε 47.0), which indicated a normal carbonyl group. The infrared absorption spectrum in Nujol showed a normal carbonyl band at 1710 $cm^{-1}$.

Found: C, 59.18; H, 9.01; Cl, 13.56. Calcd. for $C_{13}H_{23}O_3Cl$: C, 59.36; H, 8.74; Cl, 13.50%.

To a solution of the above product (850 mg.) in water (60 ml.) and acetone (60 ml.) was added an excess amount of sodium bicarbonate. Acetone was removed by distillation at 60~65°C. The residue was processed by the same procedure as that used for the preparation of IXa to afford 655 mg. (89.7%) of IXa, m. p. 57.5~60.7°C. Admixing with a sample of IXa showed no change of melting point.

**12-(Dimethylamino)-10-oxododecanoic Acid Hydrochloride (Vb).**—A mixture of 10-oxoundecanoic acid[4] (IVb) (9.60 g.) and dimethylamine hydrochloride (3.93 g.) was heated at 110°C. To the resulting melt was added paraformaldehyde (1.44 g.) and the mixture was stirred at 105°C for 45 min. Evaporation under reduced pressure to remove moisture gave a solid which was crystallized from absolute ethanol (24 ml.) and absolute acetone (24 ml.) to afford the crystals of 12-(dimethylamino)-10-oxododecanoic acid hydrochloride; yield 3.55 g. (25.2%), m. p. 138~139.5°C. From the mother liquor 0.3 g. of the additional crop was obtained, m. p. 137~139°C. The total yield was 27.3%. An analytical sample was obtained by repeated recrystallization from ethanol, m. p. 138.5~139.5°C.

Found: C, 57.17; H, 9.63; N, 4.85. Calcd. for $C_{14}H_{28}O_3NCl$: C, 57.23; H, 9.60; N, 4.77%.

**Methyl 12-(Dimethylamino)-10-oxododecanoate Methiodide (VIIb).** — A mixture of 12-(dimethylamino)-10-oxododecanoic acid hydrochloride (Vb) (4.5 g.) and absolute methanol (46 ml.) was saturated with dry hydrogen chloride and allowed to stand overnight. The solvent was removed by distillation under reduced pressure to afforded a crude product of methyl 12-(dimethylamino)-10-oxododecanoate hydrochloride, which was triturated with water (5.7 ml.) and 50% aqueous potassium carbonate solution (10.4 ml.). The separated oil was extracted with eight 18 ml. portions of ether. After the extract was dried over fused potassium acetate, the ether was removed by distillation to give colorless prisms of methyl 12-(dimethylamino)-10-oxododecanoate (VIb) melting at 34.0~35.5°C; yield 1.7 g. (40.5%). The crude free ester (1.7 g.) was dissolved in a mixture of absolute benzene (7.5 ml.) and absolute acetone (4.8 ml.) and to the solution was added methyl iodide (8.5 g.). The reaction was exothermic and immediately afforded a crystalline methiodide (VIIb), which was washed with benzene-acetone (2:1); m. p. 173°C (decomp., sintered at 141~142°C); yield 2.2 g. (34.7% based upon Vb).

Found: C, 45.97; H, 7.78; N, 3.80. Calcd. for $C_{16}H_{32}O_3NI$: C, 46.49; H, 7.80; N, 3.39%.

**Methyl 10-Oxo-11-dodecanoate (VIIIb).** — A sample of methiodide VIIb (2.20 g.) was placed in a small distillation flask and heated at 164°C in an oil bath under highly reduced pressure (0.005 mmHg). Colorless crystals of methyl 10-oxo-11-dodecenoate (VIIIb) were obtained in a receiver cooled in a dry ice-methanol bath; yield 1.02 g. (84.5%). Microdistillation gave an analytical sample, b. p. 95°C (bath temperature) (0.005 mmHg),

m. p. 12.2~13.2°C. Maxima in the ultraviolet absorption spectrum were observed in methanol at 209 and 317 mμ, with ε 9730 and 39.2, respectively. The infrared absorption spectrum in liquid film showed maxima at 1747 (ester C=O), 1692 (conjugated C=O), 1620 $cm^{-1}$ (C=C).

Found: C, 69.26; H, 9.65. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

**10-Oxo-11-dodecenoic Acid (IXb).**—A solution of methyl 10-oxo-11-dodecenoate (VIIIb) (1.112 g.) in acetone (36 ml.) and 35% hydrochloric acid (6 ml.) was kept at 21°C for 21 hr. The solution was cooled in an ice-bath and adjusted to pH 8.2~8.4 with a saturated solution of sodium bicarbonate (42 ml.) and with solid sodium bicarbonate (9 g.). After removal of acetone by distillation at 65°C the solution was shaken with two 10 ml. portions of ether to remove any unchanged ester. The water-layer was adjusted to pH 1.8~2.0 with 3 N hydrochloric acid and extracted with five 10 ml. portions of ethyl acetate. After the extract was dried over sodium sulfate, ethyl acetate was distilled off under reduced pressure to yield a crude product of 10-oxo-11-dodecenoic acid (IXb) (850 mg.) melting at 47~53.5°C, which was recrystallized from petroleum benzine (b. p. 45~80°C); yield 548 mg. (51%), m. p. 56.0~56.8°C. It gave a negative iodoform reaction. Maxima in the ultraviolet absorption spectrum were observed in methanol at 209~210 and 321 mμ with ε 8660 and 27.9, respectively. The infrared absorption spectrum in Nujol showed maxima at 1702 (C=O) and 1615 $cm^{-1}$ (C=C).

Found: C, 67.76; H, 9.36. Calcd. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

**Bioassays.**—It is interesting to find that both 11-oxo-12-tridecenoic acid (IXa) and 10-oxo-11-dodecenoic acid (IXb) possess antitumor and antifungal activities. The minimum necessary concentrations of both IXa and IXb for the anti-HeLa cell effect were 125 mcg./ml. Against cells of Ehrlich cartinoma, IXa and IXb had potencies of 1.3 and 1.4 units/mg. (in terms of sarkomycin potency) by cylinder plate method, respectively. The daily intraperitoneal injection of 125 mcg. of IXa and IXb inhibited the ascites increase and prolonged the survival period of mice bearing ascities type of Ehrlich cartinoma by intraperitoneal route. Intravenous acute toxicity tests of IX and IXb in mice indicated the same $LD_{50}$ dose of 670 mcg./mouse.

Both IXa and IXb completely inhibited the growth of *Trichophyton mentagrophytes* and *Penicillium chrysogenum* in a concentration of 7.8 mg./ml., but had comparatively weak activities against other fungi and bacteria tested.

## Summary

1) 11-Oxo-12-tridecenoic acid (IXa) has been prepared from ethyl 9-bromononanoate (II) via 11-oxododecanoic acid (IVa) and the corresponding Mannich base Va.

2) 10-Oxo-11-dodecenoic acid (IXb) has been prepared from 10-oxoundecanoic acid (IVb) via the corresponding Mannich base Vb.

3) It has been found that IXa and IXb possess antitumor and antifugal activities.

The authors are indebted to Dr. H. Umezawa, National Institute of Health, Tokyo, for antitumor assays. Analyses of compounds were performed by Mr. S. Nakada of this laboratory. This work has been supported in part by the Cancer Research Grant of the Ministry of Education and by a grant from the Research Society of Microbiological Chemistry, to which the authors' thanks are due.

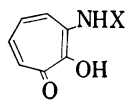
# *On Oxazolo[5 : 4-b]tropones*[1]

By Tetsuo Nozoe, Kozo Doi* and Kazuo Kitahara**



(Received August 29, 1960)

In the course of trying to prepare a pyridotropolone from 3-aminotropolone (I), it has been found that the condensation product of the aminotropolone and ethyl ethoxymethylenemalonate is not the anticipated vinylaminotropolone(II) but the dihydro-oxazolotropone (III), and that the latter III results in fission to form the oxazolotropone (IV) and ethyl malonate on pyrolysis[2]. An analogous observation has also been found in the

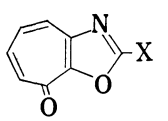
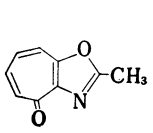
condensation product of *o*-aminophenol and ethoxymethylenemalonate[3]. The structure of the oxazolotropone (IV) was elucidated, at that time, from the similarity of its ultraviolet absorption to that of 2-methyloxazolo[5 : 4-b]-tropone (V) which had been obtained from the reaction of the aminotropolone and acetic anhydride[4].



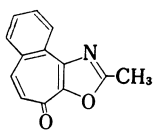
I : X=H
VI : X=CHO

II

III

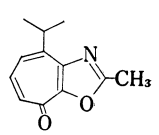


IV : X=H
V : X=$CH_3$



In this communication the present authors will deal with some reactions of the oxazolotropone (IV) and its derivatives, and with the condensation products of the aminotropolone and benzaldehydes in relation to the subject.

Oxazolo[5:4-b]tropone (IV) was also prepared readily by application of methods analogous to those used for the preparations of benzoxazole from *o*-aminophenol to the aminotropolone. Thus, IV was obtained easily on heating the aminotropolone and formamide[5] and on heating 3-formylaminotropolone (VI) in a sealed tube[6].



There have been known to date besides IV, the following oxazolotropones: 2-methyloxazolo-[5 : 4-b]tropone[4] (V) and its bromo derivatives, 2-methyloxazolo[4 : 5-b]tropone[7] (VII), and 2-methyloxazolo[5 : 4-b]benzo[d]tropone[8] (VIII). Recently preparations of 2-methyloxazolo[5 : 4-b]tropones from several diaminotropolones and acetic anhydride have been reported[9].

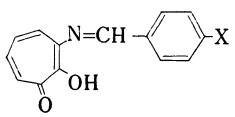
Nicholls and Tarbell[8] assigned the absorption maxima at 1617 and 1567 $cm^{-1}$ in the infrared spectrum of VIII to the tropone carbonyl and the conjugated C=N stretching vibration, respectively. The oxazolotropone (IV) has maxima at 1635 and 1588 $cm^{-1}$, and has a further sharp maximum at 3120 $cm^{-1}$, which is probably considered to originate in the CH vibration of the oxazole ring of IV, because a corresponding absorption is absent in the 2-methyloxazolotropones (V, VII and VIII); benzoxazole has also a maximum at 3125 $cm^{-1}$, whereas 2-methylbenzoxazole lacks this absorption[10].

It had been reported that 3-amino-4-isopropyltropolone affords a monoacetate of m. p. 70.5~73°C on being heated with acetic anhydride[11]. This monoacetate, however, was found to be an oxazolotropone (IX) because of the close resemblance of its ultraviolet absorption to that[2] of IV.

Oxazolotropone (IV), similarly to benzoxazole, was readily hydrolyzed by dilute acid or alkali to form 3-aminotropolone (I). In either case, the formylaminotropolone (V) was not isolated as the intermediate of the reaction.

It has been known that tropolone methyl ethers react with liquid ammonia to give 2-aminotropones. Oxazolotropone (IV) is also regarded as a methyl ether analogue of tropolone and an examination, therefore, was directed to find a possibility of formation of 1, 3-diazaazulene derivative from IV.

When oxazolotropone (IV) was allowed to stand in liquid ammonia overnight, there was obtained the aminotropolone (I) as an ammonolysis product. The 2-methyloxazolotropone (V) resulted in formation of I and additional acetamide on being treated in the same way as the above. The reaction mechanism is probably interpreted as follows:



The proposed machanism seems to be endorsed by the following facts: a) While tropolone acetate was ammonolyzed under the same

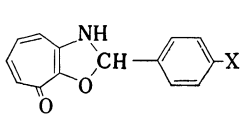
11) T. Nozoe, Y. Kitahare, E. Kunioka and K. Doi, *Proc. Japan Acad.*, **26**, 38 (1950).



condition to give tropolone and acetamide, 3-acetylaminotropolone was recovered unreacted. b) While the dibenzoyl compound of the aminotropolone was also ammonolyzed readily to give the *N*-benzoylaminotropolone and benzamide under the same condition, the former was recovered likewise in an unreacted state. These facts suggest that the formation of *O*-acylated compound as an intermediate occurs in the respective reaction of the oxazolotropone and liquid ammonia. The cleavage of this kind of oxazole ring recalls the reaction of imino ethers and ammonia resulting in the formation of the corresponding alcohol and amidine[12].

In the subsequent papers[2,3], the authors are to discuss a ring-chain tautomerism between aromatic vinylamines possessing a hydroxyl group in the ortho position and oxazoline derivatives. According to Sachs and Brunetti[13], the reaction product of *o*-aminophenol and 2,4-dinitrobenzaldehyde exists in the form of 2-(2,4-dinitrophenyl)benzoxazoline in place of the expected 2,4-dinitrobenzylidene-*o*-aminophenol. It seems to be very interesting to find whether such a fact would also be applicable to the condensation products of the aminotropolone (I) and benzaldehydes.

Unlike 5-aminotropolone[14], 3-aminotropolone (I) did not give any reaction product when heated with benzaldehyde. Even on being heated with more reactive *p*-nitrobenzaldehyde at 150°C for one hour, a condensation product was not obtained. This difficulty, however, was overcome easily by the use of caustic alkali in the reaction. When an equimolar mixture of the aminotropolone, respective benzaldehyde and sodium hydroxide was heated in methanol, the azomethine derivative (X, XI and XII) could be readily prepared. These products showed red coloration with ferric chloride test and hydrolyzed readily to form the aminotropolone (I) with water or aqueous alcohol. These facts mean that they do not exist in the form of their ring-tautomers of XIII. The same reaction of the aminotropolone and *p*-nitrobenzaldehyde afforded 2-(*p*-nitrophenyl)oxazolotropone (XIV), the structure of which was assumed from the fact that it agreed with a reaction product of the aminotropolone and *p*-nitrobenzoyl chloride.

XIV

While the reaction of the aminotropolone and benzoyl chloride in pyridine produced a mixture of the dibenzoylated and *N*-benzoylated compounds, the reaction of the aminotropolone and *p*-nitrobenzoyl chloride under the same condition resulted in the formation of the oxazolotropone (XIV), which showed no coloration with ferric chloride. An oxazole ring formation in the reaction with benzaldehydes or benzoyl chlorides seems to be more rapid in the case of the aminotropolone (I) than in the case of *o*-aminophenol[15].

## Experimental

The ultraviolet absorptions were measured in methanol solution with a Beckman model DU spectrophotometer. The infrared absorption was measured on potassium bromide disk with a Perkin-Elmer model 21 infrared spectrometer, using a rock salt prism.

**Oxazolo[5:4-b]tropone (IV).** — a) 3-Aminotropolone (I, 0.28 g.) and formamide (1 ml.) was heated under reflux at 220°C. Benzene (2 ml.) was added to the reaction mixture at room temperature and the residual solid was collected. It gave IV (0.1 g.), m. p. and mixed m. p.[2] 150~151°C, after sublimation in vacuo following recrystallization from benzene. b) A mixture of the aminotropolone (I, 1.4 g.) and 80% formic acid (30 ml.) was heated under reflux for 3 hr. The evaporated residue of the solvent was crystallized from ethanol to give 3-formylaminotropolone (VI, 1.2 g.) as yellow prisms, m. p. 167~168°C (reported[4] m. p. 168~169°C). When VI (0.3 g.) in a sealed tube was heated on an oil bath of 250°C for 30 min., the oxazolotropone (IV, 0.1 g.) was obtained.

**Hydrolysis of the Oxazolotropone (IV).** — A mixture of IV (30 mg.) and 3 N hydrochloric acid (1 ml.) or 2 N sodium hydroxide (1 ml.) was heated at 50°C for 30 min. Neutralization of the reaction mixture gave 3-aminotropolone (I), m. p. and mixed[4] m. p. 97~98°C.

**2-Methyl-4-isopropyloxazolo[5:4-b]tropone (IX).** —A mixture of 3-amino-4-isopropyltropolone[11] (30 mg.) and acetic anhydride (1 ml.) was heated under reflux for one hour. The evaporated residue of the solvent, after sublimation in vacuo following crystallization from petroleum ether (b. p. 40~60°C), gave the oxazolotropone (IX) as colorless prisms, undepressed on admixture with an authentic sample which had been reported[11] to be a monoacetate of the aminotropolone.

15) R. D. Desai, *J. Chem. Soc.*, **1934**, 1186.

**Ammonolysis of the Oxazolotropone (IV).**—A solution of IV (0.7 g.) in liquid ammonia (50 ml.) was allowed to stand in a pressure bottle for 24 hr. at room temperature. Ammonia was allowed to evaporate, the residue was washed out with methanol (50 ml.), and the evaporated residue of the solvent was crystallized from benzene to give the aminotropolone (I, 0.53 g.).

**Ammonolysis of the 2-Methyloxazolotropone (V).**—A solution of V (0.5 g.) in liquid ammonia (50 ml.) was allowed to stand for 3 days at room temperature. The residual solid of evaporation of ammonia, afer recrystallization from dilute methanol, afforded the aminotropolone (I, 0.3 g.). The evaporated residue of the mother-liquor, after chromatographic purification (alumina—benzene) following crystallization from petroleum ether (b. p. 40~60°C), gave acetamide (50 mg.) of m. p. 80~81°C.

**Ammonolysis of Tropolone Acetate.**—A solution of tropolone acetate (0.4 g.), which prepared according to Doering's description[16], in liquid ammonia (40 ml.) was allowed to stand overnight at room temperature. The evaporated residue of ammonia was dissolved in water, the residual solution was acidified with dilute hydrochloric acid, and extracted with chloroform (20 ml.). The extract, after re-extraction with dilute alkali followed by evaporation in vacuo, gave acetamide (50 mg.). The alkaline extract, after acidification with dilute hydrochloric acid, and after being extracted with chloroform and subsequent evaporation of the solvent, gave tropolone (0.27 g.). The result similar to the above has been recently reported by Sato[17]. An experiment on ammonolysis of 3-acetylaminotropolone under the same condition ended in the recovery of unreacted material.

**Condensation of 3-Aminotropolone (I) and Benzaldehydes.**—To a solution of I (0.28 g.), respective benzaldehyde (0.02 mol.) and methanol (5 ml.), was added a solution of sodium hydroxide (80 mg.) in water (0.5 ml.), and the mixture was heated under reflux for 30 min. Then the reaction mixture was diluted with water (10 ml.), neutralized with acetic acid, and extracted with chloroform (30 ml.). The evaporated residue of the solvent was crystallized from a suitable solvent to give :

*3-Benzylideneaminotropolone (X):* yellow leaflets (chloroform), m. p. 142~143°C,

Found : N, 6.19. Calcd. for $C_{14}H_{11}O_2N$ : N, 6.22%.

*3-p-Chlorobenzylideneaminotropolone (XI):* yellow prisms (chloroform), m. p. 124~125°C,

Found : N, 5.68. Calcd. for $C_{14}H_{10}O_2NCl$ : N, 5.40%.

*3-Anisylideneaminotropolone (XII):* yellow prisms (benzene), m. p. 110~111°C.

Found : N, 5.34. Calcd. for $C_{15}H_{13}O_3N$ : N, 5.49%.

All of the three reaction products showed red coloration with alcoholic ferric chloride and hydrolyzed easily to form the aminotropolone (I) on being shaken with water or aqueous alcohol.

**2-*p*-Nitrophenyloxazolo[5 : 4-b]tropone (XIV).**—a) A solution of sodium hydroxide (0.1 g.) in water (0.5 ml.) was added to a solution of the aminotropolone (I, 0.35 g.), *p*-nitrobenzaldehyde (0.4 g.) and methanol (5 ml.), and heated under reflux for 30 min. The reaction mixture, treated as above, afforded the oxazolotropone (XIV, 0.2 g.) as yellow needles, m. p. 251~252°C. It did not show any coloration with ferric chloride.

Found : C, 62.69 ; H, 3.01 ; N, 10.45. Calcd. for $C_{14}H_8O_4N_2$ : C, 62.69 ; H, 3.12 ; N, 10.51%. $\lambda_{max}^{MeOH}$ mμ (log ε): 265 (4.44), 374 (4.06).

b) A mixture of the aminotropolone (0.14 g.), *p*-nitrobenzoyl chloride (0.19 g.), and pyridine (4 ml.) was stirred for one hour at room temperature. It was then diluted with water (10 ml.) and the residual solid was collected. Recrystallization of it from nitrobenzene gave the above XIV, m. p. and mixed m. p. 251~252°C.

**Benzoylation of 3-Aminotropolone (I).**—A solution of I (0.14 g.), benzoyl chloride (0.14 g.) and pyridine (2 ml.) was stirred for 20 min. at room temperature, then diluted with water (10 ml.), and the residual solid (0.19 g.) of m. p. 150~152°C, was collected. Its fractional recrystallization from a mixture of benzene and methanol afforded 3-benzoylaminotropolone benzoate from the less soluble portion, and 3-benzoylaminotropolone from the more soluble portion,

*3-Benzoylaminotropolone Benzoate :* pale yellow leaflets, m. p. 174°C, which showed no coloration with ferric chloride.

Found : C, 73.29 ; H, 4.40 ; N, 4.07. Calcd. for $C_{21}H_{15}O_4N$ : C, 73.29 ; H, 4.38 ; N, 4.06%.

*3-Benzoylaminotropolone :* pale yellow needles, m.p. 146°C, which showed red coloration with ferric chloride.

Found : C, 69.62 ; H, 4.72 ; N, 6.00. Calcd. for $C_{14}H_{11}O_3N$ : C, 69.70 ; H, 4.59 ; N, 5.80%.

When a mixture of the dibenzoylated compound (0.5 g.) and liquid ammonia (60 ml.) was allowed to stand for 7 days at room temperature, 3-benzoylaminotropolone and benzamide were obtained by treatment similar to the above description.

The authors express their gratitude to Messrs. K. Kato, S. Ohyama, A. Iwanaga and S. Azumi for microanalyses, and to Mr. Y. Ikegami for the infrared spectral measurement.

# *Colloid Chemical Studies on Starching Materials. III. Dynamic Viscosity and Dynamic Rigidity of Starch Solutions*

By Masayuki NAKAGAKI* and Kazuko MURAGISHI

(Received August 18, 1960)

In recent years, anomalous flow properties of colloidal systems have been investigated extensively in the field of rheology, in which the flow property is explained by a combination of rigidities and viscosities. Examples of the combination frequently used are so called Maxwell's model and Voigt's model. Even for fluid, it is required to presuppose some rigidity element to explain its flow property on the basis of these models. The existence of a kind of rigidity may be understood by considering the fact that the so-called structural viscosity of a solution can be explained by assuming a kind of yield value, as shown in a previous paper of this series on dilute solutions of polyvinyl alcohol[1].

In the present paper, starch solutions, also known to show structural viscosity, are examined by a rheometer to obtain the frequency dependencies of dynamic rigidity and dynamic viscosity, and an attempt is made to explain these by Maxwell's and Rouse's model.

## Experimental

**Rheometer.**—A top-drive coaxial rheometer was used. Details of the rheometer were described by Nakagawa and Seno[2]. The sample to be studied was put in the gap between the coaxial internal and external cylinders. The radius of the internal cylinder $r_1$ was 2.00 cm. and that of the external cylinder $r_2$ was 2.50 cm. The depth $l$ of the immersion of the internal cylinder was 15.0 cm., which was equal to the height of the cylinder. The moment of inertia $I$ of the internal cylinder was 3005 g. cm$^2$. The internal cylinder was hung by a quenched steel wire whose diameter was 1.0 mm., and whose length was 92.5 cm. The torsional constant of the wire determined from the period of the free torsional oscillation, $k$, was $0.90\times10^5$ dyne cm.

At the top of the wire, a sinusoidal torsional oscillation was applied and the oscillation of the internal cylinder was recorded on a photographic paper as a Lissajous' figure obtained by combining perpendicularly the oscillation of the internal cylinder and the oscillation at the top of the wire. The Lissajous' figure thus obtained was an ellipse.

The dynamic viscosity $\eta$ and the dynamic rigidity $G$ are calculated by the equations:

$$\left.\begin{aligned}\eta&=\frac{R}{4\pi l}\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)=47.8\times10^{-5}\times R(\text{poises})\\ G&=\frac{K}{4\pi l}\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)=47.8\times10^{-5}\times K(\text{dyne/cm}^2)\end{aligned}\right\}\quad(1)$$

where $R$ and $K$ are the quantities to be determined experimentally by using the equations:

$$\left.\begin{aligned}R&=k\sin\phi/\omega p\\ K&=k(\cos\phi/p-1)+I\omega^2\end{aligned}\right\}\quad(2)$$

Here, the lag angle $\phi$ and the amplitude ratio $p$ are to be obtained by the analysis of the photographic picture, and $\omega$ is the angular frequency. The latter is defined by

$$\omega=2\pi/T_f\quad(3)$$

where $T_f$ is the period of oscillation. All experiments were made in a thermostat at 30°C.

**A Check of the Rheometer by Using Distilled Water.**—Distilled water is an example of so-called Newtonian liquid, for which $G=0$ and $K=0$. All the Lissajous' figures obtained for distilled water by the present rheometer were linear, which give $\sin\phi=0$ and $R=0$. This means that the viscosity of distilled water was too small to be detected by this apparatus, that is $\eta\fallingdotseq0$. Since $\sin\phi=0$ and $\cos\phi=1$ for distilled water, Eq. 2 can be simplified to

$$1/p=1-(I/k)\omega^2\quad(4)$$

Therefore the relation between $1/p$ and $\omega^2$ should be expressed by a straight line which intersects with the ordinate at $1/p=1$ and has an inclination of $-0.0333$ according to the values of $I$ and $k$ given above. In Fig. 1, the experimental values are shown by open circles, while the theoretical relation give by Eq. 4 is shown by a straight line. The agreement is fairly good. Apparent values of the rigidity $G$ of distilled water calculated from the experimental values of $p$ will give the experimental error. The error in the worst case was about 18 dyne/cm$^2$ (for $\omega=11.5$).

**Materials and Preparation of Pastes.** — The materials used were potato starch, sweet potato starch, and rice starch of pharmaceutical grade. The starch, dried in a desiccator and weighed accurately, was put in a flask, water was added, and it was heated at 90°C for 30 min. stirring with a glass rod inserted through a hole in a rubber stopper fitted loosely to the flask. For the heating, the temperature of a water bath was raised gradually from room temperature to boiling, and kept boiling

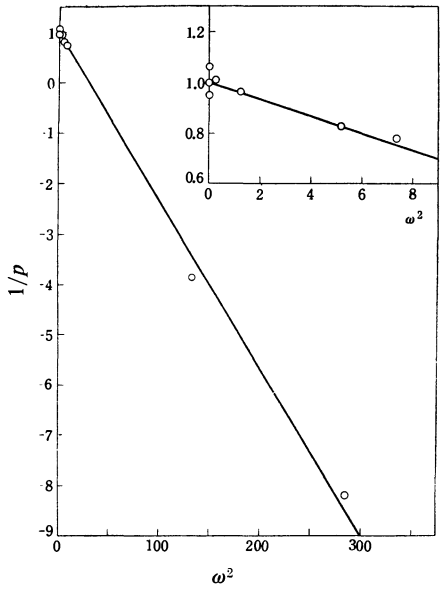

Fig. 1. Distilled water.

for 30 min. The temperature in the flask was 90°C when the bath water was boiling. Then, the flask was placed in cold water for cooling. The paste was used for the measurement immediately after it was cooled, and the measurement was finished in the same day.

## Results and Discussion

The values of the dynamic viscosity $\eta$ and the dynamic rigidity $G$ thus obtained are shown in the following figures. Fig. 2 is for 3% potato starch paste, Fig. 3 is for 5% potato starch paste, Fig. 4 is for 5% sweet potato

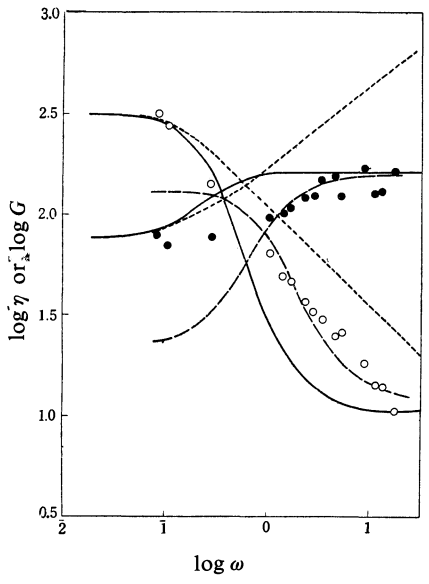

Fig. 2. $\eta(\bigcirc)$ and $G(\bullet)$ of 3% potato starch paste.

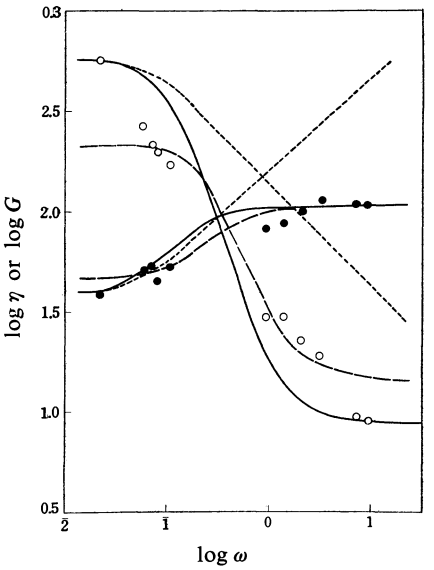

Fig. 3. $\eta(\bigcirc)$ and $G(\bullet)$ of 5% potato starch paste.

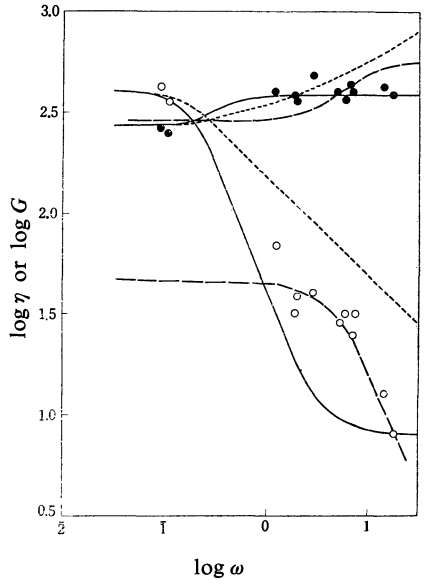

Fig. 4. $\eta(\bigcirc)$ and $G(\bullet)$ of 5% sweet potato starch paste.

starch paste, and Fig. 5 is for 5% rice starch paste. In these figures, the abscissa is $\log\omega$, while the ordinate is $\log\eta$ for open circles and is $\log G$ for closed circles.

For all these pastes, the dynamic viscosity decreased and the dynamic rigidity increased with the increase of the frequency. This is, as is well known, the usual viscoelastic behavior. To describe the viscoelastic behavior, Maxwell's four element model is often used. By this model the frequency dependence of

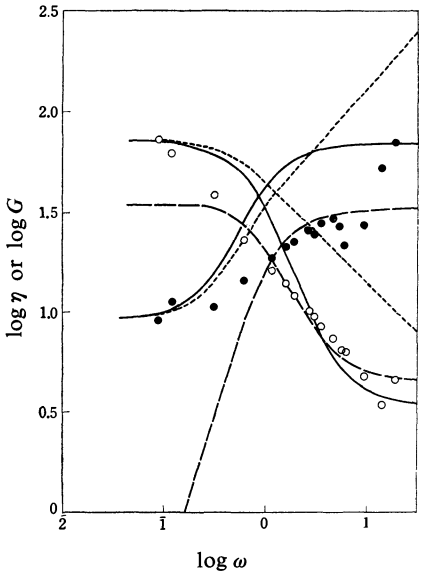

Fig. 5. $\eta$(○) and $G$(●) of 5% rice starch paste.

the dynamic viscosity and the dynamic rigidity are expressed by the equations,

$$\eta=\eta_2/(1+\tau_2^2\omega^2)+\eta_3 \quad (5)$$

$$G=G_1+G_2\tau_2^2\omega^2/(1+\tau_2^2\omega^2) \quad (6)$$

where, $\eta_2$, $\eta_3$, $G_1$ and $G_2$ are constants, and $\tau_2$ is also a constant called relaxation time, and is given by the relation,

$$\tau_2=\eta_2/G_2 \quad (7)$$

An attempt was made to see how well these equations can explain the experimental results.

In order to find out the values of the parameters, $G_1$, $G_2$, $\eta_2$, $\eta_3$ and $\tau_2$, attaching importance equally to both $\eta$ and $G$, the following procedure was at first used. By using Eqs. 5, 6 and 7,

$$\left.\begin{aligned}\eta&=B-\tau_2 G\\ B&=\eta_3+\eta_2+\tau_2 G_1\end{aligned}\right\} \quad (8)$$

can be derived. Therefore, if one plots experimental values of $\eta$ and $G$ of the same $\omega$ value on the ordinate and the abscissa, respectively, one should obtain a linear relationship and one can determine the value of $B$ and $\tau_2$. Then, by plotting experimentally obtained $\eta$ and $(B-\tau_2 G)$ on the ordinate (these quantities are not necessarily equal with each other because of experimental errors and any deviation from Maxwell's model), and $1/(1+\tau_2^2\omega^2)$ on the abscissa, one should again obtain another linear relationship which gives the value of $\eta_2$ and $\eta_3$. The parameter $G_1$ is obtained from these values on the basis of the second equation of Eq. 8. Thus, one should be able to determine the values of all the parameters, $\eta_2$, $\eta_3$, $G_1$, $G_2$, and $\tau_2$. However, the experimental data seemed not to agree with Maxwell's model in the present case, because two expected linear relationships were not exactly satisfied. By trying, however, to draw straight lines to satisfy the experimental plots as far as possible, the values of the parameters were determined, as shown in lines called I in Table I. Calculated values of $\log\eta$ and $\log G$ by using these values are shown in Figs. 2—5 with broken curves. It is seen that these curves partially satisfy the experimental plots but not in the whole range of the frequency.

The second method to determine the parameter values of Maxwell's four element model was used as follows, according to the experience that most curves in the previous case were already almost horizontal in the larger and smaller range of $\log\omega$. Eqs. 5 and 6 show that

$$\left.\begin{aligned}&\eta(\tau_2\omega\ll 1)=\eta_2+\eta_3\\ &\eta(\tau_2\omega\gg 1)=\eta_3\\ &G(\tau_2\omega\ll 1)=G_1\\ &G(\tau_2\omega\gg 1)=G_1+G_2\end{aligned}\right\} \quad (9)$$

On the basis of these equations, it was assumed that the experimental values of $\eta$ and $G$ for the smallest $\omega$ are $(\eta_2+\eta_3)$ and $G_1$, respectively, and those for the largest $\omega$ are $\eta_3$ and $(G_1+G_2)$. The values of the parameters thus obtained

Table I. Parameters in Maxwell's four element model
(in c. g. s. units)

| Starch | Concentration | No. | $G_1$ | $G_2$ | $\eta_2$ | $\eta_3$ | $\tau_2$ |
|---|---|---|---|---|---|---|---|
| Potato | 3% | I | 22.5 | 129 | 120 | 13.0 | 0.933 |
| | | II | 78.5 | 83.1 | 303 | 10.6 | 3.65 |
| Potato | 5% | I | 45.3 | 60.0 | 200 | 15.0 | 3.33 |
| | | II | 38.8 | 66.2 | 550 | 8.82 | 7.55 |
| Sweet potato | 5% | I | 290 | 287 | 43.2 | 3.17 | 0.150 |
| | | II | 268 | 120 | 411 | 8.01 | 3.43 |
| Rice | 5% | I | 0.32 | 32.6 | 30.5 | 4.60 | 0.937 |
| | | II | 9.21 | 59.6 | 67.6 | 3.41 | 1.13 |

are cited in line II of Table I. By using these values, solid curves in Figs. 2—5 were obtained. Comparing these curves with experimental plots, it is seen that $\log\eta$ decreases with the increase of $\log\omega$ more slowly in experimental plots than in Maxwell's model, and that $\log G$ increases at greater values of $\log\omega$ in experimental plots than in Maxwell's model. Moreover, it is by no means guaranteed experimentally that $\log\eta$ and $\log G$ curves are almost horizontal in the larger and smaller ranges of $\log\omega$.

Considering that these two attempts were not successful, it may be concluded that the viscoelastic behavior of starch paste can not be explained by Maxwell's four element model. Then, Rouse's model was examined. Rouse[3] studied the viscoelastic properties of high polymer solution and obtained theoretical equations. Neglecting the viscosity of solvent, $\eta_s$, because it is far smaller than the viscosity of paste, the equations are:

$$\left.\begin{aligned}\eta&=\eta_0 f_1(\tau\omega)\\ f_1&=(6/\pi^2)\sum_{p=1}^{N}[p^2/(p^4+\tau^2\omega^2)]\end{aligned}\right\}\quad(10)$$

and

$$\left.\begin{aligned}G&=(6/\pi^2)(\eta_0/\tau)f_2(\tau\omega)\\ f_2&=\sum_{p=1}^{N}[\tau^2\omega^2/(p^4+\tau^2\omega^2)]\end{aligned}\right\}\quad(11)$$

The values of $f_1$ and $f_2$ are given in Rouse's paper. These equations are essentially a modification of Maxwell's theory. On comparing these equations with experimental data, it turned out to be necessary to introduce a constant $G_0$ into Eq. 11 to give

$$G=G_0+(6/\pi^2)(\eta_0/\tau)f_2(\tau\omega)\quad(12)$$

Referring the results of the second method of Maxwell's four element model (the line II in Table I), the value of $\eta_0$ should be equal to $(\eta_2+\eta_3)$ and $G_0$ to $G_1$ in order to satisfy the experimental values for small $\omega$ values. If it is further assumed that the value of $\tau$ is equal to $\tau_2$ of the second method, the dotted curves in Figs. 2—5 are obtained. Values of both $\log\eta$ and $\log G$ thus calculated from Eqs. 10 and 12, respectively, are in all cases greater than experimental values. If the value of $\tau$ is to be changed to improve the agreement between the calculated values and the experimental values, the value of $\tau$ should be larger for $\log\eta$ (to shift the theoretical curves toward the left), and smaller for $\log G$ (to shift the curves to the right). Therefore, Rouse's equation can not explain both $\log\eta$ and $\log G$ simultaneously by using a common set of $\eta_0$, $G_0$, and $\tau$. The other feature of Rouse's curves to be mentioned here is that $\log\eta$ decreases with the increase of $\log\omega$ too slowly and $\log G$ increases too rapidly, if they are compared with the experimental data. This difficulty will be removed if one assumes that there are large aggregates of polymer molecules with large values of $\eta_0$ and $G_0$ in a paste under small frequency and that the aggregates change to smaller ones of smaller $\eta_0$ and $G_0$ with the increase of the frequency. Such an assumption of the structural change of paste with the frequency will be discussed in detail in a following paper of this series.

Comparing the values of parameters in the line II of Table I, it is seen that the rigidity of sweet potato starch paste is much greater than potato starch paste, and both the rigidity and viscosity of rice starch paste are smaller than those of potato and sweet potato starch pastes. These are comparisons for pastes prepared by heating at 90°C for 30 min. The viscoelastic properties of starch paste would change by changing the method of preparation, so that the above stated results do not exclude an expectation that rice starch paste would have larger $\eta$ and $G$ values than potato starch paste if the pastes are cooked at a higher temperature for a longer time.

The authors wish to thank Dr. Tsurutaro Nakagawa for his kind advice concerning the construction of the rheometer. The authors also thank Dainihon Ink Manufacturing Co. for supporting this project.

## Summary

The frequency dependences of dynamic viscosity and dynamic rigidity of (3 and) 5% starch pastes were measured by using a top-drive coaxial rheometer for potato starch, sweet potato starch and rice starch at 30°C. The results were compared with Maxwell's four element model and Rouse's model. Neither fit the experimental results. A structural change of the paste depending on the frequency was suggested.

# *Dielectric Investigation on Coals. V. Microwave Dielectric Constant*

By Kazuo CHITOKU and Keniti HIGASI

(Received August 25, 1960)

Dielectric methods have been applied to the study of coals during these several years[1-4]. In the laboratory of the present writers[1,2] measurements were made directly on polished coal plates as well as on mixtures of coal powder and paraffin-wax, and a frequency range from 300 c./sec. to 50 Mc./sec. was employed. In contrast to the work by Groenewege et al.[3,4], special attention was paid to the frequency dependence of dielectric constants and losses of coals. In the present paper new and more complete information will be given which was obtained by use of a wider frequency range including a microwave measurement at 4.28 cm. wavelength. Representative coals were kindly selected and provided for this measurement by Dr. H. Honda, Resources Research Institute of Japan.

### Experimental Apparatus and Method

The dielectric measurement at the microwave frequency of 7000 Mc./sec. was made by use of the transmission method developed by von Hippel and others[5,6]. The block diagram of the apparatus is shown in Fig. 1.

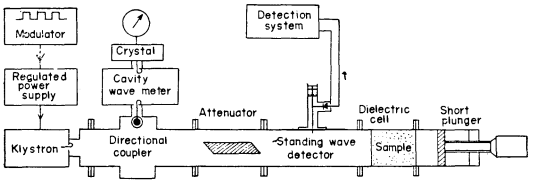

Fig. 1. Block diagram of the apparatus for measuring dielectric constant and loss at 7000 Mc./sec.

The complex dielectric constant $\varepsilon^* = \varepsilon' - j\varepsilon''$ is given by

$$\varepsilon' - j\varepsilon'' = \frac{(1/\lambda_c)^2 - (\gamma_2 d/2\pi d)^2}{(1/\lambda_c)^2 + (1/\lambda_g)^2} \qquad (1)$$

where $\lambda_c$ and $\lambda_g$ are the cut-off wavelength and the wavelength in the air-filled guide, respectively. $\gamma_2$ is the complex propagation factor of the coal sample and $d$ is the thickness of the sample. For determining $\gamma_2 d$ of the sample, the standing wave ratio $E_{min.}/E_{max.}$ and the distance from the sample

boundary to the position $E_{min.}$ were measured[6]. The ambiguity in finding $\gamma_2 d$ can be avoided by carrying out both open and short circuit measurements by the standard method. Further, as the samples treated here had low dielectric losses the simplification due to Dakin and Works[7] could be introduced into the calculation. Values of $\varepsilon'$ obtained independently in this manner by open and short circuit methods were compared with each other (see Table I). A weighted mean value is taken for each sample.

The sample material which was made of coal powder and paraffin-wax was prepared in the form having the exact dimension required by the size of the wave guide, the possible error being $\pm 0.05$ mm. (see Fig. 1).

The measurement at the frequency range between 1~20 kc./sec. was made by a low frequency bridge (Yokogawa BV-z-103) (see Ref. 2 for further information.). For the frequency range between 1~50 Mc./sec. a Q-meter (Yokogawa CA-102) was used. In order to compare the values of dielectric constants obtained by three different apparatuses, the absolute determination of dielectric constants becomes necessary. For this purpose, standard reference materials of dielectric constants provided by the Government Electrotechnical Laboratory, Tokyo, were measured with the apparatuses described above and compared with the results on coals. The maximum error in the dielectric constant is believed to be 5% and reliability in values of dielectric losses are somewhat lower but the latter are not so important in the interpretation as dielectric constants. All the measurements were carried out at room temperature.

### Experimental Materials

All the coal specimens examined in these experiments were kindly provided by Dr. H. Honda, Resources Research Institute, Japan. The chemical analyses of the samples are given in Table II. The paramagnetic susceptibility has been examined by the present writers for the following specimens[8]: No. 4, 0.40; No. 8, 0.28; No. 11, 1.23; No. 12, 3.90 $10^{-8}$ c. g. s. electromagnetic units per gram.

On account of its exceptionally high dielectric constant, water is the greatest cause of error in the dielectric measurement. Great care was taken to eliminate any traces of moisture contained in the samples. The coal samples were reduced into powder form below 200 mesh and strongly dried by heating at 105°C and reduced pressure of $10^{-2}$ mmHg for 30 hr.

About 26 g. of dried powder of coal thus obtained was mixed with 20 g. of melted paraffin-wax, cooled in a mold and cut carefully into a shape suitable for the measurement. The volume percent of coal in the mixture was estimated for each sample by measuring the densities of coal and paraffin-wax. The properties of solid paraffin-wax used are: density 0.914/24°C, m. p. 58.5~60°C, dielectric constant 2.29/1 Mc., 2.26/7000 Mc. and $\tan\delta$ 0.000/1 kc.~7000 Mc.

### Results

Dielectric constants $\varepsilon'$ and $\tan\delta$ obtained for the coal mixture are recorded in Table III.

In order to determine the value of the dielectric constant of a coal from that of a mixture, Böttcher's equation[1,9,10] was employed, in which $\varepsilon'$, $\varepsilon_1'$ and $\varepsilon_2'$ are the dielectric constant

$$\frac{\varepsilon'-\varepsilon_1'}{3\varepsilon'} = v_2 \frac{\varepsilon_2'-\varepsilon_1'}{\varepsilon_2'+2\varepsilon'} \qquad (2)$$

of the mixture, the paraffin-wax and coal particles, respectively and $v_2$ is the volume fraction of the coal particle in the mixture. The value $\varepsilon_2'$ for each specimen of coal thus obtained is shown in parentheses below that for the mixture.

a) Values of $\varepsilon_1$ used in calculating $\varepsilon_2$ by Eq. 2.

**Dielectric Constant and Oxygen Content.**— Dielectric constants obtained at 1 kc./sec. and 7000 Mc./sec. are plotted against oxygen content (Fig. 2). Intermediate frequency dielectric constants lie between the two curves.

Dielectric constants decrease sharply at first but increase regularly with increase in oxygen content after reaching a minimum at about 8%. From functional group analysis of coal it has been found that the amounts of hydroxyl groups, carboxyl groups, carbonyl groups and methoxyl groups increase with oxygen content[11]. Among them, the hydroxyl group is regarded as the most important*. From the infrared analysis, the absorption band at 3.0 $\mu$ is ascribed to the existence of associated OH and NH bonds[12]. One might infer from these

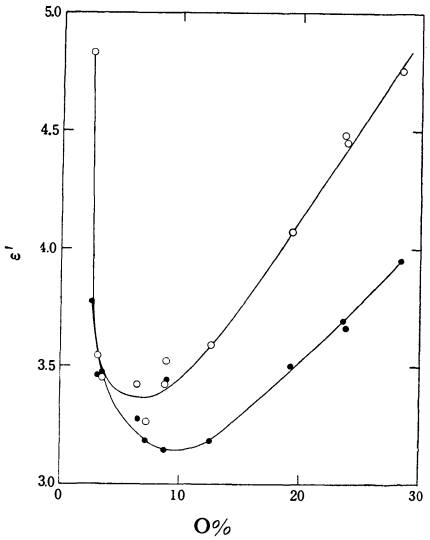

Fig. 2. Dielectric constants of coals ($\varepsilon_2'$) at frequencies 1 kc./sec. and 7000 Mc./sec. and oxygen content (dry-ash-free basis).
—○— 1 kc. —●— 7000 Mc.

pieces of evidence that polar groups which are closely associated with the oxygen content are mainly responsible for the dielectric constant of coal containing more than 10% oxygen. This seems parallelled by the fact that dielectric constants of polymers increase with the amount of polar groups contained in them[13,14]. Indeed, coals generally speaking are a sort of high-polymers having some polar groups.

**Dielectric Constant and Carbon Content.** — Dielectric constants obtained at three frequencies, 1 kc./sec., 1 Mc./sec. and 7000 Mc./sec. are plotted against carbon content (Fig. 3). For the sake of comparison, optical dielectric constants as defined by the refractive index $n$ and the absorption index $k$ for visible light of the wavelength 5460 Å.

$$\varepsilon_\infty = n^2(1-k^2) \qquad (3)$$

are plotted as dotted lines in the same graph. The optical measurement is due to Huntjens and van Krevelen[15]. There are available other optical measurements[16], but they are not recorded here in order to prevent the figure from becoming overcrowded with points.

From a glance at Fig. 3, it will be seen that in the region C 85~89% all the dielectric constants, at audio, radio and microwave frequencies converge so that they become almost identical to each other. The plotted curve for

optical dielectric constants lies between these three curves. This is probably anomalous, but it must be remembered that optical dielectric constants were obtained for coals of different origins**. It may be reasonable to assume that microwave values in this region are almost identical with the optical dielectric constant.

With the decrease in carbon content (less than 80%) the difference between the optical and the microwave dielectric constants becomes significant. It was unexpected that there should be such a large difference between these values in this region. If this difference is due to the rotation of polar groups, these groups must have a small size[14]. One might infer from this that the perticular polar groups responsible for this phenomenon are hydroxyl groups situated at the periphery of the aromatic system, because the internal rotation of non-associated OH groups around the C-O axis will be least sterically hindered.

Fischer found that diphenyl ether has an anomalously small relaxation time[17]. Recently

17) E. Fischer, *Z. Elektrochem.*, **53**, 16 (1949).

an explanation has been given for this observation as arising from the internal rotation of the two benzene rings around C-O axes[18]. Coal is sometimes considered as built up of aromatic ring complexes linked through oxygen or non-aromatic bridges containing oxygen atoms[19]. Possibly these units might provide certain contributions to the microwave dielectric constant, if a particular type of internal rotation is to occur. But roughly speaking the hydroxyl group will be mainly responsible for this effect.

It would be a matter of speculation to estimate dipole moments for coals. However, if coal may be regarded as a supercooled liquid[3], the Onsager equation for liquids may be used for this purpose[1e,f]. Further, on account of the low dielectric constant, the Debye equation will give practically the same moment values the Onsager equation[13]. It can be shown that the dipole moment $\mu$ for the unit having the molecular volume $M/d$ is

$$\mu = A\left[(\varepsilon_2' - \varepsilon_\infty)\frac{M}{d}\right]^{1/2} \qquad (4)$$

where $A$ for Debye equation is

$$A^2 = \frac{27kT}{4\pi N(\varepsilon_2'+2)(\varepsilon_\infty+2)}, \qquad (5)$$

in which $k$ is Boltzman constant, $N$ is Avogadro constant and $T$ is the absolute temperature. Further, at room temperature, $T=298°C$

$$A^2 = \frac{0.147\times10^{-36}}{(\varepsilon_2'+2)(\varepsilon_\infty+2)} \qquad \text{Debye}$$

In similar way it can be shown that

$$A^2 = \frac{0.147\times10^{-36}(2\varepsilon_2'+\varepsilon_\infty)}{3\varepsilon_1'(\varepsilon_\infty+2)^2} \qquad \text{Onsager}$$

There exist no reliable data for the molecular weight of coal. According to van Krevelen and Schuyer[3] the average molecular weight is in the vicinity of 2500. We shall assume an arbitrary molecular volume $M/d=2000$ for the purposes of the present calculation. For coal with a density of 1.3, this assumption gives a molecular weight of 2600.

Regarding the static dielectric constant $\varepsilon_2'$ in Eq. 1 we shall use values obtained at frequency of 1 kc. Optical dielectric constants $\varepsilon_\infty$ are calculated by Eq. 3 using van Krevelen's data, which are supposed to be somewhat higher than those of the coals considered here; the estimated dipole moment is consequently slightly smaller than the actual moment. Further, the $A$ value for the Debye equation will be used in the calculation of the moment. The result is shown in Table IV.

TABLE IV. DIPOLE MOMENTS OF COALS ($\mu$) FOR THE MOLECULAR VOLUME ($M/d=2000$)

| No. | Specimen | C% | $\varepsilon_2'$/1 kc. | $\varepsilon_\infty$ | $\mu$, D |
|---|---|---|---|---|---|
| 1 | Taihei | 65.10 | 4.75 | 2.85 | 4.1 |
| 2 | Tempoku | 70.37 | 4.45 | 2.90 | 3.8 |
| 3 | Nakago-kaso | 70.92 | 4.48 | 2.91 | 3.8 |
| 4 | Nakago | 74.33 | 4.07 | 2.96 | 3.3 |
| 5 | Kasima | 77.94 | 3.59 | 3.05 | 2.4 |
| 6 | Pocahontas (USA) | 82.79 | 3.52 | 3.20 | 1.8 |
| 7 | Hutago | 83.16 | 3.42 | 3.21 | 1.5 |
| 8 | Yubari | 84.85 | 3.26 | 3.28 | 0 |
| 9 | Hasima | 86.59 | 3.42 | 3.36 | ~0 |
| 10 | Kamati | 89.47 | 3.45 | 3.53 | 0 |
| 11 | Yatake | 89.55 | 3.54 | 3.54 | 0 |
| 12 | Onuki | 91.16 | 4.83 | 3.68 | — |

As an example we shall consider a dipole moment 3.8 D obtained for specimen No. 2 Tempoku brown coal. If this magnitude of moment arises only from OH groups which have complete freedom of rotation around C-O axis, the number of OH groups in a volume 2000 cc. will be estimated by

$$\mu^2_{obs} = n\cdot\mu^2_{OH} \qquad (6)$$

where $\mu_{obs}$ and $\mu_{OH}$ are moments observed and that of the OH group respectively. Putting $\mu_{obs}=3.8$ D and $\mu_{OH}=1.56$ D[20] we obtain $n=5.9$; there are about 6 OH groups capable of rotation.

On the other hand, functional analysis reveals that this particular coal specimen has a hydroxyl (phenolic) percentage of 10.3%. In molecular volume $M/d=2000$ ($d=1.41$), this gives 291 g. oxygen, that is 18 OH groups. Therefore, one may conclude that about one-third of the total OH groups can rotate freely. The hydroxyl percentage chemically determined does not represented the amount of OH group actually existing in coal. There is no strong reason for supposing that a certain fraction of OH groups has complete freedom of rotation while another fraction has not and that other polar groups can not make a contribution to dielectric constant. In fact, the estimation of the dipole moment described above and its related discussion has only qualitative significance.

## Summary

1. Using the transmission method, resonance method and bridge method, dielectric constants

18) K. Higasi and C. P. Smyth, to be published in *J. Am. Chem. Soc.*

19) S. G. Ward, *J. Inst. Fuel*, 21, 80 (1947); cited in Ref. 3, p. 207.

20) Y. Kurita and M. Kubo, This Bulletin, 27, 364 (1954). This is not the moment of OH group moment itself but the component of the phenolic OH moment perpendicular to the C-O axis.

and losses are measured on paraffin-wax mixtures of twelve specimens of coal ranging from C 65 to 92%.

2. Dielectric constants of coals are estimated for these coals by means of Böttcher's equation.

3. The relation between dielectric constant and oxygen content is discussed and it is shown that polar groups contribute to dielectric constant.

4. From the comparison with optical dielectric constant, the motion of dipoles in coals in the electric field can be discussed. Rough estimates of dipole moments are also given.

The present writers wish to thank Dr. H. Honda for his cooperation in this work and also Dr. H. Baba for his assistance in performing the calculation of microwave dielectric constants.

# *Polarographic Behavior of Vanadium and Iron in Thiocyanate*

By G. S. DESHMUKH and J. P. SRIVASTAVA

(Received June 13, 1960)

Thiocyanate has been used extensively as a complexing agent for a number of cations. Meite's[1] observation that iron (III) is reduced in a medium composed of 0.7 M KCNS, 0.02 M sulfuric acid and 0.004% gelatin with a half-wave potential >0.0 volt is contradicted by the data of the "Polarographic spectra"[2] giving $E_{1/2}$ vs. S. C. E. as −0.2 volt. The condition for the latter observation has not been defined.

Direct estimation of $VO^{2+}$ based on the catalytic action of the ion on potassium chlorate and potassium iodide reaction has been developed recently by Shiokawa[3]. Polarographic characteristics of vanadyl ion showed that it is reducible or oxidizable depending on the nature of the complex formed with the supporting electrolyte[4]. Syrokomskiĭ and Nazareva[5] devised a new type of coulometer to effect anodic oxidation of $VO^{2+}$ to $VO^{3+}$ which is titrable with Mohr's salt solution.

Preliminary investigations showed that thiocyanate in presence of mineral acids is capable of reducing vanadium(V) to lower valency states. Vanadium(V) and thiocyanate solution when mixed together developed the green coloration characteristics of trivalent vanadium ion, which on raising the acidity of the solution turned blue. The intermediate green state was initially mistaken to be vanadium green, corresponding to molybdenum blue, and was found to be very stable even on prolonged exposure to air. Spectrophotometric studies revealed that it is only the mixture of vanadium(V) and vanadium(IV). This conclusion was further confirmed when the green solution was shaken with isobutyl alcohol. The solution separated into two layers; the yellow aqueous layer and blue tetravalent vanadium in the organic layer.

The present communication reports in detail a study of polarographic behavior of vanadium (IV) thus obtained and iron(III) in potassium thiocyanate. Appropriate conditions for the simultaneous determination of the two elements in presence of each other have also been described.

## Experimental

Leeds and Northrup Electrochemograph Type E was used for recording the polarograms in conjunction with an external saturated calomel reference electrode connected through an agar-potassium chloride bridge to the electrolysis cell. The temperature was maintained throughout at 25±0.1°C. A Beckman zeromatic pH meter was used for measuring the pH of the solutions. The dropping mercury electrode had $m^{2/3}t^{1/6}$ value of 2.414 $mg^{2/3}/sec^{1/2}$ with open circuit.

Vanadyl sulfate solution was prepared by dissolving the reagent grade vanadium pentoxide in dilute sulfuric acid and reducing it by sulfur dioxide. Excess of sulfur dioxide was boiled off and the solution standardized against potassium permanganate. Iron solution was obtained by dissolving a weighed quantity of "A. R. ferric ammonium sulfate" in distilled water. This was

also standardized against potassium permanganate. All other chemicals used were of reagent grade.

## Results and Discussion

**Characteristics of Polarographic Waves.**—A number of vanadium(IV) and iron(III) polarograms were recorded at different pH values. It was observed that vanadium(IV) gets reduced at and below pH≈3. The two reduction stages of vanadium(IV) are well developed when the pH of the solution was below 2.0 but above 1.5. Further increase in acidity shifted the half-wave potentials of the first wave towards positive potentials. The wave was completely obliterated below a pH of 0.5. In less acidic solutions (between pH 2.0~3.5), the first wave was drawn out and ill defined. Iron polarograms also were well defined below pH 3.0 but the $E_{1/2}$ ($E_{1/2}=-0.17$ volt vs. S. C. E. in 1.0 M potassium thiocyanate containing 0.005% gelatin at pH 1) was not much affected by the pH of the solution (cf. Table I).

Thiocyanate concentration had considerable effect on the half-wave potential of vanadium. While the first wave was shifted towards negative potentials with increasing thiocyanate concentration, the $E_{1/2}$ of the second wave moved to more positive potentials. The polarograms of iron were also shifted towards negative potentials by the increased concentrations of the supporting electrolyte. The shift in both the cases i. e., the first wave of vanadium and the polarograms of iron, towards negative potentials with the increasing thiocyanate concentrations may possibly be attributed to the superimposition of the anodic wave of thiocyanate. During the course of experiments it was further observed that the half-wave potential of the iron wave was dependent not only on the thiocyanate concentrations but also on the iron and thiocyanate ratio. Conjugating it with the previous observation that the $E_{1/2}$ of iron polarograms remain unaffected by the pH of the solution, it may

|---|---|---|---|---|
| | | 1st wave | 2nd wave | |
| 1 | 5.0 | −0.30 | −0.49 | −0.31 |
| 2 | 3.75 | −0.28 | −0.51 | −0.29 |
| 3 | 2.50 | −0.24 | −0.53 | −0.26 |
| 4 | 1.25 | −0.25 | −0.56 | −0.20 |
| 5 | 1.00 | −0.25 | −0.56 | −0.17 |
| 6 | 0.50 | — | −0.57 | −0.15 |
| 7 | 0.25 | Washed off | −0.58 | −0.15 |

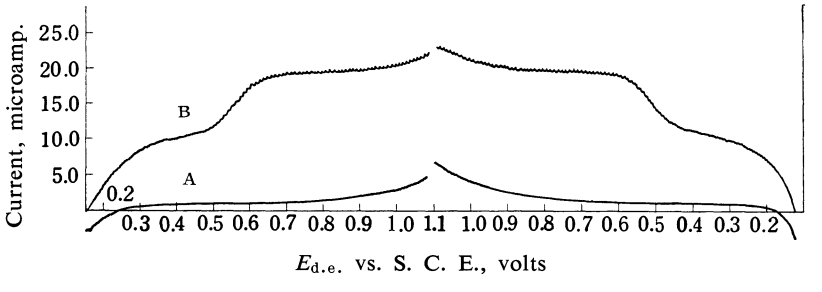

Fig. 1. Direct and reverse vanadium (2.19 mM) polarograms

Temperature 25±0.1°C
Drop time 3.33 sec.
Gelatin concn. 0.005%
Recorder damping 2.0
Recorder range 50 μA
pH of solution 1.6

| Waves | Zero line | $E_{1/2}$ of 1st wave | $E_{1/2}$ of 2nd wave |
|---|---|---|---|
| A | 0.0 | Blank | — |
| B | 2.5 | −0.21 | −0.537 |

be concluded that over the pH range studied a series of iron thiocyanate complexes are formed depending on the iron : thiocyanate ratio. Shifting of the second wave of vanadium towards more positive potentials with increasing thiocyanate concentrations suggest that the V(II)-NCS complex apparently has a lower dissociation constant than the V(III)-NCS complex (cf. Table II).

A study of the typical polarogram and its log plot shows that the vanadium waves are reversible (Fig. 1). The polarogram was obtained with a mixture of 2.19 mM vanadyl sulfate and 1.0 M potassium thiocyanate and 0.005% gelatin as maximum suppressor. In agreement with the general equation

$$E_{d.e.} = E_{1/2} - \frac{0.059}{n} \log \frac{i}{i_d - i}$$

the plot of $E_{d.e.}$ vs. $\log \frac{i}{i_d - i}$ is a straight line. The slope of 0.07 volt for the second wave suggests one electron transfer in reduction. As both the waves of vanadium have the same height, it was concluded that vanadium gets reduced first to vanadium(III) and finally to vanadium(II).

Iron polarograms exhibit only one reduction stage, and thus suggest the possibility of only one electron change. $E_{1/2}$ for iron reduction could not be assigned due to its dependence both on iron as well as on thiocyanate concentration but under the most restricted conditions of 2.00 mM iron and 1.0 M thiocyanate with 0.005% gelatin as maximum suppressor the $E_{1/2}$ observed was $-0.17$ volt vs. S. C. E.

The average $E_{1/2}$ for 2.19 mM vanadyl sulfate in 1.0 M potassium thiocyanate and 0.005% gelatin as maximum suppressor at pH 1.5 was found to be $-0.21$ volt, and to be $-0.54$ volt for the first and second wave respectively.

Under the conditions defined, a series of vanadium(IV) polarograms were run to plot the calibration curve. All the wave heights for the first wave were read from the plots at $-0.45$ volt and the corresponding values for the residual current were deducted to obtain the $i_d$ for vanadium(IV) alone. The wave heights for the second stage reduction were calculated by extrapolating the plateau of the two waves.

The values of $I$ obtained for different concentrations (cf. Table III) show that the reduction for both the waves are diffusion controlled. A linear concentration-current relationship is also followed by iron polarograms. The wave heights for iron polarograms were obtained by taking the difference of the actual and residual wave height at the same potential i. e., at $-0.45$ volt.

Table III. Diffusion current constant for vanadium polarograms

| Solution No. | Concentration of vanadium mM | $I(I=i_d/cm^{2/3}\ t^{1/6})$ of vanadium waves | |
|---|---|---|---|
| | | 1st wave | 2nd wave |
| 1 | 0.438 | 1.43 | 1.65 |
| 2 | 0.876 | 1.42 | 1.65 |
| 3 | 1.09 | 1.42 | 1.65 |
| 4 | 1.31 | 1.42 | 1.65 |
| 5 | 1.75 | 1.42 | 1.66 |
| 6 | 2.19 | 1.42 | 1.65 |
| 7 | 2.62 | 1.42 | 1.65 |
| 8 | 3.5 | 1.42 | 1.66 |
| 9 | 3.94 | 1.42 | 1.65 |
| 10 | 4.38 | 1.42 | 1.65 |

The effect of different cations on vanadium polarograms was also studied. Cobalt and manganese do not interfere with the polarogram. Nickel and chromium(III) develop their own waves at more negative potentials but the diffusion current plateau for vanadium is not appreciably distorted. The presence of molybdenum(VI) and tungsten(VI) is detrimental as these ions deteriorate the vanadium waves, thus making the measurement of diffusion current practically impossible. Cupric ion has a typical effect of shifting the vanadium waves to more negative potentials. This results in the formation of only one wave which is probably the resultant of the waves comprising the wave heights due to $Cu^{2+}$ and both the vanadium waves. The presence of nitrates, chlorides, bisulfates and ammonium ions has no effect on vanadium polarograms. None of these above mentioned ions except molybdenum and tungsten affect the iron polarograms. Molybdenum and tungsten completely distort the wave.

**Recommended Procedure of Analysis.**—The appropriate amount of unknown solution to give a final vanadium concentration above 0.4 mM and iron concentration above 0.5 mM is mixed with potassium thiocyanate. The overall potassium thiocyanate concentration is maintained at 1.0 M. The acidity of the solution is adjusted to pH 1.5 with hydrochloric acid and the mixture allowed to stand for 15 min. During this period vanadium(V) gets reduced to vanadium(IV). The appearance of violet color (being a mixture of blue due to vanadium(IV) and blood-red due to iron(III) thiocyanate) indicates the completion of the reduction. This solution when polarographed exhibits a two-step reduction, the first being the composite wave due to the reductions of iron(III) to iron(II) and vanadium(IV) to vanadium(III), and the second one being due to the degradation of vanadium(III) to vanadium(II). In order to derive the vanadium

content of the solution, the wave height of the second stage reduction is measured by extrapolating the plateaus and reading it from the calibration curve.

On subtracting the height of the first wave of vanadium as read from the calibration curve for the corresponding value of vanadium obtained previously, from that of the composite wave (the polarogram of the mixed iron and vanadium solution), the contribution due to iron alone is calculated. In the procedure adopted, wave heights of iron and vanadium polarograms are appreciable, only if the concentrations of corresponding elements are above the prescribed limit, i. e., 0.5 mM and 0.4 mM respectively.

TABLE IV. SIMULTANEOUS DETERMINATION OF IRON AND VANADIUM

| Solution No. | Vanadium added mM | Vanadium recovered, mM | Iron added, mM | Iron recovered mM |
|---|---|---|---|---|
| 1 | 0.438 | 0.438 | 0.4 | 0.42 |
| 2 | 0.87 | 0.87 | 0.8 | 0.81 |
| 3 | 1.31 | 1.33 | 1.2 | 1.21 |
| 4 | 1.75 | 1.79 | 1.6 | 1.62 |
| 5 | 2.19 | 2.21 | 2.0 | 2.0 |
| 6 | 2.62 | 2.66 | 2.4 | 2.4 |
| 7 | 3.16 | 3.16 | 2.8 | 2.82 |
| 8 | 3.50 | 3.50 | 3.2 | 3.18 |
| 9 | 3.94 | 4.10 | 3.6 | 3.6 |
| 10 | 4.38 | 4.42 | 4.01 | 4.01 |

Values obtained by the above procedure are reported in Table IV. It may be seen that the results are within the limits of experimental error. The method provides a convenient procedure for the simultaneous determination of iron and vanadium contents and may suitably be adopted to the analysis of vanadium steels provided copper(II), molybdenum(VI), and tangsten(VI) are sequestered.

The authors wish to express their sincere thanks to Professor S. S. Joshi for his advice and to Dr. G. B. Singh, Head of the Chemistry Department, for facilities during the course of this study. The financial aid by the Government of India to one of us (J. P. S.) is also gratefully acknowledged.

# *The Thermal Decomposition of Dimethyl Ether in the Presence of Hydrogen Sulfide*

By Naomi IMAI and Osamu TOYAMA

(Received August 23, 1960)

The catalytic action of hydrogen sulfide on the thermal[1] as well as photochemical[2] chain decomposition of acetaldehyde has been studied in this laboratory, and its catalytic effect has been attributed to the reactions between methyl radicals and hydrogen sulfide molecules and between hydrosulfide radicals and acetaldehyde molecules, both taking place faster than the reaction between methyl radicals and acetaldehyde molecules. Methanethiol was also found to have an analogous catalytic action on the thermal decomposition of acetaldehyde[3].

Dimethyl ether has been known to decompose thermally by a chain mechanism involving methyl radicals[4-6] and its decomposition may therefore be expected to be catalyzed by hydrogen sulfide like that of acetaldehyde. In the present work the kinetics of the thermal decomposition of dimethyl ether in the presence of hydrogen sulfide has been studied in the temperature range 360 to 440°C and compared with the results obtained in the absence of hydrogen sulfide.

## Experimental

*Materials.* — Dimethyl ether was prepared by dehydration of methyl alcohol by concentrated sulfuric acid at 80°C, decarbonated and dried by potassium hydroxide and calcium chloride, and purified by bulb-to-bulb distillation. Hydrogen sulfide was

prepared by dropping water on aluminum sulfide in an evacuated vessel, dried by passing through a trap at −78°C and purified by bulb-to-bulb distillation. The cupric oxide used in analysis was a commercial sample.

*Apparatus.* — The apparatus used in the present work is similar to that described previously[8]. The reaction vessel is a glass cylinder of about 162 cc. capacity.

*Procedure.*—Required quantities of dimethyl ether and hydrogen sulfide were mixed and left at room temperature for about 30 min. before pyrolysis, and then introduced into the reaction vessel which had already been kept at the experimental temperature. After an appropriate time of reaction, usually corresponding to less than five per cent decomposition, the reaction mixture was expanded into an analytical system. Methane and carbon monoxide in products were analyzed quantitatively in the same way as described previously[7]. Hydrogen was oxidized by cupric oxide at 260°C to water vapor and the amount of the latter was determined from its pressure by an oil manometer. As it was found that the adsorption of the water on the glass wall led to incorrect estimates of hydrogen, calibration was made with known amounts of hydrogen. The amounts of hydrogen thus corrected seem to be still not very accurate. When the amount of hydrogen formed by the decomposition was very small, it was not determined.

## Results and Discussion

In Table I are listed the amounts of methane, carbon monoxide and hydrogen formed by the decomposition of dimethyl ether both in the absence and in the presence of hydrogen sulfide at various conditions. It has been well known that dimethyl ether decomposes thermally according to the following stoichiometric equations[6,8,9].

$$CH_3OCH_3 \rightarrow CH_4 + CH_2O$$

$$CH_2O \rightarrow CO + H_2$$

It is shown in Table I that, even in the presence of hydrogen sulfide, the amount of

7) N. Imai and O. Toyama, This Bulletin, 33, 652 (1960).

8) P. J. Askey and C. N. Hinshelwood, *Proc. Roy. Soc.*, A115, 251 (1927).

9) E. Leifer and H. C. Urey, *J. Am. Chem. Soc.*, 64, 994 (1942).

carbon monoxide formed is always equal to that of hydrogen within the experimental error and is always less than 30% of that of methane. Fig. 1 shows plots of the amounts of methane, carbon monoxide and hydrogen against the time obtained from series of runs (a) in the absence and (b) in the presence of hydrogen sulfide under otherwise constant conditions. It is seen in the figure that the rate of formation of methane remains constant for 30 min. during which 7.4 (a) and 2.3 (b) % of the ether have decomposed, while those of carbon monoxide and hydrogen increase with time. These observations indicate that carbon monoxide and hydrogen are produced by the decomposition of formaldehyde as represented by the above equation in the presence of hydrogen sulfide as well as in its absence.

It is generally agreed that the main feature of the thermal decomposition of dimethyl ether can be explained by the following chain mechanism[4].

$$CH_3OCH_3 \rightarrow CH_3 + OCH_3 \quad (1)$$

$$OCH_3 + CH_3OCH_3 \rightarrow CH_3OH + CH_3OCH_2 \quad (2)$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_3OCH_2 \quad (3)$$

$$CH_3OCH_2 \rightarrow CH_2O + CH_3 \quad (4)$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad (5)$$

The steady state equations derived from this scheme yield the rate equation

$$-d[CH_3OCH_3]/dt = R_{CH_4} = k_1^{1/2}k_3k_5^{-1/2}[CH_3OCH_3]^{3/2} \quad (I)$$

in general agreement with experimental results obtained by various workers[6,8,9]. Also in this work, the rate of decomposition of the ether alone was found to be proportional to the 3/2 power of the concentration of dimethyl ether at 420°C as seen in Fig. 2. From the slope of the straight line in the figure, the value of $k_1^{1/2}k_3k_5^{-1/2}$ was obtained. At other temperatures, values of $k_1^{1/2}k_3k_5^{-1/2}$ were calculated from the concentration of ether and the rate of formation of methane, making use of Eq. I. They are listed in Table II.

TABLE II. VALUES OF $k_1^{1/2}k_3k_5^{-1/2}$ AND $k_1^{1/2}k_7k_8^{-1/2}$

| Temp. °C | $k_1^{1/2}k_3k_5^{-1/2}\times10^3$ ($mol^{1/2}\,cc^{1/2}\,sec^{-1/2}$) | $k_1^{1/2}k_7k_8^{-1/2}\times10^2$ ($mol^{1/2}\,cc^{1/2}\,sec^{-1/2}$) |
|---|---|---|
| 360 | 0.223 | 0.240 |
| 380 | 0.855 | 0.847 0.864[a] |
| 400 | 2.73 | 2.60 |
| 420 | 9.68 | 8.75 |
| 440 | 28.8 | |

a) Obtained from a series of runs with varied ether concentrations and a constant hydrogen sulfide concentration (Fig. 4).

Now in the presence of a sufficient amount of hydrogen sulfide, the reactions of methyl and methoxyl radicals with hydrogen sulfide may be so much faster than those with dimethyl ether, that the latter reactions may be neglected compared to the former. Hence reaction 2 may be replaced by reaction 2′ and reaction 3 by reactions 6 and 7.

$$OCH_3 + H_2S \rightarrow CH_3OH + HS \quad (2')$$

$$CH_3 + H_2S \rightarrow CH_4 + HS \quad (6)$$

$$HS + CH_3OCH_3 \rightarrow H_2S + CH_3OCH_2 \quad (7)$$

If, in addition, the concentration of hydrosulfide radicals is much higher than that of methyl radicals, the chain will terminate by reaction 8, reaction 5 being negligible compared to reaction 8.

$$HS + HS \rightarrow \text{products} \quad (8)$$

The above chain mechanism consisting of reactions 1, 2′, 6, 7, 4 and 8 leads to the following rate equation.

$$-d[CH_3OCH_3]/dt = R_{CH_4} = k_1^{1/2}k_7k_8^{-1/2}[CH_3OCH_3]^{3/2} \quad (II)$$

If the chain is sufficiently long, it is readily shown that in the steady state

$$k_6[CH_3][H_2S] = k_7[HS][CH_3OCH_3]$$

or

$$[HS]/[CH_3] = (k_6/k_7)([H_2S]/[CH_3OCH_3]) \quad (III)$$

Therefore, when the quantity in the right-hand side of Eq. III is very large, the rate of decomposition will be represented by Eq. II.

Fig. 3 shows the dependence of the rate of formation of methane on the concentration of hydrogen sulfide at varied temperatures. The rate increases with the increase in the concentration of hydrogen sulfide, until it attains a constant value. Fig. 4 shows that the rate of formation of methane in the presence of $2.32\times10^{-6}$ mol. $cc^{-1}$ of hydrogen sulfide at 380°C is proportional to the 3/2 power of the concentration of the ether. Both Figs. 3 and 4 thus indicate that Eq. II holds when the ratio $[H_2S]/[CH_3OCH_3]$ is large. Values of $k_1^{1/2}k_7k_8^{-1/2}$ determined from the constant values of the rate in Fig. 3 and from the slope of the straight line in Fig. 4 are listed in Table II together with those of $k_1^{1/2}k_3k_5^{-1/2}$. The fairly good agreement of the two values of $k_1^{1/2}k_7k_8^{-1/2}$ at 380°C obtained by different methods shows again the validity of Eq. II.

The values given in Table II lead to the following Arrhenius expressions:

$$k_1^{1/2}k_3k_5^{-1/2} = 10^{15.16\pm0.13} \times \exp\{-(54{,}500\pm400)/RT\} \quad mol^{-1/2}\,cc^{1/2}\,sec^{-1/2}$$

$$k_1^{1/2}k_7k_8^{-1/2}=10^{15.26\pm0.24}\times\exp\{-(51{,}800\pm700)/\boldsymbol{RT}\}\ \mathrm{mol}^{-1/2}\,\mathrm{cc}^{1/2}\,\mathrm{sec}^{-1/2}$$

The expression for $k_1^{1/2}k_3k_5^{-1/2}$ shows a good agreement with that of $10^{15.11}\exp(-55{,}600/\boldsymbol{RT})$ $\mathrm{mol}^{-1/2}\,\mathrm{cc}^{1/2}\,\mathrm{sec}^{-1/2}$ obtained by Benson and Jain[6] who studied the thermal decomposition of dimethyl ether in the temperature range from 490 to 550°C.

The expression of $k_1^{1/2}k_3k_5^{-1/2}$ divided by that of $k_1^{1/2}k_7k_8^{-1/2}$ yields

$$(k_3/k_7)(k_8/k_5)^{1/2}=0.8\exp(-2{,}700/\boldsymbol{RT})$$

Assuming $k_8/k_5$ to be unity, $k_3/k_7=0.8\exp(-2{,}700/\boldsymbol{RT})$ and hence $E_7=E_3-2.7$ kcal./mol., $E$'s denoting activation energies. The result seems reasonable since hydrosulfide radicals have been shown to be more reactive towards organic molecules than methyl radicals. Reported values of $E_3$ are 8.4[10], 9.5[11] and 10.0[12] kcal./mol. and that of $A_3$ is of the order of $10^{11}\,\mathrm{mol}^{-1}\,\mathrm{cc.\,sec}^{-1}$. If we accept the intermediate value of 9.5 kcal./mol. for $E_3$, it follows that

$$k_7=10^{11}\exp(-6{,}800/\boldsymbol{RT})\ \ \mathrm{mol}^{-1}\,\mathrm{cc.\,sec}^{-1}$$

The present authors found previously that $k_6=10^{11}\exp(-2{,}600/\boldsymbol{RT})$[7]. The combination of these yields

$$k_6/k_7=\exp(4{,}200/\boldsymbol{RT})$$

It follows therefore that $k_6/k_7$ is much greater than unity at experimental temperatures although it decreases with the rise of temperature. This accounts for the fact that Eq. II holds even when the ratio $[H_2S]/[CH_3OCH_3]$ in Eq. III is not very large and that, the higher the temperature, the greater is the ratio $[H_2S]/[CH_3OCH_3]$ where Eq. II begins to be applicable, as seen in Fig. 3.

Benson and Jain have argued that the activation energy of the initial step, $E_1$, of 92 kcal./mol., obtained from their value of $E_{overall}=(1/2)E_1+E_3-(1/2)E_5=55.6$ kcal./mol. combined with $E_3=9.5$ kcal./mol., is too large compared with $E_1=81$ kcal./mol. obtained by Rice and Johnston[13], who decomposed dimethyl ether in the temperature range from 1010 to 1150°K and determined $E_1$ by an antimony mirror removal method. In order to explain this discrepancy, they suggest that the chain terminates not only by reaction 5 but also by reactions 9 and 10

$$CH_3+CH_2OCH_3\rightarrow C_2H_5OCH_3 \qquad (9)$$

$$2CH_2OCH_3\rightarrow (CH_3OCH_2)_2 \qquad (10)$$

and that reaction 4 is not unimolecular but bimolecular

$$CH_2OCH_3+\mathbf{M}\rightarrow CH_2O+CH_3+\mathbf{M} \qquad (4')$$

The rate of decomposition is then expressed as

$$-\mathrm{d}[CH_3OCH_3]/\mathrm{d}t=\frac{k_1^{1/2}k_3k_5^{-1/2}}{1+(k_{10}/k_5)^{1/2}(k_3/k_{4'})}[CH_3OCH_3]^{3/2}$$

Since $E_{10}=E_5=0$, $E_3=9.5$ and $E_4=19$ kcal./mol.[12], the denominator of the overall rate constant decreases with temperature. This situation, they believe, explains the overall activation energy greater than $(1/2)E_1+E_3-(1/2)E_5$.

However, if $E_1=81$ kcal./mol. and consequently $(1/2)E_1+E_3-(1/2)E_5=50$ kcal./mol. as they assume, $E_3-E_7=-1.8$ kcal./mol., i. e., $E_3<E_7$ and the catalysis such as shown by Eq. II cannot be expected to take place[14]. The interpretation given by Benson and Jain must therefore be regarded as incompatible with the results obtained in the present work. On the other hand, the agreement between the two overall $A$ factors in the absence and presence of hydrogen sulfide seems to support the idea that $k_{overall}=k_1^{1/2}k_3k_5^{-1/2}$, since it is probable that $A_3=A_7$ and $A_5=A_8$. The discrepancy between the overall activation energy in the pyrolysis of the ether alone and those of elementary reactions may therefore be attributed to the error in the estimation of $E_1$. Baughan et al.[15] estimated $E_1$ as 87 kcal./mol.

As seen in Table I, the time required to produce a definite amount of methane in the absence of hydrogen sulfide is about ten times as great as that in its presence, but the ratio of the amount of carbon monoxide to that of methane, compared with the same amount of the latter, is far less sensitive to the presence of hydrogen sulfide. This indicates that the decomposition of formaldehyde is also catalyzed by hydrogen sulfide. Kodama, Takezaki and Fujie[16] suggested that in the pyrolysis of dimethyl ether, formaldehyde decomposes by the following chain processes:

$$CH_3+CH_2O\rightarrow CH_4+CHO$$

$$CHO\rightarrow CO+H$$

$$H+CH_3OCH_3\rightarrow H_2+CH_3OCH_2$$

$$CH_3OCH_2\rightarrow CH_2O+CH_3$$

In the presence of hydrogen sulfide, this scheme may be modified as follows:

$$HS+CH_2O \rightarrow H_2S+CHO$$
$$CHO \rightarrow CO+H$$
$$H+H_2S \rightarrow H_2+HS$$

## Summary

Dimethyl ether has been decomposed thermally in the presence and absence of hydrogen sulfide over the temperature range 360~440°C. The rate of decomposition is enhanced by the presence of hydrogen sulfide, but the rate law is unchanged, i. e., the rate is proportional to the 3/2 power of the ether concentration, irrespective of the presence of hydrogen sulfide.

The catalytic action of hydrogen sulfide is satisfactorily explained by the steps, $CH_3+H_2S \rightarrow CH_4+HS$ (6), $HS+CH_3OCH_3 \rightarrow H_2S+CH_3OCH_2$ (7) and $CH_3OCH_2 \rightarrow CH_2O+CH_3$ (4). Overall rate constants in the absence and presence of hydrogen sulfide are represented by $10^{15.16}\exp(-54{,}500/\boldsymbol{RT})$ and $10^{15.26}\exp(-51{,}800/\boldsymbol{RT})$ mol.$^{-1/2}$ cc$^{1/2}$ sec$^{-1/2}$ respectively. The combination of these gives $k_3/k_7=0.8\exp(-2{,}700/\boldsymbol{RT})$, where $k_3$ refers to the reaction $CH_3+CH_3OCH_3 \rightarrow CH_4+CH_3OCH_2$ (3). If, therefore, the activation energy of reaction 3 is 9.5 kcal./mol. as reported by Trotman-Dickenson and Steacie, that for reaction 7 is 6.8 kcal./mol. The results obtained indicate that the decomposition of the formaldehyde formed intremediately is also catalyzed by hydrogen sulfide.

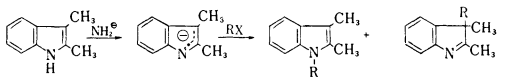
# *Alkylation of Sodio-2, 3-dimethylindole and Sodio-tetrahydrocarbazole in Non-polar Solvent*

By Masao NAKAZAKI

(Received September 26, 1960)

In the previous paper[1], the formation of 11-alkyltetrahydrocarbazolenines (IV) and 9-alkyltetrahydrocarbazoles (III) by the alkylation of tetrahydrocarbazole (I) with sodium amide and alkyl halides in liquid ammonia was reported.

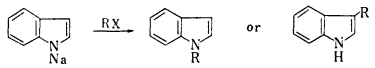


I II III IV

III a $R=CH_2C_6H_5$ IV a $R=CH_2C_6H_5$
b $R=CH_2-CH=CH_2$ b $R=CH_2-CH=CH_2$
c $R=CH_3$ c $R=CH_3$

The ratio of the yield of 11-alkyltetrahydrocarbazolenines (IV) to 9-alkyltetrahydrocarbazoles (III) was found to be affected by the halides employed: benzyl chloride gave the highest ratio and was followed by ally bromide, isopropyl iodide and methyl iodide.

The same sort of "ambident" alkylation[2,3] to give 1-alkyl-2, 3-dimethylindoles (VII) and 3-alkyl-2,3-dimethylindolenines (VIII) was observed in the alkylation of 2, 3-dimethylindole(V) in liquid ammonia with sodium amide and alkyl halides, and the ratio of *C*-alkyl/*N*-alkyl products were also found to depend on the nature of alkyl halides in the same sequence as that demonstrated in the alkylation of tetrahydrocarbazole. On the other hand, the alkylation of sodio-indole (IX) in non-polar solvent (benzene or without solvent) was studied by Funakubo[4], who reported the preparation of



V VI VII VIII

VII a $R=CH_3$ VII a $R=CH_2C_6H_5$
b $R=CH_2-CH=CH_2$
c $R=CH_3$

*N*-alkyl indoles (X) (methyl, ethyl, *n*-propyl, isopropyl, allyl, *n*-butyl, isobutyl and isoamyl) by this method.

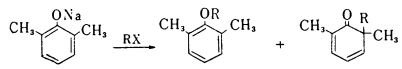
IX X XI

a $R=CH_2-CH=CH_2$
b $R=CH_2C_6H_5$
c $R=C(C_6H_5)_3$
d $R=CH_2COOC_2H_5$

But on our repetition of his experiment[1], his *N*-allylindole picrate (m. p. 169~170°C) turned out to be the picrate of recovered indole, and from the mother liquor was isolated another picrate (m. p. 105~106°C) which was established to be identical with the picrate of 3-allylindole (XIa)[5] prepared by the Grignard synthesis.

Kubota also found another example of β-alkylation of sodio-indole in non-polar solvent when he obtained 3-benzyl(XIb)[6], 3-triphenylmethyl-indole (XIc)[7] and ethyl β-indoleacetate (XId)[8] by heating a suspension of sodio-indole in dry benzene with benzyl chloride, triphenylmethyl chloride and ethyl chloroacetate respectively.

Unfortunately these authors did not dare to examine their alkylation method for 2, 3-disubstituted indoles, and this contribution is concerned with the alkylation of sodio-2, 3-disubstituted indoles in non-polar solvent as a natural extension of our alkylation studies in liquid ammonia.



Tetrahydrocarbazole (I) and 2, 3-dimethylindole (V) were chosen as representatives of 2, 3-disubstituted indoles, because various 11-alkyltetrahydrocarbazlenines (IV), 3-alkyl-2, 3-dimethylindolenines (VIII) and *N*-alkyl derivatives III and VII have been prepared by our hands[1,2] and their structures were firmly established.

The general procedure carried out in our alkylation study was as follows: to a suspension of sodium amide in liquid ammonia (prepared in situ), a solution of indole derivatives (I or V) in toluene was added and the liquid ammonia was evaporated at room temperature. After residual ammonia was expelled by heating the solution up to the boiling point of toluene, a solution of halide in toluene was added under refluxing with stirring. The separation of indolenine derivatives and *N*-alkyl derivatives was worked out by the conventional method as in the case of alkylation in liquid ammonia.

The same directing effect of the alkylation reagents was confirmed in this alkylation in non-polar solvent; i. d. with benzyl chloride and allyl bromide, sodio-tetrahydrocarbazole afforded 11-alkyltetrahydrocarbazolenines (IV) predominantly, whereas with methyl iodide, *N*-methyl derivative was the sole product isolated; 2, 3-dimethyl-indole gave only indolenine derivatives VIII with benzyl chloride and allyl bromide, but with methyl iodide, *N*-methyl derivative VIIa accompanied with a small amount of indolenine derivative VIIIc.

It is noteworthy to compare these results with the directing effects of alkylation reagents in the alkylation of sodium salt of 2, 6-disubstituted phenols (XII) in non-polar solvent, which was studied strenuously by Curtin and his collaborators[9] recently.

To explain their observation that benzyl chloride and ally bromide give predominantly the *C*-alkyl derivative(6-alkyl-2, 6-dimethyl-2, 4-cyclohexadienone) XIII, whereas methyl iodide gives XIV with a trace of XIII, various factors which seem to control the direction of alkylation were considered, however, no decisive conclusion seems have to have been reached. We have proposed a reasonable mechanism to explain the marked directing effect of benzyl

XII XIV XIII

and ally halides in the alkylation of tetrahydrocarbazole in liquid ammonia, but this can not be advanced to rationalize the ambident alkylations in non-polar solvent without further experimental supports.

Studies of alkylation of 2, 6-dimethylphenol in liquid ammonia are now in progress in our laboratory, and should be the subject of a subsequent communication.

## Experimental

**Alkylation of Tetrahydrocarbazole (I).**—*1) With Benzylchloride.*—A mixture of 5 g. of tetrahydrocarbazole and 100 cc. of toluene was added to a suspension of sodium amide in lipuid ammonia

5) Authentic *N*-allylindole (b. p. 114~116°C/6 mmHg., picrate: m. p. 79~79.5°C) was prepared by the alkylation of indole in liquid ammonia with sodium amide and allyl bromide. Ref. 1.

6) T. Kubota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **59**, 407 (1938).

7) T. Kubota and I. Mita, ibid., **59**, 409 (1936). This 3-triphenylmethyl-indole was found to be identical with the compound which had been prepared by E. Funakubo and T. Hirotani (*Ber.*, **69**, 2123 (1936)) by the reaction of the Grignard complex of indole with triphenylmethyl chloride and had been assigned the structure of *N*-triphenylmethyl derivative by them.

8) T. Kubota, Japan Pat., 166925 (1934).

9) D. Y. Curtin et al., *J. Am. Chem. Soc.*, **79**, 3156 (1957); **80**, 1391, 4339, 6016 (1958); *J. Org. Chem.*, **23**, 9 (1958).

prepared from 0.5 g. of sodium and 200 cc. of liquid ammonia. The liquid ammonia was evaporated at room temperature and the resulting suspension of sodio-tetrahydrocarbazole in toluene was refluxed in order to expel the last trace of ammonia. A solution of 4 g. of benzyl chloride in 20 cc. of toluene was added dropwise. After the solution was stirred and refluxed for 1.5 hr., the toluene was distilled with steam, and the residue was extracted with ether. The ether solution was washed with 2 N hydrochloric acid to separate the basic and neutral fractions.

*N-Benzyltetrahydrocarbazole (IIIa)*: — The ethereal extract was washed with water twice and dried over anhydrous sodium sulfate. Removal of the solvent gave a semisolid which was washed with petroleum ether-ether to give 0.5 g. of recovered tetrahydrocarbazole. The washing was concentrated to afford a pale yellow oil, which was distilled in vacuo, 0.4 g. b. p. 170~180°C/2 mmHg (literature[1]: b. p. 195°C/2 mmHg). The picrate was recrystallized from ethanol to give red needles which melted at 110~111°C, alone and admixed with an authentic sample of *N*-benzyltetrahydrocarbazole (m. p. 110~111°C).

Found: N, 11.49. Calcd. for $C_{19}H_9N \cdot C_6H_3O_7N_3$: N, 11.42%.

*11-Benzyltetrahydrocarbazolenine (IVa)*:—After the acidic solution was washed with ether, 4 N sodium hydroxide solution was added to precipitate the basic material which was extracted with ether.

The extract was washed with water and dried over anhydrous sodium sulfate. The solvent was removed to give a semisolid which was filtered free from viscous mother liquor. The crystals were recrystallized from ethanol-water to afford prisms melting at 84~85°C, which was found identical with 11-benzyltetrahydrocarbazolenine by the mixed melting point determination with an authentic specimen (literature: m. p. 85~86°C[1]). The picrate was recrystallized from ethanol to give yellow prisms, m. p. 176~177.5°C (literature: 176~177°C[1]). The mixed melting point with an authentic specimen was 176~177.5°C.

Found: N, 11.53. Calcd. for $C_{19}H_{19}N \cdot C_6H_3O_7N_3$: N, 11.42%.

*2) With Allyl Bromide.* — To a suspension of sodio-tetrahydrocarbazole in toluene prepared from 200 cc. of liquid ammonia, 0.7 g. of sodium, 5 mg. of ferric nitrate, 5 g. tetrahydrocarbazole (I) and 100 cc. of toluene, as described previously, a solution of 4 g. of ally bromide in 20 cc. of toluene was added dropwise with stirring and refluxing in a period of 2 hr. After the reaction mixture was refluxed for an additional 5 hr., the solvent was removed by steam distillation and the residue was extracted with ether. The neutral and basic fractions were separated as described above.

*N-Allyltetrahydrocarbazole(IIIb)*:—From the neutral fraction, 0.5 g. of tetrahydrocarbazole was recovered (m. p. 110~116°C). The residue was distilled in vacuo to afford a viscous pale yellow liquid, b. p. 125~128°C/2 mmHg (literature[1]: b. p. 157°C/3 mmHg). The picrate was recrystallized to give red needles melting at 76~77°C, which were found to be identical with the picrate of *N*-allyltetrahydrocarbazole by the mixed melting point determination with an authentic sample, m. p. 76~77°C[1].

Found: N, 13.05. Calcd. for $C_{15}H_{17}N \cdot C_6H_3O_7N_3$: N, 12.73%.

*11-Allyltetrahydrocarbazolenine (IVb)*: — The basic fraction gave 2.0 g. of crystals which were recrystallized from petroleum ether to afford 11-allyltetrahydrocarbazolenine, m. p. 54~56°C, identified by the mixed melting point determination with an authentic sample (literature[1]: m. p. 57~58°C). The picrate was recrystallized from ethanol to give yellow prisms, m. p. 139~142°C, the identity of which with the picrate of 11-allytetrahydrocarbazolenine was established by the mixed melting point determination with an authentic sample (literature[1]: m. p. 142~143°C).

Found: N, 12.94. Calcd. for $C_{15}H_{17}N \cdot C_6H_3O_7N_3$: N, 12.72%.

*3) With Methyl Iodide.* — The alkylation with methyl iodide was carried out following the general procedure described above. A solution of 8 g. of methyl iodide in 40 cc. of toluene was added dropwise during 6 hr. in a suspension of sodio-tetrahydrocarbazole (0.02 mol.) on toluene prepared from 200 cc. of liquid ammonia, 0.7 g. of sodium, 3.4 g. of sodium and 80 cc. of toluene. After the usual work up, the basic and neutral fractions were separated.

*N-Methyltetrahydrocarbazole (IIIc)*: — The vacuum distillation of the neutral fraction gave 1.4 g. of viscous pale yellow oil, b. p. 124~126°C/2 mmHg. The picrate was recrystallized from ethanol to give brown-red needles melting at 109~112°C. The mixed melting point with an authentic specimen[1] (m. p. 113~114°C) was 109~112°C.

Found: N, 13.79. Calcd. for $C_{13}H_{15}N \cdot C_6H_3O_7N_3$: N, 13.52%.

*The Basic Fraction*: — Removal of the ether afforded an amber yellow solid which was sparingly soluble in dilute sodium hydroxide, dilute hydrochloric acid, ethanol and ether respectively add could not be converted into crystalline picrate. This substance was not studied further.

**Alkylation of 2, 3-Dimethylindole (V).**—*1) With Benzylchloride*:—A solution of 5 g. of 2,3-dimethylindole (V) in 100 cc. of toluene was added dropwise into a suspension of sodium amide in liquid ammonia prepared from 200 cc. of liquid ammonia, 1 g. of sodium and 5 mg. of ferric nitrate. The liquid ammonia was evaporated and the remaining mixture was refluxed with stirring. To the reaction mixture, a solution of 5.3 g. of benzyl chloride in 20 cc. of toluene was added and refluxing with stirring was continued for 8 hr. After the reaction mixture was worked up as described in the alkylation of tetrahydrocarbazole, the basic and the neutral fractions were separated.

*2, 3-Dimethyl-3-benzylindolenine (VIIIa)*:—Removal of the solvent afforded 4.6 g. of a solid, which was recrystallized from petroleum ether to give crystals melting at 48~49°C, alone and admixed with an authentic specimen (m. p. 48~49°C[10]).

The picrate was recrystallized from ethanol to give

10) M. Nakazaki, S. Isoe and K. Tanno, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **76**, 1262 (1955).

yellow prisms, m. p. 137~139°C, the mixed melting point of which with an authentic sample[10] was found 137~140°C.

Found: N, 12.20. Calcd. for $C_{17}H_{17}N \cdot C_6H_3O_7N_3$: N, 12.06%.

*The Neutral Fraction:* — A small amount of 2,3-dimethylindole was recovered, but the search for *N*-benzyl derivative was fruitless.

*2) With Allyl Bromide.*—Using 5 g. of allyl bromide, the alkylation was carried out exactly as the procedure described above.

*2,3-Dimethyl-3-allylindolenine (VIIIb):* — The crude basic fraction (1 g.) was distilled in vacuo to give a yellow liquid, b. p. 125~128°C/12 mmHg. The picrate was recrystallized from ethanol to afford yellow needles m. p. 158~160°C, the mixed melting point with an authentic sample[2] (m. p. 156~157°C) showed 159~160°C.

Found: N, 13.65. Calcd. for $C_{13}H_{15}N \cdot C_6H_3O_7N_3$: N, 13.52%.

*Neutral Fraction:* — The crude neutral fraction (2 g.) was distilled in vacuo to give two fractions: 1. 1.4 g. b. p. 100~125°C/2 mmHg. which was proved as 2,3-dimethylindole recovered, 2. 0.5 g. b. p. 125~130°C/2 mmHg which did not give crystalline picrate and was not studied further.

*3) With Methyl Iodide.* — The alkylation was carried out using 12 g. of methyl iodide, and the basic and neutral fractions were separated as described above.

*2,3,3-Trimethylindolenine (VIIIc):*—The crude basic fraction (1.1 g.) was distilled in vacuo to give 0.4 g. of VIIIc, b. p. 80°C/1 mmHg, the characteristic odor of which resembles that of jasmin. The picrate was recrystallized from ethanol to afford yellow needles melting at 158°C, which was found identical with the picrate of 2,3,3-trimethylindolenine (literature[2]: m. p. 158°C) by the mixed melting point determination.

Found: N, 14.54. Calcd. for $C_{11}H_{13}N \cdot C_6H_3O_7N_3$: 14.43%.

*1,2,3-Trimethylindole (VIIa):* — From the neutral fraction, a small amount of 2,3-dimethylindole was recovered by recrystallization from petroleum ether. The mother liquor, after removal of the solvent, was distilled in vacuo to give 1.1 g. of yellow liquid, b. p. 90~93°C/2 mmHg (literature[2]: b. p. 117~120°C/6 mmHg). The picrate was recrystallized from ethanol to afford brownish-black needles, m. p. 145~147°C which was not depressed on admixing with an authentic specimen[2] of the picrate of 1,2,3-trimethylindole (m. p. 148~149°C).

Found: N, 14.70. Calcd. for $C_{11}H_{13}N \cdot C_6H_3O_7N_3$: N, 14.43%.

# *Microwave Spectrum and Molecular Structure of Monochloroacetonitrile, $CH_2ClCN$*

By Kaname WADA, Yoshikazu KIKUCHI, Chi MATSUMURA, Eizi HIROTA and Yonezo MORINO

(Received September 5, 1960)

Since the structure of the monochloroacetonitrile molecule $CH_2ClCN$ is similar to that of propargyl chloride $CH_2ClC{\equiv}CH$, it is of some interest to compare the structure of the two molecules with each other in detail. In particular, the C—Cl bond length is important in the respect because it will give some information concerning the electronic structure of the molecule. The quadrupole coupling constant of chlorine nucleus is also important for discussing the nature of the C—Cl bond.

When the present investigation was coming nearly to the end, a paper was published by Graybeal on the structure of the $CH_2ClCN$ molecule by the microwave absorption spectrum[1]. But his result seems to involve a number of unreliable data and moreover only two isotopic species, $CH_2{}^{35}ClCN$ and $CH_2{}^{37}ClCN$, were used in his study. The molecular structure and the molecular constants obtained in the present paper would be more reliable than those by Graybeal.

## Experimental

The rotational spectra of monochloroacetonitrile, $CH_2{}^{35}ClCN$, $CH_2{}^{37}ClCN$, $CD_2{}^{35}ClCN$, and $CD_2{}^{37}ClCN$, were observed at room temperature by using the recording microwave spectrometer with a 100 Kc. Stark modulation described in the previous paper[2]. The microwave was supplied by klystrons,

Varian X-12 and X-13, and the frequency was multiplied by a silicon crystal. The frequency range covered was 15000 Mc./sec. to 35000 Mc./sec.

The deuterated samples were prepared as follows: a mixture of the normal monochloroacetonitrile, heavy water and a trace of anhydrous sodium carbonate was kept on a hot water bath for a day and then distilled out. The infrared absorption spectrum showed neither the C-H stretching nor the $CH_2$ deformation bands.

## Results

Monochloroacetonitrile is a nearly prolate symmetric top molecule and both a- and b-type transitions were observed. The transitions of the b-type Q-branch, $J_{0,J}\rightarrow J_{1,J-1}$, were most easily identified because of their characteristic hyperfine patterns due to the quadrupole moment of the chlorine nucleus ($I=3/2$) and confirmed by plotting the values of $A-(B+C)/2$ and $b_P=(C-B)/(2A-B-C)$. For $CH_2ClCN$ a-type, and b-type R-branch transitions and for $CD_2ClCN$ a-type R-branch transitions were also measured. The observed center frequencies are given in Table I.

The rotational constants of $CH_2ClCN$ were determined by using the transitions, $0_{0,0}\rightarrow 1_{1,1}$, $1_{0,1}\rightarrow 1_{1,0}$, and $3_{0,3}\rightarrow 3_{1,2}$. Unfortunately none of these transitions were measured for $CD_2ClCN$ and the rotational constants were determined by using relatively low-$J$ transitions. The values are listed in Table II. The center frequencies calculated by using these constants are compared with the observed ones in Table I. (a rigid rotor calculation).

For $CH_2{}^{35}ClCN$ rough estimation of centrifugal effect is made (Table III) by assuming the expression for a symmetric top molecule, $-D_JJ^2(J+1)^2-D_{JK}J(J+1)K_{-1}{}^2-D_KK_{-1}{}^4$. The transitions used for determining the centrifugal constants are $4_{0,4}\rightarrow 4_{1,3}$, $5_{1,5}\rightarrow 6_{1,6}$, $5_{1,5}\rightarrow 6_{0,6}$, $6_{1,6}\rightarrow 7_{0,7}$, and $11_{2,10}\rightarrow 12_{1,11}$. The center frequencies calculated with the centrifugal distortion correction are compared with the observed

ones in Table III. It is seen that the discrepancy found in the rigid rotor calculation is largely reduced, even for high-$J$ transitions.

Since only two hydrogen atoms are located above and below the symmetry plane, the distance between them $r$ is given by[2]

$$r=[(I_a+I_b-I_c+\Delta)/m]^{1/2}$$

where $\Delta$ is a quantity similar to the inertia defect and $m$ is the mass of hydrogen or deuterium atom. The values of $\Delta$ and $r$ (Table IV) were determined by means of the method of least-squares using the four equations given by the four isotopic species.

The number of the rotational constants obtained is twelve. Four of them are used in obtaining the hydrogen to hydrogen distance, hence there remain eight constants for determining the other structural parameters, $d_{C-C}$, $d_{C-Cl}$, $d_{C-H}$, $d_{C\equiv N}$, ∠CCCl, ∠CCH, and ∠CCN. Since isotopes of carbon and nitrogen atoms were not available, none of these parameters could be determined. The C-C bond length adjacent to the triple bond is usually about 1.458 Å, and the C≡N bond length in cyano group is reported for a number of molecules to be 1.158 Å[3]. The assumption of the linear structure for the C—C≡N group may not influence the other structural parameters. Thus the following values were assumed: $d_{C-C}=1.458$ Å,

** Values calculated by using the rotational constants given by Graybeal. No corrections for centrifugal effects.

$d_{C\equiv N}=1.158$ Å, and $\angle CCN=180°$. The remaining five parameters were determined by the method of least-squares using the values of $A$ and $B$, as shown in Table IV.

Nuclear quadrupole coupling constant is calculated for $CH_2{}^{35}ClCN$ from the transitions $1_{0,1}\rightarrow 1_{1,0}$, $3_{0,3}\rightarrow 3_{1,2}$, and $6_{0,6}\rightarrow 6_{1,5}$, and given in Table IV. If the electronic charge distribution about the C—Cl bond is assumed to be cylindrical, the quadrupole coupling constant along the C—Cl bond axis is $-80$ Mc./sec. The value is consistent with that observed in the solid state, 76.25 Mc./sec.[4] The hyperfine structures due to the nitrogen nucleus were not resolved.

## Discussion

A quite normal value 1.7815 Å is obtained for the C—Cl bond length, which is very close to the value obtained for propargyl chloride, 1.780 Å[2], hence it is sure that neither a double bond structure nor an ionic structure contributes so much to the electronic configuration in the ground state of this molecule.

The center frequencies measured by Graybeal[1] are shown in Table V. Some of them are confirmed by the present investigation within the experimental error, but others show a definite discrepancy. Graybeal calculated the center frequencies by using the rotational constants given in Table VI. However, some of them are also in error by as much as 10 Mc./sec. It is found that the $\delta$ expansion formula he used[5] is insufficient for calculating the energy of the rotational states with $J$ as high as ten. As a result his values of $A$ are larger than the present ones by about 13 Mc./sec. (Table VI). On the other hand the constants of the present paper reproduce the

TABLE VI. COMPARISON OF THE ROTATIONAL CONSTANTS (IN Mc./sec) OBTAINED BY GRAYBEAL AND BY THE PRESENT AUTHORS

| | $CH_2{}^{35}ClCN$ | | $CH_2{}^{37}ClCN$ | |
|---|---|---|---|---|
| | Graybeal | Present | Graybeal | Present |
| $A$ | 25284.77 | 25271.30 | 25135.17 | 25122.52 |
| $B$ | 3151.61 | 3151.01 | 3081.77 | 3081.13 |
| $C$ | 2849.90 | 2848.80 | 2790.84 | 2789.56 |

frequencies of low-$J$ transitions in good agreement with the observed ones. If the centrifugal distortion is taken into account, the rotational constants given in the present paper would account even for high-$J$ transitions (Table III).

Graybeal reported the C—Cl bond length to be 1.767 Å and the C—C bond length to be 1.472 Å (Table IV). If isotopic species of carbon or nitrogen atoms were not available as in his study, it would be difficult to determine these two parameters separately. The correction due to the inertia defect has not been taken in the H···H distance obtained by Graybeal, thus the structure of the $CH_2$ group reported by him is not reliable.

The value of the quadrupole coupling constant of chlorine nucleus is observed to be $-80$ Mc./sec., which is slightly higher than that of propargyl chloride ($-75.8$ Mc./sec.)[2]

4) J. D. Graybeal and C. D. Cornwell, *J. Phys. Chem.*, 62, 483 (1958).

5) Graybeal used likely the expansion formula given by King, Hainer and Cross [*J. Chem. Phys.*, 11, 27 (1943)].

or of ethyl chloride (−70.07 Mc./sec.)[6]. This fact may be accounted for by the presence of the electronegative cyano group, since this reduces the ionic structure of the C—Cl bond. The present value of the quadrupole coupling constant of chlorine nucleus would be more reasonable than Graybeal's value −76.36 Mc./sec., since the (absolute) value obtained in the vapor phase is usually larger than that in the solid phase by several megacycles and the coupling constant of monochloroacetonitrile is 76.25 Mc./sec. in the solid state.

# *Microwave Spectrum of Propargyl Halides. I. Molecular Structure, Dipole Moment, and Quadrupole Coupling Constant of Propargyl Chloride*

By Eizi HIROTA and Yonezo MORINO

(Received September 5, 1960)

The C—Cl bond length in propargyl chloride $CH_2ClC \equiv CH$ was found by Pauling, Gordy and Saylor[1] to be $1.82 \pm 0.02$ Å. It is remarkably longer than C—Cl lengths observed in a number of other aliphatic chlorides. However, the value obtained in the previous paper[2], 1.7802 Å, was close to the usual C—Cl bond length.

The present paper will include the observation and the analysis of rotational spectra of two other isotopic species, $CH_2{}^{35}ClC{\equiv}CD$ and $CH_2{}^{37}ClC \equiv CD$, and will give a molecular structure more reliable than the previous one.

## Experimental

The spectrometer used was similar to that reported by Shimoda, Nishikawa and Itoh[3]. A 100 Kc. sine wave modulation was used. The microwave was generated by klystrons, 2K26, 2K25, 8V77, X-12, and X-13, and the frequency was multiplied by a silicon crystal. The frequency range covered was from 7000 Mc./sec. to 36000 Mc./sec. An X-band absorption cell of 3 m. in length was employed, and the Stark electrode was supported by Teflon tape grooved at its center. The spacing between the electrode and the cell was not measured, but the calibration was made by observing the Stark effect of the $J=1 \rightarrow 2$ lines of carbonyl sulfide $^{16}O^{12}C^{32}S$ at 24325.94 Mc./sec.[4]. The vacuum system was designed in such a way that the sample flew continuously through the cell, its pressure being estimated by a Pyrani gauge. The cell was cooled with dry ice when necessary. The frequency of microwave was measured by the technique developed by Shimoda[5]. The out-put power of microwave was detected by another silicon crystal and fed into a narrow band amplifier tuned with 100 Kc./sec. and then detected by a phase-sensitive detector. The signal was amplified by a low-frequency amplifier and observed on a cathode ray oscilloscope or on a recorder. The ultimate sensitivity was about $5 \times 10^{-9}$ cm$^{-1}$ when the recorder was used[6].

Propargyl chloride was synthesized by Dr. T. Shimozawa by the chlorination of propargyl alcohol[7]. The deuterated species $CH_2ClC{\equiv}CD$ was obtained by mixing normal propargyl chloride with heavy water which was made slightly alkaline by adding a small quantity of anhydrous sodium carbonate.

## Results

* Rotational constants are given in Mc./sec. and principal moments of inertia in amu Å$^2$. Conversion factor 505531 Mc./sec. amu Å$^2$ is used.

** Values are calculated by using the set of structure parameters (I) given in Table V.

symmetry plane. Thus the dipole moment has components along the a- and b-axes, and transitions of both a- and b-types are observed. The observed spectra are listed in Table I, where center frequencies are given. The assignment is made mainly by the b-type Q-branch series, $J_{0,J}\rightarrow J_{1,J-1}$. The quadrupole hyperfine structure due to chlorine atom is of some use to check the assignment.

The b-type Q-branch series mentioned above give the rotational constants $[A-(B+C)/2]$ and the asymmetry parameters $b_P$, whereas the constants $B+C$ and $B-C$ are obtained by measuring the a-type R-branch lines. The

$0_{0,0}\rightarrow 1_{1,1}$ lines are important since their frequencies are equal to $A+C$. The rotational constants and the asymmetry parameters are given in Table II, where the moments of inertia are calculated by using the conversion factor 505531 Mc./sec. amu Å$^2$. The frequencies calculated by using these rotational constants are compared with the observed ones in Table I.

In the course of searching, the spectra of two excited vibrational states were found. By comparing their intensities with those of the ground state, one is assigned to the CCCl bending mode and the other to one of the C—C≡C bending modes. The center frequencies and the rotational constants derived from them are listed in Table III.

**Structure Analysis.** — The structure of propargyl chloride is specified by eight parameters: C—Cl, C—C, C≡C, methylenic C—H, and acetylenic C—H bond lengths, and CCCl, HCH and CCH bond angles, the C—C≡C—H group being assumed to be linear. The distance between two hydrogen atoms in methylene group is directly given by the quantity $[(I_a+I_b-I_c)/m_H]^{1/2}$. The four kinds of isotopic species give fairly close values for the distance, as shown in Table IV. However, as Laurie pointed out[8], the inertia defect $\Delta$ makes this distance short and the angle HCH apparently small. Since the data on the isotopic molecules for which deuterium is substituted in the methylene group were not available, it was difficult to see how much the inertia defect was. If the value is assumed to be 0.2194 amu Å as found for chloroacetonitrile[9], the distance H···H becomes 1.7715 Å. In the following the molecular structure is calculated by assuming $\Delta$ equal to zero or 0.2194 amu Å$^2$.

| $CH_2{}^{37}ClC{\equiv}CD$ | 2.933 | $1.705_6$ |

The inertia defect arises from the zero-point vibration, and it is accepted from the case of water molecule[10] that the contribution of low-frequency vibrations to inertia defect is larger than those of high-frequency ones. The CCCl and C—C≡C bending modes are mentioned as the low-frequency vibrations in propargyl chloride, and the rotational constants are obtained in the excited states of these two vibrations as stated above. It is interesting to see how much the inertia defect and the distance H···H are changed if the rotational constants are corrected for these two vibrations. The corrected rotational constants, $A'$, $B'$, and $C'$, are given by

$$A' = A_0 + (1/2)(\alpha_1+\alpha_2)$$
$$B' = B_0 + (1/2)(\beta_1+\beta_2)$$
and $$C' = C_0 + (1/2)(\gamma_1+\gamma_2)$$

where $\alpha_1$, $\beta_1$, $\gamma_1$ and $\alpha_2$, $\beta_2$, $\gamma_2$ denote the changes of rotational constants due to the two vibrations. Their observed values are 24266.2 Mc./sec., 3077.5 Mc./sec. and 2776.8 Mc./sec., respectively. The H···H distance, 1.738 Å, calculated by using $A'$, $B'$ and $C'$ is in fact fairly larger than that obtained by $A_0$, $B_0$ and $C_0$, 1.709 Å, but still smaller than 1.772 Å which was obtained by assuming $\Delta=0.2194$ amu Å$^2$.

The parameters other than the H···H distance, seven in number, are to be determined by the remaining eight constants. Not all parameters can be determined by the present data, hence several assumptions are necessary. It is recognized that the C≡C bond length is relatively constant, irrespective of the attached groups. The value 1.207 Å is assumed for this length[11,12]. The acetylenic C—H bond length makes a small contribution to the rotational constants, hence the value 1.06 Å is assumed for this distance without strong influence upon other parameters to be obtained[12]. The lengths, C—H and C—D, are assumed to be the same. The groups C—C≡C and C—C≡N are usually considered linear, though the detailed investigations gave slightly bent structures[13]. Here the

linear structure is also assumed. Two additional assumptions are the methylenic C—H bond length equal to 1.09 Å and the CCH bond angle equal to 111°30′. These two parameters, especially the latter, affect considerably the rotational constant $A$, in spite of the light weight of a hydrogen atom. Hence some precaution must be taken for selecting the assumed values for these parameters.

First, the inertia defect is set equal to zero. The methylenic C—H bond length and the CCH bond angle are assumed to be 1.09 Å and 111°30′, respectively. The eight rotational constants, $A$ and $C$ for each isotopic molecule, are used to determine the C—Cl and the C—C bond lengths, and the CCCl bond angle. They are found to be 1.7800 Å, 1.4582 Å, and 112°9′, respectively (Table V). If the bond lengths C—Cl and C—C become longer, both $A$ and $C$ decrease, on the other hand the $A$ increases and the $C$ decreases with the increase of the

TABLE V. STRUCTURE PARAMETERS UNDER VARIOUS ASSUMPTIONS

| Set | Assumption | | Result | | |
|---|---|---|---|---|---|
| | $\Delta$ amuÅ$^2$ | ∠CCH | C—Cl Å | C—C Å | ∠CCCl |
| I | 0 | 111°30′ | 1.7800 | 1.4582 | 112° 9′ |
| $II_a$ | 0.2194 | 107°30′ | 1.7728 | 1.4766 | 111°43′ |
| $II_b$ | 0.2194 | 109°30′ | 1.7768 | 1.4724 | 111°45′ |
| $II_c$ | 0.2194 | 111°30′ | 1.7808 | 1.4690 | 111°44′ |

Other assumptions
C≡C 1.207Å
C—H (methylenic) 1.09Å
C—H=C—D (acetylenic) 1.06Å
C—C≡C—H(D) linear

CCCl angle. Thus the determination of the CCCl angle is definite, but it is somewhat difficult to determine two bond lengths separately. Still it is feasible to obtain fairly good results for the two bond lengths. The fitting of the calculated constants with the observed is carried out by the least-squares method, the mean deviation is 0.00051 Å for the C—Cl bond length, 0.00062 Å for the C—C bond length, and 0.54′ for the CCCl bond angle. If the assumed value for the C≡C length, 1.207 Å, is in error by 0.01 Å, the C—Cl is changed by 0.001 Å, the C—C by 0.007 Å, and the CCCl by 2.5′.

Thus far, the analysis gives reasonable results. However, the inertia defect is by no means equal to zero, and its effect is obvious if the HCH angle is calculated to be 103°14′ by using the observed H···H distance 1.709 Å and the assumed C—H (methylenic) distance 1.09 Å.

In the second place, the inertia defect is assumed to be 0.2194 amu Å$^2$. This value is borrowed from the result for the chloroacetonitrile molecule. An analysis by the least-squares method is carried out by using three values for the CCH angle, 107°30′, 109°30′ and 111°30′. The methylenic C—H length is fixed to 1.09 Å. As stated above, the HCH angle becomes 108°42′, a quite reasonable value. The results obtained for the C—Cl and the C—C lengths, and the CCCl angle are listed in Table V. The CCCl bond angle is relatively independent of the values assumed for the CCH angle; however, the two bond lengths are varied by 0.008 Å. It is difficult to say which case is the most reasonable, but the length of the C—C bond adjacent to the triple bond is reported about 1.460 Å in a number of related molecules[11,12]. In this respect the case 111°30′ for the CCH angle is the most favorable, where the C—C length is 1.4690 Å. It is yet by no means clear whether or not the assumed value for the inertia defect is reasonable. It is felt that the inertia defect slightly less than 0.2194 amu Å$^2$ is more reasonable, since the C—C bond length then becomes somewhat shorter than 1.4690 Å. The parameter values, which are considered the most reasonable at present, are given in the last column of Table VI, where errors are attached by taking into account the zero-point vibration, inadequacy of the assumed parameters, and so on.

**Quadrupole Coupling Constant of Chlorine Atom.** — The chlorine nuclear quadrupole coupling constant is determined by measuring the hyperfine structure of eight rotational transitions of the most abundant species $CH_2{}^{35}ClC{\equiv}CH$. By the lack of accidental degeneracy in rotational energy only the two components of the coupling constant, $\chi_{aa}$ and $\chi_{bb}$, are obtained. The least-squares method gives $\chi_{aa}=-30.4$ Mc./sec. and $\chi_{bb}=-7.5$ Mc./sec. The hyperfine structures calculated by using these values are compared with the observed ones in Table VII.

A similar analysis is carried out on the hyperfine structures of eight transitions of $CH_2{}^{35}ClC{\equiv}CD$, but it is found that the values −28.2 Mc./sec. and −9.7 Mc./sec., which are

calculated from coupling constants of $CH_2{\cdot}{}^{35}ClC{\equiv}CH$ by transforming the principal axes, explain the hyperfine structures sufficiently well.

If the values of $\chi_{aa}$ and $\chi_{bb}$ were accurate, the rotation of the principal axes due to the deuterium substitution might give the asymmetry parameter, but the present data do not warrant such a procedure. On the other hand, the second-order effect observed for the bromine nuclear quadrupole hyperfine structure of rotational spectra of propargyl bromide $CH_2BrC{\equiv}CH$ indicated that the asymmetry parameter was small[14]. The values of $\chi_{aa}$ and $\chi_{bb}$ obtained above give $\chi_{bond}=-75.8$ Mc./sec., under the assumption of the cylindrical symmetry of charge distribution about the C—Cl bond. The result is consistent with the value in the solid state, 71.6246 Mc./sec.[15]

**Dipole Moment.** — The dipole moment has two components; one along the a-axis and the other along the b-axis. The Stark effect of the $0_{0,0}\rightarrow 1_{1,1}$ transition of $CH_2{}^{35}ClC{\equiv}CH$ is measured to obtain the two components of the

14) Y. Kikuchi, E. Hirota and Y. Morino, *J. Chem. Phys.*, **31**, 1139 (1959); This Bulletin, **34**, 348 (1961).

15) T. Shimozawa, T. Chiba, I. Miyagawa and Y. Morino, ibid., to be published.

dipole moment. The presence of the chlorine nuclear quadrupole moment makes the Stark effect complicated, but it is possible to analyze the Stark effect of the $0_{0,0}\rightarrow 1_{1,1}$ transition, since the $J$ number associated is small[16].

The quadrupole energy of the state $1_{1,1}$ is small, hence the weak, the intermediate, and the strong field cases are successively met with the increase of the Stark electric field. The quadrupole energy is zero for the state $0_{0,0}$.

The calculation of the Stark effect and the quadrupole effect is carried out by taking the wave function, $|IJ\tau M_J M_I>$, as the basis. The matrix elements of the Hamiltonian for the Stark effect $H_E$ are diagonal in $M_J$ and $M_I$, but they connect different rotational states. The state $0_{0,0}$ couples with states $1_{0,1}$ and $1_{1,1}$, and the state $1_{1,1}$ with states $1_{1,0}$, $2_{1,2}$, $0_{0,0}$, $2_{2,0}$ and $2_{0,2}$ by the Hamiltonian $H_E$. The differences in rotational energies are greater than the Stark or quadrupole energies, so that the second-order perturbation is sufficient to calculate the Stark effect[17]. Thus, it is reduced to the form;

$$\sum_{J'\tau'} \frac{|(IJ\tau M_J M_I|H_E|IJ'\tau' M_J M_I)|^2}{E_{J\tau}-E_{J'\tau'}} = (\alpha+\beta M_J^2)\varepsilon^2$$

where $\varepsilon$ is the Stark field strength, and $\alpha$ and $\beta$ are constants depending upon the rotational constants, the rotational quantum numbers, and the dipole moment.

The Hamiltonian for the quadrupole energy, $H_Q$, has matrix elements, diagonal as well as nondiagonal with respect to $M_J$ and $M_I$. Matrix elements between different rotational states are ignored, since the first-order perturbation is sufficient enough to treat the quadrupole energy. The matrix elements appropriate at present are as follows:

$$\begin{aligned}
&(IJ\tau M_J M_I|H_Q|IJ\tau M_J' M_I')\\
&=P[3M_I^2-I(I+1)]\,[3M_J^2-J(J+1)]\\
&\qquad (M_J'=M_J,\ M_I'=M_I)\\
&=P[3/2+3M_I M_J+3(M_I\mp 1)(M_J\pm 1)]\\
&\quad\times\{[I(I+1)-M_I(M_I\mp 1)]\\
&\quad\times[J(J+1)-M_J(M_J\pm 1)]\}^{1/2}\\
&\qquad (M_J'=M_J\pm 1,\ M_I'=M_I\mp 1)\\
&=P(3/2)\{[J(J+1)-M_J(M_J\pm 1)]\\
&\quad\times[J(J+1)-(M_J\pm 1)(M_J\pm 2)]\\
&\quad\times[I(I+1)-M_I(M_I\mp 1)]\\
&\quad\times[I(I+1)-(M_I\mp 1)(M_I\mp 2]\}^{1/2}\\
&\qquad (M_J'=M_J\pm 2,\ M_I' M_I\mp 2)
\end{aligned}$$

where $P$ is given by

$$\begin{aligned}
P=\{&\chi_{aa}[J(J+1)+E(\kappa)-(\kappa+1)(\partial E(\kappa)/\partial\kappa)]\\
&+2\chi_{bb}(\partial E(\kappa)/\partial\kappa)\\
&+\chi_{cc}[J(J+1)-E(\kappa)\\
&+(\kappa-1)(\partial E(\kappa)/\partial\kappa)]\}/\\
&[4J(J+1)(2J-1)(2J+3)I(2I-1)]
\end{aligned}$$

which is reduced for the state $1_{1,1}$ to

$$P(1_{1,1})=-(1/60)\chi_{bb}$$

Secular determinant for the state $1_{1,1}$ factors into three groups, corresponding to $M_F=M_J+M_I=5/2$, $3/2$ and $1/2$, respectively. Secular determinants are all doubly degenerate. The case $M_F=5/2$ is the simplest, since the wave function belonging to $M_F=5/2$ is $|M_J, M_I>=|1, 3/2>$ or $|-1, -3/2>$. The secular equation is

$$3P+(\alpha+\beta)\varepsilon^2-W=0$$

The two pairs of wave functions, $[|\pm 1, \pm 1/2>, |0, \pm 3/2>]$, belong to $M_F=3/2$ and give rise to a two-dimensional secular equation:

$$\begin{vmatrix} -3P+(\alpha+\beta)\varepsilon^2-W & 3\sqrt{6}\,P \\ 3\sqrt{6}\,P & -6P+\alpha\varepsilon^2-W \end{vmatrix}=0$$

The wave functions corresponding to $M_F=1/2$ are $|\pm 1, \mp 1/2>$, $|0, \pm 1/2>$ and $|\mp 1, \pm 3/2>$, and the secular equation is

$$\begin{vmatrix} 3P+(\alpha+\beta)\varepsilon^2-W & -3\sqrt{6}\,P & 6\sqrt{3}\,P \\ -3\sqrt{6}\,P & 6P+\alpha\varepsilon^2-W & 0 \\ 6\sqrt{3}\,P & 0 & -3P+(\alpha+\beta)\varepsilon^2-W \end{vmatrix}=0$$

If the field strength $\varepsilon$ is equal to zero, the secular equations give the following energy states:

| | | |
|---|---|---|
| $W_1=3P$ | $F=5/2$, | $M_F=5/2$ |
| $W_{21}=3P$ | $5/2$, | $3/2$ |
| $W_{22}=-12P$ | $3/2$, | $3/2$ |
| $W_{31}=3P$ | $5/2$, | $1/2$ |
| $W_{32}=-12P$ | $3/2$, | $1/2$ |
| $W_{33}=15P$ | $1/2$, | $1/2$ |

Here the representation $|IFM_I M_F>$ rather than $|IJM_I M_J>$ is good. There are only two states $|F, M_F>=|3/2, 1/2>$ and $|3/2, 3/2>$ possible in the rotational state $0_{0,0}$. Since the selection rule is $\Delta M_F=0$, transition to the state $W_1$ is forbidden and two pair states $W_{21}$ and $W_{31}$, and $W_{22}$ and $W_{32}$ are degenerate, there are three hyperfine lines. If the Stark field increases so that the Stark energies $\alpha\varepsilon^2$ or $\beta\varepsilon^2$ are larger than $P$, the strong field case is apropppriate. The secular determinantes described above give the following states:

16) F. Coester, *Phys. Rev.*, **77**, 454 (1950).
17) S. Golden and E. B. Wilson, Jr., *J. Chem. Phys.*, **16**, 669 (1948).

$$W_1=(\alpha+\beta)\varepsilon^2+3P \quad M_J=1, \quad M_I=3/2$$
$$W_{21}=(\alpha+\beta)\varepsilon^2-3P \quad 1, \quad 1/2$$
$$W_{22}=\alpha\varepsilon^2-6P \quad 0, \quad 3/2$$
$$W_{31}=(\alpha+\beta)\varepsilon^2+3P \quad 1, \quad 3/2$$
$$W_{32}=\alpha\varepsilon^2+6P \quad 0, \quad 1/2$$
$$W_{33}=(\alpha+\beta)\varepsilon^2-3P \quad 1, \quad 1/2$$

This case can be expressed by the representation $|IJM_IM_J>$. The rotational state $0_{0,0}$ involves two states $|M_J, M_I>=|0, 1/2>$ and $|0, 3/2>$. Two transitions to the states $W_{22}(M_J=0, M_I=3/2)$ and $W_{32}(M_J=0, M_I=1/2)$ are allowed by the selection rules, $\Delta M_J=0$ and $\Delta M_I=0$.

The solutions for the intermediate case are obtained by solving the secular determinants given above. Eigenfunctions are obtained to calculate the transition probabilities. The change of the hyperfine patterns with the electric field, the frequencies and the intensities, is given in Fig. 1.

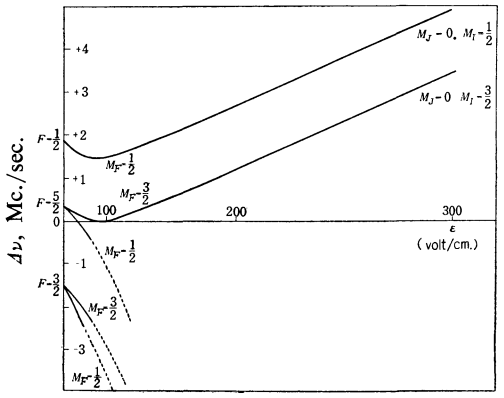

Fig. 1. Stark effect of the $0_{0,0}\rightarrow 1_{1,1}$ transition ($CH_2{}^{35}ClC\equiv CH$).

It is interesting to note that the transition to the state $W_{21}$ in case $\varepsilon=0$ shifts first to lower frequency with increasing electric field, stops at some field strength $\varepsilon_0$, and then moves to a higher frequency. The observed intensity reduces to zero at $\varepsilon_0$, because the Stark modulation is used for the measurement. This is also the case for the transition to the state $W_{33}$ at $\varepsilon=0$. The case $M_F=3/2$ is considered. The solutions are obtained by solving the secular equation, that is

$$W^{\pm}=-(1/2)\,[9P-(2\alpha+\beta)\varepsilon^2] \pm[(1/4)\,(3P+\beta\varepsilon^2)^2+54P^2]^{1/2}$$

The line mentioned above corresponds to the transition to the state $W^+$ and its frequency is given by

$$\nu=(W^++\alpha_0\varepsilon^2)/h$$

where $-\alpha_0\varepsilon^2$ is the Stark effect of the state $0_{0,0}$. Then the electric field $\varepsilon_0$, at which the Stark effect of the line changes its sign from minus to plus, is given by

$$\varepsilon_0{}^2=(P/\beta)\{-3-[216(2\alpha_0+2\alpha+\beta)^2/[\beta^2-(2\alpha_0+2\alpha+\beta)^2]\,]^{1/2}\}$$

The constants, $\alpha_0$, $\alpha$ and $\beta$, are functions of two components of dipole moments, $\mu_a$ and $\mu_b$. The Stark effect of the strong field case gives $\alpha_0+\alpha+\beta$ and $\varepsilon_0$ thus obtained provides another information on $\alpha_0$, $\alpha$ and $\beta$.

The two components thus found are $\mu_a=0.98_5$ D and $\mu_b=1.36_0$ D, and the total moment $\mu_t=1.68$ D. There are four choices for the direction of the dipole moment, but it seems most plausible that the negative direction of the dipole moment lies between the C—Cl and the C—C≡C—H bonds, at an angle of 16±7° from the former. The total dipole moment 1.68 D is compared favorably with the value obtained by the dielectric constant measurement, 1.65 D[7].

## Discussion

Pauling, Gordy and Saylor[1] explained the long C—Cl bond length by assuming a resonance structure $Cl-CH_2=C=C^+-H$, but the present result clearly shows that it is unnecessary to consider such a resonance structure. The C—Cl bond was found to be a normal value of 1.780 Å. In addition to this, the resonance structure given above predicts a small quadrupole coupling constant and a large dipole moment. These are not found in the present data either. Laurie and Lide observed the C—Cl bond length in 1-chloro-2-butyne to be

Table VIII. Comparison of molecular structures

$1.79_8$ Å[18]. The data were, however, not sufficiently accurate and in addition the presence of internal rotation complicated the problem.

It is of some help to compare the constants of the propargyl chloride molecules with those of some other molecules. Table VIII shows such a comparison, where methyl and ethyl chlorides are taken as reference substances.

The authors are greatly indebted to Professor K. Shimoda, Mr. H. Hirakawa, and their coworkers at the Department of Physics for their advice in constructing the apparatus. They should like to thank Mr. T. Oka who collaborated with them in the early stage of this investigation. They wish also to express their sincere thanks to Dr. M. Shima, Institute for Physical and Chemical Research, for supplying them with heavy water. The expenses for this research were defrayed from the Scientific Research Encouragement Grant of the Ministry of Education to which the authors' thanks are also due.

# *Microwave Spectrum of Propargyl Halides. II. Molecular Structure and Second-Order Quadrupole Effect of Propargyl Bromide*

By Yoshikazu KIKUCHI, Eiji HIROTA and Yonezo MORINO

(Received September 5, 1960)

In the previous papes[1] the C—Cl distance in propargyl chloride was reported to be close to the usual C–Cl bond length, 1.780±0.002 Å. The determination of the C—Br length in propargyl bromide is also of interest to obtain an additional assurance to the conclusion obtained in the previous paper.

An anomaly due to accidental degeneracy in rotational energy has been observed in bromine nuclear quadrupole hyperfine structure of some b-type Q-branch transitions[2]. The deviation from the first-order theory amounted to several megacycles. An analysis using the second-order perturbation has enabled us to know the direction of the principal axes and principal values of the quadrupole coupling constant of the bromine atom. It was found that the direction of the largest principal value of the coupling constants coincided with that of the C—Br bond and the asymmetry parameter was very small*.

1) E. Hirota and Y. Morino, This Bulletin, 34, 341 (1961).
2) Preliminary account is given in the paper, Y. Kikuchi, E. Hirota and Y. Morino, *J. Chem. Phys.*, 31, 1139 (1959).
* Recently the microwave spectrum of ethyl iodide was measured by Kasuya and Oka[3]. They found a hyperfine structure of the iodine atom deviating from the first-order theory.
3) T. Kasuya and T. Oka, *J. Phys. Soc., Japan*, 15, 296 (1960).

## Experimental

The spectra of propargyl bromide, $CH_2{}^{79}BrC{\equiv}CH$, $CH_2{}^{81}BrC{\equiv}CH$, $CH_2{}^{79}BrC{\equiv}CD$ and $CH_2{}^{81}BrC{\equiv}CD$, were observed by a Stark modulation spectrometer described in the previous paper. The two isotopic species of bromine have almost equal natural abundance, hence no special preparation was necessary. The deuterated samples were obtained by the method used for the preparation of deuterated propargyl chloride.

## Results

**Rotational Spectra and Rotational Constants.** —Propargyl bromide is also a nearly prolate symmetric top, similar to the chloride. The symmetry plane includes a- and b-axes, hence a- as well as b-type transitions are expected to be observed.

Table I gives the observed center frequencies. Preliminary assignment is based on frequencies expected for the assumed structure and hyperfine patterns. Transitions of a-type R-branch, $J_{1,J} \rightarrow J+1_{1,J+1}$, split into four lines and are easily identified by their characteristic hyperfine structures. The assignment of b-type Q-branch transitions is confirmed by plotting the asymmetry parameter $b_P$ versus the quantity $A-(B+C)/2$.

The rotational constants and the asymmetry

parameters are given in Table II, and the frequencies calculated by using these constants are compared with the observed ones in Table I. A rough correction is made for the centrifugal distortion by assuming the expression $-D_J J^2(J+1)^2 - D_{JK} J(J+1) K_{-1}^2$. The observed values of $D_J$ and $D_{JK}$ are given in Table II.

**Structure Analysis.**—The number of structural parameters is the same as that of the chloride. Again the H···H distance in methylene group is given by

$$r(\mathrm{H\cdots H}) = [(I_a + I_b - I_c)/m_{\mathrm{H}}]^{1/2} \qquad (1)$$

The values for the four isotopic species given in Table III are close to each other, their average being 1.7096 Å. The eight constants are left to calculate other structural parameters. Since the mass ratio of two bromine isotopes $^{79}Br$ and $^{81}Br$ is almost equal to unity and the bromine atom is located so close to the a-axis, the data are not sufficient to calculate seven parameters. The following values are assumed: methylene C—H is equal to 1.090 Å, ∠CCH to 111°30′, C≡C to 1.207 Å, and acetylene C—H to 1.060 Å. The acetylene C—H and C—D bond lengths are assumed to be equal. The linearity of the group C—C≡C—H is again assumed. By means of the method of least-squares the

bond lengths C—Br and C—C and the bond angle CCBr are found to be 1.9415 Å, 1.4549 Å, and 111°59′, respectively.

Thus far, the effect of inertia defect is ignored, but, as mentioned in the previous paper, the results given above for the three parameters do not change appreciably even by taking account of the inertia defect. In addition, since the weight of a bromine atom is more than twice as great as that of a chlorine atom, errors in the parameters C—Br and ∠CCBr may be small. The results are given in Table IV.

TABLE IV. MOLECULAR STRUCTURE

| | | | |
|---|---|---|---|
| C—Br | 1.9415 Å | H···H* | 1.7096 Å |
| C—C | 1.4549 Å | ∠CCBr | 111°59′ |

Assumed values

C—H (methylene) 1.090 Å

C—H, C—D (acethylene) 1.060 Å

| | | | |
|---|---|---|---|
| C≡C | 1.207 Å | ∠CCH | 111°30′ |

* Correction for the inertia defect is not made.

**Second-Order Quadrupole Effect.** — Theory[4] indicates that the quadrupole energy is expressed as follows, averaging over rotational states of an asymmetric molecule

$$E_Q=(IJ\tau F|H_Q|IJ\tau F)+\sum_{J'\tau'}\frac{|(IJ\tau F|H_Q|IJ'\tau'F)|^2}{E_{J\tau}-E_{J'\tau'}} \quad (2)$$

Usually the difference in rotational energies $E_{J\tau}-E_{J'\tau'}$, is much larger than the quadrupole energy hence the second terms may be omitted. For a nearly prolate symmetric top the first-order energy

$$(IJ\tau F|H_Q|IJ\tau F)=\frac{1}{J(J+1)}\{\chi_{aa}[3K_{-1}^2-J(J+1)-3\sum_n(n-1)C_nb_P^n-\sum_n nC_nb_P^{n-1}]-2\chi_{bb}\sum_n nC_nb_P^{n-1}\}\cdot\boldsymbol{f}(IJF) \quad (3)$$

is a good approximation for the quadrupole energy, where $\chi_{ff}=eQ\partial^2V/\partial f^2$, $f=a$, $b$ and $c$ are molecule-fixed axes chosen as the principal axes of inertia, and $\boldsymbol{f}(IJF)$ is Casimir's function. However, if rotational energies $E_{J\tau}$ and $E_{J'\tau'}$ are almost degenerate, the second-order terms can not be ignored. The matrix elements have been derived by Bragg[5]:

$$(IJ\tau F|H_Q|IJ+A\tau'F)=\boldsymbol{g}_\alpha(IJF)(J\tau M_J=J|\chi_{ZZ}|J+A\tau'M_J=J) \quad (4)$$

where $\chi_{ZZ}=eQ\partial^2V/\partial Z^2$ ($Z$ is a space-fixed axis), $\alpha=0$, $\pm1$, $\pm2$, and

$$\boldsymbol{g}_0=[3C(C+1)-4I(I+1)J(J+1)]\div[8I(2I-1)J(2J-1)] \quad (5a)$$

$$\boldsymbol{g}_1=[F(F+1)-I(I+1)-J(J+2)]\times[(I+J+F+2)(I-J+F)\times(J-I+F+1)(J+I-F+1)]^{1/2}\div\{8I(2I-1)J[(2J+1)]^{1/2}\} \quad (5b)$$

$$\boldsymbol{g}_2=[(I+J+F+2)(I+J+F+3)(I-J+F-1)\times(I-J+F)(J-I+F+1)(J-I+F+2)\times(I+J-F+1)(I+J-F+2)]^{1/2}\div\{16I(2I-1)[(2J+1)(J+1)]^{1/2}\} \quad (5c)$$

where $C=F(F+1)-I(I+1)-J(J+1)$. The $(J|J-1)$ and $(J|J-2)$ elements may be determined from equations given above by the Hermitian property of $H_Q$. The tensor component $\chi_{ZZ}$ is expressed in terms of direction cosines $\Phi_{Zf}$ and $\chi_{aa}$, etc., the components of $eQq$ tensor referred to the principal axes a, b and c. The result is

$$\chi_{ZZ}=(\Phi_{Za}^2-\Phi_{Zc}^2)\chi_{aa}+(\Phi_{Zb}^2-\Phi_{Zc}^2)\chi_{bb}+2\Phi_{Za}\Phi_{Zb}\chi_{ab}+2\Phi_{Zb}\Phi_{Zc}\chi_{bc}+2\Phi_{Zc}\Phi_{Za}\chi_{ca} \quad (6)$$

The asymmetric top wave functions as well as direction cosines belong to the representation of the four group[6]. Thus the matrix element of $\chi_{ZZ}$ is zero unless the direct product of the representation of the two rotational states is equal to that of $\Phi_{Zf}$ $\Phi_{Zf'}$. Table V gives the symmetry of the direction cosines and the wave functions.

The rotational wave function for a slightly asymmetric top molecule is approximately given by

$$\Psi_K^{(1)}=S_K+\alpha S_{K-2}+\beta S_{K+2} \quad (7)$$

where $S_K$ is Wang's symmetric top wave function, and the coefficients $\alpha$ and $\beta$ are given by Lide[7]. For propargyl bromide the wave function of this type is sufficient to calculate the second-order quadrupole energy, since the asymmetry parameter of the molecule is small.

Transitions of b-type Q-branches are observed to split into four lines by the quadrupole effect of bromine nucleus. For transitions of high $J$ the first-order theory predicts that the splitting $\nu_4-\nu_3$ is equal to $\nu_2-\nu_1$, but the deviation was observed, in particular, for the transition $12_{0,12}\rightarrow12_{1,11}$ (Table VI).

In applying the second-order theory described above the energies of the states which couple with the states $12_{0,12}$ and $12_{1,11}$ are first calculated. The result is shown in Tables VII

and VIII where the states are chosen by symmetry consideration.

It is to be noted that the state $11_{2,9}$ is nearly degenerate with the state $12_{1,11}$, while the energies of other states differ by more than 10000 Mc./sec. from that of the state $12_{0,12}$ or $12_{1,11}$. Since the symmetry of the state $11_{2,9}$ is $B_a$ and that of the state $12_{1,11}$ $B_b$ while that of $\Phi_{Za}\Phi_{Zb}$ is $B_c$ as is given in Table V, the state $11_{2,9}$ couples with the state $12_{1,11}$ by the quadrupole Hamiltonian of the form $\Phi_{Za}\Phi_{Zb}\chi_{ab}$. This coupling is dominant in the second-order terms, thus the second-order energy is nearly proportional to $\chi_{ab}{}^2$. The other terms $\chi_{bc}$ and

$\chi_{ca}$ are equal to zero by the symmetry of the molecule.

The line separations given in Table VI, $\nu_2-\nu_1$ and $\nu_4-\nu_3$, are expressed as

$$\nu_2-\nu_1=K\chi_{aa}+L\chi_{bb}+M\chi_{ab}^2 + (\text{small terms involving } \chi_{aa}^2,\ \chi_{bb}^2 \text{ and } \chi_{aa}\chi_{bb}) \quad (8a)$$

$$\nu_4-\nu_3=K\chi_{aa}+L\chi_{bb}+N\chi_{ab}^2 + (\text{small terms involving } \chi_{aa}^2,\ \chi_{bb}^2 \text{ and } \chi_{aa}\chi_{bb}) \quad (8b)$$

where $K$, $L$, $M$ and $N$ are constants. In these expressions the first two terms are the first-order energies and the others are the second-order energies. It is to be noted that the first two terms are the same for both equations. In employing Eq. 7 the second-order terms of $\delta$ in the coefficients, $\alpha$ and $\beta$, are neglected. After appropriate correction is made for the last term, $\chi_{ab}$ is obtained by subtracting Eq. 8b from Eq. 8a. By substituting the value of $\chi_{ab}$ into Eq. 8a or 8b, a linear equation of $\chi_{aa}$ and $\chi_{bb}$ is obtained. Another linear relation is given by well-resolved a-type R-branch transitions (Table IX), for which the second-order effect seems to be small. From these relations $\chi_{aa}$ and $\chi_{bb}$ are calculated. The results are compared with the observed ones in Tables IX and XI.

By use of $\chi_{aa}$, $\chi_{bb}$ and $\chi_{ab}$ the principal values of the $\chi$-tensor and the directions of the principal axes (x, y and z) are determined without any assumptions. The $\theta$ designates the angle between the a- and z-axes and the $\theta'$ that between the direction of the C—Br bond and the a-axis. The two angles are found to agree within experimental errors. The asymmetry parameter $\eta$, which is given by $(\chi_{xx}-\chi_{yy})/\chi_{zz}$, is close to zero for the four isotopic species, where the x-axis is taken in the (ab) plane. The average value of $\eta$ is $+0.015\pm0.013$.

## Discussion

The C—Br bond length obtained, 1.9415 $\pm$0.005 Å, is close to the values usually observed in saturated hydrocarbon bromides. Table XII shows comparison of this value with those of methyl and ethyl bromides. It is to be noted that the values for the C—Br length in those three compounds are of the same order of magnitude within experimental errors.

The z-direction of the quadrupole coupling constant coincides with the direction of the C—Br bond within errors involved in the present experiment. It is a good confirmation of the current assumption usually made. The value of $\chi_{zz}$ is compared with those of methyl and ethyl bromides in Table XII. The three values of the coupling constant are also close to each other.

The authors wish to express their sincere thanks to Dr. Makoto Shima, Institute for Physical and Chemical Research, for supplying them with heavy water. The expenses for this research were defrayed from the Scientific Research Encouragement Grant of the Ministry of Education to which the authors' thanks are also due.

# *Nuclear Magnetic Resonance Study of Hydrogen Bond in Salicylaldehyde*

By Ichiro YAMAGUCHI

(Received August 7, 1960)

It is well accepted that a strong intramolecular hydrogen bond is formed between the hydroxyl and aldehyde groups in a salicylaldehyde molecule. This evidence was obtained by various molecular spectroscopic methods[1] and dipole moment measurements,[2] and some characteristic structures for this hydrogen-bonded system were suggested on the basis of these measurements. Nuclear magnetic resonance (NMR) measurement is expected to give further informations concerning the

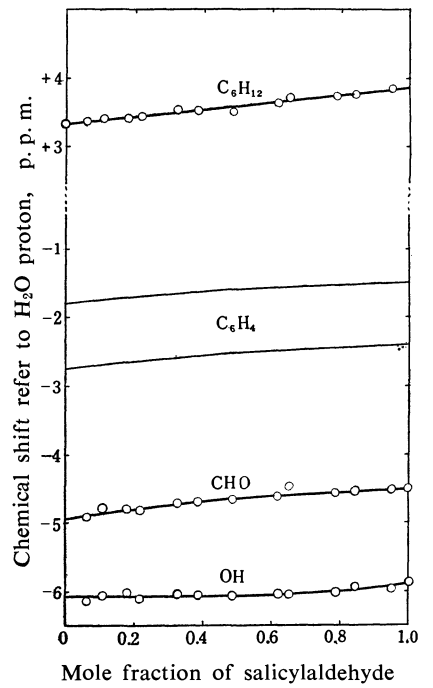
hydrogen bond in this molecule.

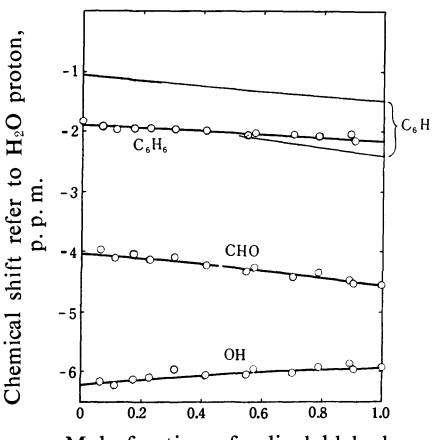
Compounds with intramolecular hydrogen bond so far well investigated by the NMR method are *o*-chlorophenol[3,4], *o*-bromophenol[5], and *o*-cresol[3,5]. The resonance field for the OH proton in these compounds was comparatively dependent on concentration in various solutions. This suggests that the intermolecular hydrogen bond in these compounds is easily disrupted by dilution of solutions. On the other hand, the intramolecular hydrogen bond in compounds such as *o*-nitrophenol or salicylaldehyde is so strong that it would scarcely form a intermolecular hydrogen bond. It is expected therefore that the OH lines of NMR for these compounds would not show remarkable concentration dependence[6].

In the present experiment, the measurement of the OH resonance shift in NMR spectrum of salicylaldehyde was carried out in solutions of several solvents with various concentrations. In addition to this, the concentration dependence of the resonance spectrum of the ring protons was also investigated.



## Experimental

NMR measurements were made at 20°C with a Varian NMR spectrometer operating at 56.4 Mc./sec. Salicylaldehyde was a guaranteed grade reagent and used without further purification. Solvents chosen in this experiment were cyclohexane and carbon tetrachloride (inert solvents), and chloroform, methanol, benzene, acetone, ether and pyridine (proton donors and acceptors). These solvents were purified for eliminating extra lines in their NMR spectra.



The sweep rate was calibrated by taking the value of the chemical shift between the methyl group proton and the benzene ring proton in toluene as 4.90 p. p. m.[7] The value of chemical shift of each line was obtained referring to an external reference of water in a capillary, and the correction for bluk diamagnetic susceptibility was made. Solutions of twelve stages of concentrations between 0.05 and 0.95 mole fractions were prepared for each solvent.

## Results and Discussion

Fig. 1a shows the concentration dependence of the chemical shifts for protons of salicylaldehyde in cyclohexane solution. The lowest curve was assigned to the OH proton by reasoning which will be described later. The next lowest is for the CHO proton. The resonance lines for the ring protons are very complex as shown later. However the corresponding magnetic fields are expressed by two lines for simplicity in the figure, showing decrease with decreasing concentration. The displacement of the lines to a higher field at higher concentration is caused by the interaction among benzene molecules. The decrease of the resonance field for the OH group on dilution seems to correspond to a charge migration from the proton to the ring. Most of the chemical

Fig. 1. Chemical shift diagrams of salicylaldehyde in several solutions;
(a) cyclohexane solution, (b) benzene solution, and (c) methanol solution.

shift diagrams observed for the other solutions have much the same feature as that for cyclohexane solution except for benzene and pyridine solutions.

Fig. 1b. shows the proton resonance in benzene solution. The field for the CHO group increases with decreasing concentration in contrast to the other observed solutions. This may be due to a hydrogen bond formation between the acidic proton in the CHO group and the $\pi$ electron system of a solvent benzene molecule; the proton is located in a region where the effect of the benzene ring is diamagnetic as in the case of chloroform in benzene solution[8].

Fig. 1c. shows the chemical shift diagram for methanol solution. The OH proton resonance line of alcohol disappears in the concentrated region. The some is true for the OH proton of salicylaldehyde but in the dilute region. This implies the exchange of protons between OH group of alcohol and that of phenol. The broadening of these two lines over all the concentration range may also be an additional evidence for this exchange process. From the separation of the above two lines for both groups, the upper limit for the exchange rate was estimated as about 330 c. p. s. It is therefore probable that even a proton contributing to a strong intramolecular hydrogen bond formation is also able to exchange.

Fig. 2 shows the concentration dependence of the chemical shift of proton resonance lines for the OH group in various solutions. Batdorf[5] measured the chemical shift of the OH proton in various phenol derivatives in saturated solutions of acetone. He showed that among the OH lines for various phenol derivatives the OH line for salicylic acid derivatives appeared at the lowest field region (around $-6$ p. p. m. referring to water proton). The OH proton lines for the other phenol derivatives appeared at considerably higher fields than that for salicylaldehyde. In general, the OH line for phenol derivatives forming merely intermolecular hydrogen bond appears in the range of about $-2$ to $-4$ p. p. m. from the water proton line. Comparing these values with those for salicylic acid derivatives with intramolecular hydrogen bond, it may be said that the strength of the intramolecular hydrogen bond in salicylic acid derivatives is ranked to be considerably high.

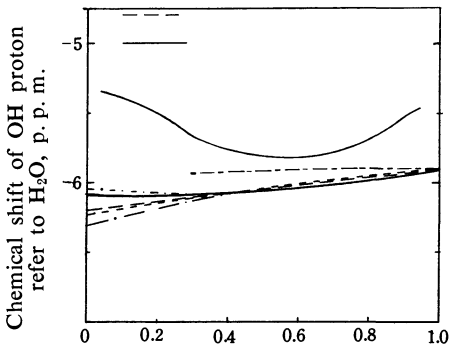

Fig. 2. OH proton resonance shift in salicylaldehyde of various solutions.
Solvent
——— Cyclohexane
—·—· Carbon tetrachloride
-·-·-· Chloroform
— — — Methanol
- - - - Benzene
—— —— Acetone
——— Pyridine

For various solutions observed, the concentration dependence of the OH lines are almost the same except pyridine solution which will be discussed later. This fact is somewhat surprising because it may suggest that the nature of the OH proton in salicylaldehyde is scarcely affected at all by the solvents with high hydrogen bond forming ability. The above fact also suggests that the intramolecular hydrogen

8) L. W. Reeves and W. G. Schneider, *Can. J. Chem.*, 35, 251 (1957).

bond in salicylaldehyde is considerably strong and does not allow a hydrogen bond to form with the other molecular species.

The resonance field of the OH proton is observed to decrease slightly as the concentration of the solution decreases. In general dilution of a phenol with some moderate solvent, intermolecularly hydrogen-bonded polymerized molecules dissociate to dimer molecules showing a decrease of the OH proton resonance field. However dissociation of dimerized ones to monomers shows an increase of the field. Thus, for intermolecularly hydrogen-bonded compounds the variation of the OH proton resonance field generally has a minimum, where the most effectively and strongly hydrogen-bonded species is seemed to form. In contrast to phenol, the field for the OH proton line of salicylaldehyde decreases monotonously with dilution of solution showing no increase even on extreme dilution. This suggests that the bonding becomes stronger as the concentration decreases and the hydrogen bond remains even in the solution of extremely low concentration. Therefore, for salicylaldehyde, the free single molecule with the intramolecular hydrogen bond is considered to be the most effectively hydrogen-bonded species. This result also suggests that in concentrated solutions there exist dimerized or polymerized molecules[9] which dissociate to monomer molecules on dilution. The broadening of the OH lines observed in concentrated range in almost all the solutions may be attributed to a rather slow exchange process of OH protons among several kinds of polymerized species.

An exceptional behavior of OH line was observed for pyridine solution. The curve in Fig. 2 shows apparently anomalous behavior. First, the resonance occurs at higher field than that for the other solutions. This may be ascribed to some change in its electronic configuration caused by interaction with a pyridine molecule. Secondly, the magnetic field decreases with decreasing concentration in concentrated range. This may arise from the same dissociation process as that the other solutions show and simultaneously from the formation of strong hydrogen bond between salicylaldehyde and pyridine. Thus the minimum resonance field appears at the equimolecular composition of the solution. The third is the increase of the curve in dilute range. This may be attributed to the formation of multiply hydrogen-bonded species with pyridine. This experimental result may suggest that the hydrogen bond between salicylaldehyde and pyridine is stronger than the intramolecular hydrogen bond in salicylaldehyde.

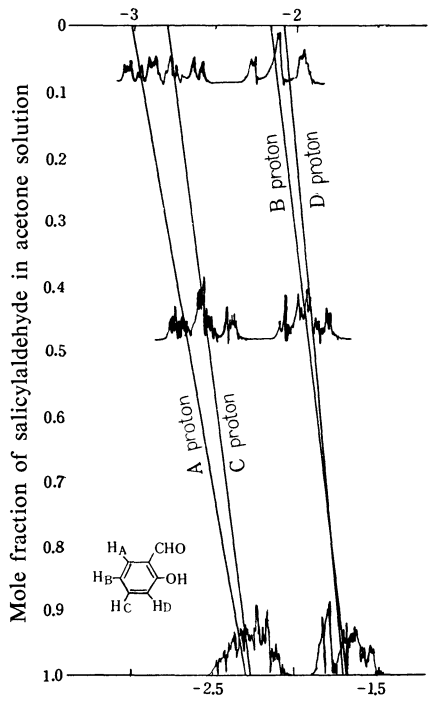

Fig. 3. Concentration dependent behavior of ring proton resonance lines of salicylaldehyde in acetone solution.

A remarkable solvent effect was also observed in the resonance spectra of ring protons, especially in the systems with proton donor or acceptor solvents. Although the spectrum of the ring protons could not be exactly analyzed, it was possible to assign the spectral lines to each proton by tracing the change in the spectral figure of the system on dilution. Fig. 3. shows an example of this solvent effect on the ring protons in acetone solution.

The whole spectrum of the ring protons displaces to lower field on dilution. This displacement is considered to arise from change in the interaction among benzene rings as mentioned previously. In a series of the spectra of solutions with different concentrations, the lines due to A proton (ortho to CHO group) and D proton (ortho to OH group) exhibit opposed dilution displacement to each other. The A proton lines displace to lower field while those of D to higher field on dilution relative to the displacement of the whole ring proton spectrum. Various effects may be attributed to these shift changes of dilution[10]. However, the essential feature to cause the

9) Simova and Skorchev also suggested the existence of dimerized molecules. See Ref. 1d.

10) A. D. Buckingham, T. Schaefer and W. G. Schneider, *J. Chem. Phys.*, 32, 1227 (1960).

spectral change, especially that for A and D protons, would probably be a charge migration in the molecule affected by the change in the hydrogen bonding situation of this molecule.

**Summary**

The concentration dependent behavior of the proton resonance spectra of salicylaldehyde in several solution systems were measured. The behavior of the OH resonance line for the solution systems showed the evidence of the existence of considerably strong intramolecular hydrogen bond in the molecule. The behavior of the ring proton spectrum on dilution suggested the occurrence of the charge migration in the ring affected by the change in the hydrogen bonding situation.

The author wishes to express his sincere thanks to Professor S. Fujiwara and Dr. A. Danno for their kind encouragement and suggestions on this work and also to Dr. H. Shimizu, N. Nakagawa and N. Hayakawa for their valuable discussions.

# *Non-benzenoid Aromatic Heterocycles. IV* [1]. An Attempted Synthesis of Indolo[3, 2-b]indole: A Hetero-pentalene*

By Hiroshi KATO and Masaki OHTA

(Received September 19, 1960)

Since the proposal of pentalene (I) by Robinson[2] as a possible aromatic substance, it has been the subject of many studies. Although dibenzopentalene and a few other condensed pentalene derivatives have recently been synthesized (showing non-aromatic polyene properties), the synthesis of pentalene or even benzopentalene is still awaited, and the results of theoretical treatments on the stability of these compounds by several groups of workers are not in accordance[3].

It has been found that substitution of –C=C– groups in a conjugated compound by hetero-atoms results in a system which shows properties of the original compound to a certain extent. These facts led the authors to attempt a synthesis of indolo[3, 2-b]indole (II) as a model of diazadibenzopentalene in order to add some experimental data concerning the stability of the proposed pentalene ring system[4]. As possible routes to indolo[3, 2-b]indole, intramolecular dehydration of 2-(*o*-aminophenyl)-indolone (III) or dehydrogenation of *N*, *N'*-dihydroindolo[3, 2-b]indole (dindole) (IV) may be considered. These two compounds, III and IV, have been prepared[5] by reduction of *o*, *o'*-dinitrobenzil by Raney nickel or by zinc and hydrochloric acid, respectively.

An attempted intramolecular condensation of 2-(*o*-aminophenyl)indolone has been briefly reported by Ruggli et al.[5], but as nothing has been described about the condensation reagent, the present authors tried to dehydrate it using a variety of condensation catalysts, none of which gave an identifiable product.

Next, the dehydrogenation of dindole was tried. When dindole was refluxed with chloranil in *n*-butanol, an intense violet coloration took place, but the color faded away gradually and tetrachlorohydroquinone was isolated from the reaction mixture. Neither, in this case, was the expected indolo[3, 2-b]indole, obtained, and an amorphous polymeric product was obtained. The elemental composition of this substance is not very far from $C_{14}H_{10}ON_2$. Attempts to isolate this colored substance were not successful, but the absorption curve of this substance in the visible region is quite similar to 2-(*o*-aminophenyl)indolone and the $R_f$ value of this compound is the same as 2-(*o*-aminophenyl)-indolone. From these facts and the supplemental data described in the experimental

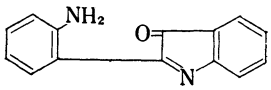
part, it may be concluded that the colored compound is 2-(*o*-aminophenyl)indolone.

These experimental data, although negative, indicate that at least some interaction exists between the two compounds (IV and chloranil) and dehydrogenation has occurred in dindole. On the basis of these data, it seemed reasonable to assume that dehydrogenation of dindole gave indolo[3, 2-b]indole as an intermediate product, but this compound is so unstable that it took up traces of water present in butanol and gave 2-(*o*-aminophenyl)indolone. When rigidly dehydrated *n*-butanol was used as solvent, the beginning of coloration required a longer period and on addition of a small amount of water, the coloration took place at once. This fact also lends some support to the above described assumption.



During the course of this investigation, the authors have known that Treibs[6] also attempted dehydrogenation of dindole using many catalysts, but indolo[3, 2-b]indole was not prepared.

## Experimental

**Attempted Cyclodehydration of 2-(*o*-Aminophenyl) indolone.**—2-(*o*-Aminophenyl)indolone[5] was treated with the following reagents under warming or at room temperature: polyphosphoric acid, concentrated sulfuric acid, acetic acid, triethylamine, and piperazine. Polyphosphoric acid and sulfuric acid gave a yellow amorphous substance, accompanied by the starting material. Acetic acid yielded a yellow polymeric substance, and in the case of triethylamine the starting material was recovered unchanged.

6) W. Treibs, private communication.

**Reaction of Dindole with Chloranil.**—a) A butanolic solution (30 ml.) of dindole[5] (0.5 g.) and chloranil (0.6 g.) was gently refluxed for four hours. At first a deep violet coloration took place, but it faded away gradually, and after four hours the solution became pale brown. The solvent was removed under reduced pressure and the residue was washed with ether and purified by chromatography (alumina-benzene). The yellow powder from the eluate was repeatedly recrystallized first from benzene-benzine and then from benzene giving yellow amorphous powder. It does not show a distinct melting point (about 300°C).

Found: C, 74.02; H, 4.40. Calcd. for $C_{14}H_{10}ON_2$: C, 75.65; H, 4.54%.

The ether washings in the above experiment were extracted with 10% aqueous sodium hydroxide and the aqueous layer was acidified which hydrochloric acid. The white crystals (0.47 g.) which separated out were recrystallized from acetic acid giving white needles, m. p. 234°C (in a sealed tube), undepressed on admixture with tetrachlorohydroquinone.

b) When chloranil or dindole alone was refluxed in *n*-butanol, no coloration took place, and chloranil gave no tetrachlorohydroquinone.

c) Dindole and chloranil was heated cautiously until the coloration took place, and the colored solution in situ was used for spectroscopic measurement. ($\lambda_{max}$ 550 m$\mu$; with a small shoulder at about 490 m$\mu$; intensity unspecified). The shape of the curve in the visible region is the same with 2-(*o*-aminophenyl)indolone. Attempts to isolate this colored substance (by chromatography) were unsuccessful. The colored substance and 2-(*o*-aminophenyl)indolone gave the same spot in paper chromatography ($R_f$=0.95, solvent: butanol-pyridine-water, 4 : 1 : 2). This colored substance seemed a little more unstable than 2-(*o*-aminophenyl)indolone, but when 2-(*o*-aminophenyl)indolone was heated with chloranil in *n*-butanol, it decomposed rapidly to give a yellow solution.

d) When rigidly dehydrated *n*-butanol (freshly twice distilled) was used as solvent, the beginning of coloration was delayed and the intensity of the color was feeble and on addition of a small amount of water, the color was intensified immediately.

The authors are indebted to Mr. Asaji Kondo for microanalyses.

# *Normal Coordinate Treatment and Assignment of Infrared Absorption Bands of Polyvinyl Chloride*

By Takehiko SHIMANOUCHI and Mitsuo TASUMI

(Received September 16, 1960)

In the analysis of infrared absorption spectra it is often of considerable importance to calculate the frequencies of the normal vibrations.

Recent developments in high-speed computers have made it possible to calculate the normal vibrations of complex molecules. We have calculated the frequencies of the polyvinyl chloride molecule using the force constants transferred from simple molecules. These results suggest a modification of the assignment proposed in former studies[1,2] and will be reported in the present paper.

## Method of Calculation and Results

The normal coordinate treatment was carried out on assuming that the polyvinyl chloride molecule is syndyotactic and takes the extended zigzag form with the repeating unit made up of two monomer units. The unit cell for this structure is shown in Fig. 1. This model belongs to a group isomorphous with to the point group $C_{2v}$[1], and in Table I symmetry species, selection rules, and dichroic properties are given.

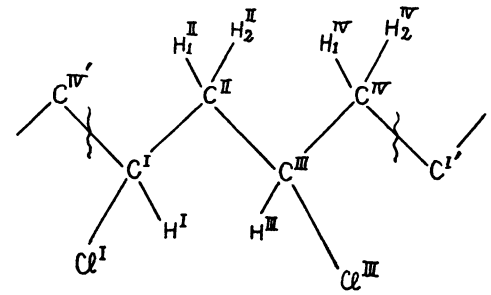

Fig. 1. Unit cell for syndyotactic structure of polyvinyl chloride.

$$S_2 = \frac{1}{2}(\Delta r_1^{II} - \Delta r_2^{II} - \Delta r_1^{IV} + \Delta r_2^{IV})$$

$$S_3 = \frac{1}{\sqrt{8}}(\Delta \varphi_1^{II} + \Delta \varphi_2^{II} - \Delta \varphi_3^{II} - \Delta \varphi_4^{II} + \Delta \varphi_1^{IV} + \Delta \varphi_2^{IV} - \Delta \varphi_3^{IV} - \Delta \varphi_4^{IV})$$

$$S_4 = \frac{1}{\sqrt{8}}(\Delta \varphi_1^{II} - \Delta \varphi_2^{II} + \Delta \varphi_3^{II} - \Delta \varphi_4^{II} - \Delta \varphi_1^{IV} + \Delta \varphi_2^{IV} - \Delta \varphi_3^{IV} + \Delta \varphi_4^{IV})$$

$$S_5 = \frac{1}{2}(\Delta \varphi_2^{I} - \Delta \varphi_4^{I} + \Delta \varphi_1^{III} - \Delta \varphi_3^{III})$$

$$S_6 = \frac{1}{2}(\Delta \varphi_1^{I} - \Delta \varphi_3^{I} + \Delta \varphi_2^{III} - \Delta \varphi_4^{III})$$

As only the vibrations in which corresponding atoms in all the unit cells move in phase are optically active for such high polymers, the calculation was done for these modes of vibration according to the method applied to polyethylene[3]. The internal coordinates and the internal symmetry coordinates used are given in Tables II and III. For the internal coordinates only the bond lengths and angles are taken and the angles of internal rotation about the C-C bond are excluded. Therefore, in this calculation the torsional vibrations of the zigzag chain are not considered, but this has comparatively little effect on the other calculated frequencies.

The potential field used is the Urey-Bradley type[4].

$$2V = K(\text{C-C})\sum_{R}(\Delta R)^2 + K(\text{C-H})_{\text{CHH}}\sum_{ra}(\Delta r_a)^2 + K(\text{C-H})_{\text{CHCl}}\sum_{rb}(\Delta r_b)^2$$

For the first calculation we used the force constants transferred from polyethylene[3], 1,2-dichloroethane[5], and 1,1,2,2-tetrachloroethane[6]. These force constants are indicated as Set 1 in Table IV. The molecular constants assumed are also given in Table IV. From these values the characteristic values, L-matrix, potential energy distribution, and Jacobian $\partial(\nu_1\cdots\nu_k)/\partial(K_1\cdots K_n)$ were calculated with the use of the PC-1 computer built in the Department of Physics, The University of Tokyo. In the next calculation, taking into account the results of the first calculation and the observed values, we introduced the new force constants, Sets 2 and 3 given in Table IV, and repeated the calculation in the same way. In the case of Set 2 the force constants are adjusted so that the calculated frequencies show the best agreement with the observed values of polyvinyl chloride. Set 3 was obtained by modifying the former sets in such a way as to make the calculated frequencies correspond reasonably to the observations for deuterated polyvinyl chloride also.

The calculated frequencies are compared with the observed in Tables V and VI, in which the assignments of bands based on the calculated potential energy distribution are also given.

* As to the dichroism of the 603 $cm^{-1}$ band we shall report later.

should have parallel dichroism when the molecular chains are oriented along the stretching direction. As shown in Table V the observed parallel bands correspond reasonably to the calculated $B_2$ frequencies. The perpendicular bands, also, show good correspondence with the calculated $A_1$ and $B_1$ frequencies. The main points of the present assignment are summarized as follows:

1) Both of the two CH stretching frequencies which belong to the $A_1$ and $B_1$ species are assigned to the band at 2967 $cm^{-1}$. The former assignment[1] of the CH stretching mode ($A_1$) to the 2820 $cm^{-1}$ band is improper because of the weak interaction between the two CH bonds. This is also the case for 1, 1, 2, 2-tetrachloroethane, in which the two CH bonds are situated nearer than in polyvinyl chloride. The CH stretching frequency of this compound appears only at 2990 $cm^{-1}$ in infrared spectra and at 2989 $cm^{-1}$ in Raman spectra[6].

2) Krimm and Liang[1] assigned the $A_1$ and $B_1$ CH bending modes to the bands at 1330 $cm^{-1}$ and 1250 $cm^{-1}$, respectively, However, because of the weak interaction between the two CH bonds such great splitting can not be expected. This expectation is confirmed clearly by our calculation. The calculated Jacobian shows that both of these frequencies depend similarly on the force constants $H$(H-C-Cl), $H(\text{H-C-C})_{\text{CHCl}}$, $F(\text{H}\cdots\text{Cl})$, $F(\text{H}\cdots\text{C})_{\text{CHCl}}$, and $\kappa_{\text{CHCl}}$, and it is impossible to separate them. The corresponding frequencies are found in 1, 1, 2, 2-tetrachloroethane at 1304 $cm^{-1}$ ($A_u$)

c See Ref. 2.

and 1308 $cm^{-1}$ ($B_g$) for the trans from, and at 1280 $cm^{-1}$ (A) and 1243 $cm^{-1}$ (B) for the gauche form. Even in the gauche form the splitting does not exceed 40 $cm^{-1}$. So, at first it seemed reasonable to assign the 1250 $cm^{-1}$ band to both $A_1$ and $B_1$ CH bending modes and the 1330 $cm^{-1}$ band to the $CH_2$ wagging mode ($B_1$). On the other hand the change of the dichroism observed for PVC films of varying degrees of stretching (which will be reported later) shows that the 1330 and 1250 $cm^{-1}$ bands should belong to $A_1$ and $B_1$ species, respectively. This fact can be understood if we assume that strong coupling takes place between one of the CH bending modes and the $CH_2$ wagging or twisting mode, and the large splitting of frequencies occurs, though it is inconsistent with the results of our calculation. This deviation may be due to the incompleteness of the force constants given in Table IV. Ambiguity is still remaining as to this point; our final assignments are shown in Table V.

3) The bands at 1228, 963 and 833 $cm^{-1}$ are assigned to CH bending ($B_2$), $CH_2$ rocking ($B_1$), and $CH_2$ rocking ($B_2$) frequencies, respectively, according to the results of the calculation. The 1228 $cm^{-1}$ band was assigned by Krimm et al.[7] to the overtone of the 615 $cm^{-1}$ band. However, this band remains definitely in the spectrum of the highly syndyotactic polymer for which the 615 $cm^{-1}$ band is observed as a shoulder of the 603 $cm^{-1}$ band. Kawasaki et al.[8] suggested that the very weak band found at 1243 $cm^{-1}$ may be assignable to the overtone of the 615 $cm^{-1}$ band.

4) The bands at 2820, 1197, 693 and 615 $cm^{-1}$ are not assigned. The 693 $cm^{-1}$ band is associated with the atactic structure and the 615 $cm^{-1}$ band with the syndyotactic structure, which is not in the ordered configuration,

7) S. Krimm, A. R. Berens, V. L. Folt and J. J. Shipman, *Chem. & Ind.*, **1958**, 1512.

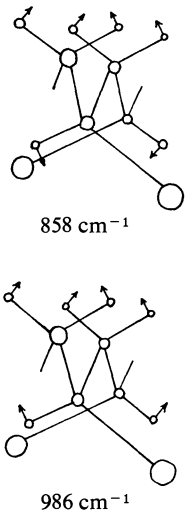
because they can not be observed for the sample prepared by radiation-induced polymerization of a urea-vinyl chloride complex[7,9-11]. The band at 1197 $cm^{-1}$ seems to behave analogously, but in a less distinct manner.

5) The band at 926 $cm^{-1}$ is only tentatively assigned to the $CH_2$ twisting frequency. It is known that for some vibrational modes, such as $CH_3$ rocking vibrations in ethane and $CH_2$ twisting vibrations in 1,2-dichloroethane, the calculated frequencies deviate considerably from the observed[4,12-14]. Therefore, it may be undesirable to assign the 926 $cm^{-1}$ band to the $CH_2$ twisting mode simply because it corresponds to the calculated value of 977 $cm^{-1}$. More detailed investigation of the intramolecular potential field seems to be necessary to settle this problem.

**Deuterated Polyvinyl Chloride.**—1) The infrared spectrum of deuterated PVC was reported by Enomoto et al.[2] Compared with the spectrum of normal PVC, it is quite complicated and hard to analyze, as many bands are found in the 800 $cm^{-1}$ to 1300 $cm^{-1}$ region. From the results of the present calculation and the observed dichroism tentative assignments are proposed for the main bands. The calculated potential energy distribution and L-matrix indicate that a strong coupling of two or more modes occurs for most bands of deuterated PVC. For example, for the calculated 858 $cm^{-1}$ ($A_1$) vibration, in-phase coupling of the $CD_2$ and CD bending modes occurs while in the case of the calculated 986 $cm^{-1}$ ($A_1$) vibration, out-of-phase coupling occurs. This is shown in Fig. 2. The in-phase mode is expected to be weak in intensity, and it probably corresponds to the very weak band at 886 $cm^{-1}$. The intensity of the out-of-phase mode is strong and it undoubtedly corresponds to the very strong band at 1017 $cm^{-1}$. A similar situation is found for the calculated 807 $cm^{-1}$ ($B_2$) and 930 $cm^{-1}$ ($B_2$) vibrations (see Fig. 3). The 930 $cm^{-1}$ mode is expected to be strong and corresponds to the strong parallel band at 937 $cm^{-1}$, and the 807 $cm^{-1}$ mode is weak and corresponds to the weak band at 806 $cm^{-1}$.

2) The bands at 594 $cm^{-1}$ and 568 $cm^{-1}$ are assigned to the CCl stretching frequencies ($A_1$ and $B_1$). These bands correspond to those at



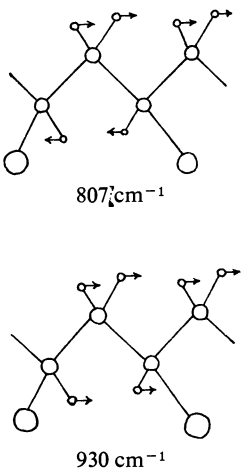


Fig. 2. Vibrational modes of 858 $cm^{-1}$ and 986 $cm^{-1}$.

Eig. 3. Vibrational modes of 807 $cm^{-1}$ and 930 $cm^{-1}$.

635 $cm^{-1}$ and 603 $cm^{-1}$, respectively, of normal PVC. Asahina and Enomoto[15] showed that the 628 $cm^{-1}$ band disappears in the sample obtained by irradiation-induced polymerization of a urea-vinyl chloride-$d_3$ complex. Therefore, this band is the contribution of the atactic structure and corresponds to the 690 $cm^{-1}$ band of normal PVC. The deuterated PVC prepared by Enomoto et al. was kindly made available to us. We measured the spectrum of this sample using a grating spectrometer (Perkin-Elmer Model 112G) and found a new band at about 573 $cm^{-1}$, which probably corresponds to the 615 $cm^{-1}$ band of normal PVC. All four bands of deuterated PVC are perpendicular.

As stated above the observed infrared absorption bands, including their dichroism, can

be satisfactorily accounted for on the basis of the calculation of normal vibrations. This gives a further confirmation of the syndyotactic configuration for the crystalline part of polyvinyl chloride. The remaining important problem is to study the potential field more thoroughly, and for this purpose the comparative investigation of other polymers and related compounds will be indispensable.

We wish to thank Professor H. Takahashi for making available the PC-1 computer. Thanks are also due to Dr. K. Nambu and Mr. S. Enomoto, who kindly gave us various samples of polyvinyl chloride.

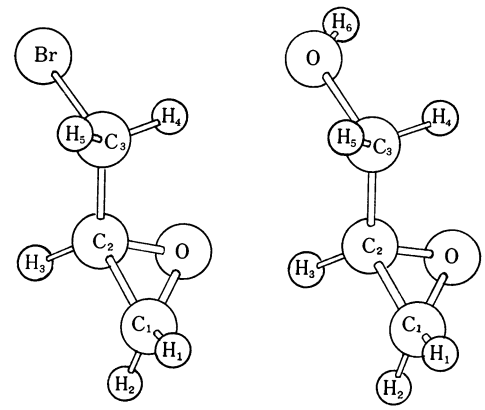
# *Molecular Structure of Epibromohydrin and Glycidol by Electron Diffraction*

By Masato IGARASHI

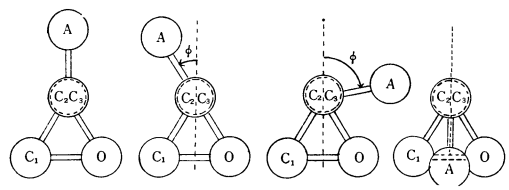
(Received September 26, 1960)



The molecular structure of ethylene oxide[1], propylene oxide and epichlorohydrin[2] has been studied previously by the electron diffraction method. As for the size of the CCO ring, the electron diffraction results have agreed almost perfectly with that of microwave spectrum study of ethylene oxide[3]. The C–C distance was 1.46±0.03 Å and the C–O distance were about 1.44 Å, whereas the values by microwave spectroscopy were 1.472 Å and 1.436 Å, respectively.

In propylene oxide and epichlorohydrin, the C–C (methyl) distance was about 1.52 Å and the angle between C–C (methyl) and CCO ring plane was about 58°. The chlorine atom in epichlorohydrin was the farthest apart from the CCO ring.

In the present paper the structures of epibromohydrin and glycidol are reported especially in regard to the configuration of the bromine atom and of the oxygen atom of alcohol in each molecule.



## Experimental

Epibromohydrin was prepared according to the procedure described in "Organic synthesis"[4]. The boiling point was 61°C at 50 mmHg. Glycidol was prepared from glycerol monochlorohydrin by the procedure of Nef[5]. The boiling point was 52°C at 10 mmHg. The apparatus of electron diffraction and the procedures of experiment were the same as those of the previous reports[1,2]. Visual intensity curves are shown in Figs. 3 and 5.

as before[2]. Making reference to the previous reports[1-3], some parameters of the molecular models for the theoretical intensity curves were assumed as follows: the CCO ring size and C-H distances adjacent, attached to the ring, are equal to those of ethylene oxide, the other C-H distances 1.09 Å, the angles $C_2C_3Br$ and $C_2C_3O$ are both 109.5°, and the angle between $C_1C_2$ and $C_3C_2H_3$ plane is 21° (Fig. 1). Other parameters such as $C_2$-$C_3$ distance and its inclination from the ring plane, $C_3$-Br and $C_3$-O distances, and the angles of internal rotation (Fig. 2) were examined.

**Epibromohydrin.**—The visual intensity curve in the region of $q=60\sim80$ was uncertain, therefore in the correlation method the maxima and minima in the region of $q=10\sim60$ were compared with the theoretical intensity curves, and radical distribution curves were calculated, using several different intensity values in the former region. On account of the damping factor $\exp(-aq^2)$ the positions of the peaks in radial distribution curves were not so much affected by the intensity in such a region. The radial distribution curve is nearly consistent with models A and K (Table I).

Molecular models for the theoretical intensity curves were constructed in the following ranges: $C_2$-$C_3$: 1.50~1.58 Å, $C_3$-Br: 1.88~1.96 Å, angle between $C_2$-$C_3$ and CCO ring: 45~70°, rotational angle $\phi$ around $C_2$-$C_3$ axis: 0~360° (Table I).

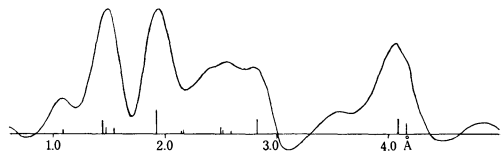

Fig. 4. Radial distribution curve of epibromohydrin. Vertical lines show the interatomic distances of model A.

The theoretical intensity curves of the models in which the rotational angles drawn in Fig. 2 are smaller than ±15° have features which resemble the observed. But as those having the other rotational angles are very far from the observed, these models can be rejected. $C_2$-$C_3$ and $C_3$-Br bond distances and the inclination of $C_2$-$C_3$ were examined mainly by the $q_{calcd}/q_{obs}$ values (Table I).

The results are as follows: $C_2$-$C_3=1.53\pm0.03$ Å, $C_3$-$Br=1.91\pm0.02$ Å, angle between $C_2$-$C_3$ and CCO ring is 58±8°, rotational angle $\phi$ is 0±15°, i. e. the bromine atom is almost trans against the midpoint of $C_1$-O.

**Glycidol.** — Theoretical intensity curves of the models in which the rotational angles are about 0° and 80° have features which resemble the observed, although the maximum of the model of 80° at about $q=33$ is not predominant compared with that of 0° (Fig. 5). The models of the other $\phi$ values such as G, H, L and M may be excluded because the apperances of the intensity curves at about $q=30$ and 50 are very different in comparison with the observed.

The radial distribution curve $RD_1$ calculated using the visual intensity curve which is shown by the solid line in Fig. 5 and spliced by the

theoretical intensity of model E at small $q$ values has a slight peak at about 3.0 Å, which might be regarded as a ghost and a somewhat larger peak at about 3.6 Å, which should correspond to the configuration $\phi=0°$.

But another radial distribution curve $RD_2$ calculated using the dashed intensity curve in the region of about $q=35$ instead of solid intensity curve and the theoretical intensity curve of model J at small $q$ values in Fig. 5, shows a more predominant peak at about 3.0 Å which corresponds to the existence of the configuration of about $\phi=80°$ (Fig. 6).

Whether the configuration of the oxygen atom of alcohol is at about $\phi=0°$, or about $\phi=80°$, or at the both positions, could not be determined by the present visual method.

The parameters other than the internal rotation were examined in the following ranges: $C_2$–$C_3$: 1.50∼1.58 Å, $C_3$–O: 1.40∼1.46 Å, angle

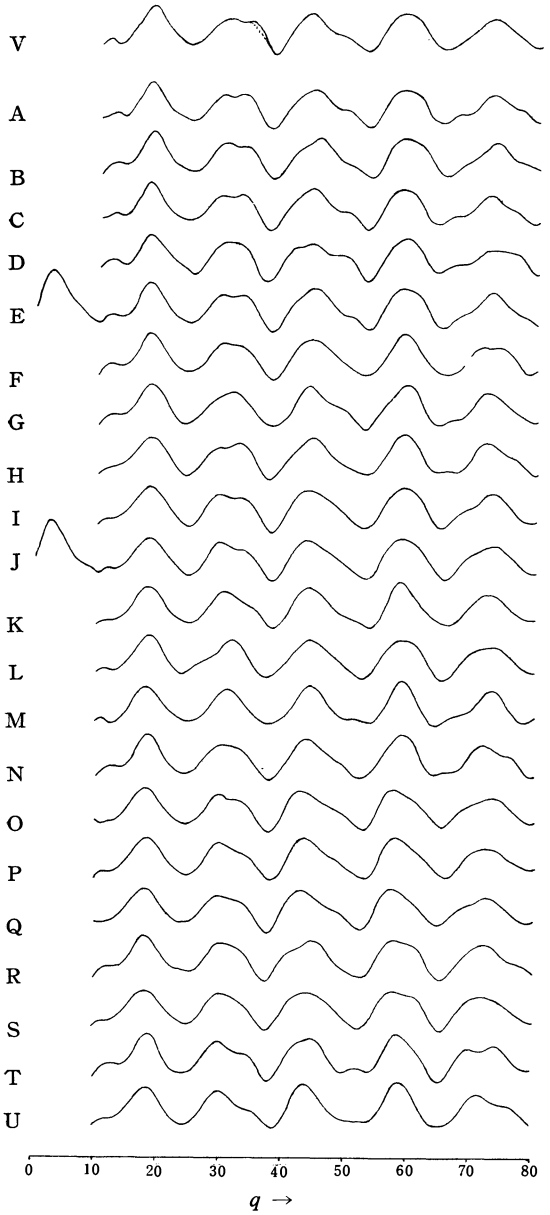

Fig. 5. Visual intensity curve (V) and theoretical intensity curves for the models from A to U (Table II) of glycidol.

between $C_2$–$C_3$ and CCO ring: 50~65° (Table II).

As the features of the theoretical intensity curves of the models in which $C_2$–$C_3$ inclinations against CCO ring plane are 50° and 65° are considerably different from the visual, both models can be excluded as inadequate. $C_2$–$C_3$ and $C_3$–O bond distances were examined mainly by the $q_{calcd}/q_{obs}$ values (Table II). The results are as follows: $C_2$–$C_3$ = 1.53±0.03 Å, $C_3$–O = 1.43±0.03 Å, angle between $C_2$–$C_3$ and CCO ring is 58±5°.

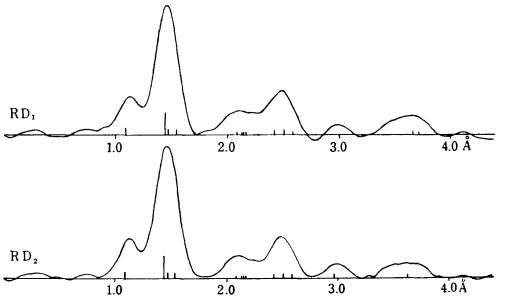

Fig. 6. Radial distribution curves of glycidol. Vertical lines show the interatomic distance of models A ($RD_1$) and O ($RD_2$).

## Discussion

As mentioned in the previous report[2] about epichlorohydrin and the present report about epibromohydrin, chlorine and bromine atoms in these compounds are almost at the trans position against the midpoint of $C_1$–O, i. e. these atoms are fathest apart from the CCO ring.

Therefore it can be thought that there is a strong steric repulsion between chlorine atom or bromine atom and ethylene oxide ring.

If the same steric repulsion is present between oxygen atom of alcohol and ethylene oxide ring and moreover no intramolecular hydrogen bond between two oxygen atoms, the oxygen atom of alcohol will be at trans too. Contrarily, if there is a stronger intramolecular hydrogen bond than the steric repulsion, the oxygen atom of alcohol will be nearer to the oxygen atom in the ring than the trans position and $\phi$ will be equal to about 80°.

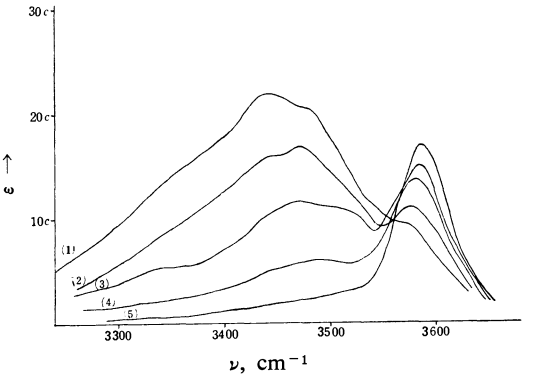

Fig. 7. Infrared absorption spectra of glycidol in carbon tetrachloride solutions. $\varepsilon$ is molecular extinction coefficient, $c$ is the concentration of satulated solution at room temperature and $\nu$ is wave number. Curves from (1) to (5) are absorption spectra of solutions of the following concentratrations; (1): $c$, (2): $1/2\,c$, (3): $1/5\,c$, (4): $1/18\,c$, (5): $1/54\,c$.

Unfortunately as the theoretical intensity curves of both the models rather resemble each other in the features which are characteristic of internal rotations, the above two cases could not be determined unambiguously.

However infrared absorption spectrums of glycidol in dilute carbon tetrachloride solutions using lithium fluoride prism did not show a deviation of O-H stretching vibration by which the intramolecular hydrogen bond can be recognized (Fig. 7). It may be supposed that in the vapor state at room temperature there exists no intramolecular hydrogen bond either, so the oxygen atom of alcohol will be almost at trans against the midpoint of $C_1$-O.

The author wishes to express his sincere gratitude to Professor A. Kotera for his guidance throughout this research and to Dr. K. Nukada and Miss. U. Maeda, Government Chemical Industrial Research Institute of Tokyo, for the infrared investigation of glycidol solution. He is also indebted to Mr. T. Wada for his help during the experiment.

# *An Electron Diffraction Investigation of the Molecular Structure of Ethylenimine*

By Masato IGARASHI

(Received September 26, 1960)

In the three membered ring compounds such as cyclopropane, ethylene oxide, ethylene sulfide and ethylenimine, the isoelectronic groups $H_2C<$, $O<$, $S<$ and $HN<$ bear a resemblance to each other, so that the structural features for these molecules are identical except for these groups.

Since two sp hybrid atomic orbitals may not be at an angle less than 90° to each other, the bonding orbitals which constitute rings CCC, CCO, CCS and CCN can not point directly at each other, but they are bent, forming the "banana bond"[1].

Electron diffraction and microwave spectrum investigations have reported the molecular structures of these ring compounds in which the nuclear distances of C–C were in most cases shorter than the normal C–C single bond distance, 1.54 Å.

By the electron diffraction method, the C–C distances were 1.53±0.03 Å[2], 1.54 Å[3] and 1.515 ±0.02 Å[4] in cyclopropane, and 1.46±0.03 Å[5] in ethylene oxide. Further, by the microwave spectroscopy the C–C distance was 1.472 Å[6] in ethylene oxide, 1.492 Å[6] in ethylene sulfide and 1.480 Å[7] in ethylenimine respectively. The HCH angles have been found to be about 116°[4] and 117°[6,7], which are larger than the tetrahedral angle, 109.5°.

In this report the results of the electron diffraction study of ethylenimine by the sector-microphotometer method are described and compared with those of the microwave spectrum study[7] (Table I).

TABLE I. MOLECULAR STRUCTURE OF ETHYLENIMINE BY MICROWAVE SPECTROSCOPY[7]

| | | |
|---|---|---|
| C–C | 1.480 Å | $\angle C_2NH$ 112° |
| C–N | 1.488 Å | $\angle CCH_2$ 159°25′ |
| C–H | 1.083 Å | $\angle HCH$ 116°41′ |
| H–H | 1.000 Å (assumed) | |

## Experimental

Ethylenimine was kindly furnished by Professor Y. Iwakura, Tokyo Institute of Technology; its boiling point was 55°C.

The electron diffraction instrument in the Department of Chemistry, Faculty of Science, the University of Tokyo[8] was used for the diffraction experiment. It incorporates with $r^2$-sector which

is rotated rapidly during exposure. Diffraction photographs were obtained on Fuji Process Hard plates. During the diffraction experiment the liquid sample reservoir has been cooled by a freezing mixture of ice and sodium chloride to reduce the amount of the sample vapor. The camera length was 11.82 cm. and the wave length of electron was 0.0578 Å, which was determined by measuring the transmission patterns of a gold foil.

Two pairs of photographs of the exposures of 25 and 50 sec., and of 30 and 60 sec. were used for intensity measurement. The optical densities of these plates were measured by the microphotometer. The photographic plates were rotated rapidly around the center of the diffraction pattern while being scanned by the microphotometer.

## Analysis

Optical densities of each pair of the diffraction photographs were converted to relative intensity by Karle's procedure[9]. A smooth background line was drawn through the intensity curve multiplied by $q$ and molecular intensity curve $M(q)$ was obtained by the following formula

$$M(q)=(I_T-I_B)/I_B, \qquad (1)$$

where $I_T$ is the total intensity and $I_B$ is the background intensity.

**Radial Distribution Curve.** — The radial distribution carve was calculated from the molecular intensity curve $M(q)$ according to the following equation:

$$f(r)=\sum_{q=1}^{90} qM(q)\exp(-aq^2)\sin(\pi qr/10) \qquad (2)$$

where the value of $a$ is chosen as 0.000284 to make the integrand of Eq. 2 converge rapidly and $q=(40/\lambda)\sin(\theta/2)$, where $\theta$ is the angle of scattering and $\lambda$ is the wavelength of the electron beam. The intensity curve from $q=0$ to $q=18$ was spliced by the theoretical intensity curve calculated for an assumed model.

A few steps of successive approximation were made to get a reasonable background line which would satisfy Karle's criterion of non-negativeness in the radial distribution curve as closely as possible. The final molecular intensity curve is shown in Fig. 1 and the radial distribution curve in Fig. 2.

The radial distribution curve consists of three peaks at about 1.09 Å, 1.49 Å and 2.19 Å. The first peak is due to bonded C-H and N-H distances, the second to bonded C-C and C-N distances and the third to non-bonded N···cH, C···cH and C···nH distances. It is difficult to separate the first and the second peaks into two components and the third into three components respectively, because these component peaks overlap each other heavily. The first peak can be resolved into its components by three distinct sets of parameters (Fig. 3 and Table II). Sets A and C are the extreme cases for the differences between C-H and N-H

TABLE II. ANALYSIS OF THE FIRST PEAK OF RADIAL DISTRIBUTION CURVE

| Set | Atomic pair | Equilibrium distance, Å | Mean amplitude, Å |
|---|---|---|---|
| A | C-H | 1.05 | 0.065 |
| | N-H | 1.14 | 0.03 |
| B | C-H | 1.09 | 0.075 |
| | N-H | 1.04 | 0.07 |
| C | C-H | 1.11 | 0.06 |
| | N-H | 1.01 | 0.04 |

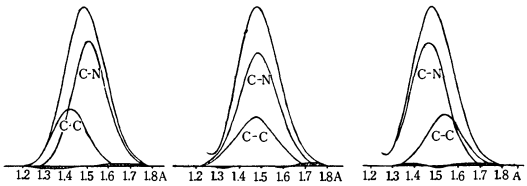

Fig. 4. Analysis of the second peak of the radial distribution curve.

TABLE III. ANALYSIS OF THE SECOND PEAK OF RADIAL DISTRIBUTION CURVE

| Set | Atomic pair | Equilibrium distance, Å | Mean amplitude, Å |
|---|---|---|---|
| D | C-N | 1.51 | 0.02 |
| | C-C | 1.42 | 0.02 |
| E | C-N | 1.49 | 0.05 |
| | C-C | 1.48 | 0.05 |
| F | C-N | 1.47 | 0.03 |
| | C-C | 1.54 | 0·03 |

equilibrium distances. So the reasonable ranges of equilibrium distances are C-H=1.05～1.11 Å and N-H=1.01～1.14 Å.

The second peak can also be resolved into two component peaks by three distinct sets of parameters (Fig. 4 and Table III).

Sets D and F are the extreme cases for the differences between C-N and C-C equilibrium distances. There is an intimate relation between the difference of atomic distances and their mean amplitudes, that is when the difference becomes larger, the assumed mean amplitudes must be smaller in order to explain the peak of radial distribution curve well. This relation shall be discussed once more later at the correlation method. Here the reasonable equilibrium distances are thought to be C-N=1.47～1.51 Å and C-C=1.42～1.54 Å.

The third peak is the lowest among the three and consists of three component peaks of non-bonded C···cH, N···cH and C···NH. Therefore there may be many reasonable sets of resolution into its components. Some probable examples are listed in Fig. 5 and Table IV. In set G the atomic distances are equivalent to $\angle CCH_2=160°$, $\angle HCH=117°$ and $\angle C_2NH=122°$, assuming C-C=1.48 Å, C-N=1.49 Å, C-H=1.08 Å and N-H=1.04 Å. In set H they are equivalent to $\angle CCH_2=130°$, $\angle HCH=117°$ and $\angle C_2NH=126°$ and in set I to $\angle CCH_2=170°$,

Fig. 5. Analysis of the third peak of the radial distribution curve.

TABLE IV. ANALYSIS OF THE THIRD PEAK OF RADIAL DISTRIBUTION CURVE

| Set | Atomic pair | Equilibrium distance, Å | Mean amplitude, Å |
|---|---|---|---|
| G | C···cH | 2.22 | 0.12 |
| | C···NH | 2.16 | 0.12 |
| | N···cH | 2.17 | 0.12 |
| H | C···cH | 2.11 | 0.11 |
| | C···NH | 2.21 | 0.11 |
| | N···cH | 2.25 | 0.11 |
| I | C···cH | 2.24 | 0.11 |
| | C···NH | 2.20 | 0.11 |
| | N···cH | 2.16 | 0.11 |

$\angle HCH=117°$ and $\angle C_2NH=125°$. Other sets of resolution show different atomic distances, so different bond angles. But by several attempts of resolution, the values $\angle HCH\approx117°$ and $\angle C_2NH=120\sim130°$ seem to be probable. When N···cH distances become longer, C···cH distances become shorter and vice versa, assuming the bonded distances are constant, and at that time a reasonable resolution of the peak is obtained, so $\angle CCH_2$ can not be determined more accurately than the range 130～170°.

**Correlation Method.**—The theoretical intensity curves were calculated using the following equation:

$$qM(q)=\sum_{i,j}Z_iZ_j/r_{ij}\exp(-b_{ij}q^2)\sin(\pi qr_{ij}/10) \qquad (3)$$

where $r_{ij}$ is the equilibrium distance between atoms $i$ and $j$ and $Z_i$ is the atomic number of atom $i$, apart from the value 1.25 for the hydrogen atom. The constant $b_{ij}$ is equal to $(\langle\Delta r_{ij}^2\rangle/2)(\pi/10)^2$, where $\langle\Delta r_{ij}^2\rangle$ is the mean square amplitude of the atomic pair $i$ and $j$.

Making reference to the results of radial distribution curve, various molecular models were selected for the theoretical intensity curves. At first in order to determine the acceptable C-C and C-N nuclear distances, theoretical intensity curves were drawn for the models in which both distances were varied in and out of the range found by the analysis of the second peak of radial distribution curve, assuming C-H=1.08 Å, N-H=1.04 Å, $\angle CCH_2=160°$ and $\angle C_2NH=120°$. In Table V the constants of the models which were examined and mean values and average deviations of $q_{calcd}/q_{obs}$ were listed. In Fig. 1 some of the intensity curves were drawn. The features of the theoretical intensity curves of these models resembled each other, so the $q_{calcd}/q_{obs}$ ratios were used to select reasonable models.

If the mean amplitudes of both C-C and C-N are assumed to be 0.05 Å, which is nearly equal to those of the normal single bonds in most cases, the most reasonable model is such

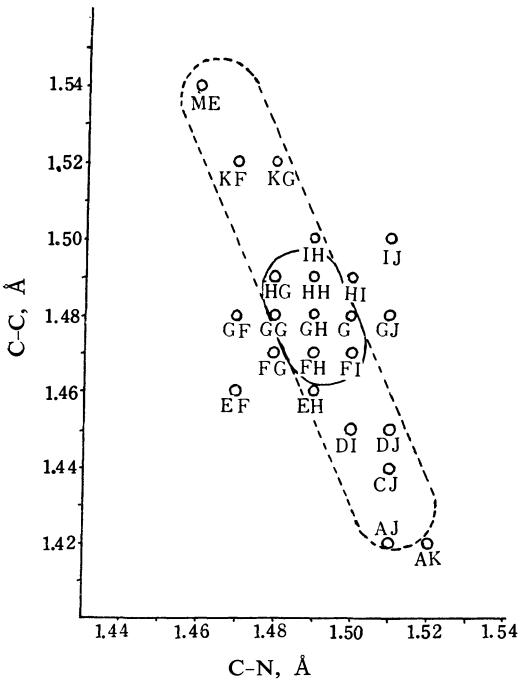

Fig. 6. The parameter chart. The area surrounded by a solid line is an acceptable region when the mean amplitudes are assumed to be 0.05Å, and the area surrounded by a broken line includes an acceptable region when the smaller mean amplitudes than 0.05Å are assumed.

that the C-C equilibrium distance is 1.48 Å and the C-N equilibrium distances are 1.49 Å. When C-N distances become longer than 1.49 Å, the acceptable model is such that the C-C distance becomes shorter than 1.48 Å and at that time the mean amplitudes of the atomic pairs should be smaller than 0.05 Å. If we fix the mean amplitudes as 0.05 Å, then in the case when the difference between C-N and C-C distances becomes larger, the amplitudes of the theoretical intensity curve become smaller at large $q$ values compared to the experimental intensity curve, as the curve ME′ and AK′ in Fig. 1. So there is an intimate relation between the difference of the two distances and their mean amplitudes. From Fig. 6 and Table V reasonable C-C and C-N distances and acceptable regions of uncertainty are concluded as follows;

$$\text{C-C} = (1.48 \pm 2d) \pm 0.02 \text{ Å}$$

$$\text{C-N} = (1.49 \mp d) \pm 0.01 \text{ Å}$$

The parameter $d$ is dependent upon the assumed mean amplitudes, M. A., of the atomic pairs. There is the following rough relation between them;

$$d = 0.05 - \text{M.A.}$$

TABLE V. LIST OF MEAN VALUES OF $q_{calcd}/q_{obs}$ AND THEIR AVERAGE DEVIATIONS WHEN C-C AND C-N DISTANCES WERE VARIED, ASSUMING THE OTHER PARAMETERS TO BE CONSTANT

| Model | C-C Å | C-N Å | Mean amplitude | Mean value of $q_{calcd}/q_{obs}$ | Average deviation of $q_{calcd}/q_{obs}$ |
|---|---|---|---|---|---|

Next C-H and N-H bond distances were investigated. There are similar relations among C-H and N-H bond distances and their mean amplitudes as in the case of C-C and C-N distances. But as the contributions of the former ones to the intensity curves are smaller than those of the latter ones, the above relation is somewhat obscure. The mean values of $q_{calcd}/q_{obs}$ and their average deviations for the models in which C-H and N-H distances have been varied, are represented in Table VI. Reasonable ranges of C-H and N-H distances are 1.05～1.11 Å and 1.00～1.11 Å, respectively.

Finally the angles HCH, $CCH_2$ and $C_2NH$ were investigated. When ∠HCH is varied from 109.5° to 130°, the $q_{calcd}/q_{obs}$ values change but slightly (Table VII). The model of 117° seems to be the best, but the above range of angles will be within the experimental error. When the angles $CCH_2$ increase, C···cH distances increase and N···cH distances decrease, consequently the $q_{calcd}/q_{obs}$ values remain

Table VI. List of mean values of $q_{calcd}/q_{obs}$ and their average deviations when C-H and N-H distances were varied, assuming the other parameters to be equal to model GH

almost unchanged (Table VIII). So the angles $CCH_2$ may be determined only in the range 130~170°, as having been mentioned in the radial distribution analysis. As the contribution of C···NH atomic pairs to the total molecular intensity curve is the smallest except that of H···H atomic pairs which is negligibly small in this case, and their distances are comparable to those of C···CH and N···CH, the angle $C_2NH$ can not be determined unambiguously. But from the $q_{calcd}/q_{obs}$ values (Table IX), the reasonable value seems to be about 120°.

## Summary and Discussion

By the radial distribution and correlation methods, the molecular structure of ethylenimine was obtained as follows;

$$C\text{-}C = (1.48 \pm 2d) \pm 0.02\ \text{Å}$$

$$C\text{-}N = (1.49 \mp d) \pm 0.01\ \text{Å}$$

where

$$d = 0.05 - \text{M.A.}$$

$$C\text{-}H = 1.08 \pm 0.03\ \text{Å},\quad N\text{-}H = 1.05 \pm 0.07\ \text{Å}$$

The angles $CCH_2$ could not be determined accurately. They seem to be in the range 130~170°. The angles HCH and $C_2NH$ also could not be determined unambiguously, but $\angle HCH \approx 117°$ and $\angle C_2NH \approx 120°$ seem to be probable.

The above values of C-C and C-N nuclear distances are consistent with the values obtained by microwave spectroscopy (Table I). They are especially consistent when their mean amplitudes are assumed to be 0.05 Å.

As for the N-H bond distance and the angle $C_2NH$, the present values coincide with those of microwave spectroscopy within the extents of uncertainty, but the most probable values of the former are somewhat larger than the latter.

The C-C distance 1.48 Å is considerably shorter than the single bond distance 1.54 Å of normal chain compounds as the other three-membered ring compounds.

The author wishes to express his gratitude to Professor A. Kotera for his guidance and encouragement throughout the course of this research, to Professor Y. Morino, the University of Tokyo for the use of the diffraction apparatus, to Dr. K. Kuchitsu and Dr. E. Hirota, the University of Tokyo for their kind aid during the experiment and calculation by the Punched Card Machine, and to Dr. S. Shibata and Dr. H. Morimoto, Nagoya University, for the microphotometer tracing.

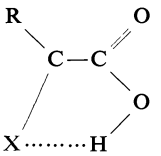
# *Intramolecular Hydrogen Bonding in α-Keto and α-Alkoxycarboxylic Acids. III*. Comparison of the Spectra in the Carbonyl Region with Those in the O–H Stretching Region*

By Michinori Ōki and Minoru Hirota



(Received July 13, 1960)

It was previously reported[1] that the O–H stretching absorption of carboxylic acids with a proton accepting group at α-position, such as monoesters of oxalic acid, α-ketocarboxylic acid, α-alkoxycarboxylic acid and α-aryloxycarboxylic acid, had two maxima. The maximum at the higher frequency has been assigned to the free O–H stretching mode and the other at the lower frequency to the O–H of the hydrogen bonded form.

Since it is a well known fact that the C=O stretching absorption ($\nu_{C=O}$) shifts to the lower frequency on hydrogen bonding formation, the frequency shift of $\nu_{C=O}$ to the lower side is also expected in a carboxylic acid which forms hydrogen bonding. Alternately, a trans carboxyl group should show $\nu_{C=O}$ at the higher frequency, because the carbonyl group becomes free on hydrogen bonding formation between the carboxylic hydroxyl group and the hydrogen accepting group at α-position. In this respect, the authors measured $\nu_{C=O}$ together with the O–H stretching absorption ($\nu_{O-H}$) and compared the spectra, thus establishing the assignment of the $\nu_{O-H}$ and $\nu_{C=O}$.

cis structure (I)

trans structure (II)

## Experimental

**Measurement and Calculation.** — All spectral measurements were carried out with a Perkin Elmer 112G grating infrared spectrophotometer as a carbon tetrachloride solution. The absorption curves were regared as an overlap of the bands with Lorentzian type envelopes and separated graphically. The half-width ($\Delta\nu^{a}_{1/2}$) and extinction coefficients at the absorption maxima ($\varepsilon_{max}$) are obtained by the above calculation and the apparent integrated intensities are obtained. The concentration of the solution is about 0.002 mol./l. for the measurements in the $\nu_{O-H}$ region and 0.0005 mol./l. for the $\nu_{C=O}$ region. The measurements are carried out through the ranges of 3580~3350 $cm^{-1}$ for the $\nu_{O-H}$ region and 1830~1690 $cm^{-1}$ for the $\nu_{C=O}$ region.

**Materials.**—The compounds used for the measurement are known unless otherwise described and their physical constants were checked prior to the measurements.

*β-Phenoxypropionic Acid.* — A solution of 250 g. (1.6 mol.) of β-phenoxyethyl chloride and 120 g. (1.85 mol.) of potassium cyanide in 600 ml. of ethanol was refluxed for four hours with stirring and the insoluble material was removed by filtration after cooling. The solvent was evaporated and the residue hydrolyzed by refluxing with 1000 ml. of 20% aqueous sodium hydroxide. The acidification followed by recrystallization from aqueous ethanol gave colorless leaves, m. p. 97°C, in 55% overall yield.

Found: C, 65.21; H, 6.30. Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.07%.

*γ-Phenoxybutyric Acid.* — To a sodium ethoxide solution prepared from 38.5 g. (1.67 mol.) of sodium and 700 ml. of ethanol, was added 520 g. (3.3 mol.) of diethyl malonate followed by 260 g. (1.67 mol.) of β-phenoxyethyl chloride and the reaction mixture was refluxed for six hours. The solvent was evaporated and the residue poured into water. The organic material was taken up in ether, dried over anhydrous sodium sulfate and then fractionated. A fraction boiling at 195~200°C/16 mmHg was collected, being crude diethyl α-(2-phenoxyethyl)-malonate (360 g.), which was refluxed with 1100 ml. of 60% acetic acid containing 85 g. of sulfuric acid. The product was treated according to the literature[2]. The acid was obtained as colorless needles, m. p. 64°C in 65% overall yield.

Found: C, 66.48; H, 6.75. Calcd. for $C_{10}H_{12}O_3$: 66.65; H, 6.71%.

## Results and Discussion

**Comparison in the Homologous Series.**—The $\nu_{O-H}$ and the $\nu_{C=O}$ absorption spectra of some compounds are shown in Figs. 1 to 4 and the data obtained by assuming that the band envelopes are expressed by the Lorentz function are given in Table I.

Among the homologs of phenoxyacetic acid, the only compound which shows two $\nu_{O-H}$ maxima is phenoxyacetic acid. The band at

higher frequency has been assigned to the $\nu_{O-H}$ of the monomeric acid, whereas the band at lower frequency has been assigned to the monomeric acid with an intramolecular hydrogen bonding. The higher homologs exhibit one band at ca. 3530 $cm^{-1}$ which can doubtless be assigned to the usual $\nu_{O-H}$ mode of monomeric acid. The results are indicative of the absence of hydrogen bonding between the carboxylic hydroxyl group and the oxygen atom of the phenoxyl group in β-phenoxypropionic and γ-phenoxybutyric acids.

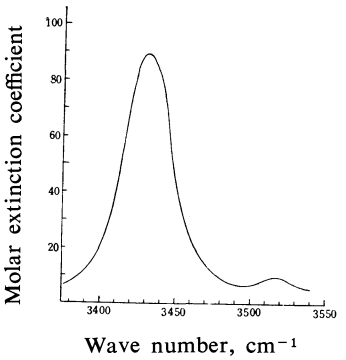

Fig. 3. The $\nu_{O-H}$ absorption of pyruvic acid.

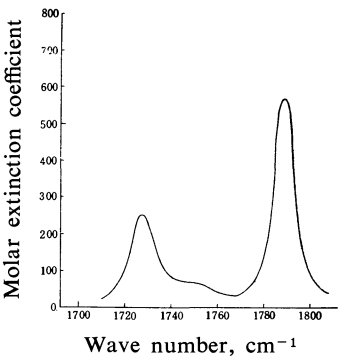

Fig. 4. The $\nu_{C=O}$ absorption of pyruvic acid.

In the carbonyl region, phenoxyacetic acid shows three maxima and a shoulder at ca. 1715 $cm^{-1}$, while β-phenoxypropionic and γ-phenoxybutyric acids exhibit only two bands. Acetic acid and benzoic acid also possess similar absorptions with the latter two compounds. Comparison of these data together with the study of the change in concentration as described later indicates that the band at about 1760 $cm^{-1}$ is arising from the cis structure of

TABLE II. COMPARISON OF THE SPECTRA OF CARBOXYLIC ACIDS CARRYING $\alpha$-HYDROGEN ACCEPTING GROUPS WITH THOSE OF THEIR ESTERS

a monomeric carboxylic acid illustrated by I, whereas the band at 1790 $cm^{-1}$ must correspond to the trans structure.

The difference ($\Delta\nu_{max}$) of the wave number between the band maxima corresponding to the cis and the trans structures is about 30 $cm^{-1}$ and may be explained in the following way. That is, the peak for the cis isomer shifts to the lower frequency because of the formation of the hydrogen bonding between the carboxylic hydroxyl and carbonyl groups, a non-planar[3] four-membered ring being formed. Although this may be taken as a peculiar phenomenon, a support is found in the accumulated data in this laboratory[4]. None of the phenylacetic, diphenylacetic and triphenylacetic acids show intramolecular interaction between the hydroxyl group and $\pi$-electrons, the existence of which is naturally expected from the analogy of *N*-methylphenylacetamide[5]. The absence of the interaction must be interpreted by considering that there is a favorable structure over the intramolecular O-H$\cdots\pi$ interaction, the energy of which is estimated as about 1 kcal./mol. The stabilization may be afforded by the presence of O-H$\cdots$O=C hydrogen bonding in the cis structure of the carboxylic acid.

The homologs of methoxyacetic acid which carries methyl groups show some variation in the $\nu_{C=O}$ absorptions according to the degree of substitution. Although the authors cannot comment precisely on the cause of the variation at the present time, it is probable that the electronic effect of the introduced methyl groups is playing an important role.

Pyruvic acid possesses two peaks at 1788.5 $cm^{-1}$ and 1725 $cm^{-1}$ and a shoulder at 1735 $cm^{-1}$ but the band at 1760 $cm^{-1}$ which is common for the other acids failed to appear. This is reasonable, since the band at 1760 $cm^{-1}$ corresponds to the cis species, the absorption of which in the $\nu_{O-H}$ region is negligibly small. The band at the highest frequency is assigned to the free carbonyl group of the carboxyl group which is due to the hydrogen bonding formation between the carboxylic hydroxyl and the $\alpha$-carbonyl groups. The origin of the two bands at the lower frequencies is determined through the study of concentration effects on the intensities. The band at 1735 $cm^{-1}$ is assigned to the dimeric carboxyl group and the other at 1725 $cm^{-1}$ to the $\alpha$-carbonyl group.

It is well known that the $\alpha$-ketocarboxylic acid has the monomer $\nu_{C=O}$ absorption at abnormally high frequency. The phenomenon has been attributed to the inductive and the field effects of the $\alpha$-keto group. However, it is now evident that pyruvic acid exclusively exists as the trans monomer with the free carbonyl group of the carboxyl group which causes the absorption at the high frequency.

**Comparison of the Spectra of the Acids with those of the Esters.**—In Table II are listed the $\nu_{C=O}$ spectra of esters together with the corresponding acids. Since the esterification cancels all posibilities of hydrogen bonding, esters of the carboxylic acids which carry the hydrogen accepting group at $\alpha$-position are expected to be normal when compared with the ordinary esters and this is proved to be the case. None of the esters show $\nu_{C=O}$ band as high as 1790 $cm^{-1}$.

Ethyl pyruvate shows one somewhat unsymmetrical $\nu_{C=O}$ band at 1733 $cm^{-1}$, which is believed to be an overlap of the ester and ketone bands. The band intensity is nearly twice that of the normal esters. Ethyl phenoxyacetate possesses two absorptions in the carbonyl region, the intensities being nearly equal. This phenomenon may be attributed to the

TABLE III. THE EFFECT OF THE CONCENTRATION ON THE INTENSITIES OF THE ABSORPTION BANDS OF PHENOXYACETIC ACID

| Concentration mol./l. | Intensity of the absorption band | | | |
|---|---|---|---|---|
| | $\nu_{C=O}$ of the trans structure of the monomer ($\varepsilon_t$) at 1790.6 $cm^{-1}$ | $\nu_{C=O}$ of the cis structure of the monomer ($\varepsilon_t$) at 1762.9 $cm^{-1}$ | $\nu_{C=O}$ of the dimer at 1737.4 $cm^{-1}$ | $\varepsilon_t/\varepsilon_c$ |
| 0.00092 | 204 | 153 | 281 | 1.33 |
| 0.00046 | 248 | 185 | 252 | 1.34 |
| 0.00023 | 300 | 226 | 221 | 1.33 |
| 0.000058 | 390 | 278 | 185 | 1.40 |

existence of the rotational isomers or to some other cause. The decisive comment cannot be made at the present stage.

**The Effects of Concentration on the $\nu_{C=O}$ Bands of Phenoxyacetic Acid.**—As was already pointed out, phenoxyacetic acid possesses three $\nu_{C=O}$ bands, the intensities of which are measured at various concentrations in carbon tetrachloride. The results are shown in Table III.

It is recognized that the intensities of the bands at 1762.9 $cm^{-1}$ and 1790.6 $cm^{-1}$ increase with the decreasing concentration, while the band at 1737 $cm^{-1}$ decreases on lowering the concentration. These behaviors indicate that two bands at the higher frequencies must be attributed to the monomeric forms of the carboxylic acid and the other at 1737 $cm^{-1}$ to the dimeric form. It is also found that the ratio of the intensities of the bands at 1762.9 $cm^{-1}$ and 1790.6 $cm^{-1}$ is almost constant at the various concentrations. This fact suggests that the equilibrium between the cis and the trans forms is not influenced by the concentration.

TABLE IV. ASSIGNMENT OF THE $\nu_{O-H}$ AND THE $\nu_{C=O}$ BANDS OF A CARBOXYLIC ACID WITH AN α-HYDROGEN-ACCEPTING GROUP

| Structure | Monomer | | Dimer $cm^{-1}$ |
|---|---|---|---|
| | Cis structure $cm^{-1}$ | Trans structure $cm^{-1}$ | |
| $\nu_{O-H}$ | 3550～3500 | 3490～3390 | 3300～2500 |
| $\nu_{C=O}$ | ca. 1760 | ca. 1790 | 1730～1710 |

**Assignment of the Band.** — From the above discussion, it is apparent that the bands can be assigned as shown in Table IV.

## Summary

The $\nu_{C=O}$ and the $\nu_{O-H}$ absorption of carboxylic acids were measured and the following conclusion was obtained; 1) The carboxylic acids carrying a proton-accepting group at α-position give three absorption bands at ca. 1790 $cm^{-1}$, ca. 1760 $cm^{-1}$ and 1740～1710 $cm^{-1}$, which can be assigned to the trans form of the monomeric acid, the cis form of the monomeric acid and the dimer, respectively. 2) The $\Delta\nu_{max}$ between the cis and the trans forms can be explained from an intramolecular hydrogen bonding between carboxylic hydroxyl and carbonyl groups.

The authors wish to express their hearty thanks to Professor Y. Urushibara for his encouragement and advice throughout this work. The authors are also indebted to Mr. H. Iwamura and Mr. K. Mutai for their technical assistance.

# *Intramolecular Hydrogen Bonding in α-Keto and α-Alkoxycarboxylic Acids. IV*[1]. *Electronic Effect in Aryloxyacetic Acids*

By Michinori Ōki and Minoru Hirota

(Received July 26, 1960)

The authors measured[1,2] the O-H stretching ($\nu_{O-H}$) and the C=O stretching ($\nu_{C=O}$) bands of various carboxylic acids and concluded that there is a hydrogen bonding in the acids carrying a hydrogen-accepting group at α-position. The hydrogen bonding is doubtlessly formed between the carboxylic hydroxyl group and the hydrogen-accepting group. Phenoxyacetic acid satisfies the above conditions and is found to exist as "free" and "bonded"[3] species, from the data obtained in O-H stretching and carbonyl regions.

The strength of the hydrogen-accepting power of the oxygen atom in the phenoxyl group may be assumed to be proportional to the electron density on the oxygen atom. Since it is known that Hammett's σ constants and the $pK_a$ values of phenols are in linear relation, it can be seen that the σ constant[4] is a measure of the electron density of the oxygen atom in the aryloxy group. Thus the electron-repelling group will enrich the electron-density on the oxygen atom to be favorable as a hydrogen acceptor and the contrary situation is expected for the electron-attracting group.

The present paper deals with the effect of the substituent in the phenyl group on the $\nu_{O-H}$ and the $\nu_{C=O}$ absorptions, thus giving another verification for the existence of a hydrogen bonding between the carboxylic hydroxyl group and the hydrogen-accepting group at α-position.

## Experimental

**Preparation of the Materials.** — Aryloxyacetic acids[5] were prepared in the following way. Equivalent amounts of sodium aryloxide and sodium chloroacetate in water were heated on a water bath for one to two hours. The reaction mixture was acidified and extracted with ether. The ethereal extract was shaken with aqueous sodium bicarbonate and the aqueous layer was acidified. The aryloxyacetic acid was recrystallized from benzene. Those which are not listed in Table I are known compounds and their physical constants agreed with the literature.

* Since the melting point (152°C) reported in the literature disagreed with that measured in this work, the purity was checked by elemental analysis.

**Measurement and Calculation.**—The measurement of the spectra were carried out with a Perkin Elmer 112G grating spectrophotometer. The materials were dissolved in carbon tetrachloride to make up concentration of ca. 0.002 mol./l. for the $\nu_{O-H}$ and ca. 0.0005 mol./l. for the $\nu_{C=O}$ measurements[6]. The spectral slit width was 1.0 $cm^{-1}$ for the $\nu_{O-H}$ region and 0.6 $cm^{-1}$ for the $\nu_{C=O}$ region. The absorption curves were assumed to be an overlap of the bands which obey the Lorentz function and the half band-widths ($\Delta\nu^a_{1/2}$) and the extinction coefficients ($\varepsilon^a_{max}$) at the maxima were obtained by Ramsay's first method[7]. That is, the approximate absorption maxima, $\Delta\nu^a_{1/2}$'s and $\varepsilon^a_{max}$ were obtained by dividing the curves graphically and the characteristic numericals were corrected by the trial and error method.

## Results and Discussion

Locations of the absorption maxima and the integrated intensities of the bands of aryloxyacetic acids are summarized in Table II.

1) Part III: M. Ōki and M. Hirota, This Bulletin, **34**, 374 (1961).

2) M. Ōki and M. Hirota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 855 (1960).

3) Although C. P. Smyth ("Dielectric Behavior and Structure", McGrawHill Book Co, Inc., New York (1955), p. 307) used the name cis and trans for the carboxyl group which has hydrogen atom between the two oxygen atoms and the other of which hydrogen atom is located outside the two oxygen atoms, respectively, "free" and "bonded" are used in this paper because of the nature of situation. However, as pointed out previously (Ref. 1), existence of a hydrogen bonding has been deduced in the cis form. Thus quotation marks are used to distinguish between the situation in this work and purely free form.

4) H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

5) A. Michael, *J. Am. Chem. Soc.*, **9**, 180 (1887).

6) *p*-Nitrophenoxyacetic, *m*-nitrophenoxyacetic and *h*-benzyloxyphenoxyacetic acids were exceptions, of which poor solubility in carbon tetrachloride did not allow to measure at this level of concentration. The measurements of the nitro compounds were run with the saturated solutions.

7) D. A. Ramsay, *J. Am. Chem. Soc.*, **74**, 72 (1952).

* Saturated solution.

** The integrated intensity can be calculated by the equation $A = 2.30 \times \frac{\pi}{2} \frac{1}{Cl} \log_{10}(T_0/T)_{max} \times \Delta\nu^a{}_{1/2}$, because the correction factors[7] are almost unity under the conditions for the measurement.

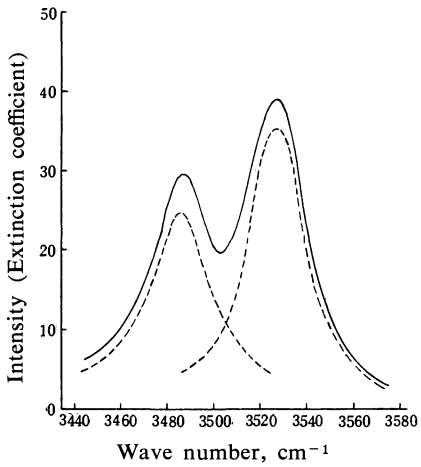

Fig. 1. The $\nu_{OH}$ absorption of *m*-methylphenoxyacetic acid.

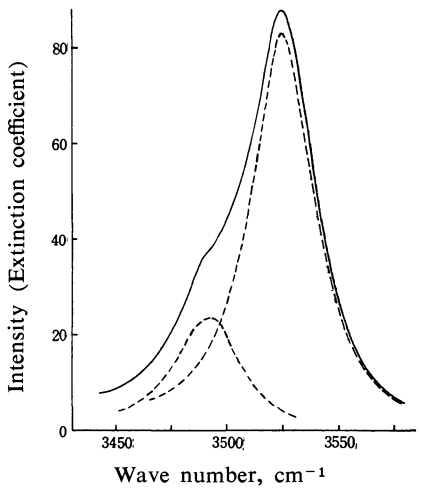

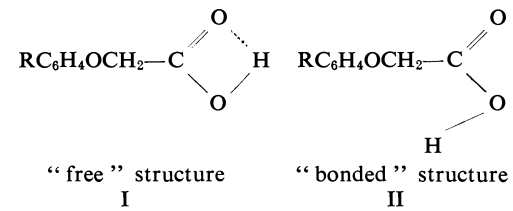

Fig. 2. The $\nu_{OH}$ absorption of *p*-chlorophenoxyacetic acid.

The aryloxyacetic acid with a substituent whose $\sigma$ value is smaller than 0.115 (for meta-methoxyl) shows two apparent maxima, as exemplified by *m*-methylphenoxyacetic acid in Fig. 1. The separation of the two absorption maxima is fairly large. According to the previous paper, the band at ca. 3525 $cm^{-1}$ is assigned to the cis structure (I) and the other at ca. 3490 $cm^{-1}$ to the trans (II). Therefore, it can be said that the electron-repelling groups enhance the contribution of the trans, "bonded" form. If it can be assumed that the larger $\Delta\nu_{max}$ represents the more stabilization, then it is also clear that the aryloxyacetic acids carrying the electron-repelling group forms the more stable hydrogen bonding.

"free" structure I "bonded" structure II

As to the substitution of the electron-attracting group, the aryloxyacetic acids do not show two maxima. *p*-Chlorophenoxyacetic and *p*-bromophenoxyacetic acids possess absorption bands with a peak and a shoulder as shown in Fig. 2, *p*-chlorophenoxyacetic acid being taken as a representative. *m*-Nitrophenoxyacetic acid shows a somewhat unsymmetrical absorption, while *p*-nitrophenoxyacetic acid a nearly symmetrical band. The error caused by the poor solubility of *p*-nitrophenoxyacetic acid prevents the division of the band into two.

The bands at higher and at lower wave numbers are undoubtedly assigned to the "free" and to the "bonded" OH's, respectively, as

reported in the previous paper. Then it is evident that the electron repelling groups favor the "bonded" form and the electron-attracting groups the "free" form.

Since an equilibrium between the "free" and the "bonded" forms is considered to be operative, an equilibrium constant $K_h$ may be expressed by Eq. 1.

$$K_h = \frac{[\text{bonded}]}{[\text{free}]} \qquad (1)$$

On the other hand, the concentrations of each of the species are proportional to the intensities of the respective $\nu_{O-H}$, as far as Beer's law is applicable. Therefore, Eq. 1 may be transformed to

$$K_h = a\frac{A_b}{A_f} \qquad (2)$$

where $A_b$ and $A_f$ are the integrated intensities due to the "bonded" and the "free" molecules, respectively, and $a$ is a constant pertaining to the magnifying power of the absorption intensity per molecule, when hydrogen bonding is formed. The value "$a$" is assumed to be equal for the series of compound.

Hammett's $\sigma$ value is defined as

$$\sigma \equiv \log (K/K_0) \qquad (3)$$

where $K_0$ and $K$ are dissociation constants of benzoic acid and the substituted benzoic acid, respectively. Thus a linear relation is expected between $\sigma$ value and $\log (A_b/A_f)$ from Eqs. 2 and 3, because $\sigma$ value is also a measure of the basicity of the oxygen atom in the aryloxyl group. The $\log (A_b/A_f)$ versus $\sigma$ diagram is shown in Fig. 3 and the relation is linear as expected.

The frequency shift ($\Delta\nu_{max}$) from the "free" molecule to the "bonded" is also plotted against the $\sigma$ value. The result (Fig. 4) may be considered as linear relation. The larger the the $A_b/A_f$ value, the more is the $\Delta\nu_{max}$. Since it is accepted that the energy of a hydrogen

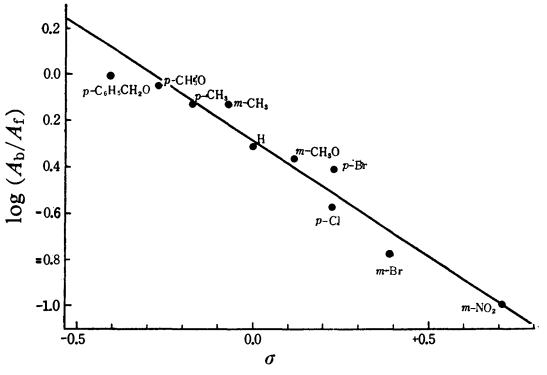

Fig. 3. The relation between the intensity ratio $A_b/A_f$ and the Hammett's substituent constant.

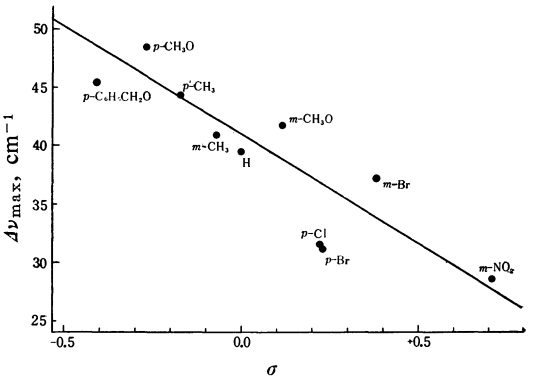

Fig. 4. The relation between the $\Delta\nu_{max}$ and the Hammett's substituent constant.

bonding is proportional to the shift of the the wave number as a rough approximation, this $\Delta\nu_{max} - \sigma$ relation seems to be reasonable.

The measurement was extended to the carbonyl region and the band at 1790 $cm^{-1}$ which is assigned[1] to the "bonded" form and the band at 1790 $cm^{-1}$ which is assigned[1] to the "bonded" form and the other at 1760 $cm^{-1}$ due to the "free" form are also found in every case.

Although these bands are nearly symmetrical, the dimer band at ca. 1730 $cm^{-1}$ always overlaps with these, making it hard to obtain the integrated intensities. $\varepsilon_b/\varepsilon_f$ is obtained in this regard, where $\varepsilon_b$ and $\varepsilon_f$ are the extinction coefficients of the "bonded" and the "free" molecules at the corresponding peaks. The results are summarized together with other data in Table III. The result indicates that, when the $\sigma$ value is large with a plus sign, $\varepsilon_b/\varepsilon_f$ is small and agrees with the tendency obtained in the $\nu_{O-H}$ measurement.

TABLE III. THE $\nu_{C=O}$ ABSORPTION OF ARYLOXYACETIC ACIDS

| Substituent | $\nu_{C=O}$ of the "free" structure | $\nu_{C=O}$ of the "bonded" structure | $\varepsilon_b/\varepsilon_f$ |
|---|---|---|---|
| *m*-$NO_2$ | 1768.9 | 1788.9 | 1.20 |
| *m*-Br | 1764.2 | 1789.8 | 1.19 |
| *p*-Cl | 1763.6 | 1790.2 | 1.27 |
| H | 1762.9 | 1790.6 | 1.37 |
| *p*-$CH_3$ | 1763.0 | 1791.0 | 1.55 |
| *p*-$CH_3O$ | 1760.5 | 1790.4 | 1.63 |

The $\nu_{O-H}$ band of the dimeric carboxylic acid is known to be a very broad band and is often masked by the $\nu_{C-H}$ band. However, the $\nu_{C=O}$ band of the dimetric acid is easily observable and it is known in this measurement that the contribution of the dimer is fairly large even in a dilute solution. From this result, the direct comparison of the absolute

intensities of the bands corresponding to the "free" and the "bonded" forms becomes less significant. Thus, the ratio $A_b/A_f$ or $\varepsilon_b/\varepsilon_f$ is exclusively used for the present discussion. The concentrations of the solutions are also included in Table III, because the contribution of the dimers may insert influence upon other data. The detailed discussion on the effect of concentration will be reported elsewhere in connection with the dissociation constant of the dimer.

## Summary

The electronic effect on the hydrogen bonding formation in aryloxyacetic acid was examined. It is found that the electron-repelling groups enhance the band at the lower frequency in O-H stretching region and the band at ca. 1790 $cm^{-1}$. The result is completely agreeable with the expectation that the electron density on the oxygen atom in the aryloxyl group controls the hydrogen bonding formation.

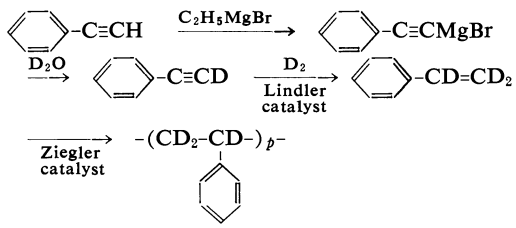
# *Stereoregular Polymers. VII.*[1] *Infrared Spectra of Isotactic Polystyrene, Isotactic Poly-α, β, β-trideuterostyrene and Isotactic Poly-p-deuterostyrene*[*1]



By Hiroyuki TADOKORO, Yoshiyuki NISHIYAMA,[*2] Shun'ichi NOZAKURA and Shunsuke MURAHASHI

(Received September 12, 1960)

Isotactic polystyrene is a very interesting polymer from the point of view of fine structure and fine texture. Its crystallinity can be varied over wide range, from amorphous to highly crystalline state by heat-treatments, and also a highly oriented sample can be made by hot stretching. We are now studying this substance by use of the X-ray, infrared and density measurements. In this paper we wish to present a report on the results obtained from the changes of infrared spectra with crystallization and the infrared dichroism of isotactic polystyrene (IPS), isotactic poly-α, β, β-trideuterostyrene (IPTDS), $-(-CD_2-\underset{\displaystyle C_6H_5}{\underset{|}{CD}}-)_p-$ and isotactic poly-*p*-deuterostyrene (IPPDS), $-(CH_2-\underset{\displaystyle D}{\underset{|}{CH}}-)_p-$.

Natta[2] measured the infrared spectra of IPS both at solid and molten states. He showed that the spectrum of IPS at the molten state is similar to that of atactic polystyrene (APS), but did not discuss it further in detail. Liang and Krimm[3] reported the detailed analysis of the infrared spectrum of polystyrene. Their analysis was, however, based only on the commercial ASP, and they have not yet examined the dicroism and the deuteration of this polymer. Deuteropolystyrenes (probably atactic) were prepared by Beachell and Nemphos[4], but the infrared spectra of their products seem not to be published yet.

**Samples.** — The samples used in this work are IPS, IPTDS and IPPDS polymerized with Ziegler catalyst. The deuterated polymers were prepared according to the following schemes:

The films for the infrared measurements were cast on a metal plate*3 from toluene solution, and were subjected to one of the following treatments: 1) quenching, 2) heat-treatment after quenching, and 3) elongation and subsequent heat-treatment. The quenched sample was prepared by heating in Wood's alloy at about 240°C*4 for 15~30 sec., and subsequent quenching in cold water. The oriented sample was prepared by stretching very slowly in boiling water, until it could be stretched no more (about 5 times of the original length). Heat-treatment was taken in Wood's alloy at about 180°C for 30 min. The crystallization and the

*3 A glass plate and the surface of water were also used for casting the film.

*4 The melting point of IPS is reported to be 230°C[2].

orientation of the samples were confirmed by the X-ray photographs.

Infrared spectra were measured by using a Hitachi Model EPI-2 recording infrared spectrophotometer with sodium chloride and potassium bromide prisms and silver chloride polarizers.

## Results and Discussion

**Features of the Spectra.** — Fig. 1 shows the spectra of IPS (a), IPTDS (b) and IPPDS (c), together with those of atactic samples (lower curve in Figs. 1a and 1c) for reference. In the figures the solid lines are for the samples subjected to heat-treatment and broken lines for the quenched samples. In Fig. 2, polarized infrared spectra of the oriented samples of IPS (a), IPTDS (b) and IPPDS (c) were shown. The solid lines represent transmission with the electric vector perpendicular to the stretching direction, and the broken lines that with the electric vector parallel to the stretching direction. In Figs. 1 and 2, the films used for the absorption measurements with sodium chloride prism are not all the same as those for the measurements with potassium bromide prism. The spectral data and the tentative assignments were also shown in Tables I—III.

As shown in Fig. 1, the spectra exhibit considerable changes with crystallization. The bands at 1364, 1314, 1297 and 1185 $cm^{-1}$ in the spectrum of IPS are very sensitive to crystallization, and have strong dichroic nature. These four bands appear in weak intensity even in the spectrum of quenched samples of IPS, while do not appear in the spectrum of APS. On the other hand, the spectra of IPTDS do not show any bands at these four positions. The band at 1070 $cm^{-1}$ of APS which splits slightly into two bands in the spectrum of the quenched IPS, undergoes large splitting with increase in intensity and sharpness in the spectrum of the crystallized IPS. The resulting two bands are at 1080 and 1048 $cm^{-1}$, showing strong perpendicular dichroism. The spectrum of the quenched IPS is similar

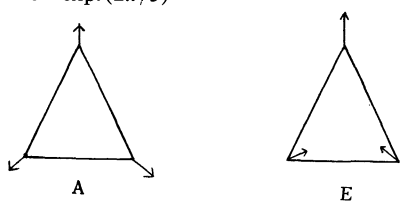
a) Data on the crystallized IPPDS.



on the whole to that of APS, but is different on the points that 1) the 1070 $cm^{-1}$ band splits in the quenched IPS and 2) the 542 $cm^{-1}$ band in APS shifts to 557 $cm^{-1}$ in the quenched IPS. These cases may be considered to be the examples that the infrared spectrum indicates the existence of localized regularity in some narrow region, which can be hardly observed from the X-ray photographs. The band at 985 $cm^{-1}$ shows marked change of intensity with heat-treatment.*5 It is an interesting fact that a band which shows behavior similar to this band in the spectrum of IPS (crystallization-sensitive and perpendicular natures) appears also at the same wave number (980 $cm^{-1}$) in the case of IPTDS. This fact suggests that these bands appear from the similar origins and it would be considered that the bands can be used for the determination of the degree of crystallinity. In the spectra of IPPDS (Figs. 1c and 2c), the band at 948 $cm^{-1}$ is also very sensitive to crystallization, but has parallel dichroism, differing from the 985 $cm^{-1}$ band of IPS. The band which appears at about 906 $cm^{-1}$ in the spectrum of APS as well as the quenched IPS splits with crystallization into two bands, i. e. the perpendicular band at 920 $cm^{-1}$ and the parallel one at 898 $cm^{-1}$ (Fig. 2a). The intensity of the 755 $cm^{-1}$ band increases remarkably with crystallization.

**Treatment with Factor Group.** — The crystal structure of IPS analyzed by Natta et al.[5] and Bunn et al.[6] belongs to trigonal symmetry class. The molecular chain in the crystalline state has a structure of three-fold screw axis. An infinitely extended molecule of three-fold screw symmetry may be represented by a one-dimensional space group. When the interchain interaction is negligible, it is adequate to consider its factor group $C(2\pi/3)$ shown in Table IV[7]. The symmetry operation, $C^1$, bringing any structural unit into coincidence with an adjacent unit, consists of a rotation of $2\pi/3$ about the screw axis followed by a translation of 1/3 of the identity period of 6.65 Å along the axis. In the case of this group $C(2\pi/3)$, there appear the species A and E. In species A whole structural units vibrate in the same phase, and the direction of the transition moment is parallel with the screw axis. In species E, the phase of the vibration of a structural unit is different from that of the adjacent structural unit by $2\pi/3$, and consequently the direction of the transition moment is perpendicular to the screw axis. In the cases in which the interaction among the structural units is so strong that the frequencies of the A and the E modes clearly split, these bands should show strong dichroism. On the contrary, in the cases in which the interaction among the structural units is not so strong, and the frequencies of the A and the E modes are nearly equal, both bands, i. e. the parallel band of the species A and the perpendicular band of the species E, superpose in the same location of the spectrum. In this case the dichroism of the more intense component will appear. Which dichroism appears may be decided by the angle between the direction of the transition moment in each structural unit and the screw axis. It should be mentioned here that the vibrational modes, in which the interaction between the neighboring helical molecules is strong, can not be interpreted by the aforementioned method of factor group for a single molecular chain.

Table IV. Symmetry species, irreducible representations, number of normal modes, and selection rules for isotactic polystyrene under the group $C(2\pi/3)$

| | E | $C^1$ | $C^2$ | Null | vib. | $n$ | I. R. | Raman |
|---|---|---|---|---|---|---|---|---|
| A | 1 | 1 | 1 | $T_\parallel$ | R | 46 | active ($\parallel$) | active |
| E | 1 | $\varepsilon$ | $\varepsilon^2$ | $T_\perp$ | | 47 | active ($\perp$) | active |
| | 1 | $\varepsilon^{-1}$ | $\varepsilon^{-2}$ | $T_\perp$ | | 47 | | |

$\varepsilon = \exp i(2\pi/3)$

**Methylene Group Vibrations.**—The $CH_2$ antisymmetric stretching band at 2924 $cm^{-1}$ shows a distinguished perpendicular nature, which is explainable by the fact that the direction of the transition moment of this vibrational mode of each structural unit is nearly perpendicular to the screw axis. On the other hand, the $CH_2$ symmetric stretching band at 2849 $cm^{-1}$ shows only very weak dichroism. The direction of the transition moment of this vibrational mode is on the bisector of the angle H-C-H of the methylene group. The angle between this direction and the screw axis is considered to be about 58° from the angle 116° of the C-C-C of the main chain of this polymer estimated by Natta et al.[8]

*5 In the spectra of APS and quenched IPS, a weak band is observed at 980 $cm^{-1}$.

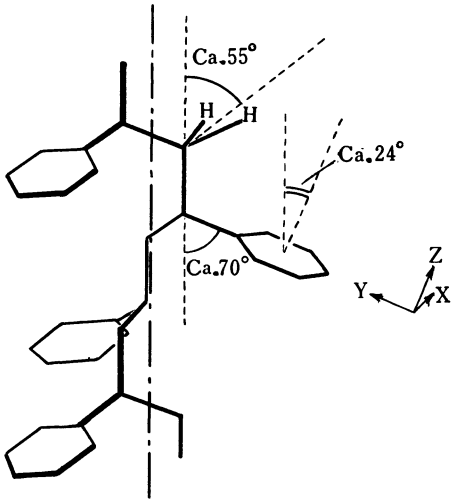

Fig. 3. The molecular structure of isotactic polystyrene in the crystalline state.

(Fig. 3). For perfect uniaxial orientation, the dichroic ratio, $R$, defined as the ratio of the optical densities with electric vector respectively parallel and perpendicular to the orientation direction, is given by $R=2\cot^2\varphi$, where $\varphi$ is the angle between the transition moment and the orientation direction. If $\varphi=54°44'$, $R=1$, i. e., the band exhibits no dichroism. The critical angle for $R=1$ is considered to increase only a small amount, when the orientation deviates from the perfect one. For instance, if the transition moments are uniformly distributed in a 20° angular range, the critical angle is 54°54'.[9] Thus the absence of the dichroic nature of the $CH_2$ symmetric stretching band could be explained, since the aforementioned angle 58° is near this critical angle. These dichroic natures of $CH_2$ stretching bands are hence considered to be characteristic of the helical structure (alternate sequence of trans and gauche conformations) of isotactic polystyrene. The same feature was found in the case of $CD_2$ stretching bands of IPTDS (2195 and 2095 $cm^{-1}$).

In the region of 1400~1100 $cm^{-1}$ the spectra of IPS and IPPDS change remarkably by heat-treatment (crystallization) and show distinguished dichroism as shown in Figs. 1 and 2. On the other hand, the absorption bands of IPTDS in this region which have comparatively weak dichroism, are not affected appreciably by heat-treatment, and are considerably different from those of IPS and IPPDS. The four bands (1364, 1314, 1297 and 1185 $cm^{-1}$), appearing in weak intensity in the spectra of quenched IPS and IPPDS, increase their intensity with crystallization, while they do not appear in the spectra of APS and APPDS (atactic poly-*p*-deuterostyrene). As these bands are absent in the spectra of IPTDS, these bands are considered to be not directly associated with the vibrations of the phenyl group, but mainly with that of the main chain. These four bands are also supposed to be closely associated with the helical structure of the IPS molecule in crystalline region, the detailed discussions of which we will report in the subsequent paper. On this problem we have briefly reported already.[10]

**Phenyl Group In-plane Vibrations.**—Now we wish to discuss the vibrational modes associated with the benzene ring. By calculating from the X-ray data of Natta et al.[5], it is estimated that the $y$ and the $z$ axes of the benzene ring shown in the figure in Table V are at an angle of about 70° and about 24° to the screw axis, respectively, and the $x$ axis at an angle of about 14° from the plane normal to the screw axis as shown in Fig. 3.

The vibrations of monosubstituted benzene which has point symmetry of $C_{2v}$ are useful for a step to the assignments of the bands due to phenyl group of polystyrene as studied by Liang et al.[3] in the case of APS previously. On the spectra and the vibrations of monosubstituted benzenes, a number of works have been done by many workers.[11-17] In Table V, we reproduce the symmetry species, the total number of normal vibrations associated with each species, $n$, and the infrared and the Raman activity to be expected, from the paper by Liang and Krimm[3]. As shown in this table, the transition moment for $A_1$ species is in the $y$ direction, that for $B_1$ in the $x$ direction and that for $B_2$ in the $z$ direction, which is the out-of-plane vibration. We may presume the dichroism of the bands, placing these phenyl groups on the three-fold screw axis. In the cases of $A_1$ and $B_1$ species (of $C_{2v}$), the component E (of $C(2\pi/3)$) must be more intense than the component A and so the dichroism should be perpendicular. On the contrary in the case of species $B_2$, the component A must be more intense and thus the parallel nature should appear.

The fact that the bands mainly due to the

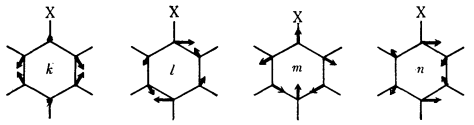
f=forbidden a=active

z-Axis is normal to the plane of the benzene ring.

CH stretching modes of phenyl group at about 3000 $cm^{-1}$ show perpendicular dichroism, is in good agreement with the presumption described above, because these bands should belong to $A_1$ or $B_1$ symmetry species.

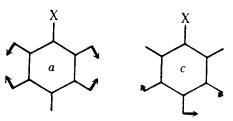


The bands at 1946, 1872, 1801, 1748 and 1675 $cm^{-1}$ (IPS and IPTDS) all show perpendicular dichroism. The similar bands in the spectra of monosubstituted benzenes have been assigned to the binary combinations of the CH out-of-plane deformation vibrations of phenyl group as shown in Table VI by Whiffen[17] and Kakiuchi[16] independently. Liang and Krimm[3] have assigned these bands in the case of polystyrene as shown in the same table. The assignments of these bands to symmetry species $A_1$ or $B_1$ by all these authors are in accord with the perpendicular dichroism of the bands. But the assignments of the component fundamental frequencies 906 and 755 $cm^{-1}$ by Liang and Krimm[3] are different from those by Whiffen[17] and Kakiuchi[16]. On this problem more detailed discussion will appear later.

TABLE VI. ASSIGNMENTS OF THE MAIN COMBINATION BANDS IN 2000~1700 $cm^{-1}$ REGION BY LIANG ET AL., WHIFFEN AND KAKIUCHI

| Wave number $cm^{-1}$ | Assignments | |
|---|---|---|
| | Liang and Krimm[3] | Whiffen[17] and Kakiuchi[16] |
| 1946 | $\nu_{17A}(A_2)+\nu_5(B_2)$, $B_1$ | $j(B_2)+h(A_2)$, $B_1$ |
| 1872 | $\nu_{17B}(B_2)+\nu_5(B_2)$, $A_1$ | $i(B_2)+h(A_2)$, $B_1$ |
| 1801 | $\nu_{10A}(A_2)+\nu_{17A}(A_2)$, $A_1$ | $g(A_2)+h(A_2)$, $A_1$ |
| 1748 | $\nu_{10A}(A_2)+\nu_{17B}(B_2)$, $B_1$ | $i(B_2)+g(A_2)$, $B_1$ |

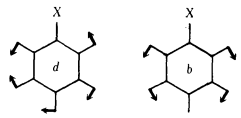
Notations of the vibrations in this table are those of Liang et al. and of Whiffen, respectively.



The four bands at 1602, 1583, 1493 and 1452 $cm^{-1}$ (IPS and IPTDS) show perpendicular dichroism, and are not affected appreciably by deuteration. These facts are consistent with the assignments to the in-plane C–C stretching vibrations of phenyl group by Whiffen et al.[13,14] as follows*6.

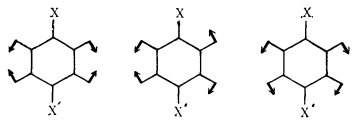
| | ($A_1$) | ($B_1$) | ($A_1$) | ($B_1$) |
|---|---|---|---|---|
| IPS | 1602 | 1583 | 1493 | 1452 $cm^{-1}$ |

Liang et al.[3] also have assigned these four bands to the C–C stretching model, except the assignments of 1602 and 1583 $cm^{-1}$ bands (to the l and k modes, respectively).



In the region of 1400~1100 $cm^{-1}$ the hydrogen deformation vibrations ($CH_2$ wagging and twisting, and CH wagging) of the main chain may couple to some extent with the in-plane vibrations of the benzene ring, showing the complex nature of the spectrum in the case of non-deuterated sample. In the spectrum of IPTDS the bands due to the vibrations of the deuterium of the main chain would shift to lower frequency region, and thus the aforementioned coupling may be removed. Accordingly the bands in this region may be considered to be mainly due to the vibrational modes of the benzene ring in the case of IPTDS. Thus the 1179 and 1154 $cm^{-1}$ bands of IPTDS may be assigned to the a and c modes of monosubstituted benzene according to the Whiffen's notation.[9] It is difficult to settle the assignments of the 1328 and 1240 $cm^{-1}$ bands from the present data.

| | ($A_1$) | ($B_1$) |
|---|---|---|
| IPS | 1185 | 1158 $cm^{-1}$ |
| IPTDS | 1179 | 1154 |

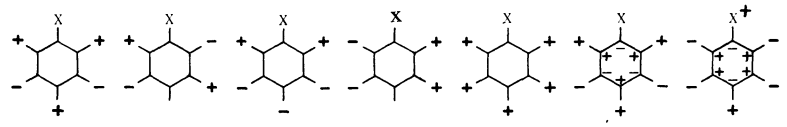


The 1070 $cm^{-1}$ band (APS) may be assigned to the d($\nu_{18B}$)($B_1$) mode. The splitting of this band in the case of IPS may be explained by the intramolecular interaction. The 1028 $cm^{-1}$ band may be assigned to the b ($\nu_{18A}$)($A_1$) mode, as Whiffen and Liang et al. assigned.

*6 In this paper the notation of the vibrational modes of the monosubstituted benzene by Whiffen (shown with h, j.···) will be mainly used for convenience, but those by Liang and Krimm ($\nu_{10A}$, $\nu_{17A}$,···) will also be added if necessary.

| | ($B_1$) | ($A_1$) |
|---|---|---|
| IPS | 1080, 1048 | 1028 $cm^{-1}$ |
| APS | 1070 | 1028 |

The 1183, 1107 and 1021 $cm^{-1}$ bands of IPPDS are considered to be the following CH in-plane modes, as Whiffen[14] and Ingold[11] assigned in the cases of *p*-substituted benzenes.



| | ($A_1$) | ($B_1$) | ($A_1$) |
|---|---|---|---|
| IPPDS | 1183 | 1107 | 1021 $cm^{-1}$ |
| PPMS | 1184 | 1110 | 1017 |

Here we have shown the data of poly-*p*-methylstyrene (PPMS) from our paper[10] for reference. The vibrational modes of the 1185 and 1028 $cm^{-1}$ band of IPS are the same with those of the 1183 and 1021 $cm^{-1}$ bands of IPPDS (and of the 1184 and 1017 $cm^{-1}$ band of PPMS) respectively. In the cases of these two vibrational modes the hydrogen atom of the *p*-position does not move significantly. Thus, the experimental fact that the substitution of the *p*-hydrogen atom with deuterium or methyl group does not affect these two bands appreciably may be reasonably explained. The 1106 $cm^{-1}$ band of IPPDS and the 1110 $cm^{-1}$ of PPMS are supposed to be characteristic of the *p*-substituted benzenes. It is natural that the bands which correspond to the c and d modes of IPS do not appear in the spectra of IPPDS and PPMS, since these modes contain the displacement of *p*-hydrogen atom.

**Phenyl Group Out-of-plane Vibrations.** — As mentioned in the previous section, the assignments of the two bands at 906 and 755 $cm^{-1}$ by Liang et al. are different from other authors (Whiffen[13] and Kakiuchi[16]), although the assignments of the other three bands (985, 965 and 842 $cm^{-1}$) in this region by all these authors are the same. They assigned these bands as shown in Table VII. The crystallization-sensitive 985 $cm^{-1}$ band may be assigned to the j mode by considering the position. The 906 $cm^{-1}$ band which splits into two bands of different polarizations with crystallization is assigned to the $\nu_{17B}$ vibration by Liang et al., while the band at 908±10 $cm^{-1}$ of monosubstituted benzenes was assigned to the i mode by Whiffen. Kakiuchi has calculated the frequency of this i mode to be 897 $cm^{-1}$ assuming the mass of the substituent atom to be infinite, and has made the similar assignment as Whiffen's. On the other hand, Liang and Krimm have assigned the 755 $cm^{-1}$ band to this i mode. The 755 $cm^{-1}$ band (the 751±15 $cm^{-1}$ band of monosubstituted benzene) was assigned to the f mode known as the "umbrella" vibrational mode by Whiffen. Kakiuchi has calculated the frequency of this mode to be 716 $cm^{-1}$, and has made similar assignment. To this f vibrational mode, Liang and Krimm have assigned the band at 700 $cm^{-1}$. Although it is difficult to decide which

assignment we should accept for polystyrene, it seems to be more favorable to apply Kakiuchi's assignment for this case, because of the agreement of the calculated value with the observed. Here we should mention the unexplainable dichroism of the 985 and 906 $cm^{-1}$ bands, which are expected to have parallel dichroism because of their symmetry species $B_2$. These complexities of the bands sensitive to crystallization, would have occurred from the interaction between the molecules in the crystalline lattice and could not be explained by the treatment on a single helical chain, which is a first approximation for the interpretation of the spectra of crystalline polystyrene.

The assignment of the CH out-of-plane vibrations of IPPDS can be made as shown in Table VIII on the basis of the work on *p*-deuterotoluene by Kakiuchi. Although the vibrational mode assigned to the 948 $cm^{-1}$ band of IPPDS is similar to that of the 983 $cm^{-1}$ band of IPS, the dichroisms of these two bands are different from each other, as described in the previous section. This difference may be explained by the change of the nature of the interaction between the molecular chains in the crystalline lattice owing to the deuteration of the *p*-position.

For detailed interpretation of the spectrum and the elucidation of the nature of intermolecular interaction in crystalline region, further accumulation of the experimental data is going on.

The authors express their sincere thanks to Professor T. Shimanouchi and Dr. M. Tsuboi of the University of Tokyo for helpful discussions and the measurements of parts of spectra by use of the Perkin-Elmer 112G spectrophotometer.

# *An X-ray Study on the Phase Transition of Aniline Hydrobromide, $C_6H_5NH_3Br$*

By Inao TAGUCHI*

(Received August 1, 1960)

Crystal structures of amine halides can be divided into two groups. To the first group belong methylammonium chloride[1] and *n*-propylammonium halides[2], in which the nitrogen atoms are surrounded by four halogen atoms. To the second group belong adenine hydrochloride[3], hexamethylenediamine dihalides[4], aniline hydrochloride[5] and cyclohexamine hydrochloride[6], in which the nitrogen atoms are surrounded by three halogen atoms. It is interesting to note that those crystals belonging to the first group always exhibit a phase transition at low temperature, whereas no report has ever been made of any phase transition in crystals belonging to the second group.

A preliminary report on the crystal structure of aniline hydrobromide, $C_6H_5NH_3Br$, has been published[7], in which it was shown that the nitrogen atom in this crystal is surrounded by four bromine atoms. During the course of refinement, it was found that the crystal exhibits a peculiar type of phase transition in the neighbourhood of room temperature. Detailed structure analyses of the crystal below and above the transition temperature will soon be reported[8]. In the present paper, an account of an X-ray study on the phase transition of aniline hydrobromide will be given.

**Outline of the Phase Transition.** — Large crystals of aniline hydrobromide in the form described by Groth[9] are easily obtained by evaporation from methanol, ethanol or acetic acid solutions. Preliminary X-ray examinations showed that most of these crystals contained stacking disorder as revealed by diffuse scattering. Crystals free from stacking disorder were found to be obtainable by slow evaporation from methanol solutions. The crystals obtained are long along the [010] axis, and the planes (001) and (100) are predominant. A sharp cleavage is found parallel with (001).

Using these 'single crystals', a series of oscillation and Weissenberg photographs were prepared, using Cu $K$ radiations, about the three principal axes. It was found that not all but many reflections are split into two closely separated spots, appearing more or less blurred. If we ignore these splittings, all the reflections could be indexed based on an orthorhombic unit cell, in accord with the axial ratios given by Groth. It is suggested that these crystals are not really single crystals, but that they consist of repeated twins or polysynthetic twins[10], such as are found in orthorhombic pyroxene[11]. All the reflections appearing on oscillation photographs are split into two along the same $\zeta$-lines, except those of ($hk0$) and ($00l$). These can be interpreted, if we assume that the twin components or domains are oriented to two different directions, and that each domain is in fact monoclinic with an axial angle $\beta$ slightly deviated from 90°, and that all the domains have their $b$- and $c$-axes in common directions. All the reflections appearing on oscillation and Weissenberg photographs were satisfactorily indexed without any ambiguity by two axial systems, as schematically shown in Fig. 1.

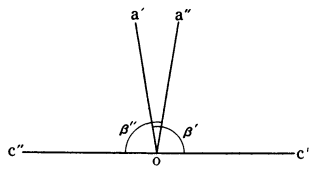

Fig. 1. Schematic representation of the orientations of the principal axes of the two components of the domains.

It was noticed that Weissenberg photographs prepared at different seasons of the year, using one and the same crystal, showed differences in detail. We were led to an assumption that these differences might be caused by a slight

variation of temperature. A series of Weissenberg photographs were taken at various temperatures, using a carefully designed temperature control camera[12], and confirmed the fact that they are really sensitive to temperature in the neighborhood of room temperature. Split reflections observed at 18°C became degenerated into a single one at 25°C, and blurred reflections at 18°C became more or less distinct. These changes were more marked at 50°C. From these observations, it was concluded that the crystal would undergo a phase transition in this temperature range, the splitting and blurring of reflections being associated with the formation of domains. The crystal does not shutter on passing the transition range.

**Variation of the Axial Angle $\beta$ with Temperature.** — From the preliminary experiments stated in the preceding paragraphs, it became clear that the splitting distances of reflections depend upon temperature, implying that the axial angle $\beta$ varies gradually with temperature. The variation of the axial angle $\beta$ with temperature was determined from the splitting distances of the reflection (002), which is the largest and most intense. The results are shown in Fig. 2. It was also found that the

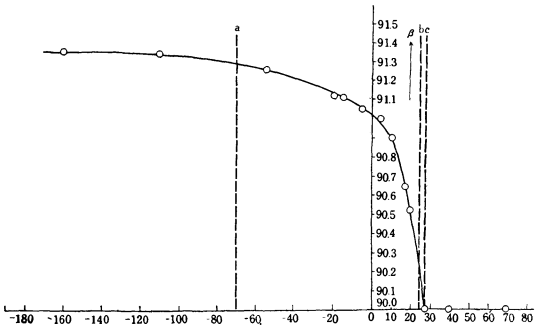

Fig. 2. Variation of the axial angle $\beta$ with temperature.

relative intensities of reflections vary with temperature, parallel with the variation of $\beta$ with temperature. The intensity variation ceases practically outside the range from +30°C to −70°C. The axial angle $\beta$ also remains unchanged outside this region. There was found to be no other phase transition down to −160°C as far as X-ray methods were employed.

The temperature variations of the axial angle $\beta$, of the relative intensities and of the fine structure of reflections were found to be reversible. Photographs taken after cooling or heating are practically the same as those taken before heat treatment.

12) I. Taguchi, *Annual Report Inst. Fiber Research, Osaka Univ.*, **8**, 45 (1954).

Now, in order to investigate the variation of the axial angle $\beta$ with temperature more precisely and to determine the transition temperature of the high temperature side, experiments at smaller temperature intervals were carried out at temperatures, ranging from 15°C to 30°C. Measurements for cooling were made after keeping the temperature of the crystal at 30°C for twenty hours. The results are shown in Fig. 3, where crosses and small circles are the values obtained for heating and cooling respectively. From all the observations and results obtained therefrom the following conclusions are made. (1) The transition temperature range is as wide as 100°C, i. e., from 27.5°C to ca. −70°C. (2) The phase change is perfectly reversible within the experimental error. (3) The phase transition is of a higher order. It was suggested that the specific heat curve would show the $\lambda$ type anomaly. The temperature range between −40°C and 24.5°C, as is shown by dotted lines a and b, might correspond to the ascending part of the specific heat curve, and the range between 24.5°C and 27.5°C as is shown by curves b and c might correspond to the declining part of the same curve. This view was recently verified by a calorimetric measurement[13].

**The Unit Cell Dimensions and Space Groups of the High and Low Temperature Modifications.** —Above 27.5°C, the crystal is orthorhombic, and below this temperature it is monoclinic. The unit cell dimensions and space groups of the two modifications, determined at 70°C and at −110°C, respectively, are given in Table I. There are four formula units in each unit cell.

Table I. The unit cell dimensions and space groups of the high and low temperature modifications

| | 70°C | −110°C |
|---|---|---|
| $a$ | 16.77±0.06 Å | 16.725±0.06 Å |
| $b$ | 6.05±0.03 | 5.95 ±0.03 |
| $c$ | 6.86±0.03 | 6.81 ±0.03 |
| $\beta$ | 90° | 91°22′ |
| Space group | $D_{2h}^{10}$-Pnaa | $C_{2h}^{5}$-$P2_1/a$ |

**Nature of the Domain Structure.**—It was found that the axis [010] and the plane (001) are in common with the two modifications and remain unaltered on passing the transition temperature. These features are illustrated schematically in Fig. 4. Since there are no appreciable changes in the axial parameters, the change of the axes can be taken as a kind of shear, which can be expressed by $\Delta\beta$ as is shown in Fig. 4.

13) H. Suga, This Bulletin, **34**, 426 (1961).

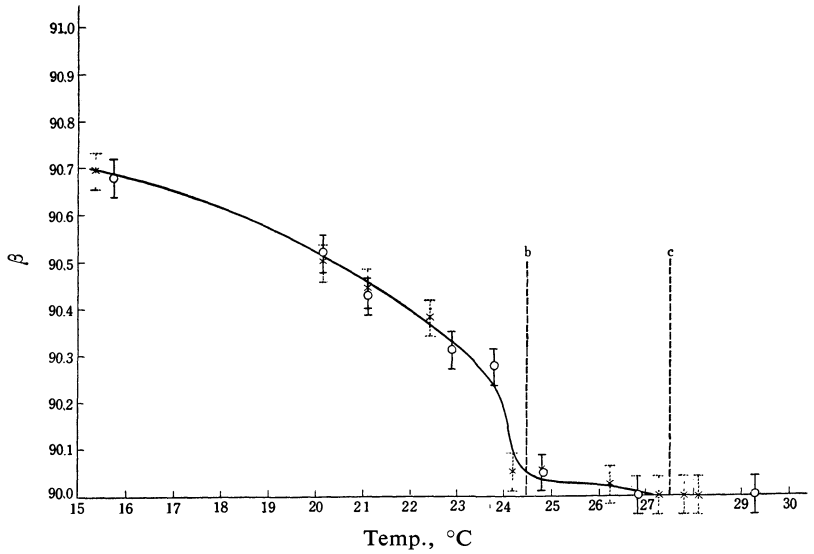

Fig. 3. Details of the variation of the axial angle $\beta$ with temperature.
○ : heating × : cooling

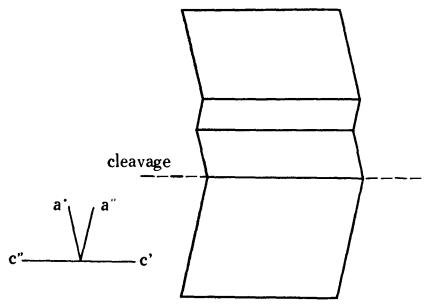

Fig. 4. Cleavage planes and the domain structure.

Below the transition temperature, the crystal is built up by domains which are oriented to the two directions, as shown in Fig. 4. These domains can be seen under a polarized microscope in certain specimens[14].

It was found that the ratios of the intensities within a pair of split reflections vary from specimen to specimen. For numerous specimens these ratios are found to be nearly at unity, as the formation of the two orientations of the domains is expected to occur with equal probability, though we have once found a specimen which is made of nearly a single domain.

Quite independent of these intensity ratios, or the abundance of the two orientations of the domains, each of a pair of split reflections shows a similar fine structure. There were found no complementary features in intensity in these split reflections, suggesting that these domains are interpenetrated.

On passing the transition temperature, no line broadening was ever found. This is in contrast to the observations reported for cobalt oxide[15], CoO, or potassium dihydrogen phosphate[16], $KH_2PO_4$. Thus the lower limit of the size of domains is of the order of $10^{-6}$ cm. No diffuse scattering associated with the splitted reflections was found, hence the domains are distributed in such a way that they are incoherent to X-ray. In this connection, it must be mentioned that in the cases of ferroelectric crystals there has never been reported any polysynthetic twinning associated with the domain formation.

As stated earlier, the (001) plane gives a perfect cleavage. The (100) plane also gives a cleavage at low temperature. It was observed that this latter cleavage becomes poorer as temperature increases, and finally vanishes at 30°C. This cleavage plane is the twinning plane between the two adjacent domains, as shown in Fig. 4. The vanishing of cleavage can be taken as a measure of the coalescence of the domain structure.

**The Mechanism of the Phase Transition.**—It will be interesting to discuss the structural change taking place during the transformation from symmetry considerations. There are four formula units in the unit cell, both of the high and low temperature modifications. The space group, $D_{2h}^{10}$-Pnaa, to which the high temperature modification belongs, requires that the anilinium ion, or more precisely the axis of anilinium ion passing through $N\text{-}C_1\cdots\cdots C_4$ atoms, should lie on a digonal axis. This

14) T. Iwai, to be published.

15) S. Greenwald, *Acta Cryst.*, 6, 396 (1953).
16) A. R. Ubbelohde and I. Woodward, *Proc. Roy. Soc.*, A188, 358 (1947).

implies that the three hydrogen atoms bound to the nitrogen atom are arranged in a statistical way so that the anilinium ion assumes a digonal symmetry in a statistical sense. In the low temperature modification, the anilinium ion is no more restricted by the digonal symmetry by virtue of the low symmetry of the crystal, $C_{2h}^5$-$P2_1/a$. Above the transition temperature, the $-NH_3^+$ group assumes two (or a multiple of two) equally stable orientations with respect to the C-N bond, or it may be flipping among different orientations. When the crystal is cooled down and passes the transition temperature, all the atoms move onto new equilibrium positions and the flipping ceases. These will be the most essential features of this phase transition.

The author would like to express his sincere thanks to Professors I. Nitta and T. Watanabé for their continued interest, and to Dr. Suga for valuable discussions.

# *The Effect of Alcohols on the Solubilization of Oleic Acid in the Aqueous Solution of Sodium Dodecyl Sulfate*

By Ryohei MATUURA, Kazuo FURUDATE, Hidetoshi TSUTSUMI and Seido MIIDA

(Received July 14, 1960)

It may well be established that the solubilizing power of the detergent towards hydrocarbons, such as *n*-heptane[1] and benzene[2], increases by adding alcohols in the detergent solution, the more markedly the longer the hydrocarbon chains of the added alcohols are. The solubilization of polar materials in the presence of alcohols in the detergent solution, however, has not been known well. Kolthoff and Graydon[3] studied the effect of *n*-amyl alcohol and *n*-octyl alcohol on the solubilization of some dyes in the potassium soap solutions and found no such regular and simple relations as for nonpolar substances. Some other studies also reported the complicated nature of the solubilization of polar materials in the presence of additives[4]. In order to make the situation clearer we have investigated the effect of various alcohols on the solubilization of oleic acid in the aqueous solution of sodium dodecyl sulfate.

## Experimental

**Materials.**—Sodium dodecyl sulfate (SDS) used was synthesized from fractionally distilled *n*-dodecyl alcohol and purified by repeated ether extraction. Its purity was confirmed by elementary analysis and surface tension measurements. The alcohols used were purified by distillation and their boiling points were as follows: *n*-butyl alcohol (117°C), *n*-hexyl alcohol (157°C), *n*-amyl alcohol (137.5~138.5°C), *iso*-amyl alcohol (132°C), *n*-octyl alcohol (194°C), *n*-dodecyl alcohol (127°C/7 mmHg) and *n*-hexadecyl alcohol (190°C/15 mmHg). Oleic acid was obtained by distillation at 211°C/6 mmHg.

**Method.** — The solubilization end point was measured by the turbidity method using a Shimadzu AKA photoelectric nephelometer. The experiment was performed at a constant temperature of 25.0°C.

## Results

In Fig. 1 the amount of oleic acid solubilized in the aqueous solution of SDS is plotted against the concentration of the latter. An almost linear relationship has been obtained. When an alcohol is added to the detergent solution beforehand, the solubilization of oleic acid decreases as shown in Figs. 2, 3 and 4 for the case of *n*-butyl, *n*-hexyl and *n*-hexadecyl alcohol, respectively. In Fig. 5 the amount of oleic acid solubilized is plotted against the amount of alcohols added to the detergent solution of 0.05 mol./l. It is seen that the solubilization of oleic acid decreases monotonously as the amount of alcohols added increases and this effect of decreasing the solubilization of oleic acid increases as the chain length of the alcohol increases.

## Discussion

It may be a general agreement that alcohols added can cause a decrease in cmc of the detergent solution and an increase in micelle volume by penetration into the micelle surface. In the case of SDS solutions, Hutchinson et al.[5] measured the cmc in the presence of *n*-hexyl, *n*-heptyl and *n*-octyl alcohols and found that the cmc decreases as the amount of alcohols added increases. When hydrocarbon is solubilized in the detergent solution in the presence of alcohols, therefore, it is evident that its solubilization increases as the amount of alcohols added increases, since hydrocarbon is considered to dissolve in the micelle interior which has been made larger by the presence of alcohols. A typical example of the solubilization of hydrocarbon in the detergent solution in the presence of alcohols may be given by the result obtained by Klevens[1], which is reproduced in Fig. 6. This shows

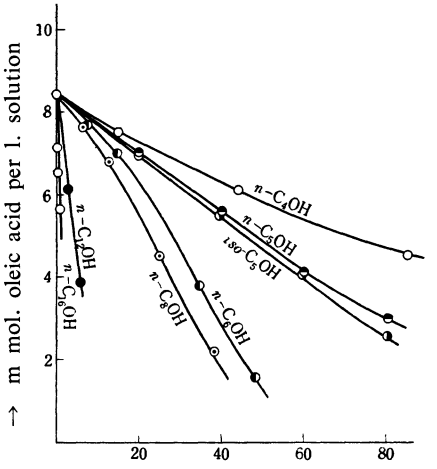

Fig. 5. The Effect of alcohols on the solubilization of oleic acid in 0.05 M SDS solution.

the effect of alcohols on the solubilization of *n*-heptane in the aqueous solution of potassium tetradecanoate. It is clearly seen that the solubilized amount of *n*-heptane increases as the amount of added alcohols increases, and that the effect of alcohols to increase the solubilization of the hydrocarbon increases with the chain length of the alcohols. The result shown in Fig. 6 is quite contrary to the result obtained in the present experiment which is shown in Fig. 5. The solubilized amount of oleic acid decreases as the amount of alcohols added increases, the more markedly the longer the hydrocarbon chain of the alcohols is. It will be reasonable to ascribe this difference to the fact that hydrocarbon dissolves in the micelle interior, while polar materials, such as oleic acid in the present experiment, dissolve in the palisade layer of the micelle. Since alcohols also dissolve in the palisade layer, oleic acid will be hindered from dissolving in the same place by already existing alcohol molecules, the result being that the solubilization of oleic acid decreases as the amount of alcohols increases in the detergent solution, as shown in Fig. 5.

In connection with the above explanation it may be interesting to note the effect of electrolytes on the solubilization of nonpolar and polar materials in the detergent solution. Klevens[6] studied the solubilization of *n*-heptane and *n*-octyl alcohol in the aqueous solution of potassium myristate in the presence of potassium chloride, potassium sulfate and potassium ferrocyanate. He found that the solubility of *n*-octyl alcohol decreases, while that of *n*-heptane increases, with the increasing electrolyte concentration in the detergent solution. Klevens explained this difference as follows. The increased aggregation of the micelles in the presence of electrolytes results in an increase in micelle interior volume which is available to a nonpolar solute, butre sults in a decrease in the micellar area which is available for penetration by a polar solute. Richards and McBain[7] also report that the presence of sodium chloride and potassium chloride decreases the solubilizing power of cetyl pyridinium chloride towards polar materials such as *n*-octyl alcohol and benzaldehyde, but increases that towards nonpolar materials such as benzene and *n*-octane. These results

conform in their behaviors to the result obtained in the present experiment, the same explanation being applied, although the additives are electrolytes in the former and alcohols in the latter experiments.

It is to be noted that the concentration of alcohols in the detergent solution shown in Fig. 5 is not so great as that in Fig. 6. We found that, in the case of *n*-butyl and *n*-amyl alcohol, when the amount of alcohols in the detergent solution becomes greater than that shown in Fig. 5 the solubilization of oleic acid turns out to increase with the concentration of the alcohols in the detergent solution. The case of *n*-amyl alcohol is shown in Fig. 7. Since these alcohols are fairly soluble in water, the solvent property of water will alter as the amount of the alcohol in it becomes greater, the result being that the solubility of oleic acid in the solvent liquid will become appreciable. Also it may be probable that the micelle-forming property of the detergent is lessened by the presence of water soluble alcohols in fairly large concentrations, the result being that the solubilization of oleic acid in the detergent micelle will decrease. These two factors counteract each other in the determination of solubility of oleic acid in the detergent plus alcohol solutions. We see in Fig. 2 that the solubilization of oleic acid decreases when the concentration of the detergent containing *n*-butyl alcohol (mole ratio 1 : 3) exceeds a certain value. This may be attributed to the predomination of the factor of lessening the solubilization in the detergent micelle. On the contrary the result obtained in Fig. 7 may be attributed to the predomination of the factor of increasing the solubility of oleic acid in the water-alcohol mixture.

## Summary

The solubilization of oleic acid in the aqueous solution of sodium dodecyl sulfate was studied in the presence of various kinds of alcohols in various concentrations. When the concentration of alcohols in the detergent solution is not so great, the solubility of oleic acid decreases as the amount of alcohols increases. This is explained by the solution of oleic acid and alcohols in the same place in the micelle, i. e., in the palisade layer. When the water soluble alcohols are used the solubilization of oleic acid turns out to increase at a certain concentration of the alcohols in the detergent solution. This is explained by the solution of oleic acid in the solvent liquid as well as in the detergent micelles.

# *Synthesis and Physical Properties of Normal Higher Primary Alcohols. III. Synthesis of Normal Higher Primary Alcohols of Even Carbon Numbers from Dodecanol to Hexatriacontanol*

By Akira WATANABE*

(Received July 23, 1960)

In the previous investigation of this series[1,2] the author confined his attention to the synthesis of normal higher alcohols of odd carbon numbers. In view of the interesting results on the physical properties, especially the transition phenomena of these alcohols in the solid state, it was felt desirable to extend the study to alcohols of even carbon numbers, and thirteen members with even carbon atoms ranging from $C_{12}$ to $C_{36}$ were synthesized and their transition points were observed.

The alcohols were all prepared by the lithium aluminum hydride reduction of the corresponding fatty acids or their ethyl esters, of which acids from $C_{12}$ to $C_{22}$ were obtained by careful purification of commercial specimens.

Tetracosanoic acid ($C_{23}H_{47}CO_2H$) was synthesized from docosyl bromide ($C_{22}H_{45}Br$) by the modified malonic ester synthesis[3]. The method employed for the synthesis of the fatty

acids with more than 24 carbon atoms is Bowman's synthesis:

$$C_2H_5O_2C(CH_2)_nBr \xrightarrow{\text{Ethyl malonate}}$$
(I)

$$C_2H_5O_2C(CH_2)_nCH(CO_2C_2H_5)_2 \xrightarrow{\text{Benzyl alcohol}}$$
(II)

$$C_6H_5CH_2O_2C(CH_2)_nCH(CO_2CH_2C_6H_5)_2 \xrightarrow{RCOCl}$$
(III)

$$C_6H_5CH_2O_2C(CH_2)_nC(CO_2CH_2C_6H_5)_2COR \xrightarrow{H_2(Pd)}$$
(IV)

$$HO_2C(CH_2)_nC(CO_2H)_2COR \xrightarrow{\text{Decarboxylation}}$$
(V)

$$RCO(CH_2)_{n+1}CO_2H \xrightarrow[\text{reduction}]{\text{Huang-Minlon}}$$
(VI)

$$R(CH_2)_{n+2}CO_2H \xrightarrow[LiAlH_4]{\text{Esterification}} R(CH_2)_{n+3}OH$$
(VII) (VIII)

Although this method was extensively applied in the preparation of odd members[1,2], the yields of the ketonic acids were low and fluctuated (maximum 37%) compared with those obtained by Bowman (70%). Nunn[4] and Hougen[5] reported similar low yields, and ascribed them to the ketonic hydrolysis of the ketoesters, although their studies appeared not to be extensive. Since it was felt necessary to increase the yield and convenience in order to develop the present study, several improvements in the synthetic technique were made and the results are reported in this paper.

It was found that partial hydrolysis of triester II occurred in spite of precautions during the reaction of alcoholysis as evidenced by the isolation of the carboxylic acid from the reaction mixture in an amount of 30% to the starting triester and by the recovery of a nearly corresponding amount of benzyl alcohol. It seemed quite probable that the presence of this acid and the alcohol was detrimental to the subsequent malonic ester condensation. The procedures were then improved as follows, giving the desired product with a fairly good and consistent yield.

After the alcoholysis the acid was removed with a sodium carbonate solution and benzyl alcohol was distilled off under reduced pressure. Tribenzyl ester III, freed from the acid and benzyl alcohol and obtained as an oil, was condensed with an acid chloride by means of sodium ethoxide to give compound IV. Hydrogenolysis of compound IV and subsequent decarboxylation yielded ketonic acid VI in a yield of 65% based on the acid chloride. Details of the procedures are given in the Experimental Part.

In order to avoid the hydrolysis of triester II, the use of sulfuric acid, hydrogen chloride, and zinc chloride as the catalysts for the alcoholysis were attempted with no success. Metallic sodium, instead of sodium ethoxide, was used in the malonic ester condensation without success, probably because the hydrogen from the reaction of sodium with the malonic ester cleaved the benzyl groups.

Another factor which affects the yield is the instability of compound IV as shown by the fact that this compound was decomposed even at room temperature by the hydrochloric acid liberated from the unchanged acid chloride on washing the reaction mixture with water. At temperature low enough to be harmless to the compound it was quite difficult to decompose the acid chloride with water when the carbon chain of the acid was long. Therefore, it is advisable to use slightly less than one equivalent of the acid chloride to obtain a good yield.

It has been known that Bowman's synthesis suffers from the catalyst poisoning which can not be avoided on account of the difficulty in purification of compound IV, and it was experienced in the previous study[2] that a long period was required for complete hydrogenolysis when the intermediate acid chloride could not be purified by distillation. However, in the present experiments, it was found advantageous to purify compound IV with activated aluminum oxide, permitting the complete hydrogenolysis with great saving in time and catalysts and with no lowering of the yield of ketonic acid V.

The ketonic acids thus obtained were all converted into the corresponding fatty acids by Huang-Minlon reduction[6] and the desired alcohols were obtained easily by the lithium aluminum hydride reduction of the fatty acids or their ethyl esters. The alcohols were purified with great care to obtain the final products with sharp melting points and excellent analytical values. For hexacosanol $C_{26}H_{53}OH$ and higher alcohols high vacuum ($2\times10^{-3}$ mmHg) distillation as well as recrystallization was employed.

An alternative chain-lengthening process for the synthesis of octacosanol $C_{28}H_{57}OH$ is Cason's method[7], which consists in the condensation of a dialkyl cadmium with a halfester-acid chloride. The accompanying flow chart indicates the reaction:

$$C_{18}H_{37}OH \xrightarrow{HBr} C_{18}H_{37}Br \rightarrow C_{18}H_{37}MgBr \xrightarrow{CdCl_2} (C_{18}H_{37})_2Cd \xrightarrow{ClOC(CH_2)_8CO_2C_2H_5}$$

$$C_{18}H_{37}CO(CH_2)_8CO_2C_2H_5 \xrightarrow[\text{reduction}]{\text{Huang-Minlon}}$$

$$C_{27}H_{55}CO_2H \xrightarrow[LiAlH_4]{\text{Ethyl ester}} C_{28}H_{57}OH$$

The alcohol obtained by this method was shown to be identical with that obtained by Bowman's method by the mixed melting point and the X-ray data[8].

Melting points, transition points and analytical data of the alcohols synthesized here are given in Table I. The transition points of the alcohols with more than 22 carbon atoms have been unknown. All the alcohols described in this paper and two previous papers, namely odd and even members from $C_{11}$ to $C_{37}$, are being studied for their physical properties and part of the results has been published from the Department of Physics of Kyoto University[9-11]. Thermal data will be reported in this Bulletin in near future.

## Experimental

Since the reactions used for the synthesis of the lower members are well known, descriptions of the experiments are omitted. Bowman's[4] method was applied with some improvements for the synthesis of the alcohols with more than 24 carbon atoms. As the conditions except those for isolation of the products, were essentially the same throughout the series, the synthesis of octacosanol is described as an illustration. Combinations of the starting materials and the intermediates are listed in Table II.

*Ethyl n-Undecane-1, 1, 11-tricarboxylate.* — It was

prepared by condensation of ethyl bromoundecanoate with ethyl malonate as already described[2].

B. p. 187°C/1 mmHg, $n_D^{28}$ 1.4435.

*Benzyl n-Undecane-1, 1, 11-tricarboxylate*.—In a 200 ml. three-necked flask, equipped with a mechanical stirrer, a dropping funnel and a reflux condenser fitted with a calcium chloride tube, were placed 0.65 g. of sodium sand (finely powdered in toluene) and 50 ml. of thiophene-free dry benzene. To the mixture was added from the dropping funnel 10 g. of ethyl *n*-undecane-1, 1, 11-tricarboxylate. The mixture was allowed to stand at room temperature for about 6 hr. with stirring and then moderately heated to the complete disappearance of the sodium. After 8.7 g. of freshly distilled benzyl alcohol was added, the condenser was replaced by a Fenske column and the mixture was heated to distill off ethanol as the benzene ethanol azeotrope. During the distillation reflux-ratio was controlled from 6 : 1 to 20 : 1 (2~3 drops per minute). When no more ethanol distilled over, the boiling point reaching 79°C and the absence of the ethanol in the final portion of the distillate being confirmed by the index of refraction, the mixture was cooled and acidified with dilute sulfuric acid. The benzene layer was separated, washed with water, with sodium carbonate solution, again with water to neutral reaction, and dried over sodium sulfate.

After evaporating the benzene, the residue was heated to 120°C in an oil bath under reduced pressure (3 mmHg), the flask being immersed into the bath as deeply as possible to remove the benzyl alcohol completely. Recovered benzyl alcohol weighed 2.5 g. The Tribenzyl ester III remained in the flask as an oil which weighed 11 g. On acidification of the above alkali washing with sulfuric acid, an oily substance separated out which gradually crystallized on standing several days. Recrystallization from ethyl acetate-petroleum ether gave the product in white crystals, m. p. 89°C. It was found not to depress the melting point when mixed with the acid obtained by hydrolysis of the triester.

*13-Keto-octacosanoic Acid* $C_{15}H_{31}CO(CH_2)_{11}CO_2H$.—In a 200 ml. three-necked flask, 0.41 g. of freshly cut sodium was placed. Absolute ethanol (5 ml.) was added to give a clear solution. All excess of the ethanol was distilled off until a crust of sodium ethoxide was formed on the surface of the residue. Then 15 ml. of dry thiophene-free benzene was added from the dropping funnel. To this suspension a solution of 11 g. of the tribenzyl ester in 10 ml. of benzene was added and the mixture was allowed to stand at room temperature with occasional shaking, while the solid gradually went into solution. The benzene was removed under reduced pressure at room temperature, leaving a brown syrup in the flask. Two portions of 10 ml. of fresh benzene were added and removed under reduced pressure to remove the last traces of ethanol. Thus the sodium salt of the tribenzyl ester was obtained as a brown viscous material, to which 30 ml. of fresh benzene was added, giving a colored solution. Then the flask was equipped with a stirrer and a reflux condenser fitted with a calcium chloride tube. A solution of 5.2 g. of palmitoyl chloride (prepared from pure acid and thionyl chloride, b. p. 148°C/1.5 mmHg) in 10 ml. of benzene was added from the dropping funnel with stirring and the mixture was refluxed for 30 min. with continued stirring.

After the reaction mixture attained room temperature the flask was immersed in an ice bath. Ice-cooled water containing 1 g. of sulfuric acid was added gradually with vigorous stirring, the temperature of the mixture being maintained at 3 to 5°C. The contents of the flask were then transfered to a separating funnel. The layers were separated with the aid of a small amount of ethanol and the benzene layer was washed with water to neutral reaction with occasional cooling to prevent the temperature from rising above 5°C. After the solution was dried over sodium sulfate the benzene was removed under reduced pressure at about 30°C of bath temperature. The condensation product remained as an oil (15 g.). A solution of 5 g. of the above product in a mixture of 15 ml. of ethyl acetate and 15 ml. of absolute ethanol was shaken with Pd-C (0.2 g.) and Pd-$SrCO_3$ (0.2 g.) in a hydrogen atmosphere at room temperature. Catalyst poisoning was so often encountered that it was necessary to add fresh catalysts frequently until a nearly theoretical amount of hydrogen was absorbed. The total amount of the catalyst used was 2.7 g. The time required for the complete hydrogenolysis was about 4 hr. The solution freed from the catalyst was refluxed for 30 min. to decarboxylate the product. Upon cooling the solution to room temperature white crystals appeared. These were collected and washed with ethyl acetate. The ketonic acid obtained showed the melting point of 91 to 94°C. Yield was 1.5 g. The filtrate and washing were combined and concentrated to a syrup. To this was added 10 ml. of acetic acid containing 1 ml. of sulfuric acid and the mixture was refluxed for 40 min. The solid residue obtained on removing acetic acid was taken up in benzene and the solution was washed and dried over sodium sulfate. Concentration and subsequent cooling of the benzene solution gave white crystals which melted at 93 to 97°C and weighed 0.6 g. The substance was combined with the acid obtained from the ethyl acetate solution and the combined crystals were recrystallized twice from benzene. The pure ketonic acid showed the melting point of 99.5°C. The yield was 1.8 g. or 65% based on palmitoyl chloride.

Found : C, 76.60 ; H, 12.45. Calcd. for $C_{28}H_{54}O_3$: C, 76.65 ; H, 12.41%.

Palmitic acid (0.15 g.) was recovered from the filtrate of the ketonic acid.

*Purification of the Condensation Product (IV)*.—The product (5 g.) was dissolved in 20 ml. of pure benzene (dried over sodium wire) and the solution was shaken with active alumina for a short period. The alumina was filtered off and the filtrate was evaporated under reduced pressure at about 30°C of bath temperature to give a colorless liquid. This was hydrogenated in the same manner as described above. Absorption of the first 280 ml. of hydrogen proceeded rapidly (30 min.) with 0.4 g. of the catalyst. The second 140 ml. was absorbed in about 1 hr. with the addition of 0.3 g. of the catalyst. The product was treated in the same way as the

above. The yield of the pure ketonic acid was 1.8 g. (65%).

*Octacosanol* $C_{28}H_{57}OH$. — Octacosanoic acid ($C_{27}H_{55}CO_2H$) was obtained from 3 g. of the ketonic acid by the Huang-Minlon reduction[6] in a yield of 77% (2.2 g.). Details were given in the previous paper[2] for the reaction of other higher alcohols. The melting point was 90.2°C (recrystallized from toluene).

Found: C, 79.10; H, 13.34. Calcd for $C_{28}H_{56}O_2$: C, 79.18; H, 13.29%.

The acid was converted into its ethyl ester by a usual method. The lithium aluminum hydride reduction[2] of 2 g. of the pure ester (recrystallized from benzene, m. p. 64°C) afforded 1.4 g. of the desired alcohol after recrystallization from benzene. The melting point was 82.5°C. Further purification of the alcohol was tried by high vacuum distillation ($2\times10^{-3}$ mmHg) followed by recrystallizations. Although the melting point and analytical data were not changed, the physical data[8] indicated that these procedures seemed to be necessary to obtain a pure sample.

The author expresses his sincere thanks to Professor Ryozo Goto, Kyoto University, for his kind guidance throughout this study. Thanks are also due to Mr. T. Araki and Mr. H. Horino for their assistance in some of the experiments. The cost of this work was partly defrayed from a grant (Shigenkagaku Kenkyuhi) from the Ministry of Education.

# *Distribution of Neptunium between Di-(2-ethyl hexyl)-phosphoric Acid and Mineral Acids*

By Eiko NAKAMURA

(Received June 28, 1960)

Solvent extraction studies on neptunium have been carried out using tri-*n*-butyl phosphate[1-4], tertiary amines[5], thenoyl tri-fluoro acetone[6], diethyl ether[7] or methyl isobutyl ketone[7], as an extractant.

However, the extraction behavior of neptunium using di-(2-ethyl hexyl)-phosphoric acid, HDEHP, has not been reported. The experimental results in the works referred to above have usually been complicated unless careful precautions were taken, because the neptunium tracer solution often contains neptunium in two or three oxidation states. Giving special attention to the oxidation states of neptunium, the extraction behavior of quadri-, quinqui- and sexi-valent neptunium in the system of diluted HDEHP vs. hydrochloric or perchloric acid was studied in this work.

Di-(2-ethyl hexyl)-phosphoric acid has been proved to be useful as a solvent extracting agent for uranium(VI) and other metals. Some works about this extracting agent have been published by a number of investigators[8-10]. Recently a comprehensive study on the extraction of metal ions from hydrochloric acid solution has been reported by Kimura[11]. According to these previous works, it seems that HDEHP behaves as a cation extracting reagent in the low acidity region. In other words, HDEHP-metal ion complex is formed with the inorganic cation in the aqueous phase, and extracted into the organic phase which is composed of the organic diluent and HDEHP. The neptunium(IV), (V) and (VI) cations also seemed to be extracted as the HDEHP-neptunium(IV), (V) or (VI) cation complex.

## Experimental

**Reagents.**—The HDEHP received from Virginia Chemicals, Co. Ltd. was purified by the method of Peppard et al.[12] It was diluted with toluene, C. P.

grade, in this work. Hydrochloric and perchloric acids, analytical grade, were used as received.

Carrier-free 2.3d-neptunium-239, 27.5d-protactinium-233 and 24.1d-thorium-234 were prepared as described in the previous paper[1,13]. The activities of these nuclides were measured by a gamma-scintillation counter. Zirconium-niobium-95 imported from the Oak Ridge National Laboratory, Tenn. USA, was used as received and measured the hard beta-rays of zirconium-95 cutting off the soft beta-rays of niobium-95.

The radiochemical purity of the tracers was checked by gamma-spectrometry, beta-ray absorption and decay.

According to the method written in the previous work[1], the quadri-, quinqui- and sexi-valent neptunium tracers were prepared. In the case of quadrivalent neptunium, hydrochloric acid was used as the aqueous medium, because neptunium(IV) is unstable in a perchloric medium[1].

**Distribution Measurement.**—All experiments were carried out with radioactive tracers. The distribution ratio, $K_d$, of a given nuclide was determined in the usual way[1,11]. The scrubbing techniques were used in every case in order to obtain the $K_d$ values exactly. In all cases both acid and solvent dependence of the $K_d$ values were determined.

## Results and Discussion

**Distribution of Sexivalent Neptunium in the System of HDEHP vs. Perchloric Acid.**—The distribution ratios of sexivalent neptunium were determined in the system of about 0.6% (v/v) HDEHP-toluene vs. perchloric acid varying the acidity from 0.1 to 0.5 N. Experimental results are shown in Fig. 1 where the curve for uranium(VI), taken from the work of Baes et al.[8], is also given for comparison. Baes et al. determined the distribution ratio of uranium in the system of 0.1 M (3.33% v/v) HDEHP-hexane vs. perchloric acid changing the acidity from 0.01 to 2.0 N.

From these results it is found that both sexivalent neptunium and uranium are extracted very well with HDEHP from perchloric acid solution. As Fig. 1 shows, both lines for neptunium and uranium have the slope of −2, suggesting a close similarity between uranium (VI) and neptunium(VI) ions.

The solvent dependence of $K_d$ values for sexivalent neptunium was determined at 0.52 N perchloric acid concentration using toluene as the diluent. Experimental results for neptunium(VI) are shown in Fig. 2 together with the solvent dependence curve for uranium at 1 N perchloric acid, which is quoted from the work of Baes et al.[8] The distribution ratios of neptunium(VI) and uranium(VI) show the second power dependence on the HDEHP concentration, again suggesting the similarity

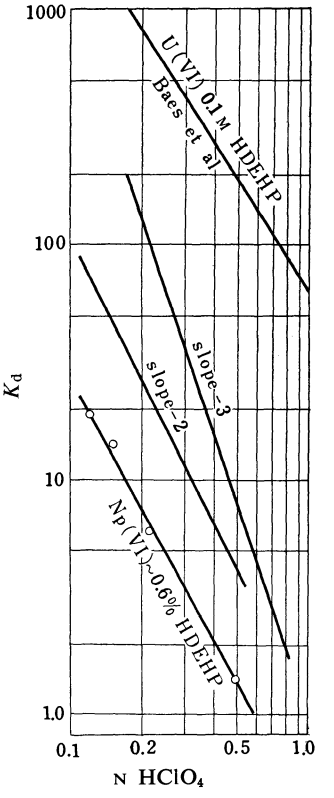

Fig. 1. The acid dependence of $K_d$ values for neptunium(VI) and uranium(VI).

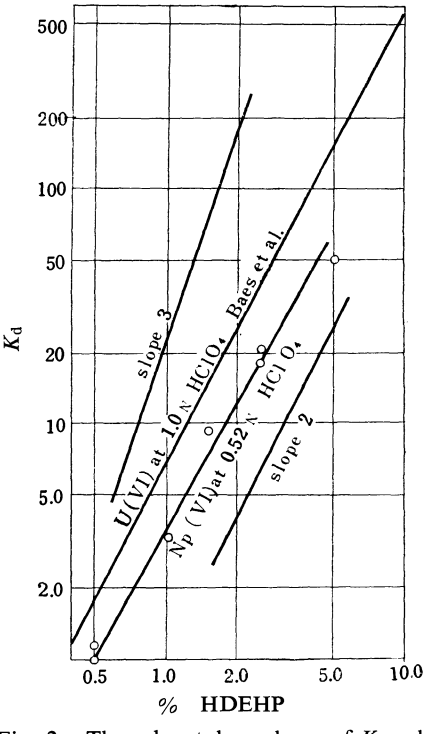

Fig. 2. The solvent dependence of $K_d$ values for neptunium(VI) and uranium(VI).

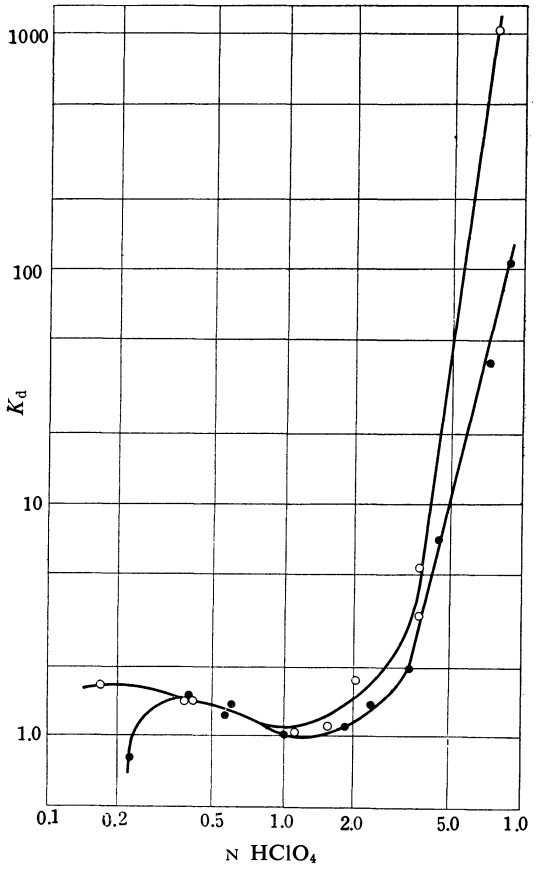

Fig. 3. The variation of the $K_d$ values for sexivalent neptunium[5] and uranium[14] in the system of 100% TBP vs. perchloric acid.
—○— U(VI) by Naitō —●— Np(VI)

between the chemistry of sexivalent neptunium and uranium in an acid solution.

The similarity between sexivalent neptunium and uranium is also found in other systems:

The acid dependence curves for neptunium-(VI)[1] and uranium(VI) in the system of 100% TBP vs. perchloric acid are given in Fig. 3 which shows that the behavior of sexivalent neptunium resembles that of uranium quite well, where the uranium curve is taken from the work of Naito[14]. Besides that found in the perchloric acid system similar behavior is also found in the nitric acid system. The acid dependence curve for neptunium(VI) also resembles that for uranium(VI)[1,2] in 100% TBP* vs. nitric acid system or in the trioctylamine vs. nitric acid system[5]. Thus it is likely that sexivalent ions of neptunium and uranium show almost the same behavior in the distribution experiments discussed above. In

* Tri-*n*-butyl phosphate.
14) K. Naito, This Bulletin, 33, 363 (1960).

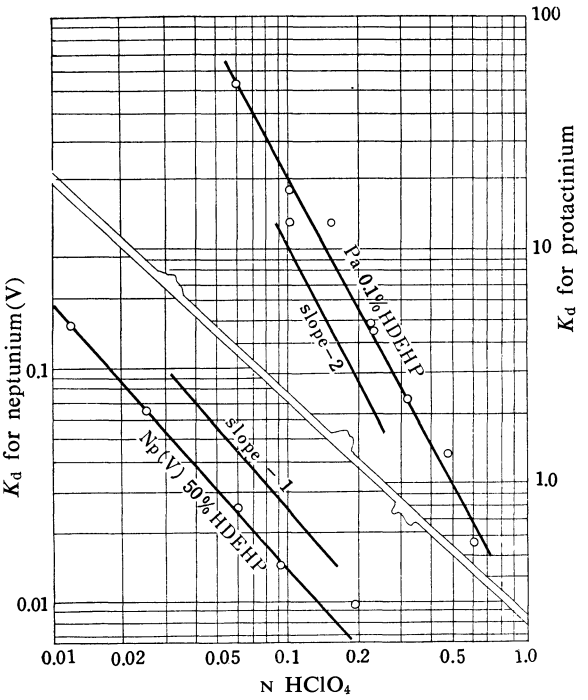

Fig. 4. The acid dependence of $K_d$ values for neptunium(V) and protactinium.

other words, the extraction mechanism of neptunium(VI) seems to be analogous to that of uranium(VI).

According to Baes et al.[8], who discussed the composition of uranium-HDEHP complex based on the acid and the solvent dependence of the $K_d$ values for uranium in the system of HDEHP vs. perchloric acid, the uranium-HDEHP complex is $UO_2A_4H_2$, where HA represents HDEHP molecule. As mentioned above, both acid and solvent dependence of $K_d$ values for neptunium-(VI) in the HDEHP vs. perchloric acid system coincide with those of uranium(VI), so that it is presumed that the neptunium(VI) ion is extracted forming the neptunium(VI)-HDEHP complex, $NpO_2A_4H_2$.

**Distribution of Quinquivalent Neptunium in the System of HDEHP vs. Perchloric Acid.**— The distribution ratios of quinquivalent neptunium were determined in the system of 50% HDEHP-toluene vs. perchloric acid varying the acidity from 0.01 to 0.2 N. The results obtained are given in Fig. 4, where the $K_d$ values for protactinium are also shown. The $K_d$ values for protactinium were so high that the relationship between the acidity and the $K_d$ values for protactinium could not be found clearly using 50% HDEHP with which the extraction of neptunium(V) was studied. Therefore, 0.1% HDEHP-toluene was chosen as the extractant in the determination of the $K_d$ values for

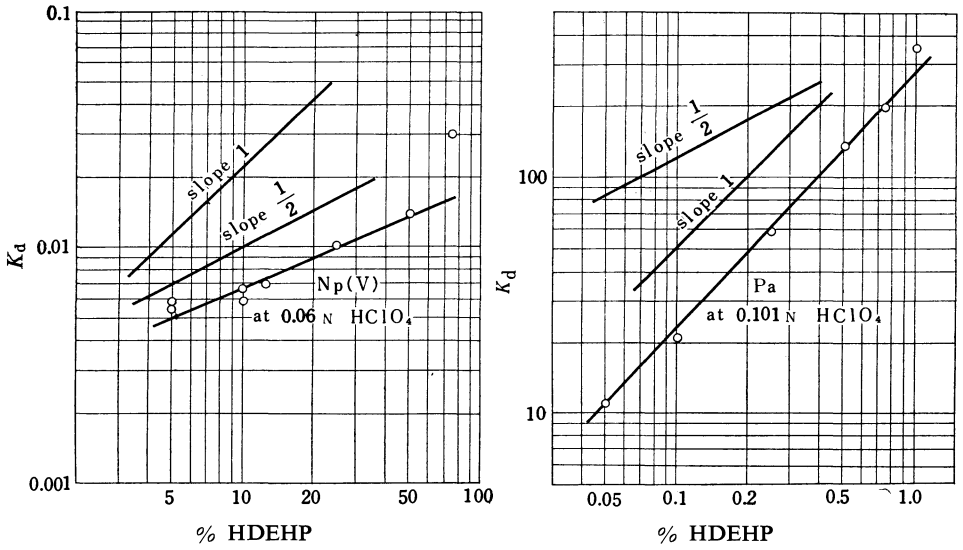

Fig. 5. The solvent dependence of $K_d$ values for neptunium(V) and protactinium.

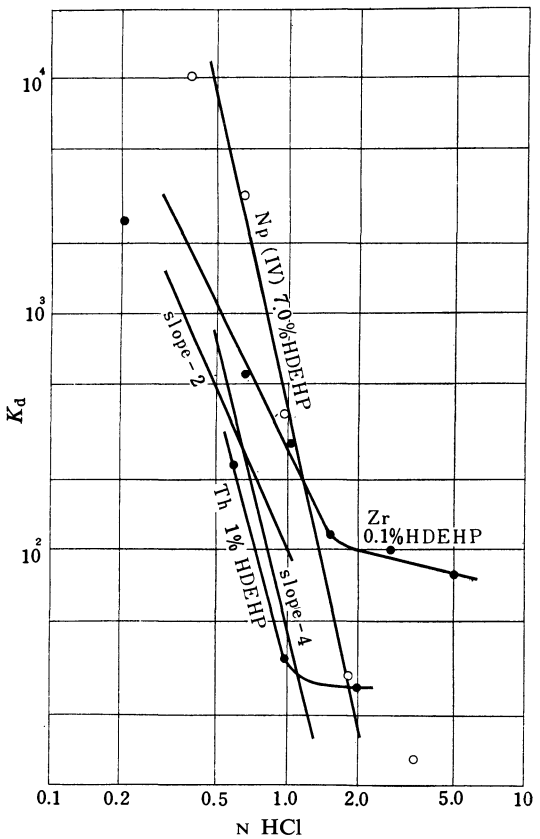

Fig. 6. The acid dependence of $K_d$ values for neptunium(IV), thorium and zirconium.

protactinium varying the acidity of perchloric acid from 0.05 to 1.0 N. As Fig. 4 shows, the slope of the line for neptunium(V) is −1, whereas that for protactinium is −2. Thus it is likely that the neptunium(V) ion behaves differently from the protactinium ion in a dilute perchloric acid medium.

The variation of the $K_d$ values of neptunium-(V) and protactinium with the concentration of HDEHP in the organic phase, keeping the concentration of perchloric acid in the aqueous phase constant, is shown in Fig. 5. As Fig. 5 shows, the line for neptunium(V) has the slope of 1/2, whereas that for protactinium has the slope of 1. Assuming that the solvent dependence of $K_d$ values for protactinium is kept at the first power up to 50% HDEHP at 0.1 N perchloric acid solution, it is calculated that the $K_d$ value for protactinium is about $10^4$, 500 times that of the $K_d$ value shown in Fig. 4. On the other hand, in the 0.1 N perchloric acid-50% HDEHP system quinquivalent neptunium shows the $K_d$ value of about $10^{-2}$ (Fig. 4). The difference of the $K_d$ values between neptunium(V) and protactinium, $10^4$ and $10^{-2}$, shows that quinquivalent neptunium is less extractable than protactinium with the organic extractant from the aqueous phase. Similar relationships are seen in other cases like the system of 100% TBP vs. some mineral acids[1].

As mentioned above, the both acid and solvent dependence of $K_d$ values for neptunium-(V) show different values from those of protactinium. These facts suggest the difference between the chemistry of quinquivalent neptunium and protactinium.

**Distribution of Quadrivalent Neptunium in the System of HDEHP vs. Hydrochloric Acid.** —The distribution ratio of quadrivalent neptunium was determined in the system of 7.0%

HDEHP vs. hydrochloric acid varying the acidity from 0.5 to 3.0 N. The results are shown in Fig. 6, where the $K_d$ values for thorium and zirconium are also given. The behavior of thorium was studied in the acidity range from 0.6 to 2.0 N using 1% HDEHP-toluene solution. Although zirconium is not a member of the actinide elements, the behavior of zirconium was studied as a quadrivalent species in the system of 0.1% HDEHP vs. hydrochloric acid varying the acidity from 0.2 to 4.0 N, where the $K_d$ values for zirconium are so high that HDEHP-toluene solution had to be diluted to 0.1%.

From these results, it is found that thorium and zirconium are more extractable than quadrivalent neptunium. As is shown in Fig. 6, the lines for neptunium(IV) and thorium both have the slope of −4. The behavior of thorium had been studied by Peppard and Ferraro who had also found negative fourth power dependence of the $K_d$ values on the acidity of hydrochloric acid[10]. On the other hand, zirconium shows a negative second power dependence on the acidity. The difference between the neptunium(IV) and zirconium ion seems to be greater than that between the neptunium(IV) and thorium ion.

The $K_d$ values for quadrivalent neptunium in the system of 0.5 N hydrochloric acid vs. HDEHP-toluene are studied, the HDEHP concentration being varied. In Fig. 7, the neptunium(IV) curve is compared with those for thorium and zirconium. The behavior of thorium is taken from the work of Ishimori[15] in the system of 0.5 N perchloric acid vs. HDEHP-toluene. Peppard and Ferraro had also given a third power dependence of the $K_d$ values for thorium on the hydrochloric or perchloric acid concentration. On the other hand, the results for zirconium obtained presently fall on a line of slope 2 in Fig. 7. Thus it is shown again that the quadrivalent neptunium ion behaves in a manner more nearly similar to thorium ion than to zirconium ion in the hydrochloric acid solution.

It is likely that the HDEHP extraction mechanism of neptunium(IV) from hydrochloric acid is similar to that of thorium ion, because both acid and solvent dependence of $K_d$ values for neptunium(IV) coincide with those of thorium. That is to say, neptunium-(IV)-HDEHP complex is supposed to have an

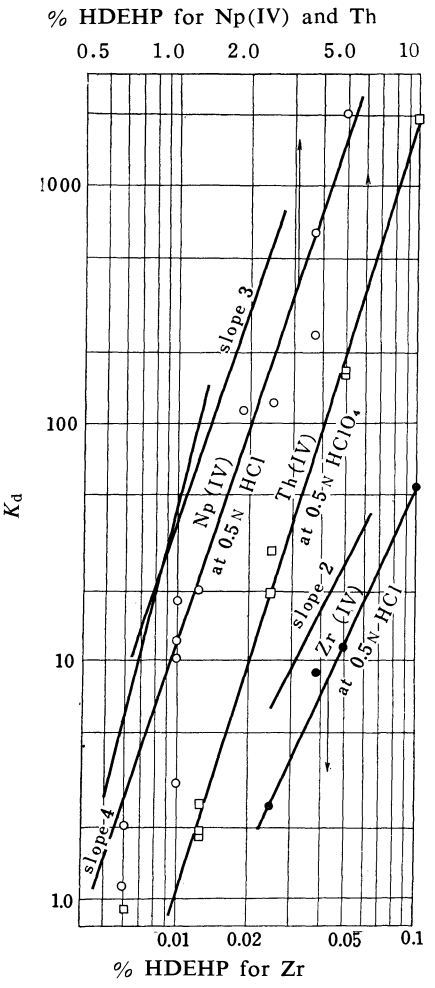

Fig. 7. The solvent dependence of $K_d$ values for neptunium(IV), thorium and zirconium.

iso-morphous structure with that of thorium-(IV)-HDEHP complex. As the formula for the thorium complex, Peppard and Ferraro gave $ThA_2(HA_2)_2$ which was proposed from the results of the infrared spectra and the elementary analysis, where HA denotes the HDEHP molecule. Therefore it might be reasonable to give $NpA_2(HA_2)_2$ for the neptunium(IV)-HDEHP complex.

The author wishes to thank Dr. Tomitaro Ishimori for criticism and suggestions which made a major contribution to this work.

# *The Competitive Reduction of Nitrobenzene and para-Substituted Nitrobenzenes with Nickel Catalysts*

By Akira SUGIMORI*

(Received July 26, 1960)

Several approaches to the elucidation of the mechanism of catalytic reduction may be possible. The present paper describes the competitive reduction of nitrobenzene and substituted nitrobenzenes with nickel catalysts. In all the cases examined, the nitro compounds with an electron attracting group in para position were reduced preferentially to those with an electron repelling group in the same position.

## Experimental

**Materials.** — Nitro compounds were purified by recrystallization or redistillation. The melting points and boiling points are listed in Table I.

TABLE I

| Compound | M. p. | B. p. |
|---|---|---|
| Nitrobenzene | | 95.5～97°C/ 17～18 mmHg |
| *p*-Nitrophenol | 113°C | |
| *p*-Nitroanisole | 52 ～ 53°C | |
| *p*-Nitroaniline | 145.5～146.5°C | |
| Ethyl *p*-nitrobenzoate | 55 ～ 56°C | |
| *p*-Nitrobenzaldehyde | 105 ～105.5°C | |

**Preparation of Catalysts.** — a) Raney nickel catalyst. The method of Adkins and Billica[1] was modified in order to obtain stable catalytic activity. One gram of nickel-aluminum alloy (Ni 40%) was treated with 7 ml. cf. 20% aqueous sodium hydroxide at 50°C for 50 min. Then the catalyst was washed ten times by decantation with 20 ml. of cold water. The pH of the last washing wad 8.5～9.0. The catalyst was then washed twice with 20 ml. of 95% ethanol.

b) Urushibara nickel A (U-Ni-A) was prepared according to Urushibara, Nishimura and Uehara[2].

**Catalytic Reduction.**—A suspension of the Raney nickel (0.4 g.) from 1 g. of the alloy in 30 ml. of 95% ethanol was shaken with hydrogen under ordinary pressure in a shaking type catalytic reduction apparatus until the catalyst absorbed no more hydrogen. Then 5 mM of a nitro compounds in 30 ml. of ethanol was added to the catalyst suspension, hydrogen was charged, and the reaction was started by shaking the reaction vessel. The temperature was maintained at 25°C, and the rate of hydrogen absorption was measured. In the reduction with U-Ni-A catalyst, 1.67 mM of a nitro compound, 1.0 g. of the catalyst and 20 ml. of 95% ethanol were used.

**Competitive Reduction.**—An equimolar mixture of two nitro compounds (each 5 mM) was reduced under the condition described above until 8～13 mM of hydrogen was absorbed, whereas complete reduction to amines requires 30 mM of hydrogen. The catalyst was removed by filtration and was washed several times with ether. The products in the filtrate and washings were analysed. In the reduction with U-Ni-A, 6.67 mM each of two nitro compounds, 1.0 g. of the catalyst and 80 ml. of 95% ethanol were used.

**Analysis of Products.**—*Competitive Reduction of Nitrobenzene and p-Nitrophenol.* — Amines were removed from the ethereal solution of the products by shaking with dilute hydrochloric acid. Then the ethereal solution was extracted with dilute aqueous sodium hydroxide, the alkaline solution was acidified with hydrochloric acid and extracted with ether, and *p*-nitrophenol, m. p. 113°C, was obtained after removal of ether from the extract. The quantity of unchanged nitrobenzene was estimated from the volume of absorbed hydrogen in the catalytic reduction of the ethereal mother liquor of the alkaline extraction.

*Competitive Reduction of Nitrobenzene and p-Nitroaniline.* — *p*-Nitroaniline, *p*-phenylenediamine and aniline were separated from unchanged nitrobenzene by extracting ten times the ethereal solution of the reaction products with hydrochloric acid. Then the ethereal solution containing the unchanged nitrobenzene was evaporated in vacuum and the residue was catalytically reduced in alcoholic solution. The quantity of absorbed hydrogen was the same as that of unchanged nitrobenzene. The acidic extract was basified with aqueous sodium hydroxide and shaken with ether. The residue from the ethereal extract was catalytically reduced in alcoholic solution to know the quantity of unchanged *p*-nitroaniline.

*Competitive Reduction of Ethyl p-Nitrobenzoate and Nitrobenzene.*—After the solvent was distilled off from the reaction products, the residue was dissolved in a mixture of 30 ml. of dioxan and 40 ml. of concentrated hydrochloric acid. The solution was heated under reflux for 5 hr. The solution was made alkaline with aqueous sodium carbonate. Then nitrobenzene was steam-distilled, and the distillate was extracted with ether. After removal of ether from the extract, the residue was dissolved in alcohol and catalytically reduced to estimate the

2) Y. Urushibara, S. Nishimura and H. Uehara. This Bulletin, **28**, 446 (1955).

quantity of nitrobenzene. The quantity of reduced ethyl *p*-nitrobenzoate was estimated by weighing *p, p'*-diethoxycarbonylazoxy-benzene which precipitated on exposure of the reaction mixture to air.

*Competitive Reduction of p-Nitrobenzaldehyde and Nitrobenzene.*—The unchanged nitrobenzene and *p*-nitrobenzaldehyde were steam-distilled from the mixture produced, and the nitro compounds were extracted from the distillate with ether. The ethereal solution was divided into two portions of known volume. The total molar quantity of the nitro compounds was calculated from the quantity of absorbed hydrogen in catalytic reduction of one portion. An acidic solution of 2,4-dinitrophenylhydrazine was added to another portion. The quantity of *p*-nitrobenzaldehyde in the unchanged nitro compounds was obtained from that of the 2,4-dinitrophenylhydrazone. The quantity of nitrobenzene was given by the difference of the quantities of the total nitro compounds and *p*-nitrobenzaldehyde.

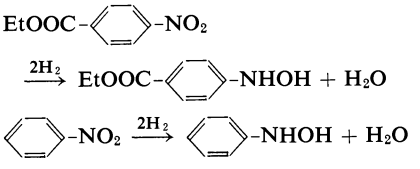
*Competitive Reduction of Ethyl p-Nitrobenzoate and p-Nitroanisole.*—The solution resulting from the competitive reduction was left under exposure to air for two days, and ethyl *p*-hydroxylaminobenzoate was changed to the corresponding azoxy compound[3]. After the precipitated *p, p'*-diethoxycarbonylazoxybenzene was collected by filtration, the solution was analysed chromatographically, and *p*-nitroanisole was obtained in white crystals. The quantity of *p, p'*-diethoxycarbonylaxoxybenzene gave the quantity of reduced ethyl *p*-nitrobenzoate, and the unchanged *p*-nitroanisole was directly weighed.

## Results and Discussion

**Separate Reduction Rates of Nitro Compounds.** — The hydrogenation curves of several nitro compounds were given in the preceding paper[3]. The increasing rates towards the end of the hydrogenation of nitrobenzene and of ethyl *p*-nitrobenzoate with Raney nickel catalyst are due to stepwise hydrogenation. Namely, the nitro compounds are reduced first to the hydroxylamines with $2H_2$, and then the hydroxylamines to amines with $H_2$, the latter process being faster than the former. In the hydrogenation of *p*-nitrobenzaldehyde and of ethyl *p*-nitrobenzoate with U-Ni-A the hydrogenation rates go down, making a break after 2 mol. of hydrogen has been consumed. This is also due to stepwise hydrogenation and here hydroxylamines are reduced more slowly than the parent compounds.

**Competitive Reduction.** — In the competitive catalytic reduction, a more reactive substance is not necessarily reduced in a greater quantity than a less reactive competitor. For example, in separate reduction nitrobenzene is reduced three times as quickly as ethyl *p*-nitrobenzoate with Raney nickel. But, when a mixture of nitrobenzene and ethyl *p*-nitrobenzoate was catalytically reduced, more ethyl *p*-nitrobenzoate was reduced than nitrobenzene. While nitrobenzene and *p*-nitrophenol are almost equally reactive in separate reduction with U-Ni-A catalyst, nitrobenzene was reduced exclusively at first in the competition with *p*-nitrophenol.

These phenomena can be explained by the difference in the affinities of substrates to nickel catalysts. In the above example, ethyl *p*-nitrobenzoate must be adsorbed, and thus reduced, preferentially to nitrobenzene. The same interpretation applies to the competitive reduction of nitrobenzene and *p*-nitrophenol with U-Ni-A catalyst.



In order to find out the sequence, if any exists, in the strengths of affinities of nitrobenzene and substituted nitrobenzenes, the following considerations will be made:

To make the matter simple, any difference in the adsorption areas of the molecules of a pair of nitro compounds is neglected until later discussion.

If it is assumed that there was no selectivity in the adsorption of the nitro compounds, each component being adsorbed with equal ease, the rates of separate hydrogenation of the two compounds will give the quantities of both compounds to be reduced in a partial hydrogenation of their mixture, and comparison of the false values calculated in this way with observed ones will give a suggestion regarding the different affinities of the two nitro compounds to the nickel catalyst.

One or two examples will be illustrated below:

A mixture of 5 mM each of ethyl *p*-nitrobenzoate and nitrobenzene was hydrogenated with Raney nickel until 251 ml. of hydrogen was absorbed, and 2.60 mM of the former was reduced and 3.15 mM of the latter remained unchanged. Both ethyl *p*-nitrobenzoate and nitrobenzene are hydrogenated stepwise and, therefore, the competing reactions are:

As the initial rates of separate hydrogenation of ethyl *p*-nitrobenzoate and nitrobenzene are 73 ml./5 min. and 216 ml./5 min., respectively, the quantity of hydrogen to be consumed for the hydrogenation of ethyl *p*-nitrobenzoate would be from the above assumption:

$$H_1 = \frac{73}{73+216} \times 251 = 63 \text{ ml.}$$

that for nitrobenzene:

$$H_2 = \frac{216}{73+216} \times 251 = 188 \text{ ml.}$$

3) A. Sugimori, submitted to this Bulletin.

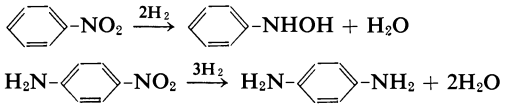
The quantities of the nitro compounds to be hydrogenated would respectively be:

$$R_1=\frac{63}{2\times22.4}=1.41 \text{ mM}$$

$$R_2=\frac{188}{2\times22.4}=4.19 \text{ mM}$$

Accordingly, the quantities of the nitro compounds left unchanged would be:

$$L_1=5.00-1.41=3.59 \text{ mM}$$



$$L_2=5.00-4.19=0.81 \text{ mM}$$

The calculated values are compared with the observed values in Table II, which is interpreted as showing that ethyl *p*-nitrobenzoate has a stronger affinity with the nickel catalyst than nitrobenzene has.

TABLE II

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Ethyl *p*-nitrobenzoate | reduced | 1.41 | 2.60 |
| | unchanged | 3.59 | — |
| Nitrobenzene | reduced | 4.19 | — |
| | unchanged | 0.81 | 3.15 |

The competitive hydrogenation of nitrobenzene and *p*-nitroaniline with Raney nickel catalyst is more complicated, because the former gives phenylhydroxylamine while the latter is reduced to *p*-phenylenediamine:

The separate hydrogenation rates of nitrobenzene and *p*-nitroaniline are 216 ml./5 min. and 134 ml./5 min., respectively. The hydrogenation of a mixture of 5 mM each of nitrobenzene and *p*-nitroaniline was stopped when 291 ml. of hydrogen was absorbed, and 4.10 mM of *p*-nitroaniline remained unchanged. From the above assumption, the quantities of hydrogen to be consumed by nitrobenzene and *p*-nitroaniline would respectively be:

$$H_1=\frac{216}{216+134}\times291=180 \text{ ml.}$$

$$H_2=\frac{134}{216+134}\times291=111 \text{ ml.}$$

The quantity of nitrobenzene to be hydrogenated to phenylhydroxylamine with 180 ml. of hydrogen is:

$$R_1=\frac{180}{2\times22.4}=4.24 \text{ mM}$$

and the quantity of *p*-nitroaniline to be hydrogenated to *p*-phenylenediamine with 111 ml. of hydrogen is:

$$R_2=\frac{111}{3\times22.4}=1.65 \text{ mM}$$

Table III gives the comparison, which shows that nitrobenzene has a stronger affinity to the nickel catalyst than *p*-nitroaniline.

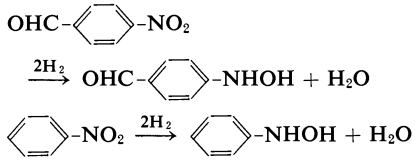


TABLE III

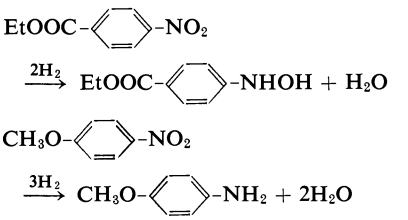
| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Nitrobenzene | reduced | 4.24 | |
| | unchanged | 0.76 | |
| *p*-Nitroaniline | reduced | 1.65 | |
| | unchanged | 3.35 | 4.10 |

Similar treatments of the other competitions are shown in Table IV.

TABLE IV



i) Nitrobenzene and *p*-nitrobenzaldehyde with Raney nickel.

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| *p*-Nitrobenzaldehyde | reduced | 1.18 | |
| | unchanged | 3.82 | 0.52 |
| Nitrobenzene | reduced | 4.78 | |
| | unchanged | 0.22 | 3.10 |

Affinity to the catalyst: *p*-Nitrobenzaldehyde >Nitrobenzene

ii) Ethyl *p*-nitrobenzoate and *p*-nitroanisole with Raney nickel.

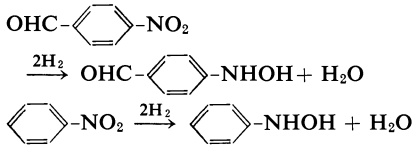
| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Ethyl *p*-nitrobenzoate | reduced | 1.83 | 3.15 |
| | unchanged | 3.17 | |
| *p*-Nitroanisole | reduced | 2.54 | |
| | unchanged | 2.46 | 2.85 |

Affinity to the catalyst: Ethyl *p*-nitrobenzoate >*p*-Nitroanisole

Separate and competitive hydrogenation of the nitro compounds were also studied with U-Ni-A catalyst. Results are shown in Table V.

TABLE V

(A) Initial hydrogenation rates of separate hydrogenations.

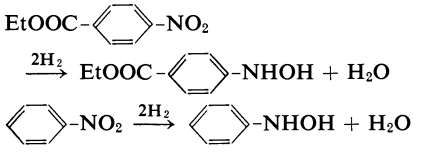


| | |
|---|---|
| Nitro compound | 1.67 mM |
| U-Ni-A | 1.0 g. |

| Compound | Rate of hydrogen absorption |
|---|---|
| Nitrobenzene | 126 ml./5 min. |
| *p*-Nitrobenzaldehyde | 126 ml./2.5 min. |
| Ethyl *p*-nitrobenzoate | 141 ml./5 min. |
| *p*-Nitrophenol | 138 ml./5 min. |
| *p*-Nitroaniline | 68 ml./5 min. |

(B) Competitive reduction

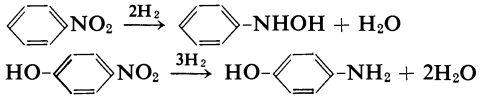
| | |
|---|---|
| Nitro compounds | 6.67 mM each |
| U-Ni-A | 1.0 g. |



i) *p*-Nitrobenzaldehyde and nitrobenzene.

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| *p*-Nitrobenzaldehyde | reduced | 4.74 | |
| | unchanged | 1.93 | |
| Nitrobenzene | reduced | 2.37 | |
| | unchanged | 4.30 | 5.60 |

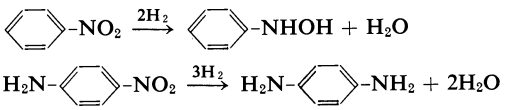
Affinity to the catalyst: *p*-Nitrobenzaldehyde >Nitrobenzene



ii) Nitrobenzene and ethyl *p*-nitrobenzoate.

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Ethyl *p*-nitrobenzoate | reduced | 3.82 | |
| | unchanged | 2.85 | |
| Nitrobenzene | reduced | 3.37 | |
| | unchanged | 3.30 | 5.13 |

Affinity to the catalyst: Ethyl *p*-nitrobenzoate >Nitrobenzene



iii) Nitrobenzene and *p*-Nitrophenol

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Nitrobenzene | reduced | 4.80 | |
| | unchanged | 1.87 | 0.34 |
| *p*-Nitrophenol | reduced | 3.47 | |
| | unchanged | 3.20 | 5.10 |

Affinity to the catalyst: Nitrobenzene >*p*-Nitrophenol

iv) Nitrobenzene and *p*-nitroaniline.

| Compound | | Calcd. mM | Obs. mM |
|---|---|---|---|
| Nitrobenzene | reduced | 5.47 | |
| | unchanged | 1.20 | 0.47 |
| *p*-Nitroaniline | reduced | 1.92 | |
| | unchanged | 4.70 | 6.10 |

Affiinity to the catalyst: Nitrobenzene >*p*-Nitroaniline

To examine further the selectivity in adsorption, the initial rates of hydrogenation of mixtures were measured and compared with the initial rates of separate reduction in Table VI.

TABLE VI

| Compound | Initial rate of separate reduction (ml. of $H_2$/5 min.) | Initial rate of the reduction of mixture (ml. of $H_2$/5 min.) |
|---|---|---|
| Nitrobenzene | 216 | 54 |
| Ethyl *p*-nitrobenzoate | 73 | |
| Nitrobenzene | 216 | 63 |
| *p*-Nitrobenzaldehyde | 52 | |
| Nitrobenzene | 216 | 208 |
| *p*-Nitroaniline | 134 | |

Table VI shows that the reduction rate of a mixture is almost the same as that of the component which is considered to have a stronger affinity to the catalyst. These data also indicate that the difference in affinities of the two components of each combination is great enough to cause completely selective adsorption.

The comparisons of the affinities of the nitro compounds to the nickel catalysts are summarized in Table VII.

TABLE VII

| Raney nickel | U-Ni-A |
|---|---|
| Ethyl *p*-nitrobenzoate >Nitrobenzene | Ethyl *p*-nitrobenzoate >Nitrobenzene |
| *p*-Nitrobenzaldehyde >Nitrobenzene | *p*-Nitrobenzaldehyde >Nitrobenzene |
| Nitrobenzene >*p*-Nitroaniline | Nitrobenzene >*p*-Nitrophenol |
| Ethyl *p*-Nitrobenzoate >*p*-Nitroanisole | Nitrobenzene >*p*-Nitroaniline |

In all the systems studied, an aromatic nitro compound with an electron attracting group in para position has a stronger affinity to the nickel catalysts than the compound with an electron repelling group in the same position.

Other factors that might have effects on the affinities of nitro compounds to the nickel catalysts must also be examined.

*Cross Section in Adsorption.*—The cross section in adsorption has been neglected in the above discussion but it might affect the apparent affinity of the nitro compound to the nickel catalysts. The molecule with a larger cross section in adsorption may be adsorbed in a smaller number than the molecule with a smaller cross section. Therefore, the same observed rate of separate hydrogenation with U-Ni-A catalyst may suggest that the hydrogenation of one molecule of *p*-nitrophenol is more rapid than that of nitrobenzene. Thus, if there were no selectivity in adsorption, *p*-nitrophenol might be reduced to a greater extent than nitrobenzene in the competitive reduction, but this was not true, and so the selectivity in adsorption rather than the molecular cross section governs the results.

Carbonyl group in ethyl *p*-nitrobenzoate and *p*-nitrobenzaldehyde can attack the active centers of the nickel catalysts, and the strong affinity of *p*-nitrobenzaldehyde and ethyl *p*-nitrobenzoate to the catalyst might be attributed to the adsorption of the carbonyl group. But this is denied, because the partial reduction of *p*-nitrobenzaldehyde gave *p*-hydroxylaminobenzaldehyde, and nitro group is preferentially adsorbed to carbonyl group by the catalysts.

The author wishes to express his hearty thanks to Professor Y. Urushibara for his kind guidance and encouragement throughout this work. He is also very grateful to Dr. M. Kobayashi and Dr. S. Nishimura for their helpful discussion.

# *Studies on Extraction of Polonium(IV) by Hexone from Acid Solution*

By Niro MATSUURA, Akira OUCHI* and Masuo KOJIMA**

(Received June 10, 1960)

Solution chemistry of polonium(IV) with a weighable quantity of polonium was developed by Bagnall et al.[1] for several years past. However, one of the present authors found that polonium(VI), having a higher oxidation potential with regard to polonium(IV), was not stable, owing to its own $\alpha$ radiation[2]. Accordingly, it is necessary to employ a minute quantity of this element (which does not cause any radiolysis) in order to distinguish the results from self radiolysis. The extraction study of polonium(IV) was undertaken, therefore, with quantities of less than one microcurie of polonium per millilitre. In the course of the present studies on polonium extraction with hexone (methyl isobutyl ketone,) some peculiarities in the extraction characteristics were observed in a certain range of acidity, suggesting that there will be one or more unestablished complex species of polonium other than $PoX_6^{2-}$[3,4]. These phenomena appeared to be closely related with the history of employed polonium sources as well as with the acid nature of the aqueous phase from which polonium was extracted[3,5-7]. In order to find out new species of polonium(IV) responsible for this peculiarity in aqueous medium, the experiments were carried out under well defined conditions concerning the history of polonium source and the acidity of the extraction system.

## Experimental

**1) Materials.**—Polonium received from Amersham, England, dated June 1959, was in the form of nitrate in 1 N nitric acid. It was used after purification in our laboratory as described below:

A portion of polonium solution was converted into 0.3 N hydrochloric acid solution from which

7) T. Ishimori, This Bulletin, **27**, 520 (1954).

polonium was deposited on a silver foil by electrochemical displacement. The deposited polonium was redissolved in 1 N nitric acid together with metallic silver and was freed from silver by precipitating silver as chloride. The supernatant liquid thus obtained was evaporated to dryness, while the residue was extracted with hot dilute hydrochloric acid. After this purification procedure was repeated several times, the extracted polonium solution was stored in 6 N hydrochloric acid. The resulting solution was the usual starting source of our experiments, though other solutions of different kinds of acid and acidities were sometimes used as well.

**2) Activity Measurement.**—Twenty microlitres of the solution, containing polonium, was pipetted by a glass micro-syringe furnished with a micrometer. In order to obtain the homogeneity of the samples for the $\alpha$ counting of polonium, two different methods were applied, one by evaporating the pipetted sample directly on a glass plate and the other depositing the polonium on a silver foil by the electrochemical displacement. The simple evaporation method was not suitable for obtaining consistent $\alpha$ activity of polonium, especially when some non-volatile material was present. In the electrochemical method it was desirable to make preliminary extraction with hexone from acid solution in the presence of an excess amount of potassium iodide. By this method all polonium activities could be transferred to an organic phase as hexa-iodo polonium complex, $PoI_6^{2-}$. The hexone solution thus obtained was placed on a silver foil, while polonium was deposited electrochemically for activity measurement. The discharge rate of electroscope, 5.575 div./min. was standardized against the counting rate of $4\pi$ flow counter for the same sample under the same condition of measurement. This yielded 977 counts/min. against 5.575 div./min., i. e., 1 div./min. corresponds to $4.7\times10^{-3}$ microcurie of $^{210}Po$.

**3) Partition of Polonium between Two Liquid Phases.** — For determining the distribution of polonium between hexone and aqueous acid solution the sample solution was shaken at room temperature in a stoppered glass test tube with the same volume of solvent, preliminarily saturated with the acid of the same concentration. The correction of volume change after extraction was needed when the extraction was made from concentrated acid solution. Although in our measurements only several ten micro microlitres of the sample was taken, the errors fell within the limit of 10%. The equilibrium of partition was established in less than 5 min. at the temperature of $20\pm5$°C.

**4) Aging of Polonium Solution.**—About 80 microlitres of the stock solution which contained a known amount of polonium was taken in 4 ml. of hydrochloric, sulfuric or nitric acid. Just after mixing a portion of polonium was extracted with hexone from the mixture. This provided the data at time 0. The rest of the polonium solution was boiled in a glass flask with reflux condenser for several hours on a steam bath, before it was cooled to room temperature. This aged solution was used as a sample for extraction of polonium.

## Results and Discussion

**1) Adsorption of Polonium on Glass Wall.**—Polonium is generally adsorbed strongly on a number of substances. For example, the adsorption on ion-exchange resins, either cationic or anionic, is so strong that polonium is hardly eluted even by an eluant of high ionic concentration. In this respect, ion-exchange technique did not give any reliable data for studying the complex chemistry of polonium. It seemed to us that the partition method was rather preferable. In the extraction method, however, the adsorption on a glass wall caused another difficulty in the accurate determination of polonium activity. In order to obtain a correct partition coefficient, it is necessary to know the loss of polonium by adsorption from the extraction system. In Fig. 1 the actual adsorption loss was shown in

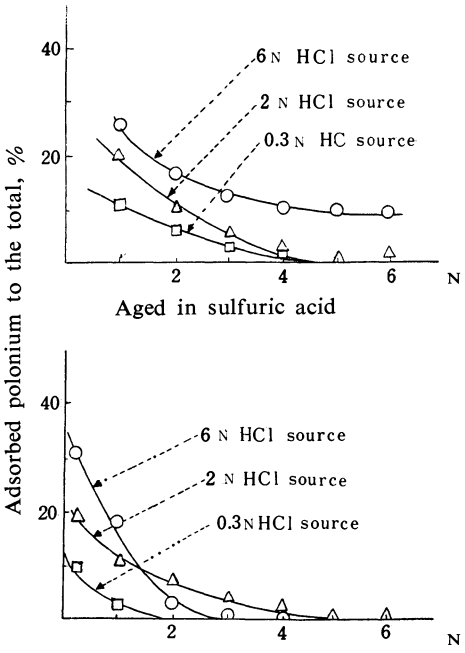

Fig. 1. Adsorption of polonium(IV) on the wall of 1 ml. glass stoppered vessel for hexone extraction.

(Po lost/Total Po used) $\times$ 100% as the function of acidity of the medium from which polonium was extracted. In the hydrochloric acid vs. hexone system the adsorption on a glass wall was very small, if the acid was stronger than 2 N. On the other hand in sulfuric acid-hexone system several hundredths of polonium was left on the surface of the glass wall regardless of the acidity so far as we examined it. Therefore, the adsorption loss cannot be neglected for the correct extraction data.

**2) Aging Effect on Nitric Acid.**—The amount of polonium extracted from nitric acid solution was nearly constant, 80% being found in the organic phase. This constant value of extraction coefficient can be obtained if the polonium source stored in 6 N nitric acid is employed for extraction after immediate dilution to a given concentration of the acid. Much lower extraction coefficients were observed, on the other hand, if polonium in 0.4 N nitric acid was extracted. In Fig, 2, the extraction

-○- 1. Extraction immediately after dilution.
-△- 2. Extraction after 1 hr.'s heating.
-□- 3. Extraction after 2 hr.'s heating.
-×- 4. Extraction after 12 hr.'s heating.
-●- 5. Extraction without aging.

coefficient curve 1 for polonium source in 0.4 N nitric acid fell with decreasing acidity. The aging before extraction by heating under reflux for 1, 2 and 12 hr. at 80°C increased the extraction coefficients up to 80% as shown in corresponding curves 2, 3 and 4 in Fig. 2. This fact suggests that polonium(IV) nitrate complex $Po(NO_3)_6^{2-}$ or $Po(NO_3)_5^-$ [8,9], which is stable in 6 N nitric acid, can be readily extracted by hexone, whereas the hydrolysed complex produced in weak nitric acid below

1 N is hardly extracted at all. The form of the latter hydrolysed ionic species cannot be detected in our experiments, though some authors suggest that the ionic formula is $PoO^{2+}$ or $Po(OH)_2$ $(NO_3)_4^{2-}$ [7].

**3) Aging Effect in Hydrochloric Acid.**— Aging effect on the extraction characteristics of polonium was also observed in hydrochloric acid as well as in nitric acid. The results were represented in Fig. 3 for the several different polonium sources aged and stored in 0.3, 2 or 6 N hydrochloric acid. In this case polonium was extracted from hydrochloric acid of 0.3~6 N for the samples aged 6 hr. under reflux (A) and non-aged (B). The minimum extraction coefficient was observed at about 2 N hydrochloric acid. This minimum appeared only in the extraction from hydrochloric acid medium. Hence, it was assumed that in hydrochloric acid there would be two different ionic species of polonium complex easily soluble in hexone. A well-established form of polonium(IV) complex in hydrochloric acid is $PoCl_6^{2-}$ which is believed to be formed easily in hydrochloric acid of higher than 6 N and stable even in more dilute acid after it was formed[10,11]. But by aging in more dilute acid solution for prolonged time, the solubility of polonium in hexone decreased as it formed some kinds of hydrolytic products which were hardly soluble in hexone.

**4) Ionic Species of Hydrolytic Product.**— It is very interesting to estimate the ratio of insoluble species to soluble species from the data of Fig. 3B. This ratio depends not only on the acidity of the extraction system but also on the history of the polonium source. Then, for example, the curve 2 in Fig. 3B, having a sharp minimum at nearly 2 N, can be analysed into two separated curves, as shown in Fig. 4 with dotted lines. These separated curves indicate two different hexone soluble complex species contributed to the extraction at the same time, though in different ways, in the acidity region, one in the range over 3 N and the other in the acidities less than 2 N. The dependence of each curve on the acidity of the extraction system can be shown in Fig. 5 by the logarithmic plots of Polonium soluble/Polonium insoluble or $E'/(1+E')$ as a function of acidity in linear scale. Here, $E'$ denotes the extraction coefficient for separated species. These plots have linear character with the tangential increment 4. Applying mass action law to this system for the hydrolytic reaction given by (1), an equilibrium relation (2) is obtained between two polonium species, soluble and insoluble, which shows dependence on the fourth power of acidity.

$$PoCl_6^{2-} + 2H_2O = Po(OH)_2Cl_4^{2-} + 2H^+ + 2Cl^- \quad (1)$$

$$\frac{PoCl_6^{2-}\ \text{soluble in hexone}}{Po(OH)_2Cl_4^{2-}\ \text{insoluble}} = K\cdot[H^+]^2\cdot[Cl^-]^2$$

10) D. J. Hunt, *Amer. Rep.*, MLM, 979 (1954).
11) K. W. Bagnall and J. H. Freeman, *J. Chem. Soc.*, 1956, 2770.

$$\text{or} \quad \frac{\text{Po(IV) soluble}}{\text{Po(IV) insoluble}} = \frac{E'}{1-E'} = K \cdot a^2_{\pm HCl}$$

Where, $a_{\pm HCl}$ is the mean activity of hydrochloric acid. It seemed from the above consideration that the species of $Po(OH)_2Cl_4^{2-}$ or $PoO^{2+}(H_2O+4Cl^-)$ is responsible for the appearance of minimum extraction from hydrochloric acid medium at the concentration about 2 N.

However, the idea is not entirely excluded that polonium nitrate complex formed in the purification process is partly extracted even from hydrochloric acid. Accordingly, it is possible to assume that the minimum value of extraction appears in the acidity most favorable to hydrolytic reaction succeeded by the following schema:

$$Po(NO_3)_6^{2-} + 2H_2O = PoO^{2+} + 2H^+ + 6NO_3^- + H_2O$$

$$\frac{PoO^{2+} + 2H^+ + 6Cl^- + H_2O = PoCl_6^{2-} + 2H_2O}{Po(NO_3)_6^{2-} + 6Cl^- = PoCl_6^{2-} + 6NO_3^-}$$

Here, unconverted nitrate complex contributes to the extraction in the concentration range of hydrochloric acid lower than 2 N. In this hypothesis, an assumption of an uncertain soluble complex of polonium is not necessary.

However, there is no reason to believe that the nitrate complex is more stable than chloro-complex nor that the conversion of nitrate complex into chloro-complex is incomplete.

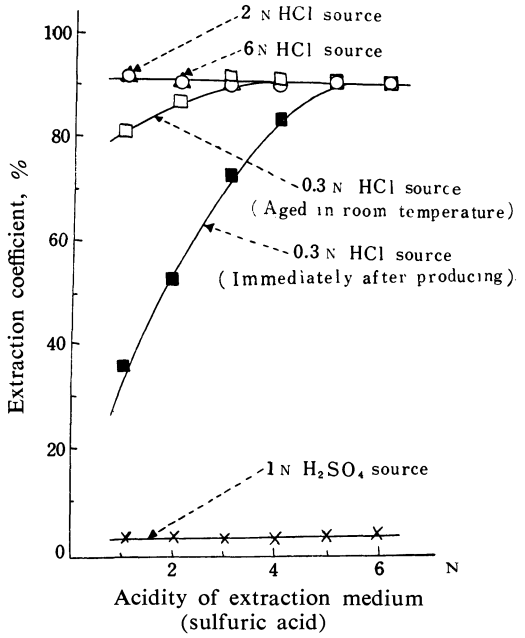

Fig. 6A. Aging effect on extraction coefficient. (Immediately after dilution.)

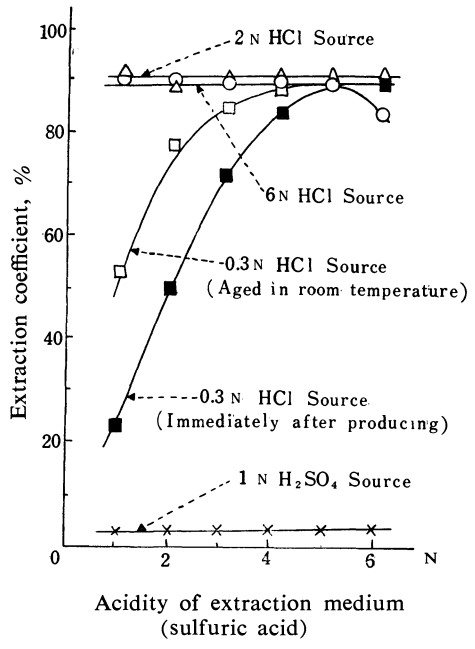

Fig. 6B. Aging effect on extraction coefficient. (Aged for 6 hr. at boiling point.)

**5) Aging Effect on the Extraction from Sulfuric Acid Medium.**—Partition equilibrium of polonium(IV) between hexone and aqueous solution of sulfuric acid was also studied with the different sources of polonium, stored in 6, 2 and 0.3 N hydrochloric acid and 1 N sulfuric acid, respectively. The results were shown in Fig. 6. Among them only the polonium source prepared and stored in sulfuric acid

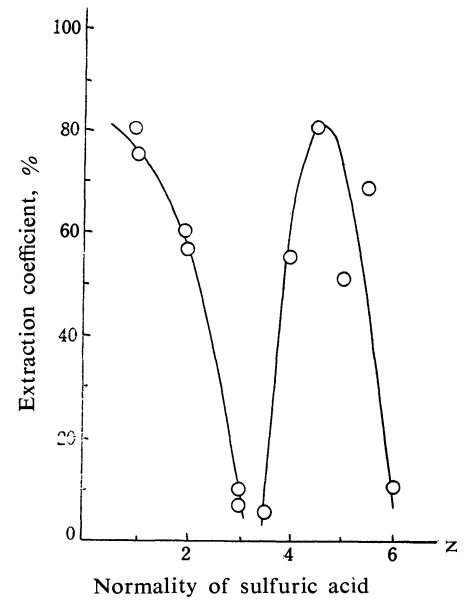

Fig. 7. Extraction of polonium(IV) in sulfuric acid.

gives extraction coefficient nearly nul in the entire range of acidity examined. This indicates that a trace quantity of chloride, if present in sulfuric acid, causes a remarkable increase of extraction yield and that the yield attains the maximum value corresponding to that of hexachloro-polonium(IV) complex, $PoCl_6^{2-}$. It can be said that one of the complex species, $PoCl_6^{2-}$ is readily formed in the presence of a minimum quantity of chloride in sulfuric acid. In our latest publication on polonium the extraction of polonium(IV) from sulfuric acid medium passed through maximum and minimum phases as shown in Fig. 7. This was observed by using the polonium source of 6 N hydrochloric acid after diluting 100 times with sulfuric acid before extraction. In this case the aging was made at 80°C for one hour by heating on a steam bath. A minimum value of extraction that appeared in the proximity of 2 N sulfuric acid is consistent with the results obtained for the extraction from hydrochloric acid by using an aged polonium source as already mentioned in 3). From this consideration the present authors prefer the ionic form $PoO^{2+}$ as the stable species of polonium(IV) in sulfuric acid to that of $PoO_3^{2-}$ which is regarded as stable in less acidic solution according to the analogy of $Te(IV)O_3^{2-}$.

## Summary

The ionic state of polonium(IV) in hydrochloric and sulfuric acid solution was studied by the solvent extraction with hexone (methyl isobutyl ketone).

1) The polonium solution stored in 0.4 N nitric acid is strongly hydrolysed by aging. The low extraction coefficient caused by hydrolysis became higher by heating the polonium solution in stronger nitric acid. On the other hand, the polonium stored in 6 N nitric acid can be extracted with constant extraction coefficient, about 80%, through the entire acidity range from 1 to 6 N., if the extraction was carried out without any aging.

2) The aging effect of polonium(IV) in hydrochloric acid is rather complicated. A minimum extraction appeared in the acidity range near 2 N hydrochloric acid. By applying mass action law the probable form of polonium(IV) in that range was $Po(OH)_2Cl_4^{2-}$ or $PoO^{2+}$, assuming that $PoCl_6^{2-}$ was the stable form of polonium(IV) in 6 N hydrochloric acid which is readily soluble in hexone.

3) Almost no polonium(IV) was extracted by hexone from sulfuric acid solution. Here, the polonium(IV) in sulfuric acid exists probably as $PoO^{2+}$ rather than as $PoO_3^{2-}$.

The authors wish to express their thanks to Professor T. Shirai and to their colleagues in the laboratory for their helpful discussions. A part of the expenses of these studies was defrayed by a grant from the Ministry of Education.

# *On the Differences in Monolayer Properties of Poly-γ-benzyl-L-glutamate and Poly-β-benzyl-L-aspartate*

By Shoichi IKEDA and Toshizo ISEMURA

(Received July 28, 1960)

Recently great progress has been made in the studies on synthetic polypeptides, especially concerninig their solutions. Among them, the solutions of poly-γ-benzyl-L-glutamate in various solvents have been investigated extensively and it is found that this polymer has a right-handed α-helical configuration in some solvents[1]. More recently it has been reported, however, that poly-β-benzyl-L-aspartate, the side chain of which has a length by one methylene group less than that of poly-γ-benzyl-L-glutamate, is quite different from poly-γ-benzyl-L-glutamate in its behavior and that the α-helix of the former polymer may be left-handed rather than right-handed[2].

According to the surface chemical studies, synthetic polypeptides with non-polar or unionized side chains are known to give monolayers of condensed type on aqueous surfaces, the surface viscosity of which is manifest at a very low surface pressure region, but only those which contain prolyl residues in some high amounts give monolayers of expanded type, the surface viscosity of which is manifest first at a very high surface pressure region[3,4]. In general, therefore, the monolayers of ordinary unionized polypeptides are of condensed type and exhibit high surface viscosities, and the only difference among those which are composed of different amino acid residues are reflected explicitly in the behavior of the surface potential, according to the difference in polarities or electric moments of their side chains. Considering the striking difference in properties of poly-γ-benzyl-L-glutamate and poly-β-benzyl-L-aspartate in crystals or in solutions, as cited above, however, it is expected that the two polymers behave in a different way in their spread monolayers, since the difference of the two polymers in solutions and in crystals will be based on the different kinds of interactions of side chain with main chain or with other side chains and such an effect of side chain of polymers will be most distinctly revealed in monolayer states.

We have thus studied the monolayers of poly-γ-benzyl-L-glutamate (PBLG) and poly-β-benzyl-L-aspartate (PBLA) by the measurements of surface pressure, potential and viscosity. We will report any marked differences in their behavior and propose possible chain configurations of these polymers in monolayers and then discuss the differences on the basis of these configurations. Further we have examined the monolayer of a copolymer of γ-benzyl-L-glutamate and β-benzyl-L-aspartate, copoly-1: 1-(γ-benzyl-L-glutamate, β-benzyl-L-aspartate) (CP(BLG, BLA)), and the equimolar mixture of PBLG and PBLA.

## Experimental

PBLG (Code No. J11A) and PBLA (J826) were prepared by polymerizing *N*-carboxy-anhydrides of the corresponding L-amino acids in dioxane with triethylamine and CP(BLG, BLA) (A227B) by copolymerizing the equimolar mixture of *N*-carboxy-anhydrides of these amino acids in (1 : 1 v/v) chloroform-dioxane with triethylamine. Their intrinsic viscosities in dichloroacetic acid solution at 25°C were 0.13, 0.11 and 0.34, respectively. Their solutions in (1 : 4 v/v) dichloroacetic acid-benzene were spread on aqueous surfaces. The equimolar mixed monolayer of PBLG and PBLA was spread from their mixed solution in the same solvent.

The surface pressure was measured by a surface balance of the hanging plate type, the surface potential by a vibrating electrode and the surface viscosity by a rotatory oscillating disk[3,4]. The temperature was regulated by heating the inside of the shielding box with a voltage controlled lamp, if necessary.

## Results

The surface pressure, $\Pi$, surface potential, $\Delta V$, and surface viscosity, $\eta$, of PBLG, PBLA and CP(BLG, BLA) are plotted against the area, expressed in the unit of Å$^2$ per (average)

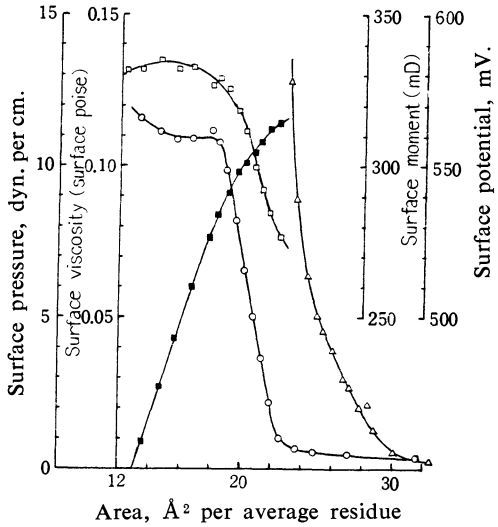

Fig. 3. Monolayer of CP(BLG, BLA) at 12.3°C. ○, surface pressure; □, surface potential; ■, surface moment; △, surface viscosity.

amino acid residue, as shown in Figs. 1, 2 and 3. All the monolayers are of condensed type. The surface potential was not definite but fluctuated from time to time at the region of large areas. However, reproducible values were observed as the surface pressure began to rise. Values of the area, $A_{\Pi\to 0}$, at which the surface pressure steeply increases on compression, and of the area, $A_{\Delta V}$, at which the surface potential becomes reproducible on compression, are tabulated in Table I. The surface pressure and potential were scarcely at all influenced by temperature. The $A_{\Pi\to 0}$ is nearly equal to $A_{\Delta V}$ for each polymer and they will represent the actual area occupied by an (average) amino acid residue.

The values of surface compressibility calculated by

$$\delta = -\frac{1}{A}\frac{\partial A}{\partial \Pi}$$

are given in Table II, which shows clearly the difference in surface pressure-area curves of the three polymers. In the region of low surface pressure the surface compressibility is in the order: PBLA> CP(BLG, BLA) >PBLG. The surface pressure-area curve of CP(BLG, BLA) is characterized by the region of very high surface compressibility such as that observed for poly-$\gamma$-benzyl-DL-glutamate[5].

The surface moments per amino acid residue calculated by the Helmholtz equation

$$\mu = \frac{A\cdot\Delta V}{4\pi}$$

are plotted against the area, as is also shown in Figs. 1, 2 and 3, and the values at 21 Å$^2$ are also listed in Table I. It is noticed that the surface moment of PBLA is about 50 mD higher than that of PBLG and CP(BLG, BLA) has an intermediate value of these two.

Although some differences are observed in surface pressure and potential between PBLG and PBLA, as described above, they are most distinctly reflected in surface viscosity behavior. The surface viscosity of PBLG is very high at very low surface pressure region, but that of PBLA is manifest first at high surface pressure region; the surface viscosity of the former is much lower than that of the latter. It is remarkable that, in spite of the condensed nature of monolayer reflected in surface pressure, PBLA has a very low surface viscosity. A monolayer of polymer with such composite properties, i. e., a monolayer of condensed type with a low surface viscosity, has never been reported. The surface viscosity-area curve of CP(BLG, BLA) is similar to that of PBLG rather than being an intermediate between PBLG and PBLA.

The surface viscosities of PBLG and PBLA were markedly influenced by temperature and they were higher as the temperature was high.

5) T. Isemura and K. Hamaguchi, ibid., 27, 125 (1954).

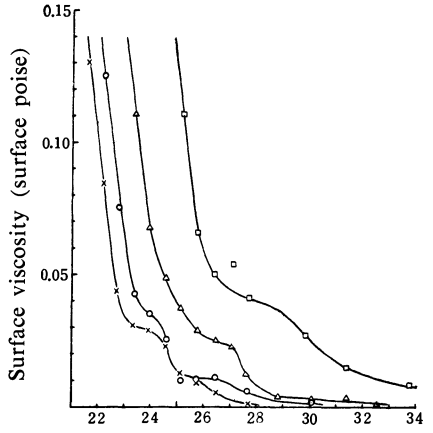

Fig. 4. Variation of surface viscosity of PBLG with temperature. □, 24.0°C; △, 16.2°C; ○, 9.0°C; ×, 5.6°C.

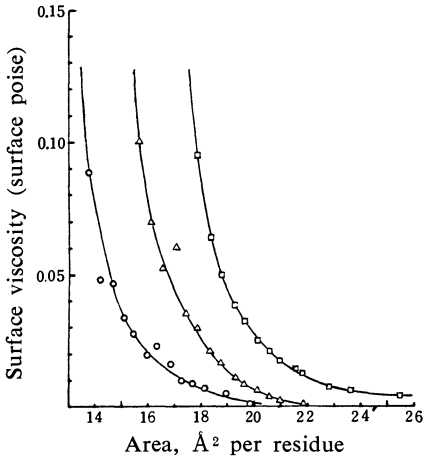

Fig. 5. Variation of surface viscosity of PBLA with temperature. □, 24.5°C; △, 17.9°C; ○, 10.8°C.

The variations of surface viscosity with temperature are shown in Figs. 4 and 5. Contrary to the common nature of the expanded monolayer[4], PBLA has a positive temperature coefficient of surface viscosity rather than a negative one.

Values of the area, $A_{\eta=0.10}$, at which the surface viscosity reaches 0.10 surface poise, are also given in Table I.

## Discussion

**Chain Configurations of PBLG and PBLA in Monolayer.**—The values of the limiting area, $A_{\Pi\to 0}$, derived from the surface pressure-area curves imply that these three polymers assume a configuration such as the β-form in monolayers. Although the limiting area, 22 Å², of these polymers is somewhat larger than that of some other polypeptides such as poly-DL-alanine, 15 Å² [3,6], this suggests that the area occupied by a residue is not defined by the main chain only but by the large side chain for these polymers. As the polymers are composed of L-amino acid residues exclusively, the side chains are oriented up and down alternatively when spread on an aqueous surface, assuming a β-configuration[6,7] but the hydrophilic or hydrophobic nature and the orientation of side chain should be different from that of non-polar polypeptides owing to the presence of two oxygen atoms.

Since the three polymers have polar groups on a side chain as well as on the main chain and then the side chain has both hydrophilic and hydrophobic nature, the side chain can change its orientation with greater ease sometimes rising into the air, sometimes lying on the surface and sometimes submerging into the water. The fluctuation of surface potential at large areas might be ascribed to such a thermal motion of the side chain. On high compression, however, the orientation of the side chain is forced to be fixed into a definite position, as given below. Thus the area, $A_{\Delta V}$, at which the surface potential gives a definite value, is nearly equal to the limiting area, $A_{\Pi\to 0}$.

As shown in Table I, the surface moments of these three polymers are much higher than those of polypeptides with non-polar side chains such as poly-DL-alanine, 160 mD[3]. This can be attributed to the contributions of the polar groups on side chain, i. e., the electric moments of the carbonyl group and the $H_2C$–O bond, to the surface moment besides that of the main chain. If the carbonyl group on the side chain is directed towards the aqueous surface with an angle $90° - \theta$, then the 'surface moment' of the side chain of PBLG and PBLA is given by

$$\text{(A)} \qquad \mu_{C=O}\cos\theta - \mu_{C-O}\cos(\theta + 30°)$$

if all the bonds on the side chain are assumed to be in trans form, or by

$$\text{(B)} \qquad \mu_{C=O}\cos\theta + \mu_{C-O}\cos(\theta + 30°)$$

if the O–C$\lesssim$O bond alone takes cis form. About half of the side chains are submerged into the aqueous subphase and surrounded by water molecules; this does not contribute to the surface moment[8]. Thus the total surface moment observed experimentally consists of

TABLE III. CALCULATED VALUES OF SURFACE MOMENTS

$\mu = 160\,\text{mD} + 1/2\,\mu(\text{side chain})$

| $\theta$ (°) | | 0 | 30 | 35 | 40 | 45 | 50 | 55 | 60 | 90 |
|---|---|---|---|---|---|---|---|---|---|---|
| $\mu$(mD) | (A) | 242 | 274 | 272 | 269 | 266 | 261 | 252 | 250 | 203 |
| | (B) | 439 | 359 | 344 | 327 | 309 | 291 | 271 | 250 | 117 |

the contributions of the main chain, 160 mD[3], and of half the 'surface moment' of the side chain. If it is assumed that $\mu_{C=O} = 360$ mD and $\mu_{C-O} = 170$ mD[9], the total surface moment can be calculated for various values of $\theta$ in either case, (A) or (B). The results are given in Table III. Comparing these calculated values with the observed values in Table I, it is found that the side chain of PBLA has a configuration with $\theta = 40°$ in which all the bonds are trans except that the O–C(=O) bond is cis. On the other hand, the configuration of the side chain of PBLG has two possible configurations from the data on surface moment alone, but it is confined to the one with all the bonds being trans other than the O–C(=O) bond and with $\theta = 55°$, if the limiting area derived from the surface pressure is taken into account. The configurations deduced thus are illustrated as follows:

It can be seen that the orientations of side chains of PBLG and PBLA are quite different from each other, although the difference in their structure is only by one methylene group in side chain length. In other words, the carbonyl group on the side chain of PBLG seems to play the role of a hydrophobic part and does not serve for the hydrophility of the side chain very well, but that of PBLA is submerged into the aqueous subphase and is indistinguishable from the carbonyl group on the main chain, thus greatly increasing the hydrophilic nature of the side chain.

The value of surface moment of CP(BLG, BLA) intermediate between PBLG and PBLA supports the configuration similar to the $\beta$-form for these three polymers in monolayer and the value, 305 mD, slightly higher than the mean value, 296 mD, suggests that the side chains of $\gamma$-benzyl-L-glutamate residue are influenced by $\beta$-benzyl-L-aspartate residue in this copolymer.

The observed value of surface moment of $\gamma$-benzyl-L-glutamate residue in PBLG, $\mu_{21A^2} = 270$ mD, may be compared with that of $\gamma$-methyl-L-glutamate residue in copoly-1 : 1-($\gamma$-methyl-L-glutamate, DL-phenylalanine). The latter copolymer has a surface moment per amino acid residue, $\mu_{19A^2} = 197$ mD[8]. Since the surface moment of poly-DL-phenylalanine is 110 mD[7], the contribution of $\gamma$-methyl-L-glutamate residue to the surface moment of the copolymer should be 284 mD, which is in accord with the surface moment of $\gamma$-benzyl-L-glutamate residue in PBLG.

**Relation of Surface Viscosity with Surface Pressure.**—As was noted before, whereas PBLG gives a high surface viscosity at areas larger than the area at which the surface pressure begins to rise steeply or the limiting area, i. e., at a very low surface pressure region, PBLA shows a high surface viscosity only at areas far smaller than the limiting area, i. e., at a high surface pressure region. In other words, the surface viscosity is much higher for PBLG than for PBLA. The behavior as was observed for PBLG has the general characteristics of monolayers of condensed type. However, that for PBLA has not been noticed for monolayers of any polymers so far examined, but only for monolayers of long chain fatty acids[10] and their mixtures with each other or with long chain alcohols[11]. This striking difference between PBLG and PBLA may be interpreted on the basis of the configurations of side chains presented above.

The monolayer of PBLG would correspond to the glassy state polymers in three dimensional state in which the interaction between segments are very strong, and consequently the monolayer is condensed and the surface viscosity is very high[4]. In this case the interaction between segments would mainly be the hydrogen bonding between peptide bonds in the main chain. The monolayer of PBLA would also correspond to the glassy state. In the case of PBLA, however, the carbonyl group on the side chain is submerged into water like

9) A. E. Alexander and J. H. Schulman, *Proc. Roy. Soc.*, A161, 115 (1937).

10) G. E. Boyd and W. D. Harkins, *J. Am. Chem. Soc.*, 61, 1188 (1939).

11) G. E. Boyd and F. Vaslow, *J. Colloid Sci.*, 13, 275 (1958).

the one on the main chain, as referred to before, and, therefore, the interactions between segments are not necessary ascribed to the hydrogen bonding between peptide bonds but also possibly to the hydrogen bonding of the carbonyl group on the side chain with the imino group on the main chain. The monolayer configuration of PBLA would be less stable than that of other polypeptides and a part of the molecular chain can easily be submerged into the aqueous subphase under compression or under shear flow. Further, the hydrophilic nature of the side chain is greatly enhanced owing to the carbonyl group in contact with water and would be responsible for reducing the resistance against compression or shear. Thus the high surface compressibility and the low surface viscosity of PBLA will be exhibited after the surface pressure begins to rise or the monolayer is compressed to the limiting area.

The specific nature of the side chain of PBLA seems to be related to its reactivity when it is reduced to remove the benzyl group on the side chain. By this treatment, PBLA does not produce poly-α-L-aspartic acid but gives poly-anhydro-L-aspartic acid[12], while PBLG gives poly-α-L-glutamic acid. This also suggests that the carbonyl group on the side chain is scarcely distinguishable from that on the main chain.

The variations of surface viscosity with temperature for PBLG and PBLA are given in Figs. 4 and 5. If the logarithms of surface viscosity of PBLA at different temperatures are plotted against surface pressure, a part of each curve gives a straight line expressed by

$$\log \eta = \log \eta_0 + c\Pi$$

as shown in Fig. 6. The same type of equation has been found for some other monolayers[4,10,11,13]. The constants of this equation for PBLA are tabulated in Table IV. No further implication of these constants is clear.

**The Equimolar Mixed Monolayes of PBLG and PBLA.** — The monolayer characteristics of the equimolar mixture of PBLG and PBLA are shown in Fig. 7. The limiting areas

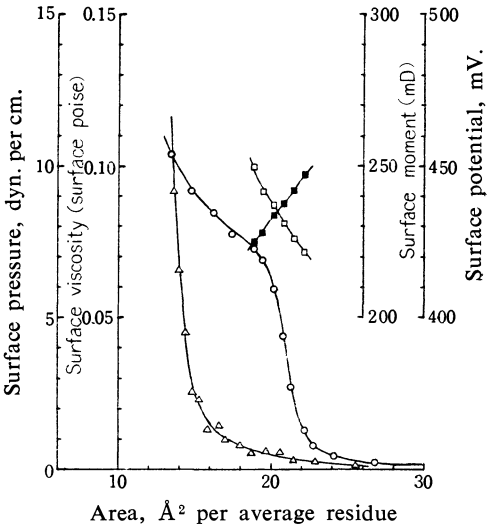

Fig. 7. Equimolar mixed monolayer of PBLG and PBLA at 19.3°C. ○, surface pressure; □, surface potential; ■, surface moment; △, surface viscosity.

derived from the surface pressure and from the surface potential are equal to each other and are about 22 Å², and the surface compressibility at the region of rise of surface pressure is intermediate between those for PBLG and PBLA and almost equal to that of CP(BLG, BLA). However, the surface moment and viscosity are much lower than those of CP(BLG, BLA). These characteristics are also given in Tables I and II. The reason for the low surface moment and the low surface viscosity of the mixed monolayer is not clear, since the dipole-dipole interaction would not be strong enough to influence monolayer properties very appreciably[14].

**Summary**

In view of the marked differences of PBLG and PBLA in crystals and in solutions, we have investigated their differences in monolayer states and further examined the monolayers of CP(BLG, BLA) and of the equimolar mixture of PBLG and PBLA.

All these polymers were found to be of condensed type and their limiting areas to be about 22 Å$^2$. The surface compressibility at the region of rise of surface pressure was in the order: PBLA>CP(BLG, BLA)>PBLG. The surface moments of all these polymers were considerably higher than those of non-polar polypeptides. The surface moment of PBLA was 50 mD higher than that of PBLG, and that of CP(BLG, BLA) gave a value intermediate between them. PBLG and CP(BLG, BLA) exhibited high surface viscosities at a very low surface pressure region, but, in spite of the condensed nature of the monolayer, PBLA showed appreciable surface viscosity first at a high surface pressure region. The surface viscosities of PBLG and PBLA were higher at higher temperatures.

From the data on surface pressure and surface moment, all these polymers were considered to have a configuration similar to the $\beta$-form in the spread state and possible configurations of side chains of PBLG and PBLA were deduced. It was found that the carbonyl group on the side chain of PBLG is far from the aqueous surface but that of PBLA is in contact with the surface and scarcely distinguishable from the carbonyl group on the main chain. Accordingly, PBLG can take a stable configuration like the $\beta$-form in monolayer, but the correspounding configuration of PBLA will be less stable owing to possible hydrogen bonding of the carbonyl group on the side chain with the imino group on the main chain and the resulting enhanced hydrophility of the side chain. This might be ascribed to the differences in surface compressibility and surface viscosity of PBLG and PBLA.

The surface pressure behavior of the mixed monolayer of PBLG and PBLA was such as was expected, but its behavior in surface potential and viscosity was very anomalous.

We wish to acknowledge to Professor J. Noguchi of Kanazawa University our indebtedness for his kind guidance in preparing the polypeptides.

# *Monolayer Studies on Polyanhydro-L-glutamic and Polyanhydro-L-aspartic Acids*

By Shoichi IKEDA and Toshizo ISEMURA

(Received August 15, 1960)

When poly-$\gamma$-benzyl-L-glutamate is reduced to remove the benzyl group in an anhydrous state, poly-$\alpha$-L-glutamic acid is obtained[1]. However, even if poly-$\beta$-benzyl-L-aspartate is treated in the same way, no poly-$\alpha$-L-aspartic acid but only polyanhydro-L-aspartic acid can be obtained[2]. Berger et al.[3] has reported that poly-$\alpha$-L-aspartic acid is prepared by this method, but Noguchi et al.[2] has suggested that the polymer obtained by Berger et al. would be a copolymer of L-aspartic acid with its andydride. Furthermore, Asai et al.[4] has shown that polyanhydro-L-glutamic acid can be produced by dehydrating poly-$\alpha$-L-glutamic acid with acetic anhydride. Polyanhydro-L-glutamic acid may be identified with either poly-L-glutarimide (I) or poly-L-pyrrolidone-2-carboxylic acid (II), and polyanhydro-L-aspartic acid with either poly-L-succinimide (III) or poly-L-propiolactam-2-carboxylic acid (IV). Noguchi et al.[2,4] has demonstrated from the

syntheses of appropriate polymers and the comparison of their infrared spectra that polyanhydro-L-glutamic acid is poly-L-glutarimide itself and polyanhydro-L-aspartic acid is poly-L-succinimide.

We have examined the monolayers of polyanhydro-L-glutamic acid, poly-DL-pyrrolidone-2-carboxylic acid, polyanhydro-L-aspartic acid and poly-L-succinimide at air-water interfaces and attempted to obtain further information concerning the structure of the polyanhydro acids. Some of these polymers are interesting in themselves for monolayer studies, since they are composed of chains of rings directly connected with each other and expected to have highly rigid structures.

## Experimental

Polyanhydro-L-glutamic acid and poly-DL-pyrrolidone-2-carboxylic acid were prepared by Professor Noguchi and his collaborators[4]. Polyanhyro-L-aspartic acid was prepared by reducing poly-$\beta$-benzyl-L-aspartate[5] in glacial acetic acid with anhydrous hydrobromic acid. Poly-L-succinimide was also prepared by Professor Noguchi et al.[2]

Surface pressure, potential and viscosity were measured by the methods as described previously[5]. Surface moment was calculated by the usual Helmholtz equation. Area was expressed in the unit of $Å^2$ per residue, a residue being assumed to consist of an anhydro acid residue plus a water molecule. The spreading solvent was a mixture of dichloroacetic acid-benzene (1 : 1 v/v) throughout the present investigation.

## Results and Discussion

**Polyanhydro-L-glutamic Acid.**—Two kinds of polymers, i. e., poly-L-glutarimide and poly-L-pyrrolidone-2-carboxylic acid, are possibly assumed as polyanhydro-L-glutamic acid. The former has a structure composed of rings exclusively, each connected directly by a C–N linkage, and is expected to be rigidly folded. The latter has a structure similar to poly-L-proline but is different from poly-L-proline by the presence of a carbonyl group in the pyrrolidone ring and expected to be highly hydrophilic. Poly-DL-pyrrolidone-2-carboxylic acid did not spread on distilled water but gave stable films on aqueous salt solutions, as illustrated in Fig. 1. The films of poly-DL-

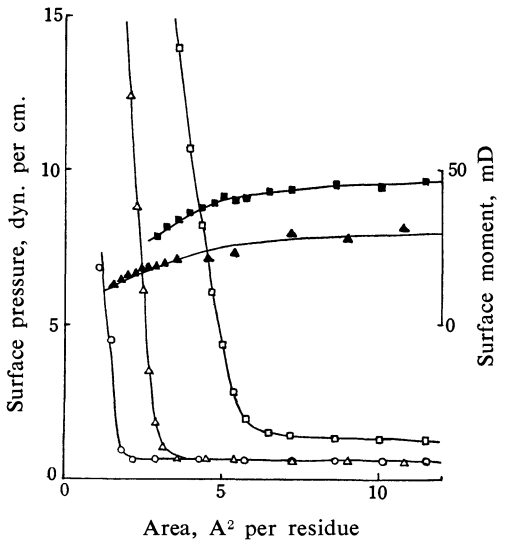

Fig. 1. Plots of surface pressure and surface moment of poly-DL-pyrrolidone-2-carboxylic acid against area (10°C). Aqueous subphases: potassium chloride solutions; ○, 0.01 M; △, ▲, 0.1 M; □, ■, 1 M.

pyrrolidone-2-carboxylic acid are of condensed type, in contrast to the expanded nature of poly-L-proline film. The reason why the film is condensed is not clear, since an expanded nature of polypeptide monolayer is ascribed to the structure devoid of hydrogen bonding[6] and polypyrrolidone carboxylic acid can include no hydrogen bond as polyproline.

On the other hand, polyanhydro-L-glutamic acid gave a stable monolayer of condensed type on distilled water, as shown in Fig. 2. This already indicates that polyanhydro-L-glutamic acid is not identical with poly-L-pyrrolidone-2-carboxylic acid but is poly-L-glutarimide itself. The limiting areas from surface pressure and surface viscosity were equally 13 $Å^2$, which was smaller than those assigned to a

□, polyanhydro-L-glutamic acid; ○, poly-L-succinimide; △, polyanhydro-L-aspartic acid.

β-configuration[6,7]. The surface potential was also low and the surface moment was about 50 mD. The low values of limiting area and surface moment also suggest that polyanhydro-L-glutamic acid might be poly-L-glutarimide, which can not be spread on aqueous surface as a monomolecular layer but has a folded configuration in film, as expected from its structure consideration.

The condensed nature of the monolayer of poly-L-glutarimide may be attributed to the rigid structure of this polymer, i. e., to its low configurational entropy. On the contrary, poly-L-proline has a relatively loose configuration in film, since its film is of an expanded type. Thus the pyrrolidine rings would not influence the flexibility of polymer chain in film very profoundly.

As referred to later, the monolayer of polyanhydro-L-glutamic acid behaves very similarly to that of poly-L-succinimide; this also supports the identity of polyanhydro-L-glutamic acid with poly-L-glutarimide. All these are consistent with the results of Asai et al.[4] and Bruckner et al.[8]

Since the ring of poly-L-glutarimide can be cleaved by dilute alkali[8,9], we have examined the monolayers of polyanhydro-L-glutamic acid on alkaline solutions of different pH's. The results on surface pressure-area relations are shown in Fig. 3 and the areas at 5 dyn. per cm. are plotted against the pH in Fig. 4. It can be seen that the film occupies smaller area as the rise of pH at the region of pH higher than 10.5 and no film can be formed at pH 13. This indicates that poly-L-glutamic acid produced by the cleavage of ring of polyanhydro-L-glutamic acid does not cause any expansion of film. When polyanhydro-L-glutamic acid was spread from its alkaline solution, no film was obtained on distilled water and even on 0.01 N hydrochloric acid or on potassium chloride solution. This suggests that the poly-L-glutamic acid thus formed should be composed of both α- and γ-linkages of peptide bonds, because poly-α-L-glutamic acid

can make films on the acid side[10], but poly-γ-L-glutamic acid forms no film on aqueous subphases of various compositions[11]. Although the cupric salt of the poly-L-glutamic acid is insoluble[8], the poly-L-glutamic acid spread from an alkaline solution gave no film on cupric sulfate solution.

**Polyanhydro-L-aspartic Acid.**—We will proceed to examine the relation of polyanhydro-L-aspartic acid with poly-L-succinimide. The behavior of the monolayer of poly-L-succinimide on distilled water is shown in Fig. 5. The

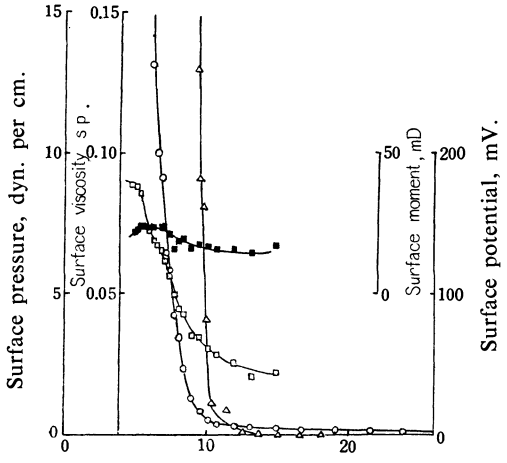

Fig. 5. Monolayer of poly-L-succinimide on distilled water (17°C).
○, surface pressure; □, surface potential; ■, surface moment; △, surface viscosity.

monolayer was of a condensed type and the limiting area determined from both surface pressure and viscosity was about 11 Å², and the surface potential was low and the surface moment was 20 to 25 mD. These low values may be attributed to the rigidly folded configuration of this polymer, which is maintained even in the spread state. Since poly-L-succinimide can be converted into poly-L-aspartic acid by dilute alkaline solutions[12-14], as poly-L-glutarimide to poly-L-glutamic acid[8,9], we have examined the monolayer properties on alkaline solutions of different pH's. The results are shown in Figs. 6 and 4. The cleavage of ring occurred at less alkaline pH for poly-L-succinimide than for poly-L-glutarimide; the

film spreads less completely as the rise of pH at the region of pH higher than 9.0 and no film can be formed at pH 11. By the same procedures as for poly-L-glutarimide, it was found that the poly-L-aspartic acid thus formed might include both α- and β-linkages. This is in accord with the result of Kovács et al.[14]

Polyanhydro-L-aspartic acid gave a stable monolayer on distilled water, as shown in Fig. 7. The spreading of this polymer was far less than that of poly-L-succinimide, and it could not be increased by the addition of salt into the aqueous subphase. Except for the

poorer spreading, however, polyanhydro-L-aspartic acid behaved very similarly to poly-L-succinimide in the monolayer state; e. g., no film was formed on an alkaline solution of pH 11, as shown in Fig. 4. Noguchi et al.[2] has confirmed that polyanhydro-L-aspartic acid is just poly-L-succinimide itself but never poly-L-propiolactam-2-carboxylic acid. Further they have referred to the Berger's polyaspartic acid[3] and concluded that it might be a copolymer of L-succinimide and L-aspartic acid. Our polyanhydro-L-aspartic acid might also be the same kind of copolymer since it occupies smaller area than poly-L-succinimide.

## Summary

To examine the structures of polyanhydro-L-glutamic acid and polyanhydro-L-aspartic acid, we have studied their monolayer properties and compared them with those of poly-DL-pyrrolidone-2-carboxylic acid and poly-L-succinimide. It was found that polyanhydro-L-glutamic acid is not identical with polypyrrolidone carboxylic acid but with poly-L-glutarimide, which has a rigidly folded configuration even in monolayer. This conclusion is in agreement with the results obtained by other methods. It was shown, however, that polyanhydro-L-aspartic acid can not be identified with poly-L-succinimide but it might be a copolymer of L-succinimide and L-aspartic acid.

We are grateful to Professor J. Noguchi of Kanazawa University for the gift of the polymers as well as for his guidance in preparing polyanhydro-L-aspartic acid.

# *On the Orientational Order-Disorder Transition in Crystalline Aniline Hydrobromide*

By Hiroshi SUGA*

(Received August 1, 1960)

In the course of X-ray structural analyses[1] of aniline hydrobromide, Taguchi[2] has recently observed a phase transition from the orthorhombic to the monoclinic system, which occurs on cooling at about 27°C. He also found that the monoclinic angle $\beta$, between the a and c axes, is not constant below the critical temperature but varies continuously over a wide range of temperature as the temperature is lowered. The detailed analyses of crystal structures above and below the transition temperature range were carried out by the same author. He found further anomalous spectra in oscillation and Weissenberg photographs below the critical temperature associated with the appearance of a hybrid structure. The detailed knowledge concerning the crystal structures above and below the transition temperature range, the unusual variation of the monoclinic angle, and the appearance of a hybrid structure stimulated us to study the thermal properties of this compound to look into the mechanism of this peculiar phase transition.

## Experimental

**Material.** — Aniline (extra pure grade manufactured by Wakō Chem. Ind., Ltd.) was added to an excess of an aqueous solution of hydrobromic acid (1st grade, the same company). The precipitated salt was washed with cold distilled water and then recrystallized from warm ethanol. The crude product thus obtained was slightly colored and found to have some lattice imperfection as revealed by X-ray photographs[1]. In order to purify the product further, it was finally subjected to fractional sublimation under high vacuum ($10^{-5}$ mmHg). The final product obtained by this procedure is colorless powder. Single crystals were also obtained by sublimation. They are transparent and colorless

and are found to be free from lattice imperfection; m. p. 283°C.

**Apparatus and Procedure.**—For the preliminary study to ascertain the occurrence of the phase transition, a differential thermal analysis was carried out in the temperature range from −150 to +300°C. The apparatus was the same in its main feature as the one used hitherto in this laboratory[3] except for attachment of an automatic recording of the temperature difference between the sample and the reference substance (in this case, KCl). The detailed description of the recorder was recently given[4]. To determine the accurate transition temperature and to study the thermal behavior more in detail, measurements of heat capacity were also carried out in the temperature range from −80 to +60°C by the use of the conduction calorimeter[5]. For the heat capacity measurements 4.4 g. of the material was used, the heating rate being 0.25~0.30°C/min. over the full temperature range. Further, the relative thermal expansion below and above the transition temperature as well as the hysteresis phenomenon associated with the phase transition were studied by employing a simple double-walled glass-made dilatometer filled with mercury as the confining liquid. About 29 g. of the material was used, and the heating and cooling rates were about 0.2°C/min.

## Results

One of the typical curves of the differential thermal analysis is reproduced in Fig. 1. From this curve it was found that there is a comparatively broad thermal anomaly over the temperature range from −50 to +25°C, with sufficient reproducibility in the repeated measurements and also there is no detectable hysteresis either in the heating or in the cooling direction. The data of heat capacity

in this temperature range are given in Table I and they are plotted in Fig. 2. As this figure shows, the excess heat capacity starts to rise gradually at about −70°C, reaches a maximum value at 22°C (critical temperature), and then drops down abruptly by as much as 9 cal./mol. deg. The general trend of the heat capacity versus temperature curve reminds us of the similarity to that of the order-disorder phase transition of binary alloy systems[6]. Table II gives enthalpy and entropy of the

transition and the difference of heat capacities at the critical temperature. To evaluate the enthalpy of transition, the excess heat capacities over the dotted line given in the figure are integrated graphically. Here the dotted line is drawn as the normal contribution of the lattice vibration to the heat capacity. By dividing the abnormal part into many sections of temperature intervals, the entropy of transition was evaluated by summing up the quotients obtained by dividing each area of these sections with the corresponding mean absolute temperature. The entropy of transition thus obtained, 1.10 e. u. is comparable in magnitude with those of $NH_4Cl$ and $ND_4Cl$[7] at their lambda point, 1.30~1.40 e. u. As is evident from Fig. 2, the heat capacity curve is of typical lambda type and there is no indication of the latent heat at the critical temperature, showing that this transition is of higher order nature.

7) C. C. Stephenson, R. W. Blue and J. W. Stout, *J. Chem. Phys.*, **20**, 1046 (1952).

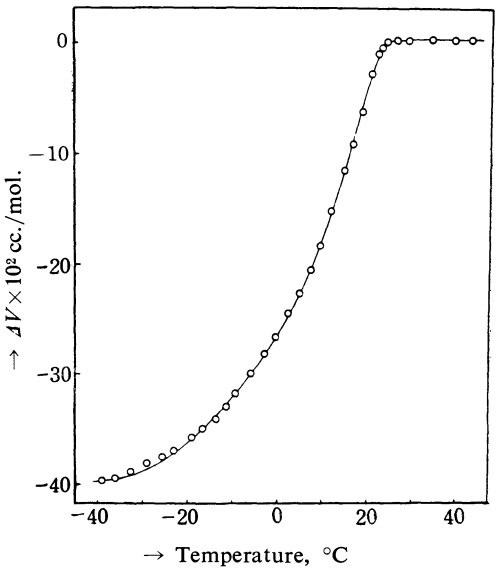

Fig. 3a. Anomalous thermal contraction of aniline hydrobromide.

Dilatometric studies revealed also the existence of abnormal expansion over the same transition range, as shown in Fig. 3. In this figure one can see that all the observed points in the heating and cooling directions can be represented by one and the same curve, showing again no hysteresis phenomenon. The dotted line in this figure means the thermal contraction extrapolated from the curve above the critical temperature by the use of the method of least squares. Fig. 3a gives the excess contraction $\Delta V$ below the dotted line and Fig. 4 the "abnormal" expansion coefficient calculated by $(1/V_0)\mathrm{d}(\Delta V)/\mathrm{d}T$, where $V_0$ is the molar volume of the crystal at the critical temperature. Although the expansion coefficient changes discontinuously at the critical point, the volume itself changes continuously over the whole range of measurements. These facts

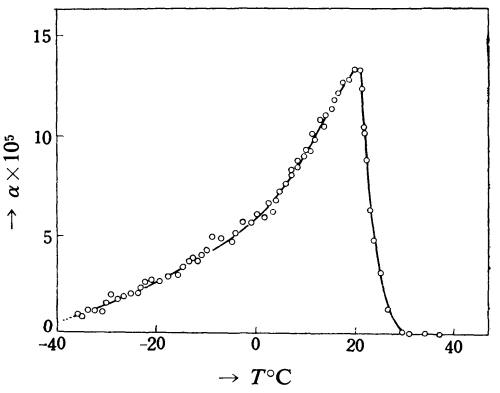

Fig. 4. Abnormal expansion coefficient of aniline hydrobromide.

also reasonably support the proposition that the transition is of higher order nature. The fact of non-existence of hysteresis phenomenon in the higher order phase transition was interpreted by Staveley et al.[8] from the point of view of lattice strain energy accompanying the phase transition.

## Discussion

Prior to the discussion of the plausible mechanism of this phase transition, it is necessary to give a brief account of the crystal structure[1,2] above and below the critical temperature. The high temperature phase belongs to the orthorhombic system ($D_{2h}^{10}-Pnaa$). In this structure, it is required from the crystal symmetry that both the principal axis of anilinium ion ($N-C_1\cdots C_4$ axis) and the $Br^-$ ion are found to lie on two different two-fold symmetry axes along the a axis. Although the positions of hydrogen atoms attached to the nitrogen atom are not yet determined, $-NH_3^+$ ionic group is surrounded by four $Br^-$ ions, of which two are slightly more distant than the other two. On cooling the crystal through the critical temperature, it is transformed into the monoclinic system ($C_{2h}^5-P2_1/a$); the monoclinic angle deviates gradually from 90° and reaches 91°22′ asymptotically in a manner shown in Fig. 8, where the unit of the ordinate is twice the quantity $\Delta\beta(=\beta-90°)$, for convenience. In the structure of the low temperature modification, the requirement of two-fold symmetry imposed to the C-N axis is lost. In this phase, in response to the variation of $\beta$, the positions of $Br^-$ ions and $-NH_3^+$ ionic groups are displaced with respect to each other, with the following sequence that the interionic distances between $Br^-$ ions and an $-NH_3^+$ ionic group become different from each other, and also that the pseudo electric dipole moments due to the displacements of the two kinds of ions in the neighboring ionic array along the a axis may be found to be antiparallel with each other in a similar manner as in the anti-ferroelectric crystal which was proposed originally by Kittel[9].

Considering the crystal structures as well as the thermal behaviors above and below the critical temperature described above it is suggested that a mechanism of orientational order-disorder of the $-NH_3^+$ group as an interpretation of this phase transition be given, based on the reason given below. In the first place, it will be natural to assume the pyramidal configuration ($C_{3v}$) of the $-NH_3^+$ ionic group. In the high temperature phase, since the C-N axis should lie on the two-fold symmetry axis, the potential energy of $-NH_3^+$ group associated with the rotational motion of this group will also have the same two-fold axial symmetry around this axis. Therefore, one has to consider necessarily some statistical randomness for the azimuthal orientation of $-NH_3^+$ group with respect to the C-N bond so far as one puts an $-NH_3^+$ group having three-fold symmetry on the axis of two-fold symmetry. On the other hand, in the low temperature phase such a requirement of two-fold symmetry is lost owing to the different crystal symmetry. Taking into account the possible formation of the N-H···Br weak hydrogen bond, possible orientations of the $-NH_3^+$ group with respect to the hydrogen atoms may be expected to be such as are represented in Fig. 5.

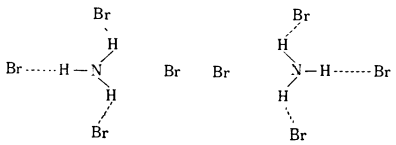

Fig. 5. Possible orientations of $-NH_3^+$ group (a- and b-types).

It is obvious from the symmetry consideration that these a- and b-type orientations are equally probable in the orthorhombic phase, whereas in the monoclinic phase one of these two types would be stabilized. We shall call this the a-type for convenience. Then, the requirement of two-fold axial symmetry in the high temperature phase will be satisfied if we distribute the $-NH_3^+$ groups between these two equilibrium orientations (a- and b-types), statistically in space and time. Thus, we may call tentatively this transition the "orientational order-disorder" type in the sense that an equal number of the a- and b-type orientations of $-NH_3^+$ groups can exist above the critical temperature whereas the number of the a-type orientation is predominant below the critical temperature. A simplified hindering potential energy curve for such a rotational motion of the $-NH_3^+$ group in the lattice may be represented schematically as in Fig. 6. This potential energy curve has 60° periodicity in the high temperature phase, while that corresponding to the low temperature phase will have 120° periodicity. As is shown in the figure, the degree of increase or decrease in depth of potential minima is assumed to be a linear function of $\Delta\beta$. Since the extent of displacement of the atomic position is assumed to be proportional to the variation of macroscopic quantity $\beta$ in a first approximation, some of the physical properties of the present crystal

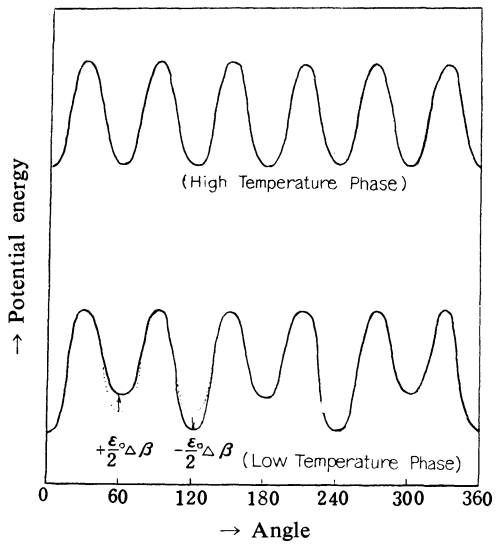

Fig. 6. Schematic representation of hindering potential for the rotational motion of $-NH_3^+$ group.

associated with the variation of $\beta$ may be considered to change proportionally with the variation of $\beta$. As a matter of fact, Horie et al.[10] have recently given an example of the temperature dependence of the angle between optic elasticity axes, $\gamma$, in adjacent domains in the hybrid structure of aniline hydrobromide in the vicinity of the critical temperature (Fig. 7); one can see here a fairly linear relationship between the temperature variation of $\Delta\beta$ and $\gamma$.

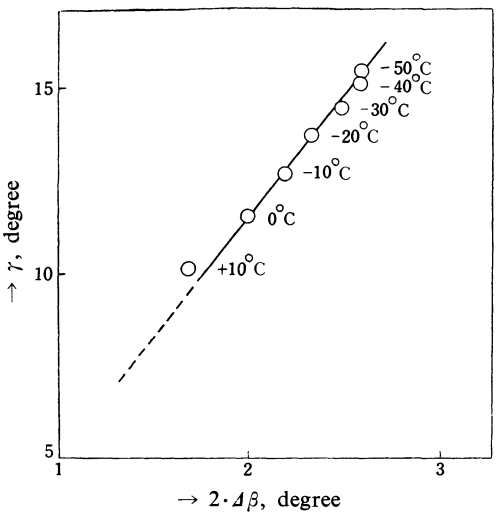

Fig. 7. Linear relationship between the temperature variation of $\Delta\beta$ and of the angle $\gamma$ between the two optic elasticity axes in adjacent domains (after Horie et al.[10]).

10) T. Horie. T. Iwai and I. Taguchi, Annual Meeting of Phys. Soc. Japan, 1956,: To be published in near future. The author would like to express his appreciation for their permission to refer to their result before its publication.

Now, let us calculate the temperature dependence of $\Delta\beta$ on the basis of the proposed model in order to compare the result with the experimental value reported by the X-ray method[2]. We define the degree of order $s$ as follows; let it be assumed that in a state specified by a set of values $(T, s)$, $N(1+s)/2$ $-NH_3^+$ groups in the a-type orientation and $N(1-s)/2$ in the b-type are distributed over the whole $N$ lattice points. The order parameter $s$ thus defined has the same character as the one proposed for the theory of order-disorder phase transition of binary alloy[11]. That is, when $s=1$ all the $-NH_3^+$ groups are in the a-type orientation; this corresponds to the state of perfect order. When $s=0$ there are as many a-type groups as b-type groups; the state of complete disorder. It is somewhat difficult to calculate the hindering potential energy for rotational motion of the $-NH_3^+$ group in the crystalline field owing to an ambiguity in the estimation of effective charge distribution of the $-NH_3^+$ group, the unknown N-H distance and also the complexity of the crystal structure, so that we shall confine our calculation at the present stage only to the differences in the energy and entropy between the two phases. The notation $\Delta$ used in the following calculation stands for the excess of any thermodynamic quantities of the ordered state over that of the completely disordered state extrapolated above the transition point. The difference in the internal energy $\Delta U$ will consist of two parts in its origins; one is the contribution from the variation of the arrangements of ions and ionic groups and the other is that from the change of orientations of $-NH_3^+$ ionic groups when the ordered state changes to the disordered state. The first part of energy difference, $\Delta U_1$, may be expressed formally by a power series in $\Delta\beta$ of which all the odd terms are omitted by the requirement that $\Delta U$ should be an even function of $\Delta\beta$, because the gradual change of either direction from the orthorhombic to the monoclinic crystal system should produce the same energy change. For example, the electro-static part of $\Delta U_1$, which is the mutual interaction energy between the pseudo electric dipole moments produced by the displacements of ions and ionic groups, is expressed by

$$-1/2\sum_{i>j}\frac{\mu_i\mu_j}{r^3_{ij}}\{3\cos(\theta_i+\theta_j)+\cos(\theta_i-\theta_j)\}$$

11) W. L. Bragg and E. L. Williams, *Proc. Roy. Soc.*, A145, 699 (1934); A151, 540 (1935); F. C. Nix and W. Shockley, *Rev. Mod. Phys.*, 10, 1 (1938).

where $\mu_i$, $\mu_j$, $\theta_i$, $\theta_j$ and $r_{ij}$ have the usual meanings. Since $\mu_i$ and $\mu_j$ may be reasonably considered to be proportional to $\Delta\beta$, the term may be rewritten by $J(\Delta\beta)^2$, where $J$ is a constant. If the higher terms in $\Delta\beta$ can be neglected, then $\Delta U_1=A(\Delta\beta)^2$, where $A$ is another constant. The second part of energy difference $\Delta U_2$, which is due to the change of potential energy at an $-NH_3^+$ group caused by the variation of the degree of order $s$, may be expressed by $\frac{1+s}{2}N\left(-\frac{\varepsilon_0}{2}\Delta\beta\right)+\frac{1-s}{2}N\left(\frac{\varepsilon_0}{2}\Delta\beta\right)$ In this case it has been assumed that the change in the depth of potential minima is proportional to the change in $\Delta\beta$ with a constant of proportionality $\varepsilon_0/2$ (see Fig. 6). Thus,

$$\Delta U=\Delta U_1+\Delta U_2=A(\Delta\beta)^2-sE\Delta\beta/2 \qquad (1)$$

where $E=N\varepsilon_0$.

On the other hand, the entropy difference $\Delta S$ is given approximately by the possible number of $N(1+s)/2$ a-type and $N(1-s)/2$ b-type arrangements of $-NH_3^+$ groups over the $N$ whole lattice points.

$$\Delta S=\boldsymbol{k}\ln\frac{N!}{\left(\frac{1+s}{2}N\right)!\left(\frac{1-s}{2}N\right)!}-\boldsymbol{R}\ln 2$$

$$=-\boldsymbol{R}\left\{\frac{1+s}{2}\ln\frac{1+s}{2}+\frac{1-s}{2}\ln\frac{1-s}{2}+\ln 2\right\} \qquad (2)$$

Here, the additional term $\boldsymbol{R}\ln 2$ appears since the completely disordered state was taken as the reference. Accordingly, the difference of Helmholtz free energy $\Delta F$ between the two phases is given by

$$\Delta F=\Delta U-T\Delta S=A(\Delta\beta)^2-sE\Delta\beta/2+\boldsymbol{RT}\left\{\frac{1+s}{2}\ln\frac{1+s}{2}+\frac{1-s}{2}\ln\frac{1-s}{2}+\ln 2\right\} \qquad (3)$$

By the equilibrium conditions, we can obtain the following set of equations. From $\partial(\Delta F)/\partial(\Delta\beta)=0$ (since there is no external shear stress), it follows

$$\Delta\beta=Es/(4A) \qquad (4)$$

$$\Delta U=-E^2s^2/(16A) \qquad (4')$$

Eq. 4′ shows that the present treatment corresponds formally to the Bragg-Williams approximation. From $\partial(\Delta F)/\partial s=0$, we have

$$s=\tanh E^2s/(8\boldsymbol{R}AT) \qquad (5)$$

$$T_c=E^2/(8\boldsymbol{R}A) \qquad (6)$$

where $T_c$ is the critical temperature, above which $s$ becomes zero. Inserting the value of $s$ derived from 5 into 2, we get a calculated total entropy change 0.83 e. u. ($-70\sim+35$°C) in comparison with the observed value 1.10 e. u. In this case, the additional entropy increment due to the increase of the available volume of ion, which may be reasonably given by $\boldsymbol{R}\ln(V+\Delta V)/V$, is quite negligible in magnitude, less than 0.01 e. u., in the same temperature interval. Combination of Eqs. 5 and 6 with Eq. 4 gives the temperature dependence of $\Delta\beta$ including the numerical factor $E/(4A)$, which can be determined, for example, by fitting the calculated value with the observed value of $\Delta\beta$ at a single temperature, say $-40$°C. The temperature dependence of $\Delta\beta$ obtained in this way is given by the dotted line in Fig. 8. Although qualitative agreement is obtained, the details are

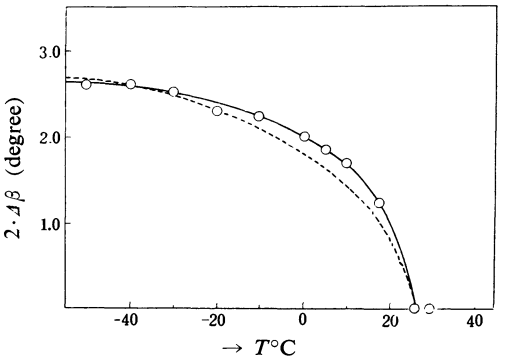

Fig. 8. Comparison of observed temperature variation of $\Delta\beta$ with the theoretical one.
○ Observed by Taguchi[2]
---- Theoretical curve ignoring volume effect.
—— Theoretical curve including volume effect.

not fully explained especially in the following points; one is that the degree of covergence of this curve to the critical point is not so steep as that of the experimental curve, and another point is that the calculated $\Delta\beta$ should increase to 1.37 times as large a value as that at $-40$°C if the curve is extrapolated to 0°K, while the corresponding value obtained by experiment[2] is only 1.12.

As already mentioned, an anomalous thermal expansion in the vicinity of the critical point appears (see Fig. 3). According to the results by Eisenschitz[12], Sato[13] and Nagamiya[14], the temperature dependence of the order parameter is appreciably affected by taking into account the anomalous thermal expansion accompanied

with the order-disorder phase transition in the case of binary alloy systems. We have then attempted to examine the effect of volume change in the present case as the next stage of refinement. After Sato's treatment, we can get the following expression for the abnormal expansion coefficient

$$\Delta\alpha=\alpha(s)-\alpha(0)=\kappa_0 \mathrm{d}s^2/\mathrm{d}T\cdot E_0 \mathrm{d}(E/E_0)/\mathrm{d}V$$
$$=\kappa_0 \boldsymbol{R}T_c/2\cdot \mathrm{d}s^2/\mathrm{d}T\cdot \mathrm{d}(E/E_0)/\mathrm{d}V \qquad (7)$$

Here, $\kappa_0$ is isothermal compressibility of the disordered phase; $V$ the molar volume; $E$ and $E_0$ the ordering energy at $T$°K and 0°K, respectively. Then, the abnormal expansion over $V^\circ$, the molar volume at 0°K, is given by

$$v=\int_0^T V^0\Delta\alpha \mathrm{d}T=\int_1^s V^0 C\mathrm{d}s^2=-CV^0(1-s^2) \qquad (8)$$

where the following abbreviations were used

$$\mathrm{d}(E/E_0)/\mathrm{d}V=B, \qquad \boldsymbol{R}T_c=C$$

By using the observed $v_{max}$ value 0.41 cc./mol. and $V_0=110$ cc.*, $C$ becomes $-3.76\times10^{-3}$.

Based on these expressions the following thermodynamic functions are derived as functions of $s$, $v$ and $T$.

$$U(s,\ v,\ T)=E_0-Es^2=E_0\{1-(1+Bv)s^2\} \qquad (9)$$

$$G(s,\ v,\ T)=E_0\{1-(1+Bv)s^2\}$$
$$+\boldsymbol{R}T/2\{(1+s)\ \ln\ (1+s)+(1-s)\ \ln\ (1-s)$$
$$-2\ \ln\ 2\} \qquad (10)$$

Here, $G$ is the Gibbs free energy**. From $\partial G/\partial s=0$ and $\partial^2 G/\partial s^2=0$, we have

$$s=\tanh 2E_0 s\{(1+Bv)+BCV_0 s^2\}/\boldsymbol{R}T \qquad (11)$$

$$\boldsymbol{R}T_c/E_0=2(1+Bv_{max}) \qquad (12)$$

The differentiation of $U(s,\ v,\ T)$ with $T$ gives an expression for excess heat capacity over that arising from lattice vibration. The maximum value is obtained from the limitation of $s\to0$.

$$C_{max}=\lim_{s\to0}(\partial U/\partial s)/(\partial T/\partial s)$$
$$=3\boldsymbol{R}/2\{1-(6BCV_0)/(1+Bv_{max})\}^{-1} \qquad (13)$$

On the assumption that the $C_{max}$ value thus defined is identical with the experimentally observed $\Delta C_p$, the following set of values can be obtained: $B=-2.44\times10^{-1}$ cc$^{-1}$, $\kappa_0=1.25\times10^{-6}$ atm$^{-1}$. By using these numerical values and the observed volume change, the refined $\Delta\beta-T$ curve is calculated and drawn by the full line in Fig. 8, where a fairly satisfactory agreement between this curve and the observed points is seen. It is to be noted that the calculated total entropy change 1.06 e. u. (from $-70$ to $+35$°C) is in good agreement with the observed one 1.10 e. u., if the same numerical values for parameters are used. The value of $\kappa_0$ obtained above seems to be somewhat smaller for this kind of crystal including organic complex ion, since the compressibility is in the range of $(2\sim7)\times10^{-6}$ atm$^{-1}$ for usual ionic crystals. Although the model proposed here is merely a possible one, it may be said that rather satisfactory results were obtained.

A preliminary study of proton magnetic resonance absorption of the powdered specimen of this crystal was recently made by Yamagata* over the temperature range between $-190$ and $+40$°C and there was no detectable change in the line width at the critical point. The observed second moment 8.35 Gauss$^2$ almost coincides with 7.82 Gauss$^2$ of the calculated value obtained by assuming the isolated $-NH_3^+$ group (the value 1.032 Å for N-H distance and tetrahedral angle were assumed) with rotational flipping motion about the C-N axis. The situations are very similar in the cases of ammonium halides[15].

## Summary

Measurements of the heat capacity ($-80\sim+60$°C) and the thermal expansion ($-40\sim+60$°C) of aniline hydrobromide were carried out covering the transition temperature which has been observed recently by X-ray methods. The observed heat capacity versus temperature curve was of the $\lambda$-shape, similar to that of the order-disorder phase transition of binary alloy systems. The following results were obtained; $T_c$ (the temperature corresponding to the heat capacity peak) 22°C, $\Delta H$ (heat of transition, $-70\sim+35$°C) $297\pm10$ cal./mol., $\Delta S$ (entropy of transition, the same temperature interval) $1.10\pm0.05$ e. u., $\Delta C_p$ (drop of heat capacity at $T_c$) $\sim9$ cal./mol. deg. Also the anomalous behavior of thermal expansion was observed in the vicinity of the critical temperature. These observations showed that the transition was of higher order nature.

Based on the lits of knowledge of the crystal structures above and below the critical temperature, the author has discussed the main feature of the phase transition from the sandpoint of the orientational order-disorder of the $-NH_3^+$ ionic group and obtained fairly satisfactory results.

* This value was taken from $d_{25}=1.58$, by the picnometric measurement of Taguchi et al.[1]

** The $G$ function expressed here does not correspond exactly to the Gibbs free energy, since the $PV$ term was neglected.

# *Optical Properties of Colored Colloidal Systems. II. Apparent Refractive Index and Extinction Coefficient of the System of Small Spherical Particles*

By Masayuki NAKAGAKI* and Tomiko FUJII

(Received September 26, 1960)

In the preceding paper of this series[1], the extinction of light by the system of colored small spheres were theoretically calculated. As a result, it was concluded that the scattering of light by colored spheres is affected by the absorption of light, the latter being expressed by the imaginary part of the refractive index of the dispersed phase. In the present paper, the calculation will be extended to the apparent refractive index of the system. The result thus obtained will be applied to the system of infinitesimally small particles, and will be used to discuss the optical properties of a dyestuff solution as an example.

## Theoretical Calculations

**Principle of the Calculation.** — The relation between the refractive index of a colloidal system or a solution, $\mu_{12}$, and the refractive indices and compositions of the components is usually given by the following equation called a mixture rule,

$$\mu_{12}=\mu_1\varphi_1+\mu_2\varphi_2 \tag{1}$$

where $\mu_1$ and $\mu_2$ are the refractive indices of the solvent and dispersed phases, respectively, and $\varphi_1$ and $\varphi_2$ are the volume fractions of the respective phases. If the concentration of the dispersed phase, $c$, is given in mol./l. unit, Eq. 1 may be rewritten as,

$$\mu_{12}=\mu_1+(M/1000\rho_2)(\mu_2-\mu_1)c \tag{2}$$

where $M$ is the molecular weight of the material of the dispersed phase and $\rho_2$ is the specific gravity of the same phase. The linear relationship between $\mu_{12}$ and $c$ as predicted by Eq. 2 has been verified experimentally by many investigators, but the value of $\mu_2$ is not equal[2] to the refractive index in bulk of the dispersed phase, $\mu_2$ (bulk). Therefore the value of $\mu_2$ obtained experimentally on the basis of Eq. 2 is an apparent refractive index of the dispersed phase. If the apparent relative refractive index $m'$ defined by

$$m'=\mu_2/\mu_1 \tag{3}$$

is used, the inclination of the straight line to give the variation of $\mu_{12}$ with the concentration $c$ is expressed as

$$\partial\mu_{12}/\partial c=(M\mu_1/1000\rho_2)(m'-1) \tag{4}$$

This equation is to be used to determine the value of $m'$ experimentally.

On the other hand, $(m'-1)$ is given theoretically by the equation[2],

$$m'-1=(3/2)\mathrm{R}[j_\perp(180)]/\alpha^3 \tag{5}$$

where $\alpha$ is a parameter defined by

$$\alpha=2\pi a/\lambda \tag{6}$$

Here, $a$ is the radius of the sphere and $\lambda$ is the wave length of light in the medium. The sign R in Eq. 5 means the real part of a complex function $j_\perp(180)$, the latter being

$$j_\perp(180)=\frac{m^2-1}{m^2+2}\alpha^3+\left(\frac{m^2-1}{m^2+2}\right)^2\times\frac{(m^4+27m^2+38)}{15(2m^2+3)}\alpha^5-i\frac{2}{3}\left(\frac{m^2-1}{m^2+2}\right)^2\alpha^6 \tag{7}$$

* Present address: Faculty of Pharmacy, Kyoto University, Sakyo-ku, Kyoto.

1) M. Nakagaki, This Bulletin, 31, 980 (1958).

2) M. Nakagaki and W. Heller, *J. Appl. Phys.*, 27, 975 (1956).

as already given in the previous paper[1], where $m$ is a complex quantity in the case of colored particles:

$$m=\mu_2^*(\text{bulk})/\mu_1=m_0-ik_0 \tag{8}$$

where $\mu^*$ means the complex refractive index.

**Apparent Refractive Index as a Function of Particle Size.**—If $k_0 \ll m_0$, the theoretical equation may be expanded in a power series,

$$m'-1=M_1-M_2k_0+M_3k_0^2+\cdots\cdots \tag{9}$$

where

$$\left.\begin{aligned} M_1&=(3/2)(X_1+Y_1\alpha^2)\\ M_2&=(3/2)Z_2\alpha^3\\ M_3&=(3/2)(X_3-Y_3\alpha^2)\end{aligned}\right\} \tag{10}$$

Here,

$$\left.\begin{aligned} X_1&=\frac{m_0^2-1}{m_0^2+2}\\ Y_1&=\frac{1}{15}\left(\frac{m_0^2-1}{m_0^2+2}\right)^2\frac{(m_0^4+27m_0^2+38)}{(2m_0^2+3)}\\ Z_2&=8m_0\frac{m_0^2-1}{(m_0^2+2)^3}\\ X_3&=\frac{3(3m_0^2-2)}{(m_0^2+2)^3}\\ Y_3&=\frac{\left\{\begin{array}{l}4m_0^{18}+66m_0^{16}-1104m_0^{14}-5033m_0^{12}\\ +12966m_0^{10}+105525m_0^8+218152m_0^6\\ +182376m_0^4+37824m_0^2-16176\end{array}\right\}}{15(m_0^2+2)^6(2m_0^2+3)^3}\end{aligned}\right\} \tag{11}$$

The results of the numerical computation are shown in Fig. 1. Crosses in the figure are the values for colorless particles calculated on the basis of the Mie theory without any approximation[2]. The agreements between these Mie values and the values obtained from Eqs. 9, 10 and 11 and shown with open circles for colorless particles are very good, although a small discrepancy can be seen in the case where both $\alpha$ and $m_0$ are large ($\alpha=0.8$, $m_0=1.3$). When $k_0$(which shows the absorption of light) is small, the apparent relative refractive index $m'$ increases with $\alpha$ (or particle size), but when $k_0$ is large, the value of $m'$ decreases (after passing a flat maximum when $m_0$ is large) with the increase of $\alpha$.

**Optical Properties of Infinitesimally Small Particles.**—The equation used in the preceding paper as well as in the preceding paragraphs of this paper are for small values of $k_0$. In the present paragraph, equations for infinitesimally small particles ($\alpha \to 0$) are examined without any restriction on $k_0$. The equations are

$$m'-1=\frac{3}{2}-\frac{9}{2}\times\frac{(m_0^2+2-k_0^2)}{(m_0^2+k_0^2+2)^2-8k_0^2} \tag{12}$$

and

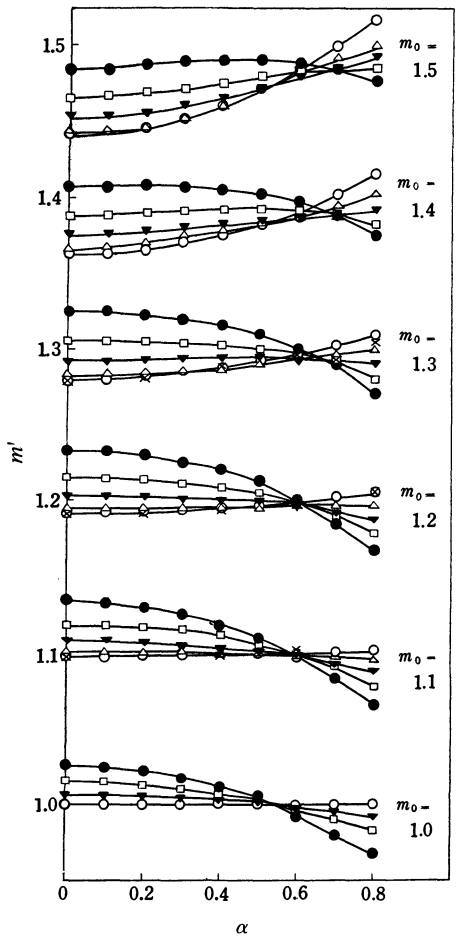

Fig. 1. $m'-\alpha$ relation for $k_0=0$ (○); 0.1 (△); 0.2 (▼); 0.3 (□); 0.4 (●). Mie's values are shown with (×).

$$\left.\begin{aligned} x&\equiv(\lambda\rho_2/3\pi)\varepsilon=\frac{12m_0k_0}{(m_0^2+k_0^2+2)^2-8k_0^2}\\ x(\text{bulk})&=(4/3)k_0\end{aligned}\right\} \tag{13}$$

where $x$ is a quantity proportional to the extinction coefficient $\varepsilon$ as already introduced in the preceding paper[1].

The numerical values of $m'$ as a function of $k_0$ were calculated for various values of $m_0$ from 0.88 to 1.24 with the interval of 0.02. A part of the results is shown in Fig. 2. Although the apparent relative refractive index $m'$ and the relative refractive index in bulk $m_0$ are parallel when $k_0$ is small, the sequence is inverted when $k_0$ is larger than about 1.4. The smaller $m'$ the larger is the $m_0$. Moreover, the value of $m'$ approaches 2.5 when $k_0$ becomes infinitely large. These results shown in Fig. 2 have not been expected by any previous investigator.

The numerical values of $x$ as a function of

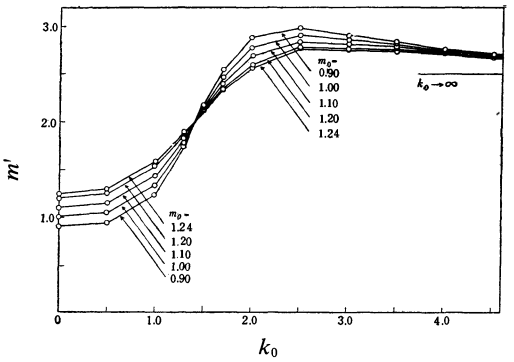

Fig. 2. $m'-k_0$ relation calculated theoretically.

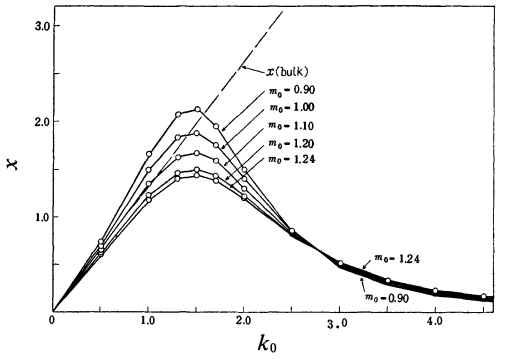

Fig. 3. $x-k_0$ relation calculated theoretically.

$k_0$ were calculated for various values of $m_0$ from 0.88 to 1.24 with the interval of 0.02. A part of the results is shown in Fig. 3. The curves have the maximum at the $k_0$ value of about 1.5. The apparent extinction coefficient or $x$ decreases for the larger value of $k_0$ and approaches zero when $k_0$ becomes infinitely large.

These results, too, have not been expected by any previous investigator[3].

## An Example for the Treatment of Experimental Data

**Materials.**—It is generally believed that acid dyes dissolve in water monomolecularly, showing a small tendency to form micelles in contradistinction to direct cotton dyes which form micelles when the temperature is not high. Therefore, an acid dye solution is used as a model of the system of colored infinitesimally small particles.

The acid dye used in this experiment was Acid Orange R (C. I. 15575, Acid Orange 8) purified by the sodium acetate-alcohol method. The purity determined by titanium trichloride titration was 96.32%.

3) In Figs. 2 and 3, theoretically calculated points were connected with straight lines for the convenience of the drawings. The actual theoretical curves should, of course, be curved smoothly.

**Determination of Refractive Index.**—The difference of the refractive index between the solution and the solvent was measured by using a differential refractometer of modified Brice type as shown in Fig. 4. Light from a

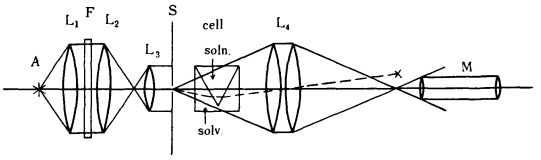

Fig. 4. Schematic diagram of differential refractometer of modified Brice type.

tungsten lamp A was collimated with lenses $L_1$ and $L_2$ ($f_1=6$ cm., $f_2=6$ cm.), filtered with a gelatine filter F, made parallel with a lens $L_3$ ($f_3=3$ cm.) and projected to a slit S. The image of the slit focused by a lens $L_4$ ($f_4=15$ cm. lens for a slide projector was used) was observed with a microscope M of the magnification of 40 times ($4\times10$). The location of the image of the slit was shifted when a solution was put in the prism cell containing solvent outside the prism in the cell. The shift of the image of the slit was measured by a micrometer in the eyepiece of the microscope M. The reading $\theta$ is proportional to the difference of the refractive index,

$$\mu_{12}-\mu_1=K\theta \qquad (14)$$

The proportionality constant $K$ was determined to be $K=4.15\times10^{-5}$ by using potassium chloride solution as a standard, the refractive index of the latter being cited in the literature[4]. The value of $\mu_1$ is also given in the literature[5].

In order to convert the experimental values of $(\partial\mu_{12}/\partial c)$ to $m'$ according to Eq. 4, the value of the density of dye, $\rho_2$, should be known. The density was assumed to be 1.5 by Robinson[6] and to be 1.0 by Atherton et al.[7] Since the accurate value of the density for the dispersed state can not be known, calculations were made here for both these density values. The results are shown in Fig. 6 with broken lines. A typical anomalous dispersion was observed as already reported for some other dye solutions[7]. In Fig. 6 and also Fig. 7, $\lambda_0$ is wavelength in vacuum.

**Determination of Extinction Coefficient.**—The extinction coefficient was determined by Shimazu spectrophotometer QR-50. The results were recalculated to $x$ by Eq. 13 for $\rho_2=1.0$ and $\rho_2=1.5$. The results are shown in Fig. 7 with broken lines.

**Calculation of $m_0$ and $k_0$.** — The quantities obtainable by experiments are $m'$ and $x$, but the fundamental quantities of theoretical interest are $m_0$ and $k_0$. To determine $m_0$ and $k_0$ from $m'$ and $x$, a graphical method is shown in Fig. 5. The $m'-x$ relation calculated theoretically for systematically varied values of parameters $m_0$ and $k_0$ make a network. A pair of experimental values of $m'$ and $x$ give one plot on this chart. Then, the values of $m_0$ and $k_0$ corresponding to this plot can be read off by interpolation. The values of $m_0$ thus obtained are shown in Fig. 6 with solid lines, and the values of $x$(bulk) calculated by Eq. 13 from the values of $k_0$ thus obtained are shown in Fig. 7 with solid lines.

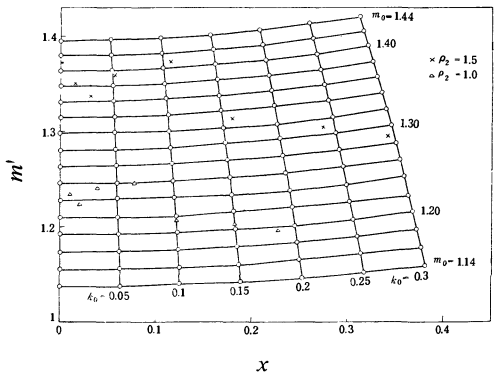

Fig. 5. $m'-x$ relation. Network shown with (○) is theoretical. Experimental data for $\rho_2=1.0$ (△) and for $\rho_2=1.5$ (×) are also ploted.

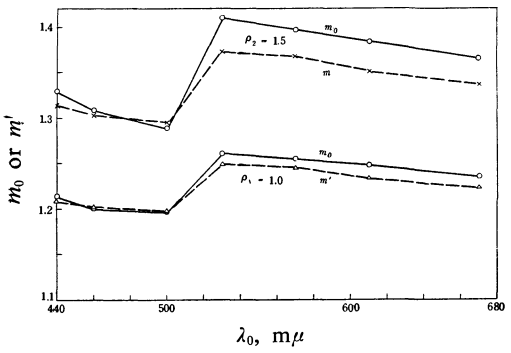

Fig. 6. Dependencies of $m_0$ and $m'$ on $\lambda_0$.

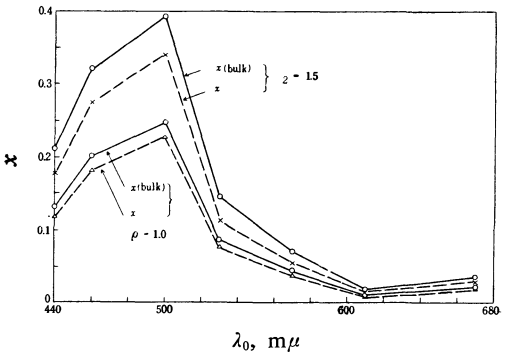

Fig. 7. Dependencies of $x$(bulk) and $x$ on $\lambda_0$.

The discrepancies between solid curves and broken curves in Fig. 6 and Fig. 7 show the error committed if one assume that the experimental $m'$ and $x$ values are equal to $m_0$ and $x$(bulk)—the latter is equal to $(4/3)k_0$—of the dispersed phase in bulk. The errors in this sense are given in Table I for the present solutions. The table shows that the error in $m'$ is less than 2.6% at the greatest, but the error in $x$ reaches as far as 21% at the greatest.

TABLE I. ERRORS COMMITTED BY IGNORING THE PRESENT THEORY

| $\lambda_0$ | $\rho_2=1.5$ | | $\rho_2=1.0$ | |
|---|---|---|---|---|
| | $\Delta m$ | $\Delta x$ | $\Delta m$ | $\Delta x$ |
| mμ | % | % | % | % |

| 670 | −2.10 | −17.7 | −0.91 | − 8.7 |

## Summary

The theoretical values of apparent relative refractive index $m'$ of colored particles was calculated as a function of particle size for various values of $m_0$ and $k_0$.

The theoretical values of $m'$ as well as $x$ were calculated for infinitesimally small particles. It was shown that $m'$ increases and, after passing a maximum point, approaches a limiting value of 2.5 with the increase of $k_0$, and that $x$ approaches zero, after passing a maximum, with the increase of $k_0$.

The values of $m'$ and $x$ of Acid Orange R solutions were measured by a modified Brice type differential refractometer and by a spectrophotometer. A method to convert $m'$ and $x$ values into $m_0$ and $k_0$ values was illustrated. The errors committed by assuming experimental $m'$ and $x$ values as $m_0$ and $(4/3)k_0$ values of bulk phase are estimated for the dye solution. The error of $x$ reached 21%, while the error of $m'$ was not larger than 2.6%.

# *A Diffusion Mechanism for Liesegang Rings*. I. Spacing Law*

By Prem Behari MATHUR**

(Received August 18, 1960)

Jablczynski's equation for spacings between Liesegang rings

$$x_n = ak^n \tag{1}$$

where $x_n$ is the distance of $n$th ring from the diffusion level, and $a$ and $k$ are constants, may be written as

$$\frac{x_{n-1}}{x_n} = \frac{1}{R} \tag{2}$$

or $$1-\frac{x_{n-1}}{x_n} = \left(1-\frac{1}{R}\right)$$

or $$(x_n - x_{n-1}) = kx_n \tag{3}$$

From statistical consideration, Eq. 3 is more sensitive form of Jablczynski's relation 1. According to the Eq. 3 the plot of $(x_n - x_{n-1})$ against $x_n$ should be straight line curves passing through the origin. In practice the curves are not found to pass through the origin when the distances of the rings are measured from diffusion level for which Eq. 1 stands. The author has advanced a theory and deduced from Fick's diffusion law a few general expressions for the Liesegang phenomenon. The theory reflects light on the mechanism of ring formation, fine structure, influence of various environmental conditions, etc.

Fick's diffusion equation

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \tag{4}$$

may have a solution

$$c = a\,e^{-\alpha x}\cos(\omega t + \beta x + y) \tag{5}$$

given by Riemann[2] for similar type of differential equations. Such a solution would be possible under conditions analogous to those operating in the propagation of sound in air, discharge of a current through a condenser and a resistance, where the motion of the matter is met by an opposing force.

In the phenomenon of Liesegang rings the two electrolytes meet and get precipitated and thus forms a new phase at the boundary of the diffusing salt and the medium. By virtue of the electrical forces at its surface and the fine nature of the particles distributed there, the boundary phase or say 'membrane' will have the tendency in certain cases to oppose the diffusion of salt and so to develop a situation where diffusion may be governed by Eq. 6.

The concentration distribution at a particular instant $t_i$ may be given by

$$c = a\,e^{-\alpha x}\cos(\beta x + \phi) \tag{6}$$

where $\phi$ is another constant equal to $(\omega t_i + y)$.

During the process of Liesegang ring formation of say silver chromate rings, the diffusion wave front of silver ions moves forward and gives rings one after another. The latter changes in concentration at the preceeding levels when one of the precipitating ions is completely removed cannot influence a ring position. By determining the values of arbitrary constants $a$ and $\phi$ in Eq. 6 from the known boundary conditions of reacting ions the equations for their concentration distribution can be obtained.

For silver ions, when $x=0$, $C \rightarrow$ maximum. In Eq. 6 $C$ will be maximum, when $\cos(\beta x+\phi)$ is unity or $(\beta x+\phi)=0$. Since $x=0$, $\phi$ must be zero to satisfy the above condition. Hence

$$c = a\,e^{-\alpha x}\cos(\beta x) \tag{7}$$

Now, the limiting maximum value of $C$ at $x=0$ is the same as the initial bulk concentration $C_0$ of silver ions; substituting this value into above equation we have $a=C_0$. Eq. 7 reduces to

$$c = C_0\,e^{-\alpha x}\cos(\beta x) \tag{8}$$

Relation 8 geometrically represents a simple harmonic curve whose amplitude $C_0\,e^{-\alpha x}$ diminishes exponentially to zero with increasing distance. As the chromate ions diffuse in the upward direction their distribution may be represented by the equation

$$C' = C_1\,e^{\alpha' x}\sin(\beta' x) + C_2\,e^{\alpha' x}\cos(\beta' x) \tag{9}$$

where damping coefficient $\alpha'$ has a positive sign. The constants $C_1$ and $C_2$ in the above equation can be determined from boundary conditions of chromate ions.

In a thin region of the precipitate the concentration of chromate ions may be taken to be equal to zero because the traces of ions

* This work is the part of author's Ph.D thesis submitted to the University of Allahabad (1956).

** Present address: Senior Scientific Officer, Central Electrochemical Research Institute, Karaikudi-3, India.

1) K. Jablczynski, *Bull. soc. chim., France* (4), 33, 1592 (1923).

2) Riemann, "Particlle Differentialgleichungen", Edit Hattendorff (1938), p. 110.; P. B. Mathur, *Bull. Acad. Polona. Sci.*, 8, 8, 429 (1960).

left there after precipitation get absorbed by the precipitates rendering practically a complete disappearance of the ions. Hence at $x=0$, $C'=0$. Substituting this condition into Eq. 9, we have $C_2=0$, so we have,

$$C'=C_1 e^{\alpha' x} \sin(\beta' x) \quad (10)$$

Let us suppose, when $x=x_0$, $C' \rightarrow$ maximum. So, in Eq. 10, $C'$ is maximum when $\sin(\beta' x_0)$ is unity or $\beta' x_0=\pi/2$ or $x_0=\pi/2\,\beta'$ and so

$$C'=C_1 e^{(\alpha'\pi/2\beta')}$$

Now the limiting maximum value of $C'$ at a distance of $x_0$ is the same as the initial bulk concentration $C_0'$ of chromate ions. Substituting this value into the above equation we have

$$C_1=C_0' e^{-(\alpha'\pi/2\beta')}$$

Eq. 10 thus reduces to the form,

$$C'=(C_0' e^{-(\alpha'\pi/2\beta')}) e^{\alpha' x} \sin(\beta' x) \quad (11)$$

Eq. 11 represents the distribution of chromate ions where $x$ is measured from zero concentration level.

Let us now suppose that $(n-1)$ rings have already formed and $n$th ring is in the process of formation. So the concentration of chromate ions at $(n-1)$th level has fallen to zero. Let $C_n$ and $C_n'$ be the concentrations of silver and chromate ions respectively at $n$th rings, and $x_n$ and $x_{n-1}$, the distances of $n$th and $(n-1)$th levels respectively from the initial diffusion level. The reference line for chromate ions corresponding to the $n$th ring is $(n-1)$th ring level, while for silver ions it is the initial diffusion level. In order that the two equations could be combined, the line of reference for the two ions must be the same. Substituting $x=(x_n-x_{n-1})$ into Eq. 11 for chromate ions and $x=x_n$ in Eq. 8 for silver ions and corresponding concentrations in the two equations, we get the following equations for silver and chromate ions respectively,

$$C_n=C_0 e^{-\alpha x_n} \cos(\beta x_n) \quad (12)$$

$$C_n'=C_0' e^{-(\alpha'\pi/2\beta')} e^{\alpha'(x_n-x_{n-1})} \times \sin[\beta'(x_n-x_{n-1})] \quad (13)$$

The distribution of the concentration product of silver and chromate ions can be obtained by combining Eqs. 12 and 13

$$C_nC_n'=C_0C_0' e^{-(\alpha'\pi/2\beta')} e^{-\alpha x_n} e^{\alpha'(x_n-x_{n-1})} \times \sin[\beta'(x_n-x_{n-1})]\cos(\beta x_n) \quad (14)$$

The above equation represents the curve shown in Fig. 1. The periodic terms cos. and sin. alternate between the limits $\pm 1$, and the concentration curve shows two types of periodicities one by broad wave PQRS and the other by narrow waves. By putting $\cos(\beta x_n)=1$, we get the curve PQRS which is the locus

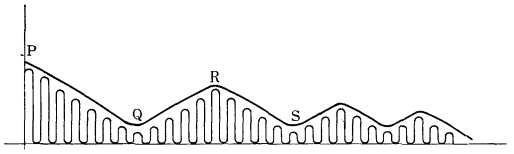

Fig. 1

of the points of maxima of narrow curves, and by putting $\sin(\beta'(x_n-x_{n-1}))=1$, the remaining equation represents only the finer structures of a half wave PQ.

The condition for the precipitation at the place is that the ionic product should exceed or be equal to the solubility product of the sparingly soluble salt at the level

$$C_nC_n' \geq S$$

In critical case $C_nC_n'=S$; so substituting the condition into Eq. 14, we have

$$S=[C_0C_0' e^{-(\alpha'\pi/2\beta')} e^{-\alpha x_n} e^{\alpha'(x_n-x_{n-1})} \times \sin[\beta'(x_n-x_{n-1})]\cos(\beta x_n) \quad (15)$$

The above equation represents the phenomenon of Liesegang Rings in general form. The graphical representation of the equation is made in Fig. 2. The dotted liness in Fig.

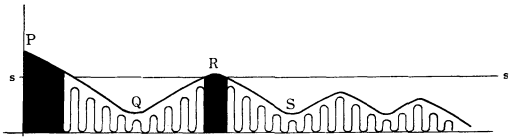

Fig. 2

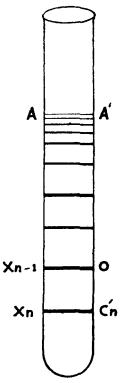

Fig. 3

2 indicates the solubility product of sparingly soluble salt. The spaces where the ionic product curve falls below SS' level indicates void regions while those places where the curve crosses the line SS' indicates the precipitate regions. Void spaces and precipitate regions have been represented in the figure by clear and dark areas respectively. The broader band structure of Liesegang systems will be given by

$$S=[C_0C_0'\,e^{-(\alpha'\pi/2\beta')}\,e^{-\alpha x_n}\,e^{\alpha'(x_n-x_{n-1})}]\times\sin\{\beta'(x_n-x_{n-1})\} \quad (16)$$

In case where the modulus of decay $\alpha$ and frequency factor $\beta'$ of the wave profile of chromate ions are sufficiently small, Eq. 16 can be simplified further by putting $e^{\alpha'(x_n-x_{n-1})}$ =unity, and

$$\sin[\beta'(x_n-x_{n-1})]=\beta'(x_n-x_{n-1})$$

So, we get

$$S=(C_0C_0'\,e^{-(\alpha'\pi/2\beta')})e^{-\alpha x_n}\,\beta'(x_n-x_{n-1}) \quad (17)$$

or $$(x_n-x_{n-1})=\left(\frac{S\,e^{(\alpha'\pi/2\beta')}}{C_0C_0'}\right)e^{\alpha x_n} \quad (18)$$

or $$(x_n-x_{n-1})=\left[P\left(\frac{S}{C_0C_0'}\right)\right]e^{\alpha x_n} \quad (19)$$

$P$ is a constant.

Since $\beta'=2\pi/\lambda'$, $\lambda'$ being the wave length of chromate ions wave, Eq. 18 can be written as

$$(x_n-x_{n-1})=\left(\frac{S\lambda'\,e^{\alpha'\lambda'/4}}{2\pi C_0C_0'}\right)e^{\alpha x_n} \quad (20)$$

or $$(x_n-x_{n-1})=\psi\,e^{\alpha x_n} \quad (21)$$

Taking the logarithm, we have

$$\log(x_n-x_{n-1})=A+\alpha x_n \quad (22)$$

where $A$ is another constant.

It may be noted here that the nature of Eq. 22 is not affected by changing the line of reference in the measurement of the rings. If $d$ is the distance of $n'$ order ring from a new reference level, then

$$x_n=(x_{n'}-d)$$

or $$\log(x_{n'}-x_{n'-1})=A+\alpha(x_n-d)$$

or $$\log(x_{n'}-x_{n'-1})=A'+\alpha' x_{n'} \quad (23)$$

Two Eqs. 22 and 23 differ only in constants.

In a Liesegang ring system $\alpha x_n$ may be considered as a small quantity for first few rings and so $e^{\alpha x_n}$ can be expanded and higher terms may be neglected. Eq. 21 thus reduces to

$$(x_{n'}-x_{n'-1})=\beta'+\alpha' x_{n'} \quad (24)$$

Eq. 24 differs from Eq. 3 in the constant $\beta$. The derivations here thus lead to an equation which is a corrected form of Jablczynski's empirical relation 1 or 3 which has already been studied by several workers. It may be noted that even Eq. 24 is a special case of more general expressions (15, 19, 20 and 23) for the phenomenon of Liesegang rings.

## Discussion

Eq. 15 has graphically been represented in Fig. 1. The figure predicts the presence of fine structure between precipitate bands. Such structures have already been reported by Riegel and Reinhands[4], Hedges[5] and Friend[6] for the silver chromate system in gelatin gel. The author also made studies on the growth of rings. Liesegang rings of silver chromate were obtained by diffusing 2.5, 5, 7.5 and 10% silver nitrate solutions through test tubes containing 2, 4, 6 and 8% gelatin gels impregnated with 0.01 M chromate. The temperature was maintained befow 16°CF during the experiment. Distinct fringes of bright yellow color closely packed rings were seen when gelatin was dilute. The rings obtained were watched continuously for 12 hr. and it was found that even precipitate rings developed not as one single ring but as an aggregate of two or more closely packed fine rings which grew thicker and thicker with time and finally small gaps in between them gradually disappeared and thick layers of precipitates were formed. The observation proves the validity of Eqs. 14 and 15. For close study of the phenomenon, it is always useful to carry out experiments at low temperature and with low concentrations of gel.

Eq. 19 indicates that the rings would get more and more packed as the initial concentrations of ions increase and solubility product decreases. The effect of solubility on silver chromate rings has been studied by Varma and Ghosh[7] and influence of ionic concentration by several other workers[8]. Their results are in conformity with the conclusions drawn above.

The theory indicates that the nature of diffusion is mainly responsible for rhythmic phenomenon; a proper type of membrane[9] however becomes a necessary condition for the occurance of the process. Several factors such as colloidal formation super-saturation, etc., may help or hinder the formation of a proper type of membrane, but they themselves cannot be considered as the cause for Liesegang rings. The phenomenon may occur even in the absence of any of these conditions.

The experimental support of various expressions obtained above for Liesegang rings justifies the use of Raimann solution for Fick's diffusion equation. The theory thus indirectly throws light on the mechanism of diffusion.

# *Structural Analysis of Liesegang Ring Systems**

By Prem Behari MATHUR**

(Received May 17, 1960)

Since the discovery of the phenomenon of Liesegang ring several types of ring systems have been produced which on the structural basis may be broadly classified into the following categories:

a) Direct and revert systems
b) Macro and micro ring systems
c) Void spaced and continuous banded systems.

In the present paper these classifications have been analyzed in the light of the quantitative theory advanced by the author[1] in an earlier communication to this journal for the phenomenon of Liesegang rings.

## Direct and Revert Systems

In the previous communication, the author obtained the following equations for Liesegang ring phenomenon,

$$(x_n - x_{n-1}) = a\left(\frac{S}{C_0 C'_0}\right)e^{\alpha x_n} \qquad (1)$$

or

$$(x_n - x_{n-1}) = K \qquad (2)$$

where $x_n$ and $x_{n-1}$ represent the distances of $n$th and $(n-1)$th rings respectively from the initial level of diffusion, $S$ the solubility product, $C_0$ and $C_0'$ the initial concentrations of the two ions and $a$, $\alpha$ and $K$ the characteristic constants.

It can be seen that the two different types of ring systems are possible as $\alpha$ in Eq. 1 is negative or positive. When $\alpha$ is positive the distances between the successive rings $(x_n - x_{n-1})$ would increase with the increase of $x_n$ as is commonly observed for this phenomenon. When $\alpha$ is negative the rings separation would decrease in the direction of diffusion of flocculating solution. Thus two different types of ring systems, which may be called a "Direct" and Revert" systems respectively could be produced.

Mathur and Ghosh[2] noted that if a diffusing electrolyte renders high peptizing influence or dissolves out the precipitate formed as a result of the interaction of the two ions, the decrease in the concentration of the peptizing ion along the diffusion path would lead to the "Revert" system of rings. The authors have noted that the ferricyanides of copper, iron, nickel and silver are peptized by the excess of the same metal ions, and this effect is more marked in the case of copper, iron, nickel and uranium ferricyanides and at the same time the revert systems have also been observed to be more prominent in these precipitate systems. Pactor[3] obtained a revert type of rings system by diffusing a solution of ammonia through a silver chromate solution peptized by acitic acid in gelatin gel. Hook[4] has obtained revert type of Liesegang ring systems of zinc, nickel, cobalt, ferrocyanides, nickel, zinc and iron cyanides, barium and mercury vandates and cerrous oxalate in gelatin medium and of chromium hydroxide and uranyl carbonate in agar-agar gel.

Periodic precipitations of "Direct" nature are of common occurrence. Silver chromate system in gelatin gel is a well known example of this type of banded structure.

### Macro and Micro Ring Systems

Gel or other peptizing agents influence the precipitation of an sparingly soluble salt by keeping the coarser matter in colloidal state. The nature of the distributed matter in a system of periodic precipitation under the influence of environmental conditions can be ascertain from Fig. 1 which is a graphical representation of the ionic product relation obtained in the previous communication[5].

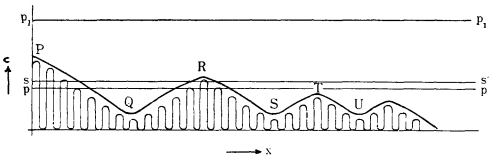

Fig. 1

$$C_nC_n' = [C_0C_0'e^{-(\alpha'\pi/2\beta')}]\, e^{\alpha'(x_n-x_{n-1})} \times \sin\{\beta'(x_n-x_{n-1})\} \times \cos(\beta' x_n)e^{-\alpha x_n} \quad (3)$$

or

$$C_nC_n' = a\, e^{[\alpha'(x_n-x_{n-1})]}e^{-(\alpha x_n)} \times \sin[\beta'(x_n-x_{n-1})]\cos(\beta x_n) \quad (4)$$

where $C_nC'_n$ is the ionic product and $\alpha$, $\alpha'$, $\beta'\beta$ and $a$ are characteristic constants. In Fig. 1, SS′ represents the solubility product level and PP′ the peptizing level. The insoluble substance formed by interaction of diffusing ions would exist in precipitate or in peptized form according as PP′ is very close to or high above the SS′ level.

When the peptizing level PP′ is little above SS′ and cuts the ionic product curve at several places, the sparingly soluble matter will precipitate out in the regions where the ionic product curve rises above PP′. Thus, at P, R, T regions the precipitate bands would appear. At intermediate spaces Q, S, U etc., where the ionic curve falls below PP′ the residual matter will exist in colloidal state. The distribution of this colloidal matter along the diffusion column would also be of periodic nature following the curve 1. Thus, translucent micro-sealed ring systems of tracer colloidal material would be produced in between the precipitate bands. Such a type of structure has been observed by several workers notedly Hedges and Henley[6], Dounin and Shamyakin[7] and Mathur and Ghosh with silver chromate in gelatin medium.

5) P. B. Mathur, *Loc. cit.*
6) E. S. Hedges and R. V. Henley, *J. Chem. Soc.*, **1928**, 2715.
7) M. S. Dounin and F. M. Shemyakin, *Kolloid-Z*, **48**, 167 (1928).

The possibility of another type of such fine system is also apparent from Eq. 4. If in Eq. 4 the damping coefficients $\alpha$ and $\alpha'$ are almost negligible the factor

$$\exp[\alpha'(x_n-x_{n-1})-\alpha x_n]$$

tends to unity and Eq. 4 reduces to the form

$$C_nC_n' = a\sin[\beta'(x_n-x_{n-1})]\cos(\beta x_n)$$

which is an equation of the Simple Harmonic Curve (Fig. 2). In such systems whatsoever be the position of PP′ closely packed fine rings without any large size void spaces in between them, would be discerned. The fine ring systems will be of precipitated material when PP′ would cut the ionic produt curve, and of colloidal matter when PP′ would be situated above it. Mathur and Ghosh have been able to obtain the micro-sized Liesegang ring systems of cobalt and silver ferricyanide under suitable experimental conditions.

### Void Spaced and Continuous Banded Systems

Let us now consider the case where damping factor $\exp(\alpha x_n)$, in Eq. 4 is large enough and at the same time the peptizing influence of the medium or of the ions present therein is moderately high on the insoluble substances. Such a system will graphically be represented by the curve P, Q, R, S and $P_1P_1'$ shown in Fig. 1. If, due to high peptizibility of the

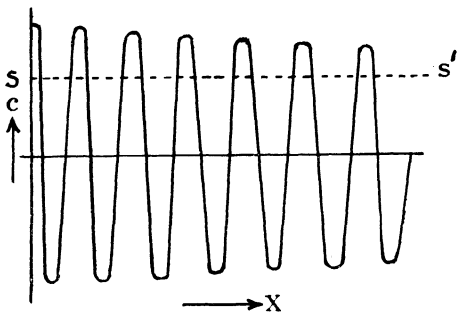

Fig. 2

insoluble salt the position of PP′ is just above the ionic product curve or if PP′ cuts the curve at some of its maxima points, the insoluble substance will exist both in colloidal as well as in precipitate form showing a continuous deposition of matter throughout the diffusion column. Due to the fact that the concentrations of ions in the regions of maxima and minima points very markedly, the colloidal particles in the neighbourhood of maxima points P, R, T will be much coarser due to the high concentration of the peptizing matter in this region in comparison to that in the minima regions. Such a system will therefore form bands of different size particles within a

continuous deposition, which will appear as alternate bands of different colors.

In cases where peptizing level is very high so much so that high concentration of a stable colloid may be produced, a very fine ring structure of colloidal matter, may appear but if it is too packed it may be left undetected.

Dhar and Chatterji[8] obtained a continuous banded system for mercuric iodide in agar gel, where a thick red color precipitate bands are followed by yellow ones and vice versa. Hatschek[9] noted a similar structure for cadmium sulphide in gelatin gel; Rastogi and Chatterji[10] reported for certain insoluble rare earth salts; Mathur and Ghosh for silver ferrocyanide and uranium ferricyanide.

Void spaced systems have already been discussed in the earlier communication. From Fig. 1, it can be seen that when peptizing level PP′ is close to the ionic product curve P, Q, R, S, the precipitate regions will be followed by void spaces and not by thick colloid bands, and so a void spaced ring system will be obtained.

It may, therefore, be concluded that the factors which control the Shape of Liesegang ring systems in gel media are (a) the damping coefficients $\alpha$ and $\alpha'$ of Eq. 3, and (b) the peptizability of the precipitate in particular environment, or say, the stability of the colloid formed under the conditions of the system. However, it may clearly be understood that colloidal formation like other factors simply influence the shape of rings in gel media, but it itself is not the cause of rhythemic phenomenon. The nature of diffusion is mainly responsible for the phenomenon, as explained in the earlier communication.

My thanks are due to Professor S. Ghosh, Head of the Department of Chemistry, Allahabad University for his keen interest in the work and valuable suggestions and also to the Scientific Research Committee of Uttar Pradesh for granting a research scholarship during the period of the work.

# "Frontier Electron Density" in Saturated Hydrocarbons

By Kenichi FUKUI, Hiroshi KATO and Teijiro YONEZAWA

(Received August 8, 1960)

Several simple quantum-mechanical methods have been proposed to discuss the physical properties of aliphatic compounds[1-3], but they were not always successful in interpreting quantum-chemically the chemical reactivity of these compounds.

In our previous papers treating aliphatic compounds, we calculated the ionization potential, the bond energy[4] and the reactivity in nucleophilic substitution[5] by using Yoshizumi's C-C skeleton method[6].

In the present paper, we have investigated the chemical reactivity of several aliphatic hydrocarbons in a metathetical reaction by using the simple LCAO MO method including all of the atomic orbitals which participate in forming C-C and C-H $\sigma$ bonds in these compounds. The molecular orbital of aliphatic hydrocarbons, $\phi_j$, may be represented by a linear combination of 1s orbitals of hydrogen atoms, $\phi_{Hl}$, and $sp^3$ orbitals of carbon atoms, $\phi_{Cr}$.

$$\phi_j=\sum_r C_{rj}\phi_{Cr}+\sum_l C_{lj}\phi_{Hl}$$

where $C_{rj}$, $C_{lj}$ are the coefficients of the $r$th $sp^3$ orbital of carbon atom and the $l$th 1s orbital of hydrogen atom in the $j$th molecular orbital, respectively.

The resonance integrals between neighboring atomic orbitals are assumed

$$\int \phi_{C,n} H \phi_{H,n+1} d\tau = b\beta$$

1) R. D. Brown, *J. Chem. Soc.*, **1953**, 2615.
2) M. J. S. Dewar and R. Pettit, ibid., **1954**, 1625.
3) J. Lennard-Jones and G. G. Hall, *Disc. Faraday Soc.*, **53**, 127 (1957).

5) K. Fukui, H. Kato and T. Yonezawa, ibid., **33**, 1202 (1960).
6) H. Yoshizumi, *Trans. Faraday Soc.*, **53**, 125 (1957).

the $sp^3$ orbital of carbon and the 1s orbital of hydrogen in a C–H $\sigma$ bond:

$$\int \phi_{C,r} H \phi_{C,r+1} d\tau = \beta$$

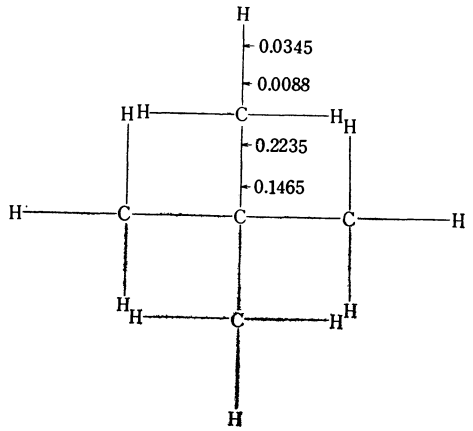
between two $sp^3$ orbitals of two adjacent carbon atoms each:

$$\int \phi_{C,r} H \phi_{C,r+1} d\tau = m\beta$$

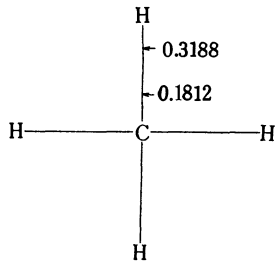
between two $sp^3$ orbitals belonging to one and the same carbon atom:

The Coulomb integrals are taken as

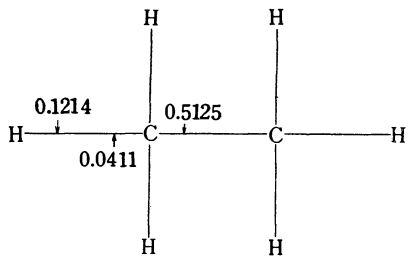
$$\int \phi_{Hl} H \phi_{Hl} d\tau = \alpha + a\beta$$



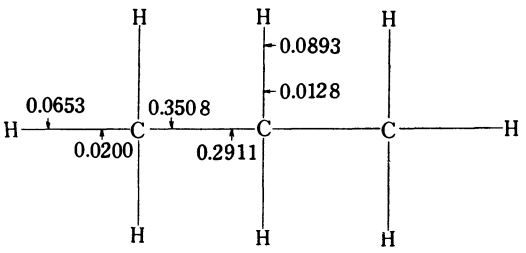
$$\int \phi_{C,r} H \phi_{C,r} d\tau = \alpha$$



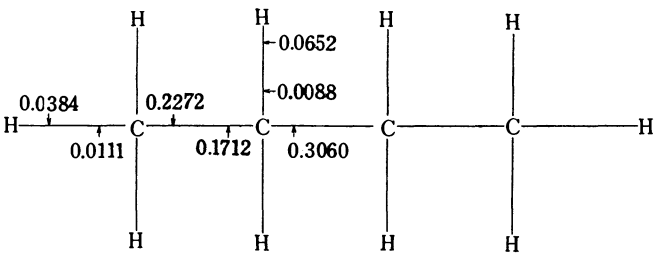
All overlap integrals are neglected.



The values of $m$ is taken as 0.34 determined by Yoshizumi, $a$ is put equal to $-0.2$ referring the value of C–H bond moment ($C^{-\delta}$–$H^{+\delta}$, 0.4 D),* and $b$ is put 1.1 which is the ratio of the overlap integral $S_{C-H}$ to $S_{C-C}$[7].



The calculated values of ionization potential and heat of formation of several compounds are listed in Table I, where the values of $\alpha$ and $\beta$ are taken as $-5.05$ eV. and $-8.8$ eV., tentatively.



Since a good agreement between the calculated and experimental values is observed in this table, the numerical estimation of these parameters is considered to be reasonable.

7) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, 17, 1248 (1949).

* The value of $a$ varies according as the hydrogen atom is primary, secondary or tertiary. In the present treatment $a$ is taken as the same for simplicity's sake. Future improvement is expected with regard to this point.

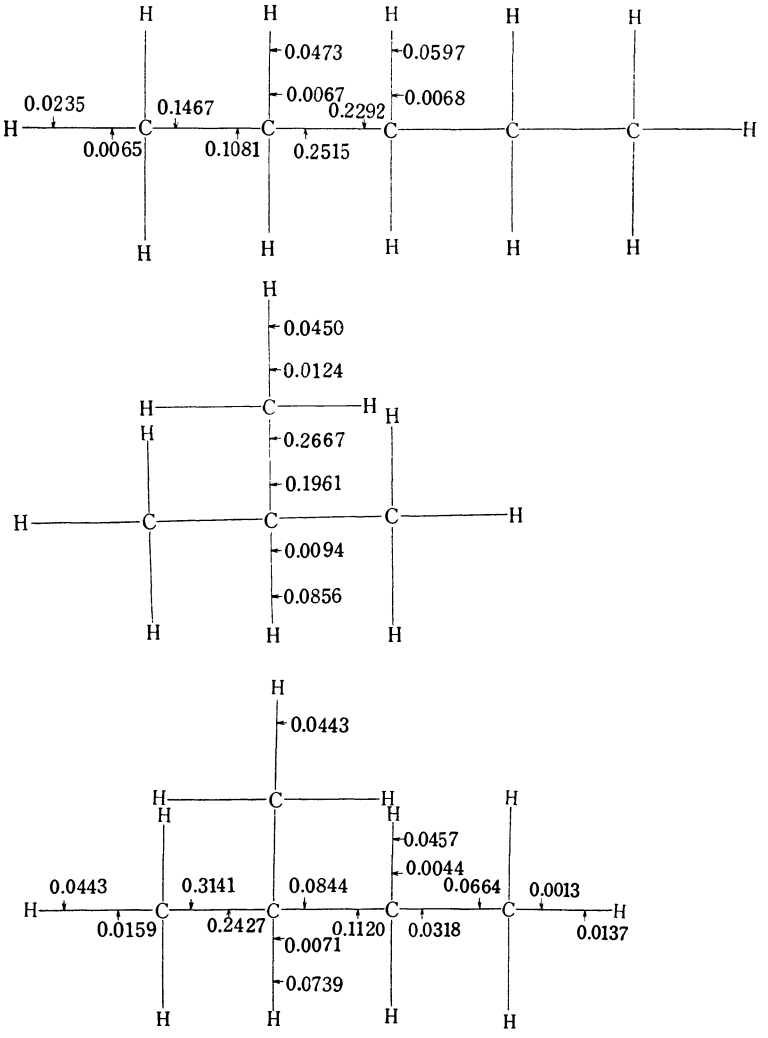


Fig. 1. The values of $f^{(R)}$ in several saturated hydrocarbons.

density[8], $f^{(R)}$, as an excellent reactivity index for a radical reaction of conjugated systems. Now we can show that $f^{(R)}$ is found to be also available as the reactivity index of saturated compounds.* The calculated values of $f^{(R)}$ in several compounds are listed in Fig. 1. It is observed that the values of $f^{(R)}$ on hydrogen atoms in these compounds is parallel with the experimental results. That is to say, the activity of hydrogen-extraction in saturated hydrocarbons increases in the order *prim.* H $<$*sec.* H $<$*tert.* H[9].

Thus, the frontier electron density has been found to relate with the experimental chemical reactivity of aliphatic saturated molecules.

An application of this fact to explaining the reaction mechanism of oxidation or pyrolysis in aliphatic hydrocarbons seems to be possible.

# *Studies on the Catalytic Double Wave of Cystine by Oscillographic Polarography*

By Mutsuaki SHINAGAWA, Hideo IMAI and Hiroyuki NEZU

(Received July 16, 1960)

Brdicka[1] has reported that in a conventional polarography cystine and cysteine develop a pronounced single catalytic wave in an ammonia buffer containing divalent cobalt. In the previous paper[2] it was reported that this catalytic wave gives a rounded maximum of good reproducibility by the addition of gelatin and that the maximum wave is split off into two waves by the addition of methyl cellulose (cf. Fig. 1). The form of these double waves resembles that of the catalytic double wave of protein, and the evolution of hydrogen as the electrolytic reductant is facilitated by the catalytic action of the cobalt(II)-cysteine complex* adsorbed on the surface of the dropping mercury electrode (DME). Accordingly, one can expect to clarify the nature of the protein wave from the analogy to the cystine wave.

The present experiment was carried out as a tentative model of the protein wave, and a possible mechanism of the cystine wave is proposed from the consideration of the adsorption equilibria among three surface active substances, i. e., the cobalt(II)-cysteine complex anion, methyl cellulose and gelatin.

1) R. Brdicka, *Collection Czechoslov. Chem. Communs.*, **4**, 148 (1933).

2) M. Shinagawa and H. Nezu, This Bulletin, **33**, 272 (1960).

* This catalytic wave occurs at a more negative potential than the potential of the reduction of cystine to cysteine, and therefore, must be caused by the reduced form, cystein.

## Experimental

A Sevcik type oscillographic polarograph[3] constructed in our laboratory[4] was used. Effects of the mercury head and the frequency of the applied triangular sweep on the oscillographic current voltage pattern were observed. The mercury head was changed from 25 to 65 cm., when the life-time of the DME changed from 5.4. to 2.0 sec. under the applied span voltage from $-0.28$ to $-2.16$ V. vs. S. C. E. (20 cycles/sec.). The rate of the mercury flow was 0.755 mg./sec. at the mercury head of 25 cm. The frequency applied was 20~60 cycles/sec., when the rate of potential change was 75~225 V./sec.

All the reagents were of analytical grade. The test solutions used are tabulated as follows:

| Test solution No. | Constituent |
|---|---|
| 0 | 0.1 F $NH_3$-$NH_4Cl$ buffer |
| 1 | $1\times10^{-3}$ F $CoCl_2$+$2\times10^{-5}$ F cystine in solution 0 |
| 2 | 0.02% methyl cellulose in solution 1 |
| 3 | 0.01% gelatin in solution 1 |
| 4 | 0.02% methyl cellulose+0.01% gelatin in solution 1 |
| 5 | 0.005~0.08% methyl cellulose in solution 0 |

3) A. Sevcik, *Collection. Czechoslov. Chem. Communs.*, **13**, 349 (1948).

4) M. Shinagawa, H. Imai and S. Chaki, *J. Electrochem. Soc. Japan*, **23**, 132 (1955); H. Imai, This Bulletin, **29**, 276 (1956).

An H-cell with low impedance was used, and the dissolved oxygen in the test solution was not removed. The temperature was 29±0.5°C.

## Results and Discussion

Under the experimental conditions described in the preceding section, the cobalt(II)-ammine complex behaves irreversibly at the DME, and the charging current, which flows when the adsorption or desorption of surface active substances occurs, becomes markedly great. The effect of the mercury head on the peak current gives information concerning the difference between the electrolytic current and the charging current and also concerning the irreversibility of an electrode process. One can obtain similar information from the effect of the sweep frequency on the peak current and the peak potential**.

**The Oscillographic Current-Voltage Pattern.** — The oscillographic current-voltage pattern of solutions 1, 2, 3 and 4 are illustrated in Figs. 2-A, B, C and D, respectively. In Fig. 2-A, two reduction steps represented by $i_p1$ and $i_p2$ are noticeable***. $i_p1$, the peak potential of which is −1.27 V. vs. S. C. E., corresponds to the reduction of the cobalt(II)-ammine complex ion. The peak height of $i_p1$ is decreased and rounded off by the addition of methyl cellulose and gelatin as is illustrated in Figs. 2-B, C and D, simultaneously the peak potential being shifted toward more negative potentials ($E_p$=−1.27, −1.31 and −1.36 V. vs. S. C. E. in solutions 2, 3 and 4, respectively.).

The second step ($E_p$=ca. −1.7 V. vs. S. C. E.)

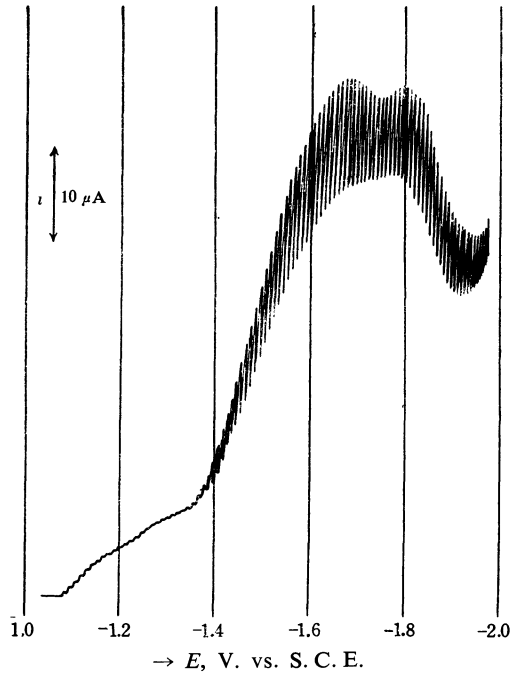

Fig. 1. The catalytic double wave of cystine by a conventional polarograph. Solution: $1\times10^{-3}$ F $CoCl_2$, $2\times10^{-5}$ F cystine, 0.002% methyl cellulose in 0.1 F $NH_3$-$NH_4Cl$ buffer. $m$=2.46 mg./sec., $t$=3.5 sec.

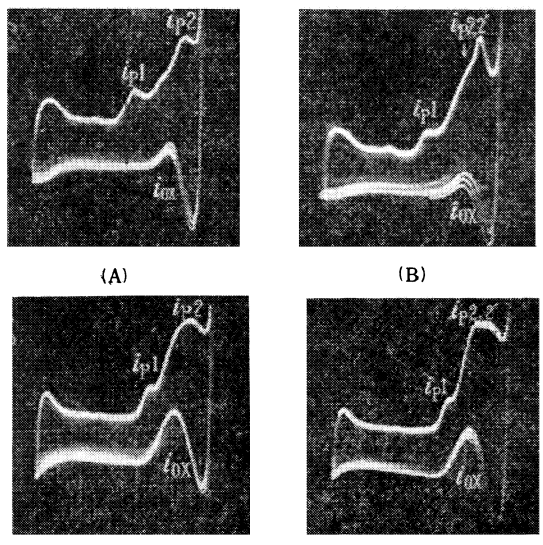

Fig. 2. The oscillographic current-voltage pattern of $1\times10^{-3}$ F $CoCl_2$ and $2\times10^{-5}$ F cystine in 0.1 F ammonia buffer (A). (B): +0.02% methyl cellulose, (C): +0.01% gelatine, (D): +0.02% methyl cellulose and 0.01% gelatin, Sweep frequency=20 cycles/sec., v=75 V./sec., $h$=25 cm., $t$=4.9 sec.

** These points of view are summarized in detail as follows in order to help the subsequent considerations.

(1) The peak of the oscillographic pattern is rounded off and the peak potential ($E_p$) is shifted toward more negative potentials in the cathodic branch as the electrode process becomes irreversible[5].

(2) No reoxidation peak can be observed in the anodic branch unless the DME forms the amalgam with the reductant.

(3) The maximal peak current (i. e. the peak current just before the electrode mercury droplet falls) of a reversible electrode process ($i_{p,r}$) is independent of the mercury head, while that of an irreversible one ($i_{p,ir}$) varies with the mercury head[6].

(4) $i_{p,r}$ is proportional to the square root of the rate of the potential change (v)[6], while $i_{p,ir}$ deviates from this proportionality[7].

(5) The maximal charging current is independent of the mercury head, and it is linearly proportional to v.

(6) The peak potential of the charging current, which flows at the adsorption or the desorption potential of surface active substances, will be shifted by the change in the concentration of the adsorbed substance.

*** $i_p2$ is accompanied by a barely perceptible peak at −1.5 V. vs. S. C. E. This peak corresponds to an irregular wave observed at the same potential by a conventional polarograph. The nature of this wave is unknown at this stage.

represented by $i_p2$ in Fig. 2 is the catalytic current. This catalytic current is accompanied by a sharp peak at $-1.72$ V. vs. S. C. E. in the presence of methyl cellulose. Since a similar sharp peak is developed at $-1.7$ V. vs. S. C. E. by the desorption of methyl cellulose in solution 5 (cf. Fig. 3), the above-mentioned sharp

(A) (B)

Fig. 3. The oscillographic current-voltage pattern of 0.1 F ammonia buffer (A) and 0.06% methyl cellulose in 0.1 F ammonia buffer (B). Sweep frequency=20 cycles/sec., v=75V./sec., $h$=45 cm., $t=2.4_5$ sec.

peak of solution 2 can be assigned to the charging current change caused by the desorption of methyl cellulose. By the addition of gelatin, the catalytic current is rounded off ($E_p=1.72$ V. vs. S. C. E.) as is illustrated in Fig. 2-C, and this wave is split off into two waves by the addition of methyl cellulose (Fig. 2-D), the potential of the first and the second peak being $-1.62$ and $-1.73$ V. vs. S. C. E., respectively. Undoubtedly, these double peaks are different in nature from the catalytic double waves developed by a conventional polarograph (Fig. 1), because the charging current becomes predominant in an oscillographic method. It may safely be assumed, however, from the coincidence of the peak potential of $i_p2'$ with the desorption potential of methyl cellulose that the desorption of methyl cellulose is closely connected with the occurrence of $i_p2'$ and presumably with that of the second maximum wave in the conventional polarography.

In the anodic branch, the current change represented by $i_{ox}$ is noteworthy. The pattern of $i_{ox}$ is pronounced by the addition of gelatin, and in this case it can be seen from Figs. 2-C and 2-D that this current is obviously cathodic (the reduction current). A cathodic current of a similar character has been observed in the solution containing indium(III) and chloride[8], corresponding to the well-known minimum wave in the conventional polarography. It is supposed that this minimum wave is caused by the electrostatic repulsion of $InCl_6^{3-}$ from the negatively charged electrode. By analogy, it can be assumed that the cobalt(II)-cysteine complex anion behaves likewise. When the electrode potential is shifted toward less negative values in the anodic branch after the repulsion of the complex anion in the cathodic branch, the complex anion will be readsorbed on the electrode surface and contributes to the catalytic reduction of the hydrogen ion. Thus, the mechanism of $i_{ox}$ leads to the idea of the repulsion of the cobalt(II)-cysteine complex anion at the potential more negative than $-1.63$ V. vs. S. C. E.

**The Variation of the Peak Current with the Mercury Head.**—The peak current is plotted against the mercury head in Fig. 4, where the

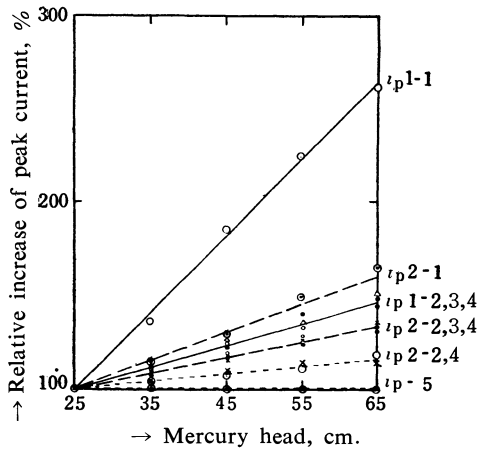

Fig. 4. The relative variation of the peak current with the mercury head. The symbols of the peak current are given in Fig. 2, and the second figure of the symbol represents the solution number given in the section of the experimental. Sweep frequency=20 cycles/sec., v=75 V./sec.

peak current is represented by the same symbols as those used in Fig. 2, and the second figure in the symbols represents the solution number given in the section of Experimental. In Fig. 4 three groups are classified according to their inclination. The first group involves $i_p1$-1 and $i_p2$-1 which have the steepest inclination among $i_p1$'s and $i_p2$'s, respectively. When the recovery of the diffusion layer in each cycle of the voltage sweep imperfect owing to the imcomplete reoxidation of the reductant (Note that $i_p1$ and $i_p2$ give no reoxidation peak in Fig. 2.), the repetition of the reduction process during the life-time of the DME results in the depletion of the oxidant at the vicinity of the electrode surface except for the supply due to the duffusion from the bulk of solution. Under

8) M. Shinagawa, H. Imai and H. Sunahara, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **77**, 1482 (1956).

this condition, the thickness of the diffusion layer will be markedly decreased by the rapid rate of the DME growth. Moreover, the fresh surface of the DME is increased by the rapid rate of the DME growth. Since the rate of the DME growth increases as the mercury head is increased, it is easy to see why these currents increase as the mercury head is increased.

The second groups involves $i_p1$-2, 3, 4 and $i_p2$-2, 3, 4, which show a moderate change with the mercury head. In this group, the effect of the drop growth seems to be retarded by the presence of the surface active substances.

The third group involves $i_p$-5. This desorption peak current of methyl cellulose is practically independent of the mercury head.

The peak heights of $i_p2'$-2 and $i_p2'$-4 were measured from the height of the charging current without paying any attention to the superposition of the preceding peak current, $i_p2$, which is markedly affected by the mercury head. Keeping this fact in mind, one can assign the slight inclination of $i_p2'$ to the superposition of the intrinsic current of $i_p2'$ on the decreasing current of $i_p2$. Accordingly, it is assumed that $i_p2'$ is practically independent of the mercury head and will be tacitly controlled by the desorption of methyl cellulose. This assumption is best realized from Fig. 5 which illustrates the relative change of $i_p2$-4 and $i_p2'$-4 with the mercury head.

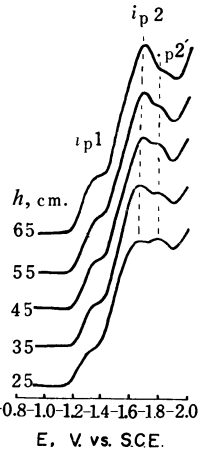

Fig. 5. The variation of the oscillographic current-voltage pattern of $1\times10^{-3}$ F $CoCl_2$ and $1\times10^{-5}$ F cystine in 0.1 F ammonia buffer containing 0.02% methyl cellulose and 0.01% gelatin with the mercury head ($h$, cm.). Sweep frequency=20 cycles/sec., v=75 V./sec.

**The Effect of the Sweep Frequency.** — The effect of the sweep frequency on the cathodic peak current is illustrated in Fig. 6. Any peak, except for the desorption peak of methyl cellulose, becomes more rounded and the peak

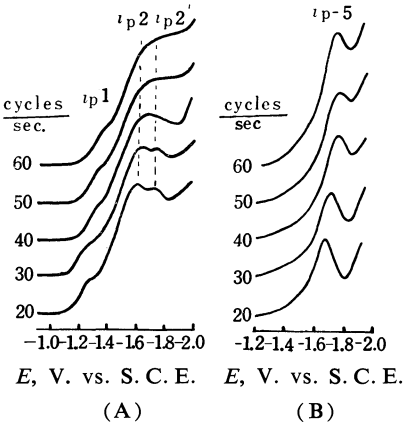

Fig. 6. The variation of the oscillographic current-voltage pattern of $1\times10^{-3}$ F $CoCl_2$ and $1\times10^{-5}$ F cystine in 0.1 F ammonia buffer containing 0.02% methyl cellulose and 0.01% gelatin (A) and the desorption charging current of 0.06% methyl cellulose (B) with the sweep frequency. $h$=45 cm.

potentional is shifted toward more negative potentials as the sweep frequency is increased. This result indicates that all of these electrode processes are irreversible. It must be pointed out here that the electrode process of $i_p2'$-4 is irreversible in nature, though it relates to the desorption of methyl cellulose as is described in the preceding section.

## Conclusion

By a conventional polarograph, cystine develops the pronounced double maximum in an ammonia buffer containing divalent cobalt, gelatin and methyl cellulose. This double wave is of interest because of the resemblance to the protein wave in the wave form and in the catalytic behavior. In the following description, it is explained why the cystine wave is developed in the form of the double maximum.

In this experiment, it was confirmed that cobalt(II)-cysteine complex, which acts as a catalyser for the depolarization of the hydrogen

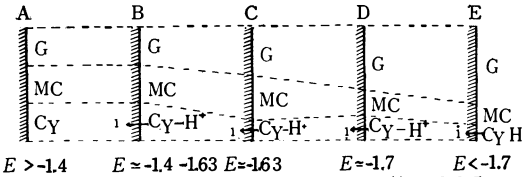

Fig. 7. The schematic representation of the adsorbed quantities of gelatin (G), methyl cellulose (MC) and the cobalt(II)-cysteine complex (Cy) on the unit surface area of the DME at each electrode potential. In this figure, i←Cy-H$^+$ means that Cy behaves as a catalysis of the hyrogen ion depolarization.

ion, desorbs from the electrode surface at about −1.63 V. vs. S. C. E. When the electrode potential becomes more negative than −1.7 V. vs. S. C. E., methyl cellulose also desorbs from the electrode surface. Accordingly, the quantity of the surface active substances adsorbed on the unit surface area of the DME at each electrode potential can be schematically expressed as is illustrated in Fig. 7.

In Fig. 7, G, MC and Cy represent the adsorbed quantity of gelatin, methyl cellulose and cobalt(II)-cysteine complex anion, respectively, on the unit surface area of the DME. The quantity of G, MC and Cy depends on each adsorbed concentration, which is in equilibrium with each concentration of the bluk of the solution and on the mutual equilibria among G, MC and Cy on the electrode surface. When the electrode potential is less negative than −1.6 V. vs. S. C. E., all of the surface active substances are adsorbed on the electrode surface as is illustrated in Fig. 7-A. As the electrode potential becomes more negative than −1.5 V. vs. S. C. E., the catalytic current gradually increases (Fig. 7-B). The cobalt(II)-cysteine complex anion, however, begins to desorb at −1.63 V. vs. S. C. E. and results in the decrease of the catalytic current (Fig. 7-C). Thus, the first maximum wave will be developed by the conventional polarograph. It is noteworthy, here, that the quantity of G and MC will be increased, corresponding to the desorption of Cy-complex. This is because the surface area to be occupied by G and MC will increase when Cy-complex desorbs.

At the potential of −1.7 V. vs. S. C. E. methyl cellulose begins to desorb from the electrode surface (Fig. 7-D). In this case, the quantity of G and Cy-complex will be increased, though the increase of Cy-complex is limited in the potential region where the desorption of methyl cellulose appreciably proceeds. Accordingly, the catalytic current will temporarily increase near the potential of −1.7 V. vs. S. C. E. (Fig. 7-E). Thus, the second maximum wave will be developed.

In the above-mentioned conclusion, the present authors proposed a possible mechanism of the cystine double wave from the consideration of the adsorption equilibria among gelatin, methyl cellulose and cobalt(II)-cystein complex anion. The criticism of this idea and its application to the protein wave is left for future.

## *Radiolysis of Crystalline Oxalato Complexes*

By Akira SUGIMORI and Gen-ichi TSUCHIHASHI

(Received December 2, 1960)

The effects of metal ions on the radiolysis of organic compounds have mainly been studied in aqueous solutions[1]. The present authors previously studied the radiation chemistry of aqueous metal salicylate complexes, and found that chelated $Fe^{3+}$ and $Cu^{2+}$ effectively increase the decarboxylation of salicylic acid[2]. The study on the radiolysis of crystalline metal complexes was also considered to be very helpful for the elucidation of the mechanism of the reaction affected by metal ions. In this paper, the radiolysis of various crystalline metal oxalato complexes is repoted.

Oxalic acid ($H_2C_2O_4 \cdot 2H_2O$), anhydrous oxalic acid ($H_2C_2O_4$), ferrous oxalate ($Fe(C_2O_4) \cdot 2H_2O$), sodium oxalate ($Na_2C_2O_4$), potassium trisoxalatoaluminate ($K_3Al(C_2O_4)_3 \cdot 3H_2O$), potassium trisoxalatochromate ($K_3Cr(C_2O_4)_3 \cdot 3H_2O$), potassium trisoxalatocobaltate ($K_3Co \cdot (C_2O_4)_3 \cdot 3H_2O$) and potassium trisoxalatoferrate ($K_3Fe(C_2O_4)_3 \cdot 3H_2O$) were irradiated with Co-60 gamma rays at room temperature, mainly

| | air | $4.4\times10^5$ | $1.46\times10^8$ | 5.5 |
| $Fe(C_2O_4) \cdot 2H_2O$ | vacuum | $1.6\times10^5$ | $1.46\times10^8$ | 0.1 |

at a does rate of $4.4\times10^5$ r./hr. and at a total dose of $1.5\times10^8$ r. both in the presence and in the absence of air.

After the quantity of evolved gas was measured, the gas was analyzed mass-spectrometrically. The quantity of decomposed complex was measured by visible light absorption spectrometry of aqueous solutions of irradiated complexes. The quantity of decomposed oxalate was measured by titrating the solutions of irradiated samples with acid permanganate solution. $G$(gas) (the number of the molecules of evolved gas), the ratio of CO to $CO_2$ in the evovled gas, $G$(−complex) (the number of the decomposed molecules of the complex) and $G$ ($-C_2O_4^{2-}$) are shown in Tables I, II and III. From the experimental results, the followings are concluded.

(1) Oxalate ions such as in sodium oxalate and ferrous oxalate are very stable to gamma ray irradiation, compared with those in metal oxalato complexes. The fairly large reactivity of oxalic acid and potassium trisoxalatoaluminate toward gamma irradiation might be attributed to the covalent character of oxalate-M (M=metal ion or hydrogen) bond. Oxalate ions with larger covalent character decompose more easily by gamma irradiation.

(2) The much larger $G$ values of $Fe^{3+}$ and $Co^{3+}$ complex than those of $Al^{3+}$ complex can not be explained only by the covalent character of oxalato-metal bond. They seem to be related with the reduction of metal ions. On gamma irradiation of $Fe^{3+}$ and $Co^{3+}$ complex, the reduction of the metal ions also occurs, and ferrous and cobaltous oxalate precipitates when the irradiated complexes are dissolved in water. Therefore, the electron transfer from oxalate to metal ions might increase the radiation-induced decomposition of oxalate.

(3) Chromium is stable in the state $Cr^{3+}$ and Cr(VI) whereas very unstable in the state $Cr^{2+}$; therefore on gamma irradiation of $K_3Cr(C_2O_4)_3 \cdot 3H_2O$ the electron transfer from oxalato to metal ion might be difficult and this might cause the lower $G$ values of $Cr^{3+}$ complex than those of $Fe^{3+}$ and $Co^{3+}$ complex. But on the reaction of $Cr^{3+}$ complex, the oxidation of $Cr^{3+}$ to Cr(VI) might occur, and a fairly large amount of CO is formed in place of $CO_2$ which is the main product in the gamma irradiation of oxalic acid and the oxalate complexes other than those with $Cr^{3+}$.

Details of this study will be published later.

## *Steric Effects of ortho-Groups on Hydrogen Bond Formation in Phenol Derivatives as Studied by Nuclear Magnetic Resonance*

By Ichiro YAMAGUCHI

(Received December 20, 1960)

In the previous report[1], the author pointed out that the chemical shift of the OH proton depends greatly on the relative position of the methyl groups to the OH group in dimethyl phenol isomers, and this was attributed to the steric effects of the methyl group on the formation of intermolecular hydrogen bond. The present report shows a dependence of the OH proton chemical shift on the size of the ortho-group.

The compounds investigated are 2, 6-dichlorophenol, 2, 6-dimethyl phenol and 2, 6-di-*t*-butyl-*p*-cresol. The chemical shifts of the OH proton in various solutions were determined by the side band technique refering to water as an external standard. The correction for the bulk diamagnetic susceptibility was not applicable except to the values extrapolated to infinite dilution because reliable data of the susceptibility for these compounds were not available.

In Figs. 1a and 1b, the OH resonance shifts (in p.p.m.) are plotted against the concentration of the solutions (in mole fraction). The curves for various solutions are comparatively separated in a wide range of the magnetic field from one another for 2, 6-dichlorophenol and 2, 6-dimethyl phenol, but not for 2, 6-di-*t*-butyl-*p*-cresol. This suggests that the size of the ortho-group would be a factor which affects the ability of the formation of an intermolecular hydrogen bond of a phenol. This effect was qualitatively pointed out by Batdorf with his NMR measurements[2].

As a measure of the extent of the ability of the hydrogen bond formation, the difference between the chemical shift at infinite dilution (extrapolated and then corrected for bulk diamagnetic susceptibility of the solvents) for carbon tetrachloride solution and that for acetone solution is taken. In Fig. 2, the values of the difference, $\Delta$, are plotted against the size of the ortho-groups, for instance the Van der Waals radii. The data for phenol[2,3] are also plotted.

In Fig. 2, the followings are observed: First, the $\Delta$ value is larger as the radius is smaller. Secondly, the $\Delta$ value for 2, 6-dichlorophenol is found above the line connecting the points for phenol and dimethyl phenol. This discrepancy may be due to weak intramolecular hydrogen bond between OH and Cl groups. Linear extrapolation of the

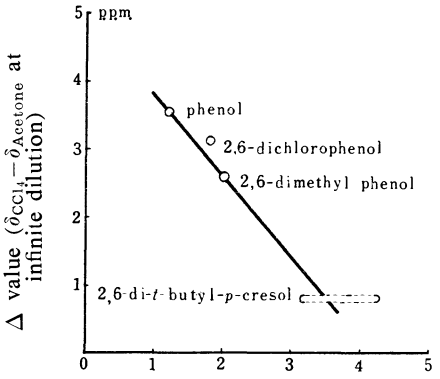

Fig. 2. Dependence of the ability of hydrogen bond formation of phenols on the size of ortho-group.

line connecting two points for 2, 6-di-alkyl phenols (alkyl=H and $CH_3$) to the $\Delta$ value of 0.8 gives a value approximately 3.5 Å as the Van der Waals radius corresponding to the size of the *t*-butyl group. This value seems to be reasonable for this group. Therefore it may be concluded that the ability of the formation of an intermolecular hydrogen bond in phenol derivatives is a linear function of the size of the ortho-group.

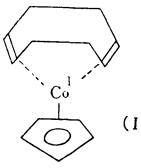
## *New Stable Olefin Complexes of Cobalt(I)*

By Akira NAKAMURA and Nobue HAGIHARA



(Received December 8, 1960)

In a previous communication the authors described the synthesis of cyclopentadienyl cobalt cyclooctatetraene (I)[1]. In that report the authors reported that I took up 2 mol. of hydrogen on catalytic hydrogenation to give orange crystals (II), m. p. 102°C. The authors supposed this compound II to be cyclopentadienyl cobalt 1, 5-cyclooctadiene considering from the proposed structure of I (cf. Fig. 1). In order to determine the correct structure of II, an attempt was made to obtain the same compound from 1, 5-cyclooctadiene. Thus 1, 5-cyclooctadiene was refluxed with cyclopentadienyl cobalt dicarbonyl in xylene under nitrogen for 15 hr. After removal of the unreacted starting materials, orange crystals were obtained by sublimation at 80°C under reduced pressure in 30% yield. These crystals were recrystallized from petroleum ether, m. p. 102.5°C. Found: C, 67.05; H, 6.76. Calcd. for $C_{13}H_{17}Co$: C, 67.24; H, 7.38%. The infrared spectrum of this compound was identical with that of II and showed the presence of $\pi$-cyclopentadienyl group. No absorption was observed at usual C=C stretching region. These facts indicate the structure of II to be $(C_8H_{12})Co(C_5H_5)$ which is shown in Fig. 2.

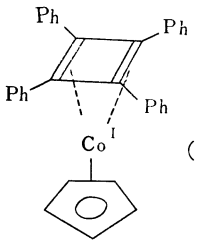
(I)

Fig. 1

(II)

Fig. 2

1, 3, 5-Cyclooctatriene yielded brown crystals (III), m. p. 90°C, by the similar reaction with cyclopentadienyl cobalt dicarbonyl. The infrared spectrum of III showed C=C stretching absorption at 1625 cm.$^{-1}$ III also gave II on catalytic hydrogenation.



II was stable in air, soluble in organic solvents and readily decomposed by bromine or by iodine in carbon tetrachloride. It also reacted with carbon monoxide (50 atm.) to give cyclopentadienyl cobalt dicarbonyl. The ultraviolet spectrum of II showed maximum at 361 m$\mu$(log $\varepsilon$: 2.87, in alcohol) and had shoulders at 235, 267 and 420 m$\mu$, as well as increasing absorption in the shorter wavelengths. I and II reacted with diphenyl acethylene in refluxing xylene to give yellowish brown crystals (IV), m. p. 256°C, in 40 and 47% yield respectively. These crystals were purified by recrystallization from benzene or by chromatography on alumina. Found: C, 81.82; H, 5.2. Calcd. for $C_{33}H_{25}Co$: C, 82.48; H, 5.24%. The analysis conformed to the composition, $(C_5H_5C{\equiv}CC_6H_5)_2Co(C_5H_5)$. IV was soluble in organic solvents and was quite stable in air. IV was thermally stable up to ca. 360°C under nitrogen and surprisingly oxidation resistant as a univalent cobalt compound. For example the solution of IV in benzene was oxidized neither by air on heating nor by iodine on warming. The ultraviolet spectrum of IV showed maxima at 241, 257 and 278 m$\mu$ (log $\varepsilon$: 4.51, 4.50, 4.46, in alcohol) and had shoulders at 287, 295 and 400 m$\mu$.

The infrared spectrum of IV showed the

1) A. Nakamura and N. Hagihara, This Bulletin, 33, 425 (1960).

presence of $\pi$-cyclopentadienyl group and mono-substituted phenyl group.

IV was reduced by sodium in liquid ammonia to give 1, 2, 3, 4-tetraphenylbutane, m. p. 181°C. IV did not react with concentrated hydrochloric acid, alcoholic potassium hydroxide and lithium aluminum hydride. It was attacked neither by carbon monoxide (100 atm.) at 290°C, by triphenyl phosphine at 150°C nor by acetylene dicarboxylic acid ester at 200°C. This remarkable stability of the compound IV together with its chemical and spectroscopic properties seems to indicate its structure involving a cyclobutadiene ring as shown in Fig. 3. Alternative structures such as those involving Co–C sigma bonds or involving tetraphenylbutadiene are less probable.

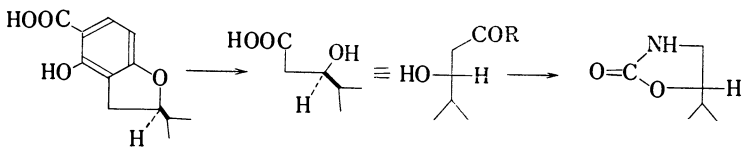
## *The Absolute Configuration of Rotenone*



By Masao NAKAZAKI and HISAO ARAKAWA

(Received December 22, 1960)

A recent short communication by Büchi et al.[1] on the absolute configuration of rotenone (I) prompts us to report our current work in this field. They submitted (−)dihydrotubaic acid (II) to exhaustive ozonolysis and obtained (+)3-hydroxy-4-methylpentanoic acid. In order to secure enough starting material, they synthesized (±)3-hydroxy-4-methylpentanoic acid and resolved it through the quinine salt to obtain the (−)acid (enantiomer of III, or IVa in Fischer projection), which they converted, via three steps into (−)2-methylpenta-3-ol with a known absolute configuration[2]. They thus established the (R) configuration[3] at position 5′ of rotenone. We also exhaustively ozonolysed (−)dihydrotubaic acid[4], m. p. 166°C, $[\alpha]_D^{25}$ −103.7° (methanol), then oxidized it with peracetic acid following our previous method[5]. The resulting hydroxy acid III was treated with diazomethane to afford the methyl ester IVb, b. p. 77∼86°C/18 mmHg $[\alpha]_D^{20}$ +19° (ethanol), which was converted into (−)3-hydroxy-4-methylpentanohydrazide IVc,

(VII): (a) R=OH, (b) R=$OCH_3$, (c) R=$NH_2$

(VIII): (a) R=H, (b) R=$COOC_2H_5$

m. p. 152~153°C, $[\alpha]_D^{19}$+43° (ethanol) with hydrazine. To relate this hydrazide IVc with D-valine, IVc was treated with nitrous acid[6] to afford (−)5-isopropyloxazolidone (V), m. p. 113~114°C, $[\alpha]_D^{18}$−44.5° (ethanol). Found: C, 55.93; H, 8.55; N, 10.98. Calcd. for $C_6H_{11}O_2N$: C, 55.79; H, 8.58; N, 10.84%.

Racemic hydrazide IVc, m. p. 149~150°C, was prepared from ethyl 3-hydroxy-4-methylpentanoate which was prepared by the reduction of ethyl 3-oxo-4-methylpentanoate with sodium borohydride. Reaction with nitrous acid converted the racemic hydrazide IVc into the oxazolidone V, m. p. 87~88°C, the I. R. spectrum of which was found sound superimposable on that of the (−)oxazolidone V from rotenone.

(−)Methyl 2-hydroxy-3-methylbutanoate[7], b. p. 62~63°/15 mmHg, $[\alpha]_D^{17}$−1.4° (etahnol) prepared from D-valine[8], $[\alpha]_D^{16}$−27.6° (6 N hydrochloric acid), was treated with liquid ammonia to give the amide VIIc, m. p. 99~100°C, $[\alpha]_D^{15}$+65.1° (methanol) (racemic compound, m. p. 104~105°C), which in turn was reduced with lithium aluminumhydride to the aminoalcohol VIIIa.

Reaction of sodium methoxide with the ethyl carbamate drivative VIIIb, which was obtained from the aminoalcohol VIIIa by the action of ethyl chlorocarbonate in pyridine, gave (+)5-isopropyloxazolidone (IX), m. p. 113~114°C, $[\alpha]_D^{14}$+44.2° (ethanol). Found: C, 56.18; H, 8.68; N, 11.13%.

(−)5-Isopropyloxazolidone (V) derived from rotenone and (+)5-isopropyloxazolidone (IX) prepared from D-valine exhibited I. R. spectra which could be superimposed in every detail.

In order to make sure that they are enantiomorphic, an equal amount of (+) and (−) oxazolidone were mixed and recrystallized to give the racemic 5-isopropyloxazolidone which melted at 87~88°C, alone and admixed with the synthetic racemic oxazolidone from the racemic hydrazide.

Thus we could confirm Büchi and Crombie's result that rotenone has the (R) configuration at position 5'.

# *On Some Dark-colored Chlorocuprates(I, II) and Related Compounds. II. Magnetic Susceptibility and Color at Liquid Helium Temperatures*

By Masayasu MORI

(Received December 19, 1960)

A series of dark-colored chloroplumbates(II, IV) and chlorocuprates(I, II) of hexammine-chromium(III) and hexamminecobalt(III) were reported in previous papers[1]. In the present paper a study on the magnetic susceptibility and the color of some of these compounds at liquid helium temperatures will be reported.

The samples studied in this research were "mixed valence compounds", $[Co(NH_3)_6]\cdot[PbCl_6]$ (I), $[Co(NH_3)_6][CuCl_5]_x[CuCl_4]_{1-x}$ ($x\sim0.75$) (II) and a single valence compound, $[Co(NH_3)_6][CuCl_5]$ (III). Measurements of magnetic susceptibility were carried out by the a. c. method[2] using a Hartshorn bridge in the temperature range, 1.3~4.2°K. The frequency used was 90 cycles/sec. The reciprocal values of the molar susceptibility ($\chi_M$) of II and III obtained in this way are plotted against absolute temperature $T$ in Fig. 1.

It is seen that the susceptibility obeys the Curie-Weiss law, $\chi_M=C/(T-\Theta)$, down to the temperature of about 2°K. The Weiss constant, ca. −2.3°K, for both II and III as seen from

1) M. Mori, This Bulletin, 24, 285 (1951); 33, 985 (1960).
2) C. J. Gorter, "Paramagnetic Relaxation", Elsevier, Amsterdam (1947).

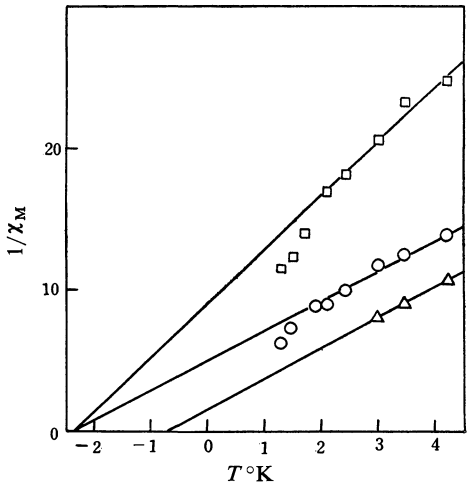

Fig. 1. Plots of $1/\chi_M$ vs. $T$°K.
—△— $CuSO_4 \cdot 5H_2O$
—○— $[Co(NH_3)_6][CuCl_5]_x[CuCl_4]_{1-x}$
—□— $[Co(NH_3)_6][CuCl_5]$

Fig. 1 is considerably different from that of $CuSO_4 \cdot 5H_2O$ (ca. −0.7°K). The magnetic moments per each bivalent copper atom calculated from the slopes are 1.57 B. M. for II and 1.47 B. M. for III*. These values are also abnormal as compared with the value of $CuSO_4 \cdot 5H_2O$, 1.92 B. M. These anomalies seem to be due to the trigonal-bipyramidal structure[3] of chlorocuprate ion, $[CuCl_5]^{3-}$, and not to the $Cu^{I}$–$Cu^{II}$ interaction, since II and III exhibit similar magnetic behaviors.

No marked change of color was observed when II (brownish black) and III (yellowish orange) were dipped in liquid helium except that the color of III appeared a little lighter. On the other hand the color of I (brownish black) changed into brown in liquid air and brick red in liquid helium. The cause and reason of such different behaviors of chloroplumbate(II, IV) and chlorocuprate(I, II) are not yet clear.

The author is very grateful to Professor Taiichiro Haseda of Tohoku University for his kind guidance and valuable suggestions in the magnetic measurement. The experiment has never been possible without the offer of the laboratory facilities for liquid helium experiments at the Research Institute for Iron, Steel and Other Metals in the Tohoku University.

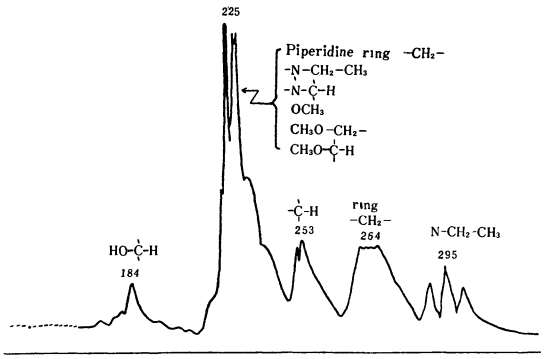
# *The Nuclear Magnetic Resonance Spectra of Some Aconite Bases: Lucaconine and Lucidusculine*

By Akira SUZUKI, Takashi AMIYA and Takeshi MATSUMOTO

(Received December 26, 1960)



An alkaloid lucaconine has beeen isolated from *Aconitum luciduscul*um, Nakai[1]. Recently, the alkaloid was identified[2] as delcosine[3] obtained from *Delphinium conolida* L. Based on several reactions of delcosine, Marion and others[4] assumed that the alkaloid possesses the same carbon-nitrogen framework and oxygen pattern as lycoctonine II[5] and suggested a tentative structure I. However, there has been no direct evidence for this substance bearing the $CH_2OCH_3$ group for R.

I R=$CH_2OCH_3$, R'=OH
II R=$CH_2OH$, R'=$OCH_3$

In *Aconitum* and *Delphinium* alkaloids, R is generally the methyl, hydroxymethyl or methoxymethyl group[6]. However, the possibility of the presence of the hydroxymethyl group in lucaconine can be excluded, since corresponding aldehydic or acidic products have not been obtained by the oxidation conditions which are expected to lead to these products[1,4,7]. The observation of NMR spectrum of lucaconine has been made to determine whether R is methyl or methoxymethyl. The NMR spectrum at 40 Mc. of lucaconine in pyridine solution is shown in Fig. 1. In this figure, although the other *Aconitum* alkaloids in which R is methyl have a strong singlet absorption characteristic of

| | (Calcd. on formula I) | (2) | (18) | (4) | (8) | (3) |

Fig. 1. The proton spectrum of lucaconine (taken on Varian 40 Mc. instrument).

$-\overset{|}{\underset{|}{C}}-CH_3$ group at about 318 c. p. s. from the signal of $\alpha$-proton of pyridine[8], such absorption can not be recognized for lucaconine. Accordingly, R is concluded to be $CH_2OCH_3$ in lucaconine. The anticipated singlet peak due to the methylene group of $-\overset{|}{\underset{|}{C}}-CH_2-OCH_3$ is, however, obscure[9] in Fig. 1, probably because of the overlapping with strong peaks of methoxyl groups, and of possible broadening due to the unequivalence of two methylene protons caused by the neighbouring asymmetric carbon atom[10]. A tentative interpretation based on the suggested structure I is also given in Fig. 1[11].

We next examined NMR spectrum of an aconite base lucidusculine[12]. Recently, one of us (T. A.) proposed formula III for the partial structure of lucidusculine on the basis of some chemical transformations[13].

III R=$CH_2OH$, one secondary OH group on the ring. Possible linkage between $C_{17}$-$C_{19}$ or $C_{17}$-$C_9$.

IV R=$CH_3$, two secondary OH groups on the ring. Possible linkage between $C_{17}$-$C_{19}$ or $C_{17}$-$C_9$.

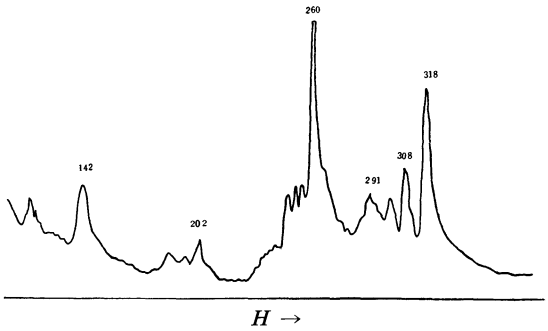

Fig. 2. The proton spectrum of lucidusculine.

The NMR trace at 40 Mc. of lucidusculine in pyridine is shown in Fig. 2. Clearly, the singlet band at 318 c. p. s. is to be ascribed to the methyl group on a quaternary carbon atom. This observation forces one to the conclusion that in lucidusculine R is actually the methyl group. The two hydroxyl groups in lucidusculine may both be secondary, since they are easily acetylated[12]. From above described results, a modified formula IV is now suggested as the partial structure of lucidusculine.

The authors express thier sincere thanks to Professor Genjiro Hazato and Dr. Kensuke Takahashi of Tohoku University for the measurement of NMR spectra. They are also grateful to Professor Harusada Suginome for his encouragement in this work.

## *The Interaction of a Surfactant with a Monolayer Studied by Radiotracer Method*

By Ryosuke SHIMOZAWA and Ryohei MATUURA

(Received February 6, 1961)

The adsorption of sodium alkyl sulfates at the solution-air interface was studied by radiotracer method and the result was already reported[1-3]. In this case if an insoluble monolayer is present on the surface of the solution, the surface count of the radioactive detergent may be different from that of the free surface, and it is expected that we may be able to know the interaction of the detergent with the monolayer substance from this difference in the surface count. We measured the interaction of sodium dodecyl sulfate (SDS) with the monolayer of octadecyl amine, octadecyl alcohol and nylon 6 spread on the surface of the solution by tracing sulfate sulfur tagged with $^{35}S$. The apparatus was almost the same as that used for measuring the adsorption of the detergent at the free surface[1]. The radioactivity of the surface of the SDS solution in the lucite tray was measured first. Then the monolayer was spread on this solution and the surface area was kept constant with the surface pressure of about 10 dyn./cm. The radioactivity of the surface in this state was measured with the same geometry as above. The spreading solvents used were a mixture of one volume ethanol and two volume benzene for octadecyl amine and octadecyl alcohol and a mixture of one volume phenol and three volume benzene for nylon 6. The result is shown in Fig. 1, in which the abscissa represents the time after spreading the monolayer on the surface and the ordinate is the surface count.

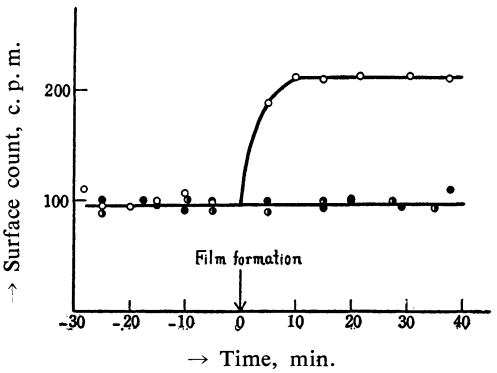

Fig. 1. Change in surface counting rate before and after film formation. Substrate is $8\times10^{-5}$ mol./l. SDS solution.
○ Octadecyl amine-SDS series
◑ Octadecyl alcohol-SDS series
● Nylon 6-SDS series

From this figure it is evident that in the presence of octadecyl amine monolayer the surface count increases to more than twice the value of the free surface, while in the case of octadecyl alcohol and nylon 6 no change is observed after spreading the monolayer of these substances. These results may show that the monolayer of octadecyl amine interacts with the molecule of SDS in the substrate solution remarkably but that of octadecyl alcohol and nylon 6 affects no such interaction as the amine monolayer. Goddard and Schulman[4] measured the surface pressure of an eicosyl amine monolayer at constant area on the surface of water and found that a remarkable increase in pressure took place by injecting sodium hexadecyl sulfate (SHS) into the substrate solution beneath the monolayer. They explained the result in terms of penetration of SHS into the monolayer and formation of a 1 to 1 stoichiometric complex. The present experiment confirms directly the strong interaction of the long chain amine monolayer with sodium alkyl sulfate in the solution. However, we found that the surface pressure of the monolayer of octadecyl alcohol and nylon 6 increases appreciably by the presence of SDS in the solution just as is the case with the amine monolayer, but the surface count with the monolayer of the former substances does not differ from the value without the monolayer contrary to the case of the latter substance, as shown in Fig. 1. These results suggest that the mechanism of the interaction of the long chain amine monolayer with SDS is different from that of the monolayer of long chain alcohol or nylon 6 with it. The quantitative treatment of the data and the detailed discussion will be reported in future.

## *Electron Spin Resonance Study on Photolysis of Acetone and Benzophenone*

By Keiji KUWATA and Kōzō HIROTA

(Received December 24, 1960)

Recently several trapped radicals formed in photolysis have been identified with organic compounds of low molecular weight by the ESR method[1]. By the use of a X-band spectrometer of high sensitivity it became possible to study the radical intermediates formed in photolysis of some ketones. Preliminary investigation on acetone and benzophenone will be reported here.

According to the kinetic studies on the photolysis of gaseous acetone, formation of several types of free radicals was proposed[2]:

$$CH_3COCH_3 + h\nu \rightarrow \dot{C}H_3CO + \dot{C}H_3$$

$$(\dot{C}H_3CO \rightarrow \dot{C}H_3 + CO)$$

$$\dot{C}H_3 + CH_3COCH_3 \rightarrow CH_4 + \dot{C}H_2COCH_3$$

$$\dot{C}H_2COCH_3 \rightarrow \dot{C}H_3 + CH_2CO$$

$$\dot{C}H_3 + \dot{C}H_2COCH_3 \rightarrow CH_3COCH_2CH_3$$

In the liquid phase photolysis of the both ketones, formation of the active intermediates was proposed[5], but their natures were not well known. Observation of ESR for these free radical intermediates will give a confirmative evidence for such mechanisms.

The spectrometer used was a type of high frequency field modulation, being similar to that of Fujimoto and Ingram, but the frequency of the field modulation was 455 kilocycles/sec. Design of a low temperature resonant cavity is shown in Fig. 1.

After an irradiation of ultraviolet light for several hours, any signal could not be observed in pure acetone, while a broad singlet was observed in pure benzophenone and in 0.1~1% solutions of the both ketones. However, the intensity of the signal decreased rapidly in the case of acetone, a half life being 50 min. at about 77°K. The characteristics of the signals observed are shown in Table I.

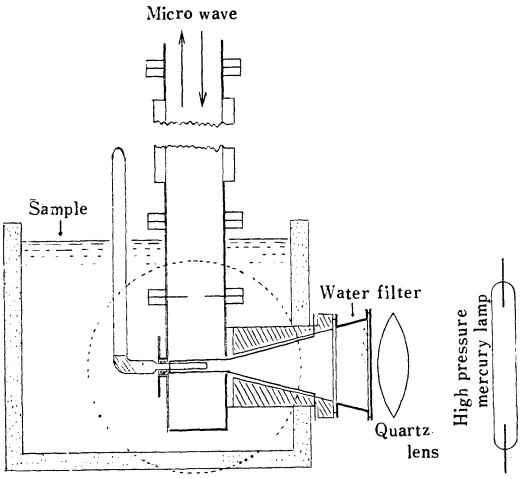

Fig. 1

TABLE I. ESR OF TRAPPED RADICALS AT ABOUT 77°K

| | Line width ($H_{msl}$) | Line shape | $g$-Factor |
|---|---|---|---|
| Acetone in ethanol and EPA (Ether, iso-Pentane and Alcohol) | 30 gauss | (gaussian) | 2.003 |
| Benzophenone | 23 gauss | 〃 | 2.003 |
| Benzophenone in ethanol and EPA | 24 gauss | 〃 | 2.003 |

An unstable free radical in the solution of acetone would be the methyl radical, but confirmative evidence for this assignment was not yet given since no hyperfine structure was observed. In the case of benzophenone a hyperfine structure neither of a quartet for the phenyl radical nor of a quartet with the small separations for the benzoyl radical was observed. The result indicates that two types of free radicals were present together or broadning of the line width occurred by some reasons, so that the hyperfine structure was smeared out. Detailed research will be published elsewhere.

The authors wish to express their thanks to Dr. M. Fujimoto and also to Dr. K. Morigaki of Osaka University for their suggestions on design of the low temperature cavity.

## *Reaction of Tetraphenyl Titanate with Amines*

By Takeshi Yoshino, Ichiro Kijima and Miyoko Ochi

(Received on December 26, 1960)

In the previous paper, the reaction of tetraphenyl titanate with ammonia, phenols, acetophenone and esters have been reported[1]. In the course of the synthetical studies on the organo titanium compounds, it has been found that the addition compounds of tetraphenyl titanate were more stable than that of tetraalkyl titanates. In the present communication, the reaction of tetraphenyl titanate (TPhT) with aliphatic or aromatic amines are described.

When TPhT was made to react with aliphatic amines (*n*-butylamine, tri-ethylamine, tri-*n*-butylamine) in toluene solution, addition compounds of TPhT could not be isolated. However, when aromatic amines (aniline, $\alpha$-naphthylamine, pyridine) were used, they gave addition compounds with TPhT (molar ratio of 1 : 1). When the addition compound of TPhT with phenol I reacted with aromatic amines, the addition compound I was converted into the addition compounds of the corresponding amines used. They also were converted into the addition compound of TPhT with ammonia. The reaction of TPhT with hexamethylenediamine gave yellow crystals, which were considered as the addition compound of TPhT with hexamethylenediamine (molar ratio of 2 : 1).

### Experimental

**1) Addition Compounds of TPhT with Aromatic Amines.** — Into a solution of TPhT (8.0 g.) in toluene (50 ml.), freshly distilled aniline (2.1 g.) was added and refluxed for 15 min. After the reaction mixture was allowed to stand at room temperature, the crystals separated out were collected by filtration and dried under reduced pressure, 8.0 g. of yellowish orange crystals were obtained. They were recrystallized from toluene. M. p. 181~183°C. (Found: Ti, 9.64; N, 2.80. Calcd. for $C_{30}H_{27}O_4NTi$: Ti, 9.33; N, 2.73%). In a similar way the following addition compounds were obtained: $Ti(OC_6H_5)\cdot C_{10}H_7NH_2$, orange crystals, m. p. 168~169°C. (Found: Ti, 8.49; N, 2.60. Calcd. for $C_{34}H_{29}O_4NTi$: Ti, 8.50; N, 2.49%); $Ti(OC_6H_5)_4\cdot C_5H_5N$, reddish orange crystals, m. p. 191~192°C. (Found: Ti, 9.53; N, 2.83. Calcd. for $C_{29}H_{25}O_4NTi$: Ti, 9.59; N, 2.80%).

When aliphatic amines (*n*-butylamine, tri-ethylamine, tri-*n*-butylamine) were used, addition compound of TPhT could not be isolated.

**2) Reaction of the Addition Compound $Ti(OC_6H_5)_4\cdot C_6H_5OH$ (I) and Aromatic Amines.**— To a solution of the addition compound I (4.0 g.), in toluene (15 ml.), aniline (2.0 g.) was added and the solution was refluxed for 15 min. After allowed to stand at room temperature, it deposited yellowish orange crystals. They were purified as described under (1), m. p. 183°C. (Found: Ti, 9.08; N, 2.86. Calcd. for $C_{30}H_{27}O_4NTi$; Ti, 9.33; N. 2.73%). $Ti(OC_6H_5)_4\cdot C_6H_5OH+C_6H_5NH_2 \rightarrow Ti(OC_6H_5)_4\cdot C_6H_5NH_2+C_6H_5OH$. In a similar way, by the use of $\alpha$-naphthylamine or pyridine, the addition compound I was converted into the corresponding addition compounds of TPhT with the above amines respectively: $Ti(OC_6H_5)_4\cdot C_{10}H_7NH_2$, m. p. 167~168°C. (Found: Ti, 8.91; N, 2.63, Calcd. for $C_{34}H_{29}O_4NTi$: Ti, 8.50; N, 2.49%); $Ti(OC_6H_5)_4\cdot C_5H_5N$, m. p. 191~192°C. (Found: Ti, 9.67; N, 2.88. Calcd. for $C_{29}H_{25}O_4NTi$: Ti, 9.59; N, 2.80%).

**3) Reaction of the Addition Compound $Ti(OC_6H_5)_4\cdot C_6H_5NH_2$ (II) and Ammonia.** — When excess of dry ammonia gas was passed at room temperature to a solution of the addition compound II (2.5 g.), in toluene (10 ml.), the addition compound II was converted into the addition compound of TPhT with ammonia III, (molar ratio of 1 : 1). M. p. 201~202°C. (Found: Ti, 10.89; N, 3.17. Calcd. for $C_{24}H_{23}O_4NTi$: Ti, 10.95; N. 3.20%).

$$Ti(OC_6H_5)_4\cdot C_6H_5NH_2+NH_3 \rightarrow Ti(OC_6H_5)_4\cdot NH_3+C_6H_5NH_2$$

In a similar way, the addition compounds $Ti(OC_6H_5)_4\cdot C_{10}H_7NH_2$ and $Ti(OC_6H_5)_4\cdot C_5H_5N$ were converted into III.

**4) Reaction of TPhT with Hexamethylenediamine.**—Into a solution of TPhT (8.7 g.) in toluene (60ml.), hexamethylenediamine (0.6 g.) was added and refluxed for 30 min. After the reaction mixture was allowed to stand at room temperature, the crystals were collected by filtration, washed with toluene and dried under reduced pressure, 4.7 g. of powdery yellow crystals were obtained. M. p. 237~239°C. The analytical data showed this compound to be an addition compound of TPhT with hexamethylenediamine (molar ratio of 2 : 1), (Found: Ti, 10.13; N, 3.45. Calcd. for $C_{54}H_{56}O_8N_2Ti_2$: Ti, 10.01; N, 2.92%).

# *On the Oxidation of β-Aminopropionitrile. II*

By Toshihisa TACHIKAWA

(Received June 16, 1960)

In the previous paper of this series[1], it was reported that β-aminopropionitrile became viscous and yielded a resinous material, when it had been stored in the air for a prolonged period. This resinous material was also obtained by bubbling air through β-aminopropionitrile and the following structure has been proposed for the oxidation product:

$$\begin{matrix}\bar{O}\text{-}\overset{+}{N}\text{-}CH_2CH_2CONHCH_2CH_2CONH_2 \\ \quad\| \\ \quad N\text{-}CH_2CH_2CONHCH_2CH_2CONH_2\end{matrix}$$

During the course of oxidation experiments, the evolution of a small amount of hydrogen peroxide was noticed. This phenomenon suggests that the oxidation reaction may be accelerated in the presence of hydrogen peroxide. The present work has been carried out to clarify the effect of hydrogen peroxide in the oxidation processes.

The effect of hydrogen peroxide on the oxidation of β-aminopropionitrile was investigated by means of ultraviolet absorption spectrum. As is shown in Fig. 1, the oxidation product similar to that in the air was obtained in the presence of 1 mol. of hydrogen peroxide per mole of β-aminopropionitrile. This result agrees quite well with that obtained from the infrared absorption measurement. Further-

more, the evidence that the oxidation product by hydrogen peroxide is the same as that in the air was also confirmed by the rapid evolution of gaseous nitrogen when this product was decomposed with sulfuric acid and by the formation of β-alanine when this product was reduced with tin and concentrated hydrochloric acid. It is understood from Table I, that 1 mol. of ammonia was evolved from 2 mol. of β-aminopropionitrile in the course of this oxidation reaction by hydrogen peroxide as was observed in the oxidation by air. Therefore, there results strongly suggest that the oxidation of β-aminopropionitrile by hydrogen peroxide proceeds through the same mechanism as that by air. At the mole ratio of 0.50 (hrdrogen peroxide/β-aminopropionitrile), a characteristic ultraviolet absorption spectrum was obtained, which may correspond to some intermediates of this oxidation reaction. Thus, ultraviolet absorption spectra were measured at different mole ratios.

It is understood from Fig. 3 that the spectra taken immediately after sampling show the presence of absorptions at 212～215, 240～242 and 307～310 mμ regardless of their mole ratios. However, on standing for 48 hr., absorptions at 212～215, 240～242 and 307～310 mμ were obtained only at mole ratios smaller than 0.7

(hydrogen peroxide/β-aminopropionitrile), and at mole ratios greater than 0.7 an absorption at 280 mμ appears as an absorption at 307~310 mμ decreases.

Since several reaction intermediates were probably contained in a sample when measurements were performed right after sampling, it was not possible to postulate a reasonable reaction process and products. However it was inferred from the spectral measurements of samples which were allowed to stand for more than 48 hr. after sampling that the second reaction took place in the presence of 0.7 mol. of hydrogen peroxide against one mole of β-aminopropionitrile.

The mechanism proposed for the oxidation of β-aminopropionitrile is as follows:

1) In the first step of the oxidation reaction, β-aminopropionitrile is presumably transformed into β-hydroxylaminopropionitrile. This reaction process agrees with the known fact that an amino group is oxidized by hydrogen peroxide to yield a hydroxylamine group[2,3]. β-Hydroxylaminopropionitrile which was synthesized from hydroxylamine and acrylonitrile, was very unstable and transformed into a viscous substance in air. An infrared absorption spectrum of this viscous material showed six bands at 3.1, 3.35, 3.45, 6.05, 6.45, 6.75 μ, as shown in Fig. 4. This spectrum was similar to that of the oxidation product by air or hydrogen peroxide.

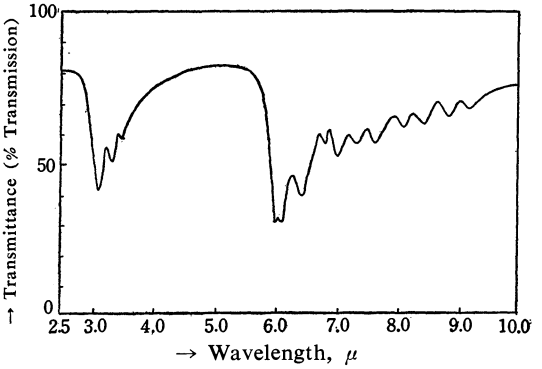

Fig. 4. Infrared absorption spectrum of the oxidation product of β-hydroxylaminopropionitrile.

2) At the next stage, β-hydroxylaminopropionitrile (or β-aminopropionitrile itself) may be hydrolyzed to yield β-hydroxylaminopropioamide (or β-aminopropioamide). This postulate is considered to be reasonable because a nitrile radical undergoes hydrolysis to produce an acid amide group in the presence of hydrogen peroxide as a catalyst[4].

3) An acid amide group thus formed reacts with a hydroxylamino group as the third step of the reaction. This reaction is well known as the reaction for the qualitative test of an acid amide group.

4) It is known that a hydroxylamino compound is a strong reducing agent and is oxidized

2) L. Mamlock and R. Wolffenstein, *Ber.*, 33, 159 (1900).
3) R. A. Henry and W. M. Dehn, *J. Am. Chem. Soc.*, 72, 2780 (1950).
4) S. Soloway and A. Lipschiz, *Anal. Chem.*, 24, 898 (1952).

to a nitroso compound. Therefore, a hydroxamic acid produced in the reaction process shown by Eq. 1 may be reduced to -CONH- group.

$$R\text{-}CONH_2 + R'\text{-}NHOH \rightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{N}\text{-}R' + NH_3 \quad (1)$$

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{N}\text{-}R' + R'\text{-}NHOH \rightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}NH\text{-}R' + R'\text{-}NO + H_2O \quad (2)$$

5) The final product of this oxidation reaction is considered to be an azoxy compound. This final reaction process may be considered reasonable accordance to the work by Bamberger[5], who reported, that the formation of azoxy compound from a hydroxylamino compound has taken place with the evolution of hydrogen peroxide, assuming a nitroso compound as an intermediate.

The oxidation process mentioned above is formulated as follows:

$$CNCH_2CH_2NH_2 + 1/2\ O_2(H_2O_2) \rightarrow CNCH_2CH_2NHOH + (H_2O) \quad (3)$$

$$CNCH_2CH_2NHOH + H_2O \rightarrow NH_2COCH_2CH_2NHOH \quad (4)$$

$$3NH_2COCH_2CH_2NHOH \rightarrow \underset{(I)}{NH_2COCH_2CH_2NHCOCH_2CH_2NHOH} + NH_2COCH_2CH_2NO + NH_3 + H_2O \quad (5)$$

$$(I) + 1/2\ O_2(H_2O_2) \rightarrow \underset{(II)}{NH_2COCH_2CH_2NHCOCH_2CH_2NO} + H_2O(2H_2O) \quad (6)$$

$$(I) + (II) + 1/2\ O_2(H_2O_2) \rightarrow \overset{-}{O}\text{-}\overset{+}{N}CH_2CH_2CONHCH_2CH_2CONH_2 \quad \underset{\|}{N}CH_2CH_2CONHCH_2CH_2CONH_2 + H_2O_2(H_2O + H_2O_2) \quad (7)$$

The secondary reaction process observed at higher mole ratios of hydrogen peroxide may be shown by Eq. 5 which corresponds to the reduction reaction by a hydroxylamino radical.

## Experimental

**Oxidation Reaction of β-Aminopropionitrile with Hydrogen Peroxide.**—To β-aminopropionitrile (15 g.) which was placed in a 100 cc. three-necked flask equipped with a thermometer, a dropping funnel and a capillary, 25% hydrogen peroxide (29.3 g.) was added dropwise at below 5°C and at reduced pressure to removed ammonia gas as soon as it was reduced during the course of the reaction. The reaction was exothermic and ammonia gas was evolved violently as hydrogen peroxide was added to the reaction mixture. The reaction mixture become viscous as the reaction proceeded. After the addition of hydrogen peroxide was completed, the temperature of the reaction mixture was brought up to 90°C to remove water and β-aminopropionitrile unreacted. The yellow, amorphous, and hydroscopic solid (17 g.) was obtained from the residue, which decomposed at 120°C.

Found: C, 43.53; H, 6.25; N, 24.62. Calcd. for $C_{12}H_{22}N_6O_5$: C, 43.63; H, 6.71; N, 24.22%.

By means of the same method in the previous paper[1], nitrogen gas (6.77 ml.) was evolved from this sample (0.1014 g.) by the decomposition with sulfuric acid and β-alanine (9.1 g.) was obtained from this sample (20 g.) by the reduction with tin (19.1 g.) and 35% hydrochloric acid (75 g.).

Found: C, 40.62; H, 7.65; N, 15.77. Calcd. for $C_3H_7NO_2$: C, 40.44; H, 7.92; N, 15.72%.

**Ultraviolet Absorption Spectrum.**—The Shimazu spectrophotometer model QR 51 equipped with a cell of 1 cm. path length was used throughout this work. Ultraviolet spectral measurements of the reaction intermediates were performed as follows: The 50% aqueous solution of β-aminopropionitrile (10 g.) through which nitrogen gas was bubbled was kept at below 5°C with stirring. After a known amount of hydrogen peroxide was added, nitrogen gas was introduced further into the reaction mixture and the ammonia gas which evolved was removed. Then, 0.01~0.03 cc. of the reaction mixture was pipetted out and measured spectroscopically after dilution to 50 cc. with water. Samples which were allowed to stand for over 48 hr. were also measured, at which time the reaction stopped completely.

**Infrared Absorption Spectrum.** — A sample for the spectral measurement was prepared in the following procedure: A sample was dissolved in methanol to obtain 3% solution. Then, a piece of thin film was prepared on a cell by evaporating methanol from the solution. The infrared spectrum was obtained with a Perkin-Elmer spectrophotometer model 21 equipped with a sodium chloride prism.

**Synthesis of β-Hydroxylaminopropionitrile.** — Acrylonitrile (80 g.) is added slowly while cooling to about 10°C into freshly prepared solution of hydroxylamine (33 g.) in methyl alcohol. After being allowed to stand for two hours at room temperature the methanol and unchanged acrylonitrile are distilled off. The residue consists of a practically quantitative yield of β-hydroxylamino-propionitrile. It is a thick liquid which decomposes when distilled even under a pressure of a few millimeters of mercury. It is extremely sensitive to oxidation; it becomes viscous in the air. The colorless amorphous and hygroscopic solid was obtained by treating this viscous material with anhydrous acetone. An infrrared absorption spectrum was recorded with a Perkin Elmer spectrophotometer model 21 on the sample film which was prepared by evaporating 2~3 drops of 3% methanolic solution on the sodium chloride window.

# *On the Oxidation of β-Aminopropionitrile. III*

By Toshihisa TACHIKAWA

(Received June 16, 1960)

In the previous papers of this series[1,2], the structure of a resinous oxidation product of β-aminopropionitrile was proposed. β-Aminopropionitrile was oxidized using either air or hydrogen peroxide as an oxidizing agent. In the previous paper[2], it was proposed that in the first step of this oxidation process β-aminopropionitrile was oxidized into β-hydroxylaminopropionitrile which was hydrolyzed to produce an acid amide compound and in the second step, these intermediates reacted to form a compound with azoxy group and -CONH- linkage.

In the present investigation, five different derivatives of β-aminopropionitrile were prepared and the effect of the substituents in the oxidation reaction was studied in addition to the identification of oxidation products of these derivatives and to the investigation of reaction mechanisms. These five derivatives of β-aminopropionitrile are as follows:

α-Methyl-β-aminopropionitrile (I)
β-Methyl-β-aminopropionitrile (II)
β-Ethylaminopropionitrile (III)
β-Dimethylaminopropionitrile (IV)
β-Methyl-α-aminopropionitrile (V)

These derivatives did not undergo any change either on standing in the open air or by bubbling air through the materials. On the other hand, these materials were oxidized with hydrogen peroxide and the results are summarized in Table I. Hygroscopic materials were obtained as oxidation products of compounds I and II. These products are quite similar to the oxidation product of β-aminopropionitrile in their hygroscopic properties. The oxidation products of I and II have their softening points at 110°C. Their infrared absorption spectra are shown in Figs. 1 and 2.

As observed in the oxidation product of β-aminopropionitrile, an absorption band at

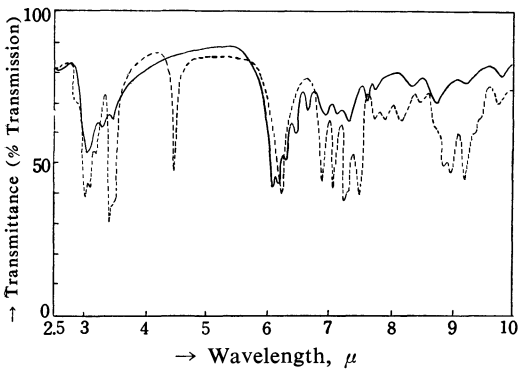

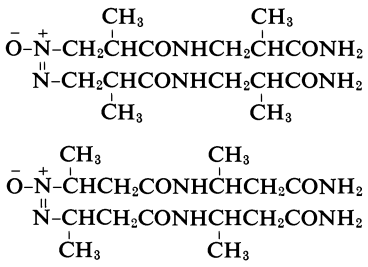

Fig. 2. Infrared absorption spectrum.
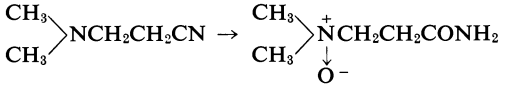
---- β-Methyl-β-aminopropionitrile
—— Oxidation product

4.5 μ due to C≡N stretching vibration disappeared and absorption bands at 3.1, 3.3, 3.4 and 6.5 μ which were caused by -CONH- vibrations and at 6.70 μ by the stretching vibration of an azoxy group appeared.

Accordingly, it seems reasonable to propose the following structures for their oxidation products:



The oxidation reaction of β-aminopropionitrile, proceeded at below 5°C to yield a viscous substance. On the contrary, it was necessary to raise the reaction temperature up to 20°C in the oxidation of compounds I and II. This means presumably that one methyl substituent introduced in β-aminopropionitrile interferes with the oxidation of an amino group.

A tertiary amino compound IV did not yield resinous material, but a crystalline substance in oxidation reaction. Recrystallization of this product from butanol gave a compound with melting point above 250°C and the composition, $C_5H_{12}N_2O_2$, which was obtained from its elemental analysis. The infrared absorption spectrum of this compound does not possess an absorption band at 4.5 μ due to C≡N stretching vibration, while the absorption bands, which correspond to C=O stretching vibration and $NH_2$ bending vibrations, appeared at 6.0 and 6.15 μ, respectively, as shown in Fig. 3. This result thus indicates the complete hydrolysis of the nitrile to the corresponding acid amide compound.

The strong absorption bands at 7.8 and 10.45 μ present a strong support to the presence of a *N*-oxide group in the molecule. These absorption bands were observed also by Parker[3] and Koelsch[4] to be caused by *N*-oxide vibrations. *N*, *N*-dimethyl-β-alanine was obtained by treating this compound with sodium hydrosulfite and hydrochloric acid. Thus, it is understood from these studies that the compound IV was transformed into β-dimethylaminopropioamide *N*-oxide as shown by the following equation:

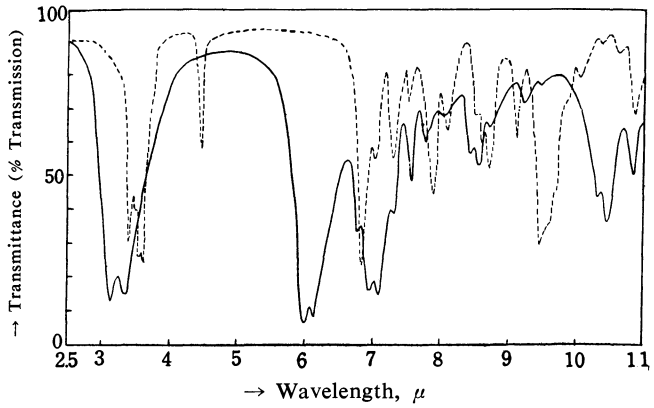


Fig. 3. Infrared absorption spectrum.
---- β-Dimethylaminopropionitrile
—— β-Dimethylaminopropionitrile *N*-oxide

3) E. D. Parker and A. Furst, *J. Org. Chem.*, **23**, 201 (1958).

4) C. F. Koelsch and W. H. Gumprecht, *J. Org. Chem.*, **23**, 1603 (1958).

From this fact it is clear that amino groups of these β-aminopropionitrile derivatives are not oxidized to aldehydes or ketones but to hydroxylamino groups.

β-Dimethylaminopropioamide *N*-oxide is comparatively unstable in the air and undergoes a gradual transformation into a reddish substance when it is stored in the air for a prolonged period. As Rogers[5] reported previously, phthalates of the *N*-oxides of β-dimethylaminopropionic esters or nitrile were prepared by the reaction of β-dimethylaminopropionic esters or nitrile with monoperphthalic acids. However, nothing has been reported about the synthesis of an *N*-oxide compound itself. It is very interesting to know that a new *N*-oxide was prepared in the present investigation. This *N*-oxide was prepared by hydrogen peroxide oxidation of the compound IV, a nitrile group which underwent hydrolysis simultaneously to yield an acid amide group. Since the compound V did not yield a resinous substance by the oxidation with hydrogen peroxide, it seems that β-aminonitrile compounds are oxidized with hydrogen peroxide by the mechanism as described in the previous paper[1], but α-aminonitrile compounds are not oxidized by the same mechanism.

## Experimental

**Preparation of α-Methyl-β-aminopropionitrile[6].**—Thirty-three grams of methacrylonitrile and 110 g. of 28% aqueous ammonia were placed in a Carius-type tube heated for 8 hr. at 70~75°C. Then, unreacted methacrylonitriles which lay above an aqueous phase were separated. α-Methyl-β-aminopropionitrile, $n_D^{20.2}$ 1.4340, $d_4^{20.2}$ 0.9180, b. p. 76.5~77.5°C/16.8 mmHg, was obtained from the aqueous phase; yield, 17.5 g.

Found: N, 33.63. Calcd. for $C_4H_8N_2$: N, 33.83%.

**Preparation of β-Methyl-β-Aminopropionitrile[7].**—A Carius-type tube containing 41 g. of allyl cyanide and 200 g. of 28% aqueous ammonia was heated for one hour at 70°C. The reaction mixture became homogeneous after this treatment and then distilled in vacuo to give the product, β-methyl-β-aminopropionitrile; yield, 34.5 g., b. p. 84.7~85.0°C/23 mmHg.

**Preparation of β-Dimethylaminopropionitrile[8].**—This was prepared from 60 g. of 50% aqueous dimethylamine and 35 g. of acrylonitrile. Yield, 33.1 g., b. p. 83~85°C/37 mmHg.

**Preparation of β-Ethylaminopropionitrile[8].**—This was prepared from 70% aqueous ethylamine and 45.0 g. of acrylonitrile. Yield, 13.0 g., b. p. 78~80°C/16 mmHg.

**Preparation of α-Methyl-α-aminopropionitrile.**—To a mixture containing 110 g. of acetonecyanhydrine and 400 ml. of methanol, ammonia gas was introduced at 15°C with stirring until the solution was saturated with ammonia. After being allowed to stand for 2 days in an ice bath, the reaction mixture was distilled in vacuo to yield α-methyl-α-aminopropionitrile; 35 g., b. p. 48.7~50.2°C/12 mmHg.

**Oxidation Reaction with Hydrogen Peroxide.**—Twenty-five per cent hydrogen peroxide was added dropwise to aminonitrile placed in a 100 ml. flask equipped with a thermometer, a dropping funnel and a capillary, keeping the reaction temperature below 5°C. This reaction proceeded under reduced pressure to remove ammonia gas. After the addition of hydrogen peroxide was completed, the reaction temperature was raised gradually up to 50°C, and the ammonia and water were removed. Unreacted aminonitrile was also displaced from the reaction mixture by treating it with anhydrous acetone. When β-dimethylaminopropionitrile was employed as an aminonitrile compound and treated as described above at 50°C, a crystalline product was obtained. Recrystallization of this product from butanol gave glittering needle-like crystals.

**Reduction and Hydrolysis of the β-Dimethylaminopropioamide *N*-Oxide.**—β-Dimethylaminopropioamide *N*-oxide (13.2 g.) in 50 cc. methanol was boiled with 30% hydrochloric acid (20 g.) for an hour. After cooling and basification with aqueous sodium hydroxide, the reacted solution was stirred with sodium hydrosulfite (25 g.) for 2 hr. at room temperature. The reacted solution was acidified with hydrochloric acid and evaporated at reduced pressure. The residue was extracted with cold ethanol. Evaporation of the ethanol left a crystalline residue which was recrystallized from ethanol and formed leaflets (8.6 g.) m. p. 186.5~188°C[9]. The melting point was not depressed by admixture with *N*, *N*-dimethyl-β-alanine hydrochloride.

**Infrared Absorption Spectrum.**—A sample of the oxidation products of the compounds I and II were dissolved in methanol to obtain 3% solution. Then, a piece of thin film was prepared on a cell by evaporating methanol from the solution. The potassium bromide disk method was employed to prepare a sample of the oxidation product of IV.

The Perkin-Elmer model 21 spectrophotometer was used to obtain spectral data.

The author wishes to express his sincere thanks to Professor Ryozo Goto of Kyoto University for his kind advice, and also to Mr. Murataro Nakashima, President of Kunoshima Chemical Co., for his permission to publish this paper.

# *Effect of Solvent on Carbonyl Stretching Frequency of Ketones*

By Kōzō Inuzuka, Mitsuo Ito and Sunao Imanishi

(Received July 29, 1960)

It is well known that ketones and aldehydes show characteristic infrared absorption bands assignable to the C=O stretching vibration of molecule. In our previous works[1,2] we studied the solvent effect on $n-\pi^*$ absorption bands of some ketones on the basis of a theoretical equation proposed by McRae[3]. In these studies we found a certain relationship between the solvent-induced shift of the ultraviolet $n-\pi^*$ absorption frequencies and that of infrared C=O frequency. It is found in the present work that the same McRae's equation can also be applied to the interpretation of the solvent shift of the C=O stretching frequency for both nonpolar and polar solvents. The intensity of the C=O stretching vibration is influenced by the polarity of the solvent. The magnitude of the bond moment derivative measuring the infrared absorption intensity increases for polar solvents, especially for solvents which tend to form hydrogen bonds with the solute molecules. However, this intensification for the C=O bands is not so large as for the OH bands. In this paper we intend to estimate the bond moment derivative for the C=O bond and its increase on hydrogen bonding.

## Experimental

Infrared absorption measurements of ketones were made with a Hitachi E. P. I double beam spectrophotometer with an sodium chloride prism, using 0.1 mm. cell. Solvent effects were observed for acetone, mesityl oxide, acetophenone and benzophenone. The solvents used were *n*-hexane, ethyl ether, carbon tetrachloride, benzene, dioxane, acetonitrile, chloroform, *iso*-butyl alcohol and ethyl alcohol. They were purified by the methods recommend by Weissberger and Proskauer[4]. Special care was taken to remove contaminating water in the solvents. Acetone was purified by the above method. Highest quality commercial mesityl oxide and acetophenone were further purified by repeated distillations. Benzophenone was recrystallized several times from ethanol.

## Results and Discussion

The positions of the carbonyl bands of four ketones in the different solvents are given in Table I. The refractive index and dielectric constant of the solvents are given in Table II. It is seen that the carbonyl frequency in a given solvent decreases in the order of acetone, mesityl oxide, acetophenone and benzophenone. This is just the order of increase of the amount of conjugation in the respective molecules. The observed parallelism between the carbonyl frequency and the extent of conjugation may be interpreted as a result of the lowering of the double bond character of the carbonyl bond with increasing conjugation. Kirkwood and Magat[5] related the frequency shift in the infrared absorption of a solution to the dielectric constant $D$ of the solvent by a formula

Table I. Frequencies ($cm^{-1}$) of C=O vibration bands of ketones in various solvents

| Solvent | Acetone | Mesityl oxide | Aceto-phenone | Benzo-phenone |

$$\Delta\nu/\nu = C(D-1)/(2D+1)$$

where $\nu$ is the frequency of an absorption band, and $C$ is a constant. This equation has been checked experimentally for a number of substances, and it generally holds only for nonpolar solvents. The linear relation is shown in Fig. 1, in which the shift of the carbonyl stretching frequency of the ketones investigated is plotted against the value $(D-1)/(2D+1)$ of nonpolar solvents. However, such a linearity is no longer seen for polar solvents. In the case of non-hydrogen bonding polar solvents, the dipole moment effect of the

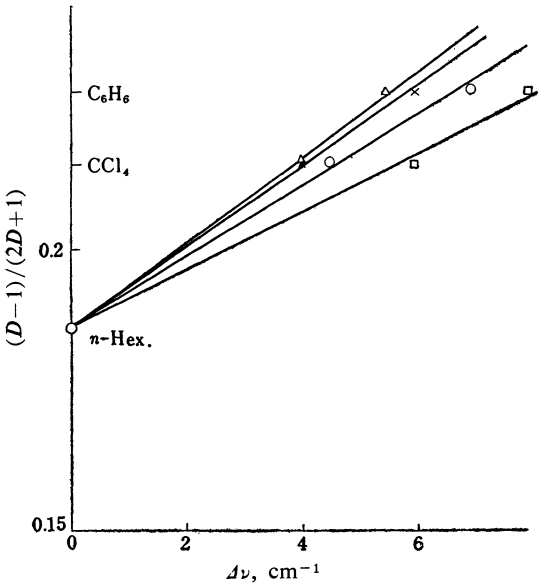

Fig. 1

solvent must be taken into consideration. In our previous paper[1] on the solvent effect on the $n-\pi^*$ absorption of ketones, observed shifts were well explained by McRae's equation as mentioned above. In the same paper it was found that the solvent induced shift of the infrared carbonyl frequency relates linearly in turn with that of the ultraviolet $n-\pi^*$ absorption frequency of the same ketone. It is then expected that the solvent effect on the carbonyl frequency itself may also be explained by the same McRae's equation. With polar solvents for which $D$ is no longer equal to $n^2$, the above equation tells us that if $n$ of all the solvents used are nearly equal, the solvent induced frequency shift must be proportional to $(D-1)/(D+2)$. We took mixtures of ethyl ether and acetonitrile in various ratios as the solvents satisfying the above condition. While the $n$ values of ethyl ether and acetonitrile are nearly the same, their $D$ values are quite different from each other. The $\Delta\nu$ vs. $(D-1)/(D+2)$ relations are shown in Figs. 2—5 for the ketones investigated, in which the approximate linearity is clearly seen for each substance.

From the above results it may be understood that the following McRae's equation holds well for both the cases of polar and nonpolar solvents.

$$\Delta\nu = A(n^2-1)/(2n^2+1) + B\{(D-1)/(D+2) - (n^2-1)/(n^2+2)\}$$

in which $A$ and $B$ are constants characteristic of the solute molecule. For nonpolar solvents $D$ is nearly equal to $n^2$, thus the second term

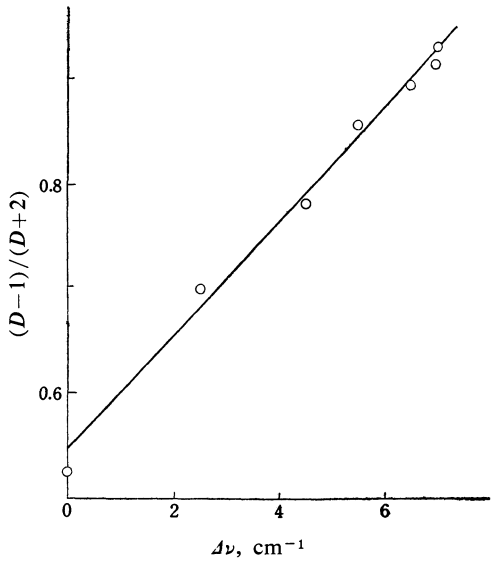

Fig. 2

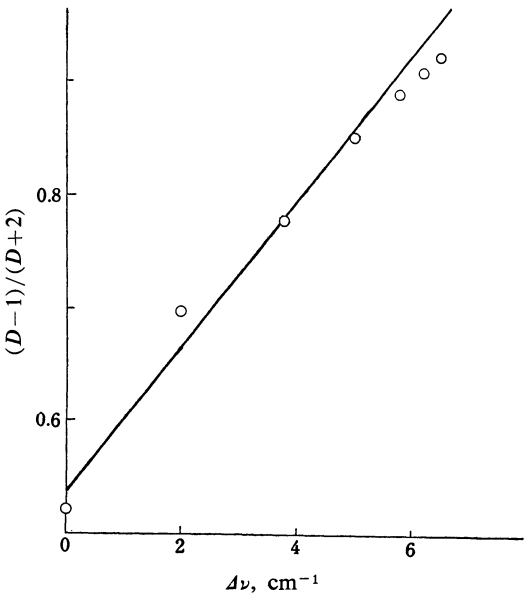

Fig. 3

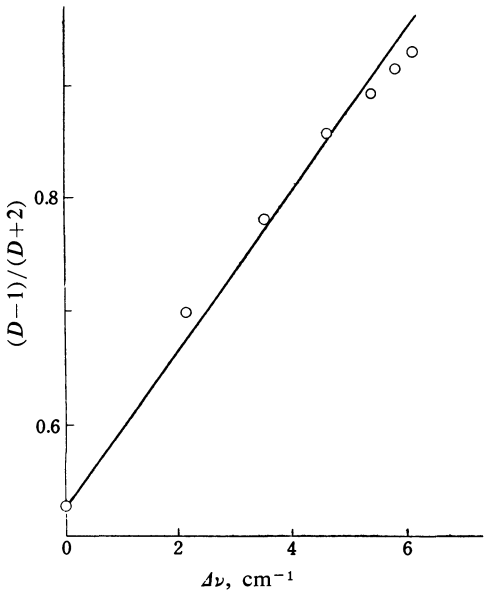

Fig. 4

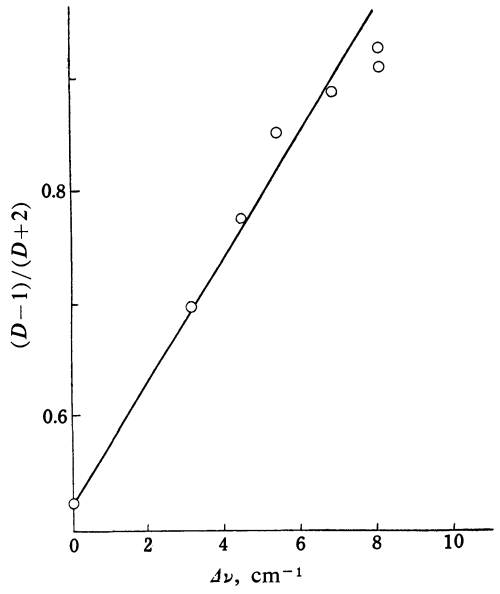

Fig. 5

vanishes. Substituting $n^2$ with $D$ in the first term we obtain an equation identical with the one derived by Kirkwood and Magat. Fig. 6 shows a comparison between the observed shifts for benzophenone and those calculated from the McRae's equation, putting 65 and 9 $cm^{-1}$ for $A$ and $B$, respectively. It is seen that the points for most solvents, except those having possibilities for forming hydrogen bonds with the solute molecule, drop near to the theoretical line. For hydrogen bonding systems large deviations occur, which may be interpreted as due to the hydrogen bonding, as this effect

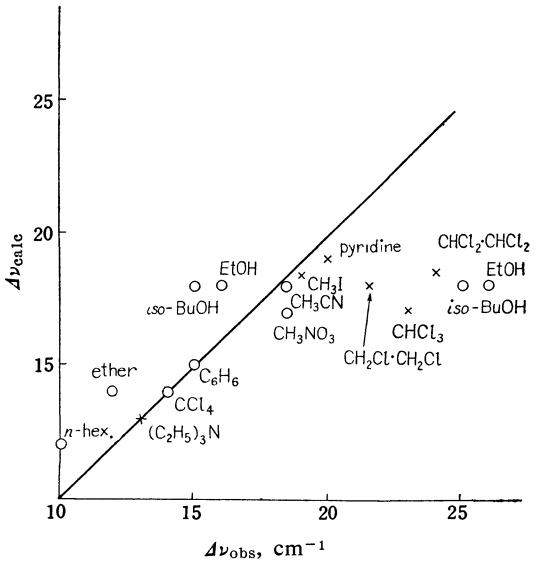

Fig. 6

is not taken care of at all by the McRae's equation. The carbonyl frequency suffers larger shifts in hydrogen bonding than in nonhydrogen bonding solvents, but this shift is much smaller than that of the hydroxyl frequency due to the same cause. In the benzophenone and ethyl alcohol system the hydroxyl frequency of the alcohol diminishes by about 150 $cm^{-1}$, while the decrease of the carbonyl frequency of benzophenone is only about 15 $cm^{-1}$. Recently Bellamy et al.[6,7] studied the solvent effect on C=O and OH bands of several molecules in various mixed solvents, suggesting that the local association effect is the dominant factor in producing the frequency shift, and that the electrostatic properties of the medium as a whole does not play an important role. If the solvent effect is principally due to the local association, two different bands will be expected for a system in which two kinds of solvents are present. Fig. 7 shows the change of the C=O frequency of mesityl oxide on changing the mixing volume ratio of ethyl ether and acetonitrile in the solvent. The band maximum changes in succession with the mixing ratio suggesting that the shift depends on the dielectric constant of the medium. The same situation obtains for acetophenone, acetone and benzophenone. These observations favor the view emphasizing the importance of dielectric constant in the solvent effect. However, the possibility of local association may not be excluded, as our experiment is not accurate enough for it.

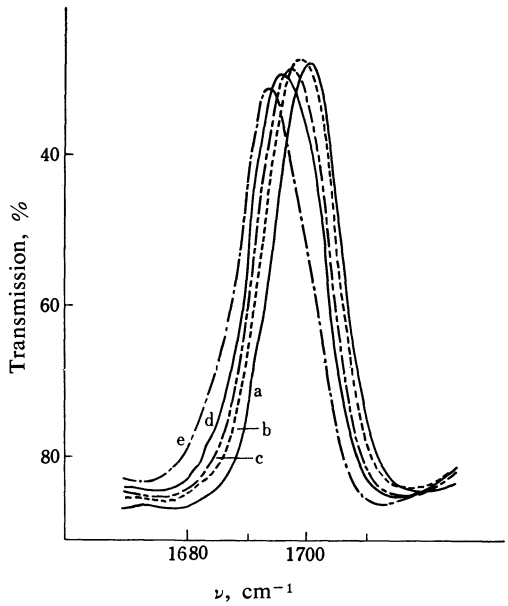

Fig. 7

On the other hand, for simplification we assumed that the C=O stretching vibration in these ketones is localized at this group and almost independent of the rest of the molecule. Therefore the normal coordinate $Q$ contains only the pure carbonyl stretching vibration.

Then

$$d\mu/dr=(1/m_c+1/m_o)^{-1/2}d\mu/dQ$$

where $\mu$ is the dipole moment, $Q$ the normal coordinate, $m_c$ and $m_o$ the masses of the carbon and oxygen atoms and $r$ the distance between the C and O atoms.

From the observed intensities $A$ in l. mol$^{-1}$ cm$^{-2}$ the change in the dipole moment with respect to the normal coordinate $Q$ is given by

$$d\mu/dQ=\pm(3c^2\times1000\,A/N\pi)^{1/2}$$

where $c$ is the light velocity and $N$ is the Avogadro number. Table III summarizes the values of $d\mu/dr$ calculated as above. They fall in the range between 4 and 6 D/Å, and show that the bond moment derivative increases with the increasing polarity of the solvent as well as with the increasing amount of conjugation, with the exception of mesityl oxide. However, the difference of the bond moment derivative for the bond of ketones in nonpolar and polar solvents is only about 1 D/Å, much smaller than the corresponding change of the OH bond moment derivatives of alcohols.

**Theoretical Calculation of $d\mu/dr$ for Ketones.**—According to Coulson the value of $d\mu/dr$ can be evaluated from the bond polarizability defined on the simple MO theory for a $\pi$ electron system. We have assumed that there is no appreciable change in the $\sigma$ electron cloud during the C=O stretching vibration. Treating the acetone molecule as diatomic $d\mu/dr$ is expressed by

$$d\mu/dr=d(qer)/dr=r_0e(dq/dr)_o+q_oe$$

where $e$ is the electronic charge, $q$ the formal charge density on the oxygen atom, $r_o$ the equilibrium distance of the C=O bond and $q_o$ the formal charge density for $r=r_o$. As $q$ is a function of the exchange integral for the carbonyl bond

$$dq/dr=dq/d\beta\cdot d\beta/dr=\pi_{o,co}d\beta/dr$$

where $\beta$ is the exchange integral between the oxygen and carbon atoms, and $\pi_{o,co}$ the atom-bond polarizability defined by Coulson et al.[8], which is calculable from the coefficients in the molecular orbital function. If we use the relation $\beta_{co}=k/r^6$ as given by Kon[9] we obtain

$$d\mu/dr=r_0e\pi_{o,co}(-6\,\beta_{co}/r_0)+q_oe$$

for which $\pi_{o,co}$ and $q_o$ have been calculated by the simple MO treatment for the C=O group*. If we take $r_0=1.23$ Å we obtain

$$d\mu/dr=8.4\text{ D/Å}$$

Instead, if the SCF molecular orbital calculated by Nagakura[10] is employed,

$$d\mu/dr=8.3\text{ D/Å}$$

is obtained. These calculated values are different from the observed 5 D/Å but the discrepancy is due to the rough approximation. As mentioned previously $d\mu/dr$ tends to be increased with the increase of the polarity of the solvent, the value of $d\mu/dr$ for solvents forming hydrogen

9) H. Kon, This Bulletin, **28**, 275 (1955).
* Using the values of Coulomb integrals of carbon and oxygen atoms $\alpha_c=\alpha+0.2\beta$ and $\alpha_o=\alpha+2\beta$, respectively, and the carbonyl exchange integral $\beta_{co}=1.4\beta$[11], 3.1D is obtained as the value of the dipole moment of acetone, in agreement with the experimental 2.7D.
10) S. Nagakura, ibid., **25**, 164 (1952).
11) L. E. Orgel, T. L. Cottrell, W. Dick and L. E. Sutton, *Trans. Faraday Soc.*, **47**, 113 (1951).

bonds with the ketone molecule increases by about 1 D/Å compared with the case of non-polar solvents.

Now, we may assume for a hydrogen bonding system the following two resonance forms

$$O\text{-}H\cdots O{=}C \qquad \Phi_n \qquad I$$

$$O^-\text{-}H\text{-}O^+{=}C \qquad \Phi_p \qquad II$$

and represent the ground state wave function of the hydrogenbonded complex by

$$\Phi = \Phi_n + c_p\Phi_p$$

where $c_p$ measures the extent of the charge-transferred form II to the system. During the C=O vibration $c_p$ changes continuously. If the dipole of $\Phi_p$ is represented by $\mu_p$, the dipole moment $\mu_T$ contributed by II is given by

$$\mu_T = \mu_p \cdot c_p^2$$

yielding

$$d\mu_T/dr_{co} = d(\mu_p c_p^2)/dr_{co}$$
$$= \mu_p dc_p^2/dr_{co} + c_p^2 d\mu_p/dr_{co}$$

For simplicity of calculation, we assume that firstly a C atom is fixed in a C=O vibration of acetone molecule $(CH_3)_2{=}C{=}O$ because of the great mass ratio of a $(CH_3)_2{=}C$ group to an O atom, and secondly a hydrogen bond OH···O=C is linear.

Since $dr_{co} = -dr_{o\cdots o}$ in the present approximation,

$$d\mu_T/dr_{co} = -\mu_p dc_p^2/dr_{o\cdots o} - c_p^2 d\mu_p/dr_{o\cdots o}$$

Substituting $r_{OH}=1$ Å, $r_{o\cdots o}=3$ Å, and the estimated $c_p$ value[12] into the above equation, we obtain

$$d\mu_T/dr_{co} = 1.2 \text{ D/Å}$$

Thus the increase of intensity due to hydrogen bonding is 1.2 D/Å, in good agreement with the observed 1 D/Å.

## Summary

The C=O stretching frequencies in acetone, mesityl oxide, acetophenone and benzophenone were measured in various solvents and the frequency shifts induced by solvents were interpreted by McRae's theoretical equation. Results show that the observed shifts can be explained in terms of the coöperating interactions between solute and solvent molecules.

Next, the intensity of the C=O group vibration bands of these ketones was observed and compared with bond moment derivatives calculated by diatomic molecular appoximation. Small changes of about 1 D/Å were observed for polar and nonpolar solvents. The increase of the bond moment derivative value in a hydrogen bonding system was attributed to the charge transfer force.

# *Magnetic and Spectrophotometric Studies on the Decoloration of Thiocyanatoiron(III) Complexes in Solutions. II. Effect of Acids*

By Chie MIYAKE*

(Received February 11, 1960)

In order to account for magnetic observations on the reaction between iron(III) and thiocyanate ions, the present writer has proposed the formations of three kinds of dimers in solutions and discussed their roles in reactions. The results have been reported in the previous paper[1].

* Present address: Nuclear Engineering Department, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka.

1) C. Miyake, This Bulletin, **33**, 867 (1960).

There seems to be much remaining to be investigated. One of the problems to be clarified first is which dimer of the three is the most abundant and stable one in the solution. In this paper are reported the experimental data which are conceivably useful for considering the above-mentioned problems.

## Experimental

**Materials.** — The iron(III) solution and potassium thiocyanate solution were prepared by the same method as that previously described. Acetic acid was purified by distillation until it became negative for the test of the iron ion. Sulfuric acid of analytical grade was used without further purification. It was confirmed that the test of the iron ion was negative. The sample solution was prepared by adding appropriate amounts of sulfuric acid (or acetic acid) and potassium thiocyanate to the iron stock solution. Before each measurement, the solution was diluted to the desired concentration.

**Measurements.** — The methods of measurements are the same as those described in the previous paper.

## Experimental Results

**Magnetic Data.** — Fig. 1 shows that the magnetic moment of iron in solutions of various acids with the same normality decreases with time. Fig. 2 shows that the magnetic moment of iron in sulfuric acid of various normalities decreases with time.

**Spectrophotometric Data.** — The spectral curves of thiocyanatoiron(III) complexes in solutions of sulfuric acid or acetic acid are shown in Fig. 3. The absorption maxima at about 460 mμ are due to thiocyanatoiron(III) complexes in the solutions. Other maxima at about 300 mμ seem to be due to sulfatoiron(III) and acetatoiron(III) complexes. The curves of thiocyanatoiron(III) complexes in sulfuric acid of various normalities are shown in

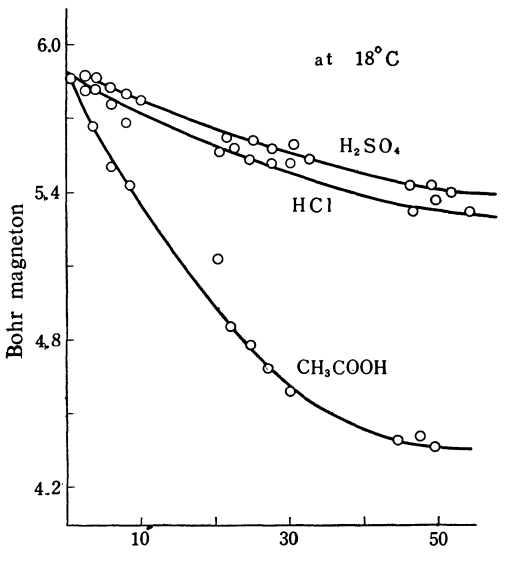

Fig. 1. Dependency of decrease in magnetic moment of iron upon kind of acid. (0.005 M iron(III), 0.5 M thiocyanate ion, 0.12 N-each acid solutions).

3: 〃 3 〃

the concentration of the hydrogen or thiocyanate ion and the above-mentioned absorbances at about 460 mμ and 320 mμ are tabulated in Table I, which can afford some knowledge about the effects of hydrochloric and sulfuric acids upon the nature of decoloration and of the formation of the dimer.

## Discussion

The magnetic moment of thiocyanatoiron(III) complexes in sulfuric acid and acetic acid solutions, when measured within fifteen minutes after the preparation, was found to be 5.91 and 5.88 Bohr magnetons, respectively. The values are characteristic of the outer orbital type of binding of the iron(III) complexes as in the case of the complexes in hydrochloric acid. As is seen in Fig. 3, no noticeable difference from the absorption for the complexes in hydrochloric acid solutions can be seen with respect to the absorption at about 460 mμ. As shown in Figs. 1 and 5, the decrease of the magnetic moment with time, which suggests the formation of complexes having the inner orbital type of binding, is also remarkable in both the solutions. However, the decrease is rather conspicuous in the acetic acid solution. This seems to be due to the unknown magnetic interaction between iron ions and acetate ions. Werbel et al.[2] pointed out that this kind of interaction makes the magnetic moment of the solution smaller while other authors proposed the formation of trimers. Some interpretation

* The absence of any noticeable effect.

for the time dependency of the magnetic moment of the acetic acid solution should be postponed to the future when sufficient data are available.

In the present paper the discussion will be conducted with the data of sulfuric and hydrochloric acid solutions. The most important fact is to determine which dimer of the three is most likely existing and prevailing during the course of reaction. According to the present author's results shown in Figs. 2 and 5 or those also given in Table I, the increase in the acidity of the solution suppresses the progress of reactions which conceivably brings about the decrease of the magnetic moment. If it is assumed that the second type of dimers containing chloride or sulfate ions may exist, the formation of dimers should increase with the increasing concentrations of acids, resulting in a great decrease of the magnetic moment. This expected relation can not be supported by the afore-mentioned experimental results. Consequently the existence of the second type of dimers is thought to be very unlikely.

A question is raised whether the dimer with hydroxo bridges or that with thiocyanate bridges is more stable. The latter dimer may tentatively be considered to be stable in the solution in which the magnetic moment decreases with the increasing concentrations of thiocyanate ions (as shown in Fig. 2 in the previous paper). However, it should be noticed that the degree of decrease of the magnetic moment can increase even at a constant concentration of the thiocyanate ion, if the acidity of the solution decreases. Therefore, it will be safely concluded that the existence of dimers through hydroxo bridges is more likely than their existence through thiocyanate bridges.

## Summary

Magnetic and spectrophotometric measurements have been carried out for the purpose of determining which of the proposed three types of dimers is most probable. The results obtained show that the second one with chloride ion bridges can safely be neglected. The existence of the first type with hydroxo bridges can be considered to be plausible.

The author wishes to express her sincere thanks to Professor H. Takaki for his interest and encouragement throughout this experiment. Her acknowledgment is also due to Dr. Y. Yamamoto for his helpful discussion and advice given in this experiment.

# *Magnetic and Spectrophotometric Studies on the Decoloration of Thiocyanatoiron(III) Complexes in Solutions. III. Structure of Thiocyanatoiron(III) Complex in Organic Solvents*

By Chie MIYAKE*

(Received July 11, 1960)

The present writer has reported the nature of the reaction between iron(III) ion and thiocyanate ions in aqueous solution in detail[1,2]. The experimental data obtained so far are rather consistently explained when we consider hypothetically the formation of a dimer containing iron(II) and iron(III) coupled by hydroxo bridges during the course of chemical reaction. However, there still remains a question whether the magnetic time change we observed is attributable to the above-mentioned dimer, or to the higher complexes, such as $Fe(NCS)_2^+$, $Fe(NCS)_3$, $Fe(NCS)_4^-$,..., which are formed by the prolonged replacement of the coordinated $H_2O$, $Cl^-$ ion etc. of the preexisting complexes with thiocyanate ions whose binding is of the so-called inner orbital type. In order to elucidate this, it is necessary at least to extract a definite species of complex having a known chemical formula by using an organic solvent and then to measure its magnetic property, because in the aqueous solution there are so many species of complexes, as shown in the previous paper[1], that it is difficult to consider which species is responsible for the measured magnetism and absorption. This paper deals with the results of measurements and the inferred structure of thiocyanatoiron(III) complex extracted by organic solvent.

## Experimental

**Materials.** — Ferric perchlorate was prepared by dissolving an appropriate amount of electrolytic iron in perchloric acid (about 4 N), oxidizing with hydrogen peroxide (30%), and evaporating the solution until crystals appeared. After perchloric acid was added to dissolve the deposit, the solution was evaporated again. The procedure was repeated until the solution gave a negative test for chloride and iron(II) ions. Violet crystals separated on cooling were filtered off with a sintered glass filter and recrystallized twice from distilled water. The stock solution of iron was prepared by dissolving the crystal of ferric perchlorate in water to the concentration of 1000 p. p. m.

The peroxides were removed from ether by shaking with a solution of ferrous sulfate acidified with sulfuric acid, until the organic phase no longer gave the test for peroxides and then the ether was purified by distillation.

Ethyl acetate used was of analytical grade.

Extraction of thiocyanatoiron(III) complex was carried out by adding the proper amount of potassium thiocyanate and shaking the iron solution with a given volume of organic solvent. After standing the whole solutions for fifteen minutes, the organic phase was separated from the aqueous solution.

**Measurements.**—Magnetic and spectrophotometric measurements were made as described previously[1].

## Results and Discussion

The magnetic moment for total iron in the ether solution of thiocyanatoiron(III) complex was found to be 6.0 Bohr magnetons. This value indicates that thiocyanatoiron(III) complex in the organic phase possesses a magnetic moment corresponding to five unpaired electrons, showing the outer orbital type of binding. Fig. 1 shows the spectral

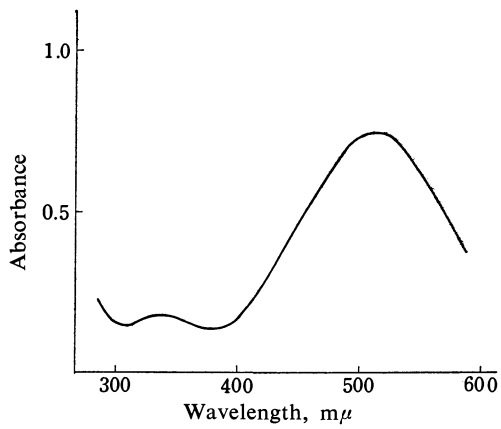

Fig. 1. Absorption spectrum of thiocyanatoiron(III) complex in ethyl acetate.

curve of the complex in organic solvents, such as ether or ethyl acetate. The absorption maximum found at 511 mμ is slightly longer in wavelength as compared to the already reported value of the complexes having one or two thiocyanate ions in term.

* Present address: Nuclear Engineering Department, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka.

1) C. Miyake, This Bulletin, 33, 867 (1960).
2) C. Miyake, ibid., 34, 471 (1961).

As to the constitution of extracted thiocyanatoiron(III) complex, no definite conclusion can be drawn as yet relating to the ratio of thiocyanate ions to iron in the complex. Babko[3] has reported the existence of $HFe(NCS)_4$ in an ether phase analogously to $HFeCl_4$ [4]. Other authors have postulated a complex having the chemical formula of $Fe(NCS)_3$ [5-8]. In our attempt to determine the ratio by gravimetric analysis of iron and sulfur as ferric oxide and barium sulfate, respectively, the values obtained are ranged over 3 to 4, the mean value being 3.6. On the other hand, repeated attempts were made to prepare crystalline thiocyanatoiron(III) complex by the evaporation of organic solutions. In no case was a pure product obtained, as the product always contained an insoluble residue whose magnetic moment was slightly smaller than that expected for a complex having five unpaired electrons. These problems are going to be studied in our laboratory and will be reported in the future. But, at least it is clearly concluded that what was extracted by the organic solvent was a higher complex possessing three or four thiocyanate ions in it. The fact that the absorption maximum in the ether phase shifts to longer region than that in the aqueous solution, that is, about 470 m$\mu$ to 511 m$\mu$, supports the existence of the higher complex in the organic phase, when we take into account the bathochromic effect due to the increase of thiocyanate ions in the complexes.

Thus, the remarkable time change of the magnetic moment of thiocyanatoiron(III) complexes which we confronted in the aqueous solution and reported previously can be attributed to the dimer possessing hydroxo bridges and the inner orbital type of binding with the smaller magnetic moment.

**Summary**

Thiocyanatoiron(III) complex was extracted by organic solvents. The magnetic moment of the complex was found to be 6.0 Bohr magnetons which is characteristic of the iron(III) complexes possessing the outer orbital type of binding. The absorption spectrum in the visible region of the complex shows the maximum of absorbance at 511 m$\mu$.

# *The Effects of Various Spinning Processes on the Fine Structure of Viscose Rayon Staples (Distribution of Chain Length of Oxidizing-hydrolyzed Residue)*

By Taketoshi KŌSHIRO and Toshikazu FUJIMURA

(Received September 29, 1959)

The object of this paper is to study the effects of various spinning processes on the fine structure of viscose rayon staples.

In the preceding paper[1], it was suggested that the distribution of crystalline size could be shown by the chain-length distribution of oxidizing-hydrolyzed residue. Determination of the average crystalline size expressed by the average degree of polymerization of acid hydrolyzed residue has been reported by many

* This paper was partially presented at the 23rd Viscose Symposium, Takatsuki, September, 1958.

1) T. Kōshiro, K. Yagami, E. Shiratsuchi and T. Fujimura, This Bulletin, 31, 606 (1958).

authors[2]. These methods, however, except for electron-microscopy[3], give little information on the distribution of crystalline size.

The oxidizing-hydrolysis conditions employed in the preceding report were so mild that it took a long time to obtain the crystalline portion of cellulose fibers. Therefore, the modification of the oxidizing-hydrolysis conditions was studied at first and revised. Various types of rayon staples (spun in concentrated sulfuric acid, dilute sulfuric acid, high zinc per cent Müller's bath etc.) were then compared by the improved method.

Carboxyl groups of oxdizing-hydrolyzed residue were determined to clarify the cause of abnormally low iodine sorption.

The relation between the distribution of crystalline size and the lateral-order distribution by Yurugi-Maeda's method was discussed.

## Experimental

**Oxidizing-hydrolysis.**—The samples were refluxed at 100±1°C in the mixture of 4 N sulfuric acid and 0.3 N potassium dichromate for 30 min. After the predetermined time, the residues were filtered off with a glass-filter and washed with hot water and methanol, and then dried in vacuo at 60°C for five hours and their yields were determined.

**Chain-length Distribution.**—The oxidizing-hydrolyzed residue was nitrated and fractionated as in the preceding report[1].

**Carboxyl Group.** — The carboxyl content was determined by titration with EDTA[4].

## Results

**Oxidizing-hydrolysis.**—Since the logarithm of the yield of residues decreases inverse-proportionally to the reaction time, as shown in Fig. 1, crystallinity $C$ is obtained by the extraporation of this time curve to zero. The crystallinity and the characteristics of crystalline portions of various rayons are given in Table I, where $R_5$ is the yield of residue after 5 hr.-hydrolysis, $\bar{P}$ is the average size of crystalline portion expressed by degree of polymerization, $U$ is the uniformity of the degree of polymerization, $P_m$ is the mode of D. P. distribution, which corresponds to the peak in the crystalline size distribution curve. The samples, which were spun in Müller's bath or in its modifications (B, Z and C) have lower crystallinity.

4) K. Ueno and Y. Yamaguchi, *J. Japan. Chem.* (*Kagaku-no-Ryoiki*), **6**, 38 (1952).

**Distribution of Crystalline Size.**—As shown in Fig. 2, the distribution curves have only one peak. From Fig. 3, some correlations between the average size of crystallites and the peak $P_m$ may generally be observed. It is noteworthy that by alkali treatment, $P_m$ of Lilienfeldt-type rayon shifts to a higher D. P. showing two peaks in its distribution chart and the longer one with almost twice the length of the shorter one (Fig. 4).

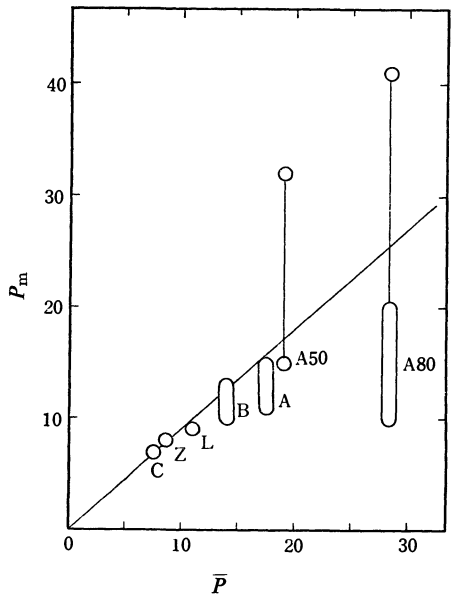

Fig. 3. Correlation between average crystalline size $\bar{P}$ and the crystalline size with maximum frequency in distribution ($P_m$).

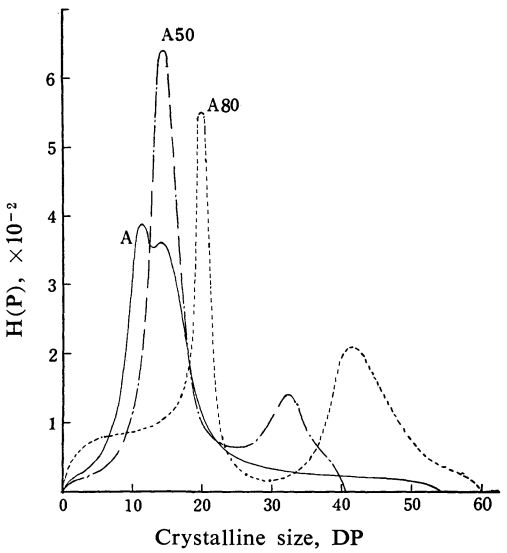

Fig. 4. Change of crystalline size distribution of Lilienfeldt-type rayon (sample A) by alkali treatment.

**Effect of Alkali Treatment.**—Lilienfeldt-type rayon and Müller's bath-type rayon which have clearly different fine structures, were immersed in alkaline solutions of various concentrations and then oxidizing-hydrolyzed. The results given in Fig. 5-a show that the apparent crystallinity that is, the yield of crystalline residue calculated on the basis of sample weight after alkali treatment increases in both Lilienfeldt and ordinary rayon after alkali treatment, and

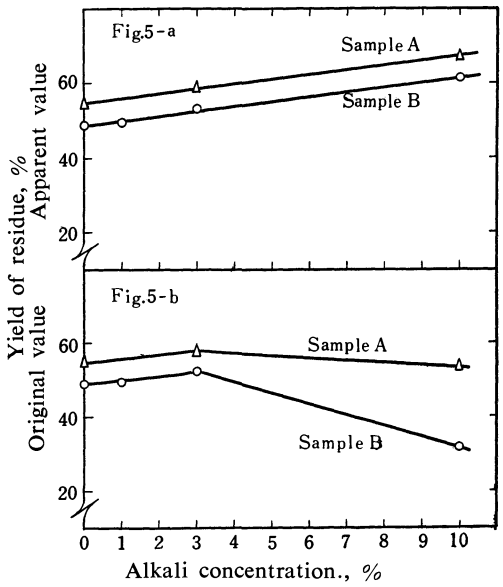

Fig. 5. Effect of alkali treatment on the yield of residue, calculated on the basis of sample weight after alkali treatment (Fig. 5-a) and untreated sample weight (Fig. 5-b).

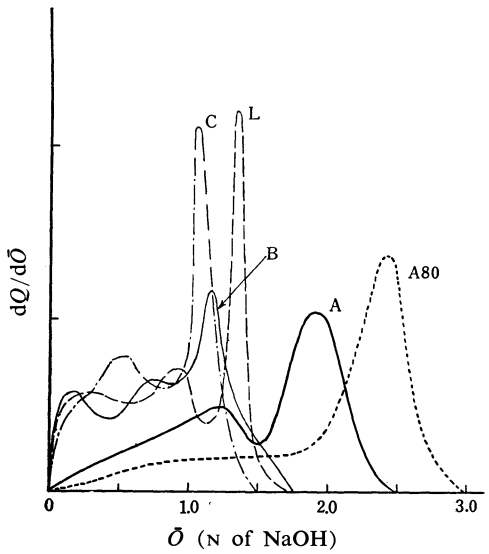

Fig. 6. Lateral-order distribution of various types of rayons by Yurugi-Maeda's method.

the tendency for recrystallization appears to be entirely the same. However, a different tendency is observed between Lilienfeldt and ordinary rayon when calculated on the basis of untreated sample weight. (Fig. 5-b)

**Relation between Crystalline Size Distribution and Lateral Order Distribution by Yurugi-Maeda**[5].—The lateral order distributions given in Fig. 6 are compared with the crystalline size distributions shown in Fig. 4. It is found that the modes of lateral order distribution, $O_m$, increase with $P_m$ or $\bar{P}$ (Fig. 7). The higher $P_m$ might correspond to the higher $O_m$.

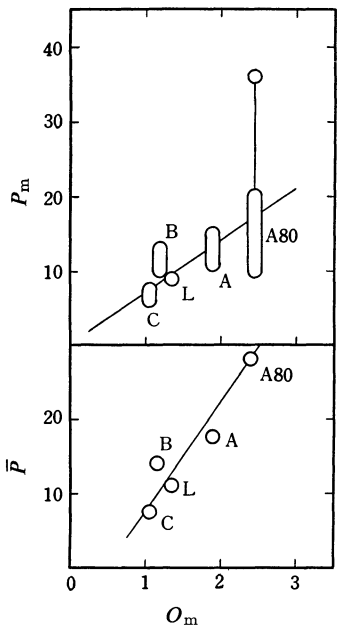

Fig. 7. The relationship between lateral-order distribution and crystalline size distribution characteristics.

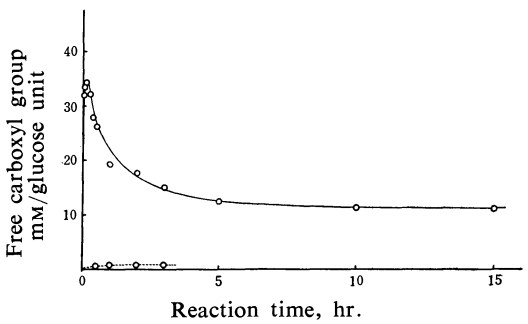

Fig. 8. Rise and fall of amount of carboxyl group during oxidizing-hydrolysis.

--- Ordinary hydrolysis with 4 N $H_2SO_4$ alone.

5) H. Maeda, *J. Soc. Textile Cellulose Ind., Japan (Sen-i Gakkai-shi)*, **12**, 6 (1956), etc.

**Carboxyl Group of Oxidizing-Hydrolyzed Residue.**—As shown in Fig. 8, the carboxyl group in oxidizing-hydrolyzed residue of Müller's bath-type rayon increased rapidly to a maximum value in the initial five minutes and decreased gradually to a levelling-off value after 5~8 hr.

## Discussion

The chief reason why the crystalline size in our experiment was smaller than the measured values by small angle X-ray scattering, electron microscope or viscosity of cuprammonium solution of the hydrolysis residue, may be due to the fact that the Staudinger's $K_m$ constant used for calculation was not appropriate, but it is justifiable for the purpose of comparing sizes. According to this experiment, not only the mean size of crystallites but also their distribution is indicated with rayons produced by different methods—particularly, spun in various kind of spinning baths. High tenacity rayon of high percentage zinc bath is generally composed of uniform and small crystallites but the size of crystallites of the Lilienfeldt-type rayon is large and also the distribution is not perfectly uniform indicating two distribution peaks, large and small. It is well known that when viscose rayon is treated with aqueous alkali solution of appropriate concentration, generally, the orientation of crystallites is disturbed, the strength is reduced and the elongation is improved, and it has also been confirmed by electron microscopy, X-ray and acid hydrolysis that the mean length of crystallites increases[6].

However, when seen from the viewpoint of distribution of length of crystallites, the entire distribution tends to increase in length of crystallites when Lilienfeldt-type rayon is treated with alkali and also, other peaks in the vicinity of about twice the peak of short particles become higher. This probably indicates the possibility that within the crystalline region of Lilienfeldt-type rayon, there is originally a defective part in short crystals which swells and relaxes by alkali treatment, next it deswells and recrystallizes during drying and fuses into one crystal. Of course, this manner of assumption is ideological and it is natural to assume that the distribution of crystallite length is not necessarily the fusion of two crystallites which recrystallize but growth occurs at the terminating part of the crystallites.

6) See e. g., P. H. Hermans and A. Weidinger, *Nature*, **165**, 238 (1950); *J. Polymer Sci.*, **6**, 533 (1951); K. Katō and K. Yamada, *High Polymer Chemistry (Kōbunshi Kagaku)*, **16**, 627 (1959); *Textile Research J.*, **29**, 368 (1959).

**Crystalline Size Distribution and Lateral Order Distribution.** — There are many low lateral order parts in fibers with many small crystallites and many high lateral order parts in fibers with large crystallites. Also, as the mode of lateral order distribution of Lilienfeldt-type rayon will shift to the high order side when its crystalline size moves to the larger side by alkali treatment, it can be assumed that lateral order distribution is affected by distribution of length of crystallites, in addition to hydrogen bond density. The small difference between both distributions may be due to the difference in the degree of depolymerization.

**Accessibility of Oxidizing-hydrolysis Residue.** —In view of the fact that, at first, carboxyl group increases rapidly and then reduces to its levelling-off value, it seemed reasonable to assume that, at first, the amorphous part is rapidly oxidized, then the oxidized amorphous part is removed by hydrolysis and finally a part of the carboxyl radicals remain on the surface of the crystallites. Therefore, it is possible that the iodine absorption accessibility of the residue is much lower than that for the residue of ordinary hydrolyzed residue due to the repulsion of iodine anion by carboxyl radicals.

**Summary**

The fractionation of oxidizing-hydrolyzed residue was applied to study the fine structure of various types of rayons.

It was assured that tirecord, high-tenacity rayon spun in high zinc percent Müller's bath, Toramomen and ordinary rayon have one sharp peak in each crystalline size distribution curve and smaller crystallites than Lilienfeldt-type rayon which shows two peaks in the crystalline size distribution curve.

The alkali-treatment of Lilienfeldt-type rayon increases not only its crystallinity but also the crystalline size, probably owing to the fusion of two adjacent crystallities.

There can be a correlation between the crystalline size distribution by oxidizing-hydrolysis and the lateral-order distribution; namely, the higher lateral-order portion may consist of the longer crystallite.

The carboxyl group in the oxidizing-hydrolyzed residue increases rapidly in the initial stage of hydrolysis and then decreases to an equilibrium value. The apparently lower accessibility by iodine sorption may be due to the negative carboxyl group remaining.

# *On the Studies of the Friedel-Crafts Acylation. II. The Relative Reactivity for Some Acyl Halides*

By Yoshiaki YAMASE

(Received August 29, 1960)

In Part I[1] the relative reactivities for benzoyl halides, phenylacetyl halides, and mesitoyl halides were measured by Calloway's method and Olivier's method; it was confirmed that the order of reactivity observed is not always in agreement with the order for acetyl halides obtained by Calloway,

$$CH_3COF < CH_3COCl < CH_3COBr < CH_3COI$$

In the present study the relative reactivities for acetyl halides, propionyl halides, isobutyryl halides, cyclohexanecarbonyl halides, and trimethylacetyl halides in the Friedel-Crafts acylation were measured by Calloway's method, and the effect of structure on the order of reactivity for acyl halides was examined. From the observation, it was found that on replacement of the methyl group in acetyl halides with a group with great steric requirement, the order of reactivity for acyl halides varies and does not agree with the order for acetyl halides, but when the methyl group is replaced with a group with a greater steric requirement, the order of reactivity for acyl halides again agrees with the order for acetyl halides.

On the other hand, it was observed that the order of reactivity for acyl halides remains the same in acylation of various aromatic compounds, even when a sterically hindered

1) Y. Yamase and R. Goto, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 1906 (1960).

or activated aromatic position is to be substituted, and is influenced by the structure of acyl halides.

## Experimental

**Methods.** — In measuring the relative reactivity for acyl halides by Calloway's method, the apparatus was the same as that used in Part I, and also in the same manner as that mentioned in Part I the measurement of the temperature was carried out at which the velocity of reaction for various acyl halides becomes sufficient to cause visible bubbles to be evolved. The temperature at which the first visible evolution of hydrogen halide occurred was taken as the temperature at which the measurable reaction began, and it was designated as the temperature of incipient reaction. The inverse order of this temperature, therefore, was regarded as the order of reactivity for the acyl halides.

**Materials.** — The acyl halides used in the acylation were acetyl halides(I), propionyl halides(II), isobutyryl halides (III) cyclohexanecarbonyl halides (IV), and trimethylacetyl halides (V). The fluorides of I, II, and IV were prepared by the reaction between the acyl chlorides and antimony trifluoride, and those of III and V by the interaction between the corresponding carboxylic acids and benzoyl fluoride. The chlorides of II, III, and V were prepared by the interaction between the corresponding carboxylic acids and benzoyl chloride, and that of IV by the interaction between the corresponding carboxylic acid and thionyl chloride. The bromides of I, III, and IV were prepared by the interaction between the corresponding carboxylic acids and phosphorous tribromide, and that of V by the interaction between the corresponding carboxylic acid and benzoyl bromide. The iodides of I, II, III and IV were prepared by the interchange of halogens between the acyl chlorides and hydrogen iodide. The physical constants of these compounds are summarized in Table I.

Table I. Boiling points acyl halides

| | Acyl halides | | |
|---|---|---|---|
| X | $CH_3COX$ | $CH_3CH_2COX$ | $(CH_3)_2CHCOX$ |
| F | 22°C | 42.5~43.5°C | 55~56°C |
| | (20~23°C) | (44°C) | (—) |
| Cl | 50~51°C | 77~78°C | 90°C |
| | (50.9°C) | (80°C) | (92°C) |
| Br | 75~76°C | 98~100°C | 114~115°C |
| | (76.7°C) | (96~98°C) | (116~118°C) |
| I | 104~105°C | 32~34°C/ 16 mmHg | 43~44°C/ 21 mmHg |
| | (108°C) | (127~128°C) | (—) |

| | Acyl halides | |

## Results and Discussion

The orders of reactivity of various acyl halides obtained by Calloway's method are described below.

**Reactivity of Acetyl Halides.** — *Acylation of Benzene.* — A mixture of aluminum chloride (0.1 mol.), benzene (0.3 mol.), and carbon disulfide (95 ml.) was cooled to about −60°C. To the solution was added the acetyl halide (0.1 mol.) in carbon disulfide (5 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table II.

*Acylation of Mesitylene.*—A mixture of aluminum chloride (0.01 mol.), mesitylene (0.01 mol.), and carbon disulfide (150 ml.) was cooled to about −60°C. To the solution was added the acetyl halide (0.01 mol.) in carbon disulfide (10 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table II.

*Acylation of Anisole.*—A mixture of aluminum chloride (0.01 mol.), anisole (0.01 mol.), and carbon disulfide (150 ml.) was cooled to about −60°C. To the solution was added the acetyl halide (0.01 mol.) in carbon disulfide (10 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table II.

From these results, the order of reactivity of the acetyl halides is independent of the nature of aromatic compounds to be acylated and increases in the following order,

$$CH_3COF < CH_3COCl < CH_3COBr < CH_3COI.$$

This order is consistent with that of acetyl halides observed by Calloway[2].

**Reactivity of Propionyl Halide.** — A mixture of aluminum chloride (0.1 mol.), benzene (13.4 g.), and carbon disulfide (100 ml.) was cooled to about −60°C. To the solution was added the propionyl halide (0.1 mol.) in benzene (10 g.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. The reaction mixture was warmed to 30°C over a period of 5 min. from the initiation of hydrogen halide evolution and was maintained at 30°C for 55 min. The yields of ketone from various propionyl halides were obtained by the ordinary method. Results are shown in Table III.

2) N. O. Calloway, *J. Am. Chem. Soc.*, **59**, 1474 (1937).

TABLE II. REACTIVITY OF ACETYL HALIDES

| | Acetyl halides | | | |
|---|---|---|---|---|
| The temp. of incipient reaction | $CH_3COF$ | $CH_3COCl$ | $CH_3COBr$ | $CH_3COI$ |
| In acylation of benzene, °C | 13 | 6 | 0 | −5 |
| In acylation of mesitylen, °C | 15 | 0 | −5 | —* |
| In acylation of anisole, °C | 5; 3 | −10; −8 | −14; −14 | —* |

* The temperature of incipient reaction for acetyl iodide could not be measured, as only a very small amount of it was used in the acylation and also it was readily hydrolyzed.

TABLE III. REACTIVITY OF PROPIONYL HALIDES

| | Propionyl halides | | | |
|---|---|---|---|---|
| | $CH_3CH_2COF$ | $CH_3CH_2COCl$ | $CH_3CH_2COBr$ | $CH_3CH_2COI$ |
| The temp. of incipient reaction, °C | 5 | −1 | −5 | −2 |
| The max. reaction temp. reached, °C | 30 | 30 | 30 | 30 |
| Reaction time, hr. | 1 | 1 | 1 | 1 |
| Ketone isolated, g. | 8.0 | 11.0 | 12.0 | 2.5 |
| Yields of ketone, % | 59.7 | 82.2 | 89.6 | 18.7 |

TABLE IV. REACTIVITY OF ISOBUTYRYL HALIDES

| | Isobutyryl halides | | | |
|---|---|---|---|---|
| | $(CH_3)_2CHCOF$ | $(CH_3)_2CHCOCl$ | $(CH_3)_2CHCOBr$ | $(CH_3)_2CHCOI$ |
| The temp. of incipient reaction, °C | 12 | 5 | 6 | 20 |
| The max. reaction temp. reached, °C | 30 | 30 | 30 | 30 |
| Reaction time, hr. | 1 | 1 | 1 | 1 |
| Ketone isolated, g. | 5.9 | 11.2 | 11.0 | 1.0 |
| Yields of ketone, % | 39.8 | 75.7 | 74.3 | 6.8 |

TABLE V. REACTIVITY OF CYCLOHEXANECARBONYL HALIDES

| | Cyclohexanecarbonyl halides | | | |
|---|---|---|---|---|
| | $C_6H_{11}COF$ | $C_6H_{11}COCl$ | $C_6H_{11}COBr$ | $C_6H_{11}COI$ |
| The temp. of incipient reaction, °C | 12 | 0 | 2 | 22 |
| The max. reaction temp. reached, °C | 30 | 30 | 30 | 30 |
| Reaction time, hr. | 1 | 1 | 1 | 1 |
| Ketone isolated, g. | 4.4 | 10.5 | 10.0 | 1.0 |
| Yields of ketone, % | 23.4 | 55.9 | 53.2 | 5.3 |

From these results, the order of reactivity of the propionyl halides is given as follows,

$$CH_3CH_2COF < CH_3CH_2COCl < CH_3CH_2COBr > CH_3CH_2COI$$

The yields of ketone were in good agreement with the reactivity observed.

**Reactivity of Isobutyryl Halides.**—A mixture of aluminum chloride (0.1 mol.), benzene (18.4 g.), and carbon disulfide (100 ml.) was cooled to about −60°C. To the solution was added the isobutyryl halide (0.1 mol.) in benzene (5 g.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. The yield of ketone was obtained in the usual manner. Results are shown in Table IV.

From these results, the order of reactivity of the isobutyryl halides is as follows,

$$(CH_3)_2CHCOF < (CH_3)_2CHCOCl \fallingdotseq (CH_3)_2CHCOBr > (CH_3)_2CHCOI$$

The yields of ketone were in good agreement with the reactivity observed.

**Reactivity of Cyclohexanecarbonyl Halides.**—A mixture of aluminum chloride (0.1 mol.), benzene (15.4 g.), and carbon disulfide (100 ml.) was cooled to about −60°C. To the solution was added the cyclohexanecarbonyl halide (0.1 mol.) in benzene (8 g.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. The yield of ketone was obtained by the same method. Results are shown in Table V.

From these results, the order of reactivity of the cyclohexanecarbonyl halides is given

Table VI. Reactivity of trimethylacetyl halides

| | Trimethylacetyl halides | | |
|---|---|---|---|
| | $(CH_3)_3CCOF$ | $(CH_3)_3CCOCl$ | $(CH_3)_3CCOBr$ |
| The temp. of incipient reaction, °C | −10 | −19 | −30 |

Table VII. Reactivity of benzoyl halides

| | Benzoyl halides | | | |
|---|---|---|---|---|
| The temp. of incipient reaction, | $C_6H_5COF$ | $C_6H_5COCl$ | $C_6H_5COBr$ | $C_6H_5COI$ |
| In acylation of mesitylene, °C | 15 | 0 | 0 | 10 |
| In acylation of anisole, °C | 13 ; 15 | 3 ; 4 | 4 ; 4 | 12 ; 12 |

Table VIII. Reactivity of acyl halides

| Acyl halides | Compounds to be acylated | Solvents | The orders of reactivity for acyl halides |
|---|---|---|---|
| $CH_3COX$ | Benzene | $CS_3$ | F<Cl<Br<I |
| 〃 | Mesitylene | 〃 | 〃 |
| 〃 | Anisole | 〃 | 〃 |
| $CH_3CH_2COX$ | Benzene | 〃 | F<Cl<Br>I |
| $C_6H_5CH_2COX$ | 〃 | 〃 | 〃 |
| 〃 | 〃 | $C_6H_5NO_2$ | F<Cl>Br>I |
| $(CH_3)_2CHCOX$ | 〃 | $CS_2$ | F<Cl=Br>I |
| $C_6H_{11}COX$ | 〃 | 〃 | 〃 |
| $C_6H_5COX$ | 〃 | 〃 | 〃 |
| 〃 | Mesitylene | 〃 | 〃 |
| 〃 | Anisole | 〃 | 〃 |
| $2,4,6\text{-}(CH_3)_3C_6H_2COX$ | 〃 | 〃 | F<Cl<Br<I |
| 〃 | 〃 | $C_6H_5NO_2$ | 〃 |
| $(CH_3)_3CCOX$ | 〃 | $CS_2$ | 〃 |

as follows,

$$C_6H_{11}COF < C_6H_{11}COCl \fallingdotseq C_6H_{11}COBr > C_6H_{11}COI$$

The yields of ketone were in good agreement with the reactivity observed.

**Reactivity of Trimethylacetyl Halides.** — A mixture of alminum chloride (0.005 mol.), anisole (0.005 mol.), and carbon disulfide (140 ml.) was cooled to about −60°C. To the solution was added the trimethylacetyl halide (0.005 mol.) in carbon disulfide (10 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table VI.

From these results, the order of reactivity of the trimethylacetyacetyl halides is given as follows,

$$(CH_3)_3CCOF < (CH_3)_3CCOCl < (CH_3)_3CCOBr (< (CH_3)_3CCOI)$$

**Reactivity of benzoyl halides.** — *Acylation of Mesitylene.* — A mixture of aluminum chloride (0.01 mol.) and carbon disulfide (90 ml.) was cooled to about −60°C. To the solution were added the benzoyl halide (0.01 mol.) and mesitylene (0.01 mol.) in carbon disulfide (10 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table VII.

*Acylation of Anisole.*—A mixture of aluminum chloride (0.01 mol.), anisole (0.01 mol.), and carbon disulfide (100 ml.) was cooled to about −60°C. To the solution was added the benzoyl halide (0.01 mol.) in carbon disulfide (10 ml.). After addition, the mixture was warmed slowly and the temperature of incipient reaction was measured. Results are shown in Table VII.

From these results, it is seen that the order of reactivity for the benzoyl halides is independent of the nature of aromatic compounds to be acylated and is given as follows,

$$C_6H_5COF < C_6H_5COCl \fallingdotseq C_6H_5COBr > C_6H_5COI$$

These orders of reactivity for the acyl halides obtained in the present study and in Part I are summarized in Table VIII.

To summarize, it was observed that when R group in acyl halides RCOX is replaced successively with $CH_3$- group, $CH_3CH_2$- and $C_6H_5CH_2$- groups, and $(CH_3)_2CH$-, $C_6H_{11}$-, and $C_6H_5$- groups, the orders of reactivity vary as follows as a result of the steric hindrance of R group, RCOF < RCOCl < RCOBr < RCOI ($R=CH_3$-), RCOF < RCOCl < RCOBr > RCOI

($R=CH_3CH_2-$ and $C_6H_5CH_2-$), and RCOF $>$ RCOCl $\fallingdotseq$ RCOBr $>$ RCOI ($R=(CH_3)_2CH-$, $C_6H_{11}-$, and $C_6H_5-$) respectively. In the acylation by mesitoyl halides and trimethylacetyl halides, the orders of reactivity were observed as follows, RCOF $<$RCOCl $<$RCOBr $<$RCOI, in spite of the large steric hindrance of $(CH_3)_3C_6H_2-$ and $(CH_3)_3C-$ groups.

On the other hand, it was observed that in acylation of benzene, anisole, and mesitylene the orders of reactivity for benzoyl halides and acetyl halides do not change, and are given as follows, $C_6H_5COF < C_6H_5COCl \fallingdotseq C_6H_5COBr > C_6H_5COI$ and $CH_3COF < CH_3COCl < CH_3CBr < CH_3COI$ respectively.

Thus it may be suggested that the order of reactivity of acyl halides does not change even when a sterically hindered or activated aromatic position is to be substituted; that is, the order of reactivity depends only on the structure of acyl halides.

The author wishes to thank Professor Ryozo Goto, Kyoto University, for his helpful discussions and criticisms.

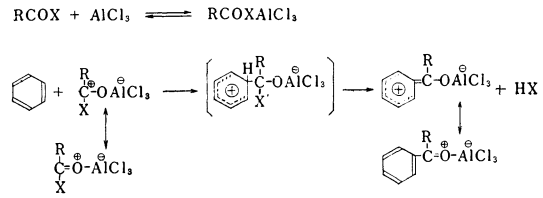
# *On the Studies of the Friedel-Crafts Acylation. III. The Reaction Mechanism*



By Yoshiaki YAMASE

(Received September 12, 1960)

The two types of mechanism, ionic and substitution mechanisms, are generally accepted at the present time for the Friedel-Crafts acylation. The concept of an ionic mechanism[1-3] is that the attacking agent is an acylium ion produced by ionization of an acyl halide under the catalytic influence of aluminum chloride. The concept of a substitution

mechanism[4-8] is that the attacking agent is an addition complex produced by the interaction of an acyl halide and aluminum chloride.

Since some evidence exists for both ionic and substitution mechanisms, they may not be dismissed.

Recently, a duality of mechanism for the Friedel-Crafts acylation, the concept of which is that the acylation by acyl halides under the influence of aluminum chloride takes place by both ionic and substitution mechanisms, seems to offer an attractive hypothesis[9-12], and it appears likely that the acylation by acyl halides under the influence of aluminum chloride takes place by one of two mechanisms, depending on the reactivity of aromatic substances and acyl halides; that is, the normal Friedel-Crafts acylation may proceed mainly by the substitution mechanism, but when a sterically hindered acyl halide is used, or when a sterically hindered aromatic position is to

be substituted, the ionic mechanism becomes important.

The order of reactivity for acetyl halides in the Friedel-Crafts acylation has been found by Calloway to be $CH_3COF < CH_3COCl < CH_3COBr < CH_3COI$, and it has been inferred from this evidence that the order of reactivity for acyl halides is the same as that for acetyl halides[13,14].

Now, if the Friedel-Crafts acylation proceeds by the ionic mechanism, the reactivity for acyl halides depends on the equilibrium concentration of the acylium ion produced by ionization of acyl halides in the presence of aluminum chloride,

$$RCOX + AlCl_3 \rightleftarrows [RCO]^+ + [AlCl_3X]^-$$

and the concentration of the acylium ion depends on the lability of the carbon-halogen bond in acyl halides. Therefore, the order of reactivity of acyl halides should be

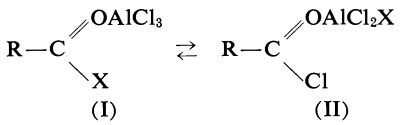
$$RCOF < RCOCl < RCOBr < RCOI$$

On the other hand, if the Friedel-Crafts acylation proceeds by the substitution mechanism, the reactivity for acyl halides should be identical with the reactivity for the addition complexes produced from acyl halides and aluminum chloride, because the attacking agent in this case is the addition complex. Then, the reactivity for acyl halides must be influenced not only by the lability of the carbon-halogen bond, but also by the steric effect of the halogen atom which reduces the reactivity of acyl halides as follows,

$$RCOF > RCOCl > RCOBr > RCOI$$

Therefore, it is possible that the order of reactivity for acyl halides does not always agree with the order of reactivity for acetyl halides.

Taking the above facts into consideration, the determinations of reactivities for some acyl halides in the presence of aluminum chloride in the Friedel-Crafts acylation have been carried out in Parts I[15] and II[16], and it has been observed that the order of reactivity for acyl halides may be influenced by the structure of acyl halides.



On the replacement of the methyl group in acetyl halides with a group with great steric requirement, the order of reactivity for acyl halides does not consist with the order for acetyl halides. But, when the methyl group is replaced with a group with greater steric requirement, the order of reactivity for acyl halides becomes consistent with the order for acetyl halides.

These phenomena can be explained reasonably on the basis of the concept that the normal Friedel-Crafts acylation proceeds mainly by the substitution mechanism, but when a sterically hindered acyl halide is used, the acylation proceeds by the ionic mechanism.

## Discussion

The halogen exchange reactions have been observed between acetyl chloride and aluminum chloride in which some of the chlorine atoms are radioactive isotopes[1], and also between 2, 4, 6-tribromobenzoyl chloride, or 2, 4, 6-trimethylbenzoyl chloride and aluminum bromide[2].

If the acylation proceeds by the substitution mechanism, it is conceivable that the attacking agents are the complexes I and II, and in the complete halogen exchange the ratio of the concentration of the complexes I and II will be 1/3.

On the assumption that there is scarcely any difference between the catalytic ability of $AlCl_3$ and $AlCl_2X$, it may be considered that of the two different kinds of complexes produced by the interaction between aluminum chloride and various acyl halides, the complexes II, $RCOClAlCl_2X$, have similar reactivities regardless of the nature of X (F, Cl, Br and I).

From this assumption, the difference of reactivities of acyl halides is nothing but that of reactivities of the complex, I, $RCOXAlCl_3$, and the order of reactivity of acyl halides can be explained by considering the difference of reactivity of the complex I.

The reactivity of the complex I is influenced by the lability of the carbon-halogen bond and the steric hindrance of the halogen atom; the effect of the carbon-halogen bond energy on the reactivity for the complex I increases in the following order, $F < Cl < Br < I$, and the steric hindrance of the halogen atom may reduce the reactivity of the complex I as follows, $F > Cl > Br > I$.

In the substitution mechanism, the order of reactivity of acyl halides is influenced by both the lability of the carbon-halogen bond and the steric hindrance of the halogen atom simultaneously and does not always agree with the order of acetyl halides.

On the other hand, in the ionic mechanism the reactivity of acyl halides depends on the equilibrium concentration of the acylium ion

TABLE I. REACTIVITY OF ACYL HALIDES

| Acyl halides | Compound to be acylated | Solvent | The order of reactivity of acyl halides |
|---|---|---|---|
| $CH_3COX$ | Benzene | $CS_2$ | F<Cl<Br<I |
| 〃 | Mesitylene | 〃 | 〃 |
| 〃 | Anisole | 〃 | 〃 |
| $CH_3CH_2COX$ | Benzene | 〃 | F<Cl<Br>I |
| $C_6H_5CH_2COX$ | 〃 | 〃 | 〃 |
| 〃 | 〃 | $C_6H_5NO_2$ | F<Cl>Br>I |
| $(CH_3)_2CHCOX$ | 〃 | $CS_2$ | F<Cl=Br>I |
| $C_6H_{11}COX$ | 〃 | 〃 | 〃 |
| $C_6H_5COX$ | 〃 | 〃 | 〃 |
| 〃 | Mesitylene | 〃 | 〃 |
| 〃 | Anisole | 〃 | 〃 |
| 2,4,6-$(CH_3)_3C_6H_2COX$ | 〃 | 〃 | F<Cl<Br<I |
| 〃 | 〃 | $C_6H_5NO_2$ | 〃 |
| $(CH_3)_3CCOX$ | 〃 | $CS_2$ | 〃 |

which, in turn, depends on the lability of the carbon-halogen bond in acyl halides. Then, the order of reactivity of acyl halides is influenced by the magnitude of the carbon-halogen bond energy and increases as follows

$$F < Cl < Br < I$$

Upon these considerations, the experimental data of reactivities for some acyl halides summarized in Table I can be reasonably explained.

**Acylation of Benzene in Carbon Disulfide or Benzene.**—In acylation of benzene in a nonpolar solvent, carbon disulfide or benzene, the order of reactivity of acetyl halides was RCOF < RCOCl <RCOBr<RCOI; for propionyl and phenylacetyl halides it was RCOF<RCOCl < RCOBr>RCOI, and for isobutyryl, cyclohexanecarbonyl, and benzoyl halides it was RCOF< RCOCl≒RCOBr>RCOI.

These results may be explained reasonably by the substitution mechanism. It has generally been considered that in the substitution mechanism the addition complex $RCOXAlCl_3$ attacks the aromatic substance by the displacement reaction of $S_N2$ type. Then, it must be considered how much effect the lability of the carbon-halogen bond and the steric hindrance of the $OAlCl_3$, R, and X groups have on the reactivity of the complex. The $OAlCl_3$ group in the addition complex may be considerably bulky and be common to various addition complexes.

In acylation by acetyl halides the reactivity of the addition complex is influenced by the lability of the carbon-halogen bond alone, since the steric hindrance of the methyl group is small. Therefore, the order of reactivity for acetyl halides is F<Cl <Br<I.

In acylation by propionyl and phenylacetyl halides, the steric hindrances of ethyl and phenylmethyl groups become great, and the reactivities of the addition complexes are influenced not only by the lability of the carbon-halogen bond but also by the steric hindrance of the halogen atom caused by the sterically hindered R groups. Consequently, the orders of reactivities of these acyl halides become F<Cl<Br>I.

In acylation by isobutyryl, cyclohexanecarbonyl, and benzoyl halides, the steric hindrances of isopropyl, cyclohexyl, and phenyl groups become considerably great, and the orders of reactivities of these addition complexes are influenced not only by the lability of the carbon-halogen bond but also by the steric hindrance of the halogen atom caused by the sterically hindered R groups. Accordingly, the orders of reactivities for these acyl halides become F<Cl≒Br>I.

**Acylation of Anisole by Mesitoyl Halides and Trimethylacetyl Halides.**—In acylation of anisole by mesitoyl[2] and trimethylacetyl halides[17], the reaction has been believed to occur by the ionic mechanism. As reported in the previous reports, in spite of the large steric hindrance of mesityl and *tert*-butyl groups, the orders of reactivities for these acyl halides were as follows, RCOF <RCOCl<RCOBr<RCOI.

These results are explained reasonably by the ionic mechanism; as a result of the great steric hindrance of acyl halides, the addition complex is not formed and the halide is completely ionized, giving the acylium ion. The acylium ion attacks anisole as an acylating agent, and the order of reactivities for these acyl halides agrees with the order of the lability of the carbon-halogen bond, F <Cl < Br <I.

**Acylation of Benzene by Phenylacetyl Halides and Anisole by Mesitoyl Halides.**—In acylation of benzene by phenylacetyl halides the reaction is believed to proceed by the substitution

17) E. Rothstein et al., *J. Chem. Soc.*, **1949**, 1950.

mechanism, and the order of reactivity of phenylacetyl halides was RCOF< RCOCl< RCOBr>RCOI in a non-polar solvent (carbon disulfide) and RCOF <RCOCl> RCOBr> RCOI in a polar solvent (nitrobenzene).

When the polar solvent, nitrobenzene, is used in place of the non-polar solvent, carbon disulfide, aluminum chloride is solvated with nitrobenzene and it forms bulkier addition complexes with acyl halides. Then, the influence of the steric hindrance of the halogen atom on the reactivity of phenylacetyl halides becomes greater, and consequently the above orders are observed.

On the other hand, in acylation of anisole by mesitoyl halides the reaction is believed to proceed by the ionic mechanism. The order of the lability of the carbon-halogen bond would always be the same regardless of the nature of the solvent and, in fact, the order of reactivity of mesitoyl halides was RCOF<RCOCl< RCOBr<RCOI.

**Acylation of Benzene, Mesitylene, and Anisole by Acetyl Halides and Benzoyl Halides.**—In acylation of benzene, mesitylene, and anisole by acetyl and benzoyl halides, the orders of reactivities of these acyl halides were $CH_3COF < CH_3COCl < CH_3COBr < CH_3COI$, and $C_6H_5COF < C_6H_5COCl \fallingdotseq C_6H_5COBr > C_6H_5COI$, respectively.

These results show that the orders of reactivities of these acyl halides are not influenced even when a sterically hindered or activated aromatic position is to be substituted and these acylations proceed by the same substitution mechanism.

From the above results, it may be considered that the normal Friedel-Crafts acylation by acyl halides proceeds mainly by the substitution mechanism. However, when sterically hindered acyl halides are used, the ionic mechanism becomes important as the formation of the addition complexes becomes difficult; that is, the mechanism of the Friedel-Crafts acylation by acyl halides is influenced by the structure of acyl halides, and not by the nature of the aromatic substances to be acylated.

# *Iodine-Catalyzed Thermal cis-trans Isomerization of Stilbene*

By Shigeru YAMASHITA

(Received August 16, 1960)

It is well known[1-3] that iodine is an efficient catalyst in the cis-trans isomerization of ethylenic compounds. However, there few studies have been undertaken in the case of stilbene. The present work has been carried out to compare these results with the results of iodine-catalyzed photochemical isomerization[4] of stilbene which is under investigation. For this purpose, just as in photochemical work, *n*-hexane has been used for the solvent and the kinetics of isomerization have been studied in as low a temperature range as possible. From the results obtained the mechanism of isomerization is discussed.

## Experimental

**Materials.**—*cis- and trans-Stilbene and n-Hexane.*—The purification of these compounds has already been described in a previous paper[5].

*Iodine.*—A commercially available reagent was used after several repetitions of sublimation.

**Apparatus and Procedure.**—To exclude the photochemical contribution, the reaction vessel, made of a brown stoppered glass tube 8 cm. long and 1 cm. in diameter, was shielded from any light source[6]. The extent of isomerization in each run, confined to a low conversion, was determined by a spectrophotometric analysis of the reaction mixture after the iodine was removed by a copper coil as described by Dickinson et al.[7] The dependence of rate on

TABLE I. RATE MEASUREMENTS AT 68.8, 65.0 AND 62.0°C WITH VARIED CONCENTRATIONS

| Reaction temperature °C | Initial concentration $\times 10^4$ mol./l. Iodine | *cis*-Stilbene | Reaction time hr. | Reaction rate $\times 10^4$ mol./l. hr. |
|---|---|---|---|---|
| 68.8 | 10.0 | 10.0 | 2.0 | 0.19 |
| 68.8 | 10.0 | 5.0 | 2.0 | 0.09 |
| 68.8 | 10.0 | 12.5 | 2.0 | 0.24 |
| 68.8 | 15.0 | 10.0 | 2.0 | 0.23 |
| 68.8 | 5.0 | 10.0 | 2.0 | 0.15 |
| 65.0 | 10.0 | 10.0 | 2.0 | 0.11 |
| 65.0 | 10.0 | 5.0 | 2.0 | 0.05 |
| 65.0 | 10.0 | 12.5 | 2.0 | 0.15 |
| 65.0 | 15.0 | 10.0 | 2.0 | 0.14 |
| 62.0 | 10.0 | 10.0 | 2.0 | 0.09 |
| 62.0 | 10.0 | 12.5 | 2.0 | 0.11 |
| 62.0 | 15.0 | 10.0 | 2.0 | 0.10 |

the concentrations of stilbene and iodine was obtained from the initial rates thus determined for solutions of varied compositions. In some preliminary experiments it was confirmed that in the absence of iodine no conversion to *trans*-stilbene takes place in this temperature range.

## Results and Discussion

The experimental results obtained in the present work are summarized in Table I. Figs. 1 and 2 show the dependence of the rate of isomerization on concentrations of *cis*-stilbene and of iodine, respectively.

These results conform to the rate expression

$$-\mathrm{d}(C)/\mathrm{d}t = k(C)(I_2)^{1/2}$$

where $(C)$ and $(I_2)$ are the concentrations of *cis*-stilbene and iodine, respectively. The Arrhenius plot of rate constant $k$ is shown in Fig. 3, from which the following expression is obtained:

$$k = 9.53 \times 10^{11} \times \exp(-25\ \mathrm{kcal.\ mol^{-1}}/\boldsymbol{RT})$$

$$(\mathrm{l^{1/2}/mol^{1/2}\ sec.})$$

A probable mechanism that explains the above rate equation is analogous to the one that Dickinson and his coworker proposed for the iodine-catalyzed thermal isomerization of cinnamic acid[8]:

$$\mathrm{I_2} \rightleftarrows 2\mathrm{I} \qquad (1)$$

$$\mathrm{C} + \mathrm{I} \rightarrow \mathrm{CI} \qquad (2)$$

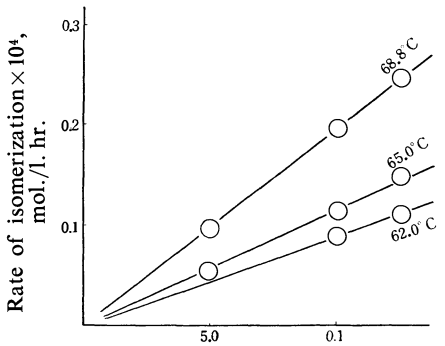

Fig. 1. Dependence of the reaction rate on the concentration of *cis*-stilbene.

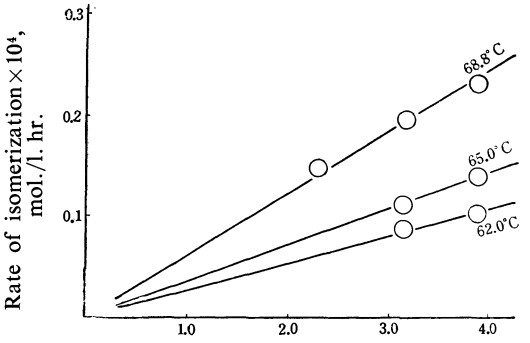

Fig. 2. Dependence of the reaction rate on the concentration of iodine.

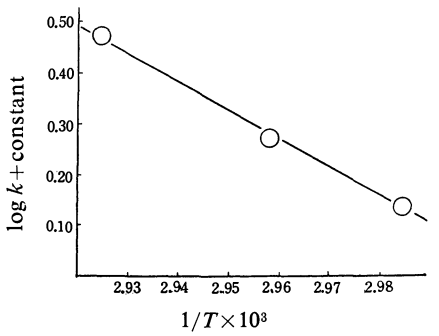

Fig. 3. Temperature dependence of the rate constant.

8) R. G. Dickinson and H. Lotzker, ibid., 59, 472 (1937).

$$CI \rightarrow C + I \quad (3)$$

$$CI \rightarrow TI \quad (4)$$

$$TI \rightarrow T + I \quad (5)$$

Here C and T represent the *cis*- and *trans*-stilbene, respectively. Assuming that reaction (1) is always in equilibrium and that the concentrations of the intermediate complexes CI and TI are sufficiently small in the stationary state, the sequence of reactions (1)—(5) lead to the following rate expression which is in good agreement with the experimental one:

$$-d(C)/dt = K^{1/2}k_2k_4/(k_3+k_4)\cdot(C)(I_2)^{1/2} \quad (6)$$

where $K$ represents the equilibrium constant of reaction (1) and also the $k_1-k_4$ rate constants for respective process (1)—(4). When combined with the dissociation energy of iodine molecules 36 kcal./mol., the overall activation energy of 25 kcal./mol. found above means that the term $k_2k_4/(k_3+k_4)$ in equation (6) has a temperature dependence corresponding to an activation energy of 7 kcal./mol. Accordingly, if $k_3$ is much greater than $k_4$, the activation energy of the step(4) may be represented as follows;

$$E_4 = 7 + Q_{CI} \text{ (kcal./mol.)}$$

where $Q_{CI}$ is the heat of formation of CI.

The present work offers no direct evidence for the intermediate complex CI. However, the formation of such a transient complex has recently been demostrated by a flash technique[9]: by flashing a solution of iodine in benzene, the formation and subsequent decay of a transient complex probably of the composition $C_6H_6\cdot I$ was observed spectroscopically[10].

It has been suggested by a number of workers[11-14] that the cis-trans isomerization catalyzed by paramagnetic molecules and atoms takes place through a triplet state of the substrate. It is therefore not unlikely that a triplet state of stilbene is involved in reaction (4), though the kinetic results obtained in the present work offer no information in favor of such an interpretation.

## Summary

The iodine-catalyzed thermal cis → trans conversion of stilbene has been studied kinetically in *n*-hexane in temperature range 62.0~68.8°C. The reaction rate obtained spectrophotometrically has been found to be proportional to the concentration of *cis*-stilbene and to the square root of iodine concentration. The overall activation energy has been found to be 25 kcal./mol. The results have been interpreted in terms of the thermal dissociation of iodine molecules followed by the formation of a transient complex between *cis*-stilbene and atomic iodine.

The author is particularly indebted to Professor O. Toyama of the College of Engineering and to Dr. T. Hayakawa for their discussions and encouragement during this investigation. The author wishes to thank Mr. H. Matsuda for his assistance.

10) The present author has studied the formation of 1:1 molecular complexes between iodine and *cis*- and *trans*-stilbene in *n*-hexane and carbon tetrachloride in the temperature range 10~30°C[5]. It may be of interest to investigate whether such a molecular complex participates in the isomerization. Unfortunately, the present study can not give any clue to this problem. In the temperature range in which the isomerization has been studied, the molecular complex $CI_2$ has such a low concentration that its contribution, if any, can not be detected.

# *Photochemical cis-trans Isomerizatin of Stilbene*

By Shigeru YAMASHITA

(Received August 16, 1960)

The photoisomerization of stilbene has been studied by Lewis and his coworkers[1] using the 254 mμ line of mercury and isooctane as the solvent. In the present investigation which was carried out with *n*-hexane solution, in connection with the study of the iodine-catalyzed photoisomerization of stilbene[2], mercury lines of longer wavelengths i. e., 313 and 334 mμ were employed.

Reaction rates and quantum yields were measured for both cis→trans and trans→cis conversions. Combining the results obtained with other information on stilbene such as fluorescence and phosphorescence, a plausible mechanism for the isomerization is presented.

## Experimental

**Materials.**—*cis-Stilbene.*—The method of preparation described in Ref. 3 was followed. The purified stilbene (b. p. 114~119°C/3.5~4.0 mmHg) was stored in the dark under reduced pressure. The absorption curve obtained with an *n*-hexane solution is given in Fig. 1 which is in good agreement with previous ones obtained with similar solvents[4,5].

*trans-Stilbene.*—The commercial reagent (m. p. 119~120°C) was used without further purification. The absorption curve given in Fig. 1 is again in good agreement with those previously reported[4,5].

*n-Hexane.*—The commercial reagent of chemically pure grade was treated with fuming sulfuric acid, concentrated sulfuric acid, and an aqueous solution of potassium permanganate, successively. After drying over anhydrous calcium chloride, the product was fractionally distilled.

**Apparatus and Procedure.**—For the light source, Mazda SHL-100 type mercury lamp was used. Through collimating quartz lens and appropriate combination of filters, a parallel light beam of a desired wavelength was projected upon the quartz reaction cell of 4-cm. diameter and 2-cm. thickness, immersed in a thermostat, which had a window for irradiation. The light intensity of the mercury lamp was kept constant within 1% by using a voltage stabilizing power supply. Care was taken to exclude scattering light, for it was found to give rise to a considerable error. For experiments with varied light intensities a required mesh of blackened copper gauze previously calibrated for its transmittance was used.

For the cis→trans conversion, Mazda UV-D2 filter combined with a potassium chromate aqueous solution (concentration, 0.2 g./l.; depth, 1.0 cm.) was used, which allowed the light in the range of wavelength 300~350 mμ to be transmitted. Principal lines of mercury which lie in this range and are expected to be effective in the isomerization are 313 and 334 mμ. For the conversion in the reverse direction, a combination of Mazda UV-D2 filter with a copper nitrate aqueous solution (concentration, 83.5 g./l.; depth, 1.0 cm.) served to allow the light in the wavelength range 310~400 mμ to be transmitted*. However, in view of the absorption curve of *trans*-stilbene given in Fig. 1, the mercury lines lying in this range and expected to be effective in the isomerization are again 313 and 334 mμ.

In every run freshly distilled *n*-hexane was used as a solvent, although the effect of the dissolved air in the reaction solution seemed to be practically negligible. Stirring of the reaction mixture in a reaction cell was not devised, because stirring or

* This combination of filters was used to enable the results obtained to be compared with those in the presence of iodine which are to be reported in a later paper.

vibrating of the reaction mixture was found to have no influence on the reaction rate.

Throughout the series of experiments the rate of isomerization was measured only in the initial stage of reaction so that the reverse reaction may be neglected. The change in concentrations of *cis*- and *trans*-stilbene due to the isomerization was determined by Hitachi a EPB-U types pectrophotometer.

The absorbance of the solution was very small in the present work, the concentration of stilbene being of the order of $10^{-5}\sim10^{-4}$ mol./l. Hence the rate of light absorption $I_a$ is given by

$$I_a = I_0(1-\exp(-\alpha cd)) \simeq I_0\alpha cd$$

where $I_0$, $\alpha$, $c$ and $d$ represent incident light quanta per unit time, molar absorption coefficient, concentration of the solute and cell thickness, respectively. $I_0$ was determined actinometrically, using potassium ferrioxalate solution[6]. From such actinometric results and from transmittancy of the reaction mixtures, quantum yields for isomerization were determined.

## Results and Discussion

Fig. 2 shows the dependence of the rates of cis→trans and trans→cis isomerization on light intensity. Fig. 3 shows the dependence of the rates on the concentrations of the two isomers of stilbene. Dependence of the rate on temperature was investigated between 10 and 30°C with the result that the isomerization in both directions was practically independent of temperature. On the other hand, there exists an appreciable difference between the quantum yields in the two directions: $\phi_{cis\rightarrow trans}$ and $\phi_{trans\rightarrow cis}$ were found to be 0.04 and 0.27 when solutions of $4\times10^{-5}$ M *cis*-stilbene and $2.5\times10^{-5}$ M *trans*-stilbene absorbed the light of $2.3\times10^{-8}$ and $0.90\times10^{-8}$ einstein/min. at 25°C, respectively.

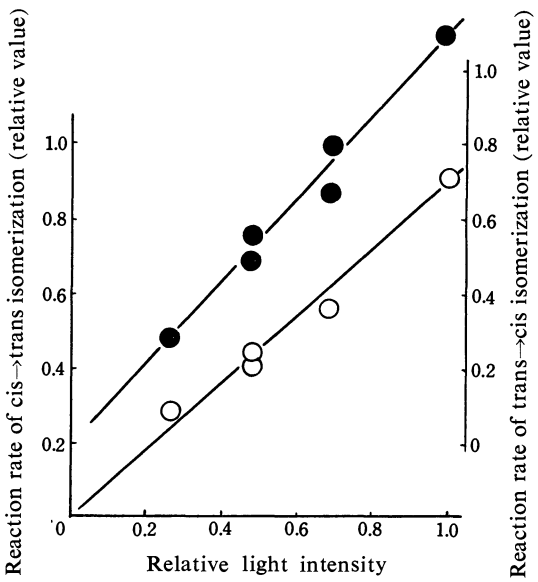

Fig. 2 Dependence of the rate of cis→trans (-○-) and trans→cis (-●-) isomerization on light intensity at 25°C.

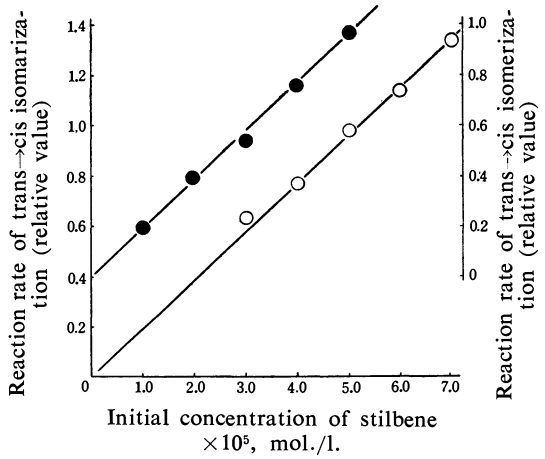

Fig. 3 Dependence of the initial rate of cis→trans (-○-) and trans→cis (-●-) isomerization on the initial concentrations of the two isomers of stilbene at 25°C.

Lewis and his coworkers have studied the reaction in isooctane solution under the irradiation with 254 mμ and obtained the quantum yield of 0.32 for the cis→trans and 0.35 for the trans→cis conversion[1]. Comparing these values with those obtained in the present work, values of $\phi_{trans\rightarrow cis}$ are in fairly good agreement, while the value of $\phi_{cis\rightarrow trans}$ is much smaller than that obtained by Lewis and his coworkers. They observed a yellow product accumulating under a prolonged irradiation of *cis*-stilbene with 254 mμ. In the present work with *cis*-stilbene, although the conversion was followed only in the initial stage, the concentration sum of *trans*-stilbene produced and *cis*-stilbene remaining was found to be constant within the experimental error of ±1% and equal to the initial concentration of *cis*-stilbene. Hence there was no need to take any side reaction into account. Presumably, these differences between the results of Lewis and his coworkers and of the present investigation are ascribed to the difference in wavelength of the light used.

As seen in Fig. 1, the absorption curve of *trans*-stilbene in solution shows a vibrational fine structure while that of *cis*-stilbene has no significant structure even at −90°C[1]. Hence, as is pointed out by Lewis and his coworkers, the excited state of *cis*-stilbene probably has a very short life.

It is known that *trans*-stilbene in solution

6) C. A. Parker, *Proc. Roy. Soc.*, **A220**, 104 (1955); C. G. Hatchard and C. A. Parker, ibid., **A235**, 518 (1956).

shows fluorescence under irradiation, but *cis*-stilbene does not. Lewis and his coworkers[1] have shown that the fluorescence obtained by a continued irradiation of *cis*-stilbene is explained by the existence of *trans*-stilbene produced by photoisomerization. Contrary to fluorescence, *cis*-stilbene shows phosphorescence while it is absent in the case of *trans*-stilbene[7,8]. Considering from the results observed in stilbene and its derivatives, the phosphorescent metastable state seems to be a triplet[9,10]. It was shown by Mulliken[11] that the potential energy curve for the lowest triplet state of ethylene has a minimum when the molecule takes a 90° twisted structure about the C=C double bond while for the singlet ground state the potential curve has a maximum at this configuration. In the case of molecules having conjugated double bonds such as stilbene and azobenzene, the situation is somewhat different. The triplet state now shows a rather flat potential energy curve which has a slight hump for the 90° twisted structure[12].

On the basis of quantum yields and absorption and fluorescence characteristics of *cis*- and *trans*-stilbene, Lewis and his coworkers presented a mechanism for the isomerization, according to which the electronic energy of excited molecules of either *cis*- or *trans*-stilbene is converted into rotational and vibrational energies in the ground state; one can discriminate neither cis- nor trans-form in this state. The normal cis- or trans-form, however, is produced as the excess energy is dissipated.

Results obtained in the present work are not necessarily incompatible with Lewis's mechanism. However, in view of the appreciable difference between the quantum yields in opposite directions and of the phosphorescence characteristics which are not taken into account in Lewis's mechanism, the following one seems to be more probable for the present case.

In Fig. 4 transitions d and h represent the light absorption and fluorescence of *trans*-stilbene respectively. Transition a represents the light absorption of *cis*-stilbene, and f an internal conversion to the ground state of *cis*-stilbene since no fluorescence is observed with *cis*-stilbene as described above. Similar radiationless transition may also be involved in h. The phosphorescent state M is produced by an internal conversion b. In solution, transitions

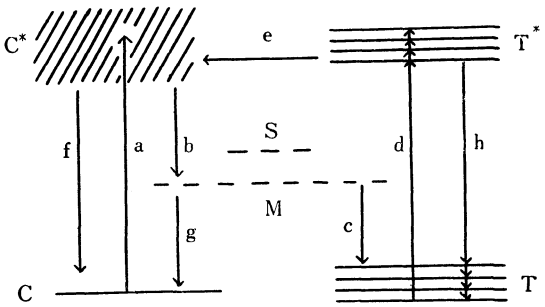

Fig. 4 Energetic schema for the photoisomerization of stilbene. C and T, the ground state of *cis*- and *trans*-stilbene respectively; C* and T*, the excited state of *cis*- and *trans*-stilbene respectively; M, the metastable state; S, the potential barrier separating *cis*- and *trans*-stilbene in the singlet ground state. The height of S relative to C is about 40 kcal./mol. so that S situates probably higher than M[12].

to the ground states, g and c, may also be principally internal conversions. The potential barrier separating the cis- and trans-forms of ethylenic compounds is generally considered to be much lower in the excited state than in the ground state[13]. On irradiating *trans*-stilbene, therefore, isomerization to cis-form may proceed via def or debg. In the case of *cis*-stilbene, the excited state is very short-lived and will be deactivated instantly through process b or f; hence the isomerization of *cis*- to *trans*-stilbene probably proceeds via abc.

The mechanism here presented appears to be consistent with the experimental findings that the rate of isomerization in both directions is proportional to the concentration of stilbene and to the light intensity and shows negligible dependence on temperature. Moreover, provided that the internal conversion f has a sufficiently large probability, the scheme given above may explain the greater value of $\phi_{\text{trans}\rightarrow\text{cis}}$ than $\phi_{\text{cis}\rightarrow\text{trans}}$, and also it may not be incompatible with the fact that phosphorescence has not been observed for *trans*-stilbene.

## Summary

The photochemical isomerization of *cis* as well as *trans*-stilbene in *n*-hexane was studied kinetically in the temperature range 10~30°C using the mercury lines of 313 and 334 mμ. Quantum yields were found to be 0.04 for the cis→trans, and 0.27 for the trans→cis conversion. Conversion rates for both directions obtained spectrophotometrically were found to be of the first order with respect to the substrate concentration, proportional to the light intensity, and nearly independent of temperature.

# *The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. III. Diffusion of Iodine-133 and Tellurium-132 in Graphite at High Temperatures*

By Seishi YAJIMA, Sumio ICHIBA, Yuichiro KAMEMOTO and Koreyuki SHIBA

(Received September 3, 1960)

One of the distinctive features of a semi-homogeneous reactor is its use of a fuel element of the mixture of graphite and uranium dioxide. It was stated in the previous paper[1] that most of the fission products were captured in graphite by recoil energy. The diffusion of fission products captured in graphite at high temperatures is an important subject from the standpoint mentioned below. The release of fission products from a fuel element causes contamination of the coolant and its facilities. On the other hand, it is desirable from the viewpoint of neutron economy to remove fission products to some extent.

But the high velocity of diffusion results in the release of the fission products emitting delayed neutrons that are important in reactor control.

This paper describes the diffusion of iodine and tellurium, following the description of the diffusion of xenon in the previous paper[1].

In operating a reactor, the behavior of iodine-135, precursor of xenon-135, must be taken into consideration as well as that of xenon-135, which has an abnormally large neutron absorption cross-section. Because of the short half-life of iodine-135, iodine-133 was used as a tracer in this experiment. On the diffusion of tellurium which shows a chemical behavior similar to iodine, tellurium-132 was used as a tracer.

## Experimental

**Preparation of Samples.**—A mixture of 1 g. of graphite powder and 50 mg. of uranium dioxide was irradiated with thermal neutrons (thermal neutron flux, about $5\times10^{11}$ neutron/cm$^2$/sec.) for 2 hr. in an experimental hole of a JRR-1 reactor. After irradiation the mixture was treated with hot 4 N nitric acid solution to dissolve the uranium dioxide and neptunium-239 produced. The graphite was washed with distilled water and dried at 100°C. It was already reported that the fission products captured in graphite were not leached out by being treated with 4 N nitric acid solution in a short period of time[2]. In order to allow short-lived

fission iodine nuclides to decay, the irradiated graphite samples were cooled for about forty hours before use. The particle sizes of graphite samples used in this experiment and analytical data on impurities are given in Table I.

**Flow System.**—*Diffusion of Iodine-133.*—A flow system is illustrated in Fig. 1. The furnace consisted of a heater of silicon carbide. The temperature of the furnace was measured with a platinum-platinum rhodium thermocouple with a

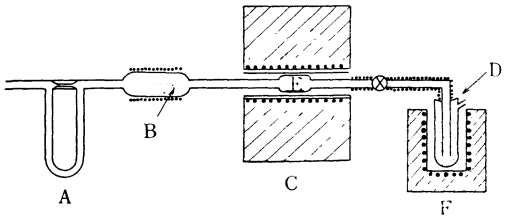

Fig. 1 Flow system.

B, Sponge titanium
C, Furnace
D, Copper trap
E, Diffusion cell
F, Heater

regulator control. The whole assembly was made of silica. The sponge titanium heated at 800°C served to remove a trace amount of oxygen in helium to avoid oxidation of the graphite surface. The silica tube from the diffusion cell to a copper trap was heated at over 300°C with a nichrome winding to prevent fission iodine from deposition on the wall of the tube. A copper trap was heated at 430°C in a furnace, because it was experimentally confirmed that fission iodine was completely captured in a copper net at 400 to 450°C.

The graphite powder mentioned above was placed in the diffusion cell. Helium gas was introduced into it. After confirming the fact that gas took the place of air, the diffusion cell with the graphite powder was slid into the preheated furnace, when the temperature was kept constant at 400, 800 and 1200°C (or 1100°C). Helium gas swept over the sample at a constant flow rate (100 ml./min.) and carried the volatile fission products diffusing out of graphite. The iodine-133 used as a measure of diffusion was separated from the fission products and was captured in a copper trap together with other fission iodine nuclides. The trap was exchanged for a new one at appropriate intervals.

*Diffusion of Tellurium-132.*—The apparatus was almost similar to that for diffusion of iodine-133. A copper trap was used to capture tellurium-132. It was found in advance that fission tellurium was completely captured in copper at 700 to 720°C. Therefore, the copper trap was heated at 710°C.

The silica tube from the diffusion cell to a trap was heated at about 700°C with a nichrome winding to avoid the deposition of fission tellurium on the wall of the tube.

**Determination of Iodine-133 and Tellurium-132 Activities.**—Activities of iodine-133 and tellurium-132 were measured with a RCL 256 channel gamma-ray

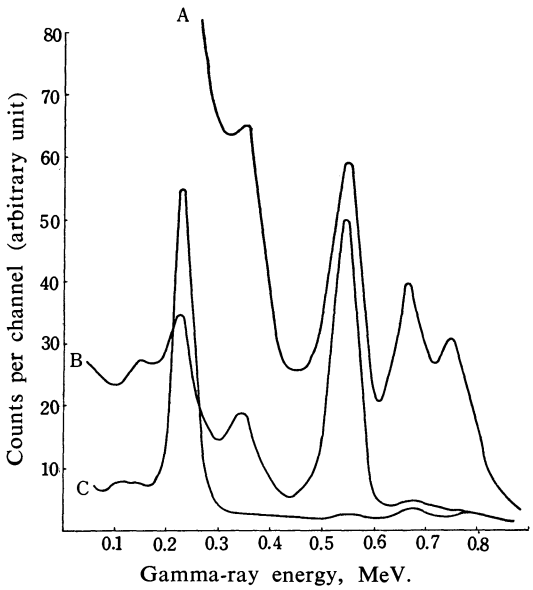

Fig. 2. Gamma-ray spectra of (A) fission products in graphite sample and (B) iodine-133 and (C) tellurium-132 in copper trap.

spectrometer with a well type sodium iodide scintillator (2 inch diameter×1.75). The gamma-ray spectra of the fission products in the graphite sample, iodine-133 and tellurium-132 in a copper trap, all cooled for forty hours after irradiation, are illustrated in Fig. 2. Iodine-132, the daughter of tellurium-132, exists in a trap in the state of transient equilibrium. Because the height of a photoelectric peak is proportional to the activity of the iodine-133 released and thus to the amount of iodine-133, the percentage of iodine released was calculated by comparing the height of the gamma-ray spectrum of the graphite sample, which was not heat-treated, with that of a trap. It was impossible to measure directly the activity of tellurium-132 in the graphite sample. Therefore, radiochemically pure tellurium was separated from the sample by the following radiochemical procedure. After burning the sample the residue was dissolved in nitric acid. The tellurium released from the sample on burning was caught in nitric acid solution and the resulting solution was combined with the solution with the residue. A tellurium carrier was then added to the solution, reduced with sulfur dioxide and precipitated as a metal. Then the activity of the tellurium metal was measured. The percentage of tellurium released was calculated as described in the case of iodine.

## Results and Discussion

Isothermal curves of the diffusion of iodine-133 and tellurium-132 in four kinds of graphite are illustrated in Figs. 3—10. These figures show that with these nuclides the respective curve apparently consists of a rapid diffusion lasting for about 30 min. and a slow diffusion

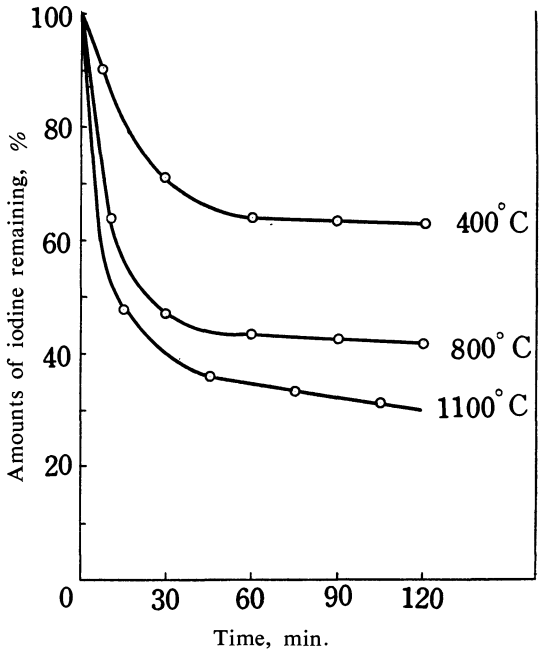

Fig. 3 Isothermal curves of diffusion of iodine-133 in natural graphite-1.

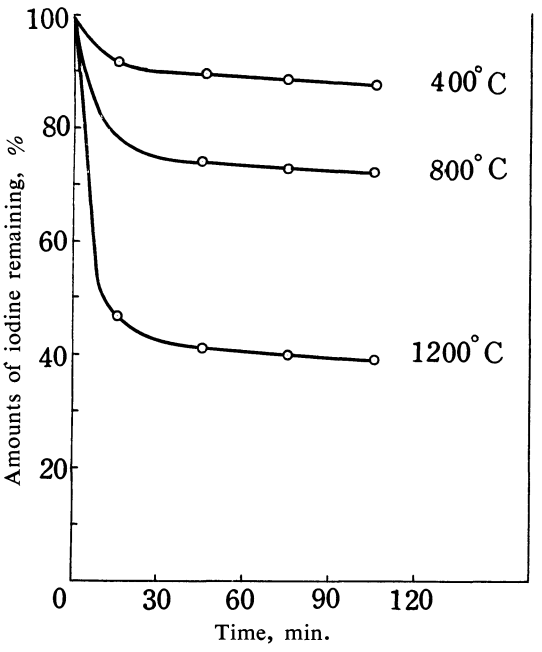

Fig. 4 Isothermal curves of diffusion of iodine-133 in natural graphite-2.

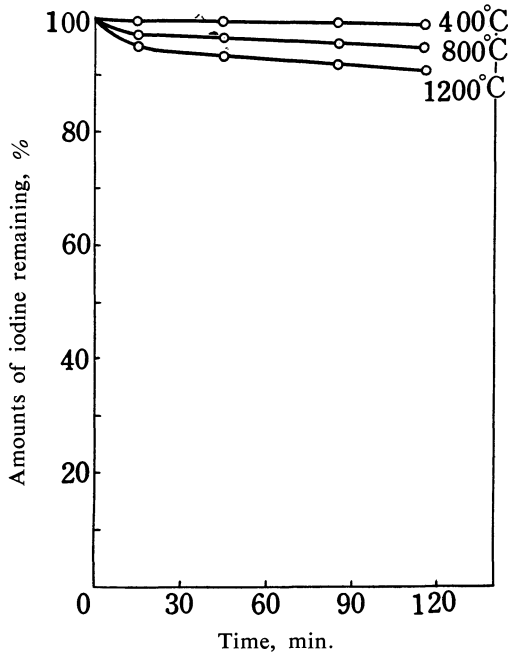

Fig. 5 Isothermal curves of diffusion of iodine-133 in artificial graphite.

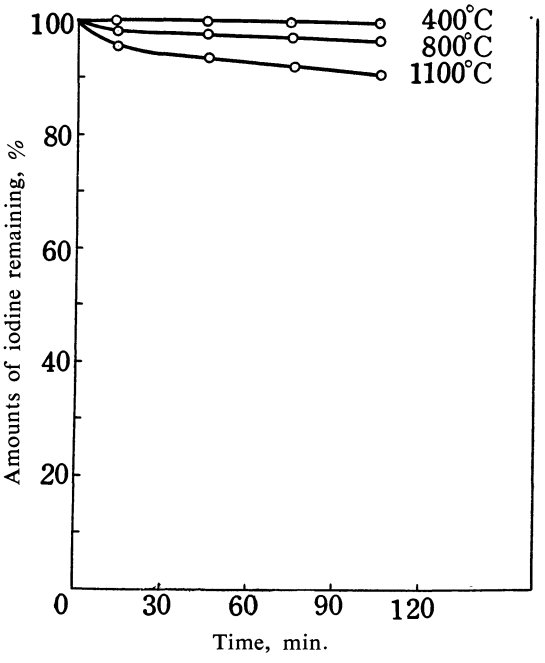

Fig. 6 Isothermal curves of diffusion of iodine-133 in amorphous carbon.

following it. This tendency is the same as that observed in the diffusion of xenon-135, where the activation energy of interlaminar diffusion of xenon-135 in graphite was calculated from a slow diffusion[1].

It has, however, been expected that there are several activation energies in diffusion in graphite. In fact, it is difficult to interpret the diffusion in graphite only from the interlaminar activation energy. A study is being continued on this subject with the use of a new method, and interesting information has

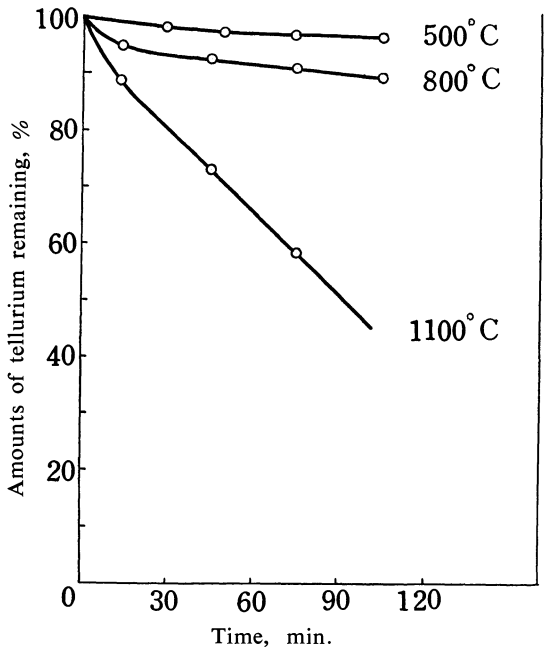

Fig. 7 Isothermal curves of diffusion of tellurium-132 in natural graphite-1.

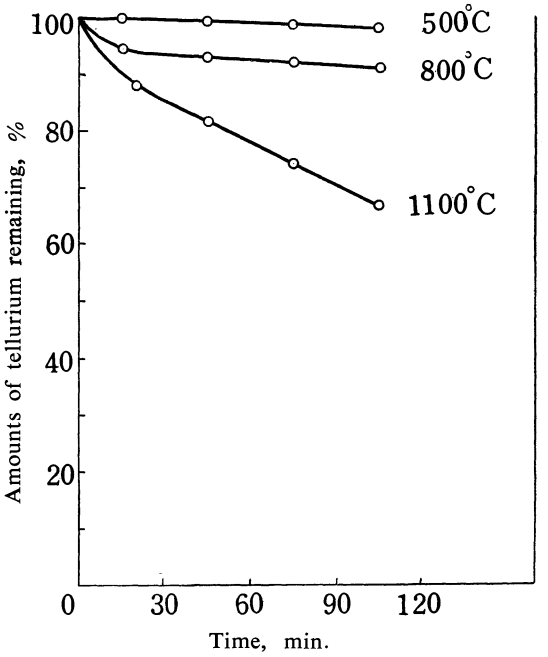

Fig. 8 Isothermal curves of diffusion of tellurium-132 in natural graphite-2.

been obtained. Details of the study will be reported later[3].

The rates of diffusion of iodine-133 and tellurium-132 in natural graphite are greater

3) S. Yajima, S. Ichiba, Y. Kamemoto and K. Shiba, This Bulletin, in press.

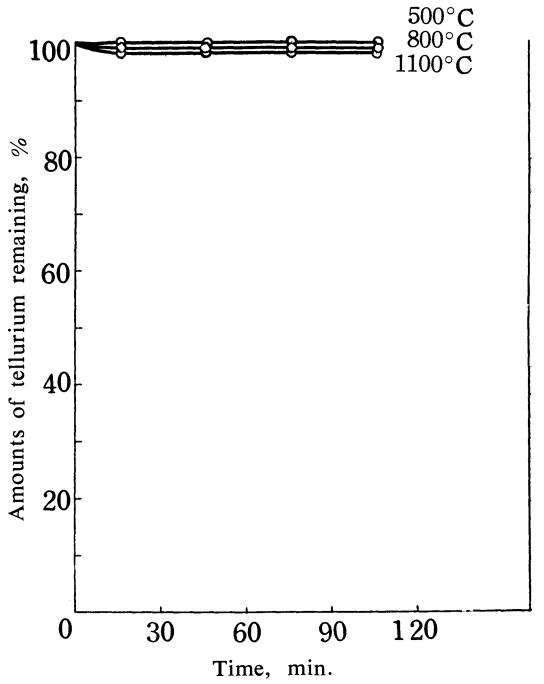

Fig. 9 Isothermal curves of diffusion of tellurium-132 in artificial graphite.

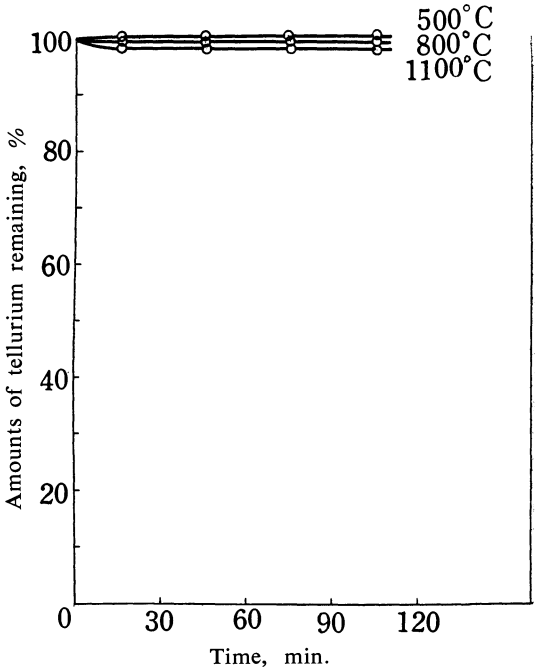

Fig. 10 Isothermal curves of diffusion of tellurium-132 in amorphous carbon.

than those in artificial graphite. This result is similar to the diffusion of xenon-135 in graphite observed in the previous work[1]. According to the X-ray diffraction and electron diffraction studies, natural graphite has a large

mosaic structure and artificial graphite has a small one. From this observation, it will be concluded that natural graphite has a lower density of dislocation than artificial graphite and that the trapping centers which are distributed along the dislocation line are less in natural graphite than in artificial graphite. Consequently, it is expected that the rates of the diffusion of iodine-133 and tellurium-132 in natural graphite, which has only a few trapping centers, are greater than in artificial graphite which has many trapping centers.

# *Preparation of 4-Aminotropolones by Amination of 3-Iodotropolones with Alkali Amides in Liquid Ammonia**

By Kozo Doi

(Received September 2, 1960)

Elimination-addition mechanisms involving intermediates of benzyne or dehydrobenzene ($C_6H_4$) type have been established in the rearrangement reactions occurring in the amination of non-activated aryl halides[1], high-temperature alkaline hydrolysis of aryl halides[2], and the coupling of aryl halides and phenyllithium[3]. Further, such mechanism has been extended to the rearrangement reaction in the amination of 3-bromopyridine[4] and the coupling of 1-chlorocyclohexene and phenyllithium[5].

The possibility of the extension of the elimination-addition mechanism involving dehydrotropolone (I), an intermediate corresponding to benzyne, in the field of tropolones has been suggested in the formation of 4-hydroxytropolone[6,7] (VII) and 4-hydroxy-6-isopropyltropolone[8] (XVII) on respective high-temperature alkaline hydrolysis of 3-bromotropolone (II) and 3-bromo-6-isopropyltropolone (V), and the formation of 4-cyanotropolone[6,9] (VIII) on high-temperature treatment of 3-bromotropolone (II) with potassium cyanide. Johnson and his co-workers[10] stated, with no experimental evidence, that dehydrotropolone (I) would be liable to form more easily than benzyne because of a decrease of the steric strain.

I

For the purpose of synthesizing 4-aminotropolones, examinations were made on the amination of 3-iodotropolones with alkali amides in liquid ammonia, the results of which will be described below in this paper.

Reaction of 3-iodotropolone (III) with three moles of potassium amide in liquid ammonia resulted in 4-aminotropolone (IX) in low yield. In order to confirm its structure, the same aminotropolone was synthesized through the Curtius reaction from 4-carboxytropolone (X), the structure of which had been established. The tropolone X was converted to 4-ethoxycarbonyltropolone (XI) in a good yield on being heated with ethanolic hydrogen chloride. The melting point (91°C) and the ultraviolet spectrum of XI were in agreement with those of the authentic sample[11] which had been obtained from the ring-enlargement of veratrole with ethyl diazoacetate. When treated with hydrazine hydrate under the ordinary condition, XI yielded the hydrazide XII which was converted with nitrous acid to the corresponding azide less soluble in water. Hydrolysis of the azide in an acidic medium afforded 4-aminotropolone (IX) in a poor yield.

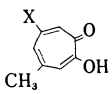
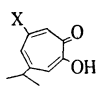
Amination of 3-iodo-6-methyltropolone[12] (IV) and 3-iodo-6-isopropyltropolone (VI) with potassium amide under the same condition as that described above resulted in the formation

II : X=Br
III : X=I



IV



V : X=Br
VI : X=I

VII : X=OH
VIII : X=CN
IX : X=$NH_2$
X : X=COOH
XI : X=COOEt

XIII : X=$NH_2$
XIV : X=COOH
XV : X=COOEt
XVI : X=$CONHNH_2$

XVII : X=OH
XVIII : X=$NH_2$

of 4-amino-6-methyltropolone (XIII) and 4-amino-6-isopropyltropolone (XVIII), respectively. The structure of the former XIII was confirmed by the synthesis of XIII from 4-carboxy-6-methyltropolone[13] (XIV) according to an authentic method[14]. The structure of XVIII was deduced from the close resemblance of its ultraviolet absorption to those of IX and XIII.

It has been known to date that the halogen atom in 3-halotoropolone is reactive and undergoes various anionoid substitutions such as the following: nitrile formation with cuprous cyanide[6], methoxylation with sodium methoxide[6], phenoxylation with sodium phenoxide[6], arylsulfonamidation with potassium arylsulfonamide[6], hydroxylation with concentrated caustic alkali[7], with aqueous sodium naphthalene-$\beta$-sulfonate[15] and with hydrochloric acid[10], and alkylation with some active methylene compounds[16]. In this reaction with potassium amide in liquid ammonia, however, the normal substitution products, 3-aminotropolones, were not isolated. This means probably that the elimination of iodide ion precedes the substitution in this reaction and the subsequent addition results in formation of 4-aminotropolones. The use of sodium amide instead of potassium amide and the use of 3-bromotropolones in place of the iodo compounds caused a marked decrease in the yield of the aminotropolones. Secondary and tertiary amines are expected to be produced as by-products[17], but no such products were separated in pure states.

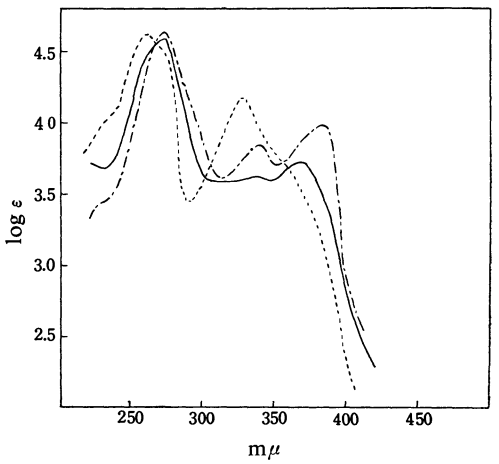

Fig. 1. The ultraviolet absorption spectra of 4-aminotropolone (IX) ; curve ——, in methanol, curve ----, in 0.1 N HCl, curve —·—·, in 0.1 N NaOH.

Fig. 1 indicates the ultraviolet absorption spectra of 4-aminotropolone (IX). In acid solution, the band near 350 m$\mu$ in the neutral solution shows a blue shift to give a tropone-type spectrum, whereas in alkaline solution it shows a red shift to give a tropolone-type spectrum. The ultraviolet spectra of the other two aminotropolones (XIII and XVIII) are also essentially similar to those of IX. These facts suggest that the aminotropolones possess an amphoteric character.

In Table I are listed some principal absorption bands in the infrared spectra of the aminotropolones.

Table I. Main absorptions of 4-aminotropolones in the infrared spectra ($cm^{-1}$)

| | $\nu_{NH_2}$ | | $\nu_{OH}$ | I | II | $\delta_{C-N}$ |
|---|---|---|---|---|---|---|
| IX | 3410 | 3325 | 3185 | 1640 | 1596 | 1335 |
| XIII | 3400 | 3340 | 3190 | 1648 | 1592 | 1325 |
| XVIII | 3400 | 3330 | 3195 | 1640 | 1588 | 1338 |

According to the result of Kinumaki, Ikegami and Aida[18], the carbonyl frequencies, measured in the solid state, of aminotropolones (3- and

5-aminotropolones, and 3, 5- and 3, 7-diaminotropolones) appear in the region of 1660～1609 $cm^{-1}$, whereas 4-aminotropolones have two bands (I and II bands in Table I) in the same region, and the II band of these two is stronger in its intensity and, therefore, it may be taken as the band due to the carbonyl stretching vibration in the respective aminotropolones. This assumption appears to be reasonably supported from the following observation on the relationship between frequencies of the II band and substituent constants.

It has been elucidated by many investigators[19] that the carbonyl frequencies of acetophenones, benzophenones, benzaldehydes and benzoic acids, and the substituent constants are in good linear relationship. It has also been found[20] in the tropolone field that Hammett's rule is satisfied between the dissociation constants and the substituent constants in a way similar to the case of benzene derivatives. It follows, naturally, that there would also be the same relationship between carbonyl frequencies of 4- and 5-substituted tropolones and substituent constants.

In Table II are shown the values of carbonyl frequency of several of the 4- and 5-substituted tropolones and substituent constants, $\sigma$, concerned.

Table II. Relationship between carbonyl frequencies and substituent constants in several substituted tropolones

| Substituent | 4-$NH_2$ | 4-Me | 4-iso-$C_3H_7$ | H |
|---|---|---|---|---|
| $\nu_{C=O}$*, $cm^{-1}$ | 1056 | 1610[21] | 1605[22] | 1613[23] |
| $\sigma$*[2] | −0.161 | −0.069 | −0.120*[3] | 0.000 |

| Substituent | 4-Cl | 4-Br | 4-$COCH_3$ | 5-Me |
|---|---|---|---|---|
| $\nu_{C=O}$, $cm^{-1}$ | 1615[24] | 1613[24] | 1620[24] | 1603[21] |
| $\sigma$ | 0.373 | 0.391 | 0.306 | −0.17 |

* All were measured in solid state.

*[2] L. P. Hammett, "Physical Organic Chemistry", McGraw-Hill Book Co., New York, N. Y. (1940).

*[3] $\sigma_m$ for *tert*-$C_4H_9$ was used.

Graphically, a fairly good linear relationship is observed between $\nu$ and $\sigma$. Therefore, the II band in Table I is considered to correspond to the carbonyl stretching frequencies of the 4-aminotropolones. The use of the values measured in solution makes it probable to expect the existence of a better linear relationship between them.

## Experimental

The ultraviolet absorptions were determined with a Beckman model DU spectrophotometer. The infrared spectra were measured on potassium bromide disks with a Perkin-Elmer model 21 infrared spectrometer, using a rock salt prism.

*Amination of 3-Iodotropolones with Potassium Amide.*

**4-Aminotropolone (IX).**—To a solution of liquid ammonia (100 ml.) and potassium amide obtained from potassium (2.6 g.), 3-iodotropolone[25] (III, 5.5 g.) was added during about 10 min., and the reaction mixture was allowed to reflux at the boiling point of ammonia. For the reaction was used a 300 ml. three-necked, round-bottomed flask equipped with a dry ice reflux condenser, an efficient mechanical stirrer and an Erlenmeyer flask fitted to one of the tubulatures of the reaction vessel by a section of rubber tubing for adding the iodotropolone. After 2 hr., ammonium chloride (2.4 g.) was added to the mixture and the ammonia was allowed to evaporate. The residual solid was dissolved in water (200 ml.), acidified to Congo red with concentrated hydrochloric acid, and extracted with chloroform (300 ml.). The extract was shaken with three 50 ml. portions of 6 N hydrochloric acid. This acid solution was combined with the foregoing aqueous solution, neutralized with sodium carbonate, and extracted continuously with ether for 5 hr. The ether extract, after evaporation of the solvent, sublimation in vacuo, and subsequent crystallization from methanol, yielded 4-aminotropolone (IX, 0.7 g.) as colorless needles, m. p. 187～188°C.

Found: C, 61.25; H, 5.08; N, 10.19. Calcd. for $C_7H_7O_2N$: C, 61.31; H, 5.15; N, 10.21%.

$\lambda_{max}$ m$\mu$ (log $\varepsilon$): 274 (4.60), 338 (3.62), 367 (3.72), in methanol; 260 (4.61), 328 (4.16) in 0.1 N HCl; 273 (4.64), 338 (3.86), 385 (4.00) in 0.1 N NaOH.

*Picrate:* A mixture of the aminotropolone (IX, 35 mg.), picric acid (120 mg.), and methanol (5 ml.) was heated under reflux for 5 min., cooled, and the residual precipitate was collected. Yellow prisms, m. p. 202～203°C.

Found: N, 15.08. Calcd. for $C_7H_7O_2N \cdot C_6H_3O_7N_3$: N, 15.06%.

**4-Amino-6-methyltropolone (XIII).**—To a stirred mixture of liquid ammonia (300 ml.) and potassium amide prepared from potassium (4.7 g.) was added 3-iodo-6-methyltropolone[12] (IV, 10 g.) at −50°C for 5 min. and the reaction mixture was allowed to reflux for 2 hr. When the following procedure was carried out essentially as described in the preceding experiment, the aminotropolone (XIII, 1.7 g.) was obtained as colorless needles (from methanol) of m. p. 199～200°C (reported[13] m. p. 199～200°C).

Found: C, 63.59; H, 5.85; N, 8.85. Calcd. for $C_8H_9O_2N$: C, 63.56; H, 6.00; N, 9.27%.

$\lambda_{max}$ m$\mu$ (log $\varepsilon$): 274 (4.64), 340 (3.67), 360 (3.68) in methanol; 260 (4.54), 328 (4.06) in 0.1 N HCl; 273 (4.62), 340 (3.84), 380 (3.95) in 0.1 N NaOH.

*Picrate:* Yellow needles (from methanol), m. p. 178~180°C.

Found: N, 14.64. Calcd. for $C_8H_9O_2N \cdot C_6H_3O_7N_3$: N, 14.94%.

**4-Amino-6-isopropyltropolone (XVIII).** — To a stirred mixture of liquid ammonia (400 ml.) and potassium amide obtained from potassium (8 g.) was added 3-iodo-6-isopropyltropolone[26] (VI, 19 g.) during 10 min. When the procedure which followed was carried out as the above, the aminotropolone (XVIII, 3.7 g.) was isolated from benzene as colorless needles of m. p. 145~146°C.

Found: C, 67.32; H, 7.18; N, 8.00. Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%.

$\lambda_{max}$ mμ (log ε): 275 (4.63), 340 (3.68), 360 (3.66) in methanol; 263 (4.55), 328 (4.08) in 0.1 N HCl; 273 (4.74), 338 (3.96), 385 (4.10) in 0.1 N NaOH.

*Picrate:* Yellow needles (from benzene-methanol), m. p. 96~97°C.

Found: N, 13.49. Calcd. for $C_{10}H_{13}O_2N \cdot C_6H_3O_7N_3$: N, 13.72%.

*Preparation by the Curtius Reaction.*

**4-Aminotropolone (IX).** — After dry hydrogen chloride was saturated in a mixture of 4-carboxytropolone (X, 1.1 g.) and ethanol (20 ml.), the mixture was heated under reflux for one hour. The solution was evaporated to dryness under reduced pressure, the residue was sublimed in vacuo, and the sublimate was recrystallized from cyclohexane to give 4-ethoxycarbonyltropolone (XI, 0.95 g.) as yellow needles, m. p. 91°C (reported[11] m. p. 90~91°C).

Found: C, 61.74; H, 5.23. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 250 (4.43), 313 (3.69), 325 (3.73), 375 (3.72), 388 (3.68).

A solution of XI (1.5 g.), 80% hydrazine hydrate (1 ml.) and ethanol (10 ml.) was heated under reflux for 3 hr.; the solution was concentrated to a small volume under reduced pressure, and the residue so obtained was recrystallized from ethanol to form tropolone-4-carbohydrazide (XII, 0.7 g.) as yellow needles, m. p. 258°C (decomp.).

Found: N, 15.63. Calcd. for $C_8H_8O_3N_2$: N, 15.55%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 230 (4.16), 245 (4.18), 297 (4.41), 386 (4.29), 440 (4.01).

To a cold stirred solution of XII (0.54 g.), concentrated hydrochloric acid (1 ml.) and water (3 ml), was added dropwise a solution of sodium nitrite (0.21 g.) in water (1 ml.), and the deposited colorless azide was collected. The crude azide was then added to a solution of acetic acid (5 ml.), concentrated hydrochloric acid (1 ml.) and water (0.5 ml.), and the mixture was heated under reflux for 2 hr. This was evaporated under reduced pressure to a small volume, diluted with water (40 ml.), neutralized with sodium carbonate, and extracted with ether continuously for 5 hr. The ether extract, after evaporation of the solvent and crystallization from methanol, afforded the aminotropolone (IX, 0.25 g.), m. p. and mixed m. p. 187~188°C.

**4-Amino-6-tropolone (XIII).**—A cold mixture of 4-carboxy-6-methyltropolone (XIV, 1.8 g.) and ethanol (10 ml.), was saturated with dry hydrogen chloride, and the mixture was heated under reflux for 2 hr. By the procedure as described in the preceding experiment 4-ethoxycarbonyl-6-methyltropolone (XV, 1.92 g.) was obtained as pale yellow needles (from cyclohexane), m. p. 103~104°C.

Found: C, 63.62; H, 5.63. Calcd. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 251 (4.46), 312 (3.66), 330 (3.72), 378 (3.72), 388 (3.72).

A mixture of XV (0.21 g.) and 80% hydrazine hydrate (0.19 g.) was heated on a boiling water bath for 20 min., acidified with dilute acetic acid, and an insoluble solid was collected. Recrystallization of it from ethanol gave 6-methyltropolone-4-carbohydrazide (XVI, 0.13 g.) as yellow leaflets, m. p. 177~178°C (decomp.) (reported[13] m. p. 171~172°C (decomp.)).

Found: N, 14.76. Calcd. for $C_9H_{10}O_3N_2$: N, 14.43%.

$\lambda_{max}^{MeOH}$ mμ (log ε): 247 (4.19), 300 (4.43), 389 (4.28), 444 (3.99).

XVI was derived, by the reported experimental procedures[13], to the aminotropolone (XIII), m. p. and mixed m. p. 199~200°C.

The author wishes to express his gratitude to Professor Y. Kitahara for his helpful guidance throughout the course of this work, to Professor T. Nozoe for his unfailing encouragement, and to Professors S. Seto and Y. Matsuki for providing experimental facilities. The author gratefully ackonwledges his debt to Mr. S. Ohyama and Miss Y. Endo for microanalyses and to Mr. Y. Ikegami for infrared spectral measurements.

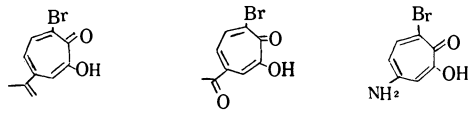
# *The Schmidt Reaction in Some Tropolone Derivatives**

By Kozo Doi

(Received September 9, 1960)



In the preceding paper[1] the author has described the syntheses of 4-aminotropolone (I) and its alkyl derivatives by the extended application of the elimination-addition mechanism involving a benzyne-type intermediate[2] to the tropolone field. As the general method for synthesizing 4-aminotropolones, however, this synthetic method, included amination of 3-iodotropolones with potassium amide in liquid ammonia, appeared to be still unsatisfactory in respect to the yield. Therefore attempts were made for the synthesis of 4-aminotropolones by application of the Schmidt reaction[3] to 4-isopropenyltropolone (β-dolabrin)[4] (II), 4-acetyltropolone[4] (III), and their derivatives.

Addition of both a solution of hydrazoic acid in chloroform and of sodium azide to a cold stirred solution of 4-acetyltropolone (III) in concentrated sulfuric acid resulted in instantaneous reaction to give 4-aminotropolone sulfate, having a composition of $C_7H_7O_2N \cdot 1/2\ H_2SO_4 \cdot H_2O$, instead of the anticipated acetylaminotropolone (IV). The desired aminotropolone (I) was readily obtained when this product was treated with sodium hydrogen carbonate. The use of excess hydrazoic acid in this reaction did not afford the tetrazole derivative, observed in the reactions with acetone and benzophenone[5]. The fact that 4-acetylaminotropolone (IV), which will be described in the subsequent paper[6], readily forms 4-aminotropolone sulfate on treatment with concentrated sulfuric acid makes it certain that IV arises as an intermediate in the reaction with III.

I II III IV

It was reported that bromination of the isopropenyltropolone (II) with *N*-bromosuccinimide yielded 3-bromo-6-isopropenyltropolone[7,8] (V) and its oxidation with hydrogen peroxide in formic acid, followed by that with sodium periodate, afforded 6-acetyl-3-bromotropolone[7] (VI). Application of sodium azide to a concentrated sulfuric acid solution of VI produced the corresponding aminotropolone (VII), in which case the sulfate of VII was not obtained owing to the decreased basicity by the introduction of the bromine atom in the molecule.

V VI VII

Fig. 1 indicates the ultraviolet absorption of VII, which possesses a maximum at a longer wavelength region than in the case of I[1].

—— 6-Amino-3-bromotropolone (VII)
---- 4-Amino-5-nitrotropolone (X, log ε +0.2)
—·— 6-Amino-3-bromo-5-nitrotropolone (XI, log ε +0.4)

In order to obtain further derivatives of the aminotropolone, nitrations with fuming nitric acid were carried out on the acetyltropolones (III and VI). Thus, 4-acetyl-5-nitrotropolone

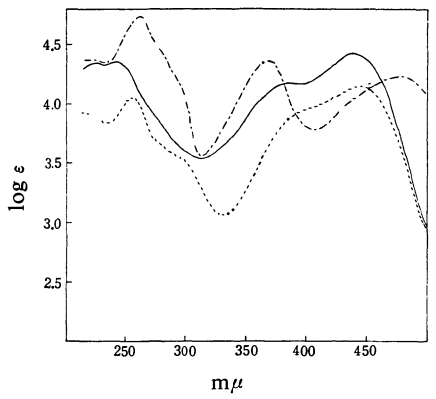
(VIII) and 6-acetyl-3-bromo-5-nitrotropolone (IX) were obtained from the respective compound. The positions of the nitro group in VIII and IX are supported from the similarity of their ultraviolet absorption spectra (Fig. 2) to that of 5-nitrotropolone[9]. It has been found that the presence of an alkyl group (especially isopropyl) in the 4-position of a tropolone effects preferential orientation of the nitro group towards the 3- or 7-position instead of the 5-position[10]. In spite of such a fact, nitration of III and VI, possessing a meta-directing acetyl group, has caused substitution of the nitro group into the adjacent position of the acetyl group. This means probably that the acetyl group is not in full conjugation with the tropolone ring. This conclusion is also supported reasonably from the fact that the absorption maximum at 437 mμ (log ε 4.42) in the longest wavelength of the ultraviolet spectrum of VIII is approximately the same value as that of 5-nitrotropolone, 435 mμ (log ε 4.41).

VIII IX X XI



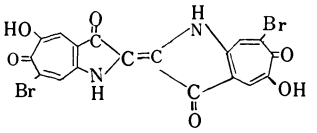


Fig. 2. Ultraviolet absorption spectra.

—— 4-Acetyl-5-nitrotropolone (VIII)
---- 6-Acetyl-3-bromo-5-nitrotropolone (IX, log ε +0.3)
—·— Indigo-type tropolone (XII)

When treated with sodium azide in a concentrated sulfuric acid solution, the above nitroacetyltropolones (VIII and IX) also yielded 4-amino-5-nitrotropolone (X) and 6-amino-3-bromo-5-nitrotropolone (XI), respectively. Their ultraviolet absorptions, indicated in Fig. 1, show that an introduction of a bromine atom in the 3-position of I, VII and IX causes a red shift of the longest wavelength maximum by 13, 8 and 7 mμ respectively, the fact of which is in approximate agreement with the observation of Tsuboi[11].

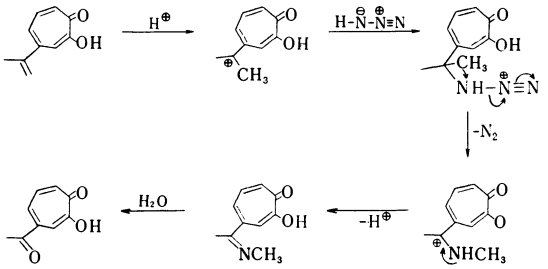
Catalytic hydrogenation of the bromo-acetyltropolone (IX) over palladized charcoal was found to give instead of the expected debromination product (VIII) an orange red product, which had its ultraviolet maximum in a longer wavelength region than that of the starting compound (cf. Fig. 2). The infrared absorption of this reaction product shows peaks at 3350 ($\nu_{NH}$) and 1648 $cm^{-1}$ ($\nu_{C=O}$). It follows, therefore, that this hydrogenation product of IX is probably an indigo-type tropolone (XII),

XII

the conclusion of which appears to be supported by the fact that 5,5′-dibromoindigo[12] has infrared peaks at 3300 ($\nu_{NH}$) and 1634 ($\nu_{C=O}$) $cm^{-1}$.

It was found that the Schmidt reaction was applicable satisfactorily to also 4-formyltropolone (XIII). Thus on being treated with an excess of sodium azide in concentrated sulfuric acid, XIII afforded the aminotropolone (I) and also 4-cyanotropolone (XIV). It has been well known in the reaction with benzaldehyde that the relative yields of the reaction products, benzonitrile and formanilide, vary

XIII XIV



according to the amount of sulfuric acid used[3], but in the reaction with XIII further detailed examinations could not be made owing to difficulty in preparing the starting material.
